

Fig. 132.3 PHYSIOLOGIC AND PATHOLOGIC PLATELET SPLENIC SEQUESTRATION. Normally, about 5% of cardiac output is to the spleen; however, a platelet that enters the spleen spends about 10 minutes there (splenic transit time = 10 min). In contrast, it usually takes only about 1 minute for a platelet to make a circulatory pass elsewhere. Thus about one-third of the platelets at any one time are located within the spleen: $(5\% \times 10 \text{ min}) : (95\% \times 1 \text{ min})$, or an approximate 1:2 ratio. In hypersplenism, the splenic blood flow can increase by a factor of 5, that is, from 5% to 25% of total blood flow per minute. Thus, even without increase in splenic transit time, up to 70% or more of the platelets can be exchangeably sequestered within the spleen. (From Arnold DM, Warkentin TE: *Thrombocytopenia and thrombocytosis*. In: Wilson WC, Grande CM, Hoyt DB, editors: *Trauma: Critical care*, vol. 2, New York, 2007, Informa Healthcare USA, p 983.)

(i.e., $5\% \times 10 \text{ min}/95\% \times 1 \text{ min}$, or a ratio of 50:95, or $\approx 1:2$). With hypersplenism, the splenic blood flow can increase up to fivefold (i.e., from 5% to 25% of total blood flow). Thus even without an increase in splenic transit time, 70% or more of the platelets can be exchangeably sequestered within the spleen.

The most important determinant of the splenic platelet pool is the spleen size. The measurement of spleen size can thus be helpful in predicting the degree of thrombocytopenia expected from excess platelet pooling in the spleen. For example, if 90% of the platelet pool is in the spleen (i.e., 10% outside the spleen), the platelet count will be reduced by sevenfold because normally, 70% of platelets lie outside the spleen. Consequently and as a general rule, even if the spleen is massively enlarged, severe thrombocytopenia ($<20 \times 10^9/\text{L}$) is rare. On the other hand, mild thrombocytopenia may be explained by mild splenomegaly that may not be detectible on physical examination but can be seen with imaging studies.

PATHOLOGIC PLATELET SEQUESTRATION: HYPERSPLENISM

Definition

Hypersplenism is a syndrome characterized by splenomegaly and any or all of the following cytopenias: anemia, leukopenia, or thrombocytopenia. Implicit in the definition is that the cytopenias will correct after splenectomy. Although splenomegaly is almost always present in hypersplenism, many patients with splenomegaly do not have hypersplenism. Hypersplenism usually is the result of an identifiable pathologic process, but rarely, the cause of the splenomegaly remains elusive, and the hypersplenism is termed *primary*.

Pathogenesis

A list of disorders producing splenomegaly and hypersplenism is presented in Table 132.4. An increase in the size of the spleen can be caused by several mechanisms. Increased workload of the spleen can be caused by immunologic stress (infection, inflammation, or an autoimmune disorder) or by increased RBC removal (RBC membrane disorders, hemoglobinopathies). Portal hypertension also increases the size of the spleen, producing congestive splenomegaly. Benign and malignant infiltrative disorders may increase splenic size (infiltrative splenomegaly) and cause hypersplenism. Some of these disorders produce thrombocytopenia by more than just hypersplenism (e.g., BM infiltration with tumor, immune-mediated platelet clearance). Thus the demonstration of an enlarged spleen does not necessarily mean that the cytopenias are caused solely by hypersplenism.

Thrombocytopenia of hypersplenism is caused primarily by increased splenic platelet pooling. A massively enlarged spleen can hold more than 90% of the total platelet mass. In the absence of altered platelet production, the total body platelet mass usually is normal, and the platelet life span is near normal. Usually, the splenic transit time remains normal (≈ 10 minutes), but the absolute number of platelets retained within the enlarged spleen is increased. All of these platelets remain part of the exchangeable pool. In hypersplenism, the thrombocytopenia is moderately severe (platelet counts of $50 \times 10^9/\text{L}$ to $150 \times 10^9/\text{L}$). Severe thrombocytopenia ($<20 \times 10^9/\text{L}$) suggests another diagnosis. Therefore it is unusual for patients with hypersplenism to have evidence of hemostatic impairment attributable to thrombocytopenia or to need specific interventions to raise the platelet count. Plasma volume expansion occurs in hypersplenism, but hemodilution plays a relatively minor role in the thrombocytopenia. In some patients with advanced liver disease, impaired hepatic production of thrombopoietin may contribute to thrombocytopenia in addition to hypersplenism.

The neutropenia of hypersplenism is caused by an increase in the marginated granulocyte pool, a portion of which is located in the spleen. The neutropenia of hypersplenism is usually asymptomatic.

TABLE 132.4 Differential Diagnosis of Splenomegaly and Hypersplenism

Infections

Acute

Viral (viral hepatitis, infectious mononucleosis, CMV infection)
Bacterial (septicemia, salmonellosis, brucellosis, splenic abscess)
Parasite (toxoplasmosis)

Subacute and Chronic

Subacute bacterial endocarditis
Tuberculosis
Malaria
Kala-azar
Fungal disease

Inflammation

Felty syndrome
SLE
Serum sickness
Rheumatic fever
Sarcoidosis
ALPS

Congestive Splenomegaly

Intrahepatic

Cirrhosis

Extrahepatic

Portal vein obstruction
Splenic vein obstruction
Hepatic vein occlusion (Budd-Chiari syndrome)

Chronic Passive Congestion

Heart failure

Hematologic Disorders

RBC disorders: hemolytic anemias, thalassemia, sickle cell disorders

Neoplasia

Malignant

MPDs
Myeloid metaplasia
Polycythemia rubra vera
Essential thrombocythemia
Chronic leukemia
Chronic myeloid leukemia
Chronic lymphocytic leukemia
Hairy cell leukemia
Lymphoma
Acute leukemia
Malignant histiocytosis

Benign

Hamartoma
Hemangioma
Lymphangioma
Fibroma

Storage Diseases

Gaucher disease
Niemann-Pick disease

Miscellaneous

Amyloidosis
Cysts

ALPS, Autoimmune lymphoproliferative syndrome; CMV, cytomegalovirus; MPD, myeloproliferative disorder; RBC, red blood cell; SLE, systemic lupus erythematosus.

Diagnosis

Thrombocytopenia is likely to be caused by hypersplenism when (1) splenomegaly is present, (2) the thrombocytopenia is mild to moderate in severity, (3) a moderately reduced neutrophil count and low-normal hemoglobin levels are found, and (4) there is no or minimal evidence of impaired hematopoiesis on BM examination.

Ultrasonography, computed tomography, and radionuclide imaging are of comparable sensitivity for documenting splenomegaly, and an imaging study should be performed if splenomegaly is not evident on physical examination. The mean platelet volume is often slightly decreased in hypersplenism, but this finding is not sufficiently specific to be diagnostically useful. An ^{111}In -labeled platelet survival study can be diagnostic of hypersplenism, demonstrating reduced platelet recovery and a normal platelet life span. Determining the cause of the splenomegaly is usually the most important issue.

Therapy

Several maneuvers can improve or correct the cytopenias attributable to hypersplenism, including total or partial splenectomy; partial splenic embolization; and in patients with congestive splenomegaly, surgical or transjugular intrahepatic portosystemic shunting. However, cytopenias secondary to hypersplenism and thrombocytopenia in particular, are almost never of sufficient severity to justify such treatment. Consequently the decision to perform one of these interventions usually depends on other considerations. For example, splenectomy should be considered for relief of pain or early satiety associated with massive splenomegaly (e.g., in myelo- or lymphoproliferative disorders) or for splenomegaly of unknown origin (for investigation of possible splenic lymphoma).

Short-term complications from splenectomy include infections, bleeding, and thromboembolism. The major long-term risk associated with splenectomy is overwhelming septicemia; this risk can be reduced by vaccination. All patients should be vaccinated against pneumococci, meningococci, and *Haemophilus* species at least 2 weeks before elective splenectomy. Moreover, “booster” doses of pneumococcus and meningococcus vaccines are recommended after 5 years.⁷ Splenectomy for congestive hypersplenism in the setting of portal hypertension is associated with high morbidity and mortality rates. Splenectomy is also associated with high morbidity (50%) and mortality (10%–15%) rates in myeloid metaplasia and does not alter the natural history of this disorder. Thus splenectomy is usually performed for palliation of intractable symptoms.

Splenectomy in Gaucher disease usually corrects the cytopenias, relieves abdominal discomfort, and improves growth in children. Partial, rather than total, splenectomy has been used in an attempt to avoid shifting the deposition of glucocerebroside from the spleen to the bones. Often, however, splenomegaly and hypersplenism recur after partial splenectomy. Enzyme replacement therapy can reduce the morbidity from hypersplenism (see Chapter 53).

DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Many drugs can cause thrombocytopenia. Some drugs (e.g., anticancer chemotherapeutic agents, valproic acid) cause dose-dependent thrombocytopenia, generally through myelosuppressive mechanisms. An important disorder encountered by hematologists is unexpected thrombocytopenia caused by immunologic (idiosyncratic) mechanisms.^{8–10} The frequency of these reactions varies considerably among drugs and ranges from very rare (<1 : 10,000) for commonly used drugs such as acetaminophen, indomethacin, naproxen, quinine or quinidine, and trimethoprim-sulfamethoxazole (TMP-SMX) to common (1%–5%) for other drugs such as gold and unfractionated heparin (UFH).

Immunologic drug-induced thrombocytopenia can occur through different mechanisms (Fig. 132.4). For example, thrombocytopenia can occur when the Fab terminus of the pathogenic IgG binds to a complex composed of drug (or drug metabolite) and a platelet membrane component (typically, platelet GPIIb/IIIa or GPIb/IX/V). The Fc portions of the pathogenic IgG molecules do not bind to platelets but interact with Fc receptors on phagocytic cells of the reticuloendothelial system, which ingest the platelets, leading to accelerated platelet clearance. Severe thrombocytopenia (platelet counts <20 × 10⁹/L) is typically observed. This mechanism is

exemplified by quinine- and quinidine-induced thrombocytopenia. A complicating issue (discussed later in this chapter) is that quinine can also rarely cause thrombocytopenia with a clinical picture of microangiopathic hemolysis¹¹ and/or DIC.

Sometimes the Fab terminus binds to a neoepitope on platelet GPIIb/IIIa induced by the drug, and the drug itself is not part of the neoepitope. This mechanism is exemplified by the GPIIb/IIIa receptor antagonists, eptifibatide and tirofiban, which bind to the Arg-Gly-Asp recognition site on GPIIb/IIIa, forming a neoepitope to which the “fiban-dependent” antibodies bind.

Another distinct form of drug-induced thrombocytopenia is exemplified by HIT (see Chapter 133). In this disorder, the Fab portion of the pathogenic IgG binds to platelet factor 4 (PF4), an α -granule protein that is immunogenic when complexed to heparin or certain other polyanions. The Fc portions of the IgG molecules bind to platelet Fc γ IIa receptors, initiating intense platelet activation (see Fig. 132.4). Perhaps because HIT is a platelet activation syndrome or because of the relatively low number of HIT antibodies that bind to platelet surfaces, the thrombocytopenia is typically mild to moderate rather than severe (see Fig. 133.3 in Chapter 133).

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA

A large number of drugs can cause a syndrome that mimics acute ITP (D-ITP); however, there are relatively few drugs for which causation is well established on both clinical and serologic grounds (Table 132.5).^{10,12–14} Typically, severe thrombocytopenia (platelet count usually <20 × 10⁹/L), together with petechiae and purpura, develop within approximately 1 week (although occasionally much longer) after initiation of therapy with the responsible drug. D-ITP is much less common than HIT. For example, a relatively “common” cause of this syndrome is TMP-SMX (co-trimoxazole), even though it occurs in only approximately one in 25,000 patients who receive this drug combination.

Important exceptions to these generalizations occur with D-ITP that results from GPIIb/IIIa receptor antagonists; these reactions are relatively common (affecting about 0.5%–1% of patients) and usually occur within hours of first use as a result of preexisting, naturally occurring antibodies. Another exception is carbimazole-induced thrombocytopenia, in which mild thrombocytopenia is explained by the presence of relatively small quantities of the platelet GP target (platelet endothelial cell adhesion molecule-1 [PECAM-1]) on the platelet surface. Besides the atypical immune-mediated syndromes of HIT and GPIIb/IIIa antagonist thrombocytopenia, the most common drugs (in absolute terms) implicated in the causation of classic D-ITP syndrome are quinine (outpatients) and vancomycin (inpatients).¹⁵

Pathogenesis

Drug-dependent binding of the Fab component of IgG to platelet GP leads to platelet destruction. This occurs because the IgG-sensitized platelets are recognized by Fc receptors of phagocytic cells. For quinine- and quinidine-induced ITP, both the GPIIb/IIIa and GPIb/IX/V complexes have been implicated as targets for the drug-dependent IgG (see Fig. 132.4). By contrast, for sulfa antibiotic- and naproxen-induced ITP, the GPIIb/IIIa complex is predominantly involved. Sometimes, drug metabolites form the antigen rather than the parent drug. A trimolecular complex is formed among IgG Fab, the drug (or metabolite), and the platelet GP. In contrast to HIT, platelet Fc receptors are not involved in D-ITP pathogenesis. Drug-dependent IgG binding is remarkably heterogeneous with respect to binding affinity, number of binding sites per platelet, and the range of drug concentrations required. A study of quinine-induced ITP identified two different types of antibodies: quinine-dependent antibodies that bound to platelets in the presence of drug and quinine-specific antibodies that reacted with quinine-conjugated albumin.¹⁶ The pathophysiologic implications of this latter group of antibodies remain unclear.

Fig. 132.4 MECHANISMS OF DRUG-INDUCED IMMUNE THROMBOCYTOPENIA. Four immune thrombocytopenic syndromes are illustrated. On the *bottom* of the schematic platelet, heparin-induced thrombocytopenia (HIT) is illustrated, indicating that immunoglobulin G (IgG) antibodies bind to complexes of platelet factor 4 (PF4) and heparin, with the Fc regions of the antibodies binding to the platelet FcγIIa receptors, resulting in platelet activation (including generation of procoagulant, platelet-derived microparticles). On the *top* of the schematic platelet, three mechanisms are illustrated that lead to increased platelet clearance by phagocytic cells. From left to right, these are (1) autoantibody-induced immune thrombocytopenia (e.g., gold-induced antiglycoprotein V [GPV] antibodies). (2) Drug-dependent antibodies reactive against drug (or drug metabolite)–platelet glycoprotein complex(es) (e.g., quinine-induced thrombocytopenia in which drug-dependent antibodies against GPIbα, GPIX, GPIIb, and GPIIIa have been implicated, resulting in an antibody/drug/glycoprotein ternary complex), and (3) antibodies against neoepitope(s) formed in the presence of a drug (e.g., eptifibatide-induced immune thrombocytopenia caused by formation of ligand-induced binding site elsewhere on the GPIIb/IIIa complex after eptifibatide binding). Note that preexisting (naturally occurring) antibodies can explain abrupt-onset thrombocytopenia in a patient receiving eptifibatide for the first time.

The fundamental mechanism that accounts for antibody formation in a small proportion of patients is unknown. One group has proposed that drug-dependent platelet-reactive antibodies are derived from a pool of naturally occurring autoantibodies with inherently weak (nonpathologic) affinity for certain platelet membrane GPs.^{8,16} However, if a certain drug is able to enhance antibody–antigen interaction, and if B cells expressing such antibodies are induced to proliferate and undergo affinity maturation in such a patient, the resulting antibody can destroy the platelets in the presence of the drug.

Clinical Features

Patients with D-ITP typically present with petechiae, purpura, and severe thrombocytopenia (platelet count often $<20 \times 10^9/L$). Systemic symptoms, such as fever and chills, may occur in patients with

abrupt-onset thrombocytopenia. Usually, the thrombocytopenia becomes clinically apparent 1–2 weeks after initiation of the drug, but the thrombocytopenia can start after a patient has been taking a drug for several years. Typically, the platelet count begins to rise in a few days after discontinuation of the implicated drug, but occasionally several weeks are required for recovery, possibly because of the generation of drug-independent IgG (platelet autoantibodies).

Sometimes drug exposure is relatively obscure. Among outpatients, the physician needs to inquire about potential exposure to quinine. Quinine is widely available: for example, as an ingredient in tonic water, as an additive to street drugs, and in some countries as therapy for leg cramps. Vancomycin is a relatively common cause of D-ITP in hospitalized inpatients; most often this occurs after the usual intravenous administration, but some reports have implicated exposure via orthopedic cement or with peritoneal administration of vancomycin.

Rarely, distinct drug-dependent IgG molecules destroy RBCs or WBCs in addition to platelets. For example, both platelet- and leukocyte-reactive quinidine-dependent IgG molecules have been detected in a patient with quinidine-induced bicytopenia. Sometimes the immune process is directed against a pluripotent hematopoietic stem cell, resulting in pancytopenia accompanied by BM aplasia or hypoplasia (e.g., gold-, carbamazepine-, or quinidine-induced pancytopenia). A BM aspirate should be performed in patients with suspected drug-induced bicytopenia or pancytopenia because a hypoplastic BM may be indicative of drug-induced aplastic anemia.

Diagnosis

A high index of clinical suspicion is required to make the diagnosis. Moreover, clinicians need to evaluate which drug (often among

several that the patient is receiving) is most likely to explain a diagnosis of D-ITP.^{10,12–14} The clinician should focus on drugs that have been started 5–10 days before the onset of the platelet count decrease (Fig. 132.5A). Also, with drugs such as quinine, in which there may be intermittent exposure (e.g., consumption of gin and tonic), a very recent exposure (previous 1 or 2 days) usually explains the abrupt onset of symptomatic thrombocytopenia.

After the physician has identified one or more potential agents, the next step is to determine whether these drugs have previously been implicated as causes of D-ITP. The box Search Strategies When Investigating Patient With Possible Drug-Induced Immune Thrombocytopenic Purpura includes some strategies for identifying drugs implicated in D-ITP.

Demonstration of drug-dependent binding of IgG to platelets in vitro can be important for diagnosis (see Fig. 132.5B). Labeled Ig-specific probes (e.g., phase II assays) or GP capture techniques (phase III assays) can be used (see Table 132.3). In other cases, D-ITP test results are negative, but the diagnosis still seems likely based on clinical features and supporting literature (see Fig. 132.6).

There are certain caveats in diagnostic testing. First, metabolites must sometimes be used instead of the parent drug to detect the IgG. Second, the target drug (or metabolite) must be included in the wash buffer used in these assays. Third, despite these maneuvers, the sensitivity of in vitro assays is relatively low, and the diagnosis of D-ITP must often be made on clinical grounds. Sometimes the diagnosis is confirmed by inadvertent or deliberate reexposure to the suspected drug. However, deliberate drug challenge is not often performed because of its potential risk.

A novel approach to identify drug-dependent platelet-reactive antibodies was reported by investigators at the Milwaukee Blood Center.²⁰ They used nonobese diabetic/severe combined immunodeficient (NOD/SCID) mice (which lack xenobodies, thereby allowing infused human platelets to circulate) to identify drug-dependent antibodies in patient sera, including antibodies that only recognize drug metabolites (presumably, mice produce the same or similar drug metabolites as humans, which are recognized by the drug-dependent antibodies).

TABLE 132.5 List of Drugs Implicated in Drug-Induced Immune Thrombocytopenia

Drugs Common to All Three Lists^{12–14}

Quinine, quinidine, rifampin, trimethoprim-sulfamethoxazole, vancomycin

George ¹²	Reese ¹³	Arnold ¹⁴
Acetaminophen	Abciximab ^a	Abciximab ^a
Alprenolol	Acetaminophen	Carbamazepine
Aminoglutethimide	Amiodarone	Ceftriaxone
Aminosalicic acid	Ampicillin	Eptifibatide ^b
Amiodarone	Carbamazepine	Ibuprofen
Amphotericin B	Eptifibatide ^b	Mirtazapine
Amrinone	Ethambutol	Oxaliplatin
Chlorothiazide	Haloperidol	Penicillin
Chlorpromazine	Ibuprofen	Suramin
Cimetidine	Irinotecan	Tirofiban ^b
Danazol	Naproxen	Heparin ^c
Diatrizoate meglumine	Oxaliplatin	
Diazepam	Phenytoin	
Diazoxide	Piperacillin	
Diclofenac	Ranitidine	
Digoxin	Simvastatin	
Ethambutol	Sulfisoxazole	
Haloperidol	Tirofiban ^b	
Interferon- α	Valproic acid	
Iopanoic acid		
Levamisole		
Lithium		
Meclofenamate		
Methyl dopa		
Minoxidil		
Nalidixic acid		
Naphazoline		
Nitroglycerin		
Oxprenolol		
Sulfasalazine		
Sulfisoxazole		
Tamoxifen		
Thiothixene		
Tolmetin		

^aSubtype of D-ITP where patient's antibodies (either naturally occurring or that are formed after treatment with abciximab) bind to platelet GPIIb/IIIa subsequent to binding of abciximab (chimeric human-murine Fab that recognizes GPIIb/IIIa) to platelets.

^bSubtype of D-ITP caused by fiban-dependent antibodies (either naturally occurring or that are formed after treatment with eptifibatide or tirofiban) that recognize neoepitopes on platelet GPIIb/IIIa that form subsequent to binding of fiban drug to GPIIb/IIIa.

^cHIT is considered a distinct subtype of D-ITP disorder, given its unusual pathogenesis centered on IgG-induced platelet activation. D-ITP, Drug-induced immune thrombocytopenia; HIT, heparin-induced thrombocytopenia.

Search Strategies When Investigating a Patient With Possible Drug-Induced Immune Thrombocytopenic Purpura

Four sources of information as to whether a drug has been implicated as a cause of D-ITP:

- **PubMed search** (<http://www.ncbi.nlm.nih.gov/pubmed>): [name of drug] and [thrombocytopenia]. By way of example, the author encountered a patient who developed severe thrombocytopenia 5 days after starting treatment with mirtazapine (Fig. 132.6). Searching [mirtazapine] and [thrombocytopenia] in December 2014 identified two reports^{17,18} of mirtazapine-induced D-ITP syndrome.
- **Drug-induced thrombocytopenia website** (<http://www.ouhsc.edu/platelets/ditp.html>): Investigators at the University of Oklahoma published a comprehensive survey of drugs implicated in D-ITP using clinical criteria¹²; a website maintained by these investigators is updated every 2 years.
- **Database from drug-dependent platelet-reactive antibody testing** at the BloodCenter of Wisconsin, 1995–2010 (http://www.ouhsc.edu/platelets/InternetPostingLab2_18_11Frames.htm): the BloodCenter of Wisconsin maintains a website reporting its experience in detecting drug-dependent platelet-reactive antibodies.¹⁹
- **Combined approach that uses clinical criteria,¹² laboratory criteria,¹⁹ and Adverse Event Reporting System.¹³** Table 132.5 (middle column) lists two dozen drugs (including those drugs identified by two other comprehensive reviews^{12,14}) for which convincing clinical and laboratory evidence exists.¹³ To review the comprehensive list of all drugs investigated in this study,¹³ interested readers can consult the online supplemental table (<http://bloodjournal.hematologylibrary.org/content/suppl/2010/06/08/blood-2010-03-276691.DC1/TableS1.pdf>).

Fig. 132.5 DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SECONDARY TO VANCOMYCIN. **A**, Timeline of D-ITP. A 66-year-old woman was admitted for prosthetic valve endocarditis 5 months after undergoing mitral valve replacement. The initiation of multiple new drugs and the onset 6 days later of progressively severe thrombocytopenia (platelet count nadir, $4 \times 10^9/L$ on day 9) suggested D-ITP syndrome. However, the timing fit several drugs (ranitidine, carbamazepine, phenytoin, gentamicin, vancomycin, and digoxin). **B**, Drug-dependent binding of antibodies was demonstrated using patient serum and vancomycin. Also, test results for heparin-induced thrombocytopenia antibodies was negative. Thus the diagnosis of vancomycin-induced D-ITP syndrome was made based on clinical and serological grounds. The patient received treatment with high-dose intravenous immunoglobulin (IVIg) and platelet transfusions. *Plt tfns*, Platelet transfusions.

Fig. 132.6 DRUG-INDUCED IMMUNE THROMBOCYTOPENIA (D-ITP) SECONDARY TO MIRTAZAPINE. The onset of severe thrombocytopenia (platelet count nadir, $12 \times 10^9/L$) on day 6 of mirtazapine therapy implicated this tetracyclic antidepressant of the piperazine-azapine group as a cause of drug-induced immune thrombocytopenia (D-ITP) syndrome. The very rapid platelet count fall (which was already manifest on day 5 of mirtazapine therapy) is explained by reduced platelet production (because the patient's platelet count was declining from postoperative thrombocytosis). Although in vitro testing for mirtazapine-dependent antibodies was negative, the low sensitivity of these assays does not rule out mirtazapine as the cause of D-ITP syndrome, particularly in a high pretest probability scenario such as this. *IVIg*, Intravenous immunoglobulin.

Management

As many drugs as possible should be discontinued in patients with suspected D-ITP. If further drug treatment is necessary, an alternate, immunologically non-cross-reactive substitute should be used. Spontaneous improvement in the platelet count usually begins within a few days of discontinuing the offending drug, although in some cases, complete recovery may take 2 weeks or longer. Platelet transfusions should be given to patients with life-threatening bleeding. High-dose intravenous immunoglobulin (IVIg), 1 g/kg given over 6–8 hours, with a second dose 1 or 2 days later if required, may be helpful in some situations. Corticosteroids appear to be relatively ineffective for treatment of D-ITP.

GOLD-INDUCED THROMBOCYTOPENIA

Gold-induced ITP occurs in as many as 1% to 3% of treated patients. A genetic predisposition is suggested by the association with HLA-DR3, which is found in approximately 85% of affected patients. The thrombocytopenia typically occurs during the first 20 weeks of therapy before a total of 1000 mg of gold has been given. Rarely, the thrombocytopenia begins much later, sometimes several months after discontinuation of the gold. Although the onset of thrombocytopenia is typically abrupt, regular platelet count monitoring is important because an early diagnosis can be made in some patients. The thrombocytopenia often persists for several months after discontinuation of the gold, probably because of gold-induced autoimmune thrombocytopenia (drug-independent gold-induced autoantibodies against gold-induced antiglycoprotein V [GPV] have been implicated) (see Fig. 132.4). Although most patients will eventually respond to corticosteroids, immediate, albeit often transient, correction of severe thrombocytopenia can usually be achieved with

high-dose IVIg. Some patients with persisting thrombocytopenia benefit from splenectomy or use of gold-chelating agents (dimercaprol, *N*-acetylcysteine). The disorder is rarely encountered because the use of gold to treat rheumatic disorders has declined.

DRUG-INDUCED AUTOIMMUNE THROMBOCYTOPENIA

Certain drugs other than gold have been reported to initiate autoimmune thrombocytopenia (e.g., levodopa, procainamide). Because the pathogenic antibodies are by definition drug independent, however, it is difficult to establish causation. The mumps–measles–rubella (MMR) vaccine can rarely ($\approx 1:40,000$) cause a severe but generally self-limited thrombocytopenia that is clinically and serologically indistinguishable from childhood acute ITP; MMR vaccination of unimmunized children with ITP and revaccination of children with prior ITP does not lead to recurrent thrombocytopenia.

DRUG-INDUCED IMMUNE THROMBOCYTOPENIA OF RAPID ONSET

A rapid onset of thrombocytopenia (within hours) can occur if a patient with preexisting drug-dependent antibodies is (re)exposed to the drug. This situation is relatively common in HIT ($\approx 25\%$ of patients identified)³ because repeated treatment with heparin is common and heparin use itself can result in the complication (HIT-associated thrombosis) that might lead to further use of heparin. Because HIT antibodies are transient, however, rapid-onset HIT occurs in patients with recent heparin exposures, usually within the past 100 days.³ By contrast, repeated episodes of quinine-induced thrombocytopenia of abrupt onset can occur many months or even years apart because these antibodies persist for much longer.

Thrombocytopenia of rapid onset is commonly seen with GPIIb/IIIa receptor antagonists (see next section).

THROMBOCYTOPENIA CAUSED BY GLYCOPROTEIN IIB/IIIa RECEPTOR ANTAGONISTS

Several thrombocytopenic syndromes have been reported with use of GPIIb/IIIa receptor antagonists (abciximab, eptifibatide, tirofiban) administered during percutaneous coronary intervention (e.g., angioplasty, stenting): (1) rapid-onset, severe thrombocytopenia within 12 hours of drug administration (in 0.4%–2% of patients), (2) rapid-onset pseudothrombocytopenia (in approximately 1% of patients exposed to abciximab [ReoPro]), (3) rapid-onset thrombocytopenia within 12 hours of a second exposure to a GPIIb/IIIa antagonist, and (4) delayed-onset thrombocytopenia beginning 5–7 days after drug administration (rare).²¹ The frequency of rapid-onset thrombocytopenia is higher among patients who receive a second course of therapy, especially if it follows the initial exposure by only a few weeks. Thrombocytopenia is typically severe (median platelet count nadir, about $5 \times 10^9/L$ to $10 \times 10^9/L$), but clinical effects vary dramatically, ranging from absence of petechiae or other signs of bleeding (in 50% of patients) to fatal hemorrhage (in less than 5%). Some patients develop anaphylactoid reactions accompanying the abrupt platelet count declines. The antibodies may cause thrombosis in some patients, likely because the pathogenic antibodies also activate platelets.²¹

These syndromes are caused by at least three mechanisms. First, antibodies of IgG (and possibly IgM) class can bind to neoepitopes on the GPIIb/IIIa complex generated by these drugs (or their metabolites), that is, ligand-induced binding sites (see Fig. 132.4). Up to 5% of humans and nonhuman primates have naturally occurring IgG antibodies that will bind to GPIIb/IIIa receptors in the presence of drug, which could explain why rapid-onset thrombocytopenia occurs so frequently with these agents. A second mechanism is applicable to abciximab, a chimeric Fab fragment comprised of murine GPIIb/IIIa-reactive sequences and human framework sequences. Interestingly, although a high frequency of normal persons (74%) have antibodies that recognize platelets coated with abciximab, these “normal” antibodies were shown to differ from those detected in patients in whom thrombocytopenia developed after a second exposure to abciximab: whereas the pathogenic antibodies recognized murine sequences within abciximab, the “normal” (nonpathogenic) antibodies were specific for the carboxyl terminus (papain cleavage site) of Fab fragments prepared from normal human IgG. Drug-dependent antibodies can also be generated about 1 week after exposure. The antibodies differ among patients with respect to the precise neoepitopes recognized and display variable degrees of cross-reactivity among the different GPIIb/IIIa receptor antagonists (“fibans”); this explains why a repeat treatment course with another GPIIb/IIIa receptor antagonist may not necessarily cause thrombocytopenia. A third mechanism involves eptifibatide-dependent antibodies that activate platelets via their FcγIIa receptors.²¹

Some naturally occurring antibodies only bind to GPIIb/IIIa when the calcium concentration is low, thus explaining pseudothrombocytopenia—falsely low platelet count estimates caused by ex vivo aggregation of platelets in blood samples collected into calcium-chelating anticoagulants, especially EDTA. The rare syndrome of delayed-onset thrombocytopenia after brief exposure might result from high-titer GPIIb/IIIa-reactive antibodies that bind even in the absence of the drug.

Platelet transfusions are indicated in patients who are bleeding, although their efficacy has not been established. Platelet transfusions are most likely to be effective for the treatment of abciximab-induced thrombocytopenia because the drug binds so tightly to GPIIb/IIIa that little abciximab is free to bind to the transfused platelets. Platelet transfusions are not indicated in pseudothrombocytopenia, which underscores the importance of reviewing the blood film when a low platelet count is reported after treatment with one of these agents.

Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Intervention

Four diagnoses should be considered in patients who develop thrombocytopenia within minutes or a few hours after a PCI and have received one or more of the following agents: (1) platelet GPIIb/IIIa inhibitor (e.g., abciximab, eptifibatide, tirofiban), (2) heparin, or (3) iodinated contrast agent.

- **GPIIb/IIIa inhibitor–induced pseudothrombocytopenia.** The patient has no symptoms or signs of bleeding, and platelet aggregates are seen in the blood film. The platelet count is falsely reported as low by the automated particle counter, which fails to count aggregated platelets. No treatment is required.
- **GPIIb/IIIa inhibitor–induced thrombocytopenia.** The platelet count falls abruptly, often to profoundly reduced levels (typical nadir, $<20 \times 10^9/L$). Hemostatic impairment is variable, ranging from petechiae to fatal hemorrhages; occasionally, patients develop anaphylactoid reactions or even associated thrombosis. Treatment involves stopping all platelet antagonists and anticoagulants and giving platelets if the patient has signs of bleeding. Prophylactic platelet transfusions can also be considered if the platelet count is very low (e.g., $<10 \times 10^9/L$). Testing for drug-dependent antibodies can be accomplished using flow cytometry or ELISA.
- **Rapid-onset HIT.** In patients who have preexisting HIT antibodies because of recent heparin exposure (generally within the past 100 days), rapid-onset HIT can occur when heparin is given during PCI. This is much less common than GPIIb/IIIa inhibitor–induced thrombocytopenia or pseudothrombocytopenia, so presumptive treatment of HIT with a nonheparin anticoagulant is rarely indicated in this situation. The platelet count nadir is usually much higher than with GPIIb/IIIa inhibitor–induced thrombocytopenia.
- **Radiocontrast-induced ITP.** Very rarely, patients who have previously received iodinated contrast can develop abrupt-onset, severe thrombocytopenia after exposure to contrast during PCI. Platelet transfusions (with or without high-dose IVIg) are appropriate for a bleeding patient.

ELISA, Enzyme-linked immunosorbent assay; HIT, heparin-induced thrombocytopenia; ITP, induced thrombocytopenia; IVIg, intravenous immunoglobulin; PCI, percutaneous coronary intervention.

Various in vitro assays using flow cytometry or enzyme-linked immunosorbent assay (ELISA) have been developed to detect these antibodies. Because some pathogenic antibodies are naturally occurring, it is theoretically possible to identify patients at high risk for rapid-onset thrombocytopenia in elective situations (see [box on Approach to Patients With Thrombocytopenia Following Percutaneous Coronary Interventions](#)).

MISCELLANEOUS DRUG-INDUCED THROMBOCYTOPENIC SYNDROMES

Drug-Induced Thrombotic Microangiopathy

Several drugs can trigger a syndrome of thrombocytopenia, fragmentation hemolysis, and renal failure known as *drug-induced thrombotic microangiopathy* (TMA). This syndrome has been established for quinine,¹¹ in which multiple quinine-dependent antibodies reactive against platelets, RBCs, leukocytes, and endothelial cells have been reported. Although TMA has been reported with ticlopidine and clopidogrel, a recent systematic review²² failed to confirm this association.

Although a similar syndrome may be caused by mitomycin, gemcitabine, cyclosporine, and tacrolimus, it should be noted that many patients who receive these drugs have an underlying illness (e.g., gastric adenocarcinoma, BM transplantation, collagen vascular disease) that itself can be complicated by TMA; moreover, high cumulative doses of the implicated drug have usually been received, suggesting a nonimmune (e.g., toxic) pathogenesis.¹¹ Furthermore,

these patients tend to be less responsive to plasma exchange than those with idiopathic TTP.

Drug-Induced Disseminated Intravascular Coagulation

On rare occasions, quinine causes severe thrombocytopenia accompanied by marked coagulation abnormalities indicative of DIC. This syndrome overlaps that of quinine-induced thrombotic microangiopathy, and the explanation for the prominent coagulopathy is unknown. Although all patients with HIT have biochemical evidence of increased thrombin generation, only about 10% to 20% have overt DIC; however, these patients often present with large and small vessel thrombosis.

Nonidiosyncratic Drug-Induced Thrombocytopenia

Most antineoplastic drugs produce dose-dependent pancytopenia because of their effect on hematopoietic cells, including megakaryocytes and their progenitor cells. Typically, the platelet count nadir occurs at a predictable time after treatment, and the count then quickly recovers. Unexpectedly severe or prolonged thrombocytopenia in patients receiving chemotherapy should suggest alternate explanations (e.g., idiosyncratic thrombocytopenia caused by another drug).

Mild to moderate thrombocytopenia develops in approximately 20% of patients who take valproic acid (an antiepileptic agent); bleeding symptoms are uncommon. The mechanism of thrombocytopenia in this setting is unknown, but the condition appears to be nonidiosyncratic because the risk of thrombocytopenia correlates strongly with serum concentrations of valproic acid metabolite. Amrinone is another agent that can cause mild, dose-dependent thrombocytopenia.

Rapid Nonimmune Drug-Induced Thrombocytopenia

Some drugs produce rapid but generally mild and transient drops in the platelet count. These drugs include heparin, protamine, bleomycin, hematin, desmopressin (particularly in patients with type 2B von Willebrand disease), and porcine factor VIII. The mechanisms for thrombocytopenia in these syndromes are obscure.

Drug Hypersensitivity Reactions

Mild to moderate thrombocytopenia is sometimes observed in patients with systemic drug hypersensitivity reactions. Co-morbid clinical features can include generalized rash, fever, cholestasis, and leukopenia. Allopurinol, isoniazid, sulfasalazine, and phenothiazine drugs, among others, have been implicated in these reactions.

Thrombocytopenia Secondary to Biologic Response Modifiers

Use of purified or recombinant biologic response modifiers such as interferon, interleukin-2, and certain colony-stimulating factors has resulted in severe, reversible thrombocytopenia in some patients. Antilymphocyte globulins can also produce severe thrombocytopenia.

OTHER CAUSES OF DESTRUCTIVE THROMBOCYTOPENIA

Incidental Thrombocytopenia of Pregnancy

Maternal thrombocytopenia occurs in 4% to 8% of pregnancies.²³ Most affected women are healthy and have no history of thrombocytopenia, and their thrombocytopenia is incidentally detected by

routine blood testing. The cause of the mild reduction in platelet count (approximately $75 \times 10^9/L$ to $150 \times 10^9/L$) is believed to represent a leftward shift in the normal platelet count range during pregnancy related to one or more of hemodilution, reduced platelet production, or increased platelet turnover.²³ This condition is benign and is not associated with an increased risk for maternal bleeding or neonatal thrombocytopenia. Accordingly, no special maneuvers are indicated in these women, and the route of delivery should be determined by obstetric indications. Epidural anesthesia is believed to be safe if the platelet count is at least $75 \times 10^9/L$.

Preeclampsia and Eclampsia

Preeclampsia is characterized by the onset of hypertension and proteinuria during pregnancy, especially in a primigravida near term. Preeclampsia complicates approximately 5% of pregnancies, and the frequency is higher in black women. Thrombocytopenia occurs in up to 50% of preeclamptic patients, and its severity generally parallels that of the underlying preeclampsia.²³ A subset of patients with preeclampsia has microangiopathic hemolysis, elevated liver enzymes, and low platelets, widely known as the HELLP syndrome. This condition usually indicates severe preeclampsia and is associated with a higher risk of fetal and maternal complications, including maternal hepatic rupture. Repeated clinical and laboratory assessment of these patients is important because this syndrome can mimic other life-threatening complications of pregnancy, such as overt DIC, TTP, septicemia, and acute fatty liver of pregnancy.

Increased platelet destruction is the mechanism for the thrombocytopenia in preeclampsia. However, activation of the coagulation system is relatively modest, suggesting that thrombin generation may not be a major driver of the thrombocytopenia. Endothelial dysfunction (e.g., impaired nitric oxide synthesis) is a potential explanation for increased platelet turnover in preeclampsia.

Pharmacologic control of hypertension and rapid delivery are the treatments for preeclampsia and usually result in resolution of the thrombocytopenia within a few days. If delivery is not an option, treatment with bed rest and aggressive antihypertensive therapy has been reported to result in an improved platelet count. However, the clinical course is markedly variable, and some patients develop life-threatening organ failure. Plasmapheresis has been used in some patients, especially if there is evidence of thrombotic microangiopathy and organ dysfunction. Plasma exchange is appropriate for patients whose clinical picture has features suggesting TTP.

Infection

Infection is a common cause of thrombocytopenia, occurring in approximately 50% to 75% of patients with bacteremia or fungemia and in almost all patients with septic shock or DIC. Even when caused by bacteremia, the thrombocytopenia is generally mild to moderate in severity and is usually not accompanied by significant coagulation abnormalities or bleeding. The likelihood of laboratory evidence for DIC increases as the platelet count falls below $50 \times 10^9/L$. The mechanisms for thrombocytopenia in septicemia in the absence of DIC are uncertain but could include chemokine-induced macrophage ingestion of platelets (hemophagocytosis) and direct activation of platelets by endogenous mediators of inflammation (e.g., platelet-activating factor) or certain microbial products. In rare situations, platelet-reactive autoantibodies are implicated. Various explanations for thrombocytopenia in different types of infection are listed in Table 132.6.

Unexplained thrombocytopenia in a hospitalized patient warrants studies to exclude infection, such as blood cultures. Prompt recognition and treatment of the infection constitute the most important therapy because platelet count recovery tends to parallel the resolution of the infection. Prophylactic platelet transfusions are generally not required unless the platelet count falls below $10 \times 10^9/L$ or comorbid clinical features increase the likelihood of serious bleeding.

TABLE 132.6 Mechanisms for Thrombocytopenia Complicating Infections

Mechanism for Thrombocytopenia	Selected Example(s) ^a
Increased Platelet Destruction	
DIC	Meningococcemia
Hemophagocytosis	Septicemia, EBV infection
Platelet-reactive autoantibodies (acute)	Varicella, subacute bacterial endocarditis (rare)
Platelet-reactive autoantibodies (chronic)	HIV infection
HUS	Verocytotoxin-producing <i>Escherichia coli</i> , <i>Shigella</i> spp., HIV infection
Antibodies against platelet-adsorbed microbial antigens	Malaria
Hypersplenism	
Acute	Disseminated <i>Mycobacterium avium</i> infection in HIV infection
Chronic	Viral chronic active hepatitis, malaria
Decreased Platelet Production	
Replacement of BM by granulomas	Ehrlichiosis, tuberculosis
Infection of megakaryocytes	HIV infection
Transient virus-induced aplasia	Parvovirus B19 infection (erythroidopenia predominates)
Multiple Mechanisms	
Platelet destruction plus hypersplenism	Recurrent malaria
Increased platelet destruction, decreased platelet production, hypersplenism	Chronic HIV infection

^aReferences can be found in Hoffman R, Benz EJ Jr, Shattil SJ, et al, eds: *Hematology: Basic Principles and Practice*, ed 3. New York, 2000, Churchill Livingstone. (e.g., concomitant coagulopathy, an invasive procedure, uremic platelet dysfunction). The use of heparin for patients with septic shock and DIC is controversial. However, heparin may be of benefit in patients with clinical evidence of DIC and microvascular thrombosis (e.g., acral tissue ischemia or necrosis). The possibility of acquired protein C deficiency complicating acute DIC should also be considered in septic patients with purpura fulminans, such as that secondary to meningococcemia, or preceding “shock liver,”^{4,5} in whom treatment with heparin²⁴ and plasma could be beneficial. Vitamin K administration is reasonable, although it will not help in the absence of vitamin K deficiency.

Thrombocytopenia in patients infected with HIV poses a special diagnostic problem because there are many potential explanations for the thrombocytopenia. These include immune platelet destruction, impaired platelet production secondary to HIV infection of megakaryocytes, drug-induced myelosuppression (commonly implicated drugs include zidovudine, ganciclovir, and TMP-SMX), HIV-associated thrombotic microangiopathy, hypersplenism, and BM infiltration by tumor or opportunistic infections. Platelet kinetic studies have shown a complex interaction of decreased platelet production, increased platelet destruction, and splenic platelet sequestration. Immune mechanisms for platelet destruction include antibodies that cross-react with GPIIb/IIIa complexes (“molecular mimicry”) and

immune complexes containing IgM antiidiotype antibodies (which could explain the paradox of high levels of platelet-associated IgG and IgM with low serum levels of platelet-reactive antibodies). Anti-HIV therapy (e.g., zidovudine, HAART) often raises the platelet count in patients with HIV-associated thrombocytopenia. Most patients with HIV-associated thrombocytopenia respond to conventional treatments for ITP, including corticosteroids, splenectomy, IVIg, and, particularly, anti-D.

Systemic Lupus Erythematosus

Immune-mediated thrombocytopenia, which occurs in as many as 25% of patients with SLE, is associated with a twofold increased risk of organ damage events. Many different types of platelet-IgG interactions are described (e.g., antiglycoprotein, antiglycolipid, β_2 -glycoprotein I [β_2 GPI]—containing immune complexes). In addition, antithrombopoietin, anti-c-Mpl (thrombopoietin receptor), and anti-CD40 ligand autoantibodies have been reported. Multiple causes for thrombocytopenia—increased platelet destruction, hypersplenism, and even impaired platelet production related to antibody-induced megakaryocytic hypoplasia—have been reported. The predominant explanation for thrombocytopenia in SLE remains unknown.

Several thrombocytopenic syndromes are seen in patients with SLE. For many patients, the thrombocytopenia is chronic, resembling ITP, and is the predominant clinical manifestation of the lupus. Often, these patients have a prolonged bleeding time despite mild thrombocytopenia. Some thrombocytopenic patients with SLE have antiphospholipid (aPL) antibodies and are at increased risk for thrombotic rather than bleeding complications (see [Chapter 141](#)). Acute, severe thrombocytopenia can be a prominent feature in patients with a severe multisystem exacerbation of lupus. Rarely, patients with SLE develop an illness that closely resembles TTP or HUS; these patients should be treated with plasma exchange. Thrombocytopenia as a feature of SLE-associated, viral-induced macrophage activation syndrome has been reported.

Treatment of the thrombocytopenia of SLE is similar to that of ITP (see [Chapter 131](#)). Corticosteroids constitute the first line of therapy, but many patients do not respond or require high doses. High-dose IVIg may be useful in patients who are bleeding to transiently increase the platelet count. Before resorting to splenectomy, one could try danazol (an attenuated androgen) in doses of 200–800 mg/day. Higher doses can cause hepatitis. Typically, several weeks of treatment are required before a benefit is seen. Splenectomy is probably as effective in achieving platelet count remission in SLE as in ITP. Patients with refractory thrombocytopenia sometimes benefit from more aggressive therapies, such as azathioprine, intermittent-pulse cyclophosphamide, plasmapheresis synchronized with pulse cyclophosphamide, cyclosporine, thrombopoietin mimetics, or rituximab.

Antiphospholipid Syndrome

Antiphospholipid syndrome (APS; see [Chapter 141](#)) is characterized by occurrence of one or more clinical events (e.g., venous, arterial or small vessel thrombosis, pregnancy loss, preterm delivery for patients with severe preeclampsia or placental insufficiency) associated with IgG, IgM, or IgA antibodies that recognize a complex of one or more protein cofactors (e.g., β_2 GPI, annexin V, prothrombin, protein C, protein S) bound to negatively charged phospholipid. Many patients (30%–50%) with this syndrome have thrombocytopenia, which is typically mild and intermittent; approximately 15% have autoimmune hemolysis. The APS should be considered in patients who develop idiopathic lower limb or abdominal vein (mesenteric, renal, adrenal) thrombosis, cerebral venous (dural sinus) thrombosis, cardiac valvulitis, nonatheromatous arterial thrombosis (especially thrombotic stroke in a patient younger than 50 years of age), dermal microvascular thrombosis (acrocyanosis, digital ulceration or

gangrene, livedo reticularis), or acute multiorgan failure associated with DIC or widespread thrombosis of the microvasculature (catastrophic APS).

The mechanism of the prothrombotic tendency in patients with APS remains elusive, but interference with endothelial cell function, impaired fibrinolysis, antibody-mediated platelet activation, formation of endothelial microparticles, interference with thrombin and factor Xa degradation by antithrombin, disturbance in the protein C anticoagulant pathway or anticoagulant activity of β_2 GPI have all been described. Disruption of the antithrombotic annexin V antithrombotic “shield” by aPL antibodies has been proposed to explain pregnancy losses through placental vascular thrombosis. Evidence indicates that thrombocytopenia in patients with APS is associated with platelet GP-reactive autoantibodies.

aPL antibodies are detected by either of two methods: (1) solid-phase ELISA with purified phospholipids (usually cardiolipin) as target antigens or (2) a “functional” assay for so-called lupus anticoagulant (LA) activity, shown by demonstrating inhibition of certain phospholipid-dependent coagulation assays, such as the activated partial thromboplastin time or the Russell viper venom time. Although aPL antibodies are frequently detected in patients with SLE, they can also be found in patients with other autoimmune disorders, malignancy, or infections or as a complication of certain drugs (e.g., procainamide). Often no associated condition is identified (“primary” APS). aPL antibodies of low titer are sometimes found in normal persons, particularly elderly individuals, or during normal pregnancy. Autoantibody “cluster” studies show that anticardiolipin, LA, and anti-double-stranded DNA antibodies occur together more often than with other SLE-associated autoantibodies (e.g., anti-Sm, anti-Ro, anti-RNP).

There are intriguing parallels between the APS and HIT: in both disorders, the antibodies are directed at a protein target (β_2 GPI and PF4, respectively) bound to a negatively charged species (anionic phospholipid and heparin, respectively). For both, high-titer IgG antibodies that result in a positive “functional” test result (LA activity and HIT-IgG-induced platelet activation, respectively) are most likely to be associated with clinical disease. Both disorders are characterized by the paradox of thrombocytopenia associated with increased risk for venous and arterial thrombosis.

To help physicians diagnose the APS, clinical and laboratory criteria have been developed. The laboratory criteria include the presence of anticardiolipin, anti- β_2 GPI, or LA antibodies (moderate- to high-titer IgG or IgM) on two or more occasions at least 12 weeks apart. The major clinical criteria are thrombosis and complications of pregnancy. Thrombosis can involve large arteries or veins or small vessels within any organ. The complications of pregnancy include one or more unexplained deaths of normal fetus(es) after week 10 of gestation or premature births (before 34 weeks) or more than three spontaneous abortions before week 10 of gestation. Some experts advocate for thrombocytopenia to be included within the criteria for APS.²⁵

Specific treatment for the thrombocytopenia is not usually required. For many patients, long-term anticoagulant or antiplatelet therapy, or both, are needed to prevent recurrent thrombosis. For patients with recurring pregnancy losses and aPL antibodies, randomized trials have documented the benefit of low-dose aspirin combined with either low-dose UFH or low-molecular-weight heparin (LMWH).

Malignancy

Thrombocytopenia complicating malignant disorders most frequently results from antineoplastic treatment or BM replacement by tumor. However, certain thrombocytopenic syndromes have been associated with malignancy, including autoimmune thrombocytopenia, DIC, and thrombotic microangiopathy.

ITP attributable to platelet GP-reactive autoantibodies can complicate neoplastic lymphoproliferative diseases such as Hodgkin disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia,

and multiple myeloma. Sometimes the thrombocytopenia responds to treatment of the neoplasm, although in some patients (particularly those with Hodgkin disease), the thrombocytopenia is indistinguishable from ITP and is not related to the activity of the lymphoma.

DIC occurs with certain malignancies, particularly adenocarcinoma of the pancreas, stomach, lung, colon, breast, and prostate. Some patients present with venous or, less commonly, arterial thrombosis as the first clinical manifestation of their malignancy. In these patients, the presence of thrombocytopenia is an important clue that should prompt investigations for DIC, such as measurement of fibrinogen or D-dimer levels. In the author's experience, the platelet count typically rises to normal or even elevated levels with heparin therapy because heparin ameliorates the DIC process; however, recurrent thrombocytopenia and thrombosis can occur within hours of discontinuing the heparin therapy.²⁶ Cancer patients with DIC and venous thrombosis are also at increased risk for warfarin-associated venous limb gangrene.²⁶ The role of various tumor-associated procoagulant substances—such as “cancer procoagulant” (a 68-kDa cysteine proteinase that activates factor X independently of tissue factor/factor VIIa) and cancer-associated tissue factor (which is expressed on tumor cells, as well as circulating microparticles)—suggest pathophysiologic parallels with microthrombosis in HIT because both cancer-associated DIC and acute HIT are risk factors for phlegmasia cerulea dolens and venous limb gangrene during anticoagulation with warfarin. Thus cancer patients with DIC should receive heparin (especially LMWH) rather than warfarin anticoagulation (see box on Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia in Chapter 133). DIC with hemorrhagic manifestations is characteristically seen in some patients with prostate cancer and in many patients with acute promyelocytic leukemia. It is crucial to recognize promyelocytic leukemia because treatment with all-*trans*-retinoic acid produces differentiation of the malignant cells, thereby rapidly reducing the life-threatening bleeding risks attributable to hyperfibrinolysis.

A destructive thrombocytopenic disorder that resembles HUS or TTP has been described in patients with advanced cancer. In some patients, mitomycin, gemcitabine, or other drugs may have contributed to the microangiopathy. DIC is not usually present. Some patients respond transiently to plasmapheresis, but for many, response to any therapy is poor.

Macrophage Activation (Hemophagocytic) Syndrome

The macrophage activation (or hemophagocytic) syndrome comprises a heterogeneous group of disorders characterized by variable cytopenias and morphologic evidence of macrophage phagocytosis of RBCs, granulocytes, and platelets; hyperferritinemia, hypercytokinemia, and sepsis-like features are characteristic, with potential for evolution to fatal multiple organ failure.²⁷ Some adult patients have an aggressive disease characterized by high fever, weight loss, prominent hepatosplenomegaly, severe pancytopenia, elevated liver enzymes, and often a terminal infection. Both T- and B-cell lymphomas can explain such a dramatic syndrome. However, similar patients with fulminant illness have been described after otherwise unremarkable bacterial or viral infections (particularly those caused by Epstein-Barr virus). In children, the high mortality rate associated with hemophagocytic lymphohistiocytosis warrants aggressive treatment, including anti-neoplastic chemotherapy and BM transplantation. Nonneoplastic but nonetheless severe hemophagocytosis can be seen in patients with certain infections (e.g., babesiosis, ehrlichiosis, HIV infection), as well as in patients with rheumatologic disorders (SLE, Still disease, ankylosing spondylitis). Laboratory indicators of macrophage activation syndrome include markedly elevated ferritin,²⁸ high levels of soluble CD163 and CD25, and morphologic evidence of hemophagocytosis. Treatment should be directed at the underlying illness. Early administration of corticosteroids and high-dose IVIg appears to benefit some patients with nonneoplastic macrophage activation syndrome.

Fig. 132.7 EARLY POSTOPERATIVE PLATELET COUNT DECLINES. (A) Distribution of early postoperative count nadirs. For both orthopedic and cardiac surgery patients, day 2 represents the most common day for the postoperative platelet count nadir to occur (data exclude day 0); beyond postoperative day 4, it is likely that a superimposed thrombocytopenic disorder is occurring. (B and C) Representative postcardiac surgery platelet count declines. Both patients illustrate early hemodilution effects (day 0) and subsequent additional early platelet count declines with nadirs of day 2 (B) and day 3 (C). Neither patient received platelet transfusions. (From Greinacher A, Warkentin TE: *Acquired non-immune thrombocytopenia*. In: Marder VJ, Aird WC, Bennett JS, et al, editors: *Hemostasis and thrombosis: Basic principles and clinical practice*, ed 6. Philadelphia, 2013, Lippincott Williams & Wilkins, p 796.)

Solid Organ and Bone Marrow Transplantation

Thrombocytopenia commonly occurs during episodes of solid organ allograft rejection. It is possible that platelet activation and deposition in the transplanted organ vasculature contribute to the rejection process. Antirejection therapies can also cause thrombocytopenia through increased platelet destruction (antilymphocyte globulin) or BM suppression (azathioprine). Posttransplantation HUS develops in approximately 5% of renal transplant recipients and in even fewer recipients of liver or heart transplants. Although cyclosporine is sometimes implicated in HUS, it can usually be safely resumed after recovery.

Early, severe thrombocytopenia caused by BM-ablative therapy invariably accompanies BM transplantation (BMT). Platelet count recovery to greater than $50 \times 10^9/L$ is more rapid (16 vs. 35 days) in patients receiving autologous mobilized peripheral blood progenitor cells than in those undergoing autologous BMT. Severe persistent thrombocytopenia despite recovery of RBCs and WBCs is relatively common after BMT or peripheral blood transplantation; autoimmune thrombocytopenia has been implicated in some patients. Late-onset thrombocytopenia after BMT that responds to corticosteroids, IVIg, and splenectomy also has been attributed to autoimmune thrombocytopenia. Rarely, transplantation-associated alloimmune thrombocytopenia can be caused by donor–recipient incompatibility involving platelet-specific alloantigens such as PI^A1 (HPA-1a) or Br^a (HPA-5b).

A syndrome of thrombocytopenia, RBC fragmentation, and renal impairment can occur in as many as 10% of patients undergoing BMT, usually beginning 3–12 months after transplantation (BMT-associated thrombotic microangiopathy). The pathogenesis remains

obscure; reduced ADAMTS13 (a disintegrin and metalloproteinase with thrombospondin 13) levels have not been implicated. The hematologic abnormalities can be mild and remit spontaneously, although patients often have residual azotemia and hypertension. More severely affected patients do not usually benefit from plasmapheresis. The syndrome has a poor overall prognosis, and many patients die irrespective of any intervention.

Cardiopulmonary Bypass Surgery

Excess bleeding is a common problem in patients who undergo heart surgery using cardiopulmonary bypass. Many of these patients receive blood transfusions, and approximately 5% require reoperation for postoperative bleeding.

Thrombocytopenia and transient platelet dysfunction (see [Chapter 159](#)) are observed in virtually every patient. Typically, the platelet count falls by 30% to 70%, primarily as a result of hemodilution but also because of bleeding and losses within the extracorporeal perfusion device. Because patients invariably receive heparin during cardiac surgery and have often received heparin in the remote or recent past, immune HIT is frequently considered in the differential diagnosis of early-onset and persisting postcardiac surgery thrombocytopenia; however, HIT is an unlikely explanation for thrombocytopenia even when anti-PF4/heparin antibodies are positive.²⁹

The bleeding time increases markedly during heart surgery (to greater than 30 minutes) but usually improves to less than 15 minutes shortly after surgery and to normal several hours later. By contrast, the thrombocytopenia persists for 3–4 days followed by recovery of the platelet count to values exceeding the preoperative baseline.

The pathogenesis and clinical significance of the hemostatic defect in these patients remain uncertain, but the explanation is probably multifactorial. Studies have described transient, *intrinsic* defects in platelet function. These defects include decreased *in vitro* platelet aggregation, decreased platelet surface membrane proteins, selective depletion of platelet α -granules, and evidence of *in vivo* platelet activation and platelet vesiculation. The platelet dysfunction in heart surgery is also attributable to an *extrinsic* platelet defect resulting from thrombin inhibition by the high doses of heparin. Furthermore, an important role for hyperfibrinolysis in the pathogenesis of bleeding is shown by elevated D-dimer levels in bleeding patients, as well as the efficacy of antifibrinolytic agents in the prevention and treatment of heart surgery-associated bleeding. Other factors in some patients include residual heparin effect after bypass (including heparin rebound) and preoperative use of aspirin and/or clopidogrel. Treatment of platelet dysfunction after cardiopulmonary bypass is discussed in Chapter 159.

THROMBOCYTOPENIA ASSOCIATED WITH CARDIOVASCULAR DISEASE

Congenital Cyanotic Heart Disease

Thrombocytopenia caused by a decrease in platelet life span occurs in some patients with severe cyanotic congenital heart disease and is approximately related to the severity of the polycythemia. Bleeding occurs in a few patients and can be related to platelet function defects, coagulopathy, or hyperfibrinolysis. Reducing the hematocrit by phlebotomy sometimes helps to correct the hemostatic defects.

Valvular Heart Disease

Increased platelet turnover is common in valvular heart disease, and some patients have mild thrombocytopenia. The pathogenesis of the platelet consumption is not well understood, but the defect could be related to increased platelet–von Willebrand factor (vWF) interactions at high shear. Indeed, high-molecular-weight multimers of vWF are reduced in some of these patients, which explains why bleeding from gastrointestinal angiodysplasia in patients with aortic stenosis (Heyde syndrome) typically resolves after aortic valve replacement.³⁰ Thrombocytopenia secondary to consumptive coagulopathy can be seen in intracardiac thrombosis associated with valvular heart disease.

Pulmonary Vascular Disorders

Disorders characterized by pulmonary hypertension can be accompanied by thrombocytopenia, the pathogenesis of which is poorly defined. Thrombocytopenia can occur in association with pulmonary embolism, possibly as a result of DIC. When evaluating such patients, the clinician should inquire about current or recent heparin exposure because HIT and pulmonary embolism are strongly associated.

HEMODILUTION AND PLATELET CONSUMPTION AFTER SURGERY

Platelet count declines of 30% to 70% occur universally after major surgery and reflect the combined effects of hemodilution and increased platelet consumption. Such hemodilution-associated thrombocytopenia is especially prominent after cardiac surgery and is proportional to the amount of fluids (crystalloid, colloid, blood products) administered. The platelet count fall is abrupt and is evident a few hours after surgery. Dilutional coagulopathy also occurs, which is responsible for the minor to moderate increases in coagulation test results that occur transiently after surgery.

Perioperative hemodilution is also usually accompanied by increased platelet consumption related to the effects of surgery. This

helps to explain why the postsurgery platelet count usually continues to decline over the next 1–3 days, with the postoperative nadir (lowest platelet count value) usually occurring at a median of postoperative day 2, with a range between postoperative days 1–4 (Fig. 132.7).² Subsequently, there is a rise in the platelet count that peaks at approximately day 14 at levels often 2–3 times the patient's preoperative baseline before it returns to baseline over the next 2 weeks ($\approx$ day 28). As described earlier in this chapter (see Fig. 132.1), these platelet count changes reflect thrombopoietin physiology.

HEPARIN-INDUCED THROMBOCYTOPENIA

Theodore E. Warkentin

Heparin-induced thrombocytopenia (HIT) is the most important drug-induced immune-mediated cytopenia for several reasons. First, heparin is a widely used anticoagulant (see [Chapter 149](#)). Second, HIT is relatively common, occurring in approximately 1% to 3% of postoperative patients, and 0.2% to 0.5% of medical patients, who receive unfractionated heparin (UFH) derived from porcine intestine for 7–14 days.¹ Third, HIT frequently causes life- and limb-threatening venous or arterial thrombosis. Finally, there are several pitfalls of HIT management, including the potential for thrombocytopenia and/or thrombosis to worsen despite stopping heparin, the high risk for warfarin-associated microthrombosis (most often manifesting as venous limb gangrene), and the potential for failure of approved direct thrombin inhibitor (DTI) therapy because of the confounding of activated partial thromboplastin time (aPTT)-monitored dosing that results from HIT-associated coagulopathies.

HIT is caused by platelet-activating immunoglobulin G (IgG) antibodies that bind to multimolecular complexes of platelet factor 4 (PF4) bound to heparin.^{2,3} Although anti-PF4/heparin antibodies are frequently triggered by heparin therapy, relatively few patients develop clinically evident HIT. Indeed, a major current problem with HIT is its “overdiagnosis”: only 5% to 10% of patients who are referred for antibody testing have a serologic profile that supports a diagnosis of HIT.⁵ The challenge for the clinician is to discern which of the (many) patients who develop thrombocytopenia in association with heparin therapy really have HIT, a conundrum magnified by the observation that at most 50% of anti-PF4/heparin antibody-positive patients have “true” HIT, as indicated by the presence of platelet-activating IgG antibodies.^{1,5}

EPIDEMIOLOGY

[Table 133.1](#) lists risk factors for HIT. The highest risk for HIT is seen in patients with multiple interacting risk factors (e.g., females given postoperative thromboprophylaxis with UFH for 2 weeks [frequency approximately 5%]).⁶ Even higher frequencies (approximately 10%) are reported in patients with ventricular assist devices who are receiving therapeutic doses of UFH. Ironically, even though the risk for HIT appears to be somewhat higher in women (odds ratio, 1.5–2.0),⁶ HIT is rare in pregnancy, particularly with the use of low-molecular-weight heparin (LMWH). The synthetic antithrombin-binding sulfated pentasaccharide, fondaparinux, although similarly immunizing as LMWH, is much less likely than LMWH to cause HIT, likely because fondaparinux does not usually increase the platelet-activating potential of HIT antibodies.⁷ Indeed, fondaparinux appears to be an effective treatment for HIT (discussed later).

Only a minority of patients who form anti-PF4/heparin antibodies following heparin treatment develop clinically evident HIT.^{2,3} The proportion of antibody-positive patients who develop HIT ranges from as high as one-third (e.g., postorthopedic surgery thromboprophylaxis with UFH) to as few as 1 in 50 (postcardiac surgery patients).^{1,2} Notably, the risk for HIT in postcardiac surgery patients who receive UFH thromboprophylaxis is only approximately 1% even though as many as 50% to 80% of patients develop detectable anti-PF4/heparin antibodies within 2 weeks of surgery.¹ In general, those at highest risk for HIT are the subgroup of patients whose anti-PF4/heparin antibodies evince strong platelet-activating properties

in vitro.^{2,3} However, patient-dependent susceptibility factors are also important, because at most only half of all patients who form platelet-activating antibodies develop HIT.

PATHOBIOLOGY

[Fig. 133.1](#) illustrates several features of HIT pathogenesis. Heparin binds reversibly and saturably to platelets and can weakly activate platelets in vitro through potentiation of $\alpha_{IIb}\beta_3$ -mediated outside-in signaling.⁸ In general, the direct platelet-activating effects of heparin, as well as its immunogenicity, are proportional to its molecular mass and degree of sulfation; consequently, LMWH is less likely to cause HIT than UFH.^{1,2,6}

Platelet activation by HIT antibodies occurs because platelet-activating HIT-IgG cross-link platelet Fc γ IIa receptors.^{1–3} The HIT antigens reside on large multimolecular complexes formed between cationic PF4—a member of the CXC subfamily of chemokines—and anionic heparin. A unique laboratory characteristic of HIT is that high heparin concentrations (10–100 units/mL) inhibit platelet activation by the pathogenic IgG⁹; this laboratory feature is exploited in diagnostic testing for HIT (see [Diagnosis](#)).

There is a characteristic timeline that underlies the HIT immune response ([Fig. 133.2](#)).³ Formation of pathogenic IgG antibodies is surprisingly fast, even in patients who have never previously been exposed to heparin. Bacterial cell walls, which are negatively charged, bind PF4, and there is evidence that bacterial infection could be responsible for preimmunization against PF4-dependent antigens.¹⁰ This could explain both the high frequency of anti-PF4/heparin immunization and of clinical HIT (i.e., HIT could represent a misdirected antibacterial immune response).¹⁰ Although heparin-treated patients can form heparin-dependent antibodies of the IgM or IgA subclass, these are unlikely to cause HIT.^{1–3}

Excess thrombin generation contributes to the pathogenesis of some of the unusual sequelae of HIT, which can include venous thromboembolism,¹¹ warfarin-associated venous limb gangrene,¹² and overt (decompensated) disseminated intravascular coagulation (DIC). Increased thrombin generation in HIT is triggered by the shedding of procoagulant microparticles from platelets activated by HIT antibodies, as well as by the expression of tissue factor by endothelial cells or monocytes activated by HIT antibodies (see [Fig. 133.1](#)).¹³

As noted, thrombocytopenia develops in only a minority of patients who form HIT antibodies.¹ The variable risk for HIT in different patient populations may reflect variations in the susceptibility of platelets to activation by HIT-IgG and/or differences in the levels and immunoglobulin class composition of HIT antibodies.^{2,3} Poorly defined clinical factors also influence the risk for HIT, which occurs more often in surgical patients than in medical or obstetric patients.⁶ Major trauma was more likely than minor trauma to be associated with HIT antibody formation and clinical HIT in one study.¹⁴ There is indirect evidence that formation of stoichiometrically optimal complexes of PF4/heparin influences the risk for immunization.¹⁵ The clinical situation influences the type of HIT-associated thrombosis: venous thromboembolism typically develops in orthopedic patients with HIT, whereas thrombosis develops equally often in arteries and in veins in cardiovascular patients with HIT.¹

TABLE 133.1**Risk Factors for Heparin-Induced Thrombocytopenia**

Heparin type	Unfractionated > low-molecular-weight heparin > fondaparinux
Patient type	Postoperative (major > minor surgery) > medical > obstetric/pediatric
Dose ^a	Prophylactic dose > therapeutic dose > flushes
Duration	11–14 days ^b > 5–10 days > 4 days or fewer
Sex	Female > male

^aImportance of heparin dose is uncertain because of confounding effect of patient type (e.g., postoperative patients tend to receive prophylactic-dose heparin whereas medical patients [e.g., with venous thromboembolism] are more likely to receive therapeutic-dose heparin); nevertheless, reported frequencies of heparin-induced thrombocytopenia (HIT) are relatively high in patients given postoperative prophylactic-dose heparin.

^bHeparin exposure beyond 14 days does not usually increase the risk of HIT beyond that of an 11- to 14-day exposure.

CLINICAL AND LABORATORY MANIFESTATIONS

Most patients with HIT have moderate thrombocytopenia; The median platelet count nadir is approximately $60 \times 10^9/L$; for 90% of patients, the platelet count nadir is greater than $20 \times 10^9/L$ (Fig. 133.3).¹⁶ In the rare patient whose platelet count falls to less than $10 \times 10^9/L$, there is often evidence of overt DIC, and red cell fragments and circulating normoblasts may be evident on examination of the blood smear. Thrombosis can occur in HIT patients even if there is a minimal decrease in the platelet count, and even if the platelet count nadir never falls below $150 \times 10^9/L$.¹

The platelet count fall usually begins 5–10 days after the initiation of an immunizing heparin exposure and while the patient continues to receive heparin (typical-onset HIT).¹⁷ Usually the immunizing trigger is heparin given during surgery (e.g., cardiac or vascular surgery) or that is started soon after surgery (e.g., thromboprophylaxis). Interestingly, starting LMWH thromboprophylaxis before elective surgery (as is more frequently done in Europe) is less likely to be associated with antibody formation compared with postoperative first-dose administration.¹⁵

HIT is recognized in approximately one-quarter of patients when the platelet count fall occurs abruptly after restarting UFH or LMWH (rapid-onset HIT). Invariably, such patients have been exposed to heparin within the previous 5–100 days,¹⁷ because HIT antibodies are transient and are only detectable for several weeks after an immunizing heparin exposure. Consequently, rapid-onset HIT, which is caused by administration of heparin to a patient with preformed HIT antibodies, is strongly associated with recent heparin exposure.

Sometimes, thrombocytopenia occurs several days after a brief exposure to heparin or worsens despite stopping heparin (delayed-onset HIT).^{4,18} On exceptionally rare occasions, a transient prothrombotic disorder that resembles HIT clinically and serologically occurs without an apparent preceding heparin exposure; triggers of so-called “spontaneous HIT syndrome” include knee replacement surgery (perhaps because of release of heparin-like glycosaminoglycans from knee cartilage) and infection.^{19,20}

HIT is a highly prothrombotic condition: At least 50% of HIT patients develop thrombosis.^{1,11,16} Both venous (deep vein thrombosis and/or pulmonary embolism) and arterial (especially aortic and iliofemoral arterial thrombosis, stroke, or myocardial infarction) thrombosis can occur.¹¹ Other complications include necrotizing skin lesions at the sites of subcutaneous heparin injection and acute inflammatory/respiratory (anaphylactoid) or transient memory disturbances after intravenous heparin bolus administration to sensitized persons. Unexplained hypotension or abdominal pain in a patient with HIT suggests bilateral adrenal hemorrhagic infarction, which can lead to acute adrenal failure; the hemorrhagic adrenal necrosis is the result of adrenal vein thrombosis.²⁰

Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia

Concurrence of limb ischemia/necrosis and thrombocytopenia suggests one of several hematologic emergencies:

- **Heparin-induced thrombocytopenia.** Occlusion of large lower-limb arteries by platelet-rich “white clots” is characteristic of heparin-induced thrombocytopenia (HIT). The major clue is an otherwise unexplained platelet count fall that begins 5 or more days after initiation of heparin. Urgent thromboembolectomy may be limb sparing. Sensitive assays for HIT antibodies give strongly positive results. See subsequent entry for warfarin.
- **Adenocarcinoma-associated disseminated intravascular coagulation.** Severe venous or arterial thrombosis can develop in patients with metastatic adenocarcinoma who have disseminated intravascular coagulation (DIC).²¹ This often occurs within hours after stopping heparin. A clinical clue is an otherwise unexplained rise in platelet count that occurs with initial or repeated heparin therapy. See next entry for warfarin.
- **Warfarin-induced phlegmasia cerulea dolens/venous limb gangrene.** Coumarin anticoagulants, such as warfarin, can lead to venous ischemia (phlegmasia cerulea dolens) or venous limb gangrene in patients with DIC caused by HIT¹² or adenocarcinoma.²¹ Limb loss can occur even though the limb pulses are palpable.
- **Sepsis-associated microvascular thrombosis.** Acquired natural anticoagulant depletion (e.g., markedly reduced antithrombin or protein C levels) can complicate DIC associated with sepsis, leading to bilateral acral limb ischemia or necrosis involving feet and (sometimes) fingers/hands (“symmetric peripheral gangrene”).
- **Septic embolism.** Rarely, infective endocarditis or aneurysmal thrombosis leads to the constellation of thrombocytopenia and acute limb ischemia.
- **Antiphospholipid syndrome.** Autoimmune thrombocytopenia and hypercoagulability can interact to produce acute limb ischemia and thrombocytopenia in patients with antiphospholipid syndrome.

Patients with HIT have an unusual predisposition to develop ischemic limb necrosis. Indeed, approximately 5% of such patients develop some degree of limb necrosis necessitating amputation. Occasionally multiple limbs are involved (see the box on **Diagnostic Considerations in the Patient With Limb Ischemia and Thrombocytopenia**).

DIFFERENTIAL DIAGNOSIS

Only approximately 10% of patients who undergo laboratory investigations for clinically suspected HIT have a serologic profile that supports the diagnosis (i.e., detectable heparin-dependent, platelet-activating IgG antibodies that recognize PF4/heparin complexes).⁵ The differential diagnosis includes postoperative thrombocytopenia (hemodilution/platelet consumption), thrombocytopenia of critical illness, and septicemia. Some non-HIT disorders mimic HIT so closely that they warrant the term *pseudo-HIT*. One example of pseudo-HIT is adenocarcinoma-associated DIC, in which the combination of progressive thrombocytopenia and severe venous limb ischemia that occurs during the transitioning of patients from heparin (either UFH or LMWH) to warfarin may suggest a diagnosis of HIT.²¹ Another disorder that can mimic HIT is the antiphospholipid syndrome: here, thrombocytopenia, thrombosis, and a false-positive PF4-dependent enzyme immunoassay (EIA) caused by anti-PF4 (not anti-PF4/heparin) antibodies can be present.²²

CLINICAL SCORING SYSTEMS

The pretest probability of HIT can be estimated using validated scoring systems. The 4Ts system represents a mnemonic that is based

Fig. 133.1 PATHOGENESIS OF HEPARIN-INDUCED THROMBOCYTOPENIA. Heparin produces mild platelet activation, resulting in release of platelet factor 4 (PF4) from platelet α -granules and the formation of immunogenic PF4/heparin complexes. B lymphocytes generate immunoglobulins G (IgGs) that recognize the PF4/heparin complexes; the Fc “tails” of the IgG bind to platelet Fc γ IIa receptors, resulting in Fc receptor clustering and consequent “strong” platelet activation. Platelet-derived microparticles are generated that accelerate thrombin generation. The heparin-induced thrombocytopenia (HIT) antibodies also recognize PF4 bound to endothelial heparan sulfate, leading to immunoinjury that causes endothelial activation. Recent evidence suggests that HIT antibodies also activate monocytes. The greatly increased thrombin generation observed in HIT helps to explain its association with venous and arterial thrombosis, as well as some of its unusual clinical features (e.g., warfarin-induced venous limb gangrene, decompensated disseminated intravascular coagulation), and also provides a rationale for treatments that control thrombin generation (e.g., with indirect [antithrombin-dependent] or with direct thrombin inhibitors). (Reprinted with permission from Greinacher A, Warkentin TE: *Treatment of heparin-induced thrombocytopenia: An overview*. In Warkentin TE, Greinacher A, editors: *Heparin-induced thrombocytopenia*, ed 4, New York, 2007, Informa Healthcare USA, p 287.)

on Thrombocytopenia, Timing (of onset of thrombocytopenia or thrombosis), Thrombosis (or other clinical sequelae of HIT), and no other explanation for thrombocytopenia, with each of the 4Ts scoring as an integer of 0, 1, or 2 points, based upon the likelihood of HIT (thus the maximum score is 8 points) (Table 133.2).²³ The presence of platelet-activating HIT antibodies is unlikely (<3%) with a low score (≤ 3 points), but relatively probable (approximately 65%) with a high score (≥ 6). An intermediate score (4 or 5) indicates a clinical profile compatible with HIT, but also with other disorders, such as sepsis; here the frequency of platelet-activating HIT antibodies is still only approximately 10% to 20%.

A newer scoring system is called the HIT Expert Probability (HEP) score (Table 133.3).²⁴ In the initial evaluation, a HEP score of 4 points or higher indicated an approximately 50% probability of HIT, whereas a score of 3 points or lower was associated with only a 3% probability of HIT.

It is uncertain whether one scoring system offers advantages over the other. In general, low scores in either system indicate a low probability of HIT, whereas high scores indicate approximately a 50:50 chance of HIT. Thus laboratory testing is crucial to establish a diagnosis of HIT.

LABORATORY DIAGNOSIS

Assays for HIT antibodies can be classified as platelet “activation” (or “functional”) and PF4-polyanion “antigen” assays (or immunoassays). Activation assays that measure serotonin release from ¹⁴C-labeled, washed platelets (i.e., the serotonin-release assay [SRA]) are quite sensitive and specific for detecting clinically significant HIT antibodies.²⁵ Important quality control maneuvers include the selection of platelet donors whose platelets respond well to Fc receptor

Fig. 133.2 CHARACTERISTIC TIMELINE OF HEPARIN-INDUCED THROMBOCYTOPENIA. Antiplatelet 4 (PF4)/heparin antibodies (by enzyme immunoassay [EIA]) per postoperative day in 12 patients with heparin-induced thrombocytopenia (HIT) and 36 seropositive non-HIT control patients. (A) Mean ($\pm$ standard error of the mean [SEM]) optical density (OD) of anti-PF4/heparin antibodies detected using commercial immunoassay (EIA-GAM) that detects antibodies of all three immunoglobulin classes (IgG, IgA, IgM). HIT patients are indicated by *blue squares*, and seropositive non-HIT controls by *green squares*. On each day beginning on postoperative day 6, there is a significant difference in the mean of the OD levels between the patients with HIT and the seropositive non-HIT controls ($p < .05$ by nonpaired t -test). At the *top* of the figure, summary data for 12 HIT patient profiles are shown for four key events (first day of antibody detection, beginning of HIT-related platelet count fall, platelet count fall $\geq 50\%$, and thrombotic event), summarized as median (*small purple squares within rectangles*), interquartile range (*rectangles*), and range (*ends of thin black lines*). (B) Mean ($\pm$ SEM) OD values of anti-PF4/heparin antibodies detected using an in-house immunoassay (EIA-Ig) that detects antibodies of the individual immunoglobulin classes, IgG (*red circles*), IgA (*green triangles*), and IgM (*blue inverted triangles*) for HIT (*solid symbols*) and non-HIT (*open symbols*). On each postoperative day beginning on day 5, there is a significant difference in the mean of the OD units for the IgG immunoassay between the patients with HIT and the seropositive non-HIT controls (** $p < .005$ for days 6–10; * $p < .05$ for days 5, 11, and 12). (From Warkentin TE, Sheppard JI, Moore JC, et al: *Studies of the immune response in heparin-induced thrombocytopenia*. Blood 113:4693, 2009.)

stimulation, as well as the inclusion of negative and positive HIT sera of variable reactivity to ensure that the test platelets identify weaker HIT sera. The characteristic activation profile produced by HIT serum includes increased platelet activation at low heparin concentrations (0.05–0.3 units/mL), but background platelet activation at high heparin concentrations (10–100 units/mL).⁹ Strong platelet activation induced by HIT sera even in the absence of pharmacologic heparin is a feature of delayed-onset HIT and may generally indicate more severe HIT.¹⁸

Fig. 133.3 SEVERITY OF THROMBOCYTOPENIA IN DRUG-INDUCED IMMUNE THROMBOCYTOPENIA: A COMPARISON OF HEPARIN-INDUCED THROMBOCYTOPENIA VERSUS OTHER DRUG-INDUCED IMMUNE THROMBOCYTOPENIA DISORDERS. Whereas drug-induced immune thrombocytopenia (D-ITP) is strongly associated with petechiae and purpura, heparin-induced thrombocytopenia (HIT) is strongly associated with thrombosis. Note: The heights of the D-ITP and HIT curves are not drawn to scale, because HIT is more common than all DITP disorders combined. (From Warkentin TE: *Drug-induced immune-mediated thrombocytopenia—from purpura to thrombosis*. N Engl J Med 356:891, 2007.)

Three enzyme(-linked) immuno(sorbent) assays (EIAs or ELISAs) are commercially available for detecting antibodies that recognize PF4 bound to heparin, to the polyanion, polyvinyl sulfonate, or to PF4 (from platelet lysate) bound to protamine. These assays are very sensitive for detecting HIT antibodies but are much more likely than washed platelet activation assays to detect clinically insignificant anti-PF4/heparin antibodies.^{2,3,5} Thus results of laboratory tests must be interpreted in the clinical context—that is, HIT is a “clinicopathologic” syndrome.⁴ Activation and antigen assays are not 100% concordant, and there are advantages if reference laboratories are able to perform both types of assay. In general, serum or plasma from patients with clinical HIT have strongly positive assay results, whereas clinically insignificant antibodies give weaker results.^{2,5} Indeed, if the EIA yields only a weakly positive result (e.g., 0.40 to 1.0 absorbance units), the corresponding probability of “true” HIT is 5% to 10% at most. In contrast, if the EIA yields a strongly positive result (>2.0 units), the probability of HIT exceeds 90%.⁹ Table 133.4²⁵ provides evidence from three studies supporting the greater diagnostic specificity of the SRA compared with the EIA: importantly, EIA+/SRA– status does *not* support a diagnosis of HIT.

PROGNOSIS

Approximately half of all patients with SRA+ HIT have clinically evident thrombosis at the time of initial diagnosis of HIT.¹¹ Among patients without thrombosis at diagnosis, there appears to be a high risk (approximately 25%–50%) for subsequent thrombosis if heparin is simply discontinued.¹¹ It is increasingly accepted that further anticoagulation is indicated in most patients strongly suspected as having “isolated” HIT^{26,27}—that is, HIT recognized because of thrombocytopenia rather than because of HIT-associated thrombosis.

THERAPY

Although it is standard practice to discontinue heparin in patients strongly suspected of having HIT, including stopping heparin “flushes” of intravascular catheters (with substitution of saline flushes), heparin cessation is not necessarily beneficial, for two reasons:

TABLE 133.2

4Ts Scoring System: Estimating the Pretest Probability of Heparin-Induced Thrombocytopenia

Points (0, 1, or 2 for Each of Four Categories: Maximum Possible Score = 8)			
	2	1	0
Thrombocytopenia (acute)	Platelet fall >50% (nadir $\geq 20 \times 10^9/L$) and no surgery within preceding 3 days	Nadir, $10\text{--}19 \times 10^9/L$; or any 30%–50% fall; or, >50% fall within 3 days of surgery	Nadir, $<10 \times 10^9/L$; or any <30% fall
Timing ^a of platelet count fall, thrombosis, or other sequelae	Clear onset between days 5–10; or ≤ 1 day (if prior heparin exposure in the past 5–30 days)	Consistent with day 5–10 fall, but not clear (e.g., missing platelet counts); or ≤ 1 day (heparin exposure within past 31–100 days); or platelet fall after day 10	Platelet count fall begins in ≤ 4 days without recent heparin exposure
Thrombosis or other clinical sequelae	New proven thrombosis; skin necrosis ^b ; anaphylactoid reaction after IV heparin bolus; adrenal hemorrhage	Progressive or recurrent thrombosis; erythematous skin lesions ^b ; suspected thrombosis (awaiting confirmation with imaging)	None
Other cause for thrombocytopenia not evident	No other explanation for platelet count fall is evident	Possible other cause is evident	Definite other cause is present

Pretest probability score: 6–8 = HIGH; 4–5 = INTERMEDIATE; 0–3 = LOW

The scoring system shown here has undergone minor modifications from previously published scoring systems.

^aFirst day of immunizing heparin exposure considered day 0; immunizing heparin is usually that given during or soon after surgery (e.g., unfractionated heparin [UFH] during cardiac surgery is more immunogenic than UFH given during preceding acute coronary syndrome or with heart catheterization); the day the platelet count *begins* to fall is considered the day of onset of thrombocytopenia.

^bSkin lesions occurring at heparin injection sites.

Reprinted, with permission, from Warkentin TE: Clinical picture of heparin-induced thrombocytopenia. In Warkentin TE, Greinacher A, editors: *Heparin-induced thrombocytopenia*, ed 4, New York, 2007, Informa Healthcare USA, pp 21–66.

TABLE 133.3 HIT Expert Probability (HEP) Scoring System

Clinical Feature	Score
1. Magnitude of fall in platelet count (measured from peak platelet count to nadir platelet count since heparin exposure)	
a. <30%	-1
b. 30%–50%	1
c. >50%	3
2. Timing of fall in platelet count	
<i>For patients in whom typical-onset HIT is suspected</i>	
a. Fall begins <4 days after heparin exposure	-2
b. Fall begins 4 days after heparin exposure	2
c. Fall begins 5–10 days after heparin exposure	3
d. Fall begins 11–14 days after heparin exposure	2
e. Fall begins >14 days after heparin exposure	-1
<i>For patients with previous heparin exposure in last 100 days in whom rapid-onset HIT is suspected</i>	
f. Fall begins <48 h after heparin reexposure	2
g. Fall begins >48 h after heparin reexposure	-1
3. Nadir platelet count	
a. $\leq 20 \times 10^9/L$	-2
b. $> 0 \times 10^9/L$	2
4. Thrombosis (Select no more than one)	
<i>For patients in whom typical-onset HIT is suspected</i>	
a. New VTE or ATE ≥ 4 days after heparin exposure	3
b. Progression of preexisting VTE or ATE while receiving heparin	2
<i>For patients in whom rapid-onset HIT is suspected</i>	
c. New VTE or ATE after heparin exposure	3
d. Progression of preexisting VTE or ATE while receiving heparin	2
5. Skin necrosis	
a. Skin necrosis at subcutaneous heparin injection sites	3
6. Acute systemic reaction	
a. Acute systemic reaction after intravenous heparin bolus	2
7. Bleeding	
a. Presence of bleeding, petechiae, or extensive bruising	-1
8. Other causes of thrombocytopenia (Select all that apply)	
a. Presence of a chronic thrombocytopenic disorder	-1
b. Newly initiated nonheparin medication known to cause thrombocytopenia	-2
c. Severe infection	-2
d. Severe DIC (defined as fibrinogen <100 mg/dL and D-dimer >5.0 $\mu\text{g/mL}$)	-2
e. Indwelling intraarterial device (e.g., IABP, VAD, ECMO)	-2
f. Cardiopulmonary bypass within previous 96 h	-1
g. No other apparent cause	3

ATE, Arterial thromboembolism; DIC, disseminated intravascular coagulation; ECMO, extracorporeal membrane oxygenation; HIT, heparin-induced thrombocytopenia; IABP, intraaortic balloon pump; VAD, ventricular assist device; VTE, venous thromboembolism. In its initial evaluation, a HEP score of ≥ 4 points indicated an approximately 50% probability of HIT, whereas a score of ≤ 3 points was associated with only a 3% probability of HIT. Reprinted, with permission, from Cuker A, Arepally G, Crowther MA, et al: The HIT Expert Probability (HEP) Score: A novel pre-test probability model for heparin-induced thrombocytopenia based on broad expert opinion, *J Thromb Haemost* 8:2642, 2010.

TABLE 133.4

Frequency of Thrombocytopenia (>50% Platelet Count Fall) Among EIA+ Patients (Polyspecific or IgG-Specific Assay) Who Received Heparin (UFH or LMWH): A Comparison of SRA+ versus SRA–Status

SRA Status	Positive in Polyspecific EIA (IgG/A/M)	Positive in IgG-Specific EIA
A. Postorthopedic Surgery		
SRA+	12/24	12/24
SRA–	0/58	0/16
<i>p</i>	< .0001	.0009
B. Venous Thromboembolism		
SRA+	4/4	4/4
SRA–	0/15	0/6
<i>p</i>	.0003	.0048
C. Postcardiac Surgery		
SRA+	4/11	NA
SRA–	0/152	NA
<i>p</i>	< .0001	NA

The data are consistent with the SRA having a high sensitivity for heparin-induced thrombocytopenia (>95%); the specificity of the SRA depends on the clinical situation but in most circumstances is at least 90%. Patients in studies A and B were tested in both the polyspecific and IgG-specific assays. EIA, Enzyme immunoassay; LMWH, low-molecular-weight heparin; NA, not available; SRA+, positive in the serotonin-release assay; SRA–, negative in the serotonin-release assay; UFH, unfractionated heparin. Reprinted, with modifications, with permission, from Warkentin TE: How I diagnose and manage HIT, *Hematology Am Soc Hematol Educ Program* 2011:143, 2011.

Currently there are two types of anticoagulant therapeutic approaches that are commonly used to treat HIT: (1) long-acting indirect (i.e., antithrombin-dependent) factor Xa inhibitors (danaparoid, fondaparinux), and (2) DTIs (argatroban, bivalirudin). In the author's opinion, indirect factor Xa inhibitors—although not approved in the United States for treatment of HIT—are the preferred treatment option for HIT, because they have numerous advantages over DTIs (Table 133.5). In addition, because approximately 90% of patients suspected of HIT do not have HIT,⁵ another advantage for indirect factor Xa inhibitors is that these agents, unlike DTIs, are safe and effective for prevention and treatment of thrombosis in numerous non-HIT settings.

Indirect Factor Xa Inhibitors: Danaparoid and Fondaparinux

Danaparoid is an anticoagulant heparinoid (mixture of glycosaminoglycans) with predominant inhibitory activity against factor Xa that is effective for treating HIT; however, danaparoid was never approved for HIT treatment in the United States (although it was approved in many other countries, including Canada and in the European Union) and was discontinued in the United States in April 2002. Danaparoid was shown to be safe and effective for treatment of HIT in an open-label randomized controlled trial (versus dextran 70) and in a retrospective comparison against anacrod (defibrinogenating snake venom) and/or vitamin K antagonist therapy.

In recent years, however, physicians have increasingly been using fondaparinux as off-label therapy for HIT. The advantages of fondaparinux include its long half-life, the fact that it does not require coagulation monitoring nor does it influence the aPTT or international normalized ratio (INR), its low potential to cross-react with HIT antibodies, and low cost. In addition, because relatively few patients with suspected HIT actually have this diagnosis, the wide experience with fondaparinux and its approval for the prevention and treatment of thrombosis in non-HIT settings constitute other advantages. To date, the experience with fondaparinux to treat HIT has

(1) heparin likely has an anticoagulant effect even in patients with HIT, and (2) HIT antibodies often cause ongoing platelet activation and hypercoagulability in the absence of pharmacologic heparin. In addition, HIT antibody levels can decline even with continued heparin. The recognition that patients with HIT have increased thrombin generation¹² provides a rationale for use of nonheparin anticoagulant agents that rapidly inhibit thrombin or its generation.

TABLE 133.5**Comparison of the Two Classes of Anticoagulants Used to Treat Heparin-Induced Thrombocytopenia**

	Indirect (AT-Dependent) Factor Xa Inhibitors: Danaparoid, Fondaparinux	Direct Thrombin Inhibitors: r-Hirudin (Lepirudin, Desirudin), Argatroban, Bivalirudin
Half-life	✓ Long (danaparoid, 25 h ^a ; fondaparinux, 17 h): reduces risk of rebound hypercoagulability	Short (<2 h): potential for rebound hypercoagulability
Dosing	✓ Both prophylactic- and therapeutic-dose regimens ^b	Prophylactic-dose regimens are not established (exception: subcutaneous desirudin)
Monitoring	✓ Direct (anti-Xa levels): accurate drug levels obtained	Indirect (aPTT): risk for DTI underdosing resulting from aPTT elevation caused by non-DTI factors, including HIT-associated DIC
Effect on INR	✓ No significant effect: thus simplifies overlap with warfarin	Increases INR: argatroban > bivalirudin > r-hirudin; complicates warfarin overlap
Protein C pathway	✓ Adverse effect unlikely (with reduced thrombin generation, there will be less thrombin to activate protein C)	Thrombin inhibition could impair thrombin-mediated activation of protein C pathway
Reversibility of action	✓ Irreversible inhibition: AT forms covalent bond with factor Xa	Irreversible inhibition only with r-hirudin
Efficacy and safety in non-HIT settings	✓ Treatment and prophylaxis of VTE (danaparoid, fondaparinux) and ACS (fondaparinux)	Not established for most non-HIT settings (exception: bivalirudin established for PCI)
Platelet activation	✓ Danaparoid inhibits platelet activation by HIT antibodies	No effect
Inhibition of clot-bound thrombin	No effect	✓ Inhibition of both free and clot-bound thrombin
Drug clearance	Predominantly renal	Variable (predominantly hepatobiliary: argatroban; predominantly renal: r-hirudin)
Cost	✓ Relatively low ^c	Relatively high ^c

Check mark (✓) indicates favorable feature in comparison of drug classes (author's opinion).

^aFor danaparoid, half-lives of its anti-thrombin (anti-IIa) and its thrombin generation inhibition activities (2–4 h and 3–7 h, respectively) are shorter than for its anti-Xa activity (approximately 25 h).

^bAlthough therapeutic dosing is recommended for HIT, availability of prophylactic-dose regimens increases flexibility when managing potential non-HIT situations.

^cAnother cost consideration is that a patient can be discharged to home on subcutaneous danaparoid or fondaparinux, whereas an additional 5–7 in-hospital days may be required for DTI-warfarin overlap before discharge from hospital.

ACS, Acute coronary syndrome; aPTT, activated partial thromboplastin time; AT, antithrombin; DIC, disseminated intravascular coagulation; DTI, direct thrombin inhibitor; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; PCI, percutaneous coronary intervention; VTE, venous thromboembolism.

Reprinted, with modifications, with permission, from Warkentin TE: Agents for the treatment of heparin-induced thrombocytopenia, *Hematol Oncol Clin North Am* 24:755, 2010.

been favorable;^{28–31} a recent retrospective propensity score-matched study of 133 fondaparinux-treated HIT patients (with 60 controls) concluded that fondaparinux has similar efficacy and safety as argatroban and danaparoid.³² Also, fondaparinux is much less likely than UFH or LMWH to precipitate rapid-onset HIT in patients who have unrecognized HIT antibodies.³³ Although fondaparinux thromboprophylaxis has been associated with rare cases of de novo HIT,²⁸ this should not deter from its use as a treatment of HIT because the potential to trigger immunization is “dissociated” from whether an anticoagulant potentiates antibody-induced platelet activation,⁷ and fondaparinux has low potential to exacerbate HIT.³³ Dosing information for danaparoid and fondaparinux is shown in Table 133.6.

In theory, oral direct factor Xa inhibitors, such as rivaroxaban (approved in the United States for thromboprophylaxis after knee or hip replacement surgery), should be effective for treatment of HIT. Anecdotal experience with rivaroxaban²⁰ for this indication is beginning to be reported.

Direct Thrombin Inhibitors: Recombinant Hirudin (Lepirudin, Desirudin), Bivalirudin, Argatroban

The recombinant hirudin-derivative lepirudin (Refludan) is a 65-amino-acid polypeptide that inactivates thrombin by forming a tight, noncovalent 1:1 complex with it. Although this agent is approved for the treatment of HIT-associated thrombosis in the European Union, the United States, and elsewhere²⁶ it was discontinued by the manufacturer in 2012.

Bivalirudin (Angiomax) is a 20-amino-acid thrombin inhibitor modeled after hirudin that is composed of two peptide fragments that recognize the active site of thrombin and its fibrinogen-binding site, linked by a tetraglycine spacer. The half-life of bivalirudin is about one-third that of lepirudin (25 versus 80 minutes), and only minor dose adjustments are needed in patients with renal insufficiency because bivalirudin is only partially cleared by the kidneys. It is approved as an alternative to heparin in patients undergoing percutaneous coronary intervention (PCI), including those with HIT. Its short half-life and predominantly extrarenal elimination are reasons why it is an option for intraoperative anticoagulation in patients undergoing cardiac surgery, when heparin is contraindicated because of acute or recent HIT. Experience using bivalirudin off-label to treat HIT outside the PCI setting is limited. Anaphylaxis has not been reported.

Argatroban (marketed as argatroban in the United States and as Novastan elsewhere) is a small-molecule (527-Da) DTI that undergoes predominantly hepatobiliary excretion and is therefore suitable for use without dose adjustment in patients with renal failure (the dose is reduced by three-quarters in patients with hepatic insufficiency). Argatroban is approved in the United States for both treatment and prevention of thrombosis in HIT. It is given in the same dosage for both indications (usual starting infusion rate of 2 µg/kg/min without an initial bolus). However, lower starting doses are usually given (e.g., 0.5–1.2 µg/kg/min), especially in critically ill patients. Argatroban (in substantially higher doses) is also approved for anticoagulation during PCI in patients with acute HIT or a history of HIT. Its half-life is 40–50 minutes. Argatroban prolongs the INR

TABLE 133.6 Treatment Schedules for Danaparoid and Fondaparinux

Anticoagulant	Therapeutic Dosing Protocol for HIT-Associated Thrombosis ^a	Anticoagulant Monitoring	Clearance	Half-Life (h)	Comment
Danaparoid	Initial bolus, 2250 units ^b IV; accelerated infusion (400 units/h × 4 h, 300 units/h 4 h; then 200 units/h IV, subsequently adjusted by antifactor Xa levels)	Antifactor Xa levels (target, 0.5–0.8 units/mL)	Renal (minor)	25	Widely approved for HIT treatment (although not in the United States); not available in the United States; low risk for in vivo cross-reactivity; prophylactic-dose therapy ^c may be appropriate when clinical suspicion for HIT is low
Fondaparinux	7.5 mg ^d subcutaneous once daily	Anti-Xa factor levels (target levels not well established)	Renal (major)	17	Not approved for HIT treatment (although increasingly used as off-label therapy). Prophylactic-dose therapy ^e may be appropriate when clinical suspicion for HIT is low, or if there is renal insufficiency

^aTherapeutic dosing is usually appropriate for strongly suspected or confirmed HIT (including “isolated” HIT, i.e., HIT without apparent thrombosis), or when thrombosis is documented.

^bAdjust IV danaparoid bolus for body weight: <60 kg, 1500 units; 60–75 kg, 2250 units; 75–90 kg, 3000 units; >90 kg, 3750 units.

^cProphylactic-dose regimen, 750 units subcutaneous every 8 h (for renal failure, reduce to 750 units every 12 h).

^dFive milligrams for body weight <50 kg and 10 mg for body weight >100 kg; the author sometimes gives 10 mg as the first and/or second dose (rather than 7.5 mg) for severe HIT. Because HIT treatment is usually started in the afternoon, the author usually gives the second dose (and subsequent doses) at 8 AM (i.e., the interval between first and second doses is often only 14–20 h rather than 24 h), which helps to achieve steady-state therapy more quickly. Dose reduction and antifactor Xa monitoring (if available) is appropriate if being used in a patient with renal insufficiency.

^eProphylactic-dose regimen, 2.5 mg subcutaneous every day (assumes normal renal function).

HIT, Heparin-induced thrombocytopenia; IV, intravenous.

TABLE 133.7 Treatment Schedules for Lepirudin, Desirudin, Bivalirudin, and Argatroban

Anticoagulant	Dosing Protocol for HIT-Associated Thrombosis	Anticoagulant Monitoring ^a	Clearance	Half-Life (min)	Comment
Lepirudin	No bolus; initial infusion rate: 0.05–0.10 mg/kg/h ^{b,c}	1.5–2.5 × baseline aPTT	Renal ^c	80	Approved dosing regimen (not shown) is too high; no longer available (withdrawn by manufacturer)
Desirudin	Not established	aPTT	Renal	120	Half-life shown is for subcutaneous administration; minimal experience for treating HIT
Bivalirudin	No bolus; initial infusion rate: 0.15–0.20 mg/kg/h	1.5–2.5 × baseline aPTT	Enzymic (80%); renal (20%)	25	Off-label treatment for HIT (although approved for PCI in patient with HIT); minor prolongation of INR (compared with argatroban)
Argatroban	No bolus; initial infusion rate: 2 µg/kg/min	1.5–3.0 × baseline aPTT	Hepatobiliary	40–50	Initial dose 0.5 µg/kg/min in hepatic insufficiency ^d ; moderate or marked prolongation of INR, which complicates overlap with warfarin anticoagulation

Dosing protocols shown are appropriate for most patients with strongly suspected or confirmed HIT whether or not complicated by thrombosis. (Dosing for bivalirudin and argatroban is substantially different when given for PCI.)

^aIn general, the patient's baseline aPTT should be used for calculating target range, when appropriate; otherwise the mean laboratory normal range can be used.

^bThis dosing protocol differs from the package insert (which advises initial bolus of 0.4 mg/kg and initial infusion rate [assuming normal renal function] of 0.15 mg/kg/h); however, this dosing regimen is now considered too high.²⁶

^cMajor dose reduction in renal insufficiency is required.²⁶

^dReduced initial dosing (e.g., 0.5–1.2 µg/kg/min) is also appropriate in patients in intensive care units, with cardiac failure, or postcardiac surgery).

aPTT, Activated partial thromboplastin time; HIT, heparin-induced thrombocytopenia; INR, international normalized ratio; PCI, percutaneous coronary intervention.

more than lepirudin or bivalirudin, and a higher-than-usual target INR during warfarin co-therapy (which depends on the thromboplastin reagent used to measure the INR) can be expected (see [Caveats in Treatment of Heparin-Induced Thrombocytopenia](#)). Argatroban reduced the frequency of a composite end point (new thrombosis, limb amputation, and all-cause mortality) from 56.5% (in historical controls) to 43.8% and 41.5% in two studies of patients with HIT complicated by thrombosis; new thrombosis event rates were reduced

from 34.8% to 19.4% and 13.1%, respectively.²⁶ In patients with isolated HIT, argatroban reduced the rate of new thrombosis from 22.4% to 6.9%, and the combined event rate of new thrombosis, limb amputation, and all-cause mortality from 38.8% to 26.9%.²⁶ Dosing information for the parenteral DTIs is shown in [Table 133.7](#).

In theory, dabigatran, an oral thrombin inhibitor, should also be effective for treatment of HIT. To date, experience for treating HIT has been minimal.

Caveats in Treatment of Heparin-Induced Thrombocytopenia

Warfarin and other vitamin K antagonists (coumarins) should not be used during the acute thrombocytopenic phase of HIT.¹² A particularly high-risk situation is HIT associated with deep vein thrombosis, especially if there is overt (decompensated) DIC. If such patients are treated with warfarin, there is a risk for progression to venous limb gangrene.^{12,26,27} The laboratory marker for this unusual syndrome is a high INR (generally, greater than 4.0), which corresponds to the combination of a marked reduction in the level of protein C together with increased thrombin generation (as evidenced by elevated levels of thrombin-antithrombin complexes) during warfarin therapy.¹² Although warfarin (in theory) should be safe in a patient whose thrombin generation is controlled (e.g., using a DTI), it is important to delay the initiation of warfarin until there is substantial resolution of the thrombocytopenia (to more than $150 \times 10^9/L$).^{26,27} Warfarin treatment should be delayed because its prolongation of the aPTT may result in *underdosing* of the DTI, and because stopping the DTI before resolution of the HIT during warfarin overlap can lead to limb loss caused by fulminant venous limb gangrene.⁴

Several case observations suggest that aPTT confounding of DTI therapy can be a factor explaining progression of thrombosis in patients with severe HIT.^{4,34} For example, patients can develop progressive thrombocytopenia and HIT-associated consumptive coagulopathy despite stopping heparin (Fig. 133.4). In such patients, aPTT monitoring of DTI therapy can fail because a brief course of DTI can abruptly lead to supratherapeutic aPTT levels—not because of anticoagulant overdosing but because of the combination of DTI and consumptive coagulopathy—and interruption/cessation of DTI therapy can be associated with rapid progression of microvascular thrombosis. In this setting, factor Xa inhibitors (danaparoid, fondaparinux) may be more effective because they do not require aPTT monitoring. Alternatively, DTI levels can be measured directly, but these assays are rarely performed in North American laboratories.

Using sensitive assays for HIT antibodies, LMWH reacts similarly to UFH in vitro. Furthermore, because LMWH can lead to worsening of clinical HIT, these agents should not be used to treat HIT.^{26,27}

Although primary treatment for HIT should include an anticoagulant that inhibits thrombin or reduces its generation, certain treatment adjuncts can be used in special situations. These include surgical thromboembolectomy, high-dose intravenous immunoglobulin, antiplatelet drugs such as aspirin, and therapeutic plasma exchange.

These caveats, along with recommendations for management of patients with suspected HIT, are summarized in the box on [Diagnosis and Treatment of Heparin-Induced Thrombocytopenia](#).

PLATELET COUNT MONITORING FOR HEPARIN-INDUCED THROMBOCYTOPENIA

The frequency of platelet count monitoring in patients receiving heparin should reflect the overall risk of HIT (i.e., the preparation, the dose, and the clinical situation).²⁶ At least alternate-day platelet count monitoring should be considered in patients at relatively high risk for developing HIT (e.g., after orthopedic or cardiac surgery). Monitoring at least two or three times a week should be considered for patients at moderate risk for developing HIT (e.g., medical patients receiving UFH, postoperative patients receiving UFH flushes or LMWH). The frequency of HIT is low with LMWH,^{1,6} particularly in medical patients or during pregnancy, and routine platelet count monitoring may not be required in such settings.²⁶ In addition, HIT rarely begins 14 or more days after initiation of a course of heparin,¹⁷ so routine monitoring beyond this period is not required. A more recent consensus conference²⁷ recommended somewhat less intensive platelet count monitoring than advised in this paragraph.

Diagnosis and Treatment of Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) should be clinically suspected when thrombocytopenia occurs during (or soon after) heparin therapy and the temporal profile of the decrease in platelet count is consistent with immune sensitization to heparin. Four relevant questions, the 4Ts, should be asked:

Thrombocytopenia: Does the patient have thrombocytopenia? A greater than 50% fall in the platelet count can indicate HIT even if the platelet count has not fallen to below $150 \times 10^9/L$. (Note: Severe thrombocytopenia, such as a platelet count below $10 \times 10^9/L$, is only rarely caused by HIT.)

Timing: Is the timing of the platelet count fall consistent with immune sensitization? In HIT the platelet count usually begins to fall 5–10 days after starting heparin (first day of heparin is day 0); a more rapid fall in the platelet count can occur if the patient is already sensitized from heparin exposure within the past 100 days.

Thrombosis: Does the patient have thrombosis or other sequelae of HIT? (Note: In addition to venous and arterial thrombosis, patients with HIT can develop necrotizing skin lesions at heparin injection sites or systemic inflammatory or cardiorespiratory reactions that begin 5–30 minutes after an IV heparin bolus.)

Other: Are there other explanations for the thrombocytopenia? HIT is less likely when there is compelling clinical evidence for another cause of the thrombocytopenia, such as positive blood cultures.

Steps in Management of Clinically Suspected Heparin-Induced Thrombocytopenia

1. Confirm that thrombocytopenia is present (repeat complete blood count), test for DIC, and test for HIT antibodies, preferably using a platelet activation test such as the serotonin-release assay.
2. Assess clinically and radiologically for thrombosis (e.g., compression ultrasound for lower-limb deep venous thrombosis).
3. Stop all heparin, including heparin flushes and possibly use of heparin-coated intravascular catheters (catheters left in situ for several days may not have much residual heparin).
4. Initiate treatment with an alternative anticoagulant, generally in therapeutic doses if HIT is strongly suspected (options: danaparoid,^{a,b} fondaparinux,^{a,c} lepirudin,^d argatroban, bivalirudin^e).
5. Although initial treatment decisions are made on clinical grounds, results of testing for HIT antibodies can influence subsequent treatment, including the decision to resume heparin if HIT has been ruled out.

Caveats

- Do not use low-molecular-weight heparin to treat HIT.
- Do not start (or continue) warfarin or other coumarins until the platelet count has returned to normal (greater than $150 \times 10^9/L$), and give only in low initial doses (warfarin, 5 mg or less) and overlap with a parenteral anticoagulant for at least 5 days.
- Do give vitamin K (e.g., 5–10 mg IV over 30–60 minutes) if HIT is diagnosed after warfarin has already been given, so as to reduce risk for coumarin necrosis and to avoid underdosing of DTI because of activated partial thromboplastin time (aPTT) prolongation by warfarin.
- Beware of confounding³⁴ of aPTT-monitored DTI therapy in patients with severe HIT complicated by HIT-associated consumptive coagulopathy (DIC) or who have other explanations for an elevated aPTT, such as warfarin therapy, liver disease, or antiphospholipid syndrome.
- Do not give prophylactic platelet transfusions (platelet transfusions are appropriate if the patient is bleeding or if there is diagnostic uncertainty).

^aNot approved for treatment of HIT in the United States (except, in the case of bivalirudin, for anticoagulation during percutaneous coronary intervention).

^bWithdrawn from the US market but available in many other countries.

^cFondaparinux is not approved for treatment of HIT, but case series suggest that it is at least as effective as DTI therapy; moreover, the risk for bleeding with fondaparinux is likely to be lower than that with DTI therapy, and fondaparinux costs less than the other agents. Also, there is greater experience with fondaparinux than DTIs for prevention and treatment of thrombosis in non-HIT situations, and only approximately 10% of patients with suspected HIT actually have the disorder. Fondaparinux also avoids the risk for confounding of aPTT-monitored DTI therapy. The author is a proponent of the use of fondaparinux to treat HIT.

^dLepirudin was discontinued by the manufacturer, April 2012.

Fig. 133.4 CONCEPTUAL FRAMEWORK OF HEPARIN-INDUCED THROMBOCYTOPENIA: FOCUS ON HEPARIN-INDEPENDENT PLATELET ACTIVATION AND DELAYED-ONSET (“AUTOIMMUNE”) HEPARIN-INDUCED THROMBOCYTOPENIA. The *upper panel* shows the timeline of heparin-induced thrombocytopenia (HIT) antibody (HIT-Ab) formation, as judged by optical density units in an antiplatelet factor 4/polyanion enzyme immunoassay. The *middle panel* illustrates a platelet count decline in the absence of heparin (or with small amounts of heparin, e.g., heparin flushes) indicating delayed-onset HIT, with intensification of HIT-associated hypercoagulability from day 7–14, especially after stopping heparin. Patients with this clinical profile often have HIT-associated consumptive coagulopathy (overt disseminated intravascular coagulopathy [DIC]), and are at risk for confounding of activated partial thromboplastin time (aPTT)-monitored direct thrombin inhibitor treatment. The *lower panel* compares different classes of anticoagulant for expected effects on HIT-associated hypercoagulability, including the risk for aPTT confounding in the setting of HIT-associated DIC. AT, Antithrombin; DTI, direct thrombin inhibitor; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PF4, platelet factor 4; PTT, partial thromboplastin time; UHF, unfractionated heparin. (From Warkentin TE: *Agents for the treatment of heparin-induced thrombocytopenia*. Hematol Oncol Clin North Am 24:755, 2010.)

ANTICOAGULATION AND PREVIOUS HEPARIN-INDUCED THROMBOCYTOPENIA

HIT antibodies are transient and usually are undetectable several weeks or a few months after an episode of HIT.¹⁷ If HIT antibodies are no longer detected, it is appropriate to use heparin for a brief indication in situations where other anticoagulants have drawbacks, for example, cardiac surgery.^{17,26,27,35} Heparin should be avoided preoperatively (e.g., argatroban or bivalirudin can be used for heart catheterization). The risk of recurrent HIT appears to be low (approximately 2%), but is possible beginning approximately one week post-reexposure for cardiac or vascular surgery even if postoperative heparin is not given, because of the possibility of regenerating strong HIT antibodies that can activate platelets in the absence of pharmacologic heparin.³⁵ Alternatively, if a patient with recent HIT remains SRA+ and heparin reexposure is desired (e.g., for urgent cardiac surgery), therapeutic plasma exchange can be used to remove HIT antibodies preoperatively; in this situation, achieving a negative SRA is the appropriate serologic endpoint (as the EIA can remain positive even when platelet-activating antibodies are no longer detectable by SRA).³⁶

Patients with acute or recent HIT who require urgent heart surgery and still have detectable antibodies have been successfully treated with alternate anticoagulant approaches (e.g., bivalirudin, or heparin plus an antiplatelet agent such as epoprostenol or tirofiban), but each of these approaches has disadvantages. For example, epoprostenol causes hypotension, and there is limited experience with its use in cardiac surgery. Bivalirudin is the most promising agent for use in cardiac surgery, but special surgical and anesthesiologic maneuvers are required (because bivalirudin undergoes proteolysis, thus posing a risk for clotting of stagnant blood in the extracorporeal circuit).

A diagnostic and therapeutic approach to HIT is shown in the box on [Diagnosis and Treatment of Heparin-Induced Thrombocytopenia](#).

THROMBOTIC THROMBOCYTOPENIC PURPURA AND THE HEMOLYTIC UREMIC SYNDROMES

Robert Schneidewend, Narendranath Epperla, and Kenneth D. Friedman

In 1924 Moschowitz reported a case of a 16-year-old girl who died of a previously undescribed illness characterized by microangiopathic hemolytic anemia (MAHA), petechiae, hemiparesis, and fever. Postmortem examination revealed numerous hyaline thrombi, most prevalent in the terminal arterioles and capillaries of the heart and kidneys. In 1936 four similar cases were reported by Baehr and colleagues, who proposed that the hyaline thrombi were secondary to agglutinated platelets. In 1947 Singer suggested that the term *thrombotic thrombocytopenic purpura* (TTP) be used to describe this disorder. In 1955 Gasser used the term *hemolytic uremic syndrome* (HUS) to describe a related syndrome consisting of Coombs-negative hemolytic anemia, thrombocytopenia, and renal failure. The clinical features of Shiga toxin–associated HUS (ST-HUS) were described in six young children who presented with renal failure following a diarrheal illness in 1962. An association to Shigella was recognized in 1975 and the linkage to Shiga toxin–producing *E. coli* (STEC) was made in 1983. These disorders are now referred to as *thrombotic microangiopathies* (TMAs), based on their shared features of MAHA, thrombocytopenia, and microvascular thrombotic lesions with resultant organ dysfunction.

By definition, MAHA and thrombocytopenia are cardinal signs/features of all TMA syndromes, leading to overlapping clinical and pathologic features. However, a multitude of different pathogenic pathways lead to vascular endothelial injury in these conditions. The vast majority of cases of TTP appear to be caused by deficiency of ADAMTS13 (a disintegrin-like and metalloprotease with thrombospondin type1 motif, family member 13), resulting in failure to control the interaction of von Willebrand factor (vWF) with platelets and subsequent organ dysfunction as a consequence of platelet-rich thrombi formation in the microcirculation (and occasionally in large vessels). Recent studies indicate that “atypical” hemolytic uremic syndrome (aHUS) is mainly attributable to a defect in the regulation of the complement mechanism and unregulated deposition of complement factor C3b on cellular surfaces. A rare autosomal recessively inherited form of aHUS occurs in patients with defects in the gene encoding for diacylglycerol kinase epsilon (DGKE), which results in a shift of endothelial cells to a prothrombotic phenotype. Finally, in STEC-HUS, endothelial injury is caused by Shiga toxin and inflammatory cytokines, perhaps inciting disease with increased frequency in individuals with specific genetic predispositions. With improved understanding of the pathogenesis of TMAs and the availability of specific therapy that targets that pathogenesis, distinction of the various TMA syndromes is clinically important. Several pathogenesis-based classification schemes for TMAs have been developed; one example is illustrated in Fig. 134.1.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of MAHA and thrombocytopenia is extensive. An example of a decision tree is shown in Fig. 134.2. Vascular damage secondary to severe sepsis, autoimmune disorders (i.e., systemic lupus erythematosus, scleroderma, antiphospholipid antibody syndrome, see Chapter 141), septic or tumor emboli, immune complex-mediated vasculitis (e.g., infective endocarditis), malignant hypertension, complications of pregnancy (severe preeclampsia,

eclampsia, HELLP syndrome [an acronym for hemolysis, elevated liver function tests, and low platelet counts]), cryoglobulinemia, or infection with rickettsial or, more rarely, hemorrhage-inducing viral organisms, may all mimic TMAs. Occasionally, patients with disseminated intravascular coagulation secondary to malignancy or sepsis present with microangiopathy of sufficient severity to be confused with primary TMAs (see Chapter 139). In the setting of renal transplantation, a biopsy may be required to distinguish TMAs from allograft rejection or recurrence of a preexisting renal vascular disorder. Occasional patients present with acute pancreatitis, acute respiratory distress syndrome, memory and personality changes, or other poorly defined neurologic symptoms, which have a broad differential diagnosis.

Clues suggesting STEC-HUS include age at the time of presentation, ingestion of undercooked ground beef or other food that might have become contaminated by cattle, contact with farm animals, or concurrent HUS in another family member. History of asynchronous presentation in a sibling would suggest inherited TTP or aHUS. Historical approaches to the distinction of TTP from aHUS have relied heavily upon the age of presentation and distribution of symptoms. However, as demonstrated by the recent trials showing the utility of eculizumab, aHUS is not uncommonly diagnosed in adults. Similarly, there is significant end-organ dysfunction overlap between these two disorders. While the kidney remains a major target organ in aHUS, renal injury of sufficient severity to require dialysis may occur in up to 10% of patients with TTP. Neurologic symptoms are reported in 25% to 79% of patients diagnosed with TTP but may also be seen in 10% to 30% of patients with aHUS.

Choosing the appropriate therapy depends on an accurate diagnosis. While symptoms may not support distinctions, several groups have reported that platelet counts and creatinine levels are significantly lower in patients with severe ADAMTS13 deficient TTP; it has been suggested that a platelet count under 30,000/ μ L or a creatinine under 2.3 mg/dL favors a diagnosis of TTP. An ADAMTS13 level below 10% in the appropriate clinical context provides strong evidence for a diagnosis of TTP, although TTP should not be excluded in patients with characteristic/prototypic presentation whose levels of ADAMTS13 are not severely reduced. STEC infection should be ruled out as soon as possible when infectious HUS is possible utilizing appropriate microbiologic studies (stool culture, immunoassay for Shiga toxin or fecal polymerase chain reaction). Children may also merit testing for a cobalamin C defect, as defects of cobalamin metabolism may present with a similar hematologic picture (including thrombocytopenia, presence of bizarre microcytic red cells on the peripheral blood film, and elevations of lactate dehydrogenase [LDH] and bilirubin).

THROMBOTIC THROMBOCYTOPENIC PURPURA

Clinical Manifestation

The classic pentad of signs and symptoms that compose the TTP syndrome include MAHA, thrombocytopenia, neurologic impairment, fever, and renal dysfunction. More recent data have shown that the majority of TTP cases, which are caused by an acquired

Fig. 134.1 AN ETIOLOGY-BASED CLASSIFICATION OF THE VARIOUS FORMS OF THROMBOTIC MICROANGIOPATHIES. Blue indicates postinfectious. Pink indicates hereditary. Green indicates autoimmune. ADAMTS13, A disintegrin and metalloproteinase with Thrombospondin type 1 motifs, member 13; CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; DGKE, diacyl glycerol kinase ϵ ; DIC, disseminated intravascular coagulation; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; MCP, membrane cofactor protein; SLE, systemic lupus erythematosus; STEC, Shiga toxin-producing *E. coli*; THBD, thrombomodulin; TMA, thrombotic microangiopathy. (Figure modified from Lorient C, Fakhouri F, Ariceta G, et al: An international consensus approach to the management of atypical hemolytic uremic syndrome in children. *Pediatr Nephrol* 31:15, 2016.)

ADAMTS13 deficiency, present with neurologic symptoms (73.9%) and fever (72.3%). Earlier recognition of this syndrome and the established efficacy of plasma exchange, however, have led to the appreciation that MAHA and thrombocytopenia, in the absence of an obvious precipitating condition, are sufficient to make a presumptive diagnosis of TTP. The evolution of this diagnostic approach has led to a significant increase in the use of plasma exchange, and it is likely that TTP is now as frequently overdiagnosed as underdiagnosed.

Approximately 10% to 40% of patients with TTP recall an upper respiratory tract infection or flu-like syndrome in the weeks preceding the diagnosis. Patients may present with malaise, fatigue, fever, or other nonspecific symptoms days to weeks in duration and are unresponsive to antibiotics or symptomatic management. The diagnosis of TTP may be overlooked until these prodromal symptoms become unrelenting or neurologic dysfunction develops. Neurologic symptoms ranging from headache and confusion to somnolence, seizures, aphasia, or coma often dominate the clinical picture in TTP and may fluctuate in severity. This is attributed to the repetitive formation and dissolution of thrombi in the cerebral microvasculature. Other less common symptoms are abdominal pain and respiratory distress. Thrombocytopenia may be severe, with median platelet counts between 10,000 and 30,000/ μ L at presentation and mucocutaneous bleeding is common.

Epidemiology

Acquired TTP (caused by autoantibody inhibition of ADAMTS13 activity) accounts for 70% to 80% of all TTP cases and occurs with an estimated annual incidence of 4–10 cases per million, but the incidence appears to be increasing, perhaps as a result of increased awareness. Interestingly, a much lower incidence was reported by the Nara Medical University Registry in Japan, with 0.4 cases per million.

Acquired TTP has a higher incidence in adults compared with children and has a female/male ratio of 3:2 and a peak incidence in the fourth decade. Additional risk factors include blood group O, obesity, and African ancestry, which is also associated with an increased risk of relapse. Nonidiopathic acquired TTP (defined as TTP associated with a known precipitant), which appears to be more common and includes drug-mediated disease, should be differentiated from TMAs based on other pathologic processes (see discussion section later in chapter).

Pregnancy is another common precipitating factor for both acquired TTP (12%–31% of individuals) and hereditary TTP. TTP most frequently develops in the second or third trimester, with the decrease in ADAMTS13 levels and increase in vWF and factor VIII that occur in normal pregnancy perhaps acting as precipitants. TTP has also been reported in approximately 0.3% of human immunodeficiency virus (HIV)-infected patients, usually in those with advanced disease.

Congenital TTP, also known as *Upshaw-Schulman syndrome*, is considerably less common than idiopathic TTP. It is estimated that there are fewer than 100 cases worldwide. A 2011 study describing the natural history of congenital TTP in Japan identified 43 cases in patients ranging in age from childhood to 79 years. Of these cases, 42% were diagnosed during childhood, 36% between the ages of 15 and 45 (all female, most commonly presenting during pregnancy), and 12% beyond 45 years of age.

Pathobiology

Most patients with TTP exhibit inherited or acquired deficiency of ADAMTS13, leading to increased levels of “unusually large” vWF multimers that induce platelet aggregation in the microvasculature. Endothelial cells secrete unusually large vWF multimers that may adhere to cell surfaces and promote platelet attachment or enter

Fig. 134.2 AN APPROACH TO DIAGNOSIS AND MANAGEMENT OF THROMBOTIC MICROANGIOPATHIES. the circulation and promote intravascular platelet aggregation. Under high shear, vWF multimers elongate along the endothelium and promote platelet adhesion through interactions with platelet glycoprotein (GP) Ib; shear stress-induced conformational changes also enhance the susceptibility of vWF to enzymatic cleavage. ADAMTS13 regulates the activity of vWF by cleaving the most hemostatically active high-molecular-weight multimers; failure of this feedback mechanism may lead to the microvascular thrombosis, tissue ischemia, and infarction characteristic of TTP. However, the factors that trigger sporadic episodes of TTP by causing endothelial damage or activation remain undefined. Moreover, some patients develop TTP despite normal levels of circulating ADAMTS13, while patients with congenital deficiencies of ADAMTS13 may not develop TTP until adulthood, or not at all. The latter observations suggest that ADAMTS13 deficiency should be considered an important predisposing factor, but not the sole cause of this syndrome. This concept is supported by studies of ADAMTS13-deficient mice, in which a TTP-like syndrome develops spontaneously in some genetic backgrounds (high vWF levels) but requires a triggering factor, such as Shiga toxin, in other strains.

Inherited ADAMTS13 Deficiency

Upshaw-Schülman syndrome is an autosomal recessive form of TTP first linked to vWF by Moake, who found unusually large vWF

multimers between disease flairs in the plasma of patients with chronic relapsing TTP. He proposed that the patients lacked a plasma enzyme that cleaves these unusually large multimers and that the abnormal multimers then caused uncontrolled intravascular platelet aggregation, thrombosis, and tissue infarction. Subsequently, a plasma metalloprotease was discovered that degrades vWF multimers by cleaving the Tyr¹⁶⁰⁵-Met¹⁶⁰⁶ bond in the vWF A2 domain. This metalloprotease is lacking in patients with Upshaw-Schülman syndrome.

When the vWF-degrading protease was isolated from plasma and cloned, it was found to be a member of the ADAMTS family of metalloproteases (Fig. 134.3). Genome-wide linkage analysis showed that Upshaw-Schülman syndrome is caused by mutations in the ADAMTS13 gene on chromosome 9q34.

ADAMTS13 is mainly synthesized by hepatic stellate cells but also in vascular endothelial cells and renal glomerular podocytes. Small amounts of functional ADAMTS13 are present in platelets. More than 150 mutations that can cause Upshaw-Schülman syndrome have been reported, and they have been found in almost all structural domains of ADAMTS13 (see Fig. 134.3). The majority of these mutations, approximately 60%, are single amino acid missense substitutions. Mutations affecting the highly conserved N-terminal domains of ADAMTS13 are associated with lower residual enzyme activity, more severe clinical phenotype, and probably presentation of disease earlier in life. Expression studies have shown that missense mutations usually prevent the secretion of ADAMTS13, although some also impair catalytic activity.

Fig. 134.3 ADAMTS13 STRUCTURE AND LOCATION OF THE MUTATIONS FOUND IN PATIENTS WITH CONGENITAL THROMBOTIC THROMBOCYTOPENIC PURPURA. ADAMTS13 is a multiple domain protein consisting of a metalloprotease domain followed by a disintegrin-like motif, a first thrombospondin-1 (TSP-1) repeat, Cys-rich and spacer domains, seven additional TSP-2 repeats, and two complement components C1r/C1s, urinary epidermal growth factor, and bone morphogenic protein-a domains. About 150 candidate mutations in ADAMTS13 spread throughout the gene have been reported in the inherited form of thrombotic thrombocytopenic purpura (Upshaw-Schülman syndrome). Most mutations are located within the N-terminal region of the protease comprising the metalloprotease domain to the Cys-rich-spacer domain of the protease. The N-terminal part of ADAMTS13 is the active part of the protein in vitro; the C-terminal part is not crucial for ADAMTS13 activity in vitro, but is essential for the normal function of ADAMTS13 in vivo. Mutations leading to amino acid substitutions (missense mutations) are found in about two-thirds of cases and truncating mutations (nonsense mutations inducing stop codon or splice/frameshift mutations) are also described. Missense and nonsense mutations are represented at the top of the figure, whereas splice/frameshift mutations are represented at the bottom of the figure. (Reproduced from Lorient C, Coppo P, Veyradier A: TTP in children. *Curr Opin Pediatr* 25:216, 2013.)

Acquired ADAMTS13 Deficiency

Almost all patients with nonfamilial, idiopathic TTP have an acquired severe reduction or absence of ADAMTS13 activity (<5%–10%), usually associated with autoantibody immunoglobulin (Ig) G inhibitors. Some of the reported variation in ADAMTS13 activity levels may reflect inclusion or exclusion of patients with acute renal failure or other preexisting conditions. For example, severe ADAMTS13 deficiency was found in 18 of 48 adults with idiopathic TMAs unselected for renal function, but it was seen in 22 of 22 patients without acute anuric renal failure. Acquired severe ADAMTS13 deficiency (<5%–10%) is rare in other settings, with the possible exception of severe hepatic insufficiency or sepsis. For example,

ADAMTS13 levels below 5% were found in 17 of 109 patients with sepsis-induced disseminated intravascular coagulation (DIC). More modest decreases (typically >40%) occur in newborns and among adults with cirrhosis, chronic renal insufficiency, pregnancy, connective tissue diseases, and various inflammatory conditions; none had levels below 6%. Therefore severe ADAMTS13 deficiency appears to be specific for TTP in the appropriate clinical setting.

ADAMTS13 levels appear normal in some cases of idiopathic TTP. This was highlighted by the unusual case reported by Froelich-Zahnd and colleagues of a patient with multiple relapses of HIV-associated TTP. With the earlier relapses, the patient had detectable ADAMTS13 activity by multiple assays and responded to plasma exchange. In contrast, with later relapses ADAMTS13 levels were

Fig. 134.4 PERIPHERAL BLOOD FILM OBTAINED FROM A 28-YEAR-OLD WOMAN WHO PRESENTED WITH FEVER, EPISTAXIS, AND ALTERED MENTAL STATUS. Note the absence of platelets and the presence of a nucleated erythrocyte and schistocytes (arrows) consistent with a microangiopathic process.

undetectable. This case suggests that patients may develop antibodies that inhibit ADAMTS13 activity in vivo but not in laboratory assays.

Antibodies against ADAMTS13 have been reported in 59% to 100% of patients with acquired severe ADAMTS13 deficiency. This variability probably reflects differences in assay sensitivity. Some antibodies may only be detected by serologic means and may promote ADAMTS13 clearance without inhibiting activity.

Other Mechanisms of Potential Relevance to Thrombotic Thrombocytopenic Purpura

ADAMTS13 activity levels are rarely severely decreased in cases of TMAs associated with stem cell or organ transplantation, cancer, infections, severe hypertension, and certain drugs. Therefore mechanisms other than ADAMTS13 deficiency can cause TMA, and various studies have implicated direct endothelial injury, platelet activation, and alterations in blood clotting as contributory factors. Evidence in support of these mechanisms include the demonstration of (1) increased levels of circulating endothelial proteins (thrombomodulin, PAI-1, vWF) and endothelial cell microparticles in TTP plasma; (2) circulating antiplatelet and antiendothelial cell antibodies, some of which may bind CD36 and impair ADAMTS13 binding to endothelial cells; (3) increased levels of circulating platelet-derived microparticles; (4) induction of microvascular endothelial cell apoptosis by plasma from patients with idiopathic, HIV-associated, or ticlopidine-associated TTP; (5) increased plasma procoagulant activity; (6) increased endothelin and decreased nitric oxide, leading to vasoconstriction; and (7) diminished plasma fibrinolytic activity because of elevated levels of PAI-1.

Laboratory Manifestations

The presence of schistocytes on the peripheral blood smear is a characteristic laboratory finding of TTP (Fig. 134.4). Schistocytes may not be apparent in rare patients at disease onset. The markedly elevated levels of plasma LDH typically seen in patients with TTP reflect both hemolysis and tissue ischemia. Nucleated red blood cells are present in many patients, and their number may be disproportionately increased in comparison with the degree of reticulocytosis. With rare exceptions, the direct antiglobulin test is negative. The prothrombin time, partial thromboplastin time, and fibrinogen levels are usually normal or only mildly perturbed; mild elevations in fibrinogen degradation products occur in 50% of patients although

more sensitive assays, such as those for prothrombin fragment 1+2, thrombin-antithrombin complexes and plasmin-antiplasmin complexes, often reveal low-grade activation of coagulation and fibrinolytic pathways. Evidence of renal involvement may include hematuria, proteinuria, granular or red cell casts, and mild azotemia, but anuria and renal failure are uncommon presenting features. Severe deficiency (<5%–10%) of ADAMTS13 in the appropriate clinical setting is considered diagnostic of TTP, though TTP cannot be entirely excluded by a normal or only moderately decreased level (see box on ADAMTS13 in the [Management of Thrombotic Thrombocytopenic Purpura](#)). Levels should be measured before initiation of plasma exchange to accurately assess baseline activity.

The prototypic vascular lesions of TTP are characterized by platelet-rich thrombi within or beneath damaged endothelium. Involved microvascular endothelial cells are swollen and in some cases detached. The subendothelium contains hyaline material that is relatively poor in fibrin and consists largely of vWF and platelet remnants. In contrast, the lesions of HUS are rich in fibrin and contain comparatively little vWF. Involved vessel walls characteristically display a paucity of mononuclear leukocytes; fibrinoid necrosis, aneurysm formation, and other evidence of vasculitis are absent. Medium- and large-sized arteries show less extensive involvement, and the venous system is typically spared. The most commonly affected organs include the brain, pancreas, heart, and adrenal glands. Involvement of other sites such as the kidney, spleen, gingiva, bone marrow, and skin (Fig. 134.5) may occur as well. Elevated troponin levels are found in 50% of patients with acute TTP, indicating cardiac involvement. A characteristic pathologic lesion involving adjacent areas of vascular dilatation and constriction accompanied by segmental hyaline changes may occur in the placenta.

Prognosis

Assuming timely diagnosis and effective therapy at initial presentation, the prognosis of primary TMA is relatively favorable. For example, although older historical data suggest a response rate in TTP to plasma exchange of approximately 80%, more recent studies have demonstrated response rates upward of 95% and mortality rates less than 5%. This apparent improvement in outcome may be generalized and reflects advances in supportive care as well as active therapies. Patients with acquired TTP continue to experience a significant relapse rate of 30% to 50%, though these numbers may be further reduced if rituximab is used for the initial treatment of patients with autoimmune disease.

Patients with congenital deficiency of ADAMTS13 may follow a chronic, relapsing course, but relapses may be prevented by periodic plasma infusions. Case reports suggest that some intermediate-purity factor VIII concentrates may also supply sufficient ADAMTS13 to prevent symptomatic relapses. Insufficient numbers of patients have been followed to determine whether overall survival is reduced in patients with congenital ADAMTS13 deficiency, and case reports suggest that these individuals may be at increased risk for stroke.

Therapy

Without therapy, the mortality rate of TTP exceeds 90%. Through the mid-1970s, splenectomy remained the only modality with more than an anecdotal response rate. Prognosis has been dramatically improved since the advent of plasma-based therapy, such that long-term survival may now exceed 90%.

Plasma Therapy in Thrombotic Thrombocytopenic Purpura

The beneficial effect of plasma therapy in TTP was first noted more than 25 years ago when the results of a prospective trial resolved the long-debated issue of the relative efficacy of plasma exchange versus

Management of Thrombotic Thrombocytopenic Purpura and Management of Atypical Hemolytic Uremic Syndrome)

Management of TTP

- A high index of suspicion is necessary to make a diagnosis of TTP.
 - ADAMTS13 activity should be determined before initiation of plasma therapy.
- Prompt initiation of therapy is required to prevent organ dysfunction or death.
- Prophylaxis is recommended during pregnancy.
- For suspected or confirmed acquired (autoimmune) TTP:
 - Plasma exchange is recommended (exchange 1–1.5 plasma volumes [40–60 mL/kg]) daily. Plasma infusion may be used until exchange is initiated.
 - Continue plasma exchange until the neurologic symptoms have resolved and the serum LDH and platelet count is normal; many experts recommend continuing plasma exchange for an additional 2–3 days thereafter.
 - Corticosteroids are often used as part of initial therapy
 - Administration of rituximab together with plasma exchange early in the course of disease appears to induce a more rapid response and may delay relapse.
 - Use of rituximab is controversial for treatment of asymptomatic patients (in clinical remission) with ADAMTS 13 deficiency.
 - Splenectomy is generally reserved for patients who are refractory to plasma exchange and rituximab.
 - Immunosuppressive agents are only recommended for patients with critical illness that is unresponsive to plasma exchange, corticosteroids, and rituximab.
 - Platelet transfusion should be reserved for life-threatening bleeds. Packed red blood cells can safely be transfused in TTP.
- For hereditary TTP (Upshaw-Schulman syndrome)
 - Plasma infusion is often sufficient to treat acute symptoms.
 - Prophylactic plasma infusion may prevent symptomatic recurrence.

Management of aHUS

- A high index of suspicion is necessary for diagnosis of aHUS.
 - aHUS is a systemic disorder
 - Advanced renal failure, hypertension and increased vascular permeability suggest a diagnosis of aHUS rather than TTP
 - Neurologic and gastrointestinal symptoms are common.
- aHUS is a diagnosis of exclusion
 - TTP should be excluded with ADAMTS13 assay
 - STEC-HUS should be excluded with stool culture and/or tests for Shiga toxin
 - Other causes of microangiopathic hemolytic anemia should be excluded with history, coagulation studies, infectious disease studies, serologies, etc.
 - Plasma studies of C3, C4, and complement control proteins (CFH, CFI, CFB) and autoantibody to CFH may be normal, as may be genetic studies (CFH, CFI, CFB, C3, MCP, THBD, DGKE). Initiation of therapy should not be delayed while awaiting test results.
- Treatment of suspected or confirmed aHUS:
 - Plasma exchange is recommended until a diagnosis of TTP is excluded.
 - Eculizumab is currently the therapy of choice for aHUS
 - Vaccination to prevent meningococcal infection is required; antibiotic prophylaxis should also be considered.
 - Early treatment reduces the risk of long-term renal impairment.
 - Thrombocytopenia and hemolysis tend to respond early, but renal recovery may take months.
 - Long-term therapy is currently recommended. If eculizumab is discontinued, close follow up to detect early relapse is suggested.

ADAMTS13, A disintegrin and metalloproteinase with Thrombospondin type 1 motifs, member 13; aHUS, atypical hemolytic uremic syndrome; CFB, complement factor B; CFH, complement factor H; CFI, complement factor I; DGKE, diacyl glycerol kinase ϵ ; LDH, lactate dehydrogenase; MCP, membrane cofactor protein; STEC, Shiga toxin-producing *E. coli*; THBD, thrombomodulin; TTP, thrombotic thrombocytopenic purpura.

only infusion of plasma. At 6 months, complete remissions were seen in 78% of patients treated with exchange versus 31% of those treated with plasma infusion. This study did not resolve the question as to whether removal of a disease-inciting agent or replacement of a missing factor accounted for the superior response, particularly because patients in the exchange arm received a threefold larger volume of plasma. Indeed, a retrospective study demonstrated no significant difference in outcome in patients with acquired TTP who received equal volumes of plasma by exchange or infusion. However, the current model for the pathogenesis of acquired idiopathic TTP suggests that plasma exchange is superior because it both removes an IgG inhibitor of ADAMTS13 and replaces the deficient protein. In contrast, plasma infusion (or potentially infusion of a factor concentrate containing ADAMTS13) suffices for patients with genetic ADAMTS13 deficiency. Large volumes of plasma are more easily administered by exchange, and unless a genetic deficiency of ADAMTS13 has been documented, plasma infusion should be reserved for situations in which exchange is not immediately available. The recovery of ADAMTS13 levels may lag behind other indicators of clinical response, and the utility of monitoring ADAMTS13 levels during treatment has not been established.

Plasma (either fresh frozen plasma [FFP] or thawed plasma) remains the most commonly used replacement product for plasma exchange. There is no clear advantage to the use of cryo-poor plasma (CPP), which is depleted of vWF. These findings are consistent with a recent study showing similar concentrations and stability of ADAMTS13 during storage at 1–5°C in CPP and FFP. Pilot studies suggest that solvent-detergent treated plasma (which contains ADAMTS13 at concentrations approximately 20% lower than those in FFP) is as efficacious as FFP and is associated with fewer allergic/urticarial reactions.

Treatment is generally initiated with the goal of exchanging 1–1.5 plasma volumes (40–60 mL/kg) daily, although the optimal regimen

has not been determined. The volume of exchange can be increased to 1.5–2 plasma volumes daily if the initial response is poor. Neurologic improvement occurs most rapidly, often within hours to days. The serum LDH level typically falls by 50% within 3 days in responders, and the platelet count begins to rise at a mean of 5 days, though normalization may take up to several weeks. Impaired renal function and disappearance of schistocytes are generally the last to improve.

Daily plasma exchange should be continued until neurologic symptoms have resolved and both a normal serum LDH and platelet count have been achieved; many experts recommend an additional 2–3 days of plasma exchange thereafter. Approximately 85% to 90% of patients show a clinical and laboratory response to plasma exchange within 3 weeks, most often within 10 days (mean 15.8; range 3–36 days). However, 20% to 40% of patients will experience an exacerbation of disease within 30 days after stopping plasma exchange, whereas approximately 30% will relapse at later dates, usually within the first year. The decision to switch to CPP or to introduce another form of therapy is empiric but is generally not considered until the patient has received a minimum of 10–14 days of daily exchange with FFP. One prospective nonrandomized study suggested that administration of rituximab early in the course of disease in conjunction with plasma exchange induced more rapid responses and reduced relapses. Little or no data are available to support either abrupt discontinuation or “tapering” of plasma exchange after remission.

Complication rates associated with plasma exchange therapy have been reported to be as high as 30%, but recent reports suggest a lower rate. The majority of adverse events are related to central venous catheter insertion, infection, allergic reactions to plasma and occasionally thrombosis.

Plasma exchange is effective for patients with or without inhibitors, and clinical responses frequently occur despite persistence of both the inhibitor and severe ADAMTS13 deficiency, although

Fig. 134.5 TISSUE SPECIMENS OBTAINED AT AUTOPSY FROM A PATIENT WITH ABNORMALITIES CHARACTERISTIC OF THROMBOTIC THROMBOCYTOPENIC PURPURA. A specimen from the heart (A) shows multiple intramyocardial microthrombi (*arrow*), hemorrhage, and early ischemic changes, with scattered foci of contraction-band necrosis (*arrowhead*). A specimen from the kidney (B) shows characteristic microthrombi in an afferent arteriole, the glomerular hilum, and glomerular capillaries (*arrows*) together with vascular congestion and parenchymal hemorrhage in the surrounding interstitium. A tissue specimen from the adrenal gland (C) shows characteristic subcapsular microthrombi (*arrows*) with congestion of the cortical arterioles and medullary parenchymal hemorrhage (*arrowhead*). A specimen from the cecum (D) shows submucosal microthrombi (*arrows*) and hemorrhagic mucosal ulceration and necrosis. Microthrombi were also present in the pancreas, thyroid gland, and other organs. (Reproduced from George, JN: *Thrombotic thrombocytopenic purpura*. N Engl J Med 354:1927, 2006, with permission. Photographs and interpretation by Patrick Stangeby.)

patients with high titer inhibitors may respond more slowly and relapse more often. Both congenital and acquired ADAMTS13 deficiency are characterized by unpredictable periods of stability between relapses, probably reflecting exacerbation of the disease by co-morbid conditions that activate or damage the endothelium, thereby increasing the release of unusually large vWF multimers, and triggering microvascular thrombosis.

Rituximab

Several reports support the efficacy of rituximab, an anti-CD20 antibody, for decreasing the level of autoantibodies and restoring normal ADAMTS13 activity in TTP. In one study, remission was noted in more than 90% of patients treated with rituximab (with plasma exchange and corticosteroids) in an acute episode of TTP within 14–21 days. In addition, patients who received rituximab with plasma exchange experienced a fivefold lower relapse rate at a median of 18 months compared with historical controls. In cases of refractory TTP, increases in platelet count were noted in more than 80% of patients with the addition of rituximab to plasma exchange and corticosteroids; the time required to achieve a platelet count response was also decreased. Though there were fewer relapses in rituximab treated patients in the short term, this may represent a delay in immune reconstitution and the number of relapses may not differ from that in controls with longer term follow up.

Prophylactic treatment with rituximab may also result in fewer TTP relapses, although again, longer-term follow-up studies are

needed. After initial prophylactic rituximab, 30% of patients had asymptomatic decreases in ADAMTS13 activity and required additional rituximab or other treatments, some of which have greater risks than rituximab. In some asymptomatic patients, sustained recovery of ADAMTS13 activity failed to occur, even with multiple courses of rituximab treatment. Therefore, the value of rituximab treatment during remission remains controversial.

Corticosteroids

Corticosteroids are often used as part of initial treatment or for patients who fail to show a brisk response to plasma-based therapy. These drugs are of little benefit when used alone, and retrospective studies do not provide compelling evidence that they improve the response to plasma exchange. However, the antiinflammatory and immunosuppressive effects of corticosteroids make them a logical adjunct for treatment of autoimmune TTP, and most experts continue to use them in patients receiving plasma exchange.

Splenectomy

Before the introduction of plasma therapy, splenectomy was the first-line treatment for TTP and induced remission in up to 50% of patients. Currently, open or laparoscopic splenectomy is reserved for patients who are refractory to plasma exchange and rituximab. Splenectomy may reduce the frequency of relapses in patients with

chronic relapsing TTP. Plasma exchange should be continued after splenectomy until the TMA resolves.

Other Modalities

Antiplatelet Agents

The response rate to aspirin, dipyridamole, sulfapyrazone, or ticlopidine as single antiplatelet agents approximates 10%, essentially indistinguishable from the natural history. Antiplatelet agents have not been convincingly shown to increase the response to plasma exchange and may promote bleeding in the setting of severe thrombocytopenia and invasive procedures.

Immunosuppressive Agents

Cyclosporine has been used as an alternative to rituximab for decreasing the risk of relapse and the time to achieve a durable remission. There is evidence that cyclosporin reduces the incidence of TTP relapse, decreases ADAMTS13 antibody levels and produces a parallel increase in ADAMTS13 activity. Cyclophosphamide and vincristine were used before the advent of rituximab. However in current practice, they are used only in patients with critical illness that is unresponsive to treatment with plasma exchange, corticosteroids, and rituximab. Reports of responses to other immunosuppressive agents including azathioprine, mycophenolate mofetil, staphylococcal protein A immunoabsorption and bortezomib also exist.

Intravenous Immunoglobulin

The efficacy of intravenous immunoglobulin remains unclear.

Supportive Care

Starting low-dose aspirin (81 mg daily) once the platelet count exceeds 50,000/ μ L has been recommended in the 2003 guidelines of the British Committee for Standards in Haematology. Folate supplementation and administration of the hepatitis B vaccine should be considered routine components of supportive care. Platelet transfusion in patients with TTP should be restricted to patients with life-threatening bleeds (see discussion later).

Blood Product Transfusion in Thrombotic Microangiopathy

Red Blood Cells

Patients with TTP often develop symptomatic anemia because of bleeding and partially compensated hemolytic anemia. Packed red blood cells can be transfused safely in this setting. In older adults and in those with impaired cardiac function, it may be prudent to provide an additional margin of safety when choosing a threshold for transfusion.

Platelet Transfusion

Historically, platelet transfusions have not been recommended for patients with TTP because they have been hypothesized to provoke fatal thrombotic events. This is based on two observations. First, there are anecdotal reports of a close temporal relationship between platelet transfusion and adverse outcomes. In these cases, there was clinical deterioration within 1–24 hours of allogeneic platelet transfusion. Second, postmortem examination in such patients revealed widespread microthrombi involving the brain, heart, lung, kidney, and multiple other organs. Furthermore, clinical deterioration after platelet transfusion has also been reported in patients with other TMAs (HUS, STEC-HUS and drug-induced TMAs). Rarely, sudden death has occurred in patients who responded to plasma therapy with a rapid rise in the platelet count.

Data from the Oklahoma TTP-HUS registry challenge this dogma. Thus none of 33 platelet transfusions administered to a cohort of 54 consecutive TTP patients (of whom 47 had ADAMTS13 activity <10%) was associated with an increase in the incidence of

death or severe neurologic events. The authors of the study concluded that there was “uncertain evidence of harm” with platelet transfusion in TTP. More recently however, this question has been revisited in a study conducted over a 5-year period (2007–2011) using a large US inpatient database (Nationwide Inpatient Sample that includes both adults and children). Based on retrospective analysis of these data, platelet transfusion was associated with a sixfold higher risk of arterial (but not venous) thrombosis and a twofold higher risk of acute myocardial infarction, after adjusting for age and gender in a population with no reported prior history of thrombosis. In experienced hands, vascular access catheters for apheresis can safely be inserted even in the face of thrombocytopenia. Therefore based on accumulating evidence, platelet transfusion in TTP patients should be reserved for those with life-threatening bleeding.

SHIGA TOXIN HEMOLYTIC UREMIC SYNDROME

Clinical Manifestations

STEC-HUS is one of the main causes of acute renal failure in children. Patients generally present with the triad of hemolytic anemia, thrombocytopenia and acute renal injury. STEC-HUS occurs most commonly after *E. coli* O157:H7–induced gastroenteritis, with rare cases reported after infection of the urinary tract or skin, or after infection with organisms other than *E. coli*. The clinical presentation begins with the sudden onset of abdominal pain and watery diarrhea, on average 4 days (range, 2–12 days) after toxin exposure. Abdominal pain may be severe and precede the onset of diarrhea. In the absence of fever, STEC-HUS may be difficult to differentiate from inflammatory bowel disease, appendicitis, ischemic colitis, or intussusception. Bloody diarrhea generally ensues on the second day, accompanied in some cases by nausea and vomiting; though up to one-third of patients do not report blood in the stool. Fever is typically absent or mild. Colonoscopy reveals edematous colonic mucosa with occasional ulceration and pseudomembrane formation.

E. coli–associated hemorrhagic gastroenteritis is complicated by HUS in 8% to 18% of sporadic cases, and in over 20% in certain epidemic outbreaks. Therefore, the disease should be suspected in a patient who presents with characteristic clinical manifestations after an episode of bloody diarrhea, although the prototypic history of a preceding hemorrhagic gastroenteritis may be absent in up to 30% of cases. Young children and older adults are at greatest risk. HUS typically develops 7 days (range, 5–13 days) after the onset of diarrhea. Patients often present with oliguria or other evidence of renal impairment; 50% of patients require dialysis, at least temporarily. The severity of MAHA varies considerably, but many affected individuals require red cell transfusion. Thrombocytopenia is common, with a median platelet count of 30,000/ μ L in one study, but may be mild or absent in up to 30% of cases at presentation. Up to 25% of patients develop neurologic manifestations, which may include irritability and somnolence and less commonly, confusion, paresis, and seizures. The mortality rate is estimated at 3% to 5%.

Epidemiology

STEC-HUS accounts for at least 90% of cases of infection associated HUS. In one study conducted in the United States, the median age of patients with STEC-HUS was 4 years; 55% of patients were younger than 5 years of age, 33% between 5 and 17 years, 6% between 18 and 44 years, and 6% older than 45 years of age. The annual incidence of STEC-HUS is estimated to be 2–3 per 10⁵ in children under age 5. STEC accounts for 80% to 86% of cases in the United States and Europe. The most common serotype of *E. coli* associated with HUS is O157:H7, although other serotypes including O26:H11, O103:H2, O111:NM, O21:H19, O145:NM and O104:H4 have been reported. The major reservoir of STEC is domestic cattle; approximately 2% to 3% harbor STEC in their gastrointestinal tract at the time of slaughter, and meat can become

contaminated during processing. The organism has also been isolated from deer, sheep, goats, horses, dogs, birds, and flies. Large outbreaks have been reported in association with ingestion of contaminated ground beef, although contamination of poultry, cheese, fruits, and vegetables has also been reported. Other cases have been attributed to ingestion of contaminated water or unpasteurized apple cider or milk. The incidence of STEC-HUS may be increasing as a result of developments in food production methods. Industrial farming generates large quantities of potentially contaminated manure that periodically enters streams, where it can contaminate feed and uncooked vegetables. A 2011 outbreak of HUS in Northern Germany that affected more than 3000 individuals was caused by enteroaggressive *E. coli* O104:H4; the infection vector was traced to bean sprouts with evidence of intrahousehold transmission. Carriage of STEC may be asymptomatic, and fecal-oral transmission may contribute to epidemic spread in day care centers, nursing homes, and petting zoos. Aerosolization in barns has been implicated in outbreaks at fairs.

STEC strains are also associated with sporadic, nonepidemic cases of HUS. The disease occurs more frequently during the summer and autumn in temperate climates. Infection by Shiga toxin-producing *Shigella dysenteriae* serotype 1 is associated with HUS in developing countries and carries a higher mortality.

Pathobiology

STEC-HUS is caused by endothelial cell damage initiated by Shiga toxin and the inflammatory cytokines they induce. The type of Shiga toxin, as well as other virulence factors, contributes to risk.

After ingestion, the noninvasive enteropathic *E. coli* bacteria colonize the terminal ileum and follicle-associated epithelium of Peyer patches, after which they colonize the colon. Once colonization occurs, STEC bacteria express numerous virulence factors by horizontally transmitted gene cassettes termed *pathogenicity islands*. One pathogenicity island contains the locus of enterocyte effacement, which contains genes for the adhesin intimin, as well as a type III (three) secretion system that mediates transfer of bacterial proteins directly into enterocytes. Their capacity to cause HUS is mediated by two 70-kDa bacterial exotoxins. The toxins are transported across the intestinal epithelium through specific para- and intercellular mechanisms and then circulate, most likely by low affinity binding to the surface of neutrophils and platelets, before being transferred to higher affinity receptors expressed on glomerular endothelial cells that are upregulated by proinflammatory cytokines.

The toxin produced by these strains of *E. coli* is identical to Shiga toxin and is therefore generally referred to as *Shiga-like toxin 1* (*Stx1*). Most strains of pathogenic *E. coli* produce a second homologous toxin, *Stx2*, which is associated with a higher risk for HUS. The toxins are carried on a lysogenic bacteriophage capable of infecting other strains of *E. coli*. Intact, 70-kDa *Stx* holotoxins consist of a 32-kDa A subunit and five 7.7-kDa B receptor-binding subunits. The toxin binds to terminal Gal α 1-4Gal β (galabiose) residues on globosyltriacylglyceramide (Gb $_3$; also known as CD77 and the human blood group *P^k* antigen). Increased expression of Gb $_3$ on glomerular microvascular and cerebral endothelium compared with other vascular beds contributes to their heightened sensitivity to apoptosis, cytotoxicity, upregulation of integrins, and procoagulant activity. The higher levels of Gb $_3$ expression in children compared with adults may explain why children are particularly prone to develop HUS.

Following binding to Gb $_3$, *Stx1* and *Stx2* are internalized and transported in a retrograde manner to the endoplasmic reticulum and translocated into the cytosol. The A subunit is proteolyzed to a 27-kDa A1 subunit that binds the 60S ribosomal subunit and cleaves adenine 4323 from the 28S ribosomal RNA. This prevents elongation factor 1-dependent binding of aminoacyl tRNA, which inhibits protein synthesis and leads to ribotoxic stress response, changes in cellular function, and apoptosis. *Stx* alters the usual balance between intestinal absorption and secretion to a net excretory phenotype. *E. coli* lipopolysaccharide and *Stx* also stimulate leukocyte and intrarenal expression of proinflammatory cytokines (including interleukin

[IL]-1, IL-1 β , IL-6, and IL-8; MCP-1; and interferon- γ), which exacerbate toxin- and leukocyte-induced endothelial dysfunction. Changes in endothelial function include upregulation of expression of *Stx* receptors, which further sensitizes cells to *Stx*-induced injury, increased expression of P-selectin and tissue factor, increased release of vWF, and downregulation of thrombomodulin expression. Early in the course of the disease, *Stx* also acts in concert with lipopolysaccharide to trigger a procoagulant state that involves platelet activation.

It remains unclear why a minority of patients infected with STEC bacteria develops STEC-HUS. Activation of complement may contribute to the pathogenesis of *Stx*-HUS. *Stx2* directly activates the alternative pathway (AP) of complement and binds to short consensus repeat (SCR) 6-8 and 19-20 of factor H, which mediate surface recognition, blocking its ability to inhibit complement activation on cell surfaces. It has been hypothesized that subtle allotypic variation in factor H (CFH) may modulate the sensitivity of CFH to *Stx2*-induced dysregulation in susceptible patients.

Laboratory Manifestations

Like TTP, STEC-HUS is characterized by MAHA and thrombocytopenia. Thrombocytopenia tends to be less severe than that observed in TTP, and renal disease is the major clinical manifestation.

Renal biopsy, although rarely required for diagnosis in endemic areas, illustrates the importance of endothelial damage. Involved glomeruli show widening of the subendothelial space, which is filled with cellular debris and fibrin. Glomerular capillary endothelial cells are swollen and occasionally detached, leading to obliteration of the capillary lumens.

Though clinical features are often sufficient for the diagnosis of STEC-HUS, bacteriologic confirmation should be sought through stool culture, testing for *Stx* (e.g., by enzyme-linked immunosorbent assay), stool analysis for *Stx* structural genes, or acute and convalescent serologies. Stool should be tested as soon as possible after the onset of diarrhea. The recovery rate for STEC appears to be at least 90% during the first 6 days but less than 33% thereafter. *E. coli* O157:H7 ferments sorbitol slowly, appearing as colorless overnight colonies on sorbitol-MacConkey agar; sorbitol-negative cultures may be further characterized using commercially available O157:H7-specific antisera. Methods to detect *Stx* or their structural genes improve diagnostic sensitivity.

Antibody titers against *E. coli* O157:H7 antigens and *Stx* rise after infection, persist for 8–12 weeks, and may be useful to confirm STEC infection in selected cases; however, they are not widely available. In some cases, further evaluation may be desired to differentiate STEC-HUS from the other TMAs, such as autoimmune disease, aHUS and TTP.

Prognosis

The outcome of patients with STEC-HUS is generally favorable, although STEC-HUS remains the most common cause of acute renal failure in children and up to 60% of children require dialysis during the acute phase. However, STEC-HUS is usually self-limited and as a result of advances in supportive care, mortality has been reduced to 3% to 5%, with death usually caused by severe involvement of the central nervous system, intestine, or myocardium. Renal insufficiency generally resolves within 2–3 weeks, although some patients have prolonged anuria, requiring several months before recovery. Despite a favorable short-term outcome, many children with STEC-HUS develop chronic renal insufficiency over time. In one report of 29 patients with “typical” childhood HUS followed for 15–28 years, 7 developed chronic renal failure and 12 developed hypertension, proteinuria, or reduced glomerular filtration rate, whereas only 10 showed no residual abnormalities. Therefore 50% to 60% of patients have complete recovery with long-term preservation of renal function. Long-term outcomes are worse in older patients. Proteinuria

persisting for more than 1 year after the initial episode of TMA is likewise associated with progressive renal disease.

Therapy

Treatment of STEC-HUS is supportive. Volume expansion within the first 4 days of the onset of diarrhea significantly reduces the incidence of progression to oliguric HUS. However, no therapy has been shown to prevent HUS or to reduce the severity of kidney injury once established. In randomized trials, neither plasma infusion nor exchange was of benefit in children or adults with STEC-HUS. Corticosteroids, heparin, urokinase, aspirin, dipyridamole, antifibrinolytic drugs and intravenous immunoglobulin are ineffective. Antimotility agents and narcotics delay clearance of *E. coli* and toxin from the gastrointestinal tract and may increase the risk for progression to TMA; therefore these agents should be avoided. Nonsteroidal antiinflammatory agents may reduce renal blood flow and should also be avoided. Most experts believe that antibiotics increase the risk for progression to HUS, probably by lysing bacteria, releasing Stx and inducing bacteriophages on which Stx genes are expressed. Therefore, routine use of antibiotic is discouraged.

Activation of complement may contribute to the pathogenesis of STEC-HUS. In support of this concept, eculizumab, an antibody to complement factor 5, was reported to reverse neurologic abnormalities, low platelet counts, and elevated LDH levels in three patients with STEC-HUS. However, insufficient data are available to validate this hypothesis. During the 2011 German O105H4 STEC-HUS epidemic, eculizumab was administered most commonly to patients with the most severe organ compromise and often late in the course of disease. The outcome in these patients was similar to that in untreated patients, suggesting a potential role. Similarly immunoadsorption appeared to potentially benefit a small cohort of patients with severe neurologic compromise; however, most of these patients also received other therapeutic interventions. Additional data on the utility of eculizumab and immunoadsorption are needed before their routine use can be recommended.

Isolation of patients with STEC-HUS should be considered because shedding of the pathogenic bacteria may continue long after cessation of diarrhea.

ATYPICAL HEMOLYTIC UREMIC SYNDROME

Clinical Manifestations

Like TTP, aHUS may present with a prodrome suggestive of an upper respiratory tract infection or with nonspecific symptoms of malaise and fatigue. Though aHUS is generally not associated with a prodrome of bloody diarrhea, a history of recent gastroenteritis may be obtained from up to 30% of patients making distinction from STEC-HUS difficult. Extrarenal manifestations may occur in up to half of the patients; neurologic manifestations are typically less common and severe than in TTP and are less likely to dominate the course. Evidence of microangiopathy on the peripheral blood film is a universal finding, and the reticulocyte count and LDH concentration are elevated, but severe thrombocytopenia is less common than in TTP. Renal involvement is more severe than in TTP, with up to 60% of patients requiring dialysis. It has been suggested that in the absence of another cause for a renal TMA (such as STEC-HUS, systemic lupus erythematosus, scleroderma, medication effect, complications of transplantation, etc.), the presence of a creatinine over 2.3 mg/dL and a platelet count over 30,000/ μ L argues against a diagnosis of TTP and favors aHUS. However, cohort studies in patients with TTP indicated that some patients did require dialysis; suggesting that these disorders may be indistinguishable on clinical grounds alone, thereby highlighting the importance of ADAMTS13 assessment.

Typically, aHUS follows a chronic relapsing course, often complicated by hypertension and renal insufficiency. Moreover, exacerbations are often preceded by infection, pregnancy, or other seemingly

incidental events. Affected patients have a high risk for recurrence after renal allografting, and HUS occasionally presents in related donors after surgery. The disorder may resemble TMA associated with pregnancy, cancer, and chemotherapy, which have similar clinical presentations, but different natural histories.

Epidemiology

aHUS is a systemic TMA in which renal failure develops in the absence of a coexisting disease. While historically considered a pediatric disease, approximately 40% of cases present in adulthood, with the remaining 60% occurring in pediatric patients. However, aHUS only accounts for 5% to 10% of all childhood HUS. Seventy percent of children have their first episode before 2 years of age, 25% of these developing before 6 months, an age at which STEC-HUS is very uncommon. Childhood aHUS is equally prevalent in males and females, with a slight female preponderance in adults. Abnormalities in complement regulation, most commonly arising from mutations in complement regulatory proteins, have been implicated in up to 70% of cases. Inheritance is autosomal dominant with approximately 50% penetrance, and aHUS may occur in siblings with or without identical genetic abnormalities. Clinical conditions that increase complement activation (including pregnancy) may unmask the genetic propensity to develop aHUS. An autosomal recessive form of aHUS attributable to defects in the gene encoding for DGKE (an enzyme involved in intracellular signaling) has recently been described. Defects in DGKE may account for up to 30% of cases of aHUS presenting before the first year of life.

The incidence of aHUS in the United States has been estimated at 2 per million. More than 1000 patients with aHUS investigated for complement abnormalities have been identified through registries in Europe and the United States.

Pathobiology

The complement system is an ancient defense mechanism that stimulates the inflammatory response and destroys pathogens by opsonization or lysis. Most commonly, aHUS is a consequence of aberrant activation of the complement AP, which leads to endothelial damage, and is the result of mutations that lead to loss or functional impairment of complement regulatory proteins, or less commonly, activating mutations in alternative complement proteins.

Complement may be activated via the classical pathway, AP or lectin pathways. The AP plays an important role in protecting the intravascular space against bacterial infection and depends on potent amplification loops (Fig. 134.6). The AP is in a constant low-level activation state because of spontaneous hydrolysis of the thioester bond in C3, and regulation by complement inhibitory proteins is required to prevent pathologic activation and complement-mediated injury to host tissues. C3b is deposited on cell membranes of both pathogens and host cells. An amplification loop consisting of complement factor B, factor D, and properdin leads to the deposition of additional C3b on the cell surface and the generation of C3b convertase (C3bBbP), which further amplifies C3b generation. In the presence of additional C3b, this convertase can cleave C5 to C5a and C5b, leading to formation of the lytic C5b-C9 complex. To protect host cells from collateral damage as a consequence of complement activation, multiple soluble and membrane-associated regulatory proteins inactivate C3b on the cell surface. These include plasma protein factor H and membrane-associated cofactor protein (MCP; CD46), both of which bind to membrane bound C3b. Then another plasma protein, factor I (CFI), cleaves and inactivates C3b. Similarly, cell-surface thrombomodulin enhances CFI-mediated inactivation of C3b. Another membrane-associated protein, decay-accelerating factor (DAF; CD55) accelerates the inactivation of C3 convertase, although mutations of DAF have not been shown to play a role in aHUS.

Mutations in several complement regulatory proteins predispose to aHUS. Mutations in CFH account for 25% of cases. Loss of

Fig. 134.6 THE ALTERNATIVE PATHWAY OF COMPLEMENT ACTIVATION. (A) The alternative pathway (AP) of the complement system originally consisted of a serine protease that cleaved C3 to the opsonin C3b and the proinflammatory anaphylatoxin C3a. (B) An amplification loop was evolved to more efficiently deposit C3b on a target and liberate C3a into the surrounding milieu. *B* indicates factor B; *D* indicates factor D, a serine protease; *P* indicates properdin, a stabilizer of the enzyme. (C) Development of a C5 convertase. The same enzyme that cleaves C3 (AP C3 convertase) can cleave C5 to C5a and C5b with the addition of a second C3b to the enzyme complex (AP C5 convertase).

function mutations have been identified throughout the protein, most commonly in the C-terminal SCRs 19 and 20, which mediate cell binding (Fig. 134.7). These mutations do not result in decreased CFH plasma concentrations, but reduce its capacity to regulate complement activation on platelet and endothelial cell surfaces and on subendothelial basement membranes. SCRs 1–4 compete with factor B for binding to C3b and serve as cofactors for CFI-mediated proteolysis of C3b. The CFH gene (*CFH*) resides in the regulators of complement activation (RCA) cluster at 1q32 close to five factor H–related proteins (CFHR 1–5). The latter contain multiple duplicated segments with homology to *CFH*. Therefore the RCA is susceptible to nonallelic homologous recombination; the mechanism likely responsible for the formation of a hybrid gene consisting of the first 21 exons of factor H (encoding the first 18 SCRs) and the last two exons of CFHR1 (encoding SCR 19 and 20), which has been associated with aHUS. In addition to genetic abnormalities in factor H, acquired deficiencies account for 5% to 10% of aHUS, which occur in a subset of individuals with homozygous deletions of *CFHR1* (either as recombination events including CFHR3 and CFHR1 [ΔCFHR1/3] or CFHR3 and CFHR4 [ΔCFHR1/4]). The autoantibodies may cross react with factor H SCR 19 and 20 and CFHR1 SCR 4 and 5, which share extensive homology.

Mutations in MCP are found in approximately 15% of patients with aHUS. MCP is present on the surface of all nucleated cells

except erythrocytes. Mutations are found throughout the extracellular domain of the protein (see Fig. 134.7) and most commonly lead to diminished cell surface expression, although some impair protein activity.

MCP and factor H bind C3b and facilitate its cleavage on the cell membrane by factor I. Factor I mutations are observed in approximately 12% of aHUS patients and most commonly result in decreased protein expression; although some mutations cause decreased catalytic activity, which is mediated through the factor I light chain. Thrombomodulin also enhances CFI-mediated degradation of C3b, and mutations of thrombomodulin have been observed in 5% of patients with aHUS in one series.

Mutations in factor B and C3 are observed in approximately 3% and 10% of aHUS patients, respectively. Mutations in factor B lead to enhanced formation or greater stability of C3 convertase on cell surfaces. Mutations in C3 may result in resistance to regulation, principally mediated by diminished ability of regulatory proteins (CFH, MCP or CFI) to interact with mutant C3b.

Recently, mutations in the gene encoding for DGKE, a lipid kinase expressed in endothelium, platelets, and renal podocytes, has been identified as the cause of an autosomal recessive form of aHUS with high penetrance. The mechanism of disease is attributed to deregulation of intracellular signaling, leading to activation of protein kinase C with a subsequent shift of the balance of endothelial cells and platelets toward a more activated and prothrombotic phenotype. Altered podocyte homeostasis has been hypothesized to occur as a consequence of abnormal protein kinase C-dependent vascular endothelial growth factor (VEGF) receptor expression, disrupting this important cell nurturing pathway. In general, patients with *DGKE*-related aHUS have no evidence of complement dysregulation. Furthermore, unlike patients with defects of the complement mechanism, patients with *DGKE*-associated aHUS have persistent microhematuria and proteinuria between flares of disease.

Mutations have been detected in up to 70% of patients with aHUS and are transmitted in an autosomal manner, accounting for the commonly observed familial inheritance pattern, although disease penetrance is only 50%. The basis for incomplete penetrance of aHUS is poorly understood. Identified precipitating factors include infection, pregnancy, and additional single nucleotide genetic polymorphisms and haplotypes in complement regulatory genes. Up to 20% of patients harbor more than one mutation in complement regulatory genes. The cause of aHUS in the 30% of patients with no identifiable complement protein mutations remains uncertain.

Laboratory Manifestations

aHUS is characterized by MAHA and thrombocytopenia. Compared with TTP, thrombocytopenia and anemia may be less severe and renal insufficiency more prominent. Reports suggest that between 6% and 15% of children do not have the full triad of thrombocytopenia, anemia, and renal dysfunction at presentation. Recent guidelines have emphasized the importance of using both clinical and laboratory studies to diagnose aHUS and to distinguish it from other TMAs.

Diagnosis of aHUS requires several criteria, including: (1) the absence of other diseases associated with TMA, (2) the absence of criteria for pathogen-associated postinfectious HUS (i.e., negative stool culture and/or Stx assays), and (3) the absence of criteria for TTP (i.e., ADAMTS13 >10%). In addition, the complement system should be evaluated. A recent consensus statement suggests obtaining levels of C3, C4, CFH, and CFI, as well as flow cytometry studies for MCP (CD46) before initiating plasma exchange therapy. However, it is important to note that decreased C3 is only found in 30% to 40% of patients and that decreased CFH or CFI is only seen in 50% or 30% of patients with mutations in these genes respectively and between 30% and 60% of patients with autoantibodies to CFH. Also, decreased levels of C3 and decreased MCP expression may be observed in the acute phase of STEC-HUS. Serologic autoantibody

Fig. 134.7 CFH, MCP AND CFI MUTATIONS ASSOCIATED WITH aHUS. This figure provides a schematic representation of the location of the mutations in the protein domains of factor H, MCP and factor I. Mutations demonstrated to impair function or decrease expression levels are depicted in bold and underlined. Polymorphisms are shown in italics. References are in parenthesis, (*) indicates unpublished data by Rodriguez de Cordoba et al. *aHUS*, Atypical hemolytic uremic syndrome; *CFH*, complement regulatory protein factor H; *CFI*, complement factor I; *MCP*, membrane cofactor protein. (Reproduced from Rodriguez de Cordoba S, Hidalgo MS, Pinot S, Torajada A: Genetics of atypical hemolytic uremic syndrome (aHUS). Semin Thromb Hemost 40:422, 2014, with permission.)

TABLE 134.1 Plasma Concentration of C3, C4, CFH, CFI, and CFB and Expression of Membrane Cofactor Protein in the Various Subgroups of Atypical Hemolytic Uremic Syndrome

	Protein Level or Expression					
	C4	C3	CFH	CFI	CFB	MCP
CFH mutation	N	Normal (decreased)	Normal (decreased)	Normal	Normal (decreased)	Normal
CFI mutation	N	Normal (decreased)	Normal	Normal (decreased)	Normal (decreased)	Normal
MCP mutation	N	Normal (decreased)	Normal	Normal	Normal	Decreased (normal)
CFB mutation	N	Decreased	Normal	Normal	Normal (decreased)	Normal
C3 mutation	N	Decreased	Normal	Normal	Normal (decreased)	Normal
THBD mutation	N	Normal or decreased	ND	ND	ND	Normal
Anti-CFH Ab	N	Decreased (normal)	Normal (decreased)	Normal	Normal (decreased)	Normal

Note: Very low C3 levels are observed in patients with homozygous CFH mutation (complete CFH deficiency) or compound heterozygous CFH mutation, and in patients with CFB or C3 gain-of-function mutations. In most of the other patients, C3 concentration is mildly decreased or normal. CFH is undetectable only in patients with homozygous CFH mutation. Decreased CFH concentration can be observed in patients with heterozygous type 1 CFH mutation, and during flares of anti-CFH antibodies-HUS. Decreased C4 plasma levels have been reported in a few patients in each of the various subgroups.

"Normal" and "Decreased" without parentheses mean most frequently, normal or decreased. "Normal" and "Decreased" within parentheses mean possible, but not frequent. "Normal or decreased" without parentheses means that normal or decreased is equally frequent.

Ab, antibodies; CFB, factor B; CFH, Factor H; CFI, factor I; ND, not documented; THBD, thrombomodulin.

Data from Loirat C, Frémeaux-Bacchi V: Atypical hemolytic uremic syndrome. *Orphanet J Rare Diseases* 6:60, 2011.

to CFH should be sent. Abnormalities of complement regulation are involved in up to 70% of cases. Finally, genetic analyses of the genes that have been implicated in the pathogenesis of aHUS are recommended, despite the fact that no defects are found in 30% to 50% of cases. Because of variable penetrance, only 20% to 30% of patients will have a family history of aHUS. Plasma concentrations of complement and complement inhibitory proteins in various subgroups of aHUS classified by mutation are shown in Table 134.1.

Prognosis

aHUS has been historically associated with a poor prognosis, especially in older adults and those with severe renal dysfunction. The mortality rate approaches 25% and 50% of surviving patients develop chronic renal insufficiency. However, identification of the central role of control of complement and DGKE in the pathogenesis of aHUS allows prognostication based on genotype. Before the advent of specific anticomplement therapy, the prognosis of patients with genetic defects of factor H or factor I deficiency was poor, with a rate of recurrence and progression to end-stage renal disease or death of 70%, whereas MCP deficiency appeared to carry a better prognosis. Aggressive plasma-based treatment slows but does not prevent progression to renal failure. Eculizumab treatment has been shown to halt disease activity and improve renal function. In fact, some participants in the single armed trials were able to discontinue dialysis therapy. Initial experience suggests that eculizumab is ineffective in patients with disease caused by DGKE mutations, but no recurrences have been observed in the few reported DGKE cases where renal transplantation was performed.

Therapy

Until recently, patients presenting with TMAs (either TTP or aHUS) were offered a trial of plasma exchange therapy. Plasma exchange may still be indicated in patients where there is uncertainty about the diagnosis of TTP or aHUS pending the results of assays for ADAMTS13 or until more definitive anticomplement therapy is available. This approach is also being questioned in patients presenting with platelet counts over 30,000/ μ L and creatinine levels over 2.3 mg/dL, findings that are observed more often in association with aHUS than with TTP. Although plasma therapy replaces missing soluble regulators of the alternative mechanism of activation of complement and may ameliorate thrombocytopenia, it does not appear to halt renal disease progression, as evidenced by a high

incidence of end-stage renal disease in pediatric patients treated with this approach. Plasma-based therapy is at best temporizing and is associated with a high rate of complications.

Therapy for aHUS is rapidly evolving with the recent approval of eculizumab, a recombinant humanized monoclonal immunoglobulin that binds C5 with high affinity and inhibits its cleavage to C5a (a proinflammatory mediator) and C5b (the first component of the C5b-9 membrane attack complex). This medication was introduced for the treatment of paroxysmal nocturnal hemoglobinuria (PNH). Its approval for HUS was based on two single-arm studies involving 37 adults and adolescents and a retrospective review of 19 pediatric patients and 11 adults. Eculizumab demonstrated activity in the majority of treated patients, whether or not they were refractory to plasma therapy and independent of whether or not a mutation of a complement control protein was demonstrated. Several patients with severe renal insufficiency were able to discontinue dialysis.

These results suggest that eculizumab is the treatment of choice for patients with established aHUS or with a high clinical likelihood in an appropriate setting (e.g., postpartum status, positive family history, younger than 2 years of age). Markers of active TMA (thrombocytopenia, LDH, and haptoglobin) respond rapidly to therapy. The results of trials and accumulating registry data suggest that the sooner treatment is initiated, the better the chance of recovery of renal function. Current data also suggest that remissions are sustained. Checking for full complement blockade should be considered in individuals where there is apparent disease reactivation. Assay of eculizumab levels or CH50 may be informative. There is a risk of relapse of aHUS with potential for irreversible renal failure upon discontinuation of eculizumab, therefore, life-long treatment is currently recommended. However, with further experience, it may be possible to identify subgroups of patients who can safely discontinue treatment. Finally, it is important to note that immunity to *Neisseria meningitidis* depends upon the lytic terminal complement C5b-9 mechanism, and the reported incidence of *Neisseria* infection in patients taking this medication for treatment of PNH was 0.42 per 100 patient-years. Therefore, all patients should be vaccinated. Prophylaxis with antibiotics is suggested if therapy is initiated before antibody response develops, but because vaccination may only confer incomplete immunity, some recommend chronic antibiotic treatment.

In general, patients with aHUS who progress to end-stage renal disease are considered candidates for transplantation. Living related donor transplants are not recommended, except possibly in the case of DGKE-associated disease, because of the risk for aHUS in the donor's remaining kidney. Thus there are reports of aHUS developing in family-related renal donors within months of donation.

Since CFH, CFI, factor B and C3 are all soluble plasma proteins, deficiency or dysfunction is not corrected by renal allografting. The outcome of renal transplantation in aHUS has been poor, with a high rate of failure because of recurrent disease. In fact, the failure rate can approach 60% to 70% and failure often occurs within the first month after transplantation. The underlying genetic defect is predictive of relapse risk, being as high as 80% with mutations in CFH, C3 and factor B, but as low as 20% in patients with defects in MCP or in those without genetic abnormalities. Before the introduction of eculizumab, combined liver and kidney transplantation was recommended; however, the 1-year survival for this complicated procedure was disappointing. Anecdotal reports suggest that eculizumab prophylaxis may prevent posttransplantation recurrence.

OTHER THROMBOTIC MICROANGIOPATHIC DISORDERS

Posttransplantation Thrombotic Microangiopathy

TMA can occur in three transplant-related settings: (1) recurrent disease after transplantation for a TMA-related disorder, (2) in association with the use of immunosuppressive medications (calcineurin inhibitors [cyclosporine A and tacrolimus] and inhibitors of the mammalian target of rapamycin [mTOR inhibitors sirolimus and everolimus]) and (3) after hematopoietic stem cell transplantation.

Recurrent Disease and “De Novo Thrombotic Microangiopathy” After Renal Transplantation

As indicated previously, there is a high risk of developing recurrent aHUS after renal transplantation in patients with disorders of complement regulation. However, it is important to note that the diagnosis of recurrent TMA depends on the correct diagnosis of the index disorder. Patients with suspected de novo TMA that is subsequently attributed to aHUS may have initially presented with hypertension, renal failure and nephrosclerosis. In a French series of renal transplant recipients whose initial diagnosis was not aHUS, 7 of 24 of those diagnosed with de novo aHUS after renal transplantation were shown to have mutations of CFH or CFI. In the majority of these individuals, renal failure was attributed to hypertension or chronic glomerulonephritis. No mutations were identified in a control group of renal transplant recipients who did not develop TMA, suggesting that underlying defects of complement should be considered when TMA develops in the postrenal transplant setting. However, the most cases of posttransplant de novo TMA are attributable to drug toxicity, rejection, viral infection (such as parvovirus, cytomegalovirus and hepatitis C), or a combination of these processes. Antibody-mediated rejection may be confirmed by demonstrating the presence of major histocompatibility complex antibody, or by renal biopsy evidence of peritubular capillary C4d staining. Antibody-mediated rejection associated with TMA has a poorer prognosis than antibody-mediated rejection alone. Plasma exchange therapy appears beneficial in this setting.

Immunosuppressive Medications

Cyclosporine A and tacrolimus are common causes of drug-induced TMAs. The pathogenesis of calcineurin-induced TMA is uncertain. Cyclosporine A causes arteriolar vasoconstriction, probably through upregulation of endothelin and thromboxane, and downregulation of vasodilators (nitric oxide and prostacyclin). In vitro studies showed that cyclosporin A induces endothelial release of complement activating microparticles, suggesting both a toxic effect on the cells and a role for complement in the pathogenesis of renal dysfunction. Cyclosporin A also enhances platelet aggregation and thromboxane release.

TMA occurs in 1% to 5% of renal transplant recipients, as well as in occasional solid organ recipients treated with cyclosporin A or tacrolimus. Calcineurin-induced TMA typically develops insidiously

with progressive, otherwise unexplained renal insufficiency. MAHA or thrombocytopenia is found in only half these patients and are usually mild. The glomerular capillary and arteriolar thrombotic lesions are similar in appearance to those in primary cases of TMA. The distinction between calcineurin-induced TMA and acute tubular necrosis or rejection can often be made by biopsy, but not in all cases. Broad alloantibody reactivity and coinfection with cytomegalovirus may predispose to cyclosporin-associated TMA.

The extent to which calcineurin-induced TMA responds to a reduction of the dose or temporary discontinuation of medication is uncertain. The prognosis is generally good, although some patients develop permanent renal failure. In many patients, cyclosporin A can be reintroduced at a lower dose; in others, tacrolimus has been substituted successfully, although the latter may also precipitate TMA. Other strategies include substitution of an alternative immunomodulatory medication. The utility of plasma exchange is uncertain.

Recent evidence suggests that mTOR (mammalian target of rapamycin) inhibitors, such as sirolimus and everolimus, can also be associated with posttransplant TMA. It is likely that mTOR inhibitors impair endothelial function, but the mechanism remains to be elucidated.

Hematopoietic Stem Cell Transplantation

TMA occurs in approximately 6% of patients who undergo allogeneic marrow transplantation; the incidence is estimated to be 0.1% to 1% after autologous marrow or stem cell transplantation. Though guidelines have been developed, diagnosis is difficult because schistocytes and thrombocytopenia are common after bone marrow transplantation, and because the differential diagnosis of fever, renal failure, and neurologic complications is extensive. The clinical manifestations typically begin months after transplantation and the kidneys appear to be a major target organ. The pathophysiology is assumed to reflect systemic endothelial cell injury from a variety of causes. ADAMTS13 activity may fall after transplantation, but severe deficiency such as occurs in TTP is uncommon. Risk factors include the use of an unrelated or mismatched donor, total body irradiation as part of the pretransplant conditioning regimen, calcineurin inhibitor treatment, systemic cytomegalovirus or other infection, older age, female gender, and graft-versus-host disease (GVHD). Systemic microangiopathy is rare, but an intestinal biopsy may be needed to distinguish TMA from GVHD in patients with refractory diarrhea. Evidence of terminal complement deposition in the skin may suggest an aHUS-like mechanism.

Withdrawal or substitution of another immunosuppressive agent for cyclosporin A, if possible, should be considered, although at the risk for worsening of the underlying GVHD. Alternative causes should be sought, and aggressive treatment of infection and GVHD should be used in all but the most overt cases. It is difficult to determine the prognosis because of variable inclusion criteria. Although patients may appear to show an initial response to plasma therapy, the long-term effectiveness of plasma exchange has not been established and mortality exceeds 50%, often caused by complications of GVHD or opportunistic infection. Defibrotide has been used with reported success in a few cases, and there have been anecdotal successes with rituximab, anti-CD25 antibodies and eculizumab.

Cancer and Chemotherapy-Associated Thrombotic Microangiopathy

TMA may occur late in the course of some patients with disseminated malignant neoplasms and large tumor burdens, most commonly adenocarcinoma of the gastrointestinal tract, breast, or lung. Patients generally present with an abrupt onset of moderate to severe MAHA and thrombocytopenia. Renal insufficiency and neurologic dysfunction occur less commonly than in idiopathic or chemotherapy-induced TMA and may result from concurrent metabolic disturbances, central nervous system metastases, stroke, or hemorrhage.

The pathogenesis of cancer-associated TMAs is poorly understood. Laboratory evidence of DIC is found in 25% to 80% of patients based on findings of elevated fibrin degradation products or more sensitive measures of increased fibrinogen turnover. However, the observation that TMA occurs in only 5% of patients with disseminated malignancy and DIC suggests the involvement of additional factors, such as microvascular occlusion, intimal proliferation induced by tumor emboli within the pulmonary vasculature, or formation of an incompletely endothelialized tumor vasculature that predisposes to platelet adhesion, activation and aggregation. Severe deficiency of ADAMTS13 is not typical. Outcomes of patients who develop TMA in the setting of chemotherapy or advanced cancer are poor because the TMA tends to be unrelenting and the co-morbidity of the malignancy is significant. Survival is generally measured in weeks. The only effective therapy is reduction of the tumor burden, a goal often not attainable. A role for plasma exchange has not been established.

Specific cancer chemotherapeutic agents have also been implicated in the development of TMA. Patients are often receiving therapy for adenocarcinoma at the time TMA develops, making attribution to the neoplasm versus its therapy difficult to determine. However, unlike cancer-associated TMA, most patients with chemotherapy-associated TMA do not have a large tumor burden, and some may be in remission. Implicated agents include mitomycin-C, gemcitabine, *cis*-platinum, bleomycin, docetaxel, 5-fluorouracil, deoxycoformycin, carboplatin, oxaliplatin, interferon- α and bevacizumab, either alone or in combination.

Patients with chemotherapy-associated TMA generally present with moderate to severe MAHA, thrombocytopenia, and renal insufficiency (median creatinine value of 4.2 mg/dL). Approximately 15% to 20% of such patients develop neurologic dysfunction. A unique feature is noncardiogenic pulmonary edema, which is observed in over 50% of patients in some series. Pulmonary function may deteriorate rapidly after red blood cell or platelet transfusion, and patients should be transfused with caution.

Chemotherapy-associated TMA is presumed to result from direct toxicity to the endothelium. Mitomycin inhibits the production of prostacyclin by umbilical vein endothelium, and infusion of mitomycin-C into the rat kidney induces histologic changes similar to those found in chemotherapy-induced TMA. Alternatively, anti-VEGF antibodies and other VEGF inhibitors have revealed a critical dependence of podocytes and glomerular endothelial cells on VEGF. Toxicity of these agents includes a TMA localized primarily to the kidney and manifested mainly by hypertension and proteinuria.

ADAMTS13 levels are not severely reduced in chemotherapy-associated TMA. Fewer than 20% of affected patients appear to respond to plasma exchange and/or corticosteroids, and more than 50% die within 2 months.

Streptococcus pneumoniae

Infection with *S. pneumoniae* may lead to desialylation of the glycolyx of cells that express the Thomsen-Freidenreich (T-F) antigen. The activity of neuraminidase related to influenza virus may present with the same complication. A naturally occurring, cold reactive IgM may recognize the exposed T-F antigen, leading to red cell agglutination in vitro and rarely hemolysis in vivo. Affected individuals have a positive antiglobulin test. Postpneumococcal HUS is the second most common cause of postinfectious HUS in children, accounting for between 5% and 15% of cases, and occurring after approximately 0.5% of infections with this organism. It generally occurs in children less than 2 years of age and is associated with significant morbidity and mortality. In two series, 75% of patients required dialysis. Extrarenal manifestations are common. The pathogenesis is not well defined but may involve interactions among the IgM, red cells, platelets, and endothelium. Alternatively, desialylation by neuraminidase may disrupt factor H binding sites, resulting in unregulated complement activation and cell injury because factor B can no longer regulate C3 convertase. Management is generally supportive, but

many experts suggest avoidance of plasma infusion because of the concern that there may be unintended infusion of IgM anti-T-F.

Disordered Cobalamin Metabolism

An autosomal recessive TMA associated with disordered cobalamin-C metabolism can occur in individuals during the first weeks to months of life. Deficiency of cobalamin-C may result in markedly elevated levels of homocysteine and methylmalonic acid, which may be responsible for vascular injury. Approximately one quarter of such patients present with HUS. Although the majority of patients have a fulminant course leading to death, some present with a more chronic form of the disease later in childhood. One adult case was reported. Therapy consists of treatment with hydroxycobalamin. Neurologic sequelae are common, as is chronic hypertension.

Miscellaneous Drug-Associated Thrombotic Microangiopathy

Although TMA has been associated with more than 75 drugs, the 9 drugs that account for 75% of the cases include clopidogrel, estrogen/progesterone, gemcitabine, interferon, mitomycin, quinine, tacrolimus and ticlopidine. The mechanisms by which these agents induce TMA may differ, as may the natural history and response to therapy. Whereas mitomycin C, gemcitabine, and cyclosporin appear to induce TMA in a cumulative dose-dependent manner, quinidine and thienopyridines (ticlopidine and clopidogrel) induce TMA through either idiosyncratic, immune-mediated mechanisms or by acute endothelial toxicity (see [Chapter 131](#)).

The first report of quinine-associated TMA described the course of three patients with a syndrome resembling idiopathic HUS. Patients generally present with severe MAHA, platelet counts below 50,000/ μ L, and renal insufficiency, usually requiring dialysis. Neurologic dysfunction occurs in a minority of patients, but it can be severe; granulocytopenia and lymphopenia have been reported. In earlier reports, the prognosis was favorable once quinine was withdrawn and plasma exchange instituted. However, in another series, 17 of 225 patients with HUS had quinine-associated TMA, 4 of whom died, and 7 survivors were left with chronic renal failure. Although this disorder occurs most commonly after the ingestion of quinine tablets, cases have been reported after exposure to quinine in beverages such as tonic water or herbal health supplements (cinchona). A careful history is sometimes necessary to establish the link between quinine ingestion and the patient's clinical disease. The pathogenesis may involve idiosyncratic, quinine-dependent antibodies reactive with platelet GPs IIb/IIIa and Ib/IX and related antigens on endothelial cells and neutrophils that promote neutrophil aggregation and binding to endothelial cells in a drug-dependent manner. Patients with quinine-induced TMA have significant early mortality, though with appropriate supportive care and treatment of the acute episode, the disorder does not recur without reexposure to quinine.

The thienopyridines are another common cause of drug-induced TTP. TTP occurs in a higher percentage of patients exposed to ticlopidine, with an incidence ranging from 1:600 to 1:4814 patient exposures in contrast to an estimated incidence of 4 per 1,000,000 to 1 per 8500–26,000 exposures to clopidogrel. No cases of clopidogrel-associated TTP were encountered in the CAPRIE and CURE studies, each of which enrolled more than 6200 patients. Despite the low incidence, the frequency with which clopidogrel is prescribed renders it the most commonly reported drug associated with TTP in the Food and Drugs Administration MedWatch database, accounting for more than 30% of all cases. The pathogenesis and natural history of TTP associated with ticlopidine and clopidogrel differ. Reductions in ADAMTS13 activity below 15% occur in 85% of patients with ticlopidine-associated TTP but in only 15% of patients with clopidogrel-associated TTP. Reduced ADAMTS13 reflects the development of anti-ADAMTS13 antibodies. TTP generally develops within 2–12 weeks of starting ticlopidine and responds

relatively quickly to plasma exchange. Spontaneous relapses may occur. In contrast, 90% of patients exposed to clopidogrel but only 10% of patients exposed to ticlopidine develop a syndrome characterized primarily by MAHA and renal insufficiency, without severe thrombocytopenia; these individuals have normal levels of ADAMTS13, usually develop disease within the first 2 weeks of exposure, and may require several weeks of plasma exchange to achieve remission. Whether plasma exchange actually improves the clinical outcome is uncertain. Spontaneous relapses are uncommon.

HIV-Associated Thrombotic Microangiopathy

An association between HIV infection and TMA has been recognized since 1984. TMA occurred in up to 7% of patients hospitalized with HIV infection. Conversely, the incidence of HIV infection in patients with TMA varied from 15% to 50% in endemic areas. In contrast, TMA is rare in HIV patients who are treated with highly active antiretroviral therapy. The mechanism of disease remains unclear, but endothelial injury is hypothesized. Coexisting opportunistic infections may be a contributing cofactor. TMA that occurs in patients with advanced or untreated HIV often responds quickly to the initiation of antiretroviral therapy and can relapse if therapy is discontinued.

In some patients with HIV infection, the associated immune dysfunction may predispose to the formation of autoantibodies against ADAMTS13. This can lead to severe ADAMTS13 deficiency and TTP, despite adequate treatment for HIV. These patients may respond to plasma exchange.

Pregnancy-Associated Thrombotic Microangiopathy

The differential diagnosis of MAHA associated with gestation is complex. TMA may be difficult if not impossible to distinguish from other causes of MAHA unique to pregnancy, such as preeclampsia, acute fatty liver associated with DIC, and HELLP syndrome. The severity of the renal and neurologic abnormalities and the time during gestation at which the signs and symptoms of TMA first appear may provide the clues needed to prevent critical delays in therapy.

Approximately 10% of cases of idiopathic TTP occur in association with pregnancy. In one series, 40 of 45 cases of TTP in pregnancy were diagnosed antepartum at a mean gestational age of 23.5 weeks. Additional studies have confirmed that TTP frequently develops in the second trimester, although some studies report more common occurrence in the third trimester or immediately postpartum. ADAMTS13 levels fall progressively during pregnancy, but severe deficiency (<10%) is seen only in women with TTP. In the absence of appropriate therapy, maternal and fetal mortality approach 90%, and TTP during pregnancy is associated with a high risk of fetal loss. Pregnancies in women with congenital ADAMTS13 deficiency have been carried to term with prophylactic plasma infusion, sometimes combined with aspirin and low-molecular-weight heparin. The prognosis of pregnancy-associated autoimmune TTP has improved dramatically since the advent of plasma exchange, and continuing pregnancy does not impair response. There is no evidence that uterine evacuation leads to resolution. Many patients carry to term successfully, although the overall risk for fetal loss remains significant. Up to 20% of patients with chronic, relapsing TTP have recurrences during subsequent pregnancies, whereas recurrence occurs in almost all women with inherited ADAMTS13 deficiency.

aHUS also occurs with increased frequency in association with pregnancy. The disorder primarily affects primiparas who present with MAHA, thrombocytopenia, renal insufficiency and hypertension beginning at a mean of approximately 26 days after delivery in one series—this later onset may help to distinguish HUS from other causes of pregnancy-associated MAHA and thrombocytopenia, such as preeclampsia and HELLP, which occur late in gestation or soon after parturition. The outcome of aHUS associated with pregnancy is poor with mortality rates up to 50% and an additional 15% are left with chronic renal insufficiency. Recent studies suggest that as in

the nonpregnant setting, pregnancy-associated aHUS is closely tied to complement AP activation, particularly factor H, and thus may respond to complement inhibitors, such as eculizumab.

HELLP syndrome complicates approximately 0.5% to 0.9% of pregnancies and approximately 10% to 20% of cases of preeclampsia. The pathogenesis is attributed to aberrant placental development, but the details remain unclear. Patients often present with abdominal pain and/or gastrointestinal symptoms, and concomitant hypertension and proteinuria. Seventy percent of cases occur before delivery and the majority of the postpartum cases occur within 48 hours of parturition. Diagnosis is based on evidence microangiopathic changes on the blood smear, thrombocytopenia and abnormal liver function studies. The differential diagnosis is broad, and includes acute fatty liver of pregnancy, TTP, aHUS, vasculitis, DIC, and infection. The timing of development of symptoms may assist in the diagnosis because TTP tends to occur earlier in pregnancy, whereas aHUS often occurs postpartum. Initial management is to stabilize the patient, treat hypertension and prepare for delivery—delivery is considered curative for HELLP syndrome.

FUTURE DIRECTIONS

Thrombotic microangiopathic syndromes are uncommon, but their associated morbidity and mortality are significant. Over the last 10 years, dramatic progress has been made in our understanding of the pathogenesis of these syndromes, and these discoveries are being translated into effective therapeutic interventions. A phase I trial of recombinant ADAMTS13 for treatment of congenital TTP has been initiated. Targeted disruption of the vWF-GP1b interaction may prevent microvascular occlusion in TTP, and a phase II trial of a targeted therapy with caplacizumab has been completed. Expanded use of anti-CD20 and other immunomodulatory approaches may reduce relapses and induce durable remissions. Drugs that block the action of Stx may be the most promising approach to ameliorating STEC-HUS. A tetravalent peptide has been shown to be effective in animal models. Alternatively, generation of highly neutralizing anti-Stx-2 antibody may provide passive immunity and a mechanism to interrupt outbreaks of STEC-HUS.

Complement factor H concentrates have received orphan drug designation in Europe. Eculizumab and other complement inhibitors may convert aHUS from a progressive disorder that often culminates in chronic renal failure or death to a manageable chronic disease. Better biomarkers are needed to aid in the diagnosis of aHUS and to monitor patients on eculizumab. Such biomarkers indicate early response before organ functional changes can be identified, allow better understanding of the optimal duration of therapy, and define who might not require life-long anticomplement therapy to prevent aHUS relapse.

The factors that trigger onset and relapse of TMAs remain to be elucidated. It is unclear why some patients with acquired TTP have multiple relapses while others do not. Although Stx triggers acute episodes of STEC-HUS, other factors must account for the fact that some individuals with congenital deficiency of ADAMTS13 present in early childhood, while others develop the disease in the fifth or sixth decades of life, if at all. Why is the penetrance of aHUS only 50% in the presence of a complement inhibitor gene mutation known to predispose to disease? Clearly, a better understanding of genetic susceptibility factors is essential, but equally important is identification of the environmental agents that incite disease, about which we currently have little information.

HEMOPHILIA A AND B

Manuel Carcao, Paul Moorehead, and David Lillicrap

EPIDEMIOLOGY

Hemophilia is the most common severe inherited bleeding disorder recognized in humans. The hereditary and sex-linked nature of the disease has been appreciated since prebiblical times, and the previous occurrence of the disease in the European Royal family has added further interest in this condition.

The prevalence of hemophilia is worldwide, with no major geographic variances aside from rare clusters of disease in areas where founder mutations have been propagated (e.g., Twillingate, Newfoundland). In many parts of the developing world the true prevalence of the condition is unknown because of inadequate diagnostic facilities, but from experiences in the developed world, we can probably assume that the prevalence of hemophilia A is approximately one in 5000 males and for hemophilia B, one in 30,000 males. These prevalence figures do show some variances among countries but except where local founder effects are important, these differences likely represent variable disease ascertainment and diagnosis. Because of the X-linked recessive inheritance of the disease, most affected subjects are male. However, for every male with hemophilia we estimate that there are on average at least two carrier females (in most cases the mother of the affected male as well as potentially some sisters of the male, his daughters and potentially his aunts). Hence the hemophilia carrier state is almost certainly much more common although there are no good data for this. Many carriers may not be diagnosed mainly because they never have affected sons. Although most hemophilia carrier women do not experience significant bleeding, some will have clotting factor levels low enough to cause symptoms.

International studies in the past decade indicate that the numbers of persons with hemophilia in the population are increasing by approximately 2% each year. There are likely several reasons for this trend, including the overall increase in population numbers, increasing longevity of persons with hemophilia, particularly because human immunodeficiency virus (HIV) and hepatitis C are having less impact on mortality than they did in the past, and increasing worldwide awareness and diagnosis of patients with milder forms of hemophilia.

The clinical signs and symptoms and inheritance patterns for hemophilia A and B are essentially identical, and it was not until the early 1950s that the two forms of hemophilia were differentiated. Subsequently, in the early 1980s, the two genes encoding factor VIII (FVIII) and factor IX (FIX) were cloned, and the specific mutations responsible for hemophilia began to be determined.

FACTOR VIII BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

The Factor VIII Gene

The FVIII gene (*F8*) encoding the FVIII protein is located at Xq28, the most distal band of the long arm of the X chromosome (Fig. 135.1). It is a large and complex structure, 186 kb in length, consisting of 9 kb of exonic DNA arranged into 26 exons and 177 kb of intronic DNA in 25 introns. Most of the exons are small, ranging in size from 69 base pairs (bp) (exon 5; the smallest exon) to 3106 bp (exon 14; the largest exon—encoding the central B domain). The correspondence of these exons with the domains of the FVIII protein

is described later. The size of *F8* introns varies from 207 base pairs (intron 17) to 32.4 kb (intron 22).

In addition to the 9-kb FVIII transcript, this locus also encodes two additional messenger RNAs (mRNAs) that, unlike FVIII, are expressed ubiquitously. Within intron 22 of the *F8* gene there are two additional coding elements, *F8A* and *F8B*. The *F8A* transcript is made up entirely of intronic sequence from intron 22, and the *F8A* mRNA is transcribed in the opposite direction to *F8*. Although the function of the *F8A* transcript/protein is unknown, there is the potential that this mRNA could act as an antisense regulator of FVIII expression. In addition, two (or more) other copies of the *F8A* sequence are located further telomeric to *F8* and are involved in a frequent intrachromosomal recombination event in approximately 45% of patients with severe hemophilia A. The *F8B* transcript is expressed in the same orientation as the native *F8* mRNA, and this transcript comprises an initial intron 22 sequence that is spliced onto exons 23 to 26 of *F8*. As with *F8A*, the *F8B* transcript is also ubiquitously expressed. Although the function of the protein is unknown, because it contains the phospholipid binding region of FVIII it may play a role in membrane binding.

Factor VIII Expression

Transcription of the *F8* gene is regulated by a promoter that contains binding sites for both tissue-specific and ubiquitous transcription factors. The mRNA transcribed from *F8* is 9 kb in length and contains 7053 nucleotides of coding (i.e., translated) sequence and short 5' and long 3' untranslated sequences. The cellular site of FVIII expression has long been a matter of controversy. The situation is complicated by the very low abundance and instability of the FVIII transcript and protein. Nevertheless, *F8* mRNA has been found to be expressed in a variety of human tissues, including liver, spleen, kidney cells, and muscle. It has long been known that hemophilia can be cured by liver transplantation. The cell types within the liver responsible for FVIII synthesis have previously been unclear, but there is now strong evidence that the liver sinusoidal endothelium is the source of FVIII production.¹ Nonetheless, FVIII levels are maintained during episodes of severe liver failure, suggesting the existence of extrahepatic sites of FVIII expression. Recently, two reports using different conditional knock-out approaches in mice have shown that the vascular endothelium is the predominant site of FVIII expression in this animal model.^{2,3}

FVIII is an acute phase reactant, and studies have shown that FVIII expression can be induced through a nuclear factor kappa-B (NFκB). FVIII is an acute phase protein whose levels increase with hormone induction (estrogen use), but the mechanistic basis for this increase is not known.

The Biosynthesis of Factor VIII

FVIII biosynthesis has been extensively investigated in vitro using cell types that do not normally express this protein, such as baby hamster kidney (BHK) or Chinese hamster ovary (CHO). Therefore conclusions about the details of this process in a physiologic context should be made with caution. After production of the primary polypeptide chain and cleavage of the 19-amino-acid signal peptide, the protein

undergoes a series of posttranslational modifications, including N- and O-linked glycosylation mainly in the B domain (Fig. 135.2) and sulfation of tyrosine residues. Furthermore, when the nascent protein transits the endoplasmic reticulum (ER), it interacts with ER chaperones, including calreticulin and immunoglobulin binding protein (BiP). Although these interactions limit the transport of malformed

or aggregated forms of the protein in heterologous cells with high levels of FVIII expression, their relevance in native FVIII-producing cells (i.e., vascular endothelium and liver sinusoidal endothelial cells) is unknown. Indeed, under conditions of high-level FVIII expression, cells can activate a classic unfolded protein response and can succumb to apoptotic cell death.

The other detail of FVIII trafficking that has attracted attention is its transit between the ER and Golgi en route to secretion. Efficient transit through the ER–Golgi boundary appears to require an interaction with glycans within the B domain of the protein. Absence of these glycans or lack of specific transport proteins responsible for this trafficking event can significantly reduce the levels of secreted FVIII.

The Factor VIII Protein Structure

The DNA sequence of the *F8* gene predicts a translated single-chain polypeptide with a molecular weight of 260 kDa consisting of 2351 amino acid residues, including a 19-residue signal peptide. Upon translocation to the ER, the signal peptide is cleaved. The remaining polypeptide is 2332 residues long.

The FVIII protein consists of three types of domains: the three A domains, which have a 35% to 40% amino acid sequence homology to ceruloplasmin and to factor V (FV); a central B domain with no known homologues; and two C-terminal discoidin-like (discoidin being a cell adhesion protein found in slime molds) C domains that are also 35% to 40% homologous to FV and to ceruloplasmin (Fig. 135.3). There are also three small “a” domains (each between 20 and 40 amino acids) consisting of predominantly acidic residues. The sequence of these domains within the protein is NH₂-A1-a1-A2-a2-B-a3-A3-C1-C2-COOH. Tyrosine residues in the a2 and a3 domains, when sulfated, contribute to the cofactor function of FVIII and enable its interaction with von Willebrand factor (VWF). As indicated, the A and C domains of FVIII have structural similarities to similar A and C domains in coagulation FV. However, FV does not contain a domain homologous to the B domain. Given these structural similarities, it is not surprising that both FVIII and FV function as cofactors for serine protease enzymes in the coagulation cascade, FVIII in the intrinsic tenase complex and FV in the prothrombinase complex.

Subsequent proteolysis of the FVIII polypeptide chain in the Golgi generates a light chain consisting of the A3-C1-C2 domains with a mass of 80 kDa and a heavy chain consisting of the A1 and A2 domains. (see Fig. 135.3).

Fig. 135.1 FACTOR VIII GENE. The factor VIII (FVIII) gene (*F8*) is located on the X chromosome at cytogenic band Xq28-qter. The 26 exons span 184 kb of genomic DNA, and there are three open reading frames expressed from the locus: the 9 kb FVIII mRNA transcript incorporating all 26 exons of the gene; the F8A transcript that is transcribed in the opposite direction to FVIII and comprises sequences from intron 22; and finally, F8B comprising an initial 5' exon derived from intron 22 sequence that is spliced to exons 23 to 26 of the *F8* gene.

Fig. 135.2 FACTOR VIII GLYCAN MODIFICATION (molecular weight, 260 kDa; plasma concentration, 100–200 ng/mL; 1 nM). The factor VIII (FVIII) protein is modified by the addition of multiple N- and O-linked glycan chains. The majority of these glycan additions are located in the B domain and appear to play a role in facilitating intracellular trafficking and secretion of the protein.

Fig. 135.3 FACTOR VIII PROTEIN ACTIVATION AND INACTIVATION. The factor VIII (FVIII) protein comprises a series of A and C domains that are homologous to factor V (FV) and ceruloplasmin and a central B domain that does not show sequence homology. The inactive precursor protein is activated by thrombin through proteolytic cleavages at three locations. Inactivation of FVIIIa occurs through two mechanisms: spontaneous dissociation of the noncovalently bound A2 domain and proteolysis mediated by activated protein C (APC).

Circulating FVIII exists as a heterodimer of the NH₂-terminus heavy chain and the COOH-terminus light chain. The two FVIII chains are bound to one another at the A1 and A3 domains by noncovalent bonds that are divalent metal ion dependent. The involved ion is likely copper, which has been found in association with FVIII.

Storage, Secretion, and Circulation of Factor VIII

After synthesis, FVIII is secreted into the circulation, where it forms a tight noncovalent complex with its multimeric partner VWF (kDa $\approx$ 0.2–0.5 nM). Whereas the plasma concentration of FVIII is 100–200 ng/mL ($\approx$ 1 nM), the concentration of VWF is approximately 10 μ g/mL (50 nM); thus the molar ratio of FVIII to VWF in the FVIII-VWF complex is about 1:50. The majority of VWF in plasma is synthesized and secreted by vascular endothelial cells. VWF binds to the a3 and C2 regions of FVIII through sequences in the D'D3 region of the mature VWF monomer. Just as the cellular source of FVIII had long been argued, so necessarily has the site at which FVIII and VWF first interact. However, the recent finding that FVIII is expressed by endothelial cells suggests that at least some of the circulating FVIII may interact with VWF before secretion and may be co-stored with VWF in Weibel-Palade bodies. In the plasma, VWF protects FVIII from proteolysis by lipid-binding proteases including factor Xa (FXa). Without this interaction—for example, in cases of type 3 von Willebrand disease (VWD; in which VWF is absent) or type 2N VWD (in which mutations occur in the FVIII binding region of VWF)—the plasma half-life of FVIII is reduced and consequently, the plasma levels of FVIII are low.

Activation and Coagulant Function of Factor VIII

FVIII plays a critical role in the propagation (amplification) phase of coagulation. The physiologic activator of FVIII is thrombin, which proteolytically cleaves FVIII at three sites: Arg372 at the NH₂-terminus of the A2 domain, Arg740 at the NH₂-terminus of the B domain, and Arg1689 at the NH₂-terminus of the A3 domain (see Fig. 135.3). These cleavages release FVIII from VWF and result in the formation of a noncovalently associated A1-A2-A3/C1/C2 heterotrimeric activated FVIII (FVIIIa) molecule. FVIII can also be activated by FXa and FIXa, although the physiologic contribution of activation by these proteases is less clear.

In its activated form, FVIII provides essential cofactor activity in the intrinsic tenase complex where FIXa is the serine protease and FX is the substrate (Fig. 135.4). This reaction takes place on a procoagulant phospholipid surface, which in normal hemostasis is likely the activated platelet. Participation of FVIIIa in the complex enhances the catalytic efficiency of this reaction about 200,000-fold, and thus severe FVIII deficiency profoundly reduces the rate of FXa generation and renders this reaction biologically futile. The exact details of the cofactor role of FVIIIa remain to be elucidated, but it is assumed that it acts as a “scaffold” protein that optimally aligns the enzymatic and substrate components of the complex on the phospholipid surface. Indeed, the FIXa and FX interactive regions of FVIII have been defined, and the cofactor binds to the phospholipid surface through hydrophobic residues in the C2 domain. Of note, the FVIII B domain is not required for cofactor function, and to date, it appears that the principal role of this region of the protein is to facilitate trafficking and secretion of the nascent polypeptide.

FVIIIa is inactivated through two processes. The predominant mechanism is through spontaneous dissociation of the A2 domain. The secondary inactivation event is via activated protein C-mediated proteolysis at Arg336 and Arg562 in the FVIIIa heavy chain (see Fig. 135.3).

Our understanding of the clearance of FVIII/FVIIIa is limited. The low-density lipoprotein (LDL) receptor-related protein and other members of the LDL receptor family contribute, but this is unlikely to be the complete story. Indeed, evolving evidence indicates

Fig. 135.4 THE INTRINSIC TENASE COMPLEX. This membrane-bound complex plays an essential role in the amplification phase of hemostasis. Participation of all components of the complex enhances the catalytic efficiency of the FXa-generating process by more than 200,000-fold. Deficiency or dysfunction of either the enzyme or cofactor involved in the complex results in a marked reduction in catalytic efficiency and the clinical manifestations of hemophilia. *FIXa*, Factor IXa; *FVIIIa*, factor VIIIa.

- X/autosome translocation

that FVIII clearance may be mainly influenced by its multimeric partner, VWF, and that a group of lectin and scavenger receptors on macrophages, and other cells, such as the sinusoidal endothelium in the liver and spleen, may remove FVIII in complex with VWF.

PATHOPHYSIOLOGY OF HEMOPHILIA A

Hemophilia A is a disorder characterized by congenital deficiency of FVIII. Almost all patients with hemophilia A have *F8* gene mutations. Because *F8* is located on the X chromosome, hemophilia A follows an X-linked inheritance pattern. As a result, most affected individuals are male. Severe and moderately severe cases of hemophilia A are unusual in females but can result from a number of genetic mechanisms; these are listed in Table 135.1. Approximately 30% to 50% of hemophilia A cases are caused by a sporadic mutation and occur without a family history of the disorder. The sporadic mutation is most commonly first evident in a female making her a carrier. However, as most carriers do not have excessive bleeding symptoms the new carrier is unlikely to be diagnosed until later when she has affected sons of her own or potentially affected grandsons. New female carriers often arise in the context of older paternal age (i.e., older paternal sperm cells). A good example of this was Queen Victoria's father who was 51 years old at the time that Queen Victoria was conceived.

The molecular genetic basis of hemophilia A has been extensively characterized over the past 25 years. A comprehensive Internet database of hemophilia A mutations is maintained and updated at <http://www.factorviii-db.org>.

A significant proportion of hemophilia A cases are the result of a recurrent mutation, an inversion mutation involving sequences in intron 22 of the gene (Fig. 135.5). The mechanism involved in generating this mutation involves an intrachromosomal recombination event in which there is an exchange between the *F8A* gene in

Fig. 135.5 THE *F8* INTRON 22 INVERSION MUTATION. In about 45% of patients with severe hemophilia A, there is a recurrent *F8* inversion mutation involving intrachromosomal recombination of F8A sequences within intron 22 of the gene and at a 5' telomeric location. This mutation always results in a severe phenotype and almost always originates in the male germline. *Cen*, Centromere; *tel*, telomere.

TABLE 135.2 Factor VIII Mutant Genotype and Inhibitor Risk in Previously Untreated Hemophilia A Patients

Multidomain deletions	≈75%
Light chain nonsense mutations	30%–40%
Intron 22 inversion	20%–25%
Single domain deletions	15%–25%
Small non-A run insertions/deletions	15%–20%
Heavy chain nonsense mutations	10%–20%
Factor VIII missense mutations	<10%
Small A run insertions/deletions	<5%
Splicing mutations	<5%

intron 22 and one of two extragenic copies of this sequence that are located 5' and telomeric to *F8*. The origin of this recurrent mutation is almost exclusively in the male germline (in sperm cells), where the single X chromosome has no partner to pair with, thereby potentially facilitating the F8A-mediated intrachromosomal recombination. The result of this event is the inversion of the *F8* gene between exons 1 and 22 and thus, although two distinct *F8* transcripts are expressed from separate promoters (exons 1–22 and exons 23–26), a contiguous FVIII protein sequence is not synthesized. The intron 22 inversion mutation is always associated with a severe phenotype and is responsible for approximately 45% of the cases of severe hemophilia A.

A second recurrent inversion mutation involving intron 1 of the *F8* gene is responsible for approximately 2% of severe hemophilia A cases. The remainder of the mutations responsible for hemophilia A involves more than 2000 different alterations with a wide array of missense, nonsense, frameshift, insertion or deletion, and splicing mutations. In addition, two transcriptional mutations have been identified in the *F8* promoter region. All regions of the gene are potential mutation targets, but, as elsewhere in the genome, certain sequences such as the CpG dinucleotide in arginine codons are more prone to mutation because of spontaneous methylation of the 5' cytosine and spontaneous deamination to thymine. To date approximately 98% of cases of hemophilia A have been associated with mutations of the *F8* locus. The location of the missing mutations is not yet resolved, but the likelihood of locus heterogeneity for hemophilia A seems small. Indeed, the recent identification of mutations deep within introns of the gene suggests that all hemophilia A mutations are likely to be found within or adjacent to *F8*.

There have been extensive genotype and phenotype studies of hemophilia A with, in general, a good correlation between null mutations and severe disease and between nonnull missense mutations and a moderate or mild phenotype. The phenotype remains generally consistent with a specific mutation both within and among families.

In addition to its utility for family counseling issues, the *F8* genotype has also been found to be a predictive factor for the development of anti-FVIII antibodies (Table 135.2). Multidomain deletions are

Molecular pathology of hemophilia B

- No predominant recurring mutation
- Majority of mutations are missense variants
- Some mild phenotypes are due to founder mutations

Fig. 135.6 THE FACTOR IX GENE (*F9*). The *F9* gene is located on the long arm of the X chromosome at cytogenetic band Xq27 centromeric to the *F8* gene and the common X chromosome fragile site. The gene comprises 34 kb of genomic DNA arranged in eight exons.

associated with the highest risk (approximately 75% risk) of inhibitor development, while the lowest risk (less than 10%) is associated with most missense and splicing mutations. The largest group is those with an average risk of 20% to 30%; this includes patients with intron 22 and intron 1 inversions, nonsense and insertion or deletion mutations. Even within these categories there is significant variability in risk of inhibitor development; for example, certain missense mutations in the C2 and C3 domains are associated with much higher risk of inhibitor development.⁴

FACTOR IX BIOLOGY: GENETICS, STRUCTURE, FUNCTION, AND PATHOPHYSIOLOGY

Factor IX Gene and Factor IX Expression

The gene that encodes FIX was cloned and characterized by two groups in the early 1980s. The gene is located on the X chromosome at cytogenetic band Xq27 and spans 34 kb of genomic sequence (Fig. 135.6). The eight exons of the *F9* gene encode an mRNA transcript of 1.4 kb that is expressed exclusively in hepatocytes. The transcriptional regulatory elements of the *F9* gene have been well characterized, and indeed there is a variant form of hemophilia B, hemophilia B Leyden, in which a postpubertal rescue of inherited FIX deficiency is the result of an activated androgen response element in the *F9* proximal promoter.⁵ Aside from this hormone-responsive element, the *F9* promoter contains a typical combination of predominantly liver-specific transcription factor binding sites.

Factor IX Protein

FIX is synthesized exclusively in hepatocytes and circulates in plasma at a concentration of approximately 5 μg/mL (90 nM). The mature circulating protein consists of 416 amino acids and has a molecular weight of 57 kDa (Fig. 135.7). The protein is initially synthesized as a prepolypeptide with a short signal sequence, which facilitates entry into the ER, and a propolypeptide sequence, which interacts with the γ-glutamylcarboxylase in the ER. The interaction with this microsomal enzyme catalyzes the posttranslational conversion of the amino-terminal 12 glutamic acid residues of mature FIX into γ-carboxyglutamyl residues (the GLA domain). This posttranslational modification enables FIX to form calcium-dependent interactions with procoagulant phospholipid membranes. A second posttranslational modification at residue 64 in the first epidermal growth factor (EGF)-like domain of the mature polypeptide involves β-hydroxylation of asparagine. This modification also plays a role in facilitating interactions with calcium and phospholipid membranes.

The structure of FIX is homologous to that of other vitamin K-dependent coagulation proteins. The domain structure includes an amino-terminal GLA sequence followed by two EGF-like domains, an activation peptide and the carboxyl-terminus catalytic domain, which is similar to the organization of procoagulant factor VII (FVII) and FX and to the anticoagulant protein C.

Fig. 135.7 THE FACTOR IX PROTEIN (415 amino acids; 57 kDa; plasma concentration, 5 $\mu\text{g/mL}$; 90 nM). Factor IX (FIX) is synthesized exclusively in hepatocytes. The protein is produced initially as a prepropeptide. The signal peptide is cleaved upon entry into the endoplasmic reticulum (ER), and the propeptide is also removed in the ER after γ -carboxylation of 12 glutamic acid residues in the N-terminal Gla domain. FIX is activated by proteolytic removal of the activation peptide and FIXa is inactivated through complex formation with antithrombin. AP, Activation peptide; CC, disulfide linkage; EGF, epidermal growth factor-like domain; PrP, propeptide; SP, signal peptide.

The FIX zymogen is activated by two processes, proteolytic cleavage mediated by factor XIa (FXIa) and by a similar process involving the FVIIa–tissue factor complex. The activation of FIX involves sequential proteolysis of two peptide bonds at arginine residues 145/146 and 180/181 (see Fig. 135.7). These cleavages release the FIX activation peptide and result in the formation of the disulfide-linked FIXa enzyme with an NH_2 -terminus light chain and COOH-terminus heavy chain. Whereas the light chain binds to procoagulant phospholipid surfaces through a calcium-mediated process involving the GLA domain, the C-terminus catalytic domain cleaves and activates the substrate FX. This reaction involves the so-called intrinsic tenase complex in which activated FVIII participates as an essential cofactor. Absence of FVIIIa in the tenase complex reduces the catalytic efficiency of the reaction by approximately 200,000-fold.

FIXa is inhibited through an interaction with the natural anticoagulant protein antithrombin (AT). The fate of FIXa–AT complexes is not well characterized, but specific AT-protease receptors on the surface of hepatocytes participate in this process.

Hemophilia B Molecular Pathology

To date, all of the mutations responsible for hemophilia B have involved the FIX gene. Although there is a combined vitamin K-dependent protein deficiency state that involves mutations of the γ -glutamylcarboxylase gene, this condition is characterized by low levels of FVII, FX, and prothrombin as well as FIX. Mutational analyses of large numbers of patients with hemophilia B have detected mutations in the FIX gene in more than 98% of cases, and it may well be that the remaining mutations are located within intronic sequences that have not yet been analyzed.

In marked contrast to hemophilia A, in which approximately 50% of mutations resulting in severe disease are caused by two recurrent gene inversion events, approximately 75% of mutations in hemophilia B are missense substitutions. There are no common recurrent FIX mutations, although mild forms of hemophilia B may show a founder effect of missense variants in some populations.

Aside from the predominance of missense mutations, multiple other mutations can produce hemophilia B ranging from large gene deletions to a mix of nonsense, insertion or deletion, and splicing changes. The full array of FIX mutations responsible for hemophilia

Fig. 135.8 MUTATIONAL BASIS OF HEMOPHILIA B LEYDEN. In this variant form of hemophilia B, patients experience a spontaneous recovery of FIX levels after puberty. The disease results from mutations in the F9 promoter that disrupt transcription factor binding. Postpubertal recovery is at least partly attributable to the expression of testosterone, with the subsequent activation and binding of the androgen receptor to its cognate sequence in the F9 promoter. Sites 1 to 4 are transcription factor binding regions. AR, androgen receptor; C/EBP, CCAAT enhancer binding protein; COUP-TF, chicken ovalbumin upstream transcription factor; DBP, D site binding protein; HNF-4, hepatocyte nuclear factor 4.

B can be reviewed in the database available at <http://www.factorix.org>. The following text highlights several distinct and clinically important hemophilia B mutations.

The most biologically remarkable hemophilia B mutations are those that produce hemophilia B Leyden, a disorder wherein FIX levels gradually increase from less than 5% at birth to more than 30% by early adulthood. Because of the low FIX levels early in life, boys with this disorder often have bleeding episodes consistent with having moderate hemophilia B. After puberty, these problems improve or even resolve to the extent that the label of hemophilia is often removed from these patients. All of the hemophilia B Leyden point mutations are located in a 40-bp region of the FIX promoter around the transcriptional start site (Fig. 135.8). Each of these mutations interferes with the binding of a liver-specific transcription factor and thus up to the time of puberty, levels of FIX expression are markedly reduced. After puberty, there is synthesis of testosterone and androgen receptor activation. Binding of testosterone to an androgen response element in the FIX promoter provides a rescue mechanism for the disrupted FIX transcriptional status. Thus any family in which a previously diagnosed hemophilia B subject now appears normal should be investigated for a FIX promoter mutation.

Since the cloning of the FIX gene in the 1980s, the association of F9 gene deletions with FIX antibody formation has been well recognized. Thus with partial and complete F9 deletion mutations, there is a 30% to 50% risk of developing a FIX antibody response. In addition to neutralizing FIX enzymatic function, these antibodies can also be associated with anaphylactic or anaphylactoid reactions to FIX infusions.⁶ The antibodies usually develop in young children (1–2 years old) after 10 to 20 exposures to FIX concentrate. In such patients FIX concentrate use is generally no longer of benefit, and attempts at inducing immunologic tolerance to FIX may be complicated by the development of nephrotic syndrome. The mechanism underlying this complication is currently unresolved.

Hemophilia B is the bleeding disorder associated with past members of the Royal families of Europe. Although the clinical picture in these individuals was consistent with severe hemophilia, the precise diagnosis was not reported until 2009. In fact, a diagnosis of hemophilia was confirmed, but not hemophilia A as had been thought and would have been expected on the basis of disease incidence, but hemophilia B (Fig. 135.9).⁷ The “Royal” F9 mutation is a splicing variant occurring at the 3' end of intron

Fig. 135.9 THE “ROYAL” HEMOPHILIA MUTATION. There is now definitive evidence that the hemophilia previously present in the European royal families was hemophilia B. The point mutation found in an affected male from the Russian royal family introduces a new acceptor splice site at the 3' end of intron 3 of the *F9* gene. The consequence of this change is the translation of 11 novel amino acids from the exon 3/4 boundary followed by a premature stop codon. A severe phenotype would be expected either because of accelerated mRNA decay or the synthesis of a nonfunctional truncated factor IX protein. (Data from Rogaeu EI, Grigorenko AP, Faskhutdinova G, et al: *Genotype analysis identifies the cause of the “royal disease.”* Science 326:817, 2009.)

3 that creates a new splice acceptor sequence that results in a novel out-of-frame transcript with 11 new amino acids followed by a premature stop codon. This mutation likely leads to either nonsense-mediated accelerated decay of the mutant FIX mRNA or to the translation of a significantly truncated nonfunctional FIX protein. In both instances, the clinical phenotype would likely have been severe.

Missense mutations elsewhere in the *FIX* gene have been informative with regards to our detailed understanding of protein structure and function. Mutations at both activation peptide cleavage sites have been described, and as with many genes, recurrent “hotspot” mutations have been documented at arginine codons with CpG dinucleotide sequences. Finally, some mild and frequently encountered FIX variants appear to be caused by founder mutations, as evidenced by a common adjacent polymorphic haplotype.

Hemophilia Diagnosis

The initial diagnosis of hemophilia depends to some extent on the family context. In families in which hemophilia has previously been identified, family counseling determines the risk of hemophilia transmission and usually results in a diagnosis being made in utero or early in neonatal life. In contrast, when there is no family history of the disease, the diagnosis will often not be made until there are signs of bleeding, and the timing of this depends on the extent of factor deficiency. In severe deficiency states, the diagnosis is usually made in the first 1–2 years of life, but with moderate and mild disease, the diagnosis may be made much later; with mild hemophilia, the diagnosis may be delayed until late adult life when bleeding occurs after a surgical intervention.

Phenotypic Diagnosis of Hemophilia

Two diagnostic strategies can be used for hemophilia. In the vast majority of cases, this involves measurement of FVIII or FIX coagulant levels in platelet poor plasma using a functional clotting assay (usually a one-stage partial thromboplastin time [PTT], i.e., clot-based assay). Although most clinical hemostasis laboratories use a one-stage PTT-based test to quantify FVIII, some laboratories use either a two-stage assay or a chromogenic assay that measures the

TABLE 135.3

Methods of Factor VIII Measurement

		Comments
1. FVIII antigen ELISA		Rarely used clinically
2. FVIII functional assays	One-stage clotting assay	>98% of clinical laboratories. Assay CV <10%.
	Chromogenic assay	May detect FVIII instability mutants
	Two-stage clotting assay	
3. Indirect measurement	Global assays e.g., thrombin generation assay	Not readily available or standardized

CV, Coefficient of variation; ELISA, enzyme-linked immunosorbent assay; FVIII, factor VIII.

generation of FXa in a purified system (Table 135.3). In these latter assays, the incubation time is often longer, which may influence test results. For example, some missense mutations causing mild hemophilia A result in the synthesis of an unstable FVIII with enhanced dissociation of the A2 domain from the remainder of the protein. These unstable mutants can sometimes be missed when a one-stage FVIII assay is used but are readily apparent with two-stage or chromogenic assays that use a prolonged incubation time.

The severity of hemophilia is based on the extent of clotting factor deficiency (severe, <1% [<0.01 IU/mL]; moderate, 1%–5% [0.01–0.05 IU/mL]; and mild, 5%–40% [0.05–0.40 IU/mL]). When making a diagnosis of hemophilia B, caution must be taken in neonates because levels of FIX can be low in normal newborns as a result of an immature carboxylase system. FIX levels double in the first few years of life. Consequently, a child may be initially labeled as having moderate hemophilia and after a few years may have FIX levels in the range of mild hemophilia. Likewise, a child may be initially misdiagnosed as having mild hemophilia B and after several years the FIX levels may normalize.

Genetic Diagnosis of Hemophilia

The other diagnostic strategy that can be used in hemophilia involves DNA analysis. Since the cloning of the FVIII and FIX genes in the early 1980s, molecular genetic approaches to hemophilia diagnosis have advanced dramatically. There are now more than 2000 different *F8* mutations associated with hemophilia A and more than 1000 *F9* mutations documented in hemophilia B.

Currently, mutations responsible for hemophilia A and B can be identified in the *F8* and *F9* genes in approximately 98% of cases. In cases in which mutations have not been found, it is likely that sequence changes are deep within introns or within distant regulatory elements, regions of the genes that are not routinely examined in diagnostic laboratories.

The strategy for genetic analysis depends on the type of hemophilia and the severity of the phenotype. For example, all patients with severe hemophilia A should be screened initially for the recurrent *F8* intron 22 and intron 1 inversion mutations. In contrast, most patients with hemophilia B require full-sequence analysis of the entire *FIX* promoter, coding region, and splice sites.

When a familial mutation has already been identified in the FVIII or FIX gene, a prenatal diagnosis can be made by either chorionic villus sampling or amniocentesis. Outside of the prenatal context, mutation testing in hemophilia can be used for carrier detection for family planning purposes and as one component of the risk analysis for inhibitor development. Determination of the hemophilic genotype is now regarded as the standard of care in comprehensive hemophilia treatment centers (see box on [Hemophilia Carrier Detection and Prenatal Diagnosis](#)).

Hemophilia Carrier Detection and Prenatal Diagnosis

The X-linked recessive nature of hemophilia naturally results in the majority of affected subjects being males. Females, however, carry and transmit the hemophilic trait and can sometimes also express clinical manifestations of the disease. Although there are rare genetic circumstances that can result in moderately severe or severe hemophilia in women (see Table 135.1), the majority of females with low FVIII or FIX levels have low factor levels because of variable skewing of the random X inactivation process that takes place early during embryonic development.

There are four ways in which hemophilia carriers can be identified. First, in light of the X-linked transmission of the disease, pedigree analysis will determine the carrier status of some women. Thus all daughters of hemophilic fathers are obligate carriers, and 50% of the daughters of a hemophilia carrier mother will also carry the mutant allele.

The second mode of identification can be through the manifestation of abnormal bleeding caused by a low FVIII or FIX level. Estimates of the percentage of hemophilia carriers who experience excessive bleeding (most often demonstrated through menorrhagia) vary but likely approximate 20% to 30%.

The third mode of carrier detection involves use of the laboratory phenotype, in which tests of the intrinsic pathway (PTT) may be abnormal and the plasma levels of FVIII or FIX may be reduced below the normal range. The etiology for low factor levels in carrier females is multifactorial and includes a woman's blood type and VWF levels in the case of carriers of FVIII deficiency as well as the ratio of inactivation of the hemophilic and normal X chromosomes, a random process that occurs early during embryonic development. If there is markedly skewed inactivation of the normal X chromosome, the plasma level of FVIII or FIX may be correspondingly reduced, and the carrier female may have a bleeding disorder. It is important to determine the FVIII or FIX levels in all carrier females to provide advice regarding potential bleeding symptoms and the risk of bleeding with surgical procedures. However, it should be noted that whereas a low plasma level of FVIII or FIX is predictive of a carrier state, the lack of a low factor level does not rule out a carrier state. In the case of carriers of FVIII deficiency, a low FVIII to VWF ratio has greater predictive power than a low FVIII level on its own, which is only found in about 20% of carrier females.

The fourth and most definitive approach to carrier diagnosis is to use molecular genetics to identify the causative FVIII or FIX mutation. Although carrier detection studies originally used analysis of linked polymorphisms to track mutant alleles, advances in sequencing technology now enable relatively easy access to direct mutation detection. This advance has significantly enhanced family counseling for hemophilic kindred and has also enabled women and their caregivers to prepare optimally for the delivery of newborns.

With current molecular genetic testing strategies, the results of mutation analyses are available within a few days in urgent circumstances. However, most often results are returned within a few weeks.

If a woman is a carrier, the causative mutation in the FVIII or FIX gene will be found in 98% of cases. If a mutation is not found, it is possible that the mutation is deep within an intron or involves a distant transcriptional element.

Ideally, carrier detection should be performed after puberty but before the woman is contemplating starting a family. In many countries, testing for the carrier status of genetic disease is prohibited before adolescence so that the girl can participate in discussions of testing options.

Prenatal diagnosis of hemophilia should begin with an evaluation of the fetal sex, which can usually be determined through a routine ultrasound examination. Recent studies suggest that free fetal DNA can be isolated from the mother's blood, with levels increasing toward term. Examination of this material for the presence of Y chromosome sequences allows for definitive sex determination. If the fetus is female, no additional studies should be performed. If the fetus is male, molecular genetic analysis can be used to identify the hemophilic mutation. Fetal DNA can be isolated from chorionic villus samples obtained after 10 weeks of gestation or from amniocytes obtained by amniocentesis from 12 to 34 weeks. The risk of miscarriage with both of these procedures is approximately 1%. If the studies are being used for making decisions about therapeutic abortion, they should be performed as early as possible. Determination of the hemophilic status of the fetus will also help plan for delivery, although consensus about the optimal obstetric management of an affected baby is lacking.

Differential Diagnosis of Hemophilia

The initial clinical suspicion of hemophilia will usually come from signs and symptoms of excessive bleeding, a family history of a bleeding problem, or abnormal coagulation test results.

There are many causes of mild bleeding manifestations, such as increased bruising and prolonged bleeding after dental and surgical procedures. These include isolated or combined deficiencies of other clotting factors (i.e., FXI, FVII, FX, FII, FV deficiency; see Chapter 137), VWD (see Chapter 138), or various quantitative or qualitative platelet pathologies (see Chapters 130 to 132). Acquired bleeding symptoms can be caused by antithrombotic drugs (e.g., antiplatelet agents and anticoagulants) or can result from autoantibodies against clotting factors (e.g., acquired hemophilia A or acquired VWD).

It should be pointed out that a low plasma FVIII level is not synonymous with a diagnosis of hemophilia A. There are a number of potential diagnoses that can result in low FVIII levels (Table 135.4). Levels of FVIII below 10% are most often the result of inherited or acquired hemophilia A or a severe form of inherited or acquired VWD (severe type 1 or type 3 VWD). Determination of VWF antigen and VWF ristocetin cofactor levels is essential for diagnosis. Occasionally, levels of FVIII below 10% can be attained with type 2N VWD. This diagnosis can be confirmed using FVIII binding studies or by genotypic analysis of the FVIII binding codons of VWF (exons 17 to 25, which encode the D'/D3 regions of the VWF protein).⁸ Levels of FVIII between 10% and 50% are also likely the result of either hemophilia A or VWD (types 1 or one of the type 2 variants, 2A, 2B, 2M, or 2N). Assessment of VWF levels must be undertaken in these cases; if the VWF:RCO/VWF:Ag ratio is below 0.6, further evaluation of a possible type 2 variant must be pursued. Rarely, mild or moderate FVIII deficiency can be co-inherited with FV deficiency (see Chapter 137). Combined inherited deficiency of

**TABLE

 - Mild hemophilia A
 - Type 1 VWD
 - Type 2N VWD
 - Combined FVIII and FV deficiency

FV, Factor V; FVIII, factor VIII; VWD, von Willebrand disease.

FVIII and FV (levels are usually between 5% and 20%) has a prevalence of approximately 1 per million. This rare inherited trait is caused by recessive mutations in one of two genes involved in the facilitation of protein transport across the ER-Golgi interface: lectin mannose binding protein type 1 or multiple coagulation factor deficiency 2.

Isolated low plasma levels of FIX are almost always caused by congenital hemophilia B. Interestingly, in contrast to acquired hemophilia A, autoantibody development against FIX is rarely encountered. Other situations in which FIX deficiency is found usually involve concomitant reductions in the other vitamin K–dependent clotting factors, such as occurs with vitamin K antagonists, vitamin K deficiency, or significant liver disease. A much less common cause of a

mild deficiency state of all of the vitamin K–dependent proteins is an inherited defect in the γ -carboxylase enzyme required for the posttranslational modification of these proteins.

CLINICAL FEATURES OF HEMOPHILIA

The clinical symptoms and signs of hemophilia A and B are essentially identical and relate to the propensity for prolonged and excessive bleeding. The bleeding tendency in hemophilia is determined in large part by the baseline activity level of the deficient or defective clotting factor. Thus in severe hemophilia (A and B), in which the baseline activity level of clotting factor is below 1% (0.01 IU/mL), spontaneous bleeding usually occurs multiple times each year. With a moderate factor deficiency state of 1% to 5% (0.01–0.05 IU/mL), spontaneous bleeding is typically infrequent, but excessive and prolonged bleeding can occur with trauma and invasive surgical or dental procedures. Finally, in mild disease, with factor levels of 5% to 40% (0.05–0.40 IU/mL), excessive bleeding is usually only documented with trauma or invasive procedures.

Pathologic bleeding can occur in the neonatal period, when intracranial bleeding can develop after traumatic delivery, especially in infants with severe hemophilia. However, most frequently, severe disease manifests with easy bruising or soft tissue or joint bleeding between 6 and 18 months of age when the young child becomes more mobile. In mild hemophilia, the disease may remain silent for many years, and occasionally a new diagnosis of hemophilia may be made in those older than 60 years of age when challenged with a surgical procedure.

The bleeding pattern in severe hemophilia is distinct and is not often seen in other bleeding disorders. In severe hemophilia, the development of hemarthroses is a classic clinical sign. Bleeding into the ankles, knees, and elbows is seen most frequently, although a hemarthrosis can occur in virtually any joint. The development of a hemarthrosis is accompanied by pain, swelling, and reduced mobility, but after repeated episodes of joint bleeding, most patients with hemophilia are able to discern intraarticular bleeding at a very early stage before any of the classic clinical signs are apparent. Repeated bleeding into a single joint results in the development of a “target joint,” one in which further bleeding episodes are facilitated by previous events, leading to a vicious cycle of joint damage. With repeated episodes of bleeding, the joints become painful and less mobile. Eventually, this can result in immobility and muscle wasting of the affected limb (Fig. 135.10).

In addition to joint bleeding, patients with hemophilia are prone to excessive and prolonged soft tissue and mucocutaneous bleeding. Bleeding into unusual sites, such as the iliopsoas muscle, can result in prolonged disability and rarely, intracranial bleeding can develop, most often after trauma.

Although bleeding is the hallmark of hemophilia, the types of bleeds and issues vary somewhat according to the age of the patient. This is particularly true in newborns in whom issues related to the birthing process can occur, which are not encountered later in life. Also, the issues encountered in infancy (the highest risk period for developing inhibitors and the time for establishing home care and prophylaxis protocols) are different from those encountered in later childhood, adolescence, and the early and late adult years.

Hemophilia in Newborns

The neonatal period is a particularly hazardous period for newborn children with severe hemophilia. Newborn babies with hemophilia can be born to mothers who are known or suspected of being carriers or can be born to mothers who are not known to be carriers. The latter has become more frequent, likely as a result of demographic changes in populations including decreasing birth rates; this scenario is now encountered in about 30% to 50% of newborns with hemophilia. It is principally in the group of children born to families with no history of hemophilia that the risk of severe bleeding is greater

Fig. 135.10 CLINICAL OUTCOME OF CHRONIC SEVERE HEMOPHILIC ARTHROPATHY. This picture shows the legs of a 55-year-old patient with severe hemophilia A who is a wheelchair user. After a lifelong experience of multiple hemarthroses, the patient has very limited mobility. His ankles and knees show deformities, and his leg muscles are markedly atrophic because of a lack of use.

because no precautions are taken to avoid bleeding. How best to deliver children known or suspected of having severe hemophilia is still a matter of debate. For the most part, physicians still recommend atraumatic vaginal delivery because this can usually be performed safely and because it avoids the increased maternal morbidity associated with cesarean section. Furthermore, delivery of a child by cesarean section does not completely eliminate the risk of intracranial hemorrhage (ICH) (Fig. 135.11). The use of vacuum extraction or forceps should be avoided because these procedures increase the risk of both extracranial (e.g., subgaleal hemorrhage and cephalohematoma) and ICH. Fetal blood sampling has not been shown to be a significant risk factor for ICH.

Intracranial Hemorrhage in Newborns

The incidence of ICH in newborn children with severe hemophilia varies from 3.5% to 4%.⁹ It is surprising that it is this low given the trauma of childbirth. Nevertheless, this is still 40- to 80-fold higher than that in the normal nonhemophilic population. If a child with known hemophilia shows any sign of ICH (e.g., unequal pupils, seizures, vomiting, and lethargy), prompt infusion of the appropriate factor concentrate should be undertaken.

In newborn boys without a family history of hemophilia, signs of ICH should prompt an urgent PTT determination along with central nervous system imaging. If the PTT is prolonged and imaging studies reveal an ICH, levels of FVIII, FIX, and VWF should be determined urgently. While waiting for the results of these levels, fresh plasma can be given at a dose of 10 mL/kg. Because FVIII deficiency is much more common than FIX deficiency, an alternative is to administer FVIII concentrate and determine the PTT 10 to 15 minutes later. If the patient has hemophilia A or type 3 VWD, the PTT should correct; in the case of type 3 VWD this correction might be

Fig. 135.11 INTRACRANIAL BLEEDING IN HEMOPHILIA. A computed tomography scan shows an intracranial bleed in a person with hemophilia. This complication most often occurs after trauma with an incidence of five per 1000 per year in patients younger than age 5 years and 1% to 2% per year in persons with hemophilia older than age 55 years.

temporary caused by the reduced half-life of FVIII in the setting of type 3 VWD. If the PTT does not correct, then it can be assumed that the child has FIX deficiency, and an appropriate FIX concentrate can be given. If FVIII concentrate is used, fresh plasma can be given while waiting for the PTT results to cover the possibility that the child has hemophilia B.

Circumcision in Newborns

Surprisingly, bleeding after circumcision only occurs in about half of patients with severe hemophilia. Consequently, the lack of bleeding after circumcision does not exclude hemophilia. In children who are suspected of having hemophilia, the hemophilic status should be confirmed before circumcision. If hemophilia is proven and the family still wishes to undertake circumcision, the appropriate factor concentrate should be administered to the child before the procedure. In general, a single dose is sufficient although some clinicians may elect to give some postoperative doses.

Other Bleeding Manifestations in Hemophilia

Although virtually all types of bleeds can occur in hemophilia, musculoskeletal bleeds (hemarthrosis, muscle bleeds, and hematomas) are most common and cause the most long-term complications. Other reasonably common bleeds include oral, dental, gastrointestinal (GI), genitourinary, and neurologic bleeding. In addition, insufficiently treated muscle and soft tissue bleeds may develop into pseudotumors (see box on [Hemophilic Pseudotumors](#)) or lead to compartment syndrome (see box on [Compartment Syndrome](#)). Finally, bleeds can occur in the context of surgery and dental procedures.

TABLE 135.5

Reasons for Differences in Bleeding Phenotype

1. Differences in factor levels
2. Differences in mutations causing hemophilia: null versus non-null mutations
3. Coinheritance of other bleeding disorders
 - VWD
 - mild functional platelet disorders
4. Coinheritance of prothrombotic disorders
 - factor V Leiden
 - prothrombin G20210A mutation
 - low levels of protein C, protein S, or antithrombin
5. Differences in the pharmacokinetic handling of factor that might be associated with patients' ABO blood group and endogenous levels of VWF in the case of hemophilia A
6. Differences in levels of physical activity
7. Differences in the structural integrity of joints, making patients more or less susceptible to joint bleeds and joint damage.

VWD, von Willebrand disease; VWF, von Willebrand factor.

Bleeding in hemophilia is broadly correlated with the endogenous level of clotting factor. Patients with severe forms of hemophilia defined as having an endogenous FVIII or FIX level of less than 1% (<0.01 IU/mL) will develop spontaneous bleeds throughout their lives beginning at about 6 to 12 months of age when beginning to crawl. Without prophylaxis, the annual incidence of bleeding increases in the first 5–6 years of life and plateaus at an average of 20–30 bleeds per patient per year. For the most part, patients with moderate hemophilia (FVIII or FIX level of between 1% and 5% [0.01 and 0.05 IU/mL]) and mild hemophilia (factor levels of >5% [>0.05 IU/mL]) only experience bleeding with trauma or surgery.

Hemophilia A and B are characterized by similar types of bleeds. However, the severity and frequency of bleeding may vary considerably among individuals with the same factor activity level. Although not conclusively proven, a number of studies suggest that the bleeding phenotype in hemophilia B seems to be less severe than that in hemophilia A patients with comparable factor levels. This is reflected in a lower median age at first joint bleed, a lower median age at start of prophylaxis, increased use of prophylaxis, and increased joint arthroplasty in patients with severe hemophilia A compared with those with severe hemophilia B. Similarly, a higher proportion of children with moderate hemophilia A than hemophilia B tend to be on prophylaxis, again suggesting differences in the severity of hemophilia A and B. The reason for this difference in clinical bleeding severity has not been well studied. For patients with severe hemophilia, one possible explanation is related to the genetics of hemophilia. Patients with severe hemophilia B generally have nonnull mutations (e.g., missense mutations) and as such are likely to have some, albeit minimal, endogenous FIX activity. In contrast, most patients with severe hemophilia A have null mutations and produce no functional FVIII. Another theoretical reason to explain the difference in the severity of bleeding is that FVIII levels tend to rise when patients with hemophilia B have a bleed because FVIII is an acute phase reactant. Because FVIII serves as a cofactor for FIX, the increase in FVIII may augment the activity of the very low levels of FIX found in patients with mild, moderate, or nonnull mutation severe FIX deficiency, thereby improving hemostatic potential and limiting bleeding.

Even in patients with the same mutation and thus with approximately the same endogenous level of clotting factor, there may be differences in bleeding predisposition. Reasons to account for this are described in [Table 135.5](#). All of these reasons for phenotypic variability may explain why some patients bleed much less than would be expected on the basis of their factor levels while others might bleed much more; these differences may also explain why some patients can experience one significant joint bleed and end up developing signs

and symptoms of chronic hemophilic arthropathy while other patients may not develop joint damage despite repeated joint bleeds.

Soft Tissue Hemorrhages and Muscle Bleeds

Bleeding into soft tissues includes spontaneous and trauma-related bleeding into subcutaneous tissues and muscles. Superficial hematomas (bruises) may resolve spontaneously without the need for treatment, and as such, bruising is not an indication for clotting factor replacement. However, in moderate and severe hemophilia, soft tissue hematomas often undergo progressive enlargement and may need to be treated. Furthermore, some soft tissue bleeds (e.g., retroperitoneal bleeds or hematomas of the neck) can cause extensive blood loss and be life or organ threatening because of their propensity to expand, thus causing compression of adjacent organs, blood vessels, and nerves and the airway in the case of a neck hematoma.

Muscle bleeds are quite common in hemophilia. The muscles most often involved are, in descending order of frequency, the calf, thigh, buttocks, and forearm. Bleeds into these locations can lead to compartment syndrome, which is an emergency situation (see box on [Compartment Syndrome](#)). A particularly problematic muscle bleed is a bleed into the iliopsoas muscle, a large muscle in the hip region. Such bleeds can rapidly expand because there is no surrounding connective tissue to restrict their growth. Consequently, significant bleeding can occur into this muscle, potentially leading to the need for blood transfusion. Patients with iliopsoas muscle bleeds have pain and restriction of movement around the hip joint; they tend to maintain the leg in a flexed position. Because of increased pressure on the femoral nerve, they may complain of paresthesia, hyperesthesia, or weakness of the quadriceps muscle. An iliopsoas bleed can be confused with a hemarthrosis of the hip (see box on Hip Joint Bleeds). Urgent ultrasonography or magnetic resonance imaging (MRI) examination is required to differentiate between the two conditions. Iliopsoas muscle bleeds need prolonged treatment with factor concentrates, as well as immobilization and physical therapy, and consequently they usually necessitate hospitalization (see box on Hemophilic Pseudotumors).¹⁰

Hemarthrosis

Bleeding into joints accounts for about 75% of all bleeding events in hemophilia and is the hallmark of hemophilia. Although any joints may be involved, the most commonly involved are the ankles, knees, and elbows. These three joints are therefore referred to as *index joints*. Less commonly involved joints are the shoulders, hips, and wrists. The least involved are the joints in the hands and feet.

There is significant variability in the time when children with severe hemophilia experience their first joint bleed. Although the median age to experience the first joint bleed is around 1.8 years, some children experience this within the first year of life (as they begin to ambulate) and others not until their fourth, fifth, or sixth years of life.¹¹ Hemarthroses become more common as children age if they are not placed on prophylactic therapy. Hemarthrosis can be either spontaneous or trauma related; however, the trauma may be

imperceptible, particularly in very young children who may not vocalize the occurrence of trauma. Mild trauma may even occur while the child is asleep, causing the child to wake up with joint pain and swelling. The onset of a hemarthrosis is often signaled by a feeling of warmth and tingling in the joint. This may last for several hours before increasing pain and limitation of joint movement set in. In patients with severe hemophilia, bleeding into the joint will continue until the patient receives hemostatic therapy or the pressure within the joint increases to the point of causing occlusion of bleeding vessels and bleeding cessation. In the later scenario, the pain in the joint may be excruciating. In patients with moderate or mild hemophilia, the bleeding may stop without the administration of hemostatic replacement but only after substantial bleeding has occurred. Consequently, joint bleeds should be treated as soon as possible to minimize the extent of bleeding and reduce the risk of long-term disabling sequelae.

Blood in a joint leads to joint damage through at least three mechanisms: iron toxicity, inflammation, and mechanical distension of the joint. Repeated joint bleeds may result in inflammation and hyperplasia of the synovial tissue within the joint (a situation referred to as *synovitis*).¹² Synovitis is the first step toward the development of hemophilic arthropathy. Any joint that undergoes repeated bleeds is referred to as a *target joint*. The strict definition of a target joint is still under discussion, but in general, most clinicians tend to accept that a joint that bleeds three or four times in a 6-month period qualifies as a target joint.¹³

A target joint is a manifestation of synovitis, and if not managed with long-term prophylaxis, such a joint will continue to bleed and will ultimately become a chronically damaged, arthropathic joint. Early stage hemophilic arthropathy is characterized by synovial hyperplasia, extensive destruction of articular cartilage, progressive loss of joint space, cystic changes within the subchondral bone, osteoporosis, and atrophy of surrounding muscles. The final stage of hemophilic arthropathy is a deformed and dysfunctional joint. At this stage, joint bleeds become less frequent as synovial hypertrophy becomes less prominent.

Determining the status of joints of patients with hemophilia at a given time or longitudinally over time necessitates both clinical and radiographic examinations. Over the past 10 to 20 years clinical and radiographic scoring systems have been developed to objectively evaluate these findings ([Table 135.6](#)). Clinical scores are the most readily available, do not require expensive radiologic equipment, and

Compartment Syndrome

A compartment syndrome arises when a bleed (usually trauma induced) occurs into a closed (encapsulated) space, such as the forearm or calf. The capsule restricts exit of blood, thereby raising the pressure within the compartment. This ultimately results in compression of blood vessels and obstruction of blood flow, leading to tissue ischemia and the potential for nerve and muscle damage. Compartment syndrome is characterized by severe pain and swelling, limb pallor, paresthesia, and reduced limb movement. Without treatment, a compartment syndrome may lead to permanent neuropathy, tissue necrosis, and even loss of the limb. This emergency condition requires urgent factor replacement and potentially surgical decompression (fasciotomy).

Hip Joint Bleeds

Hemorrhage into the hip joint is uncommon compared with other joints. However, because the clinical features of hip bleeds are less distinctive than those of more exposed joints, it is possible that the incidence of hip bleeding is underestimated. Patients with a hip bleed maintain the joint in a partially flexed position, the position of lowest pressure. This position is similar to that seen in patients with an iliopsoas muscle bleed, causing these entities to be confused.

The management of acute hemarthrosis of the hip joint is somewhat different from that of other joints because of the vascular anatomy of the hip joint, which renders the head of the femur vulnerable to ischemia in the context of a bleed, causing raised intraarticular pressure.

Pain in the hip joint region may be caused by a range of conditions (hip joint bleed, iliopsoas muscle bleed, bleeds into surrounding muscles, retroperitoneal bleed, and appendicitis). Consequently, without appropriate imaging, a hip joint bleed may be easily misdiagnosed. Ultrasonography remains the preferred modality for investigation of hip pain because plain radiographs lack sufficient sensitivity to detect a joint bleed. Persistent pain despite appropriate factor replacement may indicate impending avascular necrosis, and urgent joint aspiration by an experienced interventionalist (using ultrasound guidance) or surgeon should be considered. Graded physiotherapy should be instituted when there is symptomatic improvement. Follow-up imaging studies (MRI, bone scan, or both) should be considered for assessment of avascular necrosis.

may be the most reflective of a patient's joint disability status. Plain radiographs are relatively inexpensive and widely available but are insensitive to the soft tissue changes seen in the early stages of joint disease and furthermore involve radiation exposure. Magnetic resonance imaging (MRI) is most sensitive to early joint (soft tissue) changes and does not expose patients to radiation but is limited by high cost, more limited availability, and the need for general anesthesia in very young children. Work is ongoing on the use of point-of-care ultrasonography to evaluate acute and chronic changes in joints. Ultrasonography does not require sedation in young children; is much less expensive than MRI; and differentiates between synovium and hemosiderin, which is not always possible with MRI. However, ultrasonography also has limitations: (1) it is very operator dependent, and the interpretation of ultrasound findings can be subjective, and (2) some structures within a joint (e.g., cartilage) are not readily visualized. Automated ultrasonography is also being developed to address some of the former limitations of this imaging modality.

Mucous Membrane Bleeding

Epistaxis is not a prominent feature of hemophilia, but it certainly can occur. Oral bleeding is, however, quite common in patients with hemophilia. Often one of the first presentations of hemophilia is bleeding from the frenulum after trauma. Tongue bleeding, caused by a child biting the tongue, is also reasonably common. This can become an emergency, either because of significant blood loss or from tongue swelling to the point of airway obstruction. Excessive bleeding with loss of deciduous teeth and eruption of secondary dentition can occur but is again not common in hemophilia. Fortunately, most bleeding from the mouth can be controlled with antifibrinolytic agents, such as tranexamic acid (Cyklokapron) or epsilon aminocaproic acid (Amicar). Factor replacement may be required for more serious cases. For dental surgery, particularly if it requires a nerve block, factor replacement or DDAVP (1-deamino-8 D-arginine vasopressin, desmopressin) needs to be given to raise the factor level to at least 30% of normal.

Hematuria

In the past, hematuria was a reasonably common occurrence in patients with hemophilia. Hematuria may be associated with trauma but most often is spontaneous, episodic, and usually painless.

Hemophilic Pseudotumors

Pseudotumors are a rare but very problematic complication in hemophilia. The most common type of pseudotumor arises as a result of repeated hemorrhages into a muscle with insufficient resorption of blood between hemorrhages. Pseudotumors become walled-off cystic structures surrounded by a fibrous membrane. They may become multivacuolated over time, and parts may become calcified. These cystic lesions frequently expand into adjacent structures, leading to their destruction. Skeletal fractures and bony deformities may arise from such lesions. Another and rarer type of pseudotumor, generally only seen in adult patients, arises from within the bone itself and is often secondary to subperiosteal bleeding. This type of pseudotumor is typically observed in the long bones of the lower extremities and in the pelvis. Pseudotumors arising distally are more common in young children and most often occur in the hand. Pseudotumors may be associated with pain from rapid growth or nerve compression.

Pseudotumors are usually diagnosed by radiologic means (ultrasonography or MRI). A pseudotumor may be misdiagnosed as a neoplasm (e.g., Ewing sarcoma or osteosarcoma) or as an infection (e.g., osteomyelitis or tuberculous abscess). Biopsy of such lesions is contraindicated because of the potential for significant bleeding or infection. Small pseudotumors, particularly distal ones or pseudotumors in patients with inhibitors, are often treated conservatively with aggressive clotting factor replacement along with immobilization of the affected limb.

Unfortunately, in some instances, factor replacement alone is insufficient, and complete surgical excision is needed. This carries potential morbidity and even mortality and should only be undertaken by skilled surgeons in conjunction with appropriate hemophilia specialists. Attempts have been made at embolization of such pseudotumors, and radiation therapy has been successfully used for treatment of small pseudotumors of the hand.

Hematuria can rarely be caused by renal calculi because these are thought to be more common in males with hemophilia compared with the normal nonhemophilic male population. There is no consensus on how best to manage hematuria in patients with hemophilia, but in general, increased oral fluids along with bed rest are recommended. If despite these measures, bleeding continues or is particularly severe, factor replacement should be given; the use of steroids to manage hematuria in patients with hemophilia has been reported, but there is no conclusive evidence that steroids provide any additional benefit. Fortunately, hematuria in patients with hemophilia is not associated with progressive loss of renal function, and as such, its natural history is probably benign.

The use of antifibrinolytic agents (tranexamic acid or epsilon aminocaproic acid) is contraindicated in hematuria because of the risk of ureteral obstruction by clots.

Gastrointestinal Bleeding

GI bleeding can occur in patients with hemophilia, particularly in adults, in whom it is often associated with the chronic use of nonsteroidal antiinflammatory drugs (NSAIDs) for hemophilic arthropathy. Another potential explanation for GI tract bleeding is esophageal varices in patients with portal hypertension secondary to long-standing hepatitis C. Such patients may present with massive life-threatening melena or hematemesis.

Neurologic Bleeding

ICH is the most dangerous hemorrhagic event in hemophilic patients. It is at present, along with HIV and hepatitis C, one of the three leading causes of death in persons with hemophilia. In both neonates and children with hemophilia, ICH is the leading cause of death. ICH is also one of the leading causes of morbidity (mental retardation, seizure disorders, and motor dysfunction) in children with hemophilia.¹⁴ The incidence of ICH is highest in neonates and is

associated with the birthing process, particularly with a traumatic vaginal delivery. ICH is also seen in young children with severe hemophilia, particularly in those who are not on prophylaxis or have an inhibitor. In older adults, ICH again becomes more common, particularly in patients with coexisting HIV or hepatitis C. In such patients, mild to moderate thrombocytopenia is frequently seen either as a result of portal hypertension–induced splenomegaly or from HIV-associated immune thrombocytopenia. The combination of thrombocytopenia together with hemophilia increases the risk of central nervous system bleeding. ICH is rare in patients with mild or moderate hemophilia.

ICH may be subdural, epidural, subarachnoid, or intracerebral. Intraspinal (usually epidural) bleeding is rare, but when it occurs, can cause spinal cord compression. Most cases of ICH occur after trauma, but the trauma may be quite trivial, such that the ICH appears to occur spontaneously. Patients with ICH usually present with neurologic symptoms soon after trauma. Typical neurologic symptoms include drowsiness, loss of consciousness, seizures, headache, and vomiting. Any of these symptoms should raise the suspicion of ICH. Thus, any person with hemophilia who has neurologic symptoms or signs should immediately be given a bolus of an appropriate factor concentrate to raise the factor level to about 100%. Replacement should always be given before any diagnostic procedure (e.g., computed tomography or MRI) is performed to confirm the diagnosis of ICH. If an ICH is present, in addition to appropriate factor replacement, patients should be hospitalized for 10 to 14 days during which time they should be maintained on factor concentrate (by continuous infusion or frequent bolus infusions) to maintain a factor level over 100% at all times.

Lumbar punctures and neurosurgical interventions can safely be performed in persons with hemophilia provided that 100% factor correction is achieved.

Surgery and Bleeding

With the exception of circumcision in neonates, excessive bleeding is almost inevitable in patients with severe or moderate hemophilia who undergo surgery without adequate replacement therapy with appropriate hemostatic agents. The bleeding can be acute or can be delayed for several hours or days. In addition to bleeding, surgery in such patients is characterized by poor wound healing as a result of poor clot formation along with prolonged bleeding and subsequent infection at the wound site. For surgical management of hemophilia see later section in this chapter.

CLINICAL MANAGEMENT OF HEMOPHILIA

As a lifelong, expensive, and disabling illness, the management of patients with hemophilia is complex and ideally best undertaken through comprehensive care in hemophilia treatment centers with multidisciplinary teams of health professionals. These teams should include a physician (usually a hematologist) with specialist training in hemophilia, a dedicated nurse, a physical therapist, and a social worker. Additional members that should be available for consultation include an orthopedic surgeon, a dentist, a genetic counselor, an obstetrician/gynecologist, a psychologist, a rheumatologist, a urologist, and (increasingly, for the management of elderly persons with hemophilia) a cardiologist. Fortunately, the role of the orthopedic surgeon in the management of hemophilia has been reduced in countries where prophylactic therapy can be provided.

Over the course of a lifetime, a patient and his family will experience numerous issues related to hemophilia. Significant psychologic sequelae ensue for both affected children and their families. These children may be overprotected, and this may result in their experiencing difficulties in adjusting to the school environment and to society in general as they age. Hemophilia impacts children's school experience and what sports and recreational activities they are allowed to undertake. Some studies have shown lower academic performance

and behavioral and emotional problems in school-aged children.¹⁵ There may be multifactorial causes for this, including potentially silent ICH. These children may grow up with resentment toward their peers and nonhemophilic siblings and they may harbor suppressed anger about having the condition. Hemophilia can also impact vocational choices and opportunities for adults with hemophilia with established arthropathy. In addition to all of the psychologic sequelae of hemophilia, unfortunate men with hemophilia who acquired HIV and hepatitis C also have to deal with the myriad emotional and social ramifications of these devastating infectious illnesses.

The child's mother may experience guilt knowing that as a carrier she passed the hemophilic mutation to her son. This can contribute to marriage breakdown, although it has not been ascertained whether separation occurs more frequently in marriages of parents of children with hemophilia than in parents of children without the condition. Clearly, persons with hemophilia and their families require significant education, counseling, and support throughout the individual's lifetime.

For society in general, hemophilia with or without HIV or hepatitis C has a substantial impact, mainly because of the high cost of care.

The key aspects of hemophilia management are preventive therapy, treatment of bleeds, and care of the complications of hemophilic bleeding.

Preventive Therapy

Preventing trauma does much to reduce bleeding frequency in persons with hemophilia. One of the strategies involved in bleed prevention is restricting the child from high-risk sports (e.g., ice hockey, American-style football, rugby, and martial arts). A number of other sports (e.g., soccer, basketball, baseball, and tennis) also entail a certain amount of risk but for the child's psychologic well-being are usually permitted. Other sports considered to be relatively safe include road cycling (with a protective helmet), running, and swimming. Ideally, persons with hemophilia should be encouraged to keep active throughout their lives because osteoporosis and obesity are growing problems in this population as a result of inactivity. All patients with severe and moderately severe hemophilia should be told to wear helmets for bicycle riding, rollerblading, skateboarding, and downhill skiing. There is controversy regarding the use of helmets (outside of sports) in very young children as they are learning to walk and are unsteady on their feet and prone to falling. Some clinics advocate that patients between the ages of 1 and 2.5 years with severe forms of hemophilia wear a helmet at all times, with the exception of when they are sleeping. Whether this policy reduces the incidence of ICH is not known. Advising families on the importance of good dental hygiene is important because good oral hygiene may prevent or reduce the need for dental procedures (extractions, root canals), which entail a risk of bleeding. Unfortunately, dental care, including regular cleaning by a dentist, is often not subsidized by society and as such may be an expensive undertaking for families.

Vaccinations

Children with hemophilia have normal immune systems and should receive all routine vaccines. In addition, they should receive hepatitis B vaccinations at a young age. Recombinant factor concentrates and currently available plasma-derived factor concentrates do not transmit hepatitis B. However, patients with hemophilia are at a higher risk of requiring blood transfusions because of trauma-associated blood loss, and there is still a small risk of acquiring hepatitis B from blood transfusions. It is not clear whether patients with hemophilia should receive the hepatitis A vaccination. However, the US National Hemophilia Foundation's Medical and Scientific Advisory Council has recommended that all persons with hemophilia who are seronegative for hepatitis A should be immunized against hepatitis A.

For persons with hemophilia, all vaccines should be given with care using the smallest gauge needle possible (#25 or #27) and applying pressure to the injection site for about 5 minutes. Vaccinations should be given subcutaneously rather than intramuscularly. This is a matter of some debate, however, because the majority of carefully administered intramuscular injections can be given safely. Nevertheless, there is an increased risk of hematoma formation after intramuscular injections. Subcutaneously administered vaccinations appear to produce the same immune response as those given intramuscularly.¹⁶ The enhanced safety of subcutaneous injections renders this the preferred route.

Avoidance of Aspirin and Other Medications

Persons with hemophilia already have a severe bleeding disorder, and this can be exacerbated by aspirin. NSAIDs may also interfere with platelet function and should be avoided if possible. Cyclooxygenase-2 inhibitors have less of an effect on platelet function than traditional NSAIDs. For older persons with hemophilia with coexistent cardiovascular disease, aspirin, other antiplatelet agents, or anticoagulants may be indicated, but such patients require coordinated care by an experienced cardiologist and a hemophilia specialist.

Treatment of Bleeds

When a bleed occurs in a patient with hemophilia, immediate treatment is required to halt further bleeding. Rapid treatment prevents expansion of the bleed, accelerates healing, and reduces the risk of permanent disability. The longer the delay in providing treatment, the more bleeding that will ensue, and consequently the longer it will take to completely resorb the blood. Rapid treatment of joint bleeds will minimize damage to the joint and prompt treatment of muscle bleeds will limit expansion and reduce the risk of pseudotumor formation or compartment syndrome. Rapid treatment of ICH may be life saving and will minimize morbidity. The capacity to administer rapid treatment is enhanced if the patient/family is able to administer factor at home (see box on [Home Care](#)).

Coagulation Factor Concentrates

One of the main components of treating bleeds in hemophilia is replacement of the missing coagulation factor to achieve hemostasis.

Home Care

Hemophilic treatment is best administered in the patient's home. Having a patient or other caregiver able to administer factor allows for prompt treatment of bleeds and facilitates prophylaxis. Teaching patients and families how to administer clotting factor concentrates is labor intensive and usually falls to a dedicated hemophilia clinic nurse. It often takes a long time before families become skilled at factor infusions. Most boys with hemophilia older than the age of 3 years can be treated at home after the parents are taught how to administer factor. In some children, poor venous access precludes routine factor delivery; these children often require implantation of a central venous access device (CVAD) such as a port-a-cath or creation of an arterial-venous fistula (AVF). The teaching of home care is complex. Good sterile technique is critical to avoid CVAD or AVF infections. Later in life, children can be taught how to self-administer factor through peripheral veins. This is generally done in children between the ages of 8 and 12 years of age.

Treatment of bleeds generally consists of more than just hemostatic support (factor concentrates or DDAVP). For example, epistaxis and oral bleeding benefit from the use of antifibrinolytic therapy, and rest and physiotherapy are important components of the treatment of joint bleeds (see section on hemarthroses). The use of ice, which is routine in hemostatically normal people with musculoskeletal injuries, is controversial in hemophilia because cooling may impair hemostasis.

Until the 1970s, this entailed the use of plasma or cryoprecipitate. Plasma contains small amounts of FVIII and FIX. Consequently, when plasma is used as the source of clotting factor replacement, large volumes are needed. Cryoprecipitate contains a higher concentration of FVIII, and in the past was commonly used for hemophilia A treatment. However, neither plasma nor cryoprecipitate is virally inactivated. Consequently, both of these blood products carry a risk of viral transmission. This limitation, together with issues of volume and convenience, has rendered these products obsolete for management of bleeding in persons with hemophilia.

Plasma-derived clotting factor concentrates became available in the 1970s. In the early 1980s, it became evident that these concentrates were contaminated with HIV and hepatitis C.^{17,18} Consequently, thousands of hemophilia patients worldwide were exposed to these devastating viral illnesses, and many died of AIDS or of complications of hepatitis C.¹⁹ Out of this tragedy came the development of safer factor concentrates—plasma-derived concentrates that were subjected to effective viral inactivation methods, including solvent detergent, pasteurization, vapor treatment, nanofiltration, and dry heating—as well as recombinant clotting factors. Currently administered plasma-derived clotting factor concentrates are not associated with HIV, hepatitis B, or hepatitis C seroconversion. In theory, there still is a small risk of transmission of viruses and prions from plasma-derived concentrates. Plasma-derived concentrates are generally classified as high purity (containing only the desired factor and very little else) or intermediate purity (containing the desired factor but with other factors present). In the case of FVIII, intermediate-purity products generally contain VWF (e.g., Alphanate [Grifols], Humate [CSL-Behring], and Wilate [Octapharma]), and intermediate-purity FIX products are prothrombin complex concentrates (PCCs, e.g., Beriplex [CSL Behring], Octaplex [Octapharma], and Proplex [Shire]), which in addition to FIX, contain factors II, VII, and X, as well as protein C and S. In general, PCCs are no longer used for the management of bleeding in patients with hemophilia B because of the risk of thrombosis. In the late 1980s, recombinant factor concentrates were developed. First-generation recombinant products were stabilized by the inclusion of albumin in the final product. Second-generation products no longer contained albumin in the reconstituted preparation but were still exposed to human plasma-derived albumin during the manufacturing process. Third-generation products have no exposure to human or animal proteins and are stabilized with sucrose. Until now, most recombinant FVIII concentrates have been derived from a full-length (as opposed to B domain-deleted) complementary DNA (cDNA) constructs. However, many of the extended half-life FVIII concentrates (including the recently licensed Fc Fusion FVIII Eloctate [Biogen]) currently being developed are B domain deleted. Recombinant factor concentrates have traditionally been more expensive than their plasma-derived counterparts, but they have generally supplanted plasma-derived concentrates for hemophilia treatment because of increased safety and small volume of infusion. Until recently, there was only one licensed recombinant FIX (Benefix [Pfizer]). A second recombinant (regular acting) FIX (Rixubis [Shire]) and two extended half-life FIX (Alprolix [Biogen] and Idelvion [CSL-Behring]) were recently licensed and several more extended half-life products are close to approval.

All brands of traditional recombinant FVIII concentrates have exhibited similar efficacy and have generally been thought to have similar rates of inhibitor development.

The efficacy of a factor concentrate primarily relates to its pharmacokinetic properties (recovery and half-life), and in this respect until recently all available plasma-derived and recombinant concentrates have had similar pharmacokinetic properties.

The recovery of factor concentrate refers to the increase in factor level achieved immediately after infusion of a given amount of factor. With all FVIII concentrates, administration of 1 IU/kg of FVIII increases the FVIII level by approximately 2%. Therefore to achieve a FVIII level of 100% in an individual with severe hemophilia, a dose of 50 IU/kg is needed. FIX has a volume of distribution twice that of FVIII, and 1 IU/kg has traditionally been thought to increase the FIX level by 1%. However, the recovery of recombinant FIX is

generally lower, with 1 IU/kg increasing the FIX level by 0.8%. With the newer modified extended half-life FIX concentrates, recoveries appear to be variable, perhaps because of differences in their extravascular distribution. Children exhibit lower recoveries of clotting factor. FVIII concentrates have much shorter half-lives (approximately 8–12 hours) than FIX concentrates (approximately 18–24 hours). There are large interindividual variations in clotting factor half-life because the half-life is affected by a number of variables. In the case of FVIII, it appears to be affected by the patient's endogenous VWF level, which in turn is related to the patient's ABO blood group. Both FVIII and FIX half-lives are also affected by patient age; half-lives generally increase with age.

Recent cohort studies and a randomized open label study have challenged the assumption that the rate of inhibitor development is similar with all plasma derived and recombinant FVIII concentrates.^{20–22} The Sippet (Study on Inhibitors in Plasma-Product Exposed Toddlers) study showed a 1.87-fold higher rate of inhibitor development with recombinant FVIII versus plasma derived FVIII while the Rodin study showed a 1.6-fold higher rate of inhibitor development with a second generation recombinant FVIII as compared to a third generation recombinant FVIII. The findings of both studies have been challenged because of methodologic study design issues and also on the basis of previous studies showing contrasting results. Over the next few years these studies may impact on the choice of FVIII chosen for newborn previously untreated patients (PUP) with severe hemophilia A.

Up until the present, the choice of recombinant FVIII concentrate to use has been primarily influenced by cost. In the future, with newer extended half-life FVIII concentrates (see later section) the efficacy and inhibitor incidence between newer products may be more variable and thus may impact increasingly on choice of product.

The dose and duration of substitution therapy depend on the severity of the bleed or the extent of the surgery. Table 135.7 shows the desired factor levels for various types of bleeding events and surgeries. After the initial bolus of factor, repeat doses have traditionally been needed. For major bleeds, such as an ICH, or for major surgeries, such as joint replacement, 10 to 14 days of full factor replacement may be required, but for less severe bleeds, such as an uncomplicated hemarthrosis, two or three treatments are usually sufficient. For minor bleeds or minor surgeries (e.g., dental extraction) only 1 to 3 days of factor is required. For patients who require factor for a number of days, in addition to the initial dose of factor, bolus infusions are generally required every 6 to 24 hours depending on the severity of the bleed or the surgery. Because of variable pharmacokinetics, factor levels should be monitored. This avoids high factor levels, which might be prothrombotic and represent an unnecessary expense, as well as low factor levels, which increase the risk of bleeding. In addition, monitoring helps detect development of

inhibitors. Determining the factor level at trough every several days ensures that the patient is achieving a hemostatic level of replacement.

An alternative method for maintaining hemostasis is by continuous clotting factor infusion. A lower dose of factor is required with this form of treatment, and the peaks and troughs of repeated bolus administration are avoided. In general, a FVIII infusion rate of 2 to 3 U/kg/h is sufficient once the FVIII level is increased to 100% with a bolus infusion of 50 U/kg. There has been concern about inhibitor development with continuous infusion therapy, particularly in patients with mild/moderate hemophilia A but there is no conclusive evidence that continuous infusion poses a risk for inhibitor development.

The above recommendations are based on the use of conventional half-life FVIII and FIX concentrates; different recommendations are needed for extended half-life FVIII and FIX and continuous infusion of these products is unlikely to be necessary to maintain hemostasis in patients undergoing surgery.

Extended Half-life FVIII and FIX Concentrates

A number of extended half-life or longer acting FVIII and FIX concentrates have been developed or (at the time of writing this chapter) are undergoing prospective clinical studies (Table 135.8). Consequently, many such products are likely to be available in the next few years. These agents will alter the management of hemophilia, particularly hemophilia B. Although all of the extended half-life or longer acting agents are recombinant proteins, the technology

TABLE 135.7

Recommendations for Clotting Factor Replacement

Site of Bleed	Level Desired (%)	Hemophilia A (rFVIII) (U/kg)	Hemophilia B (rFIX) (U/kg)
Oral mucosa	>30	20	40
Epistaxis	>30	20	40
Joint or muscle	>50	30	50
GI	>50	30	50
GU	>50	50	75
CNS	>100	75	125
Trauma or surgery	>100	75	125

CNS, Central nervous system; GI, gastrointestinal; GU, genitourinary; rFIX, recombinant factor IX; rFVIII, recombinant factor VIII.

TABLE 135.8

Extended Half-Life FVIII and FIX Concentrates in Development

Product	Technology	Manufacturer	T _{1/2} (h)	T _{1/2} vs. Native FVIII/FIX
Extended Half-Life FIX				
rFIXFc	Fusion protein with Fc fragment of IgG1	Biogen Idec/Sobi	57–83	3-fold
rIX-FP	Fusion protein with albumin	CSL-Behring	89–96	>5-fold
N9-GP	Site-specific glycopegylation with a 40-kDa PEG molecule	Novo-Nordisk	96–110	>5-fold
Extended Half-Life FVIII				
rFVIII-Fc	B domain deleted FVIII fused to a monomeric Fc fragment of IgG	Biogen Idec/Sobi	18.8–19	1.5–1.7-fold
BAY-94-9027	Site specific pegylation (60 kDa PEG) of a B domain-deleted FVIII	Bayer	19	1.4-fold
BAX 855	Controlled pegylation (2–20 kDa branched chain PEG) of a full-length FVIII	Baxter (now Shire)	NA	1.5-fold
N8-GP	Single site specific glycopegylation (40 kDa PEG) of a B domain-truncated (21 AA) FVIII	Novo Nordisk	19	1.6-fold

AA, Amino acids; FIX, Factor IX; FVIII, factor VIII; IgG, immunoglobulin G; NA, not available; PEG, polyethylene glycol; T_{1/2}, half-life.

used to extend the half-life differs among products. The two main methods involve fusion technology and pegylation. Both technologies work by interfering with the natural clearance of factor concentrates by cells of the mononuclear phagocyte system and by sinusoidal endothelial cells.

Fusion technology involves linking the cDNA sequences of clotting factors to the cDNAs of proteins (the Fc portion of immunoglobulin or albumin) that have long half-lives primarily because they bind to the neonatal Fc receptor in endothelial endosomes. This protects them and whatever is attached to them from degradation within endothelial cells, and then recycles the proteins back into the plasma. There are currently two extended half-life fusion FIX concentrates: in one, recombinant FIX is bound to recombinant Fc and in the other, recombinant FIX is bound to recombinant albumin. There is also one Fc fusion FVIII. For pegylation, polyethylene glycol molecules of different sizes are bound to either recombinant FVIII or FIX. There is one pegylated FIX and at least three pegylated or glycopegylated FVIII concentrates in development.

These newer concentrates have significantly prolonged half-lives. The half-life of FIX is extended three- to fivefold, while that of FVIII is extended by about 1.5-fold likely reflecting the dominant role of VWF in FVIII clearance.

These products, particularly the newer FIX concentrates, offer the possibility for fewer infusions and the achievement of higher trough levels. The extent to which these products will transform hemophilia management including such things as prophylaxis regimens, proportion of patients on prophylaxis, adherence to prophylaxis, long-term joint outcomes, and patient quality of life remains to be determined.

Adjunctive Treatments

Desmopressin

In the mid-1970s, Mannucci and colleagues showed that DDAVP (1-deamino-8 D-arginine vasopressin, desmopressin, Ferring Pharmaceuticals, Langley, UK), a synthetic analogue of the natural antidiuretic hormone vasopressin, raises circulating levels of VWF and FVIII:C.²³ DDAVP causes the release of endogenous VWF and endogenous FVIII from the Weibel-Palade bodies in endothelial cells into the blood. DDAVP also increases platelet adhesiveness and shortens the bleeding time independent of its effect on raising FVIII:C and VWF levels. Because DDAVP is not a blood-derived product or a factor concentrate, it is free of both infectious complications and potential inhibitor development. Furthermore, it is much less costly than factor concentrates and has few, generally mild and transient adverse events (flushing, headache, mild tachycardia, and hypotension). DDAVP has antidiuretic activity and thus carries a risk of hyponatremia and seizures, particularly if given to very young children or to those with excessive fluid intake. Because of concern about hyponatremia, many clinicians do not give DDAVP to children younger than 3 years of age, and administer DDAVP only once daily unless patients are hospitalized and serum sodium levels and fluid intake are monitored. The effectiveness of DDAVP decreases with repeated administration (tachyphylaxis) because of exhaustion of VWF/FVIII stores. Therefore, DDAVP should not be given for more than 3 consecutive days.

Most patients with mild hemophilia respond to DDAVP with a doubling or tripling of their FVIII:C levels to 30% or greater. In patients with moderate hemophilia, DDAVP rarely increases FVIII:C levels into a hemostatically effective range. All individuals with mild hemophilia A should be assessed for DDAVP responsiveness to determine whether they will benefit from this synthetic product. This involves determining FVIII and VWF levels before and 30 minutes to 1 hour after DDAVP administration.

DDAVP can be administered intravenously, subcutaneously, or intranasally. The usual dose for intravenous administration is 0.3 µg/kg given in 50 mL of normal saline over 30 minutes. For

intranasal administration, the usual dose is 150 µg (1 nasal puff) for patients weighing less than 50 kg and 300 µg (1 nasal puff into each nostril) for patients weighing 50 kg or more. The maximum effect of DDAVP is achieved within 30 minutes when given intravenously and within 60 minutes when given intranasally. In general the safest approach to avoid hyponatremia is to restrict fluids in patients receiving DDAVP and to administer only isotonic solutions such as normal saline.

Because DDAVP stimulates VWF release from endothelial cells, it may increase platelet adhesiveness. In patients with hemophilia with risk factors for coronary or cerebral artery thrombosis, this may result in angina, myocardial infarction, or stroke. Consequently, DDAVP should be used with caution in elderly men with hemophilia. Because DDAVP also stimulates the release of tissue plasminogen activator, it may exacerbate bleeding. Consequently, DDAVP is often administered in conjunction with antifibrinolytic agents.

Antifibrinolytic Agents

Antifibrinolytic agents are useful in the management of bleeding from mucosal sites where there is high fibrinolytic potential (e.g., the oropharynx, nose, GI tract, and uterine-vaginal lining). In hemophilia, antifibrinolytic agents (e.g., tranexamic acid or epsilon aminocaproic acid) are generally used in the context of oral bleeding or dental surgery. Oral tranexamic acid (25 mg/kg every 6 to 8 hours) should be started 24 hours before the scheduled procedure whereas intravenous tranexamic acid (10 mg/kg every 8 hours) can be given immediately before the procedure. Tranexamic acid is available in 500-mg tablets, which can be crushed and dissolved in liquids for administration to young children. The usual dosage of epsilon aminocaproic acid is 75 mg/kg every 6 hours. In general, antifibrinolytic agents should be administered for 3 to 10 days after a bleeding episode or an invasive procedure. Longer durations of therapy are required for tonsillectomy–adenoidectomy because bleeding often occurs about 7 days after the procedure when the eschar detaches. The major contraindication to the use of antifibrinolytic agents is hematuria.

Fibrin Sealants

Experience with fibrin sealants in patients with hemophilia is increasing. Fibrin sealants function both as local hemostatic agents and as promoters of wound healing. They are particularly useful for dental procedures. Fibrin sealants have been used successfully to reduce bleeding with dental procedures, circumcision, and after excision of hemophilic pseudotumors.

Adjunctive and Alternative Management Strategies for Joint Bleeds

In the management of joint bleeds, appropriate hemostatic support is critical, but other important measures include appropriate joint rest, analgesia, and graduated physiotherapy. The application of rest, ice (for 20 minutes every 3–4 hours), compression, and elevation (RICE protocol) during the first 24 hours after a joint bleed can provide substantial benefits. The role of joint aspiration in the management of joint bleeds remains controversial, but the procedure is advocated by some groups for management of persistent pain in large-volume hemarthrosis or for exclusion of septic arthritis. Orthotics and physical therapy are of vital importance in the management of acute joint bleeds and in dealing with long-term joint damage in patients with hemophilia. Ankle guards and arch supports are useful for patients with ankle arthropathy to improve gait and weight-bearing capacity. Shoe lifts can equalize the length of the lower extremities when there is a leg length discrepancy. Muscle strength training enhances the mechanics of joint movement and provides protection and stabilization of the joint.

Surgical Management in Hemophilia

With appropriate management (factor replacement with or without other adjunctive hemostatic agents), intra- and postoperative hemorrhages can be prevented in patients with hemophilia thus allowing for surgery to be performed safely in patients with hemophilia. Ideally a multidisciplinary team is required to undertake surgery in a safe manner; physicians with expertise in the management of hemophilia patients should always be involved. Some surgeries might need to be adapted for patients with hemophilia (e.g., bioprosthetic heart valves are preferable to mechanical valves to avoid the need for anticoagulant therapy).

The most common surgical procedures in hemophilia are those undertaken to manage the complications of joint bleeds. These include surgical or arthroscopic synovectomy, nonsurgical (chemical or radionucleotide) synovectomy, various arthrodesis procedures, and joint replacement.

An open surgical or arthroscopic synovectomy endeavors to remove the inflamed and thickened synovial tissue that is the source of bleeding within the joint. Although it may reduce the frequency of bleeding, it does not improve joint mobility and may even worsen it.

Radionucleotide synovectomy has largely replaced chemical synovectomy. This involves injection of a radioisotope (e.g., yttrium⁹⁰, chromic phosphate P³²) into the joint space to obliterate synovial tissue. Compared with surgical synovectomy, radionucleotide synovectomy is less invasive, associated with a shorter hospital stay, and reduced clotting factor coverage. Consequently, the procedure is less costly than surgical synovectomy. Radionucleotide synovectomy is particularly useful for patients with inhibitors because there is a lower risk of bleeding. However, long-term safety data are lacking in hemophilia.

Arthrodesis (surgical joint fixation) is particularly useful for painful joints with greatly compromised mobility in which joint replacement is not easily undertaken (e.g., ankles).

Joint replacements (particularly of the knee and hip) are still commonly performed procedures in adults with hemophilia. The elbow, which is not amenable to arthrodesis or for the most part to joint replacement, is often the most difficult joint to manage in patients with hemophilia. It is likely that there will be less need for surgical procedures with the initiation of prophylaxis regimens in early childhood.

Prophylactic Clotting Factor Replacement

Experience has shown that if treated solely on demand, patients with hemophilia will experience frequent bleeds and will, over time, develop disabling joint disease. Prophylaxis regimens reduce bleeding and prevent or limit joint damage in patients with hemophilia. The longest experience with the use of prophylaxis comes from European centers in Sweden, the Netherlands, and Germany.²⁴ Based on numerous cohort studies, there is good evidence that patients who receive prophylaxis experience fewer bleeds and maintain better joint function than those treated on demand. There are several different prophylaxis regimens distinguished by dose and frequency of factor administration. The full-dose prophylactic regimen, often referred to as the Malmö regimen, involves administration of 25 to 40 IU/kg of conventional FVIII every other day (minimum, 3 days/week) for patients with hemophilia A and the same amount of FIX 2 days a week for those with hemophilia B. Less intense “intermediate-dose” prophylaxis regimens involve the administration of 15 to 25 U/kg 2 to 3 times a week, and low-dose prophylaxis regimens call for the administration of dosages of 10 to 15 IU/kg given once or twice a week.

Of course, new protocols will be needed for the extended-half-life concentrates and full-dose, intermediate-dose and low-dose prophylaxis regimens with these products remain to be defined. In addition, these concentrates enable achievement of higher prophylactic trough levels, which could further reduce the risk of bleeding and allow patients more flexibility in pursuing activities.

Ample evidence shows that prophylaxis must be commenced early in life to prevent joint disease. This is referred to as primary prophylaxis; prophylaxis started at a very young age (usually 2 years of age or earlier) before joint disease has developed (generally, before or immediately after the first joint bleed). In contrast, secondary prophylaxis refers to continuous long-term prophylaxis started at a later age (after 2 years of age) or after more than one joint bleed has occurred. The term tertiary prophylaxis has recently been coined to refer to prophylaxis starting after there is established joint disease. The term *prophylaxis* also encompasses short-term prophylaxis regimens given after surgery or ICH.

Comparisons of different starting prophylactic regimens have shown that patients can be started on less intensive prophylaxis regimens and gradually escalated to full-dose regimens. Although full-dose regimens prevent bleeds more effectively than intermediate- and low-dose schedules, they cost more and may not be feasible in less affluent countries. In these countries, intermediate- or low-dose prophylaxis regimens may be more affordable, and may still confer significant benefit.

Although prophylaxis has been used for decades it was only in the last 10 years that a randomized study comparing primary full-dose prophylaxis with on-demand therapy in young children with severe hemophilia was undertaken. This study demonstrated 90% fewer bleeds in patients given primary prophylaxis and after only a few years, these patients already had less joint damage than those treated on demand.²⁵ The benefits of prophylaxis include reduced hospitalization, less time lost from school or work, improved school performance, and a reduced need for orthopedic surgery. Because of these benefits, the World Health Organization, World Federation of Hemophilia, and many other national hemophilia organizations have endorsed primary prophylaxis as the standard of care for children with severe hemophilia. One other potential benefit of prophylaxis is that early initiation of prophylaxis may reduce the risk of inhibitor development, at least in the subgroup of patients with severe hemophilia with “good risk” F8 mutations.^{20,26}

The approach to prophylaxis varies by center and country. In some centers and countries, all patients are given full-dose prophylaxis, while in others, prophylaxis is individualized based on the severity and frequency of bleeding episodes.²⁷

Burdens of prophylaxis include the need for venous access and cost. Patients receiving full-dose prophylaxis often require a CVAD or AVF for repeated factor administration. Furthermore, in the short term, full-dose prophylaxis regimens in young children are threefold more expensive than on-demand therapy. However, the cost of on-demand therapy increases over time because once joint bleeds occur, the subsequent joint damage triggers more bleeding. The social costs of joint damage are high in terms of lost time from school or work and limitations in vocational opportunities for adults with arthropathy. Whereas the costs of treating patients on demand rise over time, the cost of prophylaxis may stabilize or decrease when adults become less active.

Although most children in Europe and North America are on prophylactic regimens, prophylaxis is less routinely used in developing countries. However, this trend appears to be changing with increasing use of intermediate- and low-dose prophylaxis regimens in developing countries.

Considerations for Treatment of Hemophilic Bleeding in Adults

There is little doubt that regular prophylactic infusion of clotting factor concentrate is the treatment of choice for children and adolescents. However, the role of prophylaxis in adults is less clear. Although it may seem intuitive to maintain prophylaxis throughout life, this strategy is expensive, and its benefits have not been formally evaluated. Furthermore, there is some evidence that not all children who received prophylaxis require continued prophylactic therapy as adults.

When prophylactic therapy is undertaken in adults, it should be administered in a manner best suited to the individual needs of the

patient. Thus some patients prefer to treat themselves with a small amount of clotting factor every day (e.g., 500 IU of FVIII/daily), while others prefer a once- or twice-weekly regimen with additional infusions before high-risk activities, such as sports. Prophylaxis should be used in patients with a target joint into which repeated bleeding is documented. In this instance, prophylactic concentrate infusions at regular intervals (three times a week for FVIII and twice a week for FIX) should be initiated and continued for several months or longer.

If an on-demand regimen is used, patients must be carefully counseled. Treatment should be started as soon as possible after the first signs of bleeding and, if appropriate, adjunctive measures such as rest, ice, compression, or limb elevation should be used to hasten symptom control.

Complications of Treatment

Until the mid-1970s, the biggest impediment to the management of patients with hemophilia was the lack of readily administered treatment, which virtually guaranteed that patients with severe hemophilia would develop hemophilic arthropathy, and many would die from bleeding, including ICH. By the 1980s, treatments were available, and prophylaxis programs were initiated in many countries. Unfortunately, the 1980s was the era of HIV and hepatitis C, and most patients with hemophilia treated before 1985 became infected with both, with smaller numbers also becoming infected with hepatitis A and B. Many of these patients have died. This tragedy prompted widespread implementation of blood donor screening programs and viral inactivation processes and accelerated the development of recombinant clotting factor concentrates.

The management of HIV since the 1980s has undergone tremendous advances. Currently, patients with HIV who are treated with highly active antiretroviral therapy live almost normal life spans. Infection with hepatitis C has been more problematic because it results in chronic disease in approximately 60% of those infected. A combination of interferon and ribavirin has been used with good results in patients with certain hepatitis C genotypes 2 and 3 and less satisfactory results in those with genotype 1. Several new-generation anti-hepatitis C virus therapies are now available, and these may facilitate the cure of increasing numbers of infected patients with hemophilia.²⁸ Nonetheless, many patients still develop long-term complications of chronic hepatic infection, including hepatocellular carcinoma. Co-infection with HIV and hepatitis C together with alcohol use increases the risk of liver complications. All noninfected persons with hemophilia should routinely receive hepatitis A and B vaccination to reduce the risk of infection.

Other Comorbidity in Patients With Hemophilia

With progressive improvements in hemophilia care, persons with hemophilia are living longer, and morbidities associated with aging are now complicating the clinical management of hemophilia. Although patients with hemophilia are somewhat protected from atherothrombotic events, there are increasing numbers of older patients with coronary artery disease. This problem is necessitating the development of guidelines to safely introduce antiplatelet regimens for secondary prevention in patients with coronary artery disease.

There is also an increased prevalence of hypertension in hemophilia, the pathogenic mechanism of which is currently unresolved.

Limitations to Treatment for Hemophilia

Currently, the major impediments in the management of patients with hemophilia are cost, inhibitor development, and the need for CVADs.

1. Cost: Worldwide, cost is the major issue. Currently available factor concentrates, particularly recombinant factor concentrates,

are very expensive, and prophylaxis regimens can cost as much as \$300,000 per patient per year. However, the cost has decreased in countries with tendering systems. In the next few years, widespread introduction of extended half-life factor concentrates will likely have a major impact on the price of factor concentrates—both the newer products and the current products.

2. Inhibitor development: Management of patients with inhibitors remains a challenge. Although inhibitor development is more common in patients with hemophilia A (particularly severe forms), patients with hemophilia B are difficult to manage because they often develop anaphylaxis and nephrotic syndrome. Although the genetic and environmental risk factors for inhibitor development are increasingly well understood, our capacity to prevent inhibitor development remains limited.
3. CVADs: These are useful for the management of young children with severe hemophilia. They are of particular benefit in children who develop inhibitors and require immune tolerance therapy (ITT). Most ITT regimens call for daily administration of factor, which can rarely be given by repeated peripheral venipuncture in young children. CVAD complications include infections and thrombosis. Catheter infections caused by skin organisms can produce considerable morbidity, and the CVAD often needs to be removed. In a meta-analysis of studies evaluating CVAD complications, Valentino and colleagues reported a 40% CVAD infection rate with a mean of one CVAD infection for every four patients with a CVAD in place for 1 year. Thrombosis associated with CVADs varies in significance from small fibrin sheaths to thrombi that occlude large vessels and can lead to pulmonary embolism or death. Several studies have shown that radiographically proven CVAD-associated thrombosis develops in up to 50% of patients with hemophilia with these devices. Such thrombi may impair CVAD function, thereby necessitating their removal. Because of the complications associated with CVAD implantation, some institutions recommend AVFs as an alternative. However, experience with AVFs is still limited.

Immune Responses to Exogenous Factor VIII and Factor IX

Adverse immunologic responses to replacement products are a major complication for patients with hemophilia who have access to replacement factor concentrates. These responses occur because the infused factors contain foreign epitopes. However, not all patients develop an immune response to replacement; the reasons for this are unknown.

Immune responses include anaphylactic reactions and nonanaphylactic antibody-producing responses. The latter are classified according to their effects *in vitro*: whereas immunoglobulin (Ig) G antibodies that “inhibit” the coagulant function of the replacement factor are referred to as *inhibitors*, those that do not interfere with coagulant activity are called *nonneutralizing antibodies*. *Catalytic antibodies* directly hydrolyze the target protein.

Anaphylactic Reactions

Type I hypersensitivity reactions are rare in patients with hemophilia A but have been reported with infusion of either plasma-derived or recombinant FVIII concentrates. Rarely, there is evidence of IgE mediation, suggesting that in some cases, these reactions may reflect complement activation, immune complex formation, or other mechanisms.

Approximately 3% of patients with hemophilia B experience anaphylactic reactions to FIX products; these occur with equal frequency with plasma-derived and recombinant products. The median number of FIX exposure days at the time of anaphylactic reactions is 11.²⁹ These reactions often occur in patients who have FIX inhibitors and show evidence of IgE mediation. In some cases, transient IgG1 antibodies to FIX have been detected near the time of the allergic reaction. Because

IgG1 antibodies can bind complement, this may point to an alternative mechanism for anaphylactic-type reactions without evidence of IgE mediation. Factors that may confer an increased risk for anaphylactic reactions to FIX include Hispanic race, personal or family history of other allergies, and severe hemophilia B (FIX: C <1%) caused by large deletions and nonsense mutations of the *F9* gene.³⁰ It is unclear why anaphylactic reactions are more common with FIX deficiency than in FVIII deficiency. It is possible that the extravascular distribution of FIX is more likely to provoke such a reaction. In addition, therapeutic doses of FIX contain much more protein than therapeutic doses of FVIII, which may trigger anaphylaxis. Total deletions of the *F9* gene may also include deletions of adjacent genes whose absence may predispose patients to anaphylaxis.

The acute management of anaphylaxis involves supportive care and the use of non-FVIII or non-FIX-containing bypassing agents to treat bleeding. Desensitization by repeated administration of concentrate may be successful, particularly in patients with hemophilia B. Because of the timing of anaphylactic reactions in hemophilia B, it is recommended that the first 10 (in those with missense mutations) to 20 (in those with deletion and nonsense mutations) FIX treatments be given in a controlled setting.

Inhibitory Antibody Development

This important treatment-related complication is dealt with in detail in [Chapter 136](#). The current chapter deals with selected issues concerning pathophysiologic mechanisms and inhibitor detection only.

Factor VIII Inhibitors: Pathophysiology

FVIII inhibitors in patients with hemophilia A are antibodies of the IgG isotype and are typically of the IgG1 and IgG4 subclasses, although inhibitory antibodies of other subclasses are observed as well. Some evidence indicates that IgG4 antibodies are predominant in patients with high-titer inhibitors, while IgG1 antibodies are more abundant in patients with low-titer inhibitors. The predominance of IgG4 antibodies may be a consequence of prolonged exposure to exogenous FVIII because this phenomenon has been observed with repeated administration of other antigens. Inhibitory antibodies may have higher binding affinity than noninhibitory antibodies.

Inhibitors may be classified by the kinetics of their binding to FVIII. *Type I* inhibitory kinetics is characterized by a linear relationship between the antibody concentration and the logarithm of the residual FVIII activity; at high antibody concentrations, the inhibition of FVIII is near total. FVIII inhibitors in patients with congenital hemophilia A usually have type I kinetics. Inhibitors with *type II* kinetics do not display a linear relationship, and even high antibody concentrations do not result in complete inhibition of FVIII activity. Type II kinetics are commonly seen in acquired hemophilia A.

Inhibitors are produced when a FVIII-specific memory B cell is stimulated to differentiate into an anti-FVIII antibody-secreting cell (plasma cell). This differentiation is dependent on binding of FVIII to the B-cell receptor, and subsequent interaction with a CD4 positive helper T cell. The important role of helper T cells in the genesis of inhibitors is supported by diverse data: T-cell proliferation in response to FVIII is increased in hemophilia A patients who have inhibitors compared with those without. Blockade of CD3, a component of the T-cell receptor complex, has been shown to decrease inhibitor formation in vitro, as has stimulation of cytotoxic T-lymphocyte antigen 4 (CTLA-4), an inhibitory receptor involved in the downregulation of T-cell stimulation. Decrease of inhibitor titers, and even loss of inhibitors altogether, has been observed in hemophilia A patients with inhibitors who have HIV infection, particularly those with very low numbers of CD4-positive T cells. T-cell activation that effectively produces inhibitors requires co-stimulation from antigen-presenting cells (e.g., via the CD40/CD40 ligand pathway or the CD28/B7 pathway).

Regulatory T cells (Tregs), which can suppress the activity of helper T cells, may have a role in determining whether an individual patient will be immunologically reactive or tolerant to FVIII. T-cell proliferation in response to FVIII stimulation has been observed in Treg-depleted peripheral blood from normal (nonhemophilic) human subjects. In contrast, high levels of Tregs have been shown to suppress inhibitor development in mice models; hemophilia A mice treated with rapamycin (a small molecule inhibitor of the serine kinase mammalian target of rapamycin [mTOR]) failed to develop inhibitors on exposure to FVIII and had increased number of Tregs compared with control mice. Hemophilia A mice had lower inhibitor titers in response to FVIII with infusion of Tregs taken from wild-type mice than without, and Tregs created with chimeric antigen receptor technology have been shown to suppress anti-FVIII immune responses in vitro.

Immunologic tolerance to FVIII in people without hemophilia A is not complete. Rarely, usually as a result of autoimmune disease, immunologic tolerance to FVIII fails and autoantibodies to FVIII develop; this is known as *acquired hemophilia A*. Furthermore, antibodies to FVIII, detectable by enzyme-linked immunosorbent assay (ELISA) and Bethesda assay as well as other methods, can be found in the plasma of some individuals who do not have hemophilia A. T cells that are reactive to FVIII can also be found in normal individuals, although this reactivity is transient and less intense than in hemophilia A patients. The relevance of these observations for hemophilia A patients who have inhibitors is not known. Further understanding of the mechanisms that might prevent normal individuals from developing clinically important autoantibodies to FVIII, such as T-cell suppression by Tregs or neutralization of inhibitory antibodies by antiidiotypic antibodies (antibodies to the antigen-binding region of the inhibitory antibody), might provide insight into inhibitor suppression in hemophilia A patients.

Fortunately, the majority of patients with hemophilia A who are exposed to replacement FVIII products do not develop inhibitors. The reasons for tolerance to FVIII in some patients are not clear. Genetic factors play a role in inhibitor risk (see [Chapter 136](#)). It has been hypothesized that some patients are exposed in utero, via maternal-fetal hemorrhage, to small quantities of maternal FVIII that induce immunologic tolerance in the fetus. However, there has been no observed association between inhibitor risk and intrauterine procedures such as amniocentesis, or with breastfeeding.

Another theory to explain the development of FVIII inhibitors in some patients is that of immunologic “danger signals”: if a patient has exposure to FVIII at the same time as exposure to pathogen-associated molecular patterns, such as infectious agents or vaccines, or to damage-associated molecular patterns, such as might occur in the setting of surgery or in the setting of a major bleed, this may induce an immunogenic, rather than a tolerogenic, immune response to FVIII. Although specific danger signals, for example molecular patterns that are agonists for toll-like receptors or other receptors in the innate immune system have not yet been definitively identified in association with FVIII inhibitor development; some clinical data are consistent with the danger signal hypothesis.

Transient Inhibitors

Some FVIII inhibitors may disappear spontaneously without specific management. Inhibitors may ultimately prove to be transient despite continued on-demand FVIII exposure. This typically occurs with low titer inhibitors (<5 Bethesda units [BU]) but can occur with some higher titer inhibitors as well (≤10 BU). Transient inhibitors are also possible in patients with hemophilia B, but this phenomenon is not well characterized.

Factor IX Inhibitors: Pathophysiology

As severe hemophilia B is much less common than severe hemophilia A and as a much lower percentage of hemophilia B patients develop

inhibitors, much less is known about the basic science of FIX inhibitors than about FVIII inhibitors. There is, as previously described, a relationship between FIX inhibitors and anaphylaxis to FIX that generally does not occur with FVIII inhibitors.

FIX inhibitors are primarily IgG4 subclass antibodies although some are IgG2 subclass.

Epitopes for FIX inhibitors have been identified in the γ -carboxyglutamic acid domain, which is involved in binding to phospholipid surfaces, the serine protease domain, and possibly in the activation peptide region, at which FIX is activated by activated FXI. As is the case with inhibitory FVIII antibodies, the specificity of these antibodies for epitopes in functionally important regions of the FIX molecule explains their ability to inhibit FIX's coagulant activity.

Because FIX inhibitors are antibodies of the IgG isotype, they are products of interaction between FIX-specific B cells and helper T cells, but this process is less well described than is the case for FVIII inhibitors. The roles of co-stimulatory molecules, immunoregulatory genes, and Tregs in FIX inhibitors have not been demonstrated.

Detection of Inhibitors and Antibodies

Inhibitors are detected using the Bethesda assay (see Chapter 136). The Bethesda assay will not, by definition, detect nonneutralizing antibodies (i.e., those antibodies to FVIII or FIX that do not inhibit the coagulant function of these proteins). New modifications of the Bethesda assay, including an “ultrasensitive” Bethesda assay that uses concentrated patient plasma, are being developed and may improve the reliable identification of low-titer inhibitors (Fig. 135.12).

Both neutralizing and nonneutralizing antibodies to FVIII or FIX may also be detected by ELISA. This assay can only detect and quantify the antibodies present and cannot determine their inhibitory activity, but assays that identify the epitopes to which antibodies bind can discriminate between antibodies that interfere with important functional domains of the FVIII or FIX protein and those that do not. Techniques for measuring binding affinity of antibodies may also be of clinical use in the future.

Immunogenicity of New Factor Concentrates

Many new FVIII and FIX concentrates are in different stages of development for clinical use. In view of recent research that suggests the possibility of different rates of immunogenicity between different FVIII products that are currently in use, the immunogenicity of any new products will be of interest and importance.

Every factor concentrate's immunogenicity is initially evaluated in previously treated patients (PTPs, i.e., those with a minimum of 100 to 150 prior exposure days to a FVIII or FIX concentrate). In studies of PTPs exposed to new factor concentrates, very few inhibitors have so far occurred. This suggests that in widespread clinical use, inhibitors will occur only rarely, if at all, in PTPs who switch to new concentrates.

There is less experience using new concentrates in hemophilia patients that have not yet been exposed to a factor concentrate (PUPs). Since the risk of both FVIII and FIX inhibitors is greatest early in a patient's treatment course, the immunogenicity of new concentrates in PUPs may differ from what occurs in PTPs.

There are some reasons to suspect that immunogenicity of new concentrates may not be worse than that of existing concentrates, despite the presence of additional modifications such as Pegylation or fusion to Fc or albumin. For example, pegylated versions of other protein therapeutics (e.g., asparaginase, granulocyte-colony stimulating factor) have not proven to be more immunogenic than their nonpegylated counterparts, and there is some animal evidence to suggest that FVIII and FIX concentrates that have been fused to the Fc region of IgG may be less immunogenic than standard FVIII or FIX, perhaps because of interactions with Fc receptors present on cells involved in immune responses. In addition to developing EHL factor concentrates some manufacturers are developing FVIII concentrates that are produced in human cell lines, rather than in cells obtained from other mammalian species, with the hope that factor produced in human cell lines will show reduced immunogenicity because of more “native” posttranslational modifications of the factor protein.

Of course all of this remains speculative and the results of studies of the immunogenicity of new factor concentrates in PUPs are eagerly awaited.

Nonclotting Factor Concentrate Treatments for Hemophilia

Since about 2010, there has been significant interest in developing novel strategies for treating hemophilia that do not rely upon clotting factor replacement. In 2017 some of these therapies are just beginning to enter the clinic.

There are two principal approaches that are being used to enhance hemostasis through these alternative strategies: (1) through “rebalancing hemostasis” by inhibiting natural anticoagulant pathways (e.g., through tissue factor pathway inhibitor [TFPI] or AT inhibition) and (2) through the delivery of a bispecific antibody that mimics FVIII cofactor activity (Table 135.9).

The studies involving anticoagulant pathway inhibition have, to date, focused on TFPI and AT, and have used contrasting methods to reduce production or inhibit the function of these proteins. The anti-AT approach has used the subcutaneous delivery of small interfering RNA (siRNA) to reduce synthesis of the protein.³¹ The magnitude of AT knock down is dose dependent, and the effect persists

Fig. 135.12 THE NIJMEGEN-MODIFIED BETHESDA ASSAY. This is the currently recommended methodology for quantifying anti-factor VIII (anti-FVIII) inhibitory antibodies.

TABLE 135.9 Alternative, Nonclotting Factor Concentrate Therapies for Treating Hemophilia

1. Rebalancing hemostasis strategies:
 - a. TFPI Inhibition approaches: anti-TFPI aptamer, antibody and peptide.
 - b. Antithrombin siRNA biosynthesis inhibition.
 Both approaches can be delivered by infrequent (weekly or less often) subcutaneous injections.
2. Factor VIII mimetic molecule: bispecific antibody to FIXa and FX. Can be administered by subcutaneous injection and has shown activity in FVIII inhibitor patients.

FX, Factor X; FIXa, Factor IXa; FVIII, factor VIII; siRNA, small interfering ribonucleic acid; TFPI, tissue factor pathway inhibitor.

for up to 4 weeks. In contrast, the approaches used to inhibit TFPI have focused on functional neutralization using anti-TFPI aptamers, antibodies and peptides.³² These approaches offer much promise but are not without risks; a phase III study on an anti-TFPI aptamer was halted because of unexpectedly increased bleeding with the product. It remains unclear whether any of these rebalancing approaches to hemostasis will provide sufficient procoagulant activity to eliminate bleeds in the absence of FVIII or FIX, or whether they would need to be administered as adjunctive therapies with small doses of clotting factor concentrate. Finally, the risk of generating a pathologic procoagulant response with these approaches remains a possibility that will require careful monitoring.

The other innovative approach is the use of a bispecific antibody that substitutes for the cofactor activity of FVIIIa.³³ This antibody binds to FIXa and FX and at least partially mimics the scaffold function of FVIIIa in the intrinsic tenase complex. The antibody can be administered by weekly subcutaneous injection and phase II clinical studies have shown no adverse effects and a reduction in bleeding events in hemophilia A patients both with and without FVIII inhibitors. Therefore the bispecific antibody could serve as an alternative to FVIII replacement in hemophilia A patients with or without inhibitors.

Gene Therapy for Hemophilia

Since the cloning of the FVIII and FIX genes in the early 1980s, hemophilia has been a leading candidate for the application of somatic cell gene transfer. The rationale for gene therapy in hemophilia includes the following: small increments in FVIII or FIX levels have a significant clinical benefit; regulation of FVIII or FIX levels is not critical as long as they do not reach supraphysiologic levels for extended periods of time; the site of coagulation transgene expression need not be restricted as long as sufficient amounts of the protein reach the circulation; and small (genetically modified hemophilic mice) and large (spontaneously generated hemophilic dogs) animal models of hemophilia are available for preclinical evaluation of gene transfer approaches.

Modes of Transgene Delivery

A key component to any gene transfer strategy is the development of a delivery system that enables efficient transfer of the therapeutic transgene to the recipient cell type of choice. After 30 years of investigation, viral vectors remain the most effective means of achieving high-level gene transfer. Although efforts have been made to enhance the efficiency of nonviral delivery methods such as liposome encapsulation, various physicochemical conjugates, and hydrodynamic injection, all of these approaches have limitations that preclude their advancement into the clinic at this time.

Hemophilia gene transfer studies have used three main types of viral vector: adenovirus, several forms of retrovirus and adeno-associated virus (AAV). Trials of adenoviral gene transfer have been successful in animal models of hemophilia, but the single hemophilia A patient treated with an adenoviral vector experienced significant hematologic toxicity, and no further clinical studies have been undertaken with this vector type. Thus although adenoviral gene transfer is highly efficient, these vectors elicit a major innate immune response upon cell entry, and the proinflammatory consequences of this response remain a significant safety concern. Therefore until the innate immune reactivity of adenoviral gene delivery has been mitigated, this vector system will not be used for the treatment of hemophilia.

The second viral vector approach that has shown promise in hemophilia is the retroviral system. Initial studies were performed with replication-defective γ -retroviral vectors, and one human clinical study in hemophilia A also used this vector system. The major problem with these vectors is the requirement for recipient cell replication to facilitate nuclear entry of the vector. Consequently, gene

**TABLE
135.10**

Features of Adeno-Associated Virus–Mediated Gene Therapy

- AAV is a nonpathogenic virus.
- AAV rarely integrates into the host genome.
- There are no immediate adverse effects after AAV delivery.
- Innate immune reactivity to AAV is minimal.
- Vector readministration can be achieved with different vector serotypes (different capsids).
- Cytotoxic T-cell responses to capsid protein presentation can limit the duration of expression.
- Transgene size is limited to ~5 kb.

AAV, Adeno-associated virus.

transfer with these vectors is limited to tissues in which a significant proportion of cells are cycling. In contrast, lentiviral vectors are equally capable of transducing both postmitotic and replicating cells. For this reason, most of the more recent studies of retroviral hemophilia gene transfer have used lentiviral vector protocols in which the vector construct is usually derived from elements of the human immunodeficiency virus. The other major difference between lentiviral gene delivery and gene transfer with other viral vectors is that lentiviruses integrate their genome into the recipient cell genome as a natural part of their life cycle. Although viral vectors do not possess the structural components that enable further rounds of viral replication, there is a risk of insertional mutagenesis, which can trigger activation of adjacent oncogenes or inactivation of tumor suppressor loci. Studies performed in the past 5 years indicate that lentiviral integrations are not random but tend to cluster in transcribed regions of the genome and more often occur within introns and coding regions of genes rather than in the upstream regulatory regions where γ -retroviruses insert.

Currently, the lead candidate for hemophilia gene transfer is AAV (Table 135.10). This is a small nonpathogenic human parvovirus with a small, single-stranded DNA genome of approximately 4.8 kb. Infection in humans, which for some serotypes of the virus is frequent, is not associated with any clinical disease. The various serotypes of AAV have distinct tissue tropisms, and thus by using the capsid sequence for a particular serotype, gene therapists can target specific tissues for transgene expression. As one example, AAV-8 has excellent hepatotropic properties and has been successfully used for liver transgene delivery and expression. Upon entry into recipient cells, AAV is maintained within the nucleus in the form of stable extra-chromosomal concatemers, and only a small proportion of the virus integrates into the recipient genome at sites of natural chromosomal breaks. Wild-type AAV preferentially integrates into a site on chromosome 19, but the replication-defective AAV vectors appear to insert into sites of natural chromosomal breakages. One significant limitation to AAV vectors is their small packaging capacity. Transgenes larger than 5 kb limit the capacity for viral particle assembly, and although this is not a problem for FIX (cDNA $\approx$ 1.4 kb), even the B domain deleted forms of FVIII (cDNA of $\approx$ 4.7 kb) are not easily accommodated by this vector type.

Clinical Trials of Hemophilia Gene Therapy

Approximately 100 patients with hemophilia have undergone clinical evaluation of gene transfer strategies.³⁴ An initial trial of ex vivo gene transfer for FIX was performed on two subjects in China in the 1990s. A FIX γ -retroviral vector was used to transduce autologous skin-derived fibroblasts before reimplantation. No significant increases in FIX levels were observed. Since then, one patient has been treated with an intravenous FVIII adenoviral vector; a plasmid vector was used as a second ex vivo approach in which autologous fibroblasts were implanted into the omentum, and a small cohort of patients with hemophilia was treated with intravenous FVIII γ -retrovirus. Aside from the transient thrombocytopenia associated with adenoviral

**TABLE
135.11****Challenges to Successful Hemophilia Gene Therapy**

1. Efficient transgene delivery

 - Antivector cytotoxic T-cell response

vector infusion, there were no adverse events, but none of those approaches increased FVIII or FIX levels beyond a few days, and even then, levels were in the 1% to 4% range.

In contrast, the AAV trials of gene transfer have shown evidence of therapeutic efficacy. There have now been three completed AAV FIX trials, the first into skeletal muscle and the latter two into liver. Both of the liver-directed trials, the first using hepatic artery delivery of AAV-2 and the second systemic intravenous delivery of AAV-8, have resulted in longer term expression of FIX at therapeutically relevant levels (between 2% and 10%) in some patients. Indeed, in the most recent AAV-8 liver trial, therapeutic FIX levels have now persisted beyond 3 years.³⁵ There are currently six ongoing FIX gene therapy trials, all using AAV vectors and in two instances using a gain-of-function FIX transgene encoding the FIX Padua variant that has approximately sevenfold higher specific activity compared to wild-type FIX. A recent AAV FVIII gene therapy trial has documented persistent FVIII levels of 20% to 200% in six patients.

Despite these advances, challenges persist (Table 135.11). Most significant has been the recipient immune response against the vector capsid. In some instances, potential gene therapy recipients are excluded from participation because of evidence of prior AAV exposure (neutralizing anti-AAV antibodies), but even in those without documented prior AAV immunity, several patients have developed a delayed cytotoxic T cell–mediated response with transient hepatotoxicity and subsequent reduction of transgene expression. This immune response may be mitigated by transient immunosuppression, and recent evidence from the AAV-8 trial suggests that a brief course of prednisone may be sufficient to minimize the hepatotoxicity in most patients. Of note, none of these patients has had an anti-FIX immune response.

The future for hemophilia gene therapy is promising. After two decades of excellent progress in preclinical studies, there is now realistic hope that clinical success is achievable, at least for FIX gene therapy. Although AAV vector production will need to be scaled up and methods to limit the antivector immune response remain to be optimized, larger cohort studies are now possible. All of the current clinical studies of gene therapy for hemophilia involve FIX gene transfer, and there has been no successful FVIII gene transfer in humans to date. A number of substantive challenges remain to be overcome before FVIII gene transfer is successful. These include the AAV packaging limitation for a FVIII expression cassette that will be minimally 5 kb in size, and the inherent increased immunogenicity of FVIII (see Table 135.9).

FUTURE DIRECTIONS

Already in 2017, hemophilia represents a superb example of the application of molecular science to clinical benefit. Mutation-specific diagnosis is now being incorporated into the initial workup of many patients, and family counseling for kindreds with hemophilia has been dramatically enhanced by advances in the application of molecular genetic technology. In addition, use of the hemophilic mutation as a significant risk factor for inhibitor development is prompting clinicians to evaluate novel strategies to mitigate the likelihood of this treatment complication. As our ability to analyze the genome in far greater detail at greater speed and with reduced costs

Fig. 135.13 THE FUTURE OF HEMOPHILIA A TREATMENT. This figure speculates on the therapeutic options that may well face clinicians treating patients with hemophilia A within the next 5 to 10 years. FVIII, Factor VIII; PC, Protein C; PEG, polyethylene glycol; TFPI, tissue factor pathway inhibitor; VWF, von Willebrand factor.

increases, we can look forward to an even greater potential for inhibitor risk definition.

The increasing use of recombinant factor concentrates worldwide is a strong indicator of our growing reliance on novel technologies to provide safe and effective therapies for hemophilia. In the next 5 to 10 years, we can look forward to a large number of additional innovations in the area of hemophilia treatment (Fig. 135.13). The first wave of novel products is aimed at extending the circulating half-life of the concentrates with the objective of reducing the frequency of replacement therapy.

A second, more challenging approach to improving hemophilia therapy is to develop components of an improved intrinsic tenase complex. This area of innovation is currently focused on the development of a FVIII mimetic that incorporates the various roles that FVIII plays as a “scaffold” protein in this membrane-bound complex.

Finally, various adjunctive strategies for hemophilia treatment are being pursued. These include inhibition of coagulation inhibitory proteins (tissue factor pathway inhibitor and antithrombin) with antibodies, aptamers, peptides, and inhibitory nucleic acid strategies (siRNA) and the development of novel approaches to inhibit fibrinolysis.

Overall, the future for a more diverse array of hemophilia therapeutics is highly promising. How each of these products will be used in individual patients will provide future hemophilia treaters with some interesting and ultimately gratifying challenges.

INHIBITORS IN HEMOPHILIAS

Guglielmo Mariani, Barbara A. Konkle, and Craig M. Kessler

With the availability of plasma-derived and recombinant replacement products safe from transmission of known infectious agents, the development of antibodies neutralizing factor VIII (FVIII) or factor IX (FIX) has become the major complication of hemophilia treatment.

Antibodies to FVIII can be detected (1) in healthy individuals, (2) as expression of an autoimmune disorder, and (3) in patients with FVIII or FIX deficiency (hemophilia A and B). Clinically speaking, only those antibodies that affect the clotting activity, which are therefore termed *inhibitors*, are considered relevant because they render patients refractory to treatment. In hemophilias, inhibitors occur after factor replacement therapy with FVIII or FIX concentrates. Patients with a severe deficiency (FVIII or FIX less than 1% of normal) are particularly at risk.

Inhibitor formation in hemophilia was first reported in 1941.¹ A 44-year-old man with classic hemophilia had been treated numerous times with blood products, and his hemostasis subsequently became refractory to transfusions. The authors realized that transfusion may have caused this heretofore-unknown complication and suggested that coagulation times should be checked after administration of blood products to monitor for the phenomenon. This report was soon followed by numerous cases^{2–5} reporting the development of a substance that counteracted infused blood product components. The nature of the inhibitor was shown to be an immunoglobulin (Ig) G antibody mainly of the IgG4 subclass.⁶

Alloantibody inhibitors arise much more frequently in patients with severe hemophilia A (15%–20% with a range of 8%–52%)⁷ than in those with severe hemophilia B ($\approx$ 3%–7%). Their occurrence is associated with higher morbidity and mortality if modern therapies are not available, increased cost of care, and more complicated treatment regimens.

HEMOPHILIA A

Epidemiology

It is curious that hemophilia A and B, which share an almost identical clinical phenotype, would have such a disparate incidence of alloantibody inhibitor development. The explanation may reside in the type of genetic mutation responsible for each disease. In hemophilia A, the severe phenotype is most often caused by a null mutation, which is less common in hemophilia B. Null mutations result in complete absence of a translated protein product and are more likely to predispose to inhibitor formation. Also, FIX shares significant homology with the other vitamin K–dependent clotting factors, possibly protecting against inhibitor development.⁸ Finally, it is hypothesized that because FIX is smaller and more abundant than FVIII, some FIX may cross the placenta, thereby inducing tolerance in the developing fetus.⁸

Among patients with severe hemophilia A, approximately 30% will develop an alloantibody inhibitor (compared with 3% of those with moderate hemophilia and 0.3% with mild hemophilia).⁹ Inhibitor formation occurs early after initiation of replacement therapy. Data from prospective clinical trials of recombinant FVIII reveal that inhibitor development typically arises within a median of 8 to 10 “exposure-days” (treatment-days), but a wide range is not uncommon.¹⁰ The risk for inhibitor development decreases inversely with

increasing number of exposure days and is uncommon ($\approx$ 2/1000 patient-years) after 150 exposure-days.

There appears to be a bimodal distribution of inhibitor occurrence in severe hemophilia. The incidence peaks in early childhood in those younger than 5 years of age (64.3/1000 treatment-years), falls substantially between the ages of 10 and 49 years of age (5.3/1000 treatment-years), and rises again in older age (10.5/1000 treatment-years).¹¹ The latter finding raises the possibility that there is a breakdown of tolerance with aging.¹¹ Another epidemiologic study conducted by the same organization and covering a period of 22 years, showed that the rate of inhibitor development may vary over time, although the reasons appear unclear.¹² At any rate, there is no doubt that inhibitor formation has a negative impact on overall mortality in severe hemophilia A patients, essentially cancelling out the improved life expectancy realized in patients with severe hemophilia A population over the last 30 years.¹³

Genetic Factors

One of the most significant risk factors associated with the development of inhibitory alloantibodies in hemophilia A is the presence of a positive family history. The increased concordance rate of inhibitor occurrence in brother and twin pairs^{14,15} provided the initial indication that genetic factors play a role in inhibitor development. Having a first-degree relative with an inhibitor raises the risk for inhibitor development threefold, resulting in an approximately 50% chance of inhibitor development compared with a control cohort in which there is a 15% risk.^{14,15}

Patient ethnicity first emerged as a possible risk factor for inhibitor development in retrospective analyses of the prevalence of inhibitors in various racial cohorts included within large pooled populations of hemophiliacs.^{15–18} African Americans (AA) and Latinos were observed to have a twofold higher rate of inhibitor formation compared with whites. For instance, in the Malmö International Brother Study (MIBS), inhibitors were noted in 27.4% of whites and in 55.6% of AA.¹⁵ This same trend was subsequently appreciated in prospective analyses of inhibitor development in the initial recombinant FVIII concentrate safety and efficacy trials.¹⁹

One potential and provocative explanation for the increased propensity of AA with hemophilia to produce FVIII relative to immunoreactivity is a mismatch between the host endogenous wild-type FVIII haplotype polymorphisms found only in AA (H3, H4, and H5) and their exposure to the exogenous FVIII polymorphisms found in the commercially available brands of recombinant FVIII concentrates (either H1 or H2) used for replacement therapy. The risk for alloantibody inhibitor development is significantly higher among AA with haplotypes H3 or H4 than it is in those with the H1 or H2 haplotype (odds ratio [OR] of 3.4). These observations await confirmation in larger studies.²⁰

Emerging data consistently indicate that certain FVIII mutations producing phenotypically severe hemophilia A^{7,8} are strong predictors of inhibitor development.^{21–23} Three general categories of mutations in FVIII have been considered for patients at “high risk” for inhibitor formation: (a) inversions of intron 22 (intrachromosomal recombinations), (b) large deletions affecting more than one domain, and (c) nonsense mutations involving the light chain (the risk for inhibitor formation is twofold higher with light chain mutations than with

heavy chain mutations).^{7,21} All of these mutations either eliminate FVIII protein altogether or alter the molecular conformation of the FVIII protein in such a way that innate immune tolerance cannot be achieved during fetal development. Consequently, the immune system recognizes exogenously administered native FVIII protein as “foreign.”²² The “low-risk” FVIII mutations consist of small gene deletions/insertions, missense mutations, and splice site mutations. It is postulated that some “nonfunctional” FVIII protein is produced with these FVIII gene mutations, which may be sufficient to induce partial central immune tolerance.²¹

Even with genetic information, it is not possible to predict which patients are at highest risk for development of alloantibody inhibitors. Inhibitors in the high-risk category occur 7- to 10-fold more frequently for large deletions and nonsense mutations (pooled OR, 3.6; 95% confidence interval [CI], 2.3–5.7 and 1.4 CI, 1.1–1.8, respectively)²¹ ($\approx 35\%$)²² compared with those with intron 22 inversions. Furthermore, inhibitors occur less frequently with small FVIII gene deletions/insertions ($\approx 7\%$)²² or missense mutations ($\approx 4\%$) (pooled OR, 0.5 [95% CI, 0.4–0.6] and 0.3; 95% CI, 0.2–0.4, respectively).^{21,22} Intron 22 inversions are associated with a lower inhibitor frequency than would be anticipated for a genotype that produces no circulating FVIII protein. However, recent data suggest that some of these hemophiliacs may possess intrahepatocyte-endogenous FVIII protein fragments, which can induce partial immune tolerance²¹; most recently, experimental data confirmed the low-risk categorization of intron 22 inversion by demonstrating that patients bearing this change produce intracellular peptides that may act as toleragens.^{24,25} There does not appear to be any relationship between the type of FVIII gene mutation and the relative risks for developing high-titer versus low-titer alloantibody FVIII inhibitors.²¹

Environmental Factors

Despite the strong FVIII-related genetic influences that underlie inhibitor formation, clinical observations indicate that various environmental or epigenetic pressures contribute to the development of alloantibody inhibitors. For example, within the MIBS cohort, there are discordant monozygotic twins (i.e., identical twin brothers with the same mutations) in which only one brother developed an inhibitor.¹⁴ In addition, among families with high-risk gene mutations, only about 30% of siblings with severe hemophilia A because of the intron 22 inversion develop inhibitors. Even with multidomain deletions, the highest estimated inhibitor risk only approaches 75%,¹⁵ implying that other patients with the same mutation are somehow protected against inhibitor formation.

A concerted effort has been made to explore the importance of other genetic determinants in hemophilia A patients that may contribute to alloantibody inhibitor development. Of the immune response genes, the presence of a microsatellite polymorphism in the promoter region (134 base pair variant) of the interleukin (IL)-10 gene, which may lead to upregulated B-lymphocyte activity, has been associated with a 73% incidence of inhibitor formation (OR, 4.4). A G308A polymorphism in the promoter region of the tumor necrosis factor α gene (A/A genotype) has been associated with 72.7% inhibitors and an OR of 4.0. On the other hand, there is no robust evidence that polymorphisms of major histocompatibility complex (MHC) class II alleles or of other inflammatory cytokine genes contribute to alloantibody inhibitor development.^{22–26} All in all, the associations of distinct human leucocyte antigen haplotypes and of polymorphisms of immunoregulatory genes with the risk of patients developing FVIII inhibitors seems to be modest.

Among possible environmental risk factors, age at first treatment has been implicated as a major independent contributor for inhibitor development: initial observations suggested that the earlier the first exposure to FVIII-containing products occurred, the greater the risk was for alloantibody inhibitor formation.^{26–29} Children treated before 6 months of age have a cumulative inhibitor incidence of 41% compared with a 12% incidence if initial exogenous FVIII exposure is delayed until after the first year of life. Results of a subsequent

case-control study suggested that early age of first exposure to FVIII treatment reflected the severity of the hemophilia conveyed by the particular FVIII gene mutation. Thus more intense FVIII replacement and high-risk FVIII gene polymorphisms were more strongly associated with inhibitor formation than was age. In fact, there appeared to be a protective effect against the formation of inhibitors when children were started on primary FVIII prophylaxis regimens early in life.³⁰ The United Kingdom Haemophilia Centre Doctors' Organisation (UKHCDO) study reported that peak inhibitor formation occurs in children younger than 5 years of age.¹¹

The method of FVIII infusion (continuous infusion versus bolus administration) and the clinical scenarios for FVIII replacement have also been examined for their contribution to inhibitor formation. Although administration of FVIII by continuous infusion has the advantage of requiring less factor replacement over time and avoids the peaks and troughs seen with bolus administration,³¹ intense replacement of FVIII by continuous infusion was more likely to induce inhibitor development than bolus injections (57% versus 14%) in patients who were otherwise considered to be at low risk (i.e., mild hemophiliacs).^{32,33} These results were gleaned from the retrospective examination of the medical records of 54 mild hemophiliacs, of whom only seven had received FVIII by CI; a prospective study in a larger population remains to be conducted to confirm this finding. On the other hand, intensive FVIII replacement in the context of injury, surgery, or inflammation appears conducive to inhibitor formation. In the retrospective CANAL study (concerted action on neutralizing antibodies in severe hemophilia A) of previously untreated patients (PUPs), 65% of those whose first exposure to FVIII therapy was associated with surgery developed an allogeneic FVIII antibody inhibitor (relative risk, 3.7), compared with a 23% inhibitor incidence when first exposure was not related to a “danger signal” indication.³³

As concerns surgery, a very common procedure of minor surgery, circumcision, was analyzed with respect to the occurrence of inhibitors: 3 of 25 patients among those circumcised developed an inhibitor versus 4 of 36 of age-, therapy- and intron 22 inversion-matched patients not circumcised; all inhibitors were high-titer and median ED was 16 days for both groups.³⁴ This observational study would suggest that minor surgery does not increase the risk associated with replacement therapy or intron 22 inversion.

Perhaps the most controversial “environmental” risk factor for alloantibody inhibitor development involves the type of FVIII concentrate replacement used by the patient (low- to intermediate-purity plasma-derived FVIII versus high-purity plasma-derived FVIII versus recombinant FVIII concentrates). After more than 20 years the question of whether the use of recombinant FVIII concentrates (highest purity) leads to a higher inhibitor incidence than the lower purity concentrates remains largely unresolved.^{35,36} This debate originated with the prospective trials of first-generation recombinant FVIII concentrates in PUPs, which mandated frequent monitoring for inhibitor formation (at least every 3 months).^{37,38} In the Kogenate trial, the total incidence of any inhibitor formation in patients with severe hemophilia A was 29.2% within a median of 9 exposure days.³⁹ A similar inhibitor incidence rate of 31.5% was found in a prospective trial of Recombinate.⁴⁰ Thus when compared with the inhibitor incidence rate of approximately 10% reported in older retrospective studies, which used low-purity plasma-derived FVIII concentrates and screened less frequently for inhibitors,⁴¹ recombinant FVIII seemed to be significantly more immunogenic. Prospective monitoring of patients receiving high-purity plasma-derived FVIII concentrates revealed a similar inhibitor rate as seen in those given recombinant concentrates.⁴²

A number of variables may have contributed to these observations, thus reducing their clinical relevance. The recombinant FVIII trials in PUPs were the first large prospective clinical trials of hemophilia treatment, so their comparison with results of anecdotal or retrospective case reports and case series is inappropriate.^{33–39} These trials were also the first to use routine and frequent prospective monitoring for inhibitor development. In prior studies, testing for inhibitors was done only when deemed clinically important. Continued analysis of

the results of the recombinant FVIII trials showed that almost half (11/23) of the inhibitors in the Kogenate trial were transient in nature, decreasing the prevalence of inhibitors upon extended observation.³⁹ A similar pattern was observed in the Recombinate trial; alloantibodies disappeared in 14 of 22 study subjects who developed an inhibitor despite continued treatment, eventually reducing the prevalence rate to 11.1%.⁴⁰ The older studies likely missed these ephemeral inhibitors. A Dutch study suggested that although transient inhibitors may develop earlier during treatment with ultrapure plasma-derived and recombinant FVIII concentrates compared with lower-purity plasma products, the overall risk for inhibitor development is similar.⁴³ The debate continues with conflicting results in both PUPs and previously treated patients (PTPs).^{44–46} A recent UKHCDO case-control study examined inhibitor occurrence over 25 years of observation and identified “high-intensity treatments” rather than the type of FVIII product as the main risk factor for inhibitor development.⁴⁷ Similarly an analysis of pooled data from over 2900 hemophiliacs indicated that the duration of study observation and follow-up and testing frequency for inhibitor presence, but not the source or purity of concentrate, explained most of the differences in inhibitor development seen in earlier studies.⁴²

Proposed causes of variable immunogenicity among FVIII products have included neoantigen formation during their manufacture and their content of von Willebrand factor (vWF) protein, which is present in low- and intermediate-purity plasma-derived products but absent in recombinant FVIII concentrates.²⁸ It has been suggested that vWF may interfere with FVIII-dendritic cell interactions, alter FVIII molecular conformation, or mask T- or B-lymphocyte epitopes. The former scenario has been illustrated by the fact that some, previously low immunogenic plasma-derived FVIII concentrates were rendered more immunogenic after extra viral-attenuation steps were added to their manufacturing processes.^{48–50} However, when recombinant FVIII products were administered to patients previously and extensively treated with lower-purity FVIII products, the rate of inhibitor formation was low, consistent with a low immunogenicity in this setting (relative overall risk for inhibitors, 0.8; for high-titer inhibitors 0.9; for plasma-derived products versus recombinant FVIII products 1.0; for switching FVIII products, 1.1).^{45,51} A large prospective, randomized study comparing the immunogenicity of vWF-containing products with recombinant FVIII concentrates in PUPs and minimally treated patients is ongoing. Nonetheless, most experts believe that the risk for inhibitor formation with the various FVIII concentrates is similar.

Recently, clinical prediction models for inhibitor development in the pediatric and adolescence ages⁵² evidenced the fact that treaters consider family history of inhibitors (and related major FVIII defects) and early intensive treatment as elements associated with a high risk, whereas early onset of prophylaxis and avoidance of elective surgery were considered as factors that are associated with a low risk of inhibitor development. Interestingly, the type of concentrate was not included in the prediction model. Though the results stemmed from the surveys are interesting, their probabilistic nature and the fact that a number of minor risk factors were not considered suggests that interventional studies including very large numbers of patients are needed to validate these exercises, because combinations of risk factors are many.

A recent prospective study on the influence of treatment-related determinants demonstrated that intensive on-demand treatment for hemorrhage or surgery increased the risk, whereas prophylaxis decreased the risk especially in patients with low-risk mutations.⁵³ A similarly focused prospective study on inhibitor development⁵⁴ showed that risky gene mutations, first treatment before the age of 3 months, and the dose of FVIII had a significant impact whereas the type of concentrate did not.

Recently, a prospective study focused to the type or brand of concentrate, either in PUPs or PTPs, demonstrated that different concentrates failed to elicit inhibitors with different cumulative incidence or incidence rates.⁵⁵ In contrast with this study, Peyvandi et al, in PUPs, elegantly demonstrated that exclusive use of recombinant FVIII during the period of maximum risk of inhibitor

development increases the incidence of inhibitors in comparison with plasma-derived preparations (37.2% vs. 23.2%; hazard ratio [HR], 1.87). The same effect was noted when the analysis was restricted to the high-titer alloantibodies.⁵⁶ If the contrasting outcomes of the previous trials on the topic are considered, it appears difficult to foresee the influence of this study on the clinical practice.

A longstanding issue has been that concerning the switch from one concentrate brand to another. This issue has been clarified by a study focused on the full-length and the B-domain recombinant preparations that showed that switching was not associated with an increased inhibitor development.⁵⁷

Mild Hemophilia

In patients with mild or moderate hemophilia A, inhibitors appear to develop at a cumulative incidence of 3% to 13%, commonly after periods of intense FVIII replacement associated with surgery or inflammatory states.⁵⁸ A recent, large international cohort study on 1112 patients (median age 38, interquartile range [IQR] 18–56 years) evidenced a cumulative incidence of 5.3% after a median exposure of 28 days, that increased to 6.7% at 50 and to 13.3% at 100 days. Most of the tested mutations (15/19) were located in the light chain, evenly distributed among the A3, C1 and C2 domains.⁵⁹ A particularly risky mutation (T295A) was described in 3 of 16 patients (17%).⁶⁰ This study suggests that the capacity for immune tolerance in these infrequently treated individuals may be compromised with aging and that immune challenge with FVIII replacement should be avoided whenever possible by using desmopressin (DDAVP) to enhance endogenous FVIII activity levels. Continuous lifelong vigilance for the inhibitor occurrence is warranted, particularly after occasional, intensive FVIII exposure.

Venous Access

A disturbingly high incidence of infections may occur in FVIII inhibitor patients with central venous access catheter devices (CVADs), particularly those with external devices set for immune tolerance induction (ITI) (124 episodes in 41 patients).⁶¹ This fact may be related to frequent, unprofessional catheter accessing related to the administration of replacement therapy. CVAD-associated infection did not seem to affect the ability to achieve tolerance.⁶¹ The presence of CVADs per se does not appear to be associated with increased inhibitor formation.⁴⁷

Other Factors

Other miscellaneous proposed environmental influences on inhibitor development, such as breastfeeding and receiving replacement therapy during a vaccination course, remain to be confirmed as significant risk factors.

Pathobiology of Factor VIII Alloantibody Inhibitor Formation

Circulating antigens provided by the exogenous FVIII undergo initial endocytosis and subsequent proteolysis by antigen-presenting cells, and digested peptides bind to MHC II molecules for presentation to T-cell receptor on CD4⁺ T lymphocytes.⁶² Co-stimulation signals subsequently mediate differentiation of T-lymphocytes into either T_H1 or T_H2 subsets. T_H2 cells secrete IL-4, IL-5, and IL-10 cytokines, which promote the synthesis of noncomplement-binding immunoglobulins, predominantly IgG4, by B lymphocytes.⁶² IgG4-mediated humoral responses display the following features: (1) are unable to form large immune-complexes, (2) have low potential of inducing immune inflammation, (3) are expressed in conditions of chronic antigen exposure and (4) maintain a “normal” half-life. These features accord with the clinical observations of uncomplicated anamneses in hemophiliacs and account for an inhibitor half-life in the range of 25–30 days.⁶³ Interestingly, IgG4 subclass antibodies (either inhibiting or noninhibiting) are absent in hemophiliacs without inhibitors and in healthy subjects.⁶⁴ Most recently it has been shown that the presence of anti-FVIII IgG1 subclass may herald the appearance of

Fig. 136.1 FACTOR VIII DOMAINS AND BINDING SITE BY AMINO ACID LOCATION AND EFFECT ON FACTOR VIII. Intensity of color reflects the frequency of inhibitors to the epitope.¹⁷⁰⁻¹⁷⁴ *FIX*, Factor IX; *FIXa*, activated factor IX; *FX*, factor X; *PL*, phospholipid; *vWF*, von Willebrand factor.

an inhibitor.⁶⁵ This polyclonal antibody response can result in the inhibition of FVIII function via diverse clotting impairing mechanisms because the epitopes may be different.⁶⁶ It is important to note that inhibiting antibodies to FVIII have an up to 100-fold higher affinity for FVIII than those in patients without inhibitors or healthy individuals.⁶⁷

The weak association between MHC II phenotypes and FVIII inhibitor formation is dependent on the availability of “risk” MHC class I/II alleles.^{68,69} T-lymphocyte involvement in inhibitor formation is manifested by the isotype switching and the somatic hypermutation of the B cells.⁷⁰ There are several FVIII epitopes against which CD4⁺T cells react strongly.⁷⁰ In addition, non-FVIII-associated gene polymorphisms can exert a protective influence on inhibitor development—for example, the C→T single-nucleotide polymorphism (SNP) at position -318 in the promoter region of the gene encoding for cytotoxic T-lymphocyte-associated protein-4 (CTLA4).⁷¹ This polymorphism “downregulates” the effects of the co-stimulatory signal of the B7-CD28 complex, which mediates T-cell immune responsiveness to infused FVIII. The MIBS study group reported an OR of 0.3 for inhibitor formation among a cohort of severe hemophiliacs with the T allele SNP despite their risk for inhibitors related to a FVIII intron 22 gene inversions.⁷¹ MIBS also identified polymorphisms in the IL-10 cytokine gene that are associated with inhibitor formation in severe hemophiliacs.⁷² The same group

investigated SNPs in more than 1000 genes in a cohort of 833 HA patients for the association with inhibitor occurrence, and identified 53 polymorphisms significantly associated with the risk of developing inhibitors.⁷³ This study highlighted the complexity of the mechanisms that are involved in the antibody formation against FVIII and FIX. In support of the polygenic nature of inhibitor formation, evidence is emerging that the regulatory T cell (Treg) lymphocyte system downmodulates the immune reaction to FVIII and plays a role in ITI induction.⁷⁴

FVIII exists as a heterodimer, with a heavy chain containing the A1, A2, and B domains connected to a light chain containing the A3, C1, and C2 domains (Fig. 136.1). Short intervening acidic regions (a1, a2, and a3) aid in FVIII binding to factor X and serve as important sites for FVIII proteolysis by thrombin and factor Xa (FXa).⁷⁵ By serving as a cofactor for FIX in the intrinsic tenase complex, FVIIIa promotes the conversion of FX to FXa, which together with factor Va forms the prothrombinase complex on the activated platelet surface. This complex then converts prothrombin to thrombin, which in turn amplifies the coagulation system (see Chapter 122).^{76,77}

Normally, when FVIII is secreted, it is noncovalently bound to vWF via the light chain, particularly through interactions with the A3 and C2 domain.⁷⁷ Upon thrombin activation, FVIIIa dissociates from vWF and via the C2 domain, which is no longer linked to vWF,

binds to platelet membrane-associated phosphatidylserine.⁷⁸ Neutralizing alloantibody inhibitors can interrupt this complex process (see Fig. 136.1) by (a) preventing FVIII interaction with vWF, thereby significantly decreasing its circulating half-life, (b) hampering the release of FVIIIa from vWF following thrombin activation, (c) increasing the time available for FVIII inactivation, and/or (d) preventing C2 domains from binding to the phospholipid layer.^{79–83}

Other FVIII alloantibody inhibitors interact with the A2 domain, predominantly at the Arg4844–Ile5085 epitope and interrupt FVIIIa–FIXa interactions, thereby impairing intrinsic tenase activity.⁸⁴ Regions outside the A2 and C2 domains are minor epitopes for FVIII inhibitors; however, those binding to the A3 domain also blocks the FVIIIa–FIXa interaction.⁸⁴ In most hemophilia A patients, alloantibodies recognize multiple epitopes in both the A2 and C2 domains, in contrast to autoantibodies to FVIII, which target either the C2 or A2 domain but not both.⁸⁴ Although antibodies that target B domain epitopes have been reported, these do not exert any neutralizing activity.

Another mechanism of FVIII inhibition involves alloantibodies that catalyze the proteolysis of FVIII.^{85,86} FVIII-hydrolyzing IgGs are detected in more than 50% of alloantibody inhibitor patients and functionally resemble serine proteases. In contrast to the A2, A3, and C2 epitope specificity of the classic alloantibody inhibitors in severe hemophilia A, IgG-mediated hydrolysis occurs evenly throughout the FVIII molecule with final loss of FVIII activity.⁸⁷

Clinical Manifestations

The frequency and severity of bleeding complications do not necessarily increase when an alloantibody to FVIII develops in a patient with severe hemophilia A. Similarly, no predictive relationship exists between the Bethesda unit (BU) titer and the severity of bleeding. Any person with hemophilia, regardless of severity, who is undergoing treatment and fails to respond to the FVIII dose that had previously been effective should be promptly evaluated for the development of an inhibitor.⁸⁸ Routine laboratory testing for the presence of an inhibitor is recommended before any major surgical procedure. A truncated pharmacokinetic study may be useful for inhibitor screening because even low-titer (<5 BU) inhibitors may be detected when less than 66% of the calculated incremental rise in FVIII activity is achieved within 30 minutes of administration of exogenous FVIII (i.e., decreased recovery). In general, patients with hemophilia A who have FVIII inhibitors will experience more frequent hemarthroses, more severe and progressive arthropathy, and an overall reduced quality of life compared with noninhibitor patients.^{89,90} Those with inhibitors will also have more hospital visits and absences from school or work, and will more likely require assistive devices, such as wheelchairs or crutches.⁹⁰ In the past, development of an inhibitor increased the mortality risk, but with current therapies the mortality rate is falling. However, the mortality rate for patients with inhibitors still exceeds that for those without.⁹¹

If patients with mild to moderately severe hemophilia A develop an alloantibody FVIII inhibitor, it usually occurs after a period of intense factor replacement. Genetic factors likely play a role as well. The clinical manifestations become the same as in severe hemophilias, including reduced recovery of FVIII activity after FVIII infusion. Thus a patient with a mild disease usually converts to a severe phenotype following the inhibitor development and may present with spontaneous bleeding.

Laboratory Diagnosis

In 1975, the Bethesda assay (BA) was devised as a simple and reproducible method for determining antibody titer and quantifying the extent of its inhibitory/neutralizing capacity. The assay is based on the ability of patient plasma to inactivate FVIII in normal plasma. The result is expressed in BUs.⁹² Patient plasma is serially diluted with normal plasma, incubated for 2 hours at 37°C and residual FVIII

Fig. 136.2 BETHESDA ASSAY FOR FACTOR VIII INHIBITOR QUANTITATION. Relationship between corrected residual factor VIII activity and Bethesda titer is shown. If the result is less than 25%, serial dilutions of the patient's plasma are tested until the result is between 25% and 75%. The result is multiplied by the dilution to assign the Bethesda titer. One Bethesda unit (BU) is defined by a corrected residual factor VIII of 50% in the assay (dotted line). (From Konkle BA: *Clinical approach to the bleeding patient*. In Colman RW, Marder VJ, Clowes AW, et al, editors: Hemostasis and thrombosis, Philadelphia, 2006, Lippincott, Williams & Wilkins, p 1147.)

activity is measured using a one-stage assay. One BU correlates with patient FVIII activity reduced by 50%. A standard curve is drawn, and the patient's plasma is diluted until FVIII activity is between 25% and 75%, that is, the linear portion of the standard curve. The inhibitor units are read from the graph and multiplied by the reciprocal of the dilution factor to determine the BU in undiluted plasma (Fig. 136.2).

To improve the specificity and reliability of the BA, two groups developed the Nijmegen modification of the BA.⁹³ The BA, because of a decreased FVIII activity caused by a pH increase and/or protein concentration decrease, may yield false-positive results, labelled as low-titer inhibitors. The Nijmegen modification made two important changes to the BA: plasma mixtures were buffered with imidazole to a pH of 7.4, and plasma depleted of FVIII was used to yield similar protein concentrations (Fig. 136.3). These modifications are now recommended for diagnosis of inhibitors.⁹⁴ A new standardized assay was recently proposed to reduce the cost that is mostly related to the use of FVIII-deficient plasma; instead of the latter, a 4% albumin solution was proposed. Comparison of results on 59 inhibitor samples evidenced a good agreement with the Nijmegen method together with a good reproducibility.⁹⁵

Care is needed to ensure that isolated prolongations of the activated partial thromboplastin time (aPTT) are not misdiagnosed as lupus anticoagulants or vice versa. The key maneuver to distinguish between the two possibilities is based on the incubation time: whereas the aPTT results performed immediately and after 2 hours of incubation are similar in the presence of a lupus anticoagulant, inhibitors exert their effect only after incubation. This is a critical issue because patients with lupus anticoagulants do not usually bleed, whereas the bleeding related to a FVIII inhibitor may be severe.

Based on the results of the inhibitor assay, a value less than 5 BU is considered a low-titer inhibitor. If the inhibitor titer fails to rise despite repeated challenges with clotting factor protein, the patient is termed a *low responder*. In contrast, a patient with an inhibitor titer greater than 5 BU is considered a *high responder*.⁹⁴

Overall, 75% to 80% of the immune responses are causative of the classic features of refractory hemophilia, that is, a bleeding phenotype that can hardly be treated with FVIII/FIX concentrates: this corresponds to a titer of about 5–10 BU of inhibitor or greater. Of the remaining, some may be transient, resolving within 6 months.

Fig. 136.3 METHODOLOGIC DIFFERENCES BETWEEN THE CLASSIC BETHESDA ASSAY⁹⁴ AND THE MODIFIED NIJMEGEN ASSAY.⁹⁶ (From Giles AR, Verbruggen B, Rivard GE, et al: A detailed comparison of the performance of the standard versus the Nijmegen modification of the Bethesda assay in detecting factor VIII:C inhibitors in the haemophilia A population of Canada. Association of Hemophilia Centre Directors of Canada. Factor VIII/IX Subcommittee of Scientific and Standardization Committee of International Society on Thrombosis and Haemostasis, Thromb Haemost 9:872, 1998.)

External quality control assessments examining the reliability of clotting-based inhibitor testing (Bethesda and Nijmegen) have noted considerable interlaboratory variability that could influence patient management and may contribute to differences in the incidence of FVIII inhibitors reported in various clinical settings.⁹⁶

Enzyme-linked immunofluorescence assay (ELISA)⁹⁷ or fluorescence immunoassay-based⁹⁸ methods may complement the clotting assays because these techniques also detect nonneutralizing antibodies against FVIII, but there may be discordance between the results of ELISA-based inhibitor assays, and the functional clot-based assays. Pharmacokinetic studies may be useful in patients with antibodies that are not overtly neutralizing in the BA because these antibodies may influence the circulating half-life of infused FVIII.⁹⁹

Monitoring for inhibitor development in PUPs is of paramount importance, especially when starting treatment or prophylaxis regimens because inhibitor development occurs early in the course of treatment. Guidelines recommend screening PUPs every 5th exposure day up to the 20th exposure day, and then every 3 months until the 150th exposure day.¹⁰⁰ Repeat testing should be performed before any invasive procedure or elective operation.¹⁰⁰ Considering the fact that inhibitors are antibody mixtures mainly made up of IgG4 subclass antibodies, an unstimulated inhibitor titer will decrease by 50% every 25–30 days.

Treatment

Patients with hemophilia should receive comprehensive and routine therapy at a hemophilia treatment center (HTC) of excellence, where expertise in the treatment of individuals with severe bleeding disorders and inhibitors is available. If emergency treatment or surgery is needed, patients should be transferred to the HTC as soon as possible and in a stabilized condition (see box on Treatment of Bleeding in a

Patient With Factor VIII Deficiency and an Inhibitor). Typically, the HTC and its physicians serve as a community resource to help guide the care of complex inhibitor patients at other institutions when timely transport is not feasible because of active bleeding and hemodynamic instability.

In general, there are two main aspects that should be considered: first that bleeds may be more frequent and are more difficult to treat and, second, that any available treatment is not as efficacious as FVIII in hemophilia with no inhibitors.

Minor Bleeding Episodes

In established low-titer alloantibody FVIII inhibitor patients (consistently less than 5 BU after repeated challenges) or in patients with low-titer transient inhibitors, larger doses of FVIII concentrate replacement can be given to overcome the neutralizing properties of the inhibitor. Such treatment may provide therapeutic levels of FVIII activity. The following equation approximates the dose necessary to overcome the neutralization effects of a low-titer FVIII inhibitor:

FVIII Replacement Loading Dose

$$= 2 (\text{Body Weight in kg} [(80)(100 - \text{Hematocrit})/100]) / \text{BU}$$

FVIII activity levels should be determined after the infusion to ensure that adequate therapeutic levels are achieved and sustained. For invasive procedures, maintenance of FVIII level sufficient to maintain hemostasis adequately may require continuous infusion of replacement product. If a bolus dosing protocol is chosen, the treatment interval will need to be short, every 4 hours, to start with, followed by a schedule tailored to the aPTT or the FVIII level. Once the optimal bolus dose of FVIII replacement is established, home therapy may be possible.

High-titer FVIII inhibitors are characterized by titers above 5 BU and by anamnestic responsiveness after repeated exposures to exogenous FVIII. Often, high-titer inhibitors may spontaneously fall below 5 BU, especially after prolonged lapses in FVIII reexposure. In this scenario, FVIII replacement should be avoided, if possible, so that anamnesis can be abated and the chances for successful ITI and eradication of the inhibitor can be enhanced.¹⁰¹ On the other hand, in urgent situations when “bypass” products are not available, low-titer inhibitor expression (<5 BU) may allow for effective use of FVIII concentrate replacement therapy, particularly in bleeds that are threatening to life or limb, because the anamnestic response will be delayed for several days. In these situations, administration of sufficient amounts of exogenous FVIII to overcome the immediate neutralization by the low-titer inhibitor will allow hemostasis to be achieved. Anamnestic rises in FVIII inhibitor titers have been observed after infusion of activated prothrombin complex concentrates (APCCs) to high-titer antibody patients, which are administered to bypass the inhibitor and to treat or prevent bleeding. These products contain a small amount of FVIII.^{101–104}

Low-titer FVIII alloantibody inhibitors never rise above 5 BU and do not exhibit anamnestic increases after reexposure to exogenous FVIII. DDAVP administration may also be effective in selected patients with mild to moderately severe hemophilia complicated by an inhibitor (high or low titer). A DDAVP challenge should be undertaken before any intervention before assessing the adequacy of incremental rises in FVIII activity in such patients.

Severe Bleeding Episodes

For patients who have an inhibitor titer less than 5 BU, administration of exogenous FVIII should be considered if FVIII levels can be monitored closely. This approach provides the most specific and effective therapy; however, anamnesis can occur within a week in patients with a history of a high-titer inhibitor, and switching to a bypassing agent is indicated. Anamnesis may render subsequent use

Treatment Options for Bleeding in a Patient With Factor VIII Deficiency and an Inhibitor

Low Titer, Low Responder**Mild Bleeding**

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 µg/kg IV or 300 µg intranasal (150 µg per nostril; 150 µg for patients <50 kg) for minor bleeding or treatment before minor surgery
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- FVIII dosing to raise the level to 50%
- Recombinant FVIIa (90 to 120 µg/kg, followed by 90 µg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (50 to 100 units/kg, with maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Life- or Limb-Threatening Bleeding

- FVIII dosing to maintain FVIII activity levels at 100%
- Recombinant FVIIa (270 µg/kg for one dose may be considered with caution versus 90 µg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Low Titer, High Responder**Mild Bleeding**

- Local and conservative measures, such as rest, ice, compression, and elevation
- If the patient is known to respond to DDAVP (i.e., mild hemophilia A), 0.3 µg/kg IV or 300 µg intranasal (150 µg for patients <50 kg) for minor bleeding or treatment before minor surgery
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant factor VIIa (270 µg/kg, bolus may be considered with caution versus 90 µg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg, may induce anamnesis)

Life- or Limb-Threatening Bleeding

- FVIII in high doses to maintain levels of 100%
- Frequent monitoring for an anamnestic response, usually within 5 to 7 days
- After the anamnestic response develops:
 - Recombinant FVIIa (270 µg/kg, may be considered with caution versus 90 µg/kg every 2 to 3 hours)
 - Activated prothrombin complex concentrates (50 to 100 units/kg, with a maximum daily dose of 200 units/kg)

High Titer, High Responder**Mild Bleeding**

- Local and conservative measures, such as rest, ice, compression, and elevation
- Oral antifibrinolytic therapy (ε-aminocaproic acid or tranexamic acid) for mucosal bleeding
- Recombinant FVIIa (270 µg/kg, should be considered with caution versus 90 µg/kg every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg)
- Concurrent treatment with antifibrinolytics should be administered with caution

Life- or Limb-Threatening Bleeding

- Recombinant FVIIa (270 µg/kg, should be considered with caution versus 90 µg/kg IV every 2 to 3 hours)
- Activated prothrombin complex concentrates (100 units/kg, with a maximum daily dose of 200 units/kg)
- If available, immunoadsorption can be attempted to rapidly lower the inhibitor titer so as to allow use of FVIII

Main Features of the Agents Effective for Inhibitor Treatment/Prophylaxis

- **Content** APCC: activated vitamin k-dependent clotting factors; rFVIIa: recombinant FVIIa alone
- **Mechanism of action** APCC: activate plasma FX and FII; rFVIIa: activates FX on platelets
- **Half-Life** APCC: putatively 8-12 hours; rFVIIa: 2-3 hours
- **Efficacy** APCC: about 80%; rFVIIa: about 80%

of exogenous FVIII therapy ineffective, so that even when exogenous FVIII replacement is anticipated to be effective in the short term, treatment should start with factor VIIa (FVIIa) or an APCC if prolonged periods of replacement therapy are necessary.

In the case of a severe bleed or a life-threatening emergency, the inhibitor titer should be determined as rapidly as possible, but treatment should not be delayed until the results are available. For patients with a known persistent high-titer antibody, prompt replacement treatment should consist of a bypass agent, either an APCC or recombinant FVIIa (rFVIIa).

Surgery

Surgery in patients with hemophilia, especially those who have an inhibitor, requires the involvement of an entire facility experienced in the preoperative and postoperative care of such patients. Replacement therapy recommendations for surgical procedures are similar to those for hemorrhage. For known low responders, adequate hemostasis can be achieved with higher doses of FVIII. For the high-responding patient, APCC or rFVIIa are the most effective in the postoperative setting.⁸⁻¹⁰

Prothrombin Complex Concentrates

Prothrombin complex concentrates (PCCs) were designed for treatment of bleeding events associated with hemophilia B, congenital deficiencies of the other vitamin K-dependent clotting disorders, or

with severe liver disease. PCCs were hypothesized to be useful to treat FVIII inhibitor-related bleeding because of their thrombogenic properties. Prepared from large pools of normal donor plasma, the PCCs contain the vitamin K-dependent clotting factors prothrombin, FVII, FIX, and FX, as well as anticoagulant proteins C and S. Heparin or antithrombin is added to some preparations to limit activation of the coagulation factors during the manufacturing process and with administration. All PCCs undergo a viral inactivation process. In comparison with placebo, PCCs were shown to be partially effective in controlling approximately 50% of bleeding episodes in patients with FVIII alloantibody inhibitors, compared with 25% for product containing albumin alone.¹⁰⁵ A major caveat is that administration of PCCs to treat hemorrhage in hemophiliacs with inhibitors is *not* the treatment of choice and is justified *only* in the absence of more effective therapies.¹⁰⁵

Activated Prothrombin Complex Concentrates and Factor VIIa

APCCs are PCCs that are supercharged by virtue of their partial activation during the manufacturing process with activated FVII credited for the maximum clotting potential. In a randomized, double-blind trial, an APCC showed significantly better control of bleeding events in severe hemophiliacs with inhibitors than did PCCs ($p = .0085$); however, APCC was judged effective in only 64% of the episodes versus 52% effectiveness for PCC.¹⁰⁶ Uncontrolled clinical studies have shown that APCCs are effective in treating 81% to 93% of joint bleeds.^{107,108} One should bear in mind, however, that APCCs

are never as effective in inhibitor patients as is FVIII replacement in noninhibitor patients. Use of APCCs facilitates surgery in inhibitor patients and has been reported to be effective^{108,109} and safe in large populations.¹⁰⁹

APCC administration in a secondary prophylaxis regimen has also been deemed feasible, successful, and safe in reducing the frequency of bleeding events in severe hemophilia A patients with high-titer FVIII inhibitors. In the randomized, prospective, crossover ProFEIBA study, a statistically significant 62% reduction in all bleeding events was observed during the prophylaxis phase of the study (85 units/kg on 3 nonconsecutive days/week) compared with the on-demand period (85 units/kg every 6 to 12 hours).¹¹⁰

Use of PCCs and APCCs is hampered by the lack of laboratory tests to measure efficacy or to predict the potential for anamnesis (because of the presence of small amounts of FVIII) and the risk for precipitating thrombotic complications. The incidence of thrombosis is increased with regimens that exceed the recommended dosage and in patients at risk for thrombotic events, such as older individuals with coronary artery disease.

For acute bleeds, APCCs are administered at doses of 50 to 100 units/kg every 6 to 12 hours based on the clinical severity, with the maximum daily dose capped at 200 units/kg. This broader time frame allows for use at home for treatment of acute bleeds and for prophylaxis.

rFVIIa was purified from plasma and first used to treat a patient with hemophilia A with an inhibitor in 1983.¹¹¹ Later, FVIIa produced by recombinant technology was found to be effective for preventing and treating acute bleeding. A randomized dose-finding trial determined that FVIIa effectively reversed 71% of joint and muscle bleeds within two to three doses, given every 2 to 3 hours.¹¹² Another prospective study established that 90 µg/kg rFVIIa promoted adequate hemostasis during major surgical procedures, with an efficacy rate of 83% to 100%.¹¹³

Randomized prospective studies have directly compared the efficacy and safety of one dose of an APCC (factor eight inhibitor bypassing activity [FEIBA, Baxter], 85 to 90 IU/kg) with 1 to 2 doses of FVIIa (NovoSeven [Novo Nordisk Health Care AG] 90 to 105 µg/kg/dose) to treat acute joint bleeds. Although both products showed around 80% efficacy after 12 hours, equivalence was not shown at the 6-hour primary outcome point, but this was probably because of study design and underpowered cohorts.¹¹⁴ When the primary outcome was the percentage of patients who required additional hemostatic replacement therapy 9 hours after initiation of treatment, significantly lower percentages of the 270 µg/kg (8.3%) and 3 × 90 µg/kg (9.1%) FVIIa treatment dose cohorts required rescue therapies compared with the APCC treatment group (36.4%).¹¹⁵

Use of FVIIa is associated with some drawbacks, such as the lack of effective laboratory monitoring, very short half-life (≈2 to 3 hours, which necessitates frequent administration), potential for thrombotic events (more frequently observed in noninhibitor patients), and expense.

For acute bleeding events in inhibitor patients, debate exists as to whether the more convenient dosing regimen of a single large bolus dose of FVIIa (270 µg/kg) is as safe and efficacious as the multiple-dose regimen (90 µg/kg every 2 to 3 hours as recommended in the package insert). The initial concern was related to the thrombogenic potential of larger single doses, particularly in older individuals, since the large single-dose regimen was studied predominantly in children. In reality, a recent analysis of the FVIIa dosages used in FVIII inhibitor patients in the United States¹¹⁶ ($n = 20,469$ doses, recommended dosages were the large ones, up to >270 µg/kg) revealed a very low incidence of thromboembolic complications (0.2%).¹¹⁶ Thus for serious life- and limb-threatening hemorrhages, a single 270 µg/kg bolus dose is recommended, at least to start with. Treatment of acute bleeds with FVIIa concentrate should be initiated as soon as possible because efficacy is inversely related to time to treatment.

Recently, a comparative study was conducted between Novoseven and an Iranian biosimilar of rFVIIa¹¹⁷ in the range of 90–120 µg/kg/body weight: no differences were noted in terms of efficacy score, pain reduction, increased range of motion and side-effects. For

surgery, some experts advise an initial dose of rFVIIa of 120 µg/kg, followed by repeated 90 µg/kg doses every 2 to 3 hours.¹¹⁷

Parallel-Sequential Use of Activated Prothrombin Complex Concentrates and Factor VIIa Concentrates

For active inhibitor-associated bleeding episodes that appear to be unresponsive to treatment with either the APCC or rFVIIa alone, the administration of both products simultaneously or in an alternating regimen (within 12 hours) was reported to be successful.^{119–121} This combination is not recommended by the product manufacturers, and its clinical usefulness has not been set in a scientifically valid manner. In vitro sequential spiking experiments¹²² or ex vivo systematic infusion studies using plasma specimens from inhibitor patients who have received these two types of bypassing agents alone, simultaneously, or in tandem¹²³ have demonstrated enhanced hemostasis for the combined approach. One study suggests that individualized bypass replacement therapy regimens can be designed for inhibitor patients based on the ex vivo responses observed in thromboelastogram tracings.¹²³ Even though the efficacy of parallel treatment with bypassing agents may be good in inhibitor-related refractory bleeds, these regimens may increase the risk for thrombotic complications. A recent critical review of 49 inhibitor patients (9 acquired and 40 congenital), who received both bypassing agents in combined or alternating dosing regimens, reported 10 thromboembolic events, of which 1 was fatal.¹²⁴

Prophylaxis With Activated Prothrombin Complex Concentrate and Factor VIIa

Prophylaxis regimens using either APCC or rFVIIa to prevent acute and chronic arthropathy in inhibitor patients can be classified as primary (children awaiting ITI) or secondary (patients in whom ITI failed). Though not formally compared, prophylaxis with bypassing agents in inhibitor patients is not as efficacious as FVIII replacement in patients without an inhibitor. However, an accumulation of case reports and small clinical studies has suggested that prophylaxis with bypassing agents is safe and feasible in the subset of inhibitor patients with frequent bleeds, such as in target joints. The first prospective controlled study of prophylaxis in inhibitor patients¹²⁵ showed that a daily bolus dose of 270 µg/kg of FVIIa is superior to a 90 µg/kg dose (59% versus 45%) in reducing the bleeding frequency in comparison to the preprophylaxis period. An uncontrolled study¹²⁶ described equivalent efficacy and safety for FVIIa and APCC for prophylaxis in patients with hemophilia A with inhibitors. Patients were placed on prophylaxis while awaiting initiation of ITI. In this context, the investigators favored the use of FVIIa to avoid potential anamnestic responses with APCC.¹²⁶ A recent prospective controlled trial demonstrated that a prophylaxis APCC regimen at the dose of 85 IU/kg three times/week reduced bleeding events by 62% in inhibitor patients, compared to the on-demand treatment regimen.¹⁰²

Fibrinolytic Inhibitors

ε-Aminocaproic and tranexamic acid have long safety records and are commonly used in patients with hemophilia, including those with inhibitors, as a sole treatment modality or as adjuncts to factor replacement for mucosal bleeding, dental procedures, and some orthopedic surgeries.¹²⁷

For children, ε-aminocaproic acid can be administered orally at doses of 50 to 100 mg/kg every 6 hours. If used before a surgical intervention, the first dose should be given 4 hours before the start of the procedure. In adults, a loading dose of 4 to 5 g can be given initially, followed by similar or lower doses every 6 to 12 hours until bleeding is controlled (total suggested dose is 100 mg/kg/day). Fibrinolytic inhibitors are useful adjuncts for the treatment or prevention of bleeds treated with DDAVP in patients with low-titer

inhibitors but, considering their prothrombotic potential, should be administered cautiously when APCCs are used in large doses. Anti-fibrinolytic inhibitors are considered to be safe for use in conjunction with FVIIa.¹⁰³

Newly Proposed Tools

Among the alternative treatments recently developed there is a recombinant porcine FVIII preparation (rpFVIII); a preliminary study demonstrated its efficacy in acquired hemophilia with severe bleeds.¹²⁸ The clinical rationale for this preparation is based on the fact that porcine FVIII has a limited cross-reactivity with inhibitors to human FVIII. A similar concentrate from plasma had been used for years in the UK and proved efficacious and safe¹²⁹ but in the long run anamneses to porcine FVIII were shown to occur. Whether a similar situation will occur with rpFVIII is difficult to say, as there are no data available on the molecular structure of the preparation and the clinical experience is too short. The very short half-life of rFVIIa prompted the industry to develop new products with a prolonged activity, but their development was halted because of the occurrence of antibodies to FVIIa.¹³⁰ Further, a phase I trial of a new formulation of rFVII for subcutaneous injection was performed that showed a prolonged half-life (5.6 vs. 2.7 hours for the intravenous administration and a good safety profile).¹³¹

A novel therapeutic approach has recently been reported based on the use of a conformational replica of FVIII, Emicizumab. This humanized, bispecific antibody binds both FIX and FX forming a thrombin-generation complex. This complex, *in vitro* and *in vivo*, elicits thrombin formation independent of the FVIII levels and, most importantly, the presence of an inhibitor to FVIII. A recent clinical trial showed a strong reduction of spontaneous bleeding in patients with hemophilia A with or without inhibitors.¹³² Other advantages of this drug are its bioavailability by the subcutaneous route and the long-lasting efficacy; further, aPTT remained short during the study period. This approach could represent a novel, alternative therapy for inhibitor patients.

Immune Tolerance Therapy

ITI means the frequent, regular, long-term administration of a concentrate with the goal of inducing tolerance to FVIII or FIX. Today, ITI is considered the ultimate therapy for a patient with hemophilia complicated by an inhibitor. Immunologic mechanisms that underlie ITI-induced tolerance include peripheral T-cell anergy, inhibition of B-cell memory, the formation of antiidiotypic antibodies or activity of suppressor T-cells.

The goal of the procedure is to eradicate the alloantibodies. Successful ITI enables reinitiating on-demand or prophylactic replacement therapies for bleeding.

Taking into account that about 25% of inhibitors are persistently low titer and/or transient, ITI should be exclusively proposed to those patients who are high responders (anamneses >10 BU), and clearly symptomatic.

The first successful implementation of ITI was accomplished in 1974 when a child with a high-titer inhibitor (>500 BU) required emergency reversal of a life-threatening bleed.^{133,134} Very large doses of FVIII concentrate and APCC were administered and the hemorrhage was eventually controlled. A serendipitous finding was that the inhibitor titer decreased to almost 40 BU. This was the first documentation that high-dose FVIII administration could decrease inhibitor titers and provided proof of principle for the Bonn protocol, which originally used high doses of FVIII (100 IU/kg) twice daily.^{133,134} Bypass agents are administered as needed, to treat acute bleeds that occur during ITI. This regimen is continued until the inhibitor disappears, which can take up to a maximum of 3 years.^{134,135}

The Malmö ITI protocol was developed to induce a more rapid elimination of an inhibitor in a patient with severe hemophilia B who

required urgent orthopedic surgery.¹³⁶ Unique among the ITI regimens, the Malmö protocol, to lower the inhibitor level, uses immunomodulatory therapies in conjunction with large doses of clotting factor concentrate.^{137,138}

As experience with ITI regimens increased, it became evident that low-dose FVIII protocols could also induce tolerance. Such regimens start with a dose of 25 IU/kg every other day, a 16- to 24-fold lower dose than those used in high-dose ITI protocols.^{139,140}

Because of different ITI treatment protocols and outcomes, a retrospective International Immune Tolerance Registry was established in 1989. The registry eventually collected 314 inhibitor patients (>90% high titer) who underwent mostly high-dose ITI treatment regimens.¹⁴¹ The success rate was shown to range from 50% to 60% over time. Predictors of successful ITI included a low maximum inhibitor titer (85% success with ≤20 BU titer); low immediate pre-ITI BU (59% failure rate for >20 BU); higher FVIII dosages (86% success with ≥200 IU/kg/day); age of patient at initiation of ITI (60% failure for age >20 years); and shorter time interval between inhibitor detection and ITI initiation (>70% success for <5-year interval).^{142,143} Although other registries yielded similar findings,^{144–146} uncertainty remained as to the optimal daily dose of FVIII, the use of concomitant immunosuppressive/immune-modulating agents, and the type of clotting factor replacement therapy (plasma-derived versus recombinant concentrates). Another major issue was the definition of success: stringent criteria (disappearance of the inhibitor, normal FVIII recovery and half-life) were not always accepted and therefore had an impact on the retrospective outcome evaluations. Although never formally proven, some believe that low- and/or intermediate-purity factor concentrates containing vWF may be more efficacious than recombinant FVIII for successful ITI.^{147–150}

A number of treatment-related elements that may influence ITI outcomes cannot be addressed by registries. These include the number of acute bleeds during ITI, use of CVADs, onset of infections during ITI, and the use of plasma-derived PCCs or FVIIa to treat bleeds. Most of these questions were addressed in a randomized prospective multinational ITI trial that compared high- to low-dose ITI regimens, with the decision to use recombinant or a vWF-containing FVIII replacement product left to the discretion of the treating physician.^{151,152} The results published to date have confirmed that ITI can eradicate inhibitors in almost 70% of cases, even when very stringent outcome definitions are applied. Recombinant FVIII preparations were used in 90% of the enrolled individuals, making it very unlikely that plasma-derived vWF-containing concentrates could yield results superior to the recombinant preparations. The success rates gained with high-dose (200 IU/kg daily) or low-dose (50 IU/kg three times a week) ITI regimens were similar; however, successful ITI was achieved 50% earlier with the high-dose regimen. The low-dose regimen was associated with an increased frequency of breakthrough bleeding events during ITI. This safety signal led to premature discontinuation of the study.

A high proportion of patients with a CVAD (41/99, 41%) developed access device infection, but this complication did not affect the likelihood of success¹⁵² and therefore should not reduce the ITI use as an indication; however, this untoward side effect pinpoints the need for trained and professional device nursing when long-term treatments are needed. Further prospective studies are warranted to determine the optimal and most cost-effective dosing regimens for ITI. At any rate, a recent large retrospective study¹⁵³ reporting on ITI in patients with freshly diagnosed inhibitors, stressed the importance of starting the procedure as soon as possible, no matter the inhibitor titer or other risk factors.

In mild and moderate hemophilia A, inhibitors are less common than in severely affected patients but the change in the bleeding phenotype may pose significant challenges. ITI role in this clinical context is less clear as shown by a UKHCDO study from 1998¹⁵⁴ and a more recent one published in 2012.¹⁵⁵

A number of high-risk and/or ITI-relapsed patients have been treated with Rituximab, an anti-CD20 monoclonal antibody, with or without FVIII concentrate. Success rates have ranged from 33% to 57%,¹⁵⁶ although only a few patients exhibited long-lasting

remissions. Recently, Rituximab was used at the time of the first anamnesis occurred during ITI but a major response (titer <5 BU) was seen in only 3 out of 16 (18%) patients.¹⁵⁷

Data on the risk of inhibitor recurrence during follow up are scanty. Essentially, once the inhibitor has been eradicated, the risk of a recurrence is very low, in the range of 1% to 5%, and may occur many years afterwards, as shown by some studies that tackled the matter.^{141,142,144,152,158}

The new FVIII products (glycol-pegylated, fused to an Fc protein or to albumin) have not yet been used in ITI. The question is whether these concentrates display a reduced immunogenicity in vivo, as suggested by preliminary studies in animals or in vitro.^{159,160}

HEMOPHILIA B

The development of inhibitors to FIX in severe hemophilia B follows the same general principles as in hemophilia A. Inhibitory alloantibodies may arise after administration of FIX-containing replacement products, and this phenomenon was appreciated very soon after hemophilia B was documented to be a separate entity from hemophilia A.¹⁶¹ However, several distinct features in the epidemiology and treatment of FIX inhibitors in severe hemophilia B deserve a specific mention. These include (1) the lower incidence and prevalence of FIX inhibitors; (2) the increased risk for developing anaphylaxis after administration of FIX-containing concentrates to FIX inhibitor patients; (3) the risk for developing nephrotic syndrome after exposure to FIX-containing replacement products; and (4) the lower success rate of ITI for the eradication of FIX alloantibodies.^{162,163}

Epidemiology

Patients with severe hemophilia B have a 10-fold lower risk for developing inhibitors compared with those with severe hemophilia A (3% vs. 30%).¹⁶⁴ FIX gene mutations associated with a very low risk for inhibitor formation are single amino acid substitutions, whereas the risk for inhibitor development approaches 20% with more significant mutations, such as frameshift mutations, premature stop codons, large deletions, and splice site mutations.¹⁶⁴ Patients with hemophilia B who are at highest risk for inhibitor development have a severe phenotype as a result of large gene deletions or other aberrations of the gene product, such as nonsense mutations. Although the latter mutations are found only in a small fraction of the hemophilia B population, they account for approximately 50% of the inhibitor population.¹⁶⁴

Diagnosis

As in hemophilia A, an inhibitor should be suspected in hemophilia B when a patient ceases to respond to conventional replacement treatment. Given the possibility of anaphylaxis that may occur with initial treatment of bleeding episodes, patients with high-risk FIX gene mutations should be regularly screened for alloantibody inhibitors. The laboratory diagnosis for inhibitors in hemophilia B involves a modification of the BA used for the titration of FVIII inhibitors. In this case, FIX-deficient plasma is used instead of FVIII-deficient plasma.¹⁶⁵ In contrast to the FVIII inhibitor scenario, FIX inhibitors rapidly neutralize FIX in the normal plasma/patient plasma mixing studies: there is no time-dependent increase in the inhibitory increase of FIX alloantibodies over incubation at 37°C with either high- or low-titer FIX inhibitors.

Treatment

Treatment of hemophilia B in patients with FIX inhibitors mirrors that of hemophilia A complicated by FVIII inhibitors. Both APCC and rFVIIa are the key therapeutic modalities to reverse, control, and

prevent bleeding regardless of whether it is spontaneous in nature or induced by trauma or surgery.¹⁶⁵ However, because APCC contains significant amounts of FIX, which may induce anamnesis, some experts prefer rFVIIa.

Few treatment options exist for patients with FIX inhibitors who have experienced allergic reactions to the FIX antigenic material found in plasma, as in PCC, APCC, high-purity plasma-derived FIX concentrate, or even in recombinant FIX concentrates. Anaphylaxis is in fact, a major complication that can occur soon after the infusion of FIX-containing replacement therapies, manifesting as either a type II (dyspnea and hypoxia, and generalized hypersensitivity) or a type III (anaphylaxis and hypotension) allergic reaction. The rarity of anaphylactic complications in patients with hemophilia B with FIX inhibitors (only an estimated 35 cases have been reported) does not negate the seriousness of this complication.^{162,166,167} In addition, this is likely an underreported and perhaps unrecognized event. The major risk factor for developing an anaphylactic reaction is the presence of a FIX gene null mutation, leading to an absence of circulating FIX antigenic material.¹⁶⁸

Because these severe reactions occur only after initiation of treatment, they have been observed only in children (median age 12 months), occurring early, following a median of 11 exposure days. The development of anaphylaxis occurs at the same time as the appearance of an inhibitor. A recent survey on the topic has shown that allergic reactions can be elicited with either recombinant or plasma-derived FIX concentrates at similar rates (3.9%).¹⁶⁹

Because experience with anaphylaxis is limited by its low incidence, some general practice guidelines have been developed:

1. For newly diagnosed hemophilia B patients, especially those with high-risk FIX gene mutations, the initial FIX replacement treatments should be conducted in a medical facility where hemophilia expertise and resuscitation equipment are available.¹⁶²
2. Once a FIX inhibitor has been documented, FVIIa is the treatment of choice for active bleeding and for prophylaxis against bleeding.
3. ITI is generally ineffective in these patients, although tolerance to FIX has been reported with progressively increasing doses of FIX (desensitization procedure) administered with hydrocortisone.^{162,167}
4. FIX alloantibody formation may be complicated by a nephrotic syndrome, especially in patients who previously experienced an allergic reaction to FIX replacement. The limited data available suggest that this syndrome is not the result of immune complex deposition, and it does not respond to corticosteroid treatment.^{170,171} If nephrosis occurs, FIX doses should be reduced or treatment should be discontinued and rFVIIa therapy should be used instead.¹⁷¹
5. In a few refractory cases with or without nephrosis, immune modulation (anti-CD20,^{172,173} cyclosporine A¹⁷⁴ or mycophenolate mofetil¹⁷⁵) resulted in temporary tolerance to FIX.
6. Prophylaxis regimens with FVIIa (or APCC, if anaphylaxis and/or anamnesis is not an issue) may be useful in the context of high-titer FIX inhibitors; however, controlled trials are necessary before this approach becomes the standard of care.

As information available on inhibitors to FIX is scant, the literature on ITI procedures does not support clinically useful decisions. However, ITI should be used only in those patients who never displayed allergic symptoms related to FIX concentrates. All in all, ITI is less effective than in hemophilia A as shown by the North American Immune Tolerance Registry (NAITR) where an overall success rate of 31% was reported.^{144,145}

FACTOR VII DEFICIENCY

Congenital Factor VII deficiency is the third most frequent among the congenital clotting disorders. Recent epidemiologic studies provided a higher than expected prevalence in the general population, of about 1–2 cases/10⁵, with severe phenotypes accounting for about

20% to 25%.¹⁷⁶ The latter cases may have a bleeding tendency that is more severe than hemophilia, characterized by central nervous system or gastrointestinal bleeding soon after birth, or precocious joint bleeds.¹⁷⁷ With the availability of specific concentrates, especially rFVIIa, treatment has become widespread and the occurrence of complications fairly well known. As FVII shares considerable homology with FIX, both at the gene and protein levels,¹⁷⁸ and displays a comparable distribution of disease-causing mutations, with a large predominance of missense changes,¹⁷⁷ the occurrence of inhibitors to FVII was an expected finding. The lack of severe gene lesions, as large deletions, may account for the apparently lower prevalence of inhibitors in comparison with hemophilia B. Only a recent prospective study with a centralized inhibitor screening,¹⁷⁸ provided clear cut data on the inhibitor prevalence and features; in fact, inhibitors to FVII were detected in 3 of 115 (2.6%) patients (one de novo inhibitor and two preexisting inhibitors), all high titer, and their anamneses were kinetically similar to those described in hemophilias. Importantly, FVII inhibitors were in no case associated with allergic reactions. In the presence of a high-titer inhibitor to FVII, treatment becomes a problem as there are no bypassing agents capable of triggering blood coagulation.

RARE COAGULATION FACTOR DEFICIENCIES

David Gailani, Allison P. Wheeler, and Anne T. Neff

INTRODUCTION

In this chapter the term *rare coagulation factor deficiency* is applied to disorders caused by mutations in single genes, other than those for von Willebrand factor, factor VIII, or factor IX, that cause reduced plasma activity of one or more coagulation proteins, ultimately leading to a defect in thrombin and/or fibrin formation.¹⁻³ The most common inherited deficiencies affecting plasma coagulation are those for factors VIII (hemophilia A) and IX (hemophilia B), with frequencies of 1 in 10,000 and 1 in 30,000 male births, respectively (Chapter 135). In comparison, severe deficiency of fibrinogen; one of the protease zymogens prothrombin, prekallikrein or factors VII, X, XI, or XII; one of the cofactors (factor V or high-molecular-weight kininogen); or the transaminase factor XIII occurs in one in 500,000 to 2 million individuals (Table 137.1). These conditions are primarily inherited as autosomal recessive conditions, implying carrier frequencies of approximately 1 in 1000 persons; 10-fold higher than the carrier frequency for the alleles causing X-linked hemophilia A or B. The rarity of these disorders, therefore, is due to their recessive nature, and not low allele frequency. This is important to keep in mind, as partial (heterozygous) deficiencies of these proteins are relatively common and may contribute to bleeding symptoms. As with any recessive trait, incidences are up to 10-fold higher in areas where consanguinity is common.^{1,3}

Fig. 137.1A shows a scheme reflecting our current understanding of the major enzymatic reactions involved in thrombin generation and fibrin formation. During hemostasis, factor VIIa binds to tissue factor in the wall of a damaged blood vessel. The factor VIIa/tissue factor complex converts factor X to Xa, which in turn converts prothrombin to thrombin in the presence of factor Va. Mice lacking prothrombin, or factor VII, X, or V die in utero or soon after birth, demonstrating the importance of these proteins. Thrombin, among its many functions, converts fibrinogen to fibrin. Factor IX is also activated by factor VIIa/tissue factor and, with factor VIIIa, sustains thrombin generation by activating factor X. In some situations factor IX activation by factor XIa is required. The older model shown in Fig. 137.1B highlights the order of reactions during coagulation in a prothrombin time (PT) or activated partial thromboplastin time (aPTT) assay. Here factor XI activation requires the contact factors, factor XII, prekallikrein, and high-molecular-weight kininogen. Deficiency of a contact factor does not result in abnormal bleeding indicating that other mechanisms exist for factor XI activation. For example, thrombin activates factor XI (Fig. 137.1A). Finally, factor XIII is activated by thrombin and cross-links fibrin monomers within a fibrin polymer, increasing the strength of the fibrin strands (Fig. 137.1A).

The disorders discussed in this chapter represent 3% to 5% of coagulation factor deficiencies. Their rarity, clinical heterogeneity, and the limited availability of standardized testing present challenges for establishing evidence-based treatment guidelines.¹⁻³ Common symptoms include hemorrhage with invasive procedures and childbirth, and bleeding from mucosal surfaces. Bleeding involving the central nervous system (CNS) often accompanies severe deficiencies of fibrinogen and factors XIII, X, or VII. Gastrointestinal (GI) bleeding is a particular problem in factor X deficiency, and umbilical cord bleeding is most common with fibrinogen, factor XIII, or factor X deficiency. Hemarthroses can occur with afibrinogenemia and severe deficiency of factors II or X. The World Federation of Hemophilia

(WHF, www.wfh.org) and the International Rare Bleeding Disorder Database (RBDD, www.rbdd.org) have collected information on the worldwide prevalence of rare coagulation factor deficiencies (Fig. 137.2).^{1,3,4} The European Network of Rare Bleeding Disorders (EN-RBD) recently reclassified these disorders based on clinical severity to facilitate development of evidenced-based diagnostic and treatment strategies (Table 137.2).⁴ They noted the strongest associations between bleeding severity and coagulation factor activity with fibrinogen, factor X, and factor XIII deficiencies, and weaker associations with deficiencies of factor V and factor VII. The association between factor XI levels and propensity to bleed is very weak. This chapter contains sections describing deficiency states for each coagulation factor. The number from the Online Mendelian Inheritance in Man (OMIM) database for the deficiency is given in the section title. Updated lists of mutations associated with the factor deficiencies can be found at several websites such as <http://www.hgmd.org> and <http://www.clotbase.bicnirrh.res.in>. Table 137.1 lists properties of coagulation factors and features of their deficiency states; while Table 137.3 contains treatment recommendations.

FIBRINOGEN DEFICIENCY(OMIM 202400)

Fibrinogen was first purified from plasma in the late 19th century. Fibrinogen and fibrin are designated factor I and Ia, respectively, by the International Committee for the Nomenclature of Blood Clotting. Congenital absence of fibrinogen (afibrinogenemia) was first described in 1920 and has an estimated incidence of 1 in 1 million people (Table 137.1).^{5,6} Partial deficiency is called *hypofibrinogenemia*. Fibrinogen is synthesized in hepatocytes as a 340,000-Da protein composed of two trimers, each containing an α , β , and γ chain (Fig. 137.3), which are encoded by separate genes (*FGA*, *FGB*, *FGG*) within a 50-kb region of chromosome 4. Thrombin converts fibrinogen to fibrin by cleaving fibrinopeptides A and B from the α and β chains, respectively. Fibrinogen also binds glycoprotein IIb/IIIa, facilitating platelet aggregation. Fibrinogen in platelet α -granules is taken up from plasma via a glycoprotein IIb/IIIa-dependent mechanism. Between 8% and 15% of plasma fibrinogen contains at least one γ chain that is a product of an alternatively spliced mRNA called γ -fibrinogen. γ -fibrinogen modulates thrombin and factor XIII activity and influences clot architecture.

The normal plasma fibrinogen concentration is 1.5 to 4.0 g/L (150–400 mg/dL). Afibrinogenemic patients have levels <0.1 g/L as determined by both clotting and immunoreactive assays, due to homozygosity or compound heterozygosity for fibrinogen gene mutations.^{5,6} Hypofibrinogenemia is a milder condition due to heterozygosity for a mutation. The first causative mutation for fibrinogen deficiency was reported in 1999, and over 200 fibrinogen gene deletions, frameshifts, nonsense, missense, and frameshift mutations have subsequently been identified in afibrinogenemic and hypofibrinogenemic patients (www.geht.org/databaseang/fibrinogen).⁶ The *FGA* gene is most commonly affected. Missense mutations are more prevalent in the *FGB* and *FGG* genes and cluster in the polypeptide C-termini affecting D-domain formation (Fig. 137.3) and interfering with secretion.⁶ In afibrinogenemia, fibrinogen is not secreted due to lack of synthesis of one of the fibrinogen chains or the presence of a mutant chain that alters fibrinogen structure. Nonsecretable fibrinogen polypeptides are usually degraded in the hepatocyte. Some *FGG*

TABLE
137.1

Properties of Plasma Coagulation Factors and Characteristics of Deficiency States.

Protein	Factor Plasma Half-Life (hours)	Vitamin K-Dependent Modification	Factor Level in Pregnancy	Incidence of Severe Congenital Deficiency	Autosomal Inheritance Pattern of Deficiency	Other Names for Deficiency State	Bleeding Diathesis in Severe Deficiency	Screening Tests in Deficiency	
								PT	aPTT
Fibrinogen	72–120	No	↑	$\sim 1:1 \times 10^6$	Recessive or dominant	Afibrinogenemia	Severe	↑	↑
Prothrombin	60–100	Yes	↔	$\sim 1:2 \times 10^6$	Recessive	Hypoprothrombinemia	Severe	↑	↑
Factor V	12–14	No	↔	$\sim 1:1 \times 10^6$	Recessive	Parahemophilia	Moderate to severe	↑	↑
Factor VII	3–4	Yes	↑	$\sim 1:5 \times 10^5$	Recessive	Serum prothrombin conversion accelerator deficiency	Moderate to severe	↑	↔
Factor X	20–40	Yes	↑	$\sim 1:1 \times 10^6$	Recessive	Stuart-Prower factor deficiency	Severe	↑ ↔	↑ ↔
Factor XI	45–52	No	Inconsistent	$\sim 1:1 \times 10^6$	Recessive or dominant	Hemophilia C, Plasma thromboplastin antecedent deficiency	Asymptomatic to moderate	↔	↑
Factor XII	60	No	↑	Unknown	Recessive	Hageman trait	Asymptomatic	↔	↑
Prekallikrein	Not known	No	↔	Unknown	Recessive	Fletcher trait	Asymptomatic	↔	↑
High-molecular-weight kininogen	170	No	↔	Unknown	Recessive	Flaujeac trait Williams trait Fitzgerald trait	Asymptomatic	↔	↑
Factor XIII	150	No	↓	$1:2 \times 10^6$	Recessive	Fibrin stabilizing factor deficiency	Severe	↔	↔

aPTT, Activated partial thromboplastin time; PT, prothrombin time.

Fig. 137.1 MODELS OF PLASMA COAGULATION. Unactivated plasma factors are indicated by *Roman numerals* and activated factors by *Roman numerals* followed by a lowercase *a*. Enzymes are indicated by *black lettering* and cofactors by *white lettering* in red ovals. Orange arrows indicate reactions involving enzyme activation. Some reactions require calcium ions (Ca^{2+}) or phospholipid (PL) to proceed optimally. The green arrow indicates feedback activation of factor XI by thrombin. Black arrows indicate fibrin formation. (A) A model of tissue factor (TF) initiated hemostasis. Please read the introduction to this chapter for a description of the events leading to formation and stabilization of a fibrin clot depicted in this figure. (B) The cascade/waterfall model of hemostasis. This model serves as the basis for the prothrombin time (PT) and activated partial thromboplastin time (aPTT) assays. In the PT assay a reagent containing TF is added to plasma, and the factor VIIa/TF complex induces clot formation through activation of factor X. In the aPTT assay a reagent containing a negatively charged substance initiates clot formation through activation of factor XII (contact activation; see Fig. 137.5 for details). HK, High-molecular-weight kininogen; PK, prekallikrein; TF, tissue factor.

gene mutations such as Gly284Arg (fibrinogen Brescia), Arg375Trp (fibrinogen Aguadilla), or Thr314Pro (fibrinogen Al DuPont) are associated with accumulation of the mutant γ -polypeptide in hepatocytes, leading to hepatic dysfunction and cirrhosis similar to the process associated with α_1 -antitrypsin deficiency (endoplasmic reticulum [ER] storage disease).

Acquired hypofibrinogenemia occurs in disseminated intravascular coagulation (DIC) and primary fibrinolysis (see [Chapter 139](#)). Fibrinogen levels are usually normal or increased in liver disease, but levels less than 1 g/L may be seen in cirrhosis with hepatic failure or fulminant hepatic necrosis, and indicate a poor prognosis. Patients receiving L-asparaginase for hematologic malignancies may develop severe hypofibrinogenemia (<0.2 g/L), while other coagulation factors are normal or only slightly reduced.

Hemorrhagic symptoms in fibrinogen deficiency are most significant when the plasma level is less than 0.5 g/L.^{5,6} Data from the EN-RBD database indicate spontaneous bleeds rarely occur when levels are over 0.7 g/L, while bleeding even with surgery is unusual with levels over 1.0 g/L. Most (85%) afibrinogenemic patients bleed from their umbilical cord and mucosal surfaces.⁶ Menorrhagia and bleeding from the skin, GI tract and genitourinary tract are common.⁶ Hemarthroses and muscle hematomas were common in one series

(54% and 72%, respectively), but were less frequent (25%) in another study.⁶ Hemarthrosis-related arthropathy appears to be less pronounced than in hemophilia A or B. Intracranial bleeding occurs in up to 10% of patients, and is a major cause of death, providing a justification for prophylaxis.⁶ Afibrinogenemic patients are prone to spontaneous rupture of the spleen. Hypofibrinogenemic patients are usually asymptomatic, but may have excessive bleeding with trauma or surgery, particularly if the fibrinogen level is below 0.5 g/L. In the absence of factor replacement, pregnancy loss is common in afibrinogenemic women, usually occurring in the first trimester.^{2,7} Fibrinogen-deficient mice also have difficulty sustaining pregnancy, confirming the importance of maternal fibrinogen to fetal viability. Pre- and postpartum bleeding is common,⁷ and intraabdominal bleeding from ruptured corpus luteal cysts has been reported.

Curiously, arterial and venous thromboses occur in afibrinogenemic patients, and there may actually be an increased risk of myocardial infarction. While some events are likely precipitated by known risk factors or by factor replacement, no identifiable cause is evident in most instances. Fibrinogen and fibrin downregulate thrombin activity, providing a possible explanation for these events.

Assays such as the PT, aPTT, and thrombin time will be infinitely prolonged in afibrinogenemia. In hypofibrinogenemia, the thrombin time is often prolonged, but the PT and aPTT are insensitive to low fibrinogen and may be normal. Results for the template bleeding time and standard platelet aggregometry are usually abnormal. However, the aperture closure times in the PFA-100 platelet function screen are usually normal, as this test depends on von Willebrand factor and not fibrinogen to support platelet function. The von Clauss method is most commonly used for measuring fibrinogen, based on determining the time to clot formation after addition of thrombin to plasma. The assay is not reliable at low fibrinogen levels (<10 mg/dL) and may give falsely low readings with fibrinogen variants that polymerize slowly (dysfibrinogenemia), if high levels of substances that interfere with fibrin polymerization (paraproteins, fibrin degradation products) are present, or if the sialic acid content of fibrinogen is high (newborns, liver disease). Thus it is important to demonstrate the absence of immune-reactive fibrinogen to confirm a diagnosis of afibrinogenemia. In hypofibrinogenemia functional and antigenic fibrinogen levels are proportionately decreased. A disproportionately low functional level suggests dysfibrinogenemia. Afibrinogenemic patients have low erythrocyte sedimentation rates and develop little induration with skin tests for delayed hypersensitivity because of the absence of fibrin deposition.

Fibrinogen is the main component of cryoprecipitate, the preparation used most often in the United States to treat fibrinogen deficiency ([Table 137.3](#)). Fresh frozen plasma (FFP) contains fibrinogen, but large volumes are required to correct significant deficiency. Each unit of cryoprecipitate has approximately 300 mg of fibrinogen. For a patient with a normal hematocrit, the plasma volume is approximately

Fig. 137.2 WORLDWIDE PREVALENCE OF RARE BLEEDING DISORDERS. Shown are data for each factor deficiency as a percentage of total rare bleeding disorders from data collected by the World Federation of Hemophilia (WFH, blue bars) and the International Rare Bleeding Disorders Database (RBDD, purple bars). The difference in percentage for combined factor V and factor VIII deficiency between the surveys may reflect cases of factor V deficiency with mild hemophilia A being classified as combined deficiencies in the RBDD survey. (Adapted from Peyvandi F, Menegatti M, Palla R: Rare bleeding disorders: worldwide efforts for classification, diagnosis and management. *Semin Thromb Haemost.* 39:579, 2013, with permission.)

TABLE 137.2

Plasma Factor Levels Based on European Network of Rare Bleeding Disorders Categories.

Disorder	EN-RBD Severity Category			Clinical Correlation With Factor Level
	Severe	Moderate	Mild	
Fibrinogen deficiency	Undetectable	0.1–1.0 g/dL	>10 g/dL	Strong
Prothrombin deficiency	Undetectable	≤0.1 IU/mL (≤10%)	>0.1 IU/mL (>10%)	Strong
Factor V deficiency	Undetectable	<0.1 IU/mL (<10%)	≥0.1 IU/mL (≥10%)	Weak
Factor VII deficiency	<0.1 IU/mL (<10%)	0.1–0.2 IU/mL (10%–20%)	>0.2 IU/mL (>20%)	Weak
Factor X deficiency	<0.1 IU/mL (<10%)	0.1–0.4 IU/mL (10%–40%)	>0.4 IU/mL (>40%)	Strong
Factor XI deficiency	–	–	–	Very weak
Factor XIII deficiency	Undetectable	<0.3 IU/mL (≤30%)	≥0.3 IU/mL (>30%)	Strong
Combined factor V and VIII deficiency	<0.2 IU/mL (<20%)	0.2–0.4 IU/mL (20%–40%)	>0.4 IU/mL (>40%)	Weak
Vitamin K-dependent factor deficiencies	–	–	–	Weak

TABLE 137.3
Treatment Considerations for Rare Coagulation Factor Deficiencies.

Protein	Blood Product Sources	Concentrate (Manufacturer) ^a	Minimum Plasma Level Required for Hemostasis	Minimum Plasma Level Required for Surgery	Dose of Preferred Treatment for Surgery or Bleeding	Dosing Frequency for Surgery or Bleeding	Prophylaxis for Severe Deficiency	Pregnancy: Suggested Plasma Levels for Invasive Procedures and Delivery
Fibrinogen	CRYO FFP	RiaSTAP (CSL Behring) ^a	>50 mg/dL	100 mg/dL until healing complete	20–30 mg/kg ^b FFP 15–20 mL/kg Cryo 1 bag/10 kg	Q 24–72 h depending on consumption	Keep level 50 mg/dL for recurrent bleeders	Maintain at 100 mg/dL throughout pregnancy
Prothrombin	FFP	PCC ^a	~5%	30%	20–30 factor IX units/kg	Q 48–72 h	40 factor IX units/kg Q 5–6 days	20%–30%
Factor V	FFP ^a platelets	None	~10%	25%	20 mL FFP/kg then 5–10 mL/kg q12 h	Q 12–24 h	Not usually required	15%–25%
Factor VII	FFP	NovoSeven, recombinant Factor VIIa (Novo Nordisk) ^a ; PCC	5%–10%	15%–25%	15–30 µg factor VIIa/kg	Q 2–12 h	20–30 µg/kg 2–3 times per wk	10%–20%
Factor X	FFP	PCC ^a ; Coagadex, Factor X concentrate (BioProducts Laboratory)	~10%	25%–40%	PCC: 15–20 factor IX units/kg FX: 25 factor X units/kg	Q 24 h	15–20 factor X units/kg weekly. 40–50 Factor X units twice weekly	10%–20%
Factor XI	FFP ^a	Hemoleven (LFB Biomedicaments); Factor XI concentrate (Bio Products Laboratory)	15%	30%–40%	15–20 factor XI units/kg	Q 1–2 days	Not required	May withhold treatment unless bleeding occurs
Factor XIII	CRYO FFP	Corfact ^a (Formerly Fibrogammin P, CSL Behring); Recombinant Factor XIII (Tretten, Novo Nordisk)	1%–2%	20%–50%	20–30 factor XIII units/kg	Single dose may be sufficient	40 factor XIII units/kg q 28 days	250 units/wk through wk 22, then 500 units/wk with a 1000 unit bolus during labor

^aPreferred treatment for congenital deficiency

^bAssuming baseline fibrinogen is not known.

CRYO, Cryoprecipitate; FFP, fresh frozen plasma; PCC, prothrombin complex concentrate.

Fig. 137.3 MODEL OF HUMAN FIBRINOGEN. A fibrinogen molecule consists of two trimers, each containing an α -chain (blue), β -chain (pink), and γ -chain (yellow). The amino-termini of the six chains that compose the whole molecule are linked by disulfide bonds in the central E domain, and the C-termini of the polypeptides form two nodular D domains at opposite ends of the molecule. Fibrinopeptides A (FPA; green) and B (FPB; purple) reside in the E domain and are removed by the proteolytic activity of thrombin during conversion of fibrinogen to fibrin monomer. (Adapted from Mosesson MW: *The roles of fibrinogen and fibrin in hemostasis and thrombosis*. Semin Hematol. 29:177, 1992, with permission.)

0.04 L/kg body mass (40 mL/kg). Administering cryoprecipitate at 1 unit/5 kg of body mass will increase plasma fibrinogen in an afibrinogenemic patient to approximately 1 g/L. The fibrinogen concentrate RiaSTAP (Haemocomplettan) was approved by the Food and Drug Administration (FDA) in 2009 for treating bleeding and for prophylaxis in severe fibrinogen deficiency. This preparation has gone through viral inactivation steps. In a study of 15 patients given RiaSTAP (70 mg/kg), the median plasma fibrinogen concentration 1 hour postinfusion was 1.3 g/L with a half-life of 77.1 hours. In one study, the concentrate was effective in congenital fibrinogen deficiency in 26 of 26 bleeding episodes, 10 of 11 surgical procedures, and all 90 prophylactic administrations. Subsequent studies involving trauma, cardiothoracic surgery, and obstetrical hemorrhage confirmed its ability to improve coagulation and reduce blood loss.^{5,6} Low-molecular-weight heparin may be administered with fibrinogen concentrate if there is concern that therapy may precipitate a thrombotic event. The required dose of concentrate can be determined using the following formula:

$$\text{Dose (mg/kg)} = \frac{(\text{Target level [mg/dL]} - \text{Measured level [mg/dL]})}{1.7 \text{ (kg body weight/dL)}}$$

For treating bleeding, the United Kingdom Haemophilia Centre Doctors Organization guidelines recommend that plasma fibrinogen be maintained at 1.0 g/L until hemostasis is achieved and greater than 0.5 g/L until wound healing is complete.² A similar strategy makes sense for managing surgery. A review of replacement therapy and outcomes for 50 patients with congenital fibrinogen deficiency generally agrees with these recommendations. A fibrinogen concentration of 0.5 to 1.0 g/L was sufficient for prevention or treatment of bleeding in nonsurgical or obstetrical settings, while 1.0 to 2.0 g/L was effective for preventing bleeding during surgery. One review reported that thrombotic episodes (related or unrelated to replacement) occurred in 30% of patients. As the half-life of transfused fibrinogen is approximately 3 days, dosing every 2 to 4 days is usually adequate to maintain levels in the absence of consumption. Increased dosing frequency may be necessary in cases of massive hemorrhage, major surgery or advanced pregnancy, and monitoring of the fibrinogen level is recommended to facilitate dosing. The utility of thromboelastography to provide guidance for patients receiving fibrinogen concentrate for bleeding is being investigated.

Prophylactic fibrinogen administration is recommended to maintain pregnancies in afibrinogenemic women and to reduce postpartum

hemorrhage.^{2,5,7} Therapy should be initiated early as fetal loss in the first trimester is common. One study suggested that initiating therapy before conception is beneficial. Although some authors recommend keeping fibrinogen levels above 0.5 g/L during pregnancy and peripartum, others suggest a higher level (1.0 g/L) based on reports of fetal loss in patients with levels near 0.5 g/L. Long-term prophylaxis may be useful in preventing initial bleeding in young patients or to prevent recurrence, particularly after CNS hemorrhage. Administration of 20–30 mg/kg of concentrate every 7 to 14 days to maintain plasma levels of approximately 0.5 g/L is recommended.^{5,6}

Increased use of fibrinogen concentrate has raised concerns regarding adverse events. An analysis of 27 years of pharmacovigilance data identified 21 cases of suspected viral transmission (1 per 124,300), 28 cases of thromboembolism (1 per 93,300), and 20 cases of hypersensitivity (1 per 130,600 doses) suggesting a promising safety profile.⁸ Acquired antibody inhibitors have been reported in only two patients with afibrinogenemia after replacement therapy.

Antifibrinolytic therapy with ϵ -amino caproic acid may be an effective replacement for blood products for some mucosal bleeds and for dental extractions. However, this therapy may increase the risk for thrombosis and must be used cautiously in patients with a history of thrombosis, or during pregnancy, surgery, or immobilization. Fibrin glue may be useful for tooth extraction, and estrogen/progesterone therapy may be helpful for controlling menorrhagia.⁵

DYSFIBRINOGENEMIA (OMIM 134820 α -CHAIN, 134830 β -CHAIN, AND 134850 γ -CHAIN)

In dysfibrinogenemia structural variants of fibrinogen circulate in plasma.^{9,10} Cases in which the dysfunctional protein is present at low levels may be referred to as *hypodysfibrinogenemia*. The first family with dysfibrinogenemia (15 amino acid insertion after Gln350 in the γ -chain [fibrinogen Paris I]) was described in 1964. The actual incidence of congenital dysfibrinogenemia is not known because the majority of affected individuals are probably asymptomatic.

Congenital dysfibrinogenemias are almost all autosomal dominant traits due to missense mutations in a fibrinogen gene (www.geht.or/databaseand/fibrinogen).^{6,9,10} Amino acid substitutions that alter fibrinopeptide release, cross-linking, polymerization, or degradation have been described. The diagnosis is established by identifying low fibrinogen in a rate-based clotting assay relative to immunoreactive fibrinogen. The functional defects most often reported are clearly influenced by the assays available in clinical laboratories and are unlikely to represent the full spectrum of mutations causing

Adjuncts to Factor Replacement Therapy in Congenital Factor Deficiencies

The antifibrinolytic agents ϵ -amino caproic acid and tranexamic acid can be effective adjuncts to factor replacement when treating congenital or acquired bleeding disorders, and are useful alternatives to replacement therapy for mild bleeding or minor procedures. These drugs inhibit clot dissolution by interfering with plasminogen activation and plasmin activity, and are particularly effective when bleeding involves tissues with high fibrinolytic activity such as the oral and nasal cavity. They are also useful for treating menorrhagia, limiting blood loss with surgery, controlling epistaxis and reducing some types of GI bleeding. A typical loading dose of ϵ -amino caproic acid is 50 to 100 mg/kg followed by 50 mg/kg every 6 hours (for adults dose 2 to 4 g every 6 hours). If bleeding subsequently occurs, the dose can be increased, but should not exceed 24 grams in 24 hours. ϵ -Amino caproic acid is available in oral and intravenous formulations. Identical dosing for either preparation may be used due to excellent bioavailability. For dental extraction in factor VIII or IX deficiency, many centers utilize a single 50% to 100% dose of factor concentrate followed by seven days of ϵ -amino caproic acid, and it is reasonable to use this approach for patients with some rare bleeding disorders. Patients with factor XI deficiency do well with antifibrinolytic agents alone for tooth extraction (see [Treating Factor XI Deficient Patients](#)). Prolonged therapy with antifibrinolytics must be undertaken with caution in patients who are not mobile, who have a history of thrombosis, or who have significant urogenital bleeding. These drugs interfere with urokinase-mediated fibrinolysis in the genitourinary tract that can lead to thrombotic occlusion of the ureter. Concomitant use of antifibrinolytic agents with activated prothrombin complex concentrates or recombinant factor VIIa may result in a particularly high risk of thrombus formation. Patients may develop nausea or vertigo with high doses of ϵ -amino caproic doses, and rarely, rhabdomyolysis.

Recombinant factor VIIa may stop or prevent hemorrhage in rare bleeding disorders. The mechanism by which this agent works is not completely understood, particularly for deficiencies of common pathway factors (prothrombin and factors V and X). For patients with rare bleeding disorders and an antibody inhibitor directed against the missing factor, factor VIIa may be the treatment of choice. Doses range from 15 to 120 μ g/kg every 2 to 6 hours depending upon the severity of bleeding. Because of the risk of thromboembolism with factor VIIa, we recommend frequent reevaluation and reduction to the lowest effective dose. Doses of 90 μ g/kg every 2 to 3 hours have been used in patients with congenital factor V deficiency or combined deficiencies of factors V and VIII; with acquired factor X deficiency associated with amyloidosis, and with antibody-mediated acquired prothrombin deficiency associated with lupus anticoagulants. With factor VIIa, as compared to FFP, the volume of infused material is smaller, and the risk is lower for complications such as fever, urticaria, transfusion-related acute lung injury (TRALI) and anaphylaxis. Caution must be exercised when using factor VIIa in older patients with cardiovascular disease, as arterial thrombosis can result, particularly when therapy is combined with antifibrinolytic therapy or prothrombin complex concentrate.

fibrinogen dysfunction. Variants easily detected in clinical laboratories typically have defects in fibrinopeptide release (e.g., FGA-Arg16His and FGA-Arg16Cys [fibrinogens Bicêtre and Metz]), or polymerize slowly (e.g., FGG-Ser434Asn [fibrinogen Caracas II], FGG-Arg275Cys and FGG-Arg275His). Indeed, approximately 45% of the mutations in the dysfibrinogenemia database involve substitutions at FGA-Arg16 or FGG-Arg275, at least partly reflecting the ease with which these variants are detected by common functional assays.

Most individuals with dysfibrinogenemia are asymptomatic.^{9,10} In a recent multicenter study of congenital dysfibrinogenemia 58% were identified incidentally by an abnormal coagulation test. Over a mean follow-up of 8.8 years, the incidences of major bleeding and thrombosis were 2.5 and 18.7 per 1000 patient years, respectively,¹⁰ with estimated cumulative incidences of 19.2% and 30.1% at age 50 years. There were no clear associations between symptoms and fibrinogen level, functional abnormalities, or gene mutations, consistent with older observations that common substitutions such as FGA-Arg16His

and FGA-Arg16Cys occur in asymptomatic individuals as well as patients with bleeding or thrombosis.

Bleeding symptoms tend to be relatively mild, with epistaxis, easy bruising, and menorrhagia being common.^{9,10} More serious bleeding events including soft tissue hematomas, hemarthroses, postoperative hemorrhage, and bleeding during and after pregnancy do occur, but are rarer. Major bleeding seems to occur primarily between the ages of 20 and 40 years, partly due to hemostatic challenges related to childbirth. Abnormal wound healing and spontaneous abortions have been reported.

Thrombotic events primarily involve the venous circulation, although arterial events occur.^{9,10} The mean age for venous and arterial events in one study (34 and 49 years) was significantly lower than for the general population.¹⁰ There was a high prevalence of venous thromboembolism (VTE) at the time of diagnosis, with an incidence during follow-up similar to that for carriers of the factor V Leiden (G1691A) polymorphism. A strong relationship exists between certain fibrinogen variants and venous thrombosis. Thrombosis-associated mutations tend to cluster at the C-terminus of the α -chain and near the thrombin cleavage site on the β chain. Abnormalities in fibrin polymerization and cross-linking, clot structure, and susceptibility to fibrinolysis have been described. The “Dusart Syndrome” caused by FGA-Arg554Cys (fibrinogen Paris V) was associated with venous thrombosis and sudden death in adolescents and young adults in several families. Dysfibrinogenemia was reported in 5 of 33 patients with chronic thromboembolic pulmonary hypertension, with the FGB-Pro235Leu substitution identified in three unrelated patients. Altered fibrin structure and susceptibility to fibrinolysis may result in poor clot dissolution in these patients. Despite these associations, a review of 2376 patients with venous thrombosis found dysfibrinogenemia in less than 1%, so testing for abnormal fibrinogen in patients with venous thrombosis is not widely recommended.

As discussed in the section on [Fibrinogen Deficiency](#), maternal fibrinogen is required to maintain pregnancies. Pregnancy loss, as well as peripartum bleeding and thrombosis, have been reported in dysfibrinogenemic women. In contrast to older reports, the survey cited above did not identify an increased risk of spontaneous abortion, but there was a significant risk of postpartum bleeding, particularly in patients with histories of prior bleeding.

A group of mutations in the C-terminus of the fibrinogen α -chain is associated with autosomal dominant hereditary amyloidosis. The amyloid deposits contain fragments of the variant fibrinogen. The kidneys are initially affected, but wider visceral and nerve involvement may occur. Renal grafts subsequently become involved with amyloid, and liver transplantation may be a better treatment option. The allele for one responsible mutation, FGA-Glu526Val, is relatively common and may account for 5% of patients with apparent sporadic amyloid. Acquired dysfibrinogenemia is most frequently diagnosed in liver disease, with 80% to 90% of patients with cirrhosis or liver failure showing fibrinogen dysfunction. Increased sialic acid content similar to fetal fibrinogen seems to impair fibrin polymerization in vitro, but the process probably does not contribute substantially to abnormal hemostasis. The monoclonal paraprotein in patients with multiple myeloma can interfere nonspecifically with fibrin polymerization but usually does not cause abnormal hemostasis. Acquired dysfibrinogenemia has been associated with other malignancies and bone marrow transplantation.

Dysfibrinogenemia often presents as an abnormality on routine coagulation testing (PT or aPTT). The thrombin time is frequently used as a screening test for dysfibrinogenemia, although its sensitivity is not established. The test involves measuring time to clot formation in plasma after addition of a standard amount of thrombin. The specificity for dysfibrinogenemia is low, as heparin, direct thrombin inhibitors (argatroban, dabigatran, hirudin), elevated fibrin degradation products, paraproteins, and low levels of fibrinogen all prolong the thrombin time. The reptilase time has been used as an alternative screen and is useful in combination with the thrombin time. The assay involves inducing clot formation with an enzyme from a snake venom (*Bothrops jararaca* or *Bothrops atrox*) that releases fibrinopeptide A (but not fibrinopeptide B) from fibrinogen, and is

not sensitive to heparin or direct thrombin inhibitors. The apparent plasma concentration of fibrinogen as determined by the von Clauss method (see section on [Fibrinogen Deficiency](#)) may be low in some types of dysfibrinogenemia. Levels of immunoreactive fibrinogen are usually normal, but are decreased in cases of hypodysfibrinogenemia. With some variants, serum fibrin degradation products may appear to be elevated because the variant fibrinogen is incompletely incorporated into the clot. This can lead to the false impression that DIC is present.

Most dysfibrinogenemic patients are asymptomatic, and symptoms correlate poorly with coagulation assay abnormalities, making it difficult to make general therapeutic recommendations. The patient's personal and family histories are useful for guiding therapy. Active bleeding can be treated with replacement therapy as in afibrinogenemia, and such treatment may be indicated in some patients before invasive procedures. In general, patients with thrombosis and dysfibrinogenemia should be treated in the same manner as other patients with thrombosis. There are no data on which to formulate recommendations as to duration of therapy; thus past history, family history, coexisting conditions, and the nature (idiopathic, pregnancy-related or surgery-related) and seriousness of the thrombotic event are taken into consideration. As with any thrombotic event, the risk for bleeding associated with prolonged therapy must be considered. Recurrent spontaneous abortions have been associated with dysfibrinogenemia in several families, and pregnancies have been carried to term using replacement therapy. While some investigators recommend replacing fibrinogen starting early in pregnancy, as in afibrinogenemic patients, the prothrombotic nature of the peripartum period may dictate against this approach in certain patients.

PROTHROMBIN DEFICIENCY (OMIM 176930)

More than a century ago Morawitz proposed that insoluble fibrin is formed from fibrinogen through the activity of fibrin ferment or thrombin. Thrombin was generated from a precursor, prothrombin, by thrombokinase (probably factor Xa). Prothrombin and thrombin are designated factors II and IIa. Total prothrombin deficiency is probably not compatible with life. Complete absence of the protein has not been observed in a human, and prothrombin-deficient mice succumb to bleeding in utero or shortly after birth. Severe deficiency associated with reduced plasma prothrombin antigen (hypoprothrombinemia) or circulating dysfunctional prothrombin (dysprothrombinemia) affects about 1 in 2 million people ([Table 137.1](#)).¹¹ Prothrombin deficiency is the third most common coagulation factor disorder in Puerto Rico (carrier frequency about 1 in 700), accounting for 6% of congenital bleeding disorders other than von Willebrand disease at the University of Puerto Rico Hemophilia Center. In the North American Rare Bleeding Disorder Registry, 62% of patients with prothrombin deficiency were Latino, possibly reflecting the prevalence of the pArg457Gln variant prothrombin Puerto Rico I. Globally almost 70% of patients with prothrombin deficiency are of Latin or Hispanic origin.¹¹ Prothrombin is a 72,000-Da protein that is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces ([Fig. 137.1A](#)). Thrombin is the pivotal protease in hemostasis, with multiple procoagulant activities including cleavage of fibrinopeptides A and B from fibrinogen to form fibrin ([Fig. 137.3](#)), activation of factors V, VIII, XI, and XIII, and cleavage of protease activated receptors on a variety of cells including platelets.¹¹ Thrombin forms a complex with thrombomodulin on endothelial cells that downregulates fibrinolysis by activating thrombin-activatable fibrinolysis inhibitor (TAFI) and downregulates coagulation by activating protein C.

Prothrombin deficiency is an autosomal recessive disorder manifested as hypoprothrombinemia (reduced activity and antigen; cross-reactive material [CRM]–negative [CRM–] deficiency), dysprothrombinemia (activity reduced relative to antigen; CRM+ deficiency) or a combination of both.¹¹ Plasma prothrombin activity is typically 1% to 10% of normal in hypoprothrombinemia and 1% to 20% in dysprothrombinemia. Heterozygotes for either condition have 40%

to 60% normal activity. Approximately 50 prothrombin gene mutations have been described in patients with prothrombin deficiency, three-quarters of which are missense mutations.¹¹ In dysprothrombinemia, missense mutations typically cause defects in prothrombin conversion to thrombin (e.g., prothrombin pArg457Gln [Puerto Rico I] and pArg271Cys [Madrid]), or result in functionally defective thrombin (e.g., prothrombin pArg418Trp [Tokushima]).¹¹ Prothrombin deficiency can be inherited in combination with deficiencies of other vitamin K–dependent proteins (see [Combined Deficiency of Vitamin K–Dependent Proteins](#)).

Acquired prothrombin deficiency occurs with warfarin therapy, poisoning with rodenticides such as brodifacoum, vitamin K deficiency, liver disease, and DIC. Cephalosporins, particularly those with *N*-methyl-thiotetrazole side chains, can decrease prothrombin levels. Antiprothrombin antibodies are common phospholipid-dependent antibodies in patients with lupus anticoagulants or the antiphospholipid syndrome. More rarely, patients with a lupus anticoagulant or systemic lupus erythematosus have antibodies that enhance prothrombin clearance causing true deficiency. This acquired hypoprothrombinemia occurs primarily in children under 10 years of age, usually in association with lupus anticoagulants after a viral illness. These episodes typically resolve spontaneously but excessive bleeding can occur. There are no reports of neutralizing antibodies forming after replacement therapy in congenital prothrombin deficiency, consistent with patients having at least a trace of circulating prothrombin.

Severe hypoprothrombinemia is inevitably associated with bleeding that may be life threatening. In the EN-RBD survey prothrombin deficiency is classified as severe (<1% or normal), moderate (1% to 10%) or mild (> 10%) ([Table 137.2](#)).¹² CNS hemorrhage was reported in 8% to 12% of patients, and in 20% with prothrombin levels less than 1% of normal activity.^{11,12} Soft tissue hematomas, bruising (60%), and hemarthroses (42%) are common.¹¹ The bleeding diathesis can present at circumcision in neonates, with trauma or surgery, or as easy bruising, epistaxis, menorrhagia, or GI hemorrhage. Heterozygotes occasionally have excessive bleeding with surgery or tooth extraction, but most are asymptomatic.¹¹ Bleeding tends to be less severe in dysprothrombinemia, and some variants are particularly mild. For example, homozygosity for pArg67His causes severe reduction in plasma prothrombin activity (<20% of normal) but causes relatively few symptoms.

In the PT and aPTT assays, prothrombin is converted to thrombin by factor Xa in complex with factor Va on phospholipid surfaces ([Fig. 137.1B](#)), and severe prothrombin deficiency will prolong the clotting time in both tests. Some PT and aPTT reagents are relatively insensitive to reductions in prothrombin, and mild deficiencies may be missed. The diagnosis is usually confirmed, and the degree of deficiency established, by a modified PT assay using prothrombin-deficient plasma. A prothrombin antigen level is needed to distinguish between hypoprothrombinemia (activity and antigen are equivalent) and dysprothrombinemia (activity is less than antigen). Prothrombin deficiency must be distinguished from deficiencies of fibrinogen, factor V, or factor X, which also prolong the PT and aPTT.

Prothrombin complex concentrate (PCC) approved for use in factor IX deficiency typically contains an amount of prothrombin comparable to, or higher than, the factor IX activity. It is the preferred product for treating prothrombin deficiency ([Table 137.3](#)). PCC is derived from human plasma and undergoes viral inactivation. Hemostatic levels of prothrombin are estimated to be 20% to 40% of normal for major surgery or trauma, but 10% to 15% may be adequate for milder hemostatic challenges.¹¹ A PCC dose of 20 to 30 factor IX units/kg usually produces plasma prothrombin levels of 20% to 30% of normal in a severely deficient patient. The half-life of prothrombin is about 3 days, and dosing every 2 to 3 days can maintain adequate levels until healing is complete. Alternatively, one-fourth of the loading dose each day should keep the level therapeutic. Prophylactic infusion of PCC every 5 to 6 days prevented spontaneous bleeding in one severely deficient patient. PCC administration has been associated with thrombosis, although a meta-analysis of studies using PCC to reverse the effect of warfarin suggests the risk is

relatively low (<2%). It is reasonable to maintain the factor VII, IX, and X levels at less than 150% of normal to reduce risk. Dental procedures or minor hemorrhage may respond to antifibrinolytic therapy with ϵ -amino caproic acid.¹ Prothrombin deficiency may also be treated with FFP for bleeding episodes or surgical intervention (15 to 20 mL/kg loading dose followed by 3 mL/kg/day). Because of the long half-life, additional doses may not be required in all situations. Cryoprecipitate is not a source of prothrombin, and plasma prothrombin levels do not increase after infusion or inhalation of desmopressin (1-desamino-8-D-arginine vasopressin [DDAVP]).

The postviral hypoprothrombinemia seen in young children often spontaneously resolves. Intravenous immunoglobulin has been effective in this population. Treatment of acquired prothrombin deficiency associated with lupus anticoagulants in patients with autoimmune diseases often requires immune suppression. Steroids are effective in most patients, although many relapse during weaning or after stopping treatment. Subsequent treatment with azathioprine or cyclophosphamide has successfully eradicated the antibody. Rituximab has also been reported to be effective. In a rare case of quinidine-induced lupus anticoagulant with concomitant antiprothrombin antibody, cessation of the drug led to spontaneous resolution of acquired prothrombin deficiency, but not the lupus anticoagulant. The low prothrombin activity in these patients may protect them from thrombosis, as suggested by reports of thrombosis after successful eradication of the antiprothrombin antibody.

FACTOR V DEFICIENCY (OMIM 227400)

In 1943 Quick reported that aged plasma clotted more slowly than fresh plasma in a PT assay, and proposed that a labile factor distinct from prothrombin was required for coagulation. At the same time, Owren noted that a patient with a lifelong bleeding problem lacked a plasma factor that, unlike prothrombin, did not adsorb onto aluminum hydroxide. Owren's patient was deficient in the labile factor described by Quick, which is now called *factor V*. Moderate to severe congenital factor V deficiency (1%–10% of normal level) occurs in 1 in 1 million persons (Table 137.1).^{13,14} Full length factor V, a homolog of factor VIII, is the 330,000-Da precursor of the cofactor factor Va, which facilitates prothrombin activation by factor Xa on phospholipid surfaces (Fig. 137.1).^{13,14} During coagulation, the B-domain of factor V is removed by thrombin or factor Xa to produce factor Va (Fig. 137.4). An approximately 250,000-Da form of factor V lacking 703 amino acids from the B-domain is a minor constituent in normal plasma (Fig. 137.4). Referred to as factor V-short (or factor V East Texas), it is a product of an alternatively spliced mRNA. Most (80%) factor V in blood is in plasma, with the remainder stored in platelet α -granules.¹³ In humans, platelet factor V is primarily of plasma origin. It is taken up by megakaryocytes in a process requiring low-density lipoprotein receptor-related protein-1 (LRP-1), then converted to a partially activated form.¹³

Severe factor V deficiency is an autosomal recessive trait with undetectable (<1% of normal) plasma factor V. In moderate deficiency the level is between 1% and 10% of normal (Table 137.2).^{13,14} More than 100 factor V gene mutations have been described in factor V-deficient patients.¹³ Nonsense and frameshift mutations and splice variants are common and are distributed throughout the gene. Missense mutations cluster in the A2 and C2 domains,^{13,14} and usually result in abnormal polypeptides that are degraded within the cell, resulting in low plasma factor V antigen (CRM – deficiency). While it is estimated that approximately 25% of cases of factor V deficiency are CRM+ mutations (plasma antigen exceeds activity), only two have been characterized. The Ala221Val (factor V New Brunswick) and His147Arg substitutions appear to reduce factor Va activity by affecting protein stability.

Combined deficiency of factor V and factor VIII is caused by mutations in proteins required for secretion of both (see Combined Factor V and Factor VIII Deficiency).^{13,14} A few patients have been described with abnormalities specific to platelet factor V.¹³ The Quebec platelet disorder is an autosomal dominant condition with

Fig. 137.4 SCHEMATIC DIAGRAMS OF HUMAN FACTOR V AND FACTOR Va. In factor V the heavy and light chains (yellow) are separated by a central B domain (white, amino acids 710 to 1545) that contains a basic region (blue, amino acids 963 to 1008) and acidic region (red, amino acids 1493 to 1537). Removal of the B domain by thrombin to generate factor Va involves sequential cleavages after Arginine 709, 1018 and 1545. Factor V-short is the product of an alternatively spliced factor V mRNA that lacks residues 756 through 1458, which comprise most of the B domain including the basic region. In factor V-short, the loss of the B domain basic region leaves the acidic region free to bind to TFPI.

low platelet factor V and normal plasma factor V levels. In this syndrome, excessive proteolysis of α -granule proteins is caused by overexpression of urokinase. Platelet factor V activity is also reduced in factor V New York, but the underlying mechanism is not known.

The autosomal dominant condition East Texas bleeding disorder is caused by an A2440G nucleotide substitution in exon 13 of the factor V gene. The substitution increases levels of the alternatively spliced mRNA encoding Factor V-short (Fig. 137.4), leading to increased plasma levels of this protein. In East Texas bleeding disorder plasma levels of a key regulator of coagulation, tissue factor pathway inhibitor (TFPI), are 10-fold higher than normal. TFPI-mediated inhibition of factor Xa and the factor VIIa-tissue factor complex likely contributes to the bleeding. In factor V, the B-domain contains basic and acid regions that are thought to bind to each other (Fig. 137.4).¹³ In factor V-short, the basic region is missing, leaving the acidic region free to bind to TFPI, stabilizing it in plasma. A similar bleeding disorder was observed in a Dutch family with a C2588G substitution in exon 13 of the factor V gene, leading to alternative mRNA splicing and loss of 632 amino acids from the B domain (factor V Amsterdam). These patients also have markedly elevated plasma TFPI levels.

Acquired factor V deficiency may occur with liver disease, DIC, myeloproliferative disorders or systemic amyloidosis. Patients with acquired antibodies to factor V may have bleeding that can be severe, or may be asymptomatic. Alloantibodies to factor V were often associated with exposure to topical bovine thrombin during surgery, a problem that rarely occurs now because recombinant human thrombin preparations are used. Alloantibodies to factor V also occur in some factor V-deficient patients exposed to human plasma. Factor V autoantibodies may form after surgery or blood transfusions or with cancer, autoimmune disorders, or therapy with β -lactam or aminoglycoside antibiotics.

There is striking variability in bleeding symptoms among patients with severe factor V deficiency.^{13,14} Significant bleeding does occur, but the frequency tends to be less than in patients lacking factor VIII or factor IX. Several factors may contribute to the variability. Some patients with mild bleeding symptoms despite low plasma factor V levels have sufficient platelet factor V to support thrombin generation. This implies that their factor V is unstable in plasma, but can be taken up by platelets. Patients with severe bleeding may lack plasma and platelet factor V. In one such individual treated with

plasma, factor V was taken up by megakaryocytes and was detectable in platelets 2 weeks after it was no longer detectable in plasma. Many patients with factor V deficiency have reduced plasma TFPI levels, which may offset the need for factor V in thrombin generation.¹³ Mucosal bleeding is the primary abnormality, with 60% of patients experiencing epistaxis, menorrhagia, or oral bleeding. Hematomas and hemarthroses occur in 25%, but debilitating arthropathy is infrequent. Postpartum hemorrhage is common. Severe bleeding in the CNS or GI tract has been reported, but is relatively rare.^{13,14} Trauma, surgery, and dental extraction are associated with a high bleeding risk in untreated patients. Bleeding with surgery involving the urogenital tract, the nose, or the mouth may be particularly problematic because of high local fibrinolytic activity. Mild factor V deficiency (>10% of normal factor level) is usually not associated with excessive bleeding,^{13,14} although 10%–15% of patients report some symptoms.

Thrombosis has been reported in factor V–deficient patients.^{13,14} In some cases, the deficiency may not have prevented thrombosis. Indeed, with the exception of prothrombin or factor X deficiency, thrombotic events have been reported in all severe coagulation factor deficiency states. However, the situation with factor V is more complex. Deficiency can occur in patients with the common procoagulant polymorphism factor V Arg506Gln (factor V Leiden). If Arg506Gln and a mutation causing deficiency occur on opposite alleles (*in-trans*), most plasma factor V will have the Gln506 substitution, increasing the thrombotic risk (pseudohomozygous activated protein C resistance). Such patients usually do not bleed excessively, despite reduced plasma factor V antigen.

Factor V is required for normal prothrombin activation (Fig. 137.1B), and factor V deficiency causes prolongation of the PT and aPTT. The diagnosis and severity are established with a modified PT assay with factor V–deficient plasma. With severe deficiency the template bleeding time may be prolonged. Patients with factor V deficiency should be tested for factor VIII deficiency so that combined deficiency is not missed. Factor V inhibitors cause prolongations of the PT and aPTT that do not correct on mixing with normal plasma. As for factor VIII inhibitors, factor V inhibitor titers are established using the Bethesda method.¹⁶ However, unlike inhibitors to factor VIII, which typically take 1 to 2 hours to fully inactivate their target, factor V inhibitors inhibit factor V almost immediately. The thrombin time should be normal, except in cases of inhibition induced by bovine topical thrombin, where antithrombin antibodies are also present. In patients with the East Texas bleeding disorder or factor V Amsterdam the prolonged PT and aPTT are due to the inhibitory effects of TFPI. In these patients the PT and aPTT will not completely correct on mixing with normal plasma, and the factor V activity level will be normal.

No factor V concentrate is commercially available (Table 137.3). Administration of FFP is recommended for serious bleeding or prior to surgery. The minimum factor V level for hemostasis is 10%–15% of normal.^{1,2} In a patient with less than 1% plasma factor V, this can be achieved by administering 15 to 20 mL/kg FFP, followed by 5 mL/kg every 12 hours. A plasma level of at least 25% is recommended for major surgery. Estimates of the factor V plasma half-life vary widely, but 12 to 14 hours should be assumed for replacement purposes. Infusion of 20 mL/kg FFP (over 3 to 4 hours) before surgery, followed by 5 to 10 mL/kg every 12 hours is usually adequate. Infusions should be continued for 7 to 10 days to permit wound healing. Care must be taken to avoid fluid overload from large volumes of FFP. Plasma exchange has been successful in a few factor V–deficient patients requiring surgery. Mucosal bleeding from the nose and mouth may respond to ϵ -amino caproic acid, and superficial lacerations usually respond to local pressure. Although the defect caused by factor V deficiency would hypothetically render therapy with recombinant factor VIIa ineffective, this agent has been used successfully in a patient with severe factor V deficiency requiring surgery.

Menorrhagia is common in factor V–deficient women. Symptoms may be managed with antifibrinolytic therapy (ϵ -amino caproic acid 50 to 60 mg/kg every 4 to 6 hours or tranexamic acid 15 mg/kg every

6 to 8 hours), oral contraceptives, levonorgestrel-releasing intrauterine devices, replacement therapy, or surgical intervention (endometrial ablation or hysterectomy).⁷ Replacement should be adjusted to maintain a factor V level of 10%–15% of normal. Factor V–deficient women may have significant bleeding with childbirth and should be treated in a similar manner.

Platelets are a source of factor V and may be particularly useful in patients with severe bleeding or factor V inhibitors. Platelet factor V may either be protected from inhibition or may be sufficiently different in structure from its plasma counterpart to not cross-react with antibodies directed against factor V. However, platelet transfusions are not recommended as routine first-line treatment for factor V deficiency because of the possibility of developing antiplatelet alloantibodies. Cryoprecipitate is not a source of factor V, and plasma levels do not respond to administration of DDAVP.

FACTOR VII DEFICIENCY (OMIM 227500)

Factor VII deficiency was first reported by Alexander and colleagues in 1951. Severe factor VII deficiency is the most common of the nonhemophilic coagulation factor deficiencies (Table 137.1), with an estimated prevalence of 1 in 500,000 persons.

Factor VII is the 50,000-Da precursor of the protease factor VIIa. Factors VII and VIIa bind to tissue factor, and initiate coagulation through activation of factors X and IX (Fig. 137.1A). Factor VII levels correlate weakly with clinical presentation (Table 137.2). Mice lacking factor VII develop normally in utero but succumb to bleeding at birth. An infant born lacking factor VII died from intracranial hemorrhage 12 days after birth, while another survived with replacement therapy. Thus low levels of factor VII appear to be necessary to sustain life. Activity levels of <10%, 10%–20%, and >20% have been proposed as criteria to classify deficiency as severe, moderate, or mild, respectively.¹² However, many patients with levels <10% will not have significant bleeding, even with invasive procedures. A classification system based on clinical presentation has also been suggested. Although factor VII deficiency is considered an autosomal recessive trait, the observation that bleeding symptoms are reported in up to one-third of patients with heterozygous deficiency raises questions about this concept.

More than 200 factor VII gene mutations associated with factor VII deficiency have been described, well over half of which are missense mutations. Most have been identified in single families, but some are widespread. In surveys of patients from Europe and Latin America, pAla244Val accounted for 84% of abnormal factor VII alleles in 88 unrelated Jewish patients, and in 14% and 7% of abnormal factor VII alleles in Germany and France, respectively. CRM+ variants are common. Some factor VII variants demonstrate variable activity in PT assays, depending on the species of origin of the tissue factor used. The name “factor VII Padua” has been applied to these variants, many of which have an Arg304Gln substitution that causes a defect in the interaction with tissue factor from rabbits, but not humans or oxen.

Factor VII deficiency may occur in combination with deficiencies of other vitamin K–dependent proteins (see [Combined Deficiency of Vitamin K–Dependent Proteins](#)) and in combination with factor X deficiency as a result of loss of both genes due to a chromosome 13 q34 deletion. Factor VII deficiency has also been reported in cases of trisomy 8 and in conjunction with abnormalities of bilirubin metabolism, mental retardation, microcephaly, epicanthus, cleft palate, and patent ductus arteriosus.

Reduced levels of factor VII occur with warfarin therapy, poisoning with rodenticides such as brodifacoum, liver disease, DIC, biliary tract disease, vitamin K deficiency, and cephalosporin therapy. In these situations other vitamin K–dependent factors are usually decreased, although the effect on factor VII is often greater because of its short half-life. Alloantibody inhibitors to factor VII have been reported in deficient patients after replacement therapy. Acquired factor VII deficiency has been reported as a paraneoplastic syndrome with atrial myxoma and Wilms tumor. Other scenarios rarely

associated with low factor VII include hematopoietic stem cell transplantation, aplastic anemia, and sepsis.

The clinical spectrum of bleeding in factor VII deficiency is broad.¹⁵ Not surprisingly, significant bleeds tend to be most frequent with severe deficiency and patients with levels less than 1% of normal may have a syndrome similar to severe hemophilia, with joint and soft tissue bleeding and hemarthrosis-related arthropathy. The best predictor of future bleeding risk seems to be the nature of bleeding (or its absence) at the time of diagnosis.¹⁵ CNS hemorrhage is relatively common (4% to 17%). Patients with factor VII activity of $\geq 5\%$ of normal tend to have milder symptoms (epistaxis, menorrhagia, and bruising). Although little bleeding occurs in most patients with factor VII levels $\geq 10\%$ of normal, some have significant bleeding spontaneously or in response to hemostatic challenges. In one study, 36% of heterozygotes (factor VII activity 21% to 69%) reported bleeding problems, mostly involving skin and mucous membranes, whereas another study reported a greater risk for subcutaneous bleeding in heterozygotes. Bleeding often complicates tooth extraction and surgery on the oropharynx or urogenital tract in untreated patients. Abdominal surgery and hysterectomy are associated with fewer problems. Postpartum bleeding is not common in factor VII-deficient women because factor VII levels rise in late pregnancy in all but the most severely deficient patients. Risk of postpartum hemorrhage correlates poorly with FVII level, leading some to suggest that recombinant factor VIIa be available for excessive bleeding if it occurs.

Thrombosis associated with factor VII deficiency is well documented. A study of 33 reported cases (6 arterial, 27 venous) revealed 15 with molecular studies. Nearly all patients had other thrombotic risk factors, usually acquired, and four had congenital thrombophilia. Of the 15 patients, 11 had either pArg304Gln (factor VII Padua) or pAla294Val. Those with factor VII Padua had no bleeding history, while mild bleeding was reported with pAla294Val. Treatment with vitamin K antagonists is problematic because the baseline PT is abnormal as a result of the mutation. Therapy with low-molecular-weight heparin or one of the newer direct oral anticoagulants may be a better option.

In factor VII deficiency, the PT is prolonged and the aPTT is normal. The diagnosis is confirmed, and the severity determined, by a modified PT assay using factor VII-deficient plasma. With very sensitive thromboplastin reagents, the PT may be prolonged with factor VII levels at the lower end of the normal range. When assessing patients for factor VII deficiency, the source of the tissue factor must be considered. Factor VII Padua-type variants interact poorly with the rabbit tissue factor-based reagents widely used in North America; they function better with human tissue factor and best with ox tissue factor. We routinely retest patients with apparent factor VII deficiency in rabbit tissue factor-based assays with a human tissue factor thromboplastin reagent to detect Padua-type variants.

Major considerations when treating factor VII-deficient patients include the short plasma half-life of the protein (3 to 4 hours), relatively low recovery of infused material (possibly due to a large volume of distribution), and rapid clearance in children.¹⁶ A plasma factor VII level of 15% of normal is probably the minimum required for surgery, with 15% to 25% being adequate in most cases. Of 157 surgeries performed on 83 factor VII-deficient patients with a mean baseline activity of 5% who did not receive prophylaxis, 15.3% had bleeding complications, suggesting that supplementing patients with baseline levels below 10% should prevent bleeding. Factor replacement can be accomplished with several products (Table 137.3). FFP is widely used, but its effectiveness is limited because of the large volumes required. PCC contains variable amounts of factor VII; however, these products contain other vitamin K-dependent factors in higher concentrations than factor VII, which could increase the risk for thrombosis. Recombinant factor VIIa (rFVIIa) is the preferred therapy for treating or preventing bleeding in factor VII deficiency. A prospective registry of FVII deficient patients recorded the replacement therapy given for various bleeding events (hemarthrosis, soft-tissue hematomas, epistaxis, gum bleeding, menorrhagia and others) and found that the majority responded adequately to a single relatively large dose of rFVIIa (60 $\mu\text{g/kg}$).¹⁶ The exception was treating

menorrhagia, which often required subsequent doses.¹⁶ Prophylaxis for invasive procedures may require treatment every 2 to 3 hours. In a study of 41 surgeries in 34 factor VII-deficient subjects receiving rFVIIa, bleeding occurred in only three instances, and in those, the rFVIIa dose was considered low. The minimum treatment that adequately prevented bleeding was 13 $\mu\text{g/kg/dose}$, and no less than three doses given on the day of surgery. However, patients may do quite well with much less. In one report, two doses on the day of surgery followed by daily dosing successfully controlled bleeding. Continuous infusion rFVIIa has been used to cover surgical procedures and may reduce the total amount of drug administered by 70% to 90% compared with bolus infusions.

Patients with severe factor VII deficiency who have experienced life-threatening bleeding may benefit from secondary prophylaxis, particularly if bleeding involved the CNS (50% to 70% mortality). FFP and plasma-derived factor VII concentrate have been used, but rFVIIa is the preferred agent. Interestingly, despite its short half-life, rFVIIa is effective at doses of 20 to 30 $\mu\text{g/kg}$ given 2 to 3 times per week.¹⁷ The large volume of distribution for both rFVIIa and plasma-derived FVII may explain this effect. In one registry, inhibitors were reported in 4 of 225 patients with activity levels less than 4% who received replacement. All were high titer responders (three developed in infancy). Not all bleeding episodes in factor VII-deficient patients require factor replacement. Minor injuries may be controlled with local measures. Fibrinolytic inhibitors, such as ϵ -amino caproic acid, may be effective for minor bleeding, dental surgery, or other procedures involving mucous membranes. Fibrin glue may also be effective.² Cryoprecipitate is not a source of factor VII. Plasma levels do not respond to administration of DDAVP. An infant with severe deficiency was cured with liver transplantation. AAV-vector gene therapy has shown promising results in mice and macaques, raising FVII levels to therapeutic ranges.

FACTOR X DEFICIENCY (OMIM 227600)

Factor X deficiency was first described in two patients more than 50 years ago. The missing plasma factor was called *Stuart-Prower factor* after the two index cases, and subsequently designated factor X. Patient Stuart was thought to have factor VII deficiency, but mixing his plasma with factor VII-deficient plasma corrected the clotting defect. Patient Prower had multiple coagulation assay abnormalities. The prevalence of severe factor X deficiency is estimated at approximately 1 in 1 million persons (Table 137.1).¹⁸ Factor X is a 58,000-Da protein that is the precursor of the protease factor Xa. Factor X is activated by the factor VIIa/tissue factor complex and by the factor IXa/factor VIIIa complex (Fig. 137.1A). Factor Xa catalyzes conversion of prothrombin to thrombin, and the conversion of factor V to factor Va.

Congenital factor X deficiency is an autosomal recessive trait. Factor X-deficient mice die in utero or shortly after birth from bleeding, indicating the protein is necessary for life. Humans with the severest form of factor X deficiency (activity $<1\%$ of normal) probably have a trace of factor X in their plasmas. More than 100 factor X gene mutations have been identified in factor X-deficient patients. Most are missense mutations and many are CRM+ variants.¹⁸ A three part classification system has been proposed. Type I deficiencies involve CRM-mutations, and include patient Stuart (homozygous for Val298Met). Type II deficiencies are CRM+ variants lacking activity, and include patient Prower (compound heterozygote for Arg287Trp and Asp282Asn). Type III deficiency includes variants that are activated normally by Russell viper venom but not by factor VIIa/tissue factor or factor IXa/VIIIa, variants defective only in activation by factor VIIa/tissue factor, variants defective only in activation by factor IXa/VIIIa, and variants with higher activity in chromogenic assays than clotting assays. Factor X deficiency can be inherited with deficiencies of other vitamin K-dependent proteins (see Combined Deficiency of Vitamin K-dependent Proteins) and in combination with factor VII deficiency when both genes are lost due to a chromosome 13 q34 deletion.

Acquired factor X deficiency occurs with warfarin therapy, poisoning with rodenticides such as brodifacoum, vitamin K deficiency, liver disease, and DIC, all of which reduce levels of other coagulation factors. Factor X deficiency has been reported with malignancies, infections, burn injury,²⁰⁴ proteinuria, and medications. There are rare reports of acquired factor X inhibitors, most of which resolve after treatment of underlying conditions.¹⁹ Acquired factor X deficiency may accompany systemic amyloidosis, occurring in 8.7% to 14% of patients with AL amyloidosis, but rarely in secondary (AA) amyloidosis.²⁰ Factor X binds to amyloid fibrils, which reduces the plasma half-life of the protein. Distinguishing this disorder from inherited factor X deficiency is based on the clinical setting and evidence of poor clinical response to infusion of factor X-containing products in amyloidosis patients.

A clinical classification system for factor X deficiency has been proposed based on factor X activity (severe, <10%; moderate, 10%–40%; mild, >40% of normal activity) (Table 137.2). Bleeding in factor X deficiency is severe and occurs earlier in life in patients with the lowest plasma levels.¹⁸ There is an impression that factor X-deficient patients bleed more severely than patients with other congenital coagulopathies. In a series of 102 factor X-deficient patients, the most frequent symptom was easy bruising (55%) followed by hematomas (43%). Epistaxis and hemarthrosis were common. Intracranial hemorrhage was seen in patients homozygous for the pGly380Arg mutation. Among homozygotes, hemarthrosis was very common, and all women suffered from menorrhagia. Umbilical stump bleeding occurred in 28% of newborns. Moderate to mildly affected persons (activity >10%) may have increased bruising or bleeding with trauma. While heterozygotes tend to be asymptomatic, up to one-third may have excessive bleeding from mucous membranes with invasive procedures, or with childbirth.

Because factor X is a component of the common pathway of coagulation (Fig. 137.1B), its absence prolongs the PT and aPTT, and factor X deficiency must be distinguished from deficiencies of fibrinogen, prothrombin, or factor V. Definitive diagnosis and determination of severity are established using a modified PT or aPTT assay with factor X-deficient plasma. Some factor X variants preferentially prolong either the PT or the aPTT. Congenital factor X deficiency cannot be distinguished from acquired deficiency due to amyloidosis in the laboratory, because factor X-dependent assays correct after mixing with normal plasma in both conditions. The absence of a lifelong bleeding disorder, findings of a serum M-protein, signs of amyloidosis, and histologic confirmation of amyloid in tissues point toward AL amyloidosis. A poor response to factor X infusion in the absence of an inhibitor also distinguishes the two conditions.

Factor X-deficient patients are treated with FFP or PCC for bleeding episodes (Table 137.2).¹⁸ A trough level of 10% to 20% is usually sufficient for hemarthroses and soft tissue bleeding. The half-life of factor X is 20 to 40 hours. FFP administered as a loading dose of 10 to 20 mL/kg followed by 3 to 6 mL/kg every 12 to 24 hours usually keeps trough levels above 10 to 20%.^{2,18} Higher factor X levels may be required for severe bleeding or surgery, and accumulation of factor X in plasma can be achieved by increasing the transfusion frequency to every 12 hours. PCCs with a factor X to factor IX ratio of approximately 1 : 1 will increase plasma factor X levels by 1.5% for each factor IX unit/kg body weight. A dose of 15 to 20 factor IX units/kg every 1 to 2 days has been suggested for major surgery.^{2,18} While no patient with congenital factor X deficiency has been reported to have thrombosis, there is a risk of thrombosis or DIC with PCC, and it is recommended that the plasma factor X level not exceed 50% of normal when using these products, unless absolutely necessary. Factor X levels will rise slightly in pregnancy, but severely deficient patients will require prophylaxis with invasive procedures and at delivery to prevent hemorrhage. A factor X level of 20%–40% is recommended. For patients with severe deficiency and recurrent hemorrhage, prophylactic PCC or factor X concentrate infusion is effective.¹⁸ Minor bleeding can be treated with local measures and/or ϵ -amino caproic acid. Cryoprecipitate lacks factor X, and DDAVP infusion does not affect factor X levels. A factor X concentrate is now

approved for clinical use in the United States and Europe and is considered the treatment of choice. As with prothrombin deficiency, there are no reports of acquired alloantibody inhibitors to factor X after replacement therapy in congenitally deficient patients, consistent with the concept that these patients have trace amount of plasma factor X at baseline. Severe factor X deficiency was cured by liver transplantation in a child.

Patients with acquired factor X deficiency and amyloidosis have variable responses to infusion of products containing factor X, making individual pharmacokinetic studies of factor X replacement therapy important. Treatment may involve chemotherapy, splenectomy, plasma exchange, PCCs,²¹ activated factor VIIa and factor X concentrate. The optimal hemostatic management for invasive procedures has not been determined. In one series, complications occurred in only 13% of procedures, and there was a poor correlation between the risk for bleeding and factor X levels.

FACTOR XI DEFICIENCY (OMIM 264900)

In 1953 Rosenthal and colleagues described three members of a family with abnormal hemostasis, prolonged time to clot formation in a glass tube, and a normal PT. In mixing studies, patient plasma shortened the clotting times of hemophilia A and B plasmas, indicating the missing factor was distinct from factors VIII and IX. Unlike the X-linked hemophilias, the new disorder (sometimes called hemophilia C) was transmitted as an autosomal trait. The missing factor was called *plasma thromboplastin antecedent* and subsequently *factor XI*. It is estimated that severe factor XI deficiency (<15% of normal plasma level) occurs in 1 per million persons (Table 137.1), although perhaps this number should be higher, as patients with milder deficiencies are often symptomatic. Severe factor XI deficiency is common in persons of Ashkenazi Jewish ancestry (incidence of 1 in 450).²² Factor XI is the precursor of the 160,000-Da protease factor XIa, which contributes to clotting by activating factor IX (Fig. 137.1A). The protein is a homodimer, a feature that has implications for inheritance of factor XI deficiency. Factor XI is activated by factor XIIa in the aPTT assay (Fig. 137.1B); however, it is probably activated by other proteases in vivo because factor XII deficiency does not cause abnormal bleeding. For example, factor XI is also activated by thrombin (Fig. 137.1A).

Factor XI deficiency in the Jewish population and in many other patients is an autosomal recessive condition.²² Two point mutations account for over 90% of mutant factor XI alleles in Ashkenazi Jews. Glu117Stop encodes a truncated protein, and homozygotes lack plasma factor XI.²³⁷ Glu117Stop is at least 2500 years old and is found in Jews from different ethnic backgrounds, and non-Jewish patients. Phe283Leu, occurs primarily in Jews of European ancestry and is likely of recent origin. It causes a defect in dimer formation resulting in poor secretion; with homozygotes having about 10% of normal plasma factor XI activity. Compound heterozygotes for Glu117Stop and Phe283Leu have about 3% normal activity, while heterozygotes for either mutation have activities of 50% to 60%. The allele frequencies of Glu117Stop and Phe283Leu in Ashkenazi Jews (2.2% and 2.5%, respectively) indicate a carrier frequency for an abnormal factor XI allele of approximately 5%.

More than 200 human factor XI gene mutations have been identified, and several are relatively widespread with evidence of founder effects.²² Cys38Arg has an allele frequency of 0.5% in French Basques, Cys128Stop accounts for 10% of abnormal alleles in Great Britain, and Gln88Stop is present in several families from France. In most deficient patients, factor XI activity and antigen are comparably reduced (CRM – deficiency). CRM+ factor XI mutations are rare. A three-category scheme has been proposed for classifying CRM – factor XI deficiency. Category one contains mutations that prevent protein synthesis (e.g., Glu117Stop), while mutations in category two interfere with dimer formation (e.g., Phe283Leu). Inheritance in both categories follows a recessive pattern, because mutant polypeptides do not interfere with the product of the normal allele in heterozygotes. Category three includes mutations that impair secretion

but do not prevent dimer formation (e.g., Gly400Val). In heterozygotes, mutant and wild-type polypeptides form nonsecretable dimers, trapping normal protein in the cell. This phenomenon likely accounts for families in which severe to moderate factor XI deficiency appears to be a dominant trait.

Factor XI levels decrease in liver disease and DIC but are not affected by vitamin K deficiency or warfarin therapy. Mild to moderate factor XI deficiency occurs in approximately 25% of patients with Noonan syndrome and is common in carbohydrate-deficient glycoprotein syndrome, a group of inherited disorders involving defects in glycosylation of secretory glycoproteins. Antibody inhibitors to factor XI are common after replacement therapy, particularly in patients with no circulating factor XI. For example, one-third of individuals homozygous for Glu117Stop develop inhibitors, often after a single exposure to plasma.

Bleeding in severe factor XI deficiency is usually injury-related and is most frequent in tissues with robust fibrinolytic activity, such as the oral and nasal cavities, and the urinary tract.²² Injury to these areas causes excessive bleeding in two-thirds of patients, regardless of genotype. Bleeding with injury at other locations is less frequent and tends to occur in those with the lowest factor XI levels. Bleeding may start at the time of injury or be delayed by hours, and oozing from tooth extraction may persist for days. Excessive bleeding with skin laceration, circumcision, appendectomy, and orthopedic surgery is infrequent; spontaneous bleeding (except for menorrhagia) is uncommon. In a clinical trial testing reduction of plasma factor XI as prophylaxis for venous thrombosis in knee replacement surgery, bleeding was rare despite the fact that factor XI levels were less than 5% at the time of surgery in some patients.

Bleeding correlates poorly with plasma factor XI activity (Table 137.2).^{22,23} Patients with severe deficiency may not bleed excessively, even during surgery, and a patient may exhibit different bleeding tendencies over time. Opinions differ regarding the propensity to bleed with mild deficiency (plasma level 20%–50%). Some studies describe minimal bleeding with tooth extraction, tonsillectomy, nasal surgery, and urologic surgery, while others report difficulty distinguishing severe and mild deficiency on clinical grounds.^{22,23} In a study of 45 families, the odds ratios for excessive bleeding were 13.0 and 2.6 for homozygotes and heterozygotes, respectively. Thus mild deficiency may confer a slightly increased risk for bleeding, but not as much as severe deficiency. A recent analysis indicated that ristocetin cofactor activity is significantly lower in symptomatic patients with heterozygous factor XI deficiency, compared with nonbleeders, raising the possibility that von Willebrand factor levels influence bleeding propensity. Recent work suggests that thrombin generation tests and analyses of fibrin clot structure can predict the propensity to bleed, but these findings require confirmation in prospective studies.

In the aPTT assay, factor XI is bound to the contact surface through high-molecular-weight kininogen (HK) and is activated by factor XIIa (Figs. 137.1B and 137.5). Factor XIa, in turn, activates factor IX. Therefore, factor XI deficiency prolongs the aPTT, but not the PT. Diagnosis and severity are established by a modified aPTT assay using factor XI-deficient plasma. The aPTT is often normal in heterozygotes.

Perioperative therapy should be individualized for factor XI-deficient patients (see box on [Treating Factor XI-Deficient Patients](#)). For those requiring replacement, FFP or factor XI concentrate (Hemoleven or FXI concentrate) (Table 137.2), effectively prevent bleeding.²⁴ The half-life of factor XI is 45 to 52 hours, facilitating daily or every-other-day dosing. Hemoleven has orphan drug status in the United States. A 3-year postmarketing analysis of this concentrate indicated that it was effective as prophylaxis for surgery, invasive procedures, and pregnancy, and for treating bleeding.²⁵ However, it is recommended that concentrates be used sparingly due to potential prothrombotic effects. In the past, factor XI concentrates were associated with thrombosis and DIC, mostly in older patients with cardiovascular disease receiving doses over 30 units/kg.²² However, more recent analyses indicate that patients receiving 20 to 30 units/kg also have thrombotic events. Based on this, it has been suggested that the

Fig. 137.5 CONTACT ACTIVATION. In the activated partial thromboplastin time assay, contact activation is initiated by conversion of factor XII (XII) to α -factor XIIa (XIIa) (reaction 1) when plasma is exposed to a negatively charged surface (*light green disk*). Factor XIIa converts prekallikrein (PK) to the active protease α -kallikrein (reaction 2), and α -kallikrein reciprocally activates additional factor XII (reaction 3). Factor XIIa initiates coagulation through conversion of factor XI (XI) to factor XIa (XIa) (reaction 4). PK and factor XI require high-molecular-weight kininogen (HK) to bind properly to the surface. Factor XIa ultimately promotes thrombin generation and fibrin clot formation through activation of factor IX (see Fig. 137.1).

initial dose should not exceed 10 to 15 units/kg, and concentrates should be used with caution (or avoided) in patients with a history of thrombosis, or risk factors for thrombosis.² Antifibrinolytic therapy should probably not be used concomitantly with concentrate. Cryoprecipitate does not contain factor XI.

Circumcision, orthopedic surgery, and appendectomy carry a low bleeding risk, and replacement can often be withheld unless bleeding occurs.²⁵ A similar “wait and see” approach has been proposed for factor XI-deficient women during labor and delivery, which is associated with a relatively low (~20%) rate of excessive bleeding.²² However, others advocate replacement for childbirth.² Dental procedures such as tooth extraction can be covered with antifibrinolytic therapy.²² The effectiveness of DDAVP in mild factor XI deficiency is not established, but there are reports that levels increase in response to this drug. Factor XI-deficient patients with inhibitors do not usually have increased spontaneous bleeding. Recombinant factor VIIa has been used successfully for surgery in factor XI-deficient patients with and without inhibitors, and to cover epidural block in deficient women during labor and delivery.

DEFICIENCIES OF FACTOR XII, PREKALLIKREIN OR HIGH-MOLECULAR-WEIGHT KININOGEN

Factor XII, prekallikrein, and HK are required for normal factor XI activation in the “contact phase” that initiates coagulation in the aPTT assay (Figs. 137.1B and 137.5). Patients lacking one of these proteins have prolonged aPTTs, but do not have abnormal hemostasis, even with surgery or injury. Therefore, these proteins either do not participate in hemostasis, or redundant mechanisms compensate for their absence. No specific therapy is required to prepare deficient patients for invasive procedures. Factor XII, prekallikrein or HK deficiency must be distinguished from deficiencies of factors VIII, IX, or XI, which prolong the aPTT, but cause abnormal hemostasis.

Factor XII Deficiency (OMIM 234000)

In 1955 Ratnoff and Colopy described asymptomatic individuals with a novel abnormality of surface-induced coagulation. The missing plasma component was called *Hageman factor*, after the index case,

Treating Factor XI–Deficient Patients

When preparing patients with severe factor XI deficiency (plasma factor XI level <15%–20% of normal) for an invasive procedure it is important to keep in mind that (1) a negative bleeding history does not indicate a low risk with subsequent procedures, (2) certain procedures are associated with lower bleeding risks than others, and (3) patients with very low factor XI levels (<1%) frequently develop neutralizing inhibitors after replacement therapy. These observations have led to refinements in treatment recommendations that limit exposure to factor XI by targeting replacement to certain clinical situations. In the Jewish population, patients with severe deficiency have more bleeding problems than those with mild deficiency, but this does not appear to hold for the general population. The poor correlation between plasma factor XI level and bleeding propensity means that some patients with mild deficiency (levels of 20%–40% of normal) may require factor replacement for certain types of procedures, such as surgery on the prostate or on the oral and nasal cavity.

Antiplatelet drugs should be stopped one week before surgery. The prothrombin time and platelet count should be normal, and the possibility of co-existing hemostatic abnormalities thoroughly investigated. Patients with factor XI levels greater than 40% to 50% of normal generally do not experience abnormal bleeding, and a history of excessive bleeding in such an individual suggests other hemostatic abnormalities are present. If the patient has been exposed to factor XI in the recent past, the possibility that a neutralizing inhibitor is present should be considered.

Factor replacement is required for most major surgery in factor XI deficient patients, and should be initiated prior to the procedure. Surgery on the oropharynx, nasopharynx or urinary tract should be treated with fresh frozen plasma (FFP) or factor XI concentrate to keep the plasma trough factor XI level above 40% of normal for at least seven days. Administering FFP at 15 mL/kg every 1 to 2 days is the most common way to achieve this. A similar strategy is appropriate for neurosurgery, head and neck surgery, cardiothoracic procedures, and major abdominal or pelvic surgery. For nasal surgery and oral procedures such as tonsillectomy, supplementing FFP therapy with antifibrinolytic therapy should be considered. Antifibrinolytics must be used with caution in patients receiving factor XI concentrate because of the potential for thrombotic events. For prostatectomy and other surgery on the lower urinary tract, flushing the bladder with saline containing an antifibrinolytic agent may be beneficial. In some types of minor surgery patients may receive replacement to maintain levels of 30% for 5 days. However, a “wait and see” strategy in which replacement is withheld unless bleeding

occurs appears to be appropriate for procedures such as circumcision, appendectomy and some orthopedic surgery, and with normal vaginal deliveries. In a recent phase 2 trial in which antisense oligonucleotide therapy was used to reduce plasma factor XI as prophylaxis to prevent venous thrombosis in total knee arthroplasty, patients underwent surgery with factor XI levels as low as a few percent of normal, without excessive bleeding. This demonstrates that factor XI probably plays a minor role, at most, in hemostasis during certain types of procedures. In pregnancy, there is little data to evaluate the safety of epidural anesthesia in the absence of factor coverage, and replacement therapy is generally advised.

Low doses of recombinant factor VIIa (15–30 µg/kg) every 2 to 4 hours in conjunction with antifibrinolytic therapy has been used successfully in lieu of replacement therapy in patients without factor XI inhibitors undergoing surgery. This strategy may be preferable to factor replacement in some patients with very low plasma factor XI levels (<1% of normal) because of their propensity to develop neutralizing antifactor XI antibodies. In patients with known factor XI inhibitors, a strategy based on a single dose of recombinant factor VIIa (15–30 µg/kg) followed by antifibrinolytic therapy maintained hemostasis in several patients undergoing major surgery, including a patient who required repair of an aortic dissection. The higher doses of factor VIIa typically used to treat patients with factor VIII inhibitors are not required in factor XI deficient patients with or without inhibitors, and should not be used as they may increase the risk of thrombotic complications.

Alternatives to factor replacement are recommended in several situations. Tooth extraction or skin biopsies can be managed with antifibrinolytic drugs alone (ε-amino caproic acid 5 to 6 g q6 hours or tranexamic acid 1 to 1.3 g q6 hours), starting 12 hours before the procedure and continuing for seven days. Dental procedures such as scaling or root canal can be performed safely using ε-amino caproic acid or tranexamic acid mouthwash prepared from the intravenous formulation three to four times daily with or without systemic antifibrinolytic therapy. Fibrin glues can be used in place of fibrinolytic therapy for skin biopsy or resection of skin lesions.

Patients with factor XI deficiency can experience thromboembolic episodes. Aspirin or clopidogrel can be used in factor XI-deficient patients with myocardial infarction or other manifestations of atherosclerosis, while atrial fibrillation or venous thromboembolism should be treated with warfarin, with the goal of not allowing the international normalized ratio (INR) to exceed 2.5.

and later designated *factor XII*. The incidence of severe factor XII deficiency is not known as many deficient persons likely go undiagnosed. Factor XII deficiency was reported in 1.5% to 3.0% of healthy blood donors. This high number may be partly explained by antifactor XII or antiphospholipid antibodies that interfere with factor XII activity assays. α-Factor XIIa, the activated form of factor XII, is an 80,000-Da protease that activates factor XI and prekallikrein in the contact phase of the PTT assay (Fig. 137.5). A C/T polymorphism in the 5′-untranslated region of the factor XII gene (referred to as 46C/T [or –4C/T]) strongly influences plasma factor XII levels. The frequency of 46T is high (73%) in Japanese and Han Chinese individuals who have lower factor XII levels than members of other ethnic groups, compared to 20% in whites. Factor XII activity and antigen are usually reduced in parallel, and circulating dysfunctional variants are rare.

About thirty factor XII gene mutations have been identified. Factor XII deficiency is not associated with spontaneous or excessive posttraumatic bleeding, and most cases are identified by the incidental finding of a prolonged aPTT. There is conflicting literature regarding an association between factor XII deficiency and thrombosis. Two studies reported an inverse relationship between plasma factor XII levels within the broad normal range and the risk of cardiovascular events; however, most work indicates that severe deficiency does not prevent thrombosis or increase its risk. A meta-analysis of studies examining the 46C/T factor XII gene polymorphism suggests that the correlation between the polymorphism and venous thrombosis or myocardial infarction, if present, is weak. There are reports linking

low factor XII levels to pregnancy loss or failure of in vitro fertilization. Interestingly, factor XII deficient mice do not display an abnormality in reproduction. It is possible that antibodies that interfere with factor XII function, rather than true deficiency, are responsible for pregnancy-related complications in humans.

Factor XII undergoes autoactivation when exposed to the contact surface used to initiate clotting in the aPTT assay. Factor XIIa activates prekallikrein to α-kallikrein, which reciprocally activates additional factor XII (Fig. 137.3). Factor XIIa also activates factor XI to XIa. In severe factor XII deficiency the aPTT is very long. Definitive diagnosis is established using a modified aPTT with factor XII-deficient plasma. Antiphospholipid antibodies may disproportionately affect factor XII measurements in aPTT-based assays. Factor XII antibodies are present in up to half of plasmas with antiphospholipid antibodies, and may account for many cases of presumed mild factor XII deficiency.

Prekallikrein Deficiency (OMIM 229000)

In 1965 Hathaway and coworkers described members of a family with long plasma clotting times that corrected on prolonged incubation with glass. They did not have histories of abnormal hemostasis. The missing plasma component, initially called *Fletcher factor* after the index cases, was subsequently shown to be prekallikrein. Severe prekallikrein deficiency appears to be rare. Mild cases may be missed because a low level of prekallikrein activity is often sufficient to bring

many PTT assays into the normal range. Prekallikrein is the 95,000-Da precursor of the protease α -kallikrein. Prekallikrein deficiency is an autosomal trait, presenting in the homozygous or compound heterozygous forms with plasma levels usually less than 1% of normal. CRM+ variants account for about half of cases, and are common in white and Japanese patients, while most black patients are CRM-. Partial deficiency (10%–50%) may be seen in patients with severe HK deficiency, likely due to increased clearance because prekallikrein circulates in complex with HK. Severe prekallikrein deficiency presents as a prolongation of the aPTT in a person without a history of excessive bleeding. While thrombotic events have been described in deficient patients, it is not clear that the deficiency contributed to thrombosis. Indeed, studies in mice indicate that reducing prekallikrein levels actually attenuates thrombus formation. A recent analysis raised the possibility that the incidence of hypertension may be higher in prekallikrein deficient individuals than the general population, possibly related to reduced bradykinin formation.

In the aPTT assay, prekallikrein is converted to α -kallikrein by factor XIIa, which then activates factor XII (Fig. 137.5). Severe prekallikrein deficiency causes a prolonged aPTT, and the diagnosis is confirmed using a modified aPTT with prekallikrein deficient plasma. The prolonged aPTT in prekallikrein deficiency may be shortened by increased incubation time with the contact reagent, which facilitates factor XII activation independently of prekallikrein. This distinguishes prekallikrein deficiency from deficiencies of factors VIII, IX, XI, XII, and HK, in which the prolonged aPTT does not correct with prolonged incubation. Those aPTT reagents that use ellagic acid as the contact activator are relatively insensitive to prekallikrein, and may fail to detect some deficient patients.

High-Molecular-Weight Kininogen Deficiency (OMIM 228960)

In 1974 Schiffman and Lee reported that a plasma factor distinct from prekallikrein was required for factor XI activation by factor XIIa. In 1975 asymptomatic individuals from three distinct families were described with in vitro abnormalities of coagulation, fibrinolysis, and kinin generation who appeared to lack the unknown factor. The condition, originally named for the affected families (Fitzgerald trait, Williams trait, and Flaujeac trait), was subsequently determined to be due to HK deficiency. The disorder appears to be very rare. HK is a 110,000-Da protein containing the vasoactive peptide bradykinin. Prekallikrein and factor XI circulate in complex with HK. Low-molecular-weight kininogen and HK are products of a single kininogen gene; however, low-molecular-weight kininogen does not play a role in coagulation in vitro. HK deficiency is an autosomal recessive trait. Depending on the genetic abnormality, patients may have isolated HK deficiency or combined HK and low-molecular-weight kininogen deficiency. HK deficient patients are usually identified by the incidental finding of a prolonged aPTT, and they do not bleed excessively.

In the aPTT assay, HK facilitates binding of prekallikrein and factor XI to the contact surface, enhancing their activation by factor XIIa (Fig. 137.5). Severe deficiency is characterized by a very prolonged aPTT, and definitive diagnosis is established using a modified aPTT with HK deficient plasma. Partial prekallikrein deficiency is common in severe HK deficiency, likely due to increased catabolism of prekallikrein when it is not in complex with HK.

FACTOR XIII DEFICIENCY (OMIM 134570 [A SUBUNIT] AND 134580 [B SUBUNIT])

In 1944 Robbins demonstrated that fibrin formed from purified fibrinogen was soluble in weak acid, while fibrin formed in the presence of serum or plasma was not. He proposed that a fibrin-stabilizing factor was present in plasma. In 1960 Duckert and colleagues described the first patient with deficiency of fibrin-stabilizing factor, which was subsequently designated factor XIII. The incidence

of severe factor XIII deficiency is estimated at 1 in 2 million (Table 137.1).^{25,26} Factor XIII in blood is distributed between plasma and platelets, with a small amount in monocytes. The plasma protein is a 330,000-Da tetramer composed of two catalytic A subunits and two carrier B subunits.^{25,26} Factor XIII in platelets, monocytes, and placenta has only A subunits. The A subunit of the protein in plasma appears to be synthesized primarily in hematopoietic cells, while the B subunit comes from the liver. Factor XIII is converted to the transglutaminase factor XIIIa by thrombin, and catalyzes formation of γ -glutamyl- ϵ -lysyl bonds between fibrin monomers (Fig. 137.1A), resulting in a fibrin mesh resistant to dissolution in mild acid or urea. Factor XIIIa also cross-links fibrin to plasma, extracellular matrix, and cytoskeletal proteins, enhancing clot adherence to an injury site. Congenital factor XIII deficiency is an autosomal recessive condition. The current classification scheme recognizes factor XIII-A and factor XIII-B defects. Factor XIII-A deficiency is divided into type I (quantitative) and type II (qualitative) deficiencies. In patients with apparent combined FXIII-A and -B deficiency, low levels of the A subunit are likely the result of rapid clearance because of the absence of the stabilizing B subunit.

Most cases of congenital factor XIII deficiency are due to mutations in the A subunit gene, with less than 5% in the B subunit gene. More than 75 different mutations have been reported in the factor XIII-A gene, and more than 20 in the factor XIII-B gene (www.f13-database.de). The incidence of factor XIII mutations affecting plasma activity is probably higher than suspected, considering that screening test abnormalities occur mostly in those with severely decreased plasma activity (<5% of normal). A few mutations show evidence of a founder effect, with the IVS5-1 G>A splice-site defect and Arg-661Stop nonsense mutation each identified in 10 apparently unrelated individuals.

Plasma factor XIII levels decrease in DIC and liver disease. Significant deficiency is rare in liver disease and may indicate a poor prognosis. Acquired deficiency has been reported in leukemia, Crohn disease, ulcerative colitis, and Henoch-Schönlein purpura, but levels are usually greater than 30% of normal and replacement is not required. Alloantibodies to factor XIII induced by replacement therapy are relatively uncommon in factor XIII-deficient patients. Neutralizing autoantibodies that block the activation, activity, or fibrin binding capacity of the factor XIII-A subunit, or that enhance factor XIII clearance from plasma, have been reported in older adults, in patients with systemic lupus erythematosus and lymphoproliferative disorders, and with medications such as isoniazid, penicillin, procainamide, phenytoin, and practolol. An autoantibody to the B subunit that developed in a patient with systemic lupus erythematosus enhanced clearance of the protein from plasma and was associated with life-threatening bleeding.

In patients with factor XIII levels $\leq$ 5% of normal, delayed bleeding from the umbilical stump occurs in 80% to 90% of newborns with severe factor XIII deficiency and is considered a diagnostic feature of the disorder.^{25,26} Ecchymoses, soft tissue hematomas, and prolonged bleeding with trauma are common, and recurrent soft tissue bleeding may lead to formation of hemorrhagic cysts (pseudotumors).^{25,26} Hemarthroses is less frequent than in factor VIII or IX deficiency. Bleeding that is delayed 12 to 36 hours postinjury is characteristic of factor XIII deficiency, although hemorrhage is immediate in some cases. Bleeding at the time of invasive procedures may be minimal, but delayed hemorrhage often occurs. Intracranial bleeding is more frequent in factor XIII deficiency than in other inherited coagulation disorder, with an incidence as high as 30%,^{25,26} justifying prophylactic replacement. Delayed wound healing has been observed, possibly related to a defect in angiogenesis. Spontaneous abortions occur with most pregnancies in untreated factor XIII-deficient women,^{25,26} possibly due to abnormal formation of the cytotrophoblastic shell and poor attachment of the placenta to the uterus. The issue of excessive bleeding in patients with milder (>5% of normal) factor XIII deficiency is more controversial. In at least two studies, patients heterozygous for factor XIII deficiency reported excessive bleeding, but these studies lacked control groups. Experience with pregnant women with severe factor XIII

deficiency shows that the factor XIII level needs to be higher than 10% to reliably prevent pregnancy loss, indicating that clinically significant problems can occur in patients with levels higher than 5% of normal.

The PT and aPTT measure time to fibrin clot formation, but do not assess clot stability. Thus results for these assays are normal in factor XIII-deficient patients. Clots formed in plasma lacking factor XIII are soluble in 5 M urea or 1% monochloroacetic acid, while clots from normal plasma are stable. Solubility in 5 M urea (urea clot stability assay) is often used to screen for factor XIII deficiency or inhibitors. Plasma clots lacking α_2 -antiplasmin are also soluble in the urea clot stability assay, and can be identified with specific assays. Solubility tests have low sensitivity for factor XIII deficiency, even failing to detect some samples with <2% of normal activity and probably almost all samples with levels $\geq$ 5% of normal.²⁷ Chromogenic assays that quantitatively measure factor XIIIa activity are available and are replacing the urea clot stability assays in many institutions.²⁷ These assays can also be used to detect and quantify neutralizing factor XIII inhibitors, using a mixing method with normal plasma.

The plasma half-life of factor XIII is 10 to 14 days,^{25,26} facilitating prophylactic replacement therapy. Although some consider a level of 5% adequate for hemostasis, others suggest levels greater than 10% are required to reduce bleeding risk. FFP and cryoprecipitate contain factor XIII; however, the factor XIII concentrate Fibrogammin P (marketed as Corifact in the United States; Table 137.2) is preferred for replacement.^{25,26} Fibrogammin P contains factor XIII purified from human plasma and is pasteurized. Recombinant factor XIII-A subunit (Tretten) received FDA approval in December 2013 to prevent bleeding in patients with congenital factor XIII A-subunit deficiency. Tretten is produced in yeast and contains no human blood component. In a prospective study, prophylactic replacement with recombinant factor XIII to maintain activity at >0.05 – 0.2 IU/mL prevented spontaneous bleeding without adverse effects.²⁸

Dosing regimens are the same for plasma derived and recombinant factor XIII. A regimen of 40 units/kg every 4 weeks is recommended for prophylaxis. Although concentrated recombinant or plasma-derived factor XIII are preferred for prophylaxis (or treatment of acute bleeding), if it is not available, FFP (10–20 mL/kg every 4 to 6 weeks) or cryoprecipitate (1 unit for every 10 to 20 kg body weight every 3 to 4 weeks) can be used. A dose of 20 to 30 units/kg/day should be used with major surgery to keep the plasma activity 20% to 50% of normal. For minor surgery, 10 to 20 units/kg/day for 2 to 3 days is sufficient. Bleeding can be treated with 10 to 30 units/kg/day depending on severity. In pregnancy, replacement should be started early, preferably before gestational week 5, because decidual bleeding from implantation will occur without replacement. The optimal plasma factor XIII concentration in pregnancy is not established, but $>10\%$ of normal is recommended. This can be achieved by infusing 250 units of concentrate every 7 days through week 22 of gestation, then 500 units per week until delivery, with a 1000 unit bolus during labor.

CONGENITAL DEFICIENCIES INVOLVING MULTIPLE COAGULATION FACTORS

Numerous cases of congenital deficiencies of more than one coagulation factor have been described. While most represent chance coinherence of distinct deficiencies, several represent familial syndromes (Table 137.4). Such syndromes are likely caused by abnormalities in intracellular protein processing or alterations in posttranslational modification. Common nonspecific inhibitors such as lupus anticoagulants interfere with coagulation assays and can lead to erroneous interpretations when they suggest multiple factor deficiencies. Similarly, potent inhibitors directed at a single coagulation factor (e.g., factor VIII) occasionally interfere with assays for other factors. Two familial states, combined factor V and VIII deficiency (type 1) and deficiency of vitamin K dependent factors (type 3), are well characterized.

TABLE 137.4

Combined Familial Deficiency States.

Type	Deficient Factors	OMIM Designation	Underlying Cause
1	V and VIII	227300	Mutations in LMAN1 or MCFD2 genes
2	VIII and IX	134510	Unknown
3	II, VII, IX, X, Protein C, and Protein S	277450 (gamma-glutamyl carboxylase) 607473 (vitamin K oxidoreductase)	Mutations in γ -glutamyl carboxylase (GGCX) or vitamin K oxidoreductase (VKORC1) genes
4	VII and VIII	134430	Unknown
5	VIII, IX and XI	134520	Unknown
6	IX and XI	134540	Unknown
	VII and X		Gene deletion 13q34

OMIM, Online Mendelian Inheritance in Man.

Combined Factor V and Factor VIII Deficiency (OMIM 227300)

Combined factor V and factor VIII deficiency was first reported in 1954. The familial form is an autosomal recessive trait caused by mutations in either the LMAN1 (mannose-binding lectin) or MCFD2 (multiple combined factor deficiency protein) gene.²⁹ These proteins form a cargo receptor that transports factors V and VIII from the ER to the ER-Golgi intermediate compartment. Although the incidence of this disorder is thought to be 1 in 1 million persons, the allele frequency is particularly high (~1%) in Tunisian Jews originating from a community on the island of Djerba.

Deficiency of LMAN1 or MCFD2 activity causes a defect in factor V and factor VIII secretion, lowering plasma levels to 5%–30% of normal. In Tunisian Jews, a T-to-C substitution at a donor splice site in intron 9 causes LMAN1 deficiency. A history of consanguinity, co-segregation of factor deficiencies, and similar reductions in factor V and VIII favor the familial disorder. Affected individuals bleed primarily after trauma, and epistaxis, gingival bleeding, easy bruising, and menorrhagia are common. Hemarthrosis unrelated to trauma may occur in 20% of patients, but bleeding from the GI tract or intracranial hemorrhage is less common.²⁹ Postpartum hemorrhage occurs in most affected women, and invasive procedures, including tooth extraction, are usually accompanied by bleeding in the absence of factor replacement. The PT and aPTT are prolonged. As isolated factor V deficiency also prolongs these tests, patients with factor V deficiency should have factor VIII levels measured to avoid missing combined deficiency. Patients with mucosal bleeding and menorrhagia may respond to antifibrinolytic therapy. For more significant bleeds, or in preparation for surgery or tooth extraction, a combination of FFP and factor VIII concentrate should be used. DDAVP may raise factor VIII, but not factor V levels. Trough levels of approximately 50% for factor VIII and 25% for factor V have been recommended for surgery. Plasma exchange may be used to increase factor V in situations in which volume overload from large volumes of FFP is a concern. Recombinant factor VIIa was used successfully to stop bleeding in one surgery patient.

Combined Deficiency of Vitamin K-Dependent Proteins (OMIM 277450 and 607473)

In 1966 McMillan and Roberts described a newborn girl with prolonged PT and aPTT; low levels of prothrombin and factors VII, IX, and X; and no evidence of liver disease or malabsorption.

Laboratory Testing in Rare Coagulation Factor Deficiencies

When deficiency of a coagulation factor is under consideration, it is important to keep in mind that (1) acquired conditions causing multiple factor deficiencies are more common than congenital deficiency of a single factor, and (2) common inhibitors of coagulation, such as lupus anticoagulants, heparins, and the direct oral anticoagulants (DOACs) interfere with coagulation factor assays. Unexplained prolongation of the PT or aPTT should be evaluated in a qualified laboratory. If at all possible, the plasma should be prepared from blood collected by venipuncture. In our experience, the common practice of collecting blood from central venous catheters/ports or peripheral intravenous catheters frequently introduces fluids or drugs that adversely affect clotting assays and contribute to misdiagnosis. We frequently use the thrombin time assay and factor Xa-based assays to screen samples for the presence of heparins or DOACs.

The initial evaluation of a plasma sample with a prolonged PT or aPTT should start by repeating the abnormal test on a mixture of patient and normal plasma to determine if the prolonged clotting time is related to a clotting factor deficiency (clotting time becomes normal after mixing) or an inhibitor that neutralizes clotting factor activity (clotting time remains prolonged after mixing). The mixing study should be performed with and without incubation (2 hours), as some antibody inhibitors demonstrate a time-dependent pattern of inhibition. Slight (a few second) prolongations of the PT or aPTT can be difficult to evaluate with a mixing study. We evaluate such samples with assays for lupus anticoagulants prior to measuring specific levels of coagulation factors.

The antibodies to clotting factors that most physicians are familiar with neutralize factor activity, and generate abnormal results on a mixing study (i.e., mixing with normal plasma fails to correct the abnormal clotting time). However, nonneutralizing antibodies can cause severe factor deficiency. These antibodies typically enhance clearance of the clotting factor from the plasma *in vivo*, and are not detected in a mixing study. A failure to respond to replacement therapy in the absence of a measurable

inhibitor suggests a nonneutralizing antibody is present. In our practice, we have observed severe acquired deficiencies of prothrombin, factor V, factor X, factor XI, and factor XIII caused by (or presumed to be caused by) nonneutralizing antibodies.

If the level of a vitamin K–dependent protein (prothrombin or factors VII, IX or X) is low, levels of factor V and at least one other vitamin K-dependent factor should be measured. If multiple vitamin K–dependent factors are low and factor V is normal, a process affecting vitamin K is likely. If factor V is also low, liver disease or DIC should be considered. Tests for hepatic function (albumin) or injury (transaminases) can facilitate interpretation of the coagulation factor studies. Distinguishing DIC from liver disease can be difficult, because results of standard tests such as the PT, aPTT, platelet count, fibrinogen and D-dimer may be abnormal in both conditions. Measuring factor V and factor VIII may be useful in this situation, because both are often low in DIC, while factor VIII is normal or elevated in liver disease.

It is likely that the apparent rarity of congenital factor XIII deficiency is partly due to the insensitivity of clot solubility assays still used in many places to screen for this disorder. Quantitative measurements of factor XIII activity are preferable, and are replacing solubility assays at many institutions.

Patients with factor XI, factor XII, prekallikrein or high-molecular-weight kininogen deficiency may require anticoagulation for treatment or prophylaxis for thromboembolism. Assays based on contact activation such as the aPTT or the activated clotting time (ACT) cannot be used for monitoring therapy with heparin or the direct thrombin inhibitor argatroban in these patients, because the baseline PTT and ACT are prolonged. Chromogenic heparin assays based on factor Xa inhibition are now widely available for monitoring heparin, and should be used in place of the aPTT in patients with these deficiencies. Alternatively, low-molecular-weight heparin, fondaparinux or a DOAC, which do not generally require monitoring, can be used instead of unfractionated heparin or argatroban.

She responded partially to large doses of vitamin K. Subsequently, low protein C and protein S levels were reported in association with mutations in the *γ-glutamyl carboxylase* (GGCX) gene. Although the condition is considered autosomal recessive, severe bleeding was reported in a neonate heterozygous for a GGCX mutation. Prothrombin; factors VII, IX, and X; proteins C and S; and the bone proteins osteocalcin and matrix Gla protein require γ -carboxylation of glutamic acid residues in their N-terminal Gla-domains. This process is mediated by GGCX, which uses reduced vitamin K as a cofactor. The reactions result in formation of vitamin K 2,3-epoxide, which must be reduced by *vitamin K epoxide reductase complex subunit 1* (VKORC1) to replenish the vitamin K pool. Mutations in the GGCX or VKORC1 genes can impair γ -carboxylation, resulting in reduced levels (10% to 50% of normal) of all vitamin K–dependent proteins, and a bleeding tendency that may be severe. Some patients have skeletal abnormalities resembling warfarin embryopathy, probably due to abnormalities of osteocalcin and matrix Gla protein. Vitamin K–dependent proteins are reduced in patients taking warfarin, poisoning with rodenticides such as brodifacoum, and with vitamin K deficiency. Recently, a cluster of cases of severe vitamin K deficiency causing hemorrhagic disease of the newborn were linked to a failure to administer prophylactic vitamin K after birth.³⁰ The levels of these proteins are also low in liver failure, in conjunction with other proteins synthesized in the liver (such as factor V), and in malabsorption syndromes. An acquired antibody that resulted in fatal bleeding in a patient with a lymphoproliferative disorder bound to an epitope on the Gla domain of prothrombin and factors IX and X.

Combined deficiencies of prothrombin and factors VII, IX, and X cause prolongation of the PT and aPTT. Protein C and protein S are also reduced. The abnormalities correct on mixing with normal plasma. Failure to do so suggests that a nonspecific inhibitor such as a lupus anticoagulant is present. Patients with deficiencies of vitamin K–dependent proteins should be evaluated for liver disease, malabsorption, and exposure to vitamin-K antagonists such as warfarin or brodifacoum. Toxicology screens can identify these agents in blood

long after ingestion because of their long half-lives. Some patients have adequate clinical response to vitamin K₁ (10 mg weekly), but others require unusually high doses. Nonresponders, or responders with significant bleeding episodes, can be treated with FFP or PCC.

STRUCTURE, BIOLOGY, AND GENETICS OF VON WILLEBRAND FACTOR

Paula James and Natalia Rydz

Von Willebrand factor (VWF) is an adhesive multimeric plasma glycoprotein that mediates platelet adhesion to injured subendothelium via glycoprotein (GP) 1b α , and binds and stabilizes factor VIII (FVIII) in the circulation, protecting it from proteolytic degradation. This important multifunctional protein was named after the Finnish physician, Dr. Erik von Willebrand, who first described von Willebrand disease (VWD) in 1926. In the original publication he described a severe mucocutaneous bleeding problem in a family living on the Åland archipelago in the Baltic Sea. The index case, a young woman named Hjärdís, bled to death during her fourth menstrual period at the age of 13. Dr. von Willebrand referred to the condition as *pseudohemophilia*, but noted that in contrast to hemophilia, this condition affected both genders, with females typically being more severely affected.

In the mid-1950s it was recognized that VWD was usually accompanied by a reduced level of FVIII activity and that the bleeding phenotype could be corrected by the infusion of normal plasma. In the early 1970s the critical immunologic distinction between FVIII and VWF was made, and since that time significant progress has been made in our understanding of the molecular pathophysiology of this disorder. Cloning and characterization of the *VWF* gene in the 1980s has facilitated further investigation into the function of VWF and the genetic basis of VWD.

FUNCTIONS OF VON WILLEBRAND FACTOR

VWF is a multifunctional adhesive protein that plays an important role in both primary hemostasis and blood coagulation. In primary hemostasis, VWF initiates platelet adhesion at the site of endothelial injury, whereas in coagulation, VWF stabilizes FVIII in the circulation (Fig. 138.1).

Platelet Adhesion

At the site of endothelial injury, VWF adheres to exposed collagen. The hemostatically important forms of collagen include types I, III, and VI, but VWF preferentially binds to type III collagen. The interactions of VWF with collagen are predominately mediated by the VWF A3 domain (Fig. 138.2). Once immobilized, VWF is subjected to the high shear rates of the arterial circulation and undergoes a conformational change that exposes the platelet GPIIb α binding site within the VWF A1 domain. High affinity, rapid and reversible interaction between VWF and GPIIb α tethers platelets to the endothelium where they roll until they are immobilized and activated by direct platelet-collagen binding which is mediated by two collagen receptors on platelets, GPVI and the integrin α 2 β 1 (or GPIa/IIa). The Arg-Gly-Asp (RGD) sequence within the VWF C1 domain also contributes to platelet adhesion by interacting with GPIIb-IIIa of activated platelets.

Factor VIII Stabilization

VWF binds FVIII through the VWF D'D3 domains and protects it from proteolytic degradation, thereby prolonging its half-life. In the

absence of VWF, FVIII has a half-life of approximately 2 hours in contrast to a normal half-life of 12–20 hours when bound to VWF.

BASAL VON WILLEBRAND FACTOR LEVELS

The normal level for VWF is highly variable and ranges from 50 to 150 IU/dL. Factors that contribute to the variable VWF levels include ABO genotype (see section on [ABO blood groups](#) later), Secretor genotype, race, and age. Plasma VWF concentrations have been reported to be approximately 20% higher in subjects homozygous for the Secretor (Se) allele as compared with those who are heterozygous. VWF levels in blacks are 15% higher than those in whites. Increased age has also been associated with higher VWF levels, with studies suggesting that the levels may increase by as much as 15–17 U/mL per decade.

Within subjects, VWF levels often vary over time as a result of β -adrenergic stimuli, drugs, or more sustained physiologic factors, such as pregnancy, hypothyroidism, chronic illness, or long-term use of certain medications. The vasopressin analogue, 1-deamino-(8-D-arginine)-vasopressin (DDAVP, desmopressin) transiently and reliably increases VWF and FVIII levels—a fact that, in addition to an acceptable side effect profile, has led to the use of DDAVP as a first-line treatment in certain types of VWD and mild hemophilia A. Several physiologic stressors involving β -adrenergic stimulation, such as exercise, surgery, and psychological distress, can produce an acute increase in VWF levels. VWF levels remain elevated for up to 6 days after surgery, suggesting that after the acute secretory response, there is upregulation of VWF production. A sustained elevation of VWF levels can occur with chronic diseases, such as hyperthyroidism, renal failure, diabetes, liver disease, atherosclerosis, chronic inflammatory states, and cancer. Conversely, acquired VWD, characterized by qualitative or quantitative VWF defects, can occur with certain medications, such as valproic acid, and with some chronic medical conditions (see section later on acquired [VWD](#)).

VWF levels are increased by estrogen. In premenopausal women, VWF levels vary in a cyclical fashion, with the lowest levels occurring in the early follicular phase of the menstrual cycle (days 1–7) and peak values occurring during the luteal phase. Oral contraceptives increase VWF levels and dampen the cyclical variation. This dose-dependent effect is mediated by the estrogen component and is evident with ethynylestradiol doses of 0.5 μ g or higher. Lower estrogen doses have little or no effect on VWF levels. VWF levels increase in pregnancy starting in the second trimester and achieve levels threefold higher than baseline values by the end of the third trimester. VWF levels return to baseline 1–3 weeks after delivery.

VON WILLEBRAND FACTOR GENE

Located on the short arm of chromosome 12 at p13.3, the *VWF* gene spans 178 kb and is composed of 52 exons that range in size from 1.3 kb (exon 28) to 40 bp (exon 50) (Fig. 138.2A). There is a partial, unprocessed pseudogene, *vWFP*, located on the long arm chromosome 22 at q 11.2, measuring 21–29 kb, which duplicates the *VWF*

Fig. 138.1 FUNCTION OF VON WILLEBRAND FACTOR. Role of VWF in mediating the initial events in the hemostatic process. VWF is the carrier protein for FVIII (*top*). After endothelial injury, VWF adheres to the exposed subendothelium, where it is uncoiled by the shear forces, thereby exposing GPIb α binding sites that interact with platelets (*middle*). The bound platelets are activated and the GPIIb-IIIa complex is exposed on the platelet surface. Interaction of fibrinogen and VWF with GPIIb-IIIa then consolidates the platelet adhesive event and initiates platelet aggregation (*bottom*). FVIII, Factor VIII; GP, glycoprotein; VWF, von Willebrand factor. (Used with the permission of Robert Montgomery).

gene sequence for exons 23–34 with 97% sequence homology. The pseudogene contributes to the mutation spectrum of VWD through gene conversion. The *VWF* gene is highly polymorphic with more than 160 polymorphisms in the exons and closely flanking intronic sequences; these normal variants include promoter polymorphisms, a highly variable tetranucleotide repeat in intron 40, two insertion/deletion polymorphisms and 132 distinct single-nucleotide polymorphisms involving exon and intron sequences. An International Society on Thrombosis and Haemostasis Scientific and Standardization Committee (ISTH-SSC) database of both polymorphisms and mutations is maintained at the University of Sheffield (<http://www.vwf.group.shef.ac.uk/>). The high degree of polymorphism, the large size, and the presence of the pseudogene render full *VWF* gene sequencing and data interpretation challenging.

VWF expression is tightly restricted to endothelial cells, platelets, and megakaryocytes. Cell-specific transcriptional regulation is complex and poorly understood. A 734–base pair region, spanning approximately 500 bases of the 5′-flanking region and 247 bases into the first exon, functions as a promoter and includes a minimal core promoter, as well as negative and positive regulatory regions. The positive regulatory region confers cell-specificity by relieving inhibition in specific cells, thereby allowing transcription of the *VWF* gene.

DOMAIN STRUCTURE

Encoded VWF messenger ribonucleic acid is 8.8 kb in length and the translated prepro-VWF molecule contains 2813 amino acids (AA), comprising a 22 AA signal peptide, a 741 AA propeptide, and a 2050 AA secreted mature subunit that possesses all of the adhesive sites required for the hemostatic function of VWF. The AA sequence is rich in cysteine residues, which make up 8.3% of the prepro-VWF and are abundant in all of the domains except the A domains, where only six cysteine residues are found. The cysteine residues are involved not only in interchain disulfide bonds, but also in intrachain disulfide bonds.

The VWF amino acid sequence contains four homologous repeated segments, named A through D, which make up approximately 90% of the precursor. These homologues also occur in a number of unrelated proteins. For example, VWF A domains appear in up to 22 human genes, such as leukocyte adhesion receptors, collagen receptors, and cartilage matrix protein. Likewise, homologues of VWF domains B, C, D, and CK exist throughout the genome, and are found in proteins with various functions. This suggests that the *VWF* gene is the product of a complex series of partial gene duplications.

Based on four homologous repeated segments, A through D, the domain structure of VWF has been annotated in the following sequence: S-D1-D2-D′-D3-A1-A2-A3-D4-B1-B2-B3-C1-C2-CK.

Recently, the annotation of VWF's protein structure has been revised based on structures seen using electron microscopy. The A domains are seen as globular structures and represent the major functional binding sites with VWF, to platelets and collagen. The domains previously known as B and C are reannotated as six-tandem von Willebrand C (vWC) and vWC-like domains. These domains elongate and provide flexibility to the VWF protein, an important characteristic to the functioning of VWF under different shear stresses within the circulation (Fig. 138.2B).

Functional domains important for multimerization, cleavage, and binding have been identified. The signal peptide (S) targets prepro-VWF to the endoplasmic reticulum (ER), where it is promptly cleaved. The cysteine knot (CK) domains of adjacent VWF monomers form disulfide bonds, resulting in tail-to-tail dimers. The VWF propeptide (domains D1–D2) plays an important role in VWF multimer assembly by promoting the formation of head-to-head oligomers through disulfide bonds involving D3. The A2 domain contains the Tyr1605–Met1606 cleavage site for ADAMTS13 (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13).

The VWF subunit possesses several binding sites, almost entirely encoded by exon 28 and including domains D'-D3-A1-A2-A3. In

addition, the C1 domain, encoded by exons 42–44, contains a binding site. The D' and D3 domains contain the FVIII-binding site, which interacts with the N-terminus portion of the FVIII light chain. VWF interacts with platelets via two platelet receptors; GPIIb/IIIa and GPIIb/IIIa, which mediate platelet adhesion to injured subendothelium and the aggregation of activated platelets, respectively. The binding site for GPIIb/IIIa is localized within the large disulfide loop of A1, whereas the binding site for GPIIb/IIIa is found within the RGD sequence of C1. VWF binds to collagen I and III via the VWF A1 and A3 domains and collagen VI via the A1 domain. Although the major binding site for collagen is thought to be within the A3 domain, the two sites likely have complementary roles and blood flow-mediated shear stress is important for the conformation and function of both.

BIOSYNTHESIS

VWF is synthesized in endothelial cells and megakaryocytes and undergoes a complex series of posttranslational modifications, including dimerization, glycosylation, sulfation, and ultimately, multimerization.

The fully processed protein is then either released into the circulation or is stored in specialized organelles: the Weibel-Palade bodies (WPBs) of endothelial cells or the α -granules of platelets.

Dimerization of pro-VWF monomers occurs in the ER through the formation of disulfide bonds between CK domain monomers in a tail-to-tail fashion. The location of these intersubunit disulfide bonds has been localized to a subset of cysteine residues (Cys2771, Cys2773, and/or Cys2811). In addition, the signal peptide is cleaved and most of the intrachain disulfide bonds are formed in the ER. Only pro-VWF dimers are then transported to the Golgi apparatus, where they make up the basic building blocks for further multimerization. Here, the propeptide (D1–D2) is cleaved by a propeptide processing protease, likely furin, between amino acids 763–764. The propeptide continues to be essential for VWF multimerization because under acidic conditions, it serves as an endogenous chaperone that promotes additional disulfide bond formation between D3 domains of adjacent dimers in a head-to-head orientation. The intersubunit disulfide bonds are likely mediated by the alignment of the cysteine pairs C1099 and C1142. The VWF subunit is approximately 250 kDa, whereas resulting disulfide-linked multimers can be more than 20,000 kDa.

The mature VWF subunit is heavily glycosylated with carbohydrate making up approximately 20% of the mass of the mature subunit. Although the function of these oligosaccharide chains is largely unknown, they appear to protect VWF from proteolytic degradation, maintain the multimeric structure of VWF, affect VWF interaction with platelets and collagen, and influence plasma clearance of VWF. In the ER, 12 N-linked high-mannose-containing oligosaccharide chains are added to each VWF subunit, and these appear to be necessary for VWF subunit dimerization. In addition, the propeptide has three additional potential N-glycosylation sites. Posttranslational modification continues in the Golgi with the addition of 10 O-linked oligosaccharides to the peptide chain, and the sulfation of certain N-linked oligosaccharides, such as Asn384 and Asn468. Glycan expression is determined by the cell-type. Within the postGolgi compartment of endothelial cells, the previously added N-linked glycans undergo further processing with the addition of ABO groups, as determined by the ABO genotype. Preliminary data suggest that there is less N-linked glycosylation in platelets and ABO groups are not added. The net result of this differential glycosylation is that platelet VWF is more resistant to ADAMTS13 proteolysis than plasma VWF. The cleaved propeptide remains noncovalently associated with VWF multimers and is stored and secreted with the mature VWF in a 1:1 molar ratio.

STORAGE AND SECRETION

Most of the VWF in endothelial cells consists of small multimers that are constitutively secreted. The more biologically active high-molecular-weight (HMW) VWF multimers are preferentially targeted for storage in endothelium-specific cytoplasmic granules, the WPBs. In addition to VWF and the VWF propeptide, WPBs also store P-selectin, CD63, interleukin-8, tissue plasminogen activator, and angiopoietin-2. Thus WPBs store proteins that are involved not only in hemostasis, but also in inflammation, hemodynamics, and angiogenesis. WPBs have a characteristic cigar-like shape, measuring 0.2 μm in width and 5 μm in length (Fig. 138.3), and are composed of tightly packed tubules, measuring 150–200 Å in cross-section. Platelet VWF is stored within similar tubules that are found in the periphery of α -granules and constitutes approximately 15% to 20% of total blood VWF. Tubular packing condenses the length of VWF multimers by 50-fold and is dependent on the acidic pH within the trans-Golgi, as well as the propeptide (D1D2) and the NH_2 -terminal region (D'D3A1). Long VWF multimers, which can be up to 100 μm in length, are reversibly packaged into coils. With WPB exocytosis, the filamentous strings of VWF are secreted into the circulation, where they rapidly unfurl and are capable of binding to platelets. If the tubular structure is perturbed, WPBs release short, tangled VWF that does not support platelet binding to the endothelium.

Fig. 138.3 WEIBEL-PALADE BODIES OF ENDOTHELIAL CELLS. (A) Immunofluorescence staining of a human umbilical vein endothelial cell with anti-VWF antiserum. VWF is present in the perinuclear region, where it is synthesized, and in the Weibel-Palade bodies (arrowhead) throughout the cytoplasm. Bar = 10 μm . (B) Electron micrograph of Weibel-Palade bodies of the same origin. Bar = 0.5 μm .

A variety of agonists can induce the secretion of VWF from endothelial cells. These agonists include histamine, thrombin, fibrin, the terminal complement proteins C5b-9, and β -adrenergic agonists. With endothelial cell stimulation, WPBs fuse with the plasma membrane to form a secretion pore. This leads to a rapid rise in pH and release of intracellular calcium stores. The freshly secreted unusually large (or ultra-large) VWF multimers (ULvWF) are highly active and can spontaneously bind platelets. Some of the released protein remains associated with the endothelial membrane, and some self-associate.

ADAMTS13

ADAMTS13 is a plasma protease that cleaves circulating VWF between Tyr 1605 and Met 1606 in the A2 domain. Its main target is the ULvWF multimers, which spontaneously bind GPIb α on platelets. ADAMTS13 cleaves ULvWF multimers when there is sufficient shear to unfold the A2 domain and to expose the cleavage site. ULvWF multimers that appear in plasma after WPB secretion are cleaved within 2 hours by ADAMTS13 to form shorter, less hemostatically active multimers. Proteolysis of VWF multimers is responsible for the characteristic “triplet” pattern of satellite bands

Fig. 138.4 EXAMPLE OF A MULTIMER ANALYSIS (2.25% AGAROSE GEL). Lane 1 normal human plasma (NHP) represents normal plasma multimer patterns with a characteristic “triplet” pattern of satellite bands flanking each main multimer. Lanes 2–7 show the plasma VWF multimer analysis for patients with the different subtypes of VWD (T1, type 1; 2A, type 2A; 2B, type 2B; 2M, type 2M; 2N, type 2N; T3, type 3). Type 2A and type 2B VWD both show variable loss of high-molecular-weight multimers. Types 1, 2M, and 2N demonstrate the presence of high molecular weight multimers. Finally, with type 3 VWD, there is an absence of any VWF.

flanking each main multimer band that is observed on multimer analysis gels. (Fig. 138.4).

VWF proteolysis is influenced by glycosylation and specific polymorphisms. For example, nonglycosylated recombinant VWF is cleaved more rapidly than its plasma-derived glycosylated counterparts. Likewise, addition of A or B blood group antigens to N-linked oligosaccharide chains of VWF attenuates ADAMTS13 proteolysis compared with VWF bearing the O blood group antigen. Finally, the differential glycosylation of platelet VWF renders it resistant to ADAMTS13 proteolysis. Single-nucleotide polymorphisms, such as the A/G polymorphism at position 24/1282 resulting in Tyr/Cys at 1584, have also been shown to affect the susceptibility of VWF to proteolysis.

Alterations in the balance between ADAMTS13 activity and VWF proteolysis can lead to a number of disease states. Congenital or acquired deficiency of ADAMTS13 can result in thrombotic thrombocytopenic purpura (see Chapter 134). On the other hand, enhanced proteolysis can give rise to a bleeding phenotype. For example, mutant VWF in a subtype of type 2A VWD exhibits enhanced susceptibility to ADAMTS13 cleavage, which results in loss of large VWF multimers.

CLEARANCE

VWF clearance is complex and involves multiple receptors and cell-types. Data suggest that macrophages and hepatocytes internalize and clear VWF in a process that is independent of multimer size and mediated by lipoprotein receptor-related protein and

asialoglycoprotein receptor in both cell types and sialic-acid-binding-immunoglobulin-like-lectin 5 in macrophages. C-type lactic domain family 4 member M on endothelial cells has also been shown to mediate VWF clearance in a glycan-dependent manner. Further studies are needed to decipher the relative contribution of each of these mechanisms as determinants of VWF levels.

The VWF propeptide remains associated with VWF multimers stored in WPBs and is secreted in a 1:1 molar ratio with the mature VWF subunit. After secretion, the propeptide (VWFpp) dissociates from VWF and circulates at a concentration of approximately 1 µg/mL and with a half-life of 2–3 hours. In contrast, VWF circulates at a plasma concentration of approximately 10 µg/mL and has a half-life of approximately 12–20 hours. The ratio between VWFpp and mature VWF (vWFpp/VWF:Ag) can be used to estimate the relative half-life of mature VWF; elevated ratios indicate enhanced clearance.

Changes in VWF glycosylation or point mutations can be associated with increased clearance. Blood group O subjects (see the following section on ABO Blood Groups) exhibit increased VWF clearance compared with the other blood types and have consistently elevated vWFpp/VWF:Ag ratios and shorter VWF survival after DDAVP administration. Several point mutations may lead to accelerated VWF clearance and are associated with either a type 1 or type 2A VWD phenotype. The vast majority of these are localized to the D3 domain (e.g., R1205H and C1130F), but point mutations in the A1 (I1416N), CK (C2617), and D4 domains (S2179F) have also been implicated.

VWF mutations associated with accelerated clearance are not necessarily associated with increased susceptibility to proteolysis by ADAMTS13 and vice versa. For example, the VWD Vicenza mutation, R1205, is the prototypical clearance mutation. Patients with this mutation have severely reduced plasma FVIII and VWF levels, an increased vWFpp/VWF:Ag, and a VWF half-life of 1–2 hours. However, there is no association between increased clearance of this mutant VWF and altered susceptibility to ADAMTS13 proteolysis.

ABO BLOOD GROUPS

Blood group O subjects have VWF levels that are on average 25% lower than those with non-O blood types: the mean VWF level in blood group O subjects is 74.8 IU/dL as compared with 105.9 IU/dL, 116.9 IU/dL, and 123.3 IU/dL in blood group A, B, and AB subjects, respectively. ABO antigens are added to N-linked oligosaccharide chains on the VWF subunit. Thus patients with the type O blood group genotype lack the functional glycosyltransferase that adds *N*-acetylgalactosamine and *D*-galactose to the H antigen on VWF in blood group A and B subjects, respectively. Altered glycosylation of VWF in subjects with blood type O leads to lower plasma VWF levels as a result of increased proteolysis and/or more rapid clearance. Blood group O VWF is more susceptible to ADAMTS13 proteolysis, and blood group O subjects have elevated VWFpp:vWF:Ag ratios and shorter VWF survival after DDAVP. The mean half-life of VWF in type O subjects is approximately 10 hours compared with a half-life of approximately 25.5 hours in those with other ABO blood types. Clinically, the difference in VWF levels results in an overrepresentation of blood group O patients with type 1 VWD, which is defined by a reduction in VWF levels.

AREAS OF ONGOING INVESTIGATION

There is emerging evidence that VWF may have a role in the regulation of vascular endothelial growth factor-dependent angiogenesis directly through its interaction with integrins on endothelial cells and indirectly via regulation of WPB formation and secretion of constituents such as angiopoietin-2. In addition, VWF may protect against tumor metastasis. Patients with increased VWF levels are at risk for cardiovascular events; it is unclear whether VWF contributes to atherosclerosis or whether it is a marker of endothelial dysfunction. Nonetheless, VWF plays an important role in atherothrombosis, and

drugs targeting VWF attenuate arterial thrombosis in animal models. Their utility in humans is unknown.

VON WILLEBRAND DISEASE

VWD is caused by deficient or defective plasma VWF and represents the most common inherited bleeding disorder. Bleeding symptoms reflect the defect in primary hemostasis: mucocutaneous bleeding, especially epistaxis and menorrhagia. When FVIII levels are sufficiently low, the bleeding phenotype overlaps with that of mild to moderate hemophilia; patients may experience joint or muscle bleeds. The current VWD classification recognizes three subtypes. Type 1 VWD is characterized by quantitative deficiency of VWF, type 2 VWD is characterized by qualitative defects, and type 3 VWD is characterized by an almost complete absence of VWF.

Epidemiology

VWD is the most common inherited bleeding disorder. However, because VWF levels are variable in the population and symptom severity ranges from infrequent, mild bleeding to frequent or severe bleeds, the reported prevalence depends on the diagnostic criteria and the study population. In two large epidemiologic studies, the prevalence of VWD was approximately 1% in healthy school-age children based on low VWF activity, and a personal and family history of bleeding symptoms. The prevalence of VWD in individuals who present to a primary care physician with bleeding symptoms is approximately 0.1%, whereas in patients whose bleeding symptoms are sufficiently severe to warrant referral to specialized centers, the prevalence is 20–113 per million.

Classification and Pathophysiology

The 2006 ISTH VWD classification relies on the VWF protein phenotype, which in turn often reflects the underlying pathophysiology and has implications for treatment. Type 1 VWD is a partial quantitative deficiency; type 2 (with four subtypes: 2A, 2B, 2M, and 2N) is a qualitative defect; and type 3 is a virtual deficiency of VWF (Table 138.1). The diagnosis and categorization of VWD into a type can be achieved with widely available laboratory testing. However, the differentiation among type 2 subtypes may require referral to a specialized laboratory. The current classification does not incorporate genotypic data: the diagnosis of VWD is not limited to individuals with mutations within the VWF gene. VWF mutations may not be identified in VWD patients because of the complexity of the VWF gene or because of mutations in other genes, such as those affecting

secretion or clearance, which also lead to a VWD phenotype. A third level of classification denoted by roman numerals (e.g., VWD type 2A IIA) indicates specific phenotypes and is a remnant of an older classification system that is mainly used in the research setting.

von Willebrand Disease Type 1

Type 1 VWD, a quantitative deficiency of VWF, represents approximately 70% of VWD cases. The VWF is functionally normal without a specific abnormality in ligand binding sites or a significant decrease in HMW multimers. Functional assays of VWF, such as VWF:RCO, are decreased in proportion to the decrease in VWF:Ag concentration, and the ratio of functional activity as compared with VWF:Ag is normal (i.e., VWF:RCO/VWF:Ag ratio is >0.6).

Point mutations, most frequently missense mutations, have been identified in approximately 65% of individuals with type 1 VWD and occur throughout the VWF gene. Fully penetrant, dominantly inherited missense mutations are more often identified when VWF:Ag and VWF:RCO levels are less than 25 IU/dL. In contrast, incompletely penetrant, dominantly inherited missense mutations, such as p.Tyr1584Cys and p.Arg924Gln, are identified in approximately 50% of individuals whose VWF:Ag and VWF:RCO levels are above 25 IU/dL. The extent to which incompletely penetrant VWF mutations contribute to the bleeding phenotype in individuals with VWF levels of approximately 50 IU/dL is not clear, and genetic analyses in such cases are difficult to interpret.

Missense mutations may affect VWF levels by reducing secretion and/or increasing clearance. The most frequently reported genetic mutation is a missense mutation that results in the substitution of tyrosine with cysteine at codon 1584 (Y1584C), which is found in 10% to 20% of type 1 VWD patients. Intracellular retention is a common mechanism for type 1 VWD pathogenicity and can result from missense mutations in various VWF domains. Haploinsufficiency from a heterozygous null allele results in reduced VWF expression in a small proportion of cases. A common heterozygous in-frame large deletion of exons 4–5 was reported in a cohort of type 1 VWD patients in the United Kingdom, and this and similar partial gene deletions may contribute to the spectrum of mutations in a minority of cases. A well-described pathophysiologic mechanism for VWD type 1 is increased VWF clearance, referred to as type 1C (C for increased clearance), although this designation is not included in the ISTH classification. Patients typically have very low VWF levels, an increased vWFpp/VWF:Ag ratio, and a marked but short-lived response to DDAVP. Of note, the half-life of VWF/FVIII concentrates is normal in these individuals. Missense mutations mainly occur in the D3 domain and reduce the half-life of VWF up to 15-fold. R1205H, which is known as the “Vicenza” variant, is the most common, most severe, and best characterized of these mutations. Because of the transient response to DDAVP, the utility of this medication for treatment of major bleeds is questioned in this subgroup of patients.

VWF levels increase with age in normal individuals and the same phenomena is seen in patients with type 1 VWD (but not type 2 or 3). The increase has been reported as 3.5 U/dL VWF:Ag and 7.1 U/dL FVIII:C per decade. The effect of this increase on bleeding phenotype needs further investigation.

von Willebrand Disease Type 2

Type 2 VWD is characterized by a qualitative defect of VWF activity and is further classified into variants that affect VWF-platelet interactions (2A, 2B, and 2M) and that affect VWF binding to FVIII (2N) (Fig. 138.5).

Type 2A

VWD type 2A is the most common type 2 variant, accounting for approximately 10% of all VWD cases. VWD type 2A usually is inherited as a dominant trait and is characterized by a lack of HMW

TABLE
138.1

Classification of von Willebrand Disease

Type	Description
1	Partial quantitative deficiency of VWF. Mild abnormalities in multimer structure or distribution may occur.
2	Qualitative VWF defects.
2A	Decreased VWF-dependent platelet adhesion and deficiency of HMW VWF multimers.
2B	Increased affinity for platelet GPIb α .
2M	Decreased VWF-dependent platelet adhesion with a normal multimer distribution.
2N	Decreased affinity for FVIII.
3	Almost complete deficiency of VWF.

FVIII, Factor FVIII; GPIb α , glycoprotein 1b α ; HMW, high molecular weight; VWF, von Willebrand factor.

Fig. 138.5 FUNCTIONAL DOMAINS OF VON WILLEBRAND FACTOR AND LOCATION OF TYPE 2 VON WILLEBRAND DISEASE MUTATIONS. VWF protein comprises a large N-terminal propeptide and mature subunit. Repeated protein domains are designated A through D. Highlighted are binding sites for factor VIII, platelet Gp1b, collagen, and the areas critical for dimerization and multimerization. Sites of the common mutations that result in type 2 VWD are shown. *Arrow* indicates translational start site. *FVIII*, Factor VIII; *Gp1b*, glycoprotein; *VWF*, von Willebrand factor.

and/or intermediate-molecular-weight (IMW) multimers, which are the most hemostatically active. This results in a disproportionately low functional activity compared with antigen level (i.e., VWF:RCO to VWF:Ag ratio of <0.6). The FVIII level may be low or normal. The multimer profile shows a loss of HMW and sometimes IMW multimers. This subtype may encompass missense mutations that impair dimer (CK domain) or multimer assembly (recessive mutations in the D1 and D2 domains), disrupt intersubunit disulphide bonds (D3 and D2 domains) enhance susceptibility to ADAMTS13-mediated proteolysis (A2 and A1 domains), and/or result in intracellular retention of VWF, particularly the HMW multimers (D3, A1, and A2 domains).

Type 2B

Type 2B VWD is the result of gain-of-function mutations within the Gp1b α binding site on VWF. Missense mutations are located in exon 28, in or close to the A1 domain. This results in spontaneous binding of VWF to platelets without the need for a VWF-collagen interaction. The VWF-platelet interactions selectively deplete the HMW multimers by increasing ADAMTS13 proteolysis. The increased binding of mutant VWF to platelets also triggers the formation of platelet aggregates, which are removed from the circulation resulting in thrombocytopenia. Altered megakaryocytopoiesis characterized by giant platelets with abnormal ultrastructure contributes to the thrombocytopenia.

The laboratory profile reveals a decreased VWF:RCO to VWF:Ag ratio and absence of HMW multimers, but in contrast to 2A, ristocetin-induced platelet aggregation (RIPA) reveals increased sensitivity to low doses of ristocetin. Although these features may be present to varying degrees in the majority of patients, not all cases demonstrate these classic features. For example, mutations affecting p.Pro1266Leu may enhance Gp1b α binding (RIPA) without inducing thrombocytopenia or HMW multimer loss.

Type 2M

Type 2M VWD (the M refers to multimer) is characterized by a loss of function mutation within the VWF Gp1b α binding site. The laboratory workup shows a reduced ratio of VWF:RCO to VWF:Ag but a normal multimer pattern. A number of missense mutations are reported in exon 28, and there are case reports of mutations in exons 27, 30–31, and 52. VWF exhibits reduced affinity for Gp1b α because of mutations in the A1 domain that alter protein conformation, but HMW multimers are normal. Rare mutations in the A3 domain that impair the VWF/collagen interaction are also classified as 2M VWD. In these cases, VWF:RCO may be normal, and the diagnosis requires VWF/collagen binding assays (VWF:CB).

Type 2N

Type 2N VWD (with the N referring to Normandy, where the first cases were reported) has been described as an autosomal form of hemophilia A and is an important consideration in the differential diagnosis of individuals of either sex who present with low FVIII levels. The affinity of VWF for FVIII is reduced because of mutations in the FVIII binding site or conformational changes that impair the VWF-FVIII interaction. The characteristic laboratory feature is a disproportionate decrease in the FVIII level relative to the VWF level (which may be low or normal) with a resultant reduction in the FVIII/VWF:Ag ratio. The majority of patients with VWD type 2N have a normal multimer profile, but occasional cases will demonstrate loss of HMW multimers. The majority ($\approx 80\%$) of missense mutations are located in exons 18–20 (D' and D3) with a much lower proportion of mutations in exons 17 and 24–27. Type 2N exhibits autosomal recessive inheritance, and affected individuals are either homozygous or compound heterozygous for missense mutations, or compound heterozygous for a missense mutation and a mutation resulting in a null allele. Definitive diagnosis requires evidence of reduced FVIII binding to VWF (VWF:FVIIIIB) or identification of causative mutations in the FVIII binding region of the VWF gene.

von Willebrand Disease Type 3

Type 3 VWD is defined by a virtual absence of VWF. The inheritance of type 3 VWD is autosomal recessive in about half of type 3 patients and autosomal codominant in the remainder: approximately 50% of carriers will be symptomatic and meet the criteria for type 1 VWD. This condition is characterized by prolongation of the aPTT, undetectable levels of VWF:Ag and VWF:RCO, and FVIII levels less than 10 IU/dL (i.e., less than 10% of normal). Mutations associated with type 3 VWD are found throughout the coding region of VWF, including the propeptide. Up to 80% of type 3 VWD patients have two null alleles and produce little or no VWF. Null alleles can result from a variety of mutations, with nonsense mutations accounting for about one-third. Approximately 20% of alleles carry missense mutations predominantly located in the D1–D2 (exons 3–11) and D4–CK (exons 37–52) domains. These mutations may impair dimer or multimer formation, resulting in intracellular VWF retention and decreased secretion into plasma. Large deletions, predominantly resulting in frameshift mutations affecting one or more exons, contribute to approximately 12% of the type 3 VWD mutation spectrum. Because there is little or no circulating VWF, patients with these mutations may develop alloantibodies against infused VWF.

Clinical Manifestations

The bleeding history depends on disease severity; type 3 VWD is often diagnosed early in life, whereas mild type 1 VWD may not be diagnosed until adulthood. Individuals with VWD primarily complain of excessive mucocutaneous bleeding, such as spontaneous, recurrent epistaxis, and prolonged bleeding after dental cleaning or extraction. In addition, prolonged or excessive bleeding after surgery or trauma is often reported. Affected females frequently experience menorrhagia from the time of menarche, and can have prolonged or excessive bleeding after childbirth. Musculoskeletal bleeding is unusual, except in type 2N or type 3 VWD when the FVIII:C level may be below 10 IU/dL. Bleeding assessment tools (BATs) help to standardize and quantify the bleeding history. BATs are helpful for making a VWD diagnosis. In addition, high scores are predictive of the risk of future bleeding. (see [Chapter 128](#))

Example of the Presentation and Impact of Type 1 von Willebrand Disease

J.C., a 26-year-old female, presents with delayed postpartum hemorrhage (PPH) after the delivery of her first child. The pregnancy and delivery were unremarkable. One week postpartum, the patient experienced heavy bleeding, and required a dilation and curettage. At the same time, she was started on tranexamic acid, which was continued for 2 weeks. By approximately 3 weeks postpartum, there was complete cessation of bleeding. A bleeding history was significant for the following: excessive postsurgical bleeding following tonsillectomy and adenoidectomy, which required red blood cell transfusion; excessive bleeding postdental extractions, requiring consultation with the dentist and repacking; and menorrhagia from the time of menarche, which had been well controlled with the combined oral contraceptive pill. There was no family history of VWD. Investigations revealed VWF:Ag 0.40 IU/dL, VWF:RCO 0:39 IU/dL, and FVIII:C 0.60 IU/dL. Multimer gel was unremarkable. A DDAVP challenge demonstrated that the patient was a responder. She became pregnant again 4 years later. At the time of delivery she was treated with tranexamic acid and a dose of DDAVP after the cord was clamped. Her postpartum course was uncomplicated.

This case illustrates several important points. First, type 1 VWD is a mild to moderate bleeding disorder. Patients often do not have significant symptoms on a regular basis, or symptoms may be masked or ameliorated by concomitant combined oral contraceptive use, which is common in this patient demographic. A careful bleeding history focusing on past hemostatic challenges and subsequent complications is vital in making the diagnosis. A high index of suspicion is required for unusual bleeding complications, such as delayed PPH. The importance of making the diagnosis is highlighted here. With little burden of prophylactic treatment, bleeding complications can be avoided.

Type 1 VWD accounts for up to 70% of VWD. It typically manifests as mild mucocutaneous bleeding; however, symptoms may be more severe if VWF levels are below 15 IU/dL. Epistaxis and bruising are common symptoms in children. Menorrhagia is the most common finding in women of reproductive age.

Type 2 VWD accounts for about 25% of all VWD. The relative frequency of the subtypes is 2A > 2N > 2M > 2B in European populations. Individuals with type 2A, 2B, and 2M VWD usually present with mild to moderate mucocutaneous bleeding, but bleeding episodes can be severe, particularly when VWF:RCO is very low or absent. In many patients with type 2B VWD, thrombocytopenia can develop or worsen with infection, surgery, pregnancy, or treatment with DDAVP. The symptoms of type 2N VWD are similar to those seen in mild hemophilia A (see [Chapter 135](#)) because both disorders are associated with reduced levels of FVIII:C.

Type 3 VWD is the rarest subtype and accounts for less than 5% of VWD. Prevalence estimates range from 0.55 to 6 per million, with higher rates seen with consanguineous marriage. Type 3 VWD manifests with severe bleeding, including excessive mucocutaneous bleeding and musculoskeletal bleeding.

Penetrance

In autosomal dominant type 1 VWD, mutations resulting in plasma VWF level less than 25 IU/dL are often fully penetrant, whereas those resulting in higher VWF levels are often incompletely penetrant. Mutations responsible for autosomal dominant types of VWD (2A, 2B, and 2M) are often fully penetrant. Thus in contrast to the variably positive family histories in patients with type 1 VWD, those with type 2 VWD usually have a positive family history.

Laboratory Investigations

The laboratory evaluation for VWD involves a battery of qualitative and quantitative measurements of VWF and FVIII that should be interpreted by a physician with experience in this area given the heterogeneity of possible results ([Table 138.2](#)).

Screening Tests

The complete blood cell count may show microcytic anemia as a result of iron deficiency or thrombocytopenia in type 2B VWD. The aPTT is often normal, but may be prolonged if the FVIII level is reduced below 30–40 IU/dL, as can be seen with severe type 1, type 2N, or type 3 VWD. The prothrombin time is normal in VWD.

TABLE 138.2 Table of Investigations

VWD Type	vWF:RCO IU/dL ^a	vWF:Ag IU/dL ^a	RCO/Ag IU/dL ^a	FVIII:C IU/dL ^a	Multimer Pattern ^b	Other
1	Low	Low	Equivalent	~1.5× VWF:Ag	Normal	
2A	Low	Low	VWF:RCO < VWF:Ag	Low or normal	Abnormal ↓ HMWM	
2B	Low	Low	VWF:RCO < VWF:Ag	Low or normal	Abnormal ↓ HMWM	↑ RIPA ^c (↓ platelet count)
2M	Low	Low	VWF:RCO < VWF:Ag	Low or normal	Normal	
2N	Normal/low	Normal/low	Equivalent	<30	Normal	↓ VWF:FVIII ^d
3	Absent	Absent	NA	<10	Absent	

^aRelative to the reference range (approximate values); VWF:RCO (50–200 IU/dL); VWF:Ag (50–200 IU/dL); FVIII:C (50–150 IU/dL).

^bHMWM, High-molecular-weight multimers.

^cIncreased agglutination at low concentrations of ristocetin.

^dThe ability of VWF to bind and protect FVIII is reduced. VWF and FVIII levels can look exactly like those in males with mild haemophilia A or in symptomatic hemophilia A carrier females.

Ag, Antigen; FVIII:C, FVIII level; NA, not applicable; RCo, ristocetin cofactor; RIPA, ristocetin-induced platelet aggregation; VWD, von Willebrand disease; VWF:FVIII^d, FVIII-binding assay.

Although some laboratories may also include a skin bleeding time and platelet function analysis (PFA closure time) in their evaluation of an individual with suspected VWD, these tests lack sensitivity in persons with mild bleeding or specificity for VWD.

Confirming a Diagnosis of von Willebrand Disease

The following specific factor assays should be performed even if the screening tests are normal.

von Willebrand Factor: Antigen

This assay determines the quantity of VWF protein antigen in the plasma, and is performed using an enzyme-linked immunosorbent assay (ELISA) or latex immunoassay (LIA). The normal range (which should be determined independently by each laboratory) is approximately 50–200 IU/dL.

von Willebrand Factor: Ristocetin Cofactor

The VWF:RCo activity assay measures the capacity of VWF to agglutinate platelets in response to ristocetin. The normal range is approximately 50–200 IU/dL.

Factor VIII: C Level

The functional FVIII assay determines the activity of FVIII in clot-based assays. The normal range is approximately 50–150 IU/dL.

Several analytic variables can complicate the diagnosis of VWD. Based on established reference ranges, approximately 2.5% of the normal population will have low VWF levels. In addition, assay variability, particularly for VWF:RCo, renders differentiation of type 1 VWD from type 2 VWD difficult. VWF:RCo and VWF:Ag determined by LIA have limited sensitivity, which may result in the misdiagnosis of type 3 VWD as type 1 or type 2 VWD. Finally, inappropriate sample handling can lead to decreases in VWF:Ag, VWF:RCo, and FVIII, with VWF:RCo predominantly affected. All of these factors must be considered when interpreting VWF laboratory results and at least two sets of tests using fresh samples are needed to confirm the diagnosis of VWD. Diagnostic testing should be avoided in stressed, ill, or pregnant patients (see box on **Factors to Consider When Interpreting von Willebrand Disease Results**).

Discriminating Tests to Identify von Willebrand Disease Subtype

von Willebrand Factor Multimer Analysis

Sodium dodecyl sulfate-agarose electrophoresis is used to assess VWF oligomers in plasma (see Fig. 138.4). Normal plasma contains multimers composed of over 40 VWF dimers. Multimers are classified as HMW, IMW, and low molecular weight (LMW) by counting bands 1–5 as LMW, 6–10 as IMW, and those above 10 as HMW. HMW and/or IMW multimers are decreased or missing in types 2A and 2B VWD.

Low Dose Ristocetin-Induced Platelet Aggregation

The RIPA assay tests the capacity of VWF to agglutinate platelets with varying concentrations of ristocetin. In contrast to the VWF:RCo (which evaluates the interaction between the patient's VWF and formalin-fixed platelets), the low dose RIPA assay evaluates the sensitivity of the patient's platelets to low-dose ristocetin. In cases of type 2B or platelet-type VWD, the platelet membrane is "overloaded" with high-affinity mutant VWF, resulting in abnormal

Factors to Consider When Interpreting von Willebrand Disease Results

	Considerations	Results
Preanalytical	When was the sample collected and processed? Was there a significant delay before samples were run? Were they frozen in a timely fashion?	VWF:RCo may be decreased resulting in a false-positive diagnosis of type 2 VWD
Analytical	Convention of established references High degree of assay variability, particularly for VWF:RCo A high lower limit of detection for certain VWF:Ag and VWF:RCo assays, in particular LIA-based assays	False-positive diagnosis of VWD in 2.5% of population False-positive diagnosis of type 2 in a type 1 patient may result in the misdiagnosis of type 3 for type 1 or type 2 VWD
Patient factors	Drugs (OCP, HRT, or valproic acid) ABO type Pregnancy Hypothyroidism Comorbid illness (e.g., valvular heart disease, lymphoma)	False negative or positive False negative Reversible acquired von Willebrand syndrome

Ag, Antigen; LIA, latex immunoassay; OCP, oral contraceptive pill; HRT, hormone replacement therapy; RCo, ristocetin cofactor; VWD, von Willebrand disease; VWF, von Willebrand factor.

platelet agglutination with low ristocetin concentrations. In some cases of type 2B VWD, all variables except low dose RIPA may be normal. RIPA at normal ristocetin concentrations should be normal in type 1 VWD unless VWF levels are below 10–20 IU/dL.

Binding of Factor VIII by von Willebrand Factor

The VWF:FVIII ELISA test determines the ability of VWF to bind FVIII and is useful for the diagnosis of type 2N VWD. There are no standard units for the output of this test.

Collagen Binding Assay

The VWF:CB ELISA test determines the ability of VWF to bind to collagen and is dependent on HMW VWF multimers. Consequently, the test helps to identify functional VWF discordance (i.e., to distinguish between types 1 and 2 VWD). Reduced collagen binding reflects the loss of HMW multimers or can reflect a specific collagen-binding deficiency (type 2M VWD). The normal range is approximately 50–200 IU/dL.

von Willebrand Factor Propeptide/Antigen Ratio

An increased ratio of steady-state plasma VWFpp to VWF:Ag identifies patients with mutations that increase VWF clearance. The mean ratio in normal individuals is 1.3, with a normal range of 0.54–1.98.

Desmopressin Responsiveness

DDAVP administration releases VWF stores from endothelial cells. The pattern of DDAVP response in VWD subtypes (Table 138.3)

TABLE 138.3**Desmopressin Responsiveness in the Various Subtypes of von Willebrand Disease**

VWD Type	vWF:RCO	vWF:Ag	RCO/Ag	FVIII:C IU/dL	vWF:CB	vWF:CB/vWF:Ag
1	Increase	Increase	Remains >0.7	Increase	Increase	Remains >0.7
2A	No/little change	Increase	Remains <0.7	Increase	No/little change	Remains <0.7
2M (GP1B binding dysfunction)	No/little change	Increase	Remains <0.7	Increase	Increase	Remains >0.7
3	No/little change	No/little change		No/little change	No/little change	

Ag, Antigen; vWF:CB, collagen binding assays; FVIII:C, factor VIII level; GP1B, glycoprotein 1B; RCo, ristocetin cofactor; VWD, von Willebrand disease; vWF, von Willebrand factor.

Modified from Favaloro EJ: Rethinking the diagnosis of von Willebrand disease. *Thromb Res* 127;Suppl 2:17, 2011.

may help to assign VWD subtype. In addition, a decrease in the duration of the DDAVP response may indicate an increased clearance mutation.

Genotyping

The identification of a mutation is not necessary for the diagnosis of VWD. However, genotyping should be considered when specialized testing with the VWF:FVIII:B assay is unavailable and type 2N VWD is suspected. Genotyping is also useful to discriminate between type 2B VWD and platelet-type VWD, and for prenatal assessment and alloantibody risk assessment in type 3 VWD. In mild-type 1 VWD, the likelihood of finding a mutation is low because mutations are not localized to a particular domain or exon and the results are of little clinical utility.

Differential Diagnosis

Hemophilia A

Both type 2N VWD and mild hemophilia A (caused by mutations in *F8*) result in reduced levels of FVIII:C (approximately 5–40 IU/dL) with normal or borderline low levels of VWF. Although the VWF:FVIII:B test distinguishes between the two disorders, the test is not widely available and the results may be equivocal.

In families with reduced FVIII:C, an X-linked pattern of inheritance helps identify those with mild hemophilia A. When family history is uninformative and VWF levels and function are normal, it may be preferable to perform sequence analysis of the *F8* gene before the *VWF* gene, even in symptomatic females who are simplex cases (i.e., a single occurrence in a family), because *F8* mutation and skewed X-chromosome inactivation (lyonization) are often responsible for symptoms. *F8* mutations may be detected in more than 50% of cases referred for “possible 2N VWD or hemophilia A.” When *F8* mutations are absent, or if the VWF level and function are also abnormal, *VWF* can be analyzed.

Platelet-Type von Willebrand Disease

Platelet-type VWD (PT-VWD, also called *pseudo* VWD) mimics type 2B VWD but is caused by mutations in the platelet *GP1BA*. The disorders can be distinguished by mixing patient platelets or plasma with control plasma or platelets and using aggregometry or flow cytometry to identify the defective component. However, these assays are technically challenging. In the absence of mutations in exon 28 of VWF, mutations in exon 2 of *GP1BA* are identified in approximately 10% of persons misdiagnosed with type 2B VWD. To date, missense mutations reported to affect GpIb α include p.Gly249 and p.Met255 plus a 27 bp in-frame deletion p.Pro449_Ser457del (c.1345_1371del27). Misdiagnosis of PT-VWD may result in ineffective treatment of patients. VWF concentrate is needed to correct

the reduced VWF level, but platelet transfusion may also be required if there is significant thrombocytopenia. The half-life of replaced VWF is reduced in PT-VWD because of binding to abnormal GpIb α . Consequently, VWF concentrate must be administered more frequently.

Acquired von Willebrand Syndrome

This mild to moderate bleeding disorder is a result of an acquired deficiency or dysfunction of VWF. Exclusion of a lifelong personal and family history of bleeding is an important aspect of the diagnosis. Although acquired von Willebrand syndrome (AvWS) was thought to be uncommon, cohort studies suggest that the prevalence may be significantly underestimated. When selected patient populations were screened, approximately 10% of patients with hematologic disorders, approximately 79% with aortic stenosis, and up to 100% with left ventricular assist devices were diagnosed with AvWS. The median age of diagnosis is 62 years, but the disorder may occur in any age group (range 2–96 years). AvWS has diverse pathology and may result from autoantibodies that impair VWF function or increase its clearance, adsorption of HMW VWF multimers to malignant cells or platelets, proteolytic cleavage of VWF after shear stress-induced unfolding, or decreased VWF synthesis. Diseases that have been implicated include (1) lymphoproliferative disorders and plasma cell dyscrasias, including monoclonal gammopathy of unknown significance, multiple myeloma, and Waldenström macroglobulinemia; (2) autoimmune disorders, including systemic lupus erythematosus, scleroderma, and antiphospholipid antibody syndrome; (3) aortic stenosis and ventricular septal defects, which can trigger shear-induced conformational changes that increase VWF proteolysis; (4) thrombocytosis, including myeloproliferative neoplasms that lead to a type 2 phenotype; (5) Wilms tumor or lymphoproliferative disorders that can be associated with increased VWF clearance by aberrant binding to tumor cells; (6) decreased VWF synthesis, for instance, with hypothyroidism, and drugs including valproic acid, ciprofloxacin, griseofulvin, and hydroxyethyl starch. The treatment goals can be divided into two categories: treatment or prevention of bleeding and induction of long-term remission. The agents used for prevention and treatment of bleeding in AvWS overlap with those used in VWD and include DDAVP or VWF-containing concentrates, which can transiently increase VWF levels. Other options include recombinant factor VIIa, antifibrinolytic agents, intravenous immunoglobulin, or plasmapheresis for AvWS associated with monoclonal gammopathies. Often a combination of agents is required to affect hemostasis. Maneuvers to induce long-term remission will depend on the underlying pathogenic etiology of AvWS. Whenever possible, treatment of the underlying disorder should be considered and may result in remission of the AvWS.

Management of von Willebrand Disease

The approach to the management of VWD is summarized in [Fig. 138.6](#).

Fig. 138.6 APPROACH TO THE MANAGEMENT OF VON WILLEBRAND DISEASE. *FHx*, Family history; *FVIII*, factor VIII; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *Hx*, history; *IV*, intravenous; *RCo*, ristocetin cofactor; *SC*, subcutaneous; *VWD*, von Willebrand disease; *VWF*, von Willebrand factor.

Evaluations Following Initial Diagnosis

To establish the extent of disease in an individual diagnosed with VWD, the following evaluations are recommended: (1) a personal and family history of bleeding to help predict severity and tailor treatment (use of a standardized bleeding assessment tool can be helpful); (2) a joint and muscle evaluation for those with type 3 VWD (musculoskeletal bleeding is rare in types 1 and 2 VWD); (3) screening for hepatitis B and C, as well as HIV if the diagnosis is type 3 VWD or if the individual received blood products or plasma-derived clotting factor concentrates before 1985 (this screening should be followed by vaccinations for hepatitis A and B); (4) determination of serum iron and ferritin (to assess iron stores), because many individuals with VWD are iron deficient, particularly women with menorrhagia; and (5) gynecologic evaluation for women with menorrhagia. Individuals with VWD benefit from referral to a comprehensive bleeding disorders program for education, treatment, and genetic counseling.

Treatment of von Willebrand Disease

The management of VWD can be divided into three main categories: (1) localized measures to stop or minimize bleeding; (2) pharmacologic agents that provide indirect hemostatic benefit; and (3) treatments that directly increase plasma VWF and FVIII levels.

Localized Measures

The importance of localized measures to control bleeding in VWD, such as the application of direct pressure to a site of bleeding or injury, should not be understated. Biting down on a piece of gauze may halt

bleeding from a tooth socket, and application of a compression bandage and cold pack to an injured limb may reduce subsequent hematoma formation. With epistaxis, patients may benefit from a step-wise action plan that escalates from pressure to packing after a certain time period. In selected cases, nasal cautery may be required for prolonged or excessive epistaxis.

A number of topical hemostatic agents that are predominately used to achieve surgical hemostasis may have a limited role in the treatment of VWD and bleeding; these include gelatin foam/matrix, topical thrombin, and fibrin sealants.

Indirect Therapies

Fibrinolytic inhibitors (e.g., tranexamic acid), which inhibit the conversion of plasminogen to plasmin, can be used either as sole therapy or as adjuncts to DDAVP or VWF/FVIII concentrates and may be particularly useful to control mucosal bleeding in the oral cavity or gastrointestinal (GI) or genitourinary tracts. The most common adverse events to tranexamic acid are GI side-effects and headache. Tranexamic acid is contraindicated in disseminated intravascular coagulation and bleeding from the upper urinary tract, where it can lead to obstruction by clots. Hormonal treatments (i.e., the combined oral contraceptive pill) are effective for the treatment of menorrhagia. Nonmedical treatments, such as levonorgestrel-releasing intrauterine systems or endometrial ablation, may be useful in selected patients with VWD.

Desmopressin

Most individuals with type 1 VWD and some with type 2 VWD respond to intranasal, intravenous or subcutaneous treatment with

DDAVP, which promotes release of stored VWF and raises levels 3–10-fold. Peak effects are achieved 30 and 90 minutes after intravenous and intranasal delivery, respectively. The usual parenteral dose is 0.3 µg/kg infused intravenously in approximately 50 mL of normal saline over approximately 30 minutes. The dose of the highly concentrated intranasal preparation is 150 µg for children under 50 kg and 300 µg for larger children and adults. It is important to note that highly concentrated products (e.g., Stimate) deliver 150 µg per spray, a much higher concentration than that used to treat enuresis.

After VWD diagnosis, a DDAVP challenge is advisable to assess VWF response. VWF and FVIII levels should be determined before and at several points after DDAVP administration (e.g., at baseline and at 1 and 4 hours). A threefold increase in VWF and FVIII levels to at least 0.30 IU/mL (30%) is usually considered adequate for situations such as dental procedures, minor surgery, or the treatment of epistaxis or menorrhagia.

DDAVP is safe and generally well tolerated. Common side effects include facial flushing and headache. Tachycardia, lightheadedness, and mild hypotension can occur. The most serious side effects are severe hyponatremia and seizures. Reduction of fluid intake for 24 hours after DDAVP administration is an important precaution to prevent water intoxication. Serum sodium levels should be monitored in patients receiving repeated doses of DDAVP. In addition, DDAVP should be used with caution in those younger than 2 years of age because of a higher risk for hyponatremia. There are case reports of DDAVP precipitating coronary artery vasospasm and acute myocardial infarction. Therefore DDAVP should be used with caution in patients with a history of coronary artery disease or in the older adult. In persons who are intolerant to DDAVP or have a poor VWF response, clotting factor concentrate is required.

An important limitation in the use of DDAVP is the development of tachyphylaxis with repeated administration. When given repeatedly at intervals of less than 24 hours, the magnitude of the VWF and FVIII increments can fall to approximately 70% of those obtained with the initial dose. For practical purposes, a single dose of DDAVP before dental extractions or minor procedures is usually sufficient. Although repeated doses can be given at 12 or 24 hours, the potential for tachyphylaxis must be considered. Additionally, in situations where repeat dosing is considered, more prolonged fluid restriction is required.

Although most type 1 VWD patients respond adequately to DDAVP, type 3 VWD patients typically do not respond to this drug, and the response in type 2 VWD patients is variable. Type 2A patients often exhibit an adequate response and may benefit from a DDAVP trial. Type 2M patients typically do not respond well to DDAVP. DDAVP is generally contraindicated in type 2B VWD because of the transient thrombocytopenia that accompanies the release of mutant VWF. In type 2N VWD, DDAVP produces a two-fold to ninefold increase in FVIII, but the increase persists for approximately 3 hours. Therefore DDAVP should be reserved for situations in which a transient rise in FVIII is sufficient.

von Willebrand Factor/Factor VIII Concentrates

VWF/FVIII concentrates are required for patients who do not have an adequate response, experience side effects, or have contraindications to DDAVP. Because of tachyphylaxis and the risk of hyponatremia with DDAVP, patients with severe bleeding or those requiring major or repeated surgery often need VWF replacement therapy. Purified, viral-inactivated, plasma-derived VWF/FVIII is the product most frequently used (e.g., Humate-P, Wilate). The quantity of ristocetin cofactor activity (VWF:RCo) relative to FVIII:C varies by product; Humate-P contains 2.4 VWF:RCo units for each 1 FVIII:C unit, whereas Wilate contains a 1:1 ratio. Both products contain a full spectrum of VWF multimers, including HMW multimers, and closely resemble normal plasma. Highly purified FVIII concentrates (monoclonal antibody purified and recombinant) should not be used to treat VWD because they lack VWF.

Dosing recommendations are provided either in VWF:RCo (North America) or FVIII:C (Europe) units and are weight-based; repeat infusions can be given every 8 to 24 hours, depending on the clinical situation. The goal is to maintain VWF:RCo and FVIII:C at more than 100 IU/dL at peak and at more than 50 IU/dL at trough until hemostasis is achieved. With VWF/FVIII concentrates, the FVIII:C response is higher and more sustained than predicted from the dose because of the stabilizing effect of exogenous VWF on endogenous FVIII. Details regarding dosing can be found in the product inserts. VWF:RCo and FVIII:C levels should be measured in patients receiving repeat infusions, not only to ensure adequate hemostasis but also to monitor for supraphysiological levels of FVIII because thromboembolic events have been associated with high FVIII levels. The overall incidence of thrombotic events is very low, and most cases occurred in surgical patients with other risk factors. Therefore mechanical and anticoagulant thromboprophylaxis should be considered on a case-by-case basis. Adverse reactions to VWF/FVIII concentrates are rare but include allergic and anaphylactic symptoms, such as urticaria, chest tightness, rash, pruritus, and edema.

VWF:FVIII concentrates are effective in over 97% of events. In the rare event that infusion of a VWF/FVIII concentrate is ineffective at stopping bleeding, transfusion of platelet concentrates may be beneficial, presumably because they facilitate the delivery of small amounts of platelet VWF to the site of vascular injury.

A new recombinant VWF (rvWF) concentrate, which is administered with recombinant FVIII in a 1.3 RCo:FVIII ratio, has recently been studied in a prospective phase 1 randomized clinical trial. The trial demonstrated safety, tolerability, and a pharmacokinetic profile comparable to that with plasma-derived VWF concentrates. Larger clinical studies are needed and are ongoing, but rvWF represents an important advance in the treatment options for VWD.

Prophylaxis

Short-term prophylaxis with a combination of an antifibrinolytic, DDAVP, and/or VWF/FVIII concentrates, in anticipation of a defined bleeding challenge, such as surgery, is the standard of care in the treatment of VWD. The role of long-term continuous prophylaxis, defined as primary if initiated before long-term sequelae have developed (e.g., joint damage) or secondary if initiated after the development of chronic changes, is less established in VWD than it is in severe hemophilia. Individuals with severe cases of VWD, in particular type 3 VWD and certain patients with severe type 1 or type 2 VWD, may experience recurrent joint bleeds, as well as severe and frequently recurrent nasal/oral, GI, or menstrual bleeding. The resultant anemia, hospitalizations, and absences from school or work may have a significant impact on quality of life. Although there is limited evidence, several cohort and case studies suggest that both primary and secondary long-term prophylaxis improve quality of life, alleviate anemia, reduce hospitalizations, and prevent chronic joint disease. Complications are unusual aside from rare cases of VWF inhibitor formation (approximately 3%). Controversy exists about the specific indications, schedules, and dosing of prophylactic regimens. This is the subject of an ongoing international trial, known as the VWD International Prophylaxis trial, which began recruitment of patients in 2007.

Pediatric Issues

Prenatal diagnosis for pregnancies at increased risk (generally only for type 3 VWD) is possible by analysis of DNA extracted from fetal cells obtained by chorionic villus sampling at 11–13 weeks of gestation or amniocentesis at 15–18 weeks of gestation. The disease-causing allele(s) of an affected family member must be identified before prenatal testing. Preimplantation genetic diagnosis may be available for families in which the disease-causing mutation(s) have been identified.

Assessment of a Neonate

A baby boy was born to a mother with known type 2B VWD. On the day of birth, investigations demonstrated the following: VWF:Ag 78 IU/dL, VWF:RCo 61 IU/dL, and FVIII:C 0.69 IU/dL (unclear whether these were done on mom or the baby). The mother was informed that the results were all within normal range and that her newborn infant was not affected by type 2B VWD. When he was approximately 18 months of age, the mother noted excessive mucocutaneous bleeding. Blood work at that time demonstrated: VWF:Ag 50 IU/dL, VWF:RCo 20 IU/dL, and FVIII:C 51 IU/dL. Multimer analysis revealed a lack of HMW multimers. Finally, genotyping revealed that the boy was heterozygous for the same mutation, R1306W that his mother carried.

This case illustrates several important points. Neonatal levels of VWF are increased over baseline; if investigations are performed, they should be interpreted using appropriate reference ranges. Alternatively, if a phenotypic diagnosis is being sought, it is preferable to postpone investigations, decreasing the likelihood of pretest analytical variables, such as difficulty in collecting an appropriate blood sample from a neonate, and the difficulties with interpretation of the results. Finally, in cases in which the mutation is known, genotyping is diagnostic and also the most straightforward.

The diagnosis and care of infants and children with VWD require special consideration. An accurate assessment of hemorrhagic symptoms is a key component in the diagnosis of VWD, but it often presents a significant challenge in the pediatric population. Because young children may have been exposed to few hemostatic challenges and may be prepubertal, the bleeding history may be unimpressive. The effect this negative history may have on perceived risk for bleeding is highlighted in two of the previously published bleeding scores, which assign a negative value to lack of bleeding symptoms and are based on the accumulation of bleeding symptoms or complications. Finally, the initial diagnostic assessment of an infant is complicated by the fact that VWF levels are higher in the neonatal period. Consequently, phenotypic testing of VWD should be delayed until later in childhood (see Fig. 138.6).

DDAVP should be avoided in children younger than the age of 2 because of the potential difficulty in restricting fluids. Infant males should be circumcised only after consultation with a pediatric hemostasis specialist. Typically, only patients with type 3 VWD experience spontaneous musculoskeletal bleeding, such as that seen in patients with severe hemophilia, and should be considered for long-term prophylaxis with VWF/FVIII concentrates, as discussed in the preceding section (see box on [Assessment of a Neonate](#)).

DISSEMINATED INTRAVASCULAR COAGULATION

Marcel Levi

A variety of disorders, including infectious or inflammatory conditions and malignant disease, will lead to activation of coagulation. In many cases, this activation of coagulation will not lead to clinical complications and will not even be detected by routine laboratory tests, but can only be measured with sensitive molecular markers for activation of coagulation factors and pathways.^{1,2} However, if the stimulus for activation of coagulation is sufficiently strong, the platelet count may decrease and global clotting times may become prolonged. In its most extreme form, systemic activation of coagulation is known as disseminated intravascular coagulation (DIC). DIC is characterized by the simultaneous occurrence of widespread (micro) vascular thrombosis, thereby compromising blood supply to various organs, which may contribute to organ failure.^{3,4} Because of ongoing activation of the coagulation system and other factors, such as impaired synthesis and increased degradation of coagulation proteins and protease inhibitors, consumption of clotting factors and platelets may occur, resulting in bleeding from various sites.

In view of the multiple, often contrasting mechanisms that occur in patients with DIC, a consensual definition of DIC had been a matter of debate. In 2001 the subcommittee on DIC of the International Society on Thrombosis and Hemostasis proposed a definition that reflects the central role of the microvascular milieu, i.e., endothelial cells, blood cells, and the plasma protease system, in the pathogenesis of DIC. This definition of DIC reads as follows: "DIC is an acquired syndrome characterized by the intravascular activation of coagulation without a specific localization and arising from different causes. It can originate from and cause damage to the microvasculature, which if sufficiently severe, can produce organ dysfunction."⁵

The diagnosis of DIC may be hampered by the nonspecific nature of many indicators of coagulation activation, although newly developed scoring algorithms based on readily available routine laboratory parameters show promising diagnostic accuracy.⁵ Owing to the complexity of the clinical presentation, the variable and unpredictable course, and the multitude of therapies given to patients with DIC, properly conducted clinical trials are difficult to perform and even to devise. Management relies on limited evidence from clinical trials in combination with small studies employing surrogate outcome endpoints and experience from case series, as well as from an understanding of the underlying pathophysiologic mechanisms.⁶

EPIDEMIOLOGY

Activation of coagulation in concert with inflammatory activation can result in microvascular thrombosis, which contributes to multiple organ failure in patients with severe sepsis.⁷ In support of this concept, postmortem findings in patients with coagulation abnormalities and DIC on the background of severe sepsis include diffuse bleeding, hemorrhagic necrosis of tissues, microthrombi in small blood vessels, and thrombi in midsize and larger arteries and veins. Ischemia and necrosis were invariably the result of fibrin deposition in small and midsize vessels. Importantly, intravascular thrombi appear to be the driver of the organ dysfunction. Fibrin deposition in various organs also is a characteristic finding in animal models of DIC. Thus experimental bacteremia or endotoxemia causes intra- and extravascular fibrin deposition in the kidneys, lungs, liver, brain, and other organs. Amelioration of the hemostatic defect with various interventions reduces fibrin deposition, improves organ function in these models,

and, in some cases, reduces mortality. Finally, results of clinical studies also support the concept that activation of coagulation is an important determinant of clinical outcome. DIC has been shown to be an independent predictor of organ failure and mortality.⁸ In a consecutive series of patients with severe sepsis, 43% of the patients with DIC were compared with the 27% without DIC. In that study, the severity of the coagulopathy was directly related to mortality.⁹

In addition to microvascular thrombosis and organ dysfunction, coagulation abnormalities may have other harmful consequences. Thrombocytopenia in patients with sepsis places them at risk of bleeding. For example, critically ill patients with a platelet count of $<50 \times 10^9/L$ have a four- to fivefold higher risk for bleeding than those with higher platelet counts.¹⁰ Although the overall risk of intracerebral bleeding in intensive care unit (ICU) patients is less than 0.5%, up to 88% of patients with this complication have platelet counts below $100 \times 10^9/L$. The use of anticoagulants in patients with thrombocytopenia further increases the risk of bleeding. Regardless of the cause, multivariate analyses indicate that thrombocytopenia is an independent predictor of ICU mortality and increases the risk of death by 1.9- to 4.2-fold. In particular, thrombocytopenia that persists for more than 4 days after ICU admission, or a 50% or greater decrease in platelet count during the ICU stay, is associated with a four- to sixfold increase in mortality. In fact the platelet count appears to be a stronger predictor of ICU mortality than composite scoring systems, such as the Acute Physiology and Chronic Evaluation (APACHE) II or Multiple Organ Dysfunction Score (MODS). Decreased levels of coagulation factors, as reflected by prolonged global coagulation times, also increase the risk of bleeding. Prolongation of the prothrombin time (PT) or activated partial thromboplastin time (aPTT) to over 1.5 times the control is associated with an increased risk of bleeding and mortality in critically ill patients.

PATHOBIOLOGY

Traditionally, DIC was thought to be the result of activation of both the extrinsic and intrinsic pathways of coagulation. The classical concept was that the extrinsic pathway was initiated by a tissue-derived component, which activated factor VII leading to the direct conversion of prothrombin to thrombin. This process would proceed as long as there was tissue damage from systemic infection, trauma, circulating placental components, or malignancy. In contrast, the intrinsic or contact pathway of coagulation was initiated by contact activation of factor XII which, together with its cofactors, kallikrein and high molecular weight kininogen, then activated factor XI leading to subsequent activation of factor IX. Until recently, the initiators of contact activation were thought to include collagen and artificial surfaces. In recent years the molecular mechanisms of coagulation pathway activation have been better defined (Fig. 139.1), thereby providing new insight into the pathogenesis of DIC. In general, current thinking is that thrombin and fibrin generation in patients with DIC is largely driven via the extrinsic pathway; the role of the contact system is uncertain.

Tissue Factor-Factor VII(a) Pathway

The extrinsic pathway is initiated by the tissue factor (TF)-factor VIIa complex. TF is a membrane-bound 4.5-kDa protein that is

Fig. 139.1 PATHOGENESIS OF DISSEMINATED INTRAVASCULAR COAGULATION (DIC). Pathways involved in the activation of coagulation in DIC. Both perturbed endothelial cells and activated mononuclear cells may produce proinflammatory cytokines that induce tissue factor expression, thereby initiating coagulation. In addition, downregulation of physiologic anticoagulant mechanisms and inhibition of fibrinolysis promotes intravascular fibrin deposition. *PAI-1*, plasminogen activator inhibitor, type 1.

constitutively expressed on cells that are mostly in tissues and not in direct contact with blood, such as the adventitial layer of larger blood vessels.¹² Subcutaneous tissue also contains substantial amounts of TF. When expressed on the cell surface, TF interacts with factor VII, either in its zymogen or activated form. The TF–factor VIIa complex catalyzes the activation of both factor IX and factor X. Factors IXa and Xa enhance the activation of factors X and prothrombin, respectively. In cells in contact with the blood, TF is induced by the action of mediators such as cytokines, C-reactive protein and advanced glycosylation end products. Inducible TF is predominantly expressed by monocytes and macrophages. Monocyte TF expression is enhanced in the presence of platelets and granulocytes in a P-selectin dependent fashion. This may reflect nuclear factor kappa-B (NFκB) activation that occurs when activated platelets bind to neutrophils or mononuclear cells. These cell-cell interactions also stimulate the production of interleukin (IL)-1b, IL-8, MCP-1, and tumor necrosis factor (TNF)-α. Under cell culture conditions, cytokines such as TNF-α, and IL-1 can induce TF expression by vascular endothelial cells, but the in vivo relevance of this finding is uncertain. Studies in vivo suggest that IL-6 is the dominant mediator of TF expression by mononuclear cells.

Increased monocyte TF expression and procoagulant activity has been demonstrated in DIC associated with sepsis, cancer, or coronary disease. Tissue expression of TF appears to be localized to certain organs and vascular beds, but it is uncertain whether its expression is under genetic control in an organ-specific fashion. With trauma, such as extensive surgery, brain injury, or burns, it is likely that constitutively expressed TF at the site of injury is the primary source of procoagulant material, but direct support for this concept is lacking.

The Intrinsic Pathway

The role of the intrinsic pathway in the pathogenesis of DIC is uncertain. Negatively charged substances, such as phospholipids,

polyphosphates, and glycosaminoglycans, are potential activators of the contact pathway. Studies in patients with suspected DIC have identified elevated levels of markers of activation of the contact system. In patients with meningococcal septicemia, there was a negative correlation between plasma factor XII levels and factor XIIa–C1 inhibitor complexes. Although this finding implies consumption of factor XII, and subsequent downstream activation of factor XI, an alternative explanation is that there is a negative acute phase effect with reduced synthesis of factor XII, in conjunction with thrombin-mediated activation of factor XI.

However, blockade of the contact system with a factor XIIa-directed antibody failed to prevent DIC in a balloon model of *Escherichia coli* sepsis, but diminished development of lethal hypotension. These findings provide reasonable support for the current view that the contact pathway does not contribute to DIC, but may play important roles in proinflammatory mechanisms related to vascular permeability, vascular proliferation (kininogen induces smooth muscle cell proliferation), and enhancement of fibrinolysis.¹¹

Cytokines and Other Amplification Pathways

Activation of blood coagulation requires several cofactors. For development of DIC, the surfaces of cell remnants or intact cells, inflammatory mediators, and coagulation proteins are required. The stimulus for activation depends on the underlying disease and may encompass bacterial cell compounds, such as endotoxin, TF on host or cancer cells, other cancer cell procoagulants, fat, or amniotic fluid emboli by unknown pathways. Each of these triggers interacts with other mediators: TF assembles on anionic phospholipid surfaces, which can be provided by activated platelets, leukocytes, or cancer cells; cytokines interact with receptors and induce signaling pathways that induce TF expression and other proinflammatory components via the NFκB complex.

Endotoxin is a lipopolysaccharide compound of gram-negative bacteria that induces the sepsis syndrome and DIC. Gram-negative bacteria liberate endotoxins from their membrane, which interact with cell surfaces via various pathways. In blood, endotoxin directly binds to CD14 on monocytes, and binds to endothelial cells after complexing with lipopolysaccharide binding protein (LBP) and the Toll-like receptor 4 (TLR 4) complex. Through these interactions, endotoxin induces signaling pathways that culminate in NFκB activation, and initiates the expression of proinflammatory cytokines and TF. Likewise, exotoxins, such as lipoteichoic acid (LTA) from gram-positive bacteria can also induce proinflammatory cytokine expression.

The molecular mechanisms underlying endotoxin-induced activation of coagulation have been studied in nonhuman primates. In endotoxin or *E. coli* models of sepsis, inhibition of the TF pathway abolishes the activation of coagulation, highlighting the importance of TF. IL-6 is an important mediator of procoagulant effects, whereas TNF-α is involved in the fibrinolytic response to endotoxin. Inhibition of TF with tissue factor pathway inhibitor (TFPI) reduces IL-6 levels in the baboon model, suggesting that there is extensive crosstalk between coagulation and inflammatory mediators (see later). Monocytes that express TF bind factor VII(a), shed TF, or bind to the damaged vessel wall. After interacting with platelets, circulating monocytes can trigger DIC. Microvesicles may accelerate this process, and the complex interaction between cells, membrane fragments, soluble mediators, and proteins may trigger the DIC syndrome. The severity and duration of the consumptive process are mainly determined by the potency of the triggers and the capacity of inhibitory mechanisms.

Cross Talk Among Coagulation Proteases Results in Proinflammatory Effects

In addition to activating coagulation protein zymogens, coagulation proteases also interact with specific cell receptors and trigger signaling

Fig. 139.2 PHYSIOLOGIC ANTICOAGULANT MECHANISMS IN DISSEMINATED INTRAVASCULAR COAGULATION. Physiologic anticoagulant mechanisms (activated protein C system, tissue factor pathway inhibitor (TFPI), and antithrombin) are not only involved in blocking thrombin generation and thrombin activity but also affect inflammatory pathways.

pathways that elicit proinflammatory mediators.⁷ Factor Xa, thrombin, and the factor VIIa–TF complex have such effects. Factor Xa injection into rats induces localized inflammation, probably as a result of its interaction with EPR-1 and not because of thrombin generation. Exposure of cultured endothelial cells to factor Xa stimulates the production of monocyte chemoattractant protein 1 (MCP-1), IL-6 and IL-8, and upregulates the expression of adhesion proteins that tether neutrophils to the cell surface. Further evidence for the crosstalk between inflammation and coagulation comes from the observations that IL-6 and IL-8 elicit TF-dependent procoagulant activity in monocytes and the fact that IL-6 has been identified as the critical mediator of procoagulant activity either on its own or after endotoxin challenge in vivo. Therefore cytokine production induced by factor Xa may be an important driver of coagulation in DIC.

In addition to its procoagulant functions, thrombin has a variety of noncoagulant effects. Thrombin induces the release of MCP-1 and IL-6 from fibroblasts, epithelial cells, and mononuclear cells in vitro. Thrombin also induces IL-6 and IL-8 production in endothelial cells. When generated in whole blood, IL-8 production has a procoagulant effect that is TF dependent. Cell activation by thrombin is likely mediated by protease activated receptors (PARs). The factor VIIa–TF complex also activates cells by binding and activating PAR 2.

Direct evidence of the in vivo relevance of these phenomena comes from a study showing that recombinant factor VIIa infusion in volunteers induces an increase in plasma levels of IL-6 and IL-8. Although the concentrations of factor VIIa infused far exceed those found in patients with sepsis, it is possible that factor VIIa-induced cytokine production is of physiologic importance. Therefore this information adds to the concept that several coagulation proteases induce proinflammatory mediators that augment procoagulant

activity and amplify the consumptive process. Endogenous anticoagulant pathways are essential to regulate these proteases and to prevent uncontrolled DIC.

Endogenous Anticoagulant Pathways in Disseminated Intravascular Coagulation

The development of DIC is counteracted by several mechanisms. First, coagulation inhibitors regulate the coagulation mechanism. Those inhibitors include antithrombin (AT), the protein C system, and TFPI (Fig. 139.2).⁷ AT, which complexes and inhibits thrombin and factor Xa, is one of the most important inhibitors and reduced AT levels are a characteristic of DIC. Reduction in AT levels reflects a combination of reduced protein synthesis as well as increased clearance through the formation of protease–AT complexes, and by degradation by neutrophil elastase. In addition, cytokines may impair proteoglycan synthesis in the vessel wall thereby reducing the availability of heparan sulfate for potentiation of AT activity.

In animal models of experimental bacteremia, AT concentrate infusion increases survival, reduces the severity of DIC, and lowers the levels of IL-6 and IL-8. Therefore in addition to its anticoagulant function, AT may also have an antiinflammatory effect.

Activated protein C and its cofactor protein S provide a second line of defense. Thrombin binds to thrombomodulin on the endothelial cell membrane and the thrombin–thrombomodulin complex converts protein C to its active form, activated protein C (APC).¹² In addition the thrombin–thrombomodulin complex converts the latent carboxypeptidase B–like enzyme thrombin activatable fibrinolytic inhibitor (TAFI) to its activated form. APC inactivates factors

Va and VIIIa by proteolytic cleavage, thereby downregulating the coagulation cascade. Endothelial cells, primarily of large blood vessels, express endothelial protein C receptor (EPCR) on their surface. EPCR augments protein C activation by binding protein C and presenting it to the thrombin–thrombomodulin complex on the cell surface. APC has antiinflammatory effects on mononuclear cells and granulocytes, which may be distinct from its anticoagulant activity. Administration of APC prevented thrombin-induced thromboembolism in mice, mainly through its antithrombotic effect.

Defects in the protein C mechanism enhance the vulnerability to inflammatory reactions and DIC. In patients, reduced levels of protein C and protein S are associated with increased mortality. Mice with a one-allele targeted disruption of the protein C gene, causing heterozygous protein C deficiency, developed a more severe form of DIC and associated inflammatory response compared with their wild-type counterparts. Blockade of protein C activity by infusion of C4 binding protein converted a sublethal model of *E. coli* in baboons into a lethal model. In addition, blockade of EPCR with a neutralizing monoclonal antibody also increased mortality in the *E. coli* baboon model, whereas infusion of PC protected against DIC and lethality. Therefore the protein C pathway is important in the host defense against sepsis and DIC. In situations associated with DIC and systemic inflammation, cell culture experiments suggest that TNF- α and IL-1 may downregulate thrombomodulin expression. However, in vivo studies suggest that EPCR is upregulated in sepsis; an effect mediated by thrombin. The generation of thrombin may also trigger EPCR shedding due to the activation of metalloproteinases by thrombin. It is presently unknown whether thrombomodulin is also cleaved by similar mechanisms.

TFPI provides a third inhibitory mechanism. TFPI exists in several pools including endothelial cell associated and lipoprotein bound in plasma. It inhibits the TF–factor VIIa complex by forming a quaternary complex in which factor Xa is the fourth component. Clinical studies in patients with sepsis have not provided clues as to its importance because in the majority of patients the TFPI levels are normal. This may be explained by the lack of downregulatory effects of inflammatory mediators on cultured endothelial cells. The relevance of TFPI in DIC is illustrated by two lines of experimentation. First, depletion of TFPI sensitizes rabbits to DIC induced with tissue factor infusion. Second, TFPI infusion protects against the harmful effects of *E. coli* in primates. TFPI not only blocks DIC in baboons given lethal doses of *E. coli*, but improves vital functions and survival. A study in human volunteers confirmed the potential of TFPI to block the procoagulant effects of endotoxin.

In general, normal levels and function of inhibitors is important in the defense against DIC. It should be noted, however, that there are no strong indications that patients with congenital deficiencies of inhibitors are at increased risk of DIC, but this issue requires greater exploration. In addition, the capacity of inhibitors to modify the interaction between coagulation and inflammation deserves further attention.

Fibrinolysis

In experimental models of DIC, fibrinolysis is activated, demonstrated by an initial activation of plasminogen, followed by impairment caused by the release of type 1 plasminogen activator inhibitor (PAI-1). This results in a net procoagulant state. The molecular basis for this procoagulant state is cytokine-mediated activation of vascular endothelial cells, thus TNF- α and IL-1 decrease tPA production and increase PAI-1 production. Although TNF- α increases urokinase type plasminogen activator (uPA) production by endothelial cells, endotoxin and TNF- α stimulate PAI-1 production in the liver, kidney, lung, and adrenals of mice.

The net procoagulant state is manifested by a late rise in fibrin breakdown fragments after *E. coli* challenge in baboons. Experimental data also suggest that the fibrinolytic mechanism is active in clearing fibrin from organs and the circulation. Endotoxin-induced fibrin formation in the kidneys and adrenals is most dependent on decreased

levels of uPA. In contrast to wild-type mice challenged with endotoxin, PAI-1 knockout mice do not develop thrombi in the kidney. Endotoxin administration to mice with a functionally inactive thrombomodulin gene (TMProArg mutation) and defective protein C activator cofactor function caused fibrin plugs in the pulmonary circulation, whereas wild-type mice did not develop macroscopic fibrin. This phenomenon in thrombomodulin deficient mice proved to be temporary; thrombi developed 4 hours after endotoxin administration and disappeared at 24 hours in animals killed at that time point. These experiments demonstrate that the fibrinolytic system is essential for clearance of intravascular fibrin.

Fibrinolytic activity is regulated by PAI-1, the principal inhibitor of this system. Previous studies have shown that a functional mutation in the PAI-1 gene, the 4G/5G polymorphism, not only influences plasma levels of PAI-1, but also affects the clinical outcome of meningococcal septicemia. Patients with the 4G/4G genotype had significantly higher PAI-1 concentrations in plasma and an increased risk of death. Further investigations demonstrated that the PAI-1 polymorphism did not influence the risk of contracting meningitis, but probably increased the likelihood of developing septic shock from meningococcal infection. These studies provide the first evidence that genetically determined differences in the level of fibrinolysis influence the risk of developing complications of gram-negative infection. In other clinical studies in cohorts of patients with DIC, high plasma levels of PAI-1 were one of the best predictors of mortality. These data suggest that DIC contributes to mortality in this situation, but as indicated earlier, because PAI-1 is an acute-phase protein, higher plasma levels may also be a marker of disease rather than a causal factor.

CLINICAL MANIFESTATIONS

The clinical manifestations of DIC vary depending on the underlying disorder. At the extreme end of the spectrum is acute, severe DIC, which often occurs in the setting of sepsis, major trauma, obstetric calamities, and severe immunologic responses. Diffuse multiorgan bleeding, hemorrhagic necrosis, microthrombi in small blood vessels, and thrombi in medium and large blood vessels are common findings at autopsy, although patients with unequivocal clinical and laboratory signs of DIC may not have confirmatory postmortem findings. Conversely, some patients in whom clinical and laboratory signs were not consistent with DIC have typical autopsy findings. Although this occasional lack of correlation among clinical, laboratory, and pathologic findings can partly be explained by excessive fibrinolysis post mortem, this does not account for all cases. The organs most frequently involved by diffuse microthrombi are the lungs and kidneys, followed by the brain, heart, liver, spleen, adrenal glands, pancreas, and gut. Specific immunohistological techniques and ultrastructural analysis have revealed that most thrombi consist of fibrin monomers or polymers in combination with platelets. In addition, involvement of activated mononuclear cells and other signs of inflammation are frequently present. In cases of long-lasting DIC, organization and endothelialization of the microthrombi are often observed. Acute tubular necrosis is more frequent than renal cortical necrosis. Clinically, thrombotic occlusive events occur first as a consequence of microvascular obstruction by microthrombi consisting of fibrin or platelets. These thrombi result from clots that form either in the circulation or in situ in arterioles, capillaries, or venules. Circulatory obstruction reduces organ perfusion and may lead to ischemia, infarction, and necrosis. The process is disseminated throughout the microcirculation, therefore all organs are potentially vulnerable.

In contrast to acutely ill patients with severe DIC, others may have mild or protracted clinical manifestations of consumption or even subclinical disease manifested only by laboratory abnormalities.¹ The clinical picture of subacute to chronic DIC generally occurs in patients with malignancy, in particular those with mucin-producing adenocarcinomas or acute promyelocytic leukemia (APL). The latter usually is dominated by a hemorrhagic presentation, whereas venous

BOX 139.1 Clinical Conditions Most Frequently Complicated by Disseminated Intravascular Coagulation

- Sepsis/severe infection
- Trauma/burn/heatstroke
- Malignancy
 - Solid tumors
 - Acute leukemia
- Obstetric conditions
 - Amniotic fluid embolism
 - Abruptio placentae
 - HELLP syndrome
- Vascular abnormalities
 - Kasabach-Merrit Syndrome
 - Other vascular malformations
 - Aortic aneurysms
- Severe allergic/toxic reactions
- Severe immunologic reactions (e.g., transfusion reaction)

thrombotic manifestations are more common in the former. In addition, patients with solid tumors may develop nonbacterial thrombotic endocarditis with systemic arterial embolization and infarction. Another cause of subacute to chronic DIC is the retained dead fetus syndrome. These patients have an extremely variable presentation ranging from asymptomatic to mild or moderate skin and mucous membrane bleeding.

It is important to stress that DIC is not a disease in itself but is always secondary to an underlying disorder, which causes the activation of coagulation. The underlying disorders most commonly known to be associated with DIC are listed in [Box 139.1](#) and are described in detail below.

Disseminated Intravascular Coagulation in Infectious Disease

Systemic infections are among the most common causes of DIC. Immunocompromised patients, asplenic patients whose ability to clear bacteria (particularly pneumococci) is impaired, and newborns whose anticoagulant systems are immature are particularly prone to infection-induced DIC. Infections may be superimposed on trauma or malignancies, which themselves are potential triggers of DIC. In addition, infections can aggravate bleeding and thrombosis by directly inducing thrombocytopenia, hepatic dysfunction, and shock, which can lead to diminished blood flow in the microcirculation.

Clinically overt DIC occurs in 30%–50% of patients with gram-negative or gram-positive sepsis. Extreme examples of sepsis-related DIC are streptococcus A toxic shock syndrome, which is characterized by deep tissue infection, vascular collapse, vascular leakage, and multiple organ dysfunction. M protein released from streptococci forms complexes with fibrinogen that bind to β_2 integrins on neutrophils leading to their activation, and meningococcemia, a fulminant gram-negative infection characterized by extensive hemorrhagic necrosis, DIC, and shock. More frequent gram-negative infections associated with DIC are caused by *Pseudomonas aeruginosa*, *E. coli*, and *Proteus vulgaris*. Patients with these infections may only have laboratory evidence of activated coagulation or they may present with severe DIC.

Activation of the coagulation system has also been documented with nonbacterial pathogens, such as viruses, protozoa (malaria), and fungi.¹³ Common viral infections, such as influenza, varicella, rubella, and rubeola, are rarely associated with DIC. Some viral infections can cause hemorrhagic fever characterized by fever, hypotension, bleeding, and renal failure. Laboratory evidence of DIC can accompany Korean, rift valley, and dengue-related hemorrhagic fevers. Protozoan infections, such as cerebral malaria, may be associated with overt DIC. In these cases, secondary deficiency of a disintegrin-like metalloprotease with thrombospondin type 1 repeats (ADAMTS13), the von Willebrand cleaving protease, may occur. Such deficiency

may also complicate other types of sepsis-induced DIC and may enhance platelet–vessel wall interactions, thereby contributing to microvascular thrombosis.¹⁴

Purpura fulminans is an extreme form of DIC, which is often lethal. This disorder is characterized by extensive hemorrhagic necrosis of the skin over the extremities and buttocks. The disease predominantly affects infants and children and is rare in adults. Diffuse microthrombi in small blood vessels leads to necrosis and vasculitis may also be found in biopsies of skin lesions. The disorder can occur 2 to 4 weeks after mild infection, such as scarlet fever, varicella, or rubella, or can occur during an acute viral or bacterial infection in patients with acquired or hereditary deficiencies of protein C or protein S. The syndrome mimics neonatal homozygous protein C or protein S deficiency where purpura fulminans, with or without extensive thrombosis, develops soon after birth.

Disseminated Intravascular Coagulation in Trauma, Brain Injury, Burns, and Heat Stroke

The time interval between trauma and medical intervention correlates with the development and magnitude of DIC. Experience during wars proved that fast evacuation and prompt medical care reduce the risk of DIC. Extensive exposure of TF to the blood and hemorrhagic shock are the most immediate triggers of DIC in such instances, although direct proof of this mechanism is lacking. An alternative hypothesis is that cytokines play a pivotal role in the occurrence of DIC in trauma patients. In fact, the changes in cytokine levels in trauma patients are virtually identical to those in patients with sepsis.¹⁵ The levels of TNF- α , IL-1 β , PAI-1, circulating TF, neutrophil elastase, and soluble thrombomodulin can be elevated in patients with signs of DIC, predicting multiorgan dysfunction (adult respiratory distress syndrome [ARDS] included) and death. Careful monitoring for laboratory signs of DIC, reduced fibrinolytic activity, and perhaps low AT levels may be useful to predict the outcome of such patients.

In adults and children with head injuries, mortality is high when DIC occurs. A laboratory DIC score has predictive value for prognosis in patients with head injuries, thereby supplementing the Glasgow coma score. Brain injury can be associated with DIC, most likely because the injury exposes the abundant TF of the brain to blood. Specimens of contused brain, obtained during surgery in patients with head injury, and of liver, lungs, kidneys, and pancreas obtained during autopsy, reveal microthrombi in arterioles and venules.

Bleeding, laboratory tests indicative of DIC, and vascular microthrombi in biopsies of undamaged skin have been described in patients with extensive burns. Kinetic studies with labeled fibrinogen and platelets suggest that in addition to systemic consumption of hemostatic factors, there is significant local consumption in burned areas. TF exposed at sites of burned tissue, the systemic inflammatory response syndrome induced by the burn, and the presence of superimposed infections can trigger DIC. Local activation of coagulation in the bronchoalveolar compartment may contribute to acute lung injury in these patients.

A severe hemorrhagic diathesis and multiple organ failure indicative of DIC can complicate heat stroke.¹⁶ Diffuse fibrin deposition and hemorrhagic infarctions are found in fatal cases. DIC associated with profound fibrin(ogen) degradation is evident in such patients. Potential triggers of DIC in patients with heat stroke include endothelial cell damage and TF released from heat-damaged tissues. In 18 critically ill patients with heat stroke during the 2003 heat wave in Western Europe that caused numerous deaths in France,¹⁶ there were high levels of IL-6 and IL-8. In addition, there was marked activation of white blood cells, as evidenced by β_2 -integrin upregulation and increased production of reactive oxygen species. All patients had evidence of systemic activation of coagulation and DIC was present in about 35%. There was good correlation between the extent of activation of inflammation and coagulation and the clinical severity of the heat stroke.

Disseminated Intravascular Coagulation in Obstetric Complications

Placental abruption is a leading cause of perinatal death.¹⁷ Older multiparous women or patients with one of the hypertensive disorders of pregnancy are thought to be at highest risk. The severe hemostatic failure accompanying abruptio placentae is the result of acute DIC emanating from the introduction of large amounts of TF into the circulation from the damaged placenta and uterus. Amniotic fluid has been shown to activate coagulation *in vitro*, and the degree of placental separation correlates with the extent of DIC, suggesting that leakage of thromboplastin-like material from the placental system is responsible for the DIC. Abruptio placentae occurs in 0.2% to 0.4% of pregnancies, but only 10% of these cases are associated with DIC. Different grades of severity are found among those who develop DIC, with only the more severe forms resulting in shock and fetal death.

Amniotic fluid embolism is a rare but serious complication of pregnancy and delivery. A maternal mortality rate of 86% was reported in a 1979 review of 272 cases, but in a more recent population-based study, the maternal mortality was 26%. Patients predisposed to amniotic fluid embolism are multiparous women whose pregnancies are postmature with large fetuses and women undergoing a tumultuous labor after pharmacologic or surgical induction. Amniotic fluid is introduced into the maternal circulation through tears in the chorioamniotic membranes, rupture of the uterus, and injury of uterine veins. TF in amniotic fluid is the likely trigger for DIC. Mechanical obstruction of pulmonary blood vessels by fetal debris, meconium, and other particulate matter in the amniotic fluid enhances local fibrin–platelet thrombus formation and fibrinolysis. The extensive occlusion of the pulmonary arteries and an acute anaphylactoid response reminiscent of severe systemic inflammatory response syndrome provoke sudden dyspnea, cyanosis, acute cor pulmonale, left ventricular dysfunction, shock, and convulsions. These symptoms are followed within minutes to several hours by severe bleeding in 37% of patients. Hemorrhage is particularly severe from the atonic uterus, puncture sites, gastrointestinal tract, and other organs.

Some studies provide evidence of activation of coagulation, in its most extreme form DIC, in preeclampsia and eclampsia. In a large series of patients, a good correlation was noted between the clinical severity and abnormalities in platelet counts and fibrin(ogen) degradation products. Also consistent with DIC were results of assays of sensitive parameters of thrombin generation and activation of fibrinolysis, such as TAT complexes, D-dimer, and fibrinopeptide B β 1–42. Despite these observations, administration of heparin to patients with preeclampsia and eclampsia has not resulted in convincing benefits. The HELLP syndrome, which is comprised of hemolysis, elevated liver enzymes, low platelet count, and severe epigastric pain, is another complication of pregnancy-induced hypertension. Liver biopsy findings of fibrin deposition in hepatic blood vessels and laboratory tests consistent with DIC are found in a significant proportion of patients suggesting that DIC plays a role in the pathogenesis of the syndrome. However, according to current insights, thrombotic microangiopathy rather than DIC causes the coagulation abnormalities in patients with hypertensive disorders of pregnancy.

Disseminated Intravascular Coagulation in Malignancy

Patients with solid tumors are vulnerable to risk factors and additional triggers for DIC that can aggravate thromboembolism and bleeding.¹⁸ Risk factors include advanced age, stage of the disease, and use of chemotherapy or antiestrogen therapy. Triggers include septicemia, immobilization, and hepatic metastases, which can compromise the capacity of the liver to control DIC. Microangiopathic hemolytic anemia frequently is induced by DIC in patients with malignancies and is particularly severe in patients with widespread intravascular metastases of mucin-secreting adenocarcinomas. Solid tumor cells can express different procoagulant molecules including tissue factor,

which forms a complex with factor VII(a) to activate factors IX and X, and a cancer procoagulant (CP), a cysteine protease with factor X-activating properties. In breast cancer, TF is expressed by vascular endothelial cells as well as by the tumor cells. TF also appears to be involved in tumor metastasis and angiogenesis. CP is an endopeptidase that can not only be found in extracts of neoplastic cells but also in the plasma of patients with solid tumors. The exact role of CP in the pathogenesis of cancer-related DIC is unclear. Interactions of P- and L-selectins with mucin from mucinous adenocarcinoma can induce the formation of platelet microthrombi, which probably constitute a third mechanism of cancer-related thrombosis. Depending on the rate and quantity of exposure or influx of shed vesicles from tumors containing TF, a covert or overt DIC develops.

There are numerous reports of DIC and excessive fibrinolysis complicating the course of acute leukemia. In 161 consecutive patients presenting with acute myeloid leukemia, DIC was diagnosed in 52 (32%). In acute lymphoblastic leukemia, DIC was diagnosed in 15% to 20%.¹⁹ Some reports suggest that the incidence of DIC in acute leukemia patients may increase even more during remission induction with chemotherapy. In patients with APL, DIC is present in more than 90% of patients at the time of diagnosis or after initiation of remission induction. The pathogenesis of hemostatic disturbance in APL is related to properties of the malignant cells and their interaction with host endothelial cells. APL cells express TF and CP, which can initiate coagulation, and they release IL-1 β and TNF- α , which downregulate endothelial thrombomodulin, thereby compromising the protein C anticoagulant pathway. APL cells also express increased amounts of annexin II, which binds plasminogen and tPA and promotes plasmin generation. The net result of these processes is DIC and hyperfibrinolysis, which can lead to bleeding that can be fatal. All-*trans*-retinoic acid, which is used for induction and maintenance therapy of APL, inhibits the deleterious effect of APL cells *in vitro* and *in vivo* and has reduced the frequency of early hemorrhagic death.

Disseminated Intravascular Coagulation With Vascular Disorders

Rarely, vascular anomalies can trigger DIC. With some large aortic aneurysms, localized consumption of platelets and fibrinogen can produce coagulation abnormalities and bleeding.²⁰ In a series of patients with aortic aneurysms, 40% had elevated levels of fibrin(ogen) degradation products, but only 4% had laboratory evidence of DIC or bleeding.²⁰ Factors that predispose such patients to the development of DIC include large aneurysms, dissection, and expansion. Coagulation in these cases likely is triggered by the abundant TF in atherosclerotic plaques.

Kasabach and Merritt were the first to describe bleeding in association with giant cavernous hemangiomas, benign tumors found in newborns or children that can evolve into convoluted masses of abnormal vascular channels that sequester and consume platelets and fibrinogen. Localized pain may occur, likely from thrombosis of these vascular channels and there may be bleeding after trauma or surgery because of the consumptive process. Increased fibrinogen consumption reflects hyperfibrinolysis, which may be driven by tPA released from the abnormal endothelium lining the tumor walls. Patients with this syndrome exhibit accelerated platelet turnover, and accumulation of labeled platelets and fibrinogen in the hemangiomas.

Hemangiomas may regress spontaneously; some respond to radiation or laser therapy.

Disseminated Intravascular Coagulation With Liver Disease

The levels of most coagulation factors, endogenous anticoagulants, and major components of the fibrinolytic system are reduced in patients with severe liver disease reflecting reduced synthesis. In addition, the capacity of the liver to clear factors IXa, Xa, XIa, and tPA

is decreased. Thrombocytopenia is common because of hypersplenism and decreased hepatic production of thrombopoietin. The similarities between the hemostatic defects of liver disease and those of DIC have evoked controversy as to the contribution of DIC to the coagulopathy of liver disease. Several laboratory and clinical observations support the concept that DIC accompanies hepatic disorders. These include a reduced half-life of radiolabeled fibrinogen that is reversed with heparin administration; failure of replacement therapy to significantly increase the levels of hemostatic factors (suggesting ongoing consumption); and increased levels of markers of activation of coagulation. All of these findings are consistent with increased thrombin generation. Against the DIC hypothesis are the observations that microthrombi are found in only 2% of the tissues from patients who die of liver disease, and the fact that the increased fibrinogen turnover can be explained by extravascular accumulation. Current thinking is that DIC is rare in patients with liver disease, but such patients are sensitive to the triggers of DIC because of the decreased synthetic capacity of the diseased liver and its inability to clear activated clotting factors. In patients who undergo peritoneovenous shunting for ascites, those with underlying liver disease are more likely to develop DIC than those with normal liver function.

Disseminated Intravascular Coagulation With Toxic Reactions or Snake Bites

The venom of certain snakes, particularly vipers and rattlesnakes, can produce a coagulopathy similar to DIC.²¹ Prominent among these species are the *Vipera*, *Echis* (*E. carinatus* or *E. coloratus*), *Aspis*, *Crotalus*, *Bothrops*, and *Agkistrodon*. Venoms of these snakes contain enzymes or peptides that (1) release fibrinopeptide A (*Agkistrodon rhodostoma*); (2) activate prothrombin even in the absence of calcium (*E. carinatus*); (3) activate factors X and V (Russell viper venom); (4) degrade fibrinogen (*Agkistrodon acutus*); (5) induce platelet aggregation; (6) inhibit platelet aggregation because of the presence of arginine-glycine-aspartic acid-containing peptides; (7) activate protein C; and (8) damage endothelial cells which leads to bleeding, tissue ischemia, and edema. Interestingly, victims of snake bites rarely have excessive bleeding or thromboembolism despite the abnormal coagulation tests and DIC-like picture.

LABORATORY MANIFESTATIONS

Thrombocytopenia or a rapidly declining platelet count is an important diagnostic hallmark of DIC. However, only 35% to 44% of critically ill patients develop thrombocytopenia (platelet count $<150 \times 10^9/L$). Consequently, the specificity of thrombocytopenia for the diagnosis of DIC is limited.¹⁰ A platelet count of $<100 \times 10^9/L$ is seen in 50% to 60% of patients with DIC, whereas 10% to 15% of patients have a platelet count $<50 \times 10^9/L$. In surgical or trauma patients with DIC, over 80% have platelet counts less than $100 \times 10^9/L$.

Consumption of coagulation factors leads to low levels of coagulation factors in patients with DIC. In addition, impaired hepatic synthesis, for example due to impaired liver function or vitamin K deficiency, and loss of coagulation proteins, due to massive bleeding, may also play a role in DIC. Although the accuracy of the measurement of one-stage clotting assays in DIC has been contested (because of the presence of activated coagulation factors in plasma), the levels of coagulation factors appear to correlate with the severity of the DIC. The low levels of coagulation factors are reflected by prolonged global tests of coagulation, such as the PT and the aPTT. A prolonged PT or aPTT is found in 14% to 28% of intensive care patients but is present in more than 95% of patients with DIC.

Plasma levels of factor VIII are paradoxically increased in most patients with DIC, probably due to massive release of von Willebrand factor from the endothelium in combination with the acute phase **behavior** of factor VIII. Recent studies have pointed to a relative deficiency of ADAMTS-13, the von Willebrand cleaving protease,

which results in high concentrations of ultralarge von Willebrand multimers in plasma. These large multimers promote platelet-vessel wall interaction, which can lead to thrombotic microangiopathy and organ dysfunction.¹⁴

Although determination of the fibrinogen concentration has been advocated as a useful tool for the diagnosis of DIC, this test is rarely helpful.²² Fibrinogen is as an acute-phase protein whose levels increase with inflammation. Therefore the fibrinogen level may remain within the normal range for a long period of time despite ongoing consumption. In a consecutive series of patients, the sensitivity of a low fibrinogen level for the diagnosis of DIC was 28%, and hypofibrinogenemia was only found in very severe cases of DIC.

Markers of Fibrin Generation and Degradation

Plasma levels of fibrin split products are frequently used for the diagnosis of DIC.²³ Fibrin split products were detectable in 42% of consecutive patients in the intensive care unit, in 80% of trauma patients, and in 99% of patients with sepsis and DIC. The levels of fibrin degradation products (FDP) can be quantified by immunoassay. Latex agglutination assays can be used for rapid point-of-care determination in emergency cases. None of the available FDP assays discriminate between degradation products derived from cross-linked fibrin or from fibrinogen, which may cause spuriously high levels. Therefore the FDP assay lacks specificity because in addition to DIC, high levels can be found with trauma, recent surgery, inflammation, venous thromboembolism, and many other conditions. Because FDP are metabolized in the liver and cleared by the kidneys, FDP levels are influenced by liver and kidney function.

D-dimer is a degradation product of cross-linked fibrin. Therefore this test is not influenced by fibrinogen degradation products. D-dimer levels are high in patients with DIC, but high levels can also be found in patients with venous thromboembolism, recent surgery, or inflammatory conditions. Theoretically, soluble fibrin or fibrin monomers would be useful markers of intravascular fibrin formation in DIC. Indeed, initial clinical studies suggest that if the soluble fibrin concentration exceeds a threshold level, a diagnosis of DIC can be made. Unfortunately there are no reliable tests to quantify plasma levels of soluble fibrin. Since plasma levels of soluble fibrin reflect intravascular fibrin formation, the test is not influenced by extravascular fibrin formation, which can occur with local inflammation or trauma.

Endogenous Coagulation Inhibitors

Plasma levels of physiologic coagulation inhibitors, such as protein C or antithrombin, may be useful indicators of ongoing activation of coagulation.²³ Reduced levels of these inhibitors are found in 40% to 60% of critically ill patients and in 90% of DIC patients.

Levels of protein C may correlate with the severity of the DIC. In patients with meningococcal septicemia, plasma levels of protein C are markedly reduced, which likely contributes to the purpura fulminans that occurs in these patients. Downregulation of thrombomodulin and reduced levels of protein S further compromise the capacity to generate APC. Therefore it is not surprising the low levels of protein C are a strong predictor of poor outcome in DIC patients.

Plasma levels of antithrombin also are reduced in patients with DIC. The low levels reflect consumption due to ongoing thrombin generation, decreased synthesis, and degradation by neutrophil elastase. Like protein C, low levels of antithrombin also a strong predictor of mortality in patients with sepsis and DIC.

Fibrinolytic Markers

Increased fibrinolytic activity in DIC can be monitored by measuring plasma levels of plasminogen and α_2 -antiplasmin. Low levels may indicate consumption of these proteins. The concentration of

α_2 -antiplasmin is a helpful test for assessing the dynamics of fibrinolysis. Markers of plasmin generation include plasmin– α_2 -antiplasmin (PAP) complexes, which are moderately elevated in patients with DIC. However, because the normal plasma concentration of α_2 -antiplasmin is about half that of plasminogen, α_2 -antiplasmin is susceptible to consumption when there is excessive plasmin generation. Therefore PAP levels may underestimate total fibrinolytic activity. With α_2 -antiplasmin consumption, other protease inhibitors, such as antithrombin, α_2 -macroglobulin, α_1 -antitrypsin, and C1-inhibitor may act as plasmin inhibitors as well. Fibrinolytic activity may be insufficient to degrade intravascular fibrin in patients with DIC. Fibrinolysis is suppressed by high levels of PAI-1, the major inhibitor of tPA and uPA. PAI-1 levels are often elevated in patients with DIC, and correlate with an unfavorable outcome. A functional mutation in the PAI-1 gene, the 4G/5G polymorphism, is associated with high levels of PAI-1, DIC and an increased risk of death in patients with meningococcal septicemia.

Point of Care Tests

Although thrombelastography (TEG) was developed decades ago, modern techniques, such as rotational thrombelastography (ROTEM), enable bedside assessment of coagulation and fibrinolysis, which can be helpful in acute care settings.²⁴ A theoretical advantage of TEG over conventional coagulation assays is that because TEG uses whole blood, it provides a global assessment of platelet function, coagulation, and fibrinolysis. Increased and decreased coagulation as demonstrated with TEG was shown to correlate with clinically relevant morbidity and mortality in several studies, although the superiority of TEG over conventional tests has not been unequivocally proven. TEG may be overly sensitive to some interventions, such as fibrinogen administration, which is of questionable therapeutic value. Although there are no systematic studies on the diagnostic accuracy of TEG for the diagnosis of DIC, the test may be useful for assessing the global status of the coagulation and fibrinolytic systems in critically ill patients.

The aPTT biphasic waveform analysis is a sensitive and specific test for hypercoagulability in critically ill patients. This test, which requires specific instrumentation, detects the presence of precipitates of complexes of very low density lipoprotein and C-reactive protein that form early in DIC. The appearance of such complexes in the plasma of individuals with diseases known to predispose to hypercoagulability confer a greater than 90% sensitivity and specificity for subsequent development of DIC and fatal outcome.

Diagnostic Algorithm for Disseminated Intravascular Coagulation

A simple scoring system for the diagnosis of overt DIC was developed by the subcommittee on DIC of ISTH (Box 139.2).⁵ The score can be calculated using routinely available laboratory tests including the platelet count, the PT, a fibrin-related marker (usually D-dimer), and the fibrinogen concentration. Tentatively, a score of 5 or higher is compatible with DIC, whereas a score below 5 may be indicative but is not affirmative for nonovert DIC. More refined scoring systems have been developed for the diagnosis of nonovert DIC. A recent study showed that the international normalized ratio (INR) can be used in place of the PT, further facilitating international exchange and standardization. Using receiver-operating characteristic curves, an optimal D-dimer cut-off was identified, thereby optimizing the sensitivity and the negative predictive value of the test. Prospective studies show that the sensitivity and specificity of the DIC score are 93% and 98%, respectively. Studies in series of patients with specific underlying disorders causing DIC (e.g., cancer or obstetrical complications) show similar results. The severity of DIC according to this scoring system is related to the mortality in patients with sepsis.⁹ Linking prognostic determinants from critical care measurement scores such as APACHE-II to DIC scores is an important means to

BOX 139.2 Diagnostic Algorithm for the Diagnosis of Overt Disseminated Intravascular Coagulation^a

1. Presence of an underlying disorder known to be associated with disseminated intravascular coagulation (DIC) (Table 139.2) (no = 0, yes = 2)
2. Score global coagulation test results
 - Platelet count (>100 = 0; <100 = 1; <50 = 2)
 - Level of fibrin markers (e.g., D-dimer, fibrin degradation products) (no increase: 0; moderate increase: 2; strong increase: 3)^b
 - Prolonged prothrombin time (<3 s = 0; >3 s but <6 s = 1; >6 s = 2)
 - Fibrinogen level (>1.0 g/L = 0; <1.0 g/L = 1)
3. Calculate score
4. If ≥ 5 : compatible with overt DIC; repeat scoring daily
If < 5: suggestive (not affirmative) for nonovert DIC; repeat next 1–2 days

^aAccording to the Scientific Standardization Committee of the International Society of Thrombosis and Haemostasis.⁵

^bStrong increase, greater than 5 $\times$ upper limit of normal; moderate increase, greater than upper limit of normal but less than 5 $\times$ upper limit of normal.

assess prognosis in critically ill patients. Similar scoring systems have been developed and extensively evaluated in Japan. The major difference between the international and Japanese scoring systems is a slightly higher sensitivity of the Japanese algorithm, which may reflect differences in the patient populations because the Japanese series include relatively large numbers of patients with hematologic malignancies.

DIFFERENTIAL DIAGNOSIS

There are several other causes of coagulation abnormalities in patients with underlying disorders known to be associated with DIC. A complicating factor is that patients may have multiple explanations for their coagulopathy. For example, a patient with sepsis with DIC may also have liver failure and vitamin K deficiency.

The differential diagnosis of thrombocytopenia in patients with suspected DIC is shown in Table 139.1. Sepsis itself is a risk factor for thrombocytopenia in critically ill patients and the severity of sepsis correlates with the extent of thrombocytopenia. The principal factors that contribute to thrombocytopenia in patients with sepsis are decreased platelet production, increased consumption or destruction, or sequestration of platelets in the spleen or on the endothelial surface. The decreased production of platelets in the bone marrow in patients with sepsis occurs despite high levels of proinflammatory cytokines, such as TNF- α and IL-6, and increased levels of thrombopoietin. Platelet production is impaired because of hemophagocytosis, a pathologic process characterized by phagocytosis of megakaryocytes and other hematopoietic cells by monocytes and macrophages. Hemophagocytosis may be driven by the high levels of macrophage colony-stimulating factor (M-CSF) in patients with sepsis.

Heparin-induced thrombocytopenia (HIT) is caused by a heparin-induced antibody that binds to the heparin-platelet factor 4 (PF4) complex on the platelet surface (see Chapter 133). This may result in platelet activation and consumption and arterial and venous thrombosis. A consecutive series of critically ill patients who received heparin revealed an incidence of HIT of 1%. The risk of HIT is higher with unfractionated heparin than with low-molecular-weight heparin (LMWH). Thrombosis may occur in 25% to 50% of patients with HIT (with fatal thrombosis in 4%–5%). The diagnosis of HIT is based on detection of HIT antibodies in combination with the occurrence of thrombocytopenia in a patient receiving heparin, with or without concomitant arterial or venous thrombosis. The immunoassay for heparin-PF4 antibodies has a high negative predictive

TABLE 139.1 Differential Diagnosis of Thrombocytopenia in Suspected Disseminated Intravascular Coagulation

Differential Diagnosis	Additional Diagnostic Clues
DIC	Prolonged aPTT and PT, increased FDP, low levels of antithrombin or protein C
Sepsis without DIC	Positive (blood) cultures, positive sepsis criteria, hematophagocytosis in bone marrow
Massive blood loss	Major bleeding, low hemoglobin, prolonged aPTT and PT
Thrombotic microangiopathy	Schistocytes evident on blood smear, Coombs-negative hemolysis, fever, neurologic symptoms, renal insufficiency, coagulation tests usually normal, ADAMTS13 levels decreased
Heparin-induced thrombocytopenia	Use of heparin, venous or arterial thrombosis, positive HIT test (usually immunoassay for heparin-platelet factor 4 antibodies), increase in platelet count after cessation of heparin; coagulation tests usually normal
Immune thrombocytopenia	Antiplatelet antibodies, normal or increased number of megakaryocytes in bone marrow aspirate, normal levels of TPO (TPO levels are usually normal or slightly increased in ITP); coagulation tests usually normal
Drug-induced thrombocytopenia	Decreased number of megakaryocytes in bone marrow aspirate or detection of drug-induced antiplatelet antibodies, increase in platelet count after cessation of drug; coagulation tests usually normal

ADAMTS13, A disintegrin and metalloproteinase with thrombospondin 13; aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; FDP, fibrin degradation products; HIT, heparin-induced thrombocytopenia; PT, prothrombin time; ITP, immune thrombocytopenia; TPO, thrombopoietin.

TABLE 139.2 Differential Diagnosis of Prolonged aPTT and/or PT in Suspected Disseminated Intravascular Coagulation

Test Result	Cause
PT prolonged, aPTT normal	Factor VII deficiency Mild vitamin K deficiency Mild liver insufficiency Low doses of vitamin K antagonists
PT normal, aPTT prolonged	Factor VIII, IX, or XI deficiency Unfractionated heparin Inhibitory antibody and/or antiphospholipid antibody Factor XII or prekallikrein deficiency
Both PT and aPTT prolonged	Factor X, V, II, or fibrinogen deficiency Severe vitamin K deficiency Vitamin K antagonists Global clotting factor deficiency - Decreased synthesis: liver failure - Increased loss: massive bleeding, DIC

aPTT, Activated partial thromboplastin time; PT, prothrombin time.

by cytostatic agents), or by immune-mediated mechanisms. Drug-induced thrombocytopenia is a difficult diagnosis in patients suspected of DIC because these patients are often receiving multiple drugs and have several other potential reasons for the thrombocytopenia. Drug-induced thrombocytopenia is often diagnosed based upon the timing of initiation of a new agent in relationship to the development of thrombocytopenia, after exclusion of other causes of thrombocytopenia. The observation of rapid restoration of the platelet count after discontinuation of the suspected agent is highly suggestive of drug-induced thrombocytopenia.

A prolongation of global coagulation tests may be due to a deficiency of one or more coagulation factors (Table 139.2). In addition, but more rarely, the prolonged tests may be due to an inhibitory antibody. Some of these antibodies may be clinically important, such as antibodies to factor VIII that lead to acquired hemophilia (see Chapter 136), whereas others may be less important, such as antiphospholipid antibodies (see Chapter 141). However, patients with antiphospholipid antibodies may have thrombocytopenia and may be at increased risk of thrombosis particularly if they also have a lupus anticoagulant. Inhibitory antibodies and lupus anticoagulants can be identified and distinguished with mixing studies (see Chapters 136 and 141).

In general, acquired deficiencies of coagulation factors can be due to impaired synthesis, massive loss, or increased turnover (consumption). Impaired synthesis is often due to hepatic insufficiency or vitamin K deficiency. Vitamin K deficiency may be caused by poor nutrition in combination with the use of antibiotics that impair bacterial vitamin K production in the intestine. The PT is sensitive to both conditions because this test is highly dependent on the plasma levels of factor VII, the vitamin K–dependent coagulation factor with the shortest half-life. Liver failure may be differentiated from vitamin K deficiency by measuring the levels of factor V, which is not vitamin K dependent. In fact, the factor V level is included in several scoring systems for acute liver failure. Uncompensated loss of coagulation factors may occur after massive bleeding, which can occur in trauma patients or those undergoing major surgical procedures. This is common in patients with major bleeding who receive intravascular volume replacement with crystalloids, colloids, and red cells without simultaneous administration of coagulation factors. This results in a dilutional coagulopathy, which can exacerbate the bleeding. In addition, transfusion in these patients may lead to systemic activation of inflammatory processes and may contribute to further coagulation derangements. In hypothermic patients (e.g., trauma patients) measurement of the global coagulation tests may underestimate the extent of the coagulopathy because these assays are performed at 37°C to mimic normal body temperature.

value (100%) but a low positive predictive value (10%). Although the gold standard for the diagnosis of HIT is a sensitive platelet activation assay, this test is not routinely available in most hospitals. Normalization of the platelet count 1–3 days after discontinuation of heparin may further support the diagnosis of HIT.

The group of thrombotic microangiopathies includes thrombotic thrombocytopenic purpura (see Chapter 134), hemolytic–uremic syndrome (see Chapter 134), malignant hypertension, chemotherapy-induced microangiopathic hemolytic anemia, and the HELLP syndrome. A common pathogenic feature of these disorders is endothelial damage, which triggers platelet adhesion and aggregation, thrombin generation, and an impaired fibrinolysis. The clinical consequences of extensive endothelial dysfunction include thrombocytopenia, mechanical fragmentation of red cells with hemolytic anemia, and microvascular occlusion, which leads to multiorgan dysfunction, including renal insufficiency and neurologic symptoms. Despite this common final pathway, the various thrombotic microangiopathies have different underlying etiologies (see Chapter 134).

Drug-induced thrombocytopenia is another frequent cause of thrombocytopenia in critically ill patients (see Chapter 131). Thrombocytopenia may be caused by drug-induced myelosuppression, (e.g.,

BOX 139.3 Mainstays of Supportive Treatment of Disseminated Intravascular Coagulation

Modality	Details	Expectations/Rationale
Treating the underlying disorder	Dependent on the primary diagnosis	Inhibit or block the complicating pathologic mechanism of disseminated intravascular coagulation (DIC) in parallel with the response (if any) of the disorder
Antithrombotic agents	Prophylactic heparin to prevent venous thromboembolic complications (Low dose) therapeutic heparin in case of confirmed thromboembolism or if clinical picture is dominated by (micro) vascular thrombosis and associated organ failure	Risk of thromboembolism is increased in critically ill patients, trauma patients, or patients with cancer Prevent fibrin formation; tip the balance within the microcirculation toward anticoagulant mechanisms and physiologic fibrinolysis; allow reperfusion of the skin, kidneys, and brain
Transfusion	Infuse platelets, plasma and fibrinogen (cryoprecipitate) if there is overt bleeding or a high risk of bleeding	Bleeding should diminish and stop over the course of hours Platelet count, coagulation tests and fibrinogen should return toward normal
Anticoagulant factor concentrates	Recombinant human activated protein C may be effective in sepsis and DIC (24 µg/kg/h for 4 days); Currently withdrawn from the market	Restore anticoagulation in microvascular environment and may have antiinflammatory activity Latest trials were negative.
Fibrinolytic inhibitors	Tranexamic acid (e.g., 500–1000 mg q8–12 h or ε-aminocaproic acid 1000–2000 mg q8–12 h)	May be useful if there is (hyper) fibrinolysis Bleeding ceases, but there is a risk of microvascular thrombosis and renal failure

THERAPY

Management of patients with DIC depends on vigorous treatment of the underlying disorder to alleviate or remove the inciting injurious cause. For sepsis-induced DIC, treatment includes aggressive use of intravenous organism-directed antibiotics and source control (e.g., by surgery or drainage). Other examples of vigorous treatment of the underlying condition include cancer surgery or chemotherapy, uterus evacuation in patients with abruptio placentae, resection of aortic aneurysm, and debridement of crushed tissue in the case of trauma. In addition to intensive support of vital functions, supportive treatment aimed at the coagulopathy may be helpful (Box 139.3),⁶ as outlined later.

Platelet and Plasma Transfusion

Low levels of platelets and coagulation factors may increase the risk of bleeding. However, plasma or platelet transfusion should not be instituted on the basis of laboratory results alone; it is only indicated in patients with active bleeding and in those requiring an invasive procedure or at risk for bleeding complications.⁶ The presumed efficacy of treatment with plasma, fibrinogen concentrate, cryoprecipitate, or platelets is not based on the results of randomized controlled trials. Nonetheless, transfusion of these products is rational in bleeding patients or in patients at risk of bleeding who have significant depletion of these hemostatic factors. The suggestion that administration of blood components might “add fuel to the fire” has never been proven in clinical or experimental studies.

Replacement therapy for thrombocytopenia consists of 5 to 10 U platelet concentrate to raise the platelet count to $20\text{--}30 \times 10^9/\text{L}$ and to $50 \times 10^9/\text{L}$ in patients requiring an invasive procedure.

One of the major challenges of infusion of fresh-frozen plasma in patients with DIC who are bleeding is the propensity of the added volume, which is necessary to correct the coagulation defect, to exacerbate the capillary leak syndrome. This increases the risk of causing or worsening pulmonary edema and, by extension, predisposes to ARDS and induces ascites. Coagulation factor concentrates, such as prothrombin complex concentrate, may partially overcome this obstacle, but these concentrates do not contain essential factors, such as factor V. Moreover, caution is advocated with the use of prothrombin complex concentrates in DIC because they can contain trace amounts of activated coagulation factors, which may worsen the coagulopathy. Specific deficiencies of coagulation factors, such as fibrinogen, may be corrected by administration of purified coagulation factor concentrates.

Cryoprecipitate (if available) can be used to rapidly raise the levels of fibrinogen, von Willebrand factor, and factor VIII levels in patients with DIC, particularly when there is bleeding and the fibrinogen level is less than 1 g/L. Cryoprecipitate has at least four- to fivefold more fibrinogen in each milliliter than fresh-frozen plasma. Nonetheless, fresh-frozen plasma contains sufficient amounts of fibrinogen to treat mild to moderate hypofibrinogenemia.

Anticoagulant Treatment

Heparin therapy in patients with DIC remains controversial. Experimental studies have shown that heparin can at least partly inhibit activation of coagulation in DIC. However, clinical trials have failed to demonstrate a beneficial effect of heparin on clinically important outcome events in patients with DIC and the safety of heparin is debatable in those at risk for bleeding. A large trial in patients with severe sepsis showed a small but nonsignificant benefit of low dose heparin on 28-day mortality in patients and no major safety concerns.²⁵

There is general consensus that administration of heparin is beneficial in some categories of DIC, such as metastatic cancer, purpura fulminans, and aortic aneurysm (prior to resection). Heparin also is indicated for treating thromboembolic complications in large vessels and before surgery in patients with chronic DIC. Heparin administration may be helpful in patients with acute DIC when intensive blood component replacement fails to improve excessive bleeding or when thrombosis threatens to cause irreversible tissue injury (e.g., acute cortical necrosis of the kidney or digital gangrene).

Heparin should be used cautiously in these conditions. In patients with chronic DIC because of metastatic cancer or aortic aneurysm, continuous infusion of unfractionated heparin (500 to 750 U/hour without a bolus) has been advocated. If no response is obtained within 24 hours, higher dosages can be used. In hyperacute DIC cases, such as amniotic fluid embolism, septic abortion, and purpura fulminans, intravenous bolus injection of 5000 to 10,000 U heparin may be given simultaneously with replacement therapy with blood products. Some experts, however, recommend against administration of a bolus dose of heparin under these circumstances. A heparin infusion of 500 to 1000 U/hour may be necessary to maintain the benefit until the underlying disease responds to treatment. Aside from these considerations, current guidelines recommend universal thromboprophylaxis with low doses of heparin or LMWH in critically ill patients.⁶

Theoretically, the most logical anticoagulants to use in DIC would be those directed against TF. Potential agents include recombinant TFPI, inactivated factor VIIa, and recombinant NAPc2, a potent and

specific inhibitor of the ternary complex of TF/factor VIIa and factor Xa. Phase II trials of recombinant TFPI in patients with sepsis showed promising results but phase III trials in patients with severe sepsis or severe pneumonia and organ failure failed to show a survival advantage with TFPI administration.²⁶

Recombinant human soluble thrombomodulin binds thrombin to form a complex that blocks the coagulant activity of thrombin and promotes its capacity to activate protein C. In a phase III randomized double-blind clinical trial in patients with DIC, soluble thrombomodulin was superior to heparin at reducing bleeding and improving the coagulation parameters. A systematic review and meta-analysis of mostly retrospective studies on the effect of recombinant human soluble thrombomodulin in severe sepsis demonstrated a pooled relative risk of 0.81 (95% confidence interval (CI) 0.62–1.06) in three randomized trials encompassing 838 patients, and a relative risk of 0.59 (95% CI 0.45–0.77) in nine observational studies including 571 patients.²⁷ Interestingly, meta-regression of the combined results revealed a strong relationship between the effect size of recombinant soluble thrombomodulin treatment and baseline mortality risk, which is reminiscent of a similar relationship in patients who were treated with activated protein C.^{9,28} Importantly, there was no evidence of an increased risk of major bleeding or other safety concerns with soluble thrombomodulin. Ongoing randomized trials with soluble thrombomodulin are focusing on its effects on DIC, organ failure, and mortality.

Physiologic Anticoagulant Factor Concentrates

Restoration of the levels of physiologic anticoagulants in DIC may be a rational approach.^{29,30} Based on successful preclinical studies, AT concentrates without or with concomitant heparin have been evaluated in patients with DIC. All trials have shown some beneficial effect in terms of improvement of laboratory parameters, shortening of the duration of DIC, or even improvement in organ function. In several small clinical trials, use of very high doses of AT concentrate produced a modest but not statistically significant reduction in mortality. A large, multicenter, randomized controlled trial also showed no significant reduction in mortality with AT concentrate in patients with sepsis.³¹ Interestingly, post hoc subgroup analysis suggested that AT was of benefit in patients who did not receive concomitant heparin, but this observation needs validation. In a small randomized trial in patients with burns and DIC, AT administration decreased mortality, reduced multiple organ failure, and improved coagulation parameters compared with placebo.

Because decreased function of the protein C system contributes to the pathogenesis of DIC, recombinant APC was predicted to be beneficial.³² Indeed, in a dose-ranging study, a continuous infusion of recombinant human APC at a dose of 24 µg/kg per hour was considered optimal based on reductions in D-dimer levels. A subsequent placebo-controlled phase III trial of APC concentrate in patients with severe sepsis was stopped early because of a 19% reduction in 28-day all cause mortality from 30.8% to 24.7% with APC. Interestingly, patients who manifested with “overt DIC” (see [Diagnosis section, earlier](#)) benefited more from APC than those without overt DIC.⁹ However, meta-analyses of the APC trials concluded that APC had little or no effect. A series of negative trials in patients with severe sepsis has added to the skepticism regarding the use of APC. In addition to questionable efficacy, APC increases the risk of bleeding in patients with severe sepsis. A placebo-controlled trial in patients with severe sepsis and septic shock was stopped early because there was no benefit with APC. Subsequently, the manufacturer elected to withdraw APC from the market, which has resulted in a revision of current guidelines for treatment of DIC.

Fibrinolytic Inhibitors

Most guidelines recommend against the use of antifibrinolytic agents, such as ε-aminocaproic acid or tranexamic acid, in patients with

DIC. This is because these drugs block already suppress endogenous fibrinolysis, and may further compromise tissue perfusion. In support of this concept there are reports of severe thrombosis in DIC patients treated with these agents. However, in patients with DIC accompanied by primary fibrino(geno)lysis, which occurs in some cases of acute promyelocytic leukemia, giant cavernous hemangioma, heat stroke, and metastatic carcinoma of the prostate, the use of fibrinolytic inhibitors can be considered if the patient has profuse bleeding that does not respond to replacement therapy and there is evidence of excessive fibrino(geno)lysis. In these situations, it is important to replace depleted blood components before initiating treatment with fibrinolytic inhibitors.

HYPERCOAGULABLE STATES

Julia A. Anderson, Kerstin E. Hogg, and Jeffrey I. Weitz

Arterial and venous thromboses are common problems for all clinicians. Some patients with thrombosis have an underlying hypercoagulable state. These hypercoagulable states can be divided into three categories: inherited disorders, acquired disorders, and those that are mixed in origin.

Inherited hypercoagulable states, also known as thrombophilic disorders, can be due to loss of function of natural anticoagulant pathways or gain of function in procoagulant pathways (Table 140.1). Acquired hypercoagulable states represent a heterogeneous group of disorders in which the risk for thrombosis appears to be higher than that in the general population. These include such diverse risk factors as a prior history of thrombosis, obesity, pregnancy, cancer and its treatment, antiphospholipid antibody syndrome, drug-induced thrombosis such as heparin-induced thrombocytopenia or thrombosis associated with chemotherapeutic agents, or myeloproliferative disorders. The pathogenesis of thrombosis in these situations is largely unknown and, in many cases, is likely multifactorial in origin. Mixed disorders are those with both an inherited and an acquired component; one example is hyperhomocysteinemia. Although severe hyperhomocysteinemia and associated homocysteinuria are rare genetic disorders, most cases of mild to moderate hyperhomocysteinemia result from acquired folate and/or vitamin B₁₂ deficiency superimposed on common genetic mutations in biochemical pathways involved in methionine metabolism.

Genetic hypercoagulable states and acquired risk factors combine to establish an intrinsic risk for thrombosis for each individual. This risk can be modified by extrinsic or environmental factors, such as surgery, immobilization, or hormonal therapy, which also increase the risk for thrombosis. When the intrinsic and extrinsic forces exceed a critical threshold, thrombosis occurs (Fig. 140.1). Appropriate thromboprophylaxis can prevent the thrombotic risk from exceeding this critical threshold, but breakthrough thrombosis can still occur if procoagulant stimuli overwhelm protective mechanisms.

This chapter describes the inherited, acquired, and mixed hypercoagulable states, details their laboratory evaluation, and provides practical advice for the management of these conditions.

INHERITED HYPERCOAGULABLE STATES

Inherited disorders are found in up to half of patients who present with venous thromboembolism before the age of 40, particularly those whose event occurred either in the absence of well-recognized risk factors, such as surgery or immobilization, or with minimal provoking factors, such as minor trauma, long-distance flight, or estrogens. Patients with inherited thrombophilic disorders often have a family history of thrombosis. Of greatest significance is a family history of sudden death due to pulmonary embolism or a history of multiple family members requiring long-term anticoagulation therapy because of recurrent thrombosis. Patients who present with venous thrombosis in unusual sites, such as the cerebral or mesenteric veins, those with recurrent thrombosis, and patients who develop skin necrosis upon initiation of warfarin therapy should also be suspected of having an inherited hypercoagulable state.

From a pathophysiologic perspective, inherited hypercoagulable states fall into two categories. First are those associated with loss of function of endogenous anticoagulant proteins. These include deficiencies of antithrombin, protein C, and protein S. The second

category involves gain of function in procoagulant pathways. These disorders include factor V_{Leiden} and the FII G20210A mutation, as well as increased levels of procoagulant proteins, such as factors VIII, IX, and XI. Each of these conditions will be briefly described.

Loss of Function of Endogenous Anticoagulants

Antithrombin Deficiency

Antithrombin, a single-chain glycoprotein with a molecular weight of 52,000 Da, is a member of the serine proteinase inhibitor (serpin) superfamily that was first described by Brinkhous in 1939. Antithrombin is synthesized in the liver and endothelial cells, and its gene (*SERPINC1*, previously known as *AT3*) is localized on the long arm of chromosome 1 (1q23–1q25). *SERPINC1* is composed of 7 exons and 7 introns and spans 16 kb.

Antithrombin plays a critical role in regulating coagulation by forming a 1:1 covalent complex with thrombin, factor Xa, and other activated clotting factors. Once covalent complexes are generated, they are cleared from the circulation via the liver. The rate of antithrombin interaction with its target proteases is accelerated by heparin by 1000-fold. Heparan sulfate proteoglycan, which coats the vasculature, is the physiologic counterpart of medicinal heparin.

Newborn infants have approximately 50% of normal adult antithrombin levels, and much lower levels are found in preterm infants because of liver immaturity; adult levels are attained at 6 months.

Antithrombin deficiency can be inherited or acquired, and congenital deficiency of antithrombin was the first reported inherited risk factor for venous thromboembolism. Congenital antithrombin deficiency is relatively rare, occurring in about 1 in 2000, and can be one of two types (Table 140.2), both of which are inherited in an autosomal dominant fashion and affect both sexes equally. Type I deficiency, which represents the classic deficiency state, is the result of reduced synthesis of biologically normal antithrombin. Heterozygotes with this condition have parallel reductions in antithrombin antigen and activity with levels reduced to about 50% of normal. A heterogeneous group of nonsense mutations, small deletions, insertions, or single-base substitutions are the molecular cause of most cases, although gene deletions can also be responsible. In total, more than 113 mutations have been identified as causes of type I antithrombin deficiency. An antithrombin mutation database compiled by members of the Plasma Coagulation Inhibitors Subcommittee of the Scientific and Standardization Committee of the International Society on Thrombosis and Hemostasis summarizes the mutations and can be accessed on the Imperial College London website (www.imperial.ac.uk/departmentsofmedicine/research/experimental-medicine/haematology/haemostasis-and-thrombosis/database/) or in the human gene mutation database (www.hgmd.cf.ac.uk).

Type II antithrombin deficiencies are characterized by normal levels of antithrombin with impaired functional activity due to the presence of a variant protein. This condition is mainly caused by missense mutations that result in single amino acid substitutions. The clinical consequences of type II antithrombin deficiency depend on the location of the mutation, which may involve the reactive center loop or the heparin-binding domain. For example, some mutations in the reactive center loop of antithrombin slow its interaction with target proteases and are characterized by reduced antithrombin

TABLE 140.1 Classification of Hypercoagulable States

Hereditary	Mixed	Acquired
Loss of Function		
Antithrombin deficiency	Hyperhomocysteinemia	Previous venous thromboembolism
Protein C deficiency	Obesity	Pregnancy, puerperium
Protein S deficiency	Cancer	Drug-induced: Heparin-induced thrombocytopenia Prothrombin complex concentrates L-asparaginase Hormonal therapy
Gain of Function		
Factor V Leiden	Postoperative	
Prothrombin FII G20210A	Myeloproliferative disorders	
Elevated factor VIII, IX, or XI		

TABLE 140.2 Types of Inherited Antithrombin Deficiency

Type	Antigen	Activity (No Heparin)	Activity (With Heparin)
I	Low	Low	Low
II (active site defect)	Normal	Low	Low
II (heparin-binding site defect)	Normal	Normal	Low

Fig. 140.1 THROMBOSIS THRESHOLD. Genetic and acquired risk factors continue to determine an intrinsic risk for thrombosis for each individual. This risk is increased by extrinsic or environmental factors and decreased by thromboprophylaxis. If the intrinsic and extrinsic forces exceed a critical threshold at which thrombin generation overwhelms the protective mechanisms, thrombosis will result. AT, Antithrombin; PC, protein C; PS, protein S; VTE, venous thromboembolism. (From Anderson JA, Weitz JI: *Hypercoagulability and uncommon vascular diseases*. L-asparaginase	Disseminated intravascular coagulation	
	Severe sepsis	
	Multiple trauma	
	Malignancy	
	Prolonged extracorporeal circulation	

activity in the absence or presence of heparin. In contrast, mutations in the heparin-binding domain are associated with reduced antithrombin activity in the presence of heparin but normal activity in its absence. Unlike other inherited forms of antithrombin deficiency, which are embryonic lethal in the homozygous state, mutations in the heparin-binding domain only have clinical consequences in individuals homozygous for these mutations and do not increase the risk for thrombosis in the heterozygous state.

Because of the wide variety of heritable forms of antithrombin deficiency, functional antithrombin assays are the preferred method for screening. Most functional assays use synthetic substrates to monitor the rates at which added thrombin or factor Xa are inhibited in patient plasma. However, the assays differ in terms of whether bovine or human thrombin is used and whether or not heparin is added. Defects in the heparin-binding domain of antithrombin will be detected only in the presence of heparin. When antithrombin deficiency is identified with functional assays, immunologic assays are performed to distinguish between type I and type II deficiency.

Congenital antithrombin deficiency can cause spontaneous venous thromboembolism, but thrombosis often occurs in the setting of pregnancy and the puerperium; with the use of estrogen-containing oral contraceptives; or after major trauma or surgery. Thrombotic events are rare in children, with events typically occurring from mid- to late teenage years and into the early twenties. The European Prospective Cohort on Thrombophilia (EPCOT) study compared the risks of a first episode of venous thromboembolism in asymptomatic individuals with antithrombin, protein C, or protein S deficiency with that in subjects with factor V_{Leiden} over a 6-year period. The annual incidence of venous thromboembolism was highest in those with antithrombin deficiency.¹ Likewise, in a cohort of Italian patients, the risk of venous thrombosis was higher with antithrombin deficiency than with other thrombophilic defects.² The most common sites for venous thrombosis in patients with antithrombin deficiency are the deep veins of the leg, but thrombosis can occur in mesenteric veins, as well as the renal and retinal veins. The risk for recurrence is high,³ particularly in those with lower antithrombin levels,⁴ and the risk varies depending on the subtype of antithrombin deficiency.

Acquired antithrombin deficiency can reflect decreased antithrombin synthesis, increased consumption, or enhanced clearance (Table 140.3). Decreased synthesis can occur in patients with severe hepatic disease, particularly cirrhosis, or in those given L-asparaginase, the latter as a result of drug-induced retention of antithrombin within the endoplasmic reticulum. Increased thrombin generation can result in antithrombin consumption. Disorders associated with excessive thrombin generation include acute thrombosis, disseminated intravascular coagulation (DIC), severe sepsis, multiple trauma, disseminated malignancy, extensive burns, or prolonged extracorporeal circulation. Heparin treatment can reduce antithrombin levels up to 20% by enhancing its clearance. Severe antithrombin deficiency can also occur in some patients with nephrotic syndrome because of the loss of protein in the urine.

Fig. 140.2 PROTEIN C PATHWAY. Activation of coagulation triggers thrombin (IIa) generation. Excess thrombin binds to thrombomodulin (TM) on the endothelial cell surface. Once bound, the substrate specificity of thrombin is altered so that it no longer acts as a procoagulant but becomes a potent activator of protein C (PC). Endothelial protein C receptor (EPCR) binds PC and presents it to thrombomodulin-bound thrombin, where it is activated. Activated protein C (APC), together with its cofactor, protein S (PS), binds to the activated platelet-surface and proteolytically degrades factor Va (Va) into inactive fragments (Vi). Because factor Va is a critical component of the prothrombinase complex, factor Va inactivation by APC attenuates thrombin generation. Because factor Va_{Leiden} (FVa_L) is resistant to inactivation by APC, patients with the factor Va_{Leiden} mutation have reduced capacity to regulate thrombin generation. (From Anderson JA, Weitz JI: *Hypercoagulability and uncommon vascular diseases*. In Jaff MR, White CJ, editors: *Vascular disease: Diagnostic and therapeutic approaches*, Minneapolis, MN, 2011, Cardiotext Publishing.)

Users of oral contraceptive pills or hormone replacement therapy may have moderate reductions in antithrombin levels; during pregnancy, the antithrombin levels do not fall significantly but decreases are found in preeclampsia and pregnancy-induced hypertensive illnesses.

Protein C Deficiency

The protein C pathway is an important natural anticoagulant pathway. This on-demand pathway is activated when thrombin is generated (Fig. 140.2). Thrombin binds to thrombomodulin, a transmembrane thrombin receptor found on the surface of endothelial cells. Once bound to thrombomodulin, the substrate specificity of thrombin is altered so that it no longer serves as a procoagulant enzyme, but becomes a potent activator of protein C, a vitamin K-dependent glycoprotein. Thus thrombin bound to thrombomodulin activates protein C 1000-fold more efficiently than free thrombin. The endothelial cell protein C receptor (EPCR), another transmembrane receptor on the endothelial cell surface, binds protein C and presents it to the thrombin–thrombomodulin complex for activation, thereby producing an additional 20-fold increase in the rate of protein C activation. The physiologic importance of thrombomodulin and EPCR is highlighted by the fact that deficiency of either receptor results in embryonic lethality in mice.

Activated protein C (APC) dissociates from this activation complex and acts as an anticoagulant by proteolytically degrading and inactivating factors Va and VIIIa, thereby attenuating thrombin generation. For efficient inactivation of factors Va and VIIIa, APC must bind to protein S, its cofactor. This interaction facilitates APC binding to activated cell surfaces, particularly the platelet surface, where factors Va and VIIIa are localized.

TABLE 140.4 Types of Inherited Protein C Deficiency

Type	Antigen	Activity
I	Low	Low
II	Normal	Low

APC has a half-life in the circulation of about 15 minutes, whereas thrombin has a half-life of about 10 seconds. APC is inhibited by protein C inhibitor and α_1 -proteinase inhibitor (α_1 -antitrypsin), both of which are relatively slow inhibitors. Only the activity of protein C inhibitor is enhanced by heparin, but both inhibitors appear to contribute to APC inhibition in vivo.

Protein C deficiency can be inherited or acquired. Like antithrombin deficiency, protein C deficiency is inherited in an autosomal-dominant fashion and has a proven association with venous thrombosis.⁵ Based on studies in healthy blood donors, heterozygous protein C deficiency can be found in 1 in 200 to 500 of the adult population, but many of these individuals do not have a history of thrombosis. Thus the phenotypic expression of hereditary protein C deficiency is highly variable and may depend on other, as yet unrecognized, modifying factors. In contrast to antithrombin deficiency in which the homozygous state is embryonic lethal, homozygous or doubly heterozygous protein C deficiency can occur. The prevalence of homozygous protein C deficiency is estimated to be 1 in 160,000 to 360,000 births. Newborns with these disorders may present with purpura fulminans characterized by widespread thrombosis.

Individuals with heterozygous protein C deficiency can develop skin necrosis upon initiation of treatment with vitamin K antagonists, such as warfarin. Typically, skin lesions are found on the extremities, breasts, or trunk. Starting as erythematous macules, the central regions of the cutaneous lesions become purpuric and then necrotic over a period of hours unless protein C is administered. Biopsies reveal fibrin thrombi within the vessels of the skin associated with interstitial hemorrhage. The skin lesions are clinically and histologically similar to those seen in infants with purpura fulminans and are attributable to the transient hypercoagulable state that is induced by warfarin, thereby explaining why they occur early during the course of warfarin therapy. The half-life of protein C is short and similar to that of factor VII. Starting warfarin in patients with protein C deficiency causes a further reduction in protein C levels, particularly if loading doses of warfarin are given. Thus the activity of the natural anticoagulant protein C pathway is compromised before warfarin lowers vitamin K-dependent procoagulant proteins, particularly prothrombin and factor X, into the range required for its antithrombotic effects. Warfarin-induced skin necrosis has also been reported in association with acquired deficiency of protein C.

Hereditary protein C deficiency can be further delineated into two subtypes using immunologic and functional assays (Table 140.4). Most functional assays use Protac, a protease isolated from the venom of the copperhead snake, to activate protein C in plasma. The enzymatic activity of APC can then be assayed directly using an APC-directed synthetic substrate, or it can be indirectly quantified by measuring the extent of prolongation of the activated partial thromboplastin time (aPTT). The most common form of hereditary protein C deficiency is the classic or type I deficiency state. This disorder reflects reduced synthesis of a normal protein and is characterized by a parallel reduction in protein C antigen and activity, resulting in a quantitative deficiency due to reduced synthesis or stability of protein C. A variety of genetic defects can produce type I protein C deficiency, including promoter mutations, splice-site abnormalities, in-frame deletions, frameshift deletions, in-frame insertions, and frameshift insertions in the protein C gene (*PROC*), but missense or nonsense mutations are the most common.

Type II protein C deficiency reflects synthesis of a dysfunctional protein and is characterized by normal protein C antigen with reduced functional activity, a qualitative deficiency. Most type II

protein C deficiency states are caused by point mutations. Mutations in the active site of APC reduce its activity against synthetic substrates and decrease its capacity to prolong the aPTT. In contrast, mutations that affect other protein C domains essential for its activity may reduce its anticoagulant activity but may not affect its capacity to cleave synthetic substrates activity. Therefore coagulation-based functional assays are preferred when screening patients for protein C deficiency.

Diagnosis of protein C deficiency is complicated. Protein C circulates in human plasma at an average concentration of 4 µg/mL. Plasma protein C antigen levels are widely distributed in healthy adults such that 95% of the values range from 70% to 140%. Furthermore, protein C levels increase with age particularly in postmenopausal women.⁶ The wide range of values makes it difficult to establish a normal range. Levels less than 55%, however, are likely to reflect deficiency, whereas those between 55% and 70% are considered borderline and may be consistent with a deficiency state or the lower end of the normal distribution. Acquired causes of protein C deficiency must be excluded, and to document the presence of protein C deficiency, it is necessary to repeat the testing. Family studies may also be helpful to highlight the autosomal dominant pattern of inheritance.

Acquired protein C deficiency can be due to decreased synthesis or increased consumption. Decreased synthesis can occur in patients with liver disease or in those given warfarin. Warfarin decreases functional activity more than immunologic activity; newborns have protein C levels 20% to 40% lower than those of adults, and premature infants have even lower levels. Protein C consumption can occur with severe sepsis, with DIC, and after surgery. Reduced protein C levels have also been reported in cancer patients receiving cyclophosphamide, methotrexate, 5-fluorouracil, or L-asparaginase. A particularly severe form of acquired protein C deficiency has been described in association with meningococcal septicemia. In contrast to anti-thrombin, which is excreted in the urine of patients with nephrotic syndrome, the levels of protein C are normal or elevated in patients with nephrotic syndrome.

Protein S Deficiency

Protein S serves as a cofactor for APC and enhances its capacity to inactivate factors Va and VIIIa. In addition, protein S may have direct anticoagulant activity by inhibiting prothrombin activation through its capacity to bind anionic phospholipid, factor Va, or factor Xa, components of the prothrombinase complex. The importance of the direct anticoagulant activity of protein S is uncertain.

In the circulation, about 60% of total protein S is bound to C4b-binding protein, an acute phase complement component. Because only 40% of the protein S that is free is functionally active, only patients with low free protein S levels are prone to venous thrombosis. Therefore the diagnosis of protein S deficiency requires measurement of both free and bound forms of protein S. Total protein S levels can be measured immunologically under conditions that dissociate protein S from C4b-binding protein. The free fraction can then be quantified with a monoclonal antibody that only recognizes free protein S while the functional activity of protein S can be measured using an APC cofactor assay. This assay depends on prolongation of the aPTT when diluted patient plasma is added to protein S-depleted plasma containing APC and factor Va.

Protein S deficiency can be inherited or acquired. Heterozygous protein S deficiency is inherited in an autosomal dominant manner; the prevalence varies between 1% and 7% among patients with thrombotic events. There is an association with unprovoked venous thromboembolism.⁷ Based on measurements of total and free protein S antigen and protein S activity, three subtypes of inherited protein S deficiency have been identified (Table 140.5). Type I or classical deficiency results from decreased synthesis of a normal protein and is characterized by reduced levels of total and free protein S antigen together with reduced protein S functional activity. Molecular analysis

TABLE 140.5

Types of Inherited Protein S Deficiency

Type	Total Protein S	Free Protein S	Protein S Activity
I	Low	Low	Low
II	Normal	Normal	Low
III	Normal	Low	Low

of protein S deficiency is complicated because there are two homologous protein S genes, one of which is likely a pseudogene. Nonetheless, most cases of type I protein S deficiency are caused by partial gene deletions, missense mutations, base pair insertions or deletions, premature stop codons, or mutations affecting a splice site in the gene encoding protein S (*PROS1*). Type II protein S deficiency is characterized by normal levels of total and free protein S, associated with reduced protein S activity. This type of deficiency is uncommon, and most of the causative mutations encode protein S domains involved in its interaction with APC.

Type III protein S deficiency is characterized by normal levels of total protein S, but low levels of free protein S associated with reduced protein S activity. The molecular basis of this type of deficiency appears to be similar to that of the type I deficiency states. In fact, type I and type III protein S deficiency are likely to be manifestations of the same disease because they often coexist in families. Thus younger family members present with type I deficiency, whereas older family members have type III deficiency because protein S levels increase with age.

Acquired protein S deficiency can be due to decreased synthesis, increased consumption, loss, or shift of free protein S to the bound form. Decreased synthesis can occur in patients with severe liver disease, in those given L-asparaginase, and in patients given vitamin K antagonists. Increased consumption of protein S occurs in patients with acute thrombosis or in those with DIC. Patients with nephrotic syndrome can lose free protein S in their urine, causing decreased protein S activity. Total protein S levels in these patients are often normal because the levels of C4b-binding protein increase, shifting more protein S to the bound form. C4b-binding protein levels also increase in pregnancy and with the use of oral contraceptives. This shifts more protein S to the bound form and lowers the levels of free protein S and protein S activity. The pathophysiologic consequences of this phenomenon are uncertain. An association between antiphospholipid antibodies and acquired protein S deficiency has been reported in patients with severe forms of varicella zoster virus infection complicated by purpura fulminans. In healthy neonates the total protein S antigen levels are 15% to 30% of normal, and the C4b-binding protein is significantly reduced to less than 20%, such that the free form of protein S predominates and the functional levels are only slightly reduced compared with normal adult levels.

Gain of Function Mutations

Gain of function mutations includes factor V_{Leiden}, FIIIG20210A, elevated levels of procoagulant proteins, and other less well-characterized genetic disorders. The gain of function mutations are more prevalent in the general population than those associated with loss of function.

Factor V_{Leiden}

In 1993 Dahlback and colleagues described three families with a history of venous thromboembolism. Affected family members exhibited limited prolongation of the aPTT when APC was added to their plasma. Accordingly, this phenotype was designated APC resistance (APCR). Bertina and colleagues demonstrated that APCR co-segregated with the factor V gene and was due to a single base substitution, guanine to adenine at position 1691, that produced an

Arg 506 Gln mutation at one of the APC cleavage sites on factor Va. This mutation, which is designated factor V_{Leiden} , endows activated factor V_{Leiden} with a 10-fold longer half-life in the presence of APC than its wild-type counterpart.

The factor V_{Leiden} mutation is responsible for most cases of APCR. Other causes are mutations at Arg 306, another APC cleavage site. Arg 306 is replaced by a Gly residue in factor $V_{Hong Kong}$ and by a Thr residue in factor $V_{Cambridge}$. Neither of these mutations is strongly associated with thrombosis.

The factor V_{Leiden} mutation is inherited in an autosomal-dominant fashion. The prevalence of the mutation ranges from 2% to 5% in whites, but it is rare in Asians and Africans. This racial difference likely reflects a founder effect with the mutation arising 20,000 to 30,000 years ago, after the divergence of non-Africans from Africans and Caucasoids from Mongoloid subpopulations. The prevalence of factor V_{Leiden} homozygosity is about 1 in 2500. The risk for thrombotic complications is lower with factor V_{Leiden} than it is with deficiencies of antithrombin, protein C, or protein S,⁸ and in the heterozygous state, does not appear to be a strong risk factor for recurrent venous thrombosis.⁹ The risk for thrombosis is higher in homozygotes than in heterozygotes. Acquired APC resistance may be caused by hormonal changes during pregnancy or by the administration of estrogens, such as oral contraceptive pills or hormone replacement therapy.

A diagnosis of APCR is established using a functional assay based on the ratio of the aPTT after APC addition divided by that determined before APC addition. Second-generation tests, which add dilute patient plasma to factor V-deficient plasma, are more specific for factor V_{Leiden} . A normal functional test excludes factor V_{Leiden} ; a positive functional test for APCR should be confirmed with a genetic test for the factor V_{Leiden} mutation. Some laboratories only use the genetic test for diagnosis of factor V_{Leiden} .

FII G20210A Mutation

After extensive screening of 28 families with unexplained venous thromboembolism, Poort and colleagues identified a heterozygous G to A nucleotide transition at position 20210 in the 3'-untranslated region of the prothrombin gene in five of the probands. This mutation, FII G20210A, results in elevated levels of prothrombin. Elevated levels of prothrombin, in turn, may increase the risk for thrombosis by enhancing thrombin generation or by inhibiting factor Va inactivation by APC.

The mechanism by which the FII G20210A mutation causes increased prothrombin levels appears to vary. Enhanced protein synthesis may result from more efficient 3'-end formation, increased messenger RNA stability, increased translation efficiency, or some combination of these mechanisms. An intronic FII gene polymorphism, A19911G, which influences splicing efficiency, may modulate the effect of the FII G20210A mutation such that heterozygous carriers of both mutations have a greater risk for thrombosis than those with only the FII G20210A mutation.

Like the factor V_{Leiden} mutation, the prevalence of the FII G20210A mutation is higher in whites and low in Asians, American Indians, and African Americans. A founder effect likely explains the higher prevalence in whites. The mutation may have provided a survival advantage based on a protective effect with childbirth or severe sepsis.

FII G20210A is found in 1% to 6% of whites. The mutation is more common in southern Europe than in northern Europe, a gradient opposite to that of factor V_{Leiden} . Rare individuals homozygous for the FII G20210A mutation have been identified. In the Leiden Thrombophilia Study, 6.2% of venous thrombosis patients and 2.3% of healthy matched controls had the FII G20210A mutation.¹⁰ The mutation independently confers a 2.8-fold increased risk for venous thrombosis, with no gender bias; a risk lower than that with antithrombin, protein C, or protein S deficiency. The abnormality confers a weaker increased risk of venous thrombosis than protein C, protein S or antithrombin deficiencies.

Laboratory diagnosis of FII G20210A depends on genetic screening after PCR amplification of the 3'-untranslated region of the FII gene. Although FII G20210A heterozygotes have 30% higher levels of prothrombin than non-carriers, the wide range of prothrombin

levels in healthy individuals precludes the use of this phenotype to identify carriers.

Elevated Levels of Procoagulant Proteins

Elevated levels of factor VIII and other coagulation factors, including factors XI, IX, and VII, have been implicated as independent risk factors for thrombosis. Although the molecular bases for the high levels of these coagulation factors have yet to be identified, genetic mechanisms are likely responsible because the heritability of these quantitative abnormalities is high.

Other Hereditary Disorders

The dysfibrinogenemias represent a heterogeneous group of disorders characterized by abnormal fibrinogen structure and are diagnosed by low functional and/or immunologic levels of fibrinogen, in association with prolonged thrombin and reptilase times. Acquired causes of dysfibrinogenemia, such as liver disease, must be excluded in the diagnostic work-up. Most congenital dysfibrinogenemias are asymptomatic, and are often identified as an incidental finding when coagulation testing is performed for other reasons. Up to 40% of the known dysfibrinogenemias are associated with a bleeding diathesis. Approximately 15 variant fibrinogens, which represent less than 10% of known dysfibrinogenemias, have been reported to be associated with thrombotic complications, including fibrinogen Marburg, Caracas V, Chapel Hill III, Hannover II, Nijmegen, New York I, Christchurch II and III, and Milano III. The exact mechanism by which these dysfibrinogenemias increase the risk for thrombosis depends on the nature of the fibrinogen defect. Most affect the C-terminal domain of the α chains or the thrombin cleavage site on the β chains. Some biochemical defects have been further characterized, such as defects in the release of fibrinopeptides A or B by thrombin, impaired binding of thrombin or tissue plasminogen activator to fibrin, or resistance to lysis by plasmin. It is likely that acquired and/or other hereditary factors contribute to thrombosis that occurs in patients with dysfibrinogenemia.

Polymorphisms in the gene encoding EPCR have been associated with thrombosis. An EPCR polymorphism associated with high levels of soluble EPCR has been identified. By binding circulating protein C and APC, soluble EPCR competes with cell surface EPCR for protein C and prevents circulating APC from functioning as an anticoagulant.

ACQUIRED HYPERCOAGULABLE STATES

Acquired hypercoagulable states include antiphospholipid antibody syndrome and cancer, as well as pregnancy and estrogen therapy (oral contraception or hormone replacement therapy). These disorders can occur in isolation or can be superimposed on hereditary hypercoagulable states. Heparin-induced thrombocytopenia is an immune-mediated adverse drug reaction, and is a strong, independent risk factor for arterial and venous thrombosis.

Lupus Anticoagulants and the Antiphospholipid Syndrome

First described in a study by Wasserman and colleagues in 1906 among patients with positive serologic tests for syphilis, antiphospholipid antibodies are a heterogeneous group of autoantibodies directed against proteins that bind phospholipid. Antibodies can be categorized into those that prolong phospholipid-dependent coagulation assays, known as the lupus anticoagulant (LA), or anticardiolipin antibodies (ACLs), which target cardiolipin. A subset of ACL recognizes other phospholipid-bound proteins, particularly β_2 -glycoprotein I.

Patients who have thrombosis in association with an LA and/or ACL (antibodies of the immunoglobulin [Ig]G or IgM subclass directed against cardiolipin or β_2 -glycoprotein I) are diagnosed with antiphospholipid syndrome (APS). The criteria for diagnosis of APS were updated in 2006.¹¹ APS is considered primary when it occurs

in isolation and secondary when it is associated with autoimmune disorders, such as systemic lupus erythematosus or other connective tissue diseases. Clinical manifestations of APS include one or more episode of thrombosis, one or more unexplained fetal deaths at 10 or more weeks of gestation, or three or more first-trimester miscarriages (less than 10 weeks of gestation). Placental thrombosis is hypothesized to be the root cause of the pregnancy-related complications that characterize APS. Intrauterine growth retardation, preeclampsia, and eclampsia have also been associated with APS. APS can also occur with cancer, with some infections, and with drugs, such as phenothiazines, phenytoin, hydralazine, or amoxicillin. Thrombosis in APS patients can be arterial, venous, or placental.

To make the diagnosis of APS, at least one clinical criterion and one laboratory criterion must be met. Laboratory diagnosis of APS requires the presence of LA or ACL on tests taken at least 6 to 12 weeks apart. Tests for LA are well standardized, and a LA is associated with a higher risk of thrombosis than ACL. In contrast, there is considerable variability among laboratory results of ACL tests reflecting, at least in part, different methods and lack of consensus on what constitutes a negative or positive test.¹²

The LA is detected using phospholipid-dependent clotting tests. Most screening assays are based on the aPTT. aPTT reagents differ in their sensitivity for detection of LA, and many laboratories have adopted less-sensitive aPTT reagents for routine aPTT testing. LA is suspected when the aPTT is prolonged. To explore the cause of the prolonged aPTT, patient plasma is mixed with normal plasma and the aPTT is again determined (see Chapter 129). If the aPTT remains prolonged, an LA is suspected. The diagnosis is confirmed by demonstrating that addition of excess hexagonal-phase phospholipid normalizes the aPTT, thereby documenting the phospholipid dependence of the abnormal test result.¹³ In addition to the aPTT, a battery of phospholipid-dependent clotting tests is often used for diagnosis of LA. These include the dilute Russell viper venom time and kaolin clotting time.

ACL antibodies are detected using immunoassays. Only ACL of medium to high titer and of the IgG or IgM subclass are associated with thrombosis, and the risk is higher with antibodies against β_2 glycoprotein-1 than against cardiolipin. For ACL, the amount of IgG or IgM antibody binding to cardiolipin-coated platelets is expressed in standardized GPL or MPL units, with 1 unit representing the cardiolipin-binding capacity of 1 $\mu\text{g/mL}$ affinity-purified antiphospholipid antibody from reference sera. The extent of antibody binding is influenced by both the titer of the antibody and its affinity for cardiolipin.¹⁴ Lack of standardization of ACL assays makes it difficult to compare results between laboratories.

ACL antibodies are found in 3% to 10% of healthy individuals. They also are common with certain infections (such as mycobacterial pneumonia, malaria, or parasitic disorders) and after exposure to some medications. Often, these antibodies are of low titer and are transient. ACL antibodies are detected in about 30% to 50% of patients with systemic lupus erythematosus. Of these, 10% to 20% also have an LA.

The mechanism by which antiphospholipid antibodies trigger thrombin generation is unclear. In cell cultures, these antibodies can directly activate endothelial cells and induce the expression of adhesion molecules that can tether tissue factor-bearing leukocytes or microparticles onto their surface. Tissue factor can then induce clotting *in vitro*.

Antiphospholipid antibodies also have been shown to (a) activate platelets, (b) interfere with the protein C pathway, (c) inhibit antithrombin catalysis by vessel wall heparan sulfate, (d) impair fibrinolysis, and (e) enhance transmigration of oxidized LDL into the vessel wall, thereby promoting atherothrombosis. Whether these mechanisms are operative *in vivo* has yet to be established.

In contrast to most hypercoagulable states, APS can be associated with spontaneous arterial thrombosis, as well as with venous thromboembolism. Arterial thrombosis can manifest as a stroke or transient ischemic attack. Thrombosis of the sagittal sinus or other cerebral veins, a form of venous thrombosis, can cause stroke in these patients.

Heparin-Induced Thrombocytopenia

A clinicopathologic syndrome, heparin-induced thrombocytopenia (HIT) is diagnosed on the basis of clinical features and laboratory detection of HIT antibodies¹⁵ (see Chapter 133). The risk for HIT is higher with unfractionated heparin than with low-molecular-weight heparin (LMWH) and almost never occurs with fondaparinux. HIT is more common in surgical patients than in medical patients and occurs more frequently in women.

Typical clinical features of HIT include thrombocytopenia and thrombosis (arterial or venous). Less common features include necrotic skin lesions at the site of subcutaneous heparin injection, acute systemic reactions to heparin, and rarely, DIC.^{16,17} Thrombocytopenia is the most common finding, occurring in 90% of patients. Typically, the platelet count falls 5 to 10 days after heparin is started.¹⁸ However, thrombocytopenia can occur earlier if the patient has been exposed to heparin in the past 3 months. Rarely, the onset of HIT can be delayed and occurs several days after stopping heparin.

HIT is an autoimmune-like disorder and is caused by heparin-dependent, platelet-activating antibodies of the IgG subclass. These antibodies are directed against neoantigens that are exposed on platelet factor 4 (PF4) when it forms a complex with heparin. By binding to Fc γ II receptors on platelets, these antibodies trigger platelet activation. Activated platelets and platelet-derived microparticles provide an anionic phospholipid surface on which coagulation factors assemble and promote thrombin generation. This produces a hypercoagulable state and explains why 30% to 70% of HIT patients develop thrombosis.

The diagnosis of HIT is supported by assays that capitalize on the platelet-activating properties of HIT antibodies. Functional assays, such as the platelet serotonin release assay or heparin-induced platelet activation assay, detect antibody-induced platelet activation in the presence of heparin and are the gold standard for diagnosis of HIT. In contrast, although enzyme immunoassays for detection of antibodies against PF4/heparin complexes are more sensitive than functional assays, they are less specific because only a small subset of these antibodies has the capacity to produce HIT. Consequently a negative immunoassay is useful to exclude the diagnosis of HIT, but a positive test should be confirmed with a functional assay.

When the diagnosis of HIT is established, heparin must be stopped and an alternative anticoagulant should be given. Options include direct thrombin inhibitors (such as argatroban or bivalirudin) or factor Xa inhibitors (such as fondaparinux or danaparoid). Treatment with these agents should be continued until the platelet count returns to baseline levels at which point, low-dose warfarin can be initiated.

Cancer and Its Treatment

About 25% of patients who present with venous thromboembolism have cancer. Cancer patients who develop venous thromboembolism have reduced survival compared with those without this complication. Patients with brain tumors, pancreatic cancer, and advanced ovarian, lung, gastrointestinal tract, or prostate cancer have particularly high rates of venous thromboembolism.¹⁹ Treatment with chemotherapy, hormonal therapy, and biologic agents, such as erythroid stimulating agents and antiangiogenic drugs, and surgery further increases the risk for venous thromboembolism. Additional risk factors include indwelling central venous catheters and major abdominal, pelvic, or orthopedic surgery.

The pathogenesis of thrombosis in cancer patients is multifactorial in origin and represents a complex interplay among the tumor, patient characteristics, and the host hemostatic system. Tumors can initiate coagulation by expressing tissue factor or cysteine proteases on their surface or by shedding tissue factor-bearing microparticles. In addition to its role in coagulation, tissue factor also acts as a cell-signaling molecule that promotes tumor proliferation and spread.

Patient factors that contribute to venous thromboembolism include immobility and venous stasis secondary to extrinsic

compression of major veins by tumor. Surgical procedures, indwelling central venous catheters, and chemotherapy can produce vessel wall injury. In addition, tamoxifen, selective estrogen receptor modulators (SERM), L-asparaginase, and other drugs may induce an acquired hypercoagulable state by reducing the levels of natural anticoagulant proteins.

L-Asparaginase and combination chemotherapeutic regimens, such as breast cancer regimens of cyclophosphamide, methotrexate, and 5-fluorouracil increase the risk for thrombosis. The incidence of thromboembolic events in children receiving L-asparaginase for treatment of acute lymphocytic leukemia ranges from 1.1% to 36.7%, depending on whether or not catheter-related events are included. The mechanism likely involves decreased synthesis of antithrombin, protein C, and protein S, in addition to the retention of antithrombin within the endoplasmic reticulum. Concomitant administration of steroids increases the risk for thrombosis, and age seems to be an important risk factor; older children demonstrate a more marked decrease in anticoagulant and fibrinolytic proteins than younger children, as well as a slower recovery to normal.

Patients with multiple myeloma and other plasma cell dyscrasias are at increased risk for arterial and venous thrombosis. The reason for this is unclear, but may include acquired activated protein C resistance, elevated levels of factor VIII and/or von Willebrand factor, and the influence of the paraprotein on blood viscosity and fibrinolysis. Patients treated with thalidomide or lenalidomide are at high risk for venous thromboembolism, particularly when these drugs are given in combination with dexamethasone. Current guidelines recommend low-dose aspirin or LMWH thromboprophylaxis for patients receiving these agents.^{20,21}

A proportion of patients who present with unprovoked venous thromboembolism have occult cancer. This observation has prompted some experts to recommend extensive screening for cancer in such patients. Benefits of this approach, however, are likely to be offset by potential harms. These include procedure-related morbidity, the psychological impact of false-positive tests and the cost of screening. Furthermore, early detection of cancer is only of benefit if there is potentially curative therapy. To date, only screening for breast, cervical, and possibly colon cancer has been shown to reduce mortality.

A careful history should be taken to identify any symptoms suggestive of underlying cancer. If such symptoms are present, further investigation is warranted. If there are no symptoms suggestive of underlying cancer, patients should be encouraged to undergo age-appropriate screening tests for breast, cervical, colon, or prostate cancer.

Myeloproliferative Disorders

The most common Philadelphia chromosome-negative (Ph-neg) myeloproliferative disorders, essential thrombocythemia (ET) and polycythemia vera (PV), are associated with an increased risk for thrombosis, especially arterial thrombosis, and venous thrombosis affecting the splanchnic vessels, including the hepatic and portal veins, which can lead to the Budd-Chiari syndrome, or the mesenteric veins.²⁰ Thrombosis involving the microcirculation is common in patients with ET, and patients may complain of erythromelalgia, characterized by burning pain, redness and swelling of the fingers and toes, transient visual defects, or recurrent headache. Although ET and PV may evolve to myelofibrosis or transform into acute myeloid leukemia, fatal cardiovascular events are a leading cause of mortality. The reported cumulative risk for thrombosis ranges from 2.5% to 5.0% per patient-year in PV and from 1.9% to 3% per patient-year in ET, depending on the patient risk category.²¹ Age over 60 years and a previous history of thrombosis are risk factors for serious thrombosis, whereas usual cardiovascular risk factors, such as hypertension, diabetes, dyslipidemia and smoking, may place patients at intermediate risk.

The pathogenesis of thrombosis in patients with myeloproliferative disorders is multifactorial in origin and includes leukocytosis, leukocyte activation, rheologic abnormalities due to raised red cell

mass in PV, enhanced platelet activation, and a prothrombotic endothelial phenotype.

An acquired point mutation in the Janus kinase 2 gene (*JAK2* V617F) is found in up to 95% of patients with Ph-neg PV and in 50% to 60% of those with ET. The *JAK2* gene encodes a cytoplasmic tyrosine kinase that is critical for signaling between type 1 cytokine receptors and intracellular proliferation mechanisms. Clinical observations, supported by laboratory studies, suggest an association between the *JAK2* mutation and increased leukocyte and platelet activation, particularly in reticulated platelets, and there is a correlation between the burden of the mutant allele and thrombin generation. Acquired activated protein C resistance secondary to a reduction in free protein S levels has also been demonstrated in patients with ET and PV. Overall, there is little to support routine *JAK2* screening unless splenomegaly or an elevated hemoglobin, white blood cell, and/or platelet count raises the possibility of an underlying myeloproliferative disorder. However, it may be justifiable to check for the *JAK2* mutation in patients with unexplained splanchnic or mesenteric vein thrombosis, even in the absence of evidence of these findings.

Current management of PV and ET is aimed at prevention of major cardiovascular events and is based on the patient's risk category. Low-risk patients with PV are managed with phlebotomy, whereas high-risk patients are given cytoreductive therapy. Low-dose aspirin (70–100 mg daily) is recommended for all PV patients regardless of risk category, and such therapy is highly effective for treatment of the microcirculatory disturbances in patients with ET.

Paroxysmal Nocturnal Hemoglobinuria

A rare but serious disorder, paroxysmal nocturnal hemoglobinuria (PNH) is associated with intravascular hemolysis and cytopenia.²² PNH is caused by the clonal expansion of a hematopoietic stem cell that has a somatic mutation in the X-linked *PIG-A* gene, which encodes cell surface proteins that serve as phosphatidylinositol anchors (see Chapter 31). Patients with PNH may have life-threatening thrombosis that can be difficult to recognize when it affects the splanchnic or cerebral veins. Severe persistent abdominal pain or headache in patients with PNH should prompt appropriate radiologic investigations to exclude thrombosis. Although patients with PNH who have documented thrombosis should be treated with anticoagulants, phlebotomy, cytoreductive therapy, and eculizumab are important adjunctive measures to reduce the risk for recurrence.

Pregnancy

Pregnancy is an independent risk factor for venous thromboembolism: the risk for venous thromboembolism in pregnant women is up to sixfold higher than that in age-matched nonpregnant women. About 1 in 1000 pregnancies are complicated by venous thromboembolism,²³ and the risk is highest in the postpartum period. Thus venous thromboembolic disease is the leading cause of maternal morbidity and mortality and is estimated to account for 12% of fatalities in pregnancy.

The individual risk for venous thromboembolism in pregnancy and the puerperium, defined as the 6-week period after delivery, is influenced by patient-related factors. These factors include age over 35 years, body mass index over 29, cesarean delivery, prolonged immobilization, obesity, and thrombophilia or family history of venous thromboembolism. Multiparity, ovarian hyperstimulation, and a past history or family history of venous thromboembolism are other risk factors.

Over 90% of deep vein thrombosis in pregnancy occurs in the left leg because the enlarged uterus further compresses the left iliac vein by placing pressure on the overlying right iliac and ovarian arteries. A similar mechanism likely explains the isolated left iliofemoral thrombosis that can occur in pregnancy.

Hypercoagulability of the blood occurs in pregnancy and reflects a combination of venous stasis and changes in the hemostatic system. The enlarging uterus reduces venous blood flow from the lower extremities. This is not the only mechanism responsible for venous stasis because blood flow from the lower extremities begins to decrease by the end of the first trimester, likely reflecting hormonally induced venous dilatation. Systemic factors also contribute to hypercoagulability. Thus the levels of circulating procoagulant proteins increase in the third trimester of pregnancy. These include factor VIII, fibrinogen, and von Willebrand factor, among others. Coincidentally, suppression of natural anticoagulant pathways and decreased fibrinolytic activity occur. Thus there is an acquired resistance to activated protein C that is related, at least in part, to reduced levels of free protein S. The net effect of these changes is enhanced thrombin generation, in addition to release of tissue factor from the uteroplacental circulation, as evidenced by elevated levels of prothrombin fragments and thrombin/antithrombin complexes. Platelet activation and increased platelet turnover occur, and mild thrombocytopenia, likely secondary to consumption, occurs in 8.3% of women at term. The altered levels of hemostatic proteins normalize 4 to 6 weeks after delivery.

About half of the episodes of venous thromboembolism in pregnancy occur in women with thrombophilia. The risk for venous thromboembolism in women with thrombophilic defects depends on the type of abnormality and the presence of other risk factors. The risk appears to be highest in women with a positive family history of venous thromboembolism who are homozygous for the factor V_{Leiden} or FII G 20210A mutation. There is also an increased risk in women with antithrombin, protein C, or protein S deficiency and a positive family history and a lower risk in those who are heterozygous for the factor V_{Leiden} or FII G 20210A mutation. The risk of venous thromboembolism during pregnancy is similar in all three trimesters and begins in early pregnancy. In general, the daily risk is higher in the postpartum period than it is during pregnancy. Therefore, if thromboprophylaxis is given during pregnancy, it must be administered throughout the pregnancy and continued for at least 6 weeks postpartum.

Assisted Conception and Ovarian Hyperstimulation Syndrome

The overall risk for venous thrombosis in women undergoing ovarian hyperstimulation is small (estimated as 0.1% per treatment cycle). Often, thrombosis affects veins of the upper extremities or the jugular veins; the explanation for this phenomenon remains unclear. Thrombophilia testing is not routinely recommended in women undergoing ovarian stimulation as its predictive value is low.

Hormonal Therapy

Oral contraceptives, estrogen replacement therapy, and SERM are all associated with an increased risk for thrombosis. The relatively high risk for venous thromboembolism associated with early oral contraceptives prompted development of low-dose formulations containing reduced doses of estrogen and progestin. Currently available low-estrogen combination oral contraceptives contain 20 to 50 μg of ethinylestradiol and one of several different progestogens. Even these low-dose combination contraceptives are associated with a three- to four-fold increased risk for venous thromboembolism compared with the risk in non-users. In absolute terms, this translates to an incidence of 3 to 4 per 10,000. In contrast, progesterone only methods of contraception, including pills, cutaneous implants and progesterone-releasing intrauterine devices, are associated with little or no risk of thrombosis.²⁴

Although smoking increases the risk for myocardial infarction and stroke in women taking oral contraceptives, it is unclear whether smoking affects the risk for venous thromboembolism. In contrast, obesity increases the risk for both arterial and venous thrombosis and

the risk of venous thrombosis increases steeply in those over the age of 40 years. The risk for venous thromboembolism is highest during the first 3 months of oral contraceptive use and persists only for the duration of use.

Case-control studies suggest that the risk for venous thromboembolism is 20- to 30-fold higher in women with inherited thrombophilia who use oral contraceptives than the risk for non-users with thrombophilia or users without these defects. Despite the increased risk, however, routine screening for thrombophilia is not indicated in women considering the use of oral contraceptives. Based on the estimated incidence and case fatality rate of thrombotic events, it is estimated that 400,000 women would need to be screened to detect 20,000 carriers of factor V_{Leiden} . Oral contraceptives would need to be withheld in all of these women to prevent a single death. For less prevalent thrombophilic defects, even larger numbers of women would need to be screened. Based on these considerations, routine screening cannot be recommended.

Oral contraceptive pills may cause prothrombotic side effects by inducing modest increases in levels of procoagulant factors (such as factors VII, VIII, X, prothrombin, and fibrinogen) and decreases in the levels of anticoagulant proteins (such as antithrombin and protein S). Acquired APC resistance is an almost universal finding in women taking oral contraceptives; the clinical significance of this phenomenon is uncertain.

There is good evidence that oral hormonal replacement therapy with conjugated equine estrogen (with or without a progestogen) increases the risk for myocardial infarction, ischemic stroke, and venous thrombosis. Carriers of the factor V_{Leiden} mutation receiving hormone replacement therapy have a significantly increased risk for venous thromboembolism. Data from the Heart and Estrogen Replacement Study (HERS) and the Estrogen Replacement and Atherosclerosis Trial indicate that heterozygous carriers of the factor V_{Leiden} mutation who were taking hormone replacement therapy had a 14-fold higher risk for venous thromboembolism compared with non-carriers receiving placebo. Based on this information, the use of oral hormone replacement preparations has markedly decreased. Use of transdermal hormone replacement therapy does not appear to increase the risk of venous thrombosis.²⁵

Selective estrogen receptor modulators (SERMs) are estrogen-like compounds. The prototypical SERM is tamoxifen, which serves as an estrogen antagonist in the breast, but has an estrogen agonist effect in other tissues, such as bone and uterus. Like estrogens, tamoxifen increases the risk for venous thromboembolism three- to four-fold. The risk is higher in postmenopausal women, particularly when they are receiving systemic combination chemotherapy.

Aromatase inhibitors are replacing tamoxifen for treatment of estrogen receptor-positive breast cancer. These agents are associated with a lower risk for venous thromboembolism than is tamoxifen. Raloxifene, a SERM used to prevent osteoporosis, increases the risk for venous thromboembolism threefold compared with placebo. Therefore this agent is contraindicated for prevention of osteoporosis in women with a prior history of venous thromboembolism.

Prior History of Venous Thromboembolism

A history of previous venous thromboembolism places patients at risk for recurrence. Those with unprovoked venous thromboembolism have a particularly high risk for recurrence when anticoagulant treatment is stopped.²⁶⁻²⁸ Their risk for recurrence is about 10% at 1 year and 30% at 5 years. This risk occurs regardless of whether or not there is an underlying thrombophilic defect, such as factor V_{Leiden} or the FII G 20210A mutation.

The risk for recurrent venous thromboembolism is lower in patients whose incident event occurred in association with a well-recognized and transient risk factor, such as major surgery or prolonged immobilization. These patients have a risk for recurrence of about 4% at 1 year and 10% at 5 years. Patients at highest risk for recurrence are those homozygous for factor V_{Leiden} or the FII G 20210A mutation and those with antiphospholipid syndrome, advanced

Routine Investigations to Evaluate a Patient With Thrombosis

Test	Abnormality	Diagnostic Information
Complete blood count	Elevated hematocrit Increased white count Increased platelet count Leukopenia Thrombocytopenia	Myeloproliferative disorder (e.g., essential thrombocythemia, polycythemia vera); may be found in paroxysmal nocturnal hemoglobinuria; if associated with heparin administration, consider heparin-induced thrombocytopenia
Blood film	Leukoerythroblastic changes	Underlying neoplasm invading bone marrow
Liver function tests	Abnormal tests	May point to malignancy
Renal function	Impaired renal function	Assess prior to anticoagulation with heparin or low-molecular-weight heparin or new oral anticoagulants
Urinalysis	Proteinuria	Nephrotic syndrome; may be associated with venous thromboembolism or renal vein thrombosis
PT and aPTT	Prolonged PT and aPTT	To enable safe anticoagulation to proceed if required Need to exclude lupus anticoagulant

aPTT, Activated partial thromboplastin time; PT, prothrombin time.

malignancy, or inherited deficiencies of antithrombin, protein C, or protein S. These patients' risk for recurrence is likely to be 15% at 1 year and up to 50% at 5 years.

COMBINED INHERITED AND ACQUIRED HYPERCOAGULABLE STATES

Hyperhomocysteinemia is the prototypical hypercoagulable state that occurs due to a combination of inherited and acquired factors. Homocysteine is an intermediate sulfur-containing amino acid that acts as a methyl group donor during the metabolism of methionine, an essential amino acid derived from the diet. The interconversion of methionine and homocysteine depends on the availability of 5-methyltetrahydrofolate, a methyl group donor, vitamin B₁₂ and folate, cofactors in the interconversion, and the enzyme methionine synthase. Increased levels of homocysteine can be the result of increased production or reduced metabolism. Severe hyperhomocysteinemia and cysteinuria are rare and are usually caused by deficiency in the enzyme, cystathione β -synthetase. More common is mild to moderate hyperhomocysteinemia. This can be caused by genetic mutations in methyltetrahydrofolate reductase (MTHFR) when they are accompanied by nutritional deficiency of folate, vitamin B₁₂, or vitamin B₆. Common polymorphisms in MTHFR, C677T and A1298C, are associated with reduced enzymatic activity and increased thermolability. The cofactor requirements are therefore increased with these mutations. Hyperhomocysteinemia also can be associated with certain drugs, such as methotrexate, theophylline, cyclosporine, and most anticonvulsants, as well as some chronic diseases, such as end-stage renal disease, severe hepatic dysfunction, and hypothyroidism.

A fasting serum homocysteine level over 15 mmol/L is considered elevated. Although elevated levels were a common finding, routine fortification of flour with folic acid has resulted in lower homocysteine levels in the general population. Elevated serum levels of homocysteine have been associated with an increased risk for arterial thrombosis (myocardial infarction, stroke, and peripheral arterial disease) and venous thromboembolism.

Elevated levels of homocysteine can be reduced by administration of folate with vitamin B₁₂ and vitamin B₆. Randomized trials, however, have shown that reduction of homocysteine levels with vitamin therapy does not reduce the risk for recurrent cardiovascular events in patients with coronary artery disease or stroke, nor does it lower the risk for recurrent venous thromboembolism; whether reduction of homocysteine levels is of benefit in peripheral artery disease with bypass grafts is less certain. Nonetheless, based on these negative trials and the declining incidence of hyperhomocysteinemia, the enthusiasm for screening for hyperhomocysteinemia has waned.

CLINICAL EVALUATION OF PATIENTS WITH HYPERCOAGULABLE STATES

A carefully taken history is essential to evaluate a patient with a history of thrombosis. The patient's age at the time of thrombosis, the location of the thrombosis, and results of objective diagnostic tests should be recorded. A historical record of previous thromboses and sites, and potential risk factors, such as recent surgery, trauma, prolonged immobility, pregnancy, or estrogen use should be noted. A family history of thrombosis, especially in first-degree relatives may point to a heritable thrombophilic defect; systemic symptoms, such as anorexia, weight loss, change in bowel habits, or gastrointestinal bleeding may suggest an underlying malignant condition.

A full physical examination should be conducted with attention to abdominal or pelvic masses, lymphadenopathy, and skin changes such as skin necrosis and livedo reticularis. Basic investigations are necessary to exclude acquired causes of thrombosis and to assess the patient's general health and tolerance to anticoagulation (see box on [Routine Investigations to Evaluate a Patient With Thrombosis](#)).

THROMBOPHILIA SCREENING

In the past, the indications for thrombophilia screening were somewhat controversial, and the implications of such tests were often misinterpreted. It is now apparent that testing for heritable thrombophilia does not predict the likelihood of recurrence in unselected patients with symptomatic venous thrombosis. For patients with a first episode of venous thromboembolism, thrombophilia screening is indicated only if the results influence the duration of treatment or have an impact on family counselling regarding use of estrogen-containing compounds. It is reasonable to screen patients whose first episode of thrombosis occurred before the age of 40 years, patients with thrombosis in an unusual site, such as cerebral or mesenteric veins, and those with two or more first-degree relatives with unprovoked thrombosis; retinal vein thrombosis is not an indication for such screening. Screening should not be done when patients are taking an anticoagulant. If indefinite anticoagulation therapy is planned, screening is generally not required. Neonates and children with purpura fulminans should be urgently tested for protein C or S deficiency, as should adults who develop skin necrosis in association with vitamin K antagonists (see box on [When to Perform a Thrombophilia Screen](#)).

LABORATORY EVALUATION OF THROMBOPHILIA

Screening should include functional assays for antithrombin and protein C, an immunoassay for free protein S, testing for activated

When to Perform a Thrombophilia Screen

Clinical Scenario

- First episode of unprovoked venous thromboembolism in individuals younger than 40 years of age
- Thrombosis in an unusual site (e.g., cerebral or mesenteric thrombosis)
- Two or more first-degree relatives with unprovoked thrombosis
- Three or more early pregnancy losses, or one or more fetal deaths after 10 weeks gestation

Essential Tests for Thrombophilia Screening

Basic coagulation screen

International normalized ratio (INR): to exclude warfarin effect—warfarin will lower protein C and S levels

Activated partial thromboplastin time (aPTT): to exclude heparin effect—heparin will lower antithrombin levels

Functional assay for antithrombin (with heparin to detect type II defects)

Functional assay for protein C

Functional assay for protein S (immune assays for total and free protein S)

APC resistance assay: with genetic test for factor V_{Leiden} for confirmation of abnormal results

Genetic test for FIIIG 20210A gene mutation

Anticardiolipin and β_2 -glycoprotein-1 antibodies (IgG and IgM) and lupus anticoagulant assay

protein C resistance using the modified APC sensitivity ratio with DNA testing for the factor V_{Leiden} mutation if the screening test is positive, DNA testing for the FIIIG 20210A gene mutation, phospholipid-based clotting tests to detect a lupus anticoagulant and enzyme immunoassay for ACL (see box on [Essential Tests for Thrombophilia Screening](#)). The benefits and potential harms of thrombophilia testing should always be discussed in advance with the patient because the psychological impact of knowing that they are a carrier of a genetic defect is one of the disadvantages of testing, and because test results may also impact on the cost of life insurance.

The timing of thrombophilia screening is critical. Levels of natural anticoagulants may be lower at the time of an acute thrombotic event; additionally, heparin can reduce the level of antithrombin, while vitamin K antagonists, such as warfarin, reduce the levels of protein C and protein S. Therefore testing is best performed after the acute event and when anticoagulant treatment has stopped. During pregnancy, protein S levels fall, which complicates the diagnosis of protein S deficiency.

MANAGEMENT OF THROMBOSIS IN PATIENTS WITH HYPERCOAGULABLE STATES

Thrombosis treatment is usually divided into two overlapping stages, initial treatment and extended therapy. The impact of hypercoagulable states on these two stages is discussed separately as is their impact on duration of anticoagulant therapy and recommendations for prevention of recurrence.

Initial Treatment

With few exceptions, management of initial thrombotic events in patients with hypercoagulable states is no different from the management of these events in patients without underlying hypercoagulable disorders. The exceptions are purpura fulminans in newborns with homozygous protein C or protein S deficiency, warfarin-induced skin necrosis, heparin-induced thrombocytopenia and thrombosis in patients with severe antithrombin deficiency. Newborns with purpura

fulminans require protein C or protein S concentrates or sufficient amounts of plasma to increase the levels of protein C or protein S.

Patients with severe antithrombin deficiency can usually be managed with LMWH or unfractionated heparin, although some patients may require considerably higher doses to achieve therapeutic anticoagulation. Some individuals may require antithrombin concentrates to increase plasma levels of antithrombin to a point where heparin or LMWH can be used for treatment. Antithrombin concentrates are commercially available in plasma-derived and recombinant forms. The aim of treatment with antithrombin concentrate is to initially increase antithrombin activity to greater than 120% of the normal level (based on an expected 1.4% increase above baseline activity level per IU/kg of antithrombin administered) and to then maintain antithrombin activity at over 80% of the normal level. Plasma antithrombin levels need to be monitored to ensure that levels over 80% are maintained; antithrombin has a half-life of 2 to 4 days. The role of the non-vitamin K antagonist oral anticoagulants, such as dabigatran, rivaroxaban, apixaban, or edoxaban, in patients with antithrombin deficiency and thrombosis is uncertain.

Treatment of heparin-induced thrombocytopenia involves discontinuation of heparin (including heparin flushes of indwelling central venous catheters) and the initiation of an alternative anticoagulant, such as argatroban or fondaparinux.

The management of acute venous thromboembolism in patients with APS is similar to that in other patients. However, monitoring treatment with heparin or vitamin K antagonists can be problematic because the aPTT or INR may be prolonged at baseline. Under these circumstances, heparin can be monitored using an antifactor Xa assay and warfarin can be monitored using a factor X assay. Alternatively, LMWH or fondaparinux can be used in place of heparin because these agents do not require coagulation monitoring. Although the non-vitamin K antagonist oral anticoagulants may be reasonable alternatives to warfarin, clinical data on their effectiveness in APS patients are lacking. In asymptomatic subjects with laboratory evidence of ACL or LA, but no history of venous or arterial thrombosis, appropriate thromboprophylaxis should be given at time of thrombotic challenge, such as major surgical procedures, prolonged immobilization, or pregnancy and the puerperium. There is no indication for primary preventive treatment with anticoagulants or antiplatelet agents in such individuals.

Extended Therapy

Extended treatment of thrombosis in patients with hypercoagulable states is similar to that of patients without these underlying disorders. Caution is needed when starting patients with protein C or protein S deficiency on warfarin or other vitamin K antagonists to prevent skin necrosis. Warfarin should not be started in these patients until therapeutic anticoagulation has been fully achieved with heparin or LMWH. Once started, low doses of warfarin should be given to prevent precipitous decreases in the levels of protein C or protein S; the heparin or LMWH should only be stopped when the INR has been therapeutic for at least two consecutive days.

Randomized trials have shown that usual-intensity warfarin (target INR of 2.0 to 3.0) is as effective as higher-intensity warfarin in patients with antiphospholipid syndrome. The risk for major bleeding is lower with usual-intensity warfarin than it is with higher-intensity regimens. A target INR of 2.5 with an INR range from 2.0 to 3.0 is appropriate for patients with other hypercoagulable states.

Patients with thrombosis who have a history of metastatic cancer may do better with extended treatment with LMWH. Randomized clinical trials have shown that, compared with warfarin, LMWH reduces the risk for recurrent venous thromboembolism without increasing bleeding.²⁹ Furthermore, LMWH simplifies treatment because it can be given subcutaneously once-daily without coagulation monitoring. The drug can be held before invasive procedures, and the dose may be reduced if thrombocytopenia is present. The major drawbacks of LMWH are cost and its requirement for

TABLE 140.6**Management of Women With a History of Venous Thrombosis During Pregnancy and the Puerperium**

Clinical History	Thrombophilia	Antepartum	Postpartum ^a
Prior VTE due to a transient risk factor	No	Surveillance	Yes
Prior VTE due to pregnancy or estrogens	Yes or no	Prophylactic LMWH	Yes
Prior idiopathic VTE	Yes or no	Prophylactic LMWH	Yes
Recurrent VTE	Yes or no	Treatment dose LMWH	Resume long-term anticoagulation
No prior VTE Positive family history	Antithrombin deficiency; homozygous FII G20210A; or Factor V _{Leiden} ; or dual heterozygosity for both mutations	Prophylactic or intermediate dose LMWH	Yes

^aPostpartum prophylaxis involves a 6-week course of prophylactic doses of LMWH or dose-adjusted warfarin (target INR: 2.0 to 3.0). LMWH, low-molecular-weight heparin; VTE, venous thromboembolism.

parenteral administration, although the drug has been shown to be cost-effective in patients at high risk for recurrent venous thromboembolism.

Duration of Treatment

The presence of a hypercoagulable state has no influence on the duration of anticoagulant treatment in patients whose venous thromboembolic event occurred in the setting of a well-recognized and transient risk factor, such as major surgery or prolonged immobilization due to medical illness. These patients are treated with anticoagulants for at least 3 months. For those with unprovoked venous thromboembolism, a minimum of 3 months of anticoagulation treatment is recommended at which point individualized assessment of the risk of recurrence without anticoagulation and the risk of bleeding with anticoagulation should be undertaken. Unless the risk of bleeding is high, most patients should receive extended anticoagulation therapy. Heterozygosity for factor V_{Leiden} or the FII G20210A mutation does not influence the risk for recurrence. In contrast, patients with deficiency of antithrombin, protein C, or protein S or those homozygous for factor V_{Leiden} or the FII G20210A mutation appear to be at higher risk for recurrence and likely should receive longer-term anticoagulation treatment. Likewise, patients with APS with a persistent ACL or LA are also at high risk for recurrence and require long-term treatment.

The decision to continue anticoagulation indefinitely requires consideration of the site and severity of the first episode of venous thromboembolism, information on whether or not the event was provoked, assessment of the risk for anticoagulant-related bleeding and other risk factors such as an elevated D-dimer level after stopping anticoagulant therapy.²⁵ The decision should also take into account patient adherence and patient preferences.

Treatment and Prevention of Thrombosis During Pregnancy

Thrombophilic disorders have no influence on the treatment of venous thrombosis during pregnancy. Due to its better bioavailability and longer half-life, LMWH is preferred over subcutaneous heparin; fondaparinux is reserved for women with an allergy to heparin. LMWH can be given once or twice daily in a weight-adjusted fashion. The need for dose adjustments and monitoring during the course of pregnancy remains controversial. The non-vitamin K antagonist oral anticoagulants should not be used in pregnancy or in nursing mothers because these drugs have the potential to cross the placenta and it is unknown whether they pass into breast milk.

After delivery, LMWH or warfarin should be given for at least 6 weeks. No studies have addressed the optimal duration of

anticoagulation for pregnancy-related venous thrombosis. In total, treatment should be given for 3 to 6 months from the time of diagnosis. Warfarin and LMWH can be safely administered in nursing mothers, with no detectable anticoagulant effect in breast milk.

Women with a past history of unprovoked or recurrent venous thromboembolism, those homozygous for factor V_{Leiden} or the FII G20210A mutation, and those with deficiencies of antithrombin, protein C, or protein S and a family history of venous thrombosis, should receive antepartum prophylaxis with LMWH. Postpartum, LMWH or warfarin should be given for 6 weeks. Postpartum treatment with LMWH or warfarin for 6 weeks is likely adequate for women with a history of venous thrombosis secondary to a well-defined risk factor. Prophylaxis during pregnancy, as well as postpartum, should be considered for women who developed venous thromboembolism after taking oral contraceptives particularly if they have underlying thrombophilia. Women with thrombophilic defects, but no prior history of venous thromboembolism, or family history of the same likely do not require antepartum prophylaxis or postpartum treatment, but definitive data are lacking. A summary of these recommendations is provided in Table 140.6.³⁰

Thrombophilia and Fetal Loss

About 30% of women have at least one fetal loss, and approximately 5% of women of reproductive age experience recurrent fetal loss. Women with hereditary or acquired thrombophilia have a two- to five-fold increased risk for fetal loss. Screening for APS is recommended if there is a history of three or more miscarriages before 10 weeks' gestation. Although once-daily LMWH in prophylactic doses, with or without aspirin, is often prescribed for women with recurrent fetal loss on the background of an underlying thrombophilic defect, such therapy is of no benefit and it is costly and potentially harmful.

CONCLUSIONS AND FUTURE DIRECTIONS

Inherited or acquired hypercoagulable states can now be identified in up to 50% of patients with venous thromboembolism thanks to an increased understanding of the regulation of coagulation. The role of these disorders in the pathogenesis of arterial thrombosis is less clear, and further research is necessary to identify those individuals vulnerable to arterial thrombosis after plaque rupture. Despite an improved ability to diagnose hypercoagulable states, the impact of this information on clinical decisions remains limited. Common congenital hypercoagulable states increase the risk for a first thrombotic episode but appear to have little impact on the risk for recurrence. Identification of biomarkers for patients at risk for recurrent thrombosis and elucidating new hypercoagulable states are goals for the future.

THE ANTIPHOSPHOLIPID SYNDROME

Jacob H. Rand and Lucia R. Wolgast

The antiphospholipid (aPL) syndrome (APS) is an autoimmune thrombophilic condition that is defined by a combination of clinical and laboratory criteria. This chapter reviews the current understanding of aPL-mediated pathogenic mechanisms, diagnostic tests for the condition, its clinical manifestations, and current treatment approaches.

DEFINITION OF ANTIPHOSPHOLIPID SYNDROME

APS is an autoimmune thrombophilic condition in which patients have circulating antibodies against plasma proteins that bind to phospholipids. The precise mechanism(s) by which these autoantibodies cause disease has (have) not yet been precisely established. Investigational diagnostic criteria (referred to as the Sydney Criteria), detailed in [Table 141.1](#), have been formulated to provide consistency for clinical trials. These require that patients have documented evidence of vascular thrombosis and/or obstetric complications attributable to placental vascular insufficiency; the latter include otherwise unexplained recurrent miscarriages, intrauterine growth restriction, intrauterine fetal demise, preeclampsia/toxemia, placental abruption, and preterm labor. The laboratory criteria require persistent abnormality (defined as at least two abnormal measurements at least 12 weeks apart) of one or more of the aPL assays, which include elevated anticardiolipin (aCL) immunoglobulin (Ig) G or IgM, antibodies, anti- β_2 -glycoprotein I (anti- β_2 GPI) IgG or IgM antibodies or an abnormal lupus anticoagulant (LA).

Because these criteria were intended to provide a uniformly rigorous definition of APS for standardizing clinical research and not for the diagnosis of APS in “real world” clinical practice settings, some patients may be diagnosed clinically with presumptive APS without meeting the strict investigational criteria. For example, some patients with APS have positive results on “noncriteria” clinical laboratory tests (described later) that have not been included by consensus panels as diagnostic criteria for the disorder. Also, some patients present with manifestations that have been associated with aPL antibodies that were not included in the investigational criteria. These “noncriteria manifestations” include thrombocytopenia, livedo reticularis, skin ulcers, nephropathy, migraine, cognitive defects, diffuse alveolar hemorrhage, and valvular heart disease (Libman-Sachs endocarditis).

At the present time, APS may be divided into the following subcategories: (1) Primary APS is the “stand alone” disorder, in the absence of systemic lupus erythematosus (SLE), (2) secondary APS occurs in the presence of SLE, (3) catastrophic APS (CAPS), manifests as disseminated thrombosis in large and small vessels with resulting multiorgan failure ([Table 141.2](#)), and (4) SNAPS includes patients whose diagnostic tests are entirely negative but who, on clinical grounds, are still suspected to have the disorder.

ANTIGENIC SPECIFICITIES OF ANTIPHOSPHOLIPID ANTIBODIES

β_2 -Glycoprotein I

β_2 -Glycoprotein I (β_2 GPI), a 50-kDa glycoprotein member of the complement control protein (CCP) superfamily, is a major antigenic target for aPL antibodies. The protein consists of five homologous

CCP domains, each consisting of about 60 amino acids, with a fifth domain that includes a phospholipid binding site near the carboxy-terminus of the protein. Binding of β_2 GPI to membranes that express anionic phospholipids occurs via the affinity of cationic residues near the carboxy-terminus for anionic polar heads of phospholipids that adjoin a hydrophobic loop that inserts into the lipid bilayer. Although patients with APS have been described to have antibodies that recognize all of the five domains of β_2 GPI, IgG antibodies against an epitope on domain I comprising Gly40-Arg43 has been particularly correlated with an increased risk for thrombosis; this domain I epitope is cryptic in the circulating protein and becomes exposed after β_2 GPI binds to phospholipid bilayers. The specific conformation of the unbound form of β_2 GPI is not entirely clear; transmission electron microscopy of negatively stained β_2 GPI molecules indicates that the unbound protein has a circular conformation that was attributed to the affinity of its carboxy-terminus domain (domain V) for the protein's amino-terminus domain, whereas β_2 GPI bound to phospholipid has a “J-shaped” conformation with the binding site for phospholipid near the carboxy-terminus of the J. On the other hand, small angle x-ray scattering studies indicate an “S” shape configuration for the free form ([Fig. 141.1](#)).

Other Antigenic Targets of Antiphospholipid Antibodies

Besides β_2 GPI, prothrombin (factor II), factor V, protein C, protein S, annexin A2, annexin A5, high- and low-molecular-weight kininogen, heparin, factor VII/VIIa, plasmin, vimentin, and other proteins have been identified as targets for autoantibodies in APS patients. Antibodies have also been found to bind to sulfatides, acidic glycosphingolipids that can interact with sulfatide-binding proteins such as von Willebrand factor, thrombospondin, and P-selectin.

PATHOGENIC EFFECTS OF ANTIPHOSPHOLIPID ANTIBODIES

As described later, numerous mechanisms have been proposed to explain the thrombotic manifestations of APS ([Table 141.3](#)). Although all of these are based on in vitro findings or on animal models, their in vivo significance in the human disease process remain to be established.

Antiphospholipid-Mediated Promotion of Tissue Factor Expression

aPL antibodies can bind to, injure, and/or activate cultured vascular endothelial cells. Antibody binding to β_2 GPI on the endothelial surface may trigger signaling cascades that promote the expression of tissue factor and adhesion molecules. There is evidence that annexin A2, which forms tetramers with S100 and is an endothelial surface receptor for tissue plasminogen activator and plasminogen, serves as a receptor for β_2 GPI on vascular endothelium. Annexin A2 and the signaling coreceptors, Toll-like receptor-4 (TLR4) and Toll-like receptor-2 (TLR2) have been implicated as triggers of the signaling cascade. Downstream signaling appears to involve TRAF6 (tumor necrosis factor receptor-associated factor 6) and MyD88 (myeloid differentiation factor 88). Tissue factor expression is mediated by p38

TABLE 141.1 Sydney Investigational Criteria for the Diagnosis of the Antiphospholipid Syndrome^a**Clinical**

- Vascular thrombosis (one or more episodes of arterial, venous, or small-vessel thrombosis). For histopathologic diagnosis, there should be no evidence of inflammation in the vessel wall.
- Pregnancy morbidities attributable to placental insufficiency, including: (a) three or more otherwise unexplained recurrent spontaneous miscarriages, before 10 weeks of gestation, (b) one or more fetal losses after the 10th week of gestation, (c) stillbirth, and (d) episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios that are otherwise unexplained.

Laboratory

- Medium- or high-titer aCL or anti- β_2 GPI IgG and/or IgM antibody present on two or more occasions, at least 12 weeks apart, measured by standard ELISA.
- Lupus anticoagulant in plasma, on two or more occasions, at least 12 weeks apart, detected according to the guidelines of the ISTH SSC Subcommittee on Lupus Anticoagulants and Phospholipid-Dependent Antibodies.

"Definite APS" is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.

aCL, Anticardiolipin; aPL, antiphospholipid; β_2 GPI, β_2 -glycoprotein I; ELISA, enzyme-linked immunosorbent assay; Ig, immunoglobulin.

^aModified from Miyakis et al: International consensus statement on an update of the classification criteria for definite antiphospholipid syndrome (APS). *Thromb Haemostasis* 4:295, 2006.

mitogen-activated protein kinase (MAPK). This mechanism is supported by the finding that a mutation in murine TLR-4 that disrupts LPS binding, attenuated the prothrombotic state in mice injected with aPL antibodies.

Apolipoprotein E receptor 2' (apoER2'), a member of the low-density lipoprotein (LDL)-receptor family and a multiligand receptor with a wide tissue distribution may also be a target for anti- β_2 GPI/ β_2 GPI complexes to trigger tissue factor and cell adhesion molecule expression on the endothelial surface. ApoER2' is expressed on endothelial cells, platelets, and monocytes where it has been proposed to mediate the pathogenic effects of the antibodies. Evidence from apoER2^{-/-} knockout mice supports such a role and identifies this interaction as a potential target for novel nonanticoagulant therapy.

There is evidence from a mouse model that aPL-mediated promotion of tissue factor expression can induce trophoblast injury and fetal death. In addition, tissue factor contributed to C5a-induced oxidative burst in neutrophils leading to trophoblast and fetal injury in APS. A monoclonal antibody against factor B, that disrupted the alternative pathway of complement activation, protected against aPL antibody-induced fetal loss in mice.

Activation of Platelets and Monocytes by Antiphospholipid Antibodies

Recent evidence from a mouse model indicated that aPL-induced thrombosis is a consequence of platelet activation that then promotes endothelial activation and fibrin formation. aPL antibodies can also induce platelet aggregation, an effect that might be promoted via signaling through apoER2; the β_2 GPI binding site for apoER2 on platelets was localized to its domain V. β_2 GPI also has a dampening effect on platelet adhesion by interfering with the platelet-von Willebrand factor interaction, and consequently aPL antibodies, by interfering with this dampening, can increase platelet adhesion in flow systems.

TABLE 141.2 Proposed Criteria for the Classification of Catastrophic Antiphospholipid Syndrome*

1. Evidence of involvement of three or more organs, systems and/or tissues^a
2. Development of manifestations simultaneously or in less than a week
3. Confirmation by histopathology of small vessel occlusion in at least one organ or tissue^b
4. Laboratory confirmation of the presence of antiphospholipid antibodies (lupus anticoagulant and/or anticardiolipin antibodies)^c

Definite catastrophic APS

- All four criteria

Probable catastrophic APS

- All four criteria, except for only two organs, systems and/or tissues involvement
- All four criteria, except for the absence of laboratory confirmation at least 6 weeks apart because of the early death of a patient never previously tested for aPL prior to the catastrophic APS event
- Criteria 1, 2, and 4
- Criteria 1, 3, and 4 and the development of a third event in more than a week but less than a month, despite anticoagulation

^aUsually, clinical evidence of vessel occlusions, confirmed by imaging techniques when appropriate. Renal involvement is defined by a 50% rise in serum creatinine, severe systemic hypertension ($\geq 180/100$ mmHg) and/or proteinuria (≥ 500 mg/24 h).

^bFor histopathologic confirmation, significant evidence of thrombosis must be present, although, in contrast with Sydney criteria, vasculitis may coexist occasionally.

^cIf the patient had not been previously diagnosed as having an APS, the laboratory confirmation requires that the presence of antiphospholipid antibodies must be detected on two or more occasions at least 6 weeks apart (not necessarily at the time of the event), according to the proposed preliminary criteria for the classification of definite APS.

aPL, Antiphospholipid; APS, antiphospholipid syndrome.

*Modified from Asherson RA, Cervera R, de Groot PG et al. Catastrophic antiphospholipid syndrome: international consensus statement on classification criteria and treatment guidelines. *Lupus* 12:530, 2003.

aPL antibodies increased the expression of tissue factor and other cytokines in monocytes, a process that occurred through activation of the p38MAPK and MEK-1/ERK pathways. Enhanced monocyte expression of tissue factor resulted in increased expression of vascular endothelial growth factor (VEGF) and Flt-1 tyrosine kinase receptor. aPL antibodies may also promote mitochondrial dysfunction and oxidative stress in monocytes resulting in a proinflammatory state.

Inhibition of Endogenous Anticoagulant and Fibrinolytic Mechanisms

aPL antibodies can accelerate coagulation reactions on endothelial cells and trophoblasts by disrupting an antithrombotic shield composed of annexin A5, a potent anticoagulant protein with high affinity for phospholipid membranes. The protein forms two-dimensional crystalline arrays over the phospholipid bilayers (Fig. 141.2) that shield the anionic phospholipids on cell membranes from availability for phospholipid-dependent coagulation enzyme reactions. Annexin A5 is highly expressed by endothelial cells and on the apical membranes of placental syncytiotrophoblasts, the location where maternal blood interfaces with fetal cells. Pregnant mice treated with anti-annexin A5 antibodies develop placental necrosis, fibrosis, and pregnancy loss and pregnant annexin A5-null mice develop placental infarctions and have reduced litter sizes.

Fig. 141.1 MODELS FOR PROPOSED β_2 -GLYCOPROTEIN I STRUCTURES. By x-ray crystallography, the structure of β_2 GPI showed a J shape. However, small angle x-ray scattering (SAXS) of β_2 GPI in solution revealed an S-shape conformation, with a carbohydrate chain on top of the interface between domains I and II. In contrast to the SAXS structure, transmission electron microscopy (TEM) of negatively stained unbound β_2 GPI mounted on grids showed a circular conformation, but a J shape for β_2 GPI bound to phospholipid. The arginine 39-arginine 43 epitope on domain I that is recognized by thrombogenic antiphospholipid antibodies is cryptic in the free- β_2 GPI proposed conformations. This epitope then becomes exposed and available for antibody recognition after the protein is bound to phospholipid. (Reprinted from de Laat, B, de Groot, PG: *Curr Rheumatol Rep* 2011 13:70, 2011.)

The reduction in annexin A5 on cell membranes is a consequence of its competitive displacement by aPL IgG- β_2 GPI immune complexes (see Fig. 141.2). As described later, a mechanistic assay has been developed that measures the interference with annexin A5 anticoagulant activity.

aPL antibodies can affect fibrinolytic mechanisms in several ways. APS patients have increased levels of antibodies against annexin A2, an endothelial surface receptor for tissue plasminogen activator and plasminogen; in distinction to the effect on cell signaling described earlier, aPL antibodies may also interfere with binding of plasminogen and t-PA and thereby reduce plasmin formation and fibrinolysis. Fibrinolysis may also be impaired by autoantibodies directed against the catalytic site of plasmin or t-PA, by increased levels of plasminogen activator inhibitor-1, and by inhibition of autoactivation of factor XII. Also, because β_2 GPI is a cofactor for t-PA-mediated activation of plasminogen, aPL antibodies against β_2 GPI can interfere with t-PA activity and downregulate plasmin formation.

aPL antibodies have also been reported to inhibit several steps in the protein C pathway. These include: (a) reducing the activation of protein C by the thrombomodulin-thrombin complex; (b) inhibiting

the assembly of the protein C complex; (c) inhibiting the activity of protein C directly or via its cofactor protein S, (d) binding to factors Va and VIIIa in a manner that protects them from proteolysis by APC, and (e) reducing levels of both protein C and protein S. Some aPL antibodies can directly recognize protein C or S. APC resistance has been described in APS plasmas and has been correlated with anti- β_2 GPI domain I antibodies.

Antiphospholipid-Mediated Activation of Complement

Complement activation has also been proposed to play a significant role in the APS disease process. Evidence from a mouse model has indicated that blockade of complement activation using a C3 convertase inhibitor or genetic deletion of C3 protected against pregnancy complications induced by aPL antibodies. Complement activation in APS appears to involve aPL antibody-stimulated direct injury to endothelial cells and monocytes, promotion of cell lysis and inflammation, modulation of downstream signaling via protease activated receptor-2 (PAR-2), and enhanced expression of tissue factor by

**TABLE
141.3****Proposed Pathogenic Mechanisms of Antiphospholipid Syndrome**

- I. aPL-mediated promotion of tissue factor expression
 - A. Direct injury and subsequent anti- β_2 GPI binding on endothelial cells
 - B. Signaling via annexin A2/TLR4/apoER2 inducing proadhesive prothrombotic phenotype
 - C. Induction of adhesion molecules and tissue factor on endothelial cells and cytokine release
- II. Activation of platelets and monocytes by aPL antibodies
 - A. Activation of platelets: via apoER2', GPIb α , and/or β_2 GPI-platelet factor 4 interaction
 - B. Interference of β_2 GPI in regulating vWF-mediated platelet adhesion
 - C. Activation of monocytes: results in increased tissue factor, VEGF, cytokine expression
 - D. Activation of monocytes causes mitochondrial dysfunction and oxidative stress
- III. Inhibition of endogenous anticoagulant and fibrinolytic mechanisms
 - A. Disruption of the annexin A5 anticoagulant shield
 - B. Interference with fibrinolysis via annexin A2, β_2 GPI cofactor activity, autoactivation of XIIa, direct inhibition of plasmin and increase of PAI-1
 - C. Inhibition of the protein C pathway: decreased activation of protein C, barrier of APC proteolysis of factor Va and VIIIa, prevention of protein C and EPCR binding
 - D. Interference with tissue factor pathway inhibitor
- IV. aPL-mediated activation of complement
 - A. Antibodies against β_2 GPI-HLA-DR7 complexes on cell surfaces trigger complement-mediated cytotoxicity
- V. Direct activation of trophoblasts and endometrial cells by aPL antibodies
 - A. Abnormal trophoblast proliferation, migration and invasiveness, increased trophoblast apoptosis, and reduced secretion of HCG and adhesion molecules
 - B. Disruption in the differentiation of decidual endometrial cells
 - C. Disruption of maternal spiral artery transformation and maturation
- VI. Other mechanisms
 - A. mTORC pathway-mediated vasculopathy
 - B. Release in procoagulant microparticles by endothelial cells and platelets

Atomic force microscopy picture showing the effect of antiphospholipid monoclonal antibody IS3 on a preformed annexin A5 crystal. The figure demonstrates the smooth lipid bilayer covered by the annexin A5 crystals, disrupted by antibody- β_2 GPI complexes (*white rims*) and exposing anionic phospholipids (*black holes*) to coagulation factors and accelerated coagulation. (Adapted from Rand JH, Wu XX, Quinn AS, et al: Human monoclonal antiphospholipid antibodies disrupt the annexin A5 anticoagulant crystal shield on phospholipid bilayers: evidence from atomic force microscopy and functional assay. *Am J Pathol* 163:1193, 2003.)

myeloid cells. In addition, anti- β_2 GPI antibodies may interfere with the role of β_2 GPI as a regulator of the complement cascade.

Complexes of β_2 GPI and human leukocyte antigen (HLA)-DR7 have been found in uterine decidual tissues from placentas of patients with APS, but not on normal placentas. aPL antibodies that recognize these β_2 GPI–HLA-DR7 complexes on cell surfaces can trigger complement-mediated cytotoxicity. This mechanism may play a role in the pregnancy complications of APS.

Direct Activation of Trophoblasts and Endometrial Cells by Antiphospholipid Antibodies

In addition to the prothrombotic effects of aPL antibodies, aPL antibodies may have direct effects on trophoblasts that induce abnormal trophoblast proliferation, migration and invasiveness, increased trophoblast apoptosis, and reduced secretion of HCG and adhesion molecules. Activation of MYD88 by TLR4 has been linked to increased levels of proinflammatory molecules (IL-8, IL-1 β , monocyte chemoattractant proteins) that influence trophoblast survival. Downregulation of STAT3 phosphorylation decreases IL-6 expression and reduced trophoblast migration. aPL antibodies have been implicated in the disruption of maternal spiral artery transformation and maturation and differentiation of decidual endometrial cells through activation of signaling pathways such as nuclear factor kappa-B (NF κ B). Defective placentation may result in impaired blastocyte implantation.

Other Mechanisms

Autoantibodies against tissue factor pathway inhibitor have also been reported in APS patients; these antibodies may prevent the regulation of tissue factor-mediated activation of factor IX and factor X. Some aPL antibodies cross-react with heparin and heparinoid molecules, which are highly polyanionic, and inhibit their capacity to catalyze antithrombin. aPL antibodies show cross-reactivity with oxidized LDL and antibodies against the β_2 GPI-oxidized LDL complex may promote atherosclerosis by attenuating oxidized LDL clearance. In addition to promoting thrombosis, aPL antibodies may contribute to other vascular lesions by stimulating the mammalian target of rapamycin complex (mTORC) pathway. Endothelial cells and platelets activated by aPL antibodies release microparticles containing procoagulant proteins and nucleic acids.

Genetic, Genomic, and Proteomic Studies in Antiphospholipid Syndrome

Although familial APS is rare, genetic factors appear to play a role in the development of aPL antibodies. One study of 7 families that included 30 individuals who met consensus criteria for APS concluded that the inheritance pattern of aPL antibodies appeared to be autosomal dominant; however, no specific linkages could be identified. A study done using peripheral blood mononuclear cells from aPL antibody-positive patients found a gene-expression pattern that appeared to correlate with a predisposition towards developing thrombosis. Some of the genes identified encoded proteins that are known to be involved in thrombosis, such as apolipoprotein E (apoE), factor X, and thromboxane. Other genes did not have a clear connection with the disease process; these included hypoxia inducible factor-1 α (HIF-1 α), zinc finger proteins, matrix metalloproteinase 19 (MMP19), interleukin-22 (IL-22) receptor, and hematopoietic progenitor cell antigen (CD34) precursor.

Proteomic studies may also provide insights on the proteins that might predict thrombotic risk in APS patients. Proteins reported to be differentially expressed in monocytes of APS patients with a history of thrombosis included annexin A1, annexin A2, ubiquitin Nedd8, Rho A protein, protein disulfide isomerase, and Hsp60.

ANTIPHOSPHOLIPID ASSAYS

History

The development of the current consensus-based clinical tests for APS stemmed from anomalous observations involving syphilis testing and coagulation assays. The immunoassays were developed in the early 1980s in efforts to quantify testing for syphilis by measuring the binding of antibodies in the test serum to cardiolipin (diphosphatidyl glycerol), the key antigen in the serologic test for syphilis. This assay turned out to be ineffective for detecting syphilis, but did quantify the biologic false-positive serologic test for syphilis (BFP-STS), a laboratory phenomenon that was associated with autoimmunity. Subsequent clinical studies revealed that increased levels of aCL antibodies detected with these assays were associated with thrombosis, spontaneous abortion, and neurologic disease. This constellation of clinical and laboratory abnormalities was recognized as a new disorder, named the “antiphospholipid syndrome.” It was later discovered that, in contrast to patients who were infected with syphilis, antibodies from patients with this syndrome did not recognize cardiolipin directly, but rather a “cofactor” serum protein, β_2 GPI, that binds cardiolipin in the assay. It was subsequently determined that, although β_2 GPI is the primary target antigen, aPL antibodies also may recognize several other phospholipid-binding proteins.

In the early 1950s the LA assays were derived from Conley's and Hartmann's report of two patients with SLE with prolonged activated partial thromboplastin time (aPTT) values. That led to the recognition that these were a result of anticoagulants that were associated with a BFP-STS and recurrent pregnancy loss and also with thrombosis, and ultimately to the recognition that the anticoagulant was a result of antibody-mediated inhibition of phospholipid-dependent coagulation reactions and was part of the APS. The term *lupus anticoagulant* was erroneously coined to describe these antibodies because initial studies were done with patients who had SLE; the terminology has nevertheless persisted. The current aPL tests are inherently limited because they do not measure a known disease mechanism. However, as detailed later, these assays are useful as surrogate reporters for thrombotic risk.

Lupus Anticoagulant Tests

The LA tests are performed in a variety of configurations, all of which aim to detect the inhibition of phospholipid-dependent blood coagulation reactions. These include modifications of the aPTT with LA-sensitive and LA-insensitive reagents, the kaolin clotting time (KCT), the dilute Russell viper venom time (dRVVT), the tissue thromboplastin inhibition time (TTIT), the hexagonal phase array test, and the platelet neutralization procedure. The results of LA tests can vary among laboratories; although most laboratories agree on identification of plasmas containing strongly positive LA activity, they frequently disagree about samples that are known to have weak LA activity (these are missed in approximately half the cases) and laboratories often misdiagnose factor-deficient LA-negative plasmas as being LA positive.

Despite these limitations, the presence of LA activity is more predictive and more specific for the occurrence of thrombosis or pregnancy loss than the aCL ELISA assays, in both patients with or without lupus erythematosus. For example, a meta-analysis of the risks for venous thromboembolism in individuals with aPL antibodies without underlying autoimmune disease or previous thrombosis for a 15 year period reported mean ORs of 11 for LA, 3.2 for high-titer aCL antibodies and 1.6 for elevated aCL antibodies. In a systematic literature review, 12 of 12 studies showed significant associations between LA and thrombosis, with ORs ranging from 5.7 to 9.4. LA increased the risks of arterial and venous events to the same extent. In contrast, only 15 of 28 studies showed significant associations between aCL antibodies and thrombosis. In the Antiphospholipid Antibodies Stroke Study (APASS), positivity for both LA and aCL

antibodies, but not for aCL antibodies alone, predicted a higher risk of recurrent thromboocclusive events in patients with first ischemic stroke. In the Risk of Arterial Thrombosis In relation to Oral contraceptives (RATIO) study, the presence of LA was found to be a major risk factor for arterial thrombotic events in young women with an OR of 5.3 for myocardial infarction and 43.1 for ischemic stroke. In LA-positive women on oral contraceptives, the OR for myocardial infarction increased to 21.6 and the OR for ischemic stroke increased to 201.0. For LA-positive women who were also cigarette smokers, the ORs for myocardial infarction and ischemic stroke increased to 33.7 and 87.0, respectively. Finally, the PROMISSE study demonstrated that of the available aPL markers, a positive LA was the single strongest predictor of adverse pregnancy outcomes in patients with APS.

Patient Selection

LA testing should not be routinely performed in patients without a history of thrombosis and/or pregnancy complications that may be attributable to APS or a history of SLE. The Antiphospholipid Antibodies Subcommittee of the International Society of Thrombosis and Hemostasis (ISTH) has prioritized the appropriateness of testing for LA into low, moderate, and high groups. Patients in the low-appropriateness group include elderly patients with venous or arterial thromboembolism. The moderate group includes asymptomatic patients who are incidentally found to have a prolonged aPTT (often during routine testing) and young patients with recurrent spontaneous early pregnancy loss or provoked VTE. Patients in the high-appropriateness group include those with unprovoked VTE, arterial thrombosis in young patients (<50 years of age), thrombosis in unusual sites, late pregnancy loss, and thrombosis or pregnancy morbidity in patients with autoimmune diseases (SLE, rheumatoid arthritis, autoimmune thrombocytopenia, autoimmune hemolytic anemia). In our opinion these same guidelines should also be applied to aPL testing.

Choosing the Appropriate Lupus Anticoagulant Assays

The Subcommittee on Antiphospholipid Antibodies of ISTH has proposed specific criteria for standardizing the diagnosis of LA. They recommend performing two different LA tests that are based on different assay principles. The dRVVT is widely used in clinical laboratories and is believed to be specific for detecting LA in patients at high risk for thrombosis. aPTT tests performed with silica as an activator and low phospholipid content were recommended as the second test of choice because of their sensitivity for LA.

Activated Partial Thromboplastin Time

A prolonged aPTT in an otherwise healthy individual without a history of bleeding is most frequently caused by an LA. Commercial aPTT reagents vary in their sensitivities to LA, so it is important to know the characteristics of the particular reagent that is being utilized. The LA needs to be differentiated from inhibitors of specific coagulation factors and from anticoagulant medications such as heparin. In addition to specific assays to evaluate these possibilities, the clinician can check whether the aPTT normalizes when an LA-insensitive aPTT reagent is used or when the assay is performed using frozen washed platelets as the source of phospholipid, a procedure referred to as the *platelet neutralization procedure*. Mixing and incubating the test plasma with normal plasma may be helpful in differentiating LAs from coagulation factor inhibitors. aPTTs performed on mixtures of normal plasma and plasma containing a factor VIII inhibitor usually require incubation for 1 to 2 hours at 37°C to show prolongation, whereas LA-containing plasmas typically prolong the aPTT immediately without requiring incubation. The clinician should be aware that in rare patients both types of anticoagulants, i.e., LA and specific

coagulation factor inhibitors, may coexist and yield a confusing laboratory picture. LAs may also cause artifactual decreases in contact activation pathway coagulation factor levels because those assays are based on the aPTT; these patients are sometimes misdiagnosed as having multiple coagulation factor deficiencies. This problem can be handled by repeating the coagulation factor assays after dilution of the plasma or by using an aPTT reagent that is insensitive to LA for the coagulation factor assays.

Dilute Russell Viper Venom Time

The dRVVT is considered to be one of the most sensitive LA tests. The assay uses Russell viper venom (RVV) in a system containing limiting quantities of diluted rabbit brain phospholipid. RVV directly activates factor X, leading to clotting. aPL antibodies can prolong the dRVVT by interfering with assembly of the prothrombinase complex; this prolongation is reversed by adding excess phospholipid to the reaction (sometimes referred to as a “confirmatory test”). To ensure that prolongation of the clotting time is not a result of a factor deficiency, the procedure includes mixing of patient plasma with control plasma. Anticoagulant therapy with heparin, warfarin, or direct thrombin inhibitors can yield falsely abnormal test results.

Antiphospholipid Immunoassays

Antiphospholipid Antibody and Cofactor Assays

The quantities of aCL IgG and aCL IgM bound are expressed in GPL and MPL units, respectively; one unit representing the cardiolipin binding activity of 1 µg/mL of affinity-purified aPL antibodies from reference sera. Binding reflects both the titer and affinity/avidity of the antibody. The levels of aCL antibodies detected in reference sera can vary among laboratories, particularly when the tests are done with different commercial ELISA kits.

It is important for the clinician to recognize that the majority of patients with elevated aCL antibodies detected on routine screening do not have APS. The prevalence of positive immunoassays in the asymptomatic “normal” population ranges from 3% to nearly 20%. In a prospective study of 2132 consecutive Spanish patients with VTE, 4.1% had elevated levels of aCL antibodies (i.e., about the same prevalence as in the asymptomatic healthy population). In one group of healthy young women, 18.2% had elevated levels of aCL antibodies and 12.8% were LA positive. Many individuals have elevated antibody levels in response to infections; these antibodies are not associated with thrombotic complications. Patients with syphilis, Lyme disease, and other infections may be misdiagnosed with APS based on elevated aCL antibody levels when concurrent stroke or arterial thrombosis is present.

High levels of aCL antibodies are associated with an increased risk of thrombosis. During a 10-year follow-up of patients with elevated levels of aCL antibodies, approximately 50% of those without clinical manifestations of APS at baseline went on to develop APS. The presence of elevated titers of aCL antibodies 6 months after an episode of VTE is a predictor of an increased risk of recurrence and of death. In a systematic review, 15 of 28 studies showed significant associations between aCL antibodies and thrombosis. In all cases, higher antibody titers were associated with an increased risk of thrombosis. Elevated levels of aCL antibodies, whether of high or low titer, were significantly associated with both myocardial infarction and ischemic stroke. Only high-titer aCL antibodies significantly increased the risk of deep vein thrombosis (DVT). With respect to pregnancy losses, a meta-analysis that reviewed 25 studies evaluating the impact of aPL antibodies on recurrent fetal loss showed a significant correlation with increased levels of aCL IgG, but the highest correlation was with LA.

Elevated levels of aCL antibodies of the IgG or IgM isotype are reported to be a significant risk factor for stroke. aPL antibodies are also reported to be an independent risk factor for stroke in young

women. In the APASS, 41% of patients who experienced an ischemic stroke within 30 days were aCL antibody-positive.

Anti- β_2 -Glycoprotein I Antibody Assay

β_2 GPI is the major protein cofactor recognized by aPL antibodies. ELISAs for anti- β_2 GPI antibodies are considered to be less sensitive but more specific for APS than aCL antibody assays. Although antibodies against β_2 GPI are usually found in conjunction with aCL and antiphosphatidylserine antibodies, some patients with APS only have antibodies against β_2 GPI. Despite the higher specificity (98%), β_2 GPI antibodies cannot be relied upon as a stand-alone test for APS because of its low sensitivity (40%–50%) and concurrent testing for both antibodies, along with LA is advised.

In a systematic literature review, 34 of 60 studies, of which none was prospective, showed significant associations between anti- β_2 GPI antibodies and thrombosis. Of 10 studies that included multivariate analysis, only 2 confirmed that IgG anti- β_2 GPI antibodies were independent risk factors for venous thrombosis. Anti- β_2 GPI antibodies were more often associated with venous than arterial events.

Multipositivity for Antiphospholipid Tests and Clinical Risk

Strong positivity for more than one of the aPL antibody criteria assays has been correlated with increased risk for developing clinical events in several retrospective studies and in one prospective study. One study showed that multipositivity for aPL antibodies, but not single positivity, was associated with antenatal and postnatal DVT. Another study of pregnant women with APS reported that patients with triple aPL antibody positivity and/or previous thromboembolism appeared to have a higher probability of poor neonatal outcome than patients with double or single aPL antibody positivity and no thrombosis history. A retrospective analysis of 162 APS patients who were triple-positive for LA, aCL, and anti- β_2 GPI antibodies reported a higher risk of recurrent thromboembolic events with a cumulative incidence of events of 44.2% after 10 years. This finding was confirmed in a recent prospective analysis of 104 triple positive patients without a prior history of thrombosis or pregnancy complications. When followed for a mean duration of 4.5 years, the cumulative incidence of a first thrombotic event was 37.1% (95% confidence interval (CI), 19.9%–54.3%). Male sex and the presence of other risk factors for venous thrombosis were associated with an increased risk of thrombosis in this cohort.

A risk scale has been proposed to aid in the diagnosis and management of patients with APS (Table 141.4). Both symptomatic and asymptomatic patients with triple-positive laboratory results (LA positive, aCL [IgG or IgM >40 GPL] and anti- β_2 GPI [IgG or IgM >99th percentile]) should be considered high-risk for future manifestations of APS, whereas patients who are double positive for LA, aCL (IgG or IgM >40 GPL) and/or anti- β_2 GPI (IgG or IgM >99th percentile) or single positive for LA should be considered at medium risk for APS. Finally, single positivity for aCL (IgG or IgM >40 GPL) or anti- β_2 GPI (IgG or IgM >99th percentile) should be considered low risk for APS, but treatment may be warranted if such patients develop thrombosis or pregnancy complications or have other high risk factors.

“Noncriteria” Antiphospholipid Assays

Occasionally clinicians may consider testing selected patients with one of the assays that are not included within the formal diagnostic criteria. An example of such a situation would be a patient with SLE or another autoimmune disorder who has clinical manifestations that suggest APS but who has negative assays for aCL and β_2 GPI IgG and IgM along with negative LA tests.

Immunoglobulin A Antibodies Against Cardiolipin and β_2 -Glycoprotein I

The clinical utility of testing aPL antibodies of IgA isotype remains controversial. The prevalence of true positivity to aCL IgA antibodies is very low; for example one study of 795 patients reported positive aCL IgA in only 2 patients, both of whom were also positive for IgG aCL. However, anti- β_2 GPI IgA antibodies were reported to be significantly associated with thrombosis. A recent retrospective case-control study of 56 patients with isolated anti- β_2 GPI IgA found that patients with this marker had significantly more thromboembolic events and higher polyclonal IgA levels than controls. Anti- β_2 GPI IgA was associated with an increased risk of thromboembolic events in patients with SLE.

aPL antibodies of IgA isotype (either aCL or anti- β_2 GPI) were not included in the international consensus statement on the criteria for APS classification. However, testing for the IgA isotype (particularly IgA anti- β_2 GPI) was recommended in cases where APS is suspected but the IgG and IgM tests are negative.

Annexin A5 Resistance Assay

The annexin A5 resistance (A5R) assay was designed to test for a specific pathogenic mechanism: the aPL antibody-mediated disruption of annexin A5 crystallization on phospholipid surfaces. As discussed earlier (section on Pathophysiologic Mechanisms), annexin A5 forms a crystal shield on endothelial surfaces which is disrupted by anti- β_2 GPI/ β_2 GPI complexes, thereby exposing more anionic phospholipids and accelerating coagulation reactions (see Fig. 141.2). The failure of annexin A5 to sufficiently prolong coagulation times because of interference by aPL antibodies can be detected through reduction of the annexin A5 anticoagulant ratio (A5R). A study of 96 patients demonstrated significantly lower A5R values in APS patients with a history of thrombosis than in aPL antibody-positive patients without a history of thrombosis, aPL antibody-negative patients with a thrombosis history and healthy controls. A recent study of 166 patients demonstrated a significantly lower A5R ratio in obstetric primary APS patients and thrombotic primary APS patients than in healthy controls (Fig. 141.3). Clinicians should be aware that this assay falls into the category of laboratory developed tests (LDTs) and is not commercially available in kit forms.

Anti-Domain I of β_2 -Glycoprotein I Assay

This immunoassay identifies IgG antibodies against a specific amino acid sequence, G40-R30, within domain I of β_2 GPI. A recent analysis of 198 samples from patients with a variety of autoimmune conditions revealed that the 52 patients with anti- β_2 GPI IgG antibodies could be divided into two groups: one whose antibodies recognized domain I alone and another whose antibodies reacted with all domains; only the former had positivity for LA and an increased OR for thrombosis. A recent multicenter study of 442 patients who tested positive for anti- β_2 GPI antibodies reported that specific anti-domain I IgG antibodies were more strongly associated with thrombosis and obstetric complications than anti- β_2 GPI antibodies detected using the standard anti- β_2 GPI antibody assays. Anti-domain I IgG antibodies were present in the plasma of 55% of patients, of which 83% had a history of thrombosis (OR, 3.5) and 57% had pregnancy complications (OR, 2.4).

Antiprothrombin Antibody Assay

Prothrombin is considered the second major cofactor for aPL antibodies after β_2 GPI. In a systematic literature review, 17 of 46 studies showed significant associations between antiprothrombin antibodies and thrombosis. Of the eight studies that included multivariate analyses, 2 confirmed that antiprothrombin antibodies were

TABLE 141.4**Laboratory Interpretation in Antiphospholipid Syndrome Diagnosis and Treatment***

Risk	Laboratory Result ^a	Clinical Manifestation	Treatment
High risk OR>9	Triple positive for LA, aCL (IgG or IgM >40 GPL) and anti-β ₂ GPI (IgG or IgM >99th percentile)	Venous thromboembolism Arterial thromboembolism	Long-term vitamin K antagonist, INR 2.0–3.0 Stroke: Long-term vitamin K antagonist, INR 2.0–3.0 plus aspirin 100 mg per day Myocardial infarction: Long-term vitamin K antagonist, INR 2.0–3.0 plus aspirin 100 mg per day or Long-term vitamin K antagonist, INR 3.0–4.0 Myocardial infarction with percutaneous coronary interventions and stent placement: Long-term vitamin K antagonist, INR 2.0–3.0, aspirin 100 mg per day, and clopidogrel 75 mg per day
		Pregnant women with history of pregnancy complications or thrombotic events	Unfractionated heparin plus low-dose aspirin
		Asymptomatic	Consider anticoagulant prophylaxis for high risk situations, e.g., immobilization, surgery, air travel Consider long-term vitamin K antagonist recommended to prevent thromboembolic events Consider low-dose aspirin and possible unfractionated heparin for pregnant patients
Medium risk OR 5–9	Double positive for LA, aCL (IgG or IgM >40 GPL) or anti-β ₂ GPI (IgG or IgM >99th percentile) or Single positive for LA	Venous thromboembolism Arterial thromboembolism Pregnant women with history of pregnancy complications Asymptomatic	Long-term vitamin K antagonist, INR 2.0–3.0 Long-term vitamin K antagonist, INR 2.0–3.0 plus aspirin 100 mg per day Unfractionated heparin plus low-dose aspirin No treatment, consider prophylaxis treatment in situations with increased risk: surgery or prolonged immobilization
Low risk OR 1–5	Single positive for aCL (IgG or IgM >40 GPL) or anti-β ₂ GPI (IgG or IgM >99th percentile) ^b	Venous thromboembolism Arterial thromboembolism Pregnant women with history of pregnancy complications Asymptomatic	Long-term vitamin K antagonist, INR 2.0–3.0 Long-term vitamin K antagonist, INR 2.0–3.0 Early miscarriage (does not meet clinical criteria for obstetric APS): consider low-dose aspirin Late miscarriage: unfractionated heparin plus low-dose aspirin No treatment; however, consider prophylaxis treatment in situations with increased risk: surgery or prolonged immobilization

^aLaboratory tests should be deferred until at least 12 weeks after the clinical event to avoid interferences of the acute phase of the disease. Earlier testing may yield false positive results.

^bMore information from clinical studies on homogeneous cohort of patients with single positivity is needed.

aCL, Anticardiolipin; β₂GPI, β₂-glycoprotein I; Ig, immunoglobulin; INR, international normalized ratio; LA, lupus anticoagulant; OR, odds ratio.

*Adapted from Sciascia S, Cosseddu D, Montaruli B et al: Risk scale for the diagnosis of antiphospholipid syndrome. *Ann Rheum Dis* 70:1517–1518, 2011; Pengo V, Banzato A, Bison E, et al: Antiphospholipid syndrome: critical analysis of the diagnostic path. *Lupus* 19:428, 2010; Pengo V, Ruffatti A, Legnani C et al: Incidence of a first thromboembolic event in asymptomatic carriers of high risk antiphospholipid antibody profile: a multicenter prospective study. *Blood* 118:4714, 2011; Tripodi A, de Groot PG, Pengo V: Antiphospholipid syndrome: laboratory detection, mechanisms of action and treatment. *J Intern Med* 270:110, 2011.

independent risk factors for thrombosis, and 3 other studies showed that antiprothrombin antibodies added to the risk borne by LA or aCL antibodies. However, 29 of the aforementioned studies did not demonstrate an association between antiprothrombin antibodies and risk of thrombosis.

Antiphosphatidylserine Antibody Assay

Cardiolipin is normally present in mitochondrial membranes and probably does not become exposed to plasma coagulation proteins in vivo. It was hypothesized that immunoassays for antibodies against phosphatidylserine may be more relevant because this anionic phospholipid is expressed on apoptotic cells, activated platelets, and syncytial cells. Although some studies have shown a relationship between antiphosphatidylserine antibodies and pregnancy complications, mainly recurrent miscarriages and reproductive failure, others have not. However, in arterial thrombosis, antiphosphatidylserine antibodies have been shown to correlate with APS better than aCL antibodies. Additionally, it was reported that antibodies against the phosphatidylserine–prothrombin complex (aPS/PT) were associated

with APS and LA. Additional studies are needed to confirm these findings.

CLINICAL MANIFESTATIONS OF THE ANTIPHOSPHOLIPID SYNDROME

The clinical manifestations of APS can be categorized into criteria manifestations and noncriteria manifestations. The criteria manifestations include thrombotic events, obstetric APS, and CAPS, and the noncriteria manifestations include other pathologic conditions that have been associated with aPL antibodies but have not been included in the definition of “definite APS” by the expert consensus groups.

Criteria Manifestations of Antiphospholipid Syndrome

Systemic Vascular Thrombosis

Thrombosis in APS may occur spontaneously or in the presence of predisposing factors such as estrogen therapy, oral contraceptives,

Fig. 141.3 REDUCTION OF ANNEXIN A5 ANTICOAGULANT RATIO ("ANNEXIN A5 RESISTANCE") IN PLASMAS FROM PATIENTS WITH ANTIPHOSPHOLIPID SYNDROME. The mean AnxA5 anticoagulant ratio for obstetric patients with primary antiphospholipid syndrome (APS) (group A) and thrombotic primary APS (group B) was significantly decreased compared with normal healthy controls (both $p < .0001$). The patients with isolated antiphospholipid (aPL) antibodies (group C) also showed significant reduction of AnxA5 anticoagulant ratios compared with the normal controls ($p = .007$). There were no significant differences in AnxA5 anticoagulant ratio between the groups A and B and between the groups A and C and between the groups B and C. The horizontal lines show the mean of each group; the dashed lines show the mean ± 2 SD of the 30 normal healthy controls. (From Hunt BJ, Wu, XX, de Laat B et al: Resistance to annexin A5 anticoagulant activity in women with histories for obstetric antiphospholipid syndrome. *Am J Obstet Gynecol* 205:485, 2011.)

pregnancy, the postpartum state, surgery, or trauma. Not surprisingly, occasional patients with APS-associated venous thrombosis, but generally not with arterial thrombosis, have concurrent hereditary thrombophilic conditions such as heterozygosity for the factor V Leiden mutation. Patients may present with venous and/or arterial thromboembolism in any vascular bed but the most common presentation is DVT of the lower extremities, which occurs in about half of the patients and can lead to pulmonary embolism; other sites of venous thrombosis include the thoracic veins (superior vena cava, subclavian or jugular veins), and abdominal or pelvic veins. In one study of patients with aPL antibodies and radiologic evidence of thrombosis, 59% had thrombi limited to the venous circulation, 28% had solely arterial thrombi, and 13% had both types of events.

The most significant risk factor for recurrent thromboembolism in APS is a history of a prior thromboembolic event. The risk of recurrence after a first episode of VTE in patients with aCL antibodies is about 30% at 4 years and is likely to be higher in those with a LA or with anti- β_2 GPI domain I antibodies.

Reproductive Manifestations

Routine aPL antibody screening of asymptomatic obstetrical patients is not warranted because of the high frequency of false positives with the current tests and the absence of any specified treatment for asymptomatic positives. Most studies have estimated the prevalence of aPL antibodies among general obstetric populations to be approximately 5% or less and most of these aPL antibody-positive patients are asymptomatic. Reports from cohorts of obstetric patients with recurrent fetal losses indicate that approximately 16%–38% have elevated aPL antibodies. Pregnant women with elevated aPL antibodies had significantly more obstetric complications, including preeclampsia, placental abruption, miscarriage, prematurity, intrauterine

fetal demise, intrauterine growth restriction, and oligohydramnios than aPL antibody-negative pregnant women.

Women with obstetric APS generally present with a history of recurrent (i.e., three or more) miscarriages. In approximately half of the patients, the pregnancy losses occur in the first trimester; other patients present with later losses, most in the second trimester, but some even later, including stillbirth. The specific pregnancy complications that define obstetric APS include: the absence of another explanation for the complications, three or more recurrent spontaneous first trimester miscarriages, or one midtrimester loss, stillbirth, episode of preeclampsia, preterm labor, placental abruption, intrauterine growth restriction, or oligohydramnios. Pregnant women with APS are also more prone to develop DVT during pregnancy or the puerperium. Rarely, pregnant patients can develop CAPS.

As with the thrombotic manifestations, a prior clinical history of previous pregnancy loss, complications, or thrombosis is a better predictor for future pregnancy loss than the degree of laboratory abnormality. Furthermore, recent studies have shown that positivity on more than one assay (so-called multipositivity) correlates with increased pregnancy complications. For example, one study showed that multipositivity, but not single positivity for aPL antibodies, was associated with antenatal and postnatal DVT. Another retrospective study of 128 pregnant women with APS found that patients with triple antiphospholipid positivity and/or previous thromboembolism appeared to have a higher likelihood of poor neonatal outcome than those with double or single antiphospholipid positivity and no thrombosis history.

The current consensus is that aPL antibodies do not contribute to early reproductive failure (i.e., infertility). Recently, the 14th International Congress on Antiphospholipid Antibodies Task Force also concluded that "there are no data to support the inclusion of infertility as a criterion for APS and investigation of APS in patients with infertility should not be done in routine clinical practice, being reserved only for research purposes." Although one group reported data suggesting that women with recurrent implantation failure were more likely to have positive assays for aPL antibodies compared with fertile controls, a review of 29 studies showed mixed results. Many of the studies had limitations, including problems with study design and statistical power.

Studies suggest a possible nonthrombogenic mechanism of impaired trophoblastic differentiation, proliferation, and migration that may lead to the recurrent implantation failure seen in infertile women.

Neurologic Manifestations

Ischemic stroke is frequent in APS. In a large European cohort, stroke or transient ischemic attack (TIA) was the initial manifestation of APS in 29.9% of adults with APS; in the same study, stroke or TIA was the most frequent recurrent event and contributed to a large proportion of deaths. A Latin American study of adults with APS reported that 18% presented with stroke or TIA. A multinational lupus cohort showed that aPL antibody-associated stroke accounted for 11.8% of deaths. In the European CAPS registry, cerebral manifestations occurred in 62% of patients and caused 13% of deaths.

Prospective analysis for the presence of aPL antibodies in stroke patients in the APASS demonstrated that elevated levels of anticardiolipin antibodies are associated with an increased risk for stroke but not with subsequent thromboembolic events. There was a trend for more recurrent thrombotic events in patients who tested positive for both aCL and LA than in those who tested negative for both (31.7% vs. 24.0%, $p = .07$). A subsequent study from the same group reported that elevated antibodies against β_2 GPI and LA, and not aCL or antiphosphatidylserine, were the most significant risk factors for stroke. It is important for clinicians to be aware that the presence of conventional risk factors for vascular disease adds to the baseline risk associated with the antibodies. In the RATIO study, women with LA positivity and other modifiable risk factors such as smoking or use of oral contraceptives had an increased risk of ischemic stroke. Lupus and APS patients with valvular heart lesions were also shown to be at

increased risk of cerebrovascular disease, and echocardiography should be considered for patients with APS and stroke because a high proportion of APS patients have cardiac valvular abnormalities (see later).

The diagnosis of APS should be considered when young patients present with a TIA or a stroke, particularly those without other risk factors. Rates of stroke were higher in younger patients with APS, with a rate of up to 32% in a multinational childhood registry versus 16%–21% in adult APS patients. Case-control and prospective studies have shown strong associations between aPL antibody or LA positivity and ischemic stroke in young adults with an OR of 43.1 for positive LA tests and ischemic strokes. Younger patients presenting with stroke tended to have venous, rather than arterial, occlusion with 7% of children presenting with cerebral vein thrombosis in the multinational childhood registry. In addition to the immediate impact, recurrent strokes may lead to multi-infarct dementia that can mimic other causes of dementia.

Cardiovascular Manifestations

APS should be considered in patients without the more typical risk factors for coronary artery disease and in patients with evidence of thrombotic or embolic coronary occlusion who lack angiographic evidence of atherosclerotic disease. In the RATIO population-based case-control study, the presence of a LA was a significant risk factor for arterial occlusion. LA correlated with an increased risk of myocardial infarction with an OR of 5.3, which increased to 21.6 in women who used oral contraceptives and to 33.7 in women who smoked. Elevated anti- β_2 GPI correlated with a mild increase in stroke but not with myocardial infarction. Antiprothrombin and anticardiolipin antibodies did not correlate with an increased risk of arterial thrombosis. However, antiprothrombin antibodies were reported to be a predictor of myocardial infarction in middle-aged men, and one study found that the interaction in risk between antiprothrombin antibodies and other risk factors was multiplicative.

Hepatic and Gastrointestinal Manifestations

The liver is the most commonly affected abdominal organ in APS. Occlusion of hepatic vessels supplying the biliary tree may present as acute acalculous cholecystitis with gallbladder necrosis. Gastrointestinal manifestations of APS also include esophageal necrosis with perforation, intestinal ischemia and infarction, pancreatitis, colonic ulceration, and giant gastric ulcerations. APS has been reported in patients with mesenteric inflammatory venoocclusive disease and with mesenteric and portal vein obstruction.

Renal Abnormalities

Patients with APS may present with vasoocclusive manifestations such as renal artery stenosis and/or thrombosis, renal infarction and renal vein thrombosis, and with nonthrombotic manifestations, described in the section on noncriteria manifestations. An entity named *APS nephropathy* consists of vasoocclusive disease of small intrarenal vessels characterized by fibrous intimal hyperplasia, focal cortical atrophy, and thrombotic microangiopathy. The acute form of this vascular nephropathy resembles other thrombotic microangiopathies, such as hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. A chronic form that is frequently clinically silent until late stages manifests as a vasoocclusive process that develops at all levels of the renal vasculature, from the main renal artery to glomerular capillaries and renal veins.

Retinal Abnormalities

The diagnosis of APS retinopathy should be suspected in patients with diffuse retinal vasoocclusion, particularly when characterized by

involvement of arteries and veins, neovascularization at presentation, and symptoms of systemic rheumatologic disease. Elevated aPL antibody levels were present in 5% to 33% of patients with retinal vein occlusion. Cilioretinal artery occlusion, optic neuropathy, and severe vasoocclusive retinopathy have been described with APS.

Other Organ Manifestations

aPL antibodies have been described in patients with pulmonary hypertension. A multi-institutional study of 687 patients with chronic thromboembolic pulmonary hypertension reported that aPL antibodies were a significant risk factor. In one prospective trial of 38 consecutive patients with precapillary pulmonary hypertension, approximately 30% had aPL antibodies with various phospholipid specificities.

Acute adrenal failure secondary to bilateral infarction of the adrenal glands has been reported as the first manifestation of primary APS. Adrenal hemorrhage has also been reported. aPL antibodies have also been associated with osteonecrosis. Skin manifestations may be a first sign of APS. Skin ulcerations associated with skin necrosis are a presenting feature in 3.5% of cases.

Catastrophic Antiphospholipid Syndrome

Rare patients present with a catastrophic form of APS, which is characterized by severe widespread vascular occlusion and a high mortality. The formal diagnostic criteria include evidence of involvement of at least three organs, systems and/or tissues, development of manifestations simultaneously or within 1 week, histopathological confirmation of small vessel occlusion, and laboratory confirmation of the presence of aPL antibodies (Table 141.2).

In contrast to the diagnostic criteria for APS, the diagnostic criteria for CAPS permit the presence of histologic evidence of vasculitis together with thrombosis. These patients present with evidence of severe multiorgan ischemia/infarction, usually with concurrent microvascular thrombosis. Patients with CAPS can present with massive venous thromboembolism, along with respiratory failure, stroke, abnormal liver enzymes, renal impairment, adrenal insufficiency, and areas of cutaneous infarction. The respiratory failure is usually caused by acute respiratory distress syndrome (ARDS) and diffuse alveolar hemorrhage. Laboratory evidence for disseminated intravascular coagulation is frequently present.

According to the CAPS Registry, a web based database of 433 patients with CAPS (<https://ontocrf.costaaisa.com/en/web/caps/>), the majority of CAPS patients are female (69%), in their late thirties (mean age of 38.5 years), but patients can present at any age (range 0 to 85 years). In half of the CAPS cases, the catastrophic event was their first manifestation of APS. Precipitating factors for CAPS include infection, drugs (sulfur-containing diuretics, captopril, and oral contraceptives), surgical procedures, and cessation of anticoagulant therapy. In 26.9% of cases, the patients also had SLE. The most frequently affected organ was the kidney (73% of episodes), followed by the lungs (58.9%), brain (55.9%), heart (49.7%), and skin (45.4%). Other organs were also affected including the peripheral vessels, intestines, spleen, adrenal glands, pancreas, retina, and bone marrow. An LA is present in 81.7% of patients, and aCL IgG is the most common positive aPL antibody. Improved treatment has reduced mortality from approximately 50% to 20%. Fortunately, relapse is rare in survivors. The only identified predictive factor for adverse outcome is underlying SLE.

Pediatric Antiphospholipid Syndrome

APS is a significant cause of thrombosis in the pediatric population. In a European registry, children with primary APS tended to be younger and had a higher frequency of arterial thrombotic events, whereas those with secondary APS were older and were more likely

to have venous thrombotic events associated with hematologic and skin manifestations. Children with rheumatic diseases with persistently positive criteria aPL assays were reported to have resistance to annexin A5 anticoagulant activity compared with patients with transiently positive antibodies. The catastrophic form of the syndrome has been reported in children, but occurs less frequently than it does in adults. Thrombosis is rare in newborns delivered by mothers with APS, although aPL antibodies have been found in up to 30% of such offspring.

“Noncriteria” Clinical Manifestations Associated With Antiphospholipid Antibodies and Antiphospholipid Syndrome

Cardiovascular Manifestations

In the absence of thrombotic occlusion, coronary artery disease is not a criterion for APS. However, aPL antibodies have been associated with increased susceptibility to atherosclerosis. aPL antibodies also appear to be a risk factor for adverse outcomes after all coronary revascularization procedures, interventional and surgical.

A remarkably large proportion of patients with the primary APS, approximately 35%, have cardiac valvular abnormalities detectable by echocardiography. When patients with cardiac valvular diseases that were not suspected to be associated with APS were evaluated for aPL antibodies, about 20% had evidence of aPL antibodies compared with about 10% of matched controls. Valvular abnormalities were reported in about half of patients with the combination of SLE and aPL antibodies; these abnormalities included leaflet thickening, vegetations, regurgitation, and stenosis. The mitral valve is most commonly affected, followed by the aortic valve. In a prospective follow-up of 89 patients with severe, nonspecific valvular heart disease, thromboembolic events were significantly more frequent in the aPL antibody–positive group than in the aPL antibody–negative group; however, the presence of aPL antibodies was not an independent risk factor for thromboembolic events. There was one dissenting study that failed to find a relationship between increased aCL antibodies and valvular abnormalities in patients with SLE, progressive systemic sclerosis, rheumatoid arthritis, and primary APS.

Neurologic Manifestations

aPL antibody-associated neurologic abnormalities, other than stroke, include migraine headache, seizures, chorea, Guillain-Barré Syndrome, transient global amnesia, dementia, diabetic peripheral neuropathy, and orthostatic hypotension. In the pediatric APS registry, migraine headache (7%), chorea (4%), and epilepsy (3%) were the most common nonthrombotic neurologic manifestations.

Elevated aCL antibodies are often seen in patients with multiple sclerosis but these are not associated with an increased risk for thrombosis or stroke. In one series of patients with multiple sclerosis, 9% had IgG antibodies and 44% had IgM antibodies, but there was no clinical distinction between those with or without these antibodies. Patients with psychotic disorders have also been reported to have an increased prevalence of LA and aCL antibodies. In one study, 32% (11/34) of the unmedicated psychotic patients had elevated aPL antibodies, but these patients did not appear to have an increased risk of thrombosis.

Hepatic Manifestations

aPL antibody levels are frequently elevated in patients with chronic liver diseases. In one prospective study of patients with liver disease, approximately half of patients with alcoholic liver disease and one-third of patients with chronic hepatitis C virus had elevated aPL

antibody levels. The frequency was even higher in patients with more severe cirrhosis. One review reported that about 20% of patients with chronic hepatitis B and hepatitis C had elevated aPL antibodies, most of which were cofactor independent, i.e., similar to antibodies in infections that recognize phospholipid directly rather than antibodies that recognize phospholipid-binding proteins such as β_2 GPI. Hepatitis C may be an exception because patients can present with “true” autoimmune aPL antibodies; the most common features reported were intraabdominal thrombosis and myocardial infarction. Primary biliary cirrhosis has also been associated with aPL antibodies.

Renal Manifestations

Several nonthrombotic types of renal lesions have also been identified in APS patients. Patients with aPL antibodies may present with glomerulonephritis without vasoocclusive disease. A review of 29 consecutive renal biopsies from patients with primary APS, performed at 2 institutions over 22 years, described 20 cases of APS nephropathy and identified 9 cases with distinct pathologic features including membranous nephropathy, minimal change disease/focal segmental glomerulonephritis, mesangial C3 nephropathy, and pauci-immune crescentic glomerulonephritis.

Dermatologic Manifestations

Livedo reticularis is relatively common, occurring in 24% of a series of 1000 aPL patients (Fig. 141.4). Livedo reticularis is usually widespread and can localize on nonadjacent areas on the limbs, trunk, and buttocks. Its prevalence was found to be higher in APS than was associated with SLE compared with primary APS, in women compared with men, and in patients with high levels of aCL antibodies. Livedo reticularis may be associated with other manifestations of APS such as cerebral or ocular ischemic arterial events (OR, 10.8; 95% CI, 5.2–22.5), seizures (OR, 6.5; 95% CI, 2.6–16), arterial events (OR, 6; 95% CI, 2.9–12.6), heart valve abnormalities detected on echocardiography (OR, 7.3; 95% CI, 3.6–14.7), and arterial systemic hypertension (BP >160/90 mmHg) (OR, 2.9; 95% CI, 1.5–5.7). Necrotizing vasculitis, livedoid vasculitis, thrombophlebitis, cutaneous ulceration and necrosis, erythematous macules, purpura, ecchymoses, painful skin nodules, subungual splinter hemorrhages, anetoderma (macular atrophy), discoid lupus erythematosus, and cutaneous T cell lymphoma have all been reported.

Fig. 141.4 LIVEDO RETICULARIS IN A WOMAN WITH ANTIPHOSPHOLIPID SYNDROME. (From Ruiz-Inestrosa G, Crowther M, Branch W, Khamashia MA: Antiphospholipid syndrome. *Lancet* 376:1498, 2010.)

Hematologic Abnormalities

Thrombocytopenia occurs in a large fraction of patients with APS, but is rarely significant enough to cause bleeding complications or to affect anticoagulant therapy. Most cases appear to be immune mediated and are likely to reflect mild chronic immune thrombocytopenia (ITP). In a prospective cohort study, the 5-year thrombosis-free survival of aPL antibody–positive and aPL antibody–negative ITP patients was 39% and 98%, respectively, indicating that thrombocytopenia itself is not protective against thrombosis in these patients. This has been further substantiated by a recent systematic review and meta-analysis that reported that an increased risk of thrombosis in patients with primary immune thrombocytopenia who also tested positive for antiphospholipid antibodies, particularly for LA for which the pooled OR for the risk of thrombosis was 6.11 (95% CI, 3.40–10.99).

LA by themselves are not associated with abnormal hemostasis. Therefore when patients with APS exhibit a bleeding tendency a concurrent coagulopathy must be considered. In patients with normal platelet counts, the differential diagnosis should include hypoprothrombinemia, acquired thrombocytopathy, acquired factor VIII inhibitor, and acquired von Willebrand syndrome.

TREATMENT OF PATIENTS WITH ANTIPHOSPHOLIPID SYNDROME

There is general agreement that patients with recurrent or spontaneous thrombosis require long-term anticoagulant therapy and that patients with recurrent spontaneous pregnancy losses require antithrombotic therapy for most of the gestational period and for the puerperium. There are unsettled differences of opinion regarding the approach to treatment of patients with single thrombotic events, or a history of previous thrombotic events in the remote past (i.e., >5 years), or patients with provoked thrombotic events after risk factors such as surgery, pregnancy, or estrogens. The recent categorization of patients into high, medium, and low risk groups based on multipositivity on laboratory results may help guide management (see [Table 141.4](#)).

Thrombosis

The accumulated evidence from randomized controlled trials indicates that regardless of single or multiple positivity for aPL antibodies, patients with APS and thrombosis should be treated with long-term warfarin with the dose adjusted to achieve an INR of 2.0–3.0. Although patients with unprovoked venous thromboembolism should probably be treated for the long term, duration of therapy for provoked events is debatable.

Although there is a general consensus on this therapeutic range for venous thrombosis, there is controversy as to whether patients with arterial thrombosis may warrant a higher intensity of anticoagulation because a retrospective study of a variety of patients with APS showed that an INR >3.0 was required to prevent recurrence in this group of patients. Although two major prospective, randomized, controlled trials reported no benefit, and even some downside for high-intensity warfarin, there has been debate on whether these two studies had sufficient numbers of patients with arterial thrombotic events to allow those findings to be generalized beyond venous thromboembolism. Some investigators have recommended that patients with myocardial infarction and triple positivity be treated with higher-intensity warfarin of INR 3.0–4.0 or lower-intensity warfarin of INR 2.0–3.0 plus low-dose aspirin. In addition, the triple-positive myocardial infarction patients who undergo percutaneous coronary interventions and stent implantations should be treated with triple antithrombotic regimens that include warfarin (INR 2.0–3.0), low-dose aspirin, and clopidogrel.

Clinicians should be aware that the LA may impact monitoring of anticoagulation with both warfarin and unfractionated heparin (UFH) but has no impact on treatment with low-molecular-weight

heparin (LMWH). The prothrombin time and INR results can be artifactually elevated in some patients with APS and LA. A multicenter study reported that all but one of the commercial thromboplastins in use in nine centers provided acceptable INR values for APS patients with LA. Chromogenic factor X (CFX) assays can be used as an alternative to the INR to monitor warfarin in APS patients with a prolonged baseline PT, those who are persistently positive for LA and those patients with recurrent VTE. Therapeutic CFX values range from 20% to 40%; thus a CFX of 40% would approximate an INR of 2.0, and a CFX of 20% would approximate an INR of 3.0.

LMWH is generally recommended for treatment in the acute setting. For those patients who require treatment with intravenous UFH (e.g., high risk patients for whom the short half-life of UFH may be advantageous for bridging purposes), the physician must first determine that the baseline aPTT used for monitoring and adjusting heparin dosage is not prolonged by a LA. If this is a problem, the heparin concentration may be estimated with one of the LA-insensitive aPTT reagents or measured directly with a specific heparin assay.

Fibrinolytic therapy has been used in patients with primary APS who present with extensive thrombosis of the common femoral and iliac veins extending to the lower vena cava, acute ischemic stroke, and acute myocardial infarction.

Although the direct-acting oral anticoagulants (DOACs) are as effective as warfarin for VTE treatment, they have not been extensively evaluated in APS patients. In two recent case studies, DOACs failed to prevent thrombosis in APS patients. Of 6 APS patients studied, 5 suffered recurrent venous thromboembolism and 1 suffered a recurrent TIA after transitioning to DOACs. At least two prospective randomized trials comparing warfarin with rivaroxaban are currently in progress ([ClinicalTrials.gov](#) Identifier: NCT02116036 NCT02157272), but until the results are available, DOACs should be used with caution in APS patients.

Stroke

There is controversy about the appropriate antithrombotic treatment of aPL antibody–associated stroke. Currently most hematologists and rheumatologists view APS stroke as no different from other arterial thrombotic manifestations of APS and treat with warfarin, with some debate as to whether to use an INR target of 2.0–3.0 or a higher intensity. Conversely many neurologists view APS stroke as no different from other arterial strokes and accept the APASS study conclusion that treating with aspirin alone is as effective as warfarin but associated with a lower risk of bleeding (the daily dose in that study was 325 mg; however, most guidelines recommend 81 mg/day). Guidelines issued in 2006 from the American Heart Association/American Stroke Association stated that for patients with cryptogenic ischemic stroke or TIA associated with aPL antibodies, antiplatelet therapy is reasonable and for patients who meet the criteria for APS with venous and arterial occlusive disease in multiple organs, miscarriages, and livedo reticularis, warfarin with a target INR of 2.0–3.0 is reasonable.

Pregnancy Complications

The current approach to treating pregnant women with APS and recurrent pregnancy losses or the other aPL antibody–associated complications of pregnancy includes daily low-dose aspirin (75–81 mg/day) and either UFH or LMWH. Although clinical studies have shown efficacy with UFH, most clinicians treat with LMWH because it has a better pharmacokinetic profile (it can be given once daily subcutaneously rather than twice daily) and lower risk of heparin-induced thrombocytopenia and osteopenia. Heparin is then withheld when labor begins or 24 hours prior to a cesarean section. Anticoagulation with either LMWH or warfarin (although most patients and physicians prefer LMWH for convenience, despite the need for injection) is then resumed for 6 weeks because of the increased risk of VTE in this time period. This latter

recommendation may be modified if DOACs are proven to be useful in this setting. Interestingly, the current standard of care for pregnant patients with APS is based on only two randomized controlled trials conducted prior to 2000 and included only 150 patients. More recent trials have shown conflicting results with some showing no difference in prevention of pregnancy loss in APS patients receiving aspirin alone versus aspirin and LMWH and others showing a small benefit. However, the likelihood of a good pregnancy outcome in treated women with APS has been estimated to be about 75%–80%.

The presence of elevated aPL antibodies in pregnant women without any history of spontaneous pregnancy losses, other attributable pregnancy complications, thrombosis or embolism is currently not sufficient justification for treatment. A recent systematic review found no benefit of prophylactic treatment with aspirin to prevent pregnancy complications in aPL antibody carriers in the absence of other risk factors. Because 2%–3% of the general obstetric population has low titers of aPL antibodies, with a live birth rate of 60% among these patients, it is not recommended that physicians screen for aPL antibodies or LA in their routine prenatal screening panel.

Catastrophic Antiphospholipid Syndrome

Patients with CAPS require aggressive treatment because of the high mortality. Treatment for CAPS is directed toward the thrombotic events and suppression of the cytokine cascade. Conventional anticoagulant therapy is usually insufficient and treatment modalities may include anticoagulation with heparin, immunosuppressive therapy in the form of high-dose steroids, IVIG, cyclophosphamide, azathioprine, or rituximab. Plasmapheresis may be a helpful adjunct in some patients. A triple therapy strategy of anticoagulation, steroids, and either intravenous immunoglobulin or plasma exchange or both has improved outcomes. The higher rate of this triple therapy strategy has resulted in a significant reduction in mortality rate to 30% in CAPS. Cyclophosphamide is recommended for CAPS patients with inflammatory features of SLE or high-titer aPL antibodies. Rituximab may be useful for refractory or relapsing cases of CAPS.

Asymptomatic Antiphospholipid Antibody–Positive Patients

A recent task force at the 13th International Congress on Antiphospholipid Antibodies has recommended that asymptomatic patients with no previous thrombosis but a high risk aPL antibody profile (LA positive, triple positive (LA+, aCL antibody+, anti- β_2 GPI antibody+), or persistently positive medium-high titers of aCL antibodies be given long-term prophylaxis with low-dose aspirin, especially if there are other thrombotic risk factors. Furthermore, aPL-antibody carriers should receive thromboprophylaxis with usual doses of LMWH in high-risk situations, such as surgery, prolonged immobilization and the puerperium. In addition to low-dose aspirin, aPL-antibody carriers with SLE should receive hydroxychloroquine (HCQ) as primary prophylaxis. A recent meta-analysis of five international studies that included 495 patients confirmed the benefit of low-dose aspirin in asymptomatic aPL antibody carriers with and without SLE. The risk of a first thrombotic event is significantly decreased in SLE patients and asymptomatic aPL antibody carriers treated with low-dose aspirin. Specifically, low-dose aspirin showed a protective effect against arterial but not venous thrombosis. The meta-analysis failed to show an independent protective effect of HCQ.

NONANTICOAGULANT TREATMENTS UNDER STUDY FOR ANTIPHOSPHOLIPID SYNDROME

Hydroxychloroquine

HCQ, a synthetic antimalarial drug with many antiinflammatory and antithrombotic effects has been associated with a reduced risk of

thrombosis in patients with APS and SLE. The potential effectiveness of this treatment has been supported by an animal model for aPL antibody thrombosis and by a recent reports that HCQ directly disrupts aPL IgG- β_2 GPI complexes, and also reverses the aPL antibody-mediated disruption of annexin A5 binding on phospholipid bilayers and on human placental syncytiotrophoblasts. In a longitudinal cohort study that included 272 patients with APS and 152 taking HCQ (17 of 272 patients on warfarin, 203 were on prednisolone, 112 on azathioprine, 38 on aspirin) there were fewer thrombotic complications in those taking HCQ (OR, 0.17; 95% CI, 0.07–0.44; $p < .0001$). In asymptomatic aPL antibody-positive patients with SLE, primary prophylaxis with aspirin and HCQ appeared to reduce the frequency of thrombotic events. A recently published prospective, nonrandomized study compared oral anticoagulant plus HCQ versus oral anticoagulant alone. In this study, 30% (6/20) of patients had a thrombotic event if they were on oral anticoagulant alone, despite therapeutic range INR, versus no thrombotic events in the oral anticoagulant plus HCQ group (0/20). However this study was limited by the small sample size and short follow-up. A prospective randomized controlled trial comparing HCQ to placebo in aPL-positive patients without a prior history for thrombosis ([clinicaltrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT01784523) NCT01784523) was recently terminated because of insufficient recruitment.

Rituximab

Rituximab is an anti-CD20 chimeric monoclonal antibody effective against non-Hodgkin lymphomas and approved for the treatment of rheumatoid arthritis. Limited case reports have shown rituximab as effective in treating thrombocytopenia and hemolytic anemia in aPL antibody–positive patients; however, it is unknown if rituximab is effective against aPL antibody–mediated thrombosis. An open-label, phase II pilot study demonstrated safety and effectiveness of rituximab in aPL antibody–positive patients with anticoagulant resistant manifestations but did not show any effect on aPL laboratory parameters.

Main Points and Clinical Pearls

- The antiphospholipid (aPL) syndrome (APS) is an acquired thrombophilic disorder in which patients have vascular thrombosis and/or pregnancy complications attributable to placental insufficiency, accompanied by laboratory evidence for the presence of antiphospholipid antibodies in blood.
- Rare patients have a catastrophic form of APS (CAPS) in which there is disseminated thrombosis in large- and small-vessel thrombi, often after a triggering event such as infection or surgery, and often with multiorgan ischemia and infarction.
- Laboratory testing for aPL antibodies should generally be limited to patients who present with the thrombotic and/or the pregnancy manifestations of the disorder or asymptomatic patients with autoimmune disease such as systemic lupus erythematosus because they are at increased risk for having aPL antibodies and for experiencing thrombosis.
- The syndrome is identified by persistent positivity of criteria laboratory tests including high titers for aCL and anti- β_2 GPI IgG or IgM antibodies detected by immunoassays and by positive LA using two different coagulation tests.
- Weak positive test results for aPL immunoassays are unlikely to have any clinical significance. Transient aPL antibodies can develop as a result of infection, HIV, liver disease, cancer, and certain medications such as phenothiazines, quinine, procainamide, oral contraceptives, and anti-TNF agents.
- In clinical practice selected patients may be suspected to have APS without necessarily meeting the strict investigational criteria.
- When a patient has the clinical appearance of APS but negative standard aPL assay results, think about the possibility of seronegative APS. Noncriteria tests such as anticardiolipin (aCL) and anti- β_2 -glycoprotein I (anti- β_2 GPI) immunoglobulin A

Main Points and Clinical Pearls—cont'd

antibodies and antiphosphatidylserine antibodies may help to clarify the picture.

- Long-term warfarin anticoagulant therapy is the usual treatment for thrombosis in patients with APS. The newer direct-acting oral anticoagulants (DOACs) have not been extensively evaluated in APS patients.
- Aspirin and heparin are recommended for pregnant APS patients and for prophylaxis against deep vein thrombosis during the postpartum period.
- CAPS patients have a high mortality and, in addition to anticoagulants, often require plasmapheresis and immunosuppressive agents.
- Asymptomatic patients with triple-positive aPL tests appear to be at high risk for a first thrombotic event and for recurrence. Consider treating prophylactically during high risk situations.

VENOUS THROMBOEMBOLISM

Deborah Siegal and Wendy Lim

Venous thromboembolism (VTE), encompassing both deep venous thrombosis (DVT) and pulmonary embolism (PE), remains a common medical condition that is associated with significant morbidity and mortality.

Although DVT can occur in any vein, it most commonly occurs in the leg veins. Superficial venous thrombosis occurs most frequently in varicosities and usually is self-limiting and benign. In contrast, DVT is a more serious condition. Thrombi localized to the deep calf veins often are small and therefore less commonly associated with clinically important PE or postthrombotic syndrome, but PE occurs in about 60% of patients with proximal DVT involving the popliteal, femoral, or iliac venous system.

Increased clinical suspicion and availability of reliable, noninvasive diagnostic tests have increased the frequency of diagnosis of acute VTE. In hospitalized patients this condition is largely preventable through the use of anticoagulant prophylaxis. In patients with established VTE advances in anticoagulant therapy have facilitated outpatient-based therapy.

PATHOGENESIS OF VENOUS THROMBOEMBOLISM AND CLINICAL RISK FACTORS

Venous thrombi are composed predominantly of fibrin and red cells, and usually arise in the large venous sinuses in the calf, in valve cusp pockets in the deep veins of the calf, or at sites of vessel damage. Venous thrombosis occurs when activation of blood coagulation exceeds the ability of the natural anticoagulant mechanisms and the fibrinolytic system to prevent clot formation. The current understanding of VTE pathogenesis was first described by Virchow more than 150 years ago. He proposed that thrombotic disorders were associated with the triad of stasis, vascular injury, and hypercoagulability. Stasis and vascular injury are the most frequent precipitants of VTE. In addition to activating coagulation, tissue damage and/or vascular damage can also impair fibrinolysis by reducing synthesis of tissue plasminogen activator (t-PA) and by increasing endothelial cell production of plasminogen activator inhibitor type 1 (PAI-1), the major inhibitor of the fibrinolytic pathway.

Under normal circumstances, activated coagulation factors are diluted in the flowing blood and are neutralized by inhibitors on the surface of endothelial cells or by circulating proteinase inhibitors. Activated coagulation factors that escape regulation because of reduced levels of inhibitors or because they are generated in overwhelming amounts trigger the coagulation system and fibrin formation. Homeostatic mechanisms, including activation of the fibrinolytic system with release of t-PA and urokinase, are immediately invoked to reduce the likelihood of pathologic thrombus formation.

THROMBOGENIC FACTORS

Activation of Blood Coagulation

With the exception of small amounts of active factor VII, the coagulation factors circulate as inactive protein precursors, or zymogens. Each zymogen is converted into an active enzyme that then activates the next zymogen in the coagulation pathway (see [Chapter 122](#)). Traditionally the coagulation system has been divided into the

intrinsic, extrinsic, and common pathways. Although these pathways reflect the way coagulation is measured in the laboratory, they do not reflect how coagulation occurs in vivo. In vivo, coagulation is primarily initiated via the tissue factor pathway. In this pathway, circulating activated factor VII (factor VIIa) binds to tissue factor at sites of vascular injury. The tissue factor–factor VIIa complex then activates factor IX and factor X. Levels of factor VIIa can be increased by factor Xa; however, this reaction is rapidly downregulated by tissue factor pathway inhibitor (TFPI). TFPI binds and inactivates factor Xa; the TFPI–factor Xa complex then binds the factor VIIa–tissue factor complex and prevents further activation of factor X.

In the presence of calcium, factor Xa binds to factor Va on the surface of activated platelets to form the prothrombinase complex, which converts prothrombin to thrombin. Thrombin then converts fibrinogen to fibrin, and activates platelets and factor XIII. Factor XIIIa, in the presence of calcium, cross-links fibrin, thereby stabilizing the clot. To ensure continuous generation of thrombin, thrombin and, to a lesser extent, factor Xa activate factor VIII and factor V, markedly accelerating the coagulation reactions involving these two cofactors. Thrombin also activates factor XI, which in turn activates additional factor IX, establishing a positive feedback loop.

Coagulation may be activated by contact of factor XII with collagen on exposed subendothelium of damaged vessels, by contact with prosthetic surfaces, by polyphosphates released from activated platelets, or by DNA or RNA released from damaged cells. There is mounting evidence that this pathway contributes to thrombosis. Thus mice deficient in factor XII or factor XI exhibit attenuated thrombus formation at sites of injury and factor XI knockdown with an antisense oligonucleotide attenuated VTE after elective knee arthroplasty. Therefore the contact pathway appears to be important for thrombus growth and stabilization.

Under most situations coagulation is initiated by exposure of blood to tissue factor made available locally as a result of vascular wall damage, by activation of endothelial cells, or by activated monocytes that migrate to areas of vascular injury. Factor X can be activated directly by extracts of malignant cells that contain a cysteine protease, which may be one of the mechanisms by which thrombosis is induced in patients with cancer. A factor elaborated by hypoxic endothelial cells also can directly activate factor X, potentially leading to thrombosis in patients with severe venous stasis where hypoxia occurs in the valve cusps.

Venous Stasis

Venous stasis is produced by immobility, venous obstruction, increased venous pressure, venous dilation, and increased blood viscosity. Venous return from the lower extremities is enhanced by venous valves, which prevent blood from pooling in the lower legs, and by contraction of the calf muscles, which propels blood upward from the extremities. Venous stasis may contribute to thrombogenesis by allowing stagnation of the blood with associated local hypoxia.

Immobility

Venous thrombosis can occur in immobilized persons because blood pools in the intramuscular sinuses of the calf, which are dilated during

recumbency. Many clinical examples highlight the role of stasis in the pathogenesis of VTE. For example, the prevalence of VTE at autopsy is markedly increased in persons who were confined to bed for more than 1 week before death. Preoperative immobility is associated with a higher frequency of perioperative VTE, and postoperative immobility contributes to the high incidence of postoperative VTE in patients who have undergone hysterectomy, transabdominal prostatectomy, hip or knee arthroplasty, or surgery for fractures of the lower limb. The effect of immobility on thrombus formation is well illustrated by comparing the location of thrombosis in patients with paraplegia with that in patients who have had a stroke. Whereas thrombosis occurs with equal frequency in both legs in patients with paraplegia, it occurs more frequently in the paralyzed limb in patients with a stroke.

Venous Obstruction and Increased Venous Pressure

Venous obstruction contributes to the risk of VTE in patients with pelvic tumors and to recurrent venous thrombosis in patients with persistent obstruction because of residual proximal vein thrombosis. Raised central venous pressure produces venous stasis in the extremities, which may explain the high prevalence of venous thrombosis in patients with congestive heart failure. A similar mechanism may underlie the propensity for thrombosis in the left leg during pregnancy, presumably from obstruction of the left common iliac vein by the right common iliac artery, which is accentuated by the gravid uterus.

Increased Blood Viscosity and Venous Dilation

Venous stasis can be caused by increased blood viscosity or venous dilation. The blood viscosity can be increased by polycythemia, hypergammaglobulinemia, dysproteinemias, or increased fibrinogen levels. Stasis because of venous dilation may contribute to the increased risk of thromboembolism in patients with varicose veins and in elderly patients, particularly if they are bedridden. The capacity of estrogens to cause venous dilation may contribute to the increased prevalence of thrombosis during pregnancy, in women taking estrogen-containing oral contraceptive pills or estrogen replacement therapy.

Vessel Wall Damage

Damage or injury to the vascular endothelium exposes tissue factor, which triggers coagulation. Furthermore, the exposure of blood to the subendothelium leads to platelet adhesion, activation, and aggregation.

The vascular endothelium can be damaged by direct trauma, or it can be perturbed by exposure to endotoxin, inflammatory cytokines such as interleukin-1 and tumor necrosis factor, thrombin, or low oxygen tension. Perturbed endothelial cells synthesize tissue factor and PAI-1 and internalize thrombomodulin, promoting thrombogenesis. Furthermore, damaged endothelial cells may produce less t-PA, the principal activator of intravascular fibrinolysis.

Direct venous damage may lead to venous thrombosis in patients undergoing hip surgery, knee surgery, or varicose vein stripping, and in patients with severe burns, lower limb trauma, or central venous catheters.

PROTECTIVE MECHANISMS

Endothelial Protective Mechanisms

Normal vascular endothelium is nonthrombogenic to flowing blood. Endothelial cell surface glycosaminoglycans, thrombomodulin, and endothelial protein C receptor (EPCR) are potent inhibitors of

coagulation, and vessel wall generation of prostacyclin and nitric oxide and synthesis of plasminogen activators limit platelet aggregation and fibrin deposition.

Heparan sulfate, thrombomodulin, and EPCR present on the luminal surface of endothelial cells are important modulators of thrombin activity. Heparan sulfate, a glycosaminoglycan similar to heparin, catalyzes the inhibition of thrombin and factor Xa by antithrombin. Thrombomodulin serves as a surface-bound receptor for thrombin. Once bound to thrombomodulin, thrombin undergoes a change in substrate specificity that renders it incapable of activating platelets, of converting fibrinogen to fibrin, or of activating factors V, VIII, and XIII. Instead, once bound to thrombomodulin, thrombin becomes a potent activator of protein C. Activated protein C, together with protein S, its cofactor, downregulates coagulation by, proteolytically inactivating factors Va and VIIIa. EPCR enhances protein C activation by binding protein C and presenting it to the thrombin–thrombomodulin complex for activation.

Generation of plasminogen activators by vascular endothelium limits fibrin deposition, and platelet aggregation is inhibited by the release of prostacyclin (prostaglandin I_2) and endothelium-derived nitric oxide. Plasminogen binds to the cell surface, where it can be activated to plasmin by t-PA, thereby promoting local fibrinolytic activity.

Inhibitors of Blood Coagulation

Activated coagulation factors are serine proteases and their activity is modulated by several naturally occurring plasma inhibitors. The most important inhibitors of the blood coagulation system are antithrombin, protein C, and protein S. Congenital deficiency in one of these three proteins was found in 11% of patients enrolled in a prospective study of 2132 consecutive patients presenting with VTE. Abnormalities in the fibrinolytic system including congenital dysfibrinogenemias and deficiency of plasminogen can also predispose the affected person to thromboembolism.

HYPERCOAGULABLE STATES

In addition to deficiencies of antithrombin and proteins C and S, other hypercoagulable states associated with VTE include factor V Leiden (activated protein C resistance) and prothrombin G20210A mutations, hyperhomocysteinemia, antiphospholipid syndrome, pregnancy, and malignancy. Hypercoagulable states are the subject of Chapter 140.

NATURAL HISTORY OF VENOUS THROMBOEMBOLISM

Most DVTs are asymptomatic and confined to the intramuscular veins of the calf. These distal thrombi often undergo spontaneous lysis and rarely produce long-term sequelae. In contrast, complete lysis of proximal vein thrombosis is uncommon even when anticoagulant treatment is given.

The symptoms and signs of VTE are caused by obstruction to venous outflow, inflammation of the vessel wall or perivascular tissues, and embolization of thrombus into the pulmonary circulation. Asymptomatic PE is detected by perfusion lung scanning in approximately 50% of patients with documented proximal vein thrombosis. Most clinically significant and fatal PEs arise from DVT in the proximal veins of the legs. PE occurs less commonly and tends to be less extensive in patients with calf DVT than in those with proximal DVT. Asymptomatic DVT is found in 70% of patients who present with confirmed PE. The DVT in such patients tends to be extensive and involves the proximal veins.

Extensive DVT can lead to venous valvular damage, which is a hallmark of postthrombotic syndrome. Patients with a previous history of DVT are at increased risk of recurrence, particularly when patients are exposed to high-risk situations.

PROGNOSIS OF VENOUS THROMBOEMBOLISM

Untreated or inadequately treated VTE is associated with a high complication rate, which can be decreased markedly by adequate anticoagulant therapy. Approximately 20% of untreated asymptomatic calf vein thrombi and 20%–30% of untreated symptomatic calf vein thrombi extend into the popliteal vein; in the majority of cases this occurs within 1 week. When extension occurs and is untreated, it is associated with a 40%–50% risk of clinically detectable PE. Patients with proximal DVT who receive inadequate treatment have a 47% risk of recurrent VTE over 3 months. Approximately 10% of symptomatic PE cases are estimated to be fatal within 1 hour of symptom onset. Anticoagulant therapy reduces the mortality associated with PE; without therapy, mortality rates are as high as 30%. Clinically detectable recurrence occurs in fewer than 3% of patients with proximal DVT during anticoagulant therapy. The most important determinant of VTE recurrence following discontinuation of anticoagulant therapy is the presence or absence of identifiable risk factors at diagnosis. VTE associated with transient surgical or non-surgical risk factors are associated with lower rates of VTE recurrence compared with those that are unprovoked (idiopathic). After 3 months of treatment for VTE associated with a transient surgical or nonsurgical (e.g., exogenous hormone use, immobility) risk factor, 12-month VTE recurrence rates are 1% and 5%, respectively. Subsequent recurrence rates are 0.5% and 2.5% per year. In contrast, the recurrence rate after at least 3 months of anticoagulant therapy for a first episode of unprovoked VTE is approximately 10% within the first 12 months and 5% per year thereafter. Patients with malignancy and those with a second episode of unprovoked VTE have high recurrence rates, up to 15% within 12 months and 7.5% per year thereafter following anticoagulant discontinuation.

LONG-TERM COMPLICATIONS OF VENOUS THROMBOEMBOLISM

Postthrombotic Syndrome

The postthrombotic syndrome is caused by venous hypertension, usually resulting from valve damage. Valve damage results in malfunction of the muscular pump mechanism, which leads to increased pressure in the deep calf veins during ambulation. The high pressure ultimately renders the perforating veins of the calf incompetent, so that blood flow is directed from the deep veins into the superficial venous system during muscular contraction. This leads to edema and impaired viability of subcutaneous tissues and, in its most severe form, to venous ulceration. Outflow obstruction initially may be bypassed by the development of collateral veins, but with time, the veins distal to the obstruction become dilated, and their valves become incompetent.

In patients whose thrombosis extends into the iliofemoral veins, the leg swelling at initial presentation may not resolve entirely. This is in contrast to patients with less extensive proximal vein thrombosis, in whom the swelling may subside after initial treatment but recur months or years later. Other symptoms and signs of the postthrombotic syndrome may be delayed for 5–10 years after the initial thrombotic event. These symptoms include pain in the calf that is relieved with rest and leg elevation, skin pigmentation and induration around the ankle and lower third of the calf, and ulceration in the region of the medial malleolus.

Patients with extensive thrombosis involving the iliofemoral vein frequently have greater disability and may have venous claudication, characterized by incapacitating, bursting pain with exercise. This complication rarely occurs in patients with thrombosis involving the more distal veins.

The clinical spectrum of the postthrombotic syndrome varies from a course that may mimic acute DVT to one of persistent leg pain that is worse at the end of the day and is associated with dependent edema, stasis pigmentation, and, in its most severe form, skin ulceration. Rarely, patients may complain of venous claudication

on walking. When symptoms are acute or subacute in onset, a diagnosis of postthrombotic syndrome should be considered only after recurrent DVT has been excluded by objective testing. There is no single definitive diagnostic test for the postthrombotic syndrome, but a history of objectively documented DVT, appropriate clinical findings, and evidence of venous reflux or outflow obstruction on venous ultrasonography constitute sufficient evidence to make this diagnosis.

The frequency with which postthrombotic syndrome occurs after VTE is controversial, with contemporary studies reporting incidence rates of 20%–80%. Severe postthrombotic syndrome occurs in approximately 5%–10% of patients. Risk factors for postthrombotic syndrome include proximal location of thrombosis (especially femoral or iliac veins), ipsilateral recurrent thrombosis, older age, obesity, and inadequate anticoagulant treatment.

Postthrombotic syndrome can cause significant disability and impairs quality of life. The clinical severity of postthrombotic syndrome can be assessed using the Villalta scale, a validated scoring system. Treatment for acute DVT may reduce the long-term risk of postthrombotic syndrome. In addition, there is conflicting evidence regarding the effectiveness of below-knee graduated compression stockings for reducing the risk of postthrombotic syndrome in patients with DVT. Other conservative measures may include exercise, limb elevation, compression bandages, pharmacologic management of edema, and careful attention to skin care.

Chronic Thromboembolic Pulmonary Hypertension

Chronic thromboembolic pulmonary hypertension (CTEPH) is a rare complication typically occurring within 2 years of acute PE. Patients with CTEPH present with exertional dyspnea that may progress to dyspnea at rest. With worsening pulmonary hypertension, patients may report signs or symptoms of right ventricular dysfunction such as lower extremity edema. CTEPH should be considered in patients presenting with signs and symptoms consistent with pulmonary hypertension, especially if they have a history of VTE or risk factors for VTE.

Echocardiography is a useful, noninvasive method of evaluating estimated systolic pulmonary artery pressure, right atrial enlargement, right ventricular systolic dysfunction, and septal displacement suggesting pulmonary hypertension. Ventilation/perfusion (V/Q) lung scanning has higher sensitivity for CTEPH than computed tomography (CT) pulmonary angiogram and is the preferred initial diagnostic test in this setting. Subsequent CT pulmonary angiogram is then used to exclude competing diagnoses that can cause perfusion defects on V/Q scanning.

Medical therapy for CTEPH includes anticoagulation, and pulmonary vasodilatory and remodeling therapies that are not curative and modestly improve symptoms. Medical therapy is administered at specialized centers and is reserved for patients who are not surgical candidates or as a bridge to surgical intervention. Surgical management with pulmonary thromboendarterectomy is the only potentially curative treatment option and is conducted at specialized centers.

DIAGNOSIS OF VENOUS THROMBOEMBOLISM

The diagnosis of VTE is based on objective testing as opposed to clinical assessment, which may be subjective.

Deep Venous Thrombosis

Clinical Manifestations

DVT classically causes swelling, pain, and erythema of the affected extremity. Proximal vein lower extremity DVT is more likely to be symptomatic than calf vein thrombosis. Patients with massive thrombosis involving the iliac and femoral veins may present with

phlegmasia cerulea dolens, which is severe leg pain with swelling, cyanosis, venous gangrene, compartment syndrome, and arterial compromise. Patients with phlegmasia cerulea dolens may experience circulatory collapse and shock, which may result in death or loss of the affected limb.

Differential Diagnosis

The differential diagnosis of patients with suspected DVT includes musculoskeletal disorders (muscle or tendon strains or tears), lymphatic obstruction, venous insufficiency, a ruptured popliteal (Baker) cyst, cellulitis, sciatica, muscle hematoma, and postthrombotic syndrome.

OBJECTIVE DIAGNOSTIC TESTS FOR DEEP VENOUS THROMBOSIS

Both invasive and noninvasive tests are useful for the diagnosis of DVT. Venography is the only invasive test of proven value, and venous compression ultrasonography is the most widely studied and used noninvasive test. Although other imaging modalities have been studied (e.g., magnetic resonance direct thrombus imaging), these are not commonly performed.

Venography

Venography remains the reference standard for the diagnosis of DVT, although it is rarely performed because of the availability of reliable noninvasive tests. Venography is technically difficult, and its proper execution and interpretation require considerable experience. Venography may produce superficial phlebitis and can cause DVT, but with good technique ascending venography outlines the entire deep venous system of the lower extremities, including the calf and iliac veins. It is currently used only when noninvasive testing is not feasible or the results of such testing are inconclusive.

Venous Compression Ultrasonography

Venous ultrasonography is performed using a high-resolution real-time scanner equipped with a 5-MHz electronically focused linear array transducer. The common femoral vein and femoral artery are first located in the groin, with the patient in a supine position. The femoral vein (a deep vein) is then examined along its course. Next, the popliteal vein is located and examined down to the level of its trifurcation into the peroneal and tibial veins. At each of these locations, the vein being examined is compressed gently but firmly with the transducer probe, and the results are observed on the monitor. Hard copies from freeze-frame images of both stages of the procedure are obtained and serve as a permanent record.

In symptomatic patients, venous compression ultrasonography has a sensitivity and specificity for detection of proximal DVT (femoral or popliteal vein) of more than 95%. However, ultrasonography is less sensitive for detection of calf vein thrombosis. Ultrasound examination can be repeated 7 days after the initial study to increase its sensitivity for detection of clinically important calf vein thrombosis and to improve the safety of diagnostic strategies that do not include venography in patients with suspected calf vein thrombosis. This strategy will detect the 10%–30% of calf vein thrombi that extend proximally. If the ultrasound examination result remains negative after 7 days, the risk of clinically important proximal extension is negligible, and it is safe to withhold antithrombotic treatment.

If the field of examination is extended to the distal popliteal vein and the proximal deep calf veins, venous ultrasonography detects approximately 50% of calf vein thrombi in symptomatic patients. Although there are reports that ultrasound examination of the calf

can reliably detect thrombi, most such reports have not used venography as their reference standard. Furthermore, whether the value of this test is maintained when it moves from highly specialized vascular laboratories into community ultrasonography laboratories is unknown. A potential limitation of venous ultrasonography is its inability to visualize the iliac veins and the segment of the superficial femoral vein within the femoral canal. This is not a serious limitation because isolated thrombi within the femoral canal or the iliac vein are rare. Furthermore, the obstruction produced by iliac vein thrombi often limits the compressibility of the common femoral vein segment and hence will be detected indirectly. Doppler color flow can also be used to assess for blood flow and occlusion within a vein. The combination of compression ultrasonography and Doppler is often referred to as duplex ultrasonography.

D-Dimer Assays

D-dimer assays use mono- or polyspecific antibodies against D-dimer to provide quantitative or qualitative data on the concentration of D-dimer in whole blood or plasma. D-dimer is the product of lysis of cross-linked fibrin and the levels of D-dimer are increased in patients with acute VTE. However, the test is nonspecific because the level of D-dimer can be increased in a variety of other conditions, including malignancy, inflammatory conditions, and infections. Therefore the D-dimer assay is most useful as a tool to rule out suspected DVT.

D-dimer assays have two principal limitations: (1) a positive test result is nonspecific and should not be used as the sole criterion for diagnosis of VTE, and (2) numerous test kits are available that have different sensitivities for VTE. Thus D-dimer results are not interchangeable between kits. D-dimer assays employ different standards with some using fibrinogen and others using D-dimer. This results in differences in reporting because laboratory cut-offs depend on which standard is used. This has led to confusion among clinicians regarding the use of D-dimer assays. Further, the use of an insensitive D-dimer assay to rule out VTE could result in omission of required diagnostic testing, thereby placing patients at risk for PE and death.

The optimal setting for use of a D-dimer assay is in the assessment of patients with a low clinical pretest probability of VTE. The combination of a low pretest probability (determined using a validated scoring system) and a negative result with a validated D-dimer assay rules out the diagnosis of acute VTE, obviating the need for additional testing. Evaluation of the levels of D-dimer may be of value in patients with suspected recurrent VTE, and it may assist in decision-making about optimal duration of anticoagulation.

DIAGNOSTIC STRATEGIES FOR ACUTE DEEP VENOUS THROMBOSIS

Diagnostic algorithms for the noninvasive diagnosis of clinically suspected VTE are presented in Fig. 142.1. If compression ultrasonography is not immediately available, patients can be empirically anticoagulated pending diagnostic testing on the subsequent day. In assessing patients with suspected acute DVT, clinical prediction rules assign a clinical pretest probability (high, intermediate, or low probability) based on the clinical manifestations and the presence or absence of risk factors. The Wells clinical prediction rule for DVT assigns a risk category based on the following factors: active cancer (or cancer treated within the previous 6 months), calf swelling ≥ 3 cm compared to the asymptomatic leg, swelling of superficial veins (nonvaricose), unilateral pitting edema, tenderness along the deep venous system, such as recent immobilization (≥ 3 days) or major surgery (within 12 weeks), and absence of alternative diagnosis. Acute DVT can be excluded in patients with a low clinical probability (based on a validated clinical prediction rule such as the Wells score) and negative D-dimer. Patients with moderate or high clinical probability should proceed to objective testing. Patients

Fig. 142.1 DIAGNOSTIC ALGORITHMS FOR THE MANAGEMENT OF PATIENTS WITH SUSPECTED DEEP VEIN THROMBOSIS. (A) Ultrasound examination-based strategy. (B) Clinical probability-based strategy. CUS, Compression ultrasound; DVT, deep vein thrombosis.

with a high clinical pretest probability and a negative noninvasive test result should prompt further investigation with or serial ultrasonography.

In approximately 70% of patients referred for clinically suspected DVT, the diagnosis will be excluded by objective tests. Of the 30% who have DVT, approximately 85% will have proximal vein thrombosis, and the remainder will have thrombosis confined to the calf.

PULMONARY EMBOLISM

Clinical Manifestations

The most frequently reported symptom of PE is dyspnea. Chest pain is common and typically pleuritic in nature but may be substernal and compressing. Hemoptysis is a less frequent feature.

The physical signs of PE are nonspecific. Syncope usually is associated with massive PE and is caused by a reduction in cardiac output. This in turn results in hypotension and transient impairment of cerebral blood flow. Approximately 5%–10% of patients present with shock.

Although 70% of patients with PE have venographic evidence of DVT at presentation, fewer than 20% of these patients have leg symptoms. Massive PE causes tachypnea, tachycardia, cyanosis, and hypotension. In these patients, cardiac examination may reveal a right ventricular heave, a loud pulmonary second sound, and a gallop rhythm. Physical examination of the chest may be normal, or

nonspecific abnormalities may be detected. Patients with pulmonary infarction or atelectasis may have reduced movement of the affected portion of the chest.

Differential Diagnosis

The differential diagnosis of dyspnea and pleuritic chest pain, in addition to PE, includes pneumonia, pleurisy, chest wall pain, pericarditis, atelectasis, pneumothorax, acute bronchitis, acute bronchiolitis, and acute bronchial obstruction as a result of mucous plugging or bronchoconstriction.

Diagnosis

The clinical diagnosis of PE requires objective testing. The chest radiograph is not specific for PE and usually does not show any diagnostic abnormality. Nevertheless, it is useful in excluding other causes for the presenting symptoms (e.g., pneumothorax) and is essential for interpreting V/Q lung scan findings. The electrocardiogram (ECG) is frequently normal or may show nonspecific abnormalities (e.g., sinus tachycardia). However, in the appropriate clinical setting, ECG evidence of right ventricular strain is strongly suggestive of PE. Elevated levels of cardiac troponin, brain natriuretic peptide (BNP) or N-terminal pro-BNP (NT-proBNP) can result from right ventricular strain and associated cardiomyocyte stretch.

OBJECTIVE DIAGNOSTIC TESTS FOR PULMONARY EMBOLISM

Pulmonary Angiography

Although pulmonary angiography is the reference standard for establishing the presence or absence of PE, it is no longer routinely used in clinical practice because of the availability of noninvasive imaging modalities such as CT and V/Q lung scanning.

Helical Computed Tomography Scanning

Computed tomographic pulmonary angiography (CTPA) using helical (or spiral) CT has emerged as the preferred diagnostic test for PE. When performed in experienced clinical centers with use of validated scanning protocols, helical CTPA is a useful tool to rule out PE in patients with compatible clinical symptoms with a sensitivity of 83% and specificity of 96%. The use of multiple detectors allows direct detailed visualization of the pulmonary arteries. Although less than 2% of patients with negative CTPA develop symptomatic VTE during follow-up, patients with a negative CTPA and high clinical probability should undergo bilateral leg compression ultrasonography to exclude DVT.

Ventilation/Perfusion Lung Scan

The V/Q lung scan consists of a perfusion and a ventilation component. For the perfusion component, particles of isotopically labeled microaggregates of human albumin are injected intravenously and become trapped in the pulmonary capillary bed. Their distribution reflects lung blood flow and is recorded with an external photoscanner. A normal perfusion scan excludes PE, but an abnormal perfusion scan is nonspecific.

Ventilation lung scanning is performed using either radioactive gases or aerosols that are inhaled and exhaled by the patient while a gamma camera records the distribution of radioactivity within the alveolar gas exchange units. The purpose of ventilation imaging is to improve the specificity of perfusion scanning for the diagnosis of PE. A high-probability V/Q scan (in which a segmental or greater area is

ventilated but not perfused) has a positive predictive value for PE of more than 90%, obviating the need for additional testing.

The relative ease and accessibility of CT scanning has reduced the use of V/Q scanning for the diagnosis of PE. However, V/Q scanning is frequently preferred in two patient populations: young patients and those with impaired renal function. CT scanning exposes patients to a higher dose of radiation than V/Q scanning, raising concern regarding the risk of subsequent cancer. Although this risk varies depending on a number of factors, concern about increasing the risk of breast cancer in young women has prompted use of V/Q scanning preferentially in this population. In patients with impaired renal function, contrast dye administration for the CT scan can induce contrast nephropathy, increasing mortality up to 30% after such a procedure. V/Q lung scanning should ideally be reserved for patients with normal chest radiographs because preexisting lung disease may result in indeterminate scans.

Patients with large perfusion defects (involving one or more segments or more extensive defects) and a V/Q mismatch have a 90% probability of PE. Patients with a normal perfusion scan have less than a 2% probability of having PE, excluding the diagnosis. However, most patients who have V/Q scanning performed will have neither of these findings; rather, they will have either matched defects or small perfusion defects (indeterminate scan). Patients with these findings require further investigation with either pulmonary angiography or objective tests for DVT of the lower extremities. A patient with suspected PE, an indeterminate V/Q scan result, and positive findings on compression ultrasound examination of the lower extremities can be assumed to have PE. A patient with suspected PE, an indeterminate scan, and a negative result on leg compression ultrasound examination requires additional testing (e.g., serial compression ultrasound examination after 7 days) because the thrombus may have completely embolized to the lungs.

Diagnostic Strategy for Pulmonary Embolism

A diagnostic algorithm for the management of clinically suspected PE is shown in Fig. 142.2. After a history and physical examination, ECG, and chest radiography, the clinical probability of PE should be assessed using a validated clinical prediction rule. The Wells clinical prediction rule assigns a pretest clinical probability based on the presence of the following: clinical signs of DVT, recent immobilization or surgery, heart rate above 100 beats/min, previous history of VTE, hemoptysis, active malignancy, absence of alternative diagnosis.

Fig. 142.2 DIAGNOSTIC ALGORITHM FOR THE MANAGEMENT OF PATIENTS WITH SUSPECTED PULMONARY EMBOLISM. CT, Computed tomography; CUS, compression ultrasound; PE, pulmonary embolism V/Q, ventilation/perfusion.

A low clinical pretest probability combined with a normal D-dimer excludes PE. Patients with intermediate or high pretest probability should undergo further testing. A negative helical CTPA or a normal perfusion lung scan result rules out clinically significant PE, and anticoagulant therapy can be withheld. If an intraluminal filling defect is seen on helical CTPA or the perfusion scan demonstrates one or more segmental (or larger) defects and ventilation to these regions is normal, a diagnosis of PE is made. Although a V/Q mismatch supports a diagnosis of PE, a V/Q “match” does not exclude PE, and further objective testing is required in these patients. Similarly, the diagnosis of PE cannot be excluded in patients with small perfusion defects (one or more subsegmental defects) or those with indeterminate lung scan findings (in which the perfusion defects correspond with abnormalities on the chest radiograph). In these patients, venous ultrasonography should be performed. If DVT is documented, a diagnosis of PE can be assumed, and anticoagulant therapy should be started. However, if results on these tests are negative, additional objective investigations (e.g., pulmonary angiography) are required in patients with a high clinical pretest probability. For those with a lower pretest probability of PE, an alternative strategy is to withhold anticoagulants and to perform serial noninvasive tests to detect venous thrombosis.

DIAGNOSIS OF ACUTE RECURRENT VENOUS THROMBOEMBOLISM

The diagnosis of acute recurrent VTE is challenging because the clinical manifestations of recurrence are nonspecific. In addition, there are no clinical prediction rules specifically validated for patients with suspected recurrence, and diagnostic tests for acute VTE have limitations in this setting. Following treatment of acute DVT, incomplete resolution of thrombosis may be evident as chronic venous occlusion on compression ultrasound, making it difficult to identify new abnormalities. With respect to PE, the interpretation of repeat CTPA or V/Q scanning may be difficult because of thrombus migration and variable rates of clot resolution. Therefore comparison with prior imaging can facilitate diagnosis of acute recurrence. D-dimer testing has limited utility in this setting because of the high frequency of positive D-dimer results in patients with suspected recurrence.

When assessing patients for recurrence, the adequacy of anticoagulant therapy is an important consideration (e.g., nonadherence, subtherapeutic international normalized ratio [INR] measurements, temporary interruption for procedure or surgery). Recurrent thrombosis despite adequate therapeutic anticoagulation can be seen in patients with cancer or those with the antiphospholipid antibody syndrome.

Many patients with a history of VTE will have a heightened level of concern about the risk of recurrent thrombosis, prompting them to seek testing for recurrent thrombosis even with trivial symptoms. Such patients require careful clinical and radiologic evaluation. If there is no evidence of acute recurrence, they may require counseling and education about their condition.

Patients with suspected recurrence should be treated empirically with anticoagulant therapy pending investigations.

Acute Recurrent Deep Venous Thrombosis

The optimal diagnostic strategy for suspected recurrent DVT is uncertain. The clinical history may be helpful in determining the likelihood of recurrent thrombosis. Leg pain with ambulation and leg swelling that is relieved with overnight rest is typical of the post-thrombotic syndrome. New clinically significant and persistent leg swelling, particularly if the symptoms do not abate overnight, is consistent with recurrent thrombosis and should prompt diagnostic evaluation.

To establish a diagnosis of recurrent DVT, one must demonstrate a new thrombus in a previously unaffected venous segment. A normal result on ultrasound study does not rule out recurrent calf vein

thrombosis and requires that additional testing with serial ultrasonography be performed if this is suspected. If the lack of compressibility of the veins or an intraluminal filling defect with flow seen on Doppler ultrasound studies is visualized in the venous segment previously affected, these tests are not sufficiently reliable to either confirm or rule out acute thrombosis. In these cases, serial testing to detect extension may be useful. Alternately, if the patient had a follow-up ultrasound examination, comparison with previous imaging may be useful.

Acute Recurrent Pulmonary Embolism

Patients presenting with clinical symptomatology consistent with an acute recurrent PE should be assessed urgently. Empiric anticoagulant therapy should be provided if diagnostic testing is delayed. A significant proportion of patients have persistent residual defects on CTPA or V/Q scanning even up to 11 months after the acute PE. Therefore baseline imaging (e.g., at the completion of anticoagulant treatment) can facilitate diagnosis of recurrence by evaluating differences between tests. It is important to use the same imaging modality as baseline if possible because of poor agreement between CTPA and V/Q scanning for detecting residual defects. However, cost, availability, and clinical considerations (e.g., renal failure, radiation exposure, young age, pregnancy, underlying lung disease) also influence the choice of test.

Similar to the diagnosis of initial PE, recurrent PE can be diagnosed on CTPA in the presence of a new central filling defect or occlusion of segmental or more proximal branches of the pulmonary arteries.

PROPHYLAXIS OF VENOUS THROMBOEMBOLISM

PE is a common preventable cause of death in hospitalized patients. Hospitalized patients can be classified as having a low, moderate, or high risk for developing VTE. Effective prophylaxis is cost effective and is available for high-risk groups.

Low-Molecular-Weight Heparins and Fondaparinux

Low-molecular-weight heparins (LMWHs) exert their anticoagulant effect by preferentially catalyzing the inactivation of factor Xa by antithrombin. When used in prophylactic doses once or twice daily, LMWH is an effective and safe agent for VTE prophylaxis in medical and surgical patients. Anticoagulant monitoring is not required when used in prophylactic doses. It is at least as effective as standard low-dose UFH and warfarin in most patient populations.

The anticoagulant effect of LMWH is mediated by a unique pentasaccharide sequence in the heparin molecule that binds antithrombin. The pentasaccharide moiety has been synthesized chemically as fondaparinux. Extended use of fondaparinux following hip fracture surgery significantly reduces the risk of symptomatic VTE. In patients with acute coronary syndromes, fondaparinux given at prophylactic doses was associated with decreased bleeding complications compared with therapeutic doses of enoxaparin.

Low-Dose Unfractionated Heparin

Low doses of UFH prevent thrombosis by antithrombin-mediated inhibition of thrombin, factor Xa, and other serine proteases. For prophylaxis, UFH is usually given subcutaneously at a dose of 5000 units every 8–12 hours. Low-dose UFH prophylaxis does not require laboratory monitoring and is simple and convenient to administer. It is an acceptable option for moderate-risk general surgical and medical patients, and it reduces the risk of VTE by 50%–70%. When used in these doses, UFH is both highly effective and associated with only a small increase in the risk of bleeding. Although low-dose UFH is

effective in patients undergoing elective hip surgery and reduces the incidence of venous thrombosis by approximately 40%, it is less effective than other current prophylactic strategies and thus should be reserved for patients with renal failure in whom LMWH and fondaparinux are contraindicated. Low-dose UFH has not been shown to be effective in patients undergoing surgery for hip fracture or hip or knee arthroplasty. In addition, use of subcutaneous heparin may be associated with heparin-induced thrombocytopenia, particularly in the postoperative period.

Vitamin K Antagonists (Warfarin)

When administered in doses that increase the INR to 2.0–3.0, vitamin K antagonists (VKAs) effectively prevent postoperative VTE in patients in all risk categories. VKAs can be given preoperatively, at the time of surgery, or in the early postoperative period. The antithrombotic effect of VKAs is not achieved until the fourth or fifth day of administration. Nevertheless, when used in this fashion, VKAs are effective in very high-risk patient groups. Prophylaxis with VKAs is relatively inconvenient, however, because frequent INR monitoring and dose adjustments are necessary.

Direct Oral Anticoagulants for Orthopedic Thromboprophylaxis

Rivaroxaban and apixaban are oral direct factor Xa inhibitors with excellent bioavailability that have been studied in patients undergoing total knee- or hip-replacement surgery. In a pooled analysis of randomized trials, 10 mg/day of rivaroxaban was superior to enoxaparin (40 mg once daily or 30 mg every 12 hours) for prevention of symptomatic VTE and all-cause mortality with similar major bleeding rates. Apixaban is also associated with a similar risk of symptomatic VTE and major bleeding, and reduced risk of clinically relevant bleeding compared with enoxaparin. Overall, the net clinical benefit with rivaroxaban and apixaban is similar to that with enoxaparin. However, rivaroxaban and apixaban simplify extended out-of-hospital thromboprophylaxis compared with enoxaparin because they obviate the need for daily subcutaneous injections.

Although rivaroxaban and apixaban have also been evaluated for extended thromboprophylaxis in medically ill patients, the benefit-risk profile in this setting is less certain because of an increased risk of bleeding compared with shorter courses of prophylactic dose enoxaparin.

Dabigatran etexilate is an oral direct thrombin inhibitor that also has been evaluated in patients undergoing total knee- or hip-replacement surgery. Dabigatran etexilate is a prodrug that is converted to the active agent dabigatran, which binds both free and clot-bound thrombin. In large clinical trials, once-daily dabigatran (150 mg or 220 mg once daily) was noninferior to enoxaparin 40 mg once daily but was inferior when enoxaparin was dosed at 30 mg twice daily.

The efficacy and safety of oral direct factor Xa inhibitors and direct thrombin inhibitors for thromboprophylaxis following knee- or hip-replacement surgery have not been directly compared in clinical trials.

Intermittent Pneumatic Compression

Intermittent pneumatic compression of the legs enhances blood flow in the deep veins and increases systemic fibrinolytic activity. Although few methodologically rigorous studies support the effectiveness of intermittent pneumatic compression for VTE prophylaxis, this modality has few clinically important side effects and is particularly useful in patients who have a high risk of bleeding. It also is frequently used, albeit with little supporting evidence, during the operative procedure in patients undergoing extended-duration surgery and in patients after trauma. Intermittent compression is the prophylactic

measure of choice in selected patients undergoing neurosurgical procedures; however, most of these patients should eventually receive pharmacologic thromboprophylaxis as well.

Graduated Compression Stockings

Graduated compression stockings also reduce venous stasis in the legs and are effective for preventing postoperative VTE in low- and moderate-risk general surgical patients and in medical or surgical patients with neurologic disorders, including paralysis of the lower limbs. However, graduated compression stockings may increase the risk of skin ulcers when used in hospitalized patients with stroke. In surgical patients, the combination of graduated compression stockings and low-dose UFH is significantly more effective than low-dose UFH alone. Use of graduated compression stockings alone, however, constitutes inadequate prophylaxis in patients undergoing surgery associated with a very high risk of thromboembolism. Graduated compression stockings are inexpensive and should be considered for use in all high-risk surgical patients even if other forms of prophylaxis are used.

TREATMENT OF VENOUS THROMBOEMBOLISM

The goals of treatment for VTE are to prevent death from PE, reduce morbidity from the acute event, decrease the risk of postthrombotic symptoms, and prevent CTEPH. All of these goals can be achieved with adequate anticoagulant therapy. Use of thrombolytic therapy or surgical thrombectomy is reserved for patients with severe disease or severe complications.

Anticoagulant Therapy for Treatment of Acute Venous Thromboembolism

The treatment of acute VTE currently involves administration of effective doses of anticoagulants as soon as the diagnosis is confirmed (or if testing is delayed and the clinical likelihood of disease is moderate or high, before confirmation of the diagnosis). Traditionally patients with acute VTE were admitted to hospital and given intravenous UFH, to achieve a therapeutic activated partial thromboplastin time (aPTT). A VKA, typically warfarin, was then started and the heparin continued until the INR was more than 2.0 on two consecutive measurements. Although this treatment strategy remains a practice standard, the vast majority of patients with acute DVT and/or PE can be managed in the outpatient setting because of the availability of safe and effective treatment options such as direct oral anticoagulants (DOACs; dabigatran, rivaroxaban, apixaban, edoxaban), LMWH, and fondaparinux. Patients who are hemodynamically stable, lack contraindications to treatment (e.g., severe thrombocytopenia, recent bleeding, severe renal or liver disease), have manageable symptoms, and are likely to be compliant with treatment are good candidates for outpatient therapy.

Low-Molecular-Weight Heparin and Fondaparinux

Treatment with LMWH or fondaparinux involves administration of weight-adjusted, once- or twice-daily subcutaneous injections that do not require routine monitoring of anticoagulant effect. However, the anticoagulant effect can be measured using anti-factor Xa activity assays calibrated for the specific drug for selected patients with anticoagulant-related complications such as bleeding or need for urgent surgery/procedure, those at the extremes of weight (<40 kg or >100 kg), or renal insufficiency. LMWH and fondaparinux should generally be avoided in patients with significant renal impairment (creatinine clearance <30 mL/min). For LMWH, typically one would target a peak anti-Xa level of 0.5–1.0 unit/mL measured 4 hours after a subcutaneous injection of LMWH using a twice-daily

dosing schedule. LMWH and fondaparinux do not have predictable effects on the aPTT and therefore cannot be monitored using this test.

Low-Molecular-Weight Heparin is the Treatment of Choice for Venous Thromboembolism Associated With Pregnancy and Cancer

VKAs, DOACs, and fondaparinux are contraindicated in pregnancy. In patients with cancer, use of LMWH is associated with a reduced risk of VTE recurrence and bleeding compared with VKA. Further, the anticoagulant effect of VKAs can be affected by reduced oral intake and concomitant medications which can lead to suboptimal anticoagulant therapy in cancer patients receiving chemotherapy.

Unfractionated Heparin

Although increasingly less common, selected patients may be admitted to the hospital for intravenous UFH therapy. There is no evidence that UFH therapy is superior to LMWH in any clinical setting. Practical considerations include the need for reliable intravenous access, frequent blood work, and infusion adjustment. Hence, intravenous UFH is typically reserved for patients at high risk of bleeding in whom rapid anticoagulant reversal may be necessary. Patients with significant renal impairment are also treated with UFH because LMWH is eliminated by the kidneys, leading to a risk of anticoagulant accumulation. UFH therapy can be monitored using the activated clotting time, the aPTT, or by heparin assays that measure the ability of heparin to accelerate the inactivation of factor Xa. It is important to give adequate doses of UFH at initial presentation because the risk of recurrent VTE is increased if there is failure to achieve a therapeutic level of anticoagulation. Accordingly, the aPTT ratio of 1.5 to 2.5 times the control should be maintained above a level equivalent to a heparin level of 0.3 to 0.7 units/mL, as determined by measuring anti-Xa activity. For most currently used aPTT reagents, this is equivalent to an aPTT ratio of 1.8–2.5 times the control value. To monitor UFH given by continuous intravenous infusion, the aPTT should be measured 6 hours after the bolus dose so that it reflects the anticoagulant effects of the infusion. If twice-daily subcutaneous UFH is given, a mid-interval aPTT is typically measured 6 hours after the injection. UFH can also be given in fixed doses without laboratory monitoring; in a study of more than 700 VTE patients, UFH was administered using a fixed, weight-adjusted dose without aPTT monitoring. The risks of bleeding and recurrent thrombosis were similar to those in patients treated with twice-daily LMWH.

Vitamin K Antagonists (Warfarin)

Because rapid anticoagulant effect is desired in the setting of acute VTE, initiation of warfarin therapy requires concomitant administration with a parenteral agent (UFH, LMWH), which should be continued for at least 5 days and until the INR has been between 2.0 and 3.0 on 2 consecutive days. An initial dose of 5–10 mg daily for 2 days can be given to most individuals, with doses less than 5 mg reserved for elderly patients. Subsequent dosing should be based on results of INR testing. The required maintenance dose of warfarin may be influenced by age, gender, race, nutritional status, organ function, and concomitant medications, and should be determined based on the results of routine INR monitoring. Women generally require lower warfarin doses than men. The warfarin dose variability is also affected by variation in the genotypes of the cytochrome P450 CYP2C9 and the vitamin K epoxide reductase complex, VKORC1. These enzymes influence the rate of warfarin metabolism and sensitivity, respectively. Studies using warfarin genotyping to optimize warfarin dosing have yielded conflicting results, and further study along with economic evaluation is ongoing.

Warfarin has numerous drug interactions including many commonly administered medications. Noninteracting medications should be prescribed preferentially in patients receiving warfarin to avoid adverse events. When noninteracting medications are unavailable, increased frequency of INR monitoring and dose adjustments enhance safety. Warfarin is contraindicated during pregnancy, but may be used during breastfeeding.

Direct Oral Anticoagulants

DOACs that target thrombin (dabigatran) and factor Xa (rivaroxaban, apixaban, edoxaban) are available for the treatment of acute VTE. These agents do not require routine anticoagulation monitoring and have fewer interactions with food and drugs compared with warfarin. Large phase III clinical trials have demonstrated that dabigatran, rivaroxaban, apixaban, and edoxaban are noninferior to the combination of LMWH/warfarin for the treatment of acute VTE. Treatment with LMWH is given for at least 5 days before dabigatran or edoxaban. DOACs should be avoided in patients with severe renal impairment (creatinine clearance <30 mL/min) and used with caution in those with weight above 120 kg, body mass index >40 kg/m², or active malignancy because of a lack of clinical efficacy and safety data in these populations.

Duration of Treatment

The optimal duration of oral anticoagulant therapy for treatment of VTE is unknown. Patients with VTE provoked by a clear transient risk factor are generally treated for 3 months. Patients with unprovoked (idiopathic) VTE should be treated for a minimum of 3 months, with consideration of extended therapy especially for patients at low bleeding risk in whom the clinical benefit of preventing VTE recurrence outweighs the risk of bleeding. Patients with a persistent, major risk factor for recurrence (e.g., malignancy, immobility) and patients who prefer to decrease their thrombotic risk should receive anticoagulation for longer periods or indefinitely with regular reassessments of the benefits and risks of ongoing therapy. At this time, there are no absolute predictors of recurrence, but recurrence appears to be more common in male patients and those with an elevated D-dimer assay at or around the time of anticoagulant discontinuation. The relationship between residual venous obstruction on ultrasound at the completion of initial treatment and recurrence risk requires further study.

Decisions regarding extended anticoagulant therapy should incorporate counselling regarding the expected risks and benefits, and patient values and preferences. Extended treatment reduces the risk of recurrent VTE by at least 80% with a small increased risk of bleeding. When prescribing apixaban, a reduced dose (2.5 mg twice daily) is used for secondary VTE prevention after initial 6 months of anticoagulant therapy. Low-dose aspirin reduces the risk of recurrence by approximately 30%. However, it is not considered an equivalent alternative to anticoagulant therapy given the reduced efficacy and should be reserved for patients wishing to discontinue anticoagulants who have no contraindication to aspirin therapy and/or have another indication for aspirin.

Inferior Vena Cava Filter

Anticoagulants are effective in reducing mortality from PE. However, some patients have relative or absolute contraindications to anticoagulant therapy. In these cases, there may be a role for inferior vena cava (IVC) filters (see [Chapter 143](#)). IVC filters do not treat VTE but are used to prevent PE in patients with DVT who cannot receive adequate anticoagulant therapy. In patients with active bleeding or a transient risk factor for bleeding (e.g., surgery), insertion of a temporary IVC filter followed by its removal and subsequent therapeutic anticoagulation when the bleeding risk is diminished should be

considered. Although not formally evaluated in randomized trials, this strategy likely reduces the initial risk of bleeding while eliminating the long-term increased risk of DVT associated with permanent caval interruption. In contrast, patients who have a persistent major risk factor for bleeding may be considered for insertion of a permanent IVC filter because the mortality rate associated with major bleeding during therapeutic anticoagulation is approximately 20%. This procedure is associated with a significant risk of immediate worsening of leg symptoms because of blockage of the IVC by thrombus and a long-term increase in the risk of recurrent DVT.

Thrombolytic Therapy for Massive Pulmonary Embolism

Thrombolytic therapy with streptokinase, urokinase, or t-Pa is more effective than UFH alone in correcting the angiographic defects produced by PE, and may be better than UFH in preventing death in patients with massive PE associated with shock. Based on these findings, thrombolytic therapy is the treatment of choice for patients with massive PE associated with cardiovascular collapse.

Bleeding occurs more frequently with thrombolytic therapy than with UFH. The risk of hemorrhage increases with the duration of thrombolytic infusion and usually occurs at a site of previous surgery or trauma. Intracranial hemorrhage occurs in approximately 1% of patients at risk, approximately twice as frequently as with UFH treatment.

Catheter-Directed Thrombolysis for Deep Vein Thrombosis

Catheter-directed thrombolysis (CDT) involves direct injection of a thrombolytic agent through a catheter into the vein affected by DVT, which can also be combined with mechanical thrombus removal. In a small nonblinded randomized study, CDT reduced the risk of postthrombotic syndrome but not health-related quality of life after 24 months of follow-up compared with standard therapy. It has not been shown to reduce the risk of PE or mortality, and increases the risk of bleeding. At present there is insufficient high-quality evidence supporting a net clinical benefit of CDT given the bleeding risk. CDT may be considered at centers with technical expertise in CDT in consultation with a thrombosis expert for select patients presenting with recent (less than 14 days) iliofemoral DVT with severe symptoms and low bleeding risk.

Thromboendarterectomy for Pulmonary Embolism

Thromboendarterectomy is effective in selected cases of CTEPH with proximal pulmonary arterial obstruction. Urgent pulmonary embolectomy is usually reserved for patients with a saddle embolism lodged in the main pulmonary artery or for those with massive embolism whose blood pressure cannot be maintained despite thrombolytic therapy and vasopressor agents. Although this procedure can be successfully performed by experienced surgical teams, in inexperienced hands it is associated with high complication and mortality rates. Patients with repeated episodes of PE and significant chronic pulmonary hypertension with right ventricular compromise should be anticoagulated and monitored. If pulmonary pressures do not decrease, patients should be evaluated for surgical fitness. If deemed necessary, thromboendarterectomy should be carried out in centers with expertise with optimal perioperative management, within which the likelihood of success of the procedure is high.

VENOUS THROMBOSIS IN PREGNANCY

The risk of VTE is increased during pregnancy and the postpartum period. DVT is more common than PE and affects the left leg in

greater than 80% of cases. Clinical prediction rules such as the Wells score and the use of D-dimer testing have not been validated in this setting. A high index of suspicion should be maintained in pregnant women presenting with signs or symptoms of VTE.

Pregnant women with suspected DVT should undergo proximal compression ultrasonography. However, standard compression ultrasound techniques are less sensitive for pelvic and iliac vein thromboses, which are more common in pregnancy. Pregnant women with suspected DVT and negative proximal compression ultrasound should undergo serial compression ultrasounds at 3 and 7 days. Anticoagulants can be safely withheld in patients with negative serial compression ultrasounds.

Pregnant women with suspected PE should undergo chest radiography with shielding of the abdomen to exclude alternative causes of presenting symptoms. Bilateral proximal compression ultrasounds should be done to assess for concurrent DVT in women with clinical suspicion of DVT which, if positive, would obviate the need for CTPA or V/Q scanning. Because of the low prevalence of coexistent DVT in pregnant women with suspected PE, routine compression ultrasonography in the absence of DVT symptoms may lead to delays in definitive diagnosis and treatment of PE. V/Q scanning is preferred over CTPA for diagnosis of PE in pregnancy because of reduced maternal exposure and similar fetal exposure to radiation.

Weight-adjusted LMWH is the treatment of choice for pregnancy-associated VTE. Although warfarin use during the first trimester is associated with teratogenicity, it is safe during breastfeeding. DOACs and fondaparinux, however, should be avoided during both pregnancy and breastfeeding. The duration of anticoagulant treatment for pregnancy-associated VTE is a minimum of 3 months, including the 6-week postpartum period.

CANCER-ASSOCIATED VENOUS THROMBOSIS

VTE occurs in up to 20% of patients with cancer and confers an increased risk of death, VTE recurrence, and bleeding. LMWH is the recommended treatment for acute cancer-associated VTE based on clinical data showing reduced risk of VTE recurrence with no increased risk of bleeding compared with VKA therapy. Anticoagulant treatment should be given for at least 3 months, with consideration of prolonged therapy for patients receiving ongoing cancer treatment or those with metastatic disease and who are not at high risk of bleeding.

Postoperative VTE prophylaxis with LMWH or low-dose UFH should be provided for cancer patients undergoing surgery. Extended-duration prophylaxis (4 weeks) can be considered for cancer patients at high risk for VTE and low risk for bleeding who are undergoing abdominal or pelvic surgery for cancer. Hospitalized cancer patients with reduced mobility should receive VTE prophylaxis with LMWH or low-dose UFH. In the outpatient setting, pharmacologic VTE prophylaxis is generally reserved for cancer patients with additional risk factors for VTE such as previous VTE, immobilization, or hormonal therapy treatment with angiogenesis inhibitors (thalidomide and lenalidomide).

MECHANICAL INTERVENTIONS IN ARTERIAL AND VENOUS THROMBOSIS

Steven Sauk and Suresh Vedantham

Arterial and venous thromboses are common medical conditions that are associated with significant morbidity. Patients who suffer from acute occlusions of the peripheral arteries may present with ischemic extremities, culminating in limb loss or death if left untreated. Those who suffer from venous thrombosis are not only at significant risk for recurrent thrombotic episodes and pulmonary embolism (PE), but are also at risk for the postthrombotic syndrome (PTS), which can cause significant impairment of their long-term quality of life (QOL).

For many patients with symptomatic arterial or venous occlusions, surgical therapies are required in addition to standard medical treatments to provide optimal patient outcomes. Spurred by advances in vascular imaging and catheter/device technology, and driven by the clinical needs of the large number of vascular patients with concomitant comorbidities, many patients are now referred for nonsurgical, imaging-guided endovascular interventions to eliminate thrombi and to treat associated vascular lesions. In this chapter, we discuss the use of catheter-based interventions in the management of arterial and venous thromboses.

OVERVIEW OF CATHETER-BASED THROMBOLYTIC INTERVENTIONS

Systemic thrombolysis, which refers to the dissolution of thrombus via the administration of a fibrinolytic drug into an intravenous line distant from the affected site, can be a valuable treatment option for acute myocardial infarction (MI), massive PE, and acute ischemic stroke. A primary advantage of the systemic administration route is the ability to rapidly initiate therapy in almost any clinical setting, without the need for specialized technical expertise or hospital resources. However, only a fraction of systemically administered drug reaches the target vessel. This problem is compounded when there is complete occlusion of blood flow in the target vessel such that access of the fibrinolytic drug to the interior of the thrombus is precluded. For acute MI and stroke, this limitation is overcome by the use of relatively high concentrations of fibrinolytic drugs (e.g., 50–100 mg of recombinant tissue plasminogen activator [rt-PA]) and the ability of arterial pulsations to force sufficient amounts of the drug into the fresh thrombus that occludes a small (2–4 mm) coronary or cerebral artery to effect fibrinolysis. However, with these high doses of fibrinolytic drugs, there is a small but significantly increased risk of major bleeding, a price that physicians are willing to pay given the potentially fatal consequences of ongoing vascular occlusion in these critical sites.

For occlusions in the peripheral arteries and veins, however, systemic fibrinolysis is not sufficiently effective to justify the attendant risks, presumably because of the larger vessel size, greater thrombus burden, and the presence of mature thrombus that is less susceptible to dissolution. For these reasons, catheter-directed fibrinolysis and mechanical methods for thrombus extraction and dissolution have been developed.

Catheter-Directed Intrathrombus Thrombolysis

Catheter-directed intrathrombus thrombolysis (CDT) refers to the infusion of a fibrinolytic drug directly into the thrombosed vessel via a catheter that has been inserted into that vessel using imaging guidance. The rationale for CDT is to improve the efficacy of thrombus dissolution by achieving a higher intrathrombus concentration of fibrinolytic drug, and to reduce the risk of hemorrhage by enabling the use of lower total fibrinolytic drug doses than those required for systemic fibrinolysis. Although several catheters and devices have been approved by the US Food and Drug Administration (FDA) for this purpose, none of the currently available fibrinolytic drugs is FDA approved for the specific indication of peripheral arterial or venous thrombosis.

Although the procedural details are beyond the scope of this chapter, the principles of CDT are reviewed here¹ (Fig. 143.1). First, a vascular access site is selected based upon the thrombus location and extent, and needle access into the vessel is obtained. With ultrasound-guided venipuncture, access site bleeding is rare. Under fluoroscopic guidance, the needle is exchanged over a guidewire for an angiographic catheter and iodinated contrast is injected to delineate the location, extent, and morphology of the thrombus and the status of other relevant vessels in the limb. The angiographic catheter is then exchanged for a specially designed infusion catheter with multiple side holes (akin to a soaking garden hose) that is positioned such that the side holes are embedded within the thrombus-containing vascular segment. Fibrinolytic drug is then infused. The drugs and doses commonly used for this purpose include rt-PA (0.01 mg/kg/hour up to 1.0 mg/hour), and rt-PA variants such as reteplase (0.25–0.75 units/hour), and tenecteplase (0.25–0.50 mg/hour).^{1,2} The procedure is done under conscious sedation and with local anesthesia, and the heart rate, blood pressure, and oxygen saturation are continuously monitored.

Patients are then transferred to an observation unit, usually an intensive care or step-down unit, for monitoring during the fibrinolytic drug infusion. Typically a concomitant infusion of unfractionated heparin at subtherapeutic doses is administered and the hemoglobin, activated partial thromboplastin time (aPTT), and in some centers, the fibrinogen level are measured every 6–8 hours while the fibrinolytic drug is given. Patients are monitored closely for evidence of bleeding and for changes in limb status, and the drug infusion rate is adjusted (or stopped entirely) as necessary. After 6–18 hours, patients return to the procedure room for a follow-up venogram or angiogram to assess the extent of thrombus dissolution. The infusion catheter may be repositioned and the infusion continued if there is residual thrombus. Once thrombolysis is nearly complete, the fibrinolytic drug infusion is stopped and, based on the results of the venogram or angiogram, a decision is made as to whether adjunctive treatment with balloon angioplasty or stent placement is needed—if so, this is performed, usually through the same vascular access site during the same procedure session. The catheter and sheath are then removed and systemic anticoagulation at fully therapeutic levels is reinstituted. The treated limb is closely monitored for improvement in pain, perfusion abnormalities (arterial), and/or swelling (venous).

Fig. 143.1 A 67-YEAR-OLD MAN WITH A CHRONIC LEFT ILIAC ARTERY OCCLUSION AND A RIGHT-TO-LEFT FEMORAL-FEMORAL ARTERIAL BYPASS PRESENTS WITH LEFT FOOT PAIN AND PULSELESSNESS. (A) Digital subtraction arteriography reveals patency of the right iliac artery but only a “stump” of the bypass graft is seen, consistent with graft thrombosis. (B) The lowermost aspect of the right common femoral artery was accessed and a multi-side-hole infusion catheter was positioned across the occluded graft. The radiopaque markers show the infusion zone. An infusion of recombinant tissue plasminogen activator was given at 0.5 mg/hour through this catheter. The patient received heparin (500 units/hour) through a peripheral intravenous catheter. (C) After 16 hours of thrombolysis, a repeat arteriogram reveals successful thrombus removal with residual tight focal stenosis at the proximal graft anastomosis. (D) The stenosis was subjected to angioplasty using a 6-mm balloon. (E) Repeat arteriogram shows improvement in the stenosis, but small thrombi are evident within the graft. (F) After use of the AngioJet Rheolytic Thrombectomy System to aspirate residual thrombus, the graft is widely patent. Subsequent physical examination revealed good pedal pulses and capillary refill, consistent with successful reperfusion of the limb.

Although there have been few changes to the basic CDT technique over the past 25 years, there has been a switch from biologically derived fibrinolytic drugs (streptokinase and urokinase) to recombinant drugs that are less allergenic and have greater affinity for fibrin. In addition to the standard multi-side-hole infusion catheter, a specialized multi-side-hole infusion catheter (the Ekosonic Mach 4e catheter, EKOS Corporation, WA, USA) that emits low-power ultrasound energy to ostensibly loosen fibrin strands and permit more rapid intrathrombus drug dispersion is available. Although this catheter also permits successful thrombolysis to be obtained, conclusive evidence that the addition of ultrasound energy improves patient outcomes is lacking.^{3,4}

Variation on a Theme: Percutaneous Mechanical Thrombectomy

Hemorrhagic complications are the Achilles' heel of currently available thrombolytic agents. To reduce exposure to these drugs,

specialized catheters, known as *percutaneous mechanical thrombectomy (PMT) devices*, have been developed. PMT is defined as the use of a percutaneous catheter-based device that contributes to thrombus removal via thrombus fragmentation, maceration, and/or aspiration. Although originally developed to supplant thrombolytic drugs, until recently, none of the available PMT devices has enabled safe, successful clot removal when used as a stand-alone treatment.¹ Consequently, fibrinolytic drugs are used in conjunction with PMT, except in situations where there are absolute contraindications to the use of fibrinolytic drugs and no other treatment options are available.

Recently a new thrombectomy device (AngioVac, Angiodynamics) was introduced into some clinical practices.⁵ This device, which relies upon creation of a bypass circuit to enable more robust suction thrombectomy, may provide greater thromboaspiration capability than previous devices. However, the device is somewhat inflexible and requires placement of two large access sheaths into the venous system. Given the lack of prospective data on its use, at present this device may be best targeted to urgent clinical problems for which there is no other solution (e.g., large thrombus in the suprarenal inferior vena

Fig. 143.2 A 35-YEAR-OLD MAN PRESENTS WITH A 3-DAY HISTORY OF SEVERE LEFT LOWER EXTREMITY PAIN AND SWELLING. (A) Digital subtraction venogram from a left popliteal vein approach shows patency of the lower part of the femoral vein with a short segment of duplication; a normal variant. (B) The left common femoral and iliac veins have large globular filling defects, consistent with acute iliofemoral deep vein thrombosis. (C) The Trellis device was used to deliver and disperse 10 mg of recombinant tissue plasminogen activator into the thrombus. After balloon maceration of the thrombus and subsequent placement of two 12-mm stents to treat stenosis of the left common iliac vein, the left common femoral vein and iliac vein are seen to be widely patent. The pain and swelling resolved within a few days.

cava [IVC] or right atrium in patients with contraindications to use of fibrinolytic drugs).

Variations on a Theme: Pharmacomechanical Catheter-Directed Thrombolysis

Pharmacomechanical catheter-directed thrombolysis (PCDT) refers to thrombus dissolution via the combined use of CDT and PMT devices. The rationale for utilizing both modalities is twofold: (1) fibrinolytic drugs given via CDT soften the thrombus, rendering it more susceptible to mechanical fragmentation and removal with PMT, while also dissolving thrombus fragments that may otherwise embolize; and (2) PMT devices macerate the thrombus, enhance dispersion of the fibrinolytic drug, and accelerate pharmacologic thrombolysis. Although a broad range of PCDT techniques have been used, they largely fall into two general categories. First, “first-generation” PCDT techniques incorporate PMT devices to assist traditional CDT; either a PMT device is initially used to de-bulk thrombus before starting the CDT infusion, or a PMT device is used after CDT to aspirate and/or macerate residual thrombus. Second, “single-session” PCDT techniques utilize PMT devices that can rapidly disperse the thrombolytic drug within the thrombus to enable the entire clot-removal treatment to be completed in a single on-table procedure session, thereby obviating the need for an overnight thrombolytic infusion with the required monitoring in an intensive-care unit.

Single-session PCDT techniques have attracted considerable interest. Two devices can be used for single-session PCDT. The AngioJet Rheolytic Thrombectomy System (Possis Medical, MN, USA) uses high-velocity saline jets to fracture the thrombus through a combination of rapid fluid streaming and hydrodynamic forces. Based on the Bernoulli principle of low pressure, these jets create a localized negative-pressure zone at the catheter tip, enabling clot

aspiration. With the Powerpulse PCDT technique, the AngioJet is first used to deliver a thrombolytic drug into the thrombus via a powerful pulse-spray injection.⁶ After a 20–30-minute dwell time, the AngioJet is then used to aspirate and remove the softened thrombus. The Isolated Thrombolysis technique refers to the use of the Trellis Peripheral Infusion System (Bacchus Vascular, CA, USA) to provide single-session PCDT⁷ (Fig. 143.2). The Trellis device is composed of a multilumen catheter with two balloons that, when inflated, effectively isolate a thrombus-containing treatment zone from the remainder of the venous circulation. After the device is advanced across the venous thrombus, the occluding balloons are inflated and a thrombolytic drug is injected into the thrombus via side holes in the catheter. A sinusoidal wire within the catheter oscillates to disperse the drug within the thrombus, after which liquefied thrombotic debris can be aspirated through a port in the catheter. Both single-session PCDT techniques feature rapid intrathrombus drug dispersion that promotes faster thrombolysis, thereby reduced patient exposure to the fibrinolytic drug. Because the mechanical manipulation can induce thrombus fragmentation and embolization, these methods are best suited for venous applications.

Mechanical Interventions in Peripheral Arterial Occlusion

Acute peripheral arterial occlusion (PAO) is associated with high rates of morbidity and mortality. It is usually caused by atherosclerotic disease but can also arise from other etiologies (i.e., dissection, intimal hyperplasia, in situ thrombosis secondary to a hypercoagulable state, trauma, vasculitis, or aneurysm thrombosis). Up to 15%–20% of patients with chronic peripheral artery disease will develop acute exacerbation of symptoms (acute limb ischemia), usually due to thrombosis of the involved artery, and are at high risk of limb loss. Even with treatment, the 30-day mortality rate of acute arterial

TABLE 143.1 Clinical Outcomes in Patients With Acute or Chronic Limb Ischemia Treated by Catheter-Directed Thrombolysis or Surgery in the STILE Trial

	Acute Ischemia (≤ 14 days), $n = 112$			Chronic Ischemia (>14 days), $n = 266$		
	Surgery (%)	Lysis (%)	<i>p</i> -Value	Surgery (%)	Lysis (%)	<i>p</i> -Value
Death	10.0	5.6	0.45	7.9	6.9	0.81
Amputation	30.0	11.1	0.02	3.0	12.1	0.01
Death + amputation	37.5	15.3	0.01	9.9	17.8	0.08

thrombosis is approximately 15% and the amputation rate ranges from 10% to 30%.⁸ In one study, the time from diagnosis to treatment correlated with amputation rates: 6% if thrombolytic therapy was started within 12 hours of symptom onset, 12% if started within 13–24 hours, and 20% if started after 24 hours.⁹

Rationale, Benefits, and Risks of CDT for PAO

The traditional treatment for acute limb ischemia is open surgery. However, the emergent nature of these procedures and the characteristics of the affected patient population, which tends to have high rates of concomitant coronary and cerebrovascular disease, have contributed to significant rates of perioperative complications and death. By dissolving platelet–fibrin aggregates in the microcirculation and thrombi in collateral vessels, CDT allows rapid but gradual reperfusion of the distal limb, thereby minimizing the risk of reperfusion complications and compartment syndrome.⁷ CDT enables both rapid restoration of arterial blood flow to the ischemic limb and unmasking of arterial stenotic or occlusive lesions that require treatment. Because many such lesions can be treated with endovascular techniques, such as balloon angioplasty or stent placement, CDT allows many patients to avoid the risks and inconveniences of open surgery. When surgery is required, a more limited procedure can often be performed on an elective basis in a well-prepared patient, with reduced rates of complications and death.

The major complication of CDT is bleeding.¹⁰ In the setting of PAO, the incidence of CDT-related hemorrhagic stroke is approximately 1%. The rate of major hemorrhage, defined by hypotension, need for surgical therapy, or need for blood transfusion, is approximately 5%, with minor hemorrhage (e.g., local hematoma) occurring in 15% of patients. In modern practice, the use of subtherapeutic doses of heparin during thrombolysis may help to minimize bleeding complications.¹¹ Distal embolization of thrombus fragments occurs in about 5% of cases; most of these resolve with continued lytic therapy. However, worsening ischemia can occur and generally requires percutaneous thrombus aspiration or operative intervention if the condition does not improve with thrombolysis within a few hours. Compartment syndrome, a complication that results from rapid reperfusion of the ischemic limb, occurs in 2% of patients. Death occurs in less than 1% of patients, usually in the setting of intracranial or abdominal hemorrhage, or reperfusion syndrome. Complications of CDT, which usually are minor, can also be related to intraarterial catheter insertion. Catheter-related trauma, resulting in mural dissection, puncture site pseudoaneurysm, and/or major hematoma occurs in 1%–2% of patients.

Randomized Trials: CDT Versus Surgery for Arterial Thrombosis

Three randomized controlled trials compared clinical outcomes in patients with acute PAO who were randomized to receive either CDT or surgical intervention.

The Rochester trial randomized 114 patients presenting with acute limb ischemia to catheter-directed urokinase infusion or surgery.¹² While there was no difference in limb salvage rates at 1 year, mortality at 1 year was significantly lower with urokinase than

with surgery. However, there was more bleeding with CDT than with surgery.

The Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE) trial included 393 patients who either underwent CDT with urokinase or rt-PA, or surgery.¹³ In patients with acute ischemia, CDT was associated with significantly fewer amputations, increased amputation-free survival at 1 year, and a shorter hospital stay. However, in those with chronic ischemia, surgery was associated with fewer amputations and improved amputation-free survival (Table 143.1). In a subgroup analysis, the patients with acute bypass graft occlusions had a significantly lower rate of amputations compared with those patients who underwent surgery. These data suggest that patients with acute bypass occlusion may derive the greatest benefit from CDT.

The Thrombolysis or Peripheral Arterial Surgery (TOPAS) trial randomized 544 patients with acute limb ischemia to CDT with recombinant urokinase or to surgery.¹¹ There was no difference in amputation-free survival at 1 year. However, CDT was associated with more bleeding complications, including a 1.6% rate of intracranial hemorrhage.

In summary, the results of these three trials suggest that CDT reduces the need for amputation and surgical intervention in patients with acute limb ischemia, particularly those with acute bypass graft occlusion. However, the risk of bleeding is higher with CDT than with surgery. Although outcomes in patients with acute limb ischemia are better with CDT, surgery is recommended for those with chronic ischemia. Because revascularization of nonviable limbs can precipitate a reperfusion syndrome associated with release of potassium, myoglobin, and other toxic elements from the nonviable limb, which can lead to multiorgan damage and death, patients with nonviable limbs (Rutherford class III) generally require primary amputation.

PMT, PCDT, and Ultrasound-Assisted CDT for Arterial Thrombosis

There is a paucity of data concerning the relative effectiveness and safety of newer thrombolytic techniques for PAO. The AngioJet device is FDA approved for peripheral arterial thrombus removal and is routinely utilized as an adjunct to CDT. There are limited data related to the safety and efficacy of the AngioJet, Trellis, and Ekosonic devices for the treatment of PAO. Aside from bleeding, the major complications associated with PMT and PCDT are distal embolization and local vascular injury (i.e., dissection or rupture). Although there are no randomized PAO trials comparing ultrasound-accelerated CDT with standard CDT, preliminary data from several studies suggest that ultrasound-accelerated CDT significantly reduces treatment time without increasing the rate of serious adverse events when compared with CDT alone.^{5,14}

A multicenter registry of 99 patients treated with AngioJet reported substantial or complete revascularization (defined as $<50\%$ residual defect) in 70% of patients and in-hospital and 30-day mortality rates of less than 5%.¹⁵ Another study documents higher amputation-free success rates associated with initial endovascular PCDT procedures, with low repeat intervention rates.¹⁶ However, these studies are limited by methodological deficiencies including lack of randomization. Studies using the Trellis device are limited and only case reports have described its use for acute limb ischemia; given

TABLE 143.2**Rutherford Classification of Acute Limb Ischemia**

Category	Description/Prognosis	Clinical Examination		Doppler Signal	
		Sensory Loss	Muscle Weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
IIa. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	(Often) audible	Audible
IIb. Immediately	Salvageable with immediate revascularization	More than toes, associated with rest pain	Mild, Moderate	(Usually) audible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound, anesthetic	Profound, paralysis (rigor)	Inaudible	Inaudible

TABLE 143.3**Contraindications to Thrombolytic Therapy****Absolute Contraindications**

Active bleeding
 History of stroke within the previous 3 months
 Neurosurgery (intracranial, spinal) within the previous 3 months
 Intracranial trauma within the previous 3 months

Relative Contraindications

Recent (<7–10 days) major surgery, trauma, CPR, obstetrical delivery, or cataract surgery
 Recent (<7–10 days) major invasive procedure or puncture of uncompressible vessel
 Recent (<3 months) internal eye surgery or hemorrhagic retinopathy
 Acute gastroduodenal ulcer or recent (<7–10 days) gastrointestinal bleeding
 Intracranial neoplasm, arteriovenous malformation, aneurysm, or other lesion
 Uncontrolled hypertension (systolic >180 mmHg or diastolic >110 mmHg)
 Hepatic failure, particularly in cases with coagulopathy
 Bacterial endocarditis or septic thrombophlebitis
 Pregnancy
 Severe anemia or thrombocytopenia

the potential for thrombus fragmentation and embolization, this technique does not appear to be well suited for management of arterial occlusions.¹⁷

Summary: Indications and Contraindications for Thrombolytic Therapy in PAO

The use of arterial CDT should be individualized. Reasonable candidates include those with (1) acute (<14 days) thrombosis of a previously patent bypass graft or native artery; (2) acute embolus in a vessel not readily accessible to surgical embolectomy; (3) acute thrombosis of a popliteal artery aneurysm resulting in severe ischemia when all distal run-off vessels are also thrombosed; and (4) acute arterial thromboembolic occlusions in patients who are poor surgical candidates. The clinical status of PAO patients should be classified using the Rutherford scheme (Table 143.2). Patients with Rutherford class I, class IIa, and in specific cases class IIb disease are potential candidates for CDT. Patients with category III ischemia should not be treated percutaneously because catheter-based thrombolysis often takes many hours and ischemic changes may become irreversible over the course of treatment. In patients with irreversible limb ischemia, mild-to-moderate ischemia with claudication, early postoperative bypass graft thrombosis, or large-vessel thrombi that are easily accessible by surgery, open surgery is preferred over CDT. Absolute and relative contraindications to CDT are outlined in Table 143.3.

Mechanical Interventions in Deep Vein Thrombosis

Venous thromboembolism (VTE) occurs in 350,000–600,000 persons per year in the United States alone, of which more than 250,000 cases represent a first-episode of deep vein thrombosis (DVT). The management of DVT has traditionally been anchored in a longstanding view of the disease as an “acute” condition involving an initial period of high risk of PE (which is estimated to kill over 100,000 persons in the United States each year), followed by a steadily diminishing risk over time that ultimately permits discontinuation of anticoagulant therapy in most patients. In recent years, there is better appreciation of the long-term impact of DVT in terms of the risk of recurrence, particularly in those with unprovoked VTE, and the high incidence of PTS in patients with extensive DVT.

Anticoagulation is the mainstay of initial DVT therapy. During the last few years, the number of anticoagulant options for DVT therapy has increased substantially. Historically, initial anticoagulation has consisted of administration of a parenteral anticoagulant drug (unfractionated heparin, low-molecular-weight heparin [LMWH], or fondaparinux) with subsequent transition to long-term oral vitamin K antagonist therapy for at least 3 months, with the duration of therapy dependent on the presence or absence of ongoing risk factors for recurrence.¹⁸ The preferred initial approach for most patients with cancer-related DVT has been LMWH monotherapy for at least 3–6 months. These longstanding treatment options are now supplemented by the availability of an oral direct thrombin inhibitor (dabigatran) and three oral direct factor Xa inhibitors (rivaroxaban, apixaban, and edoxaban).¹⁹

The therapeutic goals of anticoagulant therapy are to prevent symptomatic and fatal PE, thrombus progression, and late recurrent DVT. All of the currently available anticoagulants are effective in achieving these goals in most patients. In general, during the first year after discontinuation of anticoagulant therapy, recurrent VTE events occur in 3%–5% of patients whose DVT episode was provoked by a major reversible risk factor and in 10%–15% of patients with unprovoked/idiopathic DVT or cancer-related DVT.

Rationale, Benefits, and Risks of CDT for DVT:

PTS develops in 20%–50% of patients after a first episode of lower extremity DVT.²⁰ The symptoms and signs of PTS include chronic aching, swelling, fatigue, heaviness, edema, hyperpigmentation, and/or subcutaneous fibrosis in the affected limb. In severe cases, patients may experience short-distance venous claudication and venous leg ulcers, both of which limit ambulation and the ability to work and perform the activities of daily living. Consequently PTS reduces health-related QOL. In fact, in a recent large prospective cohort study, the presence and severity of PTS were the leading determinants of QOL 2 years after an initial lower extremity DVT.²¹ PTS also occurs with moderate frequency in patients with upper-extremity DVT, particularly those who present with axillosubclavian vein involvement in the dominant arm. The management of PTS results

in major economic costs to patients and society because of the direct medical costs of caring for its clinical sequelae (e.g., venous ulcers) and the indirect costs of work disability.

The pathogenesis of PTS is complex and incompletely understood. Inflammatory mediators, growth factors, extracellular matrix components, blood-borne elements, and endothelial cell factors contribute to the inflammatory response to DVT, which influences thrombus resolution, organization, and subsequent venous wall injury. Even with anticoagulant therapy, incomplete clearance of thrombus is common, and residual thrombus often blocks venous blood flow. In addition, venous valves may be damaged, resulting in valvular reflux. The combination of valvular reflux and obstruction causes ambulatory venous hypertension, which leads to edema, tissue hypoxia and injury, progressive calf pump dysfunction, subcutaneous fibrosis, and skin ulceration. Therefore, it is logical to postulate that rapid thrombus elimination and restoration of deep venous flow may prevent these untoward physiologic effects and preserve long-term venous function.

In support of this “open vein hypothesis” are studies that have observed a strong correlation between the amount of residual thrombus after a course of anticoagulant therapy and the subsequent incidence of recurrent venous thromboembolism. Moreover, data from a number of small randomized trials suggest that systemic thrombolysis and contemporary surgical venous thrombectomy are associated with improved long-term venous patency, preservation of venous valvular function, and reduced PTS compared with anticoagulation alone. However, these studies are small and all have methodologic limitations. For patients with DVT, CDT is performed using the same procedures as those used for arterial thrombolysis. Ultrasound-guided access to an extremity vein, usually the popliteal vein for the lower extremity, is obtained.¹ A venogram is performed and the CDT or PCDT methods described previously are used to remove the thrombus. After clot lysis, venography is performed to evaluate the underlying vein. Any residual stenosis is then treated with angioplasty or stenting. In general, the use of stents after DVT thrombolysis is optimally limited to the iliac vein, although it is sometimes necessary to extend contiguous stents into the common femoral vein. Patients with femoral vein stenosis, or isolated common femoral vein lesions that do not extend into the iliac vein, are best treated with angioplasty. Axillosubclavian vein thrombosis of known cause (e.g., previous central venous catheter) is amenable to balloon angioplasty if there is underlying stenosis. In patients with primary axillosubclavian vein thrombosis (“effort thrombosis”), stenosis of the subclavian vein is typically identified and is best treated with surgical thoracic outlet decompression rather than aggressive balloon angioplasty or stenting. With rare exceptions, stent placement in the subclavian vein is contraindicated because of the high frequency of stent fractures.

In a historic 473-patient multicenter registry, the use of CDT resulted in successful clot lysis in more than 80% of patients with acute proximal DVT.²² However, major bleeding was observed in 11.4% of patients, mostly access site bleeding. Intracranial bleeding was observed in 0.4% of patients and fatal PE occurred in 0.2% of patients.

In 2012, the first rigorously designed multicenter randomized controlled trial was published describing long-term outcomes with adjunctive CDT.²³ In this Norwegian study, 209 patients with acute iliac or femoral DVT were randomized to receive standard anticoagulant therapy with or without the addition of infusion-only CDT. This study demonstrated a 26% relative risk reduction (55.6% vs. 41.1%, $p = 0.04$) in the occurrence of PTS over 2 years of follow-up. Major bleeding occurred in 3% of patients, resulting in one blood transfusion and one surgical intervention. There were no intracranial bleeds. Adjunctive CDT was associated with a small QOL benefit and reduced job absenteeism over the first 6 months of follow-up; however, QOL was not different at 24 months follow-up. Overall, these findings suggest that endovascular thrombolysis may indeed improve long-term outcomes, but they are not entirely clear as to whether the degree of benefit is likely to be sufficient to justify the attendant risks and costs in large populations of DVT patients.

Limitations of this study are its modest sample size, geographical limitation to four treatment centers in Southern Norway, and possibly reduced relevance to clinical practice in the United States and other countries due to the lack of use of thrombectomy devices and limited use of stents.

Contemporary methods of PCDT have been integrated into pivotal multicenter randomized trials, including the ongoing National Institutes of Health–sponsored Acute Venous Thrombosis: Thrombus Removal with Adjunctive Catheter-Directed Thrombolysis (ATTRACT) trial, which completed patient enrollment in December 2014.²⁴ Patient follow-up is ongoing and the results should be available soon.

Acute Iliofemoral DVT as a High-Risk Condition

It is important for physicians to recognize the range of clinical presentations of proximal DVT. The extent of thrombosis is an important predictor of clinical course and long-term outcome with anticoagulant therapy. In particular, with femoral vein thrombosis, the primary collateral route by which blood leaves the limb (and by which the venous obstruction is decompressed) is via the deep (profunda) femoral vein, which empties into the common femoral vein in the groin. Consequently, thrombosis above the entry point of the deep femoral vein (i.e., in or above the common femoral vein) causes more severe outflow obstruction, which often results in more leg swelling and pain, and a higher incidence of late clinical sequelae.

Iliofemoral DVT is defined as DVT involving the iliac vein and/or common femoral vein, with or without involvement of other lower extremity veins.¹ Although physicians typically classify DVT as either distal or proximal because the risk of PE is higher with proximal DVT, patients with iliofemoral DVT have poorer clinical outcomes than patients with less extensive proximal DVT. Involvement of the common femoral vein and/or iliac vein portends a much higher risk of recurrent VTE and more severe PTS than those with less extensive DVT.²⁰ Hence, it is important to view iliofemoral DVT as a high-risk condition and to ensure the utilization of evidence-based PTS prevention measures, especially therapeutic anticoagulation of appropriate intensity and duration. These patients are readily identified because they usually present with swelling of the entire limb and most have compression ultrasound evidence of thrombus in the common femoral vein.

Patients with acute (symptom duration ≤ 14 days) iliofemoral DVT who are not at increased risk for bleeding are the best candidates for CDT and PCDT.^{1,18,25} There are no well-designed prospective studies of CDT for treatment of upper-extremity DVT; generally, such treatment is restricted to symptomatic patients with axillosubclavian vein thrombosis of recent onset, often in the context of a combined interventional-surgical strategy (i.e., for Paget-Schroetter syndrome).

Summary: Indications and Contraindications for CDT in DVT

The lack of data to establish the utility and proper indications for CDT in DVT patients does not absolve physicians of their responsibility to ensure that the long-term risks of PTS are carefully considered when crafting an individualized treatment strategy for DVT patients. The strategy should incorporate a high degree of confidence in anticoagulation drugs; a familiarity with the available (albeit imperfect) data that suggest that CDT is reasonable for selected DVT patients; and an individualized assessment of the clinical DVT severity, extent of thrombosis, comorbidities, and personal preferences of the patient.

Patients who do not meet a clinical threshold justifying the use of CDT include those with asymptomatic DVT or DVT isolated to the calf (because the risk of PTS is relatively low in these groups), and patients with chronic femoropopliteal DVT (because studies have

shown that organized thrombus is not susceptible to thrombolytic drugs).²²

The most important safety factor to consider in a patient being evaluated for DVT thrombolysis is the risk of major bleeding. Factors associated with an increased risk of bleeding include ongoing or recent bleeding; recent major surgery, trauma, pregnancy, obstetrical delivery, or cardiopulmonary resuscitation; or the presence of lesions in critical areas such as the central nervous system, which may bleed. Because CDT involves the administration of iodinated contrast material for venography, renal function is also an important consideration as are life expectancy, baseline ambulatory capacity, and comorbidities.^{1,25} Patients with limited long-term mobility or those with a life expectancy of less than 6 months are unlikely to benefit from aggressive therapy to prevent PTS. Comorbidities that increase procedure risks, such as respiratory compromise that limits the use of sedation, may also render CDT less attractive.

Urgent endovascular thrombolysis is indicated to prevent life-, limb-, or organ-threatening complications of acute DVT in situations such as phlegmasia cerulea dolens or extensive IVC thrombosis (especially with suprarenal extension, which may lead to fatal PE or acute renal failure). The use of endovascular thrombolysis in these situations is justifiable when other treatment options are lacking. In contrast, there is significant uncertainty regarding the appropriate indications for nonurgent CDT for the treatment of DVT. At present, guidelines of the American Heart Association (2011), Society of Interventional Radiology (2014), American Venous Forum and Society for Vascular Surgery (2012), and the United Kingdom's National Institute of Clinical Excellence (2012) suggest the use of CDT/PCDT as an adjunct to anticoagulant therapy for carefully selected patients with major symptomatic axillosubclavian DVT or

extensive proximal lower extremity DVT, such as those with acute iliofemoral DVT, who have a low risk of bleeding and a long life-expectancy.^{1,25–27} However, the 2016 guidelines update from the American College of Chest Physicians recommends against the routine use of CDT, with the caveat that patients who attach a high value to PTS prevention relative to bleeding risks and procedural inconvenience may choose CDT.¹⁸

Treatment of Established PTS

Patients with established PTS suffer major symptoms that significantly impair their ability to conduct their daily activities and to enjoy a normal QOL. Unfortunately once PTS has developed, there are no treatments that have consistently been shown to be effective. Despite limited evidence of benefit, elastic compression stockings are often utilized because of their low risk and ready availability. Low-dose diuretics may be useful to reduce edema. Patients with venous ulcers can be given pentoxifylline, dedicated wound care with topical antibiotics, exfoliants, and growth factors, and multilayer compression bandaging.²⁸ Despite these measures, PTS symptoms and venous ulcers often resist improvement and cause long-term hardships.

Because the severity of PTS symptoms often parallels the degree of ambulatory venous hypertension, endovascular interventions that eliminate venous obstruction and valvular reflux have been used for treatment of patients with severe PTS. Studies suggest that stent recanalization of chronically occluded iliac veins in patients with advanced PTS can be achieved in over 80% of patients and can reduce PTS symptoms, improve QOL, and enhance healing of venous ulcers²⁹ (Fig. 143.3). Accordingly, physicians who see patients

Fig. 143.3 A 46-YEAR-OLD WOMAN WITH A PAST HISTORY OF RIGHT ILIOFEMORAL DEEP VEIN THROMBOSIS (DVT) 2 YEARS AGO. She now presents to the clinic complaining of daily aching and swelling in the right lower extremity that preclude ambulation for even one block and render her unable to work. These symptoms have been present since her previous DVT. (A) A transjugular pelvic venogram demonstrates chronic narrowing of the right iliac vein with collateral formation. (B) After placement of four 12-mm stents, the right iliac vein is widely patent. The pain and swelling improved, and the patient was subsequently able to return to work.

with severe PTS, with or without ulcers, should consider consulting a venous endovascular specialist.

Inferior Vena Cava Filters

IVC filters are indicated for patients with proximal DVT or PE who have contraindications to or complications of anticoagulation, who develop symptomatic PE despite therapeutic-level anticoagulation, and/or who have severe cardiorespiratory compromise. In other circumstances, caution should be used when placing IVC filters because of ongoing uncertainty about their long-term risk–benefit ratio. Two randomized trials evaluating IVC filters are worthy of note. In the PREPIC Study, which was carried out in patients concomitantly receiving anticoagulant therapy and which was underpowered to detect an effect on fatal PE, filters appeared to provide additional protection against symptomatic PE but did not alter mortality.³⁰ Symptomatic recurrent DVT was increased in the filter group, but the overall rates of PTS and symptomatic recurrent VTE did not differ significantly. Because fatal PE rarely occurs in patients with DVT who are properly anticoagulated, IVC filters should not be routinely placed in patients with DVT. Patients who experience clinical failure of first-line anticoagulation can usually be switched to an effective alternative regimen, such as LMWH or another oral anticoagulant.

Retrievable IVC filters have the intended advantages of allowing PE prophylaxis during the period of highest risk, with subsequent removal thereafter. However, it should be noted that the stability and mechanical integrity of retrievable devices do not yet match those of older filters designed for permanent implantation, and many cases of retrievable filter migration have been reported. Therefore if there is a strong likelihood that permanent IVC filtration will be needed, it is best to select a permanent, nonretrievable IVC filter device. In DVT patients with a time-limited indication for an IVC filter, placement of a retrievable IVC filter is reasonable. However, it is important that the need for the IVC filter be reassessed every few weeks after placement so that the filter can be removed when it is no longer needed. Although many filters are placed with the intent to be retrieved, less than 50% are removed. Consequently physicians must monitor patients with these devices to ensure that they are removed when appropriate.

The recently completed PREPIC-2 study was a multicenter RCT that evaluated the use of retrievable IVC filters for the prevention of recurrent PE in hospitalized patients with acute PE and clinical features deemed to pose high risk for recurrence or death.³¹ This study did not identify a clinical benefit from IVC filter placement, either in terms of mortality or recurrent symptomatic PE. Hence a compelling justification should be present to support placement of IVC filters in VTE patients who are eligible to receive anticoagulant therapy.

At a health care system level, better studies of the use of IVC filters in different clinical scenarios should be considered an urgent priority because the devices are being used more frequently. The balance between PE prophylaxis and the long-term risks of IVC filter placement is complex and deserves more rigorous evaluation (Fig. 143.4).

CONCLUSION

Imaging-guided endovascular interventions have evolved significantly over the last 25 years and now offer the potential for improved patient outcomes in several disease states. For PAO, randomized trials have defined the role for CDT for the treatment of acute limb ischemia. For DVT, a robust body of preliminary research and one randomized trial support the potential for catheter-based thromboembolic therapies to improve long-term patient outcomes, but larger randomized trials have not yet been completed. Therefore, an individualized approach is recommended to ensure that harms are minimized and appropriate patients are selected for intervention. Multidisciplinary

Fig. 143.4 ILLUSTRATING THE COMPLEXITIES OF DETERMINING WHETHER INFERIOR VENA CAVA (IVC) FILTERS ARE OF BENEFIT OR NOT. A digital subtraction venogram shows a large globular filling defect within an IVC filter that was placed 3 days ago. Filter proponents might argue that this represents a large, potentially fatal pulmonary embolism trapped within the filter, while filter opponents might argue that this is a case of filter-induced IVC thrombosis, a major complication. Who is right?

collaboration between internists and endovascular physicians is needed to ensure optimal patient care.

ATHEROTHROMBOSIS

Roy L. Silverstein

Morbidity and mortality from atherosclerosis, the pathologic process underlying acute myocardial infarction, sudden death, stroke, and limb loss, represent an enormous burden on society and health care systems. Even though death rates from heart attack and stroke have dropped precipitously over the past 60 years (72% and 78%, respectively, from 1950 to 2008)¹, cardiovascular diseases are still the number one cause of death in the United States, accounting for more than 30% of all deaths—approximately 2200 per day (or one every 40 seconds). Unfortunately as the developing world adopts a more “Western” lifestyle (i.e., one marked by a high-fat, calorie-rich diet, and limited physical activity), these statistics are becoming the norm worldwide. The annual financial burden of cardiovascular disease in the United States in 2010 was estimated by the American Heart Association (AHA) to be \$445 billion, including \$172 billion due to lost productivity. These costs are predicted to triple over the ensuing 20 years; analyses of population survey data predict an increase in cardiovascular disease prevalence from 36.9% to 40.5%. It is interesting to note that as treatment of the acute complications of atherosclerosis improves, the burden of chronic complications, particularly heart failure, is expected to increase by as much as 25% over the next 20 years.¹

Much of our knowledge of the epidemiology of cardiovascular disease comes from large-scale, long-term population studies, the most important being the Framingham Heart Study sponsored by the National Heart, Lung, and Blood Institute (NHLBI). This ongoing prospective study began in 1948 with a cohort of ≈5200 men and women between the ages of 30 and 62 years in Framingham (MA, USA), and has since added two subsequent generations and several other cohorts. Through this study and others elsewhere in the United States and Europe major risk factors for cardiovascular disease have been identified, including cigarette smoking, low-density lipoprotein (LDL) cholesterol, systolic blood pressure, male sex, menopause, physical inactivity, body mass index, high-sensitivity C-reactive protein (hsCRP), and coronary artery calcification scores determined by radiographic imaging. Additionally, high-density lipoprotein (HDL) was identified as a protective factor. Based on these data, risk scores have been developed to guide physicians and patients, and public health campaigns developed targeting hypertension, elevated cholesterol, and lifestyle modifications. These measures have clearly contributed to the reductions in cardiovascular mortality just noted, although they cannot account for the entire decrement. Racial and ethnic disparities are well described in cardiovascular risk, with blacks having higher rates than all other groups.

PATHOBIOLOGY

Atherosclerosis is caused by the progressive formation of arterial plaques, which are characterized by accumulation of lipids, in particular cholesterol and its derivatives, and inflammatory cells in the tunica intima of large- and medium-sized arteries (Fig. 144.1). Although occlusion of blood flow by plaque encroachment into the lumen can occur and cause ischemia of downstream tissues, most of the severe clinical events associated with atherosclerosis derive from acute or subacute thrombosis at a site of an unstable, inflamed, or ruptured plaque, or at a site of recent mechanical or pharmacologic intervention, a process termed *atherothrombosis*. The past 45 years have seen a remarkable increase in our understanding of the basic

pathophysiologic mechanisms that govern plaque formation, plaque progression, and acute arterial thrombosis.² Translation of this knowledge into diagnostic, preventive, and therapeutic strategies has been impressive, but there is still a need for improvement. This chapter will summarize the current prevailing models of atherogenesis and atherothrombosis, highlighting some key knowledge gaps and potential new therapeutic targets.

LIPOPROTEIN HOMEOSTASIS AND THE “CHOLESTEROL HYPOTHESIS”

Human epidemiologic and clinical trial data and animal model studies show unequivocally that elevated levels of plasma lipids, especially LDL cholesterol, are essential for plaque development. Atherosclerotic lesions can be induced in “atheroresistant” animals, including mice and rabbits, by manipulating their diets and/or genomes to cause hypercholesterolemia. The development of mouse genetic models nearly 25 years ago³ has provided great mechanistic insights into the underlying pathobiology of plaque formation. In humans, raising LDL cholesterol levels increases the risk for atherosclerosis proportionally and lowering levels either by lifestyle change or pharmacologic intervention reduces risk proportionally. In general, lowering LDL cholesterol levels by 10% reduces risk for cardiovascular events by 25% and cardiovascular death by 10%.

Normally cholesterol levels are tightly controlled in response to diet and cellular needs by a complex transcriptional pathway mediated by sterol response element-binding protein 2 (SREBP2). At low levels of cellular cholesterol, SREBP2 is activated and binds to specific DNA sequences in target genes known as *sterol response elements* to activate their transcription. Two key target genes are *HMGCR* and *LDLR*, which encode 3-hydroxy-3-methylglutaryl coenzyme A (HMGCoA) reductase (the rate-limiting enzyme in cholesterol biosynthesis) and the LDL receptor, respectively, thereby increasing both cholesterol production and cellular LDL uptake. At high levels of cellular cholesterol, SREBP2 is inactive, cholesterol biosynthesis is turned off, and LDL receptor expression is downregulated. As shown in Fig. 144.2, statins decrease cellular cholesterol biosynthesis by inhibiting HMGCoA reductase and thereby induce an increase in LDL receptor expression, driving down plasma LDL cholesterol levels.

Multiple randomized clinical trials have demonstrated efficacy of statin class drugs in reducing risk for cardiovascular events in high-risk individuals. Initial studies focused on secondary prevention in patients with a history of a previous atherosclerotic event, but later trials demonstrated efficacy as part of a primary prevention strategy in subjects with elevated LDL cholesterol or in subjects with normal LDL cholesterol in the setting of other risk factors, such as diabetes, hypertension, or elevated plasma levels of hsCRP. The latter studies, along with those showing benefit of lowering LDL cholesterol to levels well below “normal” (e.g., to 70 mg/dL in high-risk individuals),⁴ are consistent with the concept that “normal” levels of LDL cholesterol, as defined by population means in the Western world, are not reflective of a true normal biology.

Genetic studies of rare individuals with extremely low LDL cholesterol levels identified a null mutation in a gene known as *PCSK9* that encodes a serine protease enzyme involved in downregulating LDL receptor expression. Individuals with this mutation seem to be

otherwise normal, despite nearly absent LDL, suggesting that targeting this enzyme could represent an effective strategy for cholesterol-lowering therapeutics. Indeed, humanized monoclonal antibodies inhibiting PCSK9 function were quickly developed, moved through clinical trials (OSLER and ODYSSEY) and approved by the US Food

and Drug Administration (FDA) in 2015 as second-line therapy for hypercholesterolemia.⁵ In clinical trials these agents were well tolerated and lowered LDL cholesterol by approximately 60% and decreased cardiovascular events by half, but it must be noted that long-term toxicity data are not yet available.

Cells in the periphery have the capacity to eliminate excess cholesterol through a process known as *reverse cholesterol transport* (RCT). In this pathway, summarized in Fig. 144.3, postlysosomal trafficking of intracellular cholesterol to the plasma membrane, mediated in part by actions of acyl-CoA cholesterol acyltransferase (ACAT) and Niemann-Pick type C (NPC) protein, allows the cell surface adenosine triphosphate (ATP)-binding cassette (ABC) proteins ABCA1 and ABCG1 to transport excess cholesterol to apolipoprotein (apo) A-containing lipoproteins, either nascent HDL (in the case of ABCA1) or mature HDL (in the case of ABCG1). HDL then “delivers” the cholesterol back to the liver, where it is selectively taken up by hepatocytes through a protein known as *scavenger receptor B1* (SRB1) and ultimately secreted into the bile and excreted in feces. The role of HDL in RCT probably accounts for its association with lowered risk for cardiovascular disease, but HDL particles also contain antiinflammatory and antioxidant proteins that may also contribute to lowering atherosclerosis risk.

Pharmacologic and lifestyle approaches to enhance RCT have received significant attention as potential antiatherosclerosis strategies. HDL levels can be raised by physical exercise, as well as by moderate alcohol ingestion, and these are both associated with lower

Fig. 144.1 ATHEROMATOUS PLAQUE. Cross-sectional view of a human artery taken from an autopsy, showing accumulation of yellow-colored fatty materials in the neointima.

Fig. 144.2 STATINS TARGET CHOLESTEROL AND ISOPRENYLATION PATHWAYS. The statin class of drugs inhibits the intracellular enzyme HMGCoA reductase. This enzyme converts HMGCoA to mevalonic acid, which is a precursor in the biosynthesis of the isoprenoids geranyl and farnesyl pyrophosphates, which in turn are precursors of cholesterol, as well as intermediates in isoprenyl modification of proteins, including small-molecular-weight G proteins. Because HMGCoA reductase is the rate-limiting step in these pathways, its inhibition leads to decreases in cholesterol biosynthesis, hepatic VLDL production, and protein isoprenylation (arrows). Low levels of intracellular cholesterol activate the SREBP2 gene (green), which encodes a transcription factor that binds to SRE in multiple genes, including HMGCoA receptor and LDL receptor. The ensuing increased expression of LDL receptor results in increased clearance of apolipoprotein B-containing lipoproteins (LDL and VLDL) from plasma, further lowering plasma cholesterol levels. *CoA*, Coenzyme a; *HMGCoA*, 3-hydroxy-3-methylglutaryl coenzyme A; *LDL*, low-density lipoprotein; *SREBP2*, sterol response element binding protein 2; *SRE*, sterol response element; *VLDL*, very low-density lipoprotein.

Fig. 144.3 REVERSE CHOLESTEROL TRANSPORT. Cells in the periphery, including macrophage foam cells, have the capacity to unload intracellular cholesterol via two members of the ABC transporter family: ABCA1 and ABCG1. The former transfers cholesterol to apoA and/or nascent HDL particles, whereas the latter transfers cholesterol to mature HDL. HDL interacts with SRB1 on liver cells, and through a process known as *selective cholesterol uptake*, the cholesterol within the HDL is internalized, where it can ultimately be reused or excreted via bile. The cholesterol in HDL can exchange with TG in LDL and VLDL particles through the action of an enzyme, CETP. Inhibitors of CETP thus raise plasma HDL levels and lower LDL levels. LDL and VLDL are normally cleared by cells in the periphery via internalization by LDL receptor. Statin drugs, by inhibiting HMGCoA reductase, lower intracellular cholesterol levels and raise LDL receptor levels, thus lowering plasma LDL. A microRNA, miR33a, encoded within the *SREBP* gene blocks expression of *ABCA1* and *ABCG1*. *ABC*, ATP-binding cassette; *apo*, apolipoprotein; *CETP*, cholesterol ester transfer protein; *HDL*, high-density lipoprotein; *LDL*, low-density lipoprotein; *SRB1*, scavenger receptor B1; *TG*, triglycerides; *VLDL*, very low-density lipoprotein.

cardiovascular risk. The only FDA-approved pharmacologic agent capable of raising HDL is niacin, but high doses are required and these are not easily tolerated because of side effects, especially facial flushing. A combination of high-dose niacin with a prostaglandin D₂ receptor antagonist to block facial flushing was developed, as was an extended release form of niacin, but although both raised HDL levels, neither decreased cardiovascular risk.

The circulating plasma enzyme, cholesterol ester transfer protein (CETP), functions to transfer cholesterol esters from HDL to very low-density lipoprotein (VLDL) and LDL (see Fig. 144.3). Inhibiting this enzyme raises HDL levels (and lowers LDL) significantly in humans, but a large phase III randomized clinical trial with the initially developed pharmacologic CETP inhibitor torcetrapib was halted in 2006 because of excessive all-cause mortality in the treatment group receiving a combination of atorvastatin and the study drug. This result may have been due to an off-target effect of the drug, but more recent studies with several different agents either failed to show efficacy despite raising HDL levels, or were halted in development. One agent remains in phase III trial with accrual scheduled to complete in 2017.

Failure of CETP inhibitors and niacin in clinical trials raised doubts about the potential value of RCT or HDL as targets for antiatherosclerosis therapy. An emerging concept, however, is that HDL particles are sensitive to oxidative modification in the

proatherogenic milieu, and that these modifications can render HDL particles incompetent to function in RCT.⁶ Simply raising HDL in this milieu therefore might not impact RCT. In this regard, novel assays to assess RCT—so-called *HDL efflux capacity*—have been developed⁷ and show potential as biomarkers for RCT in future drug development efforts. One such potential new target is microRNA-33a (miR-33a) which is encoded by a DNA sequence embedded in the *SREBP2* gene that was found to repress several key genes involved in cholesterol homeostasis (see Fig. 144.3), including *ABCA1* and *ABCG1*, as well as genes involved in fatty acid oxidation and glucose metabolism.⁸ Blocking miR-33a in mice increased HDL levels and inhibited atherosclerosis, suggesting that this could be a good target for therapeutic development. Other strategies to enhance RCT that are under development include direct infusion of cholesterol acceptors from ABCA1 or ABCG1, such as recombinant apoA or small apoA mimetic amphipathic peptides.

Niemann-Pick C1-like1 protein is expressed on the surface of enterocytes and hepatocytes, and functions to promote cholesterol absorption. Ezetimibe, a well-tolerated FDA-approved drug inhibits this protein and lowers LDL cholesterol by approximately 20%. Early enthusiasm for this drug waned when studies failed to show improved cardiovascular outcomes, raising doubts in general about the relationship between biochemical endpoints and clinical efficacy. These results, and others, contributed to changes in clinical guidelines that

Fig. 144.4 FOAM CELL FORMATION IS AN EARLY EVENT IN ATHEROGENESIS. LDL particles, which are transudated through a dysfunctional endothelium at arterial branch points or areas of disrupted shear, enter the intima and become trapped within the extracellular matrix. In the presence of inflammation, the LDL particles become oxidized or otherwise modified and contribute to endothelial dysfunction by interacting with receptors on endothelial cells, such as LOX1. Monocytes, in response to chemokines secreted by activated endothelial cells and/or inflammatory leukocytes and platelets, adhere to the endothelium via selectin family adhesion receptors, as well as $\beta 2$ integrins and their counterreceptors (intercellular adhesion molecule and vascular cell adhesion molecule). The monocytes then diapedese into the intima, where they differentiate into inflammatory macrophages that generate oxidant stress within the vessel wall and release proinflammatory mediators. Scavenger receptors, in particular CD36, expressed on macrophages recognize and internalize oxLDL, leading to a feed-forward loop of increased LDL oxidation and increased scavenger receptor expression, resulting ultimately in the formation of cholesterol-laden foam cells. These accumulate in the intima, in part because of signals induced by oxLDL that inhibit migration, forming plaque. *LDL*, Low-density lipoprotein; *oxLDL*, oxidized LDL; *PLA2*, phospholipase A2; *ROS*, reactive oxygen species; *SRA*, scavenger receptor A1; *TLR*, Toll-like receptor.

now no longer recommend specific LDL cholesterol targets and discourage use of nonstatin agents.⁹ A more recent trial of ezetimibe in combination with a statin, however, showed a 10% reduction in cardiovascular events at 7 years associated with a mean decrease in LDL cholesterol of 16 mg/dL compared with statin alone.¹⁰

Multiple epidemiologic and genetic studies have shown positive associations of circulating triglyceride levels with coronary artery disease risk. Genetic variants in the gene encoding lipoprotein lipase, a key regulator of triglyceride metabolism, have also been associated with circulating triglyceride levels and with coronary artery disease risk, as have genetic variants in the *APOC3* and *APOA5* genes, which encode “minor” apolipoproteins in triglyceride-rich lipoproteins that critically regulate lipoprotein lipase in a reciprocal manner.¹¹ Therapeutic interventions targeting the lipoprotein lipase pathway, including an *APOC3* antisense oligonucleotide, are under development.

FOAM CELL FORMATION AND THE FATTY STREAK

Atherosclerotic plaques develop in a geographically discontinuous manner very slowly and continuously evolve over many decades.² Autopsy studies of motor vehicle accident victims showed early “preatherosclerotic” lesions present in the aorta of otherwise healthy young children. These small superficial lesions consist predominantly of lipid-laden macrophages, so-called foam cells, and are termed *fatty streaks*. These are considered precursors of atherosclerotic plaque.

The initial event in formation of the fatty streak and atherosclerotic plaque is most likely transudation of apoB-containing lipoproteins across the endothelial cell monolayer into the arterial wall (Fig. 144.4). These lipoproteins are predominantly LDL, which is derived by remodeling of VLDL particles secreted into the plasma by hepatocytes. So-called remnant lipoproteins derived from chylomicrons produced by the intestinal epithelium may also play a role. The primary sites of lipoprotein entry are at arterial branch points or curvatures, explaining the discontinuous nature of atherosclerotic lesions. These locations are where normal laminar blood flow is disturbed. Normal laminar flow activates a specific genetic “protection” program in endothelial cells that enhances barrier function and promotes an antiinflammatory, antioxidant, antiatherogenic phenotype. Loss of these shear-dependent signals disrupts the normal endothelial architecture and increases permeability, allowing unregulated entry of lipoproteins into the tunica intima. Within the intima the lipoproteins become “trapped” by specific interactions with normal components of the vessel wall, such as glycosaminoglycans, and undergo structural modifications, including aggregation, oxidation, and, in settings of hyperglycemia, glycation.

Just as data show an unequivocal role for LDL cholesterol in atherogenesis, equally compelling studies in humans and animal models show that mononuclear phagocytes are necessary for plaque formation and progression, and that atherosclerosis is associated with a chronic inflammatory state in the vessel wall and in the systemic circulation.¹² Targeted genetic mutations that block monocyte development from hematopoietic precursors or that prevent monocyte

trafficking into tissues dramatically protect mice from experimental atherosclerosis. The earliest and most prominent cell types in human and mouse atherosclerotic lesions are monocytes and macrophages. Initial monocyte entry into the arterial intima is in response to poorly understood cues related to endothelial cell dysfunction. Environmental and genetic influences, such as hypertension, angiotensin II production, cigarette smoke, diabetes, metabolic syndrome, and chronic periodontal infection may contribute to generalized endothelial dysfunction, but it is likely that the modified lipoproteins, particularly oxidized LDL (oxLDL), trapped in the vessel wall play a major initiating role.¹³ oxLDL activates an endothelial cell receptor known as *LOX1* to induce expression of monocyte adhesion molecules and this response is dramatically amplified in the presence of angiotensin II. Other components of the “dysfunctional” endothelial cell phenotype include von Willebrand factor release from Weibel-Palade bodies and altered homeostasis of nitric oxide and eicosanoid pathways.

Monocyte recruitment to the vessel wall (see Fig. 144.4) begins with their capture and rolling along the activated endothelium mediated by specific interaction of selectin family adhesion molecules (L-selectin on circulating monocytes and P-selectin on activated endothelial cells) with their counter receptors, including PSGL1. Subsequent signals induced by endothelial-derived chemokines, including chemokine (C-C motif) ligand 5 (CCL5)/regulated upon activation, normal T-cell expressed, and secreted (RANTES), CCL2/monocyte chemoattractant protein 1 (MCP1), interleukin (IL)-8, and CXC-chemokine ligand 1 (CXCL1), lead to further recruitment of monocytes and facilitate firm adhesion of the rolling monocytes to the vessel wall. The latter is mediated by interaction of intercellular adhesion molecule 1 (ICAM1) and vascular cell adhesion molecule (VCAM) on the activated endothelial surface with specific integrin family counter receptors on monocytes; β_2 integrins for ICAM1 and $\alpha_4\beta_1$ for VCAM. By diapedesis, the adherent monocytes then traverse the disrupted endothelial junctions and enter the intima. Recent studies have suggested that a particular subset of circulating “inflammatory” monocytes, defined by high expression of the Ly6C antigen (in mice) or CD14 (in humans), are the predominant source of entering cells. The normal vasculature also contains a small number of resident macrophages, as well as “patrolling” monocytes. The latter are distinct from the Ly6C⁺/CD14^{hi} cells and exhibit a less inflammatory phenotype.

The ultimate fate of monocytes within the intima is probably determined in part by lineage-commitment programs carried by the entering monocytes and in part by local environmental cues. Most, however, seem to polarize toward the so-called *M1 inflammatory macrophage phenotype*. Investigators have, however, detected dendritic cell-like phenotypes (expressing CD11c), M2-like cells that express arginase and endothelial nitric oxide synthase (eNOS) and are highly phagocytic and antiinflammatory, and proangiogenic VEGF-expressing macrophage phenotypes within plaque.¹⁴ In addition to monocytes, lymphocytes,¹⁵ particularly T cells, also enter the intima, where they contribute to plaque formation by secreting cytokines and other mediators. Of these infiltrating lymphocytes, interferon- γ -producing T-helper (Th)1 cells and IL-17-producing Th17 cells have been shown to promote atherosclerosis, whereas the regulatory T cell subset is protective.

Reactive oxygen species (ROS) are generated by the inflammatory milieu within the atherogenic vessel wall and modify the trapped LDL by oxidizing both protein and lipid moieties (see Fig. 144.4), creating what are called collectively *oxLDL*.¹³ Modified LDL lose their affinity for the LDL receptor but gain affinity for a genetically unrelated family of receptors known as *scavenger receptors* (SRs), including SRA1 and CD36, which are present at high levels on the macrophage surface. These receptors are part of the innate immune system, and their recognition of specific structures within oxLDL presumably relates to their mimicry of similar structures found on pathogenic organisms. CD36, for example,¹⁶ also recognizes mycobacterial and *Staphylococcus* cell wall components, certain fungal structures, and falciparum malaria-infected erythrocytes. Toll-like receptor (TLR) family members, including TLR2, TLR4, and TLR6, can also recognize modified LDL and can partner with CD36 in these

functions. Unlike the LDL receptor, which is downregulated in the setting of excess ligand, SR expression is increased in the presence of oxLDL, in part via internalization of oxidized fatty acids that serve as ligands for peroxisome proliferator-activated receptor (PPAR) family transcription factors, particularly PPAR γ , which is a major positive regulator of CD36 expression.¹⁷ Thus over many months and years, the continued entry and oxidation of LDL in the intima coupled with upregulated expression of SRs leads to massive intracellular accumulation of cholesterol and formation of lipid-laden cells known as *foam cells*.

OxLDL-SR interactions initiate a cascade of events in macrophages, including internalization of the bound oxLDL, activation of proinflammatory pathways, and activation of transcriptional pathways. The CD36-oxLDL interaction, in addition to promoting ROS formation, also decreases expression of endogenous antioxidant pathways and inhibits macrophage migration. These events result in a feed-forward loop that increases leukocyte recruitment into the vessel wall, inhibits macrophage migration out of the vessel wall, and increases oxLDL formation. The net effect is formation and accumulation of lipid-laden foam cells and proinflammatory immune cells, which together form plaque (see Fig. 144.4). In mouse models, genetic deletion of SRs, especially CD36, provides substantial protection from plaque formation.

Although abundant data from animal models and correlative human studies support the oxidative stress hypothesis, considerable controversy remains because large- and medium-sized interventional trials of antioxidant therapy in humans have generally failed to prevent the complications of atherosclerosis.¹⁸ These trials, however, are difficult to interpret because of lack of convincing evidence that the tested “antioxidant” therapies actually targeted the relevant vascular or circulating oxidant pathways. These oxidant systems include NADPH oxidase, xanthine oxidase, myeloperoxidase (MPO), and uncoupled nitric oxide synthase. MPO is of particular interest because it generates a highly specific oxidized phospholipid ligand for CD36 from LDL, and because circulating MPO levels associate with risk for atherosclerosis and with risk for acute cardiovascular events.

Another potential problem with the antioxidant clinical trials is that the choice of antioxidants may have been flawed. The most used vitamin E formulations contain mainly α -tocopherol. Recent studies showed that tocopherols, in addition to having activity as antioxidants, have important cell-signaling functions mediated by specific cellular receptors. Therapy with formulations containing primarily α -tocopherol may downregulate endogenous γ -tocopherol levels, leading to imbalance in natural tocopherol signaling pathways. Furthermore, tocopherols are lipid-based structures that are themselves subject to oxidation, producing lipid peroxides that can actually promote further oxidative stress. Nevertheless, it is possible that pathways of cholesterol uptake unrelated to LDL oxidation and SR expression, such as by micro- and macro-pinocytosis of “native” LDL or aggregated LDL, may play a significant role in foam cell formation.

Important unresolved issues in the pathogenesis of early atherosclerotic lesions include understanding why macrophages do not exit the vessel wall and travel to regional nodes after ingesting modified LDL, as they would after ingesting exogenous pathogens, and why cholesterol efflux cannot keep up with LDL uptake to maintain a homeostatic state. oxLDL inhibition of macrophage migration (see Fig. 144.4) may explain the former, suggesting that blocking oxLDL-mediated signaling pathways might have therapeutic potential by facilitating macrophage exit from developing plaque. Indeed, in experimental animals, transplantation of atherosclerotic aortae from hypercholesterolemic animals into normal recipients induces migration of lipid-laden macrophages out of the vessel wall and plaque regression.¹⁹ The second issue might relate to differential gene regulation of SRs compared with cholesterol efflux transporters, and/or to intracellular cholesterol trafficking that might make it inaccessible to efflux transporters. In addition, as noted previously, HDL particles, similar to LDL, are sensitive to oxidative modification and such oxidation may produce dysfunctional HDL that does not function optimally in RCT and thus loses its atheroprotective activity.⁶

An intriguing recent development in understanding the cellular composition of plaque comes from so-called lineage marker studies that show that a surprisingly large percentage of foam cells expressing macrophage markers were actually derived from a smooth muscle cell lineage.²⁰ These studies suggest that local cues in plaque might interact with intimal or adventitial smooth muscle cells to redirect their genetic programs towards a macrophage-like phenotype. It is possible that such cells do not possess the full migratory capacity of macrophages and this could contribute to foam cell trapping in plaque.

LESION EVOLUTION: REMODELING AND THE VULNERABLE PLAQUE

In humans, plaque develops and evolves very slowly over many decades, explaining in part why animal models in which advanced lesions develop rapidly over weeks and months may not accurately reflect the human condition. Accumulation of foam cells is only one component of the atherogenic process. Early on, signals from macrophages (Fig. 144.5) and the injured endothelium, primarily platelet-derived growth factor (PDGF), stimulate adventitial smooth muscle cells to migrate into the intima and proliferate.² These cells contribute to the mass of the lesions, and secrete collagen and other factors that change the nature of the intimal extracellular matrix, and may even contribute to the burden of foam cells. Lymphocytes infiltrating from the circulation and mast cells from the adventitia also contribute to the inflammatory milieu and matrix remodeling. Platelet antigens are also readily detectable in plaque, suggesting that platelets enter the intima, where they may contribute to matrix remodeling and the inflammatory state by secreting PDGF, transforming growth factor- β , and other growth factors, along with platelet factor 4, which is a potent chemokine, also known as *CXCL4*,

for monocytes. Animal studies suggest that platelets may facilitate monocyte recruitment, acting as a bridge between the endothelium and circulating monocytes (see Fig. 144.5).²¹ Sophisticated single-cell imaging studies in mice showed that monocytes continue to traffic through the “shoulders” of even advanced stage lesions.

Plaque generally grows in an eccentric pattern within the intima and in certain instances can create significant obstruction to blood flow (Fig. 144.6, *left*). In such cases, as oxygen demand increases, tissue ischemia results, leading to angina and/or lower extremity claudication. Recent in vivo studies using advanced imaging techniques, such as intravascular ultrasound, however, demonstrate that in most cases the vessel wall remodels as plaque grows (see Fig. 144.6, *right*) so that the arterial lumen is mostly preserved and the bulk of the atheromatous mass is abluminal. These studies show that traditional two-dimensional angiographic techniques vastly underestimate plaque burden. Of note, such studies, along with careful histopathologic examinations, have led to the concept that the “quality” of the plaque may be more important than its quantity in predicting cardiovascular outcomes. Some plaques, particularly those with thick fibrous caps and cellular cores, seem to be stable (Fig. 144.7), whereas others, particularly those with thin fibrous caps, abundant leukocytes, and necrotic, lipid-rich cores, seem to be unstable and vulnerable to erosion and rupture (see Fig. 144.7). Rupture refers to the sudden loss of integrity of the fibrous cap with release of plaque material into the lumen, often followed by acute occlusive thrombosis. Erosion is a more subtle concept referring to loss of endothelial cells at the shoulder of the lesion or minimal leakage of plaque through a partially disrupted cap. Plaque erosion may lead to subocclusive thrombus formation and/or intraplaque hemorrhage and thrombosis. Repeated cycles of erosion and intraplaque hemorrhage/thrombosis may account for the apparent stepwise growth of some lesions.

Understanding factors that contribute to plaque vulnerability is an extremely important topic of research,²² but one that is difficult

Fig. 144.5 LATER EVENTS IN ATHEROGENESIS. Fatty streaks formed in the vessel wall via accumulation of foam cells (see Fig. 144.4) evolve over many years into complex plaque. In response to chemokines, monocytes continue to enter plaque, perhaps accompanied by platelets. T cells, B cells, and other inflammatory cells also accumulate. Cholesterol loading of macrophages induces apoptosis and apoptotic cells accumulate because of dysfunction of normal efferocytotic clearance pathways. Smooth muscle cells respond to PDGF, transforming growth factor β , and other signals, and proliferate and migrate into the neointima. These cells produce collagen and other matrix components, contributing to plaque growth and formation of a fibrous cap. To support plaque growth, an angiogenic response is elicited from the vasa vasora within the adventitia. PDGF, Platelet-derived growth factor.

Fig. 144.6 VESSEL WALL REMODELING CAN PRESERVE ARTERIAL LUMEN. On the *left* is a cross-section cartoon image of an artery containing a large eccentric plaque (*orange*). The vessel has undergone minimal remodeling. The atheromatous lesion is extending into the arterial lumen and would be visible on an angiogram as an obstructing lesion. On the *right* is a lesion of similar mass, but its formation was accompanied by significant vessel wall remodeling so that the lesion extends mainly into the vessel wall, preserving the lumen. On an angiogram this would be nearly invisible.

Fig. 144.7 UNSTABLE PLAQUE IS PRONE TO RUPTURE. On the *left* is a cross-section cartoon image of an artery with a plaque containing abundant smooth muscle cells and foam cells and a thick fibrous cap. On the *right* is a similar-size plaque, but with a thin fibrous cap that has ruptured allowing plaque contents to extrude into the lumen. This plaque contains smooth muscle cells and foam cells, as in the stable plaque on the left, but there is abundant angiogenesis, along with apoptotic and necrotic cells.

to model in animals. Some key features that have emerged are the degree of angiogenesis within the plaque, balance of matrix-degrading enzymes and enzyme inhibitors, level of apoptosis of cells within the plaque, deposition of calcium within the plaque, and level of systemic and local inflammation.

Plaque angiogenesis is a recently appreciated process that can be visualized by certain imaging modalities, such as ultrafast computed tomography (CT) and magnetic resonance imaging (MRI), in real time.²³ Based on analogy to tumor growth, it is not surprising that the growing plaque requires a blood supply and also that the neovessels within the plaque may, similar to their counterparts in cancer, be leaky and unstable. This neovascular instability may contribute to plaque instability by facilitating entry of inflammatory cells, platelets, and plasma components, such as fibrinogen and cell-derived microparticles (MPs). In animal models, treatment with antiangiogenic agents significantly slows plaque growth. In some disease states, such as diabetes, accelerated atherosclerosis may reflect a “microvascular” disease of the vasa vasora.

Integrity of the fibrous cap is maintained by a balance between collagen synthesis by smooth muscle cells and fibroblasts, and collagenolysis by matrix-degrading enzymes. The latter is maintained by a balance between enzymes and their endogenous inhibitors. The predominant enzymes are members of the large family of zinc-dependent matrix metalloproteinases (MMPs), which are capable of degrading most matrix components, including collagen. These enzymes are tightly regulated by a network of activators and inhibitors, and in settings in which activation exceeds inhibition, excessive matrix degradation may occur. Metalloproteases of the ADAM (a disintegrin and metalloprotease domain) family and ADAMTS (a disintegrin and metalloprotease domain with thrombospondin structural homology domains) family may also contribute to plaque instability. Although several clinical trials have studied MMP inhibitors in atherosclerosis, none has shown clear benefit to date.

A prominent feature of advanced atherosclerotic lesions is the presence of apoptotic cells, mostly of macrophage and smooth muscle cell origin. The nature of the proapoptotic signals within plaque is incompletely understood, but excess intracellular cholesterol can initiate the endoplasmic reticulum stress response, leading to apoptosis.²⁴ oxLDL signaling through SRs and/or TLRs can also induce apoptosis.²⁵ In most inflammatory sites, apoptotic leukocytes are quickly removed by phagocytes in a process known as *efferocytosis*. The efferocytotic macrophages are generally thought to be of the M2 antiinflammatory type; thus their engagement by apoptotic cells not only removes the apoptotic cell from the microenvironment, but also directly contributes to downregulation of the inflammatory state by inducing secretion of antiinflammatory cytokines and effectors. In atherosclerotic plaque, this process seems to be inefficient so that apoptotic cells accumulate, contributing to the lipid load and releasing potentially toxic contents.

Although therapeutic interventions to stabilize vulnerable plaque or prevent plaques from becoming vulnerable have not yet materialized, several imaging approaches have been studied in attempt to develop useful biomarkers to identify vulnerable plaque and therefore to identify patients who might benefit from aggressive antithrombotic and lipid-lowering therapeutic interventions. Neovascular imaging using CT or MRI is a promising technology, as is plaque characterization by optical coherence tomography, high-resolution MRI, linear infrared imaging, and thermography.²³

PLAQUE RUPTURE AND ACUTE ARTERIAL THROMBOSIS

The devastating complications of atherosclerosis, including acute coronary syndrome (ACS), stroke, gangrene, and sudden death, result primarily from acute and subacute thrombosis occurring at the site of plaque rupture (Fig. 144.8). As described in later chapters in this section, treatment and prevention strategies using aggressive antiplatelet, anticoagulant, fibrinolytic, and/or mechanical approaches have been remarkably effective at reducing major cardiovascular events, but tremendous unmet need still exists,

Fig. 144.8 ACUTE PLATELET-RICH THROMBUS AT SITE OF PLAQUE RUPTURE. An atherosclerotic artery with a ruptured plaque (as described in Fig. 144.7) serves as a nidus for formation of an acute thrombus. Tissue factor (TF) contained in plaque or expressed on circulating microparticles (MPs) leads to thrombin generation and formation of fibrin at the site of rupture. Platelets accumulate at the rupture site and are activated by plaque components, such as collagen, forming an aggregate that, if large enough, can obstruct blood flow. Blood in patients with advanced atherosclerosis is prothrombotic, in part because of oxidized low-density lipoprotein (LDL)-induced release of TF-positive MPs from monocytes. Oxidized LDL also interacts with platelets to make them more sensitive to activation and aggregation by plaque contents.

particularly in the areas of primary and secondary prevention of thrombosis.

Pathophysiologic mechanisms underlying acute arterial thrombosis center on two key concepts: (1) exposure of prothrombotic materials to the local circulation as a consequence of plaque rupture acts as a thrombotic trigger, and (2) advanced atherosclerosis is associated with a systemic prothrombotic state that accelerates or enhances pathologic thrombosis.²⁵ The former mechanism undoubtedly plays a major role. Immunohistochemical studies have convincingly shown that plaque contains abundant tissue factor (TF), and acute anticoagulation therapy directed toward blocking thrombin generation or inhibiting thrombin has proven to be effective in ACS. Plaque TF is derived mainly from smooth muscle cells, fibroblasts, and activated macrophages. Recent studies have also suggested that platelets can synthesize TF after stimulation by inflammatory mediators and thus may also contribute to the plaque procoagulant load. A significant proportion of plaque TF may be in the form of membrane-bound MPs derived from apoptotic and/or activated cells (see next section for more detailed explanation).²⁶ Exposure of flowing blood to TF exposed in or released from ruptured plaque leads to rapid activation of factor X, thrombin generation, and activation of platelets. In addition to TF, other components of plaque that become exposed to blood at sites of rupture include collagen and oxidized phospholipids, both of which can activate platelets directly. Thus aggressive antiplatelet therapy with aspirin, P2Y₁₂ inhibitors, and glycoprotein α IIb β 3 inhibitors are mainstays of the pharmacologic approach to treatment of ACS; and aspirin and P2Y₁₂ inhibitors are of proven efficacy for secondary prevention.

HYPERLIPIDEMIA, ATHEROSCLEROSIS, AND A SYSTEMIC PROTHROMBOTIC STATE

Platelet hyperreactivity has long been thought to play a role in acute atherothrombosis. Clinical studies support an association between in vitro platelet reactivity and prognosis in patients with coronary disease, and it was shown in the 1970s that platelets from patients with familial hypercholesterolemia were more sensitive to activation by epinephrine or adenosine diphosphate (ADP). Similar findings

were seen in platelets from mouse models of hyperlipidemia, such as the apoE-null strain, which was fed a high-fat diet. Of note, the time to form occlusive thrombi after arterial injury in vivo was accelerated in hyperlipidemic mice compared with controls. In that context, much attention has been paid to identifying and characterizing receptors on the platelet surface that recognize specific classes of lipids and lipoproteins.²⁵ The receptors fall into two main groups: pattern recognition innate immune receptors, including CD36, SRA, TLR4, and LDL receptor-like protein (LRP)-8 (also known as *apoER2*), and G-protein-coupled receptors, including receptors for lysophosphatidic acid (LPA), platelet-activating factor, and thromboxane.

CD36 (also known as *platelet glycoprotein IV* or *IIIb*) is of particular interest because of its known function on macrophages as a high-affinity signaling receptor for oxLDL, and because oxLDL and oxidized phospholipids are readily detectable in circulating plasma of experimental animals and patients with atherosclerosis and hyperlipidemia. Indeed, recent studies showed that oxLDL bound to CD36 on the surface of platelets in a specific, concentration-, and time-dependent manner. At high concentrations, such as might occur during acute plaque rupture, oxLDL activates platelets, and at lower concentrations, such as those observed in the circulation of individuals with atherosclerosis, oxLDL augmented platelet-aggregation responses to low doses of “classic” platelet agonists, such as ADP and collagen. More recently platelet CD36 was shown to bind MP and advanced glycosylated proteins, suggesting that circulating endogenous “danger signals” generated by oxidant stress, hyperglycemia, and inflammation could induce a prothrombotic state through this pathway.²⁷

Platelets also express SRB1, a CD36 family protein that functions in the liver as a cholesterol acceptor for HDL. The function of SRB1 on platelets is not well understood, but at least one study showed that oxHDL, but not native HDL, inhibited platelet reactivity to multiple agonists, including ADP, collagen, and thrombin via binding to SRB1. HDL is at least as susceptible to oxidation in vitro and in vivo as LDL, and it is possible that the balance between oxLDL and oxHDL and the relative expression levels of CD36, SRB1, and other receptors may determine platelet reactivity in patients with hyperlipidemia and oxidant stress.

Atherosclerotic plaque and so-called “minimally” oxLDL contain LPA, a family of biologically active lipids generated by the action of phospholipases on LDL and cell membrane lipids. Platelets express at least three different G-protein-coupled LPA receptors but the in vivo relevance of this system has not been demonstrated. Ex vivo studies, however, demonstrated that minimally oxLDL at high concentrations could induce platelet shape change and sensitize platelets to aggregate in response to other agonists. Epidemiologic studies have also associated levels of soluble phospholipase A2 with cardiovascular risk. In addition to participating in LPA biosynthesis, this family of enzymes generates free fatty acids from phospholipids that serve as substrates for cyclooxygenase and lipoxygenases, producing both pro- and antiatherogenic eicosanoids.

LRP-8 (particularly a splice variant known as apoER2) binds lipidated apoE3 (e.g., chylomicrons and remnant particles), resulting in enhanced nitric oxide production and inhibition of platelet activation by ADP and other agonists. On the other hand, LRP-8 has also been shown to bind apoB-containing lipoproteins, leading to enhanced thromboxane generation and sensitization of platelets to other agonists. Consistent with this, in mice genetic deletion of LRP-8 has an antithrombotic effect in models of arterial injury.

In addition to platelet hyperreactivity, it is also quite likely that systemic activation of the coagulation cascade contributes to the prothrombotic state associated with advanced atherosclerosis. This is consistent with studies showing that atherosclerosis is associated with increased risk for venous thromboembolic disorders, as well as arterial thrombosis. Elevated levels of circulating D-dimer and thrombin-antithrombin complexes have been reported in patients with ACS, and D-dimer levels tend to track with hsCRP. Large-scale population studies have identified elevated fibrinogen and factor VIII levels as risk factors for atherosclerosis. Recent studies suggest that a key initiator of thrombin generation in these settings is circulating TF

(see Fig. 144.8) in the form of TF-expressing MPs.²⁶ MPs are vesicular fragments that bud off from cells during either activation or apoptosis. They are 200–1000 nm in size and possess different antigenic properties depending on the cell from which they are derived. MPs can be generated from platelets, monocytes, erythrocytes, leukocytes, or endothelial cells during vascular injury and have been shown to become incorporated into developing thrombi in vivo. MPs, mostly of platelet origin, can be detected in the circulation of normal human subjects, but markedly increased numbers of circulating MPs have been reported in patients with a variety of inflammatory and prothrombotic disorders including ACS.

MPs contribute to thrombus formation through several mechanisms. A general feature of MP generation is loss of membrane asymmetry so that anionic phospholipids normally oriented in the inner membrane leaflet become exposed on the outer leaflet. Surface-exposed phosphatidylserine (PS) is a site for catalytic assembly of the prothrombinase complex and thrombin generation. Furthermore, PS on the surface of MP also has the capacity to bind to platelet CD36 and enhance platelet reactivity via the same mechanism as oxLDL.

It is important to note that MPs derived from some cells (e.g., monocytes, macrophages, smooth muscle cells, and tumor cells) are a source of circulating TF. A mechanistic link between atherogenesis and thrombosis may be oxLDL, which in vitro can induce TF-positive MP generation from blood-derived monocytes.²⁸ Of interest, a recent large clinical trial (JUPITER) testing the efficacy of statins in subjects with normal LDL, but elevated levels of hsCRP, showed that rates of venous thrombosis, as well as coronary events, were significantly decreased. In animal models, statins decrease circulating levels of oxLDL and also decrease circulating MP levels and levels of other prothrombotic and proinflammatory biomarkers, even in the absence of lowering cholesterol, suggesting that oxLDL-mediated prothrombotic activities may be important targets for thromboprevention in patients with atherosclerosis. These studies also support those showing that statins may have antiinflammatory and antithrombotic activities independent of lipid lowering. Because HMGCoA reductase is also the limiting step in biosynthesis of isoprenoids, it has been postulated that statins may dampen signaling pathways mediated by small-molecular-weight G proteins (e.g., Ras) in which membrane targeting by protein isoprenylation is required (see Fig. 144.2).

In mice, the contact activating system and intrinsic coagulation cascade have been shown to participate in arterial thrombosis after injury and to have proatherogenic properties.¹⁴ Targeting these systems is attractive in that patients with known deficiencies in factor XII or contact system proteins have no obvious phenotype and do not have a bleeding diathesis, thus presumably an antithrombotic effect could be achieved without altering normal hemostasis.

CROSS-TALK BETWEEN COAGULATION AND INFLAMMATION SYSTEMS IMPACT ATHEROGENESIS

As noted previously, atherosclerosis can be thought of as a chronic, low-grade inflammatory disease of the artery wall. Clinical studies based on biomarkers, such as hsCRP, MPO, and IL-6, also suggest that advanced atherosclerosis is associated with a systemic state of chronic inflammation and that the degree of inflammation reflects the level of risk for major complications, possibly because the more inflamed the plaque, the more vulnerable the lesion. It is also now clear that mediators of inflammation, such as IL-1, LPA, oxLDL, and circulating MPs may interact with platelets and the coagulation cascade to promote a hypercoagulable, prothrombotic state. Furthermore, mediators of coagulation, such as thrombin, TF–factor VIIa complexes, and factor Xa, may contribute to the proinflammatory state by interacting with protease-activated receptors on endothelial cells and leukocytes. Activated platelets can contribute to inflammation by facilitating monocyte adhesion to endothelium and by secreting small molecules (ATP, pyrophosphates, and serotonin), cytokines, and growth factors that have proinflammatory activity. Thus bidirectional cross-talk between the inflammation and

coagulation systems serves to enhance each other and to promote atherosclerosis.

Not surprisingly, patients with systemic autoimmune inflammatory disorders, including rheumatoid arthritis, Wegener's granulomatosis, and lupus erythematosus have been shown to have accelerated atherosclerosis, as assessed by biomarkers, such as ultrasound evidence of carotid artery intima-medial thickening, as well as major cardiovascular events. Obesity, a risk factor for atherosclerosis, is now also known to be a systemic inflammatory disorder, with evidence of inflammation readily detectable within obese central adipose tissue. Obese patients also have elevated, circulating levels of coagulation and inflammation biomarkers, including plasminogen activator inhibitor-1 (PAI-1).

Given these observations, there has been renewed interest in exploring the use of antiinflammatory agents and antithrombotic agents to slow the progress of atherosclerosis. The approach has been tempered by clinical studies showing small increases in atherosclerotic complications in patients taking cyclooxygenase (COX) inhibitors (especially those with preferential activity against COX2), but this may relate to the specific target and the complication of altered eicosanoid production, perhaps changing the balance away from antiatherothrombotic end products, such as prostacyclin and resolvins, towards proatherothrombotic products, such as thromboxane, HETE, and lipoxins. Also, although aspirin and ADP receptor antagonists definitively reduce risk for major cardiovascular events, no studies have shown an impact on burden of atheroma. Nevertheless, novel agents targeted to more specific atherothrombotic pathways, such as chemokines, LDL oxidation, SRs, lipoxygenases, phospholipase 2, leukotrienes, selectins, and IL-1 are being considered.²⁹

PLAQUE REGRESSION

Finding pharmacologic approaches to decrease the amount of arterial plaque has proved to be an elusive goal. Intravenous ultrasound has shown that very aggressive lowering of LDL cholesterol with high-dose statins and extremely rigorous dietary alterations can halt plaque progression and, in some cases, cause some regression.⁴ As noted previously, strategies to enhance RCT or to induce macrophage emigration from plaque are being developed, and strategies to stabilize plaque by targeting the neovasculature, cellular apoptosis, and efferocytosis are being considered. Specific antioxidant approaches based on fundamental understanding of the oxidation processes relevant to atherosclerosis remain viable as well, and much effort is being put into developing new animal models to study plaque regression.

ADDITIONAL FUTURE DIRECTIONS

Initial enthusiasm for large-scale genome-wide association studies (GWAS) as discovery platforms to identify novel genes and pathways that could be targeted with therapeutic or preventive effect has waned as multiple expensive studies have failed to produce impressive results. The most consistent data to come from GWAS identified a fairly large genomic region on chromosome 9p21 as a risk site, but identification of specific genes has not yet been accomplished with certainty. More recently, approaches moving beyond GWAS have coupled whole-genome or whole-exome sequencing of highly selective subjects (such as genetically isolated Icelanders³⁰ or subjects with high or low lipoprotein levels) followed by deep sequencing of specific candidate genes in larger cohorts. This approach has yielded new data identifying potential novel antiatherothrombosis targets; for example, loss of function variants of asialoglycoprotein receptor-1, NPC1L1, and APOC3 were found to be associated with decreased levels of non-HDL cholesterol and decreased risk of coronary artery disease.

An area of research that has generated significant intriguing data of potential relevance to atherosclerosis diagnostics and therapeutics is microRNA (MiR) biology. MiRs are small noncoding RNAs that regulate gene expression levels in a sequence-specific manner by

posttranscriptional mechanisms. Dozens of specific MiRs have been identified that are expressed in highly regulated tissue-specific manners, and that regulate expression of genes involved in all aspects of atherosclerosis, including hepatic lipoprotein homeostasis; macrophage, endothelial cell, and smooth muscle cell functions; mechanosensory functions; and cytokine expression.³¹ Therapeutic interventions based on specific MiRs are under development, including, as noted previously, an inhibitor of MiR-33 to raise HDL levels and promote RCT. Unbiased "omics" studies to identify expression levels of MiR-mRNA pairs that associate with cardiovascular risk or with circulating lipoprotein levels also show promise for both biomarker development and therapeutic target discovery.

Another very promising avenue of research in atherothrombosis is the gut microbiome. Elegant studies using mouse models and human subjects have identified a "metaorganismal" pathway that contributes both to the development of plaque³² and to the prothrombotic state associated with atherosclerosis.³³ Diets rich in phosphatidyl choline, choline, and carnitine (which are present in meats, eggs, and cheese) can be metabolized in the gut by specific genera of microbes to generate trimethyl amine (TMA). TMA enters the circulation and is then converted to trimethyl amine oxide (TMAO) in the liver by flavin monooxidase enzymes. TMA and TMAO levels in blood associate strongly with both risk of cardiovascular disease and arterial thrombosis in human subjects, and TMAO was shown to promote platelet activation in vitro and thrombosis in vivo in animal models. Importantly, the constitution of the gut microbiome can be influenced by diet, and thus the ability to generate TMA and TMAO can also be influenced by diet. Human subjects on vegan diets have much less ability to generate TMA/TMAO than do carnivores and omnivores, and this could be restored simply by adding back meat, eggs, or carnitine to the diet. Interestingly, atherothrombotic risk in mice could be transmitted from susceptible to resistant strains by fecal microbiome transplant,³⁴ and resistant strains could be converted to susceptible by antibiotic or dietary manipulation of the microbiome. These studies suggest that microbial enzymes and/or ecosystems could be targeted for atherothrombosis treatment and prevention strategies.

Finally, although B cells are not prominent cellular constituents of plaque, B1 subclass cells responsible for innate antibody generation are present in plaque from humans and experimental animals. These cells produce innate IgM antibodies, including a prevalent species called E06 that reacts with oxLDL. E06 and other autoantibodies against plaque constituents may be protective, perhaps by facilitating clearance of oxLDL via pathways that do not lead to foam cell formation, and/or by interfering with oxLDL-mediated activation of circulating monocytes and platelets.¹⁵ Based on these observations, passive immunization strategies against oxLDL are also being considered.

Emer McGrath, Michelle Canavan, and Martin O'Donnell

Stroke is the leading cause of acquired adult disability worldwide and the fourth most common cause of death in developed countries. Primary stroke subtypes include ischemic stroke, intracerebral hemorrhage (ICH), and subarachnoid hemorrhage (SAH). Each stroke subtype has differing etiologies, outcomes, and management strategies. The past 20 years has seen considerable advances in diagnosis (emergence of widely available neuroimaging) and treatment of acute stroke. In addition, there is an increased awareness of the importance of covert stroke (stroke on neuroimaging without a history of acute clinical stroke). In this chapter we provide an overview of stroke, with a primary focus on ischemic stroke, which is the most common cause of stroke worldwide.

DEFINITION

Stroke is defined by the World Health Organization (WHO) as “rapidly developing clinical signs of focal (at times global) disturbance of cerebral function, lasting more than 24 hours or leading to death with no apparent cause other than that of vascular origin.” This definition is conventionally considered to include ischemic stroke, ICH, and SAH. However, because of advances in our knowledge about the nature, timing, and clinical presentation of stroke and its mimics, as well as significant advances in neuroimaging (particularly magnetic resonance imaging [MRI]), an updated definition of central nervous system (CNS) infarction has been proposed by the American Heart Association (AHA)/American Stroke Association (ASA). CNS infarction (including hemorrhagic infarction) is defined as “brain, spinal cord, or retinal cell death attributable to ischemia, based on: (1) pathologic, imaging, or other objective evidence of cerebral, spinal cord, or retinal focal ischemic injury in a defined vascular distribution; or (2) clinical evidence of cerebral, spinal cord, or retinal focal ischemic injury based on symptoms persisting ≥ 24 hours or until death, and other etiologies have been excluded.” According to the AHA/ASA, a transient ischemic attack (TIA) is defined as a transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction.

EPIDEMIOLOGY

Frequency

The WHO estimates that 15 million people suffer a stroke each year, and of these, 5 million people are left with permanent disability. In the absence of further effective population-based interventions, a projected 6.5 million stroke deaths will occur in 2015 and 7.8 million deaths in 2030. A small decrease in age-specific stroke mortality rates has been projected from 2005 to 2030, which is largely because of a decline in mortality rates in high-income countries. However, because of an increasingly aging population worldwide, the crude stroke mortality rates are projected to increase across all ages, from 89 per 100,000 in 2005 to an estimated 98 per 100,000 in 2030. The increase in stroke mortality will be most marked in developing countries, where increases in stroke incidence are most prominent. Worldwide, stroke shows significant geographical variation in terms of incidence (and temporal trends), case fatality, and case mix (i.e., stroke subtypes). A systematic review of population-based studies reported that from 1970 to 2008 there was a 42% decrease in the

incidence of stroke in high-income countries, compared with a more than 100% increase in the incidence of stroke in middle- and low-income countries.

Traditional Risk Factors for Stroke

Both ischemic stroke and ICH are associated with a number of potentially modifiable risk factors, including hypertension, diabetes mellitus, smoking, poor diet, and physical inactivity. The INTER-STROKE study, which included 26,919 participants from 32 countries, reported that 10 key risk factors are associated with 90% of the population-attributable risk (PAR) of ischemic stroke, namely hypertension, smoking, waist-to-hip ratio, diet, physical activity level, diabetes mellitus, alcohol intake, psychosocial stress/depression, cardiac causes such as atrial fibrillation, and ratio of apolipoprotein B to apolipoprotein A1 (Table 145.1). Of these risk factors, five were associated with about 80% of the PAR for all stroke (hypertension, smoking, abdominal obesity, physical inactivity, and diet), and each was an important risk factor for both ischemic and hemorrhagic stroke. Thus a large proportion of stroke is potentially preventable through population-based interventions aimed at modifying these risk factors. Hypertension is the strongest risk factor for both ischemic stroke and ICH and, arguably, the most modifiable through lifestyle intervention (e.g., reducing salt intake) and use of antihypertensive medications.

PATHOBIOLOGY

Stroke can be primarily classified into ischemic stroke (Fig. 145.1) and hemorrhagic stroke. Hemorrhagic stroke is further subtyped into ICH (Fig. 145.2) and SAH. In North America and Europe, approximately 87% of strokes are caused by ischemia, with the remaining 13% occurring caused by hemorrhage.

Etiological Classification of Ischemic Stroke

Unlike acute coronary syndrome, which is primarily caused by large-vessel atherosclerosis, the underlying mechanisms for ischemic stroke are more heterogeneous. The most commonly used etiological classification is the Trial of Org 10172 in Acute Stroke Treatment (TOAST) classification system, which focuses on the pathophysiologic mechanism of ischemic stroke, based on clinical features and the results of diagnostic investigations (brain imaging, cardiac investigations, and neurovascular imaging). The five etiological subcategories in the TOAST classification system are: large-artery, cardioembolism, small-artery occlusion (or lacunar ischemic stroke), stroke of other determined etiology, and stroke of undetermined etiology.

Large-Artery Stroke

Large-artery stroke is usually a consequence of atherosclerosis in the extracranial (carotid or vertebral) and/or intracranial arteries (e.g., middle cerebral or basilar artery), with plaque rupture and thrombus formation. Ischemic stroke may result from artery-to-artery thromboembolism with distal occlusion or, less commonly, by acute

Fig. 145.1 COMPUTED TOMOGRAPHY OF BRAIN WITH RIGHT INTRACEREBRAL HEMORRHAGE.

TABLE 145.1 Traditional Risk Factors for Ischemic Stroke

Risk Factor	PAR (99% CI)
Hypertension (self-reported history or blood pressure $\geq 140/90$ mmHg)	47.9% (45.1–50.6)
Current smoking ^a	12.4% (10.2–14.9)
Diabetes mellitus	3.9% (1.9–7.6%)
Ratio of apoB to apoA1	26.8% (22.2–31.9)
Obesity (waist to hip ratio)	18.6% (13.3–25.3)
Physical inactivity	35.8% (27.7–44.7)
Diet risk score	23.2% (18.2–28.9)
Alcohol consumption (current)	5.8% (3.4–9.7)
Psychosocial factors	17.4% (13.1–22.6)
Cardiac etiologies	9.1% (8.0–10.2)

^aComparator for current smoker and alcohol intake is never or former. Apo, Apolipoprotein; CI, confidence interval; PAR, population-attributable risk. From O'Donnell MJ, Chin SL, Rangarajan S, et al: Global and regional effects of potentially modifiable risk factors associated with acute stroke in 32 countries (INTERSTROKE): a case-control study. *Lancet* 388:761, 2016.

occlusion with resultant hypoperfusion (e.g., watershed infarction). Large-vessel atherosclerosis accounts for about 20% of all ischemic strokes in high-income countries, and is predominantly extracranial in origin. Intracranial atherosclerosis has been reported to account for up to 33%–50% of ischemic strokes in parts of Asia (e.g., China and Thailand), but it is a much less common cause of acute stroke in North America and Europe. Arterial dissection, the third leading cause of ischemic stroke in young people, can lead to ischemic stroke either by local occlusion or distal thromboembolism. Predisposing factors for dissection include trauma and underlying arteriopathies, such as fibromuscular dysplasia. Less common large-vessel mechanisms of ischemic stroke include moyamoya disease, Fabry disease, and large-vessel arteritis (e.g., Takayasu arteritis and giant-cell arteritis).

Fig. 145.2 COMPUTED TOMOGRAPHY OF BRAIN WITH LEFT HEMISPHERIC ISCHEMIC STROKE.

Cardioembolism

Approximately 14%–30% of all ischemic strokes are caused by cardioembolism, with marked regional variation. A number of conditions predispose to cardioembolism, originating from the venous system (paradoxical embolism), intracardiac (e.g., atrial fibrillation), or postcardiac (aortic arch disease).

Precardiac

Paradoxical emboli occur when emboli that arise in the venous circulation (e.g., from deep vein thrombosis) cross into the arterial circulation through a patent foramen ovale (PFO), atrial septal defect (ASD), or a pulmonary arteriovenous malformation (AVM). PFO is found in up to 20% of the general population. A number of observational studies have reported an association between first ischemic stroke and PFO, particularly in younger patients, but PFO has not been shown to be a risk factor for recurrent ischemic stroke. Atrial septal aneurysm, a protrusion of part of the atrial septum through the fossa ovalis into the right or left atrium, is associated with an increased risk of ischemic stroke, particularly when it occurs in conjunction with a PFO.

Intracardiac

Left-sided cardiac sources of emboli include left atrial thrombus secondary to atrial fibrillation or flutter, left ventricle thrombus subsequent to a transmural myocardial infarction, akinetic segments of myocardium with a low ejection fraction in the setting of an old myocardial infarction, cardiac tumors such as left atrial myxoma, and abnormalities of the mitral valve (both native and artificial). Atrial fibrillation or flutter is a significant risk factor for stroke, associated with a fivefold increase in risk. In North America and Europe, about 25% of all ischemic strokes are attributed to atrial fibrillation, a proportion that increases with older age. After acute myocardial infarction, mural thrombi can arise in the presence of left ventricular aneurysms, akinetic segments of left ventricular myocardium, or new-onset atrial fibrillation or flutter. Congestive heart failure is also an independent risk factor for stroke and is associated with a two- to threefold increased relative risk of ischemic stroke. Valvular heart disease can involve both native (e.g., rheumatic heart disease) and prosthetic heart valves. Of native valvular disease, mitral stenosis has the strongest association with ischemic stroke; mitral annular calcification and mitral valve prolapse have weaker associations. Mitral stenosis is also commonly associated with atrial fibrillation, further increasing the risk of ischemic stroke. Emboli can also arise from

valvular vegetations in nonbacterial thrombotic endocarditis or infective endocarditis. Mechanical mitral and aortic valves are associated with a sufficiently high risk for ischemic stroke that indefinite oral anticoagulant therapy is indicated. Rheumatic heart disease still accounts for half of all cases of endocarditis in some regions of the world (e.g., India and Africa). Several epidemiologic studies have shown a link between ischemic stroke and *Trypanosoma cruzi* infection (Chagas disease) in South America.

Postcardiac

Atherosclerotic plaques in the aortic arch, proximal to the left subclavian artery, can be postcardiac sources of emboli, either atheromatous debris or platelet emboli, which then enter the cerebral circulation resulting in an ischemic stroke. Severe aortic arch atheromas (>4 mm in diameter) are associated with a fourfold increase in the risk of ischemic stroke and peripheral embolism. Although anatomically a large vessel source, aortic arch disease is usually included in cardiac causes of ischemic stroke because it is often identified via transesophageal echocardiography.

Small-Vessel Disease

Approximately 20% of all ischemic strokes are caused by lacunar or small-vessel infarcts. Lacunar infarcts are the result of occlusion of small, deep-penetrating arteries, such as the lenticulostriate branches of the anterior cerebral and middle cerebral arteries. The terminal pathophysiological mechanism underlying small-artery occlusion is believed to be local thrombosis secondary to microatheroma (lipid-laden macrophages, cholesterol deposits, and subintimal fibroblast proliferation) and lipohyalinosis (the intermediate stage between fibrinoid necrosis and microatheroma, which has characteristics of both arterial atheromatous lipid deposits and arteriolar hyalinization disease). Growing evidence supports the concept that damage to the glycocalyx, by factors such as hyperglycemia, hypertension, and smoking, may contribute to vascular endothelial damage. Other causes of small-artery occlusion include microemboli from atherosclerotic plaques, polycythemia vera, antiphospholipid antibodies, amyloid angiopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL), cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), Sneddon syndrome, and various types of small-vessel arteritis. The combination of mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes (MELAS) is an inherited progressive disorder characterized by mitochondrial dysfunction and early onset of stroke, typically before the age of 40 years. The mitochondrial angiopathy hypothesis suggests that the lesions are secondary to ischemia, which is caused by mitochondrial and vascular dysfunction of cerebral small arteries.

Ischemic Stroke of Other Determined Etiology

Cerebral Vein Thrombosis

Cerebral vein thrombosis accounts for less than 1% of ischemic strokes, and typically affects younger people. The superior sagittal, transverse, and cavernous sinuses are those most commonly affected by thrombosis. Venous thrombosis results in localized edema and venous infarction, which often becomes hemorrhagic, and may raise intracranial pressure (ICP). Reported risk factors for cerebral vein thrombosis include inherited thrombophilia; acquired prothrombotic states such as antiphospholipid syndrome, pregnancy, and the puerperium; infections such as otitis, sinusitis, and mastoiditis; chronic inflammatory conditions such as Wegener granulomatosis and sarcoidosis; trauma such as a head injury, dehydration, and injury to the jugular veins or sinuses during neurosurgical procedures.

Intracerebral Hemorrhage

ICH accounts for approximately 10%–15% of all strokes (a larger proportion is reported in middle- and low-income countries), and can

be classified as either primary or secondary, depending on the underlying cause. Primary ICH accounts for about 80%–90% of cases and is the result of spontaneous rupture of small intracerebral blood vessels, usually damaged by chronic hypertension (and other vascular risk factors) or amyloid angiopathy. Antithrombotic therapy, particularly anticoagulant therapy, is an important risk factor for ICH. Secondary ICH occurs as a result of vascular abnormalities (ruptured saccular aneurysm, arteriovenous malformation), tumors (e.g., cavernous angioma, intracerebral neoplasm), impaired coagulation (e.g., because of use of oral anticoagulants or bleeding disorders such as hemophilia or von Willebrand disease), hemorrhagic transformation of ischemic stroke, septic emboli, vasculitis, moyamoya disease, and alcohol or illicit drug use (e.g., cocaine, amphetamines).

Subarachnoid Hemorrhage

SAH refers to bleeding within the subarachnoid space, which is the space between the arachnoid and pia mater. SAH accounts for about 3%–5% of all strokes and is most commonly caused by rupture of an intracranial aneurysm (approximately 80%–85% of cases). Idiopathic nonaneurysmal perimesencephalic hemorrhage accounts for about 10% of cases, and the remaining 5% are caused by rare causes such as inflammatory lesions of cerebral arteries (e.g., mycotic aneurysm, polyarteritis nodosa, primary angiitis), noninflammatory lesions of intracerebral vessels (e.g., arterial dissection, cerebral arteriovenous malformations, cerebral amyloid angiopathy, cerebral venous thrombosis, moyamoya disease), vascular lesions of the spinal cord (e.g., saccular aneurysm of the spinal artery, spinal arteriovenous malformation), coagulopathy (e.g., hemophilia, von Willebrand disease), sickle cell disease, tumors (e.g., malignant glioma), trauma, and drug use (cocaine, anticoagulants).

Covert Stroke

Clinically overt stroke is considered to represent only a fraction of all episodes of cerebral infarction. The advent of contemporary MRI sequences has identified a large burden of subclinical cerebrovascular disease, which includes covert infarction, white matter hyperintensities, cerebral atrophy, and microbleeds. Covert stroke is common; for example, a systematic review of eight population-based studies reported a prevalence of silent brain infarcts in an older population of 8%–28%. Moreover, covert stroke has been associated with an increased risk of cognitive decline, dementia, depression, and gait impairment (Box 145.1).

Hematologic Disorders and Ischemic Stroke

Inherited Thrombophilia

In general, studies have reported either no association or a modest association between inherited thrombophilia and ischemic stroke.

BOX 145.1 What Is Cryptogenic Ischemic Stroke?

In some cases, the cause of stroke cannot be definitively determined and the stroke is classified as “stroke of undetermined etiology.” A stroke may be classified in this category when one of the following two conditions is met: (1) an extensive evaluation is negative, which includes large-vessel imaging, and complete cardiovascular assessment is negative; or (2) the diagnostic evaluation is incomplete. The most important determinant of the proportion of patients labeled as having cryptogenic stroke is the extent of the etiological diagnostic testing, including transesophageal echocardiography. In studies that have completed an extensive etiological workup, the proportion of patients designated as having cryptogenic stroke is small (5%–15%). In older patients with complete evaluation, paroxysmal atrial fibrillation is suspected to be a common underlying cause of ischemic stroke in older adults with “cryptogenic” ischemic stroke.

Meta-analyses of observational studies have failed to demonstrate a significant association between the factor V Leiden mutation and ischemic stroke in adults, although some small case-control studies have reported an increased risk of ischemic stroke in women with factor V Leiden using oral contraceptives. Two large prospective population studies, the Physicians' Health Study and the Cardiovascular Health Study, failed to demonstrate a significant association between the prothrombin *G20210A* mutation and ischemic stroke risk, although a large meta-analysis of 19 case-control studies reported a modest association. There is no evidence to support an association between protein C, protein S, or antithrombin deficiency and ischemic stroke risk in adults.

Antiphospholipid Syndrome

Antiphospholipid syndrome is reviewed in [Chapter 141](#). Stroke is the main acute arterial thrombotic complication of antiphospholipid syndrome, and is reported to be the initial clinical manifestation in 13% of patients subsequently diagnosed with antiphospholipid syndrome. However, the overall association between antiphospholipid antibodies (without other features of the syndrome) and ischemic stroke is less certain. Anticardiolipin antibodies have been associated with ischemic stroke in some studies, especially in young women, but not in others. The lupus anticoagulant is a more potent risk factor for ischemic stroke. For example, in the Risk of Arterial Thrombosis in Relation to Oral Contraceptives (RATIO) study, the odds ratio (OR) for an association between the lupus anticoagulant and ischemic stroke was 43.1 (95% CI, 12.2–152.2) compared with an OR of 2.3 (95% CI, 1.4–3.7) for anti- β_2 -glycoprotein I antibodies and no significant association reported for anticardiolipin antibodies. Current AHA guidelines recommend antiplatelet therapy for secondary prevention of ischemic stroke in patients with cryptogenic ischemic stroke who do not meet the criteria for antiphospholipid syndrome but have antiphospholipid antibodies. For patients with cryptogenic ischemic stroke who meet the diagnostic criteria for antiphospholipid syndrome and who have persistently moderate-to-high antiphospholipid antibody titers for more than 12 weeks, oral anticoagulant therapy for secondary prevention of ischemic stroke can be considered. The most recent American College of Chest Physicians (ACCP) guideline recommends oral anticoagulant therapy with a target international normalized ratio (INR) of 2–3 for the latter group

Sickle Cell Disease

Sickle cell disease is associated with an increased risk of stroke, particularly in those homozygous for the sickle cell gene. The risk of stroke is 11% at 20 years of age, 15% at 30 years, and 24% at 45 years. The most common mechanism underlying ischemic stroke in sickle cell disease is believed to be large-artery arteriopathy secondary to hyperplasia of the intima from repeated endothelial injury.

Myeloproliferative Disorders

Myeloproliferative disorders, such as polycythemia vera and essential thrombocythemia, are uncommon conditions associated with an increased risk of stroke. In a randomized controlled trial of daily aspirin in 518 patients with polycythemia vera, the combined rate of ischemic and hemorrhagic stroke was 1.2% in the aspirin group compared with 3.8% in the control group over 3 years. Defective platelet function in these disorders also results in an increased risk of ICH.

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenic purpura is an uncommon systemic disorder associated with an increased risk of ischemic stroke. It is

characterized by a pentad of thrombocytopenia, microangiopathic hemolytic anemia, fever, renal failure, and neurologic abnormalities including ischemic stroke (see [Chapter 134](#))

Paraproteinemias

The paraproteinemias, including Waldenström macroglobulinemia, multiple myeloma, and POEMS syndrome (characterized by a plasma-cell proliferative disorder, typically myeloma, polyneuropathy, with involvement of multiple other organ systems) are also associated with an increased risk of ischemic stroke and hemorrhagic stroke (because of thrombocytopenia).

Genetic Risk Factors

A substantial body of evidence from twin, family, and animal studies supports a genetic contribution to stroke risk. A recent meta-analysis of genome-wide association studies from more than 12,000 patients with ischemic stroke identified three loci with genome-wide significance for ischemic stroke—*PITX2* and *ZFHX3*, previously associated with an increased risk of atrial fibrillation, were associated with an increased risk of ischemic stroke, whereas *HDAC9* was associated with an increased risk of large-artery stroke. Another meta-analysis reported that APOE ϵ 2 carrier status was associated with an increased burden of white matter hyperintensities (a marker for prior cerebrovascular disease) and risk of ischemic stroke

The concordance rate for stroke is 65% higher in monozygotic twins compared with dizygotic twins, with a range of 12.8%–19.0% in monozygotic twins and 3.6%–13.0% in dizygotic twins. Family history of stroke increases the risk of ischemic stroke by about 75% and the presence of a first-degree relative with a history of hemorrhagic stroke is associated with a sixfold increase in risk of hemorrhagic stroke. A number of monogenic disorders have been associated with an increased risk of ischemic stroke, including Marfan syndrome, Fabry disease, familial moyamoya disease, homocystinuria, sickle cell disease, and MELAS. Rare Mendelian forms of stroke have been described such as CADASIL and CARASIL, which manifest as small-vessel ischemic stroke. However, most monogenic disorders are infrequent and thus have limited impact on the wider population, despite their marked effect on individual risk in young populations.

CLINICAL MANIFESTATIONS

Clinical Presentation

Stroke is a clinical diagnosis, supported by the results of neuroimaging (computed tomography [CT] or MRI of the brain). CT of the brain may be normal in patients with acute ischemic stroke, and cases of MRI-negative stroke also occur. With advances in neuroimaging, an increasing proportion of patients (about one-quarter) presenting with transient neurologic deficits (previously diagnosed as TIA) have small infarcts identifiable on high-quality MRI. Clinically, stroke is characterized by the sudden onset of typically a focal neurologic deficit, lasting more than 24 hours or leading to death because of a presumed vascular cause. Common presenting features are lateralizing weakness of the upper extremities and/or lower extremities, facial weakness, speech abnormalities (aphasia, dysarthria), visual loss (monocular visual loss or homonymous hemianopia), reduced level of consciousness, ataxia, diplopia, vertigo, and headache. A number of clinical conditions can mimic stroke. Among patients admitted to a hospital with suspected stroke, only about two-thirds are subsequently diagnosed with stroke. Common stroke mimics include migraine, seizure, syncope, hypoglycemia, primary or secondary brain tumors, transient global amnesia, and toxic-metabolic disturbances with delirium.

Ischemic Stroke versus Intracerebral Hemorrhage

Ischemic stroke and ICH can have similar presentations. Although some clinical features are more typically associated with ICH (e.g., coma, neck stiffness, seizures, vomiting, and headache) than ischemic stroke, neuroimaging is required to discriminate between them. Therefore emergent CT or MRI of brain is mandatory in all patients presenting with suspected acute stroke.

Measuring Stroke Severity

Many scales are available for measuring stroke severity, including the Scandinavian Stroke Scale, the Canadian Stroke Scale, and the National Institutes of Health Stroke Scale (NIHSS). The NIHSS is the scale most widely used in clinical practice. Other scales (e.g., Hunt and Hess, Fisher) are used to measure stroke severity in patients with SAH.

Risk of Stroke After Transient Ischemic Attack

The ABCD2 score is a validated clinical prediction score for risk of stroke in patients with TIA. Points are score for each of the following risk factors: age >60 years (1); blood pressure $\geq 140/90$ mmHg on first evaluation (1); clinical symptoms of focal weakness (2) or speech impairment without weakness (1); duration of 10–59 minutes (1) or ≥ 60 minutes (2); and diabetes mellitus (1). In combined validation cohorts, the 2-day risk of stroke was 0% for scores of 0 or 1, 1.3% for scores of 2 or 3, 4.1% for scores of 4 or 5, and 8.1% for scores of 6 or 7.

INVESTIGATIONS

Computed Tomography of the Brain

Neuroimaging is required to distinguish between ischemic and hemorrhagic stroke. On CT of the brain, early features of ischemia include loss of distinction between the gray and white matter border, sulcal effacement, loss of definition of the insula, and evolving areas of hypodensity. Scoring systems (e.g., ASPECT score) may be used to quantify the burden of ischemia, which predicts the risk of ICH in patients receiving thrombolysis. SAH is not reliably excluded by CT alone. If there is a high index of suspicion for SAH, a lumbar puncture is needed to reliably exclude this diagnosis.

Magnetic Resonance Imaging

MRI is superior to CT for detecting acute ischemia. In the acute setting, however, its use is limited by patient contraindications and availability. Diffusion-weighted imaging (DWI) may identify acute ischemia within 3–6 hours of symptom onset. For diagnosis of ICH, MRI with gradient-related echo or susceptibility-weighted imaging has been reported to provide results similar to those provided by CT of the brain (96% concordance).

Neurovascular Imaging

Extracranial and intracranial stenosis may be detected using ultrasound, CT angiography, magnetic resonance angiography, or conventional angiography. Ultrasound is a noninvasive, relatively inexpensive, and widely available imaging modality, but is dependent on ultrasonographer experience and skill. Transcranial Doppler may be used to detect intracranial large vessel stenosis, and has also been shown to risk-stratify patients with carotid stenosis with microembolic signals.

Cardiac Workup

An electrocardiogram can identify atrial fibrillation/flutter or evidence of previous myocardial infarction whereas in-hospital telemetry can identify a larger proportion of patients with paroxysmal atrial fibrillation. Based on the results of the recent CRYSTAL AF and EMBRACE trials, extended cardiac rhythm monitoring using loop recorders increases detection rates of paroxysmal atrial fibrillation in patients with cryptogenic ischemic stroke older than 55 years. Longer durations of cardiac monitoring result in higher diagnostic yield, but the optimal duration is uncertain. Transthoracic echocardiography has a low yield in patients with no previous cardiac history and a normal cardiac examination. The routine use of transesophageal echocardiography is controversial; however, this is an essential investigation in patients with suspected endocarditis. A PFO can be identified with a bubble study when performing transthoracic or transesophageal echocardiography. Although transesophageal echocardiography identifies potential etiologies of ischemic stroke in a relatively large proportion of patients, such as PFO, atrial septal aneurysm, or aortic arch disease, the treatment implications of these findings are less certain. All patients presenting with stroke should have vascular risk factor profiling, including measurement of blood pressure, fasting lipids, blood glucose, and glycated hemoglobin (HbA1c). All patients should have a complete blood count, troponin, and coagulation profile. Other useful tests, depending on clinical suspicion, may include erythrocyte sedimentation rate, antiphospholipid antibody panel, blood cultures, antineutrophilic cytoplasmic antibodies, antinuclear antibodies, homocysteine, and lipoprotein A.

THERAPY

A complete review of the management of stroke is beyond the scope of this chapter. Instead we provide an overview of the acute and chronic management of stroke.

Reperfusion Therapy for Acute Ischemic Stroke

Thrombolysis for Acute Ischemic Stroke

Intravenous tissue plasminogen activator (t-PA) is the most rigorously evaluated thrombolytic intervention in acute ischemic stroke. Current guidelines recommend administration of t-PA in patients with acute ischemic stroke presenting within 3 hours of symptom onset. Based on the results of the ECASS III trial, current guidelines recommend administration of t-PA to eligible patients up to 4.5 hours after symptom onset, provided none of the following additional exclusion criteria are met: age >80 years, NIHSS >25 , history of both prior stroke and diabetes mellitus, use of oral anticoagulant therapy at the time of acute stroke, or imaging evidence of ischemic injury involving more than one-third of the middle cerebral artery territory. The main complication of t-PA is ICH. In the Third International Stroke Trial (IST-3), which enrolled patients up to 6 hours after symptom onset, there was an increased risk of spontaneous ICH and death at 7 days compared with the control group, although total mortality was similar between the two groups at 6 months. Currently t-PA is not approved by the European Medicines Agency (EMA) beyond 4.5 hours after symptom onset (Table 145.2).

Intraarterial Fibrinolysis

Current guidelines recommend intraarterial fibrinolysis in carefully selected patients with major ischemic strokes caused by middle cerebral artery occlusion if the duration of symptoms is less than 6 hours and they are ineligible for intravenous t-PA. Rescue intraarterial fibrinolysis is an option for recanalization in patients with large-artery occlusion who have not responded to intravenous t-PA. Use of intraarterial t-PA is currently not FDA approved. Limited access to

TABLE 145.2 Eligibility Criteria for Acute Thrombolysis in Acute Ischemic Stroke**Eligibility Criteria**

Diagnosis of ischemic stroke causing measurable neurological deficit
 The neurological signs should not be minor and isolated. Caution should be exercised in treating a patient with major deficits
 Onset of symptoms <4.5 hours before beginning treatment
 The neurologic signs should not be clearing spontaneously
 The symptoms of stroke should not be suggestive of subarachnoid hemorrhage
 The patient or family members should understand the potential risks and benefits from treatment

Contraindications for Thrombolysis

Evidence of intracranial hemorrhage on CT
 Head trauma or prior stroke in previous 3 months
 Myocardial infarction in the previous 3 months
 Gastrointestinal or urinary tract hemorrhage in previous 21 days
 Arterial puncture at a noncompressible site in the previous 7 days
 Major surgery in the previous 14 days
 History of previous intracranial hemorrhage
 Elevated blood pressure (systolic >185 mmHg and diastolic >110 mmHg)
 Evidence of active bleeding or acute trauma (fracture) on examination
 Taking an oral anticoagulant or, if taking anticoagulant, INR ≥ 1.7 is a contraindication
 If receiving heparin in previous 48 hours, aPTT must be in normal range.
 Platelet count $\leq 100\,000\text{ mm}^3$
 Blood glucose concentration $\geq 50\text{ mg/dL}$ (2.7 mmol/L)
 Seizure with postictal residual neurologic impairments
 CT shows a multilobar infarction (hypodensity >1/3 cerebral hemisphere)

aPTT, Activated partial thromboplastin time; CT, computed tomography; INR, international normalized ratio.

interventional neuroradiology has been a major limitation to the use of this intervention and it has not yet been evaluated in large-scale clinical trials.

Mechanical Thrombectomy

The MR-CLEAN, ESCAPE, SWIFT PRIME, and EXTEND IA trials demonstrated the benefit of early intraarterial mechanical thrombectomy compared with intravenous thrombolysis alone in patients with acute ischemic stroke caused by large proximal artery occlusion meeting the following criteria: (1) small infarct size with no evidence of hemorrhage on baseline CT of brain; (2) evidence of proximal large-artery occlusion in the anterior circulation on vessel imaging (e.g., CT angiography); (3) symptom onset within the past 6–12 hours (three of the trials utilized a 6-hour cut-off and most of the patients in ESCAPE were enrolled within the 6-hour window); (4) rapid access to a stroke center with necessary expertise in use of second-generation stent retriever devices. Compared with intravenous thrombolysis alone, intraarterial treatment resulted in significantly higher rates of functional independence at 90 days in all four trials, with no significant difference in the risk of symptomatic ICH or death between treatment groups. The number needed to treat for one additional person to reach functional independence ranged from 3 to 7.5.

Acute Stroke Unit

Organized stroke unit (OSU) care in a dedicated, geographically identified ward with multidisciplinary teams that exclusively manage patients with stroke is associated with improved outcomes in patients with acute stroke. A meta-analysis of 26 trials ($n = 5592$) investigating OSU care reported a reduction in death (OR, 0.86; 95% CI,

0.76–0.98) and death or dependency at one year (OR, 0.82; 95% CI, 0.73–0.92) independent of age, sex, or stroke severity. Organized stroke care is associated with improved outcome for a number of reasons, including a reduced risk of medical complications such as deep vein thrombosis (caused by earlier mobilization), as well as a reduced risk of aspiration pneumonia, fever, urinary tract infection, falls, and delirium. Prompt evaluation of swallowing function and compliance with speech pathology safe swallowing guidelines help to reduce the risk of aspiration pneumonia in patients with stroke.

Blood Pressure in Acute Stroke

Although hypertension is the most important risk factor for both ischemic and hemorrhagic stroke, the optimal approach to managing blood pressure in the acute setting remains uncertain. A number of randomized controlled trials have evaluated acute blood pressure lowering in acute ischemic stroke, and meta-analyses of these trials reports no benefit of lowering blood pressure in acute phase of ischemic stroke, and current AHA guidelines recommend cautious introduction of antihypertensive therapy in those with an initial blood pressure >220/120 mmHg, unless there is an alternate indication for blood pressure lowering or the patient has received thrombolytic therapy (target <180/105 mmHg). The INTERACT-II phase III trial enrolled patients with spontaneous ICH within 6 hours of symptom onset and systolic blood pressure between 150 and 220 mmHg. There was no difference in the risk of death or major disability between patients randomized to intensive treatment (target systolic blood pressure <140 mmHg) compared with current guideline-recommended treatment (target systolic blood pressure <180 mmHg), although it was safe and an ordinal analysis of functional outcome (modified Rankin score) suggested improved functional outcomes with a blood pressure target of <140 mmHg. In the ATACH phase III trial of patients with ICH within 4.5 hours of symptom onset, an acute blood pressure-lowering target of 110–139 mmHg was not superior to a target of 140–179 mmHg for reduction in death and disability. The recent ENOS trial reported no difference in the risk of disability at 90 days between patients randomized to early (within 48 hours) blood pressure lowering after acute stroke versus no early intervention, or between patients randomized to continuation of home antihypertensives versus cessation of home medications in the acute period.

Antithrombotic Therapy in Acute Ischemic Stroke

Based on the results of two large randomized controlled trials, the International Stroke Trial (IST) and the Chinese Acute Stroke Trial (CAST), aspirin reduces the risk of recurrent stroke and death in patients with acute ischemic stroke. In general, therapeutic parenteral anticoagulant therapy is not indicated in acute ischemic stroke, with the exception of cerebral vein thrombosis. Therapeutic heparin is commonly used in patients with acute ischemic stroke and extracranial carotid or vertebral artery dissection, or symptomatic extracranial vertebral or carotid artery atherosclerotic stenosis with crescendo TIAs. However, there is limited evidence to guide clinical decision-making on optimal antithrombotic therapy in these patients. The recent CADISS trial, which included 250 patients with symptomatic carotid and vertebral artery dissection, reported no difference in the risk of recurrent stroke or death between patients randomized to antiplatelet and anticoagulant therapy. However, limitations of this study included the failure to confirm a diagnosis of dissection in 20% of participants along with very low rates of recurrent stroke.

Carotid Endarterectomy and Stenting

The European Carotid Surgery Trial (ECST) and the North American Symptomatic Carotid Endarterectomy Trial (NASCET) are the largest trials to evaluate carotid endarterectomy (CEA) in patients with recent

ischemic stroke and TIA. Based on the results of these trials, current guidelines recommend CEA in patients with 70%–99% stenosis of the ipsilateral carotid artery, provided the perioperative morbidity and mortality are estimated to be less than 6%. Although patients with 50%–69% stenosis also derive benefit from CEA, it is only recommended for selected patients based on age, comorbidities, time from stroke/TIA, and operative risk. Time from symptom onset to CEA is the primary determinant of the absolute risk reduction obtained with this procedure, with maximal benefit realized when CEA is performed within the first 2 weeks of symptom onset. Although CEA is the gold standard for patients with symptomatic significant carotid stenosis, carotid stenting is an alternative option for patients with over 70% stenosis considered to be a high operative risk for CEA.

Intracranial Stenting

Two trials have failed to show a benefit of intracranial stenting in patients with symptomatic and significant ($\geq 70\%$) intracranial stenosis. The SAMMPRIS trial reported no benefit of endovascular stenting (self-expanding stent) in addition to aggressive medical therapy, compared with aggressive medical therapy alone. The trial was stopped early because of a higher rate of stroke and death at 30 days in the endovascular group. The more recent VISSIT, which compared a balloon-expandable stent in addition to medical therapy with medical therapy alone, was terminated early because of higher rates of stroke or death at 30 days and 1 year in the endovascular group.

Prevention of Venous Thromboembolism

See Chapter 142.

Acute Management of Intracerebral Hemorrhage

Management of ICH includes both medical and surgical components. Initial strategies include monitoring in an intensive care setting in appropriate patients, intubation in those with reduced consciousness, discontinuation of antithrombotic therapy and immediate reversal of anticoagulant therapy (Chapter 149), administration of antipyretics for fever and insulin for hyperglycemia, and venous thromboembolism prophylaxis (e.g., compression stockings). Raised ICP can occur as a result of the hemorrhage itself or because of secondary edema. Management of increased ICP includes elevation of the head of the bed to 30 degrees, analgesia, and sedation. More aggressive therapies include osmotic diuretics with mannitol, drainage of cerebrospinal fluid using a ventricular catheter (ventriculostomy), hyperventilation, and neuromuscular blockade. Antiepileptic therapy should be used for seizure control, but prophylaxis is not recommended in current guidelines. The Surgical Trial in IntraCerebral Hemorrhage (STICH) showed no benefit of early surgery compared with medical management alone within 72–96 hours of onset of spontaneous ICH. However, uncertainty remains in some patient groups, and current guidelines suggest craniotomy for those with a lobar bleed of over 30 mL within 1 cm of the brain surface. Surgical evacuation is recommended in patients with cerebellar hemorrhage over 3 cm in diameter who have evidence of deterioration, brainstem compression, or hydrocephalus. Ventriculostomy with external drainage may be required for patients with intraventricular extension of ICH and a deteriorating level of consciousness. Based on a large phase III trial, current guidelines suggest that use of recombinant factor VIIa for acute ICH not associated with warfarin use is investigational and should not be used outside of a clinical trial.

Stroke Rehabilitation

Intensive rehabilitation should commence as early as possible after acute stroke. Animal models of neuroplasticity suggest that training

results in upregulation of growth-promoting factors primarily in the first 4 weeks following acute stroke, but recovery can continue for months or years after the acute event. High levels of patient (and family) motivation and engagement are associated with better outcomes from stroke rehabilitation. Substantial evidence supports a well-coordinated multidisciplinary team care (nursing, physical therapy, occupational therapy, speech therapy, dietetics, and social work) approach for optimal delivery of stroke rehabilitation. This care can be provided in the stroke unit setting or by early supported discharge teams in the patient's own home. Both strategies have been shown to improve independence in stroke patients. For older patients with stroke, physical rehabilitation in a long-term care facility effective has been shown to improve independence.

Chronic Secondary Prevention of Ischemic Stroke

Case Study

A 72-year-old man presented with right-sided weakness and expressive aphasia 4 weeks ago. CT scan of brain revealed an ischemic stroke in the left hemisphere. He was admitted to a stroke unit, and after completing a rehabilitation program, he was discharged home. Etiological investigations included ultrasound of carotids ($<20\%$ stenosis of carotids), Holter monitor (no arrhythmia), and transthoracic echocardiography with bubble study, which revealed a small PFO. He is known to have hypertension; his serum glucose and HbA1c were normal. He was initiated on aspirin at the time of diagnosis. His blood pressure in clinic today is 152/92 mmHg, and he is currently receiving perindopril 8 mg daily. His fasting LDL level was 140 mg/dL.

Antithrombotic Therapy

Current guidelines recommend aspirin, clopidogrel, or combination aspirin-dipyridamole for secondary prevention of noncardioembolic ischemic stroke. The MATCH trial, which compared the combination of clopidogrel (75 mg per day) plus aspirin (75 mg per day) with aspirin alone in patients with recent ischemic stroke or TIA found no reduction in the risk of major vascular events but an increased risk of life-threatening and major bleeding in patients treated with combination therapy over 18 months of follow-up. Similar results were noted in the SPS3 trial, which included patients with recent symptomatic lacunar infarction. The subsequently published CHANCE trial reported a lower risk of recurrent stroke at 90 days in patients with TIA or minor ischemic stroke (NIHSS ≤ 3) treated with the combination of clopidogrel (initial dose 300 mg then 75 mg per day for 90 days) and aspirin (75 mg per day for first 21 days) compared with aspirin alone. The POINT trial is currently enrolling patients with TIA and minor ischemic stroke to compare the effectiveness of combination clopidogrel (initial dose 600 mg then 75 mg per day for 90 days) plus aspirin (50–325 mg per day) versus aspirin alone for the prevention of ischemic vascular events (ischemic stroke, myocardial infarction, and ischemic vascular death), with results expected in 2017. In patients with atrial fibrillation or mechanical heart valves, oral anticoagulation is generally recommended for secondary prevention of ischemic stroke (Box 145.2). The direct thrombin inhibitor dabigatran and the oral factor Xa inhibitor apixaban have been shown to be superior to warfarin, whereas the oral factor Xa inhibitor rivaroxaban has been shown to be noninferior to warfarin for the prevention of stroke and systemic embolism in patients with atrial fibrillation. These agents are being increasingly used in clinical practice and offer a number of advantages over warfarin, including a more rapid onset of action, more predictable anticoagulant effect enabling fixed daily dosing without need for routine coagulation monitoring, and a lower risk of food and drug interactions. Randomized controlled trials of extended cardiac rhythm monitoring (event loop recording) have reported increased detection rates of paroxysmal atrial fibrillation in patients with formerly unexplained ischemic

BOX 145.2 When Should Warfarin Be Started After Acute Ischemic Stroke With Atrial Fibrillation?

We initiate all patients on aspirin in the acute setting. In patients with acute transient ischemic attack or minor ischemic stroke and in the absence of a large area of acute infarction, we usually initiate warfarin immediately, where a decision is made to use warfarin. For those with severe stroke or moderate stroke with a large area of infarction, initiating aspirin is recommended without anticoagulant therapy in the acute phase. Warfarin can be cautiously introduced 5–7 days after stroke onset after hemorrhagic transformation of the infarct has been excluded on neuroimaging in those suspected to be at increased risk of intracerebral hemorrhage. For patients who have had large infarcts, evidence of hemorrhagic transformation, progression of stroke, or uncontrolled hypertension, further delays beyond 14 days poststroke may be required prior to initiation of therapy with warfarin. We stop aspirin once a therapeutic anticoagulant effect is achieved, unless there is a compelling indication for combination of aspirin and warfarin (e.g., coronary stent). We do not bridge the initial period with treatment doses of heparin, although it may be reasonable in patients with transient ischemic attack and atrial fibrillation, as they would be expected to be a lower risk of intracerebral hemorrhage (although unproven).

stroke. Oral anticoagulants are not superior to aspirin for the secondary prevention of stroke in patients with noncardioembolic stroke (WARSS and ESPRIT) or in patients with intracranial stenosis (WASID).

Lipid Modification

Current guidelines recommend statin therapy in patients with LDL ≥ 100 mg/dL. The SPARCL trial comparing atorvastatin 80 mg daily with placebo reported a reduced risk of recurrent stroke over 5 years of follow-up in the atorvastatin group.

Blood Pressure

PROGRESS, the largest trial of antihypertensive therapy for secondary stroke prevention, compared perindopril (with or without indapamide) with placebo. Combination therapy reduced blood pressure by 12/5 mmHg and stroke risk by 43%, and produced greater reduction in blood pressure and stroke risk compared with perindopril alone. Current guidelines recommend a target blood pressure of 140/90 mmHg or less.

Patent Foramen Ovale Closure

Despite the results of three randomized controlled trials, the role of PFO closure devices remains uncertain. The randomized controlled trial CLOSURE I ($n = 909$) reported that PFO closure with the STARFlex closure device (no longer clinically available) was not superior to medical therapy alone in reducing the risk of recurrent TIA/stroke at 24 months (5.5% vs. 6.8%; hazard ratio [HR], 0.78; 95% CI, 0.45–1.35), and was associated with an increased risk of major vascular complications (3.2% vs. 0.0%; $p < .001$) and new-onset atrial fibrillation (5.7% vs. 0.7%; $p < .001$). Furthermore, in the RESPECT trial ($n = 980$), PFO closure with the Amplatzer PFO occluder was not found to be superior to medical management in reducing the risk of recurrent stroke or death during follow-up (1.8% vs. 3.3%, HR, 0.49; 95% CI, 0.22–1.11). Interestingly, PFO closure was superior to medical management in preventing recurrent stroke in the subgroup of patients with a substantial shunt (0.8% vs. 4.3%; HR, 0.18; 95% CI, 0.04–0.81) and concomitant ASA (1.1% vs. 5.3%; HR, 0.19; 95% CI, 0.04–0.87), suggesting a benefit in high-risk patients. The PC trial also did not demonstrate a benefit with device closure of PFO. However, low event rates in these three trials have precluded a definitive conclusion.

Lifestyle Modification

Lifestyle modification remains a cornerstone of stroke prevention. Important components include smoking cessation, moderate physical activity, weight reduction in overweight or obese patients, adopting a healthy heart diet with increased fruit and vegetable intake, reduced salt intake in those consuming high-salt diets, and moderate alcohol consumption.

PROGNOSIS

Prognosis after stroke depends on patient age, underlying stroke etiology, severity of neurological deficit and level of dependence, and comorbidity burden. In a large cohort of over 10,000 US patients hospitalized with ischemic stroke, 1- and 4-year mortality rates were 24.5% and 41.3%, respectively, with rates of recurrent stroke of 8.0% and 18.1% at 1 and 4 years, respectively. Early death usually occurs because of neurological complications (e.g., cerebral edema, raised ICP) or medical complications of dependency and immobilization (e.g., aspiration pneumonia). Longer-term mortality is usually caused by cardiovascular disease. Two-thirds of stroke survivors are left with chronic residual disability. In addition, patients with stroke are at an increased risk of myocardial infarction, deep vein thrombosis, urinary tract infections, hip fracture, pneumonia, and subsequent rehospitalization. Common complications of stroke in the longer term include seizure disorders, cognitive impairment and dementia, depression, and chronic pain syndromes (e.g., central poststroke pain).

FUTURE DIRECTIONS

To date, our knowledge of the epidemiology of stroke has been derived from studies in North America and Europe, with comparatively fewer studies in middle- and low-income countries, although the vast majority of the global burden of stroke occurs in these regions. In addition, a number of large ongoing epidemiologic collaborative studies (International Stroke Genetics Consortium) will clarify the role of genetics in the pathogenesis of stroke. Population-based interventions to reduce the burden of stroke will be an important focus of future research, and will include evaluation of interventions to reduce salt intake and use of combination cardioprotective therapies (e.g., Polycap) in high-risk populations. In patients with TIA and minor ischemic stroke, a phase II trial (FASTER) suggested that combination aspirin and clopidogrel may be superior to aspirin alone and this question will be addressed in a phase III trial. For acute ischemic stroke, the IST-3 trial will provide important information on use of thrombolysis within 6 hours of symptom onset in a large generalizable population. Other ongoing trials will determine the role of acute interventions designed to reduce the severity of stroke (e.g., albumin in ALIAS and hypothermic interventions). For secondary prevention, ongoing trials will clarify optimal anti-thrombotic therapy and target blood pressure in patients with small-vessel disease (SPS-3), closure devices for PFO, and anticoagulant therapy for aortic arch disease (ARCH).

ACUTE CORONARY SYNDROMES

John W. Eikelboom and Jeffrey I. Weitz

Acute coronary syndromes (ACS) lead to millions of hospital admissions worldwide each year and are a leading cause of death. Antithrombotic therapies are a cornerstone in the immediate and long-term management of ACS, reducing the risk of myocardial infarction (MI) and death in both medically and invasively managed patients. This chapter reviews fibrinolytic, antiplatelet, and anticoagulant therapies in the treatment of patients with ACS and provides a practical guide to several common hemostatic and thrombotic problems encountered in this patient population.

CLASSIFICATION

The clinical classification of ACS is based on the electrocardiogram (ECG) at the time of presentation and on blood levels of cardiac biomarkers (troponin, creatine kinase). Patients with ST-segment elevation on the ECG and elevated cardiac biomarkers are diagnosed with ST-segment elevation MI (STEMI). Patients with non-ST-segment elevation (NSTEMI) ACS are subdivided according to whether or not they have elevated blood levels of cardiac biomarkers; those with elevated cardiac biomarkers are diagnosed with non-ST-segment elevation MI (NSTEMI), and those without elevated cardiac biomarkers are diagnosed with unstable angina.¹⁻³

PATHOPHYSIOLOGY

Atherothrombosis plays a central role in the pathogenesis of ACS.⁴ Hypertension, abnormal blood glucose levels, dyslipidemia, and toxins contained in tobacco cause endothelial injury. Lipid accumulation promotes an inflammatory response characterized by the recruitment of macrophages, smooth muscle cells, and fibroblasts to the site of injury and the formation of increasingly complex and unstable plaques with a necrotic core and fibrous cap. Disruption of the fibrous cap by shear forces and its degradation by enzymatic and cellular processes expose the plaque contents to the blood. Platelets adhere to exposed subendothelial proteins and become activated and aggregate. Exposed tissue factor induces thrombin generation on cellular surfaces, further promoting the formation of a platelet-fibrin thrombus that can occlude coronary blood flow. These processes are described in more detail in [Chapter 144](#).

The clinical manifestations of coronary atherothrombosis are influenced by the extent and duration of obstruction to blood flow and the presence or absence of a collateral circulation. Patients with small plaques that do not significantly impair blood flow generally remain asymptomatic. Patients with significant flow-limiting plaques may develop ischemic symptoms (e.g., chest pain, breathlessness) during exertion when myocardial oxygen demand exceeds supply. Patients with acute plaque disruption with superimposed thrombus formation that completely obstructs coronary blood flow typically present with STEMI unless there is an adequate collateral circulation. If obstruction to blood flow is transient or partial, patients typically present with NSTEMI ACS. If myocardial ischemia results in ventricular fibrillation, sudden cardiac death supervenes.

ANTITHROMBOTIC MANAGEMENT

The goal of antithrombotic therapies in patients with ACS is to prevent new thrombus formation at the site of plaque disruption and

facilitate lysis of intracoronary thrombus. Antithrombotic drugs are also used to prevent thrombus formation on the guide wires, catheters, and stents used to open occluded arteries, and to prevent and treat left ventricular thrombus formation.

Although the pathophysiology is similar irrespective of whether patients present with STEMI or NSTEMI ACS, only STEMI patients benefit from immediate reperfusion therapy. This difference reflects the fact that most patients with NSTEMI do not have an occluded infarct-related coronary artery. Instead, they develop MI as a consequence of distal embolization of thrombus.

REPERFUSION THERAPY FOR ST-SEGMENT ELEVATION MYOCARDIAL INFARCTION

Effective approaches to coronary reperfusion include mechanical (primary percutaneous coronary intervention [PCI]) and pharmacologic (fibrinolytic therapy) methods.

Primary Percutaneous Coronary Intervention

Primary PCI is preferred over fibrinolytic therapy in patients with STEMI because it produces higher patency rates and does not cause intracranial bleeding. Unlike fibrinolysis, which only treats the thrombus, primary PCI also allows treatment of the underlying atherosclerotic plaque. However, many centers lack the facilities and expertise to perform urgent coronary interventions, and only a minority of STEMI patients worldwide is treated with primary PCI.^{5,6} Patients undergoing primary PCI are routinely treated with anticoagulant and antiplatelet therapy (discussed in sections on [antiplatelet therapy](#) and [anticoagulant therapy](#)).

Fibrinolytic Therapy

Fibrinolytic drugs are plasminogen activators that initiate fibrinolysis by converting plasminogen to plasmin. Plasmin degrades fibrin resulting in clot lysis and recanalization of thrombotic occlusion. Restoration of coronary blood flow limits infarct size and improves myocardial function and survival.

The pharmacologic characteristics of the fibrinolytic drugs most commonly used in the management of ACS are summarized in [Table 146.1](#). Streptokinase was the first agent to be evaluated in large-scale randomized controlled trials. A non-fibrin-specific agent, streptokinase, indirectly activates plasminogen, whereas the more fibrin-specific agents alteplase, reteplase, and tenecteplase directly convert plasminogen to plasmin. Reteplase and tenecteplase have longer half-lives than alteplase, enabling them to be given by double- or single-bolus injection, respectively, which simplifies administration. The direct-acting fibrinolytic agents are more fibrin specific than streptokinase because they bind to fibrin, where they convert fibrin-bound plasminogen to plasmin. Consequently, these agents produce a less marked systemic lytic state than streptokinase, which has no fibrin affinity. Avoidance of a systemic lytic state, which is characterized by a reduction in the circulating level of fibrinogen, is an important potential advantage of fibrin-specific drugs because this can be expected to be associated with a lower risk of bleeding complications.

TABLE 146.1 Pharmacologic Characteristics of Fibrinolytic Drugs Used in the Management of Patients With ST-Segment Elevation Myocardial Infarction

Characteristic	Streptokinase	Alteplase	Reteplase	Tenecteplase
Fibrin specificity ^a	–	++	+	+++
Dose	1.5 million units	100 mg	20 U	30–50 mg
Administration	Infusion over 30–60 minutes	Bolus 15 mg; then infusion 0.75 mg/kg (maximum, 50 mg) over 30 minutes, 0.5 mg/kg (maximum, 35 mg) over the next 60 minutes	Double bolus, 10 U over 2 minutes; then repeat 10 U bolus after 30 minutes	Single weight-adjusted bolus, <60 kg = 30 mg, 60–69 kg = 35 mg, 70–79 kg = 40 mg, 80–89 kg = 45 mg, ≥90 kg = 50 mg
Half-life (min)	18–23	3–4	18	20
Adjunctive antiplatelet therapy ^b Aspirin	Aspirin	Aspirin	Aspirin	Aspirin
Adjunctive anticoagulant therapy	Heparin in patients at high risk of thromboembolism ^c	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/hour (maximum, 1000 U/hour)	Heparin 60 U/kg bolus (maximum, 4000 U); 10 U/kg/hour (maximum, 1000 U/hour)	Heparin 60 U/kg bolus (maximum, 4000 U); 12 U/kg/hour (maximum, 1000 U/hour)

^aLess fibrin specificity is associated with more systemic fibrinogen depletion.

^bFibrinolytic drugs were evaluated on a background of aspirin, but the addition of clopidogrel to aspirin was subsequently shown to provide incremental benefit.

^cHigh-risk patients include those with large or anterior myocardial infarction, atrial fibrillation, known left ventricular thrombus, or previous thromboembolism.

Initial trials with streptokinase established the efficacy of fibrinolytic therapy for reduction in the risk of MI and death; subsequent trials compared the efficacy and safety of newer fibrinolytic drugs with those of streptokinase or alteplase.

Streptokinase

Streptokinase is a single-chain polypeptide derived from β -hemolytic *Streptococcus* cultures. After intravenous (IV) administration, streptokinase binds to plasminogen, and the resulting streptokinase–plasminogen enzymatic complex converts plasminogen to plasmin. Because plasmin nonspecifically degrades circulating fibrinogen as well as fibrin, streptokinase produces a systemic lytic state. Streptokinase induces the formation of antistreptokinase antibodies and can cause allergic reactions, particularly with repeated administration. Severe reactions are rare, but rash, shivering, pyrexia, and mild hypotension occur in up to 10% of patients. It is uncertain whether neutralizing antibodies reduce the efficacy of streptokinase.

The GISSI-1 (Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico 1) trial, which was conducted in 11,806 patients with STEMI, demonstrated that compared with no lytic therapy, streptokinase (1.5 million units over 1 hour) significantly reduced 21-day in-hospital mortality (10.7% vs. 13.0%; $p = .0002$). A similar reduction in mortality was seen when the same dose of streptokinase was compared with no lytic therapy in 17,187 patients with suspected MI in the ISIS-2 (International Studies of Infarct Survival 2) trial (9.2% vs. 12.0%; $p < .00001$).

Alteplase

Alteplase is a recombinant tissue-type plasminogen activator that directly converts plasminogen to plasmin. Although more fibrin-specific than streptokinase, alteplase still induces a systemic lytic state. It has a short circulating half-life of 3–4 minutes, which necessitates its administration by continuous IV infusion.

The ISIS-3 ($n = 41,299$) and GISSI-2 ($n = 20,891$) trials found no benefit of alteplase over streptokinase; findings possibly explained by the suboptimal use of heparin in conjunction with a short-acting fibrinolytic agent (heparin was given subcutaneously after a delay of 4–12 hours) and lack of front-loading of alteplase. The GUSTO-1 (Global Utilization of Streptokinase and Tissue Plasminogen Activator to Treat Occluded Arteries 1) trial ($n = 41,021$) demonstrated that front-loaded alteplase (15 mg bolus, followed by 0.75 mg/kg

[maximum, 50 mg] as an infusion over 30 minutes and then 0.50 mg/kg [maximum, 35 mg] over 60 minutes [maximum, 100 mg over 90 minutes]) plus IV heparin (5000 U IV bolus, followed by 1000 U/hour as an infusion, with the dose titrated to achieve an activated partial thromboplastin time [aPTT] of 60–85 seconds) compared with streptokinase (1.5 million units over 1 hour) with or without IV heparin, reduced 30-day mortality (6.3% vs. 7.3%; $p = .001$). The mortality benefits of alteplase were greatest in patients younger than the age of 75 years and in those with anterior MI. Despite its enhanced fibrin specificity, alteplase was not associated with less bleeding than streptokinase.

The greatest benefits of fibrinolytic therapy are seen in patients treated within 1 hour of symptom onset; there is a much smaller benefit or no benefit if treatment is commenced more than 6 hours after symptom onset.⁷

Reteplase

Reteplase is a second-generation nonglycosylated deletion mutant of alteplase. Reteplase is less fibrin specific than alteplase but has a longer half-life (18 minutes) that enables administration by double-bolus IV injection.

The INJECT trial ($n = 6010$) demonstrated that reteplase and streptokinase were associated with similar 35-day rates of mortality (9.0% vs. 9.5%), in-hospital stroke (1.2% vs. 1.0%), and major bleeding (0.7% vs. 1.0%), although reteplase was associated with a twofold higher rate of intracranial bleeding (0.8% vs. 0.4%). The GUSTO-III trial ($n = 15,059$) demonstrated that reteplase (two 10-mg IV bolus injections given 30 minutes apart) and front-loaded alteplase were associated with similar 30-day rates of mortality (7.5% vs. 7.2%) and stroke (1.6% vs. 1.7%).

Tenecteplase

Tenecteplase is a third-generation multiple point mutant of alteplase. Tenecteplase has a half-life of 20 minutes and is given by single bolus injection. Tenecteplase is the most fibrin-specific fibrinolytic drug approved for clinical use.

The ASSENT-2 (Assessment of the Safety and Efficacy of a New Thrombolytic) study, which enrolled 16,949 STEMI patients, showed that tenecteplase and alteplase were associated with similar 30-day rates of mortality (6.2% vs. 6.2%) and stroke (1.8% vs. 1.7%). Tenecteplase did not reduce the risk of intracerebral bleeding

TABLE 146.2 Management of Major Bleeding in Patients With ST-Segment Elevation Myocardial Infarction Treated With Fibrinolytic Therapy

Steps	Approach	Considerations
Stop treatment	Stop fibrinolytic drug Stop antiplatelet drugs Stop anticoagulant	Recovery of fibrinogen levels can take 24–48 hours after stopping streptokinase Antiplatelet effects of aspirin and clopidogrel last for life span of platelets (5–10 days) Heparin has a half-life of about 40 minutes; LMWH has a half-life of 3–6 hours
Local measures	Local pressure Endoscopy and local injection ^a Embolization ^a	Sustained local pressure (e.g., for 30 minutes) may be required Can be used for upper or distal lower GI bleeding Used in rare situations such as life-threatening pulmonary or intraabdominal bleeding
Laboratory evaluation	Fibrinogen PT and aPTT Anti-Xa level Cross-match blood	Levels may be undetectable (<100 mg/dL) Results are uninterpretable if fibrinogen levels are low (<100 mg/dL) PT (INR) and aPTT are elevated with warfarin; aPTT is prolonged with therapeutic doses of heparin but not with LMWH or fondaparinux Chromogenic antifactor Xa assay for LMWH and fondaparinux; this test is unaffected by low fibrinogen levels To restore blood volume and maintain hemoglobin
Reversal of fibrinolytic effect	Cryoprecipitate FFP	Recommended initial dose is 10 U; monitor by repeating fibrinogen level The half-life of fibrinogen is about 4 days Requires large volumes (e.g., 2 L) to restore fibrinogen levels
Reversal of antiplatelet effect	Platelet transfusion	Increases the number of functional platelets but does not reverse the antiplatelet effects of aspirin and clopidogrel Also see text under heading “Antiplatelet Therapy”
Reversal of anticoagulant effect	Protamine	Protamine reverses heparin and partially reverses LMWH; it has no effect on fondaparinux (also see Table 146.6)

^aAlso requires restoration of adequate hemostasis.

aPTT, Activated partial thromboplastin time; FFP, fresh frozen plasma; GI, gastrointestinal; INR, international normalized ratio; LMWH, low-molecular-weight heparin; PT, prothrombin time.

compared with alteplase (1% vs. 1%), but reduced the rate of major noncerebral bleeding (4.7% vs. 5.9%; $p < .0002$), possibly reflecting its enhanced fibrin specificity.

Adjunctive Antithrombotic Therapy in Patients Receiving Fibrinolytic Drugs

A compelling rationale exists to administer adjunctive antithrombotic therapy to STEMI patients treated with fibrinolytic therapy. Platelet-rich thrombi that form after plaque rupture are relatively resistant to degradation, and the use of concomitant antiplatelet and anticoagulant therapy may help to promote clot lysis. Fibrinolytic drugs have an early activating effect on platelets, and the plaque rupture site remains prothrombotic after successful reperfusion therapy. Evidence in support of the efficacy of adjuvant antiplatelet and anticoagulant therapy in patients with STEMI is summarized in the sections on antiplatelet and anticoagulant therapy, respectively.

Intracranial Bleeding

The most important side effect of fibrinolytic therapy is intracranial bleeding, which affects up to 1% of patients and, in the majority of cases, is either fatal or permanently disabling.⁸ Risk factors for intracranial bleeding include increasing age (particularly patients older than the age of 75 years), history of prior stroke, uncontrolled blood pressure, female sex, and low body weight. Bolus dose fibrinolytic therapy may be associated with a higher risk of intracranial bleeding than fibrinolytic therapy administered by continuous IV infusion (see Table 146.2 and box on Case 1: Bleeding After Fibrinolytic Therapy).⁹

ANTIPLATELET THERAPY

Aspirin, oral adenosine diphosphate (ADP) receptor antagonists, such as clopidogrel, prasugrel, and ticagrelor, and glycoprotein (GP) IIb/IIIa (GP IIb/IIIa) antagonists, such as abciximab, eptifibatide,

and tirofiban, are the foundation antiplatelet therapies for the management of ACS. Although the use of GP IIb/IIIa antagonists has decreased since the introduction of clopidogrel, they retain a role in high-risk ACS patients, particularly STEMI patients undergoing primary PCI.^{5,6,10} In 2015, the US Food and Drug Administration approved cangrelor, a short-acting parenteral ADP receptor antagonist, for ACS patients undergoing PCI who have not received an oral ADP receptor antagonist and who are not given a GP IIb/IIIa inhibitor. The pharmacologic characteristics of antiplatelet drugs commonly used in the management of ACS are summarized in Tables 146.3 (oral drugs) and 147.4 (IV drugs).

Oral Antiplatelet Drugs

Aspirin

Aspirin inhibits platelets by irreversibly blocking the platelet enzyme cyclooxygenase-1, thereby preventing the formation of thromboxane A₂, a potent platelet agonist and vasoconstrictor. Despite having a half-life of only 20 minutes, the antiplatelet effect of aspirin lasts for the lifetime of the platelet (5–10 days) because platelets are anucleate and lack the machinery to synthesize new enzyme.¹¹

Multiple randomized trials have demonstrated the efficacy of aspirin for the prevention of recurrent MI, stroke, or death in patients with ACS.¹² The ISIS-2 investigators evaluated the efficacy and safety of aspirin in 17,187 STEMI patients who were also randomized to receive or not to receive fibrinolytic therapy. Aspirin (162 mg/day), compared with no aspirin, significantly reduced 35-day mortality (9.4% vs. 11.8%; $p < .00001$) as well as nonfatal reinfarction (1.0% vs. 2.0%) and stroke (0.3% vs. 0.6%) without increasing bleeding. The Antithrombotic Trialists' Collaboration (ATTCC) pooled the data from 15 randomized trials of antiplatelet therapy (predominantly with aspirin) involving 19,302 acute MI patients who were also treated with fibrinolytic therapy. Compared with placebo or no antiplatelet therapy, antiplatelet therapy given for a mean duration of 1 month significantly reduced the composite outcome of MI, stroke, or death (10.4% vs. 14.2%; $p < .0001$).

Case 1: Bleeding After Fibrinolytic Therapy

A 63-year-old man with a history of hypertension presents to a rural hospital with sudden onset of severe retrosternal chest pain. An electrocardiogram (ECG) performed in the emergency department demonstrates 4-mm ST segment elevation in the anterior leads. The nearest hospital with a cardiac catheterization laboratory is more than 6 hours away. After treatment with aspirin (300 mg loading dose), clopidogrel (300 mg loading dose), and an intravenous (IV) infusion of front-loaded alteplase, he has rapid resolution of his pain and the ECG reveals normalization of the ST-segment elevation. Toward the end of the alteplase infusion, he complains of abdominal pain, becomes hypotensive, and develops melena. Hemoglobin is 10.2 g/dL, the activated partial thromboplastin time (aPTT) is 89 seconds, the international normalized ratio (INR) is 1.7, and the fibrinogen level is 80 mg/dL.

Aspirin and clopidogrel are held; the patient receives 10 units of cryoprecipitate and is started on an IV infusion of a proton pump inhibitor. He undergoes urgent upper gastrointestinal tract endoscopy with injection of a bleeding ulcer. He does not receive platelets because of concerns about the risk of recurrent myocardial infarction (MI). No further bleeding occurs, and after 48 hours he resumes aspirin. Clopidogrel is restarted 1 week later after repeat endoscopy demonstrates healing of the ulcer.

Comment

Fibrinolytic trials in patients with acute MI report a 1%–6% incidence of major bleeding and a 10% incidence of moderate bleeding during the first 30 days. The most common sources of major bleeding are the gastrointestinal tract and procedure-related bleeding. The principles of management of major bleeding in STEMI patients treated with fibrinolytic therapy are summarized in Table 146.2. Steps include (1) stop anti-thrombotic therapies; (2) use local measures when possible to control

bleeding; (3) draw blood to measure fibrinogen, prothrombin time (PT), aPTT, and possibly anti-Xa levels (to measure the anticoagulant effect of low-molecular-weight heparin [LMWH]) and for blood typing and cross-match; and (4) administer therapies to mitigate or reverse the effects of fibrinolytic, antiplatelet, and anticoagulant drugs.

The extent and duration of the systemic lytic state induced by fibrinolytic drugs are determined by their fibrin specificity. Whereas streptokinase produces profound and sustained depletion of fibrinogen (<100 mg/dL) that lasts for up to 24–48 hours, alteplase and other more fibrin-specific agents exert less pronounced and more short-lived effects on fibrinogen levels. The aPTT and PT can be markedly prolonged in patients with hypofibrinogenemia. Normal coagulation can be restored by elevating the fibrinogen level to at least 100 mg/dL. This can readily be achieved by infusing cryoprecipitate (recommended dose: 10 units). Although fresh frozen plasma also contains fibrinogen, much larger volumes are needed to increase the fibrinogen concentration to the desired range.

Platelet dysfunction caused by aspirin, clopidogrel, and fibrinolytic therapy cannot be specifically reversed, but infusion of donor platelets can help to restore platelet function. Platelet transfusion is generally reserved for patients with life-threatening bleeding because of concerns about the risk of recurrent MI. A single unit of single donor platelets can be expected to increase the platelet count by $50\text{--}60 \times 10^9/\text{L}$. Even a small number (e.g., 10%–20%) of functional (nonaspirinated) platelets is sufficient to generate sufficient thromboxane to sustain normal platelet aggregation, but a much larger number of transfused platelets is needed to overcome the antiplatelet effects of clopidogrel. In this case, bleeding was controlled with cryoprecipitate and local measures, and platelet transfusion was not required.

TABLE 146.3**Pharmacologic Characteristics of Oral Antiplatelet Drugs Commonly Used in the Management of Acute Coronary Syndromes**

Characteristic	Aspirin	ADP Receptor Antagonists		
		Clopidogrel	Prasugrel	Ticagrelor
Class	COX inhibitor	Thienopyridine (second generation)	Thienopyridine (third generation)	Cyclopentyl triazopyrimidine
Target	COX-1	P2Y ₁₂	P2Y ₁₂	P2Y ₁₂
Dose	162–325-mg loading dose; 75–325 mg/day maintenance dose	300–600-mg loading dose; 75 mg/day maintenance dose	60-mg loading dose; 10 mg/day maintenance dose	180-mg loading dose; 90 mg bid maintenance dose
Prodrug	No	Yes	Yes	No
Time to effect ^a	<1 hour	4–6 hours ^b	<1 hour	<1 hour
Drug half-life	20 min	Minutes	Minutes	12 hours
Reversible	No	No	No	Yes

^aAfter loading dose.

^bIncreased antithrombotic benefit was seen after the first hour in patients enrolled in the COMMIT trial who did not receive a loading dose, but maximum effect is not seen until after 4–6 hours.

ADP, Adenosine diphosphate; bid, twice daily; COX, cyclooxygenase.

At least four randomized controlled trials have demonstrated the efficacy of aspirin in patients with NSTEMI ACS. Pooled data from four trials that included a combined total of 3096 patients indicate that aspirin compared with placebo or no aspirin significantly reduced the composite endpoint of MI, stroke, or vascular death (6.4% vs. 12.5%; $p = .0005$).

The efficacy and safety of aspirin in combination with dipyridamole have been evaluated in PCI patients in one randomized controlled trial involving 376 patients. Aspirin (300 mg) plus dipyridamole (75 mg given three-times daily except during a 24-hour period around the time of the procedure when dipyridamole was given intravenously) reduced the risk of MI by more than half compared with placebo (1.6% vs. 6.9%; $p = .01$). These results led to the adoption of aspirin as standard therapy for patients undergoing PCI.

The CURRENT OASIS-7 (Clopidogrel Optimal Loading Dose Usage to Reduce Recurrent Events/Optimal Antiplatelet Strategy for Intervention) trial explored the optimal dose of aspirin in 25,086

ACS patients with or without ST-segment elevation on the presenting ECG and included 17,263 patients undergoing early PCI.¹³ After an initial aspirin loading dose, patients were randomized to receive aspirin at a dose of 300–325 mg/day or 75–100 mg/day for 30 days. The two doses were associated with similar rates of MI, stroke, or death at 30 days (4.2% vs. 4.4%), but the higher aspirin dose increased the rate of gastrointestinal bleeding (0.4% vs. 0.2%; $p = .04$). Based on these results, the optimal dose of aspirin for the management of patients with ACS (after an initial loading dose of 160–325 mg) appears to be 75–100 mg/day.

Clopidogrel

Clopidogrel undergoes metabolic activation in the liver to form the active moiety that irreversibly blocks P2Y₁₂, the major ADP receptor on the platelet surface as evidenced by a decrease in ADP-induced

platelet activation and aggregation. Like aspirin, the antiplatelet effect of clopidogrel lasts for the lifetime of the platelet. Clopidogrel is an effective antiplatelet drug for the prevention of MI and death when used in combination with aspirin, but has a slow onset of action and a variable antiplatelet effect that may limit its effectiveness.

The COMMIT trial, which involved 45,582 patients with STEMI, all of whom were treated with aspirin (162 mg/day), demonstrated that compared with placebo, 30 days of treatment with clopidogrel (75 mg/day) reduced the risk of MI, stroke, or death (9.2% vs. 10.1%; $p = .002$) with no increase in major bleeding (0.58% vs. 0.55%).¹⁴ There was no age restriction in the COMMIT trial, and clopidogrel was given without a loading dose. In the CLARITY (Clopidogrel as Adjunctive Reperfusion Therapy) trial ($n = 3491$), which was conducted in parallel with COMMIT, clopidogrel was given as a loading dose of 300 mg followed by 75 mg/day for 2–8 days and was compared with placebo in patients receiving fibrinolysis. Clopidogrel reduced the risk of MI or death (15% vs. 21.7%; $p < .001$). Consistent benefits of clopidogrel were demonstrated in the 1863 patients who underwent PCI after mandated angiography.

The CURE (Clopidogrel in Unstable Angina to Prevent Recurrent Events) trial, which involved 12,562 patients with NSTEMI ACS, all of whom were treated with aspirin (recommended dose: 75–325 mg/day), demonstrated that compared with placebo, a median of 9 months of treatment with clopidogrel (300 mg loading dose followed by 75 mg/day) reduced the risk of MI, stroke, or death (9.3% vs. 11.4%; $p < .001$) at the cost of an increase in major bleeding (3.7% vs. 2.7%; $p = .001$).¹⁵ Consistent benefits of clopidogrel were seen in the 2658 patients who underwent PCI irrespective of whether or not they underwent coronary stenting.

Prompted by concerns that some patients achieve suboptimal inhibition of platelet function with conventional doses of clopidogrel, the CURRENT-OASIS 7 trial compared the efficacy and safety of a higher loading and maintenance dose of clopidogrel (600-mg loading dose followed by 150 mg/day for 6 days and 75 mg/day for 23 days thereafter) with standard-dose clopidogrel (300-mg loading dose and 75 mg daily thereafter) in 25,086 patients with ACS referred for an invasive management strategy.¹³ Both regimens were associated with similar rates of the primary outcome, MI, stroke, or vascular death (4.2% vs. 4.4%), but the higher dose regimen was associated with an increase in major bleeding (2.5% vs. 2.0%; $p = .01$). However, in the 17,263 patients who underwent PCI, the higher dose regimen reduced MI, stroke, or vascular death (3.9% vs. 4.5%; $p = .039$) and stent thrombosis (0.7% vs. 1.3%; $p = .0001$) compared with the lower dose regimen.

Prasugrel

Prasugrel is a third-generation thienopyridine that is more potent and has a more rapid onset of action than clopidogrel. Prasugrel is a prodrug, but unlike clopidogrel, it requires only single-step bioconversion to form the active metabolite that irreversibly blocks the platelet P2Y₁₂ receptor.

The TRITON-TIMI 38 (Trial to Assess Improvement in Therapeutic Outcomes by Optimizing Platelet Inhibition With Prasugrel—Thrombolysis In Myocardial Infarction 38) trial evaluated the efficacy

and safety of prasugrel in 13,608 ACS patients with or without ST-segment elevation who were undergoing PCI, all of whom were treated with aspirin (recommended dose: 75–162 mg/day).¹⁶ Compared with clopidogrel (300 mg followed by 75 mg once daily thereafter), prasugrel (60 mg followed by 10 mg once daily thereafter) continued for a median of 14.5 months reduced the risk of MI, stroke, or cardiovascular death (9.9% vs. 12.1%; $p < .001$) and stent thrombosis (1.1% vs. 2.4%; $p < .001$) but did not reduce mortality and increased noncoronary artery bypass graft (CABG) major bleeding (2.4% vs. 1.8%; $p = .03$) as well as intracranial and fatal bleeding.

The TRILOGY ACS¹⁷ (Targeted Platelet Inhibition to Clarify the Optimal Strategy to Medically Manage Acute Coronary Syndromes) trial evaluated the efficacy and safety of prasugrel in 9326 aspirin-treated patients with NSTEMI ACS who were managed noninvasively. At a median of 17 months of follow-up, prasugrel (30 mg followed by 10 mg once daily in patients less than 75 years or 5 mg once daily for those 75 years or older or who weighed less than 60 kg) and clopidogrel (300 mg followed by 75 mg once daily) were associated with similar rates of MI, stroke or cardiovascular death (13.9% vs. 16.0%; $p = .21$) and similar rates of major bleeding.

Ticagrelor

Ticagrelor is a nonthienopyridine platelet P2Y₁₂ receptor antagonist. Like prasugrel, ticagrelor is more potent and has a more rapid onset of action than clopidogrel, but unlike both clopidogrel and prasugrel, ticagrelor binds reversibly to the platelet P2Y₁₂ receptor.

The PLATO trial evaluated the efficacy and safety of ticagrelor in 18,624 ACS patients with or without ST-segment elevation.¹⁸ Compared with clopidogrel (300 or 600 mg loading dose followed by 75 mg once daily), ticagrelor (180 mg loading dose followed by 90 mg twice daily) reduced the risk of MI, stroke, or vascular death by 16% (9.8% vs. 11.7%; $p < .001$) and produced a significant reduction in vascular death (4.0% vs. 5.1%; $p = .001$) and stent thrombosis (1.3% vs. 1.9%; $p = .009$). There was no increase in major bleeding (11.6% vs. 11.2%) or in intracranial or fatal bleeding, but ticagrelor increased non-CABG major bleeding (4.5% vs. 3.8%; $p = .03$).

Intravenous Antiplatelet Drugs

Glycoprotein IIb/IIIa Inhibitors

Three GP IIb/IIIa inhibitors are available for clinical use (see Table 146.4). Abciximab is a humanized version of a Fab fragment of a murine antibody directed against GP IIb/IIIa; tirofiban is a nonpeptide tyrosine derivative that selectively binds to GP IIb/IIIa; and eptifibatide is a synthetic disulfide-linked cyclic heptapeptide with high specificity for GP IIb/IIIa.

The efficacy and safety of GP IIb/IIIa inhibitors have been extensively evaluated in patients with ACS. A meta-analysis restricted to trials ($n = 6$) involving at least 1000 patients suggests a modest effect of these agents for the prevention of MI, urgent revascularization, or vascular death in patients with NSTEMI ACS (10.8% vs. 11.8%;

TABLE
146.4

Pharmacologic Characteristics of Intravenous Antiplatelet Drugs Used in the Management of Acute Coronary Syndrome

Characteristic	GP IIb/IIIa inhibitors			ADP Receptor Antagonists
	Abciximab	Eptifibatide	Tirofiban	Cangrelor
Class	Fab fragment	Nonpeptide	Cyclic heptapeptide	Nonthienopyridine
Onset	Rapid	Rapid	Rapid	Rapid
Drug half-life	10–30 min	2 hours	2.5 hours	3–6 min
Reversibility of platelet inhibition	Slow	Rapid	Rapid	Rapid
Excretion	Unknown	40%–70% renal	50% renal	Dephosphorylation

$p = .015$).¹⁹ Pooled data from a meta-analysis of 16 randomized trials involving 10,085 STEMI patients undergoing primary PCI demonstrated that adjunctive GP IIb/IIIa blockade did not reduce 30-day mortality (2.8 vs. 2.9%; $p = .75$) or reinfarction (1.5 vs. 1.9%; $p = .22$) and increased major bleeding (4.1 vs. 2.7%; $p = .0004$). However, meta-regression analysis confirmed the impression from individual trials of a mortality benefit of IV GP IIb/IIIa inhibitors in those at highest risk (see boxes on [Case 2: Stent Thrombosis](#) and [Case 3: Thrombocytopenia After Stenting](#)).²⁰

Cangrelor

Cangrelor is an IV P2Y₁₂ receptor antagonist that has been compared with clopidogrel or placebo in three randomized trials that included patients with NSTEMI ACS. An individual patient metaanalysis of the three trials²¹ demonstrated that compared with control, cangrelor reduced the risk of ischemia-driven revascularization, stent thrombosis, MI or death at 48 hours (3.8% vs. 4.7%, $p = .0007$) at the cost of an increase in GUSTO mild bleeding (16.8% vs. 13.0%, $p < .0001$) but no increase in more severe bleeding.

Case 2: Stent Thrombosis

A 49-year-old man with a history of type 2 diabetes presents with non-ST-segment elevation myocardial infarction and undergoes percutaneous coronary intervention (PCI) with placement of a drug-eluting stent in the left anterior descending coronary artery. He receives a 300-mg loading dose of aspirin and a 600-mg loading dose of clopidogrel and is discharged on aspirin 100 mg/day and clopidogrel 75 mg/day. He presents to the emergency department 3 weeks later with recurrent chest pain and anterior ST-segment elevation on the electrocardiogram. He denies missing any doses of clopidogrel. He is taken urgently to the cardiac catheterization laboratory where a diagnosis of stent thrombosis is confirmed, and he undergoes repeat PCI with thrombus aspiration.

Prompted by concern about the possibility of “clopidogrel resistance”, genotyping studies are performed and demonstrate heterozygosity for the *CYP2C19* *2 loss-of-function allele. Clopidogrel is stopped, and he is started on prasugrel (10 mg once daily) instead. He is discharged on indefinite dual antiplatelet therapy with aspirin and prasugrel.

Comment

Stent thrombosis is a potentially life-threatening complication of PCI, affecting 1%–2% of patients during the first year and presenting in almost all cases as death or myocardial infarction.²² Risk factors for stent thrombosis can be categorized as patient related, technical (procedure, stent, or lesion), or drug related. The single most important predictor of stent thrombosis is premature discontinuation of clopidogrel. High on-treatment platelet reactivity during clopidogrel therapy has also emerged as a predictor of stent thrombosis and is affected by clinical (e.g., age, diabetes, renal insufficiency) and genetic factors. Carriers of reduced-function *CYP2C19* alleles have low levels of the active metabolite of clopidogrel, diminished platelet inhibition, and an increased risk of stent thrombosis. Unlike clopidogrel, which undergoes two-step, cytochrome P450 (CYP)–dependent metabolic bioconversion in the liver, prasugrel and ticagrelor are not affected by CYP polymorphisms and consistently produce greater and more consistent inhibition of ADP-induced platelet aggregation than standard doses of clopidogrel. Higher doses of clopidogrel (e.g., 225 or 300 mg/day) in patients heterozygous for *CYP2C19**2 alleles produce levels of platelet inhibition similar to those seen with standard (75 mg) doses but have not been evaluated in clinical outcome studies.

The role of genetic testing to detect poor clopidogrel responders remains controversial. Although observational studies have demonstrated an independent association between *CYP2C19* loss-of-function alleles and the risk of stent thrombosis, analyses from multiple randomized controlled trials provide no evidence of an interaction between genotype and treatment for major cardiovascular events, including stent thrombosis.²³ It is reasonable to switch patients who have experienced stent thrombosis despite clopidogrel therapy to one of the newer P2Y₁₂ receptor antagonists (i.e., prasugrel or ticagrelor) that have been demonstrated to reduce the risk of stent thrombosis compared with clopidogrel even without laboratory testing.

ANTICOAGULANT THERAPY

Anticoagulant therapy is effective for the initial and long-term management of patients with ACS with or without ST-segment elevation.^{5,6,10} The pharmacologic characteristics of parenteral anticoagulants commonly used in the management of ACS are summarized in [Table 146.5](#). Early trials suggested that heparin and aspirin were similarly effective for the prevention of MI, but aspirin was adopted as the foundation antithrombotic therapy because it caused less bleeding than heparin. Subsequent randomized controlled trials demonstrated that the combination of heparin plus aspirin provided additive benefit. More recent trials have established the efficacy and safety of newer parenteral anticoagulants, including low-molecular-weight heparin (LMWH), fondaparinux, and bivalirudin, on a background of single- or dual-agent antiplatelet therapy for the initial management of patients with ACS.

The pharmacologic characteristics of warfarin and new oral anticoagulants evaluated in the management of ACS are summarized in [Table 146.6](#).²⁵ Warfarin is effective for the prevention of major cardiovascular events for the long-term management of patients with ACS who are also treated with aspirin, but no adequately powered randomized controlled trials have evaluated the efficacy and safety of warfarin in the context of dual antiplatelet therapy. Two new oral anticoagulants (rivaroxaban and apixaban) have been evaluated in phase III trials for long-term secondary prevention in ACS patients,^{26,27} and rivaroxaban has been approved for this indication in Europe.

Heparin

Heparin is derived from porcine intestinal mucosa and is administered by IV or subcutaneous injection. It inhibits coagulation by binding

Case 3: Thrombocytopenia After Stenting

A 65-year-old woman presenting with ST-segment elevation myocardial infarction undergoes primary percutaneous coronary intervention with placement of a bare metal stent in her circumflex coronary artery. During the procedure, she receives an intravenous bolus of abciximab in addition to aspirin, clopidogrel, and heparin. A blood count performed after returning to the coronary care unit (within 6 hours of the procedure) reveals a platelet count of $6 \times 10^9/L$, which is confirmed on repeat testing using a sample collected in sodium citrate (to eliminate platelet clumping as a cause of spurious thrombocytopenia). She is diagnosed with abciximab-induced thrombocytopenia.

Heparin is stopped, and the patient receives 1 unit of single-donor platelets with a prompt increase in her platelet count. She is continued on aspirin and clopidogrel and is started on a proton pump inhibitor. The platelet count begins to rise spontaneously on day 4 and returns to baseline levels within 1 week.

Comment

Severe thrombocytopenia (platelet count $<50 \times 10^9/L$) occurs in about 0.5% and less severe thrombocytopenia in 2%–4% of patients treated with glycoprotein (GP) IIb/IIIa inhibitors.²⁴ Thrombocytopenia caused by GP IIb/IIIa inhibitors is readily distinguished from other causes by its rapid onset, typically within 24 hours of exposure and sometimes within with first hour, and severity (count often $<10 \times 10^9/L$). By contrast, heparin-induced thrombocytopenia is usually delayed until at least 4 days after starting heparin therapy (with the exception of patients with prior exposure to heparin in the past 3 months) and platelet counts rarely fall below $30 \times 10^9/L$. The rapid onset of thrombocytopenia is believed to be caused by preformed antibodies that react with GP IIb/IIIa inhibitor-coated platelets. Spontaneous recovery of the platelet count usually occurs within days but can take several weeks. Patients with GP IIb/IIIa inhibitor-induced thrombocytopenia respond normally to platelet transfusions, which should be considered when the count is below $10 \times 10^9/L$ to reduce the risk of spontaneous bleeding. There is no evidence that steroids or IV gamma globulin alter the natural history of GP IIb/IIIa inhibitor-induced thrombocytopenia. Repeated exposure to GP IIb/IIIa inhibitors should be avoided because there is a risk of recurrent thrombocytopenia, which may be more severe than the initial episode.

TABLE 146.5 Pharmacologic Characteristics of Parenteral Anticoagulants Commonly Used in the Management of Patients With Acute Coronary Syndromes

	Unfractionated Heparin	Enoxaparin	Bivalirudin	Fondaparinux
Route of administration	IV	SC (first dose IV ^a)	IV	SC (first dose IV ^a)
Frequency of dosing	Continuous IV infusion	Twice daily; once daily if CrCl <30 mL/min	Continuous IV infusion	Once-daily injection
Clearance	Primarily nonrenal	Renal	Renal, proteolytic cleavage	Renal
Use in ACS patients with moderate renal impairment	Yes	Yes (dose reduction)	Yes (dose reduction)	Yes ^b
Use in ACS patients undergoing dialysis	Yes	No experience	Yes (dose reduction)	No experience ^c
Routine laboratory monitoring	Yes	No	No ^d	No
Dose	Adjust dose according to the results of the aPTT	Fixed weight adjusted	Fixed weight adjusted	Fixed
Accumulation in renal failure	No	Yes	Yes	Yes
Nonanticoagulant side effects	Allergy, HIT	HIT (rare)	—	—
Nonbleeding contraindications	Allergy, immune HIT	Allergy, immune HIT	Allergy	Allergy
Antidote	Protamine sulfate	Protamine sulfate partially reverses	No	No

^aThe first dose of enoxaparin was given by the intravenous route in the TIMI-11B (Thrombolysis In Myocardial Infarction 11B) and EXTRACT-TIMI 25 (Enoxaparin and Thrombolysis Reperfusion for Acute Myocardial Infarction Treatment, Thrombolysis in Myocardial Infarction 25) studies. The first dose of fondaparinux was given by the intravenous route in the OASIS-6 (Optimal Antiplatelet Strategy for InterventionS 6) trial.

^bAcute coronary syndrome patients with creatinine up to 265 μmol/L were eligible for inclusion in the OASIS-5 and -6 trials (equivalent to an estimated creatinine clearance of 15–20 mL/min in a 70-kg patient who is 70 years of age).

^cFondaparinux is contraindicated in patients with venous thromboembolism who have severe renal impairment.

^dMonitoring and dose adjustment required in patients with creatinine clearance below 30 mL/min.

ACS, Acute coronary syndromes; aPTT, activated partial thromboplastin time; CrCl, creatinine clearance; HIT, heparin-induced thrombocytopenia; IV, intravenous; SC, subcutaneous.

TABLE 146.6 Pharmacological Characteristics of Warfarin and New Oral Anticoagulants Evaluated in Phase III Trials for the Long-Term Management of Acute Coronary Syndromes

Characteristic	Warfarin	Rivaroxaban	Apixaban
Target	VKORC1	Factor Xa	Factor Xa
Prodrug	No	No	No
Bioavailability (%)	100	80	60
Dosing	Variable, once daily	Fixed, 2.5 or 5 mg twice daily ^a	Fixed, 5 mg twice daily (2.5 mg twice daily in selected patients)
Half-life	Mean: 40 hours (range: 20–60 hours)	7–11 hours	12 hours
Renal clearance (%)	Nil	66 ^b	25
Routine coagulation monitoring	Yes (INR)	No	No
Drug interactions	Multiple	Potent inhibitors of CYP3A4 and P-gp ^c	Potent inhibitors of CYP3A4 and P-gp ^c
Antidote	Yes (vitamin K, PCC, FFP)	No ^d	No ^d
Approved for ACS management	Yes	Yes, in Europe	No

^aA once-daily regimen was tested in atrial fibrillation.

^bHalf of renally cleared rivaroxaban is cleared as unchanged drug and half as inactive metabolites.

^cPotent inhibitors of both CYP3A4 and P-glycoprotein include azole antifungals (e.g., ketoconazole, itraconazole, voriconazole, posaconazole) and protease inhibitors, such as ritonavir. Potent inhibitors of CYP3A4 include azole antifungals, macrolide antibiotics (e.g., clarithromycin), and protease inhibitors (e.g., atazanavir).

^dAndexanet alfa is being developed as an antidote for rivaroxaban and apixaban.

ACS, Acute coronary syndromes; CYP3A4, cytochrome P450 3A4; FFP, fresh frozen plasma; fXa, activated factor X; INR, international normalized ratio; PCC, prothrombin complex concentrates; P-gp, P-glycoprotein; VKORC1, C1 subunit of vitamin K epoxide reductase.

to antithrombin to induce a conformational change that converts antithrombin from a slow to a rapid inhibitor of thrombin and factor Xa.

Heparin has several limitations, including immune-mediated platelet activation, which leads to heparin-induced thrombocytopenia, and nonspecific protein binding, resulting in a variable anticoagulant response and the need for routine coagulation monitoring. Despite these limitations, heparin remains widely used because it has important advantages over more recently introduced anticoagulants. First,

the anticoagulant effect of heparin can be rapidly and completely reversed with protamine sulfate. Second, heparin is suitable for use in patients with renal failure because it is predominantly nonrenally cleared. Third, unlike LMWH and fondaparinux, heparin is also highly effective for prevention of contact activation of coagulation induced by catheters and stents.²⁸

Meta-analysis of four randomized controlled trials involving 1239 STEMI patients treated with aspirin and fibrinolytic therapy demonstrated that short-term IV heparin (given for about 1 week) did not

significantly reduce death or reinfarction compared with placebo or no heparin, but increased bleeding.²⁹ However, these trials were underpowered to demonstrate a benefit of heparin. Definitive data concerning the efficacy of heparin in STEMI patients treated with fibrinolysis come from a metaanalysis of 26 trials involving 73,000 patients, in which heparin, given either intravenously or subcutaneously, reduced mortality and reinfarction compared with placebo or no heparin.³⁰ Consistent benefits were evident in a subset of five trials in which patients also received aspirin; heparin compared with placebo or no heparin reduced both mortality (8.6% vs. 9.1%; $p = .03$) and reinfarction (3.0% vs. 3.3%; $p = .04$).

Short-term heparin therapy is also beneficial when added to aspirin in patients with NSTEMI ACS. A meta-analysis of six trials involving 1353 patients demonstrated that compared with placebo or no heparin, up to 7 days of IV heparin reduced death or MI (4.5% vs. 7.4%; $p = .045$) with a nonsignificant excess of major bleeding.³¹ Heparin has not been rigorously evaluated in ACS patients undergoing PCI but is routinely used in this setting.

Low-Molecular-Weight Heparin

LMWH is derived from heparin by enzymatic or chemical methods, yielding shorter polysaccharide chains that produce a more predictable anticoagulant effect than heparin and a lower propensity for heparin-induced thrombocytopenia. LMWH is given in fixed weight-adjusted doses without routine coagulation monitoring. The anticoagulant effects of LMWH can be partially reversed with protamine sulfate.

The CREATE trial ($n = 15,570$) was the largest of four trials that evaluated the efficacy and safety of various LMWH preparations in patients with STEMI also treated with aspirin and fibrinolysis.³² Approximately half of patients in the CREATE trial were treated with dual antiplatelet therapy. The pooled data ($n = 16,943$) demonstrated that compared with placebo, initial LMWH continued for up to 7 days reduced the risk of reinfarction (1.6% vs. 2.2%; $p < .05$) and death (7.8% vs. 8.7%; $p < .05$) at the cost of an increase in major bleeding (1.1% vs. 0.4%; $p < .05$).

Most of the trials comparing LMWH with heparin for the treatment of STEMI tested enoxaparin. Pooled data from eight trials involving 27,758 patients demonstrated that compared with heparin, initial LMWH reduced the risk of MI (2.1% vs. 3.9%; $p < .05$) with similar rates of death (5.3% vs. 5.8%) at the cost of an increase in major bleeding (2.2% vs. 1.6%).³³ Consistent results were evident at 30 days.

The FRISC-1 (Fragmin during Instability in Coronary Artery Disease 1) trial evaluated the efficacy and safety of dalteparin in patients with NSTEMI ACS. Pooled data from FRISC-1 ($n = 1539$) and a second much smaller phase II study demonstrated that compared with placebo or no LMWH, LMWH reduced the risk of MI or death (1.6% vs. 5.2%; $p < .0001$) with no significant increase in major bleeding.

Multiple trials have compared LMWH with heparin in patients with NSTEMI ACS. A pooled analysis of five trials involving 12,171 patients demonstrated that LMWH and heparin were associated with similar rates of MI or death (2.2% vs. 2.3%) and major bleeding.³¹ A subsequent meta-analysis involving 21,946 patients with NSTEMI ACS demonstrated that compared with heparin, enoxaparin reduced the risk of death or MI (10.1% vs. 11.0%; $p < .05$) with no increase in major bleeding.³² The latter meta-analysis included some trials that did not involve the use of GP IIb/IIIa inhibitors and other in which they were widely used. The proportion of patients who underwent an invasive management strategy also varied among the trials.

Fondaparinux

Fondaparinux is a synthetic pentasaccharide that contains the essential five-sugar chain that binds antithrombin with high affinity and enhances the rate at which it inhibits factor Xa. Fondaparinux has a

half-life of 17 hours, which enables once-daily administration and produces an even more predictable anticoagulant effect than LMWH and does not appear to cause heparin-induced thrombocytopenia. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux.

Fondaparinux has been evaluated in patients with ACS in three large phase III randomized controlled trials. The OASIS-6 trial evaluated fondaparinux in 12,092 STEMI patients treated with single or dual antiplatelet therapy and fibrinolytic therapy.³⁴ Compared with placebo or heparin, fondaparinux (2.5 mg/day) reduced the risk of reinfarction or death (9.7% vs. 11.2%; $p = .008$) with consistent effects in patients with or without an indication for heparin therapy and in patients who received aspirin alone or the combination of aspirin and clopidogrel. Fondaparinux did not increase major bleeding. However, fondaparinux was associated with no benefit and a trend for harm in patients undergoing primary PCI.

The OASIS-5 trial evaluated fondaparinux in 20,078 patients with NSTEMI ACS treated with aspirin with or without clopidogrel. Fondaparinux (2.5 mg once daily) and enoxaparin (1 mg/kg twice a day) given for a mean of 6 days were associated with similar rates of the primary outcome of refractory ischemic, MI, or death at 9 days (5.8% vs. 5.7%), but there was a lower rate of major bleeding with fondaparinux (2.2% vs. 4.1%; $p < .001$).³⁵ At 30 days, fondaparinux was associated with a reduced rate of death compared with enoxaparin (2.9% vs. 3.5%; $p = .02$), which appeared to be explained primarily by the lower rate of bleeding. In 6238 invasively managed patients, fondaparinux and enoxaparin were associated with similar rates of the primary outcome but fondaparinux was associated with a small excess of catheter-related thrombosis (0.9% vs. 0.4%) and a reduction in major bleeding (2.4% vs. 5.1%; $p < .00001$). The risk of catheter thrombosis was largely prevented by the administration of heparin at the time of intervention.

The FUTURA OASIS-8 (Fondaparinux Trial With Unfractionated Heparin During Revascularization in Acute Coronary Syndromes) study compared the effect of standard-dose heparin (85 units/kg bolus with additional boluses based on an activated clotting time dosing algorithm) with reduced-dose heparin (50 units/kg without activated clotting time adjustment) on the primary outcome, a composite of bleeding or major vascular site access complications, in 2026 patients with NSTEMI ACS who were treated with fondaparinux and scheduled to undergo PCI within 72 hours.³⁶ The incidences of the primary outcome and of catheter-related thrombosis were similar in the two heparin dose groups, but death, MI, or target vessel revascularization occurred more often in the low-dose group. These data support the use of standard-dose heparin in patients with NSTEMI ACS who are treated with fondaparinux and scheduled to undergo PCI.

Bivalirudin

Bivalirudin is an IV direct thrombin inhibitor that binds thrombin and prevents it from interacting and its substrates. Bivalirudin has a short half-life of only 25 minutes after IV injection, making the lack of an antidote less problematic than it is for longer-acting anticoagulants. It is about 20% renally cleared, and the half-life is prolonged in patients with renal impairment. Bivalirudin does not cause heparin-induced thrombocytopenia.

The efficacy and safety of direct thrombin inhibitors in ACS patients and those undergoing PCI was examined in the Direct Thrombin Inhibitor Trialists' Collaboration metaanalysis involving data from 11 trials and 35,970 patients.³⁷ The pooled data indicated a significant benefit of direct thrombin inhibitors (including bivalirudin) compared with heparin for the prevention of MI or death. Clopidogrel and GP IIb/IIIa inhibitors were not used in the trials included in this meta-analysis.

The HORIZONS AMI (Harmonizing Outcomes with Revascularization and Stents in Acute Myocardial Infarction) trial evaluated the use of bivalirudin in 3602 STEMI patients undergoing PCI who were treated with the combination of aspirin and clopidogrel.³⁸ Compared with heparin plus GP IIb/IIIa, bivalirudin plus provisional

GP IIb/IIIa inhibitor was associated with similar rates of the primary outcome, MI, target vessel revascularization, stroke, or death (5.4% vs. 5.5%) at 30 days, but bivalirudin significantly reduced major bleeding (4.9% vs. 8.3%; $p < .0001$).

The EUROMAX (European Ambulance Acute Coronary Syndrome Angiography) trial³⁹ evaluated the use of prehospital bivalirudin in 2218 participants treated with aspirin and a P2Y₁₂ receptor antagonist (more than 50% received ticagrelor or prasugrel) being transported for primary PCI. Compared with heparin (unfractionated or low-molecular-weight) plus optional GP IIb/IIIa inhibitor, bivalirudin reduced the risk of death or non-CABG major bleeding (5.1% vs. 8.5%; $p = .001$), a difference that was primarily driven by a reduction in major bleeding (2.6% vs. 6.0%; $p < .001$). Bivalirudin was associated with an increase in stent thrombosis within 24 hours (1.1% vs. 0.2%; $p = .007$).

The single-center, open-label HEAT-PPCI (unfractionated heparin versus bivalirudin in primary percutaneous coronary intervention) trial⁴⁰ evaluated the use of bivalirudin in 1829 participants treated with aspirin and a P2Y₁₂ receptor antagonist (almost 90% received ticagrelor or prasugrel) undergoing emergency angiography. Compared with heparin (13% also received a GP IIb/IIIa inhibitor), bivalirudin (15% also received a GP IIb/IIIa inhibitor) was associated with an increase in the composite of death, stroke, reinfarction, or unplanned target lesion revascularization (8.7% vs. 5.7%; $p = .01$). The rates of major bleeding were similar (3.5% vs. 3.1%; $p = .59$), but there was more stent thrombosis with bivalirudin (3.4% vs. 0.9%; $p = .001$).

The BRIGHT (Bivalirudin vs Heparin With or Without Tirofiban) trial⁴¹ evaluated the use of bivalirudin continued for 30 minutes to 4 hours after PCI in 2194 participants with acute MI. Compared with heparin alone or heparin plus a GP IIb/IIIa inhibitor, bivalirudin reduced the risk of death, reinfarction, stroke, ischemia-driven target vessel revascularization or any bleeding (8.8% vs. 13.2%; $p = .008$, and 8.8% vs. 17%; $p < .001$), primarily driven by a reduction in bleeding (4.1% vs. 7.5% vs. 12.3%; $p < .001$) with similar rates of major adverse cardiac or cerebral events (5.0% vs. 5.8% vs. 4.9%; $p = .74$) and stent thrombosis (0.6% vs. 0.9% vs. 0.7%; $p < .77$). Prolonged bivalirudin therapy following PCI might explain the lack of excess stent thrombosis that was seen in most of the earlier bivalirudin trials.

The ACUITY (Acute Catheterization and Urgent Intervention Triage Strategy) trial evaluated the use of bivalirudin in 13,819 patients with NSTEMI/ACS undergoing PCI who were treated with the combination of aspirin plus clopidogrel as well as a GP IIb/IIIa inhibitor.⁴² Bivalirudin was noninferior to heparin or enoxaparin plus a GP IIb/IIIa inhibitor for the prevention of MI, unplanned revascularization, or death at 30 days (7.8% vs. 7.3%) but was associated with a lower rate of major bleeding (3.0% vs. 5.7%; $p < .001$).

A metaanalysis of 16 trials involving 33,958 participants⁴³ showed that compared with heparin-based treatment regimens, bivalirudin was associated with increased major adverse cardiac events and stent thrombosis and a reduction in major bleeding, with no difference in death.

Oral Anticoagulation

Warfarin is an oral vitamin K antagonist that has been evaluated in the long-term management of patients with ACS who are treated with aspirin but has not been rigorously tested on a background of dual antiplatelet therapy. Furthermore, the efficacy and safety of the combination of aspirin plus warfarin have not been compared with those of dual antiplatelet therapy.

The results from a metaanalysis of 14 trials involving 25,307 patients demonstrated that compared with placebo or no warfarin, long-term warfarin (target INR, 2.0–3.0) reduced the risk of MI, ischemic stroke or death (9.4% vs. 12.3%; $p < .0001$) at the cost of a twofold increase in major bleeding (2.6% vs. 1.1%; $p < .00001$).⁴⁴

Rivaroxaban and apixaban are orally active direct factor Xa inhibitors that have undergone evaluation in phase III trials for the long-term management of patients with ACS. The ATLAS TIMI-51 trial compared rivaroxaban (2.5 or 5 mg twice a day) with placebo in

TABLE 146.7

Strategies Aimed at Minimizing the Risk of Bleeding in Patients Treated With Triple Therapy (Dual Antiplatelet Therapy and an Oral Anticoagulant)

Proposed Approach	Rationale
Aspirin maintenance dose ≤ 100 mg/day	Higher aspirin maintenance doses increase bleeding, and there is no evidence that they improve efficacy
PPI with a preference for agents that interfere less with CYP 2C19 (e.g., pantoprazole)	Much of the excess bleeding is from the GI tract. The use of acid-suppressive agents that interfere less with CYP 2C19 minimizes the potential for a negative interaction with clopidogrel
Preference for a non-vitamin K antagonist oral anticoagulant	Dabigatran 110 mg twice daily and apixaban 2.5 or 5.0 mg twice daily are associated with lower rates of bleeding than warfarin
For warfarin, use a target INR of 2–2.5	Some evidence that a restricted target INR range reduces the risk of bleeding
Manage warfarin in a specialized anticoagulation clinic	Compared with usual care, specialist clinics achieve a higher TTR of the INR
Minimize duration of triple therapy	The risk of bleeding is highest during the first 30 days but remains elevated with long-term treatment
Avoid NSAIDs	NSAIDs are a common cause of upper GI bleeding
Avoid prasugrel and ticagrelor	Prasugrel and ticagrelor cannot be recommended because they are more potent than clopidogrel and cause more bleeding

CYP, Cytochrome P450; GI, gastrointestinal; INR, international normalized ratio; NSAID, nonsteroidal antiinflammatory drug; PPI, proton pump inhibitor; TTR, time in therapeutic range.

15,526 ACS patients, the majority of whom were also treated with the combination of aspirin and clopidogrel.²⁶ Treatment was started a median of 4.7 days after onset of symptoms and was continued for a mean of 13 months. Rivaroxaban significantly reduced the risk of MI, stroke, or cardiovascular death (8.9% vs. 10.7%; $p = .008$) at the cost of an increase in non-CABG major bleeding (2.1% vs. 0.6%; $p < .001$) and intracranial bleeding (0.6% vs. 0.2%; $p = .009$). Based on these results, rivaroxaban (2.5 mg twice daily) has been approved in Europe for post ACS patients.

The APPRAISE trial compared apixaban (5 mg twice a day; 2.5 mg twice a day in selected patients) with placebo in patients with ACS. The trial was stopped early because of an excess of bleeding with no significant reduction in ischemic events.²⁷

The oral direct thrombin inhibitor dabigatran etexilate has been tested in a phase II trial but has not undergone evaluation in a phase III trial in ACS patients (see Table 146.7 and box on Case 4: Triple Therapy).

CONCLUSIONS AND FUTURE DIRECTIONS

Antiplatelet and anticoagulant drugs are effective for the prevention of MI and death across the spectrum of patients presenting with ACS, including STEMI patients treated with fibrinolytic therapy and those undergoing mechanical reperfusion. Aggressive antithrombotic treatment regimens involving multiple antiplatelet drugs given in combination with an anticoagulant during the acute phase have substantially reduced the risk of early and late recurrent ischemic events and stent thrombosis in ACS patients but at the cost of an increased risk of bleeding. Clinicians require detailed knowledge of the pharmacology

Case 4: Triple Therapy

A 55-year-old woman with a recent anterior myocardial infarction treated who underwent primary percutaneous coronary intervention with implantation of a drug-eluting stent in the left anterior descending coronary artery is found to have a left ventricular thrombus on trans-thoracic echocardiogram. She is taking aspirin and clopidogrel. She is started on intravenous heparin, which is overlapped with warfarin until an international normalized ratio of 2 is achieved. She is discharged home on triple antithrombotic therapy with aspirin, clopidogrel, and warfarin.

Comment

Anticoagulation is indicated for the management of left ventricular thrombosis, and the combination of aspirin and clopidogrel is indicated for the management of patients with drug-eluting stents. The combination of an anticoagulant with dual antiplatelet therapy is associated with a 2%–3% incidence of major bleeding during the first 30 days and a 4%–12% incidence during the first year.⁴⁵ Strategies that may help to minimize the risk of bleeding in patients receiving triple antithrombotic are summarized in Table 146.7. The new oral anticoagulants, dabigatran etexilate (110 or 150 mg twice a day), apixaban (2.5 or 5.0 mg twice a day), or rivaroxaban (15 or 20 mg once daily), may offer an advantage if they are used instead of warfarin in patients who require triple antithrombotic therapy because they cause less serious bleeding than warfarin in direct head-to-head comparisons.^{46,47} However, all anticoagulants, including the new oral agents, increase the risk of bleeding when added to dual antiplatelet therapy.

and side-effects profile of antithrombotic therapies used in the management of patients with ACS to optimize clinical outcomes. Comparative effectiveness studies are urgently required to further define those combinations of antithrombotic drugs that will maximize the net clinical benefit for patients with ACS by minimizing the risk of both thrombotic and bleeding events.

ATRIAL FIBRILLATION

Dipak Kotecha, Keitaro Senoo, and Gregory Y.H. Lip

Atrial fibrillation (AF) is the most common cardiac rhythm disturbance. Patients with AF have impaired prognosis, with increased risk of death, stroke, and hospital admission, in addition to poor quality of life.^{1,2} The impact of AF on numerous specialties is set to increase further, as the number of patients with AF escalates to epidemic proportions and the populations that are susceptible to AF increase in prevalence. Most notably, this includes older adults and those with heart failure, both in themselves potent risk factors for stroke and systemic thromboembolism (SSE). Cardiologists and general physicians will often manage those patients with straightforward indications (and a lack of contraindications) for anticoagulation, leaving hematologists to face more difficult decisions regarding anticoagulation in patients with high bleeding risk and the consequences of therapy.

In this chapter, we provide a brief overview and background to the overall management of AF, with a focus on issues relating to SSE.

EPIDEMIOLOGY

There have been progressive increases in the incidence and prevalence of AF, and the burden of this condition is expected to increase further.³ From 2010 to 2060, the number of older adults with AF in the European Union is expected to more than double.⁴ Given that AF is a growing epidemic, the societal impact and cost of this condition will continue to increase.⁵ AF is commonly accompanied by other comorbidities, including cardiovascular (CV) diseases such as coronary artery disease and valvular heart disease, in addition to non-CV conditions affecting the lungs, kidneys, and liver.⁶

PATHOBIOLOGY

AF can be classified based on etiology, depending on whether it occurs in patients without structural heart disease or whether it complicates other cardiac conditions. AF episodes are defined as paroxysmal if they terminate spontaneously (usually within 7 days) or persistent if they continue and require electrical or pharmacologic termination. Where cardioversion to sinus rhythm is not part of the management plan, AF is considered permanent.

The pathogenesis of AF is now thought to involve an interaction between initiating triggers, often in the form of rapidly firing ectopic foci located inside a pulmonary vein, and an abnormal atrial tissue substrate capable of maintaining the arrhythmia. Although there is considerable overlap, pulmonary vein triggers may play a dominant role in younger patients with relatively normal hearts and short paroxysms of AF, and an abnormal atrial tissue substrate may play a more important role in patients with structural heart disease and persistent/permanent AF.⁷ After a period of continuous AF, electrical remodeling occurs, further facilitating the continuance of AF ("AF begets AF"). These changes are initially reversible if sinus rhythm is restored, but may become permanent and associated with structural changes if AF continues (left atrial dilatation, cardiac fibrosis, and impairment of systolic/diastolic function).

CLINICAL MANIFESTATIONS

Symptoms

Symptoms are a major reason that patients with AF seek medical advice. The most common symptoms include lethargy, dyspnea, and palpitations, associated with a reduction in exercise capacity. AF and its related symptoms therefore represent a major therapeutic challenge and burden to health care systems. However, the relationship between symptoms and the onset or recurrence of AF is not always obvious, and these symptoms may reflect other comorbidities. Given the lack of a standardized symptom classification, the European Heart Rhythm Association (EHRA) score has recently been modified for use as a clinical adjunct to classify symptoms of AF (Table 147.1). As yet, there are no outcome data supporting its use to determine management, although the modified EHRA score correlates well with more detailed quality of life assessments.⁸

Stroke and Thromboembolism

The Framingham Study has clearly shown that AF is associated with an increased risk of stroke (both ischemic and hemorrhagic). It is estimated that 20% of all strokes occur in the setting of AF; this rate increases to 25% in patients aged ≥ 80 years. Patients with AF have an age-adjusted risk of stroke that is fivefold higher than the normal population, regardless of the type of AF.⁹ Strokes in AF patients are associated with greater neurologic disability, reduced functional outcomes, and higher mortality than strokes in patients with sinus rhythm.¹⁰ Cognitive dysfunction, including vascular dementia, is present in 10%–15% of patients with AF, twice the rate in patients without AF. Cognitive disturbances can occur in the absence of an obvious stroke, as a consequence of multiple asymptomatic cerebral emboli.¹¹

In patients with AF, thrombi have a predilection to form within the left atrial appendage (LAA) due to stagnant flow and reduced emptying of this blind-ended structure (See box on [Concomitant Atrial Fibrillation and Risk of Stroke](#), and Fig. 147.1). The vast majority of atrial thrombi in nonvalvular AF (approximately 90%) are formed within the LAA. Thrombus formation in AF is consistent with the fulfillment of the Virchow triad of thrombogenesis, with intraatrial stasis, endothelial dysfunction, and a prothrombotic or hypercoagulable state due to elevated levels of D-dimer, P-selectin, and von Willebrand factor.

Heart Failure, Other Consequences, and Death

Beyond stroke, AF is associated with a range of CV and non-CV outcomes. Heart failure and AF are convergent disorders that are associated with substantial morbidity, and each of these conditions strongly predisposes to the other. AF directly leading to acute heart failure is termed tachycardiomyopathy, and is a direct result of the rapid heart rate that often responds to cardioversion to sinus rhythm. However, in the vast majority of patients, the link between AF and heart failure is less clear. The occurrence of new AF in

TABLE 147.1 Symptom Scoring in Atrial Fibrillation

mEHRA score	Symptoms	Description
1	None	
2a	Mild	Normal daily activity not affected
2b	Moderate	Normal daily activity not affected, but patient troubled by symptoms
3	Severe	Normal daily activity affected
4	Disabling	Normal daily activity discontinued

mEHRA, Modified European Heart Rhythm Association score.

Case 1: Concomitant Atrial Fibrillation and Risk of Stroke

A 77-year-old woman with syncope, progressive exertional breathlessness, and a systolic murmur was referred for urgent cardiology opinion by her family doctor. Past medical history included type 2 diabetes. On transthoracic echocardiography, the aortic valve was critically stenosed, with good biventricular function. She denied any history of palpitations and multiple electrocardiograms (ECGs) confirmed sinus rhythm. She was reviewed by a cardiac surgeon and urgently listed for a bioprosthetic aortic valve replacement. During all preoperative assessments, she remained in sinus rhythm. On the day of operation she was noted to be in atrial fibrillation (AF). Intraoperative transesophageal echocardiogram revealed a large thrombus arising from her left atrial appendage (LAA), measuring over 5 cm. The surgeon modified the approach and first opened the left atrium, physically removed the thrombus, surgically amputated the LAA, and overstitched the orifice, before proceeding to aortic valve replacement. The patient made a good recovery and was commenced on long-term warfarin due to a CHA₂DS₂-VASc score of 4.

Comment

In the context of other cardiovascular conditions, identifying symptoms of AF can be difficult. AF frequently complicates other conditions, particularly those that have a structural impact on the heart, such as heart failure and valve disease. This patient most likely had paroxysmal AF that was not detected despite numerous preoperative ECGs. The large thrombus in the LAA would have placed her at high risk of a fatal stroke. Surgical amputation of the LAA is a viable option during cardiac surgery; however, as more than 10% of clots arise from outside the LAA, patients still require long-term anticoagulation depending on predicted risk. In this patient, a CHA₂DS₂-VASc score of 4 is equivalent to an estimated stroke rate of 4%–5% per year.

patients with heart failure is associated with increased mortality,¹² irrespective of the type of heart failure (whether systolic or diastolic dysfunction).¹³ Regardless of the development of heart failure, AF is linked with higher mortality in women (1.9-fold) and men (1.5-fold).¹⁴

DIAGNOSIS AND DIFFERENTIALS

Diagnosing Atrial Fibrillation

Advances in diagnostic technology are leading to more decisive therapeutic approaches. Among the various diagnostic tools, the simplest method of detecting AF is the electrocardiogram (ECG), which is often prompted by an irregular pulse. Diagnostic ECG criteria include absence of P waves, fibrillatory waves between QRS complexes, and irregular R-R intervals (Fig. 147.2). In paroxysmal AF, ambulatory ECG monitors are helpful, with longer-term monitoring now easily achieved with loop recorders implanted using a local anesthetic. In cases of embolic stroke with undetermined source (previously called cryptogenic stroke), implantable loop recorders are recommended to capture episodes of silent AF that would benefit from anticoagulation.

Key Investigations

Cardiac ultrasound (echocardiography) in AF contributes to risk stratification, diagnosis of complications, and management of associated conditions. Transthoracic echocardiography is a noninvasive method that provides a comprehensive assessment of cardiac structure and function. In patients where exclusion of the left atrial appendage thrombus is required, transesophageal echocardiography is the modality of choice; in addition to visualization of dense spontaneous echo contrast, LAA-emptying velocities of <20 cm/s are strongly associated with incident SSE.¹⁵ Other imaging techniques, such as computed tomography and magnetic resonance imaging, are being used more frequently and have complementary roles in the management of patients with AF.

Blood tests are important in the initial assessment of AF, and should include tests for thyroid, renal, and hepatic function, in addition to serum electrolytes, full blood count, and global tests of coagulation, such as prothrombin time/international normalized ratio (INR) and activated partial thromboplastin time. Biomarkers (such as troponin, B-type natriuretic peptide, and D-dimer) have the potential for refining risk prediction for SSE, but their role in management requires further evaluation before routine measurement can be recommended.¹⁶

Differential Diagnoses

Other atrial rhythms may resemble AF on an ECG, but these can often be distinguished by the presence of discrete P waves (e.g., atrial tachycardias). Atrial flutter, in the typical form, is characterized by a sawtooth pattern of regular atrial activation, visible as flutter waves in leads II, III, aVF, and V1. Atrial flutter commonly occurs with 2:1 AV block, resulting in a ventricular rate of approximately 150 beats/min (unless rate control medications have been taken). It should be remembered that persistent atrial flutter is also associated with SSE, and hence requirements for anticoagulation are similar to those for AF. Supraventricular tachycardias can be readily distinguished from other narrow complex tachycardias (and often effectively treated) by the use of intravenous adenosine. Broad complex tachycardia should be treated urgently as ventricular tachycardia, unless there is good reason to suspect a bundle-branch block pattern (for example, hemodynamically stable irregular AF with preexisting left bundle branch block).

HEART RATE AND RHYTHM CONTROL

Aside from anticoagulation (see later), management of AF involves control of the rapid heart rate in the majority of patients and therapy to restore sinus rhythm in selected individuals. Compared with rate control therapy, rhythm control does not appear to reduce adverse outcomes; hence the strategy for managing patients with AF is dependent on the presence of ongoing symptoms.^{17,18} Thus, modern management of AF is largely patient-centered and symptom-directed.

Rate Control

Rate control can be achieved with beta-blockers, non-dihydropyridine calcium channel blockers (CCB; diltiazem and verapamil), and cardiac glycosides (digoxin and digitoxin). Unfortunately there are few robust randomized trials in this field, leaving the choice of therapy up to individual clinicians based on patient factors such as the presence of heart failure or hypertension. Traditionally beta-blockers have been the preferred therapy due to a presumption of improved prognosis in patients with concomitant heart failure. Recent data, however, suggest that unlike their effect in patients with sinus rhythm, beta-blockers do not reduce mortality or cardiovascular hospitalization in heart failure patients with AF.¹⁹ CCB are typically avoided in patients with reduced ejection fraction due to negative inotropic effects, but can be useful drugs in those with preserved

Fig. 147.1 LEFT ATRIAL APPENDAGE AND THROMBUS. The *top panel* shows the left atrial appendage (LAA) using two orthogonal planes from a mid-esophageal view using transesophageal echocardiography. The *bottom panel* shows the same view taken after the patient was found to be in atrial fibrillation (AF), with a large clot arising from the LAA and extending into the body of the left atrium.

cardiac function. Digoxin has not been tested in randomized trials in AF, but in heart failure with sinus rhythm, digoxin reduces symptoms and hospital admissions without affecting mortality. Digoxin is often useful as adjunctive therapy in patients with ongoing symptoms and uncontrolled heart rates. Conventional approaches to target to a strict heart rate (<80 beats/min) have not proved to be better than a more lenient approach, both for prognosis and symptom control.²⁰ Hence in most patients, the heart rate should be kept at <110 beats/min, with up-titration of therapy if symptoms persist.

Rhythm Control

The aim of rhythm control is to restore normal sinus rhythm and improve symptoms (or heart function). This can be achieved using antiarrhythmic drugs, electrical cardioversion, and catheter or surgical ablation. A full review of this expanding field is beyond the scope of this review, and readers are advised to refer to guideline documents, which are frequently updated (<http://www.escardio.org/guidelines/clinical-practice-guidelines/atrial-fibrillation-management>).

In brief, all antiarrhythmic drugs have the potential for side effects (e.g., thyroid dysfunction and pulmonary fibrosis with long-term amiodarone use, and the proarrhythmic effects of class I antiarrhythmics). However, in selected patients, they can be helpful to restore and maintain sinus rhythm.²¹ Direct current electrical cardioversion is an effective method to achieve rhythm control, although patients will require heavy sedation/anesthetic, and recurrence of AF is common. Catheter ablation of AF involves radiofrequency ablation or cryoablation to the endocardium, typically involving isolation of the pulmonary veins (see box on [Interventional Approach to Atrial Fibrillation](#)). Although direct evidence of improvement in long-term outcomes is pending, there are studies that suggest that ablation improves symptoms and ejection fraction, even in patients with AF and heart failure.²² Surgical ablation, either targeting the pulmonary veins or with the more extensive Cox-Maze approach, is typically performed in patients undergoing cardiac surgery for other reasons (e.g., valve replacement or coronary artery bypass grafting). Regardless of the method of rhythm control, there remains a risk of recurrent (often asymptomatic) AF, and clinicians should not stop long-term anticoagulation in patients with risk

Fig. 147.2 ELECTROCARDIOGRAM OF ATRIAL FIBRILLATION.

factors for SSE, even if the patient appears to be in normal sinus rhythm.

PREVENTION OF STROKE AND THROMBOEMBOLISM

The risk of SSE in AF varies, depending on several clinical factors, including age, gender, previous embolic events and vascular disease, hypertension, diabetes mellitus, and heart failure. In most cases of AF related to valvular heart disease (such as mitral stenosis), there are rarely any reasons not to anticoagulate patients due to the high baseline risk of SSE, regardless of other patient characteristics. Risk stratification scores can be helpful in clinical practice in nonvalvular AF to initially identify those patients at lowest risk of SSE that do not require antithrombotic therapy (i.e., a CHA₂DS₂-VASC score 0 in men, 1 in women; Table 147.2). Subsequent to this step, effective stroke prevention (oral anticoagulation) can be offered to patients with one or more additional stroke risk factors (i.e., CHA₂DS₂-VASC score ≥ 1 in males, ≥ 2 in females). This approach is better than a categorical approach to stroke risk (i.e., low/moderate/high) and basing treatment decisions on these artificial risk categories, given that stroke risk is a continuum and because clinical risk scores have limited predictive value for identifying “high-risk” subjects.

Oral anticoagulation can be achieved using a well-controlled, adjusted-dose vitamin K antagonist (VKA, e.g., warfarin), with time in therapeutic range (TTR) $>70\%$, or one of the non-VKA oral anticoagulants (NOACs) (see later). Deciding between a VKA and an NOAC can be assisted using the SAME-TT₂R₂ score,²³ which is a simple clinical risk score to help identify those patients likely to do well on a VKA (patients with a high TTR [SAME-TT₂R₂ score 0–2]), or those for whom an NOAC would be a better treatment option (less likely to achieve a good TTR [SAME-TT₂R₂ score >2])^{24,25} (Table 147.3). Although in some health care systems NOACs are routinely used as first-line therapy, the majority of patients with AF globally are still treated with VKAs.

Anticoagulants

The most commonly used anticoagulants in AF are VKAs such as warfarin, which reduce the risk of stroke by nearly two-thirds (i.e.,

TABLE 147.2 Risk Stratification for Incident Stroke and Systemic Thromboembolism and Bleeding

CHA ₂ DS ₂ -VASC Score for SSE Prediction		HAS-BLED Score for Bleeding Prediction	
Clinical Characteristic	Points	Clinical Characteristic	Points
CHF or LVEF $\leq 40\%$	1	Hypertension	1
Hypertension	1	Abnormal renal/liver function	1 or 2
Age ≥ 75	2	Stroke	1
Diabetes	1	Bleeding	1
Stroke/TIA/TE	2	Labile INRs	1
Vascular disease	1	Elderly (age >65 years)	1
Age 65–74	1	Drugs or alcohol	1 or 2
Sex category (female)	1		
Cumulative score	Range 0–9	Cumulative score	Range 0–9

For the CHA₂DS₂-VASC score, estimated stroke and thromboembolism event rates at 1 year follow-up are 0.78% (0 points), 2.01% (1 point), 3.71% (2 points), 5.92% (3 points), 9.27% (4 points), 15.26% (5 points), 19.74% (6 points), 21.50% (7 points), 22.38% (8 points), 23.64% (9 points); see Olesen JB, Lip GY, Hansen ML, et al: Validation of risk stratification schemes for predicting stroke and thromboembolism in patients with atrial fibrillation: nationwide cohort study. *BMJ*. 342:d124, 2011.

Hypertension = systolic blood pressure >160 mmHg; vascular disease = prior myocardial infarction, peripheral artery disease, and/or aortic plaque; abnormal renal function = dialysis, transplant, creatinine >2.6 mg/dL or >200 μ mol/L; abnormal liver function = cirrhosis or bilirubin $>2\times$ normal with AST/ALT/AP $>3\times$ normal; labile INR = unstable/high INRs, time in therapeutic range $<60\%$; drugs = antiplatelet agents, nonsteroidal antiinflammatories; alcohol = eight or more drinks/week.

AST, Aspartate aminotransferase; ALT, alanine aminotransferase; AP, alkaline phosphatase; CHF, congestive heart failure; INR, international normalized ratio; LVEF, left ventricular ejection fraction; SSE, stroke or systemic thromboembolism; TE, thromboembolism; TIA, transient ischemic attack.

Case 2: Interventional Approach to Atrial Fibrillation

A 66-year-old man was referred to a cardiac electrophysiologist with a 6-month history of irregular palpitations that cause considerable distress. He had presented to his local emergency department twice and on both occasions was found to be in rapid atrial fibrillation (AF) that reverted spontaneously. Treatment with beta-blockers had not reduced the frequency of symptoms and the patient had developed profound lethargy with higher dosage. He was treated with two antihypertensive agents. The family doctor had already commenced warfarin, with a target international normalized ratio (INR) of 2.5. The patient elected to have catheter ablation after a discussion of alternative pharmacological options and the procedural risks. He underwent radiofrequency ablation, achieving isolation of the four pulmonary veins, accessed through the femoral vein with a transseptal puncture of the interatrial septum. Warfarin was continued without interruption, maintaining an INR of 2.0 to 3.0. The procedure was uncomplicated and the patient was discharged the following day. At 3 months he remained free of symptoms. The CHA₂DS₂-VASc score was 2 and the patient elected to switch to a non-vitamin K antagonist (VKA) oral anticoagulant (NOAC) to reduce the need for regular blood tests.

Comment

In some patients, AF can substantially reduce quality of life, and a strategy of rhythm control is the most appropriate choice. The number of catheter ablation procedures is rapidly increasing worldwide, and it can be offered as first-line therapy in place of antiarrhythmic drugs in selected patients. Complication rates are low in experienced centers, with 1 in 100 risk of cardiac tamponade and 1 in 500 risk of stroke. The procedure is frequently performed without interruption of VKAs and with only brief or no interruption of NOACs. There is mounting evidence that uninterrupted anticoagulant therapy periprocedurally is safer than stopping the anticoagulant and bridging with heparin. Long-term freedom from AF is 50% to 80% after catheter ablation, but this is variable and multiple ablation procedures may be necessary. Regardless of the apparent restoration of sinus rhythm, anticoagulation should continue in patients with two or more CHA₂DS₂-VASc risk factors. In this patient, a CHA₂DS₂-VASc score of 2 is equivalent to an estimated stroke rate of 3% to 4% per year.

reduce the overall risk of stroke from 4.5% to 1.4% per year).²⁶ A key consideration in the use of warfarin is the TTR (maintaining the INR between 2.0 and 3.0 in nonvalvular AF). To achieve optimal reduction in SSE, TTR should be maintained above 65%–70%. Antiplatelet agents such as aspirin are inferior to oral anticoagulation for stroke prevention and are associated with similar bleeding risks;²⁷ hence their use for primary prevention of SSE in AF is now discouraged. Recently, four NOACs have become available, including the oral direct thrombin inhibitor dabigatran and the oral factor Xa inhibitors apixaban, edoxaban, and rivaroxaban. All have shown equal or greater efficacy than warfarin in reducing SSE and generally have

lower risks of major bleeding.²⁸ Additionally, VKAs have numerous interactions with vitamin K-containing foods and other medicines, and the anticoagulant activity of NOACs is not influenced by dietary vitamin K intake and there are few drug–drug interactions. Because they produce a more predictable anticoagulant effect than VKAs, NOACs do not require routine coagulation monitoring. A specific issue with NOACs is the lack of routinely-available antidotes for patients who suffer major bleeding or require reversal in preparation for urgent surgery. However, there is no evidence that the outcome of major bleeds is worse in patients treated with NOACs than it is in those receiving VKAs. NOACs should not be used in patients with prosthetic heart valves.

Secondary Stroke Prevention

The highest risk of recurrent stroke is in the early phase after a first stroke or transient ischemic attack. Prevention of recurrent stroke with anticoagulation is effective but requires a multidisciplinary approach with stroke physicians, hematologists, and cardiologists to carefully select appropriate patients and minimize the risk of hemorrhagic transformation. All NOACs are associated with a lower risk of intracranial bleeding than VKAs; hence if a patient suffers a stroke while on warfarin, clinicians may consider switching to an NOAC.

Nonpharmacologic Strategy

Left atrial appendage occlusion can be used to reduce the risk of stroke for patients with AF that are unable to tolerate anticoagulation.²⁹ The US Food and Drug Administration (FDA) has recently approved the Watchman device for this indication, although it should be remembered that antiplatelet or anticoagulant therapy is often required in the initial stage of endothelialization. Surgical approaches to ligate or excise the LAA may be considered for patients with AF undergoing cardiac surgery or thoracoscopic maze surgery. However, in most cases it is advisable to continue oral anticoagulation (based on the CHA₂DS₂-VASc risk score), as not all SSE in AF arise from the LAA.

Periprocedural Anticoagulation

Interruption of anticoagulation temporarily increases thromboembolic risk, whereas continuing anticoagulation increases the risk of bleeding associated with surgical procedures. Individuals undergoing low bleeding risk procedures (e.g., dental and cutaneous procedures) can continue anticoagulation (warfarin within the target INR range and probably NOACs as well). Individuals at high or moderate thromboembolic risk should limit the period without anticoagulation to the shortest possible interval,³⁰ with or without bridging with low-molecular-weight heparin (LMWH). For individuals undergoing major surgery or those with a high bleeding risk procedure, full-dose LMWH bridging should be delayed for 2 to 3 days after hemostasis has been secured.³¹

Details on the pharmacologic properties of available anticoagulants are provided in [Chapter 149](#).

ANTICOAGULANT-RELATED BLEEDING

Risk of Bleeding

Risk management of anticoagulation-related bleeding is complicated because many of the risk factors for bleeding are also risk factors for stroke. The HAS-BLED score (see [Table 147.2](#)) was derived and validated in the Euro Heart survey population,³² with scores ≥ 3 indicating a high risk of bleeding and the requirement for attention to minimize bleeding complications. Of note, the HAS-BLED score should not be used to withhold anticoagulation, but rather

to identify bleeding risk factors that can be modified to reduce bleeding risk.

Reversal of Anticoagulation

The management of bleeding is still a clinical challenge in the setting of anticoagulation. In patients taking VKAs, physicians have many years of experience with reversing the agent by using a number of therapies, such as intravenous vitamin K, fresh frozen plasma (FFP), and prothrombin complex concentrate (PCC). When rapid reversal is needed, PCC is preferred over FFP; recombinant factor VIIa is not recommended. In contrast, reversal agents for specific NOACs have only recently become available, and action is usually limited to supportive care (e.g., ceasing therapy, volume resuscitation, and hemodynamic support). Nonetheless, PCC is often administered in patients with life-threatening bleeds. Given their short elimination half-lives, time is the most important factor in bleeding associated with NOACs. This emphasizes the importance of asking patients about the exact time of last intake and ascertaining factors influencing plasma concentrations and hemostasis (e.g., age, comorbidities, and concomitant use of antiplatelet drugs).³³

FUTURE DIRECTIONS

Current gaps in the evidence base for management of AF include comparison of different rate control therapies, defining the place of rhythm control with hybrid approaches to restoration of sinus rhythm, and determining how best to manage patients with AF and concomitant heart failure. We have seen an evolution in the anti-thrombotic management of AF in recent years due to widespread availability of NOACs. It is hoped that greater uptake of all forms of anticoagulation will result in reductions in the burden of stroke and thromboembolism due to AF. Though reduction in stroke will remain a major priority for these patients in the future, the risk of death remains unacceptably high, with etiology typically due to sudden cardiac death and progressive heart failure. Further attention on these areas is vital, considering the rapidly increasing incidence and prevalence of AF, and the burden this condition places on patients and health care systems.

PERIPHERAL ARTERY DISEASE

Reena L. Pande and Mark A. Creager

Peripheral artery disease (PAD) is an important manifestation of systemic atherosclerosis with significant morbidity and mortality.¹⁻⁴ PAD affects the lower extremities and is defined as a stenosis or occlusion in the aorta or in the arteries supplying blood to the legs, including the iliac, femoral, popliteal, or infrapopliteal vessels (peroneal, posterior tibial, and anterior tibial arteries). Stenosis is typically caused by atherosclerosis. Nonatherosclerotic causes of vascular disease also can obstruct the peripheral arteries (see later discussion). There are two major clinical consequences of PAD. First, PAD can cause leg symptoms that include intermittent claudication, which impairs walking ability and diminishes quality of life, and rest pain, which occurs when there is critical limb ischemia (CLI). Second, as an atherosclerotic disorder, PAD is associated with as much as a four- to sixfold increased risk of cardiovascular death, myocardial infarction (MI), and stroke. This chapter reviews the epidemiology, pathophysiology, and management of PAD.

EPIDEMIOLOGY

Prevalence and Incidence

The prevalence of PAD has been determined from several epidemiologic studies. Early studies determined the prevalence of PAD from the presence of symptoms, such as intermittent claudication, or history of peripheral revascularization. Many patients with PAD are asymptomatic, and the use of noninvasive diagnostic testing, specifically measurement of the ankle-brachial index (ABI), has provided further clarification of the overall prevalence of disease. In most of these studies, an ABI of 0.90 or less was used to define PAD. Based on data from the National Health and Nutrition Examination Survey (NHANES), the prevalence of PAD in adults 40 years of age or older is estimated to be 5.9%, accounting for approximately 7.1 million adults in the United States alone.⁵ In addition, PAD is estimated to affect as many as 202 million individuals worldwide, with increasing prevalence in both high and low-middle income countries.⁶ There is a sharp increase in the prevalence of PAD with increasing age, approximating 16.8% of women and 19.8% of men older than age 65 years in the German Epidemiological Trial on ABI (GetABI study). In a US-based observational study that examined a selected population of adults older than 70 years or adults ages 50 to 69 years with a history of diabetes or smoking, the prevalence of PAD was 29%.⁷ Recent studies have also shown higher PAD prevalence in populations of lower socioeconomic status, including lower education and lower income levels,⁸ as well as a disproportionate burden among some race/ethnicity groups, particularly blacks, as compared with Hispanic or non-Hispanic white populations.

The incidence of PAD, which is largely based on the development of symptomatic disease, is less well established. Data from the Framingham Heart Study show an incidence rate of intermittent claudication of less than 0.4 per 1000 per year in younger men (35–45 years) and a rate as high as 6 per 1000 per year in older men (older than 65 years). The incidence of symptomatic PAD is lower in women at most age groups, although the estimates are more comparable in the oldest age group. Estimates of the incidence of PAD based on ABI are less commonly reported. One such study reports an incidence of 1.7 per 1000 person-years for ages 40 to 54 years, 1.5 per 1000 person-years for ages 55 to 64 years, and 17.8 per 1000 person-years for ages 65 years and older. When the diagnosis of PAD is based on

ABI alone, the differences in incidence between men and women are less evident. In the Cardiovascular Health Study, for example, there are no gender differences in the incidence of PAD based on ABI after adjusting for cardiovascular risk factors. At the other end of the spectrum, CLI represents only 1% to 2% of the patients with PAD. The incidence of CLI is estimated to be approximately 400 to 1000 per million individuals per year.²

Risk Factors

Atherosclerotic risk factors, including smoking, diabetes, hypertension, hyperlipidemia, renal insufficiency, and inflammation, contribute to the development of PAD.

In virtually all population-based studies, smoking has been one of the strongest risk factors for PAD. The risk is highest for current smokers compared with nonsmokers, with a two- to four times increased odds of PAD, and the risk of PAD increases in a dose-dependent manner relative to the number of cigarettes smoked and the duration of tobacco use. In the Women's Health Study, smoking more than 15 cigarettes per day increased the risk of incident PAD approximately 17-fold, and the risk was lower in former smokers than in active smokers. In the Edinburgh Artery Study, smoking was two to three times more likely to cause lower extremity PAD compared with coronary artery disease (CAD).

Diabetes is also a potent risk factor for PAD and increases the risk of PAD by two- to fourfold. Data from the Rotterdam study and the San Luis Valley Diabetes study reveal that upwards of 12% to 20% of individuals with PAD have coexisting diabetes. Moreover, the risk of PAD increases depending on the duration and severity of diabetes. In the Strong Heart Study, individuals with PAD had a more than twofold higher prevalence of diabetes compared with those without PAD, and the diabetes tended to be of longer duration (11.7 vs. 8.4 years, $p < .001$) and associated with higher glycosylated hemoglobin levels. Patients with PAD who have concomitant diabetes are also more likely to develop intermittent claudication and ischemic ulceration and to require major amputation compared with those without diabetes.

Hypertension is a more modest risk factor for the development of PAD compared with its importance as a risk factor for coronary and cerebrovascular disease.¹ Although evidence suggests that hypertension increases the prevalence of PAD by 1.5- to 2.2-fold, the association of hypertension with incident or symptomatic PAD is less clear. Among American Indians in the Strong Heart Study, those with PAD had a higher mean systolic blood pressure, and the prevalence of PAD was significantly higher in those with established hypertension. In the Framingham Heart Study, hypertension increased the risk of developing intermittent claudication. However, in the Whitehall study of more than 18,000 men ages 40 to 64 years, there was no significant association between elevated blood pressure and claudication symptoms. Similarly, in the ARIC (Atherosclerosis Risk in Communities) study, there was no association of hypertension with incident PAD in subjects with diabetes. In the Women's Health Study, however, the risk of incident PAD increased by 43% with every 10-mmHg increase in systolic blood pressure.

Dyslipidemia, specifically elevated total cholesterol, low-density lipoprotein (LDL) cholesterol and triglycerides, and reduced high-density lipoprotein (HDL) cholesterol, is associated with PAD. Epidemiologic studies, such as the Cardiovascular Health Study and

the Framingham Heart Study, have shown that a 10-mg/dL increase in total cholesterol increases the risk of PAD by 5% to 10%. In the Strong Heart study, individuals with PAD had significantly higher levels of total cholesterol, triglycerides, and LDL cholesterol than those without. The Whitehall study also demonstrated that an elevated total cholesterol level was associated with symptoms of intermittent claudication.

Chronic renal insufficiency has been recognized to be significantly associated with PAD in several studies. In the NHANES, renal insufficiency (defined as a glomerular filtration rate <60 mL/min) was associated with a 2.5-fold higher odds of PAD even after adjustment for other cardiovascular risk factors. In the Heart and Estrogen/Progesterone Replacement (HERS) study, renal insufficiency was also associated with an increased risk of incident peripheral vascular events, including revascularization and amputation. Moreover, renal insufficiency increases the mortality risk in patients with PAD irrespective of other risk factors, including diabetes.

Several other nontraditional factors have been associated with PAD. Markers of systemic inflammation, such as C-reactive protein (CRP), are elevated in patients with PAD. In the Physicians' Health Study, the risk of developing symptomatic PAD was approximately twofold higher in those in the highest CRP quartile compared with those in the lowest quartile. Other markers of inflammation, such as soluble intercellular adhesion molecule 1 (sICAM-1), a leukocyte adhesion molecule, are also associated with PAD in this population and in the Women's Health Study. Insulin resistance is associated with both prevalent PAD as shown in data from the NHANES study and with incident PAD as demonstrated in the Cardiovascular Health Study. The protective effect of bilirubin, an endogenous antioxidant, was explored in NHANES; there was evidence of an inverse association between total serum bilirubin levels and PAD. The impact of genetics on the development of PAD has not been well explored, but a family history of PAD has been associated with development of PAD.

PATHOBIOLOGY

Atherosclerosis is a progressive vascular disease characterized by lipid accumulation and formation of plaque in the arterial walls (see [Chapter 144](#)). The pathophysiology of atherosclerosis includes endothelial dysfunction, vascular inflammation, and cellular proliferation. Early in the atherogenic process, recruitment of inflammatory cells and accumulation of lipids promote development of a lipid-rich atheroma. Inflammation promotes the elaboration of proteases that weaken the vessel wall and allow positive remodeling with outward expansion of the arterial wall to accommodate the intimal expansion that occurs as a result of plaque formation. Although positive remodeling initially preserves the arterial lumen, continued plaque growth results in progressive narrowing of the lumen, which then limits blood flow and oxygen supply to target organs. This process may be enhanced by biomechanical factors, such as turbulent blood flow, particularly in areas of altered shear stress. This phenomenon is of particular significance at branch points along the arterial tree, which are predisposed to atherosclerotic plaque formation.

Increasingly, it has been recognized that atherosclerotic plaque formation is a dynamic biologic process that exhibits marked heterogeneity; some plaques remain "stable", but others have a more "unstable" pathophysiology. Stable atherosclerotic plaques may be asymptomatic or symptoms can occur with exertion if demand exceeds supply. On the other hand, "vulnerable" or unstable plaques are prone to acute rupture, and superimposed thrombi may cause sudden arterial insufficiency. Studies have shown that acute atherothrombosis is not restricted to plaques that produce stenosis; many lesions without flow-limiting disease are prone to rupture. Evidence suggests that disruption of the fibrous cap overlying the atheroma is promoted by proinflammatory cytokines. Plaque disruption exposes the highly prothrombotic lipid-rich core of the atheroma to the blood, a process that triggers platelet aggregation and fibrin formation.

Although PAD is mostly caused by atherosclerosis, other causes include thromboembolism, atheroembolism, vasculitides (e.g., thromboangiitis obliterans, giant cell arteritis, Takayasu arteritis), trauma, popliteal artery entrapment, cystic adventitial disease, fibromuscular dysplasia, and endofibrosis of the iliac artery ([Table 148.1](#)). Nonvascular causes of leg pain should also be considered in the differential diagnosis, including lumbosacral spine disease (causing pseudoclaudication), acute and chronic venous diseases, hip or knee osteoarthritis, myositis, and others ([Table 148.2](#)).

CLINICAL MANIFESTATIONS

The majority of patients with PAD are asymptomatic at presentation. Typical claudication symptoms are present in only 10% to 35% of patients and CLI in 1% to 2%.¹ The classic symptoms of PAD include intermittent claudication and rest pain, the latter occurring in patients with CLI. Intermittent claudication is defined as exertional discomfort in the muscles of the lower extremities that is variably described as pain, aching, burning, fatigue, or heaviness. Symptoms arise with leg exercise, typically walking, and are relieved after a predictable duration of rest (usually <10 minutes). Intermittent claudication occurs with effort and not at rest, and symptoms do not abate until activity ceases; a change in position is unnecessary. Although many patients with PAD report atypical symptoms, most have impaired walking ability exemplified by reduced walking speed or distance. CLI arises when there is inadequate perfusion to meet the resting metabolic demands of the tissues. Patients with CLI have pain at rest, typically affecting the toes, feet, or both; they may have accompanying tissue loss with nonhealing ulcers, tissue necrosis, or gangrene ([Fig. 148.1](#)).

DIAGNOSIS

The diagnosis of PAD is often evident from the history and physical examination. An important diagnostic feature is diminished or absent pulses in the legs. The examiner should palpate the femoral, popliteal, dorsalis pedis, and posterior tibial pulses. Absence of selected pulses provides insight into the location of critical stenoses. The groin should be auscultated for femoral artery bruits, which may be indicative of turbulent flow from atherosclerotic plaque. Other findings

suggestive of PAD include pallor of the soles of the feet upon leg elevation and the development of rubor when the feet are then placed in the dependent position. Signs of chronic limb ischemia include muscle atrophy; hair loss; thickened nails; and in severe stages, cyanosis, pallor, and coolness of the skin of the feet.

Ankle–Brachial Index

The ABI is a simple, noninvasive test for the diagnosis of PAD.⁹ Normally, when measured in the supine position, the systolic blood pressure in the legs is the same as that in the arms. However, pulse wave amplification may yield a higher systolic pressure at the ankle. Therefore the ratio of the ankle to the brachial systolic pressure, designated as the ABI, should be 1.0 or slightly higher. A diminution of the ankle systolic blood pressure relative to the brachial artery pressure indicates a stenosis or occlusion in the aorta or in arteries of the lower extremities.

The ABI is determined by measuring the systolic blood pressure in both arms (brachial arteries) and in both ankle arteries (dorsalis pedis and posterior tibial arteries) after the patient has been in the supine position for at least 5 to 10 minutes.¹ To measure these pressures, sphygmomanometric cuffs are sequentially inflated at each location to suprasystolic pressures. The onset of systole with subsequent cuff deflation is determined with a Doppler device that is placed over the artery. The ABI for each leg is calculated by dividing the higher of the two ankle pressures by the higher of the two arm pressures. Taking into account the intrinsic variability in blood pressure over time, an ABI of 0.90 or less is indicative of PAD. At this threshold, the ABI has excellent sensitivity (90%) and specificity (>95%) compared with angiography. An ABI of 0.91 to 1.0 is considered borderline.¹⁰ Vascular calcification, as often occurs in patients with diabetes or renal insufficiency, may preclude accurate determination of systolic blood pressure at the ankle. For this reason, an ABI that is markedly elevated (e.g., >1.4) is considered inaccurate and indicative of vascular calcification. In this circumstance, other simple noninvasive diagnostic tests, such as assessment of the toe–brachial index or pulse volume recordings, may be useful to detect PAD. In some cases of PAD, the ABI is normal at rest. This is particularly common in patients who have proximal disease, such as iliac artery

stenosis, and an extensive collateral circulation. In such cases, measurement of the ABI after walking will detect a decrease in the ankle systolic pressure relative to brachial artery systolic pressure, thereby revealing the presence of PAD.

Noninvasive Testing and Imaging for Diagnosis of Peripheral Artery Disease

Several other noninvasive tests may help in the diagnosis of PAD and in the identification of sites of stenosis. These tests include segmental pressures with pulse volume recordings, duplex ultrasonography, computed tomography angiography (CTA), magnetic resonance angiography (MRA), and conventional contrast angiography. When measuring segmental leg pressures, systolic blood pressure measurements are obtained at multiple levels in the leg, typically in the upper thigh, lower thigh, upper calf, ankle, and across the metatarsal region of the foot. Systolic blood pressures in these sites are then compared with the higher of the arm systolic blood pressures. A significant drop in blood pressure (>20 mmHg) from one level to the next can localize arterial stenosis with a high degree of precision. An upper thigh pressure that is lower than the arm pressure indicates stenosis in the distal aorta or in the iliac or femoral arteries (or both). In patients with vascular calcification, measurement and interpretation of segmental pressures are unreliable. Pulse volume recordings can also be obtained at each level using a plethysmographic instrument that records the change in volume of that limb segment with each arterial pulsation. A normal waveform resembles an arterial waveform with a brisk upstroke and a prominent dicrotic notch in the downstroke (Fig. 148.2). Abnormal waveforms, which appear distal to a hemodynamically significant stenosis, have a parvus et tardus appearance with a blunted upstroke and decreased pulse amplitude.

Duplex ultrasonography is used both for diagnosis of PAD and for the surveillance of bypass grafts or stents after revascularization procedures. Color Doppler can identify abnormal flow with turbulence and Doppler aliasing suggesting an area of stenosis (Fig. 148.3). Pulse Doppler sampling can then confirm flow acceleration in a diseased segment. A peak systolic velocity (PSV) in a diseased segment that is more than twice the PSV in the proximal segment indicates a hemodynamically significant stenosis of at least 50%. Duplex ultrasonography has been shown to be accurate and reproducible with sensitivity and specificity of 88% and 96%, respectively, compared with angiography.¹¹ However, duplex ultrasonography is a time-consuming and operator-dependent procedure.

The most commonly used imaging modalities for diagnosis of PAD are MRA and CTA. The two tests have relatively comparable diagnostic accuracy for identification of arterial stenosis. MRA has been shown to have a sensitivity of 95% and specificity of 97% to detect stenosis greater than 50%, and CTA was shown to have a sensitivity of 91% and specificity of 91%.

MRA takes advantage of the inherent magnetic properties of human tissue. Pulsed magnetic sequences cause protons within cells to spin and align, generating a frequency of energy that can be detected by the scanner. Various tissues have different frequencies that allow delineation of the structures and tissues within the body. The addition of the paramagnetic contrast agent gadolinium allows selective imaging of moving blood (Fig. 148.4). This flow-related enhancement of the vasculature produces angiographic images. Although MRA has the advantage of using nonionizing radiation, it has several limitations. For example, MRA cannot be performed in patients with implanted cardiac devices or other metal objects. Although MRA can be used in patients with vascular stents, ferromagnetic metals in the stents may produce artifacts that limit assessment of the stented vessel. MRA is contraindicated with renal insufficiency because gadolinium administration in such patients can rarely be associated with nephrogenic systemic fibrosis. Claustrophobia may also preclude MRA.

Similar to MRA, CTA also has excellent specificity and sensitivity for detection of arterial stenosis. The advent of large-volume imaging with multidetector scanners enables rapid image acquisition and high

Fig. 148.2 SEGMENTAL LEG PRESSURE MEASUREMENTS AND PULSE VOLUME RECORDINGS. The ankle-brachial index (ABI) is normal in the right leg. The greater than 20-mmHg drop in systolic blood pressure between the lower thigh and the calf in the left leg suggests stenosis involving the distal left femoral artery, popliteal artery, or both. There is also evidence of blunting of the pulse volume recording with a parvus et tardus waveform. The significant difference in brachial artery systolic blood pressure is suggestive of left subclavian artery stenosis. *Amp*, Amplitude; *DP*, dorsalis pedis; *PT*, posterior tibial; *PVR*, pulse volume recordings; *Spd*, speed.

resolution. Advantages of CTA include the capacity to rapidly visualize the entire arterial tree and to delineate vascular calcification and intraluminal thrombus. Limitations of the test include the exposure to ionizing radiation and the need for iodinated contrast agents, which is problematic in patients with renal impairment. In addition, extensive arterial calcification may prevent accurate determination of the degree of stenosis.

MRA and CTA have largely supplanted conventional catheter-based angiography for PAD diagnosis. Nonetheless, invasive contrast angiography remains the gold standard for the diagnosis of PAD.

Catheter-based angiography is most useful in situations in which concurrent endovascular interventions are planned or in preparation for surgical revascularization. Limitations to catheter-based angiography include the invasive nature of the procedure, the need to administer iodinated contrast, and the radiation exposure. Potential complications include arteriovenous fistula or pseudoaneurysm formation at the access site, atheroembolism, dissection, and contrast-induced renal insufficiency. Alternatives to iodine-based contrast agents, such as carbon dioxide and gadolinium, can be used when administration of iodinated contrast is contraindicated.

Fig. 148.3 DUPLEX ARTERIAL ULTRASOUND DEMONSTRATING DOPPLER INTERROGATION OF THE POPLITEAL ARTERY. Turbulence of color Doppler flow indicates possible stenosis, confirmed by elevated peak systolic velocity, monophasic waveform, and spectral broadening.

Fig. 148.4 Representative projection imaging from a gadolinium-enhanced magnetic resonance angiogram demonstrating segmental occlusion of the left common iliac artery (indicated by *dashed white line*), as well as nonobstructive atherosclerotic disease in the distal aorta and more distally in the external iliac arteries.

PROGNOSIS

Prognostic considerations are broadly divided into limb outcomes and overall cardiovascular outcomes. Limb prognosis is dependent on the severity of symptoms at initial presentation; concurrent risk factors, such as cigarette smoking and diabetes; and the likelihood of successful revascularization in those with threatened limb viability. Among patients with claudication symptoms, leg discomfort remains stable in the majority ($\approx 70\%$ – 80%), worsens in about 10% to 20%, and progresses to CLI in a small percentage.¹ Data from the

Reduction of Atherothrombosis for Continued Health (REACH) registry, which enrolled patients with established PAD on the basis of clinical symptoms, abnormal ABI, and prior revascularization, demonstrated a 23.6% rate of new adverse limb events over 4 years including new revascularization procedures as well as ischemic amputations.¹² These data are consistent with findings from the TRA2°P-TIMI 50 trial, which evaluated the impact of the novel agent vorapaxar in patients with PAD, where the rate of peripheral artery revascularization in the placebo treated group was 22.2%¹³ over a median period of three years. Prognosis is worst for those with CLI, where mean amputation-free survival at 1 year is only 50%. Outcomes are worse for patients with PAD who continue to smoke or have coexisting diabetes; such patients have even higher rates of ischemic ulceration and amputation.

Given the high risk of concomitant coronary and cerebral artery disease, individuals with PAD are also at increased risk of MI, stroke, and cardiovascular death. The mortality rate is increased two- to fourfold in patients with PAD compared with those without PAD, as confirmed in a meta-analysis of 16 cohort studies from the ABI collaboration.¹⁴ Furthermore, a graded association has been noted with lower ABI associated with increased mortality.¹⁴ In patients with PAD, the risk of MI is increased by 20% to 60%, and the risk of stroke is increased by 40%. The REACH registry found that the 1-year event rate for the composite of cardiovascular death, MI, and stroke was 6.2% in individuals with PAD. The highest event rates were in those with polyvascular disease compared with rates in patients with atherosclerosis involving only one vascular bed.¹⁵

THERAPY

The major goals in the management of patients with PAD are to (1) reduce the risk of cardiovascular morbidity and mortality and (2) improve lower extremity symptoms and preserve limb viability. Aggressive cardiovascular risk factor modification is indicated for all patients with PAD. This includes treatment of dyslipidemia, hypertension, and diabetes (including regular foot care) and the use of antiplatelet therapy. Encouragement of healthy lifestyle habits remains a cornerstone of the management of individuals with PAD; these include smoking cessation, a diet enriched in fruits and vegetables and limited in saturated fats, and regular physical activity.¹

Dyslipidemia

Treatment of dyslipidemia with statins decreases major cardiovascular events in patients with all manifestations of atherosclerosis. The 4S study (Scandinavian Simvastatin Survival Study) was one of the first to demonstrate a clear benefit of lipid-lowering therapy for secondary prevention in patients with atherosclerosis and dyslipidemia. Subsequently, the Heart Protection Study demonstrated that statin therapy was associated with a 22% relative risk reduction in adverse cardiovascular events in patients with vascular disease, including PAD. Recent practice guidelines recommend the use of high-intensity statin therapy, such as atorvastatin 80 mg daily or rosuvastatin 20 mg daily, for individuals with established atherosclerotic vascular disease, including those with PAD to lower cholesterol and to reduce the risk of atherosclerotic events in this population.¹⁶ Statin use is not only associated with lower cardiovascular event rates, but also with approximately 18% lower rates of adverse limb outcomes, including worsening symptoms, peripheral revascularization, and amputations.

The appropriate management of non-LDL cholesterol (HDL and triglycerides) is less clear. Although reduced HDL levels are a risk factor for atherosclerosis, studies with medications that increase HDL levels and lower triglyceride levels have yielded conflicting results. The VA-HIT study (Veterans Affairs High-Density Lipoprotein Intervention Trial) showed that gemfibrozil reduced the risk of fatal coronary disease or nonfatal MI by 22% over a median of 5.1 years in patients with known CAD. However, in a study of patients with

PAD, bezafibrate did not affect the rate of coronary events or stroke. In addition, in the FIELD (Fenofibrate Intervention and Event Lowering in Diabetes) study, fenofibrate did not reduce coronary events in diabetics, although its use was associated with fewer nonfatal MIs and revascularization procedures. Although niacin also reduces lipid levels, its efficacy for reducing cardiovascular events has been called into question based on recent studies showing no added benefit in patients with established atherosclerotic vascular disease.¹⁷ Subgroup analyses showed no meaningful differences in the subset of patients with established PAD.

Hypertension

Treatment of hypertension is a critical component of the management of patients with atherosclerotic PAD. Such treatment reduces the risk of stroke, MI, and congestive heart failure. Management of hypertension should follow current guidelines. Although there is concern that lower systemic blood pressure may exacerbate symptoms of claudication or CLI, the majority of patients experience no change in their symptoms. Several studies have found that antihypertensive drugs reduce cardiovascular events in patients with PAD. The HOPE (Heart Outcomes Prevention) study demonstrated a 22% reduction in cardiovascular events with ramipril in patients with atherosclerotic disease, including those with PAD. ONTARGET (Ongoing Telmisartan Alone and in Combination with Ramipril Global Endpoint Trial) demonstrated that telmisartan and ramipril produced similar reductions in cardiovascular death, MI, stroke, or hospitalization for heart failure (16.7% and 16.5%, respectively; relative risk [RR], 1.01; 95% confidence interval, 0.94–1.09), albeit at the cost of greater risk of hypotension, syncope, and renal insufficiency when the combination of telmisartan and ramipril was used. In a substudy of the ABCD (Appropriate Blood Pressure Control in Diabetes) trial, intensive blood pressure lowering in patients with PAD was associated with a 65% relative reduction in the risk of MI, stroke, or cardiovascular death compared with modest blood pressure-lowering therapy. The INVEST study (International Verapamil-SR/Trandolapril Study) demonstrated that a calcium channel blocker–based antihypertensive strategy was comparable to a beta-blocker–based strategy in patients with concomitant PAD. A J-shaped relationship was noted between achieved systolic blood pressure and outcomes with the best outcomes noted in individuals achieving a systolic blood pressure between 135 and 145 mmHg.

Diabetes

In patients with PAD with concomitant diabetes, the goals of diabetes care include control of hyperglycemia and attention to diabetic foot care. Not only is diabetes associated with adverse limb outcomes (increased risk of ischemic ulceration and amputation in patients with PAD), but it also is associated with increased mortality. Aggressive glycemic control reduces both macrovascular events (MI, stroke, and death) and microvascular events (nephropathy, neuropathy, and retinopathy) in patients with type I diabetes. Although aggressive glycemic control reduces microvascular events in individuals with type II diabetes, reductions in macrovascular events have not been shown. Several recent studies, such as the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified Release Controlled Evaluation), Action to Control Cardiovascular Risk in Diabetes and Veterans Affairs Diabetes trials, have failed to show a reduction in cardiovascular events with aggressive treatments aimed at lowering the hemoglobin A1c to 6%. Likewise in patients with type II diabetes who were at risk for cardiovascular events, the PROactive study (Prospective Pioglitazone Clinical Trial in Macrovascular Events) failed to show a reduction in the primary composite endpoint of cardiovascular or limb outcomes (lower rates of extremity revascularization or amputation) with pioglitazone. However, the study did show a significant 16% reduction in the secondary endpoint, a composite of total mortality, nonfatal MI, or stroke, with

pioglitazone. Several recent studies have evaluated the cardiovascular effects of newer classes of glucose-lowering agents including the glucagon-like peptide-1 (GLP-1) analogues, such as semaglutide and liraglutide, and sodium glucose co-transporter-2 (SGLT-2) agents, such as empagliflozin. These studies have demonstrated the safety and efficacy in reducing cardiovascular events in patients with diabetes with existing cardiovascular disease or at high cardiovascular risk.^{9a-c} A recent meta-analysis also showed no significant differences among nine different classes of glucose-lowering drugs and risk of cardiovascular or all-cause mortality.^{9d} Consequently, although the optimal glycemic control required to reduce macrovascular complications in patients with type II diabetes remains unclear, guidelines recommend treatments that maintain the level of hemoglobin A1c below 7%.

Foot care is a critical component of diabetes management, particularly in those with PAD. Diabetes increases the risk of foot injury because of the associated peripheral neuropathy and decreased sensation, thereby increasing the risk of ulcer formation. Resting limb ischemia and amputation are more frequent in patients with PAD with diabetes than in those without diabetes. Therefore careful attention to foot care is imperative to prevent skin breakdown, infections, ulceration, and amputation.

Antiplatelet Therapy

Antiplatelet therapy is recommended for patients with atherosclerosis, including patients with symptomatic PAD.¹⁰ The Antiplatelet Trialists' Collaboration meta-analysis showed that antiplatelet therapy produces a 22% to 32% reduction in the relative risk of stroke, MI, or vascular death in patients with high-risk vascular disease, including prior stroke or transient ischemic attack or MI. In a subset of patients with evidence of PAD based on symptoms of claudication or prior lower extremity bypass or angioplasty, antiplatelet therapy also produced a 22% relative risk reduction. The meta-analysis included studies that evaluated a variety of antiplatelet agents, such as aspirin, dipyridamole, picotamide, and ticlopidine. The benefits of aspirin have been called into question with a recent meta-analysis showing no significant effect of aspirin on cardiovascular events in patients with PAD.¹⁸ The largest of the studies included in this meta-analysis was the POPADAD (The Prevention Of Progression Of Asymptomatic Diabetic Arterial Disease) study,¹⁹ which randomized patients with ABI below 0.99 and no known cardiovascular disease to 100 mg of aspirin or placebo, and showed no significant difference between the groups (hazards ratio [HR], 0.98; 95% CI, 0.76–1.26). The AAA (Aspirin for Asymptomatic Atherosclerosis) trial explored whether aspirin (100 mg/day) was of benefit in asymptomatic individuals with PAD diagnosed solely on the basis of an abnormal ABI.²⁰ Compared with placebo, aspirin had no effect on the composite endpoint of fatal or nonfatal MI, stroke, or revascularization.

When clopidogrel was compared with aspirin in the CAPRIE trial, clopidogrel was associated with an 8% reduction in cardiovascular events. The CHARISMA study showed no benefit of dual antiplatelet therapy with aspirin plus clopidogrel in a population of patients with established CAD, cerebrovascular disease, or PAD or in those with risk factors for these disorders. In a post-hoc analysis that focused on patients with symptomatic or asymptomatic PAD, there also was no benefit of dual antiplatelet therapy for the primary endpoint. However, the risk of MI and repeat hospitalization for ischemic events was lower with dual antiplatelet therapy (HR, 0.63; 95% CI, 0.42–0.96 and HR, 0.81; 95% CI, 0.68–0.95, respectively).

Newer antiplatelet agents have also been evaluated in patients with PAD. The TRA2P-TIMI 50 study found that the addition of vorapaxar, a protease-activated receptor-1 antagonist, significantly reduced the composite endpoint of cardiovascular death, MI, or stroke by 13% in patients with established atherosclerosis manifesting as a prior MI, ischemic stroke, or established PAD. Among the subset of patients with PAD, vorapaxar did not significantly affect the composite endpoint, but did reduce the risk of hospitalization for acute limb ischemia by 42% ($p = .006$) and peripheral artery revascularization by 16% ($p = .017$), albeit with an increased risk of bleeding (HR

1.62, $p = .001$). More recently, the EUCLID study compared ticagrelor (90 mg twice daily) to clopidogrel in patients with symptomatic PAD. There was no statistically significant difference between the two therapies in reducing a composite endpoint including cardiovascular death, MI, or ischemic stroke (HR 1.02, $p = 0.65$), and no difference in rates of acute limb ischemia (HR 1.03, $p = 0.85$). Additionally there was no difference bleeding risk between clopidogrel and ticagrelor. The PEGASUS-TIMI 54 study also demonstrated the benefits of ticagrelor in reducing major cardiovascular events among patients with PAD.^{20a,20b}

Treatment of Lower Extremity Symptoms

Treatments that target the symptoms and signs of PAD are implemented to improve function and mobility and preserve limb viability. Established treatments can be broadly categorized into supervised exercise therapy, pharmacotherapy, and revascularization. Therapeutic angiogenesis has also been explored as a potential therapeutic option.

Exercise Therapy

Supervised exercise therapy improves walking distance by as much as 100% to 150% in patients with PAD. Patients are recommended to walk on a treadmill or track three to five times per week for a duration of at least 45 minutes per session for 3 to 6 months. Exercise should continue until patients develop moderate to severe claudication; after a rest period, they should resume walking with the cycle repeated until the session is over. As patients improve, walking speed and treadmill grade can be increased. Recent studies have shown that home-based exercise therapy is also effective when home activities are monitored and quantified²¹ or when paired with periodic and facilitated group behavioral training.²² The CLEVER (The Claudication: Exercise Versus Endoluminal Revascularization) trial showed that a 6-month supervised exercise training program in patients with aortoiliac disease and claudication produced a greater improvement in walking time than optimal medical therapy alone or stenting.²³ In contrast, in the IRONIC (Invasive Revascularization or Not in Intermittent Claudication) study, improvement in disease-specific quality-of-life measures was greater for stenting than supervised exercise therapy in patients with life-limiting claudication. While prior studies had evaluated the benefits of supervised exercise therapy in comparison to revascularization, the ERASE study assessed the impact of exercise therapy in addition to endovascular revascularization. The study showed that combination treatment resulted in greater walking distance and quality of life at 1 year than supervised exercise therapy alone.^{23a} It remains clear that physical activity should be recommended as a part of a multifaceted approach to improving symptoms in patients with PAD.

The mechanisms responsible for the benefits of exercise remain unclear. Potential mechanisms include collateral blood vessel development as a consequence of upregulation of angiogenic growth factors, endothelium-dependent vasodilation because of enhanced nitric oxide bioavailability, more efficient walking biomechanics, and improved skeletal muscle metabolism.

Pharmacologic Therapies

Although many medications have been evaluated, few have improved the symptoms of claudication in patients with PAD. Only two medications are approved by the Food and Drugs Administration; cilostazol and pentoxifylline. Cilostazol is a phosphodiesterase 3 (PDE3) inhibitor with both vasodilator and antiplatelet properties. The precise mechanism by which cilostazol confers benefit in patients with PAD is unknown. Several randomized trials have shown that compared with placebo, cilostazol produces an approximately 50% increase in walking time and improves perceived quality of life. Because other PDE3 inhibitors (e.g., milrinone) have been linked to

increased mortality in patients with congestive heart failure, cilostazol should not be used in this subpopulation of patients with PAD. However, cilostazol has not been associated with an increase in mortality. Evidence for the efficacy of pentoxifylline, a hemorrheologic agent, is less robust than that for cilostazol, and pentoxifylline is less likely to be of clinical benefit.

Statins have also been explored for the treatment of claudication to exploit their pleiotropic effects, such as attenuation of inflammation. One study showed an improvement in pain-free walking time with atorvastatin but no significant increase in maximal walking time. Other studies revealed an increase in walking time with simvastatin. Another study, however, showed no benefit of niacin plus lovastatin on walking times compared with placebo.

Revascularization

Lower extremity revascularization is reserved for patients with CLI or lifestyle-limiting claudication symptoms despite maximal medical therapy. For those with CLI, prompt revascularization is necessary. Revascularization in such patients may alleviate resting limb pain, accelerate the healing of ulcers, and reduce infection. In patients with claudication, revascularization can lessen leg discomfort and improve quality of life. Options for revascularization include endovascular (percutaneous) intervention or open surgical revascularization.

Endovascular intervention, which includes percutaneous transluminal balloon angioplasty (PTA) and endovascular stenting, is increasingly being used as a less invasive option for revascularization in patients with PAD (Fig. 148.5). The advances in technology of balloon-expandable and self-expanding stents have widened the population of patients with suitable anatomic lesions that stand to benefit from these procedures. Eligible patients include those with severe or disabling symptoms of claudication and those with limb-threatening ischemia. Clinical outcomes for endovascular revascularization depend on the type and length of the lesions. Treatment of stenoses is more likely to be successful than treatment of total occlusions, and success is influenced by a variety of morphologic characteristics, as delineated in the TASC (TransAtlantic Inter-Society Consensus) Working Group classification for iliac and femoropopliteal lesions.² Durability and patency are greatest for iliac artery lesions; the likelihood of long-term patency with endovascular interventions is lower with disease in more distal arteries. Patency rates decrease with increasing lesion length, the presence of diffuse disease or multiple lesions, and poor run-off, as well as other adverse patient characteristics, such as diabetes, active smoking, and renal failure.¹

For aortoiliac interventions, endovascular treatment affords excellent long-term patency, especially when combined with stenting. Five-year patency rates are approximately 94% and are comparable to rates achieved with surgical intervention. Results are less durable for femoropopliteal PTA with studies showing variable benefit of standard nitinol stents in the femoropopliteal arteries depending on lesion length and other factors.^{23b} Compared with bare-metal stents, drug-eluting stents (DES) have shown promise for femoral artery revascularization; a recent study showed improved survival free of major vascular events (death, amputation, or revascularization) with DES.²⁵ Several trials have demonstrated the benefits of drug-eluting balloon over standard (uncoated) balloon angioplasty for femoropopliteal artery revascularization resulting in reduced rates of restenosis and target vessel revascularization with comparable safety.^{23c}

Endovascular treatment of infrapopliteal artery stenosis is typically reserved for patients with limb ischemia. Recent studies have shown that DES use is safe for below-knee limb ischemia and may improve outcomes. For example, in the PARADISE (Preventing Amputations Using Drug Eluting Stents) study, a prospective, nonrandomized study of 106 patients, the 3-year amputation-free survival rate after DES implantation for treatment of limb ischemia involving the infrapopliteal vessels was 68%. In the IN.PACT DEEP study, infrapopliteal artery revascularization with a drug-eluting balloon was noninferior to standard balloon angioplasty with respect to the primary endpoints of target lesion revascularization and late lumen loss.

Fig. 148.5 CONVENTIONAL CONTRAST ANGIOGRAPHY ILLUSTRATING USE OF A SELF-EXPANDING NITINOL STENT TREATMENT OF AN OCCLUSION OF THE SUPERFICIAL FEMORAL ARTERY. (A) Occlusion in the mid-superficial femoral artery. (B) Balloon angioplasty. (C) Stent deployment in the lesion. (D) Angiogram after stent deployment (*Reproduced from Thukkani and Kinlay²⁴.*)

Surgical revascularization remains the gold standard for peripheral revascularization with the choice of operation depending on the location of the stenosis. Options include (1) aortoiliac or aortofemoral reconstruction for proximal disease involving the aorta or iliofemoral vessels, (2) femoral-popliteal bypass (either above- or below-knee popliteal) for superficial femoral artery or popliteal artery disease, and (3) femoral-distal (tibial or peroneal) bypass for distal arterial stenosis. Aortobiiliac or aortobifemoral bypass graft surgery for aortoiliac occlusive disease (“inflow”) produces excellent long-term results with 5-year patency rates ranging from 85% to 90%. Surgical treatment of infrainguinal disease (“outflow”) also produces durable results, although outcomes depend on the type of bypass conduit used. Vein grafts are the most durable; femoral-popliteal vein bypass grafts have an expected 5-year patency rate of approximately 66%. The 5-year patency rate for prosthetic grafts, such as polytetrafluoroethylene (PTFE), is lower, about 47%.¹ Limitations of surgical interventions include the need for general anesthesia and the attendant risk of cardiovascular events and death associated with major noncardiac surgery in patients with atherosclerosis. Given the potential for coexistent cardiovascular disease, preoperative assessment is important to identify and limit the risk of cardiovascular events in vascular surgery patients.²⁶

Whereas revascularization is indicated for most patients with CLI to preserve limb viability, the comparative efficacy and safety of endovascular revascularization and surgical reconstruction for CLI is not known. A contemporary registry has sought to evaluate the comparative safety and effectiveness of surgical and endovascular interventions in patients with symptomatic PAD.^{26a} The BEST-CLI Trial (Best Endovascular versus Best Surgical Therapy in Patients with Critical Limb Ischemia) is an ongoing trial that is comparing the relative benefits of surgical versus endovascular treatment in this population.²⁷

Therapeutic Angiogenesis

Several clinical trials have explored the utility of angiogenic growth factors for improvement of walking time in patients with claudication or for promotion of healing and preservation of limb viability in patients with CLI. Angiogenic factors investigated have included vascular endothelial growth factor, fibroblast growth factor, hepatocyte growth factor, and hypoxia inducible factor-1 α .²⁸ Despite encouraging results with these agents in animal models of hind-limb ischemia, none of the human studies has demonstrated a benefit of gene therapy. It is not known whether the lack of success is because of the choice of gene, mode of delivery, or other factors.

Early data on infusion of endothelial progenitor cells (EPCs) have been mixed. In experimental models, EPC infusion in hind-limb ischemia models promoted angiogenesis, as indicated by capillary density, and reduced the need for amputation. Preliminary studies in humans suggested that infusion of autologous CD34 cells may reduce amputation rates in patients with CLI. In a pilot study, intramuscular injection of CD34 cells in patients with CLI was also shown to be safe with a nonsignificant trend towards improved amputation-free survival. A meta-analysis of 12 trials showed that while there was an overall benefit of bone marrow-derived cell therapy, these benefits were considerably less and nonsignificant when only placebo-controlled randomized trials were assessed. In fact, more recent data from the placebo-controlled JUVENTAS study found that repetitive infusion of bone marrow mononuclear cells into the common femoral artery did not reduce amputation rates in patients with severe limb ischemia not amenable to revascularization. A recent meta-analysis reviewed the existing literature on cell-based therapies in the treatment of critical limb ischemia and demonstrated improved amputation free survival and wound healing without significant impact on mortality.²⁹

FUTURE DIRECTIONS

A better understanding of the factors that contribute to intermittent claudication and CLI is needed to craft innovative and durable therapeutic interventions for management of the limb complications of PAD. In addition, greater knowledge is needed about the unique contributors to atherogenesis and thrombosis in the lower extremities compared with other arterial beds. Further understanding of downstream effects of compromised blood flow, such as changes in skeletal muscle energetics and impaired neural function, will inform the design and development of novel pharmacotherapies for individuals with PAD. Finally, more comparative efficacy studies are needed to clarify ongoing debates with respect to the relative benefits of exercise training versus invasive therapies; endovascular versus surgical revascularization; and the impact of cell-based therapies in the treatment of PAD. Greater knowledge dissemination regarding PAD diagnosis and risks associated with PAD remain key to early detection and implementation of risk factor modification therapies to improve the care of this high-risk population.

ANTITHROMBOTIC DRUGS

Iqbal H. Jaffer and Jeffrey I. Weitz

Arterial or venous thromboembolism is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute myocardial infarction, ischemic stroke, and limb gangrene, whereas deep vein thrombosis can lead to pulmonary embolism, which can be fatal, and to the postthrombotic syndrome. Most arterial thrombi are superimposed on disrupted atherosclerotic plaque because plaque rupture exposes thrombogenic material in the plaque core to the blood.¹ This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that can temporarily or permanently occlude blood flow. In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption.¹ Although they can develop after surgical trauma to veins or secondary to indwelling central venous catheters, venous thrombi usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses, where they are triggered by stasis. Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Endothelial cells lining the valve cusps become activated and express adhesion molecules on their surface. These adhesion molecules tether tissue factor-bearing leukocytes and microparticles to the surface of activated endothelial cells, where the tissue factor triggers coagulation. Local thrombus formation is exacerbated by reduced clearance of activated clotting factors as a result of impaired blood flow. If the calf vein thrombi extend into more proximal veins of the leg, thrombus fragments can dislodge, travel to the lungs, and produce a pulmonary embolism.

Arterial and venous thrombi are composed of platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear in the injured arteries. In contrast, venous thrombi, which form under low-shear conditions, contain relatively few platelets and are composed predominantly of fibrin and trapped red cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi are red in color, reflecting the trapped red cells.

Antithrombotic drugs are used for prevention and treatment of thrombosis. Targeting the components of thrombi, these agents include (1) antiplatelet drugs, which inhibit platelets; (2) anticoagulants, which attenuate coagulation; and (3) fibrinolytic agents, which induce fibrin degradation (Fig. 149.1). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis are focused mainly on antiplatelet agents, although in the acute setting they often include anticoagulants and fibrinolytic agents. Anticoagulants are the mainstay of prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi. Antiplatelet drugs are less effective than anticoagulants in this setting because of the limited platelet content of venous thrombi. Fibrinolytic therapy is used in selected patients with venous thromboembolism. For example, patients with massive pulmonary embolism can benefit from systemic or catheter-directed fibrinolytic therapy. Catheter-directed fibrinolytic therapy also can be used as an adjunct to anticoagulants for treatment of certain patients with extensive deep vein thrombosis involving the iliac and femoral veins.

This chapter is focused on antithrombotic agents. In addition to describing antiplatelet, anticoagulant, and fibrinolytic drugs that are

in current use, new agents in advanced stages of development also are discussed.

ANTIPLATELET DRUGS

Role of Platelets in Arterial Thrombosis

In healthy vasculature, circulating platelets are maintained in an inactive state by nitric oxide (NO) and prostacyclin released by endothelial cells lining the blood vessels. In addition, endothelial cells also express ADPase on their surface, which degrades ADP released from activated platelets. When the vessel wall is damaged, release of these substances is impaired and the subendothelial matrix is exposed. Platelets adhere to exposed collagen and to von Willebrand factor via glycoprotein (GP) VI and GPIb-IX, respectively; receptors are constitutively expressed on the platelet surface. Adherent platelets undergo a change in shape, secrete ADP from their dense granules, and synthesize and release thromboxane A₂. Released ADP and thromboxane A₂, which are platelet agonists, activate ambient platelets and recruit them to the site of vascular injury.

Disruption of the vessel wall also exposes tissue factor-expressing cells to the blood. Tissue factor initiates coagulation. Activated platelets potentiate coagulation by binding clotting factors and supporting the assembly of activation complexes that enhance thrombin generation. In addition to converting fibrinogen to fibrin, thrombin amplifies its own generation and serves as a potent platelet agonist, thereby recruiting additional platelets to the site of injury.

When platelets are activated, GPIIb/IIIa ($\alpha_{IIb}\beta_3$), the most abundant receptor on the platelet surface, undergoes a conformational change that enables it to ligate fibrinogen. Divalent fibrinogen molecules bridge adjacent platelets together to form platelet aggregates. Fibrin strands, generated through the action of thrombin, then weave these aggregates together to form a platelet-fibrin mesh.

Antiplatelet drugs target various steps in this process (Fig. 149.2). The commonly used drugs include aspirin, thienopyridines (clopidogrel and prasugrel), ticagrelor, cangrelor, dipyridamole, GPIIb/IIIa antagonists, and vorapaxar. Each is briefly described in the following.

Aspirin

The most widely used antiplatelet agent is aspirin. As a cheap and effective antiplatelet drug, aspirin serves as the foundation of most antiplatelet strategies.

Mechanism of Action

Aspirin produces its antithrombotic effect by irreversibly acetylating and inhibiting platelet cyclooxygenase-1 (COX-1), a critical enzyme in the biosynthesis of thromboxane A₂ (see Fig. 149.2). At high doses (about 1 g/day), aspirin also inhibits COX-2, an inducible COX isoform found in endothelial cells and inflammatory cells. In

Fig. 149.1 CLASSIFICATION OF ANTITHROMBOTIC DRUGS.

endothelial cells, COX-2 initiates the synthesis of prostacyclin, a potent vasodilator and inhibitor of platelet aggregation.

Indications

Aspirin is widely used for secondary prevention of cardiovascular events in patients with coronary artery disease, cerebrovascular disease, or peripheral vascular disease. Compared with placebo, aspirin produces about a 25% reduction in the risk of cardiovascular

FIGURE 151-2

Fig. 149.2 SITE OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A₂ (TXA₂) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA₂ release attenuates platelet activation and recruitment to the site of vascular injury. Clopidogrel, prasugrel, ticagrelor, and cangrelor block P2Y₁₂, a key adenosine diphosphate (ADP) receptor on the platelet surface. Therefore these agents also attenuate platelet recruitment. Vorapaxar inhibits type 1 protease-activated receptor (PAR-1), the major thrombin receptor on platelets. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen binding to activated glycoprotein (GP) IIb/IIIa. vWF, von Willebrand factor.

death, myocardial infarction, or stroke in these patients. There is mounting evidence that aspirin is of limited benefit for primary prevention in subjects without clinical evidence of cardiovascular disease.² Although metaanalyses demonstrate a reduction in nonfatal myocardial infarction with daily aspirin use, this benefit is partially offset by an increase in gastrointestinal bleeding. Nonetheless, there also is evidence that aspirin reduces cancer mortality. If used for primary prevention, aspirin should be restricted to those at moderate to high risk of cardiovascular events.²

Dosages

Aspirin is usually administered at doses of 75 to 325 mg once daily. There is no evidence that higher-dose aspirin is more effective than lower aspirin doses, and some analyses suggest reduced efficacy with higher doses. Because the side effects of aspirin are dose-related, daily aspirin doses of 75 to 150 mg are recommended for most indications. When rapid platelet inhibition is required, an initial aspirin dose of at least 160 mg should be given.

Side Effects

Most common side effects are gastrointestinal and range from dyspepsia to erosive gastritis or peptic ulcers with associated bleeding. These side effects are, at least to some extent, dose related. Use of enteric-coated or buffered aspirin in place of plain aspirin does not eliminate the prostaglandin-mediated gastrointestinal side effects. The risk of major bleeding with aspirin ranges from 1% to 3% per year and is higher when aspirin is used in conjunction with anticoagulants, such as warfarin. When dual therapy is used, low-dose aspirin should be given (75 to 100 mg daily). Eradication of *Helicobacter pylori* infection and concomitant administration of proton pump inhibitors may reduce the risk of upper gastrointestinal bleeding, particularly in patients with a history of peptic ulcer disease.

Aspirin should not be administered to patients with aspirin allergy characterized by bronchospasm. This problem occurs in about 0.3% of the general population, but it is more common in those with chronic urticaria or asthma, particularly in subjects with coexisting nasal polyps or chronic rhinitis. Hepatic and renal toxicity are observed with aspirin overdose.

Aspirin Resistance

The term *aspirin resistance* has been used to describe both clinical and laboratory phenomena.³ Clinical aspirin resistance is defined as the failure of aspirin to protect patients from ischemic vascular events. This is not a helpful definition, because it is made after the event occurs. Furthermore, it is not realistic to expect aspirin, which blocks only thromboxane A₂-induced platelet activation, to prevent all vascular events.

Aspirin resistance also has been described biochemically as failure of the drug to produce its expected inhibitory effects on tests of platelet function, such as thromboxane A₂ synthesis or arachidonic acid-induced platelet aggregation. However, the tests used for the diagnosis of aspirin resistance are not well standardized. Furthermore, there is no definitive evidence that these tests identify patients at risk of recurrent vascular events, or that resistance can be reversed either by giving higher doses of aspirin or by adding other antiplatelet drugs. Until such information is available, testing for aspirin resistance remains a research tool.

ADP Receptor Antagonists

P2Y₁₂ is the major ADP receptor on platelets. Agents that inhibit P2Y₁₂ include oral agents such as the thienopyridines as well as ticagrelor, and cangrelor, which is a parenteral inhibitor.

Thienopyridines

The thienopyridines include clopidogrel and prasugrel, as well as ticlopidine, which is rarely used.

Mechanism of Action

The thienopyridines are structurally related drugs that selectively inhibit ADP-induced platelet aggregation by irreversibly blocking P2Y₁₂ (see Fig. 149.2). Clopidogrel and prasugrel are prodrugs that must be metabolized by the hepatic cytochrome P450 (CYP) enzyme system to acquire activity. Consequently, their onset of action is delayed unless loading doses are given. The metabolic activation of prasugrel is more efficient than that of clopidogrel. Consequently, prasugrel produces more rapid, higher, and more uniform P2Y₁₂ blockade than clopidogrel.

Indications

When compared with aspirin in patients with recent ischemic stroke, myocardial infarction, or peripheral arterial disease, clopidogrel reduced the risk of cardiovascular death, myocardial infarction, and stroke by 8.7%. Therefore clopidogrel is more effective than aspirin, but it also is more expensive. In some patients, clopidogrel and aspirin are combined to capitalize on their capacity to block complementary pathways of platelet activation. For example, the combination of aspirin plus clopidogrel is recommended for at least 4 weeks after implanting a bare metal stent in a coronary artery and for at least 1 year in those with a drug-eluting stent. Concerns about late in-stent thrombosis with drug-eluting stents have led some experts to recommend long-term use of clopidogrel plus aspirin for this indication.

The combination of clopidogrel and aspirin also is effective in patients with unstable angina. Thus in 12,562 such patients, the risk of cardiovascular death, myocardial infarction, or stroke was 9.3% in those randomized to the combination of clopidogrel and aspirin and 11.4% in those given aspirin alone, a 20% relative risk reduction.⁴ However, combining clopidogrel with aspirin increases the risk of major bleeding to about 2% per year. This bleeding risk persists even if the daily dose of aspirin is 100 mg or less. Therefore the combination of clopidogrel and aspirin should be used only when there is a clear benefit. For example, this combination has not proven to be superior to clopidogrel alone in patients with acute ischemic stroke or to aspirin alone for primary prevention in those at risk for cardiovascular events.

When compared with clopidogrel in 13,608 patients with acute coronary syndromes undergoing percutaneous coronary interventions (PCIs), prasugrel reduced the combined rate of cardiovascular death, myocardial infarction, or stroke from 12.1% to 9.9%, a decrease driven mainly by a reduction in nonfatal myocardial infarction.⁵ However, prasugrel increased the rate of major bleeding and fatal bleeding, particularly in patients over the age of 65 years, in those weighing less than 60 kg, and in those with a history of stroke.⁵ Therefore prasugrel should not be used in patients with these characteristics. Prasugrel was compared with clopidogrel in 7243 aspirin-treated patients under the age of 75 years with unstable angina or myocardial infarction without ST-segment elevation. At a median follow-up of 17 months, the primary endpoint, the composite of cardiovascular death, myocardial infarction, and stroke had occurred in 13.9% of the prasugrel group and in 16.0% of the clopidogrel group, a difference that was not statistically significant.⁶ Rates of major bleeding and intracranial bleeding were similar with the two treatment regimens. Therefore prasugrel has no advantage over clopidogrel in medically managed patients with acute coronary syndrome.

Dosing

Clopidogrel is given once daily at a dose of 75 mg. Because its onset of action is delayed for several days, loading doses of clopidogrel are given when rapid ADP receptor blockade is desired. For example, patients undergoing coronary artery stenting are often given a loading dose of 600 mg, which produces inhibition of ADP-induced platelet

aggregation within 6 hours. Prasugrel is given as a loading dose of 60 mg followed by 10 mg once daily. Partial inhibition of ADP-induced platelet aggregation is evident within 1 hour of prasugrel administration.

Side Effects

Gastrointestinal and hematologic side effects, other than bleeding, are rare with clopidogrel and prasugrel.

Clopidogrel Resistance

There is considerable between patient variability in the capacity of clopidogrel to inhibit ADP-induced platelet aggregation.⁷ Nonresponsiveness to clopidogrel is termed *clopidogrel resistance*, and platelets from patients with this phenomenon exhibit high reactivity to ADP. Reduced responsiveness to clopidogrel reflects, at least in part, genetic polymorphisms in CYP2C19, which is critical for metabolic activation of clopidogrel in the liver. Thus loss-of-function *CYP2C19*2* and *CYP2C19*3* alleles are found in 2% of white individuals, 4% of black individuals, and 14% of Asian individuals, and the levels of the active metabolite of clopidogrel are reported to be up to 33% lower in carriers of either of these alleles than in those with healthy alleles. Patients with clopidogrel resistance are reported to have a higher risk of ischemic complications after PCI, including myocardial infarction and stent thrombosis. On the basis of these findings, some experts recommend pharmacogenetic testing and point-of-care assessment of platelet reactivity to predict or assess clopidogrel responsiveness. However, attempts to manage such patients with higher doses of clopidogrel or with additional antiplatelet drugs have not resulted in improved outcomes. Instead, patients with clopidogrel resistance may benefit from a switch to prasugrel, which produces more uniform inhibition of ADP-induced platelet aggregation, or to ticagrelor.

Ticagrelor

An orally active agent belonging to the cyclopentyl-triazolopyrimidine class, ticagrelor acts as a direct inhibitor of P2Y₁₂.

Mechanism of Action

Ticagrelor reversibly binds to P2Y₁₂ at a location distinct from the ADP binding site and blocks ADP-mediated receptor activation in a noncompetitive fashion, likely through an allosteric mechanism. Because it does not require metabolic activation, ticagrelor has a more rapid onset of action than clopidogrel or prasugrel.

Indications

When compared with clopidogrel in 18,624 patients with acute coronary syndromes, ticagrelor reduced the rate of cardiovascular death, myocardial infarction, or stroke from 11.7% to 9.8%.⁸ All-cause mortality was also reduced with ticagrelor compared with clopidogrel (4.5% and 5.9%, respectively; $p < .001$), but ticagrelor produced more major bleeding not related to bypass surgery (2.8% and 2.2%, respectively).⁸ An invasive strategy was planned for 72% of the patients entered in the trial. In this subset, the primary composite endpoint occurred in 9.0% of patients randomized to ticagrelor and in 10.7% of those given clopidogrel, a 16% relative risk reduction.⁹ Rates of major bleeding were similar with ticagrelor and clopidogrel (11.6% and 16.5%, respectively; $p = .88$). Therefore ticagrelor also was superior to clopidogrel in patients undergoing coronary interventions.

If cost is not an issue and patients are compliant with twice-daily dosing, ticagrelor is a reasonable alternative to clopidogrel in patients with acute coronary syndrome, regardless of whether they are managed medically or undergo PCI with stent implantation. For these indications, ticagrelor should be given for at least 1 year. It also is reasonable to use ticagrelor in place of clopidogrel in patients with clopidogrel resistance or in those who develop in-stent thrombosis despite clopidogrel therapy.

Dosing

Ticagrelor is given as a 180-mg oral loading dose followed by 90 mg twice daily. Although the trial comparing ticagrelor with clopidogrel was not powered to compare outcomes in different geographical regions, patients enrolled in North America did not have the same benefit as those from other countries. On the basis of post hoc analysis, the only baseline covariate associated with this difference was the higher dose of aspirin used in the United States.¹⁰ Consequently, it is recommended that when ticagrelor is combined with aspirin, the daily aspirin dose should be less than 100 mg.

Side Effects

Ticagrelor produces dyspnea, which is usually mild and dose related, asymptomatic bradycardia with ventricular pauses, and a modest increase in the levels of uric acid. The mechanisms responsible for these side effects are unclear. One possible explanation relates to the capacity of ticagrelor to inhibit adenosine reuptake by erythrocytes, thereby increasing circulating levels of adenosine. In addition to explaining the dyspnea and the bradycardia, the resultant adenosine-induced vasodilation and increased myocardial perfusion could also endow ticagrelor with beneficial effects that are independent of P2Y₁₂ blockade.

Cangrelor

Cangrelor is the only available parenteral inhibitor of P2Y₁₂.

Mechanism of Action

Cangrelor is a rapidly acting reversible inhibitor of P2Y₁₂. It has an immediate onset of action after intravenous administration, a half-life of 3 to 5 minutes, and an offset of action within 1 hour.

Indications

Cangrelor is licensed for use in patients undergoing PCI, in whom it produces rapid ADP receptor blockade in those who have not received pretreatment with clopidogrel, prasugrel, or ticagrelor and are not receiving a GPIIb/IIIa inhibitor.

Dosing

Cangrelor is administered as a 30 µg/kg intravenous bolus before PCI followed by an infusion of 4 µg/kg/min for at least 2 hours or for the duration of PCI, whichever is longer. When transitioning to oral P2Y₁₂ inhibitor therapy, ticagrelor can be given at a loading dose of 180 mg at any time during the cangrelor infusion or immediately after discontinuation. In contrast, loading doses of prasugrel or clopidogrel (60 and 600 mg, respectively) should be given only after cangrelor is stopped, because cangrelor blocks the interaction of their active metabolites with P2Y₁₂.

Side Effects

The major side effect of cangrelor is bleeding.

Dipyridamole

Dipyridamole is a relatively weak antiplatelet agent on its own. An extended-release formulation of dipyridamole combined with low-dose aspirin, a preparation known as Aggrenox, is used for prevention of stroke in patients with transient ischemic attacks.

Mechanism of Action

By inhibiting phosphodiesterase, dipyridamole blocks the breakdown of cyclic AMP (cAMP). Increased levels of cAMP reduce intracellular calcium and inhibit platelet activation. Dipyridamole also blocks the uptake of adenosine by platelets and other cells. This produces a further increase in local cAMP levels because the platelet adenosine A₂ receptor is coupled to adenylate cyclase (Fig. 149.3).

Indications

Dipyridamole plus aspirin was compared with aspirin or dipyridamole alone, or with placebo, in patients with an ischemic stroke or transient ischemic attack. The combination reduced the risk of stroke by 22.1% compared with aspirin alone and by 24.4% compared with dipyridamole alone. In a second trial, researchers compared dipyridamole plus aspirin with aspirin alone for secondary prevention in patients with ischemic stroke. Vascular death, stroke, or myocardial infarction occurred in 13% of patients given combination therapy and in 16% of those treated with aspirin alone. When Aggrenox was compared with clopidogrel, however, there was no difference in efficacy, and there was more intracranial bleeding with Aggrenox.¹¹ Although Aggrenox is used for stroke prevention, because of its vasodilatory effects and the paucity of data supporting the use of dipyridamole in patients with symptomatic coronary artery disease, Aggrenox should not be used for stroke prevention in such patients.

Fig. 149.3 MECHANISM OF ACTION OF DIPYRIDAMOLE. Dipyridamole increases levels of cyclic adenosine monophosphate (cAMP) in platelets by (A) blocking the reuptake of adenosine and (B) inhibiting phosphodiesterase-mediated cAMP degradation. By promoting calcium uptake, cAMP reduces intracellular levels of calcium. This, in turn, inhibits platelet activation and aggregation. *AMP*, Adenosine monophosphate; *ATP*, adenosine triphosphate.

Dosing

Aggrenox is given twice daily. Each capsule contains 200 mg of extended-release dipyridamole and 25 mg of aspirin.

Side Effects

Because dipyridamole has vasodilatory effects, it must be used with caution in patients with coronary artery disease. Gastrointestinal complaints, headache, facial flushing, dizziness, and hypotension also can occur. These symptoms often subside with continued use of the drug.

GPIIb/IIIa Receptor Antagonists

As a class, parenteral GPIIb/IIIa receptor antagonists have an established niche in patients with acute coronary syndromes. The three agents in this class are abciximab, eptifibatide, and tirofiban.

Mechanism of Action

A member of the integrin family of adhesion receptors, GPIIb/IIIa is found on the surface of platelets and megakaryocytes. With about 40,000 to 80,000 copies per platelet, GPIIb/IIIa is the most abundant receptor. Consisting of a noncovalently linked heterodimer, GPIIb/IIIa is inactive on resting platelets. When platelets are activated, inside-outside signal transduction pathways trigger a conformational activation of the receptor. Once activated, GPIIb/IIIa binds adhesive molecules, such as fibrinogen and, under high shear conditions, von Willebrand factor. Binding is mediated by Arg-Gly-Asp (RGD) sequences found on the fibrinogen and von Willebrand factor, as well as by the Lys-Gly-Asp (KGD) sequence located within a unique dodecapeptide domain on the γ -chains of fibrinogen. Once bound, fibrinogen and/or von Willebrand factor bridge adjacent platelets together to induce platelet aggregation.

Although abciximab, eptifibatide, and tirofiban all target the GPIIb/IIIa receptor, they are structurally and pharmacologically distinct (Table 149.1). Abciximab is a Fab fragment of a humanized murine monoclonal antibody directed against the activated form of GPIIb/IIIa. Abciximab binds to the activated receptor with high affinity and blocks the binding of adhesive molecules. In contrast to abciximab, eptifibatide and tirofiban are synthetic small molecules. Eptifibatide is a cyclic heptapeptide that binds GPIIb/IIIa because it incorporates the KGD motif, whereas tirofiban is

TABLE 149.1

Features of GPIIb/IIIa Antagonists

Feature	GPIIb/IIIa Antagonists		
Generic name	Abciximab	Eptifibatide	Tirofiban
Trade name	ReoPro	Integrilin	Aggrastat
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma half-life	Short (min)	Long (2.5 h)	Long (2.0 h)
Platelet-bound half-life	Long (days)	Short	Short
Renal clearance	No	Yes	Yes
Dosing	0.25 mg/kg bolus followed by a 12-h infusion of 10 μ g/min	Two 180 μ g/kg boluses given 10 min apart	25 μ g/kg boluses followed by an 18-h infusion of 0.15 μ g/kg/min
Adjustment for renal impairment	No	Yes	Yes

KGD, Lys-Gly-Asp; RGD, Arg-Gly-Asp.

a nonpeptidic tyrosine derivative that acts as an RGD mimetic. Abciximab has a long half-life and can be detected on the surface of platelets for up to 2 weeks. Eptifibatide and tirofiban have shorter half-lives.

In addition to targeting the GPIIb/IIIa receptor, abciximab also inhibits the closely related $\alpha_v\beta_3$ receptor, which binds vitronectin, and $\alpha_M\beta_2$, a leukocyte integrin. In contrast, eptifibatide and tirofiban are specific for GPIIb/IIIa. Inhibition of $\alpha_v\beta_3$ and $\alpha_M\beta_2$ may endow abciximab with antiinflammatory and/or antiproliferative properties that extend beyond platelet inhibition.

Indications

These agents are used in high-risk patients undergoing PCIs, particularly those with ST-segment elevation acute myocardial infarction who have not been adequately pretreated with antiplatelet drugs or in those requiring rapid platelet inhibition. Tirofiban and eptifibatide are occasionally used upstream for intervention in high-risk patients with unstable angina.

Dosing

All of the GPIIb/IIIa antagonists are given as an intravenous bolus followed by an infusion. Because they are cleared by the kidneys, the doses of eptifibatide and tirofiban must be reduced in patients with renal impairment.

Side Effects

In addition to bleeding, thrombocytopenia is the most serious complication. Thrombocytopenia is immune mediated and is caused by antibodies directed against neoantigens on GPIIb/IIIa that are exposed upon antagonist binding. With abciximab, thrombocytopenia occurs in up to 5% of patients. Thrombocytopenia is severe in about 1% of these individuals. Thrombocytopenia is less common with the other two agents, occurring in about 1% of treated patients.

Vorapaxar

An orally active inhibitor of the type 1 protease-activated receptor (PAR-1), vorapaxar inhibits the major thrombin receptor on platelets.^{12–14}

Mechanism of Action

Thrombin is a potent platelet activator that acts through the PARs.¹⁴ PAR-1 is the highest-affinity thrombin receptor on platelets; PAR-1 also is expressed on endothelial cells and atherosclerotic plaques.¹⁵ Vorapaxar is a synthetic analogue of himbacine, which is a natural product. Given orally, vorapaxar is rapidly absorbed from the gastrointestinal tract and inhibits platelet PAR-1 in a reversible fashion; however, because of its long half-life (8 to 12 days) and its high-affinity interaction with PAR-1, vorapaxar is effectively an irreversible inhibitor of PAR-1.

Indications

Vorapaxar is indicated for reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or peripheral artery disease. The drug is administered in conjunction with aspirin and/or clopidogrel. Vorapaxar is contraindicated in patients with a prior history of intracranial bleeding, stroke, or transient ischemic attack.

Dosing

Vorapaxar is given orally at a dose of 2.5 mg once daily.

Side Effects

The major side effect is bleeding, including intracranial and fatal bleeding.

ANTICOAGULANTS

There are both parenteral and oral anticoagulants. Currently available parenteral anticoagulants include heparin, low-molecular-weight heparin (LMWH), fondaparinux, and direct thrombin inhibitors (hirudin, bivalirudin, and argatroban). The oral anticoagulants include the vitamin K antagonists, of which warfarin is the agent most often used in North America, and the non-vitamin K antagonist oral anticoagulants (NOACs) that target either thrombin (dabigatran etexilate) or factor Xa (rivaroxaban, apixaban, and edoxaban).¹⁴

Parenteral Anticoagulants

Heparin

A sulfated polysaccharide, heparin is isolated from mammalian tissues rich in mast cells. Most commercial heparin is derived from porcine intestinal mucosa and is a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues.

Mechanism of Action

Heparin acts as an anticoagulant by activating antithrombin (previously known as *antithrombin III*) and accelerating the rate at which antithrombin inhibits clotting enzymes, particularly thrombin and factor Xa. Antithrombin, the obligatory plasma cofactor for heparin, is a 58,000-Da single-chain polypeptide that is a member of the serine protease inhibitor (serpin) superfamily. Synthesized in the liver and circulating in plasma at a concentration of $2.6 \pm 0.4 \mu\text{M}$, antithrombin acts as a suicide substrate for its target enzymes.

To activate antithrombin, heparin binds to the serpin via a unique pentasaccharide sequence that is found on one-third of the chains of commercial heparin (Fig. 149.4); heparin chains lacking this pentasaccharide sequence have little or no anticoagulant activity. Once bound to antithrombin, heparin induces a conformational change in the reactive center loop of antithrombin that renders it more readily accessible to its target proteases. This conformational change enhances the rate at which antithrombin inhibits factor Xa by at least two orders of magnitude, but it has little effect on the rate of thrombin inhibition by antithrombin (Fig. 149.5). To catalyze thrombin inhibition, heparin serves as a template that binds antithrombin and thrombin simultaneously. Formation of this ternary complex brings the enzyme in close apposition to the inhibitor, thereby promoting the formation of a stable covalent thrombin–antithrombin complex.

Only pentasaccharide-containing heparin chains composed of at least 18 saccharide units (which correspond to a molecular weight of 5400) are of sufficient length to bridge thrombin and antithrombin together. With a mean molecular weight of 15,000 and a range of 5000 to 30,000, almost all of the chains of unfractionated heparin are long enough to affect this bridging function. Consequently, by definition, heparin has equal capacity to promote the inhibition of thrombin and factor Xa by antithrombin and is assigned an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1 : 1.

In addition to activating antithrombin, heparin also can catalyze heparin cofactor II. This 66,000-Da serpin, which is found in plasma at a concentration of $1.2 \pm 0.4 \mu\text{M}$, is a specific inhibitor of thrombin. Two features account for the specificity of heparin cofactor II. First, the reactive site of heparin cofactor II contains the sequence Leu444–Ser445, a peptide bond that is not readily susceptible to

Fig. 149.4 MECHANISM OF ACTION OF HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN, AND FONDAPARINUX, A SYNTHETIC PENTASACCHARIDE. (A) Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units, which correspond to a molecular weight of 5400, are of sufficient length to perform this bridging function. With a mean molecular weight of 15,000, all of the heparin chains are long enough to do this. (B) Low-molecular-weight heparin (LMWH) has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin does because, with a mean molecular weight of 4500 to 5000, at least half of the LMWH chains are too short to bridge antithrombin to thrombin. (C) The pentasaccharide accelerates only factor Xa inhibition by antithrombin because the pentasaccharide is too short to bridge antithrombin to thrombin.

cleavage by coagulation proteases other than thrombin. Second, heparin cofactor II possesses a unique anionic sequence at its N-terminal. In its unactivated state, this sequence forms an intramolecular bond with the positively charged glycosaminoglycan binding site located on the body of heparin cofactor II. When heparin or dermatan sulfate, a glycosaminoglycan that interacts only with heparin cofactor II, binds to heparin cofactor II, this N-terminal sequence is displaced, which enables its tethering to a positively charged domain on thrombin known as *exosite 1*. This tethering interaction occurs only with thrombin and facilitates thrombin inhibition by heparin cofactor II (Fig. 149.6).

Maximum catalysis of heparin cofactor II by heparin requires heparin chains composed of at least 26 saccharide units, which corresponds to a molecular weight of 7800. Longer heparin chains activate heparin cofactor II to a greater extent than shorter chains because the longer chains are of sufficient length not only to bind to heparin cofactor II but also to bind to thrombin to form a ternary complex. Formation of this complex brings thrombin and heparin cofactor II into close apposition.

Fig. 149.5 COMPARISON OF THE STIMULATORY EFFECTS OF PENTASACCHARIDE AND UNFRACTIONATED HEPARIN ON CATALYSIS OF ANTITHROMBIN-MEDIATED INHIBITION OF THROMBIN (IIa), FACTOR IXa (IXa), AND FACTOR Xa (Xa). Second-order rate constants of inhibition of factor IIa, IXa, or Xa by antithrombin, measured in the presence of heparin (green bars) or fondaparinux (pink bars) were divided by those determined in the absence of glycosaminoglycan and are plotted as fold increases over the uncatalyzed rate of inhibition. (Reprinted with permission from Wiebe et al: J Biol Chem 228:35767, 2003.)

The interaction of heparin with heparin cofactor II is not mediated by the antithrombin-binding pentasaccharide sequence. Because heparin lacks a specific heparin cofactor II binding domain, heparin's affinity for heparin cofactor II is lower than that for antithrombin. Consequently, 10-fold higher heparin concentrations are needed to accelerate thrombin inhibition by heparin cofactor II in plasma than are necessary to enhance thrombin's inactivation by antithrombin. Therefore it is likely that heparin cofactor II contributes to the anticoagulant activity of heparin only when the drug is given in high doses.

Heparin causes the release of tissue factor pathway inhibitor (TFPI) from the endothelium. A factor Xa-dependent inhibitor of tissue factor-bound factor VIIa, TFPI may contribute to the antithrombotic activity of heparin. Longer heparin chains induce the release of more TFPI than shorter chains.

Pharmacology

Heparin must be given parenterally. It is usually administered subcutaneously or by continuous intravenous infusion. When used for therapeutic purposes, the intravenous route is most often employed. If heparin is given subcutaneously for treatment of thrombosis, the dose of heparin must be high enough to overcome the limited bioavailability associated with this method of delivery.

After entering the circulation, heparin binds to a variety of plasma proteins other than antithrombin, which decreases the anticoagulant activity of heparin. The levels of heparin-binding proteins vary between patients because some of these proteins are acute-phase reactants whose levels are elevated in ill patients, whereas others, such as high-molecular-weight multimers of von Willebrand factor, are released when platelets or endothelial cells are activated by thrombin. Activated platelets also release platelet factor 4 (PF4), a highly cationic protein that binds heparin with high affinity. The large amount of PF4 found in the vicinity of platelet-rich arterial thrombi has the potential to locally neutralize the anticoagulant activity of heparin.

Because the levels of heparin-binding proteins are so variable between patients, the anticoagulant response to fixed or weight-adjusted doses of heparin is unpredictable. Consequently, coagulation monitoring is essential to ensure that a therapeutic response is obtained when heparin is administered for treatment purposes.

Fig. 149.6 CATALYSIS OF HEPARIN COFACTOR II (HCII) BY GLYCOSAMINOGLYCANS. In its unactivated form, the acidic N-terminal tail of HCII is tethered to the positively charged glycosaminoglycan-binding site on the body of the serpin. The binding of heparin or dermatan sulfate to this binding site displaces the N-terminal tail, thereby facilitating the interaction of this anionic domain with exosite 1 on thrombin. Glycosaminoglycan binding also evokes a conformational change in the reactive center loop of HCII that contributes to the formation of the HCII–thrombin complex. Longer heparin chains bind not only to HCII but also to the heparin-binding domain on thrombin, so-called exosite 2. Heparin-mediated bridging of HCII to thrombin enhances the rate of inhibition. Consequently, longer heparin chains that contain at least 26 saccharide units promote thrombin inhibition by HCII to a greater extent than shorter chains. Unlike heparin, dermatan sulfate does not need to bind to thrombin for maximal enhancement in the rate of thrombin inhibition, because shorter dermatan sulfate fragments are just as active as longer ones.

Heparin is cleared through a combination of a rapid, saturable and a much slower first-order mechanism. The saturable phase of heparin clearance is thought to be caused by binding to endothelial cell receptors and macrophages. Bound heparin is internalized and depolymerized. The slower, nonsaturable mechanism of clearance is largely renal. At therapeutic doses, a large proportion of heparin is cleared through the rapid, saturable, dose-dependent mechanism. The complex kinetics of clearance renders the anticoagulant response to heparin nonlinear at therapeutic doses, with both the intensity and duration of effect rising disproportionately with increasing dose. Thus the apparent biological half-life of heparin increases from approximately 30 minutes after an intravenous bolus of 25 U/kg, to 60 minutes with an intravenous bolus of 100 U/kg, to 150 minutes with a bolus of 400 U/kg.

Monitoring

Heparin therapy can be monitored using the activated partial thromboplastin time (aPTT), anti-factor Xa level, or the activated clotting time (ACT). Although the aPTT is the test most often employed for this purpose, there are problems with this assay. aPTT reagents vary in their sensitivity to heparin, and the type of coagulometer used for

testing can influence the results. Consequently, laboratories must establish a therapeutic aPTT range with each reagent–coagulometer combination by measuring the aPTT and anti-factor Xa level in plasma samples collected from heparin-treated patients. For most of the aPTT reagents and coagulometers in current use, therapeutic heparin levels are achieved with a two- to threefold prolongation of the aPTT.

Anti-factor Xa levels also can be used to monitor heparin therapy. With this test, therapeutic heparin levels range from 0.3 to 0.7 U/mL. Although this test is gaining in popularity, anti-factor Xa assays have yet to be standardized, and results can vary widely between laboratories.

The ACT is used to monitor heparin when high doses are given (>100 U/kg) to patients undergoing PCI or cardiac surgery with cardiopulmonary bypass (CPB) and those requiring extracorporeal membrane oxygenation (ECMO). The ACT varies depending on which test kit is used. For PCI, the target ACT is 250 to 300 seconds in patients not receiving GPIIb/IIIa inhibitors and 200 to 250 seconds if a GPIIb/IIIa inhibitor is given. For CPB, a target ACT longer than 480 seconds is desirable, whereas for ECMO, the target ACT ranges from 140 to 240 seconds.

Up to 25% of heparin-treated patients with venous thromboembolism require more than 35,000 U/day to achieve a therapeutic aPTT. These patients are considered heparin resistant. It is useful to measure anti-factor Xa levels in these patients because many will have a therapeutic anti-factor Xa level despite a subtherapeutic aPTT. This dissociation in test results occurs because elevated plasma levels of fibrinogen and factor VIII, both of which are acute-phase proteins, shorten the aPTT but have no effect on anti-factor Xa levels. Heparin therapy in patients who exhibit this phenomenon is best monitored using anti-factor Xa levels instead of the aPTT. Patients with congenital or acquired antithrombin deficiency and those with unusually high levels of heparin-binding proteins often require very high doses of heparin to achieve a therapeutic aPTT or anti-factor Xa level. If there is good correlation between the aPTT and the anti-factor Xa levels, either test can be used to monitor heparin therapy.

Dosing

For prophylaxis, heparin is usually given in fixed doses of 5000 U subcutaneously two or three times daily. With these low doses, coagulation monitoring is unnecessary. In contrast, monitoring is essential when heparin is given in therapeutic doses because a subtherapeutic anticoagulant response has been associated with a higher risk of recurrent thrombosis. Fixed-dose or weight-based heparin nomograms are used to standardize heparin dosing and to shorten the time required to achieve a therapeutic anticoagulant response. At least two heparin nomograms have been validated in patients with venous thromboembolism and reduce the time required to achieve a therapeutic aPTT. Weight-adjusted heparin nomograms also have been evaluated in patients with acute coronary syndromes.

Unmonitored twice-daily subcutaneous heparin proved as effective and safe as once-daily LMWH for initial treatment of venous thromboembolism in one study.^{15a} High doses of heparin were used; treatment was started with a dose of 333 U/kg followed by 250 U/kg twice daily thereafter. This regimen may be an option for patients with renal insufficiency where LMWH or fondaparinux is problematic.

Limitations

Heparin has pharmacokinetic and biophysical limitations (Table 149.2). The pharmacokinetic limitations reflect heparin's propensity to bind in a pentasaccharide-independent fashion to cells and plasma proteins. Heparin binding to cells explains its dose-dependent clearance, whereas binding to plasma proteins results in a variable anticoagulant response and can lead to heparin resistance.

The biophysical limitations of heparin reflect the inability of the heparin–antithrombin complex (1) to inhibit factor Xa when it is incorporated into the prothrombinase complex, the complex that converts prothrombin to thrombin, and (2) to inhibit thrombin bound to fibrin. Consequently, factor Xa bound to activated platelets

TABLE 149.2 Pharmacokinetic and Biophysical Limitations of Heparin

	Limitations Mechanism
Poor bioavailability at low doses	Limited absorption of long heparin chains
Dose-dependent clearance	Binds to endothelial cells
Variable anticoagulant response	Binds to plasma proteins whose levels vary from patient to patient
Reduced activity in the vicinity of platelet-rich thrombi	Neutralized by platelet factor 4 released from activated platelets
Limited activity against factor Xa incorporated in the prothrombinase complex and thrombin bound to fibrin	Reduced capacity of heparin–antithrombin complex to inhibit factor Xa bound to activated platelets and thrombin bound to fibrin

within platelet-rich thrombi has the potential to generate thrombin, even in the face of heparin. Once this thrombin binds to fibrin, it too is protected from inhibition by the heparin–antithrombin complex. Clot-associated thrombin can then trigger thrombus growth by locally activating platelets and amplifying its own generation through feedback activation of factors V, VIII, and XI. Further compounding the problem is the potential for heparin neutralization by the high concentrations of PF4 released from activated platelets within the platelet-rich thrombus.

Side Effects

The most common side effect of heparin is bleeding. Other complications include thrombocytopenia, osteoporosis, and elevated levels of transaminases.

Bleeding. The risk of heparin-induced bleeding increases with higher heparin doses. Concomitant administration of drugs that affect hemostasis, such as antiplatelet or fibrinolytic agents, increases the risk of bleeding, as does recent surgery or trauma. Heparin-treated patients with serious bleeding can be given protamine sulfate to neutralize the heparin. Protamine sulfate, a mixture of basic polypeptides originally isolated from salmon sperm, binds heparin with high affinity, and the resultant protamine-heparin complexes are then cleared. Typically, 1 mg of protamine sulfate neutralizes 100 U of heparin. Protamine sulfate is given intravenously. Anaphylactoid reactions to protamine sulfate can occur, and drug administration by slow intravenous infusion is recommended to reduce the risk of these problems.

Thrombocytopenia. Heparin can cause thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is an antibody-mediated process that is triggered by antibodies directed against neoantigens on PF4 that are exposed when heparin binds to this protein (Table 149.3). These antibodies, which usually are of the immunoglobulin G subtype, bind simultaneously to the heparin–PF4 complex and to platelet Fc receptors. Such binding activates the platelets and generates platelet microparticles. Circulating microparticles are prothrombotic because they express anionic phospholipids on their surface and can bind clotting factors, thereby promoting thrombin generation.

HIT can be associated with thrombosis, either arterial or venous. Venous thrombosis, which manifests as deep vein thrombosis and/or pulmonary embolism, is more common than arterial thrombosis. Arterial thrombosis can manifest as ischemic stroke or acute myocardial infarction. Rarely, platelet-rich thrombi in the distal aorta or iliac arteries can cause critical limb ischemia.

The diagnosis of HIT is established using enzyme-linked assays to detect antibodies against heparin–PF4 complexes or with platelet activation assays. Enzyme-linked assays are sensitive, but they can be positive in the absence of any clinical evidence of HIT. The most specific diagnostic test is the serotonin release assay. This test is

TABLE 149.3 Features of Heparin-Induced Thrombocytopenia

Features	Details
Thrombocytopenia	Platelet count of 100,000/ μ L or less or a decrease in platelet count of 50% or more
Timing	Platelet count falls 5–10 days after starting heparin
Type of heparin	More common with unfractionated heparin than LMWH
Type of patient	More common in surgical patients than medical patients; more common in women than in men
Thrombosis	Venous thrombosis more common than arterial thrombosis

LMWH, Low-molecular-weight heparin.

TABLE 149.4 Management of Heparin-Induced Thrombocytopenia

Stop all heparin
Give an alternative anticoagulant, such as lepirudin, argatroban, bivalirudin, danaparoid, or fondaparinux.
Do not give platelet transfusions.
Do not give warfarin until the platelet count returns to its baseline level. If warfarin is administered, give vitamin K to restore the INR to normal.
Evaluate for thrombosis, particularly deep vein thrombosis.

INR, International normalized ratio.

performed by quantifying serotonin release when washed platelets loaded with labeled serotonin are exposed to patient serum in the absence or presence of varying concentrations of heparin. If the patient serum contains the HIT antibody, heparin addition induces platelet activation and subsequent serotonin release.

Management of HIT is outlined in Table 149.4. Heparin should be stopped in patients with suspected or documented HIT, and an alternative anticoagulant should be administered to prevent or treat thrombosis.¹⁶ The agents most often used for this indication are parenteral direct thrombin inhibitors, such as lepirudin, argatroban, or bivalirudin, or factor Xa inhibitors, such as fondaparinux or danaparoid. Oral factor Xa inhibitors, such as rivaroxaban, have been used successfully to manage HIT.

Patients with HIT, particularly those with associated thrombosis, often have evidence of increased thrombin generation that can lead to consumption of protein C. If these patients are given warfarin without a concomitant parenteral anticoagulant to suppress thrombin generation, the further decrease in protein C levels induced by warfarin can trigger skin necrosis. To avoid this problem, patients with HIT should be treated with a direct thrombin inhibitor or fondaparinux until the platelet count returns to normal levels. At this point, low-dose warfarin therapy can be introduced, and the thrombin inhibitor or fondaparinux can be discontinued when the anticoagulant response to warfarin has been therapeutic for at least 2 days. HIT also is covered extensively in Chapter 133.

Osteoporosis. Treatment with therapeutic doses of heparin for over 1 month can cause a reduction in bone density. This complication has been reported in up to 30% of patients given long-term heparin therapy, and symptomatic vertebral fractures occur in 2% to 3% of these individuals.

Studies in vitro and in laboratory animals have provided insights into the pathogenesis of heparin-induced osteoporosis. These investigations suggest that heparin causes bone resorption, both by decreasing bone formation and by enhancing bone resorption. Thus heparin affects the activity of both osteoblasts and osteoclasts.

Elevated Levels of Transaminases. Therapeutic doses of heparin frequently cause modest elevation in the serum levels of hepatic transaminases, without a concomitant increase in the level of bilirubin. The levels of transaminases rapidly return to normal when the drug is stopped. The mechanism responsible for this phenomenon is unknown.

Low-Molecular-Weight Heparin

Consisting of smaller fragments of heparin, LMWH is prepared from unfractionated heparin by controlled enzymatic or chemical depolymerization. The mean molecular weight of LMWH is about 5000, one-third the mean molecular weight of unfractionated heparin. LMWH has several advantages over heparin (Table 149.5) and is used instead of heparin for most indications.

Mechanism of Action

Like heparin, LMWH exerts its anticoagulant activity by activating antithrombin. With a mean molecular weight of 5000, which corresponds to about 17 saccharide units, at least half of the pentasaccharide-containing chains of LMWH are too short to bridge thrombin to antithrombin (see Fig. 149.4). However, these chains retain the capacity to accelerate factor Xa inhibition by antithrombin because this activity is largely the result of the conformational changes in antithrombin evoked by pentasaccharide binding. Consequently, LMWH catalyzes factor Xa inhibition by antithrombin more than thrombin inhibition. Depending on their unique molecular weight distributions, LMWH preparations have anti-factor Xa to anti-factor IIa ratios ranging from 2:1 to 4:1.

Pharmacology

Although usually given subcutaneously, LMWH also can be administered intravenously if a rapid anticoagulant response is needed. LMWH has pharmacokinetic advantages over heparin. These advantages reflect the fact that shorter heparin chains bind less avidly to endothelial cells, macrophages, and heparin-binding plasma proteins. Reduced binding to endothelial cells and macrophages eliminates the rapid, dose-dependent, and saturable mechanism of clearance that is a characteristic of unfractionated heparin. Instead, the clearance of LMWH is dose independent, and its plasma half-life is longer. Based on measurement of anti-factor Xa levels, LMWH has a plasma half-life of about 4 hours. LMWH is cleared almost exclusively by the kidneys, and the drug can accumulate in patients with renal insufficiency.

LMWH exhibits about 90% bioavailability after subcutaneous injection. Because LMWH binds less avidly than heparin to

heparin-binding proteins in plasma, LMWH produces a more predictable dose response, and resistance to LMWH is rare. With a longer half-life and more predictable anticoagulant response, LMWH can be given subcutaneously once or twice daily without coagulation monitoring, even when the drug is given in treatment doses. These properties render LMWH more convenient than unfractionated heparin. Capitalizing on this feature, studies in patients with venous thromboembolism have shown that home treatment with LMWH is as effective and safe as in-hospital treatment with continuous intravenous infusions of heparin. Outpatient treatment with LMWH streamlines care, reduces health care costs, and increases patient satisfaction.

Monitoring

In the majority of patients, LMWH does not require coagulation monitoring. If monitoring is necessary, anti-factor Xa levels must be measured because most LMWH preparations have little effect on the aPTT. Therapeutic anti-factor Xa levels with LMWH range from 0.5 to 1.2 U/mL when measured 3 to 4 hours after drug administration. When LMWH is given in prophylactic doses, peak anti-factor Xa levels of 0.2 to 0.5 U/mL are desirable.

Indications for LMWH monitoring include renal insufficiency and morbid obesity. LMWH monitoring in patients with a creatinine clearance of 50 mL/min or less is advisable to ensure that there is no drug accumulation. Although weight-adjusted LMWH dosing appears to produce therapeutic anti-factor Xa levels in patients who are overweight, this approach has not been evaluated extensively in those with morbid obesity. It may also be advisable to monitor the anticoagulant activity of LMWH during pregnancy because dose requirements can change, particularly in the third trimester. Monitoring also is important in high-risk settings, such as in patients with mechanical mitral valves who are given LMWH for prevention of valve thrombosis.

Dosing

The doses of LMWH recommended for prophylaxis or treatment vary depending on the LMWH preparation. For prophylaxis, once-daily subcutaneous doses of 4000 to 5000 U are often used, whereas doses of 2500 to 3000 U are given when the drug is administered twice daily. For treatment of venous thromboembolism, a dose of 150 to 200 U/kg is given if the drug is administered once daily. If a twice-daily regimen is employed, a dose of 100 U/kg is given. In patients with unstable angina, LMWH is given subcutaneously on a twice-daily basis at a dose of 100 to 120 U/kg.

Side Effects

The major complication of LMWH is bleeding. Recent metaanalyses suggest that the risk of major bleeding may be lower with LMWH than with unfractionated heparin. HIT and osteoporosis are less common with LMWH than with unfractionated heparin.

Bleeding

The risk of bleeding with LMWH is increased with concomitant use of antiplatelet or fibrinolytic drugs. Recent surgery, trauma, or underlying hemostatic defects also increase the risk of bleeding with LMWH.

Although protamine sulfate can be used as an antidote for LMWH, protamine sulfate incompletely neutralizes the anticoagulant activity of LMWH because it binds only the longer chains of LMWH. Because longer chains are responsible for catalysis of thrombin inhibition by antithrombin, protamine sulfate completely reverses the anti-factor IIa activity of LMWH. In contrast, protamine sulfate only partially reverses the anti-factor Xa activity of LMWH because the shorter pentasaccharide-containing chains of LMWH do not bind to

TABLE 149.5 Advantages of Low-Molecular-Weight Heparin Over Heparin

	Advantage	Consequence
Better bioavailability and longer half-life after subcutaneous injection	Can be given subcutaneously once or twice daily for both prophylaxis and treatment	
Dose-independent clearance	Simplified dosing	
Predictable anticoagulant response	Coagulation monitoring is unnecessary in most patients	
Lower risk of heparin-induced thrombocytopenia	Safer than heparin for short- or long-term administration	
Lower risk of osteoporosis	Safer than heparin for extended administration	

protamine sulfate. Consequently, patients at high risk for bleeding may be more safely treated with continuous intravenous unfractionated heparin than with subcutaneous LMWH. In addition to the potential for complete reversal with protamine sulfate, the short half-life of intravenous heparin also is an advantage if major bleeding occurs.

Thrombocytopenia

The risk of HIT is about fivefold lower with LMWH than with heparin. LMWH binds less avidly to platelets and causes less PF4 release. Furthermore, with lower affinity for PF4 than heparin, LMWH is less likely to induce the conformational changes in PF4 that trigger the formation of HIT antibodies. LMWH should not be used to treat patients with HIT, because most HIT antibodies exhibit cross-reactivity with LMWH, and there are case reports of thrombosis when patients with HIT were treated with LMWH.

Osteoporosis

The risk of osteoporosis is lower with long-term LMWH than with heparin. For extended treatment, therefore, LMWH is a better choice than heparin because of the lower risk of both osteoporosis and HIT.

Fondaparinux

A synthetic analogue of the antithrombin-binding pentasaccharide sequence, fondaparinux differs from LMWH in several ways (Table 149.6). Fondaparinux is licensed for (1) thromboprophylaxis in medical, general surgical, and high-risk orthopedic patients and (2) as an alternative to heparin or LMWH for initial treatment of patients with established venous thromboembolism. In some countries, fondaparinux also is approved as an alternative to heparin or LMWH for treatment of patients with acute coronary syndromes.

Mechanism of Action

As a synthetic analogue of the antithrombin-binding pentasaccharide sequence found in heparin and LMWH, fondaparinux has a molecular weight of 1728. Fondaparinux binds only to antithrombin (see Fig. 149.4) and is too short to bridge thrombin to antithrombin. Consequently, fondaparinux catalyzes factor Xa inhibition by antithrombin and does not enhance the rate of thrombin inhibition.

Pharmacology

Fondaparinux exhibits complete bioavailability after subcutaneous injection. With no binding to endothelial cells or plasma proteins, the clearance of fondaparinux is dose independent, and its plasma

half-life is about 17 hours. The drug is given subcutaneously once daily. Because fondaparinux is cleared unchanged via the kidneys, it is contraindicated in patients with a creatinine clearance less than 30 mL/min, and it should be used with caution in those with a creatinine clearance less than 50 mL/min.

Fondaparinux produces a predictable anticoagulant response after administration in fixed doses because it does not bind to plasma proteins. The drug is given at a dose of 2.5 mg once daily for prevention of venous thromboembolism. For initial treatment of established venous thromboembolism, fondaparinux is given at a dose of 7.5 mg once daily. The dose can be reduced to 5 mg once daily for those weighing less than 50 kg and increased to 10 mg for those weighing more than 100 kg. When given in these doses, fondaparinux is as effective as heparin or LMWH for initial treatment of patients with deep vein thrombosis or pulmonary embolism and produces similar rates of bleeding.

Although not licensed for this indication in the United States, fondaparinux has been used in place of heparin or LMWH in patients with acute coronary syndrome. When the prophylactic dose of fondaparinux (2.5 mg daily) was compared with treatment doses of enoxaparin in patients with non-ST-segment elevation acute coronary syndrome, there was no difference in the rate of cardiovascular death, myocardial infarction, or stroke at 9 days.¹⁷ However, the rate of major bleeding was 50% lower with fondaparinux than with enoxaparin, a difference that likely reflects the fact that the dose of fondaparinux was lower than that of enoxaparin. In patients with acute coronary syndrome who require PCI, there is a risk of catheter thrombosis with fondaparinux unless adjunctive heparin is given.

Side Effects

Fondaparinux does not cause HIT, and, in contrast to LMWH, there is no cross-reactivity of fondaparinux with HIT antibodies. Interestingly, fondaparinux induces the formation of HIT antibodies to the same extent as LMWH. In contrast to heparin or LMWH, however, fondaparinux is too short to cluster PF4 tetramers together, which is a prerequisite for HIT antibody binding. This phenomenon explains not only why HIT antibodies do not cross-react with fondaparinux but also why fondaparinux does not cause HIT despite the fact that it induces the formation of HIT antibodies. Although fondaparinux has been used successfully for HIT treatment, large clinical trials are lacking, and the drug is not licensed for this indication.

The major side effect of fondaparinux is bleeding. There is no antidote for fondaparinux. Protamine sulfate has no effect on the anticoagulant activity of fondaparinux, because it fails to bind to the drug. Recombinant activated factor VII reverses the anticoagulant effects of fondaparinux in volunteers, but it is unknown whether this agent will control fondaparinux-induced bleeding.

Parenteral Direct Thrombin Inhibitors

Heparin and LMWH are indirect inhibitors of thrombin because their activity is mediated by antithrombin. In contrast, direct thrombin inhibitors do not require a plasma cofactor; instead, these agents bind directly to thrombin and block its interaction with its substrates. Approved parenteral direct thrombin inhibitors include hirudin derivatives (lepirudin and desirudin), argatroban, and bivalirudin (Table 149.7). Lepirudin and argatroban are licensed for treatment of patients with HIT, whereas bivalirudin is approved as an alternative to heparin in patients undergoing cardiac surgery or PCI, including those with HIT. Desirudin is licensed for thromboprophylaxis after elective hip replacement surgery.

Lepirudin and Desirudin

Recombinant forms of hirudin, lepirudin, and desirudin are bivalent direct thrombin inhibitors, which interact with both the active site

TABLE 149.6 Comparison of Low-Molecular-Weight Heparin and Fondaparinux

Features	LMWH	Fondaparinux
Molecular mass (Da)	4500 to 6000	1728
Catalysis of factor Xa inhibition	Yes	Yes
Catalysis of thrombin inhibition	Yes	No
Bioavailability after subcutaneous administration (%)	90	100
Plasma half-life (h)	4	17
Renal excretion	Yes	Yes
Induces release of tissue factor pathway inhibitor	Yes	No
Neutralized by protamine sulfate	Partially	No

TABLE 149.7 Comparison of the Properties of Hirudin, Bivalirudin, and Argatroban

	Hirudin	Bivalirudin	Argatroban
Molecular mass (Da)	7000	1980	527
Site(s) of interaction with thrombin	Active site and exosite 1	Active site and exosite 1	Active site
Renal clearance	Yes	No	No
Hepatic metabolism	No	No	Yes
Plasma half-life (min)	60	25	45

and exosite 1, the substrate-binding site on thrombin. Lepirudin is given by continuous intravenous infusion, whereas desirudin is administered subcutaneously twice daily. Lepirudin has a plasma half-life of 60 minutes after intravenous infusion, whereas the half-life of desirudin is about 2 hours. Both drugs are cleared by the kidneys and can accumulate in patients with renal insufficiency. A high proportion of lepirudin-treated patients develop antibodies against the drug. Although these antibodies rarely cause problems, in a small subset of patients they can delay lepirudin clearance and prolong its anticoagulant activity. Serious bleeding has been reported in some of these patients.

Desirudin is given subcutaneously in low doses and does not require monitoring. In contrast, lepirudin is usually monitored using the aPTT, and the dose is adjusted to maintain an aPTT that is 1.5 to 2.5 times the control. The aPTT is not an ideal test for monitoring lepirudin therapy, because the clotting time plateaus with higher drug concentrations. Although the ecarin clotting time provides a better index of lepirudin dose than does the aPTT, the ecarin clotting time has yet to be standardized.

Argatroban

A univalent inhibitor that targets the active site of thrombin, argatroban is metabolized in the liver. Consequently, this drug must be used with caution in patients with hepatic insufficiency. Argatroban is not cleared via the kidneys, so this drug is safer than lepirudin for patients with HIT who have renal insufficiency.

Argatroban is administered by continuous intravenous infusion and has a plasma half-life of about 45 minutes. The aPTT is used to monitor its anticoagulant effect, and the dose is adjusted to achieve an aPTT 1.5 to 3 times the baseline value, but not to exceed 100 seconds. Argatroban also prolongs the international normalized ratio (INR), a feature that can complicate the transitioning of patients from argatroban to warfarin. This problem can be circumvented by using the levels of factor X to monitor warfarin in place of the INR. Alternatively, the argatroban infusion can be stopped for 2 to 3 hours before INR determination.

Bivalirudin

A synthetic 20-amino acid analog of hirudin, bivalirudin is a divalent thrombin inhibitor. Thus the N-terminal portion of bivalirudin interacts with the active site of thrombin, whereas its C-terminal tail binds to exosite 1. Bivalirudin has a plasma half-life of 25 minutes, the shortest half-life of all the parenteral direct thrombin inhibitors. Bivalirudin is degraded by peptidases and is partially excreted via the kidneys. When given in high doses for PCI or cardiac surgery, the anticoagulant activity of bivalirudin is monitored using the ACT. With lower doses, its activity can be assessed using the aPTT.

Studies comparing bivalirudin with heparin plus GPIIb/IIIa antagonists suggest that bivalirudin produces less bleeding. This

feature plus its short half-life makes bivalirudin an attractive alternative to heparin in patients undergoing PCI, and it is licensed for this indication. Bivalirudin also is approved for management of patients with HIT who require PCI or cardiac surgery.

ORAL ANTICOAGULANTS

Current oral anticoagulant practice dates back to the mid- to late-1930s when the vitamin K antagonists were discovered as a result of investigations into the cause of hemorrhagic disease in cattle. Characterized by a decrease in prothrombin levels, this disorder is caused by ingestion of hay containing spoiled sweet clover. Hydroxycoumarin, which was isolated from bacterial contaminants in the hay, interferes with vitamin K metabolism, thereby causing a syndrome similar to vitamin K deficiency. A variety of coumarin derivatives is available. The agent most widely used in North America is warfarin.

The repertoire of oral anticoagulants has expanded with the introduction of the non-vitamin K antagonist oral anticoagulants (NOACs), which are also known as *direct oral anticoagulants* (DOACs). These agents include dabigatran, which targets thrombin, and rivaroxaban, apixaban and edoxaban, which target factor Xa.¹⁴ The NOACs are licensed for thromboprophylaxis after hip or knee replacement, stroke prevention in patients with atrial fibrillation, and for treatment and secondary prevention of venous thromboembolism.

Warfarin

A water-soluble vitamin K antagonist, warfarin was initially developed as a rodenticide. Like other vitamin K antagonists, warfarin interferes with the synthesis of the vitamin K–dependent clotting proteins, which include prothrombin (factor II) and factors VII, IX, and X. Warfarin also reduces the synthesis of the vitamin K–dependent anticoagulant proteins, proteins C, S, and Z.

Mechanism of Action

All of the vitamin K–dependent clotting factors possess glutamic acid residues at their N-termini. A posttranslational modification adds a carboxyl group to the γ -carbon of these residues to generate γ -carboxyglutamic acid. This modification is essential for expression of the activity of these clotting factors because it permits their calcium-dependent binding to negatively charged phospholipid surfaces. The γ -carboxylation process is catalyzed by a vitamin K–dependent carboxylase. Thus vitamin K from the diet is reduced to vitamin K hydroquinone by vitamin K reductase (Fig. 149.7). Vitamin K hydroquinone serves as a cofactor for the carboxylase enzyme, which in the presence of carbon dioxide replaces the hydrogen on the γ -carbon of glutamic acid residues with a carboxyl group. During this process, vitamin K hydroquinone is oxidized to vitamin K epoxide, which is then reduced to vitamin K by vitamin K epoxide reductase (VKOR).

Warfarin inhibits VKOR, thereby blocking the γ -carboxylation process. This results in the synthesis of vitamin K–dependent clotting proteins that are only partially γ -carboxylated. Warfarin acts as an anticoagulant because these partially γ -carboxylated proteins have reduced or absent biologic activity. The onset of action of warfarin is delayed until the newly synthesized clotting factors with reduced activity gradually replace their fully active counterparts.

The antithrombotic effect of warfarin depends on a reduction in the functional levels of factor X and prothrombin, clotting factors that have half-lives of 24 and 72 hours, respectively. Because of the delay in achieving an antithrombotic effect, initial treatment with warfarin is supported by concomitant administration of a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with established thrombosis or at high risk for thrombosis. This strategy also helps to prevent warfarin-induced skin necrosis (see later).

Fig. 149.7 THE VITAMIN K CYCLE AND ITS INHIBITION BY WARFARIN. Dietary vitamin K is reduced by vitamin K reductase to generate vitamin K hydroquinone. Vitamin K hydroquinone serves as a cofactor for the vitamin K-dependent carboxylase that converts glutamic acid residues at the N-termini of the vitamin K-dependent precursors to γ-carboxyglutamic acid residues, thereby creating the so-called Gla domain. By binding calcium, the Gla domain is critical for the interaction of the vitamin K-dependent clotting factors with negatively charged phospholipid membranes. During vitamin K-dependent carboxylation, vitamin K is oxidized to vitamin K epoxide. Vitamin K epoxide is then converted to vitamin K by vitamin K epoxide reductase. Vitamin K antagonists, such as warfarin, interfere with this cycle by inhibiting vitamin K epoxide reductase and vitamin K reductase. Of these two enzymes, vitamin K antagonists more readily block vitamin K epoxide reductase than vitamin K reductase. Consequently, supplemental vitamin K can overcome the inhibitory effects of vitamin K antagonists.

Pharmacology

Warfarin is a racemic mixture of R and S isomers; of these, the S isomer is more active. Warfarin is rapidly and almost completely absorbed from the gastrointestinal tract. Levels of warfarin in the blood peak about 90 minutes after drug administration. Racemic warfarin has a plasma half-life of 36 to 42 hours, and over 97% of circulating warfarin is bound to albumin. Only unbound warfarin is biologically active.

Warfarin accumulates in the liver, where the two isomers are metabolized via distinct pathways. Oxidative metabolism of the more active S isomer is effected by CYP2C9.¹⁸ Two relatively common variants, *CYP2C9*2* and *CYP2C9*3*, have reduced activity. Patients with these variants require a lower maintenance dose of warfarin. The target of warfarin is VKOR. Polymorphisms in the C1 subunit of this enzyme (VKORC1) also can render patients less or more responsive to the anticoagulant effects of warfarin.¹⁸ These findings have prompted a recommendation that patients starting on warfarin should be tested for these polymorphisms and that this information should be incorporated into their warfarin-dosing algorithms. Whether this approach will increase the efficacy and/or safety of warfarin therapy is uncertain.

In addition to genetic factors, diet, drugs, and various disease states influence the anticoagulant effect of warfarin. Fluctuations in dietary vitamin K intake affect the activity of warfarin. A wide variety of drugs can alter absorption, clearance, or metabolism of warfarin. Because of the variability in the anticoagulant response to warfarin, coagulation monitoring is essential to ensure that a therapeutic response is obtained.

Monitoring

Warfarin therapy is most often monitored using the prothrombin time, a test that is sensitive to reductions in the levels of prothrombin,

factor VII, and factor X.¹⁹ The test is performed by adding thromboplastin, a reagent that contains tissue factor, phospholipid, and calcium, to citrated plasma and determining the time to clot formation. Thromboplastins vary in their sensitivity to reductions in the levels of the vitamin K-dependent clotting factors. Consequently, less sensitive thromboplastins will prompt the administration of higher doses of warfarin to achieve a target prothrombin time. This is problematic because higher doses of warfarin increase the risk of bleeding.

The INR was developed to circumvent many of the problems associated with the prothrombin time assay. To calculate the INR, the patient's prothrombin time is divided by the mean normal prothrombin time, and this ratio is then multiplied by the international sensitivity index (ISI), an index of the sensitivity of the thromboplastin used for prothrombin time determination to reductions in the levels of the vitamin K-dependent clotting factors. Highly sensitive thromboplastins have an ISI of 1.0. Most current thromboplastins have ISI values that range from 1.0 to 1.4.

Although the INR has helped to standardize anticoagulant practice, problems persist. The precision of INR determination varies depending on reagent-coagulometer combinations. This leads to variability in the INR results. Also complicating INR determination is unreliable reporting of the ISI by thromboplastin manufacturers. Furthermore, every laboratory must establish the mean normal prothrombin time with each new batch of thromboplastin reagent. To accomplish this, the prothrombin time must be measured in fresh plasma samples from at least 20 healthy volunteers using the same coagulometer that is used for patient samples.

For most indications, warfarin is administered in doses that produce a target INR of 2.0 to 3.0.¹⁹ An exception is patients with mechanical heart valves in the mitral position, where a target INR of 2.5 to 3.5 is recommended.²⁰ Vitamin K antagonists have a narrow therapeutic window. Thus studies in atrial fibrillation demonstrate an increased risk of cardioembolic stroke when the INR falls below 1.7 and an increase in bleeding with INR values over 4.5. Likewise, a study with patients receiving long-term warfarin therapy for unprovoked venous thromboembolism demonstrated a higher rate of recurrent venous thromboembolism when the warfarin dose was adjusted to achieve a target INR of 1.5 to 1.9 than with a target INR of 2.0 to 3.0. Rates of major bleeding were similar.

Dosing

Warfarin is usually started at a dose of 5 to 10 mg. The dose is then titrated to achieve the desired target INR. Because of its delayed onset of action, patients with established thrombosis or those at high risk for thrombosis are given concomitant treatment with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux. Initial prolongation of the INR reflects reduction in the functional levels of factor VII. Consequently, concomitant treatment with the parenteral anticoagulant should be continued until the INR has been therapeutic for at least 2 consecutive days. A minimum 5-day course of parenteral anticoagulation is recommended to ensure that the levels of prothrombin have been reduced into the therapeutic range with warfarin.

Because warfarin has a narrow therapeutic window, frequent coagulation monitoring is essential to ensure that a therapeutic anticoagulant response is obtained. Even patients with stable warfarin dose requirements should have their INR determined every 2 to 4 weeks.¹⁹ More frequent monitoring is necessary when new medications are introduced because many drugs enhance or reduce the anticoagulant effects of warfarin.

Side Effects

Like all anticoagulants, the major side effect of warfarin is bleeding. A rare complication is skin necrosis. Warfarin crosses the placenta and can cause fetal abnormalities. Consequently, warfarin

should be avoided during pregnancy, particularly during the first trimester.

Bleeding

At least half of the bleeding complications with warfarin occur when the INR exceeds the therapeutic range. Bleeding complications may be mild, such as epistaxis or hematuria, or more severe, such as retroperitoneal or gastrointestinal bleeding. Life-threatening intracranial bleeding also can occur.

To minimize the risk of bleeding, the INR should be maintained in the therapeutic range. In asymptomatic patients whose INR is between 3.5 and 4.5, warfarin should be withheld until the INR returns to the therapeutic range. If the INR is over 4.5, a therapeutic INR can be achieved more rapidly by administration of low doses of sublingual vitamin K.

Patients with serious bleeding need treatment that is more aggressive. These patients should be given 5 to 10 mg of vitamin K by slow intravenous infusion. Additional vitamin K should be given until the INR is in the normal range. Treatment with vitamin K should be supplemented with prothrombin complex concentrate to replace the missing vitamin K–dependent clotting factors.¹⁹

Warfarin-treated patients who experience bleeding when their INR is in the therapeutic range require investigation into the cause of the bleeding. Those with gastrointestinal bleeding often have underlying peptic ulcer disease or a tumor. Similarly, investigation of hematuria or uterine bleeding in patients with a therapeutic INR may unmask a tumor of the genitourinary system.

Skin Necrosis

A rare complication of warfarin, skin necrosis usually is seen 2 to 5 days after initiation of therapy. Well-demarcated erythematous lesions form on the thighs, buttocks, breasts, or toes. Typically the center of the lesion becomes progressively necrotic. Examination of skin biopsies taken from the border of these lesions reveals thrombi in the microvasculature.

Warfarin-induced skin necrosis is seen in patients with congenital or acquired deficiencies of protein C or protein S. Initiation of warfarin therapy in these patients produces a precipitous fall in plasma levels of proteins C or S, thereby eliminating this important anticoagulant pathway before warfarin exerts an antithrombotic effect through lowering of the functional levels of factor X and prothrombin. The resultant procoagulant state triggers thrombosis. Why the thrombosis is localized to the microvasculature of fatty tissues is unclear.

Treatment involves discontinuation of warfarin and reversal with vitamin K, if needed. An alternative anticoagulant, such as heparin or LMWH, should be given in patients with thrombosis. Protein C concentrates or recombinant activated protein C can be given to patients with protein C deficiency to accelerate healing of the skin lesions; fresh frozen plasma may be of value for those with protein S deficiency. Occasionally, skin grafting is necessary when there is extensive skin loss.

Because of the potential for skin necrosis, patients with known protein C or protein S deficiency require overlapping treatment with a parenteral anticoagulant when initiating warfarin therapy. Warfarin should be started in low doses in these patients, and the parenteral anticoagulant should be continued until the INR is therapeutic for at least 2 to 3 consecutive days.

Pregnancy

Warfarin crosses the placenta and can cause fetal abnormalities or bleeding. The fetal abnormalities include a characteristic embryopathy, which consists of nasal hypoplasia and stippled epiphyses. The risk of embryopathy is highest if warfarin is given in the first trimester of pregnancy. Central nervous system abnormalities also can occur with exposure to coumarins at any time during pregnancy. Finally, maternal administration of warfarin produces an anticoagulant effect in the fetus that can cause bleeding. This is of particular concern at delivery, when trauma to the head during passage through the birth canal can lead to intracranial bleeding. Because of these potential

problems, warfarin is rarely used in pregnancy, particularly in the first and third trimesters. Instead, heparin, LMWH, or fondaparinux can be given during pregnancy for prevention or treatment of thrombosis.

Warfarin does not pass into the breast milk. Consequently, warfarin can safely be administered to nursing mothers.

Special Problems

Patients with a lupus anticoagulant or those who need urgent or elective surgery present special challenges. Although observational studies suggested that patients with thrombosis complicating the antiphospholipid antibody syndrome required higher-intensity warfarin regimens to prevent recurrent thromboembolic events, two recent randomized trials demonstrated that targeting an INR of 2.0 to 3.0 is as effective as higher-intensity treatment and produces less bleeding. Monitoring warfarin therapy can be problematic in patients with antiphospholipid antibody syndrome if the lupus anticoagulant prolongs the baseline INR.

If patients receiving long-term warfarin treatment require an elective invasive procedure, warfarin can be stopped 5 days before the procedure to allow the INR to return to normal levels. Those at high risk for recurrent thrombosis can be bridged with once- or twice-daily subcutaneous injections of LMWH when the INR falls below 2.0. The last dose of LMWH should be given 12 to 24 hours before the procedure, depending on whether LMWH is administered twice or once daily, respectively. After the procedure, warfarin can be restarted.

Dabigatran

The active moiety of dabigatran etexilate, dabigatran targets the active site of thrombin and blocks its procoagulant activities. Dabigatran inhibits both free and fibrin-bound thrombin.

Mechanism of Action

Dabigatran etexilate is a prodrug with an oral bioavailability of 6% to 7%. Once absorbed, the drug is rapidly biotransformed by esterases to dabigatran, the levels of which peak 1 to 2 hours after oral administration. Dabigatran has a half-life of 12 to 14 hours. About 80% of the drug is excreted unchanged by the kidneys (Table 149.8). Potent permeability glycoprotein (P-GP) inhibitors, such as ketoconazole, are contraindicated.

Indications

Dabigatran is licensed for thromboprophylaxis after hip arthroplasty in the United States, and it is licensed for this indication and for thromboprophylaxis after knee arthroplasty in most other countries. Dabigatran also is licensed for stroke prevention in patients with nonvalvular atrial fibrillation and as an alternative to warfarin for treatment of venous thromboembolism.

When compared with warfarin in patients with atrial fibrillation, dabigatran at the 150-mg twice-daily dose was superior for reduction

TABLE 149.8 Comparison of Dabigatran, Rivaroxaban, Apixaban, and Edoxaban

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	Thrombin (IIa)	Factor Xa	Factor Xa	Factor Xa
Active drug	No	Yes	Yes	Yes
Onset Time (h)	0.5–2	2–4	3–4	1–3
Half-life (h)	12–17	5–13	~12	9–11
Renal excretion (%)	80	33	27	50

in both hemorrhagic and ischemic stroke.²¹ Rates of major bleeding were similar with dabigatran and warfarin, whereas rates of intracranial and life-threatening bleeding were lower with dabigatran. At the 110-mg twice-daily dose, dabigatran was noninferior to warfarin for stroke prevention but was associated with significantly less intracranial and major bleeding.²¹ In those over the age of 75 years, there was more gastrointestinal bleeding with dabigatran than with warfarin with the 150-mg dose but not with the 110-mg dose.²²

For treatment of acute venous thromboembolism, dabigatran was compared with warfarin after a 5- to 7-day course of heparin or LMWH. Dabigatran was noninferior to warfarin for prevention of recurrent venous thromboembolism, but it produced less major plus clinically relevant nonmajor bleeding.²³

When dabigatran was compared with warfarin in patients with mechanical heart valves, there was a trend for more ischemic strokes and more bleeding with dabigatran.²⁴ Consequently, dabigatran and the other NOACs are contraindicated in patients with mechanical heart valves; warfarin remains the anticoagulant of choice for such patients.

Dosing

For thromboprophylaxis after hip or knee arthroplasty, dabigatran is given once daily at a dose of 220 mg; a half-dose is given on the day of surgery. For stroke prevention in atrial fibrillation, dabigatran is given at a dose of 150 mg twice daily. A dose of 75 mg twice daily is used in the United States for patients with a creatinine clearance of 15 to 30 mL/min, whereas the 150-mg twice-daily dose is recommended for those with a creatinine clearance over 30 mL/min. In other countries, a dose of 110 mg twice daily is used for patients over the age of 80 years or in those 75 years of age or older who have risk factors for bleeding. For treatment of venous thromboembolism, dabigatran is given at a dose of 150 mg twice daily.

Monitoring

Routine coagulation monitoring is unnecessary. However, determination of the anticoagulant activity of dabigatran can be helpful to assess adherence, detect accumulation or overdose, determine its contribution to bleeding, and optimize the timing of surgery or intervention. The aPTT and thrombin time can be used for qualitative assessment of the anticoagulant activity of dabigatran, whereas the diluted thrombin time or ecarin clotting time can be used to quantify dabigatran levels if the tests are performed with dabigatran calibrators.

Drug Interactions

Dabigatran is a substrate of the efflux P-GP transporter. Consequently, coadministration with potent P-GP inhibitors such as quinidine, ketoconazole, amiodarone, and verapamil can increase plasma concentrations of dabigatran by decreasing its reabsorption into the gastrointestinal tract. In contrast, potent P-GP inducers such as rifampicin can reduce plasma dabigatran concentrations by increasing its reabsorption.

Side Effects

Dabigatran can be associated with dyspepsia. Taking the drug with food often helps to alleviate this problem. Bleeding is the major side effect of dabigatran. Dabigatran can rapidly be reversed with idarucizumab, a humanized monoclonal antibody fragment that binds dabigatran with high affinity.²⁵ Idarucizumab is given as an intravenous bolus of 5 g and is licensed for dabigatran reversal in patients with serious bleeding or in those requiring urgent surgery or intervention.

Dabigatran crosses the placenta and should not be used in pregnant women. The safety of dabigatran in women who are breastfeeding and in children has not been established.

Rivaroxaban

An oral factor Xa inhibitor, rivaroxaban is an active drug that targets the active site of factor Xa even when the enzyme is incorporated into the prothrombinase complex.

Mechanism of Action

Rivaroxaban has an oral bioavailability of 80%, and plasma levels peak 2 to 3 hours after drug administration. Absorption of rivaroxaban is enhanced by food; consequently, when given in doses of 15 or 20 mg once daily, rivaroxaban should be taken with a meal. The half-life of rivaroxaban is 5 to 9 hours in healthy young subjects and 11 to 13 hours in elderly subjects (Table 149.8). About one-third of the drug is cleared unchanged by the kidneys. The remainder is metabolized in the liver, and half of the inactive metabolites is cleared by the kidneys; the rest is excreted in the feces. The pharmacokinetic and pharmacodynamic profile is dose dependent and is not influenced by age, gender, or body weight.

Indications

Rivaroxaban is licensed for thromboprophylaxis after elective hip or knee arthroplasty, for treatment of venous thromboembolism, and for stroke prevention in patients with nonvalvular atrial fibrillation. When compared with enoxaparin for thromboprophylaxis after hip or knee arthroplasty, rivaroxaban significantly reduced the risk of venous thromboembolism with similar or slightly higher rates of major bleeding.²⁶ In patients with atrial fibrillation, rivaroxaban was noninferior to warfarin for prevention of stroke and systemic embolism, but it was associated with less intracranial bleeding and hemorrhagic stroke and a similar rate of major bleeding.²⁷ In patients with acute venous thromboembolism, an all-oral rivaroxaban regimen was as effective as conventional anticoagulant therapy consisting of heparin followed by a vitamin K antagonist, but it was associated with less major bleeding.^{28,29} When compared with placebo as an adjunct to dual antiplatelet therapy in patients with acute coronary syndrome, rivaroxaban (at a dose of 2.5 mg twice daily) reduced the primary efficacy endpoint—the composite of cardiovascular death, myocardial infarction and stroke—from 10.7% to 9.1%.³⁰ Rivaroxaban increased the risk of bleeding, including intracranial bleeding, compared with placebo, but there was no increase in fatal bleeding.

Dosing

For thromboprophylaxis after hip or knee replacement surgery, rivaroxaban is given once daily at a dose of 10 mg.²⁶ When used for stroke prevention in patients with atrial fibrillation, the dose is 20 mg once daily. The dose is reduced to 15 mg once daily for those with a creatinine clearance of 15 to 49 mL/min. For treatment of venous thromboembolism, rivaroxaban is started at a dose of 15 mg twice daily for 3 weeks, followed by 20 mg once daily thereafter. When used as an adjunct to antiplatelet therapy in stabilized patients with acute coronary syndrome, rivaroxaban is given at a dose of 2.5 mg twice daily.

Monitoring

Rivaroxaban prolongs the prothrombin time more than the aPTT, but its effect on these tests is reagent dependent. Plasma concentrations of rivaroxaban can be quantified using a chromogenic anti-factor Xa assay with drug-specific calibrators.

Drug Interactions

Coadministration of rivaroxaban with dual inhibitors of CYP3A4 and P-GP, such as ketoconazole, itraconazole, ritonavir, and clarithromycin, increases drug exposure and the risk of bleeding, whereas coadministration with dual inducers of CYP3A4 and P-GP, such as rifampin, carbamazepine, phenytoin, and St. John's wort, decreases exposure and increases the risk of stroke and other thromboembolic events.

Side Effects

The major side effect is bleeding. Although prothrombin complex concentrate partly reverses the anticoagulant effects of rivaroxaban in volunteers, its utility for treatment of bleeding is uncertain. Nonetheless, prothrombin complex concentrate (30 to 50 U/kg) should be considered for patients with life-threatening bleeds. If the bleeding continues, activated prothrombin complex concentrate or recombinant factor VIIa can be used.

Specific reversal agents for rivaroxaban are in development. Most advanced is andexanet alfa. A recombinant variant of factor Xa that has its active site serine residue replaced with an alanine residue to eliminate catalytic activity and its membrane-binding domain removed to circumvent incorporation into the prothrombinase complex, andexanet competes with factor Xa for binding rivaroxaban and sequesters it until it can be cleared.^{25,31} Andexanet also reverses heparin, LMWH, and fondaparinux by competing with factor Xa and thrombin for the antithrombin–heparin complex.

Ciraparantag is a second reversal agent that is at an earlier stage of development than andexanet. A synthetic, cationic small molecule, ciraparantag binds rivaroxaban and neutralizes its anticoagulant activity.³² Ciraparantag also binds dabigatran, apixaban, edoxaban, heparin, LMWH, and fondaparinux.

Rivaroxaban crosses the placenta and should not be used in pregnant women. The safety of rivaroxaban in women who are breastfeeding and in children has not been established.

Apixaban

An oral factor Xa inhibitor, apixaban inhibits free factor Xa and factor Xa incorporated into the prothrombinase complex. It is licensed in many countries, for thromboprophylaxis after hip or knee replacement surgery, for treatment and secondary prevention of venous thromboembolism, and for stroke prevention in atrial fibrillation.

Mechanism of Action

Apixaban binds reversibly to the active site of free factor Xa or factor Xa incorporated into the prothrombinase complex. The drug has 50% oral bioavailability, and plasma levels peak 3 to 4 hours after drug administration. The half-life of apixaban is about 12 hours (Table 149.8). Apixaban is metabolized in the liver via CYP3A4/5-dependent and independent pathways. About 27% of the drug is cleared unchanged by the kidneys, and the remainder is excreted in the feces.

Indications

Apixaban is licensed for thromboprophylaxis after elective hip or knee arthroplasty, for stroke prevention in patients with nonvalvular atrial fibrillation, and for treatment of venous thromboembolism. When compared with enoxaparin for thromboprophylaxis after hip or knee arthroplasty, apixaban was at least as effective and safe.^{33–35} For treatment of venous thromboembolism, an all-oral regimen of apixaban (10 mg twice daily for 7 days followed by 5 mg twice daily thereafter) was compared with conventional anticoagulant therapy consisting of enoxaparin followed by warfarin. Apixaban was noninferior to conventional therapy for prevention of recurrent venous

thromboembolism, but it was associated with less bleeding. Apixaban was superior to aspirin for stroke prevention in atrial fibrillation patients unwilling or unable to take warfarin and did not significantly increase the risk of bleeding.³⁶ When compared with warfarin in patients with atrial fibrillation, apixaban significantly reduced the risk of stroke and systemic embolism, and it was associated with less major bleeding and lower all-cause mortality.³⁷

Dosing

For thromboprophylaxis, apixaban is given twice daily at a dose of 2.5 mg. For stroke prevention in patients with atrial fibrillation, the dose is 5 mg twice daily, and the dose is reduced to 2.5 mg twice daily in patients with at least two of the following criteria; age of 80 years or older, body weight of 60 kg or less, and serum creatinine of 1.5 mg/dL or higher. In patients with venous thromboembolism, apixaban is started at a dose of 10 mg twice daily for 7 days followed by 5 mg twice daily thereafter. After 6 months, the dose can be reduced to 2.5 mg twice daily.

Monitoring

Routine monitoring is unnecessary. Apixaban has little effect on the prothrombin time or aPTT. Plasma drug levels can be quantified using an anti-factor Xa assay with apixaban calibrators.

Drug Interactions

Coadministration of apixaban with dual inhibitors of CYP3A4 and P-GP, such as ketoconazole, itraconazole, ritonavir, and clarithromycin, increases drug exposure and may increase the risk of bleeding. In contrast, coadministration with dual inducers of CYP3A4 and P-GP, such as rifampin, carbamazepine, phenytoin, and St. John's wort, decreases exposure and may increase the risk of stroke and other thromboembolic events.

Side Effects

The major side effect is bleeding. Management of bleeding with apixaban is identical to that with rivaroxaban. Apixaban crosses the placenta and should not be used in pregnant women. The safety of apixaban in women who are breastfeeding and in children has not been established.

Edoxaban

Another oral factor Xa inhibitor, edoxaban inhibits free factor Xa and factor Xa incorporated into the prothrombinase complex.

Mechanism of Action

Edoxaban binds reversibly to the active site of free factor Xa or factor Xa incorporated into the prothrombinase complex. The oral bioavailability is 62%, and plasma levels of edoxaban peak 1 to 2 hours after drug administration. The half-life of edoxaban is 10 to 14 hours. Of the administered edoxaban dose, about 50% is excreted via the kidneys as unchanged drug, and the remainder is excreted in the feces (Table 149.8).

Indications

Edoxaban is licensed for stroke prevention in patients with nonvalvular atrial fibrillation and for treatment of venous thromboembolism.

When compared with warfarin in patients with atrial fibrillation, the higher-dose edoxaban regimen (60 mg once daily with dose reduction to 30 mg once daily for the indications listed earlier) was noninferior for prevention of stroke and systemic embolism, but it was associated with less intracranial bleeding and less major bleeding.³⁸ In patients with venous thromboembolism who had received at least 5 days of heparin, edoxaban was noninferior to warfarin for prevention of recurrent venous thromboembolism and was associated with less bleeding.³⁹

Dosing

Edoxaban is given once daily at a dose of 60 mg, both for treatment of venous thromboembolism and for stroke prevention, in patients with atrial fibrillation. The dose is reduced to 30 mg once daily in patients who have a body weight of 60 kg or less, have a creatinine clearance of 15 to 50 mL/min, or are taking potent P-GP inhibitors such as verapamil, quinidine, or dronedarone. In the United States, there is a black box warning against the use of edoxaban in patients with atrial fibrillation who have a creatinine clearance over 95 mL/min.

Monitoring

Edoxaban prolongs the prothrombin time more than the aPTT, but its effects on the prothrombin time are reagent dependent. Plasma edoxaban concentrations can be quantified using an anti-factor Xa assay with edoxaban calibrators.

Drug Interactions

Edoxaban is a substrate of P-GP, and coadministration with potent P-GP inhibitors such as quinidine, verapamil, or dronedarone increases drug exposure and has the potential to increase the risk of bleeding.

Side Effects

The major side effect is bleeding. Management of bleeding with edoxaban is identical to that with rivaroxaban and apixaban. Edoxaban crosses the placenta and should not be used in pregnant women. The safety of edoxaban in women who are breastfeeding and in children has not been established.

FIBRINOLYTIC DRUGS

Role of Fibrinolytic Therapy

Used to degrade thrombi, fibrinolytic drugs can be administered systemically or they can be delivered via catheters directly into the substance of the thrombus. Systemic delivery is used for treatment of acute myocardial infarction, acute ischemic stroke, and most cases of massive pulmonary embolism. The goal of therapy is to produce rapid thrombus dissolution, thereby restoring antegrade blood flow. In the coronary circulation, restoration of blood flow reduces morbidity and mortality by limiting myocardial damage, whereas in the cerebral circulation, rapid thrombus dissolution decreases the neuronal death and brain infarction that produce irreversible brain injury. For patients with massive pulmonary embolism, the goal of fibrinolytic therapy is to restore pulmonary artery perfusion.

Peripheral arterial thrombi and thrombi in the proximal deep veins of the leg are most often treated using a catheter-directed approach. Catheters with multiple side holes can be used to deliver fibrinolytic drugs. In some cases, intravascular devices that fragment and extract the thrombus are used to hasten treatment.

Fig. 149.8 FIBRINOLYTIC SYSTEM AND ITS REGULATION. Plasminogen activators convert plasminogen to plasmin. Plasmin then degrades fibrin into soluble fibrin degradation products. The system is regulated at two levels. Type 1 plasminogen activator inhibitor (PAI-1) regulates the plasminogen activators, whereas α_2 -antiplasmin serves as the major inhibitor of plasmin.

Mechanism of Action

Commonly used fibrinolytic agents include streptokinase, recombinant tissue-type plasminogen activator (rt-PA), which is also known as alteplase or activase, and two recombinant derivatives of rt-PA, tenecteplase and reteplase. All of these agents act by converting the proenzyme, plasminogen, to plasmin, the active enzyme (Fig. 149.8). Plasmin then degrades the fibrin matrix of thrombi, thereby producing soluble fibrin degradation products.

Endogenous fibrinolysis is regulated at two levels. Plasminogen activator inhibitors, particularly the type 1 form, known as PAI-1, prevent excessive plasminogen activation by regulating the activity of tissue-type plasminogen activator (t-PA) and urokinase-type plasminogen activator (u-PA). Once plasmin is generated, plasmin inhibitors, particularly α_2 -antiplasmin, regulate it. The plasma concentration of plasminogen is twofold higher than that of α_2 -antiplasmin. Consequently, with pharmacologic doses of plasminogen activators, the concentration of plasmin that is generated can exceed that of α_2 -antiplasmin. In addition to degrading fibrin, unregulated plasmin also can degrade fibrinogen and other clotting factors. This process, which is known as the systemic lytic state, reduces the hemostatic potential of the blood and increases the risk of bleeding.

The endogenous fibrinolytic system is geared to localize plasmin generation to the fibrin surface. Both plasminogen and t-PA bind to fibrin to form a ternary complex that promotes efficient plasminogen activation. In contrast to free plasmin, plasmin generated on the fibrin surface is relatively protected from inactivation by α_2 -antiplasmin, a feature that promotes fibrin dissolution. Furthermore, C-terminal lysine residues exposed as plasmin degrades fibrin serve as binding sites for additional plasminogen and t-PA molecules. This creates a positive feedback that enhances plasmin generation. When used pharmacologically, the various plasminogen activators capitalize on these mechanisms to a lesser or greater extent.

There are two pools of plasminogen: circulating plasminogen and fibrin-bound plasminogen (Fig. 149.9). Plasminogen activators that preferentially activate fibrin-bound plasminogen are considered fibrin specific. In contrast, nonspecific plasminogen activators do not discriminate between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in the generation of unopposed plasmin that can trigger the systemic lytic state. Alteplase and its derivatives are fibrin-specific plasminogen activators, whereas streptokinase is a nonspecific agent.

Streptokinase

Unlike other plasminogen activators, streptokinase is not an enzyme and does not directly convert plasminogen to plasmin. Instead, streptokinase forms a 1:1 stoichiometric complex with plasminogen.

Formation of this complex induces a conformational change in plasminogen that exposes its active site (Fig. 149.10). This conformationally altered plasminogen then converts additional plasminogen molecules to plasmin.

Streptokinase has no affinity for fibrin, and the streptokinase–plasminogen complex activates both free and fibrin-bound plasminogen. Activation of circulating plasminogen generates sufficient amounts of plasmin to overwhelm α_2 -antiplasmin. Unopposed plasmin not only degrades fibrin in the occlusive thrombus but also induces a systemic lytic state.

When given systemically to patients with acute myocardial infarction, streptokinase reduces mortality. For this indication, the drug is usually given as an intravenous infusion of 1.5 million units over

30 to 60 minutes. Patients who receive streptokinase can develop antibodies against the drug, as can patients with prior streptococcal infection. These antibodies can reduce the effectiveness of streptokinase.

Allergic reactions occur in about 5% of patients treated with streptokinase. These may manifest as a rash, fever, chills, and rigors. Although anaphylactic reactions can occur, these are rare. Transient hypotension is common with streptokinase and has been attributed to plasmin-mediated release of bradykinin from kallikrein. The hypotension usually responds to leg elevation and administration of intravenous fluids and low-doses of vasopressors, such as dopamine or norepinephrine.

Alteplase

A recombinant form of single-chain t-PA, alteplase has a molecular weight of 68,000. Alteplase is rapidly converted into its two-chain form by plasmin. Although single- and two-chain forms of t-PA have equivalent activity in the presence of fibrin, in its absence, single-chain t-PA has 10-fold lower activity.

Alteplase consists of five discrete domains (Fig. 149.11). The N-terminal A-chain of two-chain alteplase contains four of these domains: residues 4 through 50 make up the finger domain, a region that resembles the finger domain of fibronectin; residues 50 through 87 are homologous with epidermal growth factor; and residues 92 through 173 and 180 through 261, which have homology to the kringle domains of plasminogen, are designated as the first and second kringle domains, respectively. The fifth alteplase domain is the protease domain; it is located on the C-terminal B-chain of two-chain alteplase.

The interaction of alteplase with fibrin is mediated by the finger domain and, to a lesser extent, by the second kringle domain. The affinity of alteplase for fibrin is considerably higher than that for fibrinogen. Consequently, the catalytic efficiency of plasminogen activation by alteplase is two to three orders of magnitude higher in the presence of fibrin than in the presence of fibrinogen. This phenomenon helps to localize plasmin generation to the fibrin surface.

Although alteplase preferentially activates plasminogen in the presence of fibrin, alteplase is not as fibrin-selective as was first predicted. Its fibrin specificity is limited because, like fibrin, (DD)E, the

Fig. 149.9 CONSEQUENCES OF ACTIVATION OF FIBRIN-BOUND OR CIRCULATING PLASMINOGEN. The fibrin specificity of plasminogen activators reflects their capacity to distinguish between fibrin-bound and circulating plasminogen. This, in turn, reflects their affinity for fibrin. Plasminogen activators with high affinity for fibrin preferentially activate fibrin-bound plasminogen. This results in the generation of plasmin on the fibrin surface. Fibrin-bound plasmin, which is protected from inactivation by α_2 -antiplasmin, degrades fibrin to yield soluble fibrin degradation products. In contrast, plasminogen activators with little or no affinity for fibrin do not distinguish between fibrin-bound and circulating plasminogen. Activation of circulating plasminogen results in systemic plasminemia and subsequent degradation of fibrinogen and other clotting factors.

Fig. 149.10 MECHANISM OF ACTION OF STREPTOKINASE. Streptokinase binds to plasminogen and induces a conformational change in plasminogen that exposes its active site. The streptokinase–plasmin(ogen) complex then serves as the activator of additional plasminogen molecules.

Fig. 149.11 DOMAIN STRUCTURES OF ALTEPLASE (TISSUE-TYPE PLASMINOGEN ACTIVATOR [t-PA]), TENECTEPLASE, DESMOTEPLEASE, AND RETEPLASE. The finger (F), epidermal growth factor (EGF), first and second kringles (K1 and K2, respectively), and protease (P) domains are illustrated. The glycosylation site (Y) on K1 has been repositioned in tenecteplase to endow it with a longer half-life. In addition, a tetra-alanine substitution in the protease domain renders tenecteplase resistant to type 1 plasminogen activator inhibitor inhibition. Desmoteplase differs from alteplase and tenecteplase in that it lacks a K2 domain. Reteplase is a truncated variant that lacks the F, EGF, and K1 domains.

major soluble degradation product of cross-linked fibrin, binds alteplase and plasminogen with high affinity. Consequently, (DD)E is as potent as fibrin as a stimulator of plasminogen activation by alteplase. Whereas plasmin generated on the fibrin surface results in thrombolysis, plasmin generated on the surface of circulating (DD)E degrades fibrinogen. Fibrinogenolysis results in the accumulation of fragment X, a high-molecular-weight clottable fibrinogen degradation product. Incorporation of fragment X into hemostatic plugs formed at sites of vascular injury renders them susceptible to lysis. This phenomenon may contribute to alteplase-induced bleeding.

A trial comparing alteplase with streptokinase for treatment of patients with acute myocardial infarction demonstrated significantly lower mortality with alteplase than with streptokinase, although the absolute difference was small. The greatest benefit was seen in patients less than 75 years of age with anterior myocardial infarction who presented less than 6 hours after symptom onset.

For treatment of acute myocardial infarction or acute ischemic stroke, alteplase is given as an intravenous infusion over 60 to 90 minutes. The total dose of alteplase usually ranges from 90 to 100 mg. Allergic reactions and hypotension are rare, and alteplase is not immunogenic.

Tenecteplase

A genetically engineered variant of t-PA, tenecteplase was designed to have a longer half-life than t-PA and to be resistant to inactivation by PAI-1. To prolong its half-life, a new glycosylation site was added to the first kringle domain (see Fig. 149.11). Because addition of this extra carbohydrate side chain reduced fibrin affinity, the existing glycosylation site on the first kringle domain was removed. To render the molecule resistant to inhibition by PAI-1, a tetra-alanine substitution was introduced at residues 296 to 299 in the protease domain, the region responsible for the interaction of t-PA with PAI-1.

Tenecteplase is more fibrin specific than t-PA. Although both agents bind to fibrin with similar affinity, the affinity of tenecteplase for (DD)E is significantly lower than that of t-PA. Consequently, (DD)E does not stimulate systemic plasminogen activation by tenecteplase to the same extent as t-PA. As a result, tenecteplase produces less fibrinogenolysis than t-PA.

For coronary fibrinolysis, tenecteplase is given as a single intravenous bolus. In a large phase III trial in which almost 17,000 patients were enrolled, the 30-day mortality rate with single-bolus tenecteplase was similar to that with accelerated dose t-PA.^{40,41} Although rates of

intracranial hemorrhage also were similar with both treatments, patients given tenecteplase had fewer noncerebral bleeds and a reduced need for blood transfusions compared with those treated with t-PA. The improved safety profile of tenecteplase likely reflects its enhanced fibrin specificity. These properties have prompted studies comparing tenecteplase with alteplase in patients with acute ischemic stroke.⁴¹

Reteplase

A recombinant t-PA derivative, reteplase is a single-chain variant that lacks the finger, epidermal growth factor, and first kringle domains (see Fig. 149.11). This truncated derivative has a molecular weight of 39,000. Reteplase binds fibrin more weakly than t-PA because it lacks the finger domain. Because it is produced in *Escherichia coli*, reteplase is not glycosylated. This endows it with a plasma half-life longer than that of t-PA. Consequently, reteplase is given as two intravenous boluses, which are separated by 30 minutes. Clinical trials have demonstrated that reteplase is at least as effective as streptokinase for treatment of acute myocardial infarction, but the agent is not superior to t-PA.⁴²

Desmoteplase

A recombinant form of the full-length plasminogen activator isolated from the saliva of the vampire bat, desmoteplase (see Fig. 149.11) is more fibrin specific than t-PA.⁴³ Although preliminary studies with desmoteplase for treatment of acute ischemic stroke were promising, further development has been halted.

CONCLUSIONS AND FUTURE DIRECTIONS

Arterial and venous thrombosis reflects a complex interplay among the vessel wall, platelets, the coagulation system, and the fibrinolytic pathways. Activation of coagulation also triggers inflammatory pathways that may contribute to thrombogenesis. A better understanding of the biochemistry of blood coagulation and advances in structure-based drug design have identified new targets and resulted in the development of novel antithrombotic drugs. Well-designed clinical trials have provided detailed information on which drugs to use and when to use them. Despite these advances, however, arterial and venous thromboembolic disorders remain a major cause of morbidity and mortality. Therefore the search for better targets and more potent or more convenient antiplatelet, anticoagulant, and fibrinolytic drugs continues.

DISORDERS OF COAGULATION IN THE NEONATE

Mihir D. Bhatt, Karin Ho, and Anthony K.C. Chan

The neonatal stage is a period of rapid physiologic changes, some of which affect the hemostatic system. The hemostatic system is a dynamic system that evolves gradually from birth into the mature adult form. Evaluation of disorders of coagulation in the neonate requires an understanding of the evolution of physiologic normal values for age, the congenital disorders that present in early life, and the clinical settings common in neonatology that affect hemostasis and thrombosis risks. The rapid evolution of the blood coagulation system after birth leads to a dynamic group of age-dependent reference ranges for the levels of the various components that should be considered physiologically normal. *Developmental hemostasis* is the term applied to the evolution of the hemostatic and fibrinolytic systems through infancy and childhood into adult age.

DEVELOPMENTAL HEMOSTASIS

The coagulation system in children provides innate protection from thrombosis without an increased risk for bleeding. The hemostatic system evolves throughout childhood and most rapidly during the neonatal period. Changes in the plasma concentrations of proteins involved in blood coagulation lead to a dynamic group of reference ranges for preterm and term infants. Although different from adult values, these reference ranges are neither abnormal nor pathologic. The relative rarity of hemorrhagic or thrombotic complications in this population suggests that the neonatal coagulation system is physiologically replete.

Laboratory Evaluation

The pioneering work of the late Dr. Maureen Andrew paved the way for research into developmental hemostasis. The concept of developmental hemostasis is now widely accepted, and her seminal papers describing the reference ranges for healthy premature and full-term neonates are still widely quoted.^{1,2} Laboratory evaluation of thrombosis or bleeding in neonates must take into account the age-related reference ranges for healthy newborns, which differ significantly from adult levels. In addition, because coagulation assay results vary depending on the type of analyzer and reagents used, caution should be taken when prior publications of defined reference ranges for neonates are used.³ Each laboratory that performs coagulation tests on neonatal samples must therefore develop their own age-related reference ranges specific to their analyzer and reagent combination in order to effectively diagnose and manage neonates with suspected hemostatic abnormalities. Neonatal samples should be drawn by experienced staff. Samples are processed in 1-mL tubes containing 0.1 mL of 3.2% buffered sodium citrate, aiming for a final ratio of one part citrate to nine parts blood.

Although recently researchers have started to look into age-specific differences in the quantitative levels of hemostatic proteins,⁴ functional assays that are reagent and analyzer specific are still predominantly used in pediatric studies for hemostatic diagnosis. Changes in functional protein levels correspond to changes in global tests of coagulation. The prothrombin time (PT), expressed in seconds, in full-term and premature neonates is similar to that in adults, despite the fact that neonates have relative deficiencies of the vitamin K-dependent coagulation factors. However, samples from cord blood exhibit a prolonged PT compared with samples

from adults.¹ The activated partial thromboplastin time (aPTT) is prolonged in newborns, which is attributed to relative deficiencies in the contact factors. Other tests, such as the thrombin time and thromboelastography, are less sensitive to age-related changes. The thrombin time in neonates is similar to that in adults when measured in the presence of calcium, which compensates for the unique fetal form of fibrinogen that has increased sialic acid content. Thromboelastography values vary very little with age. The template bleeding time is reported to be normal in neonates, but this is an unreliable test in neonates and is not recommended for evaluation of bleeding disorders. Investigations into neonatal hemostatic pathology are limited by the lack of normal reference values for the neonatal population and the difficulties associated with obtaining clean blood samples for testing.

Blood Coagulation Proteins

The synthesis of fetal and neonatal coagulation proteins begins at approximately 10 weeks of gestation, and plasma concentrations of these proteins increase with gestational age. Maternal coagulation proteins cannot cross the placenta. However, maternal drug intake can affect the synthesis of fetal vitamin K-dependent coagulation proteins, with warfarin, phenytoin, barbiturates, and antibiotics serving as examples.

In the healthy newborn, plasma levels of procoagulant factors such as thrombin, factor (F)VII, FIX, FX, and prothrombin (the vitamin K-dependent coagulation factors), as well as FXI, FXII, prekallikrein, and high-molecular-weight kininogen (the contact factors), are about 50% lower than adult values (Table 150.1).^{1,2} The levels rise as the infant ages, and they reach about 80% of normal adult values by 6 months of age but remain decreased throughout childhood.⁵ The levels of fibrinogen, FV, FVIII, and FXIII in neonates are similar to those in adults and remain so throughout childhood.^{2,5} The level of von Willebrand factor (vWF) in newborns is about twofold higher than adult values and gradually decrease over the first 6 months of life,² whereas the levels of antithrombin (AT) are lower than adult levels in the first 3 months of life and are comparable to the levels seen in patients with heterozygous AT deficiency. The physiologic ranges for coagulation factors in healthy newborns who have received intramuscular vitamin K after delivery are shown in Table 150.2.

Regulation of Thrombin

Despite decreased and delayed thrombin generation, neonates have excellent hemostasis. Thrombin regulation in neonatal plasma is similar to that in plasma from adults who are receiving therapeutic doses of anticoagulants. The concentration of thrombin generated in neonatal plasma is proportional to the available prothrombin concentration, whereas the rate of thrombin generation depends on the level of other procoagulant proteins. Clots formed from neonatal plasma bind less thrombin than clots formed from adult plasma, in part because of reduced thrombin generation. The reduced capacity to generate thrombin and the reduction in fibrin-bound thrombin may protect neonates from thrombosis.

Thrombin is inhibited by AT, α_2 -macroglobulin, and heparin cofactor II. In neonates, the α_2 -macroglobulin concentration is

TABLE 150.1 Neonatal Versus Adult Hemostasis

Component	Neonatal Versus Adult Level	
Primary hemostasis	↔ ↑	Platelet count vWF
Coagulation factors	↓ ↓ ↓ to ↔ ↔ ↔	FII, FVII, FIX, FX FXI, FXII FV, FXIII Fibrinogen FVIII
Anticoagulant factors	↓ ↑	TFPI, AT, PC, PS α ₂ M
Fibrinolysis	↓ ↔ to ↑	Plasminogen PAI

α₂M, α₂-Macroglobulin; AT, antithrombin; F, factor; PAI, plasminogen activator inhibitor; PC, protein C; PS, protein S; TFPI, tissue factor pathway inhibitor; vWF, von Willebrand factor.

Modified from Guzzetta NA, Miller BE: Principles of hemostasis in children: Models and maturation. *Paediatr Anaesth* 21:3, 2011.

twofold higher than that in adults. The overall capacity of newborn plasma to inhibit thrombin is similar to that of adult plasma, owing in part to the increased binding of thrombin by α₂-macroglobulin. Thrombin inhibition by heparin cofactor II is catalyzed by a dermatan sulfate-like proteoglycan, which is produced by the placenta and is found in both maternal and fetal plasma.

Regulation of thrombin generation is accomplished by upstream inhibition of the clotting proteins in the prothrombinase and tenase complexes (see Chapter 126). Plasma concentrations of protein C are low at birth and gradually increase to adult levels by 6 months of age. Although the total concentration of protein S is low at birth, the functional activity of protein S is comparable to that in adults because low levels of C4b-binding protein result in more free protein S. The interaction of protein S with activated protein C in neonatal plasma may be limited by the elevated levels of α₂-macroglobulin. Free tissue factor pathway inhibitor levels are lower than in adults, although total levels of tissue factor pathway inhibitor in neonatal plasma are similar to those in adult plasma.

The Fibrinolytic System

Although the levels of some of the components of the fibrinolytic system in neonates are different from those in adults, the clinical relevance of this finding is probably minimal. The fibrinolytic system regulates fibrin deposition by generating plasmin, which solubilizes fibrin. At birth, the fibrinolytic system has all the key components, but there are important age-related differences in the quantity and quality of the fibrinolytic proteins and enzymes. Plasma concentrations of plasminogen, tissue plasminogen activator (t-PA), and α₂-antiplasmin (α₂AP) are decreased, whereas plasma concentrations of plasminogen activator inhibitor 1 (PAI-1) are increased. As well, plasmin generation and overall fibrinolytic activity are decreased.⁶ The capacity to generate plasmin in newborn plasma is generally reduced compared with adult plasma, which likely reflects the decreased plasminogen concentration. Despite lower levels of fibrinolytic components, the newborn fibrinolytic system is still effective.

The whole-blood clotting time and euglobulin clot lysis time are global assays of fibrinolytic activity but reflect only part of the physiologic fibrinolytic potential. Maneuvers that induce the release of endogenous fibrinolytic components, such as venous occlusion, desmopressin infusion, or exercise, provide more sensitive measures of *in vivo* fibrinolytic activity.⁶

Plasminogen levels are lower in neonates than in adults, and fetal plasminogen binds to cellular receptors with lower affinity because of

its increased sialic acid and mannose content. Although healthy neonates have lower plasmin-generating potential than adults, baseline levels of t-PA can increase up to eightfold with illness. Neonates with severe plasminogen deficiency have only a minimally increased risk for thrombosis, and most of their clinical findings are the result of impaired extravascular fibrinolysis. The major plasmin inhibitors circulate at near-adult levels in the neonate.

The contribution of differences in the neonatal and adult fibrinolytic systems to the protection from thromboembolic complications in childhood remains to be elucidated. Imbalance in the fibrinolytic system, whether hereditary or acquired, can lead to thrombotic or bleeding complications. Hereditary disorders, although rare, include plasminogen deficiency, PAI-1 deficiency, and α₂AP deficiency. The efficacy and safety of fibrinolytic therapy may be influenced by age-dependent differences in the fibrinolytic system. Data are lacking on the optimal doses of fibrinolytic agents for the pediatric population, especially for neonates. t-PA is the agent of choice, with the most common dose and duration of treatment being 0.5 mg/kg per hour infused over 6 hours.⁷

Platelets

Platelet production starts around the end of the first trimester of gestation and reaches adult values in the middle of the third trimester. Therefore platelet counts in term and premature newborns are not different from those in adults. Similarly, mean platelet volume and platelet ultrastructure in neonates closely resemble those in adults. Yet, all the main platelet functions are deficient at birth. Neonatal platelets exhibit reduced phospholipid metabolism, calcium mobilization, granule secretion, and aggregation in response to agonists compared with adult platelets.⁸ Although thrombocytopenia is common in neonates, thrombocytosis is rare and is associated with prematurity.

There are two proposed theories behind the reduced platelet function at birth. One hypothesis suggests that platelet activation and degranulation at the time of labor and delivery lead to exhausted circulating platelets; the other suggests that intrinsic platelet peculiarities account for neonatal platelet deficiency. Indeed, differences in intrinsic signal transduction in the neonatal platelets alter platelet aggregation and activation responses. Platelet aggregation studies showed that aggregation of neonatal platelets was reduced in response to a number of agonists, including ADP, epinephrine, collagen, and thrombin and thromboxane analogues. This is especially true in preterm infants. Flow cytometric studies using monoclonal antibodies directed against platelet activation markers also indicate that platelets from cord blood or from neonates on the first postnatal day are hyporeactive compared with adult platelets.⁸ This hyporesponsiveness is transient, and the platelets regain normal reactivity 10 to 14 days after delivery. However, the exact duration of hyporeactivity remains to be elucidated because some studies suggest that functional defects persist beyond the neonatal period.⁹

Despite the reduced platelet reactivity at birth, platelet adhesion may be enhanced because of the presence of higher concentration of functionally more potent high-molecular-weight vWF multimers in the plasma. Consistent with this concept, the bleeding time and the platelet function analyzer (PFA-100) closure time are shorter in neonates than in adults.⁸ In healthy neonates, enhanced platelet adhesion immediately after delivery may compensate for the reduced platelet activation in response to agonists. Nonetheless, sick neonates may be at increased risk for bleeding.⁸

If available, the PFA-100 closure time is preferred over the bleeding time as a means of assessing platelet-related hemostasis. Bleeding time is an *in vivo* screening test that reflects the interaction between platelets and the blood vessel wall, but it is as variable in neonates as it is in adults. Also, the devices used for measuring bleeding time are not suitable for use in small infants. Consequently, the bleeding time is rarely determined. Although the PFA-100 will not detect mild defects in platelet function, such defects rarely cause serious bleeding in neonates.

TABLE 150.2 Reference Values (Ranges) for Common Coagulation Tests and Blood Coagulation Protein Levels by Age, Comparing Two Comprehensive Prospective Studies With Different Methodologies

	Day 1		Day 3 (Ref. 3) vs. Day 5 (Ref. 2)		1 Month–1 Year		Adult (Measured)	
	Ref. 3	Ref. 2	Ref. 3	Ref. 2	Ref. 3	Ref. 2	Ref. 3	Ref. 2

The Vessel Wall

Studies in vitro and in neonatal animals suggest that the endothelium from neonates has greater antithrombotic potential than the endothelium from adult vessels. In both rabbit venous and aortic models, neonatal endothelium expresses more heparan sulfate proteoglycans than adult endothelium, which results in greater AT-mediated anticoagulant activity in rabbit kits than in adults. Circulating levels of endothelial cell adhesion markers vary with age, implying dynamic expression and/or secretion of these proteins as a function of age.

NEONATAL HEMORRHAGIC DISORDERS

Significant bleeding in neonates should prompt clinical evaluation. In sick infants, acquired factor deficiencies or thrombocytopenia are frequently to blame, but rare congenital factor deficiencies can also manifest with neonatal bleeding. Attention to maternal factors

(e.g., infection, thrombocytopenia, drugs) is critical when evaluating neonates. Initial empirical therapy consists of platelet and/or factor supplementation, which is often administered while diagnostic studies are under way.

EVALUATION OF THE BLEEDING NEONATE

Neonatal, peripartum, maternal, and family history are each important in the evaluation of a newborn with hemorrhagic complications. Maternal history of prior pregnancies, medications, and illnesses can provide clues to the hemostatic disorder in the neonate. The family history, such as parental ethnicity and consanguineous marriage, may help to identify congenital bleeding disorders. Maternal infection, drug use, or immune thrombocytopenia can lead to neonatal thrombocytopenia. Maternal deficiency of vitamin K or consumption of drugs that impair vitamin K metabolism can reduce the levels of the vitamin K-dependent coagulation proteins at birth. Vitamin K administration in the delivery room should be confirmed.

On physical examination, the location and characteristics of bleeding (e.g., procedural, mucosal, cutaneous, intraventricular), whether diffuse or localized, in addition to the general appearance of the baby as sick or well, will help to identify the underlying etiology of the hemorrhage. In ill-appearing newborns, disseminated intravascular coagulation (DIC) or liver disease may result in acquired factor deficiencies. These disorders tend to present with diffuse bleeding. Well-appearing newborns are more likely to have localized bleeding or ecchymoses because of thrombocytopenia from a transplacental antibody, vitamin K deficiency, or a rare inherited factor deficiency.

Laboratory evaluation of the hemorrhage in newborns should include sepsis evaluation and determination of the platelet count, PT, aPTT, thrombin time, and fibrinogen concentration. If the test results are normal, bleeding newborns or infants should be assessed for FXIII and α_2 AP activity. Deficiencies of FXIII, α_2 AP, or PAI-1 are not detected with routine screening, and specific testing is needed if deficiencies are suspected. The approach to laboratory screening is summarized in Fig. 150.1, which has been modified from Blanchette and Rand.¹⁰ Platelet function should be evaluated when primary hemostatic defects are suspected.¹¹ In male infants with a family history of hemophilia or when hemophilia is suspected, the levels of FVIII and FIX should be determined, regardless of the degree of aPTT prolongation.

Neonatal Thrombocytopenia

The following factors are important to consider when evaluating neonates with thrombocytopenia: congenital or acquired, sick or well,

maternal antibody or drug, and platelet size. A classification of neonatal thrombocytopenia is provided in Table 150.3. Thrombocytopenia is defined as a platelet count less than $150 \times 10^9/L$.¹² Platelet counts in the range of 100 to $150 \times 10^9/L$ are common in healthy neonates; these mostly reflect transient thrombocytopenia and require no further investigation unless there is a further decrease in the count. More severe thrombocytopenia (platelet count $<50 \times 10^9/L$) in neonates rarely manifests with bleeding, particularly in the absence of maternal antiplatelet antibodies. The estimated prevalence of thrombocytopenia is in the range of 1% to 5% of all newborns. The prevalence of thrombocytopenia increases to 22% to 35% in neonates admitted to the neonatal intensive care unit (NICU), with the rates increasing with decreasing gestational age. With severe thrombocytopenia, platelet transfusion may be necessary to treat or decrease the risk of bleeding.

Causes of neonatal thrombocytopenia include decreased platelet production, increased platelet consumption, and/or hypersplenism (see Chapters 131 and 132). Other contributing factors include infection, placental insufficiency, genetic disorders, medications, DIC, or immune deficiency. In well-appearing newborns, thrombocytopenia is usually immune mediated and related to maternal transplacental immunoglobulin G antibodies or drugs (e.g., quinine, hydralazine, thiazides, tolbutamide). In sick newborns, platelet destruction is often related to infection, DIC, extracorporeal membrane oxygenation (ECMO), thrombosis, or mechanical ventilation for hyaline membrane disease. Large-vessel thrombosis can also lead to thrombocytopenia, as can specific syndromes, such as renal vein thrombosis (RVT), necrotizing enterocolitis, or vascular anomalies (Kasabach-Merritt syndrome). Platelet production can be impaired with hypoxic-ischemic

injury, perhaps because fetal megakaryocytes are particularly sensitive to hypoxia. Transient mild to moderate thrombocytopenia is common in newborns from pregnancies that were complicated by intrauterine growth restriction or pregnancy-induced hypertension. Other rare causes of decreased platelet production in neonates include primary congenital platelet or marrow disorders and infiltrative disorders. These are summarized in Table 150.4.

Neonatal Alloimmune Thrombocytopenia

Neonatal alloimmune thrombocytopenia is the platelet equivalent of hemolytic disease of the newborn. It affects approximately 1 in 2000 pregnancies. When fetal platelets express paternal human platelet antigens (HPAs) that the mother lacks, transplacental passage of maternal immunoglobulin G directed against fetal platelets can occur and usually results in severe neonatal thrombocytopenia (platelet count $<30 \times 10^9/L$). This may result in major bleeding, particularly intracranial hemorrhage (ICH), which can occur in 10% to 20% of untreated pregnancies.¹² Incompatibilities for HPA-1a account for the majority of cases of neonatal alloimmune thrombocytopenia in white populations. About half of the cases of neonatal alloimmune thrombocytopenia occur in the first pregnancy because fetal platelets pass into the maternal circulation early in the pregnancy. Treatment options include transfusion of antigen-negative platelets if available (HPA-1a $\pm$ 5b). Although large randomized studies are lacking, the threshold count for platelet transfusion in most studies is $30 \times 10^9/L$. High-dose intravenous immunoglobulin and/or a trial of random donor platelets can be given if compatible platelets are unavailable. The recommended total dose of intravenous immunoglobulin is 1 to 2 g/kg administered either at a dose of 0.4 g/kg daily for 3 to 5 days or at a dose of 1 g/kg daily for 1 or 2 days.¹³

Inherited Thrombocytopenia

Most cases of inherited thrombocytopenia are the result of decreased platelet production because of abnormal hematopoietic stem or progenitor cell development. Such disorders are often associated with congenital anomalies, which can inform the course of investigation and aid in the diagnosis.¹² Disorders that present with neonatal thrombocytopenia include Bernard-Soulier syndrome, type 2B von Willebrand disease (vWD), Wiskott-Aldrich syndrome, Fanconi anemia, thrombocytopenia with absent radii syndrome, amegakaryocytic thrombocytopenia with radioulnar synostosis, congenital

Platelet Function Disorders

Qualitative platelet disorders are rarely associated with overt neonatal bleeding. Patients presenting with bleeding who have normal coagulation test results and platelet counts require further investigation.

Bleeding may be from mucocutaneous sites, sites of capillary blood sampling, cephalohematoma, umbilical stump, or at sites of procedures. Platelet function disorders result from defects in a number of structures and signaling pathways as outlined in Table 150.5. Only the most severe genetic disorders of platelet function present in the neonatal period. These include Glanzmann thrombasthenia and Bernard-Soulier syndrome (see Chapters 125 and 130). Maternal medications may affect platelet function, most notably aspirin, although low-dose aspirin does not appear to alter neonatal platelet function. Neonatal medications may also affect platelet function. Common offenders include nitric oxide, prostaglandin E₂, indomethacin, and aspirin.

It is especially challenging to diagnose platelet function disorders in neonates because of the technical limitations of many platelet function assays and the need for large volumes of blood for testing. Initial screening for suspected platelet function disorders can be performed using the PFA-100 analyzer followed by evaluation of platelet morphology and platelet aggregation responses using light transmission aggregometry. Flow cytometry can be used to evaluate specific surface glycoproteins, and electron microscopy studies can be used to assess platelet granule morphology.

Although the PFA-100 is a sensitive test for detecting hemostatic disorders in the pediatric population, it is relatively nonspecific. Light transmission aggregometry is highly reproducible in patients with inherited mucocutaneous bleeding if properly standardized. Absent

platelet aggregation in response to all agonists and deficiency of $\alpha_{IIb}\beta_3$ on flow cytometry are diagnostic for Glanzmann thrombasthenia (see Chapters 125 and 130). Flow cytometry also provides definitive diagnostic information about Bernard-Soulier syndrome, dense granule deficiency, and Scott syndrome.

Platelet transfusions are often given if the patient is bleeding. However, the potential risk of human leukocyte antigen allosensitization if normal platelets are given to patients with congenital deficiency of platelet surface antigens must be weighed against the severity of bleeding when functional defects are suspected. It is recommended to restrict platelet transfusion in patients with Glanzmann thrombasthenia. Recombinant activated FVII (rFVIIa) has been used to avoid allosensitization. Other adjunctive measures include local control such as use of fibrin sealant in oral bleeding and antifibrinolytic medications, such as tranexamic acid.

Vitamin K Deficiency Bleeding

Vitamin K is an essential cofactor for γ -glutamyl carboxylase, the enzyme required for posttranslational carboxylation of prothrombin; FVII; FIX; FX; and proteins C, S, and Z. Many newborns are deficient in vitamin K, whether measured in cord blood or indirectly by measuring the levels of the vitamin K-dependent coagulation proteins. Risk factors for bleeding with vitamin K deficiency include maternal malabsorption, maternal intake of drugs that impair vitamin K metabolism, exclusive breastfeeding, and neonatal malabsorption. Classification is based on the time of presentation.

Early vitamin K deficiency bleeding occurs in the first 24 to 48 hours of life and is usually associated with maternal intake of drugs (e.g., phenytoin, barbiturates, antibiotics), which cross the placenta and impair vitamin K synthesis. Classical vitamin K deficiency bleeding manifests from days 2 to 7 of life and is related to low placental transfer of vitamin K, low concentrations in breast milk, lack of gastrointestinal bacterial flora, and poor oral intake. Gastrointestinal bleeding is the most common presentation, but procedural bleeding, bruising, or ICH can occur. Late-onset vitamin K deficiency-related bleeding can occur at times up to 12 weeks of age, usually in association with exclusive breastfeeding or with neonatal fat malabsorption, and often manifests as catastrophic bleeding, including ICH. Congenital vitamin K deficiency is an autosomal recessive disorder that occurs because of mutations in the genes encoding γ -glutamyl carboxylase or the vitamin K_{2.3}-epoxide reductase complex. Neonates with this disorder often have severe bleeding, including ICH. Genotype analysis is necessary to confirm the defects.¹⁴

The diagnostic criteria for vitamin K deficiency bleeding include an elevated international normalized ratio (INR), normal levels of fibrinogen, and a normal platelet count. The diagnosis is confirmed if the INR normalizes after administration of vitamin K and the bleeding stops. The aPTT is prolonged with severe vitamin K deficiency. Prophylaxis with a single dose of vitamin K (0.5 to 1 mg) in the delivery room prevents early- and classic-onset bleeding. Although oral dosing may be effective, because of the potential for impaired absorption, regurgitation, or noncompliance, parenteral administration by the intramuscular, subcutaneous, or intravenous route is preferred. Additional doses of oral vitamin K should be given at days 7 and 28 in breastfed infants.

Vitamin K-induced coagulopathy should be treated with vitamin K, which can be given by intravenous infusion or by subcutaneous injection (to minimize anaphylactoid reactions). Intramuscular injection should be avoided with severe deficiency because of the potential for hematoma formation. If there is bleeding, fresh frozen plasma (FFP) at a dose of 10 to 15 mL/kg body weight can be given. Owing to the potential for thrombotic complications, prothrombin complex concentrate should be reserved for life-threatening bleeding or situations where FFP may produce volume overload. Prothrombin complex concentrate has the added benefit of decreased volume load. In the absence of published guidelines, extrapolation from adult data suggests that a prothrombin complex concentrate dose of 50 units/

kg is sufficient. The overall prognosis of vitamin K deficiency bleeding is good.

Inherited Coagulation Disorders

Prolonged aPTT

In neonates, the aPTT is physiologically prolonged compared with adult values. Hemophilia is the most common inherited coagulation disorder, as discussed in detail in [Chapter 135](#). Evaluation for FVIII, FIX, and FXI deficiencies should be undertaken immediately in any neonate bleeding with an isolated prolongation of the aPTT or a positive family history. Cord blood samples can be used in those with a family history, thereby avoiding the need for peripheral venipuncture, but careful sampling is important to avoid maternal contamination of the sample. In term and preterm infants, FVIII levels are within the normal adult range despite physiologic differences in the hemostatic system. Thus confirmation of hemophilia A is possible in the neonatal period, regardless of gestational age of the child or severity of the condition. However, because the levels of the vitamin K-dependent clotting factors, including FIX, are reduced at birth (and even lower in preterm infants), diagnosis of hemophilia B, particularly mild hemophilia B, is difficult in the neonatal period.

Male newborns with a family history of hemophilia should be evaluated before receiving intramuscular injections, including vitamin K. Typically newborns with hemophilia and bleeding appear well. Male infants far outnumber females in this population, given the location of both FVIII and FIX genes on the X chromosome. However, severe FVIII or FIX deficiency can, albeit rarely, present in females, such as in Turner syndrome or extreme lyonization. Approximately one-third of cases of hemophilia are the result of spontaneous mutations; consequently a family history may be lacking. FXI deficiency is inherited in an autosomal dominant or recessive manner, so female newborns with bleeding and isolated prolongation of the aPTT should also be tested. Evaluation of hemophilia carrier status in mothers of unknown status (e.g., single prior affected child or positive history in maternal grandmother) can be performed genetically because factor levels in carriers are variable and can overlap with normal levels. Most bleeding episodes in newborn males occur after circumcision or umbilical stump separation, although ICH is reported in approximately 3.5% of newborns with hemophilia,¹⁵ and cephal-hematoma is common. Joint bleeding is unusual in the neonatal period. Patients with known or suspected hemophilia and those with severe deficiencies of FVII, FX, or FXIII should be screened for ICH. Although cranial ultrasonography is often used for screening purposes, computed tomography or magnetic resonance imaging is more sensitive for detection of small parafalcine bleeds, which can also occur in a small percentage of normal neonates.¹¹ Neonates with hemophilia A or B are treated with recombinant FVIII or FIX concentrates, respectively. Routine prophylaxis is controversial after uncomplicated term delivery but is recommended for high-risk situations, such as prolonged labor, forceps delivery, or for preterm infants.

Isolated Prolonged PT

In term neonates, the PT is normal. Inherited FVII deficiency is a rare, autosomal recessive condition with a strong gene dosage effect. Neonatal bleeding can occur in severe cases (i.e., homozygosity or compound heterozygosity for two mutations in the FVII gene). FVII deficiency can be associated with microcephaly or midline defects because disruption of chromosome 13q can lead to loss of adjacent genes. As a vitamin K-dependent protein, FVII deficiency can occur in association with deficiencies of the other vitamin K-dependent clotting proteins with abnormalities of the vitamin K pathways. Low doses of rFVIIa can be used for treatment of isolated FVII deficiency; FFP and/or vitamin K can be used for management of combined deficiencies.

Prolonged PT and aPTT

The association of bleeding with prolongation of both the PT and aPTT in a healthy newborn may indicate vitamin K deficiency or congenital deficiencies of prothrombin, FV or FX, as well as rare combined deficiencies. Routine prophylactic administration of vitamin K₁ to newborns can complicate the diagnosis of vitamin K deficiency bleeding in neonates.¹⁶ More commonly, combined PT and aPTT prolongation occurs in sick newborns with DIC or severe hepatic disease. Combined factor deficiencies are rare but must be considered when the laboratory findings or clinical course is confusing. Autosomal recessive mutations in LMAN1 (ERGIC-53) or MCFD2 can lead to combined FV and FVIII deficiency because of defective intracellular processing of the factors. Mutations in γ -glutamyl carboxylase are associated with inherited combined deficiencies of all the vitamin K-dependent proteins. FVII deficiency has rarely been reported in combination with FV, FVIII, FIX, FX, FXI, and protein C defects, as reviewed by Girolami et al.¹⁷

FXIII Deficiency

FXIII is a transglutaminase that cross-links fibrin, thereby rendering it resistant to lysis. FXIII deficiency is inherited in an autosomal recessive manner, and the prevalence of FXIII deficiency is estimated to be 1 in 3 million to 1 in 5 million. Homozygotes usually have FXIII levels of less than 1% and have a severe bleeding diathesis. Patients with heterozygous FXIII deficiency are usually asymptomatic but have reduced levels of FXIII.¹⁸ Neonates with FXIII deficiency may present with umbilical bleeding a few days after birth, a frequent finding that occurs in 80% of cases. More severe bleeding, including ICH, occurs in 25% to 30% of patients, a frequency higher than that in patients with hemophilia. ICH is the major cause of death and disability in neonates with FXIII deficiency, and ICH in a child with no other risk factors should prompt a search for FXIII deficiency.

FXIII deficiency is not detected with screening PT, aPTT, or thrombin time assays. Specific assays for FXIII or urea clot solubility testing are used for diagnosis. The clot solubility test is sensitive to very low levels of FXIII (<1%) but is normal if FXIII levels are in the 1% to 3% range. Consequently, FXIII immunoassays are preferable.¹⁸

Treatment of FXIII deficiency includes FFP, cryoprecipitate, or plasma-derived FXIII concentrate. The prognosis is excellent, but affected patients face a lifelong risk for bleeding, and those with severe deficiency require prophylaxis. In 2013, the US Food and Drug Administration approved a new recombinant FXIII A-subunit for use as routine prophylaxis in patients with FXIII deficiency.

Other Inherited Deficiencies Associated With Neonatal Bleeding

vWD, which is the most common inherited bleeding diathesis, is described in detail in [Chapter 138](#). vWD is rarely associated with neonatal bleeding and may be associated with the most severe subtypes. In a case series that included 55 newborns with vWD, there were no bleeding complications, although cases of scalp hematomas and bleeding after vitamin K injection or umbilical stump detachment were reported. Acquired forms of vWD also are rare but may complicate obstetric management of affected mothers and can affect their newborn babies. A family history of vWD, especially type 2 vWD, should prompt vWD evaluation in the neonate before circumcision and possibly before intramuscular injections. There is a possible association of vWD with acute idiopathic pulmonary hemorrhage. The diagnosis of vWD may be difficult because vWF concentrations are high at birth and there is a large proportion of high-molecular-weight vWF multimers. Children with a diagnosis of type 3 vWD should be tested for mutations that predispose them to inhibitory alloantibody formation before aggressive replacement with exogenous vWF.¹⁹ Treatment of neonates with vWD involves administration of

plasma-derived concentrates that contain vWF (e.g., Humate-P or Alphanate), dosed initially at 40 to 60 ristocetin cofactor units/kg.

Although most of the bleeding problems in neonates are acquired, patients with severe deficiencies of coagulation factors can present in the neonatal period. Autosomal recessive deficiencies, in either homozygous or compound heterozygous state, are grouped as rare coagulation disorders that can manifest as severe bleeding diatheses. In the neonatal period, severe deficiencies of fibrinogen, FVII, FX, and FXIII are the most likely disorders to present with bleeding conditions. One common feature of these disorders is the association with ICH.²⁰ Deficiency of fibrinogen can manifest with bleeding in the soft tissues, bleeding after circumcision, or bleeding after umbilical stump detachment. The diagnosis can be established with fibrinogen assays, and treatment involves replacement with cryoprecipitate or, if available, fibrinogen concentrate (see box on [Recommended Dosing for Transfusion in Neonatal Hemorrhage](#)). Severe FXI deficiency is more prevalent in Ashkenazi Jews and can present with bleeding in newborns after hemostatic challenges, such as circumcision. FV and prothrombin deficiencies are the other rare autosomal recessive homozygous deficiencies that can cause hemorrhagic symptoms.¹¹

Not all deficiencies result in a bleeding diathesis. Even complete deficiencies of the contact factors, which include high-molecular-weight kininogen, prekallikrein, and FXII, are not associated with a bleeding phenotype. Autosomal recessive deficiencies of α_2 AP and PAI-1 have been associated with bleeding, but not in the neonatal period.

Liver Disease

Acute liver disease or hepatic failure is uncommon in neonates. Liver disease in neonates may be caused by viral hepatitis, parenteral nutrition, cholestasis, hypoxic injury, or metabolic disease. Rare disorders that cause liver failure in neonates include hereditary tyrosinemia, neonatal hemochromatosis, and hemophagocytic lymphohistiocytosis. Liver dysfunction can affect the hemostatic balance, resulting in activation of the coagulation and fibrinolytic systems, reduced synthesis of coagulation factors, poor clearance of activated hemostatic components, thrombocytopenia, platelet dysfunction, loss of coagulation proteins into ascites fluid, and failure to use vitamin K.²¹

Owing to reduced synthesis of multiple coagulation proteins, laboratory workup typically reveals a prolonged PT and aPTT. Acute liver disease also results in elevated liver enzyme levels, direct hyperbilirubinemia, and elevated ammonia concentrations. The platelet count may be reduced, especially if hypersplenism is present, and platelet dysfunction is common. Hypofibrinogenemia is a late manifestation of liver disease, and elevated fibrin degradation products and

D-dimer occur because of delayed hepatic clearance. Assays of FV, FVII, and FVIII can help distinguish between liver disease, vitamin K deficiency, and consumptive coagulopathy (e.g., DIC). FV and FVIII are not vitamin K-dependent clotting factors. FV is synthesized in the liver, whereas FVIII is synthesized in multiple cell types, and the levels of both in neonates are similar to those in adults. Deficiency of all three implies consumption, whereas decreased levels of FV and FVII with a normal FVIII level suggest liver disease.

Treatment should include replacement with FFP and/or cryoprecipitate, as well as platelet transfusion. Fibrinogen concentrate has been used as an alternative to cryoprecipitate. Patients with biliary atresia or other cholestatic liver failure syndromes may also benefit from parenteral vitamin K. The outcome is dependent on treatment of the underlying cause of liver disease.

Intraventricular Hemorrhage

Intraventricular hemorrhage (IVH) is associated with significant morbidity and mortality in the newborn period, particularly in premature infants. In the United States, it is estimated that approximately 12,000 premature infants and 20% to 25% of very low-birth-weight infants develop IVH each year. With improvements in neonatal care, the incidence of IVH is decreasing.

The etiology of IVH is multifactorial and includes prematurity of the cerebral vasculature and ischemia-reperfusion injury related to ventilatory support, blood pressure lability, and ECMO. Other risk factors for IVH include vaginal delivery, severe respiratory distress syndrome (RDS), low Apgar scores, pneumothorax, hypoxia, hypercapnia, seizures, patent ductus arteriosus, and infection. Many of these risk factors induce IVH by altering cerebral blood flow. Coagulopathy and thrombocytopenia can contribute to IVH, but their role in the pathogenesis of IVH is uncertain. One study reported hypofibrinogenemia, thrombocytopenia, or prolonged clotting time in 11 of 15 neonates with IVH and in only 5 of 35 unaffected newborns. Hemorrhage complicating cerebral vein thrombosis may explain some cases of IVH (especially in full-term infants), and heterozygosity for the FV Leiden mutation was reported in 18% of neonates with grades 2 to 4 IVH compared with 3% of controls. Cerebellar hemorrhage should raise suspicion of organic acidemia, such as methylmalonic, propionic, or isovaleric acidemia.

Vitamin K, indomethacin, AT, FFP, FXIII, tranexamic acid, and ethamsylate has been evaluated for prevention of IVH with mixed results. rFVIIa may be useful for treatment of IVH, but additional studies are needed to determine its efficacy and safety.

Extracorporeal Membrane Oxygenation

ECMO is occasionally used for treatment of neonates with severe pulmonary hypertension or cardiomyopathy. The ECMO pump, oxygenation membrane, and large-bore catheters can induce thrombosis, which necessitates administration of high-dose systemic anticoagulation, thereby placing patients at risk for bleeding. Thrombosis and hemorrhage are common complications in pediatric ECMO patients, particularly if ECMO is initiated after open heart surgery. Approximately 15% of neonates on ECMO sustain an ICH.²²

With the doses of heparin used during ECMO, the PT and aPTT may not correlate with the activated clotting time (ACT). Furthermore, there is evidence that the heparin dose provides prognostic information in ECMO patients independent of the ACT, suggesting that an ACT of 180 to 220 seconds may not provide adequate anticoagulation. Prolonged ECMO is associated with depletion of clotting factors and high levels of fibrin degradation products. Consequently, the aPTT and ACT are prolonged and the levels of D-dimer are increased even when low doses of heparin are administered.

A retrospective study of 29 nonsurvivors of ECMO revealed that most patients have a coagulopathy characterized by a prolonged PT and aPTT, as well as being thrombocytopenic, and most had low

Recommended Dosing for Transfusion in Neonatal Hemorrhage

PRBC: 10 to 15 mL/kg single-donor PRBC infused over 4 hours
 Platelets^a: 10 mL/kg raises platelet count by 75,000 (goal >50,000 if bleeding, >20,000 if not bleeding)
 FFP: 10 to 20 mL/kg every 6 to 12 hours for purpura fulminans
 Cryoprecipitate: 0.15 units/kg raises fibrinogen about 100 mg/dL (goal >150 mg/dL if bleeding, >50 mg/dL if not bleeding)
 vWF: 40 to 60 ristocetin cofactor units/kg of plasma-derived FVIII/vWF preparations
 Factor VIII: for hemophilia A—50 units/kg load, then 25 units/kg every 12 hours; recombinant factor preferred (monitor FVIII)
 Factor IX: for hemophilia B—80 to 100 units/kg daily; recombinant factor preferred (monitor FIX)
 Factor VIIa: for severe factor VII deficiency—20 to 30 μ g/kg every 6 to 12 hours
 FFP, Fresh frozen plasma; PRBC, packed red blood cells; vWF, von Willebrand factor.
^aVolume limits transfusion of platelets by the “unit” in small neonates. Practices vary; follow institutional guidelines for volume dosing or volume reduction.

levels of fibrinogen despite ACT values that were within the acceptable range of 180 to 220 seconds in the final 24 hours of ECMO. Thus routine laboratory testing is inadequate for predicting or preventing thrombotic or hemorrhagic complications in pediatric ECMO patients. Thrombin generation assays, anti-FXa heparin levels, and thromboelastography have been suggested as alternatives to the ACT. Data supporting the use of these tests are lacking.

In neonates with established thrombosis or at risk for thrombosis, daily FFP infusion is sometimes used as a source of plasminogen and anticoagulant proteins. Data supporting this approach are lacking.

Respiratory Distress Syndrome

RDS, also known as *hyaline membrane disease*, is an acute pulmonary process that is common in premature neonates. The disorder is characterized by hyaline membrane formation and fibrin deposition in diffuse areas of atelectasis. Although severe RDS is associated with increased thrombin generation and decreased levels of AT, interventions aimed at addressing these abnormalities have yielded inconclusive results. Plasmin or plasminogen may enhance survival; heparin is of uncertain benefit, and AT supplementation may increase mortality. Additional studies are needed to explore the utility of anticoagulant or thrombolytic therapies in RDS. A laboratory profile consistent with mild DIC is common in RDS; fibrinogen levels are decreased, and levels of D-dimer are elevated. An unexpected increase in ventilatory support should raise the suspicion of pulmonary embolism in this population.

NEONATAL THROMBOEMBOLIC DISORDERS

The incidence of thromboembolism (TE) has a bimodal peak, with an increased occurrence in newborns and adolescents. Important risk factors for the development of neonatal TE include vascular catheterization, a hypercoagulable state conferred by the developing coagulation system, and comorbidities such as congenital heart disease, dehydration, sepsis, congenital nephritic syndrome, necrotizing enterocolitis, and asphyxia.³

Laboratory workup often reveals a hypercoagulable state such as decreased levels of AT, protein C, and protein S; defective fibrinolysis; hyperactive platelets; elevated levels of clotting factors (i.e., fibrinogen, FVII, FVIII); and the presence of antiphospholipid antibodies or thrombophilic defects, such as FV Leiden or the prothrombin gene mutation.¹⁻³ A family history of TE or miscarriages may indicate a hereditary thrombophilia.

Consensus guidelines have been developed for the management of neonatal TE.⁷ Heparin, either unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH), remains the mainstay of treatment in newborns. If the thrombus is limb or life threatening, thrombolytic therapy may be considered. Most recommendations are of low-grade level because the evidence in this patient population is derived from case reports, case series, registries, and extrapolation from studies in adults. Large, multicenter, prospective controlled clinical trials are needed to generate evidence-based guidelines; such studies are problematic in neonates.

Incidence

Current estimates of the incidence of neonatal TE are derived from three international registries, each with different inclusion criteria. Registry data from Canada, Germany, and the Netherlands indicate the incidence of TE in neonates to be 24 per 10,000 NICU admissions, 0.51 per 10,000 live births, and 14.5 per 10,000 live births, respectively.²³⁻²⁵ Two-thirds of thromboembolic events are venous, and 80% are either catheter associated or develop after a severe illness.²⁶ Arterial thromboembolic events in neonates usually present as strokes or emboli to the limbs from catheter-associated thrombi. Neonatal TE is associated with significant mortality and morbidity.

Acquired Thrombophilia

Indwelling Catheters

Central venous and arterial access is essential for the advanced care provided in modern neonatology. The most common acquired thrombotic risk factor in neonates is the presence of an indwelling vascular catheter. In a recent literature review by Park et al,²⁷ the incidence of TE in neonates with central venous catheters was 9.2%. Length of catheter stay, infusion of blood products, and malpositioned umbilical venous catheters were found to be important risk factors. The most frequently reported sites of thrombosis are hepatic veins, right atrium, and inferior vena cava.²⁵ The incidence of catheter-associated deep vein thrombosis (DVT) is influenced by the method of detection. When catheters are used for total parenteral nutrition, it is estimated that DVT is diagnosed in 1% on clinical grounds, in 35% by echocardiography, and in 75% by venography. Although contrast venography is regarded as the reference standard for the diagnosis of thrombosis in neonates with central venous catheters, ultrasonography is more commonly used because it is noninvasive, is easy to perform at the bedside, and does not expose patients to ionizing radiation.

DVT often causes pain, swelling, and discoloration of the affected limb. Loss of catheter patency, evidence of collateral circulation, and/or unexplained thrombocytopenia should raise the suspicion of DVT. Prospective imaging studies performed before central access catheter removal demonstrate thrombi in up to 86% of patients.²⁴ Treatment often begins with removal of the catheter, although consideration of anticoagulation before catheter removal is warranted, especially in infants with right-to-left intracardiac or intrapulmonary shunting. Small catheter-associated thrombi may resolve without specific therapy. Larger thrombi or those in locations associated with greater morbidity (e.g., sinovenous, renal, portal) may warrant short courses of heparin or thrombolytic agents.⁷ Platelets should never be administered through arterial catheters because of the potential risk for TE.

Disseminated Intravascular Coagulation

Neonates are susceptible to DIC because of their immature anticoagulant and fibrinolytic systems. Most cases of neonatal DIC are associated with tissue ischemia and acidosis secondary to sepsis, low-output cardiac failure, perinatal asphyxia, severe RDS, or necrotizing enterocolitis. Other causes of DIC are conditions that lead to consumptive coagulopathy such as large vascular anomalies, severe liver disease, massive hemolysis, or hereditary thrombophilia. DIC may present with hemorrhage and/or TE. Bleeding in a well-appearing neonate is usually the result of an inherited deficiency of a coagulation protein or immune-mediated thrombocytopenia rather than DIC. In contrast, bleeding in a sick preterm neonate is more likely the result of DIC. Patients with DIC often exhibit a prolonged PT, aPTT, and thrombin clotting time, decreased fibrinogen and FVIII levels, thrombocytopenia, and increased levels of D-dimer (Table 150.6).

Definitive therapy requires identification and reversal of the trigger for DIC. FFP, platelets (if bleeding is severe), and cryoprecipitate (if the fibrinogen concentration is low) are given to replace the consumed factors. Reasonable treatment targets include maintaining the fibrinogen level over 100 mg/dL, the platelet count over $50 \times 10^9/L$, and the PT close to normal. Heparin should be given if there is TE along with AT concentrate if indicated. Successful treatment of DIC depends on reversal of the trigger and provision of aggressive supportive care. Therapy aimed at reversing the coagulopathy has little effect on DIC outcome.

Hereditary Thrombophilia

Spontaneous TE is rare in healthy newborns, and this presentation should prompt evaluation for hereditary thrombophilia. Among the

TABLE 150.6 Diagnosis of Neonatal DIC

aPTT, Activated partial thromboplastin time; FDPs, fibrin degradation products; PT, prothrombin time; TCT, thrombin clotting time.

known causes of hereditary thrombophilia, only homozygous or compound heterozygous protein C and/or protein S deficiency is sufficient to induce neonatal TE. Other inherited thrombophilic conditions include FV Leiden, prothrombin mutation, AT deficiency, elevated lipoprotein(a), maternal anticardiolipin antibodies, and nonspecific inhibitors.

Hereditary thrombophilia should be suspected in patients with spontaneous and extensive TE, ischemic skin lesions, or purpura fulminans. The Subcommittee for Perinatal and Pediatric Thrombosis of the Scientific and Standardization Committee of the International Society on Thrombosis and Haemostasis recommended that pediatric patients with spontaneous TE be tested for a full panel of genetic and acquired thrombophilic defects.²⁸ However, because of the difficulty in obtaining a large volume of blood, one can consider performing these tests in stages unless the result of the testing has immediate impact on patient management. On initial presentation of TE, DNA-based assays can be performed. Testing for levels of natural coagulation inhibitors should be delayed until 6 months of age when the levels approach those in adults and until anticoagulant treatment is discontinued.

Specific Neonatal Thrombotic Syndromes

Renal Vein Thrombosis

The renal vein is one of the most common sites of neonatal thrombosis. The incidence of RVT is estimated to be 0.5 per 1000 NICU admissions and 2.2 per 100,000 live births.^{23,25} RVT is more common in males and in the left renal vein, although 28% to 44% occur bilaterally. Two-thirds of neonates with RVT present within 3 days postnatally, whereas 7% of neonates can present with RVT in utero.²⁹ Most common clinical manifestations of RVT include hematuria, palpable flank mass, and thrombocytopenia. Neonates may also have coexisting hypertension, proteinuria, renal failure, adrenal hemorrhage, and anemia. RVT is associated with prematurity, umbilical venous catheters, diabetic mothers, asphyxia, and infections. FV Leiden, prothrombin gene mutation, and elevated lipoprotein(a) have also been found in association with RVT. However, these are common traits, and it would be inaccurate to say they are proven to be causal, despite the associations. Most infants with RVT will experience complete, cortical, or segmental infarction of the affected kidney(s) and/or hypertension.²¹

Diagnosis is reliably confirmed by Doppler ultrasound examination. There are no evidence-based treatment guidelines, and most cases of RVT result in loss of renal tissue, regardless of the treatment.²⁹ Neonates with RVT should be followed for persistent hypertension and progressive renal insufficiency. Unilateral RVT without uremia or clot extension into the inferior vena cava can be managed with heparin or LMWH. Treatment should be given for at least 3 months if there is extension into the inferior vena cava. Bilateral RVT with renal failure should be treated with thrombolytic therapy followed by heparin or LMWH.⁷

Portal Vein Thrombosis

The true incidence of portal vein thrombosis (PVT) is unknown, but it is estimated to range from 1% to 43% of neonates with umbilical venous catheters.³⁰ The wide variation in incidence reflects differences in imaging protocols. In another study, the incidence of PVT was estimated to be at least 36 cases per 10,000 NICU admissions.³¹ When ultrasonography is performed prospectively, 43% of neonates with umbilical venous catheters have asymptomatic PVT.

Major risk factors for PVT include umbilical venous catheters and sepsis/omphalitis. The role of inherited thrombophilia in PVT is controversial. There are multiple studies reporting on the association of inhibitor protein deficiencies (protein C, protein S, and AT) with PVT; however, it is difficult to ascertain whether the deficiencies are genetic or acquired, because the testing is done in the presence of TE.³⁰ Long-term complications of PVT include lobar atrophy and portal hypertension with associated gastrointestinal bleeding. Complications are more frequent with ectopic umbilical venous catheter placement (below or in the liver) or when thrombi are occlusive. Ultrasonography may reveal evidence of prior PVT with cavernous transformation of the portal vein and subsequent splenomegaly and reversal of portal flow.³² Spontaneous resolution of PVT is common, but detection of PVT is important, even in asymptomatic patients, because PVT can lead to portal hypertension, which may manifest up to 10 years later.³² Neonates with umbilical venous catheters should be monitored by ultrasonography, and catheter removal and/or anticoagulation should be considered for PVT.

Purpura Fulminans

Purpura fulminans is characterized by disseminated purpuric lesions often associated with bullae and necrosis. The histopathology of these lesions reveals diffuse cutaneous microthrombi with surrounding hemorrhage. Diffuse thrombosis, including stroke, retinal infarcts, limb gangrene, and DIC, can occur in purpura fulminans. Causes include severe protein C, protein S, or AT deficiency, either acquired as a complication of sepsis or inherited as homozygous or compound heterozygous conditions. Some infants with severe protein C deficiency do not develop TE until adulthood, suggesting that additional factors influence the neonatal presentation. Treatment with heparin and replacement with protein C concentrate or FFP are indicated. Long-term anticoagulation is often needed.³³

Arterial Ischemic Stroke

Perinatal arterial ischemic stroke (AIS) is an important cause of cerebral palsy, epilepsy, and cognitive impairment. Perinatal AIS mostly occurs in full-term neonates with a prevalence of 28.6 to 93 cases per 100,000 live births. Presenting features include seizures and lethargy. In the neonatal period, AIS often presents with focal or generalized seizures, although pathologic hand preference before 1 year of age is most common if the stroke was asymptomatic in the newborn period. Ischemic injury is usually detected by magnetic resonance angiography, and unilateral lesions favor the left hemisphere. Diffusion-weighted magnetic resonance imaging is superior to cranial ultrasonography or computed tomographic scanning.⁷

Risk factors for perinatal AIS are different from TE risk factors in older infants and children because maternal and placental factors play a more important role, and some events even occur in utero.³⁴ The most common acquired risk factors for perinatal AIS are perinatal asphyxia, fetal distress, chorioamnionitis or other infections, preeclampsia, congenital heart disease, and dehydration. The contribution of congenital thrombophilia to perinatal AIS risk is unclear, although maternal anticardiolipin antibodies may be present for a brief period. In most cases of perinatal AIS, a hypercoagulable state is not detected. One potential mechanism

of stroke is embolism of placental thrombi via the umbilical vein and through the patent foramen ovale of the fetus or neonate. Evaluation of placental pathologic conditions is important because demonstration of placental thrombi or abruption may be indicative of maternal prothrombotic state. Furthermore, if placental thrombi are seen histologically, the risk for recurrent events is especially low. Long-term developmental outcomes depend on the extent of the stroke and location of the lesion; strokes involving Broca and Wernicke areas, the internal capsule, or the basal ganglia have a poor outcome.

Treatment depends on whether the stroke is embolic or nonembolic in origin. For nonembolic AIS, current guidelines recommend against anticoagulation or aspirin for neonates with first AIS, especially if the infarct is large or there is evidence of hemorrhage. Anticoagulant or aspirin therapy is recommended for neonates with recurrent AIS.⁷ In a patient with a documented cardioembolic stroke, anticoagulant therapy is suggested.

Cerebral Sinovenous Thrombosis

Based on data from the Canadian Pediatric Ischemic Stroke Registry, the prevalence of cerebral sinovenous thrombosis (CSVT) is 0.67 per 100,000 children, with 43% occurring in the neonatal period.³⁵ The clinical presentation may be relatively silent, or patients may manifest with diffuse neurologic changes, seizures, and IVH. The most frequently involved vessels are the superior and lateral sinuses, and up to one-third of cases have associated venous infarction and subsequent hemorrhage.²¹ Up to 31% of full-term neonates with IVH have associated CSVT, suggesting that the pathophysiology of IVH in full-term neonates is different from that in premature infants.

Risk factors for neonatal CSVT include perinatal asphyxia, diffuse hypoxic injury, dehydration, infection, congenital heart disease, and severe illness, with ECMO now recognized as a specific risk factor. The frequency of hereditary thrombophilia in neonates with CSVT ranges from 20% to 40%, with FV Leiden and MTHFR C677T occurring most often. In contrast to purpura fulminans, no cases of congenital deficiencies of protein C, protein S, or AT have been reported in association with CSVT. Multiple risk factors (maternal, neonatal, perinatal, or prothrombotic) are found in over half of neonates with CSVT.⁷ Although the diagnosis of CSVT in neonates is often made by transcranial ultrasonography, magnetic resonance venography is the most sensitive diagnostic test. On the basis of data from the Canadian Pediatric Ischemic Stroke Registry, neonatal CSVT is associated with cerebral parenchymal infarcts in 42% of cases, and 83% of these are hemorrhagic infarcts.³⁵

Aside from treatment of the underlying conditions, when relevant, there are no standard treatment guidelines. Nonetheless, good results have been obtained with anticoagulant therapy, and UFH or LMWH is given, provided that there is no significant ICH. Extended treatment with LMWH or a vitamin K antagonist is recommended for a minimum of 6 weeks and no longer than 3 months.⁷ The goal of anticoagulation is not to prevent recurrence; rather, it is to prevent progression and minimize neurologic sequelae. In a study by Kenet et al,³⁶ none of the 75 neonates with CSVT had a recurrence after a median follow-up of 36 months. For those with significant hemorrhage, radiologic monitoring at 5 to 7 days is recommended, and anticoagulation should be initiated if there is evidence of thrombus propagation.⁷ Anticoagulation is associated with a high rate of hemorrhage, so treatment plans should be individualized. In older patients, punctate hemorrhage behind a cerebral venous infarct is not an absolute contraindication to anticoagulation, but studies in neonates are lacking. Nevertheless, in the Canadian registry, 36% of neonates were treated with UFH or LMWH, mostly for 3 months, and no cases of death or neurologic compromise from hemorrhage were reported.³⁵ Overall, neurologic impairment was reported in up to two-thirds of cases, and approximately 2% died.

Principles of Therapy

Supportive Therapy

As with other age groups, therapeutic modalities available to neonates include supportive care, anticoagulation, thrombolytic agents, and surgical thrombectomy. The British Haemostasis and Thrombosis Task Force and the American College of Chest Physicians have proposed guidelines for the management of neonatal TE.³⁷ Supportive therapy is recommended for clinically silent thrombi, including catheter-associated events. As soon as practical, clotted catheters should be removed, and all documented thrombi should be followed by serial imaging. If venous access is required, one can either monitor the clot closely or provide anticoagulation therapy.

Vitamin K Antagonist Therapy

Vitamin K antagonists, such as warfarin, are not recommended for neonates, because liquid preparations are not available, monitoring is complicated, and doses are variable owing to alterations in the dietary intake of vitamin K.

Heparin (UFH or LMWH)

UFH or LMWH is the mainstay of anticoagulant therapy in neonates. The UFH and LMWH dosing regimen is outlined in the box on Treatment of Neonatal TE. Neonates require higher doses of heparin than adults, owing to lower native AT levels, increased volume of distribution, and faster clearance.^{3,38–40} Additionally, they may require supplementation with AT concentrate or FFP in cases of heparin resistance. Anticoagulation is monitored using anti-FXa assays. Therapeutic anti-FXa levels are 0.3 to 0.7 units/mL for UFH and 0.5 to 1 units/mL for LMWH. There are two types of anti-FXa assays: (1) with exogenous AT added and (2) without exogenous AT. The addition of exogenous AT allows measurement of the UFH effect without the influence of AT deficiency (if present), whereas the anti-FXa assay without exogenous AT allows measurement of the *in vivo* UFH effect.⁴¹ Studies comparing the two types of anti-FXa assays found a lack of correlation. Hence, it is necessary to know the type of anti-FXa assay conducted in a particular laboratory when interpreting results. In neonates, the discrepancy between assays may also be increased owing to lower baseline AT levels.³ The aPTT level can also be used to monitor UFH; aPTT values that correlate with anti-FXa levels of 0.3 to 0.7 units/mL are considered therapeutic.

Prophylactic UFH is recommended to maintain patency of umbilical arterial lines (0.25–1 units/mL, 25–200 units/kg/day, the lowest dose possible) and for cardiac catheterization (bolus dose of 100–150 units/kg with catheter insertion, repeat for prolonged procedures). In most other cases, LMWH has emerged as the anticoagulant of choice in the neonatal setting, both for prophylaxis and for treatment. The advantages of LMWH include better bioavailability, longer half-life allowing twice-daily administration, dose-dependent clearance, predictable anticoagulant response, and a lower risk of heparin-induced thrombocytopenia (HIT) and osteoporosis than with UFH. Although the current American College for Chest Physicians guidelines recommend a dose of 1.5 mg/kg of LMWH for treatment of neonatal TE,⁷ there is growing evidence to suggest that neonates may, in fact, require higher doses up to 1.7 mg/kg and 2.0 mg/kg for term and preterm neonates, respectively, to obtain a therapeutic anti-FXa level.⁴²

HIT antibodies are found in up to 1.5% of neonates, particularly in those who have undergone cardiac surgery. Overt HIT with TE, however, is rare, but it can occur. Mothers with HIT can passively immunize their fetuses. Diagnostic criteria for HIT are described in detail in Chapter 133. Treatment includes cessation of heparin and anticoagulation with argatroban, danaparoid, or lepirudin.⁴³

Treatment of Neonatal Thromboembolism

Unfractionated Heparin (UFH)

Bolus: 75 units/kg over 10 minutes
 Maintenance: 28 units/kg/h; therapeutic goal, anti-FXa of 0.3 to 0.7 units/mL

Prophylaxis: 10 units/kg/h

Follow platelet count to detect possible HIT (risk is low)

Enoxaparin

1.5 mg/kg subcutaneously every 12 hours (with normal renal function; round dose to nearest milligram; consider higher dose [see text]⁴²)

Check anti-FXa level by peripheral venipuncture 4 to 6 hours after second or third dose; therapeutic goal, anti-FXa of 0.5 to 1 units/mL (0.4 to 0.6 units/mL if concurrent thrombocytopenia or other bleeding risk factor)

Follow platelet count to detect possible HIT (risk is low)

Hold for 24 hours before procedures

Prophylaxis With Enoxaparin

0.75 mg/kg subcutaneously every 12 hours

If checked, anti-FXa level 4 to 6 hours after second or third dose should be less than 0.4 units/mL

Hold for 12 hours before procedures

Purpura Fulminans

Concurrent heparin: UFH dose of 28 units/kg/h with target anti-FXa of 0.3 to 0.7 units/mL; LMWH dose of 1.0 to 1.5 mg/kg every 12 hours with therapeutic target anti-FXa range of 0.5 to 1 units/mL and replacement with FFP or protein C concentrate

FFP: 10 to 20 mL/kg every 6 to 12 hours for purpura fulminans
 Protein C concentrate for severe protein C deficiency: load with 100 to 120 units/kg, then 60 to 80 units/kg every 6 hours × three doses (goal protein C activity 100%). Once therapeutic anticoagulation is achieved, maintenance therapy with 45 to 60 units/kg every 6 to 12 hours (goal protein C activity >25%).

Antithrombin Repletion

AT (functional) should be maintained at greater than 50% of normal levels for effective heparin-based anticoagulation

Dose in international units = (desired – current AT^a)

× weight (kg)

AT, Antithrombin; FFP, fresh frozen plasma; HIT, heparin-induced thrombocytopenia; LMWH, low-molecular-weight heparin; TE, thromboembolism; UFH, unfractionated heparin.

^aExpressed as percentage of normal level based on functional AT level.

Tissue Plasminogen Activator Thrombolysis for Neonatal Thromboembolism

Concurrent Heparin (UFH or Enoxaparin) Should Be Considered at Prophylactic Dosing; UFH Preferred

Life- or limb-threatening thrombi: starting dose of 0.1 to 0.5 mg/kg/h for up to 6 hours

If no response, consider increase by 0.1 mg/kg/h increments to maximum 0.5 mg/kg/h

Consider using FFP 10 mL/kg before thrombolytic therapy

Maintain fibrinogen greater than 100 mg/dL

Maintain platelet count above $100 \times 10^9/L$

Reversal of severe bleeding with aminocaproic acid at 100 mg/kg intravenously every 6 hours

FFP, Fresh frozen plasma; TE, thromboembolism; t-PA, tissue plasminogen activator; UFH, unfractionated heparin.

Low-dose thrombolysis is recommended to open occluded catheters. t-PA is the drug that has been most widely studied in pediatric patients. Transfusion support for hypofibrinogenemia and thrombocytopenia should be provided to minimize the bleeding risk. Contraindications for thrombolytic therapy include active bleeding and major surgery or bleeding within the past 10 days, whereas relative contraindications include severe asphyxia within 7 days, generalized seizures within the last 48 hours, sepsis, or prematurity of less than 32 weeks of gestation. If UFH or LMWH is given concomitantly with t-PA, it should be administered at prophylactic doses (0.75 mg/kg every 12 hours for LMWH or 10 units/kg/h for UFH; see box on **t-PA Thrombolysis for Neonatal TE**). Surgical thrombectomy is reserved for organ-, limb-, or life-threatening thrombosis when t-PA administration is impractical or predicted to be ineffective. Thrombolytic therapy may be of benefit in a select group of pediatric patients with massive pulmonary embolism or extensive DVT.

Fondaparinux may be a reasonable option in selected cases, but experience in neonates is limited.

Thrombolytic Therapy

Guidelines for thrombolytic management of neonatal TE are provided by the British Haemostasis and Thrombosis Task Force³⁷ and the Scientific Subcommittee on Perinatal and Pediatric Thrombosis of the International Society of Thrombosis and Haemostasis.⁴⁴ Both groups agree that thrombolysis should be considered for extensive TE associated with organ dysfunction or limb-threatening ischemia.

CONSULTATIVE HEMATOLOGY

This page intentionally left blank

HEMATOLOGIC CHANGES IN PREGNANCY

Caroline Cromwell and Michael Paidas

Hematologic conditions are often seen during pregnancy. These range from the simple to the complex. The primary physiologic hematologic changes during pregnancy relate to the expansion of plasma volume.¹ In addition to physiologic changes of pregnancy, a prothrombotic state develops as the pregnancy advances that is thought to prepare the mother and fetus for eventual placental separation.² All require proper planning, anticipation, and discussion with the treating physicians as well as the patient. The effect of the condition on the pregnancy, and conversely the effect of the pregnancy on the condition, should be considered. The evolving clinical picture as the pregnancy progresses must also be taken into account. Multidisciplinary planning and communication are essential.

Anemia and thrombocytopenia are common hematologic conditions seen for a variety of reasons during pregnancy and are addressed in this chapter. Inherited and acquired bleeding disorders affect pregnant women, and coagulation parameters must be monitored during pregnancy and delivery. Venous thromboembolism (VTE) during pregnancy remains a high-morbidity, high-risk situation that is challenging for clinicians. These more common hematologic problems and dilemmas in management are discussed in this chapter.

ANEMIA IN PREGNANCY

Anemia in pregnancy affects approximately half of all pregnancies worldwide. It is more prevalent in underdeveloped countries.

The World Health Organization classifies anemia in pregnancy as hemoglobin below 11 g/dL, although in developing countries it is clinically defined as hemoglobin below 10 g/dL.¹ Physiologic anemia occurs during pregnancy as the blood volume increases to a greater proportion than the red blood cell (RBC) mass, resulting in a dilutional anemia. Total circulatory volumes increase by approximately 50% greater than the prepregnancy volume. Plasma volume and RBC mass return to baseline during the first and second postpartum months. Common maternal signs of anemia include pallor, tachypnea, fatigue, and headache. Hemoglobin levels less than 6 g/dL in pregnant women can be associated with significant maternal and fetal complications. At these levels, tissue oxygenation decreases and may lead to high-output congestive heart failure in the mother.²⁻⁴ Multiple studies have shown a correlation between maternal anemia and increased rates of both preterm (<37 weeks of gestation) and low-birth-weight deliveries.⁵⁻¹³ There are varied etiologies behind anemia in pregnancy.

Iron-Deficiency Anemia

Iron-deficiency anemia is the most common cause of anemia in pregnancy. It has been identified as a risk factor for preterm delivery and low birth weight. Iron requirements increase during pregnancy because of maternal and fetal erythropoiesis. Generally, hemoglobin levels decrease throughout pregnancy and then may increase during the last month of pregnancy. Ferritin levels also increase in the last month of pregnancy because it is an acute-phase reactant. Erythropoietin levels increase throughout pregnancy. The clinical symptoms of iron deficiency are similar to those in nonpregnant patients and include fatigue, pallor, tachycardia, and poor exercise tolerance. The diagnosis and treatment of iron-deficiency anemia are generally

similar to those in nonpregnant patients. Anemia and low ferritin levels are considered diagnostic.

Because the typical diet in the United States provides only 50% of daily iron requirements for pregnant women and because of the relatively high prevalence of iron deficiency among women of child-bearing age, routine iron supplementation in pregnancy is recommended.¹⁴ Currently, the Centers for Disease Control and Prevention, the American Dietetic Association, and the American College of Obstetrics and Gynecology recommend 15 to 30 mg/day of elemental iron to prevent adverse outcomes from iron-deficiency anemia.¹⁴⁻¹⁸ Treatment should be from the beginning of gestation to 3 months postpartum. On the basis of results of a study by Casanueva et al,¹⁹ weekly therapy with 120 mg of iron appears to be a safe and effective alternative to daily therapy. The side effects associated with iron therapy—constipation, diarrhea, nausea—are well known.

Intravenous iron is appropriate in certain circumstances; evidence from a recently published randomized trial by Al et al supports the use of intravenous iron therapy to replenish iron stores in appropriately selected patients, including those who have not tolerated a trial of oral iron therapy and those with severe iron deficiency.²⁰

Multiple studies have shown that routine iron supplementation in pregnancy decreases the incidence of iron-deficiency anemia. In a randomized, double-blind study in which 275 iron-replete pregnant women received either a daily iron supplement or placebo from the time of enrollment (all women were enrolled before week 20) to 28 weeks of gestation, the incidence of both low-birth-weight and preterm low-birth-weight infants was lower among women who received daily iron.²¹ Nonetheless, there are limits to the effectiveness of routine iron supplementation. After all, the recommendation by prominent public health organizations for universal iron supplementation has not led to a commensurate decrease in the incidence of iron-deficiency anemia in pregnancy^{22,23} or an increase in maternal hemoglobin levels.^{24,25} Compliance is an important factor in this discussion. A large, multicenter, randomized, controlled trial on the benefits of iron supplementation during pregnancy in the United States is needed to draw more definitive conclusions.

Other Nutritional Deficiencies

Folate deficiency and, less commonly, vitamin B₁₂ deficiency are the next most common causes of anemia in pregnancy. Cobalamin and folate are critical for fetal growth because they are necessary for the production of tetrahydrofolate. Tetrahydrofolate is key in the DNA synthesis pathway.

Folate deficiency accounts for 95% of megaloblastic anemias in pregnancy.²⁶ Folate deficiency complicates between 1% and 4% of pregnancies in the United States and affects approximately one-third of pregnancies worldwide.²⁷ Similar to iron-deficiency anemia, the incidence of megaloblastic anemia in pregnancy is increased in adolescents, women of low socioeconomic status, and women with multiple closely spaced births.²⁸ The folic acid requirement for nonpregnant women is 50 to 100 µg/day, but this increases to 150 µg during pregnancy as RBC mass in the mother increases and as fetal demands for folate grow with cell proliferation.²⁹

Diagnosis of folate deficiency is best based on RBC folate levels. An elevated homocysteine level also helps confirm the diagnosis. Pregnant women should at least receive 400 µg of folic acid per day. Vitamin B₁₂ deficiency is much less common during pregnancy.

Diagnosis of vitamin B₁₂ deficiency can be aided by the assessment of homocysteine and methylmalonic acid. If a woman is found to be deficient in vitamin B₁₂ during pregnancy, vitamin B₁₂ injections are indicated. These are usually injected weekly for 4 to 8 weeks and then monthly.

HEMOGLOBINOPATHIES AND PREGNANCY

Sickle Cell Disease

Every year more than 300,000 children are born with either sickle cell disease or thalassemia. Prenatal counseling now exists in many countries. In the United States, all newborns are screened for sickle cell disease (see [Chapters 42 and 43](#)). Management of pregnant patients with sickle cell disease requires coordination of care between the hematologist and obstetrician. Many women with sickle cell disease experience more frequent vasoocclusive crises and other sickle cell–related complications during pregnancy.³⁰ The increased frequency of vasoocclusive crises, particularly during the latter half of pregnancy, likely results from heightened metabolic requirements in pregnancy, increased venous stasis, as well as the physiologic prothrombotic and inflammatory state associated with pregnancy. In addition, pathophysiologic changes in the renal and immune function of patients with sickle cell disease increase their susceptibility to urinary tract infections and pyelonephritis. By causing tissue hypoxia, sickling of RBCs within the placental vasculature may cause deleterious effects on the fetus.³¹

Additional significant complications occur in pregnant women with sickle cell disease. The incidence of preeclampsia, thromboembolic events, placental abruption, intrauterine growth retardation, low birth weight, and postpartum infections are higher among women with hemoglobin SS, SC, and S β -thalassemia than among women without sickle cell disease. One study noted a higher incidence of stillbirths and perinatal mortality among patients with sickle cell disease,³² but another study revealed an increased risk of preterm labor and premature rupture of membranes in women with hemoglobin SS disease.³³ Despite advances made in sickle disease, a recent meta-analysis highlights that risks for pregnancy in patients with SS genotype remains high with regard to mortality, a fourfold higher risk of stillbirth and a 2.43 higher relative risk of preeclampsia. These risks were amplified in low-income countries. Because of the increased risk for such complications, women with sickle cell disease should receive close medical attention throughout the prenatal period. This includes counseling about intrauterine diagnosis of sickle cell disease when appropriate. Pregnant women can undergo chorionic villi sampling as early as the ninth week of gestation or amniocentesis in the 15th to 16th weeks. A reticulocyte count along with hemoglobin, iron, and folate levels should be obtained to assess for deficiency states and bone marrow suppression. Urinalysis with urine culture is performed as often as every trimester to monitor for asymptomatic bacteriuria. Finally, beginning around 28 weeks of gestation, patients should have weekly clinic visits and begin serial ultrasonography.

Treatment of sickle cell disease during pregnancy warrants careful consideration. Hydroxyurea should be avoided. If pregnancy is being considered it should be discontinued. Women should receive 5 mg/day of supplemental folic acid. Studies examining the benefit of prophylactic blood transfusions or exchange transfusions have not led to definitive conclusions.³⁴ Although they may lead to alloimmunization, prophylactic transfusions appear to decrease the incidence of vasoocclusive crises and decrease maternal and fetal morbidity and mortality.³⁵ A conservative approach reserves transfusions for patients whose hemoglobin levels fall below 6 g/dL, patients who develop progressive complications related to sickle cell disease, and patients with obstetric complications.³⁶ Following this approach, 60% to 75% of women with sickle cell disease will require transfusion therapy during pregnancy. Patients with a sickle cell crisis during pregnancy should receive aggressive analgesic therapy, hydration, and oxygen while undergoing evaluation for infection or other precipitating influences.

At the time of delivery, pregnant women with sickle cell disease are managed in a manner similar to those with high cardiac output anemia. Supplemental oxygen, hydration, and adequate oxygenation during anesthesia should be given to prevent sickling of RBCs and the associated complications. During the postpartum period, hemoglobin levels are followed closely, and prophylaxis for VTE is administered unless contraindications preclude it.

Thalassemias

Pregnant women with an underlying thalassemia typically have β -thalassemia minor or α -thalassemia trait—conditions with a relatively benign clinical phenotype—rather than β -thalassemia major or hemoglobin H disease (see [Chapter 41](#)). Because of delayed pubertal growth or hypogonadism with associated anovulation, women with β -thalassemia major and hemoglobin H disease rarely become pregnant. Case reports indicate that when it does occur, pregnancy in women with hemoglobin H disease can be complicated by severe hemolytic anemia and hepatosplenomegaly. However, in the setting of widespread transfusion and iron chelation therapy, pregnancy is more frequent in the thalassemia population. Pregnancy outcomes among women with β -thalassemia major were recently examined in 10 patients with homozygous β -thalassemia. Of 15 pregnancies, there were 14 live births, a 20% incidence of intrauterine growth restriction (IUGR), and 21% were low-birth-weight children. In patients with β -thalassemia intermedia, approximately 50% of pregnancies are complicated by preterm delivery, third-trimester stillbirth, or IUGR.³⁷

Pregnancy is a common setting for the diagnosis of β -thalassemia minor or α -thalassemia trait in previously asymptomatic women who are found to be anemic on routine laboratory evaluation during pregnancy. Several studies indicate that the physiologic anemia of pregnancy may be exacerbated in women with thalassemia minor, although findings from at least one study suggest otherwise.³⁸ β -Thalassemia minor and α -thalassemia traits do not have an adverse effect on fetal development, fetal morbidity and mortality, or maternal morbidity and mortality.³⁹

Similar to those with sickle cell disease, women with thalassemia require vigilant follow-up throughout their pregnancies. This includes interval monitoring of maternal vital signs and fetal heart rate, maternal hemoglobin levels, and fetal growth as assessed by ultrasonography beginning around the 24th week of gestation. Patients are screened for folate and iron deficiency. They should also be assessed for iron overload, which can develop in individuals with thalassemia as a result of increased intestinal iron absorption, frequent blood transfusions, and rapid turnover of plasma iron.⁴⁰ Prenatal genetic testing can be performed if desired, with results used to counsel parents of the child and guide optimal care of the fetus. In terms of therapy, there are no specific treatment recommendations for women with thalassemia during pregnancy, aside from folate supplementation and supportive care. In pregnant women with evidence of iron overload, chelation therapy using deferoxamine has been used safely, although the potential for teratogenicity associated with the agent must be considered in this setting.⁴¹

OTHER HEMOLYTIC ANEMIAS

Hereditary Spherocytosis

Hereditary spherocytosis is the most common inherited hemolytic anemia among people of northern European descent (see [Chapter 46](#)).⁴² Few cases of pregnancy in individuals with hereditary spherocytosis have been reported. Published reports indicate there may be an increased incidence of first trimester fetal loss in patients with hereditary spherocytosis.⁴³ Because some patients have only low levels of hemolysis under normal conditions, the disease may not become clinically apparent until pregnancy. Pregnant women with hereditary spherocytosis can exhibit a variety of clinical manifestations. These include folate deficiency related to the increased requirements of

pregnancy superimposed on chronic hemolysis, hemolytic crisis, and aplastic crisis.^{44,45} The results of two small series suggest that pregnancy outcomes for women with hereditary spherocytosis are generally good, with improvements in outcomes for splenectomized patients.⁴⁶ Care is primarily supportive.

Glucose 6-Phosphate Dehydrogenase Deficiency

Favorable pregnancy outcomes observed in women with hereditary spherocytosis and pyruvate kinase deficiency stand in contrast to those in women with glucose 6-phosphate dehydrogenase (G6PD) deficiency. The deficiency of G6PD leads to hemolytic anemia in the face of oxidative stress (see Chapter 45). The condition increases the risk of spontaneous abortion, low-birth-weight fetuses, and neonatal jaundice.⁴⁷ Women with G6PD deficiency should be instructed to strictly avoid medications with oxidative potential. Complications after the ingestion of oxidative drugs can even occur in a carrier of the G6PD deficiency gene if her male fetus has inherited the disease.⁴⁸

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare clonal disorder caused by somatic mutation in the membrane-anchoring protein *PIGA* (see Chapter 32). *PIGA* mutation leads, in turn, to deficient function of critical membrane proteins that in wild-type individuals are anchored by the gene product of *PIGA*. Features of the clinical phenotype include hemolysis, thrombosis, and bone marrow failure. Hemolysis results from deficiency in the membrane proteins CD55 and CD59, which renders affected individuals susceptible to complement-mediated intravascular hemolysis.

The clinical manifestations of PNH can have a devastating impact on pregnancy. Reported cases highlight the significant pregnancy-associated morbidity and mortality in women with this condition. Complications include severe anemia, thrombocytopenia, thrombotic events, preterm delivery, low-birth-weight infants, neonatal death, and maternal death.^{49,50} A study by Ray and colleagues⁵⁰ reviewed pregnancy outcomes in 24 women with PNH and found a 20% maternal mortality rate.

Owing to the high-risk nature of these pregnancies, women with PNH require close medical attention in the antenatal, perinatal, and postnatal periods. Prophylactic anticoagulation is recommended because of the high incidence of thrombotic events during pregnancy. Warfarin is contraindicated because of its teratogenicity. Low-molecular-weight heparin (LMWH) is favored over unfractionated heparin (UFH) because it less frequently causes heparin-induced thrombocytopenia (HIT). Anticoagulation should be interrupted during the perinatal period but, in the absence of contraindications, reinitiated thereafter and continued for 6 weeks postpartum.⁵¹

Results of a phase III trial by Hillmen and colleagues⁵² demonstrated that eculizumab, a humanized monoclonal antibody against the terminal complement protein C5, can reduce levels of hemolysis, stabilize hemoglobin, minimize transfusion requirement, and improve quality of life in patients with PNH. There are case reports describing success in patients chronically receiving eculizumab throughout pregnancy with uncomplicated deliveries. However, a large randomized trial has not been performed. Supportive care is used as needed throughout pregnancy. RBC transfusions are used in the treatment of anemia. In the setting of thrombocytopenia and bleeding, platelet transfusions may also be necessary.

Autoimmune Hemolytic Anemia

Autoimmune hemolysis can occur during pregnancy and lead to anemia (see Chapter 47). The relatively small size of immunoglobulin (Ig)G immunoglobulin molecules allows them to cross the placenta; thus the IgG subtype of autoimmune hemolytic anemia can adversely affect fetuses. In contrast, the larger IgM antibodies do not cross the

placenta. Patients with autoimmune hemolytic anemia are treated with glucocorticoids and, if necessary, intravenous immunoglobulin (IVIg). Supportive transfusions are administered when needed.⁵³ In rare instances, pregnancy appears to precipitate the development of autoimmune hemolytic anemia in a previously unaffected woman. The etiology of this phenomenon is not known.⁵⁴ Women in this circumstance have been treated in the standard fashion with favorable results.

THROMBOCYTOPENIA

Thrombocytopenia during pregnancy is quite common. It occurs in approximately 10% of pregnancies.⁵⁵ Although there is not one clear value to define thrombocytopenia in pregnancy, generally a platelet count less than 100,000 is considered cause for concern. There is some physiologic thrombocytopenia that occurs during pregnancy. Gestational thrombocytopenia (GT) is the most common cause of thrombocytopenia in pregnancy followed by preeclampsia and immune thrombocytopenia. Much rarer causes include disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), and hemolytic uremic syndrome (HUS), and medication induced. The evaluation of thrombocytopenia is essential to rule out any systemic disorders that may affect pregnancy management.

Gestational Thrombocytopenia

GT is quite common during pregnancy. The platelet count is generally never lower than 70,000/ μ L. This occurs mainly in the third trimester. Patients are asymptomatic and have no history of thrombocytopenia. The platelet count normalizes within 3 months of delivery but often normalizes within 1 week. The etiology of GT remains unclear, but it is thought in part to be autoimmune in nature and demonstrates a clear overlap with mild idiopathic thrombocytopenic purpura (ITP).

The management of patients with GT is uncomplicated. Typically, they can receive epidural anesthesia. However, practice varies at each institution in terms of platelet threshold for epidural anesthesia. Platelet counts greater than 100,000/ μ L are considered safe for epidural anesthesia. There are studies demonstrating safe administration of epidural anesthesia in pregnant patients with platelet counts as low as 70,000/ μ L.⁵⁶

Immune Thrombocytopenia

ITP is responsible for pregnancy-associated thrombocytopenia in approximately 3% of cases (Chapter 132). It is the most common cause of thrombocytopenia during the first two trimesters of pregnancy.⁵⁷ ITP can recur in women with previously documented disease or can develop de novo during pregnancy.

ITP is usually not diagnosed during pregnancy. Pregnant patients with ITP usually have a long-standing history of thrombocytopenia. ITP may be difficult to distinguish from GT because patients with these conditions can present with similar clinical and laboratory findings. Elevated levels of platelet-associated IgG and antibody titers can be found in both conditions.⁵⁸ Furthermore, assays that detect antibodies against the glycoprotein receptors IIb/IIIa and Ib/IX are not specific for ITP.⁵⁹ Whereas thrombocytopenia in the first trimester or early portion of the second trimester should raise suspicion for ITP, thrombocytopenia that develops later in pregnancy should raise suspicion for GT. A preconception platelet count can also be helpful in distinguishing between the two. It is important to attempt to distinguish between ITP and GT because there is a small but significant risk of neonatal thrombocytopenia in the setting of ITP.⁶⁰

In terms of diagnostic evaluation, human immunodeficiency virus, hepatitis, and lupus should be tested for if clinically indicated. Platelet antibody testing is not considered helpful. The peripheral smear may demonstrate an increased platelet size but should otherwise

TABLE 151.1 Initiation of Treatment in Pregnant Patients With Idiopathic Thrombocytopenic Purpura

Platelet Count	Treatment
<10,000/ μ L	Platelet transfusion for life-threatening bleeding
10,000-30,000/ μ L	Consider monitoring in first trimester; treat in second or third trimester
>30,000/ μ L	Clinically monitor

be normal. Bone marrow biopsy and aspirate are not indicated unless there are other hematologic abnormalities present.

Treatment options are generally similar to those for nonpregnant patients with ITP (Table 151.1). Platelet transfusions are reserved for life-threatening bleeding because the lives of transfused platelets are usually short in ITP. Glucocorticoids are considered first-line treatment; prednisone is usually initiated at 1 mg/kg based on the patient's baseline weight. Side effects of prednisone should be discussed with the patient and include weight gain, bone loss, hypertension, and gestational diabetes. IVIg can also be used. It is a means of rapid increase in platelet count. It is particularly used to help increase platelet counts a few days before delivery.⁶¹ It is usually administered at a dose of 2 g/kg over 2 days. However, the improvement in platelet count is fairly transient. Splenectomy is also an option indicated for refractory thrombocytopenia; it is best performed during the second trimester.

Other agents such as danazol, cyclophosphamide, and vinca alkaloids, although used in the management of ITP in nonpregnant individuals, are teratogenic and should be avoided during pregnancy.⁶² Use of cyclophosphamide has been associated with birth defects. Danazol may cause clitoral enlargement and labial fusion in female fetuses when given in the first trimester.^{63,64} The use of rituximab has never been studied systematically in this setting and is considered a pregnancy class C drug. Although case reports of its use exist, it is not generally recommended in this case. Animal data indicate that thrombopoietin mimetics may cause fetal harm, and little is known about their use in pregnant patients. A registry has been developed for pregnant patients treated with thrombopoietin mimetics.

As discussed previously, maternal antiplatelet IgG can cross the placenta and cause thrombocytopenia in fetuses. Percutaneous umbilical blood sampling is the most accurate means to obtain the fetal platelet count. However, the procedure is associated with a high complication rate and 1% fetal mortality.⁶⁵ Intrapartum fetal scalp sampling represents an alternative, but the accuracy of this technique is only 50% to 70%.⁶⁶ The maternal platelet count and antiplatelet antibody level do not accurately predict the fetal platelet count.⁶⁷ Overall, 10% of babies born to mothers with ITP have a platelet count less than 50,000/ μ L, but less than 5% have a platelet count less than 20,000/ μ L.⁶⁸ Treatment of pregnant women with IVIg or steroids does not appear to affect the platelet count of fetuses.^{68,69} Thrombocytopenia places neonates at risk for bleeding events, including intracranial hemorrhage, although this complication is rare.⁷⁰

In terms of delivery, at present, available guidelines on the subject suggest that obstetric factors, rather than hematologic ones, should guide the manner of delivery.⁷¹ After the delivery of a child, the cord blood platelet count is checked and the newborn platelet count followed because thrombocytopenia is often most severe 4 to 6 days after delivery and resolves as maternal antiplatelet IgG is cleared.

Preeclampsia and HELLP Syndrome

Thrombocytopenia in pregnant woman also occurs in association with preeclampsia and HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), potentially severe multisystem disorders associated with pregnancy. In previously healthy nulliparous women, the incidence of preeclampsia is between 2% and 7%.⁷²

Thrombocytopenia is observed in 15% to 50% of patients with this condition.^{73,74} Clinical manifestations include a maternal syndrome characterized by hypertension, proteinuria, and systemic abnormalities as well as a fetal syndrome characterized by fetal growth restriction, preterm delivery, and hypoxia-induced neurologic damage.^{72,74}

In most instances, preeclampsia occurs during a woman's first pregnancy, but it can recur in a subsequent pregnancy or occur for the first time in a woman with one or more previously unaffected pregnancies. Risk factors for the disorder include, but are not limited to, preeclampsia in a previous pregnancy, a family history of preeclampsia, chronic hypertension, obesity, multifetal gestation, rheumatic disease, and preexisting thrombophilia.⁷² With respect to thrombophilia, a case-control study by Mello and colleagues⁷⁵ suggests that the prevalence of an underlying thrombophilia is significantly higher among women who develop preeclampsia during pregnancy than among those who have uneventful pregnancies.

HELLP syndrome represents a severe variant of preeclampsia. In the majority of cases, patients who develop the syndrome are white and multiparous.⁷⁶ The median age of affected patients is 25 years. The time of presentation during pregnancy ranges from the midtrimester (15%) to term (18%). In 30% of patients who develop HELLP, it develops within 2 days after delivery.⁷⁷ Patients typically exhibit vague symptoms such as malaise, fatigue, epigastric or right upper quadrant pain, nausea, vomiting, and flu-like symptoms. Because of the nonspecific nature of these symptoms, diagnosis is often delayed; one study found an average time to diagnosis of 8 days in women with HELLP syndrome.⁷⁸ Clinical findings at the time of diagnosis (weight gain or edema, hypertension, and proteinuria) are similar to those observed in preeclampsia.⁷⁷

Although various criteria have been used in diagnosing HELLP syndrome, they generally share the following features: signs of microangiopathic hemolytic anemia, serum lactate dehydrogenase greater than 600 U/L or serum total bilirubin greater than 1.2 mg/dL, aspartate aminotransferase greater than 70 IU/L, and a platelet count lower than 100,000/ μ L.⁷⁹ Martin and colleagues⁷⁷ further defined HELLP syndrome on the basis of platelet count. According to this classification, patients with class 1 HELLP syndrome have a platelet count lower than 50,000/ μ L, those with class 2 disease have a platelet count between 50,000 and 100,000/ μ L, and individuals with class 3 HELLP syndrome have a platelet count higher than 100,000/ μ L. As might be expected, women with class 1 HELLP syndrome required a recovery period in the aftermath of their illness.

Although the precise mechanism through which preeclampsia develops is uncertain, research in the field continues to advance understanding of the underlying pathophysiology. Endothelial cell dysfunction after placentation appears to play a central role in the pathogenesis of the disease. During development of the placenta, placental trophoblast cells interface with the epithelial layer of the uterus, forming the decidua. Penetration and remodeling of maternal spiral arteries beginning at week 9 during pregnancy increase placental perfusion and improve oxygenation for the developing fetus under normal conditions.⁸⁰

Cellular abnormalities such as those described impair placental implantation and vasculogenesis, leading to fetal hypoxia and the release of vasoactive compounds such as endothelin, nitric oxide, and prostaglandins. High levels of endothelin, a potent vasoconstrictor, are seen in preeclamptic patients, and injection of endothelin into rabbits produces a syndrome similar to HELLP syndrome.^{81,82} The activity of endothelin, nitric oxide, and prostaglandins leads to hypertension and platelet activation. Angiogenic factors such as vascular endothelial growth factor 1 (VEGF 1) are elevated in preeclampsia compared with normal pregnancy. Injury to the vascular endothelium results in fibrin deposition, further platelet activation, and the release of additional vasoactive agents such as serotonin and thromboxane A₂. The etiology of thrombocytopenia in preeclampsia is likely related to increased antiplatelet IgG levels⁸³ or to activation of the coagulation cascade with subsequent consumption of platelets.^{84,85}

These events lead to the multisystem dysfunction seen in patients with HELLP syndrome. Fibrin deposition in the hepatic sinusoids

causes hepatocellular injury. Patients can develop right upper quadrant pain if intraparenchymal or subcapsular hemorrhage occurs. DIC was observed in 21% of patients with HELLP in one series, and placental abruption was seen in 16% of patients.⁸⁶ Other manifestations of HELLP syndrome include acute renal failure, pulmonary edema, shock, cerebrovascular accident (CVA), eclampsia, retinal detachment, diabetes insipidus, and an increased incidence of cesarean section.

HELLP syndrome is associated with high maternal and neonatal mortality rates. Maternal mortality rates range from 1.1% to 24.2%.⁸⁷ The immediate cause of death is most often rupture of the liver, DIC, acute renal failure, pulmonary edema or acute respiratory distress syndrome (ARDS), shock, or CVA. Perinatal deaths resulting from placental abruption, asphyxia, or extreme prematurity occur in 10% to 15% of patients. After delivery, infants born to women with preeclampsia or HELLP can develop a self-limited neonatal thrombocytopenia. Uncertainty exists regarding whether infant thrombocytopenia in these instances results from preeclampsia or HELLP itself or from a related complication such as neonatal sepsis.^{88–90} HELLP recurs in subsequent pregnancies of affected women in 3% to 27% of cases. There is also an increased risk of preeclampsia, placental abruption, and preterm delivery in these pregnancies.^{91–100}

In caring for a patient with preeclampsia or HELLP syndrome, the clinician's primary concerns are the mother's health and safety. The clinician must also consider the stage of pregnancy at time of diagnosis, the condition of the fetus, and desires of the patient in making management decisions. Definitive treatment for preeclampsia and HELLP involves delivery of the fetus; it is indicated for women who present after 34 weeks of gestation and those with evidence of multisystem dysfunction. However, conservative, supportive care without immediate delivery can be pursued for women who are relatively asymptomatic, hemodynamically stable, at less than 32 to 34 weeks of gestation, and without evidence of abnormal coagulation parameters.^{100,101} Magnesium sulfate, which reduces cerebral vasoconstriction and ischemia, should be administered for seizure prophylaxis.¹⁰² Parenteral labetalol or hydralazine is given for blood pressure control. Systemic corticosteroids appear to lessen the risk of maternal ARDS and reduce neonatal complications when administered to women who present at less than 34 weeks of gestation.¹⁰³ In addition to these measures, volume status is closely monitored to prevent plasma volume expansion and ensure adequate urine output.

Persistent right upper quadrant pain, which may herald a liver hematoma or rupture, hemodynamic instability, coagulation profile abnormalities, or a decline in clinical status, should prompt delivery by cesarean section. As mentioned previously, delivery is also indicated if the fetus is at least 32 to 34 weeks of gestation at the time

when signs and symptoms of preeclampsia or HELLP develop. In a clinically stable woman, vaginal delivery can be attempted.¹⁰⁴ When cesarean section is required, transfusion of RBCs, platelets, and fresh frozen plasma (FFP) is performed as necessary before and during surgery. Severe hypofibrinogenemia should be treated with cryoprecipitate.

Patients are monitored closely in the postpartum period. Magnesium should be continued for 12 to 48 hours after delivery and blood pressure controlled appropriately. Although hypertension typically resolves within 6 weeks after delivery, some women require long-term antihypertensive therapy.¹⁰² Coagulation and platelet abnormalities tend to resolve within 24 to 48 hours after delivery. Some patients, however, experience an ongoing decline in platelet count and should be followed until counts normalize. Postpartum eclampsia can occur for up to 48 hours after delivery; thus patients and health care providers should remain vigilant in monitoring for suggestive signs and symptoms.¹⁰⁵ Treatment options in the setting of severe postpartum preeclampsia and HELLP include corticosteroids and plasmapheresis.^{106,107}

In light of the morbidity and mortality associated with preeclampsia and HELLP, considerable research has been focused on prevention of these conditions. The efficacy of various preventive strategies, including magnesium supplementation, low-dose aspirin, zinc supplementation, antihypertensive drugs, and heparin therapy, among others, has been the focus of observational studies, systematic reviews, and randomized trials. Initial small studies suggested that low-dose aspirin reduces the risk of preeclampsia, although patients who received aspirin had a higher incidence of placental abruption and bleeding.^{108–115} Larger, randomized trials failed to confirm the benefit of low-dose aspirin.^{109,110}

Thrombotic Thrombocytopenic Purpura–Atypical Hemolytic Uremic Syndrome

TTP and HUS/atypical HUS are also important considerations in the evaluation of pregnant women with thrombocytopenia (Chapter 135). Similar to preeclampsia and HELLP syndrome, they are multisystem disorders associated with high morbidity and mortality rates in the absence of appropriate therapy. Microvascular injury and platelet agglutination with resulting thrombocytopenia and microangiopathic hemolytic anemia are pathologic hallmarks of TTP and HUS (Fig. 151.1). They are rare conditions overall, but the incidence of both increases in pregnancy.¹¹⁶ In the case of TTP, in fact, estimates suggest that approximately 10% of cases occur in pregnant or postpartum women.¹¹⁷

Fig. 151.1 MICROANGIOPATHIC HEMOLYTIC ANEMIA. Microangiopathic hemolytic anemia in pregnancy, peripheral blood smear (A, B). Evidence of microangiopathy with the formation of schistocytes, fragmented forms and spherocytes, associated with polychromasia and nucleated red blood cells (A, B, detail).

Because they share many common clinical features, TTP and aHUS are often categorized as a single entity, TTP-HUS. However, the pathophysiologies underlying the two conditions are distinctive. TTP is associated with unusually large multimers of circulating von Willebrand factor (vWF), which foster platelet aggregation and thrombus formation. Under normal circumstances, a vWF-cleaving protease referred to as *ADAMTS13* (a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13) cleaves these multimers into smaller multimers of normal size. In TTP, function of the cleaving protease is impaired. *ADAMTS13* deficiency characterizes familial TTP. Inhibition of *ADAMTS13* protease activity by an autoantibody characterizes the acquired form of TTP. An inhibitory autoantibody can be found in 70% to 85% of patients with TTP.¹¹⁸ On the other hand, impaired vWF-cleaving protease activity does not appear to play a role in the pathogenesis of a HUS.¹¹⁹ Our understanding of the pathogenesis of atypical HUS has evolved in recent years as this disorder has been recognized to be associated as a complement-mediated disorder. With this dysregulation of complement, a picture of profound inflammation evolves. In contrast to TTP, there is typically more severe renal involvement with less severe thrombocytopenia. There can be some similarity found between the features of TTP-HUS and HELLP syndrome. It can be difficult to distinguish TTP and HUS from HELLP syndrome because they both have signs of microangiopathy. TTP tends to occur earlier in pregnancy, with a mean onset at 23.5 weeks, although it can occur at any point from the first trimester through the postpartum period.¹²⁰ HUS primarily occurs after delivery; 90% of cases occur in the postpartum period, with a mean onset at 26 days after delivery.¹²¹ TTP and HUS do not cause hypertension or liver necrosis. Furthermore, TTP and HUS frequently persist after delivery, but HELLP syndrome typically resolves in the postpartum period.

Treatment of TTP-HUS involves emergent plasmapheresis within 24 to 48 hours of diagnosis. The response rate among pregnant women treated with plasmapheresis for TTP is approximately 75%. By comparison, the overall response rate in patients with TTP is approximately 80% to 90%.¹²²⁻¹²⁵ Long-term sequelae in surviving patients include chronic renal failure, hypertension, and recurrence of TTP-HUS. TTP-HUS recurs in approximately 50% of subsequent pregnancies.¹²⁶ Infusion of FFP represents an alternative to plasmapheresis, although plasmapheresis is the preferred treatment modality. The response rate after FFP infusion is 64%.¹²⁷ Corticosteroids have also been used successfully in the treatment of pregnancy-associated TTP-HUS, with a response rate of 26%.¹²⁵ Conversely, antiplatelet agents such as aspirin do not play a role in the treatment of pregnancy-associated TTP-HUS.¹²⁸

Disseminated Intravascular Coagulation

DIC in pregnant women can occur in various clinical settings, including HELLP syndrome, TTP-HUS, placental abruption, amniotic fluid embolism, uterine rupture, intrauterine fetal demise, sepsis, elective abortion, and acute fatty liver of pregnancy (AFLP).

Severe placental abruption sufficient to cause fetal death occurs in 0.12% of all pregnancies.¹²⁹ This condition leads to a consumptive hypofibrinogenemia, and (when fibrinogen levels fall below 100 to 150 mg/dL) bleeding may ensue. Maintenance of adequate urine output and a hematocrit level greater than 30% are important components of care for women who have had a placental abruption. Either vaginal delivery or cesarean section is appropriate in the context of severe placental abruption. In a woman undergoing cesarean section after abruption, the platelet count should be maintained at 50,000/ μ L or above through platelet transfusion and fibrinogen replaced with FFP or cryoprecipitate.

Amniotic fluid embolism is a rare but often lethal condition with a mortality rate of approximately 80%.¹³⁰ About 10% to 15% of these patients develop a coagulopathy. DIC in this setting most likely follows the release of thromboplastin-rich material into the maternal circulation. DIC seen in association with uterine rupture and intrauterine fetal demise presumably occurs through a similar

mechanism.¹³¹ On the contrary, bacterial endotoxin or exotoxin mediates sepsis-associated DIC in pregnant women with pyelonephritis, chorioamnionitis, endometritis, or septic abortion.¹³² On rare occasions, elective abortions that use hypertonic solution and those complicated by hemorrhage can be associated with DIC.¹³³

AFLP, or acute yellow atrophy, occurs in 1 of every 5000 to 10,000 pregnancies, most often in the third trimester of primiparous women.¹³⁴ Maternal and fetal mortality are 5% and 15%, respectively. Although the pathogenesis of AFLP is not clear, microvesicular fatty infiltration of the liver's central zone is observed and presumably plays a central role in the development of this disease.¹³⁵ In some cases, fatty infiltration can be detected by ultrasonography or computed tomography (CT).¹³⁶ Patients present with a variety of symptoms, including malaise, fatigue, right upper quadrant pain, dyspnea, and mental status changes. Laboratory findings include abnormal liver function test results consistent with cholestatic disease, elevated ammonia, low fibrinogen and antithrombin levels, and elevated prothrombin time, with evidence of DIC. Hepatic dysfunction can impair gluconeogenesis. Diabetes insipidus may be present. The clinical course of AFLP resembles those of HELLP syndrome, TTP, and HUS, although the microangiopathy and thrombocytopenia are not as severe.¹³⁷ With supportive care, the condition typically resolves within 10 days after delivery.

LEUKEMIA AND LYMPHOMA

The diagnosis of hematologic malignancy during pregnancy can be incredibly traumatic for a pregnant patient and her family, and it is a treatment challenge for the physician. Although great strides have been made in the treatment of this heterogeneous group of diseases, the treatment of pregnant patients is limited because of the lack of research in this area and limited pregnancy safety data. The need to treat the patient and risk to the fetus must both be taken into account. Diagnosis can be difficult because many of the nonspecific signs that accompany these disorders, including fatigue, anemia, loss of appetite, and weight loss, can occur at various times during a normal pregnancy. Diagnostic imaging is limited mainly to ultrasonography and magnetic resonance imaging (MRI). Although the radiation dose from a CT scan is considered low, it is usually avoided. Diagnostic procedures such as bone marrow or lymph node biopsy can usually be performed safely during pregnancy.

In terms of treatment, the risk of teratogenicity from treatment appears highest during fetal organogenesis, which occurs mainly during the first trimester of pregnancy.¹³⁸ Ideal dosing is unknown, but dosing is usually based on the woman's prepregnancy weight.

In the largest study of its kind, Aviles and Neri¹³⁹ followed 84 children born to mothers with hematologic malignancies, including 29 women with acute leukemia and 38 who received treatment during the first trimester. Assessing growth and development, hematologic parameters, psychological characteristics, and cognitive function over 19 years, the authors found no significant, long-term, deleterious consequences related to treatment. The risk of childhood malignancies was not increased. In a retrospective report following the outcome of 54 newborns of women treated with chemotherapy specifically during the first trimester, long-term development was found to be normal. However, this is in contrast to general incidence of congenital malformations found by others for treatment given during this time period.

Hodgkin Lymphoma

That hematologic malignancies are among the most commonly diagnosed cancers during pregnancy reflects to a large extent the relatively high incidence of Hodgkin lymphoma in women between the ages of 15 and 24 years.¹⁴⁰ On the basis of results of several retrospective studies, Hodgkin lymphoma diagnosed during pregnancy appears to have no significant effect on pregnancy outcome.¹⁴¹ A single-institution experience published by Dilek and colleagues,¹⁴² however,

highlights complications that may occur in pregnant women with Hodgkin disease because children born to three of five women with the disease had complications, including death. Remission rates and 20-year overall survival rates among women diagnosed with Hodgkin disease during pregnancy are reportedly similar to those observed in nonpregnant women with the disease.^{143,144} In rare instances, Hodgkin lymphoma metastasizes to the placenta, so the placenta and newborn infant should be examined for evidence of malignancy.¹⁴⁵ Staging during pregnancy can be performed with CT, but MRI is preferred to reduce to exposure of the fetus to radiation.

Similar to other malignancies managed during pregnancy, treatment of women with Hodgkin disease is challenging. Generally, chemotherapy at any point in pregnancy increases the risk of an unfavorable outcome.¹⁴² The teratogenic effects of chemotherapy and radiation during pregnancy are a primary concern. However, the standard regimen of Adriamycin (doxorubicin), bleomycin, vinblastine, and dacarbazine does not appear to increase teratogenic risk when given in the second or third trimester.

Non-Hodgkin lymphoma (NHL) rarely occurs during pregnancy. There are case reports and case series of women with NHL who have been treated successfully with chemotherapy during the second and third trimesters of pregnancy.¹⁴⁵ In a review of 121 cases of pregnancy-associated NHL, 75% had stage IV disease at diagnosis, and reproductive organ involvement was found in half the cases. Placental and fetal involvement were uncommon.^{146,147}

Alkylating agents given during the first trimester can result in fetal malformations or death, although there are reports of children who received chemotherapy during the first trimester with no subsequent deficits.¹⁴⁸ On the basis of available data, response and recurrence rates among women treated for NHL during pregnancy are similar to those seen in the treatment of pregnant women with Hodgkin disease.

Acute and Chronic Leukemias

Treatment of acute myeloid leukemia cannot be delayed. Minimal data are available on the treatment of patients with acute leukemia, but in patients treated with chemotherapy during the first trimester, outcomes were poor. For patients in the first trimester, planned abortion should be discussed, followed by treatment with standard induction chemotherapy.¹⁴⁹

Patients in the second and third trimesters should be treated immediately. There is an association of preterm delivery, IUGR, and spontaneous abortion with treatment in the second and third trimesters.¹⁵⁰ In terms of treatment options, daunorubicin is preferred because idarubicin has increased placental transfer. Amphotericin B is considered the antifungal of choice in pregnancy because there have been no reports of teratogenicity.^{151,152} If treatment is not delayed, pregnant women can have outcomes similar to those of nonpregnant patients.

Among acute leukemias arising within the myeloid lineage, acute promyelocytic leukemia is unique in terms of clinical features, particularly DIC and associated bleeding complications, and therapy, which involves all-*trans* retinoic acid (ATRA) in conjunction with traditional chemotherapy. Concern regarding the teratogenic effects of ATRA is warranted. In the 1980s, Lammer and colleagues¹⁵³ noted an increased risk of fetal malformation after in utero exposure to the retinoid isotretinoin. In a recent case report, Carradice et al¹⁵⁴ described a bleeding complication that occurred after ATRA initiation in a pregnant woman with acute promyelocytic anemia. However, authors of a review of 13 women treated during pregnancy with ATRA administration for acute promyelocytic anemia found no evidence that the agent led to fetal malformation when used in the treatment of pregnant women.¹⁵⁵

Similar concerns regarding toxicity of therapy arise in managing pregnancies conceived before and during treatment of chronic myeloid leukemia (CML). Imatinib, a small-molecule inhibitor against the BCR-ABL tyrosine kinase, is the standard of care for treatment of CML. In animal studies, imatinib exhibited

Imatinib Therapy

A 38-year-old woman with a history of chronic-phase chronic myeloid leukemia on imatinib therapy for 5 years becomes pregnant. She has had a complete cytogenetic response. She asks what to do about her imatinib therapy.

Imatinib is teratogenic and should not be used during pregnancy. It has been linked to spontaneous abortions and to fetal malformations, including skeletal abnormalities, hydrocephalus, and exophthalmos. Although there are case reports documenting fetal exposure at various stages of pregnancy without harm, it is not recommended. Case reports suggest that patients who have achieved maximal response to therapy fare better when their treatment is held for pregnancy, as opposed to patients who have not achieved best response.

teratogenicity in rats and impaired spermatogenesis in dogs, monkeys, and rats.¹⁵⁶ In a series of 19 pregnancies involving a mother or father undergoing imatinib-based therapy for CML, three pregnancies resulted in a spontaneous abortion, and two others produced children with minor malformations.¹⁵⁷ The remaining 13 pregnancies resulted in the delivery of a healthy child. Among mothers in this study who had previously achieved a complete hematologic remission with imatinib and interrupted therapy during pregnancy, a majority (five of nine) lost the hematologic remission. These findings highlight the important therapy-related implications for mother and fetus, which must be weighed carefully in determining an appropriate course of management (see box on [Imatinib Therapy](#)). Currently, it is recommended by specialists in the field that patients undergoing treatment with imatinib for CML use proper contraception.¹⁵⁷

The Myeloproliferative Neoplasms: Essential Thrombocythemia, Polycythemia Vera, and Myelofibrosis

Essential thrombocythemia (ET) has a bimodal peak of distribution, so it is the most common myeloproliferative neoplasm (MPN) in women of childbearing age (see [Chapters 69, 70, and 71](#)). Although evidenced-based guidelines do not exist for the management of pregnancy in this setting, more and more information regarding this topic is being reported.¹⁵⁸ Although some variation is seen in the rates of complications among various studies, overall, all of the studies noted a consistent increase in the rate of complications compared with pregnant women without MPN.¹⁵⁸ Pregnancy alone is a risk factor for thrombosis, and pregnancy confers a sixfold increase in the rate of thrombosis in pregnant patients *without* MPN. Thrombosis is a major source of morbidity and mortality in patients with MPN. It is thought that the prothrombotic state that exists in MPN is behind a majority of the morbidity that can develop during pregnancy. Thrombotic occlusion of the placental circulation has been observed.

In a study documenting 103 pregnancies occurring in 62 patients with MPN, the rate of live births was 60%, and the first trimester abortion rate was 32%. Fetal complications occurred in 40% of cases and maternal complications in 9%. The risk of fetal loss for patients with ET was 3.4-fold higher than for those in the aged-matched control population.¹⁵⁹

A pooled outcome analysis of 461 pregnant patients with ET demonstrated that first-trimester loss occurred in 25% to 40% of patients with a live birth rate of 50% to 70%. Late pregnancy loss occurred in 10% of cases.¹⁶⁰ Postpartum thrombotic complications occurred in 5.2% of patients. In a recent analysis of all publications of pregnant patients with ET that had more than 30 patients per study, a mean rate of live birth obtained from the literature was 60.6% (range, 50%–75.4%).¹⁶¹

Studies of pregnancy in the setting of polycythemia vera (PV) are much fewer and consist mainly of case reports. One of the largest studies to date consisted of 18 pregnancies. There were 11 live births

and 7 miscarriages.¹⁶² First trimester loss is the most frequent complication in patients with PV.¹⁶¹ Information regarding pregnancy in primary myelofibrosis is even sparser, with overall fewer than 20 cases reported in the literature. However, on the basis of these, fetal loss is common.¹⁶³ In women of childbearing age with an MPN, a discussion when the patient is not pregnant should occur, outlining pregnancy management and risks. Women should be informed if they are taking a drug with teratogenic potential, and the risk of unplanned pregnancy should be recognized.

Continuing aspirin is considered standard if there is no clear contraindication, extrapolating from the results of the European Collaboration on Low-dose Aspirin in Polycythemia Vera (ECLAP) study, which confirmed the importance of aspirin in the management of MPNs.¹⁶⁴ Certain features may confer a patient at more risk of maternal or fetal complications during pregnancy. These include cardiovascular risk factors, prior thrombosis, and prior pregnancy-related complications that may have been caused by MPN or for which no other cause can be identified. In these settings, cytoreductive therapy or LMWH can be considered. There are no clear evidence-based management guidelines in these settings, but local practice is to use LMWH. Six weeks of postpartum LMWH should be considered in the postpartum setting if there is no contraindication. It is clear that management of these patients requires close collaboration with a hematologist and high-risk obstetrician.

BLEEDING DISORDERS

von Willebrand Disease

Affecting approximately 1% of the population, von Willebrand disease (vWD) is the most common inherited disorder of coagulation (see Chapter 139). By mediating platelet adhesion and functioning as a carrier for circulating factor VIII (FVIII), vWF plays a vital role in hemostasis. According to the most widely used classification by Sadler,¹⁶⁵ there are three types of vWD: type 1 (partial deficiency of vWF); type 3 (severe deficiency of vWF); and type 2, which includes four subtypes that involve qualitative defects in vWF. FVIIIc, vWF antigen (vWF:Ag), and the ristocetin cofactor activity (vWF:Rco) are important components of the laboratory diagnosis. vWD does not impair fertility or increase the likelihood of miscarriage.¹⁶⁶ Thus the management of pregnancy in patients with the condition is an important feature of the overall care for these individuals.

For pregnant women with vWD, bleeding at parturition and in the postpartum period is of primary concern. Related concerns include the administration of anesthesia, perineal hematoma, episiotomy blood loss and healing, and bleeding at surgical sites. Approximately 75% of women with moderate to severe vWD experience significant peripartum bleeding.¹⁶⁷ Overall there is a 20% risk of postpartum hemorrhage in women with vWD. In a normal pregnancy, FVIIIc and vWF levels increase, beginning in the second trimester.¹⁶⁸ They peak as the pregnancy nears term. Among many pregnant women with vWD, particularly those with type 1 disease, a similar increase in FVIII and vWF levels is observed. FVIIIc levels in pregnant women with vWD peak at 29 to 32 weeks of gestation, but vWF:Ag levels peak at approximately 35 weeks of gestation.¹⁶⁹ The risk of peripartum bleeding is related to the level of these factors.¹⁷⁰ In most instances, vWF:Ag, FVIIIc, and vWF:Rco levels should be assessed during the first and third trimesters to determine the bleeding risk for individuals with vWD. However, this may be less relevant for patients with type 3 vWD, in whom levels tend to remain low throughout pregnancy. Patients without a documented bleeding disorder who have bleeding complications during pregnancy should be evaluated for vWD because many with the disorder have a mild clinical course and remain undiagnosed for a long period.¹⁷¹

As a general rule, therapy can be rendered either in the setting of a spontaneous bleeding event or in a prophylactic context for the high-risk individual. Mainstays of therapy for pregnant women with vWD include DDAVP (1-deamino-8-D-arginine-vasopressin; desmopressin), a synthetic analogue of vasopressin, and vWF-FVIII

concentrates (Humate-P, Alphanate). Cryoprecipitate can be used on an emergent basis if vWF-FVIII concentrates are unavailable, but it is avoided if possible during pregnancy because it poses a small risk of bloodborne infection.¹⁷² Although antifibrinolytic therapy plays a role in the management of individuals with vWD, it is also generally avoided during pregnancy and lactation because of its potential teratogenicity and effects on newborns. Data concerning the toxicity of antifibrinolytic therapy in pregnancy are limited.

Exerting its effect through the type 2 vasopressin receptors, DDAVP rapidly and transiently increases levels of FVIII and vWF.¹⁷³ It is administered by continuous intravenous infusion over 30 minutes in the setting of an acute bleeding event. On a prophylactic basis, it can be given subcutaneously or inhaled nasally.¹⁷⁴ Although highly effective when used in an appropriate clinical context, DDAVP does have limitations. Patients who have never received DDAVP therapy should be tested for responsiveness to the agent during the second trimester. Because of its potential oxytocic effect, DDAVP is pregnancy risk category B.¹⁷⁵ Owing to its antidiuretic effect, DDAVP can cause fluid retention and hyponatremia. Finally, DDAVP has uncertain utility in the management of women with type 2 and type 3 vWD because of an underlying genetic defect in these individuals. vWF-FVIII concentrate is indicated for these patients.

Multidisciplinary care by an experienced obstetrician and hematologist should be provided for pregnant women with vWD. This becomes particularly important as parturition nears. In providing care for this population of patients, clinicians aim to control the consequences of the disease in pregnant and postpartum mothers. FVIIIc and vWF:Rco levels, partial thromboplastin time (PTT), type and crossmatch, and a complete blood count are obtained at the time of hospital admission. Women with vWD should be monitored for bleeding at the time of delivery, with blood cell products and DDAVP available for use as needed. vWF:Rco and FVIIIc levels of 50 IU/dL generally serve as a target at parturition and in the postpartum period; expert opinion suggests that women with levels below this should receive replacement products.¹⁷⁵

In the management of pregnant women with vWD, the provision of regional anesthesia during delivery is an important topic. Some anesthesiologists use epidural anesthesia in patients with mild disease with or without the use of DDAVP.^{176,177} For patients with moderate to severe disease, an alternative form of analgesia may be considered. If epidural analgesia is used in a patient with moderate to severe disease, prophylactic factor replacement therapy is indicated. The epidural catheter should be removed soon after delivery because falling factor levels in the postpartum period increase the bleeding risk.¹⁷⁵

The route of delivery is also an important matter in patients with vWD. To minimize the risk of neonatal hemorrhage, some obstetricians recommend cesarean delivery for patients with type 2, type 3, and clinically moderate type 1 disease. However, neonatal bleeding occurs in the setting of cesarean delivery as well, and delivery methods have not been rigorously compared.^{167,176}

Prenatal testing is a challenge in women with vWD. The specific mutations involved in the pathogenesis of type 1 and type 3 vWD are not known. Multiple mutations are involved in the pathogenesis of type 2 vWD. Fetal blood vWF levels can be obtained if necessary, but inherent risks are associated with the procedure.¹⁷⁸ Expectant mothers should be informed of these risks in making decisions about prenatal genetic testing.

HEMOPHILIAS

The hemophilias (A and B) are X-linked recessive diseases characterized by hemarthrosis and subcutaneous and intramuscular bleeding (see Chapter 136).¹⁷⁹ Hemophilia A results from deficient production of FVIII, and hemophilia B from deficient production of FIX. As X-linked disorders, hemophilia A and B occur most often in men, but they can occur in women under several circumstances, including X-chromosome inactivation (lyonization), X hemizyosity, and double heterozygosity as can occur in the female offspring of an

affected father and carrier mother.¹⁷⁹ In the United States, women account for 1.7% of patients with hemophilia A and 3.2% of patients with hemophilia B.¹⁸⁰ Fifty percent of male offspring from a female carrier inherit the disorder, whereas 100% of male offspring from an affected mother inherit the disease. Female carriers in both disorders can be detected through laboratory screening and pedigree analysis.¹⁸¹ Women with hemophilia and pregnant women with an affected fetus must be monitored closely during pregnancy for bleeding events that compromise the well-being of either the mother or the fetus. Fetal umbilical blood sampling can be used to check FVIII and FIX levels. Chorionic villus sampling may also be used.¹⁸²

At parturition, women with hemophilia A whose FVIIIc level lies below 50% of the normal range should receive purified FVIII. Levels should be greater than 80% for surgery and maintained at 30% to 40% for 3 to 4 days postoperatively. Rarely, thrombosis can occur in the aftermath of FVIII replacement therapy.¹⁸³ Among neonates with hemophilia, 6% to 10% have hemorrhagic complications in the perinatal period, including intracranial hemorrhage. Vacuum extractors, forceps delivery, and scalp electrodes should be avoided. To date, no studies have rigorously compared the outcomes of vaginal and cesarean delivery in this patient population. Neonatal blood should be assayed for FVIIIc levels and PTT immediately after birth. Neonates with low FVIIIc levels may require serial cranial ultrasounds to rule out bleeding.¹⁸⁴

Hemophilia B is treated in a similar fashion. However, it should be noted that cryoprecipitate contains low levels of FIX and should not be used as replacement therapy in the management of this condition. Purified FIX is the agent of choice for patients with hemophilia B. Meanwhile, individuals with other clotting factor deficiencies should receive FFP or specific clotting factor products to maintain factor levels at greater than 25%.¹⁸⁵ One exception to this pertains to the management of patients with FXIII deficiency; the occurrence of spontaneous recurrent abortions and uterine bleeding in these individuals necessitates regular infusions of FFP or FXIII concentrate to maintain pregnancy.¹⁸⁶

VENOUS THROMBOEMBOLIC DISEASE AND PREGNANCY

VTE disease is a leading cause of maternal morbidity and mortality.¹⁸⁶ The risk of VTE increases two- to fourfold during pregnancy and the early postpartum period.¹⁸⁷ In women who have had a previous VTE event, pregnancy appears to increase the risk of a recurrent thromboembolic event.¹⁸⁸ Various factors account for the prothrombotic state associated with pregnancy. Increased estrogen levels early in pregnancy increase venous distention and contribute to venous stasis.¹⁸⁹ Increased plasma volume and compression of the inferior vena cava by the gravid uterus contribute to venous stasis as well.¹⁹⁰ In addition, studies have demonstrated decreased blood flow velocity in pregnant women, particularly in the left leg when pregnant women lie in a

supine position. This phenomenon likely explains the increased risk of left leg thrombosis among pregnant women.¹⁹¹ Furthermore, whereas the concentration of coagulation factors changes during pregnancy, the concentration of vWF, fibrinogen, and prothrombin, along with factors V, VII, VIII, IX, X, and XII increase, and the concentration of factor XI and protein S decrease (Table 151.2).^{192–194} Finally, fibrinolytic activity decreases during pregnancy as the levels of plasminogen activator inhibitors 1 and 2 increase.¹⁹⁵ Other factors, including high body mass index, smoking, immobilization, and age older than 35 years, should also be considered when assessing the thrombotic risk of a pregnant woman (see box on **Bleeding Associated With Factor XI Deficiency**).

Because of the prothrombotic physiology associated with pregnancy, a clinician's concern for VTE in a pregnant woman should prompt immediate evaluation. To assess for lower extremity thrombosis, venous compression ultrasonography remains the initial test of choice. Ultrasonography poses no threat to the fetus and can detect thrombosis of the proximal common femoral and popliteal veins with a sensitivity of 95% and specificity of 96%. Despite the efficacy of ultrasonography, limitations to its use do exist. The test is less effective for the diagnosis of calf vein thrombosis, with a sensitivity and specificity in the 60% to 70% range.¹⁹⁶ For this reason, a woman with suspected lower extremity deep venous thrombosis should undergo serial ultrasonography if the initial evaluation is nondiagnostic.¹⁹⁷ Similarly, thrombus in the common iliac vein can evade diagnosis by venous compression ultrasonography.

In such cases, other modalities, such as contrast venography and magnetic resonance venography, can be considered. Although contrast venography exposes the fetus to radiation and should thus be used with caution during pregnancy, its use may be warranted when clinical suspicion for an underlying thrombotic event is high.¹⁹⁶ Serum D-dimer tests are often used in conjunction with imaging studies to assess for thrombosis in nonpregnant patients. The sensitivity of D-dimer tests for the presence of thrombus ranges from 85%

TABLE 151.2 Hemostatic Changes in Pregnancy

von Willebrand factor, fibrinogen	↑
Tissue plasminogen activator	↓
Prothrombin, D-dimer	↑

Prolonged PPT Postpartum

A 22-year-old woman presents to the emergency department (ED) 4 days postpartum. Her delivery was uncomplicated, and her hemoglobin at delivery was 9.9 g/dL with a partial thromboplastin time (PTT) 37 seconds. She returns to the ED 4 days later with complaints of weakness and vaginal bleeding and is found to have a large hematoma at the episiotomy site. It is surgically drained but immediately recurs, and persistent bleeding is noted. Her hemoglobin decreases to 5.9 g/dL. Repeat laboratory evaluation reveals her PTT to be 66 seconds.

Acquired hemophilia should be considered in the postpartum patient with bleeding and prolonged PTT. It is an uncommon disorder, thought to be immune mediated, with development of autoantibodies against factor VIII. Treatment must be targeted at inhibitor eradicator and control of bleeding. For acute bleeding, activated prothrombin complex concentrates or recombinant FVIIa should be used.

Bleeding Associated With Factor XI Deficiency

A 25-year-old woman is referred for prolonged partial thromboplastin time (PTT) discovered during pregnancy. Evaluation reveals severe factor XI deficiency. She has no history of easy bruising or bleeding. She is at 30 weeks of gestation and is presenting for evaluation before delivery.

Bleeding associated with factor XI deficiency can be quite variable, ranging from no bleeding symptoms to bleeding associated with trauma or surgery. For a patient without a history of bleeding, prophylaxis is not necessary but fresh frozen plasma (FFP) should be available if needed. Epidural is usually contraindicated in patients with severe factor XI deficiency, and women should be advised to speak with the treating anesthesiologist before delivery in order to plan alternative strategies. If consideration for regional block anesthesia is made, it is usually administered with FFP prior and with documentation of normalization of the PTT.

In patients with a bleeding history, FFP should be administered before delivery, as well as 2 to 3 days later to reduce the risk of delayed hemorrhage.

to 95%.¹⁹⁸ However, several pregnancy-associated conditions elevate D-dimer levels, including preterm labor, placental abruption, and hypertension of pregnancy, thus undermining the utility of the test somewhat in pregnant women by decreasing its specificity.¹⁹⁵ Nonetheless, when normal, the D-dimer assay provides the clinician with useful information.

When lower extremity imaging reveals no evidence of thrombus in a pregnant woman with suspected pulmonary embolism (PE), the clinician has several options. Helical CT has become the standard modality for the diagnosis of PE in nonpregnant individuals at many centers. However, even with abdominal shielding, the procedure results in fetal radiation exposure (approximately 16 mrad) because of internal scatter.¹⁹⁹ Although this low level of radiation exposure probably does not cause harm to the fetus, repeated imaging during the course of pregnancy is to be avoided.¹⁹⁷ Ventilation/perfusion (V/Q) scanning is frequently used in the evaluation of pregnant women with suspected PE but has limitations as well. Results of a prospective study indicate that when used in this patient population, V/Q scanning infrequently yields a conclusively positive result (1.8% of cases) and is often nondiagnostic (24.8% of cases).²⁰⁰ Finally, pulmonary angiography can be used in the evaluation of PE in rare instances when the previously described diagnostic tests yield nondiagnostic results in the face of a high clinical suspicion.

VTE in pregnancy is treated with heparin. Until LMWH was introduced in the late 1980s, UFH was the anticoagulant of choice for treatment of pregnant women with VTE. Because it does not cross the placenta, UFH is nonteratogenic. However, drawbacks to UFH therapy, including heparin-associated osteoporosis, HIT, and the drug's unpredictable pharmacokinetics, are well documented.¹⁸⁶ Heparin-associated osteoporosis can develop in women who receive at least 1 month of therapy; it is likely related to a toxic effect of heparin on osteoblasts.²⁰¹ Because of its more favorable side effect profile, reliable pharmacokinetics, and equal efficacy in treating VTE, LMWH now represents the most commonly used anticoagulant for treatment of VTE in pregnancy.²⁰² The risk of osteoporosis and HIT appears to be less with LMWH-based anticoagulation than with UFH-based anticoagulation.^{203,204} Although practice patterns vary, it is reasonable to base the initial dose of LMWH on early pregnancy (rather than current) weight.²⁰⁴ Because clearance of LMWH increases during pregnancy, twice-daily dosing regimens are preferred to once-daily regimens.²⁰⁵ In terms of duration of therapeutic anticoagulation, many clinicians continue therapy at full dose through the entire pregnancy and puerperium based on the rationale that pregnancy itself represents a risk factor for recurrent VTE.²⁰² In contrast, other clinicians advocate initial anticoagulation with full-dose LMWH for a designated period followed by conversion to an intermediate dose. This approach may be beneficial for individuals susceptible to side effects of anticoagulation such as bleeding or osteoporosis.¹⁸⁶ The risk of significant bleeding with LMWH during pregnancy is estimated to be around 2%.

Warfarin is contraindicated in pregnant women. It crosses the placenta and can cause both fetal hemorrhage and nervous system abnormalities and other teratogenic effects.²⁰⁶ Warfarin can be used in the postpartum period after initiating therapy with concurrent heparin and in this setting does not appear to increase the risk of bleeding in children of lactating mothers.¹⁹⁶

Anticoagulation should be discontinued at the time of parturition. UFH and LMWH should, in most circumstances, be stopped 12 to 24 hours before delivery. If the risk of recurrent VTE is particularly high in a woman receiving LMWH, the clinician can convert to intravenous UFH and treat until 4 to 6 hours before delivery, minimizing the time off anticoagulation.

The risks of regional anesthesia must be weighed carefully in women receiving anticoagulation because therapy increases the likelihood of bleeding, hematoma formation, and potential neurologic compromise. In a woman undergoing elective delivery with discontinuation of anticoagulation 12 to 24 hours prior, epidural anesthesia may be used. UFH or LMWH may be reinitiated 6 to 12 hours after delivery or after removal of the epidural catheter. Then, after therapeutic levels of UFH or LMWH have been achieved, warfarin may

be initiated. The newer target specific oral anticoagulant should not be used during pregnancy until safety data in this population have been established.

PROPHYLACTIC ANTICOAGULATION DURING PREGNANCY

Given the prothrombotic state associated with pregnancy itself, prophylactic anticoagulation should be considered in pregnant women with a history of VTE. Recurrence rates for VTE during pregnancy may be as high as 12% based on the results of retrospective studies.²⁰⁷ Conversely, Brill-Edwards and colleagues²⁰⁸ prospectively studied 125 pregnant women with prior VTE in a study that excluded women with known thrombophilia. Study subjects did not receive prophylactic anticoagulation during the antenatal period, but they did receive anticoagulation therapy for 4 to 6 weeks postpartum. The authors documented a VTE recurrence rate of 2.4%. Women who had a temporary risk factor at the time of their initial VTE event and lacked laboratory evidence of an underlying hypercoagulable disorder at the time of study enrollment experienced no recurrences during pregnancy. On the basis of the results of this study, routine prophylactic anticoagulation for women with a single previous VTE event is not recommended. However, patients with a known hypercoagulable state, those with multiple previous VTE events, and those considered high risk for recurrent VTE should receive prophylactic anticoagulation during pregnancy and for 4 to 6 weeks postpartum. As previously discussed, prophylactic anticoagulation can be discontinued at parturition and reinitiated 6 to 12 hours postpartum.

The management of pregnant women with prosthetic heart valves is controversial and deserves special attention, although a full review of the topic is beyond the scope of this review. Coupled with the prothrombotic physiology of pregnancy, the presence of a prosthetic valve places such women in an ultra-high-risk category. Before the introduction of LMWH, options for anticoagulation in this patient population included (1) warfarin throughout pregnancy; (2) warfarin with UFH during weeks 6 to 12, the period of major organogenesis; and (3) UFH throughout pregnancy.¹⁸⁶ More recently, LMWH has been used in this setting, although its safety and efficacy have been questioned on the basis of several studies. Overall, a lack of rigorous, comparative studies hinders evidence-based management of women with prosthetic heart valves. Current recommendations allow for one of three therapeutic strategies, initiated after a thorough discussion of risks and benefits with the patient: (1) warfarin, with LMWH or UFH substituted during weeks 6 to 12; (2) dose-adjusted UFH throughout pregnancy; or (3) dose-adjusted LMWH throughout pregnancy.¹⁸⁶

THROMBOPHILIA AND PREGNANCY

Thrombophilias, inherited and acquired, increase the risk of VTE in pregnant women and adversely affect pregnancy outcomes. Included within this category of diseases are factor V Leiden, prothrombin gene polymorphisms, antiphospholipid antibody syndrome, antithrombin deficiency, and protein S and C deficiency. In addition, hyperhomocysteinemia and methylenetetrahydrofolate reductase C677T mutation have been studied. There are varied results when assessing the literature in regard to the risk of pregnancy-associated VTE in the setting of an inherited thrombophilia. Authors of a 2005 meta-analysis reviewed the risk of VTE during pregnancy by the specific thrombophilia present. The inherited thrombophilias (with the exception of *MTHFR* mutation) were associated with a statistically significant increase in the risk of VTE during pregnancy.²⁰⁹ Because the overall incidence of VTE in pregnancy is low, however, in women without a history of thrombosis, the absolute risk conferred by thrombophilias is generally low. The positive predictive value of factor V Leiden heterozygosity was 1 in 500. Prothrombin heterozygosity was 1 in 200. Women with homozygosity for these mutations,

double heterozygosity, and antithrombin III deficiency were at highest risk. Given the increased risk of VTE, prophylactic anticoagulation is warranted.

Screening for inherited thrombophilia in patients with recurrent miscarriage or pregnancy complications such as preeclampsia or placental abruption is not indicated. Thrombophilia screening is indicated only in patients with a prior thromboembolic event or a high likelihood of thrombophilia. Selective screening based on personal and family history is recommended (see box on [The TIPPS \(Thrombophilia in Pregnancy Prophylaxis Study\) Trial](#) and box on [Thrombophilia During Pregnancy](#)).

Prophylactic treatment of carriers of low-risk mutations with any personal or family history of VTE is not indicated. In patients with

recurrent miscarriage, anticoagulation has been used in efforts to improve rates of live birth. There have been varied results in clinical trials using anticoagulation in the setting of recurrent miscarriage. However, in the large, multicenter, randomized, placebo-controlled study examining the use of aspirin or aspirin plus heparin in women with unexplained miscarriage, there was no improvement in the live birth rate compared with placebo.²¹⁰

Antiphospholipid Antibody Syndrome

The antiphospholipid antibody syndrome ([Table 151.3](#)) is the most common form of acquired thrombophilia.²¹¹ Antiphospholipid antibodies include lupus anticoagulant antibodies and anticardiolipin antibodies. They can occur as a manifestation of various conditions, such as systemic lupus erythematosus (SLE) and other rheumatic diseases, infection, and drug reactions. Antiphospholipid antibodies exert their prothrombotic effect through several mechanisms. For example, they inhibit the activity of anticoagulants thrombomodulin, protein S, protein C, β_2 -glycoprotein I, and prostacyclin.^{212–214} They interact with phospholipids on the surface of platelets, increasing platelet adhesiveness and production of von Willebrand multimers.^{215,216} In pregnant patients, antiphospholipid antibodies decrease levels of annexin V, a potent vascular endothelial anticoagulant produced by placental trophoblasts.²¹⁷ Nonpregnant individuals with antiphospholipid antibody syndrome can develop arterial and venous thromboses. In pregnant women, antiphospholipid antibody syndrome can manifest as thrombotic events, spontaneous abortion, preeclampsia, and HELLP syndrome, as well as IUGR.^{218–221}

Antiphospholipid antibodies can be detected in 5% of healthy pregnant women and 37% of pregnant women with SLE.²²² Thrombotic events occur in approximately 5% of pregnant women with antiphospholipid antibodies.²²¹ All pregnant women with SLE should undergo testing for antiphospholipid antibodies. Women who sustain recurrent spontaneous abortions or a thromboembolic event during pregnancy should also undergo evaluation for the disorder. A history of either vascular thrombosis or fetal loss coupled with the presence of either lupus anticoagulant antibodies or anticardiolipin antibodies establishes the diagnosis of antiphospholipid antibody syndrome.²²³

False-negative laboratory results do occur and do so more frequently in pregnant than in nonpregnant women. This may be because of the increased concentration of clotting factors observed in pregnancy.²²⁴ Women with antiphospholipid antibody syndrome who have sustained prior thrombotic events receive therapeutic anticoagulation during pregnancy. Those with antiphospholipid antibodies but no manifestations of the clinical syndrome should receive prophylactic anticoagulation.

The TIPPS (Thrombophilia in Pregnancy Prophylaxis Study) Trial

The TIPPS trial was the first large randomized controlled trial in which researchers examined the effect of low-molecular-weight heparin (LMWH) in pregnant patients with thrombophilia and a history of on adverse pregnant outcomes or venous thromboembolism (VTE). The TIPPS investigators studied 292 pregnant women who were randomly assigned to dalteparin or no dalteparin. The primary objective of the study was to identify if LMWH prophylaxis in thrombotic pregnant women results in a greater than 33% relative risk reduction in the composite outcome measure of severe or early-onset preeclampsia, small-for-gestational-age infants (<10th percentile), pregnancy loss, or VTE. Dalteparin did not reduce the incidence of the primary composite outcome in both intention-to-treat analysis (dalteparin, 25 [17.1%] of 146; 95% confidence interval [CI], 11.4%–24.2%; vs. no dalteparin, 27 [18.9%] of 143; 95% CI, 12.8%–26.3%; risk difference, –1.8%; 95% CI, –10.6% to 7.1%) and on-treatment analysis (dalteparin 28 [19.6%] of 143 vs. no dalteparin 24 [17.0%] of 141; risk difference, +2.6%; 95% CI, –6.4% to 11.6%). Major bleeding did not differ. More minor bleeding was seen in the dalteparin group (28 [19.6%] of 143) than in the no-dalteparin group (13 [9.2%] of 141; risk difference, 10.4%; 95% CI, 2.3–18.4; $p = .01$).

The conclusion from the study was that prophylactic dalteparin did not reduce the occurrence of venous thromboembolism, pregnancy loss, or placenta-mediated pregnancy complications in pregnant women with thrombophilia.

Some debate and controversy exist regarding the trial and its conclusions.

Cons: It took 12 years to randomize 292 women from 21 referral centers. Some physicians raised concern over the amount of time it took to accrue the number of patients and the accuracy of the patient base it represents. Others argued that eligibility criteria were based on a rationale that had already changed by the time the study was concluded.

Pros: The article confirms that women who are at low risk of thrombosis should not be treated with low-molecular-weight heparin and that this widespread practice should be stopped.

Cons: Many of these women were women who would be placed in “lower-risk” categories to begin with, such as women who were heterozygous for thrombotic mutations such as factor V Leiden mutation with one family member with a history of thrombosis.

Thrombophilia During Pregnancy

A 25-year-old woman wishes to become pregnant. Her mother experienced a deep vein thrombosis at the age of 70 years, underwent thrombophilia evaluation, and was found to be heterozygous for the factor V Leiden mutation. She herself has never had a thrombotic episode, just recently discontinued her birth control, and was told to see a hematologist before she became pregnant. Her primary care physician tested her for factor V Leiden, and she was found to be heterozygous for the mutation. She is asking if she should be on anticoagulation during her pregnancy.

Every case of thrombophilia during pregnancy needs to be assessed on a case-by-case basis. Asymptomatic women who harbor thrombotic conditions but have never manifested clinical manifestations do not require anticoagulation.

**TABLE
151.3**

Antiphospholipid Antibody Syndrome

Vascular Thrombosis

One or more episodes of arterial or venous thrombosis confirmed by imaging

Pregnancy morbidity

Death of a fetus beyond 10 weeks of gestation with normal fetal morphology

Premature birth before 34 weeks of gestation

Three or more consecutive spontaneous abortions before 10 weeks of gestation

Laboratory criteria (all measured on two or more occasions at least 12 weeks apart)

Lupus anticoagulant on two or more occasions at least 12 weeks apart

Anticardiolipin antibody

Anti-B₂ glycoprotein IgM or IgG

Ig, Immunoglobulin.

FUTURE DIRECTIONS

Management of the hematologic complications of pregnancy continues to be a challenge. The physicians and patient involved all benefit from a multidisciplinary approach. In certain disorders, the management is clear and will likely remain unchanged in the future. In other disorders, treatment paradigms may shift as new treatments are discovered for the nonpregnant patient. In all instances, further well-designed studies will continue to advance evidence-based management of the pregnant patient.

HEMATOLOGIC MANIFESTATIONS OF CHILDHOOD ILLNESS

Arthur Kim Ritchey, Sarah H. O'Brien, and Frank G. Keller

The hematologic response to systemic illness in children is similar to that in adults. A number of disorders occur more frequently in children, however, and some are unique to the pediatric population. In addition, interpretation of the hematologic response is predicated on knowledge of the normal developmental changes that occur within the hematopoietic system throughout childhood (Table 152.1). This chapter focuses on the hematologic manifestations of common or unique systemic diseases that occur in neonates, children, and adolescents. Illnesses that often require hematologic consultation are emphasized. Systemic diseases that produce hematologic abnormalities that are similar in adults and children are discussed in other chapters. For a comprehensive review of the subject, readers are referred to a published textbook.¹

INFECTIOUS DISEASE

Infection, especially viral infection, is the most common problem encountered by pediatricians. Although most infections do not produce significant hematologic sequelae, all classes of microorganisms have been implicated in the pathogenesis of hematologic abnormalities that range from mild and clinically irrelevant to severe and life threatening. This section describes the changes seen in red blood cells (RBCs), white blood cells (WBCs), platelets, and the coagulation system that are routinely encountered, are associated with a specific infection, or have a potentially serious clinical impact.

Changes in Red Blood Cells

The anemia of chronic inflammation or infection in children is similar to that seen in adults in terms of both clinical and hematologic findings and pathogenesis.² However, anemia with acute infections occurs more commonly in children than in adults.

Anemia of Acute Infections

A mild to moderate anemia of uncertain etiology may occur in the setting of both acute viral infections and more serious bacterial infections. In a study of children with mild viral or bacterial infections in the outpatient setting, anemia was documented in 5% of children 4 to 12 years of age, 17% of children 6 months to 4 years of age, and 33% of infants 6 to 11 months of age.³ In 14 of 15 young children, the anemia resolved within 3 to 4 weeks. However, multiple mild infections may predispose infants to the development of a more chronic, mild anemia or low-normal hemoglobin that may be caused by iron deficiency, thus warranting a trial of iron supplementation.

Among children hospitalized with moderately severe inflammatory processes, the incidence of mild anemia (hemoglobin, 10.1–11.0 g/dL) is as high as 78%.⁴ In a study of hospitalized children with either pyelonephritis bacteremia, average age 5 to 6 years, 60% had anemia.⁵ No evidence of hemolysis was seen in this group of children. Follow-up hemoglobin measurements in a subset of patients showed levels had returned to normal without specific intervention. These data suggest that there is no indication to investigate the mild anemia of acute infection. Specific acute bacterial infections associated with a high incidence of anemia (44%–74%) include bone and

joint infections, typhoid fever, brucellosis, and invasive *Haemophilus influenzae* infections.

The anemia associated with *H. influenzae* meningitis is the most thoroughly studied of the anemias of acute infection to date. A majority of children with *H. influenzae* meningitis have mild anemia on admission, with hemoglobin in the 9–11 g/dL range, and up to 90% become anemic during the course of the illness.⁶ This is in contrast with meningitis secondary to *Streptococcus pneumoniae* or *Neisseria meningitidis*, in which anemia is uncommon. The pathophysiology of the anemia of *H. influenzae* disease appears to be multifactorial. Shurin and associates⁷ have shown that *H. influenzae* capsular polysaccharide, polyribosylribitol phosphate, binds to erythrocytes, which, in the presence of antibody and complement, can result in intravascular and extravascular hemolysis. They further hypothesize that polyribosylribitol phosphate alone may induce more rapid clearance of RBCs, perhaps on the basis of decreased RBC deformability. In addition, hypoferrremia may limit bone marrow response to hemolysis. As a result of immunization with pneumococcal and *H. influenzae* vaccines in early childhood, it is uncommon to see infections secondary to these organisms currently.

Acute Hemolytic Anemia

Acute hemolysis has been observed with infections from all classes of microorganisms but is relatively uncommon. The anemia may be mild to severe, and the condition is manifested in children in either of two ways: (1) clinical presentation with symptoms and signs of infection predominating in a child subsequently found to have anemia or (2) clinical presentation with the manifestations of acute hemolytic anemia.

The mechanism of hemolysis in patients presenting with an infectious disorder depends on the infecting organism, but hemolysis is extravascular in most cases.⁸ Reported mechanisms include the following:

- Release of hemolysins (*Clostridium perfringens* sepsis)
- Invasion of the RBCs (malaria)
- Alteration of the RBC surface:
 - Direct adherence by the organism (*Bartonella* spp.)
 - Alterations of antigenic phenotype by neuraminidase (influenza virus)
 - Cold agglutinins (*Mycoplasma* spp., *Listeria* spp., Epstein-Barr virus [EBV], *Leptospira* spp., *Rubella* spp.⁸)
 - Absorption of capsular polysaccharide (*H. influenzae*)
- Mechanical mechanisms (microangiopathy associated with disseminated intravascular coagulation [DIC] or hemolytic uremic syndrome [HUS])
- Oxidative damage in persons with congenital enzyme deficiencies (e.g., hepatitis or brucellosis⁹ with glucose-6-phosphate dehydrogenase [G6PD] deficiency, *Campylobacter jejuni* infection in neonates)

Acute, infection-associated hemolytic anemia in one study lagged behind the clinical infection by 3 to 7 days.¹⁰ Most children were shown to have adsorption of microbial antigens to the RBC surface, suggesting an “innocent bystander” mechanism of erythrocyte

TABLE 152.1 Normal Hematologic Values in Childhood

Age	Hb (g/dL)		RBCs Hct (%)		MCV (fL)		Total ($\times 10^3/\mu\text{L}$)		White Cells		Coagulation

^aThe normal range for the PT and aPTT varies between laboratories. The time at which normal adult values are attained is 1 week for the PT and 2 to 9 months for the aPTT. The platelet count is within the adult range from birth.

aPTT, Activated partial thromboplastin time; Hb, hemoglobin; Hct, hematocrit; MCV, mean corpuscular volume; PT, prothrombin time; RBC, red blood cell.

Data from Rudolph AM, Hoffman JIE, editors: *Pediatrics*, ed 17, East Norwalk, CT, 1982, Appleton-Century-Crofts, p 1036, and from Nathan DG, Oski FA, editors: *Hematology of infancy and childhood*, ed 3, Philadelphia, 1987, Saunders, p 1679.

sensitization, ultimately leading to hemolysis. A minority of patients in this series had classic autoantibody-mediated hemolytic anemia.

Autoimmune hemolytic anemia (AIHA) in children usually is transient, is not associated with underlying systemic disease, and carries a low mortality rate. Children frequently have a history of concurrent or recently resolved infection, especially viral upper respiratory tract infection. Anticytomegalovirus (anti-CMV) immunoglobulin G (IgG) has been implicated as the cause of acute AIHA in infants with CMV disease. Although mycoplasma pneumoniae is usually associated with cold agglutinin syndrome, there is a report of multiple episodes of warm antibody-mediated hemolytic anemia in a child with Down syndrome.¹¹ Parvovirus has been rarely associated with AIHA. In some, but not all, cases, the Donath-Landsteiner antibody was identified.¹² In the typical acute, transient cases, 59% to 68% of children have a history of recent infection, but only 0% to 20% of those with the less common chronic course have such a history of infection.

Aplastic Crisis

Temporary arrest of RBC production has been observed in children with infections, but anemia is uncommon because of the long RBC lifespan. In two situations, however, severe anemia has been linked with infection and cessation of erythropoiesis: (1) B19 parvovirus infection in patients with an underlying hemolytic anemia and (2) transient erythroblastopenia of childhood (TEC).

The B19 parvovirus has been a known pathogen in animals for years but has only recently been linked with human disease.¹³ It is the etiologic agent of fifth disease (erythema infectiosum), a mild illness with a characteristic “slapped cheek” facial erythema and a generalized reticular rash. In normal volunteers infected with B19 parvovirus, a mild, transient, and clinically irrelevant drop in the hemoglobin and reticulocyte count was observed.¹⁴ In normal children, this infection usually is not associated with hematologic abnormalities, although reports of both hematologic and nonhematologic effects are increasing.¹⁵ In children with sickle cell disease, spherocytosis, and other hemolytic anemias, B19 parvovirus infection can produce a severe anemia associated with peripheral reticulocytopenia and marrow erythroblastopenia—the “aplastic crisis.” There may be other transient cytopenias noted during the RBC aplastic crisis.¹⁶ Recovery within 1 to 2 weeks is the rule, but transfusion may be necessary.

B19 parvovirus infection also has been associated with prolonged anemia and reticulocytopenia in children with acute lymphoblastic

leukemia (ALL) in remission, those with solid tumors receiving chemotherapy, those with immunodeficiency, those who have undergone renal transplant, those with AIHA, and as the initial manifestation of human immunodeficiency virus (HIV) infection. Human parvovirus also has been identified as a cause of nonimmune hydrops fetalis.¹⁷

TEC is a syndrome characterized by temporary arrest of RBC production with moderate to severe anemia in previously normal infants and toddlers. Although no specific infectious agent has been proved to cause TEC, the frequency of a history of infection within 1 to 3 months, the seasonal clustering, and the similarity to childhood idiopathic thrombocytopenic purpura (ITP) all suggest a possible viral etiology. B19 parvovirus has not been definitively associated with TEC.¹⁸

Changes in White Blood Cells

Children, as a rule, have the expected leukocyte response to infection. Infants and young children normally have a lymphocyte predominance (see Table 152.1), however, and any leukocyte response to infection must be judged on the basis of age-related normal values.

The predictive value of the peripheral WBC and differential counts in suspected bacterial infections has been extensively evaluated in infants and children. Todd has shown that in hospitalized children, a neutrophil count greater than 10,000/ μL or a band count greater than 500/ μL is associated with an 80% chance of having a bacterial infection.¹⁹ In children undergoing evaluation for possible meningitis, Lembo and colleagues²⁰ found that a ratio of immature to total neutrophils greater than 0.12 was more strongly associated with and more sensitive for bacterial meningitis than was the total WBC count or the total band count. Febrile children between the ages of 3 and 48 months are at increased risk for bacteremia, especially with *S. pneumoniae*. McCarthy and associates²¹ demonstrated a threefold increase in the risk of bacteremia in febrile (temperatures $>40^\circ\text{C}$) children younger than 2 years of age who had a WBC count of 15,000/ μL or greater. In this setting, the WBC count was a more sensitive indicator of the presence of pneumonia or bacteremia than was the absolute neutrophil or band count. The degree of leukocytosis (i.e., $>25,000/\text{mm}^3$ vs. $<15,000/\text{mm}^3$) probably has no further discriminative ability.²² Other studies have found both the WBC count and absolute neutrophil count (ANC) to be of value in differentiating bacterial from nonbacterial infection; the band count was not helpful.

There are recognized exceptions to the anticipated leukocyte response to infection that may serve as a clue to the diagnosis. In

typhoid fever and brucellosis, leukopenia and neutropenia are prominent early in the illness. Shigellosis is associated with a variable leukocyte count, but the count often is normal, with a greater percentage of bands than neutrophils. Illnesses associated with lymphocytosis include pertussis (whooping cough), infectious lymphocytosis, infectious mononucleosis, and other viral infections. Neutropenia can be seen in bacterial sepsis from meningococci, pneumococci, staphylococci, and other bacteria and is associated with a poor prognosis. Black children (and adults) normally have lower WBC and neutrophil counts than those seen in whites; leukocyte and neutrophil response to serious infection may be decreased.²³

Neutropenia

The most common cause of neutropenia (neutrophil count $<1500/\mu\text{L}$) in children is viral infection. A number of specific viruses are associated with neutropenia, including hepatitis virus, roseola virus, rubella virus, mumps virus, adenovirus, coxsackievirus A21, EBV, human herpesvirus-6 (HHV-6), and influenza virus.²⁴ The most common clinical setting, however, is the incidental discovery of neutropenia in a child with a nonspecific viral syndrome. Usually the neutropenia in this situation continues for less than 30 days and is rarely associated with infectious or long-term²⁵ complications. In one large study of 1888 otherwise healthy children with fever and ANC counts below $1000/\mu\text{L}$, there was only a 1.3% incidence of serious bacterial infection in children older than 3 months of age (1 bacteremia infection, 13 urinary tract infections). The risk was higher in infants younger than 3 months of age (3.3%), similar to the risk of febrile infants of the same age without neutropenia.²⁶ Neutropenia also has been associated with a number of bacterial, rickettsial, and fungal infections.²⁷ Although infection is the most common cause of transient neutropenia in childhood, the febrile child discovered to have incidental neutropenia should have repeat blood counts done within 3 to 4 weeks to rule out chronic neutropenia.

Eosinophilia

The most common cause of eosinophilia worldwide is parasitic infection. In the United States, visceral larva migrans (*Toxocara* infestation) is the most common cause of exaggerated eosinophilia (WBC count 30,000–100,000/ μL with 50%–90% mature eosinophils) in children.²⁸ Mild to moderate eosinophilia ($\geq 600/\mu\text{L}$) is most often seen in children with allergic rhinitis or asthma but also is characteristic of chlamydial pneumonitis in infants.

Changes in Platelets or Coagulation

Thrombocytosis

Thrombocytosis (platelet count $>500,000/\mu\text{L}$) is known as an acute-phase reaction to infection, but it has been infrequently identified in children in the past. There is a particularly high incidence of reactive thrombocytosis in patients with bacterial infections, especially pneumonia with emphysema, and *H. influenzae* meningitis. Inflammatory cytokines, such as interleukin (IL)-1, IL-6, and thrombopoietin, may play an etiologic role in the reactive thrombocytosis of infection.²⁹ The vast majority of children with thrombocytosis have platelet counts between 500 and 700,000/ μL , but 6% to 8% have counts between 700 and 900,000/ μL and only 0.5% to 3% have platelet counts above 1,000,000/ μL .³⁰ Thrombocytosis may be more common in simple acute infections than was previously recognized. Heath and Pearson³¹ documented a 13% incidence of thrombocytosis in ambulatory patients; children with an increased platelet count were more likely to have a diagnosis of infection. In a Japanese study of more than 7500 hospitalized patients with platelet counts greater than 500,000, 6% of patients had thrombocytosis with an age-dependent incidence: 12.5% in neonates, 35.8% in 1-month-old babies, 12.9%

in 6- to 12-month-old infants, and 0.6% in 11- to 15-year-old children. Infection was the cause of the thrombocytosis in 67.5% of the cases.³² Complications of reactive thrombocytosis are rare, but hemorrhagic or thrombotic complications may occur if there are additional acquired risk factors. Antiplatelet therapy is not indicated in patients with reactive thrombocytosis secondary to infection. Although the most common cause of thrombocytosis in children is infection, the list of considerations in the differential diagnosis of an elevated platelet count is extensive³³ and rarely includes underlying childhood malignancy.

Thrombocytopenia

Thrombocytopenia can be seen in patients who have infections with all types of organisms. Common viral agents include varicella virus, EBV, influenza virus, rubella virus, mumps virus, measles virus (wild or vaccine strains), HHV-6, hepatitis A virus, and CMV. The primary mechanism of the thrombocytopenia is immune destruction, although a direct viral effect on the platelet, megakaryocyte, or hematopoietic stem cell has been demonstrated. Because childhood ITP is thought to be secondary to infection in most instances, the definitions of “thrombocytopenia with infection” and “childhood ITP” tend to merge. Thrombocytopenia from infection usually is transient, although instances of chronic thrombocytopenia from specific viral infections (e.g., varicella or CMV) have been documented.^{34,35}

Thrombocytopenia also is associated with bacterial sepsis. The low platelet count may be an isolated finding or associated with DIC. Corrigan³⁶ documented a 61% incidence of thrombocytopenia in 45 children with sepsis. The degree of thrombocytopenia was mild to moderate (64% had platelet counts $>50,000/\mu\text{L}$), but platelet counts ranged as low as 8000/ μL . There was no evidence of DIC in 39% of those with low platelet counts. Thrombocytopenia in the setting of bacterial sepsis probably is also mediated by an immune mechanism with elevated platelet-associated IgG.

Petechial bleeding without thrombocytopenia can be seen in both bacterial and viral disease, especially that caused by meningococci, streptococci, and echoviruses. The explanation for the petechial rash in these infections is either vasculitis or platelet dysfunction.

Disseminated Intravascular Coagulation and Purpura Fulminans

Disseminated intravascular coagulation is uncommon after childhood infections and, if present, usually is accompanied by shock, with at least a 50% mortality rate. The most common organisms producing DIC are bacterial, especially the gram-negative bacteria (meningococci, *H. influenzae*, *Aerobacter* spp., and others) but also gram-positive organisms (*Staphylococcus aureus*; group B streptococci; *S. pneumoniae*, particularly in asplenic hosts; and *Bacillus anthracis*). DIC also is associated with disseminated viral (varicella, measles, and rubella), rickettsial (Rocky Mountain spotted fever), fungal, mycoplasmal, and parasitic infections.

Purpura fulminans is a rare syndrome, seen in extremely ill children with DIC. Purpura fulminans is characterized by the rapid progression of ecchymotic skin lesions, especially of the extremities, that may progress to gangrene, ultimately resulting in amputation.³⁷ This syndrome has been described as a postinfectious purpura, with scarlet fever, upper respiratory tract infection, and varicella as the most common preceding illnesses and a latent period of 0 to 90 days after infection. A similar clinical picture can be seen in children with DIC and acute bacterial sepsis, especially meningococcemia.

Increasing evidence indicates that DIC with purpura fulminans is associated with deficiency of the naturally occurring anticoagulants. Children with postviral purpura fulminans have been shown to have acquired protein S deficiency, anti-protein S antibody, or the presence of a lupus anticoagulant.^{38,39} In children with infectious purpura, protein C activation is impaired, as reflected in low levels of protein C, protein S, and antithrombin. These findings are consistent with

downregulation of the endothelial thrombomodulin–protein C receptor pathway.⁴⁰ The severity of protein C deficiency has been associated with increased morbidity and mortality.⁴¹ There are minimal data on the frequency of inherited thrombophilia in children who develop purpura fulminans. In one report, the frequency of factor V Leiden was not different from that in healthy children; the presence of factor V Leiden was not associated with an increased mortality rate, although complications were increased.⁴² In another study of 16 children with purpura fulminans, 6 (37%) of 16 patients studied had the factor V Leiden mutation. All of the children in this study survived, but 10 (63%) required amputation.⁴³

Treatment of purpura fulminans consists of antibiotics for suspected bacterial infection, volume replacement for shock, and heparin. Although there is controversy regarding the routine use of heparin in DIC, its use in purpura fulminans has been associated with an improved outcome when it is started early in the course of the disease and continued for 2 to 3 weeks.⁴⁴ Theoretically, to improve the efficacy of heparin, it is reasonable to infuse fresh frozen plasma or antithrombin III (AT III) concentrates⁴⁵ if the AT III level is low. There is anecdotal evidence that infusion of AT III concentrates or protein C concentrates partially corrects or normalizes the hemostatic abnormalities.^{46,47} However, in the KyberSept trial, a double-blind, placebo-controlled trial of the use of AT III concentrates in 2300 adults with sepsis, researchers found no difference in mortality at day 28 after diagnosis.⁴⁸ In a phase II trial of protein C concentrate in the treatment of sepsis and purpura fulminans in children, there was dose-dependent activation of protein C and normalization of coagulation imbalances. Although there was no improvement in the mortality rate, the study was not powered to detect these changes.⁴⁹

In initial trials, recombinant human activated protein C (drotrecogin alfa [activated]) reduced the mortality rate in adults with severe sepsis,⁵⁰ but in pediatric trials, there was no noticeable improvement in mortality (children have a lower mortality rate than adults), and there were significant bleeding risks.^{50,51} Although activated protein C has been used in patients with purpura fulminans, the data do not suggest a beneficial effect on mortality.^{52,53} Use of nonactivated protein C concentrates early in the course of purpura fulminans may, however, decrease the need for subsequent skin grafts and amputations.⁵⁴ In October 2011, this agent was withdrawn from the market after a major study showed no efficacy for the treatment of sepsis. Recombinant tissue plasminogen activator (t-PA) has been used in an attempt to restore organ perfusion by dissolution of diffuse microvascular thrombosis⁵⁵; however, in a retrospective multicenter study of 62 patients with meningococcal purpura fulminans treated with systemic t-PA, there was a high incidence of intracerebral hemorrhage without proven efficacy in reduction of mortality or incidence of amputation.⁵⁶ Other treatments, such as regional sympathetic blockade, topical nitroglycerin, and local infusion of t-PA, have been used to improve regional blood flow to the affected part. The mortality rate for postinfectious purpura fulminans has declined from 90% in the past to 18%,⁵⁷ but the amputation rate has remained high.⁴³ The outcome for patients with acute bacterial sepsis and purpura fulminans has also improved, but a mortality rate as high as 50% continues to be reported.

Coagulation Inhibitors

Acquired inhibitors of coagulation in children with infection are usually transient and mild but may be associated with severe bleeding.⁵⁷ They are often detected after a viral illness, during antibiotic therapy, or incidentally (frequently before tonsillectomy or adenoidectomy). Both specific inhibitors of coagulation factors (especially factors VIII and IX) and lupus anticoagulants have been demonstrated. Although previously thought to be uncommon, studies have found 50% to 90% of children with infection have at least one positive test result for an antiphospholipid antibody (aPL).^{58,59} Significant bleeding is usually seen only in children with specific factor inhibitors, although hemorrhage also has been described with lupus anticoagulants.⁶⁰ In symptomatic patients, treatment with prednisone has

been associated with remission of bleeding manifestations. Complete resolution without recurrence is the most common event. Thrombosis in the setting of transient postinfectious coagulation inhibitors is rare, although splenic infarction from aPLs has been reported during infection with EBV and mycoplasma pneumonia.^{61,62}

Pancytopenia

Pancytopenia in a child should alert the clinician to the possibility of disorders such as leukemia, aplastic anemia, or disseminated neuroblastoma.⁶³ Infectious causes of pancytopenia are uncommon, and disseminated disease is most often present. Organisms implicated in patients with pancytopenia include *Mycobacterium tuberculosis*, atypical mycobacteria, *Histoplasma capsulatum*, *Leishmania* spp., *Salmonella enterica* subsp. *enterica* serovar Typhi, *Mucor* spp., *Brucella* spp., *Fusobacterium necrophorum*, *Mycoplasma pneumoniae*, and *Ehrlichia canis*.²⁷ Virus-associated or reactive hemophagocytic syndrome is an additional, although rare, cause of pancytopenia. Children with HIV infection and concomitant infection with *Mycobacterium avium-intracellulare* or parvovirus B19 have been reported to have pancytopenia.

Human Immunodeficiency Virus Infection in Children and Adolescents

Infection with HIV is more common in adults but is now recognized as a leading cause of immunodeficiency in infants and children.⁶⁴ Acquisition of HIV in a majority of infected children (most of whom are younger than 2 years of age) is by vertical transmission from an infected mother to her infant. In a 1989 study of children younger than 13 years of age with acquired immunodeficiency syndrome (AIDS), 80% have a parent with AIDS or AIDS-related complex (ARC), 13% have a history of blood transfusion, and 5% have hemophilia or another coagulation disorder.⁶⁵ Other “adult” routes of infection (sexual contact, intravenous needle use) are possible, especially in adolescents and sexually abused children.

Significant advances in the treatment of HIV infection in children have been made since the availability of antiretroviral therapy (ART).⁶⁶ As a result of programs to prevent mother-to-child transmission, there has been a dramatic decrease in the number of children in the United States infected with HIV. The Centers for Disease Control and Prevention (CDC) estimates the number of children born with HIV between 1991 and 2011 decreased from 1650 to 110 cases per year.⁶⁷ Rates of death, AIDS, opportunistic infection, and organ-specific disease (including thrombocytopenia) have all decreased since the advent of ART.⁶⁸ Reviews of HIV infection in children are available.^{69,70}

The hematologic manifestations of AIDS in children are similar to those in adults (see [Chapter 157](#)) and depend on the stage of the HIV infection and the presence of coexistent disease.^{71,72} Anemia is by far the most common finding (seen in 70%–90% of cases), although the incidence has decreased with effective antiviral therapy.^{73–75} Moderate anemia (hemoglobin less than 8–9 g/dL) has been identified as an independent risk factor for disease progression in children.⁷⁶ Although there have been few studies of severe anemia (hematocrit <25%), in one study it correlated with development of an opportunistic infection and death within 7 months.⁷⁷ As in adults, inadequate RBC production is the most important pathogenetic mechanism for the anemia. The etiology for reduced erythropoiesis is multifocal, including direct effects of HIV, associated infections, medications, and deficiency of micronutrients.⁷³ Although Coombs-positive hemocytic anemia has been described,⁷⁸ studies suggest that the finding of a positive direct antiglobulin test result is more likely a reflection of hypergammaglobulinemia. Although evidence indicates that erythropoietin may improve the hemoglobin and quality of life of patients with HIV and anemia,⁷⁹ the evidence is not strong.⁸⁰

Leukopenia and neutropenia are commonly seen in HIV-infected children (occurring in 47% and 41%, respectively), with severe

neutropenia associated with opportunistic infections. Immune neutropenia and also circulating anticoagulants have been described. Lymphopenia is progressive but less prominent in children than in adults until late in the course.

Thrombocytopenia is present in 13% to 30% of pediatric patients with AIDS and can be associated with clinically significant and even fatal hemorrhage, although in the modern era of highly active antiretroviral therapy (HAART), the incidence in adults is as low as 0.6%.⁸¹ The mechanism of the thrombocytopenia in most cases is immune destruction, with a high percentage of patients having antiplatelet antibodies or immune complexes,⁸² although amegakaryocytic thrombocytopenia has been reported.⁶² Variable therapeutic responses to both corticosteroids and intravenous IgG have been demonstrated; some children have spontaneous remissions.^{82,83} Treatment with ART has resulted in an increase in the platelet count in some children.⁸⁴ Thrombosis has also been described and is associated with severe disease.⁸⁵

Isolated thrombocytopenia as a presenting manifestation of HIV infection has been reported in a number of children, usually infants and even in a neonate.^{65,86} There have been no associated clinical stigmata of AIDS or ARC, and patients have been responsive to standard treatment (intravenous IgG or prednisone), often with sustained remissions. In a few patients with prolonged follow-up, no further manifestations of HIV infection were seen. Although it has been suggested that HIV testing may be indicated in all children with ITP, it seems most reasonable to check the HIV status of those with risk factors for AIDS and those outside the typical age group for ITP, especially infants.

COLLAGEN VASCULAR DISEASE AND ACUTE VASCULITIS

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) (formerly called *juvenile rheumatoid arthritis*) includes a group of disorders with varied clinical presentations, courses, and outcomes. Systemic juvenile idiopathic arthritis (sJIA), which occurs in 10% of patients, is a multisystem disease characterized by fever, rash, polyarticular (often destructive) arthritis, hepatosplenomegaly, and lymphadenopathy. New understanding of the pathogenesis of sJIA points to abnormalities in innate immunity (cytokines IL-1, IL-6, IL-18, neutrophils, and macrophages), distinguishing it from other forms of JIA, suggesting sJIA is an autoinflammatory syndrome rather than an autoimmune disease.⁸⁷ Another distinguishing feature of JIA is the association with macrophage activation syndrome (MAS) (see later discussion). Patients with JIA commonly demonstrate hematologic abnormalities that are proportional to disease activity. In the polyarticular presentation, more than four joints are involved, but the systemic findings are absent. This group, which accounts for 25% of patients, also may exhibit hematologic abnormalities. Pauciarticular JIA is characterized by involvement of fewer than four joints and is rarely associated with hematologic abnormalities.

Children with ALL may have a similar presentation to that of children with sJIA, which includes fever, joint pain, hepatosplenomegaly, and isolated cytopenias. Because about 5% of children with ALL are misdiagnosed as having JIA, before initiation of corticosteroid therapy, it is important to perform bone marrow aspiration to rule out leukemia in any patient thought to have sJIA. Distinguishing features of children ultimately diagnosed with ALL after referral to a rheumatologist include atypical pattern of pain (nonarticular bone pain and night pain with no morning stiffness) and cytopenias, especially thrombocytopenia.⁶⁵

The incidence of anemia is 50% to 60% in patients with systemic or polyarticular JIA and 10% in those with pauciarticular arthritis. The anemia usually correlates with disease activity, worsening during acute flare-ups; however, there is no relationship to the duration of illness. RBCs may be normochromic/normocytic or microcytic/

hypochromic. The reticulocyte count usually is low. Iron studies often show low serum iron, increased free erythrocyte protoporphyrin, low-normal or elevated total iron-binding capacity, and normal or low serum ferritin. Serum erythropoietin levels usually are mildly elevated (but not as high as in iron deficiency). The bone marrow does not show erythroid hyperplasia in response to the anemia and has diminished (but not absent) iron stores. The etiology of the anemia may be chronic disease, iron deficiency, or both.

Although it is difficult to differentiate anemia of chronic disease from iron-deficiency anemia, studies in patients with systemic-onset chronic JIA suggest defective iron supply as the primary cause.⁸⁸ Transferrin receptor levels are inversely related to hemoglobin levels in this population. The finding of elevated serum transferrin receptor levels may be a reliable indicator for diagnosis of iron deficiency in JIA.⁸⁹ Oral iron has been effective in raising the hemoglobin in iron-deficient anemic patients with JIA, and intravenous iron has been effective in raising the hemoglobin level in children unresponsive to oral iron.⁸⁸ Excessive production of IL-6, tumor necrosis factor- α (TNF- α), and other inflammatory cytokines has been documented in patients with JIA and may provide an explanation for the abnormalities in iron metabolism. IL-6 may enhance ferritin synthesis and increase hepatic uptake of serum iron. Increased ferritin results in reticuloendothelial iron blockage and diminished iron absorption.⁸⁸ In one study of treatment with anti-TNF- α therapy, the hemoglobin as well as markers of abnormal iron metabolism improved significantly.⁹⁰ Less common causes of anemia in patients with JIA include erythroid aplasia, suppression of erythropoiesis by circulating inhibitors, hemolysis, and a macrocytic anemia probably related to increased folate clearance and low plasma and RBC folate levels.

In sJIA, leukocytosis with mean WBC counts up to 30,000/ μ L and neutrophilia with a left shift occur in 90% of patients, especially those with active disease. Leukocytosis is less common in polyarticular arthritis and usually absent in pauciarticular disease. Leukocytosis is so prevalent in sJIA that the presence of neutropenia should alert the clinician to question the diagnosis and ensure that other possibilities such as systemic lupus erythematosus (SLE) and ALL are not overlooked. Nonetheless, neutropenia has been reported in several patients with JIA.⁹¹ Other causes of neutropenia are bone marrow suppression caused by therapy with tocilizumab,⁹² gold, or nonsteroidal antiinflammatory drugs (NSAIDs),⁹³ and, in adults, Felty syndrome, comprising the triad of rheumatoid arthritis, splenomegaly, and neutropenia.

The platelet count is elevated in about half of the patients with sJIA. IL-6, a cytokine that stimulates thrombopoiesis, is elevated in patients with active sJIA, and increased levels of IL-6 are correlated with elevated platelet counts.⁹⁴ Persistent thrombocytosis may serve as an adverse prognostic marker for long-term outcome in JIA.

Thrombocytopenia may result from bone marrow suppression by gold therapy, the rare consumptive coagulopathy, or platelet trapping in Felty syndrome. Thrombocytopenia is also seen in the potentially life-threatening complication of MAS (see discussion of MAS below). Because thrombocytopenia is uncommon in JIA, however, an unexplained low platelet count should lead the clinician to consider alternative diagnoses, such as SLE or ALL. On the other hand, isolated thrombocytopenia may be the only presenting sign in a child who later develops JIA or another collagen vascular disease. Therefore JIA and SLE should be considered in the differential diagnosis of ITP in children who are older than 9 years of age and female. Appropriate screening tests for autoantibodies (e.g., antinuclear antibody assay, direct Coombs test) should be performed at diagnosis and periodically if new symptoms develop.

Disseminated intravascular coagulation may occur in children with sJIA after hepatic damage, as part of the MAS, from aspirin or gold therapy, or during disease flare-ups treated with NSAIDs when serum albumin is low.⁹⁵ These patients often are very ill and may require early and aggressive medical therapy as well as platelet and coagulation factor replacement to control the coagulopathy. The incidence of coagulation abnormalities in nonbleeding patients with sJIA is controversial. One study demonstrated prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT) and

elevated fibrinogen, factor VIII, and fibrinopeptide A levels in up to 50% of these patients,⁹⁶ but other studies have not confirmed such findings. Another study found elevation of D-dimer levels in 96% of systemic-onset JIA patients; serial measurements of D-dimer levels appeared to parallel response to treatment.⁹⁷ In apparent distinction, decreased fibrinolytic activity and increased plasminogen activator inhibitor have been found in patients with active JIA, especially those with the systemic form. Antibodies against factor VIII and the lupus anticoagulant are occasionally seen in children with JIA.

Macrophage Activation Syndrome

MAS is a life-threatening multisystem disorder most closely resembling hemophagocytic lymphohistiocytosis (HLH) that occurs primarily in patients with systemic-onset juvenile idiopathic arthritis (sJIA).^{98,99} This syndrome usually occurs early in the course of active sJIA and can even be a presenting feature,¹⁰⁰ although it has been reported to occur later and during a quiescent phase.¹⁰¹ It is estimated that approximately 7% of patients with sJIA develop MAS, and the mortality rate is between 10% and 20%.¹⁰² MAS has also been reported in other systemic inflammatory disorders, including SLE and Kawasaki disease.¹⁰⁰

The main clinical features of MAS include a high unremitting fever, hepatosplenomegaly, lymphadenopathy, bleeding, rash, and central nervous system manifestations. Neurologic symptoms include lethargy, irritability, disorientation, headache, seizures, and coma. Children with MAS are acutely ill, and almost 50% require intensive care unit care.¹⁰³ The diagnosis may be delayed because the presentation mimics an acute exacerbation of sJIA or severe infection. Of interest, some patients have shown a paradoxical improvement in the underlying inflammatory disease at the onset of MAS. Precipitating factors that have been implicated include a flare-up of the underlying disease, aspirin or other NSAID toxicity, viral infections, a second injection of gold salts, methotrexate therapy, and sulfasalazine therapy.¹⁰³

Typical laboratory features include pancytopenia, hypofibrinogenemia (<250 mg/dL), elevated liver enzymes (>40 IU/mL), hypertriglyceridemia (>160 mg/dL), and marked elevation of ferritin ($>10,000$ ng/mL). Other laboratory findings with less sensitivity and specificity include coagulopathy, hyponatremia, and hypoalbuminemia. The hallmark of this disorder is the presence of hemophagocytic histiocytes, usually seen in the bone marrow, although they can also be found in the liver and other organs. These characteristic macrophages are regarded as confirmatory evidence rather than a requirement for a diagnosis because they have not been documented in as many as 20% of patients with the classical clinical and laboratory findings of MAS.^{103,104}

There are no accepted diagnostic criteria for MAS in sJIA. Preliminary diagnostic guidelines have been proposed (Table 152.2).¹⁰⁴ In a study comparing these preliminary diagnostic guidelines with HLH-2004 guidelines, the preliminary guidelines were best able to identify MAS in the setting of sJIA.¹⁰⁵ An international consensus survey of diagnostic criteria for MAS was completed by 232 physicians.¹⁰⁵ The following were the top nine diagnostic criteria identified by more 50% of respondents in order of frequency:

1. Falling platelet count
2. Hyperferritinemia
3. Bone marrow hemophagocytosis
4. Increased liver enzymes
5. Falling leukocyte count
6. Persistent continuous fever $>38^{\circ}\text{C}$
7. Falling erythrocyte sedimentation rate
8. Hypofibrinogenemia
9. Hypertriglyceridemia

These features may provide the best candidates for future refinement of diagnostic criteria. The diagnostic guidelines are similar to criteria for the diagnosis of HLH,¹⁰⁶ although a number of differences should

TABLE 152.2

Preliminary Diagnostic Guidelines for Macrophage Activation Syndrome in Systemic Juvenile Idiopathic Arthritis^a

Laboratory Criteria

1. Decreased platelet count ($\leq 262 \times 10^9/\text{L}$)
2. Elevated levels of aspartate aminotransferase (>59 IU/L)
3. Decreased white blood cell count ($\leq 4.0 \times 10^9/\text{L}$)
4. Hypofibrinogenemia (≤ 250 mg/dL)

Clinical Criteria

1. Central nervous system dysfunction (irritability, disorientation, lethargy, headache, seizures, coma)
2. Hemorrhages (purpura, easy bruising, mucosal bleeding)
3. Hepatomegaly (≥ 3 cm below the costal margin)

Histopathologic Criterion

Evidence of macrophage hemophagocytosis in the bone marrow aspirate

Diagnostic Rule

The diagnosis of macrophage activation syndrome requires the presence of any two or more laboratory criteria or of at least two clinical or laboratory criteria. A bone marrow aspirate for the demonstration of hemophagocytosis may be required only in doubtful cases.

^aThe suggested criteria are useful only in patients with active systemic-onset juvenile idiopathic arthritis. The laboratory thresholds are examples only and are not specific for the diagnosis (see text).

From Ravelli A, Magni-Manzoni S, Pistorio A, et al: Preliminary diagnostic guidelines for macrophage activation syndrome complicating systemic juvenile idiopathic arthritis. *J Pediatr* 146:598, 2005.

be emphasized. In MAS, clinical features are weaker discriminators than laboratory features. Although the presence of fever was universal in patients with MAS, it had a low specificity rate because of the high incidence of fever in patients with sJIA without MAS. The pattern of fever may be of more importance because patients with MAS tend to have nonremitting fever as opposed to the high spiking fevers seen in sJIA. The other clinical criteria may occur late in the course of MAS, resulting in abnormal laboratory findings being more helpful in making a diagnosis early in the course of the illness. Because blood counts are usually elevated in patients with sJIA, the decrease in counts seen with MAS may actually result in a “normal” blood count, although in patients with HLH, cytopenias are usually well below the normal levels. Laboratory markers of T-cell activation (soluble IL-2 receptor [SCD25]) and of macrophage activation (soluble CD163 [SCD163]) have been shown to be elevated in patients with MAS and may serve as useful diagnostic markers in the future.¹⁰⁷

The pathogenesis of MAS is similar to that proposed for HLH.^{106,108} Indeed, it has been proposed that MAS be considered one of the subtypes of acquired HLH.¹⁰² The presentation of MAS is a result of an ineffective immune response to an endogenous or exogenous stimulus leading to an exaggerated inflammatory state produced by a release of high levels of cytokines. These proinflammatory cytokines include TNF- α , IL-1, IL-6, IL-8, IL-12, IL-18, macrophage inflammatory protein-1 α (MIP-1 α), and interferon- γ (IFN- γ) released by stimulated lymphocytes and histiocytes. Defective natural killer (NK) cell function and cytotoxic T-cell activity have been documented in patients with MAS as well as in those with HLH and may be the common pathway leading to the clinical presentation.¹⁰⁹ NK-cell function in patients with active sJIA but without MAS has also been found to be abnormal.¹¹⁰ This may explain why MAS is almost exclusively seen in the systemic form of JIA and not the other subtypes of the disease. Mutations in the perforin gene and the *MUNC 13-4* gene have been described in some patients with HLH. The cytotoxic function of NK cells is mediated by the release of perforin and other cytolytic granules into the target cell, leading to cell death. Abnormalities of both perforin gene and *MUNC 13-4* polymorphisms have been found in patients with MAS.^{109,111,112}

Treatment of MAS should be started promptly and not delayed for lack of hemophagocytosis if the clinical and laboratory features are consistent with the diagnosis. The initial treatment should be

high-dose corticosteroid therapy followed by cyclosporin A (CsA) if there is not a rapid response. Intravenous methylprednisolone with doses from 2 to 30 mg/kg/day has been the most common corticosteroid reported in the literature and is usually effective in controlling hyperinflammation.¹⁰³ The corticosteroid of choice used in the treatment of HLH is dexamethasone, but its use has not been reported in MAS. CsA has been very effective in inducing remission either when used as initial treatment or in cases of corticosteroid failure.^{101,103} In addition to immunosuppression, there should be withdrawal of any suspected triggering medications and treatment of infection. Intravenous immunoglobulin (IVIg) therapy has usually been ineffective, although it has been reported to induce a full recovery in one case of a child who failed high-dose corticosteroids.¹¹³ For unresponsive patients, treatment with etoposide or other HLH salvage therapy may be necessary. Etanercept and infliximab have also been reported to induce clinical responses in patients with MAS.^{114–116} These drugs are recombinant soluble TNF- α receptor fusion proteins that bind to TNF- α , blocking its effect. Although use of these agents to reduce the elevated levels of TNF- α found in this disorder is attractive, these agents should be used with caution because there are case reports of MAS developing after the initiation of etanercept.¹¹⁷ Anakinra, a recombinant IL-1 receptor antagonist, has shown promising results in treatment of sJIA as well as MAS.^{117,118}

Kawasaki Syndrome

Kawasaki syndrome is an acute multisystem disorder characterized by an abrupt onset of fever unresponsive to antibiotics; bilateral conjunctival injection; reddening of the lips, tongue, or oral mucosa; reddening, induration, or peeling of the skin on the hands or feet; polymorphous truncal rash; and cervical lymphadenopathy. This disorder occurs most commonly in children younger than 2 years of age and has many features of a severe vasculitis. The most serious complication is development of coronary artery aneurysms, which occurs in 20% of children and is responsible for the 3% mortality rate; death often is caused by coronary artery thrombosis or rupture. The etiology of Kawasaki disease is unknown. The immunologic and clinical characteristics of this disorder are similar to those of diseases associated with superantigen production, of which toxic shock syndrome is a classic example.¹¹⁹

Children with Kawasaki syndrome may have a mild, normochromic, normocytic anemia with reticulocytopenia. Rarely, a severe Coombs-positive, antibody-mediated hemolytic anemia has been reported after administration of IVIg. Leukocytosis is almost universal, with mean neutrophil counts of 21,000/ μ L. Ninety-five percent of patients have neutrophilia, with a left shift persisting up to 3 weeks. The finding of vacuoles and toxic granulation in neutrophils is a helpful adjunct in the diagnosis of Kawasaki disease. Activated neutrophils and monocytes may play a role in aneurysm development through the production of elastase. Granulocyte colony-stimulating factor levels have been correlated with coronary artery dilation during the acute phase of Kawasaki syndrome.¹²⁰

Studies of cellular immunity show normal total T-cell numbers but decreased suppressor T cells, causing relatively elevated T helper-cell levels during the first 4 weeks of disease.¹²¹ The change of T-cell subsets plus B-lymphocyte stimulation may contribute to the exaggerated production of all major Ig classes during the first 8 weeks of the disease.¹²² An unusual infiltration of IgA-producing plasma cells within vascular tissue in Kawasaki syndrome, with an oligoclonal IgA response, suggests that the immune stimulation is antigen driven.¹²³ Circulating immune complexes and high C3 (but not C4) levels are found during weeks 1 and 3. During the acute phase, increased levels of the cytokines IL-1, IL-6, IL-8, IFN- γ , and TNF are noted in the circulation, as well as of IL-1, IL-2, IFN- γ , and TNF in blood vessels and skin biopsies.¹¹⁹ Declining serum IL-6 levels appear to correlate with clinical response after treatment with IVIg.¹²⁴

Impressive thrombocytosis occurs in 85% of patients by the second week, peaking during the third. Platelet counts of up to 2 million/ μ L are not uncommon, and the mean platelet count is

700,000/ μ L. Thrombocytosis may serve as a marker of possible atypical Kawasaki disease in infants younger than 1 year of age. In a study of more than 25,000 infants with unexplained fever, 8.8% with a platelet count greater than 800,000/ μ L were found to have Kawasaki disease, as opposed to 0.4% of those with a platelet count less than 800,000/ μ L.¹²⁵ Thrombocytosis is preceded by elevated thrombopoietin levels.¹²⁶ However, 2% of patients may have thrombocytopenia caused by a consumptive coagulopathy. Platelets demonstrate hyperaggregation on exposure to adenosine diphosphate, epinephrine, and collagen *in vitro*. These abnormalities may persist for as long as 9 months after diagnosis.¹²⁷ During the first month, levels of factor VIII, fibrinogen, thromboxane B₂, and thromboglobulin are increased. AT III and fibrinolysis activity are decreased. The PT, aPTT, and thrombin time usually are normal.¹²⁸

Prevention and treatment of existing coronary aneurysms constitute the primary therapeutic goals. Aspirin suppresses platelet aggregation but does not affect aneurysm formation. Combining aspirin with high-dose IVIg infusions reduces aneurysm formation, decreases fever, and normalizes laboratory signs of inflammation.¹²⁹ The use of corticosteroids is controversial, with conflicting data regarding increased aneurysm formation after steroid use.^{130–132} However, in a randomized, double-blind, placebo-controlled trial, a single pulsed dose of intravenous methylprednisolone, in addition to conventional therapy, did not improve coronary artery outcomes.^{133,134} In subgroup analysis of children with persistent fever, coronary outcomes were better in the corticosteroid group. If children at highest risk of primary treatment failure could be identified initially, corticosteroid use might be of benefit in this group. Infliximab has been used in the treatment of IVIg-resistant patients, with limited success.¹³⁵ Guidelines for the diagnosis, treatment, and long-term management of patients with Kawasaki syndrome have been published.^{133,136,137}

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (HSP) (anaphylactoid purpura) is a systemic vasculitis characterized by unique purpuric skin lesions, transient arthralgias or arthritis (especially affecting the knees and ankles), colicky abdominal pain, and nephritis. Recognition of HSP is important, not so much for its hematologic abnormalities (which are rare) as for the unusual nonthrombocytopenic purpuric lesions, which are frequently confused with the hemorrhagic rash of ITP. This vasculitis occurs most commonly in children 3 to 7 years old, often 1 to 3 weeks after an upper respiratory tract illness. The presenting sign in 50% of children is a characteristic rash, which may begin as urticaria. As these eruptions fade, they are replaced by brownish-red maculopapular lesions and petechiae. The petechiae coalesce, forming areas of raised or “palpable” purpura on the buttocks, legs, and extensor surfaces of the arms, with a symmetric distribution. The rash may fade but can recur for months, especially with increased activity. Children younger than 3 years of age often have painful soft tissue swellings of the scalp and face (especially periorbital areas) and on the dorsa of the hands and feet. Infantile acute hemorrhagic edema is an acute vasculitis affecting infants and children younger than 2 years of age, which may be a benign form of HSP.

Sixty-seven percent of patients experience colicky abdominal pain, often associated with vomiting, hematemesis, or melena from submucosal hemorrhage and edema of the small bowel wall. With severe edema, the bowel wall may become a leading point for intussusceptions.¹³⁸

Renal involvement occurs in 30% to 50% of patients, especially boys and older children, and may present after initial systemic symptoms. Hematuria, either microscopic or gross, may occur with proteinuria during the first 3 weeks of the illness but rarely after 6 months. With progressive involvement, hypertension, impaired renal function, and renal failure can occur in up to 15% of children, with an associated mortality rate of 3%. In occasional patients, an acute scrotum that mimics testicular torsion may develop; however, surgical exploration may not be necessary if appropriate clinical and

radiographic features are present. Other rare manifestations of HSP include neurologic, cardiac, and pulmonary events.

Anemia occasionally develops as a result of gastrointestinal (GI) tract blood loss or decreased RBC production caused by renal failure. The leukocyte count is normal. Despite the impressive purpura, the platelet count is normal or increased with normal platelet function. Coagulation factor levels usually are normal, although transient decreases in factor XIII activity and vitamin K deficiency from severe vasculitis-induced intestinal malabsorption have been reported. Signs of increased fibrinolysis, as evidenced by elevation of D-dimer and other markers, have been described.¹³⁹ Bleeding in the GI tract; the lungs; or, rarely, the central nervous system is caused by a necrotizing vasculitis and not a hemostatic defect.¹³⁸ Hypercoagulability does not play a role with normal frequency of *MTHFR*, prothrombin, and factor V Leiden gene mutations.¹⁴⁰

HSP is considered an IgA-mediated inflammation of small vessels. Biopsy of skin or other involved tissue reveals a leukocytoclastic vasculitis. Immune complexes of IgA with complement, IgG, or IgM have been found circulating in the serum¹⁴¹ and deposited in blood vessel walls of the kidneys and in intestinal and skin lesions.¹⁴² The mechanism of production, accumulation, and deposition of IgA immune complexes in the blood vessel is unclear. It has been suggested that HSP may be a systemic form of IgA nephropathy, although this is controversial.^{143,144} Both disorders have identical features on renal biopsy and are characterized by mesangial proliferation, occasional focal sclerosis, and crescent formation.¹⁴⁵

Treatment is mainly supportive, although corticosteroids have been found to provide symptomatic relief with severe joint, scrotal, or abdominal pain.^{146,147} They do not alter skin involvement or prevent renal involvement. Recent studies have suggested that corticosteroids plus azathioprine, cyclosporin A, or cyclophosphamide may have a role in the management of severe renal involvement.^{148–152} Rituximab has been reported to be effective in decreasing the symptoms of three patients with severe, refractory chronic HSP.¹⁵³ The prognosis is good for full recovery, except in children with renal failure.

CARDIOPULMONARY DISEASE

Congenital Heart Disease

Congenital heart disease (CHD) occurs in about 1% of live births. Structural heart malformation usually follows predictable patterns such that six defects account for 70% of all cardiac disorders: ventricular septal defect, atrial septal defect, tetralogy of Fallot, patent ductus arteriosus, pulmonary stenosis, and aortic stenosis. Children with cardiac abnormalities may be acyanotic or cyanotic, depending on the underlying lesion. Hematologic abnormalities occur most often in children with cyanotic critical congenital heart disease (CCHD). Polycythemia is the bone marrow response to chronic hypoxemia in patients with CCHD. The decreased arterial oxygen content stimulates erythropoietin production, which in turn increases erythropoiesis. The resultant increased RBC mass increases the oxygen-carrying capacity of the blood, resulting in improved tissue oxygenation. With adequate compensation, erythropoietin levels fall to normal, and higher RBC production is maintained. A second compensatory mechanism is an increase in 2,3-diphosphoglycerate (2,3-DPG) levels in the RBCs when the arterial oxygen tension is less than 70 mmHg. The higher 2,3-DPG level causes a right shift of the oxyhemoglobin curve, resulting in greater oxygen release to the tissues.

Polycythemia in cyanotic children is beneficial up to a point. Because the relationship between the hematocrit and blood viscosity is hyperbolic, minor increases in the hematocrit above 70% cause marked increases in blood viscosity. This higher viscosity results in impaired perfusion within the microvasculature, with ultimately less tissue oxygen delivery. The impairment is magnified in severe polycythemia (hematocrit level >75%) such that headache; irritability; dyspnea; and even formation of pulmonary, renal, or central nervous

system thrombi may result.¹⁵⁴ To prevent these complications, the hematocrit level should be maintained around 60% through the use of exchange transfusions. Small aliquots of the patient's blood are slowly removed and replaced by equal volumes of plasma or 5% albumin. Care should be taken to remove blood slowly because vascular collapse, cyanosis, stroke, and seizures have been reported with too rapid an exchange. Apheresis (erythrocytapheresis) also has been shown to be an effective means of decreasing viscosity in patients with polycythemia.

Infants with CCHD are at risk of developing iron-deficiency anemia. The deficiency may result from the combination of poor iron stores at birth (especially in premature infants), increased iron needed for enhanced erythropoiesis, poor iron intake because of poor feeding, and ongoing iron losses as a consequence of phlebotomy or exchange transfusion. These children may exhibit symptoms of iron deficiency (irritability, anorexia, poor weight gain) or worsening cyanosis. The hemoglobin may be normal for age but inappropriately low for the degree of hypoxemia. Low RBC indices and hypochromic, microcytic RBCs are the best indices of iron deficiency in this setting.¹⁵⁵ Children with polycythemia who have iron-deficiency anemia are at increased risk for cerebral vein thrombosis because of the poor deformability of the iron-deficient RBCs, which further increases blood viscosity.¹⁵⁶ To prevent this complication and to allow for maximal tissue oxygenation, all infants should be fed iron-rich infant formula and receive iron replacement therapy as needed to normalize RBC indices. Hemolytic anemia, characterized by mechanical destruction of RBCs and manifested by the presence of schistocytes in the peripheral blood smear, is occasionally seen after the placement of prosthetic heart valves.

Routine screening of patients with CHD has demonstrated coagulation abnormalities in 20% to 59% of children with acyanotic defects and in 40% to 50% of those with cyanotic heart disease (Table 152.3).¹⁵⁷ Only 11% of children with CCHD have any clinical evidence of bleeding preoperatively. However, children with underlying hemostatic defects have a greater frequency and severity of postoperative bleeding.^{157,158} Presurgical screening tests should include at least a platelet count, platelet function assay (e.g., closure time), PT, and aPTT. Further investigations may be indicated if there is a history of bleeding or abnormal results on screening tests. Acquired von Willebrand syndrome has been reported in patients with CHD and is

TABLE 152.3 Coagulation Abnormalities in Congenital Heart Disease

Abnormality	Incidence (%)	
	Acyanotic CHD	Cyanotic CHD
Prolonged bleeding time	11	28
Prolonged PT		20
Prolonged aPTT		19
Thrombocytopenia	12–40	0–36
Abnormal platelet aggregation	14	38–70
Increased fibrinolysis	12	0–10
Abnormal clot retraction	10	
Low fibrinogen	16	12
Increased fibrin split products		Occasionally
Decreased factors II, V, VII, VIII, IX, X, XI, XII		Occasionally
Decreased protein C		25 ^a

possibly associated with an increased bleeding risk, especially in those receiving aspirin. The multimer pattern reveals decreased large-molecular-weight multimers.¹⁵⁹ Children with polycythemia have contracted plasma volumes; therefore when blood samples are collected, extra care should be taken to ensure the proper 1:9 ratio of 3.8% sodium citrate to blood to prevent artificial abnormalities in coagulation test results.

The etiology of the coagulation abnormalities in CCHD is unclear. Earlier reports suggesting a role for consumptive coagulopathy have not been confirmed. Protein C levels in 8 of 29 term infants with CCHD were significantly lower than in control participants with no evidence of familial deficiency. Of these infants, two had thrombotic complications, and four had consumptive coagulopathy.¹⁶⁰ Platelets have shortened survival times (even with normal counts), and normal to increased numbers of megakaryocytes in the bone marrow have been reported.¹⁶¹ This increased platelet destruction does not appear to be attributable to DIC. Both the platelet and coagulation abnormalities are directly proportional to the degree of hypoxemia and polycythemia. For example, whereas children with oxygen saturation greater than 60% have a mean platelet count of 315,000/ μ L, those with oxygen saturation less than 60% have a mean count of 185,000/ μ L.¹⁶¹ The mild platelet and coagulation abnormalities usually are decreased or corrected after surgical repair of the heart defect.^{157,162} With bleeding or if surgery is not possible, the coagulopathy may be treated by correction of polycythemia to a hematocrit level of 60% by using slow plasma exchange transfusion.¹⁶³

Cystic Fibrosis

Cystic fibrosis (CF) is a multisystem disorder of exocrine gland dysfunction characterized by chronic pulmonary disease, pancreatic exocrine insufficiency, hepatic dysfunction, abnormal reproductive organ function, and intestinal obstruction associated with abnormally high sweat electrolyte levels. It is an autosomal recessive disease with an incidence of 1 in 2000 live births.

Severe hemolytic anemia caused by vitamin E deficiency may be the presenting manifestation of CF. Dolan¹⁶⁴ initially linked deficiency of vitamin E with severe hemolytic anemia in infants who presented with pallor, edema, hypoproteinemia, and thrombocytosis. This complication can be seen as early as 6 weeks of age.

Many children with CF are chronically hypoxic, yet they do not have the expected augmented erythroid response. In a study by Vichinsky and colleagues,¹⁶⁵ none of 42 children with CF had polycythemia, and 30% (especially the boys and the older children) had a normochromic, normocytic, or hypochromic microcytic anemia with reticulocytopenia. In contrast with children with CCHD, there was no appropriate increase in RBC 2,3-DPG levels, no right shift of the oxyhemoglobin curve, and either a low or a normal erythropoietin level. In vitro assays showed normal erythroid progenitor cell numbers and no serum inhibitor of erythropoiesis. Up to 66% of the children studied had abnormalities consistent with iron deficiency, and all responded to oral or parenteral iron therapy.

It appears that the etiology of anemia in CF is multifactorial. A blunted erythropoietic response to hypoxia plus iron deficiency secondary to iron malabsorption or poor dietary iron intake may each be partially responsible for the development of anemia. If iron deficiency persists despite adequate oral supplementation, the possibility of ongoing blood loss or of iron malabsorption that may necessitate parenteral iron replacement should be considered. Soluble transferrin receptor levels may be helpful in distinguishing iron deficiency from anemia of chronic inflammation in CF because, unlike serum ferritin and transferrin, soluble transferrin receptor does not appear to be an acute-phase reactant.^{166,167}

Use of multiple antibiotics in patients with CF is routine. There have been a number of case reports of adult patients with severe, life-threatening hemolytic anemia attributed to piperacillin.^{168,169} This complication has not been reported in children to date.

Findings of studies of neutrophil function in children with CF are conflicting. Some reports indicate impaired chemotaxis, chemiluminescence, granule release, and superoxide production,^{170–172} but others have demonstrated factors in patient sputum that actually enhance neutrophil and monocyte responses to stimulants.^{173,174} Although these sputum factors may improve neutrophil killing ability, they also may worsen neutrophil-mediated lung damage through increased release of neutrophil elastase.¹⁷⁵ Evaluation of immune function has revealed impaired lymphoproliferative responses to *Pseudomonas* spp. and other gram-negative bacterial antigens, defective opsonization, increased levels of circulating immune complexes, and decreased numbers of T-helper cells in 30% of patients.^{152,176} The contribution of these findings to frequent pulmonary infection is still under investigation.

Children with CF usually do not experience clinically significant bleeding owing to impaired hemostasis despite the risk of liver disease and vitamin K deficiency from malabsorption. An exception may be infants younger than 1 year of age, in whom rare case reports of vitamin K–deficient hemorrhage have been reported in association with CF.^{177–179} Routine coagulation tests usually yield normal results, with an occasional prolonged PT reported. A study by Corrigan and colleagues^{156,180} revealed that 60% of 24 patients had a more subtle deficiency of prothrombin activity, thought to be caused by vitamin K deficiency. Other investigators, using direct measurement of vitamin K and protein induced by vitamin K absence/antagonist-II (PIVKA-II), have reported conflicting percentages of patients to be vitamin K deficient,^{181,182} with another uncontrolled study demonstrating normalization of PIVKA-II values in many patients by routine administration of daily oral vitamin K.¹⁸³ Routine vitamin K supplementation is recommended for all patients with CF,¹⁸⁴ although there are inadequate data to define the ideal dose.¹⁸⁵

Children with CF appear to have a particularly high predisposition to recurrent venous thrombosis. In one study of 19 patients with recurrent venous thrombosis, 6 had CF, but none of 101 patients with thrombosis without recurrence had CF. A striking association with respiratory tract colonization with *Burkholderia cepacia* was noted, as was the frequent presence of a central venous catheter. Several of the recurrences occurred while patients were on therapeutic anticoagulation.¹⁸⁶ Studies of small populations of both children and adults have documented an increased incidence of protein C and protein S deficiency, as well as lupus anticoagulants.^{187–189} These abnormalities are likely acquired defects in most patients with CF because of the potential for having subclinical vitamin K deficiency, liver function abnormalities, and recurrent infections. Follow-up studies have not shown persistent abnormalities in many patients. The incidence of activated protein C resistance and factor V Leiden was similar to that in the general population. Although it would be anticipated there would be an increased frequency of venous thrombosis because of the increased use of central venous catheters, at least one large study of older adolescents and adults with CF who had totally implanted venous access devices revealed a very low incidence of complications.¹⁹⁰ Whether patients with CF have a greater risk of venous thrombosis than the control population awaits a larger prospective controlled trial.

HEMATOLOGIC MANIFESTATIONS OF CHILDHOOD GASTROINTESTINAL DISEASE

Milk Protein–Induced Enteropathy and Heiner Syndrome

The association of iron deficiency with dietary intake of cow's milk in young infants is established. A major contributing factor is the relatively poor bioavailability of iron in cow's milk compared with breast milk. In addition, the rapid growth of infants and corresponding rapid increase in RBC mass necessitate an increased requirement for dietary iron. The role of cow's milk in inducing occult GI blood loss in infants was carefully documented more than three decades ago in a sentinel

paper that also demonstrated a correlation between the amount of milk ingested and the amount of fecal blood lost.¹⁹¹ GI blood loss in response to cow's milk ingestion appears to be most prevalent in infants younger than 6 months of age and occurs with diminishing frequency in older infants.¹⁹² The majority of affected infants outgrow their milk protein sensitivity by 3 years of age. The GI blood loss may be ameliorated by heat denaturing of the milk proteins. Occasionally, toddlers and older children have been documented to have milk-induced GI bleeding with associated iron-deficiency anemia.^{193,194} Substantially limiting cow's milk consumption and prescribing iron supplementation are sufficient to correct the iron deficiency and associated hypoproteinemia with edema in most children.¹⁹⁵

A variety of GI syndromes associated with cow's milk sensitivity, with varying manifestations and severity, have been described. Associated findings may include vomiting, diarrhea, poor growth, and hypoproteinemia; however, some patients may have occult blood loss and iron-deficiency anemia without associated complaints. At the severe end of the spectrum, cow's milk protein-induced enterocolitis may occur.¹⁹⁶ Such patients may present with acute, severe bloody diarrhea; vomiting; abdominal distention; methemoglobinemia; and shock even in the absence of anemia.¹⁹⁶ Even minute amounts of cow's milk protein in human breast milk may be sufficient to precipitate a severe event.¹⁹⁷ In patients with chronic occult GI blood loss, esophagogastroduodenoscopy may reveal gastritis or gastroduodenitis, and colonoscopy may demonstrate modest histologic abnormalities in the proximal colon.^{194,198} The immunopathobiology of cow's milk protein allergy syndromes has not been fully elucidated. Most of these syndromes affecting the intestinal tract only are non-IgE mediated.^{199,200} Wilson et al¹⁹¹ reported the frequent presence of precipitating antibodies to milk proteins in their study population as a whole. However, the presence of such antibodies did not appear to predict milk-induced GI bleeding. The roles that genetic predisposition, intestinal and immunologic immaturity in young infants, exposure to cow's milk protein in breast milk, GI infections, or other factors may play in the development of milk protein enteropathy are not fully understood.

In 1962, Heiner et al described a syndrome in infants and young children that included chronic cough, recurrent lung infiltrates, poor growth, GI symptoms, blood loss, iron-deficiency anemia, and pulmonary hemosiderosis associated with multiple serum precipitins to cow's milk proteins.²⁰¹ Others have confirmed and further detailed this rare syndrome.^{201–203} Additional manifestations may include intermittent wheezing; hilar lymphadenopathy; eosinophilia; elevated levels of serum IgE, IgM, or IgA; chronic rhinitis; adenoidal hypertrophy; hypercapnia; and cor pulmonale. A feature of this syndrome is rapid improvement of the pulmonary manifestations after eliminating cow's milk from the diet.

Celiac Disease

Celiac disease, or gluten-sensitive enteropathy, is an inflammatory and malabsorptive process resulting from an aberrant intestinal T-cell immune response to ingested dietary gluten, leading to injury of the mucosa of the small intestine.²⁰⁴ Classical celiac disease has been characterized as frequently affecting infants and young children, leading to steatorrhea, failure to thrive, weight loss, and nutritional deficiency. With the advent of improved screening techniques, the prevalence is recognized to be greater than previous estimates. Celiac disease broadly affects both children and adults, many of whom may have minimal classical symptoms of the disorder. Treatment is usually institution of a gluten-free diet, with resolution of the process in the majority of cases.

Iron deficiency is frequently present in celiac disease in children and adults and may be the sole recognized manifestation of the disorder.¹⁷⁹ Dietary iron absorption occurs primarily within the proximal small intestine, the same region most affected by celiac disease. As a result, iron deficiency in celiac disease appears to be caused primarily by impaired absorption of dietary iron, although a component of chronic GI blood loss may also apply in a minority of patients.^{205,206} Iron deficiency in celiac disease may be refractory to iron

supplementation, and a significant percentage of children and adults with iron-deficiency anemia who do not respond to therapeutic oral iron replacement have celiac disease.

Folic acid and, with a lesser frequency, vitamin B₁₂ deficiency may also result from the malabsorptive process in celiac disease. Manifestations may include macrocytic anemia, leukocytopenia, and pancytopenia. Neurologic findings may be present with vitamin B₁₂ deficiency. Other vitamin and micronutrient deficiencies, including copper and vitamin K deficiency, have been observed in celiac disease. Splenic hypofunction may occur with some frequency in adults with celiac disease but appears to be less common in children. A number of case reports have suggested an association of pulmonary hemosiderosis with celiac disease.^{207,208} The pathophysiology of this association is not known, but the pulmonary process may improve with initiation of a gluten-free diet.

A high index of suspicion is important for diagnosing celiac disease in children, particularly those who are minimally symptomatic or who may be at increased risk for development of celiac disease. The latter group includes children with trisomy 21, Turner syndrome, IgA deficiency, autoimmune thyroiditis, and type 1 diabetes mellitus, as well as those with a family history of celiac disease. In addition to correcting the nutritional deficiencies and growth failure in children with celiac disease, recognition of the disease and institution of a gluten-free diet may minimize the risk of some of the associated conditions of celiac disease, including the development of non-Hodgkin lymphoma involving the intestinal tract.

Inflammatory Bowel Disease

Anemia is a very common extraintestinal manifestation of inflammatory bowel disease (IBD), particularly in children with Crohn disease, in whom the historical prevalence of anemia approaches 70% to 80%.^{209,210} A more recent series of studies suggests that the prevalence of anemia may be declining in Crohn disease, perhaps because of more effective therapy.²¹¹ The etiology of anemia in IBD appears to be multifactorial, but the most common contributing factors are iron deficiency related to chronic GI blood loss or iron malabsorption caused by intestinal mucosal injury and decreased absorption and sequestration of iron stores as is seen in the anemia of chronic inflammation. These broad mechanisms for anemia may coexist, and it is sometimes difficult to determine the predominant mechanism. Measurement of serum soluble transferrin receptor and the hemoglobin content of reticulocytes can be helpful in this setting.²¹² Other factors contributing to anemia in IBD may also be present in individual patients, including immune-mediated hemolytic anemia, hemophagocytosis, malnutrition, folate and vitamin B₁₂ deficiency, and the suppressive effects of medications on hematopoiesis.²¹³

Specific treatment of anemia in IBD may be difficult. Oral iron supplementation is not always effective. Comparative studies of oral versus intravenous iron supplementation suggest the intravenous route may result in better short-term improvement in anemia; however, long-term outcome data are lacking.^{214,215} Some patients may respond to supplemental erythropoietin administration as well.²¹⁶ Patients with IBD may have impaired enterocyte-mediated intestinal absorption of iron, the degree of which appears to correlate with disease activity.²¹⁶ The role that induction of hepcidin expression by mediators of inflammation, particularly IL-6, plays in the anemia of IBD is an intriguing area of ongoing investigation.^{217,218}

Other hematologic manifestations of IBD include leukocytosis and thrombocytosis, hyposplenism, an increased propensity toward thrombosis, and therapy-related leukopenia and thrombocytopenia. There may be an increased incidence of immune-mediated thrombocytopenia associated with IBD.²¹⁹

Other Gastrointestinal Disorders

In addition to the disorders already discussed, other GI disorders that occur in children and adolescents may be associated with the

development of anemia. Examples include antral gastritis, duodenal and colonic polyps, parasitic infestations, and GI malignancies. GI stromal tumors, although rare, usually present in teenage girls with anemia related to GI blood loss.²²⁰ In a recent report of small experience of endoscopic evaluation of the upper GI system in children and teenagers between the ages of 9 and 17 years presenting with iron-deficiency anemia who did not have hematologic or chronic diseases, heavy menstrual flow or obvious blood loss demonstrated abnormal findings in 57% of patients.²²¹ This small study suggests that careful evaluation of the GI system should be considered in children and adolescents with unexplained iron-deficiency anemia and in those in whom the iron deficiency does not correct appropriately with oral iron supplementation.

ENDOCRINE DISEASE

Hematologic Manifestations of Thyroid Disorders

The associations between thyroid disorders and hematologic abnormalities are diverse.²²² The most commonly reported findings include anemia of several etiologies and abnormalities of hemostasis. Specific associations in childhood and adolescence appear to be less common than in adults. However, some rare disorders with both hematologic and thyroid manifestations appear to be particularly pertinent to the pediatric population.

Congenital hypothyroidism has multiple etiologies, including thyroid agenesis, thyroid-stimulating hormone resistance, disorders in thyroid hormone production, and central hypothyroidism. Screening programs for congenital hypothyroidism have been widely adopted as part of neonatal screening programs for several decades, resulting in marked improvement in the clinical manifestations of congenital hypothyroidism. A series of 50 infants with congenital hypothyroidism identified by neonatal screening found that modest normocytic, normochromic anemia, correlating with the severity of the hypothyroidism, is present during the first year of life despite thyroid hormone replacement.²²³ By comparison, a separate publication on infants also identified by neonatal screening demonstrated no anemia, and 6 of 23 infants were found to be polycythemic.²²⁴ The differences in these reports is not understood but may reflect, in part, the differences in the pathophysiology of congenital hypothyroidism.

The association between autoimmune thyroid disease and anemia is well recognized. The anemia may be exacerbated by several mechanisms, including iron deficiency, pernicious anemia, and AIHA. In adults, the anemia of uncomplicated hypothyroidism is typically normocytic or macrocytic, with modest anisocytosis present on the peripheral smear.²²² In children and adolescents, the same findings appear to be present. Additionally, children may have a decrease in linear growth velocity as a manifestation of hypothyroidism, suggesting that investigation of thyroid function is appropriate for children with macrocytic anemia and declining growth rate.²²⁵ Pernicious anemia and iron deficiency may be less common in children with autoimmune thyroid disease than in adults. However, parietal cell antibodies are found in a significant percentage of children and adolescents with autoimmune thyroid disease, a finding that may predispose them to the development of both iron deficiency and pernicious anemia during young adulthood.²²⁶

Disturbances of hemostasis are also well recognized as a manifestation of thyroid dysfunction. Overt hypothyroidism and hyperthyroidism modify the hemostatic balance in opposite directions, with hypothyroid patients having an increased risk of bleeding and hyperthyroid patients having an increased risk of thrombosis.²²⁷ There are few reports of bleeding or thrombosis in children and adolescents attributed to uncomplicated overt thyroid dysfunction. Of interest is the association between acquired von Willebrand disease and hypothyroidism reported in several adolescent girls, which may be a cause of menorrhagia.^{228–230} This hemostatic imbalance may improve with thyroid hormone replacement.

More global immune dysregulation syndrome may result in both endocrine dysfunction, including thyroid abnormalities, and

cytopenias. The association of the autoimmune polyglandular syndrome, a heterogeneous group of disorders, and pernicious anemia has been reported in children.²³¹ Additionally, the immunodysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, which is caused by loss-of-function mutations of the *FOXP3* gene, has been associated with immune cytopenias, including hemolytic anemia, neutropenia, and thrombocytopenia.²³²

ANOREXIA NERVOSA

Anorexia nervosa is a psychiatric disorder occurring in about 1 in 800 adolescent girls; it is characterized by an inability to maintain a minimal normal body weight, intense fear of being fat, body image distortion, and amenorrhea. The profound weight loss is accompanied by hypothermia, hypotension, edema, lanugo, and metabolic changes and is associated with a mortality rate of 5% to 18%. A mild, normochromic, normocytic anemia with reticulocytopenia occurs in about 30% of patients.²³³ Acanthocytes or spur cells have been reported and may be caused by low serum α -lipoprotein levels. The causes of the anemia probably are decreased RBC production and a relative increase in plasma volume. A few patients have had slightly decreased RBC survival. Serum vitamin B₁₂ and folate levels usually are normal. Despite low serum iron and decreased bone marrow iron stores in 80% of patients, iron-deficiency anemia is uncommon except during recovery, when iron supplementation is necessary. The severe hypophosphatemia seen during refeeding of severely malnourished patients has been associated with hemolytic anemia.

Up to 50% of patients have leukopenia, with an absolute decrease in numbers of neutrophils, lymphocytes, and monocytes.^{234,235} The neutropenia may be quite severe. An increased incidence of infection is not usual, although with increasing use of central venous catheters, more serious bacterial infections are being reported.²³⁵ Bone marrow reserves are normal despite marrow hypoplasia and a normal to slightly decreased size of the marginal pool. Impaired neutrophil chemotaxis, intracellular killing of staphylococci, and decreased complement levels have been demonstrated in patients with anorexia. These findings are associated with occasional skin abscess formation.

Patients with anorexia nervosa have no apparent bleeding diathesis. The platelet count is normal to slightly decreased,^{233,236} and the in vitro platelet aggregation response to epinephrine, adenosine diphosphate, and collagen is exaggerated. Coagulation defects are uncommon, except for those related to vitamin K deficiency reported in bulimia.

The hematologic changes in anorexia nervosa are directly correlated with total body fat mass depletion.²³⁷ A bone marrow pattern on magnetic resonance imaging suggestive of gelatinous transformation of bone marrow (serous atrophy) is seen in patients with the lowest hematologic parameters. Direct examination of the bone marrow reveals hypoplasia with loss of fat stores and replacement by a gelatinous acid mucopolysaccharide ground substance. Focal or extensive necrosis may be present.²³⁸ Bone marrow histiocytes are relatively increased in number and have prominent blue-green granules. With nutritional supplementation, bone marrow hypoplasia reverses, the gelatinous material disappears, and the hematologic abnormalities, including neutrophil defects and low complement levels, resolve by 8 weeks.

THROMBOEMBOLIC COMPLICATIONS IN CHILDHOOD ILLNESS

Improvements in medical and surgical care, particularly advances in critical and supportive care, have led to increased survival among children with malignancy and chronic illnesses. However, the extended survival of these children has led to comorbidities such as thromboembolic complications. The increased risk of thromboembolism in children with chronic illnesses is multifactorial and can include the illness itself, medical and surgical interventions, or the central venous line used to administer therapy.

In a recent analysis of 13,449 admissions at US children's hospitals, the majority (63%) of patients with venous thromboembolism (VTE) had one or more complex chronic conditions, most commonly cardiovascular disease (28%), followed by malignancy (14%) and neuromuscular (11%) and respiratory (7%) diseases.¹⁸⁶ This review focuses on four childhood illnesses commonly associated with thromboembolism: malignancy, CHD, nephrotic syndrome, and SLE. In addition to the diseases discussed in this review, other chronic illnesses of childhood have been associated with thromboembolism, including sickle cell anemia, IBD, diabetes, and CF. Children receiving home total parental nutrition also have an increased risk of thrombosis because of the combination of a central venous catheter and infusion of hyperosmolar solutions that can injure the vascular endothelium.^{239,240} As the incidence of pediatric VTE increases, the concept of thromboprophylaxis in hospitalized children is receiving increased attention. The end of this section reviews the small but growing body of literature on this topic.

Thromboembolism in Pediatric Cancer

Although thrombosis is a well-known complication of pediatric malignancy, the overall incidence is low compared with adults with cancer. Most epidemiologic studies in this area have been limited to single-center experiences or specific cancer types. The reported incidence of thromboembolism in pediatric cancer ranges from 2% to 14% when based on clinical symptoms and up to 44% to 50% when children undergo routine radiographic screening.^{241–248} In a report of 17 years' experience at McMaster Children's Hospital, 7.9% (95% confidence interval, 6.0%–10.0%) of oncology patients experienced thromboembolism. Increasing age, certain cancer types (hematologic malignancies and sarcomas), intrathoracic disease, and catheter dysfunction were associated with a higher risk of thromboembolism.²⁴⁸ Because many thrombotic events in pediatric cancer are catheter related, the majority of thrombosis described in the literature is located in the upper venous system.

Factors associated with an increased risk of catheter-related thrombosis include insertion of peripherally inserted central catheters or Hickman catheters and a history of catheter occlusion and infection.²⁴⁹ There is increasing evidence of a bidirectional relationship between catheter-associated infection and thrombosis, and ongoing clinical studies are underway to better delineate the relationship between occlusion, infection, and thrombosis in central lines.²⁵⁰ Right atrial thrombi are also frequently seen, with a reported incidence of 9% to 14% in children with indwelling catheters.^{245,251} Typically asymptomatic, these thrombi are often found incidentally on routine surveillance echocardiograms of children receiving anthracycline chemotherapy. Patients with asymptomatic catheter-related thrombosis are at risk for postthrombotic syndrome (persistent pain, swelling, or skin changes) after catheter removal, and screening cancer survivors for these symptoms should be part of the long-term follow-up care for these patients.²⁴⁹ The occurrence of postthrombotic syndrome is associated with a history of catheter occlusion, history of catheter-related VTE, and the use of two or more catheters, and is also a predictor of decreased health-related quality of life.²⁵²

There are several mechanisms by which malignancy increases the risk of thromboembolism.^{253,254} These include direct activation of the coagulation system; inhibition of fibrinolysis through secretion of plasminogen activator inhibitor-1; and the release of cytokines, which themselves induce procoagulant and antifibrinolytic activity. Studies have also documented increased thrombin generation at the time of cancer diagnosis that persists for several months after initiating therapy. Malignant cells can also adhere to platelets, leukocytes, and the endothelium through adhesion molecules present on their surfaces. Finally, as tumors increase in size, they may compress or occlude blood vessels, leading to reduced blood flow and stasis. Non-catheter-related lower-extremity VTE can occur as a result of immobilization.²⁵⁵

Published studies indicate that patients with hematologic malignancies and sarcomas appear to have the highest risk of thromboembolism. In a meta-analysis including 1752 children with ALL, the

incidence rate for symptomatic thrombosis was 5.2%.²⁵⁶ As opposed to other types of cancer, cerebral venous thrombosis and stroke are frequently seen in ALL, particularly in the setting of asparaginase therapy. Asparaginase, an essential component of induction chemotherapy, reduces the synthesis of both coagulation factors and inhibitors as a consequence of asparagine depletion.²⁵⁷ Higher incidences of thrombosis appear to be associated with lower doses of asparaginase given over longer treatment durations, as well as prednisone.²⁵⁶ In a large Italian cohort (n = 2042), VTE occurred in 2.4% of patients and was associated with male sex and the presence of factor V Leiden and prothrombin G20210A.^{257a} Similarly to other studies, 40 of the 48 events occurred during the induction cycle of chemotherapy, likely due the prothrombotic effects of active disease, asparaginase, and prolonged steroid therapy. A predictive model incorporating high-dose prednisone, asparaginase in combination with steroids, the presence of a central venous catheter, and the presence of inherited thrombophilias has demonstrated validity in the ability to identify children at high risk of thrombosis in a large population of children with ALL, although modifications are likely necessary when treatment protocols vary.²⁵⁸ As a secondary outcome of this study, high-risk patients without low-molecular-weight heparin (LMWH) prophylaxis showed significantly reduced thrombosis-free survival during induction therapy compared with those who did receive prophylaxis; LMWH was administered according to preference of the treating physician (see box [How to Manage Thromboembolism in the Setting of Pediatric Cancer](#)).

The incidence of thromboembolism in sarcoma ranges from 14% to 16%.^{259,260} Thrombotic events in sarcoma are frequently detected at the time of presentation and may be asymptomatic. Patients with greater disease burden or metastatic disease appear to be at highest risk. Brain tumors, the most common solid tumor in children, have a relatively lower risk of thrombosis in children than in adults. Researchers in pediatric and adolescent studies have reported an incidence of only 0.5% to 2.8% as opposed to the 18% to 28% incidence of thrombosis in adults with brain tumors.^{248,261–263}

Because the incidence of thromboembolism increases with age, cancer-related thrombosis is of particular concern in adolescents and young adults with cancer, an increasing number of whom are cared for at children's hospitals. In a study of 2001 to 2008 national discharge data from US children's hospitals, 5.3% of adolescents and young adults (15–24 years of age) with cancer had a discharge diagnosis of VTE.²⁶⁴

Thromboembolism in Congenital Heart Disease

Although CHD affects only 1% of live births, almost 50% of infants younger than 6 months of age and 30% of older children who develop VTE have underlying cardiac disorders.²⁶⁵ Also, the majority of children receiving prophylactic anticoagulation are those with complex CHD, prosthetic heart valves, or severe acquired cardiac diseases such as cardiomyopathy. Children with CHD are at risk of venous, arterial, and intracardiac thrombosis, as well as embolism to the central nervous system. CHD is also the most common associated diagnosis among children hospitalized with arterial ischemic stroke in the United States.²⁶⁶

Cardiac catheterization is the most common procedure performed in children with CHD, and it is used for both diagnostic and therapeutic purposes. Access is typically obtained through the femoral artery. Historically, thromboembolism of the femoral artery was a common complication of this procedure, particularly in younger patients. In the 1970s, a randomized clinical trial demonstrated that the use of unfractionated heparin prophylaxis reduced the incidence of femoral artery thrombosis from 40% to 8% in children younger than 10 years of age.²⁶⁷ Even when heparin prophylaxis is the standard of care, postthrombotic syndrome is commonly identified in children after cardiac catheterization, although fortunately most children have mild manifestations.²⁶⁸ The Fontan procedure, which diverts systemic venous return directly to the pulmonary arteries, is the definitive palliative surgical treatment for most congenital univentricular heart

lesions.²⁶⁹ Unfortunately, thromboembolic events continue to be a major cause of morbidity and mortality associated with this procedure. The reported incidence of these complications in cohort studies ranges from 1% to 19% and includes venous thrombosis of the Fontan circuit, right atrial thrombosis, and stroke.²⁶⁹ Thromboembolic events may occur anytime after the procedure but often present months to years later.²⁷⁰ There is no consensus regarding the optimal type or duration of anticoagulation that Fontan patients should receive, nor are there data that any one prophylactic regimen is effective in reducing thromboembolic complications. Institutional protocols, if they exist, range from no anticoagulation to aspirin to warfarin. The American College of Chest Physicians (ACCP) guidelines suggest either therapy with aspirin (1 to 5 mg/kg/day) or therapeutic heparin followed by warfarin to achieve a target international normalized ratio of 2.5 but state that the optimal duration of therapy is unknown.²⁷¹ In a recently published international randomized trial of aspirin (5 mg/kg/day) versus warfarin as primary thromboprophylaxis in the first 2 years after Fontan surgery, there was no difference in thrombosis rates between groups.²⁷² However, the overall thrombosis rate was still substantial, suggesting that alternative approaches need to be considered. In a retrospective cohort of more than 400 Fontan patients, although the total prevalence of thromboembolism was low (2.7%), patients with symptomatic thromboembolism had a high mortality rate (73%). The two high prevalence periods for thrombosis were within 6 months of surgery and then long-term thromboembolism occurring more than 15 years from surgery.²⁷³

There is even less data on the role of anticoagulation or antiplatelet therapy in other cardiac procedures with the potential risk of thromboembolism. These include the placement of endovascular stents and Blalock-Taussig shunts as well as Norwood and Glenn procedures, which are typically performed before the definitive Fontan procedure. The ACCP recommends perioperative heparin therapy for these procedures.²⁷¹ The need for antiplatelet therapy after these procedures remains unknown, although aspirin unresponsiveness has been associated with postoperative thrombosis.²⁷⁴ Postoperative chylothorax is also strongly associated with VTE.²⁷⁵ Finally, thrombosis remains a significant cause of morbidity in children awaiting cardiac transplant, and thromboprophylaxis with warfarin should be considered at the time a patient is placed on the waiting list.^{271,276}

Long-term anticoagulation therapy is clearly indicated for children with prosthetic heart valves. Because there are few prospective studies and no randomized trials in children, these recommendations are based on the high-quality evidence supporting thromboprophylaxis in adults.²⁷¹

Thromboembolism in Nephrotic Syndrome

The increased risk of thromboembolism in pediatric nephrotic syndrome is multifactorial.²⁷⁷ The same urinary losses that lead to profound hypoalbuminemia in these patients also cause acquired deficiencies of anticoagulant proteins such as antithrombin and free protein S. In addition to deficiencies of anticoagulants, increased levels of procoagulants (fibrinogen, factor V, and factor VIII), hypercholesterolemia, and increased platelet aggregation have all been described in nephrotic syndrome. Finally, the therapeutic interventions for nephrotic syndrome can increase the risk of thromboembolism. Diuretics cause reduced intravascular volume, leading to hemoconcentration, and steroids and cyclosporine increase procoagulant activities.

The incidence of thromboembolism in pediatric nephrotic syndrome ranges from 1.8% to 9.2% in published series.^{277–281} This contrasts with adult nephrotic syndrome, in which incidence rates as high as 44% have been reported.²⁷⁸ The most common locations in children are the deep veins of the lower extremities, renal veins, and cerebral veins, and events are frequently associated with the use of central venous catheters. Although pulmonary embolism is clinically diagnosed in less than 1% of patients, a frequency of 27% (7 of 26) was found in a series of nephrotic children who underwent screening with ventilation/perfusion scans.²⁸² These data suggest that pulmonary

symptoms may not always be caused by fluid overload in this population and that pulmonary embolism should at least be considered in any nephrotic patient with a significant change in respiratory status.

Prophylactic anticoagulation is recommended for adult nephrotic syndrome as long as the patient has proteinuria or severe hypoalbuminemia. However, no studies have been performed to evaluate the efficacy or safety of this practice in pediatric patients, and prophylaxis is generally not used in children without a history of thrombosis.²⁸³ One reason for the controversy is that predictors of thrombosis have not been clearly established in this population. Even decreased plasma concentrations of antithrombin, a well-recognized risk factor, are not a consistent finding in nephrotic children who develop thromboembolism.²⁸⁴ The most consistent biologic risk factor to date is the presence of severe hypoalbuminemia.²⁷⁷ Age (infancy or ≥ 12 years) at diagnosis of nephrotic syndrome, membranous histology, severe proteinuria, and history of thromboembolism preceding the diagnosis of nephrotic syndrome have also been identified as significant predictors of thromboembolism.^{280,285}

Although the traditional duration of anticoagulation for deep venous thrombosis (DVT) is 3 months, some form of anticoagulation should be continued or resumed in the setting of active nephrotic disease.²⁸⁶ To avoid hemoconcentration, diuretics must be avoided or used judiciously in patients who have experienced a thromboembolic event. Finally, it is important to remember that the efficacy of heparin can be impaired in the setting of decreased antithrombin levels.

Thromboembolism in Systemic Lupus Erythematosus and Antiphospholipid Syndrome

The reported incidence of thromboembolism in pediatric SLE ranges from 9% to 17%, similar to rates reported in adult patients with SLE.^{287,288} Although DVT of the lower extremities is still the most common manifestation, patients with SLE are more likely than patients with malignancy, CHD, or nephrotic syndrome to experience arterial and central nervous system thrombosis. In approximately half of cases, thrombosis occurs before or at the time of SLE diagnosis.²⁸⁹ The significant association between the presence of aPLs and thromboembolism is well described in patients with SLE.²⁹⁰ aPLs are a heterogeneous group of antibodies directed against plasma proteins and phospholipid complexes. They most frequently occur in the setting of SLE but are also associated with JIA, epilepsy, and other diseases.²⁹¹ There are multiple aPL subtypes, including lupus anticoagulants, anticardiolipin antibodies, anti- β_2 -glycoprotein I antibodies, and antiprothrombin antibodies. The exact mechanism of aPL-associated thromboembolism has not been elucidated, but recent data suggest that lupus anticoagulant antibodies interfere with the function of the protein C pathway, leading to an acquired activated protein C resistance.²⁹²

aPLs are quite common in the pediatric SLE population. Authors of an analysis of 12 published series of children with SLE reported a global prevalence of 48% for anticardiolipin antibodies and 23% for lupus anticoagulants.²⁹¹ Recent work has been focused on the predictive value of aPL subtypes for the risk of thromboembolic events. In a cohort of 58 children with SLE, the presence of lupus anticoagulants had the highest predictive power for thromboembolism.²⁹³ The presence of anticardiolipin antibodies was also predictive, but only if they were persistent (positive on at least two occasions 3 months apart). Other studies have confirmed the strong predictive power of aPLs, particularly lupus anticoagulants, for the risk of thromboembolism.^{287,294,295} However, pediatric patients with SLE with negative test results for aPLs rarely develop thrombotic events.

On the basis of these data, it is recommended that children with SLE routinely be screened for lupus anticoagulants, and if antibodies are present on more than one occasion, families should be counseled on the presenting symptoms of stroke and other thrombotic events.^{295,296} Prophylaxis with low-dose aspirin may be reasonable, especially in the setting of other thrombotic risk factors. However, there are not yet data to support routine prophylactic anticoagulation with lupus anticoagulants in patients with SLE in the absence of a

history of thromboembolism.²⁸⁷ Patients who develop DVT can be treated with the standard 3 months of anticoagulation. However, all children with systemic inflammatory disorders such as SLE, rheumatoid arthritis, and IBD are at risk for recurrent thrombi when their inflammatory process is exacerbated. Therefore children with systemic inflammation and a history of thrombosis should receive prophylactic anticoagulation until the inflammation is well controlled.^{297,298}

Antiphospholipid syndrome (APS) is defined as a thrombotic event and persistence of aPL positivity for at least 12 weeks after diagnosis of VTE and occurs both in children with SLE and in those who do not have underlying SLE, although they may develop the disease later. In a meta-analysis of 16 pediatric studies, there was a statistically significant association between persistent aPL positivity and first thromboembolism, with an overall odds ratio of 5.9 (95% confidence interval, 3.6–9.7).²⁹⁹ The management of thromboembolism in primary and secondary APS is different from most other pediatric thromboembolisms. Patients with APS have a high risk of thrombus recurrence when off therapy, and most affected children are treated indefinitely.^{289,297} However, the appropriate duration or intensity of prolonged therapy is not known. For children with VTE in the setting of aPL, the ACCP guidelines suggest management as per general recommendations in pediatric VTE, given that there is no evidence to support or refute the role of extended anticoagulation in patients with APS.²⁷¹

The international Ped-APS Registry was established in 2004, and a published report of the first 121 patients has provided insight into the clinical and immunologic manifestations of pediatric APS.²⁸⁹ As opposed to APS in adults, pediatric APS is only slightly more frequent in girls (female-to-male ratio, 1.2:1), likely because women with recurrent fetal losses are not included in this population. Similarly to adults, approximately half of patients present with primary APS. Thrombotic events are diverse and include DVT of the lower extremities (40%), arterial ischemic stroke (26%), and cerebral sinus vein thrombosis (7%). Multiple aPL positivity is frequent (81% with anticardiolipin antibodies, 72% with lupus anticoagulants, and 67% with anti- β_2 -glycoprotein I antibodies), but two-thirds of patients tested negative for one or more of the aPL tests, emphasizing the importance of testing for all subtypes in clinical practice. Nineteen percent of pediatric patients with APS experienced a recurrent thrombotic event, even higher than the proportion reported in adult patients.^{300,301} Catastrophic APS (life-threatening multiorgan thrombosis) occurs rarely in pediatric patients (approximately 10% of all cases occur in patients <18 years of age), but it has clinical and laboratory features similar to those of adult catastrophic APS.³⁰²

It is important to note that transient lupus anticoagulants, likely the result of infections or immunizations, have been well described in healthy children. These incidentally found antibodies are not associated with an increased risk of thrombosis or bleeding.

Thromboprophylaxis During Childhood Illness

The use of thromboprophylaxis to prevent hospital-acquired VTE has become the standard of care in adult institutions. Even though the risk of thrombosis in hospitalized children is much lower than in adults, there are patients in pediatric hospitals (particularly adolescents and young adults) who should undergo systematic screening for thrombosis risk and application of prophylactic measures.³⁰³ Multi-center prospective studies are required to determine the safety and efficacy of prophylaxis, as well as the age cutoff at which prophylaxis should begin to be considered, but these studies will be very difficult to complete because of the relative rarity of thrombosis in the pediatric setting. In a single-center prospective safety evaluation of anticoagulation prophylaxis in high-risk patients 14 years of age and older, there have been no major bleeding complications.³⁰³

The 2008 ACCP guidelines discuss the use of thromboprophylaxis in only a few specified settings.²⁸⁶ The guidelines recommend prophylaxis for children receiving long-term home parenteral nutrition and for patients with complex cardiac conditions and associated procedures. Routine prophylaxis is not recommended in children with central venous lines (including those with cancer).

HEMATOLOGIC COMPLICATIONS OF SOLID ORGAN TRANSPLANT IN CHILDREN

The frequency and success of solid organ transplant in children have been increasing over the past decade. In 2004, there were 1816 transplants in children, representing 7% of all recipients.^{308–310} This is an increase of 13% over the previous decade. Of the transplants done in 2004, the majority were renal transplants ($n = 765$), followed by liver ($n = 529$) and then heart ($n = 250–290$). The success rate has been also improving impressively, with 5-year survival after kidney transplant being 95% to 96%, liver transplant 79% to 83%, and cardiac transplant 70% to 75%.

Hematologic complications after solid organ transplant are a common problem. Although most of the evidence regarding the type, frequency, and etiology of these complications has been studied in adults,³¹¹ there are increasing reports in children. After renal transplant, 60% of children are reported to be anemic. After liver transplant, 36% of children will have a hematologic problem, and of these, 54% are anemic events, 19% anemia and neutropenia, 12% thrombocytopenia, 8% neutropenia, and 2% pancytopenia.³¹² After heart, heart–lung, or double-lung transplant, 51% of patients have been reported to have hematologic problems, including anemia (49%), neutropenia (14%), thrombocytopenia (14%), and anemia plus neutropenia with or without thrombocytopenia (23%).³¹³ The etiology of these hematologic problems is most commonly a result of infection followed by medication effect. Miscellaneous causes include blood loss, microangiopathic hemolytic anemia (MAHA), autoimmune cytopenias, posttransplant lymphoproliferative disease (PTLD), and multifactorial.

In the next section, discussion of the hematologic complications of solid organ transplant is divided into cell type and by organ type when feasible. The incidence, etiology, and natural history of the problem are addressed. Much of the data is derived from adult studies, but information from pediatric studies is emphasized.

Red Blood Cells

Anemia is a common problem after transplant, occurring in 66% of kidney transplant recipients at the time of transplant³¹⁴ and in 60% to 84% after transplant.³¹⁵ In liver transplant recipients, the incidence is 20% to 35%,^{312,316,317} and in recipients of heart or heart–lung or double-lung transplant, it is 30% to 70%.^{313,318} There are distinct patterns of presentation of the problems associated with RBCs, including early posttransplant anemia, HUS/MAHA, late anemia from immunosuppressant drugs (ISDs), late anemia from other causes, and pure red cell aplasia (PRCA).

Early Posttransplant Anemia

Early posttransplant anemia is defined as anemia that occurs within 6 months from the time of transplant. The etiologies include the following:

1. Postoperative hemorrhage
2. Hemolytic anemia secondary to passenger lymphocyte syndrome or HUS/MAHA
3. Infection, including bacterial sepsis or viral infections such as CMV, EBV, or parvovirus
4. Medication, including immunosuppressive drugs and other drugs
5. After renal transplant, iron deficiency or prior uremia or bone disease

Passenger Lymphocyte Syndrome

Passenger lymphocyte syndrome is a graft-versus-host reaction.^{1,319–321} Antibodies made by donor B cells (“passengers”) transplanted with the organ are made against host RBCs. This direct antiglobulin-positive

How to Manage Thromboembolism in the Setting of Pediatric Cancer

Prompt diagnosis is the first key step in proper management of cancer-related venous thromboembolism (VTE). In pediatric cancer, the majority of VTE is related to a central line. It is important to recognize that line dysfunction may be the first sign of a thrombosis and to consider thrombosis when line dysfunction cannot be explained or patency easily restored (see figure).²⁵⁴

When treating thromboembolism in a patient with cancer, low-molecular-weight heparin (LMWH) is the preferred choice. Warfarin, although it is less expensive and can be given orally, is difficult to regulate in the setting of multiple chemotherapy agents, frequent invasive procedures, and changing vitamin K stores because of antibiotics and illness.^{247,304,305} A randomized clinical trial in adult patients with cancer demonstrated that LMWH was more efficacious than and as safe as warfarin in preventing recurrent thromboembolism.³⁰⁶ The 2008 American College of Chest Physicians guidelines recommend the use of LMWH in the treatment of cancer-related venous thromboembolism for a minimum of 3 months and until the precipitating factor (e.g., use of asparaginase) has resolved.²⁸⁶ Other practical suggestions have been reported, but none are supported by any systematic observations.^{260,286,304}

- A minimum of two doses of LMWH should be held before lumbar punctures and other invasive procedures.
- For intramuscular asparaginase injections, applying firm pressure and administering the medication at the trough of the anti-Xa level are probably adequate to avoid bleeding.
- Clinicians should maintain platelet counts above 50,000/ μ L in the first 2 weeks of anticoagulation. After that period, the LMWH dose should be adjusted according to platelet count (50% dosing for platelet counts 20 to 50,000/ μ L; hold doses for platelet counts <20,000/ μ L).

Asparaginase-Related Thrombosis

Management of asparaginase-related thrombosis in acute lymphoblastic leukemia can be particularly challenging, and researchers at the Dana-Farber Cancer Institute recently published their experience with rechallenging pediatric and adult patients with asparaginase after a first thrombosis.³⁰⁷ In this retrospective review, survival was similar in patients with and without thrombosis, and the following guidelines were suggested:

- Asparaginase can be resumed when symptoms of thrombosis have resolved and there is evidence of clot stabilization or improvement on repeat imaging, typically after about 4 weeks of anticoagulation.
- Because of the protein depletion experienced by patients receiving asparaginase, anti-Xa levels should be monitored frequently.
- If LMWH at previously adequate doses no longer adequately anticoagulates the patient, antithrombin levels should be checked and antithrombin repleted as necessary.

Management of central venous line (CVL) related thrombosis. *LMWH*, Low-molecular-weight heparin; *r-UK*, recombinant urokinase; *t-PA*, tissue plasminogen activator; *UFH*, unfractionated heparin.

immune hemolytic anemia occurs within 3 to 24 days after transplant. Rh antibodies, especially anti-RhD, are the most common type of antibody. The anemia can be mild to severe but is self-limited, lasting from a few days to 3 months. The incidence of this complication increases as the size of the transplanted organ increases:

	Antibody-Positive, n (%)	Hemolysis, n (%)
Kidney	17	9
Liver	40	29
Heart-lung	70	70

The incidence also varies depending on the blood type of the donor and recipient:

61% with O donor and A recipient
 22% with O donor and B recipient
 17% with AB donor and non-AB recipient

Pediatric cases have been reported after all types of solid organ transplant, and the incidence appears to be the same in children and adults, at least after liver transplant.

Treatment consists of observation alone if the case is mild and transfusion if severe.³¹⁹ When transfusing RBCs, the ABO type of the

transfused product should be identical to or compatible with the recipient serum, regardless of donor type. When transfusing platelets or fresh frozen plasma, the product should be compatible with both the recipient and donor. Empiric therapy used in the management of severe cases includes corticosteroids, plasma exchange, and RBC exchange.

Hemolytic Uremic Syndrome/Microangiopathic Hemolytic Anemia

HUS/MAHA after solid organ transplant has been described most often in adults who have the typical clinical presentation for this disorder.^{322–324} The majority of cases have been described in renal transplant recipients (90% of cases reported), but HUS/MAHA has been seen with all transplant types. The median time of onset is 30 days after transplant, ranging from 8 days to 9 months,³²² and 80% of cases occur within 90 days and 96% within 1 year.³²⁴ After renal transplant for HUS, 23% of patients have a recurrence, but the incidence varies depending on the original type of HUS. When a transplant is done for diarrhea-associated HUS, the recurrence rate is less than 10%. The incidence increases when the original diagnosis is atypical adult HUS and increases even more with familial HUS (60% recurrence rate). In children who underwent transplants for HUS, there was an 8.8% recurrence rate,³²³ although the rate was 80% for those who underwent transplants for atypical HUS and

factor H or I deficiency. However, other genetic abnormalities of the complement system are not associated with this high rate of recurrence. Genetic screening is recommended before transplant, not only to determine risk but also to develop posttransplant management plans³²⁵ (see later).

The calcineurin inhibitors CsA and tacrolimus (TAC) have triggered the HUS in all of the nonrenal transplant cases and half of the renal transplant cases. Sirolimus alone and especially in combination with cyclosporin has been associated with development of thrombotic microangiopathy.³²⁶ The possibility of an infectious trigger has been suggested for the development of MAHA.

Treatment consists of discontinuing or decreasing the dose or switching the calcineurin inhibitor. Plasma exchange is an unproven therapy. The outcome for graft survival is 60% for de novo HUS but only about 33% for recurrent HUS. In children who undergo transplants for atypical HUS, especially those with a known high-risk genetic mutation, perioperative plasma exchange and the use of the terminal complement inhibitor eculizumab have shown promising efficacy in preventing HUS recurrence.³²⁵ Eculizumab has been approved by the US Food and Drug Administration for the treatment of pediatric and adult patients with atypical HUS.

Late Posttransplant Anemia

Anemia occurring more than 6 months after transplant is termed late *posttransplant anemia*. Causes of late anemia that are common to all solid organ transplants include the following^{312–314,316,318}:

1. Infection with viruses, particularly EBV and parvovirus, and, more rarely, CMV
2. Drug effect caused by myelosuppression, hemolytic anemia, or other drug effects (e.g., trimethoprim/sulfamethoxazole, dapsone)
3. Rejection or PTLD
4. Anemia of chronic disease
5. Iron deficiency
6. Acute renal failure
7. Uncommon or multifactorial

Etiologies of late anemia in the renal transplant setting include end-stage renal disease or low erythropoietin levels (68% of patients will have levels <2 standard deviations below the norm).³¹⁴ After renal transplant, young children have less anemia than older children and young adults. This may be because of the large donor kidney with higher erythropoietin levels and creatinine clearance relative to the size of the patient.

Risk factors for chronic anemia in children after liver transplant were determined in a cohort of 1026 children followed prospectively.³²⁷ The late anemia in this group was mild to moderate, with a mean hemoglobin of 10.24 g/dL. In multivariate analysis, the following factors were found to be significantly associated with chronic anemia:

1. History of GI bleeding
2. Leukopenia
3. CsA-based therapy
4. Glomerular filtration rate less than 90 mL/min/1.73 m²
5. Corticosteroid use
6. Antihypertensive drug use

Immunosuppressant Drugs

There is a wide variation—1% to 53%—in the reported incidence of anemia secondary to ISDs. This variation may be a result of the lack of a specific test for drug-associated anemia and the lack of prospective studies. Indirect evidence for the association, however, is quite strong—that is, the ISD is stopped or changed and the anemia improves. There is a clear association of HUS/MAHA with the ISDs CsA and TAC in the early posttransplant period, but a number of studies have documented the association of late anemia with these

agents as well. In a study of children after liver transplant, half of the cases of anemia were attributed to ISD.³¹² The diagnosis was usually made by excluding other causes of anemia and on the basis of evidence of resolution of the anemia after a change in the ISD dose or switching to an alternative drug (median time for resolution, 4 months).

In a study of children and young adults after cardiothoracic transplant, approximately 25% of the cases of anemia were attributed to TAC, primarily because no other cause was found.³¹³ The nadir hemoglobin in these patients was 7.3 to 8.8 g/dL, with reticulocytes ranging from 1.5% to 6.7%. Only one patient had a direct antiglobulin study performed, and the results were negative. Four of five patients with simultaneous anemia and neutropenia recovered counts within 5 weeks of switching to CsA. In another study of 50 pediatric renal transplant patients, the prevalence of anemia was 60%, with 30% having hemoglobin levels below 10 g/dL. The TAC dose was found to be significantly associated with the presence of anemia.³²⁸

The association of PRCA and TAC was first reported in adults. Two children were reported to develop PRCA while taking TAC 8 and 47 months after liver transplant.³²⁹ Neither had evidence of parvovirus B19 infection. When there was no evidence of spontaneous recovery after 2 to 3 months of observation, they were switched from TAC to CsA, and both recovered within 3 weeks. Of interest, in a study of adults after liver transplant, erythropoietin production was found to be reduced in patients receiving cyclosporin but not TAC.³³⁰

There are a number of case series of AIHA associated with the use of TAC and other ISDs in both children and adults.³³¹ AIHA has been seen after liver, small bowel, multivisceral, kidney, and heart transplants. Onset of severe anemia has occurred from 2 months to many years after transplant. The direct antiglobulin test has revealed warm, mixed, or cold antibodies. The common finding in all cases was use of TAC immunosuppression, although other ISDs were also used in a few cases. Treatment was variable, including corticosteroids, IVIg, plasmapheresis, rituximab, and splenomegaly. TAC was discontinued in many cases with replacement by alternative ISDs, including cyclosporine or sirolimus. Resolution of the AIHA was the usual outcome with some rapid and apparently sustained responses to rituximab and switching to an alternative ISD.^{332–336}

Nonimmune hemolysis has also been documented in adults. In a retrospective study of 81 patients (median age, 39 years; range, 12 to 66 years) after lung transplant, 20% developed hemolytic anemia in the first year after transplant.³³⁷ All were taking CsA, and none received TAC. The anemia was mild to moderate; there was no evidence of autoantibody formation or MAHA; and other causes of anemia were excluded. The researchers in that study postulated an auto- or alloimmune mechanism to explain this phenomenon.

Anemia has been reported to be associated with all of the currently used ISDs, including mycophenolate mofetil (MMF) and sirolimus. Although direct comparison of all of the drugs has not been performed, it appears that TAC and CsA are associated with a similar incidence of anemia,³³⁸ occurring less commonly with the other drugs. One possible mechanism of the development of autoimmune antibodies posttransplant is the chronic T-cell suppression resulting from the use of these agents followed by release of B-cell control. As noted earlier, treatment has been empiric and has included the standard treatments for AIHA, including rituximab. Reduction in dose or switching the type of the ISD appears to be an effective therapy.

Pure Red Blood Cell Aplasia Associated With Parvovirus B19

PRCA was initially reported in adults in 1986, and multiple reports have been published since then. Authors of a review of the literature in 2006 reported 91 cases of parvovirus B19 infection posttransplant in adults.³³⁷ Seventy-four were in solid organ recipients, with the majority after kidney transplant (71%), followed by heart–lung transplant (16%) and then liver transplant (12%). Ninety-nine percent of the patients were anemic, and one-third also had leukopenia and 18% also had thrombocytopenia. The average time to onset was 1.75 months posttransplant, with a range of 1 week to 96 months. The most reliable test to diagnose infection was the

parvovirus B19 polymerase chain reaction (PCR), with results being positive in 85% of cases; IgM results were positive in 78% and IgG in 39%. Treatment with IVIg was used in 84% of patients, and there was a recurrence in 28%. The three deaths occurred only in patients after liver transplant who developed myocarditis and cardiogenic shock. Of interest, in a prospective study of 47 solid organ transplant recipients, none were found to have molecular evidence of parvovirus B19 in the first year after transplant.³³⁹

In a review of parvovirus B19 infection in children after transplant, there were 16 case reports: 5 each after liver, heart, and renal transplant and 1 after bone marrow transplant.³⁴⁰ The onset was at a median of 8 months, with a range of 1 to 24 months. Although only 3 of 14 tested were IgM positive, all were PCR positive. There were no associated symptoms in 7 of 14, but other reported symptoms include cytopenias, rash, myocarditis, and pneumonia. All 10 patients who received IVIg treatment were cured, although recurrences have been reported.

Platelets

Problems with platelets, including thrombocytopenia and thrombocytopathy, have been reported after transplant, primarily in adults. After liver transplant, almost all patients develop a transient thrombocytopenia. Delayed thrombocytopenia is much less frequent. It has been reported in 12% of children after liver transplant,³¹² 8% after cardiothoracic transplant,³⁰⁸ and outside the setting of HUS/MAHA very infrequently after kidney transplant. Causes of platelet problems posttransplant include medication effect, immune etiology, HUS/MAHA, infection, and other miscellaneous causes.

Immediate Thrombocytopenia After Liver Transplant

More than 90% of adults have been reported to have thrombocytopenia within the first week after liver transplant.^{341–345} Nadir counts usually occur between days 4 and 6 posttransplant, with an average count of 58,000/ μ L (range, 19,000 to 330,000/ μ L). An increase in thrombopoietin is seen on days 4 to 6, and increased reticulated platelets are noted on days 7 and 8. There are few reported clinical sequelae from the mild thrombocytopenia, although the lowest platelet counts have been associated with the most severe and complicated posttransplant course. Resolution is usually seen in 2 weeks. Lack of resolution is associated with a poor prognosis for graft and overall survival. In a study of children who received a living donor liver transplant, preoperative platelet count, graft-to-recipient weight ratio, and acute rejection were identified as risk factors for developing early thrombocytopenia in multivariate analysis.³⁴⁶

There is controversy regarding the etiology of this transient thrombocytopenia. One theory is that it is a nonimmune consumptive process reflected by increased markers of thrombin generation.³⁴⁵ The liver may be the site of platelet sequestration. A second theory is that it is unlikely to be a consumptive process because of the lack of platelet activation after day 1. The thrombocytopenia is more likely a result of low levels of thrombopoietin seen pretransplant. With new production and rising levels of thrombopoietin from the new liver, there is a subsequent increase in platelet production, resulting in normalization of the platelet count soon after transplant. Although the specific etiology has not been clarified, there is general consensus that it is not immune mediated.

Lymphocyte-depleting antibodies such as rabbit antithymocyte globulin (rATG) are being used with increasing frequency as induction-type therapy in pediatric liver and intestine transplants. rATG does exacerbate the transient thrombocytopenia seen immediately after solid organ transplant but resolves in a similar 1- to 2-week period. Treatment of this transient thrombocytopenia is supportive. Platelet transfusions are of uncertain benefit. Although originally azathioprine was believed to be a cause of this thrombocytopenia, there is no evidence that alteration of azathioprine dose is necessary.

Delayed Posttransplant Thrombocytopenia

Delayed thrombocytopenia is not a major problem after solid organ transplant, and most of the data are published in adult series. In one retrospective study of 36 adult liver transplant recipients, mild thrombocytopenia ($<140,000/\mu$ L) was seen in 54% of patients at 1 year and 25% at 3 years after transplant.³⁴⁷ However, severe thrombocytopenia ($<50,000/\mu$ L) was seen in only 9% of patients at 1 year and in no patients at 3 years after transplant. The thrombocytopenia was associated with splenomegaly in some patients. No clinical bleeding problems were noted after 1 year from transplant. In one report, 3 (12%) of 25 pediatric liver transplant recipients were found to have isolated thrombocytopenia.³¹² The etiology of the thrombocytopenia in these children was cavernous transformation of the portal vein, autoimmune, and unknown. In two other children in this series, thrombocytopenia was associated with additional cytopenias, and the cause was possibly related to TAC. In an additional study of 126 children who underwent cardiothoracic transplant, 9 (8%) were noted to have isolated thrombocytopenia. Infection was the most common etiology ($n = 262$). In patients with combined cytopenias, including thrombocytopenia, two-thirds were related to either infection or PTLT and 20% possibly secondary to TAC.

Sirolimus has been associated with mild thrombocytopenia in adults, although the reported frequency has varied. In a study of renal transplant recipients, 23% were reported to have mild thrombocytopenia,³⁴⁸ but no liver transplant patients taking the drug were found to be thrombocytopenic.³⁴⁹ In 66 pediatric kidney transplant recipients taking sirolimus, there were no reported cases of thrombocytopenia.³⁵⁰ Low platelet counts are usually seen within the first 4 weeks of treatment and are associated with higher sirolimus blood levels.^{351,352} Similarly to TAC and CsA, sirolimus has been shown to potentiate agonist-induced platelet aggregation, although this is not the proven explanation for the thrombocytopenia.³⁵³ A 25% to 50% dose reduction is often effective in resolving sirolimus-mediated thrombocytopenia.

Immune-Mediated Thrombocytopenia Posttransplant

There are many case series of immune-mediated thrombocytopenia after all types of solid organ transplant in children and adults and either alone or in combination with other cytopenias.³³¹ Eight adults after liver transplant were reported to have immune thrombocytopenia (incidence, 0.7%).³⁵⁴ The low platelets were seen 53 months after transplant on average, with a range of 1.9 to 173 months. Three patients had demonstrable antiplatelet antibodies. Steroids provided effective therapy in four and rituximab in four, although splenectomy was ultimately necessary in three. Seven of the eight survived with normal platelet counts. Five children were reported to have severe thrombocytopenia ($<10,000/\mu$ L) within 2 to 4 months after starting TAC.^{334,355} All were documented to have antiplatelet antibodies. Responses were seen to steroids, rituximab, or anti-RhD.

Two cases after heart or lung transplant in adults have been reported.³⁵⁶ These cases occurred 60 to 460 days after transplant and responded to prednisone and IVIg. Acquired Glanzmann thrombasthenia has been reported in two children after cardiac transplant.^{335,357} Both were receiving TAC and had demonstrable antibodies against glycoprotein IIb/IIIa. One patient had multiple autoantibodies, and the other subsequently developed additional antiplatelet antibodies. One child responded to prednisone therapy and switching from TAC to CsA. The other responded to rituximab after prednisone and IVIg therapy failed.

Alloimmune thrombocytopenia was reported in three recipients of organs from the same donor (two kidneys and a liver).³⁵⁸ Development of human platelet antigen-1a (HPA-1a; Pl^{A1}) antibodies from donor B cells were documented in an example of passenger lymphocyte syndrome. The thrombocytopenia in these cases was particularly refractory to standard treatment, except transfusion of HPA-1a-negative platelets. One patient died, another required splenectomy,

Treatment of Immune-Mediated Thrombocytopenia After Solid Organ Transplant in Children

There is no standard approach to the treatment of immune-mediated thrombocytopenia that occurs after solid organ transplant. First, all other causes of thrombocytopenia should be ruled out before beginning therapy for what is often a presumptive diagnosis of immune-mediated thrombocytopenia. If the thrombocytopenia is mild to moderate ($>20,000$ to $30,000/\mu\text{L}$) with no associated bleeding symptoms, we usually observe without intervention and monitor the platelet count on at least a weekly basis. If the platelet count is less than $10,000$ to $15,000/\mu\text{L}$ or if there is bleeding, immediate treatment is initiated with high-dose corticosteroids: 4 mg/kg/day of prednisone (or intravenous equivalent) divided into three or four doses and continued for 4 days. If there is a response (i.e., platelet count $>20,000/\mu\text{L}$), the corticosteroid is dropped to 2 mg/kg/day divided into two or three doses and then slowly tapered to zero over the subsequent 2 to 3 weeks. Intravenous immunoglobulin or anti-RhD in standard doses for childhood idiopathic thrombocytopenic purpura can be used if there is no response to high-dose corticosteroids.

For patients who have recurrent or chronic thrombocytopenia requiring multiple courses of treatment to maintain platelet counts greater than $10,000$ to $15,000/\mu\text{L}$, we have used vincristine (1.5 mg/m^2 [maximum dose, 2 mg] intravenously weekly for 6 weeks) with success. Rituximab (375 mg/m^2 intravenously weekly for 4 weeks) has infrequently been used in this situation. For patients taking tacrolimus with refractory thrombocytopenia, serious consideration should be given to switching to an alternative immunosuppressant drug because this may be necessary for resolution of the thrombocytopenia. Involvement of both the transplant team and the hematology team is necessary for ideal management of these complex patients.

and one patient's thrombocytopenia resolved after an episode of severe graft rejection (see box on [Treatment of Immune-Mediated Thrombocytopenia After Solid Organ Transplant in Children](#)).

Infection-Associated Thrombocytopenia Posttransplant

Although there are few published reports, one would expect the same hematologic problems, including thrombocytopenia, associated with bacterial sepsis or other serious infections as seen in nontransplant patients. Infection with HHV-6 and the herpesvirus group has been studied closely. HHV-6 is commonly seen after transplant, mostly in stem cell transplant recipients. In adults after liver transplant, there are case reports of a syndrome of HHV-6 infection with thrombocytopenia, fever, and encephalopathy.³⁵⁹ This syndrome has not been reported in children with HHV-6 infection.^{360,361}

Herpesvirus infection after kidney transplant in children is seen in about one-third of patients, with CMV being the most common infection.³⁶² The hematologic abnormalities associated with herpesvirus infection include thrombocytopenia and leukopenia, with incidence rates of 31% and 24%, respectively. These and other symptoms of herpesvirus infection occur at the same frequency as in nontransplant patients. There is a case report of a child after liver transplant who developed measles complicated by autoimmune thrombocytopenia and neutropenia.³⁶³

White Blood Cells

Leukopenia and neutropenia after solid organ transplant are uncommonly reported in the literature, although this may not reflect the true incidence seen in practice.³⁶⁴ Authors of two reviews of hematologic complications in children after transplant reported isolated neutropenia in 2 (3%) of 70 patients after liver transplant and 9 (8%) of 106 patients after cardiothoracic transplant.^{312,313} Neutropenia was also seen in combination with other cytopenias.³³¹ Although there are

predominantly case reports in the pediatric literature, in one review of neutropenia after 400 renal transplants in adults, 35 cases (9%) were reported.³⁶⁵ The etiology of leukopenia or neutropenia is similar in children and adults and includes immunosuppressive agents; other myelosuppressive drugs (e.g., ganciclovir); infection (e.g., CMV, sepsis); and, less frequently, INF, PTLT, hypersplenism, and idiopathic. Use of TAC is often implicated as a possible contributing factor.

Both filgrastim (granulocyte colony-stimulating factor) and sargramostim (granulocyte macrophage colony-stimulating factor) have been used to treat neutropenia in adults and children. In adults, it has resulted in improvement of the WBC count in more than 90% of patients after three or four doses.^{365,366} There was no evidence of precipitation of rejection. In the case reports of children, both agents have been found to be effective in most patients, but there is a suggestion that efficacy may be affected by continuation of TAC.^{364,367,368} Although cytokine therapy has been shown to increase the neutrophil count, there is insufficient data to prove the effectiveness of preventing or treating infection or decreasing mortality.³⁶⁹

There has been one report on the use of granulocyte transfusions in solid organ transplant recipients, including one child. Of the 14 patients studied, 11 showed an increase in ANC greater than $1000/\mu\text{L}$ by the end of the course. Of 12 patients with infections, 4 (33%) showed a clinical response. Additional studies are needed to evaluate the efficacy of granulocyte transfusions in transplant patients.³⁶⁹

Azathioprine is well known to cause myelosuppression and has been associated with moderate to severe neutropenia. Azathioprine is catabolized *in vivo* by xanthine oxidase and thiopurine methyltransferase (TPMT). TPMT activity can vary considerably depending on a genetic polymorphism. Approximately 0.3% of white persons are homozygous and 11% are heterozygous for deficiency of TPMT. Severe myelosuppression, including fatal neutropenia, has been documented in transplant patients who are homozygous for TPMT deficiency and receiving azathioprine.³⁷⁰ Some data suggest that monitoring 6-thioguanine nucleotides (the metabolites of azathioprine) may allow for individualized management of azathioprine dosing with fewer side effects, although this has not become common practice.^{371,372}

Neutropenia has also been associated with the use of MMF and sirolimus. Neutropenia and thrombocytopenia have been noted as side effects of MMF since 1998.³⁷³ Leukopenia may affect 5% to 11% of patients taking the drug, and pseudo Pelger-Huet anomaly has also been noted.^{374,375} The leukopenia is often seen within 2 to 8 months after starting the drug. Filgrastim has been effective in reversing the neutropenia, although some patients require decreasing the dose or stopping the drug. Ganciclovir and valacyclovir are commonly used simultaneously with MMF to treat or prevent CMV disease. These drugs are also known to be associated with neutropenia.³⁷⁶ There may be an interaction between these drugs that increases the risk for neutropenia.^{377,378} It may be necessary to stop ganciclovir as well as MMF for the neutropenia to improve.³⁷⁴ Of note, serious infections are infrequently encountered.

In two reports of the use of sirolimus in children, neutropenia was the most common toxicity, along with hepatitis, hyperlipidemia, and mouth ulcers.^{379,380} It is not clear whether the neutropenia is directly related to serum level of the drug. Most counts improve with a decrease in the drug dose, although a few patients need to have the drug discontinued.

Pancytopenia

Pancytopenia is seen in two settings after solid organ transplant. The first is early after liver transplant for acute liver failure from acute infectious hepatitis.^{381,382} This represents the known aplastic anemia that can be seen in as many as one-third of patients after non-A-E hepatitis. Treatment and outcome are similar to those in patients with posthepatic aplastic anemia who do not require liver transplant. The second setting is delayed pancytopenia, which may be secondary to infection with or without PTLT.³⁸³ A number of cases have been

associated with the use of TAC.^{312,384} Hemophagocytic syndrome has also been reported in the posttransplant setting, usually caused by an acquired viral infection.³⁸⁵

HEMATOLOGIC ASPECTS OF POISONING

It has been estimated that about 6 million children, most younger than 5 years of age, ingest some toxin each year. The effects of toxins on the blood are diverse, usually nonspecific, and in most situations overshadowed by the nonhematologic manifestations of the exposure.³⁸⁶ With certain toxins, however, bleeding, anemia, or change in the appearance (color) of the blood may be an important component of the clinical sequelae of an acute exposure.

The abnormalities of hemostasis after poisoning are numerous, and the mechanisms vary. Bleeding may be the only manifestation of warfarin toxicity secondary to an overdose of the drug or ingestion of a rodenticide containing warfarin. Any hepatotoxic substance (e.g., iron, acetaminophen) may lead to decreased synthesis of clotting factors and resultant coagulopathy. Bleeding in these circumstances is delayed for at least 24 hours, although there appears to be an early coagulopathy in iron poisoning that may be caused by a direct effect on clotting protein function and not hepatotoxicity.³⁸⁷ DIC has been seen after ingestion of mushrooms of the *Amanita* genus or after a bite from the brown recluse spider (*Loxosceles reclusa*). Poisonous snake bites can result in coagulation abnormalities characterized by hypofibrinogenemia with or without thrombocytopenia or a DIC-like syndrome.³⁸⁶ Severe thrombocytopenia has been described with elemental mercury poisoning.

Acute hemolytic anemia may be the presenting manifestation after exposure to drugs and toxins in children with G6PD deficiency or hemoglobin Zürich or (rarely) in otherwise healthy children. Severe hemolytic anemia has been seen after the bite of the brown recluse spider and of a rattlesnake and after a wasp sting.

Exposure to certain toxins may result in characteristic color changes of the blood, which in turn may be reflected clinically in abnormal skin color. The child with methemoglobinemia (see next paragraph) presents with a slate-gray cyanosis unresponsive to 100% oxygen administration. On exposure to air, the blood retains a distinct brown color. Patients with toxic exposure to carbon monoxide or cyanide have increased levels of carboxyhemoglobin or cyanhemoglobin, respectively, resulting in a cherry-red color of the blood and skin, but only with high concentrations of the offending hemoglobin.

Infants (up to 4 months of age) are at particular risk for developing methemoglobinemia because of a reduced amount (approximately 60% of normal) of cytochrome b5 reductase present in neonatal RBCs. Methemoglobinemia has been described in infants with diarrheal illness and in infants exposed to exogenous agents.³⁸⁸

Yano and colleagues³⁸⁹ described 11 patients with transient methemoglobinemia, all infants younger than 1 month of age who presented with vomiting, diarrhea, and acidosis. In prospective studies of infants younger than 6 months of age with diarrheal disease, 64% had elevated levels of methemoglobin (with a mean $\pm$ SD of 10.5% $\pm$ 12.3%); 31% were cyanotic; most infants were small or failing to thrive; there was no association of methemoglobinemia and acidosis; and all children recovered from their illness.^{390,391} Although most infants with endogenous methemoglobinemia can be managed with support and hydration, treatment with methylene blue (1 mg/kg) is indicated in symptomatic or more severely affected children (i.e., with methemoglobin >20%–30%).

Nursery epidemics of methemoglobinemia have been reported in normal newborns exposed to disinfectants or aniline dyes used to mark diapers. Infants fed formulas made with well water containing a high concentration of nitrates have developed methemoglobinemia. EMLA cream (Akorn Pharmaceuticals, Lake Forest, IL), a eutectic mixture of the local anesthetics lidocaine and prilocaine, has been effective in decreasing pain in infants undergoing circumcision. Methemoglobinemia has been reported with EMLA use in this situation, but only in overdose.³⁹² Other ingestions associated with methemoglobinemia include phenazopyridine (Pyridium), dapson,

metoclopramide, and nitroethane (an artificial fingernail remover). Although the list of oxidants reported to cause methemoglobinemia is long, methemoglobinemia caused by exogenous agents is uncommonly seen in infants and children.³⁹³

Lead Poisoning

Lead poisoning in children has been a serious public health problem for decades. However, the most serious toxic effects of lead (e.g., encephalopathy) commonly seen in the past are rarely encountered today, primarily because of measures instituted to decrease lead exposure (e.g., no-lead paint, no-lead gasoline) and screening programs in high-risk areas. Mean blood lead levels in the United States have declined, from 15 μ g/dL between 1976 and 1982 to 3.6 μ g/dL between 1988 and 1991.³⁸³ Nonetheless, lead toxicity remains a problem, especially in high-risk children. In 2010, 6% of impoverished children aged 1 to 2 years were found to have lead levels above the upper reference range.³⁹⁴ Additionally, children arriving from other countries with less stringent public health requirements regarding lead exposure remain at risk for significant lead toxicity.³⁹⁵ Increasing evidence shows that even low levels of lead exposure are associated with a significant decline in neurodevelopmental outcome, and in 1991, the CDC lowered the intervention level of lead in the blood from 25 to 10 μ g/dL.^{395,396} Reviews of the public health issues relating to lead poisoning in children have been published.³⁹⁷

The occurrence of lead poisoning in children with sickle cell disease may be underrecognized. Pica may be a manifestation of sickle cell anemia, even in the absence of iron deficiency, predisposing children to lead ingestion.³⁹⁸ Additionally, some children with sickle cell disease may be at risk for environmental lead exposure, including substandard housing with lead paint. The signs and symptoms of lead toxicity may resemble those of sickle cell disease, including abdominal pain, peripheral neuropathy with extremity pain, constipation, and hyponatremia.³⁹⁹ Lead toxicity should be considered in the differential diagnosis of children with unusual manifestations of sickle cell disease.

The primary hematologic effect of lead is interference at multiple points along the heme synthetic pathway. The two most important effects are inhibition of δ -aminolevulinic acid dehydratase and ferrochelatase, resulting in the accumulation of heme intermediates such as protoporphyrin. A shortened RBC survival time accompanies lead poisoning and probably is caused by decreased activity of pyrimidine 5-nucleotidase (also resulting in basophilic stippling of the RBC) and possibly inhibition of G6PD and the pentose shunt.⁴⁰⁰

The anemia of lead poisoning has classically been described as a hypochromic, microcytic anemia, as might be expected from the effects of lead on heme synthesis. Although anemia has been said to be a common finding in lead intoxication, in reality, anemia is uncommon unless the lead poisoning is severe or there is associated iron deficiency.

A strong association exists between lead poisoning and iron deficiency in children. Both tend to occur in the same population of predominantly lower socioeconomic status. Experimentally, iron deficiency has been shown to increase lead absorption, retention in tissues, and toxicity. Iron deficiency also decreases lead excretion during chelation.⁴⁰¹ Lead may impede iron absorption and metabolism, leading to a vicious circle of increasing lead toxicity and worsening iron deficiency. In a study of children with lead poisoning (blood lead ≥ 30 μ g/dL), 86% were found to have iron deficiency, and 100% of those with more severe lead poisoning (CDC risk class III) were iron deficient.⁴⁰²

A number of reports of children with lead toxicity have documented the infrequent occurrence of anemia without concomitant iron deficiency. Cohen and colleagues⁴⁰² found anemia in 12% and microcytosis in 21% of iron-sufficient children with severe lead poisoning (CDC risk classes III and IV). The combination of anemia plus microcytosis, however, was found in only one of the 58 children in their series. Yip and associates⁴⁰³ found a 30% incidence of anemia in less severely affected children (CDC classes I to III), but of those with either mild or no iron deficiency, only 6% were anemic. Clark

and coworkers,⁴⁰⁴ using multiple linear regression analysis, found transferrin saturation to be the most important predictor of mean corpuscular volume, hemoglobin, and zinc protoporphyrin levels in children with lead poisoning.

Two important points emerge from the foregoing information: (1) children with significant lead poisoning may have neither anemia nor microcytosis, and (2) children with documented lead poisoning should be screened for underlying iron deficiency. Discussion of the immediate treatment and long-term management of patients with lead poisoning can be found in a recent review.⁴⁰⁵

global metabolic defects have diverse manifestations; especially prominent are neurologic abnormalities, failure to thrive, and unexplained metabolic acidosis. Although the hematologic findings may be overshadowed by the systemic illness, the recognition of a characteristic pattern of signs and symptoms may lead expeditiously to the correct diagnosis. Table 152.4 is a compilation of inborn disorders of metabolism that may manifest in infancy or childhood with hematologic cytopenias.⁴⁰⁶ Additional information regarding metabolic disorders is available through the Online Mendelian Inheritance in Man website (<http://www.ncbi.nlm.nih.gov/omim>).

HEMATOLOGIC ASPECTS OF METABOLIC DISEASES

A number of congenital disorders of metabolism may manifest hematologic abnormalities as part of the clinical presentation. Such

SPLENOMEGALY IN CHILDREN

Splenomegaly is a problem frequently encountered by both pediatricians and pediatric hematologists. Although the spleen is rarely a site

TABLE 152.4 Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood

Category	Disease	Defect	Hematologic Findings	Associated Findings
Lysosomal enzyme defects	Gaucher disease type 1	Glucocerebrosidase deficiency	Anemia, thrombocytopenia	Splenomegaly, bone abnormalities, delayed puberty, lipid-engorged macrophages (Gaucher cell) in BM
	Niemann-Pick disease type A	Acid sphingomyelinase deficiency	Anemia	Feeding difficulties, hepatosplenomegaly, developmental delay, neurodegenerative course, cherry-red macula, lipid-laden macrophages (foam cells) in BM
	Wolman disease	Acid lipase deficiency	Anemia, thrombocytopenia	Emesis, diarrhea, hepatosplenomegaly, vacuolization of lymphocytes, lipid-laden macrophages in BM, adrenal calcification
	Aspartylglycosaminuria	Aspartylglycosaminidase deficiency	Neutropenia	Recurrent infections, diarrhea, hernias, lens opacities, neurologic abnormalities, vacuolated lymphocytes
Defects of heme synthesis	Congenital erythropoietic porphyria	Uroporphyrinogen III cosynthase deficiency	Anemia, thrombocytopenia	Hemolysis, staining of diapers, photosensitivity, developmental delay, splenomegaly, erythrodontia
	Erythropoietic protoporphyria	Ferrochelatase deficiency	Anemia, thrombocytopenia	Hemolysis, photosensitivity, neurologic abnormalities, hepatobiliary dysfunction
Defect of amino acid metabolism	Tyrosinemia type 1	Fumarylacetoacetate hydrolase deficiency	Anemia, thrombocytopenia	Failure to thrive, emesis, hepatopathy, neurologic abnormalities, bleeding, "cabbage-like" odor, renal tubular dysfunction
Defects of organic acid metabolism	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase deficiency	Anemia, thrombocytopenia, neutropenia, pancytopenia	Acidosis, emesis, neurologic abnormalities, odor of "sweaty feet"
	Methylmalonic acidemia	Methylmalonyl-CoA mutase deficiency	Anemia, thrombocytopenia, leukopenia, pancytopenia	Acidosis, neurologic abnormalities, failure to thrive, emesis
	Mevalonic aciduria	Mevalonate kinase deficiency	Anemia, thrombocytopenia	Acidosis, cataracts, neurologic abnormalities, hepatosplenomegaly
Defects of organic acid metabolism	Propionic acidemia	Propionyl CoA carboxylase deficiency	Anemia, thrombocytopenia, neutropenia, pancytopenia	Ketotic hyperglycinemia, acidosis, neurologic abnormalities
	Pyroglutamic aciduria	Glutathione synthetase deficiency	Anemia, neutropenia	Hemolysis, neurologic abnormalities, metabolic acidosis
Membrane transport defect	Lysinuric protein intolerance	SLC7A7 gene mutations	Anemia, thrombocytopenia, leukopenia, pancytopenia	Malabsorption, protein intolerance, hyperammonemia, neurologic abnormalities, glomerulonephritis, pulmonary hemorrhage, hemophagocytosis
Glycolytic pathway defects	Triosephosphate isomerase deficiency	Triosephosphate isomerase deficiency	Anemia	Hemolysis, neurologic abnormalities, myopathy
	Phosphoglycerate kinase deficiency	Phosphoglycerate kinase deficiency	Anemia	Hemolysis, neurologic abnormalities

TABLE 152.4**Hematologic Manifestations of Metabolic Disease With Onset in Infancy and Childhood—cont'd**

Category	Disease	Defect	Hematologic Findings	Associated Findings
Defects of vitamin metabolism	Cobalamin metabolic defects	Cobalamin transport and use defects	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, failure to thrive, neurologic abnormalities
	Folate metabolic defects	Folate transport and use defects	Anemia, thrombocytopenia	Megaloblastosis, ringed sideroblasts, diarrhea, failure to thrive, neurologic abnormalities
	Holocarboxylase synthetase deficiency	Holocarboxylase synthetase deficiency	Thrombocytopenia	Acidosis, hyperammonemia, respiratory distress, neurologic abnormalities, skin rash
Defect in metal metabolism	Wilson disease	<i>ATP7B</i> gene mutation	Anemia	Hemolysis, liver dysfunction, neurologic abnormalities, Kayser-Fleischer rings, arthropathy
Defects of purine and pyrimidine metabolism	Hereditary orotic aciduria synthase deficiency	Uridine-5'-monophosphate	Anemia, leukopenia	Megaloblastosis, orotic acid crystalluria, immunodeficiency
	Lesch-Nyhan syndrome	Hypoxanthine-guanine phosphoribosyltransferase deficiency	Anemia	Megaloblastosis, hyperuricemia, nephrolithiasis, neurologic abnormalities, self-mutilation
Defects of carbohydrate metabolism	Galactosemia	Galactose-1 phosphate uridyltransferase deficiency	Anemia	Hemolysis, failure to thrive, neurologic findings, jaundice, emesis, diarrhea, hepatic dysfunction, cataracts, gram-negative sepsis
	Glycogen storage disease type 1b	Deficient hepatic transport of glucose-phosphate	Anemia, neutropenia	Hypoglycemia, acidosis, hepatomegaly, xanthomas, inflammatory bowel disease
	Hereditary fructose intolerance	Aldolase B deficiency	Anemia, thrombocytopenia	Poor feeding, emesis, failure to thrive, neurologic findings, hypoglycemia, liver dysfunction, ringed sideroblasts, coagulopathy, hemophagocytosis, shock
Mitochondrial disorders	DIDMOAD syndrome (Wolfram syndrome)	Mitochondrial DNA deletion	Anemia, thrombocytopenia, neutropenia, pancytopenia	Megaloblastosis, ringed sideroblasts, diabetes insipidus, diabetes mellitus, optic atrophy, deafness
	Pearson syndrome	Mitochondrial DNA deletions	Anemia thrombocytopenia, neutropenia, pancytopenia	Ringed sideroblasts, vacuolization of BM precursors, exocrine pancreatic dysfunction, metabolic acidosis
Lipoprotein disorder	Abetalipoproteinemia	Microsomal triglyceride transfer protein defects	Anemia	Hemolysis, acanthocytosis, bleeding, emesis, diarrhea, failure to thrive, neurologic findings
Miscellaneous disorders	Barth syndrome (endocardial fibroelastosis-2)	Tafazzin gene mutations	Neutropenia	Cardiomyopathy, endocardial fibroelastosis, skeletal myopathy, short stature, 3-methylglutaconicaciduria, abnormal mitochondria
	Cyclic hematopoiesis	Neutrophil elastase gene mutation	Neutropenia	Recurrent oral ulcers, poor dentition, recurrent fever, malaise
	Severe congenital neutropenia (Kostmann syndrome)	Neutrophil elastase gene mutation	Neutropenia	Severe invasive infections, acute leukemia
	Wiskott-Aldrich syndrome	<i>WAS</i> gene mutations	Thrombocytopenia	Eczema, infections, small platelets

BM, Bone marrow; CoA, coenzyme A; DIDMOAD, diabetes insipidus, diabetes mellitus, optic atrophy, deafness.

of primary disease, it may reflect systemic involvement in a variety of disorders. The spleen is the largest collection of lymphoid tissue in the body, with a unique association between the bloodstream and the reticuloendothelial compartment of the spleen. Splenomegaly may result when there is antigenic stimulation of the lymphoid system (e.g., infection), obstruction of blood flow within or distal to the spleen (e.g., portal vein obstruction), exaggeration of one of the normal functions of the spleen because of an underlying

abnormality (e.g., hemolytic anemia, splenic sequestration), or infiltration of the spleen by a foreign cell (e.g., leukemia, storage diseases).

The spleen tip normally is palpable in preterm infants; up to 30% of full-term neonates have a palpable spleen. A spleen can be felt in up to 5% to 10% of normal children, but most of these are in the infant or toddler age group. As a general rule, a spleen easily palpable below the costal margin in any child older than 3 to 4 years of age

must be considered abnormal until proven otherwise. That some palpable spleens may indeed be normal is attested to by the study of McIntyre and Ebaugh,⁴⁰⁷ who found that 3% of healthy college freshmen have palpable spleens, of which about one-third persist. “Pretenders” of splenomegaly include the left lobe of the liver, a left upper quadrant tumor such as Wilms tumor or neuroblastoma, the “wandering spleen,” and the proptotic spleen (seen in children with a depressed diaphragm from obstructive pulmonary disease, such as asthma or bronchiolitis).

The most common cause of acute splenomegaly in children, especially young children, is a viral infection. Splenic enlargement in this setting is mild to moderate and usually transient. When the history and physical findings suggest a viral etiology, a complete blood count with differential, platelet count, and reticulocyte count should be performed to rule out unsuspected leukemia or hemolytic anemia and to determine whether there is an atypical lymphocytosis. The child should be reevaluated in approximately 4 weeks (or sooner if symptoms persist). If splenomegaly persists beyond 4 to 6 weeks, the splenic enlargement may be considered chronic.

A list of causes of splenomegaly in children is presented in Table 152.5.⁴⁰⁸ Symptoms from splenic enlargement are uncommon, although massive splenomegaly may cause abdominal discomfort and early satiety. If the spleen is sufficiently large, there may be increased destruction or sequestration of one or more of the formed elements of the blood (hypersplenism). Cytopenias tend to be mild to moderate, with the platelet count affected the most. An approach to the pediatric patient with splenic enlargement is outlined in the box on Evaluation and Management of Children With Splenomegaly.

Evaluation and Management of Children With Splenomegaly

When evaluating a child with chronic splenomegaly, the clinician must consider all of the possibilities noted in Table 152.5. Clues from the history and physical examination may suggest a specific etiology and direct a tailored approach to the diagnostic laboratory evaluation. If, on the other hand, there is no apparent cause of the enlarged spleen, a number of screening laboratory tests should be performed, including a complete blood count with differential, platelet count, and reticulocyte count; evaluation of the peripheral smear; determination of sedimentation rate; liver function tests; determination of antibody titers to Epstein-Barr virus, cytomegalovirus, and *Toxoplasma* spp.; antinuclear antibody assay; and ultrasound evaluation of the liver, spleen, and portal system (the last with Doppler flow technique). Further evaluation, including bone marrow examination, may be necessary if the screening tests do not reveal the cause of the splenic enlargement.

Management of splenomegaly usually is that of the underlying disease, when such treatment exists. Splenectomy may be indicated in selected conditions, but the potential benefits from splenectomy must be weighed against the risk of postsplenectomy sepsis, a rapidly progressive bacteremia, most commonly from *Streptococcus pneumoniae*, with a mortality rate of approximately 50%. The risk of postsplenectomy sepsis depends on the age of the patient and the nature of the underlying disorder. Patients younger than 3 years of age and those with a compromised immune or reticuloendothelial system are most susceptible. When elective splenectomy is indicated, it is advisable to (1) postpone surgery until the patient is at least 5 to 6 years of age; (2) administer pneumococcal, meningococcal, and *Haemophilus influenzae* vaccines (if the patient was not previously immunized) at least 1 to 2 weeks before splenectomy; (3) consider use of prophylactic penicillin for at least 4 years; and (4) manage significant febrile illnesses as possible postsplenectomy sepsis at all times. In addition to the risk of postsplenectomy sepsis, the rare complication of postsplenectomy portal or splenic vein thrombosis must also be considered.

For children younger than 5 years of age with severe symptoms from hemolytic anemia, hemoglobinopathy, or hypersplenism, partial splenectomy should be considered. In a number of studies, up to 90% of the spleen has been removed safely, with a high rate of success and preservation of splenic function.^{409,410} Regrowth of the spleen to variable degrees has been noted, with occasional need for reoperation.

**TABLE
152.5**

Causes of Splenomegaly in Children

Disorders of the Blood

Hemolytic anemia: congenital or acquired
Thalassemia
Sickle cell disease
Leukemia
Osteopetrosis
Myelofibrosis, myeloid metaplasia, thrombocythemia

Infections: Acute and Chronic

Viral

Congenital (e.g., TORCH association)
Mononucleosis (e.g., EBV, CMV infection)
Virus-associated hemophagocytic syndrome
Human immunodeficiency virus

Bacterial

Sepsis or abscess
Brucellosis
Salmonellosis
Tularemia
Tuberculosis
Subacute bacterial endocarditis
Syphilis
Lyme disease

Fungal

Histoplasmosis (disseminated)

Rickettsial

Rocky Mountain spotted fever
Cat-scratch disease

Parasitic

Toxoplasmosis
Malaria
Leishmaniasis (kala-azar)
Schistosomiasis
Echinococcosis

Hepatic and Portal System Disorders

Acute or chronic active hepatitis
Cirrhosis, hepatic fibrosis, biliary atresia
Portal or splenic venous obstruction (Banti disease)

Autoimmune Disease

Juvenile rheumatoid arthritis
Systemic lupus erythematosus
Autoimmune lymphoproliferative syndrome (Canale-Smith syndrome)

Neoplasms and Cysts

Lymphomas (Hodgkin and non-Hodgkin)
Hemangiomas and lymphangiomas
Hamartomas
Congenital or acquired (posttraumatic) cysts

Storage Diseases and Inborn Errors of Metabolism

Lipidoses: Gaucher disease, Niemann-Pick disease, others
Mucopolysaccharidoses
Defects in carbohydrate metabolism: galactosemia, fructose intolerance
Sea-blue histiocyte syndrome

Miscellaneous Disorders

Histiocytoses
Reactive
Langerhans cell
Malignant
Sarcoidosis
Congestive heart failure
Familial Mediterranean fever

CMV, Cytomegalovirus; EBV, Epstein-Barr virus; TORCH, toxoplasmosis, other infections, rubella, cytomegalovirus infection, herpes simplex.

HEMATOLOGIC MANIFESTATIONS OF LIVER DISEASE

Christopher Hillis and Wendy Lim

The liver plays key roles in the synthesis and clearance of proteins involved in hematopoiesis and hemostasis. The liver produces hematopoietic growth factors such as thrombopoietin, contributes to heme biosynthesis and is a site of extramedullary hematopoiesis. Cytopenias are detected in approximately 75% of patients with liver disease. The liver plays a major role in hemostasis through synthesis of coagulation factors, coagulation inhibitors, and fibrinolytic proteins. The liver is also involved in the clearance of plasma proteins, including activated coagulation factors, proteolytic enzyme-inhibitor complexes, fibrin, and fibrinogen degradation products. Lipid metabolism involves the liver, which in turn can affect the structure of the red blood cell (RBC) membrane. As a consequence, chronic liver disease is frequently associated with multiple hematologic abnormalities.

Liver cirrhosis is often associated with the development of portal hypertension, which leads to the formation of portal gastropathy and gastric, esophageal, or rectal varices, which can result in gastrointestinal (GI) bleeding. Portal hypertension also causes hypersplenism increasing the fraction of circulating platelets, leukocytes and erythrocytes sequestered in the spleen which can manifest with varying degrees of cytopenias.

This chapter discusses several common hematologic abnormalities encountered in liver disease including RBC, leukocyte, and platelet abnormalities, coagulopathy and thrombosis.

RED BLOOD CELL ABNORMALITIES

Morphologic Abnormalities

The size and shape of the RBC membrane can be affected by abnormal lipid metabolism caused by liver disease. Excess cholesterol in the outer RBC membrane bilayer is thought to be responsible for morphologic abnormalities, including macrocytosis and target cells (Fig. 153.1), and for impaired migration of integral membrane proteins causing a loss of RBC membrane fluidity and deformability. RBCs with excess membrane cholesterol are also rendered less deformable from oxidative damage caused by an inability to repair peroxidized membrane lipids. When these less deformable RBCs traverse through the splenic microcirculation, cytoskeletal damage and permanent deformation can occur, resulting in the formation of acanthocytes (spur cells) and increased clearance in the reticuloendothelial system.

Spur cell anemia is a hemolytic anemia most commonly caused by chronic or severe liver disease. Life-threatening hemolysis can ensue, as well as disseminated intravascular coagulation (DIC), GI bleeding or liver failure depending on the primary cause. Spur cell anemia associated with hereditary diseases such as neuroacanthocytosis syndromes or lipoprotein disorders tends to be milder (see Chapter 45). Treatment options for spur cell anemia associated with liver disease are limited. The most effective therapy is liver transplantation. Clinical improvement using flunarizine, pentoxifylline, and cholestyramine has been documented in case reports.

Anemia

The etiology of anemia is multifactorial, although acute and chronic GI hemorrhage are primary contributors. Fluid retention increases whole blood volume in patients with cirrhosis causing an apparent anemia, as 60% to 70% of these patients will have a normal red cell

mass but a subnormal hematocrit from hemodilution. Hypersplenism results in sequestration of erythrocytes. Erythropoiesis is reduced by nutritional deficiencies in folate or vitamin B₁₂ resulting from poor intake or malabsorption, iron deficiency, bone marrow suppression from alcohol or viral hepatitis, hepatitis-associated aplastic anemia, treatment-related toxicities for viral hepatitis (e.g., interferon, telaprevir, boceprevir), and anemia of chronic disease. Patients with chronic liver disease or cirrhosis can also experience nonimmune hemolysis because of acquired alterations in the RBC membrane (e.g., spur cell anemia), Zieve syndrome (hemolytic anemia, hypertriglyceridemia, and jaundice), or treatment-related toxicities (e.g., ribavirin).

The therapeutic approach to anemia in liver disease includes transfusional support for symptomatic disease, identification and treatment of GI bleeding, supplementation for documented iron, vitamin B₁₂, or folate deficiencies, discontinuation of bone marrow suppressive medications or alcohol, and appropriate treatment for the primary cause of liver disease.

Small studies have suggested that inadequate production or response to erythropoietin (EPO) also contributes to chronic anemia in hepatic disease, although the association is controversial. Nonetheless, EPO supplementation has demonstrated clinical efficacy, cost-effectiveness, and increased quality of life in patients with hemoglobin levels less than 12 g/dL undergoing antiviral therapy for hepatitis C. The use of EPO to maintain a hemoglobin greater than 10 g/dL may obviate the need for dose reduction or discontinuation of ribavirin, either of which reduce rates of sustained viral response. It may take up to 6 weeks to observe a significant rise in hemoglobin in response to EPO.

WHITE BLOOD CELL ABNORMALITIES

Leukopenia

Leukopenia, particularly neutropenia, has been observed in up to 55% of patients with cirrhosis. Splenic sequestration is considered to be the main culprit; however, reduced production of leukocytes may also be a consequence of altered granulocyte colony-stimulating factor (G-CSF) and granulocyte macrophage colony-stimulating factor (GM-CSF) levels, bone marrow suppression mediated by primary infections or toxins (e.g., hepatitis B or C, alcohol), or medications (e.g., interferon). Immune-mediated neutropenia can occur in the context of hepatitis C or autoimmune hepatitis, and increased apoptosis may also be responsible for a shortened neutrophil life span. Furthermore, impairment in neutrophil recruitment and phagocytic function may contribute to an increased susceptibility for severe and recurrent infections in patients with cirrhosis. G-CSF and GM-CSF have been safely used in patients with cirrhosis and neutropenia in the setting of hypersplenism or treatment of viral hepatitis, resulting in improvements in leukocyte counts. The impact of these treatments on risk of infection or response to antiviral therapy is unclear.

PLATELET ABNORMALITIES

Thrombocytopenia

Thrombocytopenia is the most common cytopenia associated with liver disease, occurring in up to 77% of patients with cirrhosis.

Fig. 153.1 RED BLOOD CELL MORPHOLOGY IN LIVER DISEASE. (A) Macrocytes have a mean corpuscular volume greater than 100 fL and can be oval shaped. Commonly associated disorders include liver disease and vitamin B₁₂ and folate deficiency. (B) Target cells are characterized by the bull's-eye appearance of the red blood cell (RBC). They are a result of an increased surface-to-volume ratio related to excess RBC membrane (e.g., liver disease) or disproportionate reduction of cytoplasmic content (e.g., hemoglobinopathies, iron deficiency). (C) Acanthocytes, or spur cells, typically appear as contracted RBCs lacking central pallor with multiple irregular membrane projections. The morphologic appearance reflects the irreversible cytoskeletal damage that has occurred because of passage of nondeformable RBCs through the reticuloendothelial system. They are most commonly seen in severe liver disease but can also be features of rare neuroacanthocytosis syndromes or lipoprotein disorders.

Platelet counts are usually mildly to moderately reduced; severe thrombocytopenia ($<30\text{--}40 \times 10^9/\text{L}$) and spontaneous bleeding are uncommon.

Many factors contribute to thrombocytopenia in liver disease. Decreased platelet counts may result from hypersplenism. There may be impaired thrombopoiesis related to nutritional deficiencies (folate or vitamin B₁₂); direct toxicity of alcohol, viral hepatitis, or interferon treatment; or reduced hepatic synthesis of thrombopoietin. Autoantibodies to platelet antigens have been demonstrated in patients with cirrhosis, suggesting that accelerated destruction of platelets can occur via immune-mediated mechanisms. Hepatitis C is a secondary cause of immune thrombocytopenia. Although controversial, the presence of low-grade DIC may contribute to platelet consumption. Thrombocytopenia in patients with cirrhosis, especially in combination with leukopenia, has been associated with increased morbidity and mortality.

Platelet Dysfunction

Laboratory evaluation of platelet function has demonstrated abnormal bleeding times (BTs), PFA-100 results, and platelet aggregation in response to multiple agonists in some individuals with liver disease, implying that there may be a component of platelet dysfunction. Intrinsic platelet defects leading to abnormal platelet aggregation or adhesion include impaired transmembrane signaling and thromboxane A₂ synthesis, storage pool deficiency, or defects in platelet glycoprotein Ib or $\alpha_{\text{IIb}}\beta_3$ receptors. Extrinsic defects resulting in platelet dysfunction include circulating fibrin(ogen) degradation products, bile salts, abnormal high-density lipoproteins, reduced hematocrit, and excess production of nitric oxide and prostacyclin.

The clinical significance of platelet dysfunction demonstrated *in vitro* is unclear. Although prolonged BTs are present in up to 40% of patients with cirrhosis and appear to be correlated with disease severity, they have not been predictive of bleeding. Improvement in BT in randomized trials of DDAVP (desmopressin) did not translate into reductions in surgical blood loss, transfusion requirements, or improved control of variceal hemorrhage. This discordance between laboratory findings and clinical bleeding may be explained by two observations. First, platelets studied under physiologic flow conditions show normal adhesion to fibrinogen and collagen even in

cirrhosis. Second, elevated levels of von Willebrand Factor (vWF) are commonly found in patients with cirrhosis and may compensate for thrombocytopenia or platelet dysfunction.

Platelet transfusions can be used to treat thrombocytopenia caused by liver disease but are generally not indicated unless the patient has severe thrombocytopenia ($<10\text{--}20 \times 10^9/\text{L}$) or platelets less than $50 \times 10^9/\text{L}$ with bleeding symptoms. Platelet counts greater than $50\text{--}70 \times 10^9/\text{L}$ are usually considered adequate for invasive procedures. Less commonly attempted interventions for thrombocytopenia secondary to liver disease include splenectomy, partial splenic arterial embolization, and transjugular intrahepatic portosystemic shunt (TIPS), which are associated with unpredictable results and procedural risks. Thrombopoietin mimetic agents (e.g., eltrombopag, romiplostim) may offer potential treatment for these patients. In a phase II trial of 74 patients with hepatitis C–related cirrhosis and platelet counts of $20\text{--}70 \times 10^9/\text{L}$ randomized to eltrombopag (30, 50, or 75 mg/day) or placebo, the primary endpoint of achieving a platelet count greater than $100 \times 10^9/\text{L}$ at week 4 was seen in 75% to 95% of patients taking eltrombopag compared with 0% in the placebo group. Furthermore, 36% to 65% of patients taking eltrombopag were able to complete a 12-week course of antiviral treatment compared with 6% of the placebo group. However, another trial evaluating eltrombopag in chronic liver disease was stopped because of an increase in portal vein thrombosis (PVT), highlighting some of the toxicities that can be associated with these new agents. Further study is required before recommendations can be made about their use as no study has demonstrated a reduction in bleeding with these agents.

COAGULATION AND LIVER DISEASE

The manifestations of aberrant coagulation in liver disease reflect a complex interplay between procoagulant and anticoagulant mechanisms. Patients with cirrhosis are at an increased risk of bleeding and thrombosis.

Deficiencies in coagulation factors, vitamin K deficiency, dysfibrinogenemia, and systemic fibrinolysis can all contribute to impaired hemostasis. Clinical manifestations range from asymptomatic laboratory abnormalities to life-threatening hemorrhage. Most spontaneous bleeding in chronic liver disease, however, is not because of abnormalities in coagulation but variceal bleeding resulting from portal

hypertension and vascular deformities. Over 80% of bleeding episodes in patients with cirrhosis are a result of variceal bleeding.

Hepatic dysfunction leads to reduced synthesis of most coagulation factors. The number and degree of clotting factor deficiencies reflect the severity of liver damage. Factor VII levels, having the shortest half-life (6 hours) of the coagulation factors, often decline early and are reflected by prolongation of the prothrombin time (PT)/international normalized ratio (INR). Conversely, factor VIII and vWF levels may be normal or elevated in liver disease because of upregulated compensatory extrahepatic synthesis or impaired hepatic clearance.

Reductions in factors II, VII, IX, and X in patients with liver disease may also result from vitamin K deficiency caused by malnutrition, malabsorption, use of antibiotics, or biliary tract obstruction. For these coagulation factors, vitamin K is required as a cofactor in γ -carboxylation, a process that converts inactive precursors to biologically active factors.

Defects in coagulation factors are suggested by prolonged PT/INR and partial thromboplastin time (PTT) measurements and confirmed by individual factor levels. However, these routine screening tests of coagulation do not identify patients at risk of bleeding. Both the PT and INR have been incorporated into prognostic indices (Child-Pugh and Model of End-stage Liver Disease scores) as markers of synthetic dysfunction to estimate the severity of liver disease and stratify patients for transplant, respectively. Factor V levels have been studied as a prognostic indicator in acute fulminant hepatic failure. Acute liver failure is associated with more pronounced elevations in the INR, yet is associated with less spontaneous bleeding than chronic liver failure reflecting the importance of hemodynamics (portal hypertension) on the risk of bleeding.

Despite their routine use in clinical practice, several significant limitations exist in applying the PT/INR or PTT in the context of liver disease. First, the INR has not been validated for patients with cirrhosis. Second, there is no evidence that demonstrates correcting these abnormal values with plasma or procoagulant agents prevents bleeding or improves outcomes. Several reasons may account for the lack of correlation between PT/INR or PTT with bleeding. Liver disease results in deficiencies of procoagulant proteins but also deficiencies in the natural anticoagulant proteins, including antithrombin and proteins C and S. PT/INR and PTT assays reflect procoagulant protein levels only and do not reflect alterations in anticoagulant proteins, the role of the endothelium and platelet number or function. Small studies have demonstrated normal thrombin generation in cirrhotic patients and patients with acute liver failure and prolonged PT and PTTs. Tests of thrombin generation (e.g., thromboelastography, rotational thromboelastometry) have been studied in liver transplantation to assess hemostasis and guide transfusions but not to predict the risk of bleeding in patients with liver disease undergoing other invasive procedures.

Being an acute phase reactant, fibrinogen synthesis is generally preserved unless liver disease is severe. Acquired dysfibrinogenemia, however, has been described in approximately 75% of patients with chronic liver disease, acute liver failure, and cirrhosis but is not thought to contribute significantly to bleeding. Aberrant polymerization of fibrin monomers may be related to excess sialic acid residues on fibrinogen, interfering with the activity of thrombin. Laboratory findings of dysfibrinogenemia include elevated PT, PTT, or thrombin time, low or normal fibrinogen by immunologic assay and reduced fibrinogen by functional assay.

The presence of hyperfibrinolysis in liver disease and its contribution to bleeding risk is controversial. Triggers of increased fibrinolysis may involve release of tissue plasminogen activator (t-PA) in the setting of infection or surgery, reabsorption of ascitic fluid with fibrinolytic activity, and altered synthetic or metabolic functions of the liver. With the exception of t-PA and plasminogen activator inhibitor-1 (PAI-1), all fibrinolytic and antifibrinolytic proteins are synthesized in the liver. Decreased hepatic clearance of t-PA and reduced synthesis of α_2 antiplasmin and thrombin-activatable fibrinolysis inhibitor favor an increase in circulating plasmin and a hyperfibrinolytic state in cirrhosis. Available laboratory tests cannot adequately assess the overall activity of profibrinolytic and antifibrinolytic components. Shortened whole blood euglobulin clot lysis time and elevated levels of D-dimer, fibrin, and fibrinogen degradation products are suggestive of increased fibrinolysis. These abnormal laboratory indices have been observed in nonbleeding patients but are seen more frequently in bleeding patients and have been reported to correlate with GI bleeding, severity of liver failure, and variceal size. Hyperfibrinolysis may theoretically aggravate bleeding through consumption of coagulation factors, inhibition of fibrin polymerization, and reduced platelet aggregation via degradation of vWF and glycoprotein Ib and $\alpha_{IIb}\beta_3$. Hyperfibrinolysis likely plays a more important role in hemostasis during liver transplantation. Conversely, patients with acute hepatic failure show evidence of impaired fibrinolysis with elevated PAI-1 levels and decreased plasminogen.

TREATMENT OF LIVER DISEASE-RELATED BLEEDING

Treatment and correction of asymptomatic hemostatic abnormalities in patients with liver disease is generally not indicated and potentially harmful. Interventions may be indicated when there is active bleeding or before a planned invasive procedure. Most of the evidence for the prevention of bleeding in patients with chronic liver disease is based on studies of the perioperative management of patients undergoing liver transplantation.

RBC transfusions should be provided to maintain an adequate hemoglobin or hematocrit levels and for symptomatic anemia. A randomized controlled trial demonstrated that a restrictive RBC transfusion threshold in patients with an acute upper GI bleed reduced rebleeding and increased survival. In general, platelet transfusions are not indicated for isolated thrombocytopenia in the absence of bleeding. An effort should be made to maintain platelet counts greater than $50 \times 10^9/L$ with active bleeding or before invasive procedures. Platelet transfusion may be effective if there is suspected platelet dysfunction. Patients with cirrhosis often have smaller platelet increments in response to transfusion caused by splenic sequestration. In acute variceal bleeding, minimization of blood product administration should be the goal as the increase in central venous pressure associated with volume overload can increase variceal bleeding. Increased portal pressures caused by large volume plasma or red cell transfusion has been shown to increase rebleeding rates in animal models. During invasive procedures, a balanced strategy of maintaining low portal pressures by minimization of total circulating volume while maintaining adequate tissue perfusion has been shown to decrease bleeding.

A trial of oral vitamin K can be considered in patients with prolonged PT or INR. Vitamin K can be given intravenously for earlier onset of action but carries a small risk of anaphylaxis. Subcutaneous and intramuscular administrations are not preferred because of inconsistent absorption and risk of hematoma formation, respectively.

Hemostatic Balance in Liver Disease

	Promotes Thrombosis	Promotes Bleeding
Primary hemostasis	- Increased vWF - Decreased ADAMTS13	- Thrombocytopenia - Platelet dysfunction
Secondary hemostasis	- Increased factor VIII - Decreased protein C, protein S, antithrombin	- Factor deficiencies: II, V, VII, IX, XI - Vitamin K deficiency - Hypofibrinogenemia - Dysfibrinogenemia
Fibrinolysis	- Reduced plasminogen - Increased PAI-1	- Reduced α_2-antiplasmin, TAFI, factor XIII - Increased t-PA

ADAMTS13, A disintegrin and metalloproteinase with thrombospondin; PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin activatable fibrinolysis inhibitor; t-PA, tissue plasminogen activator; vWF, von Willebrand factor.

If no improvement is seen after 10 to 20 mg of vitamin K, additional vitamin K is unlikely beneficial. Although it may be reasonable to use vitamin K replacement alone in asymptomatic patients, it should be considered as an adjunct to other therapy in actively bleeding patients.

Frozen plasma (FP) has traditionally been used to correct liver-related coagulopathy because it replaces all the coagulation and fibrinolytic factors. Despite its widespread use, its clinical effectiveness in reducing bleeding has not been supported by data from randomized controlled trials. Guidelines variably support the use of 10 to 20 mL/kg of FP for major hemorrhage or prevention of bleeding before major invasive procedures. Evidence-based guidelines recommend against the use of platelets or plasma as prophylaxis against bleeding in liver disease laboratory parameters, including a complete blood count (CBC), PT, PTT, fibrinogen, and D-dimer, should be followed to assess therapeutic effect. In general, moderate correction of the PT and PTT is achieved after FP transfusion but is transient, and repeat doses may have to be administered every 6 to 12 hours to maintain the effect. Patients should be monitored for complications of FP, including transfusion reactions and volume overload. Plasma infusion may not be well tolerated in patients with liver disease who already have expanded intravascular plasma volume. Plasma exchange in addition to FP has been described primarily in the setting of acute liver failure and in preparation for liver transplantation. However, the efficacy of this approach has not been thoroughly studied in controlled trials.

The presence of hyperfibrinolysis, DIC, and dysfibrinogenemia may exacerbate bleeding and are inadequately treated with FP alone. These disorders should be suspected if coagulation parameters fail to correct with FP or there is persistent bleeding. Administration of cryoprecipitate, rich in fibrinogen, vWF, factor VIII, and factor XIII, may help control bleeding. One unit of cryoprecipitate for every 10 kg of body weight increases plasma fibrinogen by approximately 50 mg/dL. Cryoprecipitate carries similar risks to FP. Although antifibrinolytic agents could be considered in the setting of hyperfibrinolysis, no randomized trials have demonstrated efficacy or safety outside the setting of liver transplantation. Tranexamic acid has been shown to reduce blood loss and the need for transfusion in liver resection, transplantation and variceal bleeding. Thrombotic risks must be weighed and DIC must be excluded before usage.

Three- and four-factor prothrombin complex concentrates (PCCs) contain the vitamin K–dependent factors II, IX, and X and may or may not contain variable amounts of factor VII. They are effective in reversing anticoagulation with vitamin K antagonists (VKAs), but have not been widely studied in liver disease. Data are limited to case reports and small, uncontrolled studies describing improvement in coagulation parameters, subjective clinical improvement, and safe administration in patients with liver disease. The use of PCCs in liver disease should be undertaken cautiously because of the risk of DIC, thrombotic complications, and anaphylaxis; its use should be restricted to emergency situations such as refractory bleeding or if FP administration is limited by risk of circulatory overload.

Recombinant factor VIIa (rFVIIa) is formally approved for the treatment and prevention of bleeding episodes in patients with hemophilia and inhibitors, acquired hemophilia, and congenital factor VII deficiency. Because of proven efficacy in these other disorders, rFVIIa has been investigated for GI or variceal bleeding in liver disease, liver resection or biopsy, and liver transplantation. Studies have demonstrated transient normalization of the PT after rFVIIa, yet correlation with improved clinical outcomes has been inconsistent. The only two randomized trials examining rFVIIa in active GI and variceal bleeding did not show any benefit over placebo. rFVIIa appears to reduce blood loss and blood product requirements when used prophylactically in invasive procedures or surgery; however, there is no clear mortality benefit. These potential benefits may be offset by an observed increase in arterial thromboembolic events, particularly in elderly adults. Compared with FP, rFVIIa can be given in small volumes and has no infectious risk. Additional research is required to establish the overall benefit and risk of rFVIIa, and clinicians should proceed with the use of rFVIIa judiciously in the interim.

Management of Coagulopathy in Liver Disease

- Actively bleeding patients should be adequately resuscitated. Admission to the intensive care setting may be appropriate.
- Basic coagulation tests should be ordered to identify the cause of bleeding; these include CBC, PT (INR), PTT, thrombin clotting time, fibrinogen, D-Dimer, FDP, and mixing studies. The need for more specialized tests will be dictated by the clinical situation and response to therapy.
- It is important to identify any localized source of bleeding (e.g., varices) amenable to procedural intervention to achieve hemostasis.
- A trial of 5 to 10 mg of vitamin K is reasonable in asymptomatic patients with prolonged PT and PTT but should be used with other therapies in actively bleeding patients.
- In patients with thrombocytopenia platelet transfusions can be used, targeting platelet counts greater than $50 \times 10^9/L$.
- In patients who can tolerate volume, FP 4 to 6 units (1000–1500 mL) given over 1 to 2 hours can be used to replace coagulation factors. Coagulation parameters should be monitored to document effect and determine the timing and need for additional units.
- Dysfibrinogenemia or hypofibrinogenemia should be suspected if coagulation assays do not correct with FP or fibrinogen levels are low, respectively. Replacement can be attempted with 10 to 20 units of cryoprecipitate while following laboratory results.
- Patients who are intravascularly overloaded or who do not respond to FP should be considered for rFVIIa. Low doses of rFVIIa (25–50 $\mu g/kg$) are generally used, and repeated doses may be required because of the short rFVIIa half-life of 2 to 3 hours. rFVIIa may be most suitable as a temporizing measure to enable invasive procedures or hemostasis to be achieved by other means. Avoid use in the setting of DIC.

CBC, Complete blood count; DIC, disseminated intravascular coagulation; FDP, FP, frozen plasma; INR, international normalized ratio; PT, prothrombin time; PTT, partial thromboplastin time; rFVIIa, recombinant factor VIIa.

HYPERCOAGULABILITY AND THROMBOSIS IN PATIENTS WITH LIVER DISEASE

Although retrospective studies have reported variable rates of venous thromboembolism (VTE) in patients with cirrhosis, it is clear that these patients are not “autoanticoagulated” and thus not immune to thrombotic events as once believed. The risk of VTE may actually be higher in patients with liver disease than those without. Reported incidences of deep venous thrombosis (DVT) or pulmonary embolism (PE) have ranged from 0.5% to 6.3%. Thrombotic complications can also involve portal, mesenteric, and hepatic veins. PVT occurs in approximately 8% to 15% of patients with cirrhosis and is associated with both severity of disease and inferior prognosis in liver transplantation.

Despite the increased bleeding risks in liver disease, patients may benefit from prophylactic or therapeutic anticoagulation. Hepatic thrombosis or PVT may result in worsening liver function, ascites, varices, and hemorrhage. Furthermore, microvascular thrombosis has been proposed to promote hepatic fibrosis and progression of cirrhosis. Clinical decisions are limited by a paucity of studies establishing the optimal dose, duration, monitoring, or choice of anticoagulant and importantly, clear clinical benefit and safety.

There are currently no standard means of identifying patients with liver disease requiring thromboprophylaxis nor means to reconcile the perceived increased risk of bleeding in these patients. Standard pharmacologic thromboprophylaxis may be safe and should not be withheld in patients with abnormal coagulation studies in the absence of bleeding. Guidelines on thromboprophylaxis do not address cirrhosis, so decisions remain individualized. Patients who may particularly benefit from primary prophylaxis are those awaiting liver transplantation because PVT worsens the long-term posttransplant prognosis. Small trials have recently suggested that low-molecular-weight heparins (LMWHs) may be safe for thromboprophylaxis in cirrhosis. Use of VKAs for thromboprophylaxis in patients with liver

Hemostatic Indices in Liver Disease

Laboratory Changes	PT	PTT	TCT	Fib	Clauss	Plt	Platelet Aggregation	FVII	DD	ELT
Thrombocytopenia	N	N	N	N	N	↓	N	N	N	N

DIC	N/↑	N/↑	N/↑	↓	↓	↓	N	N/↓	↑	↓

^aDifferentiating between vitamin K deficiency and liver disease can be challenging with conventional laboratory tests. If available, performing a factor II assay with and without Echis venom (factor II biologic and factor II Echis) may be useful. Ecarin is derived from *Echis carinatus* snake venom and can activate prothrombin irrespective of γ -carboxylation. Factor II activity (biologic) is reduced in both vitamin K deficiency and liver disease. In contrast, the factor II Echis is reduced in liver disease but is normal in vitamin K deficiency.

Clauss, Clauss fibrinogen; DD, D-dimer; DIC, disseminated intravascular coagulation; ELT, euglobulin lysis time (measure of fibrinolysis); Fib, fibrinogen; FVII, factor VII functional assay; N, normal; Plt, platelet; PT, prothrombin time; PTT, partial thromboplastin time; TCT, thrombin clotting time.

disease may be complicated by unreliable INR measurements. Trials involving non-VKA oral anticoagulants such as direct thrombin and factor Xa inhibitors have usually excluded patients with liver disease.

A similar risk–benefit analysis must be completed before therapeutic anticoagulation for confirmed VTE. Expert opinion recommends screening for varices and appropriate treatment with β -blockers or endoscopic therapy before anticoagulant initiation to mitigate bleeding potential. There are several indications for therapeutic anticoagulation in the setting of cirrhosis, including DVT or PE, acute PVT, and Budd-Chiari syndrome. The comprehensive management of these disorders is beyond the scope of this chapter. Treatment options for portal vein or hepatic vein thromboses may include one or more of anticoagulation, systemic or local thrombolysis, or TIPS. There are no truly evidence-based guidelines for the management of anticoagulation in these patients. LMWH appears safe for the treatment of PVT and often results in recanalization. The use of LMWHs is complex owing to issues of dosing and monitoring, secondary to the hemostatic profile of liver disease. The potency of LMWH may be higher in liver disease and anti-Xa levels potentially underestimate the actual LMWH mass. VKAs for the treatment of PVT have been shown to have a high complication rate owing to a narrow therapeutic window. Anticoagulation should be approached cautiously but not withheld needlessly as mounting clinical experience demonstrates the safety of appropriate anticoagulation. The American College of Chest Physician 2012 guidelines recommended a minimum of 3 months of anticoagulation for acute PVT in the absence of cirrhosis, with consideration for long-term anticoagulation in patients with persistent thrombotic risk factors or concerns for extension into mesenteric veins. Individualized assessment has been recommended for patients with PVT with cirrhosis. Overall recanalization after 6 months has been observed in up to 75% of PVT patients with cirrhosis and minimal major bleeding. The value of anticoagulation for chronic PVT is uncertain, particularly in patients with cirrhosis with varices. Hepatic vein thrombosis is more uncommon than PVT, and even less evidence exists to guide therapy. Anticoagulation is usually instituted acutely and maintained long-term to prevent recurrence in the absence of contraindications. Symptomatic patients may require additional interventional therapies as mentioned earlier, including possible liver transplantation.

FUTURE DIRECTIONS

Liver disease can cause a variety of hematologic manifestations. Patients may have concurrent coagulopathic, hypercoagulable, and hyperfibrinolytic features. Bleeding or thrombosis may be the end result of a reduced capacity of the hemostatic system to maintain homeostasis in the face of physiologic stress. Advancements in patient care will evolve with improved understanding of pathophysiology and

refinement of laboratory assays. Moreover, strategies to safely manage patients with liver disease and a high-risk of bleeding or thrombosis are required.

HEMATOLOGIC MANIFESTATIONS OF RENAL DISEASE

Mark A. Crowther and Ali Iqbal

Renal dysfunction is associated with a number of hematologic abnormalities including anemia, platelet dysfunction, and thrombosis. Morphologic abnormalities may include the presence of echinocytes characterized by abnormal red blood cell (RBC) membranes with multiple small, evenly spaced projections.¹ Certain conditions including hemolytic uremic syndrome (HUS) involve complex interactions between glomerular microvasculature and the coagulation cascade manifesting as microangiopathic hemolytic anemia and thrombocytopenia. Among renal transplant patients, posttransplant lymphoproliferative disorder can occur. The underlying pathophysiology and treatment of these hematologic manifestations of renal disease are discussed here.

ANEMIA

Anemia is common in chronic kidney disease (CKD) and is associated with poor outcomes, including reduced quality of life, increased cardiovascular disease, hospitalizations, cognitive impairment, and mortality. In a study of 5222 patients with CKD (defined by serum creatinine >1.5 mg/dL and >2.0 mg/dL in females and males, respectively) the prevalence of anemia was 47.7%.² Anemia in CKD is usually normocytic, hypoproliferative and is multifactorial, being contributed to by relative erythropoietin (EPO) deficiency, iron deficiency, and disordered iron homeostasis.³

Relative Erythropoietin Deficiency

EPO is a glycoprotein hormone mainly produced in the kidney by interstitial fibroblasts.⁴ With normal kidney function, hypoxic conditions in the outer medulla trigger production of EPO, which binds to receptors on erythroid progenitors ultimately leading to increased RBC production.⁵ Patients with CKD have insufficient EPO levels because of two proposed mechanisms; decreased production capacity caused by tissue damage as well as an altered hypoxic set point for the production of EPO.⁶ As a result, anemic CKD patients have 10–100 times lower EPO levels compared with similarly anemic patients with normal renal function.³

Erythropoiesis stimulating agents (ESAs) were introduced in the late 1980s for the treatment of anemia of CKD. Several observational studies have demonstrated clinical benefits with the use of ESAs, including reduction in heart failure, regression of left ventricular hypertrophy, improved energy levels, and improved overall quality of life.^{7,8} However, targeting near normal hemoglobin (Hb) levels is associated with increased hospitalization, graft/fistula thrombosis, stroke, and a trend towards increased mortality.^{9,10} Therefore the 2012 KDIGO (Kidney Disease Improving Global Outcomes) clinical practice guidelines recommend the use of ESAs to target Hb levels less than 11.5 g/dL. These guidelines recommend considering initiation of ESAs when Hb is less than 10 g/dL for both dialysis and nondialysis CKD patients.¹¹

True Iron Deficiency

CKD patients, particularly those on hemodialysis, have increased iron losses because of chronic bleeding, phlebotomy, and blood loss in the hemodialysis apparatus.¹² Furthermore, the use of ESAs

in CKD patients causes depletion of iron stores through increased erythropoiesis. Therefore optimization of iron status is a mainstay of management for anemia of CKD. The 2012 KDIGO guidelines recommend a trial of intravenous iron therapy for dialysis patients and oral iron therapy for nondialysis patients for a transferrin saturation of less than 30% and ferritin less than 500 ng/mL, and when an increase in Hb concentration with a decrease in ESA dosing is desired.¹¹

Disordered Iron Homeostasis

Patients with CKD often have a functional iron deficiency in addition to true iron deficiency. This is related to an excess of hepcidin, a key hormone involved in iron homeostasis (see [Chapter 35](#) and [Chapter 36](#)). Excess hepcidin in CKD patients is thought to be secondary to increased production caused by chronic inflammation as well as decreased renal clearance. The hepcidin–ferroportin axis is currently being investigated as a potential therapeutic target in CKD patients with anemia.³

UREMIC BLEEDING

Patients with CKD have increased bleeding because of frequent use of anticoagulant and antiplatelet drugs, defects in platelet aggregation as well as abnormal platelet-endothelial cell interaction. One of the major factors contributing to platelet dysfunction is a defect in glycoprotein IIb/IIIa.¹³ Other factors include ineffective ADP response to stimulated aggregations and increased production of nitric oxide.^{14,15} Anemia also contributes to uremic bleeding caused by altered flow of platelets with reduced proximity and interaction with endothelial cells.¹⁶

Treatment for uremic platelet dysfunction is indicated in patients with CKD who are actively bleeding or scheduled to undergo a procedure with a risk of bleeding.

Desmopressin (DDAVP) is an effective therapy in reducing bleeding time within 1 hour of administration through increased release of von Willebrand factor (vWF) multimers from endothelial cells.¹⁷ Another treatment option is conjugated estrogen, which achieves peak effect over 5 to 7 days.¹⁸ The mode of action is not well understood, but is thought to result from a reduction in nitric oxide¹⁹ (see [Chapter 130](#)). Correction of anemia, whether through ESAs or RBC transfusions to a level greater than 10 g/dL, has also been shown to improve bleeding time in CKD patients.^{20,21} Renal replacement therapy, in the form of peritoneal dialysis, hemodialysis, or renal transplantation, clears uremic toxins and corrects uremic platelet dysfunction.²²

THROMBOSIS

Thromboembolism is a serious and well-established complication of nephrotic syndrome. The nephrotic syndrome is defined by a 24-hour urinary protein greater than 3.5 g/day, associated with edema, hypoalbuminemia, hyperlipidemia, lipiduria, and thrombosis.²³ Patients with nephrotic syndrome have an increased risk of venous and arterial thrombosis as demonstrated in a retrospective study of 298 patients followed for a mean of 10 years. The absolute

risk of venous and arterial thrombosis was 1% and 1.5% per year, respectively, which is about eight times greater than the general population.^{24,25} There are certain high-risk factors for developing venous thromboembolism (VTE), including degree of hypoalbuminemia as well as type of nephrotic syndrome (membranous nephropathy being the highest risk).^{26,27} The mechanism of hypercoagulability is multifactorial and involves all stages of hemostasis. Nephrotic syndrome patients have increased platelet aggregation and adhesion because of elevated levels of vWF and unbound arachidonic acid (usually albumin bound).^{28,29} There is also increased activation of the coagulation cascade caused by an imbalance between synthesis and urinary loss of thrombotic and antithrombotic factors. For certain plasma proteins, including factor XII, antithrombin, and free protein S, urinary losses exceed synthesis.^{30–32} For higher-molecular-weight proteins, including factors V, VIII, vWF and fibrinogen, excess synthesis relative to losses lead to accumulation.^{33,34} Decreased fibrinolysis also occurs because of reduced plasminogen levels and reduced availability of albumin as a cofactor for plasminogen–fibrin interaction.^{35,36}

The management of thromboembolic events (renal vein thrombosis, deep venous thrombosis [DVT], pulmonary embolism [PE]) associated with nephrotic syndrome is similar to conventional anticoagulation strategies for DVT or PE, with the use of heparin, low-molecular-weight heparin, warfarin or direct oral anticoagulant agents many of which require renal dose adjustment.³⁷ The direct thrombin and factor Xa inhibitors have a variable degree of renal clearance, with Dabigatran being the most and Apixiban being the least renally cleared.^{37a} These agents, however, have not been studied specifically in patients with VTE related to nephrotic syndrome.³⁸ In terms of duration of therapy, most experts recommend continuing anticoagulation as long as the patient remains nephrotic.³⁷ Prophylactic anticoagulation for patients with nephrotic syndrome is a controversial issue and must be balanced with the risk of bleeding. Some experts recommend prophylactic anticoagulation in patients who are high risk for VTE (membranous nephropathy, albumin <20 g/L) with low to intermediate risk of bleeding.³⁷

HEMOLYTIC UREMIC SYNDROME

HUS is defined by concomitant microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and acute kidney injury³⁹ (see [Chapter 132](#)). Pathology reveals thrombotic microangiopathy characterized by microvascular platelet thrombi, vessel wall thickening, and detachment of endothelial cells from the basement membrane. Damage to microvascular glomerular endothelium is the inciting and sustaining event involved in platelet consumption and MAHA. HUS may occur secondary to Shiga toxin–producing bacteria, *Streptococcus pneumoniae* infection, drugs, or primary complement dysregulation (atypical HUS). In Shiga toxin–associated HUS, the toxin binds to the high affinity Gb3 receptor expressed on glomerular endothelial cells leading to cell damage. In atypical HUS, the fenestrated endothelium of the glomerulus is particularly susceptible to uncontrolled alternative complement pathway activation arising from impaired regulatory proteins or hyperactive components. In the renal transplant population, an acquired HUS or thrombotic microangiopathy (TMA) syndrome may occur secondary to immunosuppressive drugs such as cyclosporine and tacrolimus, ischemia reperfusion injury, and viral infections.⁴⁰ The kidney plays a central role in all of these processes, as initial damage to glomerular endothelial cells leads to loss of thromboresistance and platelet activation and consumption, causing thrombocytopenia with microangiopathic hemolytic anemia.⁴⁰

In adults with nondiarrheal or idiopathic HUS, initial management is similar to thrombotic thrombocytopenic purpura with plasma exchange therapy. If plasma exchange is not immediately available, plasma infusion may be used as a temporary alternative. In patients with atypical, or complement mediated HUS, eculizumab, a monoclonal antibody against C5, may be considered.⁴¹ In adults with postdiarrheal HUS, supportive therapy is the mainstay of

treatment with intravenous fluids, platelet and red blood cell transfusions, and hemodialysis as indicated for acute kidney injury (AKI).

HEMATOLOGIC ABNORMALITIES IN THE RENAL TRANSPLANT PATIENT

Several hematologic abnormalities can occur in the renal transplant patient, including posttransplant lymphoproliferative disorder (PTLD), posttransplant erythrocytosis (PTE), and acquired TMA secondary to drugs or infection. PTLD is a rare complication in organ transplant recipients. PTLD is caused by proliferation of Epstein-Barr virus (EBV)–infected B cells because of reduced T-cell surveillance as a result of immunosuppression. PTLD may present along a spectrum of disease, from an infectious mononucleosis like syndrome (early lesions), polyclonal lymphoid hyperplasia (polymorphic PTLD), to monoclonal malignancies including B- or T-cell lymphoma (monomorphic PTLD).⁴² Among renal transplant recipients, one study demonstrated an incidence of 1.4% (344) out of 25,127 patients.⁴³ Risk factors for the development of PTLD include the use of T-cell depleting induction agents, EBV-negative recipient with positive donor, history of pretransplant malignancy and younger age. Treatment of PTLD includes a reduction in immunosuppression for all types, with the addition of rituximab for polymorphic PTLD. Chemotherapy is used in monomorphic PTLD and also for a subset of patients with polymorphic disease.⁴²

Posttransplant erythrocytosis is defined as an elevated hemoglobin and hematocrit after renal transplantation that persists for more than 6 months in the absence of another cause. PTE occurs in about 10% to 15% of transplant recipients and is thought to be multifactorial, potentially related to unregulated erythropoietin secretion from the native kidneys. As with other forms of erythrocytosis, patients may experience headache, lethargy, plethora and are at increased risk for thromboembolic events. Treatment consists of blockage of renin angiotensin aldosterone system, through ACE inhibitor or ARB therapy.⁴⁴

HEMATOLOGIC MANIFESTATIONS OF MALIGNANCY

Page Widick, Andrew M. Brunner, and Fred Schiffman

Hematologic abnormalities are commonly seen among patients with malignancy. These derangements range from the incidental to the life-threatening, and may complicate management and require additional therapy. Hematologic abnormalities can be seen as the initial manifestation of cancer, providing a crucial diagnostic clue. In addition, the hematologic aspects of cancer, as well as the therapies that we use to treat these irregularities, can provide insight into the biology of tumorigenesis. This chapter reviews some of the impact that malignancy can have on erythrocytes, leukocytes, platelets, and hemostasis.

ERYTHROCYTES

Anemia

The most common hematologic manifestation of cancer is anemia; anywhere from 30% to 90% of patients with cancer have documented anemia before the initiation of any treatment. Anemia occurs across many different malignancies, including 40% of patients with early-stage colon cancer and 80% of patients with advanced colon cancer. The pathogenesis of cancer-related anemia is multifactorial, and can arise from direct cancer tissue invasion with resultant blood loss, involvement of the bone marrow, hemolysis, a direct effect of chemotherapy or radiation therapy, and chronic renal dysfunction associated with malignancy, among other causes. These causes can be further divided among anemia resulting from blood loss, anemia caused by erythrocyte destruction, and anemia caused by a hypoproliferative marrow state. A number of cancer-specific mechanisms can be responsible for a hypoproliferative state, including nutritional deficiencies, decreased erythropoietin (EPO) production because of acute or chronic kidney injury, and injury to the bone marrow itself. The most common nutritional abnormality in cancer-related anemia is iron deficiency; up to 29% to 60% of all cancer patients may have iron-deficiency anemia, which can be secondary to poor oral intake, as well as from blood loss, commonly seen in gastrointestinal and gynecologic malignancies. Compounding any deficiency in total body iron stores are the effects on erythropoiesis and iron homeostasis as a result of cancer-associated inflammation and cytokine activation. Many cancers are associated with a systemic inflammatory state, manifested by elevated levels of cytokines, which can directly inhibit erythropoiesis and suppress the amount of iron available for erythropoiesis. When serum EPO concentrations are measured among cancer patients, these levels are inappropriately low in comparison to patients without malignancy but who have the same degree of anemia caused by iron deficiency. Cancer patients also often demonstrate increased levels of hepcidin, a protein critical to iron homeostasis, which acts by decreasing the binding to and breaking down of the iron transporter ferroportin. This subsequently results in increased storage of iron in the form of ferritin, and at the same time decreases free iron that would be used in erythropoiesis. In contrast to iron deficiency, B₁₂ deficiency is a less common cause of anemia in malignancy, seen in only 5% to 10% of patients.

Many chemotherapeutics have hematologic sequelae; patients undergoing treatment may experience varying degrees of anemia resulting from chemotherapy-induced bone marrow suppression. The European Cancer Anaemia Survey prospectively studied over 15,000 patients with a variety of solid tumors undergoing treatment. Before therapy, 10% of patients had hemoglobin levels below 10 g/dL, and

during therapy this increased to almost 40% and was correlated with a worsening performance status. In the same study, radiation therapy alone had less impact on the incidence of anemia, but the combination of chemotherapy and radiation led to a greater degree of anemia than chemotherapy alone. Anemia caused by chemotherapy is related to the cumulative dose, combination of chemotherapeutics, and dose schedule. For example, in the treatment of lung cancer with cisplatin and paclitaxel, anemia worsens with an increasing total dose of cisplatin, when cisplatin is added to paclitaxel, and if paclitaxel is given over a 24-hour period rather than shorter courses.

Anemia in cancer patients can also occur in the setting of red cell destruction, such as is seen in autoimmune hemolytic anemia, or in the setting of microangiopathic hemolytic anemia (MAHA), which is associated with concurrent thrombocytopenia. Although a true incidence of MAHA among cancer patients is difficult to determine, some studies suggest that 5% to 10% of mucin-producing disseminated adenocarcinomas are associated with a MAHA. It is important to distinguish secondary thrombotic microangiopathies (TMAs), as seen in patients with malignancy, from thrombotic thrombocytopenic purpura (TTP), given the marked differences in underlying pathophysiology. TTP is the result of congenital or acquired absence or inhibition of the von Willebrand cleaving enzyme, a disintegrin and metalloproteinase with thrombospondin motifs-13 (ADAMTS13). Secondary TMAs may have a slight decrease in ADAMTS13 activity, but do not have the severe deficiency of ADAMTS13 activity, with a level of less than 10%, such as seen in TTP. Accordingly, patients with secondary TMAs typically have a poor response to therapeutic plasma exchange. Cancer-associated TMAs may arise from direct endothelial damage rather than diminished ADAMTS13 activity. Cancer patients may also develop a MAHA related to the use of a number of drugs used in the treatment of cancer, including cyclosporine, mitomycin, and gemcitabine, and antivascular endothelial growth factor (anti-VEGF) agents.

Treatment of Cancer-Related Anemia

Hemoglobin levels typically decrease early in the course of chemotherapy treatment; with greater than half of patients experience a greater than 1 g/dL drop over the course of the first 9 weeks of therapy. The treatment of anemia related to malignancy depends upon correct identification of the underlying etiology. As noted previously, iron-deficiency anemia is very common in patients with malignancy. Among those patients with cancer who have an absolute iron deficiency (transferrin saturation <20%, ferritin <30 ng/mL), there is evidence that they may benefit from a short course of either oral or low-dose intravenous iron. In this setting, the addition of erythropoiesis stimulating agents (ESAs) is not necessary.

For many patients, transfusion of blood products is an effective therapeutic intervention. Red cell transfusion provides rapid symptomatic relief and is also a source of iron; one unit of packed red blood cells (RBCs) contains roughly 200 mg of iron. Logistic limitations with RBC transfusion, and transfusion-related morbidities have spurred the incorporation of ESAs as alternative agents for treating anemia in cancer patients. The use of ESAs during myelosuppressive treatment increases the hemoglobin level and decreases transfusion requirements by approximately 50%; however, ESA use is associated with an increased rate of cardiovascular and thrombotic events, and may be associated with poorer overall survival and time to cancer

progression. This relationship between ESA use and thrombosis may be related to the target hemoglobin concentration as higher hemoglobin targets are associated with increased rates of thrombotic events in cancer patients.

In addition to thrombotic events, a number of concerns have been raised about ESA use and potential worsening of overall survival or time to disease progression. Data regarding ESAs and progression of disease are conflicting; some studies in patients with breast cancer and patients with head and neck cancer suggested worsening progression-free survival or local control of disease with ESA use. The mechanism behind tumor progression is unknown but may relate to decreased chemosensitivity in the setting of ESA use or relate to tumor vascularity and oxygen supply. One study isolated breast cancer stem-like cells, which are thought to promote tumor progression and relapse, and identified expression of the EPO receptor on the cell surface of these chemoresistant cells. Moreover, the concurrent administration of ESAs during chemotherapy had a chemoprotective effect. Other mechanisms that may underlie the association of EPO administration with tumor progression include augmentation of red cell mass and effects on tumor oxygenation.

Because of concerns about thrombotic events, as well as the potential for worsened overall survival and time to disease progression, ESA use is generally restricted to certain indications in patients with cancer. In general, transfusion of blood products and, if indicated, iron therapy, remain the standard of care for anemia associated with malignancy. Future studies considering the safety of ESAs for lower target hemoglobin levels, as well as alternative preparations of iron therapy may provide viable treatment options for cancer patients with anemia. There are some instances where ESAs may be useful adjuncts, specifically among patients with moderate or severe chronic kidney disease, or in palliative settings. In such situations, reversible causes of anemia should be ruled out before ESA use, and the minimal amount of EPO be used to avoid RBC transfusion.

Erythrocytosis

Outside of patients with myeloproliferative neoplasms, and specifically polycythemia vera, erythrocytosis is an uncommon manifestation of cancer. Polycythemia vera, and other myeloproliferative neoplasms, are typified by acquisition of somatic mutations that upregulate the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling pathway, typically the JAK2 V617F mutation, and phenotypically present as an expansion of myeloid-origin cells, with an elevated hemoglobin and suppressed EPO levels. In these cancers, erythrocytosis is caused by primary expansion of the malignant clone. In contrast, when erythrocytosis is seen in association with solid tumors, it typically is the result of a paraneoplastic phenomenon. This can be seen in the setting of increased erythropoietin levels related to malignancy, for instance with clear cell renal cell carcinoma. Other rare causes of cancer-associated erythrocytosis may include aromatase inhibition in breast cancer. There may be an association with a common predisposing condition; for instance, patients with von Hippel-Lindau disease are at risk for renal and central nervous system tumors, and the mechanism of erythrocytosis is typically through paraneoplastic EPO expression. Nonetheless, elevated RBC counts are rare in patients with malignancy, particularly those receiving chemotherapy, and usually do not require intervention.

PLATELETS

Thrombocytopenia

Chemotherapy and immunosuppressive agents are the most common causes of thrombocytopenia in the cancer patient. For instance, patients receiving cisplatin/gemcitabine for bladder cancer or carboplatin/gemcitabine for lung cancer have rates of clinically significant thrombocytopenia of 30% to 60%. Among patients with

hematologic malignancy, thrombocytopenia is even more common, particularly with induction or conditioning chemotherapy regimens. The typical mechanism by which chemotherapy causes thrombocytopenia is through marrow suppression; however, some agents are also associated with immune-mediated thrombocytopenia. Immune thrombocytopenia is typically characterized by a sudden and isolated drop in platelet count. For example, trastuzumab and oxaliplatin have both been associated with immune-mediated thrombocytopenia. Thrombocytopenia may also be a result of bone marrow infiltration by tumor cells, thrombotic microangiopathy, consumptive coagulopathy, or as an autoimmune manifestation of the malignancy itself. Bone marrow involvement, often occult, is more common in prostate, lung, and breast cancer; such patients typically have multiple cell lines involved, and display a leukoerythroblastic appearance on the peripheral smear. The laboratory features of disseminated intravascular coagulation (DIC), elevated D-dimer, and fibrinogen degradation products, can be seen in cancer patients, and are more common with advanced disease, where they may be present in up to 90% of patients.

Treatment of thrombocytopenia in cancer patients is generally supportive. For patients with active bleeding, platelet transfusion and correction of other coagulopathies are the mainstays of therapy. The use of agents such as tranexamic acid in these patients may be considered as well. In the absence of active bleeding, a threshold of $<10 \times 10^9/L$ for prophylactic platelet transfusion is generally recommended. This is based on a study which randomized 600 patients with hematologic malignancies to prophylaxis or no prophylactic transfusions; both were treated for bleeding events. Rates of World Health Organization grade 2, 3, or 4 bleeding were high in both groups, but higher (50%) in the no-prophylaxis group (50%), compared with the prophylaxis group (43%). Prophylactic platelet transfusion has been used in patients with solid tumors, but without as much evidence-based support.

Other agents, with or without platelet transfusion, may also have a role in chemotherapy-related thrombocytopenia. Thrombopoietin (TPO) receptor agonists are an area of increasing interest in the management of thrombocytopenia during chemotherapy, particularly as a means to maintain treatment schedules which may be delayed by thrombocytopenia. A 2015 phase I trial compared placebo to eltrombopag in patients receiving gemcitabine-based chemotherapy and found that fewer patients receiving eltrombopag required dose delays and/or reductions in chemotherapy compared with those receiving placebo. This evidence is promising and further clinical trials may reveal a role for romiplostim and/or eltrombopag in the management of thrombocytopenia resulting from malignancy.

Thrombocytosis

While thrombocytopenia may be more clinically apparent because of bleeding or delays in the administration of chemotherapy, reactive thrombocytosis is actually more common than thrombocytopenia in patients with solid tumors. The clinical impact of thrombocytosis is less clear; however, having a platelet count greater than $350 \times 10^9/L$ before initiating chemotherapy is associated with a greater risk for venous thromboembolism (VTE). Cancer-related thrombocytosis is thought to be mediated by inflammatory cytokines, and elevated levels of interleukin (IL)-6, IL-11, and TPO have been documented in cancer patients. Rarely, thrombocytosis may be the result of a paraneoplastic phenomenon, which has been described in breast and ovarian malignancies. In many tumor types including breast, renal cell, gastric, and advanced stage non-small cell lung cancer, elevated platelet counts seem to confer an adverse prognosis. The mechanism for this association is unclear.

Platelet Dysfunction Secondary to Malignancy

In addition to abnormalities in absolute platelet number, cancer patients may have alterations in platelet function, which can

contribute to tumor progression. Platelets derived from cancer patients are in an activated state, with increased surface P-selectin expression and elevated serum levels of platelet factor IV and β -thromboglobulin. Activated platelets may contribute to the thrombophilic state in cancer patients, and also interact with leukocytes, endothelial cells, and tumor cells, all of which may contribute to the early stages of tumor cell dissemination. A number of platelet receptors may contribute to the platelet support of metastasis, including glycoprotein (GP) IIb/IIIa, adenosine diphosphate (ADP) receptors, P-selectin and thrombin receptors, and others, with likely multiple mechanisms underlying the platelet effects on malignancy. Platelets stabilize otherwise short-lived tumor cells in the circulation. Platelet-tumor cell interaction enhances tumor cell adhesion to the vessel wall, and appears to alter vessel wall permeability, and in this way may facilitate tumor cell invasion. Platelets protect tumor cells from immune surveillance and destruction, in part by shielding tumor cells from natural killer cells, although other mechanisms are likely. Platelets provide nutrient support (growth factors) and release pro-angiogenic factors. Platelets contain numerous growth factors, coagulation factors and adhesive molecules, chemokines, and bioactive lipids that may enhance metastatic efficiency. Platelets are enriched in angiogenic growth factors such as basic fibroblast growth factor and VEGF, as well as other mediators, and may regulate angiogenesis. Selective P-selectin and thrombin receptor activation on platelets may release α -granules enriched in either VEGF or endostatin. Platelet-derived transforming growth factor- β and direct platelet-tumor cell interactions promote epithelial mesenchymal transformation and tumor metastases.

LEUKOCYTES

Neutropenia

Neutropenia is common during treatment with chemotherapy, particularly with antimetabolite use. Other etiologies of neutropenia in cancer patients include infiltration of the bone marrow space and occasionally, radiation therapy, particularly when sites of active hematopoiesis are included in the radiation field, such as with the pelvis or spine. In addition, particularly in the course of treatment, cancer patients may experience viral or antibiotic-mediated neutropenia.

Patients who develop neutropenia during chemotherapy are at risk for neutropenic fever. A number of comorbid conditions are predictive of the development of neutropenic fever, including older age, poor performance status, comorbid medical conditions, low baseline

white blood cell counts, low body mass index/BSA, advanced disease, and the use of myelosuppressive chemotherapy agents. General treatment principles for neutropenic fever include the consideration of prophylactic antibiotics or myeloid growth factor support, such as granulocyte colony-stimulating factor (G-CSF). Consideration should be given to the elevated risk of FN associated with specific chemotherapeutic agents, including situations where dose-dense or intense chemotherapy regimens provide survival benefit. Depending on the regimen and disease, prophylactic G-CSF should be considered, particularly when there is a greater than 20% overall risk of FN; once a patient develops FN, G-CSF is typically reserved for situations where they are not responding to appropriate treatment and develop life-threatening conditions.

Several tumors express G-CSF receptors; there is a theoretic concern that exogenous G-CSF may increase proliferation of these tumors. In addition, the use of myeloid growth factors during chemotherapy for solid tumors has been theorized to increase the risk of subsequent myeloid malignancy by acting as a survival signal to hematopoietic progenitor cells damaged by chemotherapy. A meta-analysis of 25 randomized clinical trials found that there was an almost twofold increase in acute myeloid leukemia in those patients assigned to receive chemotherapy with growth factor support, compared with those who did not receive growth factor support, although the absolute rates of secondary leukemia were low in each group.

An important consideration during chemotherapy is to recognize that benign neutropenia related to certain ethnicities, particularly in those of African and Middle Eastern descent, may be a contributing factor and does not require dose-adjustment of chemotherapy.

BONE MARROW METASTASES

Multiple lineage cytopenia in association with cancer warrants consideration of bone marrow metastasis (Fig. 155.1). Metastatic carcinoma can involve bone marrow and may lead to subsequent marrow fibrosis and failure. Bone marrow metastases occur in fewer than 10% of patients with metastatic disease, and are more common in patients with lung, breast, or prostate carcinoma. Patients with solid tumors who have bone marrow involvement are more likely to experience cytopenias from chemotherapy, and typically carry a worse prognosis. For example, patients with extensive small cell lung cancer with bone marrow metastases have significantly shorter time to progression and significantly shorter survival time than other patients with extensive disease. The precise mechanism for poor outcomes is unknown, but may relate to greater overall tumor burden, as well as to specific biologic features that allow the tumor to grow in the bone marrow

Fig. 155.1 PERIPHERAL BLOOD AND BONE MARROW FROM A PATIENT WITH METASTATIC BREAST CANCER. The patient was a 77-year-old woman who presented with anemia and thrombocytopenia. On physical examination she was found to have a breast mass. (A) The peripheral smear showed a leukoerythroblastosis (*top*) with nucleated red blood cells and immature granulocytic precursors. Platelets were reduced, and red blood cells exhibited anisopoikilocytosis (*bottom*) with occasional teardrop forms and rare schistocytes. (B) The bone marrow biopsy was fibrotic and had thickened bone with new bone formation. (C) The bone marrow cavity was replaced by tumor cells infiltrating through bands of fibrosis.

niche, which also render it resistant to therapy. Such tumor cell evasion strategies could include changes in homing, adhesion, immune escape, and angiogenic potential. Laboratory studies suggest that tumors that secrete more proangiogenic and proinflammatory cytokines may be more likely to metastasize to the bone marrow. The bone marrow niche itself may also play a role in promoting tumor survival and in decreased immune surveillance. One example is the occurrence of bone marrow micrometastases in women with early-stage breast cancer; approximately 30% of women with stage I to III breast cancer may have bone marrow micrometastases, which is associated with worse prognosis.

The pathophysiology by which marrow involvement by cancer causes cytopenias is not fully understood. Total marrow replacement by tumor is rare, and only a small percentage of marrow may be needed to support normal peripheral blood counts, as indicated by the observation that normal blood counts are often found in normal older adults with hypocellular marrows. Cancer may disrupt normal bone marrow interactions required for normal hematopoiesis, such as those that include osteoclast signaling and growth of specific bone marrow stromal cell populations.

THROMBOSIS AND CANCER

The association of thrombosis and cancer is widely recognized, dating to the middle of the 19th century, and can be considered the earliest recognized paraneoplastic syndrome. Armand Trousseau was the first to associate thrombosis and malignancy, the first to suggest screening for malignancy in recurrent or idiopathic thromboembolic disease, the first to suggest that the pathophysiology was not mechanical obstruction, but a change in the character in the coagulation system itself, and the first to suggest that the association may be integral to the cancer growth itself. Particularly poignant was the fact that Trousseau predicted his own occult malignancy when he developed “phlebitis,” dying 6 months later of gastric cancer. More recently, some of the biologic mechanisms underlying the increased risk for thrombosis in patients with cancer have been better delineated.

The incidence of cancer-associated thrombosis has steadily increased in recent years, in part related to the increasing age of the population, with an associated increase in cancer prevalence, longer survival with active malignancy, and better detection tools. Patients with active malignancy have a higher risk for thrombosis than other medical patients: for instance, surgical oncology patients have a higher thrombosis rate than other surgical patients undergoing major procedures. Although reports of thrombosis rates vary, in general approximately 15% to 20% of cancer patients develop VTE at some point during their illness; conversely, approximately 20% of all VTE events occur in cancer patients.

Cancer is a potent risk factor for venous thrombosis, and increases the relative risk by roughly 6- to 10-fold. In comparison, the common hereditary thrombophilia, homozygous factor V Leiden, increases the risk for venous thrombosis by approximately fivefold. Virtually all solid tumor types, as well as hematologic malignancies, carry this significantly increased risk for thrombosis. Certain tumor types, particularly mucinous adenocarcinomas, appear to have particularly high risk for thrombosis including lung, gastrointestinal cancers—notably pancreatic adenocarcinoma—as well as primary brain tumors.

Development of thrombosis in the cancer patient generally carries prognostic impact. In patients with advanced solid tumors, those who have venous thromboembolic disease at the time of presentation have a 1-year survival nearing only 10%, compared with 1-year survival of closer to 40% among those without thrombosis at diagnosis. It is less clear whether this thrombotic tendency is simply a marker of aggressive disease or whether the development of thrombosis itself is the cause of the increased mortality. Thrombosis is second only to disease progression as a cause of death among cancer patients, and accounts for nearly 10% of deaths among patients receiving outpatient chemotherapy. This mortality risk appears to be independent of cancer stage at the time of thrombus identification. The risk may, however, vary depending on the underlying malignancy, and also

according to the timing of the VTE event. One study in patients with gastroesophageal malignancy undergoing chemotherapy failed to show an association between VTE and overall survival. The risk of mortality associated with VTE may therefore reflect the underlying cancer biology. Mucinous adenocarcinomas, for example, may directly release tissue factor (TF) and circulating mucin molecules that activate the clotting cascade and platelets, thereby promoting thrombosis.

Biologic Mechanisms Underlying Thrombosis in Cancer

The etiology of thrombosis is typically described in the context of the classic Virchow triad: stasis or altered blood flow, injury to the vessel wall, and hypercoagulability intrinsic to the blood and circulating plasma. Cancer contributes to thrombosis by mechanisms within all three of these categories. Mechanical compression and/or disruption of blood vessels by a tumor may cause disrupted flow or stasis. Upon interaction with cancer cells, monocytes or macrophages release cytokines, including tumor necrosis factor, IL-1, and IL-6, which damage vascular endothelial cells. The damaged vessel surface has reduced expression of naturally occurring anticoagulants, such as thrombomodulin, heparan sulfate, CD39/ecto-ADPase, nitric oxide, and prostacyclin. The damaged endothelium also has increased expression of procoagulant proteins, particularly TF; circulating blood is exposed to the procoagulant subendothelial matrix, which contributes to a hypercoagulable state.

Despite the contributions of stasis and vessel changes in cancer-associated thrombosis, the best-documented contributing factor to thrombosis in the cancer patient is elevated procoagulant plasma factors, many of which are generated by the tumor itself. TF plays a critical role in the initiation of the coagulation cascade, particularly via the extrinsic pathway, by binding to and activating factor VII. TF is increased in a number of malignancies, including pancreatic cancer, breast cancer, and non-small cell lung cancer, compared with the nontransformed epithelium. Low oxygen levels are often found in the tumor microenvironment, which result in the activation and upregulation of proteins encoded by oncogenes, such as RAS or MET, and inactivation of tumor suppressor genes such as *TP53* or *PTEN*. The downstream effect of this is to directly induce TF expression, as well as other genes involved in hemostasis. Targeting the human *MET* oncogene to mouse liver using a lentiviral vector results in hepatocarcinoma, associated with a coagulopathy similar to that in malignancy, with striking thrombotic events, similar to Trousseau syndrome, the migratory thrombophlebitis associated with malignancy. Elevated TF expression and activation of the coagulation system appear to correlate with both thrombotic tendency and disease progression.

In addition to TF expression in tumors, activated endothelium, and tumor-associated macrophages, TF is also increased in platelets and microparticles from cancer patients compared with healthy controls. The generation of TF-expressing microparticles may be an important mechanism of cancer hypercoagulability. Microparticles are vesicular structures released from cell membranes under a variety of situations, including activation, malignant transformation, stress, or death. They can be detected in plasma in a wide range of disease states, including sepsis and cancer. Microparticles are generally considered to be between 100 nm and 1000 nm in diameter. Microparticles have been reported to arise from platelets, monocytes, endothelial cells, and tumor cells and carry on their surfaces a range of proteins that are derived from the cell of origin, including TF. Cancer cells, directly and indirectly, lead to the generation and circulation of TF-bearing microparticles, and the levels of circulating TF-bearing microparticles in pancreatic cancer patients appear to correlate with the subsequent risk for venous thromboembolic disease. In one study, approximately a third of patients with detectable TF-bearing microparticles developed venous thrombosis, compared with no thrombotic events in those without detectable TF-bearing microparticles.

Coagulation and Tumor Progression

The activation of coagulation in cancer may also play a role in tumor progression. For example, TF expression levels often correlate with a more aggressive tumor phenotype, and both clotting-dependent and clotting-independent signaling mechanisms of TF may be important in regulating tumor metastasis. TF promotes angiogenesis and is coexpressed with VEGF on malignant cells.

Thrombin is the key terminal enzyme of the coagulation cascade, and results in fibrin deposition and platelet activation; it also serves as a growth factor for a number of cell types including fibroblasts, endothelial cells, smooth muscle cells, and tumor cells. The cellular effects of thrombin are mediated through seven transmembrane-spanning G protein–coupled protease-activated receptors (PARs), principally PAR1. PAR1 is activated by thrombin through cleavage of its N-terminus, which exposes a tethered ligand that then binds to the second transmembrane domain of the receptor. PARs are expressed on platelets and other cells, as well as on tumor cells. Thrombin-activated tumor cells have PAR1-dependent enhanced expression of a number of cell surface integrins. Thrombin may enhance tumor progression via several mechanisms, including enhancing tumor cell proliferation, activating tumor–platelet adhesion, tumor adhesion to the matrix or endothelium, tumor implantation, growth, and metastasis, and tumor angiogenesis. Thrombin alters tumor cell gene expression with upregulation of angiogenesis-related genes such as *VEGF*, matrix metalloproteinase 2 (*MMP-2*), angiopoietin 2 (*ANG2*), and other genes and microribonucleic acids affecting tumor cell proliferation and invasion.

Diagnosis of Coagulopathies in Cancer Patients

Thrombotic events in patients with cancer are diagnosed in a similar fashion to those in patients without cancer. However, several subtleties exist. For example, thrombosis may be confused with either intravascular disease progression and/or intravascular fungal infections. In many cases, the diagnosis of thrombosis, or an abnormality in coagulation, may be made in an asymptomatic patient, leading to a more complicated decision regarding the risks and benefits of therapy. A process of fibrin formation and degradation is continuous in the setting of many patients with malignancy, and may relate to elevated thrombin–antithrombin complexes and fibrin degradation products. Thus cancer is thought by some to be a process of “chronic DIC.” Of note, in two prospective studies of routine coagulation parameters in cancer patients, *elevated* fibrinogen and platelet counts were the most frequent alterations, not diminished as typically seen in DIC. The clinical spectrum of coagulopathy in cancer ranges from asymptomatic to life-threatening thrombohemorrhagic disease. Thrombotic manifestations of DIC include arterial and venous thromboembolism, migratory thrombophlebitis, marantic endocarditis, and microvascular thrombosis with organ failure or skin necrosis. The consumptive phase of DIC may manifest as bleeding, treatment of which is supportive and patient specific. Some may respond favorably to low-dose heparin, and/or plasma therapy, while waiting for treatment of the underlying malignancy. In general, the treatment of cancer-associated DIC is centered on the treatment of the underlying tumor.

With increased use of high-resolution computed tomographic imaging studies, pulmonary emboli (PEs) are increasingly being identified incidentally, in the absence of clinical suspicion. This has led to the question of how to manage incidentally discovered thrombosis. A retrospective cohort study of the period from 2004 to 2010 compared the rate of recurrent VTE and overall survival between those patients whose PEs were detected incidentally on imaging studies with those whose PEs were suspected by classic clinical criteria; there was no difference in recurrent VTE or overall survival when both groups were anticoagulated. A separate prospective observational study enrolled consecutive cancer patients newly diagnosed with combined deep venous thrombosis and PE from 2006 to 2009; 60% of the incidental thromboses were PEs, whereas only 26% of the

symptomatic events were PEs. There was also a lower risk for recurrent thrombosis among those patients with an incidental thrombus compared with those with a symptomatic thrombus, and no differences in major bleeding and overall survival between groups. Taken together, these two studies support the routine anticoagulation treatment of an incidentally found thrombosis, and do provide some insight into the risk of recurrent thrombosis according to the mechanism of presentation.

Intravenous Catheter Thrombosis in Malignancy

Many patients with cancer undergo placement of a central venous catheter (CVC), commonly in the form of an implantable port, for chemotherapy infusion. Presence of an indwelling central line is a risk factor for thrombosis; this is augmented in patients with underlying cancer. Nearly 15% of patients with cancer may develop a CVC-associated thrombosis, and the risk of thrombosis is increased if there is an exit site infection, among male patients, and in the presence of metastatic disease; risk also varies according to the type of catheter, being higher with a peripherally inserted central catheter compared with an implanted port catheter. Particular malignancies also contribute to the risk of CVC-related thrombus; there is a significantly higher rate of CVC thrombus in patients with acute promyelocytic leukemia (32%) when compared with those with other types of acute myelogenous leukemia (6%). Because of the high risk of bleeding in cancer patients, routine VTE prophylaxis is not recommended among cancer patients with CVCs, in spite of the known thrombotic risk. For those patients that develop CVC-associated thrombosis, general treatment recommendations are for anticoagulation for 3 months. Low-molecular-weight heparin (LMWH) is preferred over the vitamin K antagonist, warfarin, in this population, and anticoagulation is continued while the line is in place. These guidelines may change as further studies reveal more information regarding newer anticoagulation agents.

Management of Thrombosis in Patients With Cancer

Cancer patients with a VTE have a high rate of recurrent thrombosis and bleeding after anticoagulation when compared with the general population, and merit a tailored treatment approach. One study compared recurrent thrombosis and major bleeding rates in patients with VTE with and without an underlying malignancy, managed with dose-adjusted intravenous unfractionated heparin or weight-adjusted LMWH, followed by warfarin. The 12-month cumulative incidence of recurrent thromboembolism among cancer patients was 20.7% versus 6.8% in patients without cancer, whereas the 12-month cumulative incidence of major bleeding was 12.4% in patients with cancer and 4.9% in patients without cancer.

Warfarin can pose certain difficulties in cancer patients for several reasons: there are numerous and often unpredictable drug interactions, cancer patients have variable nutritional intake, with unpredictable amounts of vitamin K in their diets, and the frequent use of antibiotics can result in altered bioavailability of dietary vitamin K. Further, there is a frequent need to interrupt anticoagulation for procedures, and there often is a coexisting thrombocytopenia, whose impact on coagulation may be complicated by the long half-life of warfarin. The long-term use of LMWH in cancer patients has been compared with warfarin, most notably in the CLOT trial. In this study, patients with cancer and VTE received dalteparin 200 IU/kg subcutaneously once daily for 5 to 7 days, and were then randomized to either continued dalteparin 150 IU/kg subcutaneously once daily, or to dose-adjusted warfarin with a target international normalized ratio of 2 to 3. Patients treated with dalteparin had a lower hazard ratio for recurrent thromboembolism compared with the oral-anticoagulant group (0.48); rates of major (6% versus 4%) and all bleeding (14% versus 19%) were similar. In this study, there was no difference in overall survival. A similar study that compared enoxaparin with warfarin for treatment of venous thrombosis in cancer also

showed an approximately 50% reduction of combined outcome of major bleeding or recurrent VTE within 3 months with enoxaparin compared with warfarin (10.5% versus 21.1%). Based on a number of similar studies, and reflected in a number of current treatment guidelines, LMWH is generally preferred for cancer patients with VTE who do not have other contraindications.

Oral anticoagulation agents that directly inhibit factor Xa or thrombin are increasingly used in the treatment of VTE. The anti-Xa agents rivaroxaban and apixaban along with the direct thrombin inhibitor dabigatran have been shown to be effective in VTE prophylaxis after major hip and knee surgeries, as well as in stroke prevention in patients with atrial fibrillation. However, few patients with cancer have been evaluated in these trials, and no studies have specifically considered the treatment of malignancy associated VTE using these inhibitors. A small phase II study evaluating the safety and tolerability of apixaban found a low risk of major bleeding (2.2%) during 12 weeks of therapy in 125 patients with metastatic or advanced cancer *without thrombosis*. Safety concerns regarding these agents include the possible interactions with chemotherapeutic agents as well as the inability to reverse them quickly in a population that has potential to rapidly develop cytopenias and bleeding. While these agents are not currently recommended for malignancy-associated VTE, future study may further clarify the feasibility and efficacy of these agents in patients with malignancy and thrombosis.

FUTURE DIRECTIONS

Future studies on hematopoiesis and coagulation in cancer patients have the potential to provide insight into new treatment strategies for the many hematologic manifestations of cancer, as well as the treatment of the underlying malignancy. Historically, management of the hematologic manifestations of malignancy have centered on supportive care; however, these may also play a role in tumor survival and growth. For example, a deeper understanding of how growth factors may play a role in mediating tumor growth could identify new therapeutic targets and strategies. Platelets appear to play increasingly intricate roles in tumor metastasis and survival. Given the prevalence of thrombosis in cancer patients, new anticoagulation strategies will also prove increasingly important in the management of this unique population.

INTEGRATIVE THERAPIES IN PATIENTS WITH HEMATOLOGIC DISEASES

David S. Rosenthal, Ann Webster, and Elana Ladas

Complementary and alternative medicine (CAM) is tremendously popular in the United States and many parts of the world to help people with wellness and health.¹ In the United States alone, an estimated \$36 to \$47 billion is spent annually by the public on CAM methods of therapy,² and in a National Health Interview Survey in 2007 and again in 2015, 37% of adults used at least one form of CAM.³ Over the past decade, CAM practices have become even more popular, especially in individuals with a chronic disease such as hematologic malignancies and cancer.⁴ In 1998 the National Center for Complementary and Alternative Medicine (NCCAM) was established at the National Institutes of Health (NIH) to study the efficacy and safety of CAM practices. The term CAM caused consternation among many in the field, who perceive that their patients are forgoing conventional therapy. That is generally not the case. The term CAM is controversial because the words complementary and alternative have completely different meanings and should not be connected by an “and” but by an “or.” Whereas complementary therapies were defined by NCCAM as therapies used to complement or to be used alongside conventional methods of therapy, alternative methods referred to those therapies used instead of known conventional therapies and have not been shown to be effective. The term integrative medicine (IM) or integrative health (IH) is used to more accurately describe the complementary therapies being used in US medical settings today. These therapies are used alongside conventional therapies in a therapeutic environment. In 2014 NCCAM was renamed “The National Center for Complementary and Integrative Health (NCCIH),” which more accurately reflects the work as only a minority of individuals are forgoing conventional therapies. The components of IM or IH (1) combine the best of both conventional and evidence-based complementary therapies, (2) emphasizes patient participation, (3) promote the primacy of the patient–provider relationship and the importance of shared decision making, (4) emphasizes the contribution of the therapeutic encounter itself, and (5) optimizes the individual’s innate healing capacity.⁵

Although many integrative therapies such as acupuncture, massage, and meditation are quite beneficial for hematology/oncology patients by helping them to cope with the disease, reducing their stress and symptoms related to the conventional therapy or to the disease process itself, many alternative interventions are unproven and could be harmful for patients who may believe that these interventions can cure them of their malignancy. An American Cancer Society study concluded that as many as 61% of cancer survivors used some form of complementary or alternative therapies.⁴ In addition, the majority of people do not share their use of these therapies with their primary care providers. According to a survey by Eisenberg et al,⁶ patients do not think that their physicians need to know about their use of these interventions and many patients responded that their physician never asked about such use. Because there are many potential drug–drug, drug–herb, drug–radiation, and antioxidant–drug interactions, it is extremely important for patients to share their use of integrative therapies and alternative treatments with their providers and similarly for physicians to ask about their patients’ usage.⁷

Through the NCCIH and IM centers, more information and education is available to the public and to physicians, on the importance of physicians’ “asking” about the use of integrative therapies and alternative therapies and patients “telling” about the use of these

therapies (<http://www.nccih.nih.gov>). Many hematology/oncology centers have established IM programs where complementary therapies such as acupuncture, massage, nutrition, physical activity, and stress management are offered alongside the conventional therapies of chemotherapy, radiation, and targeted therapies. These programs provide guidance to patients in choosing the safest and most effective integrative therapies that could be incorporated into their plans of care. Despite the level of evidence supporting standard treatment, some patients decline chemotherapy, radiation, or surgery. Instead, they choose to pursue an alternative therapy. Sometimes this choice is because of a cultural belief, because they believe that natural products are potentially less toxic, or because they believe that the alternative treatment will offer a “cure” for their disease. Alternative medicine practitioners and clinics exist in our country and around the world that offer a “cure,” usually for a significant amount of out-of-pocket fees. Unfortunately, these clinics rarely ever provide any scientific evidence and typically do not conduct research or report their results except in advertisements.

On the other hand, there is an increasing body of research on the benefits of many complementary and integrative therapies. Clinical studies provide evidence that some integrative therapies are beneficial to patients by improving their quality of life, reducing their symptoms from the disease, and decreasing the side effects from treatment. One of the major concerns, however, is the use of botanicals, herbs and over-the-counter (OTC) drugs in conjunction with chemotherapy and radiation therapy (see later). Some may reduce the effectiveness of certain chemotherapies, and others may reduce metabolism of an active drug, enhancing its potential toxicity.

INTEGRATIVE THERAPY DOMAINS AND THEIR USE

According to the NCCIH, “most integrative therapies fall into one of two subgroups—natural products or mind and body practices” (Table 156.1). There is also an abundance of whole-systems practices that include ayurvedic medicine and traditional Chinese medicine. The whole-systems approaches incorporate many of the integrative therapies. Mind–body approaches include meditation, mindfulness meditation, guided imagery, music therapy, creative arts therapy, self-hypnosis, yoga, tai chi, and qigong, among many other types of physical and spiritual practices. Energy-based therapies include reiki and healing touch. Body-based manipulative therapies include chiropractic and massage therapy. Examples of natural products include dietary supplements, antioxidants, vitamin megadoses, specialized diets, and herbs.

In the literature, there is a paucity of information on the use of integrative therapies in the treatment of hematologic malignancies.⁸ In India there is a significant use of ayurvedic medicine. In a German study of a large group of patients with chronic lymphocytic leukemia (CLL), approximately 44% used integrative therapies with 26% using vitamin supplementation, 18% mineral supplementation, 14% homeopathy, 7% acupuncture, and 9% mistletoe therapy. In the United States, 30% to 80% of pediatric hematology/oncology patients used one or more complementary therapies in conjunction with their conventional care. In the US pediatric group, there is an especially high use of vitamin and nutritional supplements,^{8,9} with

TABLE 156.1 Integrative Therapies Domain

• Natural products	

mind–body therapies a close second. Because many patients do not report their use of complementary therapies to their primary care hematologist/oncologist, there are markedly disparate data from one study to another. In other countries, such as Mexico, Ireland, and Canada, there is a high use of CAM therapies ranging from 42% to 60% in the pediatric patients. Therapies include vitamins, minerals, reflexology, etc.^{10,11}

In a review by Wesa and Cassileth,¹² the major reason why leukemia patients use integrative therapies or remedies not prescribed by their hematologist/oncologist is in an effort to improve their treatment outcome and to manage their symptoms. For those with leukemia, the integrative therapies that were felt to be most beneficial included mind–body interventions such as self-hypnosis, meditation, guided imagery, and breath awareness. Massage and reflexology are also frequently used to decrease symptoms (see subsequent discussion on massage). Acupuncture is very beneficial for symptom management with minimal side effects (see later discussion of acupuncture).

RESEARCH TECHNIQUES OF INTEGRATIVE THERAPIES

Research in the United States on integrative therapies is partially financially supported by the NIH through NCCIH and the Office of Cancer Complementary and Alternative Medicine at the National Cancer Institute (NCI). Investigators have tried to apply the same research principles used to evaluate new chemotherapy programs for leukemias and lymphomas (i.e., the traditional randomized clinical trial).¹³ This approach has been problematic because it is often difficult to identify the proper controls for integrative therapies such as mind–body techniques, acupuncture, and massage. As a result, meta-analyses on integrative therapies reveal an abundance of pilot studies and nonrandomized clinical studies that are often criticized on the basis that any positive result may be attributable to the placebo effect.¹⁴ In the case of acupuncture research, sham or “fake” acupuncture has been used as a control in which nontraditional needles are used but not placed in the meridian spots and not stimulated.

In randomized clinical trials of acupuncture effectiveness, comparing active acupuncture with “sham” acupuncture, only those who are naive to acupuncture can participate. With massage therapy, randomized clinical trials have used an educational program of equivalent attention time to attempt to control for the placebo effect. This has been similarly true for research on energy therapies such as reiki and many of the mind–body programs.

Whole-systems research is another approach taken by integrative therapists.¹⁴ This involves combining nutrition, physical activity, and stress and symptom management therapies together as an intervention in evaluating quality of life measures over a period of time. This type of research creates many variables and is totally contrary to the current widely accepted reductionist method of research.

The study of herbs and other OTC unregulated products has been fraught with confounding variables, specifically the lack of standardization of the product studied.¹⁵ For example, PC-SPES, a compound of eight herbs manufactured by a single company, was demonstrated in a pilot study in men undergoing active surveillance for prostate cancer to be associated with a decrease in prostate-specific antigen levels. The promising trends of this phase I and later a phase II study led to a randomized clinical trial of PC-SPES. During the phases of this randomized clinical trial, there were

complications that led to the reevaluation of the constituents of PC-SPES. Although evaluations of the product showed no evidence of any phytoestrogens in any of the eight herbal compounds at the onset of the study, during the randomized clinical trial, phytoestrogens were found, and patients began to demonstrate breast engorgement. Other lots of the product did not contain phytoestrogens but were demonstrated to have contaminants such as dicoumarol, and some individuals were noted to experience increased bruising. Investigators have attempted to overcome the standardization issue of herbs by studying their individual proteins in *in vitro* models, and others have attempted to closely monitor the constituents of the herbs by protein fractionation, ensuring that the product remains constant during the research study. Most herbs and botanicals are not regulated by the US Food and Drug Administration (FDA), potentiating issues of quality control, possible contamination, and stability issues. The United States Pharmacopeia (USP) does verify the identity, strength, purity, and quality of some supplements and applies its USP verification label, <http://www.usp.org/uspverified>. [ConsumerLab.com](http://www.consumerlab.com) also performs independent testing and applies its approval stamp.

REVIEW OF RESULTS OF INTEGRATIVE THERAPIES IN HEMATOLOGY/ONCOLOGY PATIENTS

Most studies on the use of integrative therapies in hematology/oncology disorders investigate the effect on patients' quality of life and symptomatic relief of stress, pain, fatigue, and anxiety. The results discussed here will be reviewed in terms of improvement in symptoms and quality of life, and when appropriate, the effect on immune function and survival if investigated. In most studies, the major symptoms for which integrative therapies are used include anxiety, neuropathy, fatigue, pain, chemotherapy-induced nausea and vomiting (CINV), worsening immune system, stress, and depression.

Literature on Outcomes: Science, Safety, and Efficacy

In making decisions about what integrative therapies physicians should recommend, Weiger et al¹⁶ suggest that decisions be based on safety and efficacy. If an intervention is safe and effective such as acupuncture for CINV, it can be appropriately recommended. If a therapy is unsafe or toxic and has been demonstrated to be ineffective, it should not be recommended, and patients should be cautioned about its use. For example, laetrile (Amygdalin) may contain varying amounts of cyanide, and in clinical studies has been shown to be ineffective in treating cancer. Many interventions, products, and substances are safe, but their effectiveness is unknown. With these, the physician should be cautious and recommend their use with the following proviso: if this is a substance taken orally, it should be evaluated as to whether it has any unfavorable interactions with chemotherapy or medications that the patient is already taking or whether it interacts with a disease process such as causing hypoglycemia in a diabetic patient. Taking one new OTC substance at a time is good common sense, and patients should be told to observe any change in symptoms, whether they are favorable or unfavorable, before adding another substance to their oral regimens, especially if there is little or nothing known about the agent. With respect to drug–drug and drug–herb interactions, websites are available for professionals as well as for lay audiences. A list of these websites is given in [Table 156.2](#). Most of these websites list the various terms by which a given agent is known and provide information on each agent's constituents, reasons for use, evidence for safety or toxicity, and evidence of effectiveness. Most importantly, these websites list the adverse effects of these substances and the drug–drug, drug–herb, and drug–disease interactions when known. When asked about the use of an OTC substance that is not FDA regulated or [ConsumerLab.com](http://www.consumerlab.com) approved, physicians should consult one of the databases to ensure safety and lack of adverse interactions (see [Table 156.2](#)).

INDIVIDUAL INTEGRATIVE THERAPY MODALITIES**Mind–Body Therapies**

Mind–body therapies are frequently studied interventions in patients with chronic diseases such as hematologic malignancies.¹⁷ Mind–body therapies focus on the interactions between the brain, mind, body, and behaviors and on the ways in which emotional, mental, social, spiritual, and behavioral factors can directly affect health. Mind–body therapies are used throughout the world in treatment, disease prevention, and health promotion.

A diagnosis of a hematologic malignancy can be very stressful. Stress is part of normal physiologic body functioning and can be divided into good stress and bad stress. Chronic stress can be caused by an unexpected situation such as experiencing a new diagnosis (e.g., leukemia), an uncomfortable interaction with a colleague, painful treatments, loss of a loved one or a job, or just the pressures of modern life. Chronic stress has been shown to decrease immune functioning by inhibiting the body's ability to make T cells, B cells, macrophage cells, and interferon—four major components of the immune system. Research in the field of psychoneuroimmunology has shown that decreasing stress can actually boost immune function. Prolonged or severe stress not only weakens the immune system, it strains the heart, damages memory cells, and deposits fat at the waist rather than at the hips and buttocks (a risk factor for heart disease, cancer, and other illnesses). When stress persists for too long or becomes too severe, the normally protective mechanisms become overburdened, a condition that Bruce McEwen, at Rockefeller University, refers to as “allostatic load.”

Stress has even been shown to take a toll on gene expression.¹⁸ Investigations into mind–body therapies using functional genomics have revolutionized the understanding of mind–body therapy mechanisms and their effects on human physiology. Existing trials focusing on gene expression changes brought about by mind–body therapies have revealed intriguing connections to the immune system.¹⁹

Mental health professionals have significantly underestimated the importance of lifestyle factors as contributors to physical, emotional, behavioral, and spiritual pathologies. Mind–body therapies have been underused in health care.

In the 1970s Dr. Herbert Benson popularized the “relaxation response,” the performance of “a time out” in normal daily functions. Benson coined this term after observing that when monks meditated, they experienced decreases in their pulse, blood pressure, and respirations. Although there are now known genetic, environmental, and dietary factors that play a significant role in causation of chronic disease, stress may be a lesser but significant factor. Mind–body techniques (Table 156.3) include transcendental meditation or the relaxation response, mindfulness meditation, biofeedback, guided imagery, and hypnosis. In addition, music therapy, and modified physical activities such as yoga, tai chi, and qigong also are mind–

body programs. There are several common forms of meditation: (1) concentrative meditation, which focuses on a phrase or a visual image such as the relaxation response; (2) mindfulness meditation or awareness, in which the client becomes aware of his or her thoughts and feelings and focuses on those issues; and (3) expressive meditation used in tribal societies consisting of fast deep breathing, shaking, whirling, and dancing.¹⁷

Mind–body interventions are often self-taught or presented by a professional. Double-blinded trials are difficult to conduct partly because the presence of an empathetic professional giving the therapeutic modality may be considered a placebo effect. Mind–body interventions are often accompanied by other integrative therapy interventions, making pure studies unevaluable; however, randomized clinical trials have demonstrated that relaxation training and guided imagery significantly reduce nausea and anxiety.²⁰

Compared with medication, relaxation therapy showed similar decreases in anxiety and depression, although medication might have been slightly faster in its effect. Other randomized trials have shown decreases in tension, depression, anger, and fatigue during relaxation training or imagery. In children, hypnosis has been found to be especially effective. In a randomized clinical trial comparing hypnosis or nonhypnotic distraction such as the relaxation techniques versus joining a placebo attention-control group, the children in the hypnosis group reported significant reduction in anticipatory nausea and CINV.

Mind–body therapies have also been used to alleviate pain. In a study of children undergoing bone marrow or lumbar puncture procedures, hypnosis significantly reduced the pain as well as anxiety. A recent study has shown that a relaxation response training reduced anxiety in women undergoing breast biopsies.^{20a} Also a study of mind–body therapies for men just diagnosed with prostate cancer, preparing to go through radiation treatments, found that mind–body therapies reduced anxiety, improved sleep, reduced fatigue, and improved concentration in all of the participants.^{20b}

Expressive arts therapy and music therapy as well as repetitive exercise, yoga, tai chi, qigong, and Pilates also can reduce stress and anxiety. Music therapy is considered a mind–body therapy that reduces stress and anxiety because it uses a variety of active and passive music experiences, live or recorded. This technique can be used either independently or with a music therapist. Randomized trials have shown statistically significant improvements in mood and physical discomfort. In patients with hematologic malignancies admitted for autologous stem cell transplantations, patients receiving an individualized program of live music therapy had a significant improvement in mood or what is referred to as “courageous coping.” Music therapy has also been shown to be an effective adjunct to antiemetic therapy. Studies of immune function have yet to show any statistically significant improvement in immune function.

Studies have shown that prayer is good medicine and is considered by many to be a mind–body therapy. Dr. Harold Koenig, director of Duke University's Center for Spirituality, Theology and Health, studied the connection between spirituality and well-being. Prayer is associated with less depression, anxiety, better physical health and well-being. People who have a prayer practice have less cardiac disease and hypertension and better measurable immune functioning. Mind–body therapies, such as hypnosis, give people hope and foster acceptance of one's physical condition.²¹ Yoga and physical activity have been studied to determine whether there is a related reduction in symptoms of depression and anxiety. In general, the practice of yoga has increased from 5.2% of the 45–64 age population in the year 2000 to 7.2% in 2012. A number of yoga practices may be helpful for people with cancer in reducing stress and managing side effects, both during and after chemotherapy and medical procedures. Restorative yoga postures can be both energizing and relaxing, requiring almost no physical effort. Yoga can also help with pain. Yoga also stresses the value of community. There is evidence that participating in a cancer support group may increase odds of survival. So far, there are no scientific studies on whether yoga can improve survival rates. However, suggestive evidence comes from Dr. Dean Ornish, best known for his work using a comprehensive lifestyle program that included yoga for heart disease. Dr. Ornish has been studying a similar approach for prostate cancer. In a 12-week yoga intervention in healthy subjects, it was demonstrated that there was greater improvement in mood and anxiety than a metabolically matched walking exercise. The authors demonstrated an acute increase in thalamic GABA (γ -aminobutyric acid) levels alongside the improvement in mood and anxiety scales. White et al²² demonstrated the potential benefits of physical activity for children with acute lymphocytic leukemia.

In summary, it is evident that mind–body therapies can reduce anxiety, temper the adverse effects of chemotherapy and radiation treatments, relieve pain, and possibly stimulate immune responses. By reducing stress and anxiety, these therapies can help patients deal with a wide range of relationship issues and decision making as they move through the diagnostic and therapeutic phases of their malignancy. Mind–body approaches have very minimal risk and potentially significant benefits. Most importantly, they are often self taught and therefore low cost. Mind–body practices should be considered as an adjunct to usual care regardless of whether patients are beginning or recovering from chemotherapy.

Acupuncture

Overview and Definitions

One of the major components of traditional Chinese medicine has been the use of acupuncture. For more than 2000 years, this traditional practice has been used in the Far East to “correct an imbalance in yin-yang and qi (energy).” It is believed that with acupuncture, “blocked” channels can be unblocked, reducing symptoms. Acupuncture is the stimulation of certain points on the body by needles or alternatively by pressure called acupressure. Both techniques take advantage of the meridians described by traditional Chinese medicine. Acupuncture points are situated along meridians, which are channels for “qi.” Sham or “fake” acupuncture implies the use of needles that are not inserted to the same depth, not put in the meridian points, and not given stimulation. Electroacupuncture implies the use of added electric pulses to create additional or accentuated stimulation. Several studies have shown that electroacupuncture provides greater symptom relief than regular acupuncture.

Research on Usage and Effectiveness

Most acupuncture in the Western world is used to manage symptoms, not treat disease.²³ Research studies have demonstrated release of neurotransmitters and change of brain functional magnetic resonance

imaging signals during acupuncture. Acupuncture was confirmed as an effective intervention for CINV at an NIH consensus conference in 1997. Whether this beneficial effect is attributable to an induced relaxation response or a direct antiemetic effect is not known.

Randomized clinical trials on acupuncture have been used in a variety of settings. As mentioned earlier, only individuals who are naive to acupuncture can take part in acupuncture studies because they will note the difference between active acupuncture and its sham component. Acupuncture has been shown to be effective in randomized clinical trials in cancer-related fatigue, cancer-related pain, and postoperative pain as well as reduced CINV in adults and children. In addition, acupuncture can improve radiation-induced xerostomia, vasomotor symptoms such as hot flashes, and chemotherapy-induced neuropathies.

Several randomized clinical trials conducted in China have suggested that acupuncture could be effective in reducing the marrow suppression in patients on aggressive chemotherapy. Analysis of these trials performed by Lu et al²⁴ suggest that acupuncture is associated with an increase in neutrophils and total white blood cell count in patients during chemotherapy or chemoradiation therapy. The weighted mean difference of over 1000/ μ L white blood cells on average is a statistically significant difference. Lu et al²⁵ carried out a small, randomized, sham-controlled clinical trial in the United States exploring this issue in ovarian and breast cancer patients receiving aggressive chemotherapy. Using manual and electrostimulation two to three times per week for a total of 10 sessions beginning 1 week before the second cycle of chemotherapy, the median leukocyte count in the active acupuncture arm at the first day of the next cycle was significantly higher than in the sham arm. The median leukocyte nadir, neutrophil nadir, and recovering absolute neutrophil counts were all higher but not statistically different. The result showed improved neutrophil counts both at the nadir and rebound points during chemotherapy, but the sample size of the study was underpowered.

Uncontrolled pilot studies of acupuncture have shown effectiveness in reducing anxiety and improving mood and other quality-of-life measures in patients with both oncologic and hematologic disorders. These studies have shown improvement in sleeplessness, depression, and xerostomia. Acupuncture improved xerostomia inventory scores in 18 patients who received radiation therapy and had pilocarpine-resistant xerostomia. In patients with hot flashes and vasomotor symptoms caused by chemotherapy, acupuncture attenuated some of the hot flashes. In a controlled study comparing venlafaxine and acupuncture, no statistical difference was found between the favorable response to acupuncture and the medication. One study suggested that acupuncture may be useful for drug-induced neuropathy from thalidomide/bortezomib therapy for multiple myeloma. Ear acupuncture was shown to be effective for phantom pain in a 16 year old after an amputation for osteosarcoma

Safety

With the increasing use of acupuncture in the United States because of evidence of its effectiveness, there are concerns about its safety when used in the community, especially with hematology patients and those getting chemotherapy and radiotherapy. However, reports of major side effects of acupuncture are rare and usually are evident when performed by untrained practitioners.²⁶ In closely monitored clinical trials, there is a low incidence of adverse events. In one study, the rate of minor adverse events was 14 per 10,000 sessions; serious events were 0.05 per 10,000 treatments and 0.55 per 10,000 individual patients. Common adverse events include blood-borne infections and internal organ and tissue injury. In general, acupuncture should be avoided in patients with severe neutropenia and thrombocytopenia (absolute neutrophil count <500/ μ L and platelets <25,000/ μ L). However, in one study of acupuncture given during stem cell transplantation, there were no bleeding side effects in individuals with severe thrombocytopenia (platelet counts <20,000/ μ L). Another study in children and adolescents undergoing

chemotherapy including stem cell transplantation found that acupuncture was safe among those with severe thrombocytopenia.²⁷

Massage and Touch Therapies

Overview and Definitions

Massage has been defined by some as “rhythmic and methodical stretching and compressing of the muscles and connective tissue through the touch of the therapist’s hands.” There are many types of massage and hands-on soft tissue therapies (Table 156.4). Therapies include Swedish massage, aromatherapy massage, reflexology, acupressure, and manual lymphatic drainage massage. Swedish massage provides broad, flowing, soothing strokes (effleurage), generally applied with a lotion or massage oil from distal to proximal areas on extremities. In addition, there is usually gentle kneading of soft tissues (petrissage). Aromatherapy has often been combined with massage in which selected scented oils are blended with the usual massage oil to enhance the beneficial effects of both physical and emotional well-being. Reflexology focuses on manual pressure to specific areas of the feet that, in traditional Chinese medicine, are linked with remote areas of the body. Acupressure massage uses the meridian theory of traditional Chinese medicine in which focal pressure is applied to acupuncture needle sites with the goal of adjusting the flow of energy similar to the theory in acupuncture. Manual lymphatic drainage is the application of light, flowing strokes of massage in specific patterns with the goal of alleviating lymph edema after lymph node resection or radiation therapy.

Research on Usage and Effectiveness

Corbin²⁸ has reviewed the value of massage as well as the difficulties in performing scientific research. Many randomized clinical trials use a crossover arm and attempt interventions that try to control for the placebo effect. The various measurement tools used to assess outcomes involve numeric rating scales, visual analog scales, profile of mood status, the S state trait anxiety inventory, the European Organization for Research and Treatment of Cancer quality of life questionnaire, and others. In a critical review of potential benefits of massage, Joske et al²⁹ identified eight randomized controlled clinical studies in hematology/oncology patients totaling more than 357 patients. Specifically, there was evidence of anxiety reduction with less benefit for analgesia. In autologous bone marrow transplantation patients, the massage group had significantly decreased distress and nausea scores early in the trial, but these were not long standing. Massage therapy has been found to reduce state anxiety and boost mood in many metaanalyses, probably its most beneficial attribute. Pain may be alleviated, but this has not been demonstrated to be statistically significant. Numerous studies have shown trends not only in decreased anxiety but also in nausea, pain, fatigue, and depression.

To date, there is little evidence suggesting that massage therapies have any effect on immune function or survival outcomes in hematology/oncology patients. A small randomized study did find

higher natural killer (NK) cells and lymphocyte cells during massage. Similarly, in a study in human immunodeficiency (HIV) patients, there was a significant increase in NK cell fighter toxicity during the massage period. In some trials, there is a short-term effect on NK cell activity; however, long-term clinical effect has not been demonstrated. A significant effect of effleurage massage on cellular immunity, cortisol, oxytocin, anxiety, depression, or quality of life has also not been demonstrated in more rigorous randomized clinical trials. In another randomized clinical study, dopamine levels, NK cells, and lymphocytes increased from the first to last day of the massage therapy. In a study of children with HIV, a control arm had a greater relative risk of CD4 count decline than the massage therapy children. Lymphocyte loss was also more extensive in the control participants, and more of the control group than the massage group lost greater than 50/mm³ CD8 lymphocytes. The immediate effects of massage therapy are decreased anxiety, depressed mood, and anger. The long-term effects of massage include reduced depression and hostility as well as increased urine meridopamine, serotonin values and NK cell number, and lymphocytes. However, it is not clear that these results were statistically significant.

Weaknesses exist in many of the massage therapy studies reported to date such as small sample sizes and lack of controls. Most of the practitioners have not been blinded to the hypothesis of the studies. Furthermore, no systematic approach has been identified to determine the optimal number of massage treatments in a trial and within-group comparisons. Strong evidence shows that massage therapy can be very helpful in alleviating anxiety and stress in patients. However, more rigorous study designs, adequate statistical power, better identification of predictors for response to massage, and study of the psychologic and biologic mechanisms are needed. There is also a need for larger sample sizes and rigorous design reporting on massage therapy.

Safety

The concern that massage therapy can spread a tumor is unfounded. However, direct pressure over known tumor sites is usually discouraged. In general, massage therapy of all types is quite safe. The NCI urges massage therapists to take specific precautions with all cancers and avoid massaging open wounds, bruises, or areas with skin breakdown. Also massage directly over tumor sites, areas with a thrombosis, and sensitive areas after radiation therapy should be avoided.

Nutrition and Supplements

Nutrition

Nutritional guidelines for patients with hematologic malignancies should be based on the recommendations of the American Cancer Society and the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR).^{30,31} The AICR clearly states that cancer survivors should follow its nine nutrition and physical activity guidelines for risk reduction.³¹ Adherence to the WCRF/AICR cancer prevention guidelines has been associated with a 34% lower hazard of death (95% confidence interval [CI], 0.59–0.75) compared with participants within the lowest adherence. Moreover, the WCRF/AICR score was also significantly associated with a lower hazard of dying from cancer, circulatory disease, and respiratory disease.³²

The first recommendation is to be as lean as possible without being underweight, a recommendation that has been further endorsed by the American Society of Clinical Oncology.³³ A recent meta-analysis among adults with leukemia, found that obesity is associated with an increased risk (relative risk [RR] of 1.26; 95% CI, 1.17–1.37; $p < .001$) of leukemia and is associated with reduced mortality (RR, 1.29; 95% CI, 1.11–1.49; $p = .001$). Obesity has also been associated with an increased incidence of acute myeloid leukemia (AML) (RR, 1.53; 95% CI, 1.26–1.85; $p < .001$), chronic lymphocytic leukemia (RR, 1.17; 95% CI, 1.08–1.27; $p < .001$), chronic myeloid leukemia

(RR, 1.16; 95% CI, 1.04–1.30; $p = .007$) and acute lymphoblastic leukemia (ALL) (RR, 1.62; 95% CI, 1.12–2.32; $p = .009$).³⁴ Similar results have been observed for children and adolescents with ALL and AML.^{35,36} Children and adolescents who were obese at diagnosis and remained overweight/obese during treatment experienced reduced survival (hazard ratios, 1.43 and 2.30, respectively). Importantly, those patients whose weight classification became a healthy weight eliminated this risk factor. Similar results have been reported in children and adolescents with AML.

The second AICR recommendation is to be physically active for 30 minutes every day. Although few studies have evaluated physical activity and hematologic malignancies, data suggest that low physical activity may increase the risk of non-Hodgkin lymphoma (NHL) and increasing activity may reduce the risk, especially for follicular and small lymphocytic lymphoma.

The third recommendation is to avoid sugary drinks and limit consumption of energy-dense foods. This is obviously linked with the body-weight guideline because sugary drinks contribute many empty calories to the standard American diet. In addition, the contribution of insulin and insulin-like growth factor type 1 to the development of malignant disease is being increasingly appreciated in a number of cancers, leading to the investigation of blockade of the insulin-like growth factor 1 receptor as a novel treatment for some malignant diagnoses. High-sugar diets are tightly linked to obesity, thus adhering to a diet low in simple sugars, such as the low-glycemic diet, may not only reduce the risk of weight gain but also reduce risk of treatment-related toxicities during and after treatment.

Fourth, the AICR suggests that people eat a greater variety of fruits, vegetables, whole grains, and legumes such as beans. Data from the US Centers for Disease Control and Prevention demonstrate that the American public falls far short on the conservative recommendation to consume at least five servings of fruits and vegetables daily, with only 14% of adults meeting the guideline. Plants are rich sources of fiber, antioxidants, and phytonutrients, many of which are believed to be useful in cancer-risk reduction. In one study, dietary fiber intake was associated with a lower risk of all NHL subtypes. Another analysis found that high consumption of fruits and vegetables was associated with a lower risk of all NHL subtypes, particularly follicular lymphoma, in women but not men.³⁷

Fifth, the AICR recommends limiting consumption of red meats (beef, pork, and lamb) and avoiding processed meats. Epidemiologic studies suggest that consumption of fried red meats as well as dairy products leads to an increased risk of NHL.³⁷ Conversely, consumption of higher levels of omega-3 or marine fatty acids has been shown to be inversely correlated with lymphoma risk. Additional studies in an Australian cohort suggest that a diet high in fish may also be protective against the development of other hematopoietic malignancies—leukemias and multiple myeloma as well as NHL.³⁸

Sixth, the AICR guidelines state that if consumed at all, alcoholic drinks should be limited to two for men and one for women per day. Although moderate alcohol consumption may be associated with cardiovascular benefits, alcohol use has been associated with an increased risk of a number of malignancies. A pooled analysis of nine case-control studies of NHL revealed that ever drinkers, compared with never drinkers, had a 17% lower risk of NHL, a finding the investigators attributed to a possible beneficial effect of moderate alcohol consumption on immune function. A cohort study in 126,293 multiethnic adults used lifelong abstainers and infrequent drinkers as the referent and reported a relative risk of 0.5 for the development of both lymphocytic and myeloid leukemias in those consuming three or more drinks daily without any contribution of choice of beverage (wine, beer, or liquor). With regard to patients already diagnosed, a cohort of 575 female NHL cases in Connecticut was followed for a median of 7.75 years. Compared with never drinkers, wine drinkers experienced better overall survival (75% vs. 69% five-year survival; $p = .030$) and disease-free survival (70% vs. 67%; $p = .049$). The favorable effect for wine drinkers was seen mainly in patients with diffuse large B-cell lymphoma. Resveratrol, a red-wine polyphenol known for its potential cardioprotective effects, is also believed to have potential in cancer risk reduction and perhaps

even as an adjunct to conventional therapy. An *in vitro* study involving ALL cell lines demonstrated that red-wine polyphenols caused growth inhibition and apoptosis. Although these cell line experiments often produce elegant results regarding mechanism of observed *in vitro* action, whether the phytonutrients have the same benefits in humans consuming the whole foodstuffs or concentrated supplements remains uncertain. A large prospective study of over 120,000 individuals with 17 years of follow up found no inverse relationship of lymphoid or myeloid neoplasms and alcohol consumption; if anything there was an increased risk rather than a decreased risk of lymphoid neoplasms.³⁹

Supplements

Most conventional medical and radiation oncologists recommend that their cancer patients avoid all supplements, especially during active radiation and chemotherapy. This recommendation is primarily based on the absence of convincing data supporting therapeutic benefit. Three other valid concerns about supplement use are (1) the potential for supplement–drug interactions via a pharmacokinetic or pharmacodynamics pathway; (2) the oxidant–antioxidant issue; (3) the impact of supplements on clotting, a particular problem for patients with hematologic malignancies on or off anticoagulants, and (4) purity or authenticity of the nutrition or herbal supplement.

Concurrent use of a supplement, particularly a botanical, with chemotherapy could lead to a clinically important interaction that could yield an increase or decrease in the effects of either component. Considering that 35% of currently prescribed oncology drugs are metabolized by the CYP3A4 isoform of the hepatic cytochrome p450 enzyme system, use of supplements that either induce or inhibit the pathway can be problematic.⁴⁰ In treatment of hematologic toxicities, cyclophosphamide, the epipodophyllotoxins, and the vinca alkaloids are all dependent of CYP3A4 for their metabolism. For example, the botanical supplement St. John's wort used for the treatment of mild depression is a strong inducer of many CYP isoforms. In a classic pharmacokinetic interaction study, 10 healthy volunteers were administered a single 400-mg oral dose of imatinib before and after 2 weeks of treatment with 300 mg of St. John's wort three times daily. The investigators found that the pharmacokinetics of imatinib were significantly altered by St. John's wort, with reductions of 32% in the median area under the concentration–time curve ($p = .0001$), 29% in maximum observed concentration ($p = .005$), and 21% in half-life ($p = .0001$). The conclusion was that coadministration of St. John's wort might compromise the clinical efficacy of imatinib. It is generally recommended that cancer patients receiving any intervention avoid taking St. John's wort.

Patients with hematologic malignancies are often at increased risk for bleeding problems. A small case series performed among children with cancer suggests that the Chinese herb Yunnan Baiyao may alleviate uncontrollable bleeding in patients with cancer; however, clinical trials are not yet available to confirm the findings of this case series. There has been a long-standing tendency to attribute thrombocytopenias of unclear etiology in cancer patients to botanical supplements that they are taking, particularly traditional Chinese medicine herbs. It is critical that the use of Chinese herbal products is accompanied by a certificate of authenticity to ensure purity and absence of contamination.

Warfarin is a frequently prescribed anticoagulant, itself derived from a botanical, which can be impacted in a number of ways by diet and dietary supplements. Inappropriate control of anticoagulation because of fluctuation in warfarin effect exposes the patient to risks of increased bleeding or thromboembolic complications. Warfarin is metabolized by the cytochrome p450 system isoforms, including CYP3A4. In addition, it is also highly protein bound and hence can interact with medications or supplements that are also highly protein bound, resulting in displacement and causing increases in international normalized ratio (INR) and necessitating warfarin dose reduction. Finally, the anticoagulant effect of warfarin can be antagonized by vitamin K intake. Patients prescribed warfarin are often

advised not to eat green leafy and cruciferous vegetables or to consume green tea because they are rich in vitamin K and might interfere with the anticoagulant effect. An alternative is to allow the patient to consume a healthful diet and adjust the warfarin dose accordingly to maintain the desired INR.

Omega-3 Fatty Acids

Fish oil is the most commonly used natural product among adults and its use has increased from the 2007 to 2012 NHIS survey. Omega-3 fatty acids have been reported in isolated cases to potentiate the anticoagulant effects of warfarin. Omega-3 fatty acids may lower thromboxane A₂ levels within the platelet as well as decrease factor VII levels. These factors, which make the omega-3s attractive as antiinflammatory and cardiovascular agents, need to be borne in mind in patients on warfarin therapy. Taken in the absence of warfarin, omega-3s are not believed to be a significant cause of bleeding at doses of less than 4000 mg/day. Epidemiologic data suggest an inverse relationship between the intake of marine omega-3 fatty acids and the development of a number of hematologic malignancies and the good risk-to-benefit profile.

The role of omega-3 fatty acids may be instrumental in symptom management among individuals with hematologic malignancies. Evidence suggests that doses of up to 4000 mg/day may help alleviate nausea/vomiting associated with cancer therapy. Studies have been performed in both adults and children with cancer. Other studies suggest that omega-3 fatty acids may help prevent cognitive decline in children who have received whole body radiation. While the latter is still in its infancy, evidence evaluated from the pediatric literature suggest that this may be beneficial for pediatric malignancies as well.

Vitamin D3

Vitamin D is one of the few remaining vitamins that has not been shown to be ineffective in protecting against malignant disease. An ongoing randomized clinical trial is currently looking at a two-by-two factorial design of omega-3 fatty acids and vitamin D3 supplementation in older adults to assess cancer risk reduction, among other endpoints. At the same time, increasing evidence suggests that vitamin D deficiency may be related to the risk of a number of solid tumors, particularly breast, colon, prostate, and pancreas. An inverse relationship has been described between the development of NHL and sun exposure, particularly recreational, nonoccupational sun exposure. One proposed explanation for this unexpected finding is that sun exposure is actually a surrogate marker of vitamin D status, and it is actually vitamin D sufficiency that is protective against lymphoma.⁴¹ In a metaanalysis of eight studies to date, the investigators found no conclusive evidence that vitamin D was providing the observed benefit, although serum levels were not available in any of the studies. Hence it may be appropriate in view of the widespread incidence of vitamin D insufficiency, especially in older adults, for integrative oncologists to measure 25-hydroxy-vitamin D levels in patients with hematologic malignancies and supplement with a fat-soluble vitamin D3 preparation to bring the levels into sufficient or optimal range. Moreover, with the inclusion of high-dose steroids for many hematologic malignancies, adequate D3 becomes essential in the maintenance of bone health during and after treatment.

Preclinical evidence suggests that vitamin D may have a role in the treatment of hematologic malignancies.^{42,43} A recent review on the role of vitamin D for the treatment of AML and ALL concluded that differentiation-based therapy may be further enhanced by the addition of vitamin D. To date, there are no published clinical trials describing the use of vitamin D for the treatment of hematologic cancers. Most clinical studies have explored its effect on treatment-related toxicities especially among children and adolescents with ALL. While data appears encouraging, additional trials are necessary before the inclusion of vitamin D3 into the standard of care for hematologic malignancies.

Green Tea

Green tea (*Camellia sinensis*) is an increasingly consumed beverage being sought after for multiple potential beneficial health effects. An

inhibitor of CYP3A4 metabolism as well as a potent source of vitamin K, green tea may interact with prescribed anticancer drugs or anticoagulant therapies. However, green tea polyphenols have been shown to have antiproliferative activity against a wide variety of cell lines, including CLL,⁴⁴ multiple myeloma, and human promyelocytic leukemia HL-60. Epigallocatechin-3-gallate (EGCG) is the specific green tea polyphenol that is an antioxidant with chemopreventive and chemotherapeutic actions. Present in situ in the beverage, EGCG has also been prepared as green tea extract (GTE) supplements and even more concentrated EGCG capsules that patients can purchase in health food and supplement emporiums. The publication of the CLL data has led to increased use of EGCG in patients with low-grade lymphomas. A phase I study in patients with asymptomatic stage 0 to II CLL demonstrated that the Polyphenon E preparation use was well tolerated in 33 participants and that the majority of participants had decreased total lymphocyte counts, lymphadenopathy, or both (NCT00262743). Of note, when taken on an empty stomach, GTE preparations have been associated with a risk of hepatotoxicity. The question of whether health benefits against hematologic malignancies can be achieved by simply drinking an as yet undetermined quantity of the beverage or higher dose preparations such as GTE or EGCG is not known.

Patients with multiple myeloma are now frequently advised by their oncologists not to consume green tea at all because of its potential to negate the treatment effects of bortezomib, found in mouse studies.

Other commonly used OTC products include turmeric, melatonin, medicinal mushrooms, and Chinese herbs. Studies are being conducted regarding their efficacy and safety.

Antioxidants

Antioxidants (e.g., beta-carotene; lycopene; vitamins C, E, and A) are substances that counteract free radicals and prevent them from causing tissue and organ damage. They are among the most common classes of supplements used by patients with hematologic malignancies. Their use is directed for cytotoxic effects, for synergy with conventional therapy, or to lessen the toxicity of conventional therapy. Estimates of antioxidant use by patients with cancer have varied considerably, with rates ranging from 13% to 87% depending on the survey, the type of disease studied, and a variety of other individual and demographic factors.⁴⁵ Specific prevalence data on the use of antioxidants among patients with only hematologic malignancies has generally not been reported in the surveys. With survival of childhood ALL exceeding 90% for standard-risk groups, extreme caution should be exercised in combining antioxidant supplementation with the effective treatment.

Evidence supporting the potential role of antioxidants in preventing and treating disease include preclinical studies. These studies have correlated oxidative stress and an antioxidant-depleted diet with the development of diseases, including cancer. Increased consumption of green tea (which contains the anticarcinogenic agent, EGCG) has been associated with a reduced incidence of leukemia. In addition, decreases in antioxidant enzymes or the micronutrients thiol, vitamin E, vitamin C, beta-carotene, or zinc and increases in the production of reactive oxygen species have been reported in leukemia patients. In one study in children with ALL, higher levels of oxidative stress at diagnosis were associated with a poor prognosis.

In another prospective observational study conducted among children with ALL, low plasma⁴⁶ and dietary antioxidant⁴⁷ levels directly correlated with treatment-related toxicity. These types of data have led many patients with hematologic malignancies to take antioxidant supplements primarily in conjunction with conventional cancer treatment.

Much of the controversy surrounding antioxidants and cancer therapy has arisen because radiation therapy and certain classes of chemotherapy agents exert some of their anticancer effects through the generation of reactive oxygen species or free radicals. Some of these agents include the anthracyclines (e.g., doxorubicin), platinum-containing complexes (e.g., cisplatin and carboplatin), and alkylating agents (e.g., cyclophosphamide and ifosfamide). The theoretical

BOX 156.1 Recommendations for Patients

"All patients with hematologic problems should be asked specifically about their use of complementary and alternative therapies."

"All patients with hematologic problems should receive guidance about the advantages and limitations of complementary therapies in an open, evidence-based, and patient-centered manner by a qualified professional."

Adapted from Deng GE, Cassileth BR, Cohen L, et al: Integrative oncology practice guidelines. *J Soc Integr Oncol* 5:65, 2007.

concern is that antioxidants might somehow interfere with or counteract the activities of these anticancer agents. However, to date, preclinical experiments and clinical studies have not definitively shown impact on treatment outcome.⁴⁸ Of particular note, an observational cohort study from the Fred Hutchinson Cancer Research Center in Seattle evaluating the prevalence of supplement use in persons before receiving hematopoietic stem cell transplant (HSCT) and the association of select supplements with outcomes found that pretransplant intake of vitamin C (≥ 500 mg/day) or vitamin E (≥ 400 IU/day) was associated with increased risk of relapse or mortality.⁴⁹ Others have reported deficiencies before and immediately after HSCT.⁵⁰ However, few clinical studies have built upon observational studies. One small study performed among patients with AML and ALL undergoing HSCT (NCT01432873) randomized adults ($n = 77$) to selenium (200 μ g, twice daily) or placebo beginning on the day of conditioning therapy and continuing to day 14 post-HSCT. No effect on proinflammatory cytokines were observed.⁵¹ Another small study investigated the addition of vitamin C to conventional treatment for acute promyelocytic leukemia; no beneficial effects on outcome were observed.⁵²

Recent studies have shown interactions of antioxidant supplements with the proteasome inhibitor bortezomib. Vitamin C, at orally achievable concentrations (equivalent to 1 g/day, a dose frequently used by patients), inhibited the in vitro multiple myeloma cell cytotoxicity of bortezomib and blocked its inhibitory effect on 20S proteasome activity. In addition, green tea polyphenols and dietary supplements carrying hydroxyl groups, including flavonoid compounds such as quercetin, bind and inhibit the activity of bortezomib on malignant B cells and multiple myeloma cells in vitro, although by mechanisms independent of their antioxidant activity. Taken together, these studies suggest that antioxidant supplements should be avoided in patients taking bortezomib and other boronic acid proteasome inhibitor therapy.

The precise role of antioxidant supplementation in the patients with hematologic malignancies remains to be determined. Studies adequately evaluating the impact of supplementation on toxicity and disease-free survival have not yet adequately demonstrated that the benefits of supplementation clearly outweigh the risks; therefore the possibility of harm must be strongly considered (Box 156.1). Recommendations for clinical practice at the present time include the following:

- Patients should be advised to avoid dietary antioxidant supplements above the basic nutritional requirements as defined by the National Academy of Science, Dietary Reference Intakes during radiation therapy and stem cell transplantation. Until safety data is available, doses should not exceed the upper tolerable limit during treatment.
- Patients should avoid dietary antioxidant supplements while receiving bortezomib and other boronic acid proteasome inhibitor therapy. Counseling patients to avoid supplementation while receiving chemotherapy associated with high oxidative stress (anthracyclines, alkylating agents, platinum-containing agents, topoisomerase I and II inhibitors) is encouraged.
- Use of antioxidant supplements while receiving chemotherapy associated with low oxidative stress (purine or pyrimidine analogues, antimetabolites, monoclonal antibodies, vinca alkaloids,

taxanes, and corticosteroids) is less likely to be associated with interactions. Caution should be taken with other agents (e.g., antiangiogenic agents, tyrosine kinase inhibitors) for which there is insufficient information.

HEMATOLOGIC MANIFESTATIONS OF HIV/AIDS

Howard A. Liebman and Anil Tulpule

Human immunodeficiency virus type 1 (HIV-1) is the pathogenic infectious agent responsible for the development of the acquired immunodeficiency syndrome (AIDS). Chronic HIV infection leads to progressive immunodeficiency and immune dysregulation resulting in an increased risk for opportunistic infections, increased incidence of certain malignancies, autoimmune disorders, and varied organ system dysfunction. Although nearly every organ system can be affected by HIV infection, hematologic manifestations involving the bone marrow and peripheral blood occur in all patients in the course of the disease. This chapter will provide a general overview of the epidemiology of AIDS, HIV virology, and immunopathogenesis, and more comprehensive review of the hematologic manifestations of HIV infection.

DEFINITION AND EPIDEMIOLOGY OF HIV INFECTION

Although the original definition of AIDS was based upon clinical symptoms and signs alone, knowledge of the viral pathogenesis has led to a series of revised case definitions by the US Public Health Service (USPHS) and Centers for Disease Control and Prevention (CDC). The present case definition for HIV-1 infection divides the disease into three stages as defined by CD4⁺ lymphocyte counts and the presence of AIDS-defining conditions (Tables 157.1 and 157.2). A diagnosis of AIDS can be made by recognition of well-characterized clinical symptoms and signs (see Table 157.2) with evidence of HIV infection (clinical AIDS). HIV infection in an individual with a blood CD4 lymphocyte count of less than $0.2 \times 10^9/L$ classifies the patient as having “immunologic AIDS.” With the advent of routine testing for HIV infection in developed countries, a significant proportion of individuals with HIV infection who are receiving highly active antiretroviral therapy (HAART) have little or no clinical manifestations of viral infections and can maintain near normal immunologic function. However, many of the same individuals suffer from HAART-related toxicities. The World Health Organization (WHO) originally used an alternative case definition because of the limited availability of resources for serologic, virologic and immunologic testing of patients in poor countries, but after 2007 required serologic confirmation of HIV-1 infection. Therefore the early estimates of HIV-related disease worldwide were limited by this more clinically based definition.

The CDC estimates the 2013 prevalence of HIV infection in the United States at 1,201,039 Americans age greater than 13 years with a 2013 estimated incidence of 50,000 new infections. The WHO has estimated that there were 2.7 million new HIV infections in 2013 with an estimated prevalence worldwide of 33 to 37 million people infected by HIV, with 2.1 million new infections and 1.5 million HIV-related deaths. Sub-Saharan Africa accounts for 71% of all HIV infections. Vertical transmission from mother to infant continues in Africa and areas in Asia because of a lack of antiviral medications.

A second, but molecularly distinct virus, HIV-2, is endemic to regions of West Africa. HIV-2 and the simian immunodeficiency virus of sooty mangabeys are essentially identical, confirming its simian origin that subsequently crossed over into man. Less is known about the epidemiology of HIV-2, but infection appears to result in a less virulent clinical course than HIV-1 infection. Despite being structurally closely related to HIV-1, infection with HIV-2 does not

provide protection against HIV-1 infection and coinfection is frequent in sex workers in West Africa.

TRANSMISSION OF HIV-1

HIV-1 may be transmitted by sexual contact with an infected individual, by use of contaminated needle in parenteral drug use, exposure to infected blood products, or by prenatal transmission from infected mother to her infant.

HIV-1 has been recovered from both semen of HIV-infected men and from cervical and vaginal secretions of HIV-infected women. The virus can be detected in seminal fluid during the first 4 weeks of infection. Several factors are associated with increased viral content of seminal fluid including advanced symptomatic HIV infection, higher plasma viral loads, CD4 lymphocyte counts less than $0.2 \times 10^9/L$, the presence of leukocytes in the seminal fluid, and HAART. Factors that influence the levels of HIV-1 in female vaginal secretions include advanced HIV stage of HIV infection, menstruation, concomitant vaginal infection, ulcerative and nonulcerative sexually transmitted diseases, and a high HIV-1 viral plasma load. Prevention and treatment of sexually transmitted disease has been associated with a decrease in HIV-1 transmission.

The risk of HIV infection with transfusion of a single unit of infected blood is estimated at greater than 90%. The use of coagulation factor concentrate prepared before routine screening of blood products for HIV-1 in the United States resulted in a sadly high incidence of HIV infection in patients with congenital bleeding disorders. With active blood product screening and inactivation protocols used in the preparation of coagulation factor concentrate, HIV transmission has been essentially eliminated. With screening of all blood units in the United States, receipt of a unit of screened blood is associated with an estimated risk of transmission of approximately 1 in 500,000.

HIV-1 may be transmitted to a fetus or infant from the mother in utero, at the time of delivery, or postpartum through breastfeeding. The risk is greatest when the mother has advanced HIV disease, higher HIV viral load in the plasma, and active injection drug use. At time of delivery, active chorioamnionitis, premature rupture of amniotic membranes (>4 hours) and vaginal delivery, as opposed to elective cesarean section, have been associated with an increased risk of maternal-infant transmission. Prematurity, low gestational age, and breastfeeding have been reported as risk factors for HIV transmission. The use of antiretroviral agents in pregnancy, delivery, and during the first 6 weeks of life has resulted in a significant reduction in transmission from an estimated 25% to 8% with zidovudine alone and ever greater benefit with the use of HAART. To date, except for the use of efavirenz, there is no evidence to suggest an increased risk of congenital birth defects with the use of antiretroviral agents for this indication. The use of antiretroviral therapy during pregnancy has resulted in a nearly 50% reduction in the number of children with perinatal acquired HIV infection. The WHO reported that in 2013, 67% of pregnant women living with HIV infection in low- and middle-income countries are receiving some form of effective HIV prophylaxis.

Transmission can also occur by the sharing of needles and syringes between injection drug users. The use of cocaine and other

TABLE 157.1 Surveillance Case Definition for HIV Infection in Adults and Adolescents (Age >13 Years)

Stage	Laboratory Evidence	Clinical Evidence
Stage 1	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count of ≥500 cells/μL or CD4 ⁺ T-lymphocyte percentage of ≥29% ^a	No AIDS-defining condition (see Table 157.2)
Stage 2	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count of 200–499 cells/μL or CD4 ⁺ T-lymphocyte percentage of 14–28% ^a	No AIDS-defining condition (see Table 157.2)
Stage 3	Laboratory confirmation of HIV infection and CD4 ⁺ T lymphocyte count of <200 cells/μL or CD4 ⁺ T-lymphocyte percentage of <14% ^a	Documentation of an AIDS-defining condition with laboratory confirmation of HIV infection (see Table 157.2)
Stage unknown	Laboratory confirmation of HIV infection and no information on CD4 ⁺ T-lymphocyte count or percentage	No information on presence of an AIDS-defining condition

^aThe CD4⁺ T-lymphocyte percentage is percentage of the total lymphocyte count.

noninjection drugs can be associated with an increased risk of HIV infection in that their use is frequently associated with high-risk sexual behaviors. Needlestick exposures can also result in transmission of HIV from infected patients to health care workers. The risk of transmission is increased if the patient who is the source of the contaminated needle has more advanced disease with a high plasma viral load, if the needle injury is deep, if there is visible blood on the needle, or if the injury directly enters a vein or artery. The estimated risk of acquiring HIV is approximately 0.3% per needle injury exposure if the source of the blood is a patient with advanced HIV infection (stage 3 AIDS). The use of a 4-week course of antiretroviral therapy as postexposure prophylaxis has been shown to significantly reduce the risk of transmission. Prophylaxis using drug regimens recommended by the CDC should be initiated within 72 hours of exposure and

Fig. 157.1 STRUCTURE OF THE HIV VIRION. Two coding strands of genomic ribonucleic acid (RNA) are packaged in the nucleoid core with p7, p9, and p24 proteins and reverse transcriptase. The core is surrounded by the p17 matrix protein lining the inner surface of the envelope. The envelope consists of a lipid bilayer derived from the infected cell and glycoprotein spikes that consist of the outer glycoprotein (GP) 120 molecule, which contains the binding site for CD4, and GP41, which anchors the glycoprotein complex to the envelope and mediates fusion of the viral membrane with the cell membrane during viral penetration.

continued for a duration that is based upon the stage of the patient who was the source of the exposure and the type of exposure.

ETIOLOGY AND PATHOGENESIS

Human Immunodeficiency Virus 1

HIV-1 is a member of the primate *Lentivirinae* subfamily of retroviruses.³ Retroviruses are RNA viruses that induce a chronic cellular infection by converting their RNA genome into a DNA provirus that is integrated into the genome of the host cell. The genome of the virus contains three major genes necessary for viral replication and cellular invasion. The *env* gene codes for a 160-kDa precursor protein which is processed into a 120-kDa surface glycoprotein (GP) noncovalently linked to a 41-kDa transmembrane protein. The GP120–GP41 complex is necessary for virus binding to CD4 and CCR5 on the cell membrane and fusion of the viral envelope with the cell membrane allowing for the release of the viral genome into the host cell. The *gag* gene codes for the four viral structural core proteins. These proteins form the nucleocapsid for the viral genome and assist in assembly of the replicating virus before viral release from the cell membrane. The *pol* gene codes for three functional enzymes; a reverse transcriptase necessary for formation of the proviral double-stranded DNA, an integrase necessary for stable integration of the proviral DNA into the host cellular DNA, and viral protease necessary for processing viral membrane and core proteins (Figs. 157.1 and 157.2).

In addition to these three essential genes, the 9-kDa genome of HIV-1 contains six additional genes (*VIF*, *VPU*, *VPR*, *TAT*, *REV*, *NEF*) necessary for the regulation of viral gene expression, cellular latency, and each gene product playing an important role in the life cycle of HIV.

Life Cycle of HIV-1 (Fig. 157.3)

Cellular infections begin with engagement of HIV-1 GP120 binding to CD4 surface membrane protein resulting in a conformational change in GP120 allowing for further high affinity binding to chemokine CCR5 receptor. Thymic helper-inducer (CD4) lymphocytes, macrophage-monocytes, Langerhans cells, follicular dendritic cells,

Fig. 157.2 HIV LIFE CYCLE. Binding of the virion to the cell surface is mediated by a specific interaction of the glycoprotein (GP) 120 envelope glycoprotein with cellular CD4 and members of the chemokine receptor family of proteins (CCR5 or CXCR4). Penetration occurs as the viral membrane fuses with the cellular membrane in a process that requires the GP41 transmembrane protein. The viral capsid is uncoated, and viral genomic ribonucleic acid (RNA) is reverse transcribed and duplicated by the viral reverse transcriptase to produce a double-stranded copy of viral deoxyribonucleic acid (DNA). The viral DNA is transported to the nucleus, where it integrates into the host chromosomes. After appropriate activating signals, the provirus is transcribed by cellular RNA polymerase and transported to the cytoplasm. Proteins are translated and processed through biochemical steps that, depending on the protein, involve glycosylation (GP120 and GP41), cleavage (envelope proteins, gag, pol), myristoylation (p17), and phosphorylation (rev, nef). Packaging of genomic RNA with viral proteins occurs as envelope glycoproteins are inserted into the cell membrane and new virion subsequently buds outward from the plasma membrane. Viral protease continues protein processing to completion during viral budding.

megakaryocytes, and thymic cells express both CD4 and CCR5 receptor molecules and are susceptible to HIV-1 infection. Rare individuals who are homozygotes for the delta32 deletion in CCR5 are highly resistant to HIV-1 infection. The structural diversity of GP120 viral receptors has resulted in HIV-1 strains with selective or restricted patterns of infection with strains that readily infect monocytes, whereas others are tropic for CD4 lymphocytes. Some CD4⁺ tropic strains may also use the CXCR4 chemokine receptor in addition to the CCR5 receptor. With advanced late stage HIV infection, such individuals are more likely to have viral strains capable of infecting cells expressing either chemokine receptor.

Upon binding to the CD4 and CCR5 receptors, the viral transmembrane GP41 mediates fusion with the host cell membrane. The internalized viral nucleocapsid dissociates after binding to cellular cyclophilin, releasing the diploid viral RNA genome that is associated with the viral reverse transcriptase. Reverse transcription proceeds to synthesis of a single strand of complementary DNA, followed by

degradation of the viral RNA by ribonuclease H activity of p66. The reverse transcriptase then acts as a DNA polymerase forming a double-stranded DNA provirus. The reverse transcriptase of HIV has a significant rate of base substitution errors, estimated as high as 1 in 1700 to 1 in 2000 nucleoside bases, resulting in an average of 5 to 10 nucleoside mutations for each replication cycle. This explains the high degree of genomic diversity observed between HIV-1 viral isolates.

A linear form of the provirus is integrated into the host DNA by the viral integrase. In kinetic studies of HIV-1 infection, viral DNA is present in the cytoplasm within 2 to 3 hours of infection, and viral nuclear DNA has been detected by 24 hours. The gene product of *VPR* assists in transport of the viral pro-DNA into the nucleus for subsequent integration. After integration of the viral genome, the HIV-1 infected cell may develop either a latent or persistent form of infection.

HIV-1 does not replicate readily in resting lymphocytes and macrophages. Cellular transactivation by, for example, nuclear factor kappa-B (NFκB) can enhance proviral transcription. HIV-1 proviral transcription leads to the expression of regulatory proteins *tat*, *rev*, and *nef*. *Tat* is a protein essential for HIV replication and in conjunction with the cellular proteins TAK (Tat associated kinase) and Cyc T (cyclin T) promotes viral RNA elongation resulting in a 1000-fold increase in HIV-1 expression. *Rev* is a viral protein that is also essential for replication by regulating nuclear export of unspliced viral RNA. *Nef* and *vpu* proteins modulate the downregulation of cellular CD4.

The structural proteins of the *GAG*, *POL*, and *ENV* genes are expressed as precursor proteins and subsequently cleaved by viral protease yielding mature viral proteins. This final step in protein processing is essential for the assembly of mature infectious virus. For this reason, inhibition of the viral protease has proven a fruitful target for HAART. The products of the *ENV* gene, GP120 and GP 41, are transported to the cell membrane and the assembled ribonucleoprotein core moved from the cytoplasm to the membrane surface for subsequent budding. The efficient packaging of the viral RNA is dependent upon packaging signals in the *Gag* region of the viral RNA. Final budding is dependent upon the product of the *VPU* gene that also assists in transport of *ENV* products to the cell membrane and association with the ribonucleoprotein core.

Pathogenesis of HIV Infection

HIV infection results in progressive immunodeficiency and immune dysregulation. By progressive depletion of helper CD4 thymic lymphocytes, there is decreased response to soluble antigens, decreased helper response to immunoglobulin (Ig) synthesis, and impaired delayed hypersensitivity. Decreased γ interferon (IFN) production leads to a decreased cytoplasmic killing of intracellular organisms. There is also defective natural killer function and decreased T-lymphocyte-mediated cytotoxicity of viral infected cells. An imbalance of CD4, CD25^{bright}, Foxp2⁺ regulatory cells, and CD4/interleukin (IL)-17 lymphocytes may result in the expression of autoreactive T and B lymphocytes accounting for the increased incidence of autoimmune disorders associated with HIV infection and defective CD8 responses against HIV-infected lymphocytes. Viral expression in activated CD4 lymphocytes results in rapid cell death; whereas infection of macrophages, dendritic cells, and nonreplicating CD4 lymphocytes accounts for a persistent and long-lived reservoir of HIV-1 infected cells. High-level viral replication and budding associated with potent immunostimulation from acute and chronic infections may contribute to accelerated lymphocyte cytotoxicity.

In addition to the direct cytopathic effect of viral replication in CD4 lymphocytes, formation of syncytial multinucleated giant cells by fusion of infected CD4 lymphocytes expressing GP120 on their membrane with uninfected CD4⁺ lymphocytes, is another mechanism for CD4 depletion. Viral strains capable of forming such syncytia in vitro appear to be associated with a more aggressive clinical course.

Fig. 157.3 TYPICAL PERIPHERAL BLOOD AND BONE MARROW FINDINGS IN HIV. The peripheral smear not uncommonly shows anemia, which is sometimes macrocytic (A), but can be normochromic and normocytic. There frequently is a neutrophilia with left shift, toxic granulation, and some mild dysplastic change in the granulocytes (B). In some patients, particularly those with severe disease, some of the segmented neutrophils show cytoplasmic inclusions similar to Howell-Jolly bodies seen in red cells (B, *top, right cell*). These are nuclear in origin and are not microorganisms. The bone marrow can show granulocytic hyperplasia with left shift and megaloblastoid change in the myeloid and erythroid cell lines (C). Typically, there is also a reactive plasmacytosis (D). The biopsy specimen can be hypocellular, normocellular, or hypercellular (E) and commonly shows cellular atypia/dysplasia (*insert*) and atypical reactive lymphoid infiltrates (F), poorly formed (G) or well-formed granuloma (H), and increased plasma cells (I).

The host immunologic response against HIV-infected lymphocytes by cytotoxic T lymphocytes and antibody-mediated cellular cytotoxicity may also contribute to CD4 lymphocyte loss in HIV disease. Some CD4 lymphocytes may also be destroyed by an “innocent bystander” mechanism secondary to the binding of free GP120 to their surface CD4 protein. In vitro studies have found that binding of the GP120 with anti-GP120 antibodies to the CD4 receptor can induce programmed cell death or apoptosis in the lymphocyte. Defective production of immune-stimulatory cytokines (IL-2) production and expression of inhibitors of T-lymphocyte proliferation such as transforming growth factor- β (TGF- β) may also contribute to the progressive loss of CD4 lymphocytes.

The development of progressive CD4 lymphocyte depletion and its resulting immunodeficiency is closely linked to the degree of viral production. The level of plasma HIV-1 viral RNA, in addition to the CD4 lymphocyte count, is a major prognostic indicator of disease progression. The advent of HAART capable of marked suppression of viral replication has radically changed the natural history of HIV infection. Efficient viral suppression with reduction in blood and tissue viral reservoirs has resulted in prolonged immunologic reconstitution characterized by increased CD4 lymphocyte numbers, reduced opportunistic infections, and prolonged survival. However, significant immune defects do persist and complete immunologic reconstitution with normal immune regulation does not occur.

There appears to be a more selective effect of HIV cytotoxicity on memory CD4 lymphocytes and Th1 lymphocyte subsets. This contributes to a profound imbalance in host immune responses with resulting B lymphocyte dysregulation leading to polyclonal

hypergammaglobulinemia and defective cellular immune responses against malignant or viral infected cells (including HIV-infected lymphocytes). Infection of monocytes, macrophages, and dendritic cells not only provides a long-lived reservoir for HIV, but further contributes to the immunologic dysfunction caused by their role in antigen presentation and cytokine production.

CLINICAL COURSE OF HIV-1 INFECTION

Serial assessment of HIV-1 RNA in plasma and CD4⁺ lymphocytes has proven to be a reliable means for following HIV-1 infection and predicting the course of disease in individual patients. The use of HAART has significantly changed the natural history of HIV disease. With active surveillance programs that can find HIV-1 infected individuals before the development of symptomatic disease, the early use of HAART based upon USPHS guidelines has resulted in significant decreases in the incidence of HIV-defining opportunistic infections. Based upon laboratory markers of disease progression, guidelines from the USPHS recommend the initiation of HAART in all symptomatic HIV-1 infected patients and asymptomatic patients with CD4⁺ lymphocyte counts less than $0.35 \times 10^9/L$ or when plasma HIV viral load reaches 55×10^6 copies/L or greater. However, earlier institution of HAART after acute HIV infection could result in a more balanced immune reconstitution with less loss of CD4 memory cells.

Three general stages of HIV infection have been characterized that include an acute retroviral syndrome, an asymptomatic stage, and a

period of symptomatic conditions which may or may not fulfill criteria for classification as symptomatic AIDS (see Table 157.2). The acute retroviral syndrome occurs in approximately 50% to 80% of newly infected individuals. The onset of symptoms occurs 1 to 3 weeks (range 5 days to 3 months) after primary infection. Symptoms last from 1 to 2 weeks and can include significant fatigue, headache, malaise, fever as high as 40°C, sore throat, and myalgias. A morbilliform rash can be observed in 40% to 50% of patients, with generalized lymphadenopathy occurring toward the end of the acute illness. Symptoms are similar to those observed in other viral syndromes such as mononucleosis. Laboratory findings may include lymphocytosis, occasional neutropenia, and mild thrombocytopenia. Most symptoms subside within a month. However, lymphadenopathy may persist in over 50% of patients and is termed the persistent generalized lymphadenopathy (PGL) syndrome of HIV infection. Patients may be serologically negative during the acute retroviral syndrome and if there is high clinical suspicion, patients should be tested by reverse transcriptase-polymerase chain reaction (PCR) for the presence of plasma virus RNA, which is frequently present in high levels.

With resolution of the acute retroviral syndrome, patients may enter a phase of asymptomatic infection with lower levels of viral replication as determined by their plasma viral load with serologic evidence of infection. Without antiretroviral therapy, this phase may persist for nearly a decade. Progression can be variable and is determined by a variety of viral, immunologic, and host factors. Coinfections with other viruses such as hepatitis B and C, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and herpes viruses can impose additional immunologic stress leading to accelerated progression of disease and additional AIDS-defining clinical conditions. Infection with human herpes virus 8 is associated with the well-characterized AIDS-defining complications of Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease. EBV infection may contribute to the high incidence of lymphoma, including central nervous system lymphomas, observed in the severely immunosuppressed HIV patients.

A distinct subset of HIV-1 infected patients has a significantly slower rate of HIV disease progression and maintains good immunologic function for extended periods without antiretroviral therapy. These individuals, termed long-term nonprogressors, are a population of significant clinical and research interest. They include patients who are heterozygous for the delta 32 deletion in the CCR5 chemokine coreceptors for HIV infection. This mutation is estimated to occur in 15% of white people. Patients with human leukocyte antigen (HLA)-B27 and HLA-B57 also appear to have better control of HIV viral replication and slower disease progression. This may result from an inability of these patients' T regulatory lymphocytes to suppress CD8-cytotoxic lymphocyte HIV-specific responses.

In the absence of antiretroviral therapy, HIV infected patients develop progressive immunodeficiency with the development of opportunistic infections, central and peripheral neurologic symptoms, HIV-associated malignancies, fatigue, weight loss, and a general wasting syndrome (see Table 157.2).

HEMATOLOGIC AND BONE MARROW ABNORMALITIES IN HIV-1 INFECTION

The hallmark of HIV infection is the CD4⁺ lymphopenia. However, during the course of the disease about 70% to 80% of patients with HIV/AIDS will develop anemia, 50% will develop neutropenia, and 40% will develop thrombocytopenia. The presence of cytopenias in addition to the CD4⁺ T lymphopenia of HIV disease has long suggested that the suppressive effects of HIV on the hematopoietic compartment are far more broadly based than just a select subset of T cells. A number of studies have assessed the bone marrow microenvironment, the cytokine milieu, and the number and the function of primitive hematopoietic elements in HIV disease. A low fraction of progenitor cells can be infected *ex vivo* by HIV under some conditions. The growth of these few cells infected by HIV may not be

impaired as a result of infection. However, *in vivo* infection of progenitor cells rarely if ever occurs. Progenitor populations such as those yielding megakaryocytes or monocytes can be infected. Recent studies have documented infection and depletion of intermediate myeloid precursors, including the common myeloid precursor, granulocyte-monocyte precursor, and even the megakaryocyte-erythroid precursor (MEP) despite the failure of MEP to express CD4.

HIV infection leads to hematopoietic inhibition *in vivo* by depleting myeloid and erythroid colony-forming precursor activity. This activity may be caused by an indirect mechanism rather than direct infection of CD34⁺ cells. The presence of messenger RNA for and cell surface expression of HIV receptors CD4 and the chemokine receptors CXCR-4 and CCR-5 have been demonstrated in fractionated cells representing multiple stages of hematopoietic development (see box on Hematologic Manifestations of Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome). Productive infection by HIV via these receptors is observed with the notable exception of stem cells, in which case the presence of CD4, CXCR-4, and CCR-5 is insufficient for infection.¹ Although direct infection of stem cells does not occur, alterations in stem cell number and function have been documented. HIV replication in the bone marrow microenvironment is believed to be the essential component causing decreased hematopoietic cell production in HIV infection.² The exact mechanism by which the microenvironment induces these alterations is unknown. Mononuclear-macrophage cells can develop productive HIV infection and the resultant aberrant release of cytokines, such as TGF- β , tumor necrosis factor- α (TNF- α), and IL-1 can contribute to the suppression of hematopoiesis. TNF- α is a potent mediator of inflammation and host response to infectious diseases, with pleiotropic effects such as tissue damage, caloric wasting, and impairment of hematopoiesis. It has been observed that HIV suppresses hematopoiesis through induction of TNF- α . TNF-binding protein has been shown to reverse *in vitro* hematopoietic defects.³ The relationship of virus replication to inducing the hematopoietic defects is most readily apparent in the clinical changes seen when patients initiate potent antiretroviral therapy. When patients begin HAART, an increase in white blood cells (WBCs), polymorphonuclear neutrophils, and platelets in addition to an increase in CD4⁺ T cells occurs as plasma HIV RNA levels decline.⁴ T-cell kinetics studies have demonstrated a markedly shortened half-life of peripheral blood T cells from approximately 82 days to 23 days. Initiation of antiretroviral therapy does not improve lymphocyte half-life. The increase in T-cell numbers in the peripheral blood of patients treated with HAART appears to be a result of improved production, which in turn may be caused by one of several mechanisms: expansion or redistribution of existing subsets of cells or *de novo* production of T cells from the thymus. The increase in T cells following initiation of HAART is biphasic. In

BOX 157.1

Hematologic Manifestations of Human Immunodeficiency Virus/Acquired Immunodeficiency Syndrome

In addition to the CD⁺ T cell lymphopenia, which is the hallmark of HIV infection, other cytopenias are the most common manifestations in these individuals. During the course of the disease thrombocytopenia and neutropenia occurs at a rate of 40% and 50% respectively. Anemia can occur in up to 70%. Direct infection of the hematopoietic stem cells by HIV does not account for the degree of cytopenias seen. In fact, *in vivo* infection of the stem cells by HIV occurs rarely if ever. However, HIV infection leads to hematopoietic inhibition *in vivo* by depleting granulocytic, monocytic, erythroid, and megakaryocytic colony forming units. Progenitor populations such as those yielding megakaryocytes and monocytes are infectable. Macrophages in the bone marrow stroma can develop productive HIV infection with the resultant release of cytokines (TGF- β , TNF- α , IL-1) that contribute to suppression of hematopoiesis. Importantly, there are etiologies that are more specific to causing anemia, thrombocytopenia and neutropenia respectively. Hence these entities are discussed separately.

HIV, Human immunodeficiency virus; IL-1, interleukin 1; TGF- β , transforming growth factor β ; TNF- α , tumor necrotic factor α .

the interval immediately following the start of therapy, there is a prompt increase in both CD4⁺ and CD8⁺ cells that is composed predominantly of cells of a memory phenotype (CD45RO⁺ or CD45RA⁺ CD62L⁻). This increase is slightly different for CD4⁺ cells, which increase more briskly (0.027/day) and plateau at approximately 3 weeks compared with CD8⁺ cells (increase of 0.008/day), which plateau at 8 weeks.⁵ This increase is thought to be largely caused by redistribution from peripheral tissues, perhaps related to a changing level of activation of the cells with declining viral antigen stimulation. This initial increase in circulating cell numbers does not achieve normal blood levels of lymphocytes. The secondary, much slower phase of T-cell increase tends to be sustained for months to years, with a greater contribution of cells with a naive phenotype (CD45RA⁺ CD62L⁺). The naive population rises along with cells bearing the T-cell receptor excision circle, an indicator of recent T-cell receptor rearrangement that accompanies early T-cell differentiation. It is this population that is generally regarded as thymus dependent and that is capable of truly expanding the immune repertoire. In addition, in vivo models have further defined that T-cell generation, from precursor populations both endogenous and exogenous to the thymus, accompanies control of viremia.

Evaluation of Cytopenias in HIV-Infected Individuals

The evaluation of cytopenias in patients infected with HIV requires a review of complete blood count and thorough examination of the peripheral blood smear (see box on [Peripheral Blood Smear and Bone Marrow Morphology in HIV/AIDS](#)). Although there is a gradual fall in CD4⁺ lymphocytes during the asymptomatic phase of HIV infection, a mild lymphocytosis may at times be seen, caused by an increase in CD8⁺ lymphocytes. Atypical or activated lymphocytes may frequently be seen. Lymphopenia is present in the advanced stage of the disease. Anemia, when present, is usually normocytic and normochromic. It can be at times macrocytic, either because of the effect of certain antiretroviral drugs such as zidovudine or stavudine, or seen in patients with advanced HIV disease. Occasionally red blood cell (RBC) anisocytosis, poikilocytosis, and rouleaux can sometimes be seen in patients with untreated advanced HIV disease. Also hypogranular neutrophils and Pelger-Huët forms may rarely be present in patients with advanced HIV disease. However, in comparison to patients with myelodysplasia (MDS), agranular neutrophils and neutrophils with the acquired Pelger-Huët anomaly are not a predominant feature in patients with HIV infection. Thrombocytopenia is associated with normal sized platelets, except occasional large platelets may be seen when there is immune-mediated destruction of platelets with preserved marrow function.

The bone marrow in patients with HIV can be hypercellular, normocellular, or hypocellular. In a majority of cases the normal bone marrow architecture is often disturbed, with dysplastic changes similar to those seen in MDS ([Fig. 157.4](#)).⁶ In [Fig. 157.5](#) are shown additional features seen in the bone marrow of HIV-infected individuals. HIV-associated stromal changes include edema, gelatinous transformation, and increased reticulin fibers. Dense collagen fibrosis, however, is not a feature of the HIV bone marrow. There are some important features distinguishing the morphology of the bone marrow of an HIV-infected individual from that of patients with MDS. Dyserythropoiesis is usually less severe in HIV than observed in MDS, and occurs predominantly in patients treated with HAART. Megaloblastic changes are usually associated with zidovudine and stavudine therapy. In contrast to MDS, in which erythropoiesis may be hyperplastic, the myeloid/erythroid ratio in HIV is usually normal and there may even be neutrophilic and megakaryocytic hyperplasia.

BOX 157.2 Peripheral Blood Smear and Bone Marrow Morphology in HIV/AIDS

The peripheral blood smear of a patient with HIV/AIDS might show anisocytosis, poikilocytosis, and rouleaux formation. Anemia, when present, is usually normocytic and normochromic. Sometimes macrocytic can be seen even in the absence of AZT therapy. Lymphopenia is seen in advanced disease. Hypogranular neutrophils and Pelger forms are rarely present. Platelets can be normal or hypogranular. In cases of thrombocytopenia, the platelets can be normal sized or large when thrombocytopenia is caused by immune destruction with persevered marrow.

The bone marrow is usually hypercellular, but can be normocellular or hypocellular. Interstitial and perivascular polyclonal plasmacytosis is usually present. HIV-associated stromal changes include edema, gelatinous transformation and increased reticulin fibers (dense collagen fibers are not a feature of HIV). Normal bone marrow architecture is often disturbed and dysplastic changes can be seen, including dyserythropoiesis, dysgranulopoiesis, and abnormal megakaryocytes (including clustures and bare megakaryocytic nuclei). However, the following features distinguish the bone marrow morphology in HIV from that of MDS: dysplasia is less severe in HIV. Dyserythropoiesis occurs mainly in patients on HAART. Megaloblastic changes are associated with AZT therapy. Although erythropoiesis is usually hyperplastic in MDS, myeloid to erythroid ratio is usually normal in HIV. Increase blasts can be seen in MDS but never in HIV. Lastly, in contrast to MDS, the bone marrow in HIV often shows eosinophilia, lymphohistiocytic infiltrates and plasmacytosis.

AIDS, Acquired immunodeficiency syndrome; AZT, zidovudine; HAART, highly active antiretroviral therapy; HIV, human immunodeficiency virus; MDS, myelodysplastic syndrome.

Fig. 157.4 ACID-FAST ORGANISMS IN GRANULOMA. Large poorly formed granuloma in the bone marrow (A) is composed of loosely aggregated histiocytes, lymphocytes, and plasma cells (B), with occasional giant cells (C). The acid-fast stain shows rare elongated, slightly beaded organisms, typical of *Mycobacterium tuberculosis* (D, top). In *Mycobacterium avium* complex, the organisms frequently stuff histiocytes (D, bottom).

Fig. 157.6 CLASSIC HODGKIN LYMPHOMA INVOLVING THE BONE MARROW OF A PATIENT WITH ACQUIRED IMMUNODEFICIENCY SYNDROME. (Zhao X, Sun NC, Witt MD, et al: Changing pattern of AIDS: a bone marrow study. *Am J Clin Pathol* 121:393, 2004.)

Fig. 157.7 HUMAN PARVOVIRUS INFECTION IN HUMAN IMMUNODEFICIENCY VIRUS. The peripheral blood smear shows anemia with no polychromasia (A). The marrow biopsy shows mostly granulocytic and megakaryocytic elements with a lack of erythroid forms (B), except for rare large pronormoblasts with nuclear inclusions (B, center). On the aspirate, the large degenerating pronormoblasts have nuclear inclusions that resemble large nucleoli (C). These are viral inclusions. Sometimes the pronormoblasts are totally degenerated and present as only bare nuclei with the viral inclusion still obvious (C, right). An immunostain for parvovirus in a degenerated pronormoblast is illustrated (D).

An increase in blasts can be seen in MDS, but never in bone marrow in HIV infected patients, unless they have an associated leukemia. In contrast to MDS, the bone marrow in HIV patients often shows eosinophilia, lymphohistiocytic infiltrates, and reactive plasmacytosis. Although a bone marrow examination is not routinely required to evaluate isolated anemia, thrombocytopenia, or neutropenia in patients with HIV infection, a bone marrow examination can be useful in the evaluation of unexplained fever and in patients with pancytopenia suspected of having marrow infiltration with an infectious agent or malignancy. Granulomas are observed in approximately 15% of bone marrow trephines and may result from the HIV infection alone, but a thorough search for mycobacterium and other infections is required. A particular effort should be made to identify bone marrow involvement with opportunistic infections, which could include mycobacterial (Fig. 157.6), fungal, protozoal, and/or viral infections.⁶ Cytopenias in HIV-infected individuals may also be caused by bone marrow involvement by non-Hodgkin lymphoma

(Fig. 157.7), Hodgkin lymphomas, Kaposi sarcoma, and Castleman disease.

The etiology of cytopenias in HIV/AIDS is frequently multifactorial (see box on **Etiologies of Cytopenias**). In addition to HIV infection, the medications often prescribed to HIV-infected patients can account for a significant proportion of cytopenias. A thorough review of the medications and supplements taken by a patient with HIV/AIDS with a cytopenia is essential. Tables 157.3 and 157.4 list antiretroviral and anti-infective medications prescribed for prophylaxis/treatment of opportunistic infections and their association with hematologic toxicities.

The clinical presentation and management of individual cytopenias can be unique and therefore the diagnosis and management of anemia, thrombocytopenia, and neutropenia in HIV/AIDS are addressed separately later. In addition, the emerging issue of thrombosis in HIV and principles of antiretroviral therapy management will also be discussed in this chapter.

BOX 157.3 Etiologies of Cytopenias

The etiologies of cytopenias are multifactorial. The common etiologies for anemia, thrombocytopenia, and neutropenia include HIV infection and its effect on the bone marrow, medications, and bone marrow infiltration with infectious agents or malignancies. Hence the first step in the treatment of any cytopenia is to optimize antiretroviral therapy. Any offending agent/agents causing the cytopenia should be discontinued if possible and infections or malignancies involving the bone marrow should be appropriately treated. In addition, appropriate workup should be done to diagnose conditions that can affect specific cell lines. For instance, the cause of anemia includes anemia of chronic disease with a blunted production as well as response to erythropoietin, which can be effectively treated with erythropoietin. Parvovirus B19 can cause isolated red cell aplasia and can be treated with red cell transfusion and IVIg. Other causes of anemia encountered in the immune competent population should be considered and appropriately treated. HIV-related autoimmune thrombocytopenia responds to HAART, steroids, anti D, IVIg, and splenectomy. G-CSF/GM-CSF should be used when needed to treat neutropenia. The treatment of thrombosis in patients with HIV/AIDS is similar to treatment of this condition in the general population.

AIDS, Acquired immunodeficiency syndrome; G-CSF, granulocyte-colony stimulating factor; GM-CSF, granulocyte-macrophage-colony stimulating factor; HAART, highly active antiretroviral therapy; HIV, human immunodeficiency virus; IVIg, intravenous immunoglobulin.

Red Blood Cell Abnormalities and Anemia

Anemia can occur at any stage of HIV disease, but is more frequent and severe in advanced disease.⁸ There is increasing evidence suggesting that anemia in HIV disease is independently associated with an increased risk of disease progression and mortality.^{8,11} Anemia is associated with an increased risk of death in HIV-infected patients regardless of CD4 count, and survival is not significantly different between patients with drug-related anemia and anemia attributed to other causes.⁸ Correction of anemia in HIV-infected patients has been associated with measurable improvements in quality of life⁹ and increased survival.⁸

Detection and treatment of the underlying cause of the anemia should be an immediate goal, which may involve the treatment of opportunistic infections or gastrointestinal blood loss. In general, the etiology of anemia seen in HIV infection is often multifactorial, with several mechanisms playing a role in an individual patient. Diagnosing the cause or causes of anemia is essential to proper therapy.

Anemia Resulting From Decreased Red Blood Cell Production

The most common cause of anemia in HIV disease is decreased RBC production. Frequently encountered mechanisms responsible for decreased RBC production in patients with HIV disease are listed in Table 157.5. Examples include anemia of acute and chronic inflammation (chronic disease anemia) with a blunted production of and response to erythropoietin and cytokine suppression of bone marrow colony-forming unit–granulocyte, erythrocyte, macrophage, megakaryocyte (CFU-GEMM). Infection or infiltration of bone marrow by infectious agents such as atypical mycobacterium, tuberculosis, CMV, and/or fungal organisms can result in profound anemia, although most often associated with pancytopenia. Parvovirus B19 can cause isolated red cell aplasia in the more severely immunocompromised individuals. Bone marrow infiltration by HIV-associated lymphomas, in addition to anemia, can cause neutropenia and thrombocytopenia. Nutritional deficiencies, including vitamin B₁₂ and folic acid deficiency, are not uncommon. Other causes of anemia including anemia secondary to blood loss or hemolysis as seen in the non-HIV patient population can also occur in patients infected with HIV.⁷ Most significant is that most patients with advanced HIV

disease are often treated with one or more medications that can affect RBC production and survival.

Before the HAART era, treatment of HIV disease with high doses of zidovudine was a major cause of myelosuppression and anemia in patients with AIDS. More recent studies, even in the era of HAART, continue to report a high prevalence of anemia among HIV-infected patients.¹⁰ Acute and chronic inflammation is the most frequent cause of anemia in HIV infection. This is characterized by the classic findings of decreased serum iron concentration, reduced total iron binding capacity, a normal or high ferritin, an inappropriately low reticulocyte count for the degree of anemia, and reduced blood levels of erythropoietin. HIV infection itself may account for anemia. Therefore initiation of HAART may result in improvement or normalization of hemoglobin levels in patients who are anemic at baseline. Frequently this occurs in parallel with improvement in CD4⁺ lymphocyte count, but can occur with only marginal increase in CD4⁺ lymphocyte numbers. The use of HIV protease inhibitors in HAART also appears to improve hematopoiesis.¹³ A report by the Women's Interagency HIV Study has shown that the use of HAART is associated with decreased prevalence of anemia among women.¹⁴ HAART may also decrease the risk of anemia developing in patients who are not anemic at the initiation of therapy. Although the use of HAART is associated with decreased prevalence among people with AIDS generally, the prevalence of anemia remains high among persons with low CD4 counts.¹⁵

Parvovirus B19 is a member of the *Parvoviridae* family and is responsible for several diseases in humans, including erythema infectiosum (fifth disease) in children, hydrops fetalis, acute arthropathy in adults, aplastic crisis in patients with chronic hemolytic disorders, and pure red cell aplasia in immunocompromised individuals. Parvovirus-induced pure red cell aplasia in association with HIV infection was described over a decade ago.¹⁶ Parvovirus B19 infection is generally limited to human erythroid progenitor cells and leads to erythroid cell death. In hosts with normal immune responses and normal erythrocyte production, acute infection causes a self-limited (4–8 days) interruption in the production of erythrocytes that does not result in significant anemia. However, if host immune responses are impaired, this can result in persistent infection of erythroid precursors leading to a prolonged and severe anemia.

The seroprevalence of parvovirus B19 infection is similar among HIV-infected and noninfected individuals. Furthermore, HIV-infected individuals who have serologic evidence of parvovirus B19 infection usually do not have evidence of active infection (i.e., parvovirus B19 viremia). Parvovirus B19–induced red cell aplasia seen in HIV patients often occurs in individuals with low or absent levels of B19-specific antibodies.¹⁶

Clinically the disease presents in patients with findings consistent with profound anemia characterized by weakness, pallor, dyspnea, and tachycardia. Hemoglobin values as low as 4 to 5 g/dL and absolute reticulocyte counts of less than $5 \times 10^9/L$ ($<0.1\%$) are commonly reported. Detection of parvovirus IgG and IgM is not reliable because levels of antibodies may be low or undetectable among patients and are not diagnostic of acute parvovirus B19 red cell aplasia. The most reliable diagnostic study of parvovirus B19 infection is the detection of parvovirus DNA by either PCR or dot-blot hybridization. Because the high sensitivity of PCR may lead to positive test results for months after the original infection, dot-blot hybridization may be a better test for making a diagnosis of acute infection resulting in red cell aplasia. Histologic examination of bone marrow aspirates reveals hypocellularity, markedly decreased maturing erythrocytes, and occasional giant pronormoblasts. The presence of giant pronormoblasts in a bone marrow aspirate or biopsy is diagnostic of parvovirus B19 infection.⁶

Initial therapy for parvovirus-induced red cell aplasia should be aimed at correcting the anemia through RBC transfusions. Treatment with intravenous immunoglobulin (IVIg 0.4 g/kg daily for 5 days) can lead to a rapid decrease in the level of parvovirus viremia, improvement in the reticulocyte count, and resolution of the anemia. Recurrence is commonly seen if there is no improvement in the patients' immunologic function. If the anemia recurs within 6 months of the

initial therapy, monthly maintenance therapy with 0.4 g/kg IVIg may be required. Immune reconstitution resulting from the successful use of HAART may lead to complete remission of this condition.¹⁷

Anemia Resulting From Ineffective Red Blood Cell Production

Ineffective production of red cells can occur with deficiencies of folate or vitamin B₁₂. Ineffective production of RBCs is frequently characterized by concomitant decreases in platelets and neutrophils accompanied by megaloblastic red cell morphology with large oval macrocytes and hypersegmented neutrophils. In addition to a low reticulocyte count there may be elevations in indirect bilirubin and serum lactate dehydrogenase. Because of the relatively small tissue stores of folate, patients with advanced HIV disease who have poor dietary intake, excessive alcohol ingestion, and/or jejunal disease may become deficient in folate. More commonly reported in patients with

advanced HIV infection is decreased serum B₁₂ levels. Low serum B₁₂ has been documented in approximately one-third of patients with AIDS. Patients with advanced HIV infection (AIDS) appear to acquire gastrointestinal defects resulting in B₁₂ malabsorption. The mechanisms responsible for decreased B₁₂ absorption observed in these patients include both infections of and other acquired disorders of the small intestine and ileum, food B₁₂ malabsorption secondary to inadequate gastric acid production, and true pernicious anemia with antibodies to the H⁺/K⁺ parietal cell pump and intrinsic factor. However, not all cases of low serum levels of B₁₂ are associated with true metabolic B₁₂ deficiency as characterized by elevated methylmalonic acid. This may result from the finding that some patients with neutropenia secondary to a hypocellular bone marrow may have low serum levels of transcobalamin (TC) I, the major serum B₁₂ carrier protein, which is found in the specific granules of neutrophils. However, transport of B₁₂ into cells is mediated by TC II, which carries only 25% to 30% of serum B₁₂, and for that reason the newer assays that measure B₁₂ bound to TC II (holotranscobalamin II

TABLE 157.4 Agents for Treatment and Prevention of Opportunistic Infections With Hematologic Toxicities

Drug Class	Drug Toxicities	Hematologic
Antifungal agents	Amphotericin B deoxycholate and lipid formulations	Anemia
	Anidulafungin	Deep vein thrombosis (rare)
	Flucytosine	Bone marrow suppression
	Micafungin	Hemolysis, leukopenia
Anti- <i>Pneumocystis</i> pneumonia agents	Dapsone	Methemoglobinemia, hemolytic anemia (especially in patients with G6PD deficiency), neutropenia.
	Primaquine	Methemoglobinemia, hemolytic anemia (especially in patients with G6PD deficiency).
	Trimethoprim-sulfamethoxazole (TMP-SMX)	Bone marrow suppression.
Antitoxoplasmosis agents	Pyrimethamine	Neutropenia, thrombocytopenia, megaloblastic anemia.
	Sulfadiazine	Bone marrow suppression.
Antimycobacterial agents	Rifampin	Thrombocytopenia, hemolytic anemia.
	Rifabutin	Neutropenia anemia, thrombocytopenia
Antiviral agents	Ganciclovir	Neutropenia, thrombocytopenia, anemia,
	Interferon-alfa and peginterferon-alfa	Neutropenia, thrombocytopenia.
	Ribavirin	Hemolytic anemia.
	Valaciclovir	At a high dose of 8 g/day: thrombotic thrombocytopenic purpura/hemolytic uremic syndrome reported in advanced human immunodeficiency virus patients and in transplant recipients
	Valganciclovir	Neutropenia, thrombocytopenia, anemia.
Antiparasitic agents	Albendazole	Neutropenia
	Benznidazole	Bone marrow suppression.
	Fumagillin (investigational)	Oral therapy: neutropenia, thrombocytopenia.
	Miltefosine	Ocular therapy: minimal systemic effect or local effect Leukocytosis, thrombocytosis.
Treatment for syphilis	Pentavalent antimony (sodium stibogluconate)	Leukopenia, anemia, thrombocytopenia

TB, Mycobacterium tuberculosis; RT, reverse transcriptase.

assays) may be more reflective of serum B₁₂ status in neutropenic HIV infected patients.

A diagnosis of B₁₂ deficiency should include not only a low serum B₁₂ level, but normal or elevated blood levels of folic acid, elevated blood homocysteine, and elevated methylmalonic acid levels in a patient with normal renal function. With a diagnosis of B₁₂ deficiency, an effort should be made to determine the causes of B₁₂ malabsorption, and treatment begun with monthly administration of parenteral B₁₂ to correct the deficiency. If anemia and cytopenias result from the B₁₂ deficiency alone, treatment should result in correction within 4 to 6 weeks. Because B₁₂ deficiency is also associated with a variety of neurologic defects, including motor and sensory neuropathy, cognitive defects including dementia, and the most severe neurologic manifestation of subacute combined degeneration of the spinal cord, the possibility of B₁₂ deficiency should be considered in any HIV-infected patient with neurologic symptoms.

Anemia Resulting From Increased Red Blood Cell Destruction

Anemia resulting from hemolysis of RBCs can result from processes either intrinsic or extrinsic to the RBC. Examples of intrinsic defects include hemoglobinopathies, RBC membrane defects, or RBC enzyme functional deficiencies such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. Exclusive of G6PD deficiency, the majority of patients with these RBC defects have a life-long history of anemia. Diagnosis in most circumstances can be made by careful review of the peripheral blood smear. G6PD deficiency is an X-linked disorder and found predominantly in men. Hemolysis occurs when erythrocytes are exposed to oxidative stress. Depending upon the

degree of enzyme deficiency, patients may not have had a previous documented episode of hemolysis. G6PD deficiency–associated hemolysis can occur in HIV infected patients who are taking dapsone or trimethoprim and sulfamethoxazole combinations for pneumocystis prophylaxis or treatment. In some patients, the degree of hemolysis does not result in significant anemia because RBC destruction is well compensated by effective RBC production and patients can continue on treatment. However, patients with the Mediterranean form of G6PD may develop severe hemolysis, and treatment with such medications is contraindicated.

Extrinsic causes of RBC hemolysis observed in patients with HIV infection include microangiopathic hemolytic disorders such as thrombotic thrombocytopenic purpura (TTP, discussed in the section on thrombocytopenia), vasculitis, or disseminated intravascular coagulation. Patients will have associated thrombocytopenia and demonstrate RBC fragmentation on the peripheral blood smear. Autoimmune hemolytic anemia rarely occurs in HIV-infected individuals, although a positive antiglobulin (Coombs) test is not uncommon. Patients with documented autoimmune hemolysis may respond to treatment with corticosteroids, rituximab, or splenectomy. The risk of HIV progression with the use of corticosteroids and rituximab does not appear to be an issue in patients receiving HAART.

Impact of Anemia on HIV Disease Progression and Survival

Anemia has been shown to be an independent risk factor for clinical progression of HIV disease. In a patient in whom HAART is to be initiated, anemia, CD4 cell count $<0.2 \times 10^9/L$, HIV viral load, and a pretreatment diagnosis of clinical AIDS are well established risk factors for rapid disease progression. A moderate anemia of 8 to 14 g/dL in men or 8 to 12 g/dL in women is associated with a relative hazard of disease progression or death of 2.2 (95% confidence interval [CI], 1.6–2.9), $p < .0001$, whereas a more severe anemia of less than 8 g/dL has a relative hazard of 7.1 (95% CI, 2.5–20.1, $p < .0002$).

Anemia has a significant impact on overall survival in HIV-infected patients. A Baltimore study of 2348 HIV-infected patients found that a hemoglobin of 6.5 to 8 g/dL was predictive of a threefold risk of death and a hemoglobin of <6.5 g/L was predictive of a fourfold increased risk of death. A European study of 6725 HIV-infected patients found the hemoglobin level at baseline was an independent prognostic factor for survival along with the CD4⁺ lymphocyte count and HIV plasma viral load. For each 1 g/dL decrease in hemoglobin level, the relative hazard of death was 1.39 (95% CI, 1.34–1.43; $p < .0001$). Additional cohort studies from the United States including the Multistate Adult and Adolescent Spectrum of HIV Surveillance Project and the Women's Interagency HIV Study have also confirmed that anemia is an independent risk factor for mortality in HIV infected individuals.

Management of Anemia and the Use of Erythropoietin in HIV-Infected Patients

Treatment of anemia should be directed toward correcting the underlying cause whenever possible. The use of blood transfusion should be minimized and reserved for patients who have rapid decreases in hemoglobin levels, extremely low hemoglobin levels, or pronounced anemia-related symptoms. A number of clinical trials of antiretroviral medication combinations (HAART) have shown that suppression of HIV replication is associated with improvement in anemia. In addition, improvement of anemia on HAART has been found to occur independent of the patients' sex, race, mode of HIV infection, change in CD4⁺ lymphocyte count, and additional therapies for anemia. Improvement in anemia, with an increase in the reticulocyte count, can be seen as early as 8 to 12 weeks, with maximum improvement usually obtained by 12 months.

Erythropoietin supplementation has been shown to be beneficial in HIV-infected patients with well-established anemia and when the hemoglobin level is decreasing or has decreased slowly. A blunted

response to erythropoietin, as observed in anemia of acute and chronic inflammation, is common in HIV-infected patients with anemia. However, erythropoietin (Epogen; Procrit) therapy should be considered for refractory anemia in symptomatic patients with a hemoglobin level of <11 g/dL in men and <10 g/dL in women. The primary goal should be to maintain quality of life and functional status. Many patients may be asymptomatic with lower hemoglobin (9–10 g/dL) and physicians should use erythropoietic agents only for symptomatic patients with these lower hemoglobin levels. The initial adult dose is 40,000 units subcutaneously per week, which has been shown to be equivalent to treatment three times a week at 100 to 200 U/kg.¹² Also darbepoetin alfa given at a dose of 3.0 μ g/kg every 2 weeks has been shown to be as equally effective. Onset of action as characterized by an increase in the reticulocyte count is within 1 to 2 weeks, with increased hemoglobin noted in 2 to 6 weeks. The baseline level of endogenous serum erythropoietin has been shown to be predictive of response to the therapeutic use of erythropoietin. A baseline erythropoietin level of greater than 500 IU/L is associated with a significantly lower response to treatment. Response to erythropoietin therapy also depends on the severity of anemia, presence of active infection and available iron stores. If hemoglobin fails to increase more than 1 g/dL after 4 weeks of therapy, the dose may be increased to 60,000 units weekly. After an additional 4 weeks, if hemoglobin does not increase by at least 1 g/dL from baseline, therapy should be discontinued. When combined with the use of HAART, erythropoietin treatment may result in a more rapid improvement in hemoglobin, but has not been shown to improve survival or statistically reduce the total number of transfusions. This may be because of the marginal contribution that erythropoietin supplementation may have in the background of the significant improvement in immune status and bone marrow function provided by effective antiretroviral therapy.¹⁵

LEUKOPENIA AND NEUTROPENIA: INCIDENCE AND PATHOGENESIS

Leukopenia is common in patients with advanced HIV infection occurring in up to 85% of patients with clinical AIDS. In such patients, low WBC counts are frequently a result of both decreased lymphocytes and neutrophils.⁷ Neutropenia ($<1.5 \times 10^9/L$) is reported in 5% to 10% of HIV-infected patients with the highest prevalence in patients with advanced HIV infection (AIDS). In a 7.5-year longitudinal study of 1729 women with HIV infection an absolute neutrophil count (ANC) of less than $1 \times 10^9/L$ was documented in 31%. HIV-related risk factors for the development of neutropenia include a high plasma HIV viral RNA and a low CD4⁺ lymphocyte count. In turn, the use of HAART is associated with a lower risk of developing neutropenia. Decreases in the neutrophil count are often transient, self-limiting, and rarely of clinical significance, but a neutrophil count of less than $0.5 \times 10^9/L$ of prolonged duration does pose a significant risk of infection. In a study of 87 consecutive HIV-infected patients who developed neutrophil counts of less than $1 \times 10^9/L$, the median duration of neutropenia was 13 days and nadir neutrophil count was $0.66 \times 10^9/L$. Infection occurred in only 6 (8%) of 71 evaluable patients, of whom 4 patients had neutrophil counts less than $0.5 \times 10^9/L$. Ten (12%) patients had neutrophil counts less than $0.5 \times 10^9/L$ and received granulocyte colony-stimulating factor (G-CSF) treatment, which artificially altered the natural history of neutropenia in this patient population.

Decreased in vitro colony growth of the CFU-granulocyte macrophage (GM) progenitor cell has been reported, which may explain the neutropenia observed with HIV infection alone. Inhibitory substances produced by HIV infected cells have been reported to suppress neutrophil growth and differentiation in vitro. A number of inflammatory cytokines including TGF- β and TNF- α may directly suppress myelopoiesis or inhibit the production of important myeloid growth factors, G-CSF and GM-CSF. Decreased serum levels of G-CSF have been observed in afebrile neutropenic HIV-infected patients. The HIV proteins tat and p24 have also been reported capable of suppressing myelopoiesis.

The most common causes of neutropenia in HIV infected patients are medication-related myelosuppression. In a study of 87 consecutive HIV-infected patients with neutrophil counts of $<2 \times 10^9/L$, only three patients were not receiving medications associated with a risk of neutropenia and 66% were receiving three or more myelosuppressive medications. Neutropenia is a common complication reported with many of the drugs used to treat opportunistic infections such as *Pneumocystis carinii*, toxoplasmosis or CMV infection.⁷ These medications are listed in Table 157.4. Although neutropenia resulting from HIV-related myelosuppression often improves with HAART, antiretroviral-associated neutropenia can be observed with higher doses of zidovudine. Zidovudine-associated neutropenia resolves with dose reduction or discontinuation of the medication.⁷ In a study of 62 HIV-infected patients with neutrophil counts of $1 \times 10^9/L$ or less, cancer chemotherapy, zidovudine, trimethoprine-sulfamethoxazole and ganciclovir were the medications most commonly responsible for neutropenia. In the same report, medication-related neutropenia associated with infection was most often seen in the patients receiving cancer chemotherapy. Rare cases of agranulocytosis have been reported with the use of the antiretroviral drugs, abacvir and indinavir.

Neutropenia is often observed in patients with bone marrow involvement by opportunistic infections such as *Mycobacterium avium* or CMV. Bone marrow involvement with HIV-associated malignancies and their subsequent treatment can also result in significant and prolonged neutropenia. However, malignancy treatment-related neutropenia in clinical trials appears to be less severe in patients receiving simultaneous HAART.

Abnormalities of Neutrophil and Monocyte Function

A number of acquired functional defects have been described in both neutrophils and monocytes from patients with HIV infection. Many of these defects are observed in patients with advanced disease with high levels of plasma viral RNA and CD4⁺ lymphopenia. Impaired chemotaxis and reduced expression of leukocyte adhesion molecules necessary for migration of neutrophils to sites of infection have been reported. Decreased opsonization of antibody coated bacteria because of Fc receptor dysfunction and decreased superoxide production necessary for optimal intracellular killing of bacterial and fungal organisms have been observed in both neutrophils and macrophages from HIV-infected patients. Defective intracellular killing of mycobacterial and fungal organisms may also be caused in part by defective production of IFN- γ .

Management of Neutropenia in HIV-Infected Patients

Impact of HAART and Use of Granulocyte-Macrophage-Colony Stimulating Factor and Granulocyte-Colony Stimulating Factor

Treatment of neutropenia should be guided by the underlying cause. This may require treatment of active infection or removal of medications associated with the development of neutropenia. The use of HAART has clearly been shown to reduce the risk of developing leukopenia and neutropenia and significantly increasing the neutrophil counts in treated patients. The Women's Interagency HIV Study of 1729 HIV-infected women found that the use of HAART, without zidovudine, was associated with protection against developing neutropenia. In addition, HAART, even incorporating zidovudine, was associated with resolution of neutropenia in women with advanced HIV disease. Another study of 66 HIV-infected patients treated with HAART reported statistically significant increases in total leukocyte and neutrophil counts after 6 months of treatment. These studies support the use of effective HAART as the initial approach to the management of mild to moderate leukopenia and neutropenia in HIV infected patients.

Sargramostim or GM-CSF (Leukine) and filgrastim or G-CSF (Neupogen), are the primary pharmacologic agents used in the treatment of severe neutropenia in HIV-infected patients and have been shown in clinical studies to be safe and effective. A long-term study of 105 HIV-infected patients randomized to receive weekly injections of GM-CSF ($125 \mu g/m^2$) or placebo while receiving zidovudine antiretroviral therapy reported after 6 months of treatment that GM-CSF treated patients were more likely to have a HIV plasma RNA level below level of detection and less zidovudine resistance mutations. A study of 123 HIV-infected leukopenic patients treated with GM-CSF treated for 12 weeks were compared with 121 untreated leukopenic patients showed the total leukocyte count including neutrophils and monocytes increased by 65% at week 12 when compared with baseline values ($p < .001$). In the untreated leukopenic HIV-infected patients, the total leukocyte count decreased by 24% below baseline values at week 12 ($p < .001$). Common side effects of treatment with GM-CSF include fever, fatigue, myalgias, bone pain and headache.

A randomized study of 258 HIV-infected patients with CD4⁺ lymphocyte counts below $0.2 \times 10^9/L$ and neutrophil counts of $<1 \times 10^9/L$ were randomized to one of two dose regimens of G-CSF ($1 \mu g/kg/day$ or $300 \mu g$ three times a week) versus no treatment. Patients in the control group who developed severe neutropenia ($<0.5 \times 10^9/L$) were then randomized to one of the treatment regimens. The intention-to-treat analysis found the incidence of severe neutropenia ($<0.5 \times 10^9/L$) was 1.7% in the treated group versus 22% in the untreated controls. The incidence of bacterial infections was 31% lower in the treated group, with fewer severe bacterial infections and significantly fewer hospital days (45% reduction) for bacterial infections.

The use of G-CSF has been associated with a reduction in severe neutropenia in patients treated for CMV infection with ganciclovir (Cytovene), but the evidence is unclear as to whether it offers a clear clinical benefit.¹⁹ However, in general it has been shown to be safe and effective in raising leukocyte counts when administered to patients with HIV infection receiving antiretroviral therapy.^{7,19} G-CSF is indicated for drug-induced, cancer-related and HIV-related neutropenia with an ANC of less than $0.5 \times 10^9/L$ cell/mcl. The initial dose is $1-10 \mu g/kg/day$ and should be titrated by $1 \mu g/kg/day$ to obtain a neutrophil count of $1.0 \times 10^9/L$. Most patients will respond to a dose of $1 \mu g/kg/day$. G-CSF usage should be carefully monitored and the dose reduced or stopped when the neutrophil count exceeds $1.0 \times 10^9/L$.

THROMBOCYTOPENIA IN HIV INFECTION

Thrombocytopenia, alone or in association with anemia and/or leucopenia, is frequently seen in approximately 40% of HIV-infected patients in the course of their disease. Thrombocytopenia has been reported to be the first sign of HIV infection in up to 10% of infected individuals. The most common cause of thrombocytopenia in HIV infection is HIV-related autoimmune thrombocytopenia, which is clinically indistinguishable from classic immune thrombocytopenia (ITP).

An association between AIDS and ITP was described before HIV had been isolated and characterized. HIV infects CD4⁺ lymphocytes, monocytes, and macrophages, and some experimental evidence also documents infection of megakaryocytes. Although a number of different mechanisms have been reported by which HIV infection can produce thrombocytopenia, the ability of effective antiretroviral therapy to improve platelet counts demonstrates a clear relationship between viral replication, the expression of viral related proteins, and the host response to platelets.

Epidemiology

Thrombocytopenia was first associated with AIDS before the discovery of HIV. Before the use of HAART, HIV-associated

thrombocytopenia (HIV-ITP), platelet count $<150 \times 10^9/L$ was identified in approximately 5% to 30% of HIV-1 infected patients. Thrombocytopenia is more prevalent in patients with advanced HIV infection defined as a CD4-lymphocyte count of $<0.2 \times 10^9/L$, clinical AIDS, and among intravenous drug abusers. The Multicenter AIDS Cohort Study of 1611 HIV-positive homosexual and bisexual men reported a platelet count of $<150 \times 10^9/L$ in 6.7%. The incidence of thrombocytopenia was only 2.8% in men with CD4 lymphocyte counts $>0.7 \times 10^9/L$, but rose to 10.8% in those with CD4⁺ lymphocyte counts of $<0.2 \times 10^9/L$. A review of 1004 HIV-infected patients seen in two HIV/AIDS clinics, identified platelet counts of $<150 \times 10^9/L$ on at least one determination in 110 (11%) patients, 42 (4.2%) patients had platelet counts of $<100 \times 10^9/L$ and 15 (1.5%) had a platelet count of $<50 \times 10^9/L$. Thrombocytopenia was more prevalent in patients with a clinical AIDS (21.2%) and a CD4⁺ lymphocyte count of $<0.2 \times 10^9/L$ (20%).

A review of the medical records of 36,515 HIV-infected participants in the Multistate Adult and Adolescent Spectrum of Disease Project reported a 1-year incidence of thrombocytopenia of 3.7%, defined as a platelet count of $<50 \times 10^9/L$. The incidence and severity of thrombocytopenia was associated with the stage of disease with an incidence of 1.7% among patients with HIV infection, but not clinical or immunologic AIDS, 3.1% among persons with immunologic AIDS (CD4⁺ lymphocytes $<0.2 \times 10^9/L$) and 8.7% in patients with clinical AIDS. By logistic regression analysis, clinical AIDS, CD4 lymphocyte count of $<0.2 \times 10^9/L$, age >45 years, intravenous drug use, lymphoma and/or anemia was associated with a platelet count $<50 \times 10^9/L$.

An increased incidence and severity of thrombocytopenia in HIV-infected intravenous drug users compared with HIV infected homosexuals has been reported. Mientjes et al reported a platelet count of $<150 \times 10^9/L$ in 29/182 (16.4%) homosexual HIV-infected men compared with 38/181 (36.9%) HIV-infected intravenous drug users. None of the homosexual men had a platelet count of $<50 \times 10^9/L$, whereas 6 (5.8%) of intravenous drug users had a count of $<50 \times 10^9/L$. These differences may be explained, in part, by the higher incidence of coinfection with hepatitis C and underlying liver disease in HIV-infected intravenous drug users.

In a prospective multicenter cohort study of 738 HIV infected hemophilia patients, the incidence over time of HIV-related conditions was determined in 130 children and 193 adults. The 10-year cumulative incidence of thrombocytopenia (platelets $<100 \times 10^9/L$) after seroconversion was $43\% \pm 7\%$ in adults and $27\% \pm 6\%$ in children. The mean CD4 counts were significantly higher in children (514 ± 61 cells/ μl) than adults (260 ± 24 cells/ μl) with thrombocytopenia ($p = .0004$).

Most clinical data have been obtained before the widespread use of HAART in patients with early HIV-infection. There are few data on the current prevalence of thrombocytopenia in patients under active antiviral treatment. However, recent prospective data from the Women's Interagency HIV study have documented a reduction in the incidence of anemia and neutropenia in HIV-infected women on HAART. These findings are in accord with the impression that there has been a similar reduction in the incidence of thrombocytopenia, especially platelet counts $<50 \times 10^9/L$ in compliant patients.

Pathophysiology

Multiple mechanisms may contribute to the development of CITP in the HIV-infected patient and these have recently been reviewed. Proposed mechanisms include accelerated platelet clearance because of immune complex disease, and anti-platelet GP antibodies, and/or anti-HIV antibodies that cross-react with platelet membrane GPs (antigenic mimicry). The ability of the HIV-1 to rapidly mutate may facilitate both its ability to escape immune surveillance and to mimic host antigens. Direct infection of megakaryocytes results in defective platelet production and megakaryocytic apoptosis.

Epidemiologic studies suggest that the pathogenesis of thrombocytopenia is partially dependent on disease burden. HIV-associated

thrombocytopenia developing early after infection more often resembles classic ITP in which thrombocytopenia is mediated primarily by peripheral destruction, whereas thrombocytopenia in patients with immunologic AIDS (CD4 lymphocytes $<2 \times 10^9/L$) is attributable predominantly to decreased platelet production and ineffective hematopoiesis. Although platelet counts may improve with antiretroviral therapy in both patient populations, patients with advanced disease are less likely to respond to classic primary ITP therapy such as splenectomy, corticosteroids, IVIg or anti-RhD. Initial studies of HIV-associated ITP suggested an immune complex mechanism was responsible for the thrombocytopenia, wherein platelets were cleared from the circulation as "innocent bystanders." More recent studies have shown that these immune complexes contain antibodies that cross-react with both HIV and platelet GPs. These antibodies also cross-reacted with sequences on HIV nef, gag, env, and pol proteins. Similar cross-reactivity between HIV viral proteins and platelet GPs has been reported in the studies of Bettlaieb and coworkers who eluted Ig from platelets from patients with HIV-associated ITP and found these antibodies bound to antigenic epitopes common to both platelet GPIIb and HIV GP160.

Studies of platelet kinetics have demonstrated that HIV-ITP is frequently associated with decreased platelet production. Megakaryocytes express the CD4 receptor and coreceptors necessary for HIV infection. Cytopathic infection of HIV of the megakaryocyte has been demonstrated and is the postulated primary mechanism for impaired megakaryopoiesis. However, the potential of cross-reactive antibodies between HIV-related proteins and platelet GPs capable of inducing apoptosis of megakaryocytes as has been described with primary ITP has not been studied.

Clinical Manifestations

HIV-seropositive patients can develop thrombocytopenia several years before the development of overt AIDS, and the early disease is clinically indistinguishable from classic ITP. However, the clinical picture of HIV-ITP is often mild, with only a minority of patients having platelet counts of less than $50 \times 10^9/L$. Major bleeding is rare and only a few cases of fatal hemorrhage have been reported. There has been greater variability in patients with hemophilia A. For example, Finazzi and coworkers documented thrombocytopenia (platelets $<100 \times 10^9/L$) in 14/124 (11%) hemophiliacs, only one of whom had a major hemorrhage. In contrast, Ragni and colleagues reported a platelet count of $<100 \times 10^9/L$ in 30/87 (36%) hemophiliac patients, with 11 (13%) having a platelet count $<50 \times 10^9/L$. Nine of the 11 patients (82%) had major bleeding complications and 3 suffered fatal hemorrhage.

Severe thrombocytopenia in patients with advanced HIV infection is frequently associated with additional cytopenias. In a study of 52 HIV-infected intravenous drug users with thrombocytopenia, 4 patients (8%) with advanced HIV infection had a hypocellular bone marrow examination and pancytopenia. HIV-infected drug users were also more likely to have antibodies to both hepatitis B and C and to have abnormal liver function studies. The role of immune-mediated platelet destruction versus bone marrow failure in patients with advanced HIV disease is still uncertain.

Treatment of HIV-Associated Immune Thrombocytopenia

HIV-associated ITP is generally responsive to therapeutic interventions used in classic ITP. Therapy with prednisone produces a major hematologic response (platelet count $>100 \times 10^9/L$) in over half of all patients, although only a minority will maintain platelets $>50 \times 10^9/L$ after cessation of steroids. Despite the initial anxiety regarding the use of corticosteroids in HIV-infected, immune-suppressed patients, no deleterious effect of short-term treatment with prednisone have become evident. However, long-term treatment with corticosteroids should still be avoided and other coinfections such as

tuberculosis, CMV or hepatitis C should be excluded before initiating treatment with corticosteroids. IVIg and anti-RhD are equally effective in increasing platelet counts acutely in severely affected patients, but a crossover study clearly demonstrated a longer duration of response with the latter agent.

Splenectomy has proven to be safe and effective in refractory patients with HIV-TTP. After splenectomy, there is a transient increase in the peripheral blood CD4 lymphocyte count, which reflects redistribution from the splenic pool into the circulation rather than an improvement in the patient's immunologic status.

HIV-related hematologic cytopenias have been shown to correlate with plasma viral load. Effective antiretroviral therapies have resulted in improvement in several HIV-related cytopenias, including HIV-CITP. Zidovudine monotherapy increased platelet counts in 60% to 70% of HIV-CITP patients. Although other antiretroviral drugs have been shown to improve hematologic parameters in patients with advanced HIV infection, their efficacy as monotherapy for the management of HIV-CITP is less well documented. Use of HAART in both de novo and zidovudine-refractory HIV-CITP has induced sustained platelet responses in association with effective viral suppression.

Responses to zidovudine and HAART may be more limited in HIV-infected intravenous drug users, possibly reflecting the impact of associated liver disease and infection with hepatitis C virus (HCV). In a prospective placebo-controlled, double-blind, randomized trial, 12 of 14 zidovudine refractory HIV-infected intravenous drug users with elevated serum alanine aminotransferase suggestive of underlying liver disease who were treated with IFN- α had a statistically significant increase in their platelet counts by week 4 of therapy. Similar responses to IFN- α therapy alone have been reported in HIV-seronegative, HCV infected patients. An open label trial of IFN- α in a cohort of predominantly homosexual men documented responses in nine of 16 patients, with responses occurring as early as 2 weeks after the initiation of treatment. Such rapid responses preclude the possibility that improvement in the platelet count is solely caused by suppression of concomitant HCV infection. At present, there are no data evaluating the efficacy of the new approved thrombopoietin receptor agonists, romiplostim and eltrombopag, in the management of HIV-related thrombocytopenia, but long-term efficacy and safety data regarding the use of these agents in primary ITP would suggest that they would be effective in the management of HIV-associated ITP.

THROMBOTIC MICROANGIOPATHY AND THROMBOTIC THROMBOCYTOPENIC PURPURA

Thrombotic microangiopathy including both TTP and the hemolytic uremic syndrome (HUS) is a well-described complication of HIV infection seen in approximately 1% of patients. The incidence of this complication appears to have decreased with the advent of HAART. The incidence of TTP appears to be similar to that observed in the general population, whereas HUS appears frequently in patients with advanced HIV infection.

TTP can occur any time in the course of HIV infection and has been reported in some patients to be the initial manifestation of HIV infection. This life-threatening disorder is characterized by thrombocytopenia and microangiopathic (fragmentation) hemolytic anemia. The original description of this disorder emphasized a classic pentad of fever, thrombocytopenia, microangiopathic hemolytic anemia, renal failure, and neurologic abnormalities. However, most patients present with only one or two manifestations of the original pentad and isolated thrombocytopenia may be the initial finding. Therefore it is essential that the evaluation of thrombocytopenia includes a careful review of the peripheral blood smear.

TTP is the result of a failure to process endothelial derived high molecular weight von Willebrand factor caused by an absence of/or inhibitor to the von Willebrand factor cleaving protease (ADAMTS13). Measurement of ADAMTS13 activity before the initiation of plasma exchange will report levels nearly always less than 10%

and additional assays will often detect an inhibitor to the protease. First-line therapy is daily plasma exchange until remission and maintenance of platelet count at $150 \times 10^9/L$, though there are a number of reported differences in how to use plasma exchange in the management of this disorder. Initial plasma exchanges should be at least a 1.5 plasma volume exchanges. Corticosteroids such as prednisone (1 mg/kg/day) can also be given with the exchanges. If plasma exchange is not immediately available, infusion of fresh frozen plasma alone has been shown to be effective in patients with HIV-associated TTP. In classic TTP, relapses can occur in up to 30% of patients; however, relapse in HIV-associated TTP appears to be less frequent. Patients who relapse can be treated with repeat exchange combined with immunosuppressive therapy including such agents as vincristine or rituximab.

HUS most likely results from endothelial perturbation secondary to either HIV or other viral infections such as CMV, drug or toxin induced such as observed with *Escherichia coli* 0157:H7 infection. Recent data suggest that the primary event leads to unregulated complement activation caused either by inhibitors of complement regulatory protein such as complement H or congenital abnormalities in complement regulation. In these patients, measurement of ADAMTS13 activity will uniformly report levels near normal and above 30%. Many patients will respond to aggressive plasma exchange, but complete remissions are rare. Recently the inhibitor of complement C5a, eculizumab, has been approved for the treatment of atypical HUS, but there are no reports of its use in HIV-associated HUS.

THROMBOEMBOLIC DISEASE

Since the beginning of the AIDS epidemic, an unexpectedly high incidence of venous thromboembolism (VTE) has been observed among people with HIV disease. The most compelling data in support of an increased risk of VTE in HIV disease estimated the incidence of thrombosis in their HIV-infected population to be about 2.6 per 1000 person-years. Given the fact that cohorts of patients with HIV infection tend to include a disproportionate number of younger individuals compared with the general population, this figure represents an increased incidence of VTE. The increased incidence in venous thrombosis was disproportionately greater among patients with clinical AIDS, those older than 45 years, those with AIDS-defining illnesses (particularly CMV infection), and those taking indinavir (Crixivan) or megestrol acetate (Megace). However, 53% of the thrombotic events occurred in individuals without history of recent hospitalization.

In a study comparing the risk of VTE in HIV-infected patients to an age-matched uninfected control population, there was no statistical difference in the overall risk of VTE (2.8% HIV-infected versus 1.8% controls) except in the HIV-infected patients less than 50 years (3.31% HIV-infected versus 0.53% controls; $p < .0001$). A study of 37,535 HIV-infected veterans compared with 37,535 age, race and site-matched uninfected controls found in evidence that a 39% increased incidence in VTE in the pre-HAART era (before 1996) and a 33% increased incidence in the era of HAART. The increased risk of thrombosis was independent of a diagnosis of malignancy, HIV-related opportunistic infections, or the use of central catheters. The development of a thromboembolic event was associated with a statistically increased mortality in all groups.

Role of Inflammation and Its Effect on the Protein C and S Anticoagulant System

With advancing HIV disease, there are progressive prothrombotic hemostatic changes, specifically a decrease in protein S and an increase in factor VIII. There is a well-documented association between acute and chronic inflammation and activation of the hemostatic system. Inflammatory cytokines such as TNF- α , IL-1, and IL-6 have been shown to activate coagulation and downregulate activation of protein

C. Activated protein C (APC) is a major inhibitor of coagulation, degrading activated coagulation factors VIIIa and Va. Inflammation can also result in a decrease in functional protein S, the cofactor of APC, which most likely explains the acquired protein S deficiency observed in some HIV-infected patients, with and without thrombosis.

An important additional component of the inflammatory state, which further contributes to an increased risk of thrombosis, is the inflammation-induced increase in factor VIII coagulant protein. Factor VIII levels greater than 1500 units/L (150%) are an independent risk factor for idiopathic VTE. A study of 94 HIV-infected women and 50 HIV-negative controls who were participants in the Women's Interagency HIV Study documented a progressive prothrombotic state with advancing HIV disease characterized by progressive decreases in protein S activity associated with a progressive increase in Factor VIII activity. The decreases in protein S activity and reciprocal increases in factor VIII activity closely correlated with decreasing CD4⁺ lymphocyte count and were most significant in the women with clinical AIDS. This study provides evidence for a link between advancing HIV disease characterized by decreasing CD4⁺ lymphocyte count and the development of clinical AIDS with opportunistic infections and hemostatic changes associated with an increased risk for venous thrombosis. This acute and chronic inflammatory state is the most likely pathogenic mechanism for development of VTE in HIV-infected individuals.

Anticardiolipin Antibodies

It is well established that antiphospholipid antibodies (anticardiolipin antibodies [ACA] and lupus anticoagulant) are associated with a hypercoagulable state. The incidence of elevated ACA in asymptomatic HIV disease is reported to be as high as 50% and even higher in patients with clinical AIDS. Recent reports have documented the presence of ACA in HIV-infected individuals with VTE. However, two small studies reported no correlation between high levels of ACA and thrombosis in HIV infection. Because the increased thrombotic risk associated with the antiphospholipid antibody syndrome is predominantly associated with the lupus anticoagulant and β 2GP 1, it is not surprising that increased ACA alone was not associated with a significantly increased risk of thrombosis. Thus the contribution of antiphospholipid antibodies to the development of VTE in HIV disease remains unknown and will require larger prospective studies that include assays for the lupus anticoagulant and anti- β 2GP antibodies.

Role of Protease Inhibitors

Several investigators have found protease inhibitors to be associated with VTE. Sullivan et al. reported that the use of indinavir (Crixivan) was associated with an increased risk of VTE. In a case series, George et al.²⁹ reported unexplained thrombosis in HIV patients receiving protease inhibitors. Abnormalities of glucose metabolism and serum lipids are commonly observed with protease inhibitor therapy. These include acquired insulin resistance, increased low-density lipoprotein cholesterol, and decreased high-density lipoprotein (HDL) cholesterol. Insulin resistance is associated with acquired defects in the fibrinolytic system, including increased levels of plasminogen activator inhibitor and tissue plasminogen activator. Similar fibrinolytic abnormalities have been observed in patients with documented insulin resistance who are treated with protease inhibitors.

HDL has been shown to significantly enhance the activity of the APC complexed with protein S. This APC complex plays an essential role in downregulating thrombin generation. The lipoprotein abnormalities associated with the use of protease inhibitors, when combined with other acquired defects in the protein C anticoagulant pathway, may further depress the anticoagulant activity of the APC complex and subsequently promote increased thrombin generation. Thus there are a number of pathogenic mechanisms that could predispose

HIV-infected patients to VTE. The majority of reported hemostatic abnormalities appear to primarily affect the protein C and S inhibitory mechanisms. However, the available studies reporting an increased risk of VTE in HIV disease are only suggestive at present because most supporting data come from case reports and one uncontrolled retrospective study. Larger prospective studies are needed to assess the true relative risk of VTE in HIV-infected individuals and to determine the primary pathogenic mechanisms responsible for thrombosis in this population.

Management of Venous Thromboembolism With HIV Infection

The overall management principles and goals of therapy for VTE are the same for people with and without HIV infection, although extra caution is needed to anticipate possible drug interactions with HAART, particularly with the use of warfarin. Initial therapy for the patient presenting with deep vein thrombosis and/or pulmonary emboli involves the use of either intravenous unfractionated (UF) heparin or preferentially subcutaneous low-molecular-weight (LMW) heparin. Oral anticoagulants can be started immediately upon achieving therapeutic heparin levels, and under optimal circumstances heparin treatment can be completed and the patient discharged from the hospital within 5–7 days. LMW heparin preparations given subcutaneously without monitoring have been shown to be safe and effective treatment for VTE and may be preferable because they also allow for safe outpatient management. In a meta-analysis of clinical trials comparing LMW heparin with UF heparin, LMW heparin preparations were associated with a lower risk of major bleeding compared with adjusted-dose intravenous UF heparin.

The greatest difficulties in the management of VTE in HIV-infected patients occur with the use of oral anticoagulants. The optimal therapeutic range for oral anticoagulation with warfarin in patients with VTE is a prothrombin time (PT) international normalized ratio (INR) of 2–3. No data suggest that HIV-infected patients require a different degree of anticoagulation. However, most studies have found that general medical patients managed as outpatients have a therapeutic INR in only 60% of assays. Although there are no published data regarding the use of oral anticoagulants in HIV-infected patients, individuals receiving HAART appear to have greater difficulty in maintaining therapeutic anticoagulation, most likely because of complex drug interactions. With a reported annual risk of major bleeding with oral anticoagulants of 2% to 3% and bleeding-related fatality of 20%, careful PT monitoring of HIV-infected patients is mandatory. They should be monitored at least weekly for the first 6 to 8 weeks and should then have their PT checked every 2 weeks. In patients in whom maintaining therapeutic levels is difficult, home monitoring using devices approved by the US Food and Drug Administration may be indicated. Patients who have significant difficulty maintaining a therapeutic INR or have had bleeding complications caused by poor control of their anticoagulation can be treated with long-term LMW heparin as has been recommended for the long-term management of cancer-related VTE. In both HIV-infected and HIV-negative patients with malignancies who develop VTE, long-term management with LMW heparin appears to be associated with a significantly lower risk of recurrent VTE. Drug–drug interactions may also limit the use of the new oral anticoagulants. Potent inhibitors (lopinavir, ritonavir, indinavir, conivaptan) or inducers (carbamazepine, rifampin, phenytoin) of Cyp3A4 and P-GP can significantly increase the bleeding risk or conversely decrease the efficacy of these agents.

Oral anticoagulation in the patient with VTE should be maintained for at least 6 months. Patients with unprovoked VTE who have had major pulmonary emboli, recurrent thromboemboli, or underlying inherited or acquired prothrombotic defects may benefit from longer courses of oral anticoagulation. However, the decision to extend anticoagulation to prevent recurrence of thrombosis must be weighed against the significant risk of bleeding in this population.

HEMATOLOGIC ASPECTS OF PARASITIC DISEASES

David J. Roberts

Parasitic diseases are not common in medical, let alone hematologic, practice in North America or Europe. However, much of the world's population is infected by and becomes symptomatic as a result of a plethora of parasites, and many of these infections represent global public health problems.

Although some significant parasitic diseases are transmitted in temperate climates, the majority of parasites of significance to human health are endemic in the tropical world. This reflects not only socioeconomic circumstances but also the origin of our species in tropical Africa, where the human host, parasites, and also vectors have established complex relationships over evolutionary timescales.¹ Notwithstanding such geographic variation in the incidence of parasitic disease, both travelers and recent immigrants now present to hematology clinics and laboratories all over the world with increasing frequency. Even in those circumstances, there are marked variations in practice in North America as well as in Europe, where the United Kingdom reports more cases of imported malaria than the United States and indeed has a 10-fold greater incidence of malaria per capita, reflecting the increased frequency of travel to and from endemic areas compared with North American populations.

Patients with malaria, leishmaniasis, trypanosomiasis, and babesiosis may present directly or indirectly to hematologists. This chapter is concentrated on the biologic, clinical, and hematologic features of these infections and the hematologic aspects or complications of their treatment. Comprehensive accounts of the general medical aspects of these diseases are provided in many other recent textbooks.²⁻⁴

MALARIA

Malaria is a major public health problem in tropical areas, and it is estimated that it is responsible for 600,000 to 900,000 deaths annually and 150 to 300 million infections.⁵ The vast majority of morbidity and mortality caused by malaria is caused by infection with *Plasmodium falciparum*, although *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae* are also responsible for human infections. A fifth species, *Plasmodium knowlesi*, has been shown to cause human infection in some parts of Southeast Asia (for review, see the article by Millar and Cox-Singh⁵). In endemic areas, a significant proportion of the mortality and morbidity is from anemia. In Europe and North America, malaria is not infrequently a clinical problem in travelers or recent arrivals from malaria-endemic areas, and hematologists may be involved in the diagnosis and management of the disease. Moreover, in nonendemic areas, malaria may cause a fatal transfusion-transmitted infection, and detection of blood donors who may be carrying the disease represents a major challenge for blood services.

Epidemiology

Approximately 1 billion people live in areas of endemic or epidemic malaria. The global mortality and morbidity were revised to 350 million cases and 1 million deaths per year, respectively, following an evaluation of the prevalence of infection in Southeast Asia (Fig. 158.1). There is, however, substantial evidence that the incidence of severe disease is now falling, sometimes spectacularly, in many parts of Africa following the widespread introduction of artemisinin combination treatment, impregnated bed nets, and residual spraying because the resources available for malaria control have increased

substantially through the Global Fund and the World Health Organization's "Roll Back Malaria" campaign (www.rbm.who.int). The current estimated annual death total from malaria in Africa is 630,000.⁶

The distribution of malaria is determined by features of host, vector, and parasite. In summary, the global distribution of autochthonous or endogenous malaria is limited by the lower temperature limits for development of the parasite in the mosquito (sporogony) of 20°C for *P. falciparum* and 15°C for other human malarias. Within these limits, transmission does not occur above 1500 m in arid regions or in the Central and South Pacific (because of the absence of suitable vectors). In addition, *P. vivax* malaria is rare in Africa, where the population frequency of the blood group Duffy negative (Fya⁻Fyb⁻) is high. *P. ovale* requires a lengthy period of sporogony and is confined to areas of Africa and Southeast Asia with a high density of susceptible *Anopheles* spp. *P. knowlesi* is transmitted from macaque monkeys in forest areas of Borneo, Malaysia, Thailand, and Vietnam.⁵

In some malarious areas the seasonal pattern of clinical malaria is determined by the increase in vector density after rainfall, leading to an increase in new infections as transmission increases. In naive individuals, parasites can cause chronic infection lasting many months.

The intensity of transmission determines the distribution of clinical symptoms in different age groups.⁷ In general, in areas of high transmission, younger children experience severe disease. Where transmission is less intense, older children experience severe disease. Finally, if the rate of transmission is very low, few cases of malaria are seen in any age group, and such populations would have little natural immunity. In such areas, a sudden increase in vectorial capacity (through the accidental introduction of efficient vectors or higher density, biting, or survival of the resident vectors), more rapid parasite sporogony, or migration of infected or nonimmune populations can result in epidemics where large numbers fall ill in all age groups. The transition from high to low transmission has been classified by holoendemicity, hyperendemicity, mesoendemicity, and hypoendemicity. These categories can be related epidemiologically to age-specific rates of parasite prevalence or splenomegaly and theoretically to the reproductive ratio of malarial infection.⁸

Malaria exerts a substantial selection for human traits that protect from infection. Sickle cell trait and thalassemia traits protect from infection and are truly polymorphic characteristics in many parts of the world. Understanding genetic epidemiology has provided the foundation of population genetics and has provided classic examples of principles of genetic selection in vivo—for example, balancing selection for sickle cell trait and negative epistasis for sickle cell trait and α -thalassemia. The homozygous forms of these characteristics cause significant clinical disease, such as sickle cell disease, β -thalassemia, and glucose-6-phosphate dehydrogenase (G6PDH) deficiency. In endemic areas these genetic diseases represent major public health problems (for review, see Williams⁹ and Luzzatto et al¹⁰).

Parasitology

In *P. falciparum* (see later for a discussion of the other human parasites) the infective sporozoite forms are inoculated into the bloodstream from the salivary glands of a female *Anopheles* mosquito

Fig. 158.1 GLOBAL MALARIA ENDEMICITY. Areas are colored according to malaria endemicity (prevalence): *light green*, hypoendemic (areas in which childhood infection prevalence is less than 10%); *medium green*, mesoendemic (areas with infection prevalence between 11% and 50%); *dark green*, hyperendemic and holoendemic (areas with an infection prevalence of 50% or more); unclassified areas (*yellow*) represent only 6% of the global population at risk and are caused by discrepancies in recent data. *Gray* areas are a combined mask of areas outside the transmission limits and areas of population density less than 1 person/km². (Data from Snow RW, Guerra CA, Noor AM, et al: *The global distribution of clinical episodes of Plasmodium falciparum malaria*. *Nature* 434:214, 2005.)

(Fig. 158.2). These thin, needle-shaped cells, 10 to 12 μm in length, circulate briefly with a half-life of approximately 30 minutes before traversing macrophages and several hepatocytes and ultimately residing in a single hepatocyte.^{11,12} Here rapid multiplication takes place over 5 to 8 days to produce a liver schizont, 80 μm in diameter and containing $30,000 \pm 10,000$ merozoites that are released into the bloodstream, where they infect erythrocytes.¹³ When ready to leave hepatocytes, the parasite induces cell death in the hepatocytes and causes the release of merozoites in membrane-enclosed structures or merozoites that are extruded from the infected cell, thereby avoiding host cell defense mechanisms.¹⁴

The merozoites bind and then invade red blood cells (RBCs; for review of RBC and merozoite interactions, see Satchwell¹⁵). The host plasma membrane is invaginated to form the parasitophorous vacuole. For the first 10 hours the developing parasites appear as fine “ring forms.” Between 10 and 15 hours the cytoplasm thickens, and 16 hours after invasion, granules of the black pigment hemozoin, the end product of hemoglobin digestion, begin to appear. Ligands are expressed at the surface of the infected RBC that mediate adhesion to host receptors on venular endothelium. These trophozoites no longer circulate throughout the body but are sequestered in the peripheral circulation. Nuclear division begins, at approximately 30 hours, to form schizonts containing up to 32 merozoites. At 48 hours the RBC is ruptured to release the merozoites into the circulation to continue further cycles of asexual multiplication.

The erythrocytic cycle of schizogony may achieve a 10-fold increase in parasitemia in vivo and a patent or microscopically detectable infection 6 days after the liver stage is completed. After two or more cycles the infection becomes clinically apparent by the paroxysms of fever that accompany the release of merozoites. Cycles of schizogony continue until the rate of parasite multiplication is reduced by chemotherapy, specific or nonspecific defense mechanisms, or occasionally the demise of the host.

Some merozoites do not multiply but become committed during the previous erythrocytic cycle to form male or female gametocytes.¹⁶ Gametocytes are distinguished by dispersed pigment in a single nucleus, in a fully grown parasite, and are sequestered for the first 5 days of their development in the peripheral circulation. Thus 8 to 10

days after the start of clinical infection, mature, crescent-shaped gametocytes appear in the blood.

The sexual phase (or sporogony) of the parasite life cycle begins after a male and female gametocyte are ingested by a feeding female *Anopheles* mosquito. In the midgut of the mosquito the gametocytes shed the RBC membrane. This change is apparently precipitated by the drop in temperature. A female gametocyte forms a single macrogamete, but male gametocytes undergo several rounds of nuclear division to produce flagellated microgametes. These microgametes are motile and migrate to fertilize a macrogamete. The resulting zygote enlarges to form a mobile ookinete and migrates through the epithelial wall of the mosquito midgut to rest finally on the external surface. The oocyst divides repeatedly to form up to 10,000 sporozoites, which travel up through the hemolymph to enter the acinar cells of the salivary glands. Once there, they are infective when injected into the host.

Major differences exist in the life cycles of other human *Plasmodium* spp. First, in *P. vivax* and *P. ovale* infections, some sporozoites entering the liver form dormant hypnozoites that begin to divide only after a variable period of some months to cause further blood-stage infections or relapses. Second, the cycle of erythrocytic development in *P. malariae* takes 72 hours and thus causes quartan fever (i.e., on days 1 and 4).

The Pathophysiology of Malarial Anemia

Malaria gives ample reasons for both increased RBC destruction and reduced RBC production (see Fig. 158.3 for overview).

Loss of Infected Erythrocytes

Destruction of RBCs is inevitable as parasites complete their 48-hour growth cycle and lyse their temporary host cell. Some parasites may be removed from erythrocytes as immature ring forms by phagocytic cells, leaving the RBCs with residual parasite antigens to continue to circulate, albeit with reduced survival.¹⁷ Infected erythrocytes may

Fig. 158.2 PLASMODIUM LIFE CYCLE. (A) The asexual life cycle begins when sporozoites from a female mosquito taking a blood meal enter the circulation and invade hepatocytes. (B) Up to 10,000 merozoites are formed. Following rupture of the hepatocyte, infective merozoites are released and invade erythrocytes (red blood cells [RBCs]). (C) Within RBCs, the parasite develops through the stages of rings, trophozoites, and schizonts. Mature schizonts burst to release erythrocytic merozoites that invade new RBCs. (D) A small proportion of merozoites in RBCs transform into male and female gametocytes that are ingested by the mosquito. (E) The male and female gametes fuse and transform into an oocyst, which divides asexually into many sporozoites that migrate to the salivary gland from where they are released during the next blood meal.

also be phagocytosed by macrophages following opsonization by immunoglobulins and/or complement components.^{18,19} Other signals for recognition of infected erythrocytes by macrophages include abnormally rigid membranes and exposure of phosphatidylserine and other altered host antigens and, in animal models of malaria, antiphosphatidylserine antibodies.^{20–23}

Loss of Uninfected Erythrocytes

The activity and the number of macrophages are increased in malarial infection, and increased removal of uninfected cells may occur. Moreover, the signals for recognition of uninfected erythrocytes for removal by macrophages are enhanced. Uninfected erythrocytes bind increased amounts of immunoglobulin and/or complement as detected in the direct antiglobulin test (DAT or Coombs test).²³ These antibodies do not have a particular specificity but are more likely to represent immune complexes absorbed onto the surface of RBCs.²³ Furthermore, hemozoin may activate complement directly and cause deposition of C3b on uninfected RBCs.²⁴ However, an association between positive DAT results and severe anemia has not been established.²⁵ More recent studies have shown not only that RBCs from patients with malaria were more susceptible to phagocytosis but also that RBCs from children with acute malaria had increased surface immunoglobulin G (IgG) and low levels of RBC CR1 and CD55 compared with control subjects.²⁶

Role of the Spleen

Some degree of splenomegaly is a normal feature of malarial infection, and the prevalence of splenomegaly in regions of malarial transmission is used as a major indicator of the level of malarial endemicity. The importance of the spleen in host defense against malaria has been demonstrated in experimental systems, and individuals whose spleens have been surgically removed are thought to be more susceptible to severe infection. Indeed, the phenomenon of parasitic sequestration is thought to have evolved primarily as an immune evasion strategy so the mature parasite can avoid passing through the spleen.²⁷

Active erythrophagocytosis is a conspicuous feature within the bone marrow during *P. vivax* and *P. falciparum* malaria,^{28,29} and it is highly probable that this also occurs within the spleen. Cytokines may be responsible for activating macrophages during malarial infection. Children with acute *P. falciparum* malaria have high circulating levels of interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α),³⁰ a synergistic combination of cytokines that activates macrophages.

Researchers in several studies have attempted to define the pathophysiologic changes in the spleen during acute malaria. In animal models, malaria is accompanied by increased intravascular clearance of infected or rigid, heat-treated cells by the spleen,³¹ as well as alterations in the splenic microcirculation.³² In studies of human malaria, it has been found that increased splenic clearance of heated RBCs occurs during acute attacks.³³ More recent, histologic studies and ex vivo models of splenic function suggest that the spleen removes not only mature infected RBCs but also uninfected cells marked for clearance by low deformability, aggregated band 3, complement deposition, or phosphatidylserine exposure. Moreover, “pitting” of ring-stage infected cells may remove the parasite and leave the RBC marked with parasite antigen to return to the circulation (reviewed by Buffet et al³⁴).

Changes to the uninfected RBCs during infection also contribute to their own enhanced clearance by phagocytes. Uninfected RBCs in children and adults with severe disease are less deformable, and this is a significant predictor of the severity of anemia and indeed outcome, consistent with the notion that these cells are being removed by the spleen.²⁰ It has also been found that IgG-sensitized RBCs are rapidly removed from the circulation by the spleen and that unusually rapid clearance persists well into the convalescent phase.³⁵

Thus all the available evidence points to increased reticuloendothelial clearance in *P. falciparum* malaria, persisting long after recovery. These changes are presumably a host defense mechanism, maximizing the clearance of parasitized erythrocytes.

The Role of Ineffective Erythropoiesis in Severe Malarial Anemia

Reticulocytopenia has been confirmed in numerous clinical studies of malarial anemia.^{36–38} The histopathologic study of the bone marrow of children with malarial anemia shows erythroid hyperplasia with increased numbers of erythroid precursors (Fig. 158.4). However, the maturation is abnormal by light and electron microscopy. Abdalla et al^{39,40} described the hallmark characteristics of such abnormal maturation, namely cytoplasmic and nuclear bridging and irregular nuclear outline. They later confirmed that the distribution of the erythroid progenitors through the cell cycle is abnormal in malarial anemia, with an increased proportion of cells in the G₂ phase compared with healthy control subjects.⁴¹ Dormer et al³⁸ confirmed these findings using the same criteria as Abdalla et al; they studied six patients with falciparum malaria before and after treatment.

Ineffective erythropoiesis also contributes to anemia in animal models of malaria. A recent study has shown that vaccinated *Aotus* monkeys, after a challenge infection, may develop moderate to severe anemia following rapid clearance of uninfected erythrocytes, but with low reticulocyte counts, indicating bone marrow

Fig. 158.3 PATHOGENESIS OF MALARIAL ANEMIA. Severe malarial anemia is characterized by destruction of infected red blood cells (iRBCs) following schizogony and clearance of both iRBC and uninfected RBCs. During malarial infection, changes in membrane protein composition occur, and the resultant immune complexes of RBC, Ag, and immunoglobulin (e.g., RBC-RSP2-Ig) are cleared by MØ to the spleen, where they become activated. Pigment-containing MØ may release inflammatory cytokines and other biologically active mediators such as 4-hydroxynonenal. MIF may be released by MØ, or a plasmodial homologue may suppress erythropoiesis. Malarial pigment or other parasite products may have a direct inhibitory effect on erythropoiesis. Inhibition of erythropoiesis may occur at one or more sites in the growth and differentiation of hematopoietic progenitors. Both indirect and direct effects may cause suppression of the bone marrow and spleen, resulting in inadequate reticulocyte counts for the degree of anemia. *Ab*, Antibody; *Ag*, antigen; *Epo*, erythropoietin; *GPI*, glycosylphosphatidylinositol anchors of merozoite proteins; *Hs*, hemozoin; *Ig*, immunoglobulin; *IL*, interleukin; *MIF*, macrophage inhibitory factor; *MØ*, macrophages; *RSP2*, ring surface protein-2; *TNF-α*, tumor necrosis factor-α.

Fig. 158.4 BONE MARROW ASPIRATE IN MALARIA. Although erythropoiesis is usually normoblastic in individuals with acute or chronic malaria, the examination of bone marrow frequently shows changes reflecting dyserythropoiesis, such as the irregular nuclei and cytoplasmic bridges in erythroblasts seen in this figure. Two young rings of *Plasmodium falciparum* can be seen in an erythrocyte. (Courtesy Dr. Saad H. Abdalla.)

dysfunction.⁴² Erythropoiesis is disrupted in mice during malarial infection. Mice infected with *Plasmodium berghei* show reduced bone marrow cellularity, erythroblasts, burst-forming units–erythroid, and colony-forming units–erythroid as early as 24 hours postinfection.⁴³ The cellularity and colony-forming unit–spleen content of the femoral marrow of BALB/c mice infected with *Plasmodium chabaudi adami* decreases as the parasitemia increases.⁴⁴

Modulation of Erythropoiesis by Cytokines

Given the importance of erythropoietin (Epo) to erythropoiesis, attention has been focused on the levels of this crucial cytokine in malarial infection. Serum Epo was appropriately raised in studies of African children with malarial anemia, and high levels of this cytokine may improve the outcome of disease.^{45,46} More recently, African children with severe malaria, particularly young children, were shown to have supraphysiologic levels of Epo compared with age-matched community control subjects with nonmalarial anemia.^{47,48} There is now evidence from clinical studies that these high levels of Epo in children with malarial anemia may exert a cytoprotective effect and reduce the risk for neurologic sequelae or death in children with cerebral malaria.⁴⁹ Indeed, in a murine model of cerebral malaria, exogenous Epo downregulated the inflammatory responses induced by dendritic cells, induced regulatory T cells, reduced endothelial activation, and improved the integrity of the blood–brain barrier.⁵⁰

The prime candidates for the host factors mediating dyserythropoiesis are imbalances of TNF- α , IFN- γ , and interleukin-10 (IL-10). The concentrations of TNF- α and IFN- γ have been correlated with the severity of the disease.⁵¹⁻⁵³ Whereas low concentrations of TNF- α (<1 ng/mL) stimulate erythropoiesis, higher levels of TNF- α have been shown to suppress erythropoiesis.⁵³ Furthermore, it is possible that high levels of these inflammatory cytokines may contribute to reduced and abnormal production of erythrocytes and also to increased erythrophagocytosis.

Recent evidence has suggested that the release of hepcidin is associated with malarial infection and that high levels of hepcidin could contribute to the sequestration of iron and impair erythropoiesis.^{54,55} The stimulus for hepcidin secretion may be proinflammatory cytokines such as IL-6, but malaria-infected erythrocytes may also enhance hepcidin production by peripheral blood mononuclear cells. Intriguingly, hepcidin released during blood-stage parasitemia may be a key regulator of *P. falciparum* liver-stage development.⁵⁶ These data now support suggestions from large-scale studies of iron supplementation that iron may be unhelpful and possibly even harmful when given during acute malarial infection. Indeed, there are both clinical and experimental evidence that iron deficiency may confer protection from severe malaria. Malaria parasites show reduced growth in RBCs from subjects with iron deficiency, and infection is augmented during the phase of iron supplementation after severe iron deficiency.⁵⁷

High levels of the T-helper cell type 2 (Th2)-type cytokine, IL-10, might prevent the development of severe malarial anemia. Low levels of IL-10 have been described in African children with severe malarial anemia.⁵¹ Similarly, defective IL-12 production has been shown experimentally to be associated with increased severity of malaria in a rodent model, and low IL-12 levels have been associated with severe malaria in African children.⁵⁸ The role of IL-12 in clinical malaria appears complex, but in toxoplasma infection in mice, IL-12 has been shown to have a key role in activating natural killer (NK) cells that primes monocytes in the bone marrow for a regulatory function, which could be important in malaria.⁵⁹

Modulation of Erythropoiesis by Infected Erythrocytes

There is also substantial evidence that lysate of infected erythrocytes may directly modulate the function of host cells. During its blood stage, the malaria parasite proteolyses host hemoglobin in an acidic vacuole to obtain amino acids, releasing heme as a byproduct, which is auto-oxidized to potentially toxic hemozoin (aquaferriprotoporphyin IX [$\text{H}_2\text{O}-\text{Fe}_{\text{III}}\text{PPIX}$]). β -Hemozoin forms as a crystalline cyclic dimer of $\text{Fe}_{\text{III}}\text{PPIX}$ and is complexed with protein and lipid products as malarial pigment or hemozoin. Schwarzer et al⁶⁰⁻⁶² showed that the function of monocytes and of monocyte-derived macrophages is severely inhibited after ingestion of malaria pigment or hemozoin. These cells were unable to repeat phagocytosis and to generate oxidative burst when appropriately stimulated. Furthermore, after phagocytosis of hemozoin, human and murine myeloid cells were unable to kill ingested fungi, bacteria, and tumor cells⁶³ or to respond to IFN- β stimulation, but instead responded by increased release of IL-1 β , TNF- α ,⁶⁴ macrophage inflammatory protein-1 α (MIP-1 α), and MIP-1 β .⁶⁵

The hemozoin polymer of heme moieties may be complexed with biologically active compounds. The oxidation of membrane lipids catalyzed by the ferric heme produces the lipoperoxides.^{62,66} There is accumulating evidence that 4-hydroxynonenal (HNE) and other lipoperoxides, including 15-hydroxyarachidonic acid [15-(*R,S*)-HETE], may play a role in the pathophysiology of malaria. It has been shown that HNE and HETE are generated in parasitized erythrocytes and that HNE and endoperoxides produced in pigment-containing monocytes or macrophages may cause cell-cycle arrest and impair erythroid growth.^{66,67} Hemozoin may also directly inhibit erythroid development in vitro and cause apoptosis of erythroid precursors.⁶⁸ Furthermore, increased levels of plasma hemozoin and pigment in monocytes have been associated with anemia.⁴⁹

Modulation of Erythropoiesis by Infection

In children presenting with acute malaria, bacteremia is associated not only with anemia but also with excess mortality.⁶⁹ Parvovirus B19 may cause a transient reticulocytopenia and thus severe and sudden anemia in those with a hemolytic anemia or fetal anemia and intra-uterine death. Most children in Africa have serologic evidence of infection early in life. However, acute infection with this virus is uncommon in those presenting with severe malarial anemia.^{46,70}

Prevalence and Etiology of Anemia in the Developing World

In endemic areas the etiology of anemia is complex. Acute or chronic malarial infection is a major precipitating factor in children with severe anemia causing admission to hospital.⁴⁷

Longitudinal studies from The Gambia have shown that whereas the mean hemoglobin levels in children vary significantly through the year, anemia is much more common in the rainy season, when malaria transmission is at its highest.⁷¹ However, the rains are also associated with an increase in waterborne diarrheal disease and poor food supplies. So the seasonal increase in anemia in malaria-endemic areas arises on a background of low or frankly deficient stores of hematinics and/or other micronutrients. Iron deficiency, which affects at least 20% of the world's population, is a major factor in the seasonal surge of anemia in the tropical rainy season. Low iron stores at birth and dietary iron deficiency may be exacerbated by hookworm or schistosomal infection. It is now also clear that malarial infection is associated with reduced uptake of available iron and reduced incorporation of iron into developing erythroid cells.^{54,55} Folate deficiencies and/or increased requirements may occur in many populations, although frank folate deficiency is uncommon.

A low baseline hemoglobin level at the start of the season for malaria transmission is a major risk factor for developing severe malarial anemia and has encouraged studies aimed at preventing the development of anemia by hematinic supplementation with or without antimalarial prophylaxis or surveillance.⁷²

Quantifying the contribution of these individual factors to anemia reliably requires intervention studies. In Tanzania, Menendez et al⁷³ and Schellenberg et al⁷⁴ have shown that iron supplementation and antimalarial prophylaxis prevented 30% and 60%, respectively, of all cases of moderate anemia presenting during the malaria transmission season in children and in infants.

Translating the results of these studies from well-defined and carefully controlled study areas has not been easy. Considerable concerns about iron supplementation programs for children have been raised in sub-Saharan Africa and in areas of high malaria endemicity. One large trial of iron supplementation was stopped because of increased hospital admission and death in the group receiving iron. However, meta-analysis of iron supplementation in malaria-endemic areas has shown that iron alone or with antimalarial treatment does not increase the risk for clinical malaria or death when regular malaria surveillance and treatment services are provided.⁷⁵ It is increasingly clear that iron supplementation in these areas must be based on either defining iron-deficient children or combining iron administration with effective infection control and treatment strategies.^{75,76}

Features of Malarial Anemia

The Spectrum of Disease Caused by Malarial Infection

The signs and symptoms of malarial infection in humans are caused by the asexual blood stage of the parasite. Infection with blood-stage parasites may result in a wide range of outcomes and pathologic conditions. Indeed, the spectrum of severity ranges from asymptomatic infection to rapidly progressive, fatal illness. The clinical presentation of malarial infection is also wide and influenced by age,

immune status, and pregnancy, as well as by the species, genotype, and perhaps the geographic origin of the parasite. In endemic areas, many infections present as an uncomplicated febrile illness. In more severe forms of the disease, children may present with prostration or inability to take oral fluids, or in younger children an inability to suckle. Alternatively, these children may exhibit a number of syndromes of severe disease, including anemia, coma, respiratory distress, and hypoglycemia and may also have a high rate of bacteremia.^{69,77}

In most age groups, anemia is frequently accompanied by more than one syndrome of severe disease, and the already substantial case fatality rate of 15% to 20% for severe malaria in African children rises significantly when multiple syndromes of severe disease are present.⁷⁷ The age distribution of anemia and other syndromes of severe disease is a consistent but puzzling feature of the epidemiology of clinical malaria. Children born in endemic areas are protected from severe malaria in the first 6 months of life by the passive transfer of maternal immunoglobulins and by fetal hemoglobin. Beyond infancy, the most common form of presentation of severe disease changes from anemia in children aged 1 to 3 years old, in areas of high transmission, to cerebral malaria in older children, in areas of lower transmission.⁷⁸ As transmission intensity declines further, severe malaria is most frequently found in older age groups.

The Clinical Features of Malarial Anemia

The blood stage of falciparum malaria may cause life-threatening anemia; a hemoglobin level of less than 5 g/dL is considered to represent severe disease. Children with anemia may present with malaise, fatigue, and dyspnea or respiratory distress, which usually represents metabolic acidosis, but in an ill child acute respiratory infection must be carefully excluded.^{77,79}

Acidosis is due largely to excessive lactic acid and other anions. Salicylate toxicity and dehydration may also play a role. However, the majority of children presenting with respiratory distress are severely anemic, have a metabolic acidosis secondary to reduced oxygen-carrying capacity, and respond to rapid transfusion of fresh blood (for review, see English et al.⁸⁰). A minority of those with respiratory distress do not respond to appropriate resuscitation. They probably represent a heterogeneous clinical group and may have renal failure, systemic bacterial infection, or a more profound syndrome of systemic disturbance caused by malarial parasites.

However, a large randomized trial of a bolus of fluids in the treatment of African children with shock and life-threatening infections showed somewhat surprisingly that fluid boluses significantly increased 48-hour mortality in these critically ill children with impaired perfusion.⁸¹ Fluid resuscitation must be carefully supervised, and it may be relevant that after transfusion in children with acute malarial anemia, BNP levels do fall, suggesting at the very least that cardiac function must be carefully monitored during fluid and blood therapy for acute malaria.⁸²

Hemolytic Syndromes, Including Blackwater Fever

The sudden appearance of hemoglobin in the urine, indicating severe intravascular hemolysis leading to hemoglobinemia and hemoglobinuria or blackwater fever, received particular attention in early studies of anemia in expatriates living in endemic areas. There was an association between blackwater fever and the irregular use of quinine for chemoprophylaxis. This drug can act as a hapten and stimulate production of a drug-dependent, complement-fixing antibody. Recent studies of sudden intravascular hemolysis have shown that it is rare in Africa but more common in Southeast Asia and Papua New Guinea, where some cases are associated with G6PD deficiency and treatment with a variety of drugs, including quinine, mefloquine, and artesunate.⁸³ Treatment with artesunate may be associated with sudden severe hemolysis, but it is also recognized that artesunate can cause transient and mild reduction in hemoglobin levels after the acute episode of malaria as previously infected ring-stage parasites are

cleared from the circulation. However, in the majority of cases, the cause of sudden hemolysis cannot be accounted for, and it seems likely that unidentified hemolytic mechanism(s) may operate.

The Hematologic Features of Malarial Infection

The anemia of falciparum malaria is typically normocytic and normochromic, with a notable absence of reticulocytes, although microcytosis and hypochromia may be present because of the very high frequency of α - and β -thalassemia traits and/or iron deficiency in many endemic areas.^{47,71}

The anemia of malaria may be accompanied by changes in the white cell and platelet counts and in clotting parameters, but these changes are not in themselves diagnostic, nor do they guide management. Malaria is accompanied by a modest leukocytosis, although leukopenia may also occur. Occasionally, leukemoid reactions have been observed. Leukocytosis has been associated with severe disease.^{84,85} A high neutrophil count may also suggest intercurrent bacterial infection. Monocytosis and increased numbers of circulating lymphocytes are also seen in acute infection, although the significance of these changes is not established.⁸⁶ However, malarial pigment is often seen in neutrophils and in monocytes and has been associated with severe disease and unfavorable outcome.^{87,88}

Thrombocytopenia is almost invariable in malaria and so may be helpful as a sensitive but nonspecific marker of active infection. However, severe thrombocytopenia (platelet count $<50 \times 10^9/L$) is rare. Increased removal of platelets may follow absorption of immune complexes or platelet activation, but there is no evidence for platelet-specific alloantibodies.⁸⁹ By analogy with erythropoiesis, there may be a defect in thrombopoiesis, but this has not been established. Thrombocytopenia has not generally been associated with disease severity, although a study from Papua New Guinea has shown that severe thrombocytopenia identifies both children and adults at increased risk of death from falciparum or vivax malaria, particularly in those with concurrent severe anemia.⁹⁰ Indeed, platelets have been shown to contribute to disease pathology in both animal and human malaria.⁹¹ Moreover, in human infections, platelets may form clumps with infected erythrocytes.⁹² One explanation of inconsistent relationships reported between the severity of malaria and the thrombocytopenia may be that findings of low levels of platelets might not only be a marker of parasite burden but also be protective from severe disease and/or be associated with anti-inflammatory cytokine responses.⁹³

Disordered coagulation and clinical evidence of bleeding are not infrequent in nonimmune adults contracting malaria and presenting with severe disease. Patients may present with bleeding at injection sites, gums, or epistaxis. Abnormal results of laboratory tests for hemostasis, suggesting activation of the coagulation cascade, occur in acute infection. However, histologic evidence of intravascular fibrin deposition is notably absent in adults dying as a result of severe malaria.⁹⁴ Factor XIII, normally responsible for cross-linking fibrin, is inactivated during malarial infection, and these data may explain low levels of fibrin deposition in the face of increased procoagulant activity.⁹⁵

During acute disease the levels of a disintegrin and metalloproteinase with thrombospondin motif 13 (ADAMTS13) protease are moderately reduced, and the concentration of high-molecular-weight von Willebrand multimers is increased. Such multimers may play a role in the adherence of infected RBCs and platelets to endothelium, but the role of this adhesive pathway in the etiology of severe and cerebral malaria has not been established.⁹⁶

The bone marrow is typically hypercellular. The most striking findings are of grossly abnormal development of erythroid precursors or dyserythropoiesis. The developing erythroid cells typically demonstrate cytoplasmic and nuclear bridging and irregular nuclear outline.^{39,40} These changes are probably central to the pathophysiology of malarial anemia and are discussed in detail later. The proportion of abnormal erythroid precursors and the degree of dyserythropoiesis are markedly greater in chronic compared with acute infection,

suggesting that the inhibition and abnormal maturation of erythroid precursors may have somewhat differing etiologies in acute and chronic infection.³⁹

The role of hematinic deficiency in children presenting with malaria and anemia may be difficult to assess. The relative importance of absolute and functional iron deficiency have not been defined. Iron will not be absorbed during acute infection, because hepcidin levels are raised.^{54,55} Nevertheless, many hospitals give a course of iron supplementation after an episode of acute malaria, although no general guidelines have been established. Chronic hemolysis may increase folate requirements, but frank deficiency is uncommon in children presenting with acute malaria, at least in East Africa.⁴⁷ Folate deficiency may be more common in West Africa, and protocols for folate supplementation after malaria must reflect local experience.

Malarial Anemia in Pregnancy

Pregnancy is accompanied by a series of physiologic changes that predispose not only to anemia but also to malaria. Hemodilution causes a physiologic decrease in hemoglobin. Moreover, the demand for both iron and folate increases as the fetus grows and often precipitates frank folate or iron deficiency, particularly in multigravid women.

Occult malarial infection, often without fever, may cause anemia and placental dysfunction. This effect is greatest in primigravidas and has been attributed to the adhesion of parasitized erythrocytes to chondroitin sulfate A and hyaluronic acid in the placenta^{97,98} (for review, see Rogerson et al⁹⁹). Fetal growth is impaired, and babies born to women with placental malaria are, on average, 100 g lighter than those born to women without malaria. The subsequent contribution of malaria to infant mortality is substantial.¹⁰⁰ Furthermore, the increase in hematopoiesis demanded by hemolysis during malarial infection may precipitate frank folate deficiency. Finally, women who are not immune to malaria are more likely to develop hypoglycemia and pulmonary edema during pregnancy. The increase in maternal and fetal morbidity and mortality secondary to malaria may be prevented by routine hematinic supplementation and by intermittent treatment with antimalarials during the second and third trimesters with sulfadoxine-pyrimethamine (Fansidar).¹⁰¹

Hyperreactive Malarial Splenomegaly

Although splenomegaly secondary to malarial infection usually regresses as immunity is acquired, some people living in endemic areas develop progressive, massive splenomegaly.¹⁰² The pathophysiology of such hyperreactive malarial splenomegaly (HMS) is poorly understood but certainly results in B-cell hyperplasia with high levels of polyclonal IgM, reaching a level greater than two standard deviations (SDs) above the local reference mean. The specific antimalarial antibody titer is high, although only a small proportion of the polyclonal IgM response is directed at malarial antigens. B-cell hyperplasia may provoke proliferation of both T cells and macrophages, and IgM levels may cause cryoglobulinemia and stimulate erythrophagocytosis.

Patients may present typically between 20 and 40 years old, with massive splenomegaly without lymphadenopathy, anemia that may be severe, neutropenia, and thrombocytopenia. The anemia may cause life-threatening hemolytic crises and/or neutropenia associated with severe bacterial infection. Thrombocytopenia is rarely symptomatic. The bone marrow shows hypercellularity, with a lymphocytosis in marrow and peripheral blood. The high IgM levels distinguish HMS from chronic lymphocytic leukemia or other lymphoproliferative disorders. However, the polyclonal proliferation of B cells may transform to a true clonal lymphoproliferative disorder. This appears to be derived from a naive B cell, although the exact classification of such lymphoproliferative disorders is poorly defined¹⁰³; however, there is a single report of a high incidence of B prolymphocytic leukemia in one population.

Treatment for HMS is lifelong antimalarial prophylaxis. Signs and symptoms usually subside over 1 to 2 years, but relapse may occur if antimalarial therapy ceases. Splenectomy is contraindicated because it is technically difficult, with considerable intra-operative mortality, and it may predispose to severe infection.

Anemia and *P. vivax*, *P. ovale*, and *P. malariae* Infection

In *P. vivax* and *P. ovale* malaria, high parasitemias are rare because invasion of erythrocytes is limited to reticulocytes. However, there is an emerging consensus that *P. vivax* mono-infection may cause severe disease with cerebral malaria and/or anemia (for review, see Price et al¹⁰⁴). The vivax-infected RBC can adhere to host cells, but sequestration in the peripheral circulation and organ-specific syndromes of disease are much less common than in falciparum malaria.

P. vivax malaria has been associated with anemia during pregnancy and with low birth weight of children of affected mothers. Here cytokines or other inflammatory mediators appear to cause placental dysfunction.¹⁰⁵ *P. malariae* infection is also rarely fatal but is distinguished by the persistence of blood-stage parasites for up to 40 years. It can, however, cause a progressive and fatal nephrotic syndrome.¹⁰⁶

Malaria Diagnosis

The diagnosis of malaria is based on the identification of circulating blood-stage parasites. The standard methods of preparing thick and thin films are straightforward and allow a simple method to diagnose infection (Table 158.1).^{107–109} However, malaria diagnosis poses particular problems for inexperienced staff. The main biologic problem is that the level of circulating parasites is only weakly associated with the overall parasite burden because falciparum-infected erythrocytes are sequestered in capillary venules; thus the parasitemia is not a reliable guide to the severity of disease. Second, missing or delaying the diagnosis of falciparum malaria may result in serious morbidity and mortality. Finally, the most sensitive methods for diagnosis of infection, namely microscopy, require both skill and time.

**TABLE
158.1**

Malaria Diagnosis

- Thick and thin films should be prepared for cases of suspected malaria.
- Immunochromographic tests lack sensitivity to detect low levels of parasites that may be highly clinically significant.
- Routine Giemsa or May-Grünwald-Giemsa stains are unlikely to give satisfactory results, because the pH is too low.
- Films can be stained with Giemsa or Leishman stain (thin films) or Field stain (thick films). (For details, see Bailey JW, Williams J, Bain BJ, et al: Guideline: the laboratory diagnosis of malaria. *Br J Haematol* 2013;163[5]:573. doi: 10.1111/bjh.12572.)
- Two hundred high-power fields ($\times 100$ objectives) should be examined in a thick film.
- Asexual parasitemia should be reported after counting 1000 RBCs in a thin film. A graticule or grid may help counting.
- If parasitemia is less than 1:1000 RBCs, parasitemia may be counted in a thick film in relation to the number of WBCs.
- During active infection, a daily parasite count should be obtained.
- Counting and species determination of malaria parasites should be verified by a second observer.
- Reports on negative films despite a strong clinical suspicion of malaria should be qualified that negative films do not exclude a diagnosis of malaria. Repeat films should be requested if clinically appropriate. Thrombocytopenia may heighten suspicion of malaria.

RBC, Red blood cell; WBC, white blood cell.

In endemic areas, laboratory staff are skilled at the examination of thick films and routinely are able to detect 1 parasite in 100 high-power fields of a thick film, which corresponds to a sensitivity of approximately 5 to 50 parasites/ μL .^{107,110} Thin films are used for determining the species of the parasites, and the circulating asexual forms of the four main malaria species can be readily identified, whereas the sexual forms (gametocytes) of the species require some skill and regular practice (Figs. 158.5 and 158.6).

Nevertheless, diagnosis of malaria by microscopy in nonendemic countries has proven problematic. Routine laboratories may only achieve sensitivities of the order of 500 parasites/ μL using thick films.^{110,111} Quality assurance schemes show that performance of routine hematology laboratories in the recognition of and species determination of malaria parasites is poor.^{109,111}

There has therefore been a strong drive to use nonmicroscopic methods for malaria diagnosis. It is now apparent that these methods are not sufficiently sensitive for clinical diagnosis, although they may have a role in detecting parasites of more than 500 parasites/ μL when experienced staff are not available and/or as part of an out-of-hours service. However, it must be emphasized that these tests are no substitute for careful microscopy. Operationally, this means that hematology laboratories need to make the diagnosis of malaria and

must maintain the skills needed for reliable examination of thick films.

A number of methods based on the fluorescent staining of parasite deoxyribonucleic acid (DNA) and/or ribonucleic acid (RNA) and the concentration of parasites have been devised.^{112–114} However attractive these methods may appear, their sensitivity is limited by background staining of cellular debris, and the limit of their sensitivity is approximately 100 parasites/ μL . The time taken in preparing samples and the specialized equipment and skills needed to use these methods limit their effectiveness in routine practice.

Detection of circulating malarial antigens is another potentially attractive, but ultimately limited, alternative to the laborious method of screening blood films. The widely available tests detect *Plasmodium* histidine-rich protein 2 (BinaxNOW Malaria test) and *Plasmodium*-specific lactate dehydrogenase (OptiMal-IT test) by immunochromatography.¹¹⁵ The formulation of the tests using dipstick antigens allows rapid testing to be performed by laboratory staff. However, the sensitivity is variable and may range from 100 to 1000 parasites/ μL , and this is comparable to the sensitivity achieved by inexperienced microscopists and may approach that achieved by experienced microscopists. The current recommendations for malaria diagnosis in the United Kingdom emphasize that the optimum diagnostic

Fig. 158.5 BLOOD-STAGE MALARIA (THIN BLOOD FILMS). *Plasmodium falciparum*: Fine rings (A) predominate, with mature trophozoites and schizonts (B) appearing uncommonly in the peripheral circulation because infected cells adhere to postcapillary venules. Host cells are not enlarged. Basophilic clefts and spots of irregular shape and size (Maurer clefts and dots) may be seen in erythrocytes containing more mature parasites. They are thought to be aggregates of parasite proteins that are being exported from the parasite to the surface of the red cell. Crescent-shaped male (C) and female gametocytes (D) are diagnostic. *Plasmodium vivax*: All stages of asexual parasites, from young trophozoites (E) to schizonts, appear in the peripheral circulation in vivax malaria together with gametocytes. The parasites are large and ameboid and produce schizonts with approximately 16 daughter cells (merozoites) (F). Pigment is well developed. Host red cells are enlarged and uniformly covered with fine eosinophilic stippling (Schüffner dots). Gametocytes are round, with the male (microgametocytes; G) being approximately 7 μm and the female (macrogametocytes; H) being 10 μm or more in diameter.

Continued

Fig. 158.5, cont'd *Plasmodium ovale*: Intraerythrocytic ring forms (I) have a prominent nucleus. The older parasites (J) differ from *P. vivax* in being more compact and producing about eight merozoites at schizogony. Like *P. vivax*, the host red cells contain Schüffner dots and tend to be ovoid and fimbriated. Male (microgametocytes) and female (macrogametocytes) gametocytes (K and L) are smaller than those of *P. vivax*. *Plasmodium malariae*: All intraerythrocytic stages may appear in the peripheral circulation, from young trophozoites (M) to compact schizonts with eight merozoites. Band forms (N) stretching across the red cell are common. With special staining, a very fine stippling (Ziemann dots) is sometimes seen. Host red cells are not enlarged. Gametocytes, no larger than their host cells, are round and compact with distinct blackish pigment, being finer in the males (O), in which the nucleus is more diffuse and the cytoplasm somewhat mauvish, whereas the granules are fewer and larger in the female (P), which stains a bluer color.

Fig. 158.6 BLOOD-STAGE MALARIA (THICK BLOOD FILMS). *Plasmodium falciparum*: Usually only young rings (A) are seen in acute infections, although sometimes in very large numbers. *Plasmodium vivax*: All stages may be present; here two young trophozoites are seen (B), with Schüffner dots seen as “ghost cells” in the thinner parts of the film where the host cell has been hemolyzed. *Plasmodium ovale*: The Schüffner dots of *P. ovale* also may show up in a thick film as a ghost cell, but the parasite can be distinguished from *P. vivax* by the solid appearance and heavy pigment even of young trophozoites (C). *Plasmodium malariae*: Younger parasites can be recognized by their heavy pigment, but this may be so heavy that it obscures the other inner structures. Schizonts containing up to eight merozoites with a central mass of pigment (D) are characteristic. *P. malariae* is difficult to differentiate from *P. ovale* in thick films, in which the parasites are easily confused. However, unlike *P. malariae*, *P. ovale* may be seen in ghost cells (C).

procedure is examination of thick and thin blood films by an expert to detect and speciate the malarial parasites. However, *P. falciparum* and *P. vivax* malaria can be diagnosed almost as accurately using rapid diagnostic tests (RDTs) that detect plasmodial antigens, depending upon the product. However, RDTs for other *Plasmodium* species are not as reliable.¹¹⁶

Amplification of circulating parasite DNA using the repeated ribosomal RNA (rRNA) genes is an extremely sensitive method of malaria diagnosis.¹¹⁷ The sensitivity may be as low as 0.005 parasites/ μ L or 5 parasites/mL.^{118,119} Undoubtedly, this is a useful tool for reference laboratories and epidemiologic surveys.

Treatment

Malaria requires urgent effective chemotherapy to prevent progression of disease and may be the most crucial public health intervention to reduce global mortality from malaria. The drug treatment of malaria must take account of the expected pattern of drug resistance in the area where infection was contracted, the severity of clinical disease, and the species of parasite. The spread of drug-resistant parasites and the optimal use of affordable, effective drugs are of continual concern, and these have recently been reviewed (Table 158.2).^{116,120,121}

Artemisinin-based combination treatments have been the mainstay of treatment for falciparum malaria in Southeast Asia for more than 10 years and are now recommended as first-line treatment throughout the rest of the world.¹²² However, resistance to these drugs is emerging, and very young children (particularly those underweight for age), patients with high parasitemias, and patients in very low transmission intensity areas with emerging parasite resistance are at risk for treatment failure and should be monitored closely.^{120,121} The hematologic side effects of antimalarial drugs in use today are few. Amodiaquine is associated with neutropenia and agranulocytosis. Artemisinin-based treatments may cause reticulocytopenia and hemolysis in approximately 10% to 15% patients following intravenous artesunate treatment. Hemoglobin concentrations should be checked approximately 14 days following treatment in those treated with intravenous artemisinins.¹¹⁶

In severely ill patients, good nursing care is vital. Monitoring and treatment of fits and hypoglycemia are essential, and antipyretics should be given.¹²³ Certainly, blood transfusion is in principle a straightforward solution to the treatment of severe malarial anemia, although controversy exists over the trigger for transfusion and the rate of administration of blood. The standard regimens of cautious and slow delivery of blood have been challenged by the demonstration that rapid initial flow rates may correct lactic acidosis and

TABLE 158.2 Commonly Used Antimalarial Drugs and Their Side Effects

	Oral Dose	Parenteral Dose	Side Effects
Sulfadoxine-pyrimethamine	Sulfadoxine 25 mg/kg Pyrimethamine 1.25 mg/kg as a single dose (maximum 1500 mg sulfadoxine and 75 mg pyrimethamine)	For IM injection, doses as for oral	Use with caution in first trimester Causes kernicterus in neonates Skin rashes, fatal Stevens-Johnson syndrome
Artemether	3.2 mg/kg day 1 1.6 mg/kg days 2–7	3.2 mg/kg IM day 1, then 1.6 mg/kg for 3 days, then oral	Reticulocytopenia
Artesunate	4 mg/kg once daily for 7 days	2.4 mg/kg IM day 1, then 1.2 mg/kg for 3 days, then oral	Reticulocytopenia
Artemether/lumefantrine	Fixed-dose combination: artemether (20 mg) with lumefantrine (120 mg), adults give 4 tablets initially, followed by 5 further doses of 4 tablets each given at 8, 24, 36, 48, and 60 hours (total 24 tablets over 60 hours) If 5–15 kg, then 1 tablet initially followed by 5 further doses of 1 tablet each, given at 8, 24, 36, 48, and 60 hours (total 6 tablets over 60 hours); 15–25 kg, then 2 tablets initially, followed by 5 further doses of 2 tablets each given at 8, 24, 36, 48, and 60 hours (total 12 tablets over 60 hours); body weight 25–35 kg, 3 tablets initially, followed by 5 further doses of 3 tablets each given at 8, 24, 36, 48, and 60 hours (total 18 tablets over 60 hours)		
Quinine	10 mg/kg of salt (maximum 600 mg) every 8 hours for 7 days, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 hours for 7 days [unlicensed indication]	20 mg/kg in 10 mL/kg isotonic fluid over 4 hours, then 10 mg/kg over 2 hours given every 12 hours in children and every 8 hours in adults, together with or followed by either doxycycline 200 mg once daily for 7 days or clindamycin 450 mg every 8 hours for 7 days [unlicensed indication]	Thrombocytopenia, intravascular hemolysis (blackwater fever) when used prophylactically, nausea, tinnitus, deafness

IM, Intramuscular.

hypovolemia. However, in nonimmune patients and in pregnant women, blood transfusion must be accompanied by careful hemodynamic monitoring to avoid precipitating or exacerbating pulmonary edema. A recent randomized clinical trial showed that red cell longer-storage RBC units are not inferior to shorter-storage RBC units for tissue oxygenation as measured by reduction in blood lactate levels and improvement in cerebral tissue oxygen saturation among children with severe anemia.¹²⁴

Whatever clinical guidelines emerge, in reality blood transfusion in the heartland of malaria-endemic areas is beset by many practical and theoretic problems. First, the absence of well-characterized donor panels (and thus systematic blood collection) frequently jeopardizes the supply of blood. Second, even when standard screening for human immunodeficiency virus (HIV) is in place, the residual risk for HIV transmission in the serologic window of infectivity remains at 1 in 2500 to 1 in 6000. At a practical level, positive indirect antiglobulin test results in the setting of acute infection may make the exclusion of alloantibodies difficult. Depending on the clinical urgency and transfusion history, the least serologically incompatible blood may have to be given.

One therapeutic option available in North America and in Europe for the urgent treatment of nonimmune patients with severe disease would be an exchange blood transfusion. This procedure removes nonsequestered, infected erythrocytes and possibly circulating toxins. In the absence of evidence from trials for the use of exchange transfusion in malaria, some have suggested that this treatment could be given for hyperparasitemia (>20%) in severely ill nonimmune patients.^{125,126} The salient features that make this clinical problem a major public health concern are the very large numbers of children affected and the difficulty of satisfactory treatment by blood transfusion outside specialist centers.

Malaria as a Transfusion-Transmitted Infection

Malaria is undoubtedly the most common transfusion-transmitted infection in the world. In endemic areas a large proportion of adult donors will be parasitemic, perhaps 20% to 80%, depending on the rate of transmission. Here donor deferral is impractical, and treatment of recipients with a course of effective antimalarials is the most practical alternative. In nonendemic areas, transmission of malaria is an occasional but potentially devastating complication of blood transfusion, and considerable thought and resources are required to combat the problem effectively.

The first case of transfusion-transmitted malaria (TTM) was in 1911.¹²⁷ Between 1911 and the mid-1970s the incidence of TTM rose to more than 140 cases per year, with *P. vivax* the most common species causing infection, although the proportion of cases from *P. falciparum* has steadily increased, perhaps reflecting the speed and destination of international travel. It is striking that the background problem, namely malaria in returned travelers, is much more common in the United Kingdom than in the United States, with the per capita incidence differing by nearly a factor of 10 and a higher proportion of cases from *P. falciparum* in Europe and the United Kingdom compared with the United States.¹²⁸

Recent experience in the United Kingdom and the United States has emphasized the seriousness of TTM. Two of the last five cases of malaria owing to blood transfusion in the United Kingdom were fatal.¹²⁹⁻¹³¹ In the United States, 14 cases of TTM were reported between 1990 and 1999, but only 5 cases were reported between 2000 and 2009.^{132,133} Detecting these cases after transfusion is frequently delayed because malarial infection acquired in nonendemic countries rarely figures in immediate differential diagnosis and requires careful examination of the blood film.

The mainstay of preventing TTM in the United Kingdom is donor deferral backed up by detection of circulating antibodies to malaria antigens. The guidelines for donor deferral were carefully revised after analysis of circumstances of recent TTM (Table 158.3).¹³⁴ These criteria recognize that malaria in the nonimmune patient is likely to present within 6 months of return from an endemic area

TABLE 158.3 UK Donor Selection Guidelines for Donors at Risk of Transmitting Malaria

Donor Risk Category	Guidelines
Resident	Defined as having lived in sub-Saharan Africa (except South Africa) or Papua New Guinea for a continuous period of 6 months at any time of life Permanent deferral unless malaria antibody test results are negative at least 6 months after returning from a malarious area Any subsequent visits to any malarious area each require a 6-month deferral period and negative antibody test results before reinstatement
History of malaria	Permanent deferral unless malarial antibody test results are negative at least 3 years after cessation of treatment or last negative test results
Undiagnosed febrile illness	While abroad or within 4 weeks of return Deferral for 12 months or 6 months if malarial antibody test results are negative
All other risks	Deferral for 12 months or 6 months if malarial antibody test results are negative

and that significant immunity to falciparum malaria may be acquired by residence after 6 months in a malarious area.

The criteria also require that residents, as well as those having had malaria or an undiagnosed febrile illness, may be reinstated, after six months without malaria or a fever that could have been due to malaria or three years after treatment for an episode of malaria, if antimalarial antibodies cannot be detected. The importance of anti-malarial antibody testing rests on the fact that it is a very sensitive method to detect chronic infection, whereas the identification of circulating malarial antigens or nucleic acids or microscopy would fail to detect a level of 1 parasite/mL, which would still give a highly infectious dose in a unit of blood.

The assays for antimalarial antibodies previously used indirect immunofluorescence antibody tests (IFATs) to detect reactivity to a crude parasite lysate as a target antigen. However, an enzyme-linked immunosorbent assay (ELISA) using recombinant malarial antigens has proved to be a more practical if slightly less sensitive alternative to IFATs.^{131,134,135} These tests detect antimalarial antibodies in less than 2% of donors who have visited endemic areas. It has been calculated that the return of 90% of malarial antibody-positive visitors to the donor pool releases an extra 50,000 units per year in the United Kingdom, and this is a highly cost-effective process to reduce the attrition of eligible blood donors. In the United States, over 200,000 donors per year are deferred after travel to malaria-endemic areas.

Donor deferral is based on the potential of a donor to carry malaria and is therefore based on the area of travel, length of stay or residence, elapsed time since leaving the endemic area, and history of malaria. It has been repeatedly shown that application of even the most thorough donor questionnaires allows some of those carrying malaria to give blood because guidelines are frequently incorrectly applied or questions are answered inaccurately in routine practice.^{133,136}

In Canada donors reporting diagnosis or treatment of malaria defer permanently, and in the United States donors are deferred for 3 years after treatment.¹³³ The criteria will inevitably cause unnecessary deferral of those who never actually had malaria but also permit some individuals with low-level chronic infection to donate because malaria not infrequently presents more than 3 years after travelers return from endemic areas.^{132,133} The last case of malaria transmitted in the United Kingdom was by someone who had left a malarious area 8 years previously, and the longest recorded case of recrudescence of malarial infection is 44 years for *P. malariae*.

Permanent deferral of all those visiting malaria-endemic areas is unlikely to be a viable strategy to prevent TTM because donor bases

are declining. Preventing malaria transmission through blood transfusion requires comprehensive, regularly reviewed, and effectively implemented guidelines for donor deferral and laboratory testing. Even the best strategy is a compromise, and medical laboratory staff should be aware of the rare but potentially serious possibility of fever after transfusion that could be caused by malaria.

VISCERAL LEISHMANIASIS

Leishmaniasis is a generic term for infection by 30 or so species of the obligate intracellular parasites from the genus *Leishmania*. Visceral leishmaniasis (VL), or kala-azar, presents with a wide spectrum of systemic and hematologic features.

Epidemiology

VL occurs in all countries bordering the Mediterranean Sea and across the Middle East, including Saudi Arabia and Yemen. Indian VL occurs in the eastern regions of India (particularly Assam, Bengal, Bihar, Uttar Pradesh, Tamil Nadu, and Sikkim) and in Nepal and Bangladesh. African kala-azar is endemic in Kenya, Ethiopia, and the Sudan and sporadically elsewhere in tropical Africa. In the Americas, VL occurs in foci across Mexico, Central America, Colombia, Venezuela, Guyana, Brazil, Bolivia, and northern Argentina (Fig. 158.7).

The total burden of disease is difficult to estimate but significant. Leishmaniasis burden is endemic in 88 countries, with 200,000 to 400,000 new cases of VL per year, with the vast majority occurring in India, Bangladesh, Nepal, Northern Sudan, and northeastern Brazil.¹³⁷ VL is associated with poverty and undernutrition in endemic areas, particularly in the hyperendemic foci of the southern part of the Sudan and the Ganges river basin. In the Mediterranean area, it

is increasingly seen in association with HIV infection, where infection rates in HIV-infected people may be as high as 10%.

VL is caused by a number of species of the *Leishmania donovani* complex.^{138,139} In the Mediterranean region and areas in the Middle East and Central Asia through to China, *Leishmania infantum* predominates, whereas *L. donovani* is more prevalent in India. *Leishmania tropica* is a less common cause of VL in these areas. Throughout their range in the Old World, parasites are transmitted by the female sandfly of the *Phlebotomus* genus. Leishmaniasis is caused by different parasites and vectors in the New World, where *Leishmania chagasi* and *Leishmania amazonensis* are transmitted by the *Lutzomyia* genus of sandfly.

Leishmania organisms are present in blood, and so the disease can be transmitted by blood transfusion, as a sexually transmitted disease, as a congenital infection, by needle sharing for intravenous drug abuse, or within a laboratory by intradermal inoculation of *L. donovani* promastigotes.^{140,141} Very few cases of leishmaniasis have occurred as transfusion-transmitted infections in Europe or North America, with under 10 cases in infants or immunocompromised patients reported over the last 50 years. In endemic areas, this problem represents a much greater but unquantified risk.

Parasitology

Leishmania amastigotes live and multiply within macrophages by binary fission. They are round or ovoid bodies, approximately 2 to 3 μm in diameter. Occasional rupture of cells allows invasion of uninfected monocytes and macrophages by free forms. Sandflies ingest amastigotes within macrophages from blood or skin. In the insect's stomach, free amastigotes multiply and divide asexually, becoming elongated and developing flagella as metacyclic promastigotes. Within 2 weeks, such infective forms migrate through the

Fig. 158.7 EPIDEMIOLOGY OF VISCERAL LEISHMANIASIS (VL). VL caused by parasites of the *Leishmania donovani*–*Leishmania infantum* complex occurs in the Mediterranean littorals, the Middle East, and adjacent parts of the former Soviet Union, the Sudan, East Africa, the Indian subcontinent and China, and South America (*Leishmania chagasi*). An arid, warm environment provides ideal ecologic conditions for the breeding of many species of sandfly. Zoonotic kala-azar from *L. infantum* and *L. chagasi* is commonly associated with dry, rocky, hill country, where cases are typically scattered. In India, *L. donovani* is essentially an anthroponosis. This type of kala-azar may occur in severe epidemic fashion, as can kala-azar in the Sudan.

lining of the stomach and enter the proboscis of the sandfly, allowing them to be inoculated in the human host while the sandfly takes a blood meal. Promastigotes are taken up by macrophages, where they become amastigotes by simple fission.

The large, elongated, fusiform promastigote measures 15 to 20 μm in length and 0.5 to 3.5 μm in width. Cultured promastigotes may also demonstrate rounded forms 4 to 5 μm in diameter. In Giemsa or other Romanowsky stains, a large nucleus and smaller, distinct rodlike kinetoplast are obvious. The organisms must be distinguished from *Histoplasma capsulatum*.

Pathology

Parasites spread within macrophages to local lymph nodes and then to the liver, spleen, and bone marrow. They are also present more widely, in particular in the gastrointestinal tract and epidermis. In the subclinical cases, a cellularly mediated immune response causes a granulomatous lesion and resolution of the infection. However, in clinical VL little if any inflammatory response to the rapidly extensive and expanding parasite-laden macrophages is seen. Where it shows, a granuloma develops at the site of the initial inoculation but may not be apparent at the time of presentation.

Clinical Features of Visceral Leishmaniasis

The spectrum of clinical disease is wide, ranging from asymptomatic infection to acute or chronic illness. Perhaps only 1% to 3% of all infections are symptomatic, with an incubation period of 10 days to 10 years but typically between 3 and 6 months.

The high number of seropositive individuals in relation to clinical cases suggests that spontaneous cure without symptoms or with mild systemic symptoms and hepatosplenomegaly occurs in the majority of individuals. In a large series of children with VL in Brazil, the overall case fatality rate was 10%, and mucosal bleeding, jaundice, dyspnea, bacterial infections, and low neutrophil count of less than 500/mm³ or low platelet count of less than 50,000/mm³ were associated with a poor outcome.¹⁴²

In endemic areas, a significant number of seropositive children, who do not develop classic VL, have a subclinical form of disease with malaise, fever, poor weight gain, intermittent cough, diarrhea, hepatomegaly, and variable splenomegaly. In these cases, leishmania were neither cultured nor seen in bone marrow aspirates.¹⁴³ There are also reports of VL presenting as mild, nonspecific illness with fever, fatigue, cough, and abdominal pain in army personnel returning from the Middle East. In these cases, *L. tropica* was isolated from bone marrow or lymph nodes.¹⁴⁴

Patients with typical chronic VL often present with malaise and considerable fatigue and the slow onset of low-grade fever, anorexia, and weight loss. They usually have anemia, progressive and occasionally massive splenomegaly, hepatomegaly, lymphadenopathy, and hypergammaglobulinemia, with increasing skin pigmentation (hence the name *kala-azar* from the Hindi for "black sickness"). Patients may have jaundice, petechia, or purpura; heart murmurs; and edema. The size of the spleen is related to the length of infection and severity of the pancytopenia. In Africa, patients may have diffuse polymorphic papular lesions at presentation. Oral, nasal, nasopharyngeal, and laryngeal ulcers may occur during active disease or after treatment. The large spleen, often extending to the right iliac fossa, may be painful. Other features of acute disease include cough, epistaxis, and in some severe cases concurrent infection of the respiratory or gastrointestinal tracts and/or tuberculosis.

The typical features of VL may be preceded by bacteremia, bacterial infection, acute hepatitis, or Guillain-Barré syndrome. VL may be associated with hepatic necrosis, cholecystitis, or neuropathy. Occasionally, lymphadenopathy may occur without systemic features of the disease. Here histology shows noncaseating granulomas and amastigotes within macrophages. A more acute presentation in recent immigrants and visitors to endemic areas may include a high periodic

fever similar to classic malaria, with malnutrition, bleeding, hepatitis, and/or acute renal failure.

Immunocompromised Hosts

Coinfection with HIV and VL is now a well-recognized clinical entity in the Mediterranean region and undoubtedly occurs more widely^{145–147} (for review, see Lindoso et al¹⁴⁸ and Alvar et al¹⁴⁹). VL occurs in the setting of late-stage acquired immunodeficiency syndrome (AIDS) with CD4⁺ lymphocyte counts of less than 200 $\times 10^6/\text{L}$. Patients present with fever, splenomegaly, and pancytopenia with frequent and sometimes atypical involvement of the gastrointestinal and respiratory systems and skin. The typical hematologic features of VL are sometimes absent, and serologic tests are often negative, although antibodies to 14- and 16-kDa *Leishmania* antigens may be detected by Western blot analysis.¹⁵⁰ However, organisms are plentiful in bone marrow and even in buffy coat preparations. Some patients may have few symptoms, and the diagnosis of VL in immunocompromised patients requires a high index of suspicion. Treatment is difficult, with poor responses to pentavalent antimony. Liposomal amphotericin is the drug of choice. However, relapses are usual, and maintenance treatment is required.¹⁴⁸

VL may also occur after transplant and after immunosuppressive treatments, including chemotherapy, rituximab, or other immunodeficiency states.^{151,152} Although patients present with a typical combination of fever, pancytopenia, and splenomegaly, the diagnosis may be missed if not considered.

Hematologic Features

VL causes a moderate normocytic, normochromic anemia.¹⁵³ The pathogenesis of anemia is multifactorial and includes hemodilution, shortened RBC survival, and reduced erythropoiesis.¹⁵⁴ The plasma is low, with plentiful stored iron typical of the anemia of chronic disease.¹⁵⁵ One report has suggested that Epo levels are reduced compared with what would be expected for the degree of anemia.¹⁵⁶ Occasionally, folate deficiency secondary to malabsorption and/or increased cell turnover or coexistent iron deficiency are associated with macrocytic or microcytic anemia, respectively.¹⁵⁷

The direct Coombs test results are usually positive for C3 components, and IgG and anti-I agglutinins may be present, but the presence and strength of the test is not correlated with the severity of the anemia. The positive direct Coombs test results appear to be caused by absorbed immune complexes onto erythrocytes.¹⁵⁸ The neutrophil survival is reduced, and the differential white blood cell count shows neutropenia, relative lymphocytosis, and low eosinophil levels, with a white blood cell count typically in the range 2 to 4 $\times 10^9/\text{L}$.

Neutrophil function may be impaired.¹⁵⁹ Pancytopenia is more severe in those with concurrent HIV infection. A leukemoid reaction to infection has been reported.

Typically the platelet count is reduced to 50 to 200 $\times 10^9/\text{L}$ as platelet survival is reduced. Mucosal bleeding may occur, but extensive purpura is uncommon.

The prothrombin time is usually mildly prolonged to 2 to 4 seconds longer than in control subjects, secondary to impaired liver function. Fibrinolytic activity is increased, and in advanced cases, fibrinogen levels may be reduced. Disseminated intravascular coagulation or vasculitis may occur.^{153,159} Full coagulation screening is advisable if a splenic aspirate or bone marrow biopsy is planned.

The bone marrow is usually hypercellular, with increased erythroid, myeloid, and platelet precursors. Lymphocytes may be increased, and macrophages contain Leishman-Donovan bodies (Fig. 158.8).¹⁶⁰ If weight loss and malabsorption are extensive, the marrow may undergo gelatinous transformation.

The mechanisms of leukopenia and thrombocytopenia are multifactorial. There is evidence for reduced bone marrow production of granulocytes and platelets and also for their autoimmune destruction

Fig. 158.8 *LEISHMANIA INFANTUM* IN MACROPHAGE FROM BONE MARROW. Although typically found in macrophages as shown here, isolated extracellular amastigotes from disrupted host cells are commonly seen in such preparations.

and/or increased splenic clearance. After treatment, hematologic recovery is slow, and full recovery may take many months.¹⁵⁵

Laboratory Features

The epidemiologic context and clinical features can suggest a diagnosis of leishmaniasis. Hematologic and biochemical tests are non-specific; biochemical tests may show mild elevation of bilirubin and transaminase levels and more commonly a raised level of alkaline phosphatase. Previously the nonspecific formol-gel test was used to indicate hypergammaglobulinemia. Diagnosis is confirmed by direct examination of parasites by microscopy, culture, or polymerase chain reaction (PCR) (for detailed review, see Boelaert et al¹⁶¹ and Srividya et al¹⁶²).

Morphology

The pathognomic amastigotes of *Leishmania* spp. can be found in a variety of sources. The diagnosis is often made by splenic puncture or by bone marrow aspiration where large numbers of amastigotes may be seen within macrophages. Amastigotes are stained using Giemsa or other Romanowsky stains and demonstrate a purple nucleus and the large anterior kinetoplast (see Fig. 158.8).

In nonimmunocompromised patients with VL, splenic aspirates are positive in more than 95%, bone marrow aspirates positive in more than 85%, buffy coat macrophages positive in more than 70%, and lymph nodes positive in more than 60%. In practice, samples are taken from the least invasive sites first, although lymphadenopathy is not invariable.

Where coinfection of HIV and leishmania occurs, amastigotes are more reliably found in bone marrow than in peripheral blood and may also be demonstrated in biopsy specimens from a wide variety of sites. Biopsy material can be stained with polyclonal anti-*Leishmania* serum and indirect immunofluorescence. However, direct demonstration of parasites is less sensitive than culture or PCR.

Splenic Aspiration

Splenic aspiration is rarely performed in North America and Europe but is a common diagnostic procedure in endemic areas. Aspiration is contraindicated in the presence of a bleeding tendency, portal hypertension, or a splenic hydatid cyst. Splenic aspirates are obtained from the middle of the long axis of the spleen. After the skin is cleaned, a 21-gauge needle attached to a 5-mL syringe is inserted subcutaneously in line with the long axis of the spleen. The needle

should be swiftly inserted to a depth of approximately 2 or 3 cm at an angle of roughly 45 degrees to the skin, applying negative pressure. The needle should be withdrawn immediately while maintaining negative pressure and taking only a few seconds for the entire procedure. The splenic tissue may be expelled from the needle using a small amount of air and by fixing the stain using standard procedures.

Culture

Amastigotes may be grown as motile promastigotes from aspirates on the classic Novy-MacNeal-Nicolle (NNN) medium or other suitable media at 22°C to 24°C, and populations double only every 2 to 3 days.^{163,164} Inoculation of material into the susceptible golden hamster is no longer used to grow parasites.

Molecular Methods

The PCR may detect low levels of infection and has been used for diagnosis and monitoring of treatment as well as to determine the genotype of the parasites.^{165,166} Blood from filter paper can be used to prepare DNA, but as for direct morphology, PCR from bone marrow samples is a more sensitive method to demonstrate parasites.¹⁶⁷ It may be particularly useful for monitoring treatment and relapse in HIV- and *Leishmania*-infected patients.¹⁶⁷ Isothermal DNA amplification methods are being applied to develop tests to be used where sophisticated equipment is not available.¹⁶⁸

Serologic Tests

Serologic tests have to be interpreted in light of the clinical findings. The tests are useful to screen suspected cases or populations for VL. However, they are unreliable in immunocompromised patients, who frequently are seronegative in spite of patent infection. Conversely, those harboring a subclinical infection may be seropositive, but samples may fail to yield evidence of parasites. Finally, serologic findings are positive many years after treatment or self-cure.

An indirect IFAT or ELISA using freeze-dried *Leishmania* antigen has sensitivity and specificity greater than 95%. A DAT is also available with purified, freeze-dried antigen and is a highly sensitive and specific test.¹⁶⁹ The freeze-dried antigen is very stable even when stored in extreme conditions.

The ELISA and immunochromatographic tests using *Leishmania* recombinant K39 antigen are 100% sensitive and more than 98% specific in Asia.^{170,171} The sensitivity and specificity of the DAT and K39 immunochromatographic test are broadly similar, although the K39 test was less sensitive in the Sudan than in Asia.^{161,172} An alternative target antigen for serologic tests such as recombinant K28 and a rapid point-of-care test are now being developed.²¹

Treatment in patients without HIV coinfection may be monitored using urine antigen tests for detection of the K39 and K26 *Leishmania* antigens. These test results become negative 3 weeks after commencing treatment.

Management

General supportive care is important and includes correction of nutritional and hematinic deficiencies, blood transfusion in severe anemia, and antibiotics for secondary infections (for review of diagnosis, therapy, and management, see report from the World Health Organization¹⁷³).

Specific chemotherapy for VL uses a number of potentially toxic drugs. Intercurrent infections must be identified and treated, and general measures include improvement of nutritional status (for review of treatment, see Sundar et al¹⁷⁴ and Copeland et al¹⁷⁵). Use of pentavalent antimonials, including sodium stibogluconate (Pentostam) and meglumine antimonate (Glucantime) are now limited,

especially in South Asia, by increasing drug resistance. There is concern that drug resistance will develop to the alternative therapies, and combination treatment aiming at short courses that also delay the development of drug resistance are in progress.⁵³

Amphotericin B is effective against *Leishmania* and is used in endemic areas where high levels of resistance to pentavalent antimonials are present. It may be given as a slow intravenous infusion in 5% dextrose over 4 to 6 hours, beginning at 250 µg/kg/day, increasing to 1 mg/kg/day until a total dose of 20 mg/kg/day has been given. Side effects include anaphylaxis, anemia, fever, bone chills, bone pain, and thrombophlebitis. Hypokalemia and hypomagnesemia are significant problems, and potassium loss and supplementation may be reduced by the concurrent use of amiloride to prevent renal tubular potassium leakage.¹⁷⁶

Reduced toxicity from amphotericin is achieved using a liposomal amphotericin preparation (AmBisome), which has been made more widely available through preferential pricing in endemic areas. It is an effective and safe treatment and is used when affordable. A test dose of 1 mg should be given, and then the recommended dose is 1–3 mg/kg daily for 10–21 days to a cumulative dose of 21–30 mg/kg, alternatively 3 mg/kg for 5 consecutive days, followed by 3 mg/kg after 6 days for 1 dose. In patients with HIV, a dose of liposomal amphotericin at 4 mg/kg/day on days 1 to 5 followed by 4 mg/kg/day on days 10, 17, 24, 31, and 38 is recommended. The relapse rate is high, and close monitoring of patients is required.

Miltefosine is a new drug and effective orally against VL in India and Africa.^{177,178} The current regime is 2.5 mg/kg/day for adults and children older than 2 years for 4 weeks. Higher than 95% cure rates have been achieved. Gastrointestinal upset occurs frequently. Miltefosine is teratogenic and may reduce fertility. It has a long half-life and has a low therapeutic index, which may contribute to the development of resistance, and so combination chemotherapy is being investigated to combat development of resistance.

Intramuscular paromomycin has been used at a dose of 20 mg/kg/day for 21 days. It has been shown to be equivalent to amphotericin B for the treatment of VL in India.¹⁷⁹ Moreover, patients treated for VL in Africa with sodium stibogluconate and paromomycin have an improved outcome compared with therapy with sodium stibogluconate alone.¹⁸⁰

Post-kala-azar dermal leishmaniasis may occur in up to 10% of patients after treatment for VL. It is seen mainly in India and is common in Africa. It occurs after treatment of VL and may appear up to 10 years after treatment. It presents as a maculopapular rash spreading around the mouth, trunk, and limbs. These nodules and papules contain amastigotes. Prolonged treatment may be required to eliminate infection.

Leishmaniasis as a Transfusion-Transmitted Infection

Leishmaniasis poses problems as a potential transfusion-transmitted infection in endemic areas. The disease can be transmitted by blood and platelet concentrates, although leukodepletion by filtration reduces organisms by many orders of magnitude and so probably also the risk for transmission. In Europe, given the low absolute risk for transmission, donor deferral is used to reduce the risk for donation by anyone who is parasitemic.¹⁸¹ However, surveys of blood donors in areas where the parasite is transmitted suggest parasite DNA can be detected in 0.3% to 1.75% of blood donors. It has been noted that service personnel returning from the Middle East represent a group of potential donors who may have been exposed to infection.¹⁸²

AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is caused by the flagellate protozoa *Trypanosoma brucei* spp., named after David Bruce, a Scottish parasitologist

who first demonstrated the parasite in the blood of cattle affected by nagana. In humans, Aldo Castellani demonstrated trypanosomes in the cerebrospinal fluid (CSF) of patients with sleeping sickness. Bruce was able to show the protozoa in blood and demonstrated that they were transmitted from antelopes to cattle by the tsetse fly and blood of patients with sleeping sickness.

Epidemiology

Trypanosomes are transmitted by some species of the large and distinctive tsetse flies (*Glossina* spp.) in a sporadic distribution south of the Sahara and north of the Zambezi River. Of the three subspecies, *Trypanosoma brucei brucei* infects animals, whereas *Trypanosoma brucei gambiense* causes infection and sleeping sickness in Central and West Africa, and *Trypanosoma brucei rhodesiense* causes disease in East and Central Africa. *T. b. gambiense* is transmitted mainly between humans by the *Glossina palpalis* group in foci along watercourses in West and Central Africa. *T. b. rhodesiense* is transmitted by the *Glossina morsitans* groups widely distributed in the East African savannah. Here the disease is clearly a zoonosis, with antelopes and domestic cattle as reservoir hosts; it afflicts mainly hunters, guides, and game wardens and may occasionally occur in tourists on safari in the game parks of East Africa (Fig. 158.9).

Historically the disease has caused major epidemics, causing hundreds of thousands of deaths, and has prevented human settlement in large areas of Africa. Over 50 million people are now at risk for trypanosomiasis, and it has been estimated that the disease causes over 50,000 deaths each year. Most cases are reported in the Democratic Republic of the Congo and northwestern Uganda, with a few hundred or fewer each year reported in neighboring East African countries.

Case-finding and control measures have substantially reduced the risk for epidemics. Epidemics of disease have been associated with a breakdown in health services, for example, in villages in the areas of Lake Victoria in Uganda and more recently in the Democratic Republic of the Congo, Angola, and southern Sudan (for review of current epidemiologic and clinical aspects of this disease, see Simarro et al,¹⁸³ Brun et al,¹⁸⁴ and Franco et al¹⁸⁵).

Parasitology

The small, mobile trypomastigotes circulate and may be seen in peripheral blood. These flattened, fusiform organisms are pleomorphic but are typically of a size similar to a red blood cell, approximately 20 µm long, and have an undulating membrane, attached to the protruding flagellum, extending from the anterior pole of the elongated body (Fig. 158.10). Parasites multiply by binary fission and may cause chronic parasitemia and evade humoral immune responses by clonal antigenic variations of the major surface glycoprotein.¹⁸⁶

When trypomastigotes are taken up in a blood meal by the tsetse fly, they multiply in the midgut by simple fission. Later they penetrate the wall of the gut and migrate to the salivary glands. There, as morphologically distinct epimastigotes, they become infective (or metacyclic) trypomastigotes 15 to 30 days after first infecting the fly. In endemic areas, up to 1% to 5% of flies may be infected. Flies remain infective until they die, several months later.

Pathology

The lymphatic, cardiac, and central nervous systems are involved by the disease. Initially, proliferation of trypanosomes within lymph nodes and the spleen is accompanied by expansion of the lymphocytes, macrophages, and erythrophagocytosis. Polyclonal activation of lymphocytes results in high production of IgM and rheumatoid factor, and anti-DNA antibodies may appear. Later fibrosis and endarteritis supervenes with proliferation of endothelial cells and perivascular infiltration of plasma cells and lymphocytes. The liver

Fig. 158.9 DISTRIBUTION OF *TRYPANOSOMA BRUCEI* INFECTION IN HUMANS. African trypanosomiasis is confined to equatorial Africa, with a patchy distribution depending on detailed topographic conditions. It is caused by two subspecies of *T. brucei*: *T. b. gambiense* infection is widespread in West and Central Africa, transmitted mainly by riverine species of tsetse fly (*Glossina*), but *T. b. rhodesiense*, transmitted mostly by savannah species, is restricted to the eastern and east-central areas of Africa, with some overlap between the two. Although domestic pigs form an important reservoir for *T. b. gambiense* infection, various wild ruminants are the major sources for *T. b. rhodesiense*. The epidemic reemergence of African trypanosomiasis in recent years is exemplified by the death of at least 96 people in Angola in 2003, when 3115 cases were confirmed among a suspected 270,000 new cases in that country. In the same year it was estimated that some 500,000 people across Africa had trypanosomiasis, which was likely to have a mortality rate of approximately 80%. Recent reports indicate a spread of transmission from the northern toward the southern parts of Angola. (Modified from World Health Organization Map No. 98005.)

Fig. 158.10 ORIGINAL MICRO-PHOTOGRAPH OF *TRYPANOSOMA (TRYPANOZOON) BRUCEI GAMBIESE* IN HUMAN BLOOD BY J. EVERETT DUTTON. Polymorphic trypanosomes were first discovered more than a century ago, in 1895, by David Bruce in the blood of domestic cattle with the wasting disease nagana in South Africa. The first observation of these protozoa in humans was made by R. M. Forde, who noted, in 1902, “small worm-like, extremely active bodies” in the blood of a sick European seaman in The Gambia. The parasites seen here in a Romanowsky-stained thin blood film, which were described and named by Dutton in 1902, are responsible for sleeping sickness in West Africa. (Reproduced by kind permission of the Director, Liverpool School of Tropical Medicine.)

shows infiltration of the portal tracts and fatty degeneration. In *T. b. rhodesiense*, cardiac involvement may be extensive, with endocarditis, myocarditis, and pericarditis leading to extensive damage and death.

In the second stage of the disease, trypanosomes multiply within the central nervous system (CNS) and cause a chronic meningoencephalitis. Edema, hemorrhages, granulomatous lesions, and thrombosis contribute to cerebral degeneration. Lymphocytosis and plasma cells with large eosinophilic inclusions (Mott cells) may be found in the CNS.

Intriguingly, nonpathogenic species of African trypanosomes may be killed by the human high-density lipoprotein particles astonishingly subverting a parasite pathway for heme uptake. The complex of haptoglobin-related protein and apolipoprotein L1 (ApoL1) are taken up into the parasite by a parasite glycoprotein receptor, which binds the haptoglobin-hemoglobin complex.^{187–190} *T. b. rhodesiense* is resistant to killing by human sera because the ApoL1, which induces parasite apoptosis, is neutralized in the lysosome by serum resistance-associated protein, which binds to a specific ApoL1 domain. The selection of trypanolytic ApoL1 variants have a cost. In African Americans, focal segmental glomerulosclerosis and hypertension-attributed end-stage kidney disease are associated with two independent sequence variants in the *APOL1* gene.¹⁹¹

Clinical Features

T. brucei gambiense

Local inflammation at the site of inoculation causes a distinctive chancre or painful, indurated ulcer appearing 2 to 3 days after an infective bite and lasting for up to 1 month. Trypanosomes multiply in the lymphatic system for 6 to 14 days before causing patent infection in the blood, characterized by waves of parasitemia and fever. Later, invasion of the CNS may occur by transit of organisms through the choroid plexus and/or endothelial cells.

In the blood stage of infection, fever, headache, and arthralgia are prominent. Lymphadenopathy is common, particularly in the posterior triangle of the neck (Winterbottom sign). There may be

intermittent rashes (often circinate erythema), pruritus, or edema. Moderate splenomegaly occurs in 10% to 20% of patients. A few infected patients are asymptomatic.

This early stage of infection may last for up to 2 years or more before CNS involvement, although rapidly progressive disease may occur. The CNS phase of disease is marked by the progressive onset of headache; disinhibited behavior changes; and mood, thought, and sleep disturbances. Wasting is prominent. Signs of diffuse CNS damage in the last phases of the disease include dementia, extrapyramidal and cerebellar dysfunction, and hyperesthesia. Tendon reflexes are increased, and signs of upper motor neuron lesions are widespread. Death usually occurs by intercurrent infection.

T. b. rhodesiense

T. b. rhodesiense is more virulent, causing a more serious acute disease, with systemic features including serous effusions; hepatocellular jaundice; and a mild, normocytic, normochromic anemia. Hepatosplenomegaly and lymphadenopathy are common, but involvement of cervical lymph nodes is less typical. Myocarditis is rare but may cause death before CNS involvement. Here CNS disease occurs sooner and is more rapidly progressive than *T. b. gambiense* infection and is fatal within 1 to 3 months.

Infection with *T. b. gambiense* may resolve in the vast majority of cases. Where infection persists, there is typically a long asymptomatic phase. Numerous lymph nodes are enlarged to 1 to 2 cm in diameter and are soft, mobile, and painless.

The differential diagnosis of trypanosomiasis includes malaria, typhoid, fever, and viral hepatitis in the acute phase, whereas lymphadenopathy may suggest infectious mononucleosis or tuberculosis. In the cerebral phase of the disease, syphilis, tuberculosis, HIV-associated cryptococcal meningitis, or chronic viral encephalitis must be considered.

Children

Those affected in utero may be born with CNS abnormalities. In children the disease is more rapidly progressive, and epileptic seizures and psychomotor retardation are the principal features of the disease.

HIV

The frequency of HIV seropositivity has been reported to show no significant differences between those presenting with trypanosomiasis and age-matched control subjects.^{192,193} These results do not exclude the possibility that coinfections may modulate the course of the disease or the effectiveness of treatment.

Hematologic and Laboratory Features

The main hematologic features are a normocytic, normochromic anemia and moderate thrombocytopenia.¹⁹⁴ The anemia of trypanosomiasis is multifactorial. Hemodilution, hemolysis, and dyserythropoiesis or ineffective erythropoiesis all contribute to the pathogenesis. Hemolysis may be caused directly by lytic factors released by trypanosomes or indirectly by deposition of immune complexes and subsequent clearance of coated erythrocytes. In vitro studies have suggested that the variant surface glycoprotein from trypanosomes may be shed and taken up onto the erythrocyte membrane, where antibody and complement deposition could contribute to hemolysis. Bone marrow response is inadequate, and although the nature of the defect is unclear, there is failure in incorporation of iron into erythroid precursors, as is seen in many forms of the anemia of chronic disease. In mice infected with human trypanosomiasis, TNF- α contributes to bone marrow suppression, but detailed studies of the pathogenesis of anemia in human infections have not been reported. Serum IgM

levels may be elevated to four times normal and with raised IgG levels may cause an increased erythrocyte sedimentation rate.

The white blood cell count may be elevated with monocytosis, lymphocytosis, and circulating plasma cells, but eosinophilia is absent. Plasma cells with eosinophilic inclusion or Mott morular cells may occasionally be seen.

Petechia and purpura may be secondary to vascular injury, thrombocytopenia, and a complex but poorly defined coagulopathy. Abnormal liver function may cause prolonged clotting times. Functionally, both thrombosis and fibrinolysis are increased, and fibrin degradation products (D-dimers) are raised in acute disease; in *T. b. rhodesiense*, a frank disseminated intravascular coagulation may become evident.¹⁹⁵

Examination of the bone marrow shows hypercellularity. Gelatinous degeneration may be seen in patients with wasting.

Mononuclear cells are present late in the disease, and the cell count corresponds to the degree of neurologic involvement and may reach more than 300/ μ L in severely ill patients. The CSF protein levels are elevated (0.4 to 1.0 g/L).

As disease progresses, the circulating parasites become scarce. However, anemia and endocrine dysfunction, including amenorrhea, reduced libido, and impotence becomes apparent.

Parasitologic Assays

Direct detection of the parasite is particularly important in light of the toxicity of the treatment. Trypanosomes may be detected in lymph node aspirates and in wet and thick blood smears (Fig. 158.11). An aspirate may be taken from enlarged nodes. Aspirated fluid can be examined under a coverslip, and motile trypanosomes are typically seen at the edges of the coverslip.

Trypanosomes can be seen in wet smears, where a drop of blood is placed on a slide and examined under a coverslip. Alternatively, thick

Fig. 158.11 *TRYPANOSOMA BRUCEI RHODESIENSE* IN HUMAN BLOOD. *T. brucei brucei* parasitizes wild and domestic animals but does not infect humans. The different subspecies can be distinguished with certainty only by biochemical techniques, such as electrophoretic typing of their isoenzymes or by the use of DNA probes. *T. brucei gambiense* and *T. b. rhodesiense* (and *T. b. brucei* of animals) are virtually indistinguishable in blood films. Note the small kinetoplast and free flagellum. Both subspecies from humans will infect guinea pigs, but only *T. b. rhodesiense* is infective to rats, in which the parasites are polymorphic—that is, long, thin, intermediate, and short, stumpy forms of trypomastigotes may coincide.

or thin Giemsa-stained blood films are made as for malaria diagnosis. The sensitivity may be increased by microcentrifugation.¹⁹⁶

More recent methods used to detect the low levels of parasitemia seen in *T. b. gambiense* include quantitative examination of the buffy coat using acridine orange¹⁹⁷ and small-scale ion-anion exchange chromatography.¹⁹⁸ Erythrocytes are retained in the column, whereas trypanosomes are eluted and are visible after concentration by centrifugation. The sensitivity of detection with these methods ranges from 10⁴/mL for wet smears to 10²/mL for ion-exchange columns and centrifugation. In *T. b. rhodesiense*, examination of the blood is more likely than aspiration of lymph nodes to yield a positive result.

Inoculation of the aspirate or samples into susceptible animals or in vitro culture has been used to detect low-level parasitemia. Mice and rats were used to detect *T. b. rhodesiense*, whereas the multimammate rat (*Mastomys natalensis*) and guinea pigs were used for *T. b. gambiense*. PCR of the 18S rRNA gene can detect parasites with sensitivity similar to that of parasitologic and serologic methods.¹⁹⁹

Cerebrospinal Fluid

Trypanosomes may be found in the CSF as disease progresses, although a double-centrifugation technique may be required to demonstrate organisms. In this technique, 5 to 10 mL of CSF is centrifuged, and the sediment is taken up into a capillary tube and recentrifuged before the capillary tube is examined under a coverslip (Fig. 158.12).²⁰⁰ Specific molecular markers for this stage of CNS disease are being sought by proteomic analysis of the CSF.

Serology

Serologic tests are used for passive population screening in control programs (for review, see Chappuis et al.²⁰¹). A Card Agglutination Test for Trypanosomiasis (CATT) is robust and can be used without extensive laboratory facilities.^{202,203} The test contains freeze-dried trypanosomes with the LiTat 1.3 variant antigens and can be obtained from the Institute of Tropical Medicine Antwerp (www.itg.be). It is quite sensitive (>95%), but it lacks specificity owing to cross-reactivities with animal *Trypanosoma* spp. Although useful as a patient screening test in a hospital for suspected cases of trypanosomiasis, the predictive value for positive test results falls when screening populations for active cases. It has nevertheless been reported to double the number of active cases found. Some patients may have false-negative results for this test if they are infected by parasites that do not express

this variant antigen. Further versions of this assay have been developed to use dried blood on filter paper, namely the micro-CATT and macro-CATT, but these are less sensitive than the whole-blood assay.

In *T. b. gambiense*, serologic tests are not widely available, and direct examination of blood and CSF for parasites is the first line of investigation. The card indirect agglutination trypanosomiasis test (TrypTect CIATT) can detect circulating antigens in *T. b. gambiense* and *T. b. rhodesiense* infection by latex agglutination. The sensitivities of the test are 95.8% for *T. b. gambiense* and 97.7% for *T. b. rhodesiense*, and therefore significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single- and double-centrifugation.²⁰⁴

A rapid latex agglutination test (LATEX/*T. b. gambiense*) contains a mixture of three variable surface antigens of the bloodstream form of trypanosomes and has been used to detect antibodies in patients infected with *T. b. gambiense*. At 1:16 serum dilution, test specificity was 99%, whereas sensitivity ranged from 83.8% to 100%, depending on the geographic origin of the samples. The test sensitivity falls to 66% for CSF samples from second-stage patients.²⁰⁵ A rapid latex agglutination test, LATEX/IgM, for the semiquantitative detection of IgM in CSF is available.²⁰⁶ Finally, immunofluorescence assays and ELISA tests for antibodies using whole parasites are highly sensitive and specific, although they are less practical for mass screening. A series of new approaches is being evaluated for control and elimination of trypanosomiasis, including tiny targets for tsetse fly control, use of RDTs, and oral treatment with fexinidazole or oxaboroles.²⁰⁷

Treatment

Treatment of trypanosomiasis depends on the subspecies of trypanosome present. The drugs may be difficult to source and are toxic, so treatment requires expert help.

Early-stage *T. b. gambiense* may be treated with pentamidine for 14 days (intravenously or more usually intramuscularly, 4 mg/kg/day). Hematologic side effects include neutropenia, and more general side effects include hypotension, hypercalcemia, hyperkalemia, renal failure, and hyperglycemia. Pentamidine will not cure CNS disease, and so examination of the CSF is required after initial treatment of the blood-stage disease.

Eflornithine (α -difluoromethylornithine) for 14 days (IV; 100 mg/kg every 6 hours) is effective for CNS treatment for *T. b. gambiense*.²⁰⁸ It is a toxic drug suppressing DNA replication by inhibition of ornithine decarboxylase and thus polyamine synthesis and DNA replication. It causes dose-dependent bone marrow suppression with anemia, neutropenia, and thrombocytopenia in the majority of patients. The effects are reversible and are rarely dose limiting. It is effective neither in children nor in patients with coinfection with HIV, where melarsoprol is required.

Melarsoprol is a trivalent organic arsenical compound and is more toxic but cheaper than eflornithine. It is used in Africa for the treatment of late-stage CNS trypanosomiasis. It is given as three daily intravenous injections at a dose of 3.6 mg/kg up to 180 mg on two occasions 1 week apart. If the CNS leukocyte count is greater than 20/mm³, a further three injections are given 1 week later.

Melarsoprol causes a secondary encephalopathy in 5% to 10% of treated cases and is fatal in half of these.²⁰⁹ The incidence and severity of encephalopathy may be reduced by concurrent administration of prednisolone (1 mg/kg/day up to 40 mg) started 1 to 2 days before melarsoprol treatment.²¹⁰ When steroids are used, it is necessary to give patients antimalarial and antihelminthic therapy, especially if *Strongyloides stercoralis* is present.

Prior treatment of blood-stage disease with pentamidine may reduce antigen levels and possibly adverse events. Promethazine, anticonvulsants, and antiemetics are important adjunctive treatments before commencing CNS therapy.

Polyneuropathy occurs in 10% of cases treated with melarsoprol and may be severe, causing quadriplegia. If neuropathy is suspected, melarsoprol should be stopped immediately and thiamine (100 mg, three times daily) given until symptoms subside.

Fig. 158.12 TRYPOMASTIGOTE OF *TRYPANOSOMA BRUCEI* IN CEREBROSPINAL FLUID. A single organism is seen in this sample taken from cerebrospinal fluid filtered in a “minicolumn.”

Patients require prolonged specialist follow-up over 2 years, including blood and CSF examination for parasites. A rising CSF leukocyte count is a good guide to CSF relapse even in the absence of a demonstration of parasites.²¹¹

In treatment for early-stage *T. b. rhodesiense*, suramin is given as five intravenous injections (20 mg/kg, up to 1.5 g) on days 1, 3, 6, 14, and 21. Adverse effects include fever, proteinuria, paresthesia, pruritus, and urticaria. Hemolytic anemia, agranulocytosis, and thrombocytopenia have been reported as side effects. Combination therapies of the antitrypanosomal drugs nifurtimox and eflornithine, and also the combination of melarsoprol and nifurtimox, are under trial for the treatment of second-stage disease to increase the efficacy of treatment and to overcome increasing drug resistance.²¹²

African Trypanosomiasis as a Transfusion-Transmitted Infection

Trypanosomiasis is a transfusion-transmitted infection. Asymptomatic or early-stage patients with trypanosomiasis are clearly a threat to the blood supply. Patients are excluded in the United Kingdom, Europe, and North America by the general donor queries relating to fever and constitutional symptoms. In endemic areas, exclusion of infected donors with early-stage *T. b. gambiense* is clearly a more complex problem because patients may be asymptomatic for long periods if the degree of risk is unknown and no specific screening procedures are in place. In summary, hematologic involvement in trypanosomiasis is peripheral to the main two features of the disease, but examination of lymph node aspirates, blood, and CSF is essential for diagnosis and management of the disease. Occasionally, patients may become severely ill and have complex hematologic abnormalities. In endemic areas, trypanosomiasis may pose a risk to the blood supply.

AMERICAN TRYPANOSOMIASIS

American trypanosomiasis (or *Chagas disease*, named after the Brazilian parasitologist Carlos Chagas) is caused by infection with *Trypanosoma cruzi*. This flagellated protozoan is transmitted by the triatomine insects, the reduviid bugs. The acute phase of infection is characterized by fever and high parasitemia, followed by a chronic phase with positive serologic results and low parasitemia but with end-organ damage to the heart, peripheral nervous system, and gastrointestinal tract, causing a chronic cardiomyopathy, neuropathy, megaesophagus, and megacolon.

Epidemiology

Chagas disease may occur in the Americas from the southern United States to Chile, but the highest prevalence is in Bolivia and Brazil (Fig. 158.13). There are approximately 10 million seropositive people in Latin America, and the number of people infected and the incidence of new infection are falling rapidly.²¹³ Infections are found not only in rural areas but also in recent immigrants to urban areas in North and South America and to Europe.²¹⁴ It is estimated that approximately 100,000 seropositive individuals are living in the United States. True, endogenous (autochthonous) infection in the United States is vanishingly rare, but human infections have been reported in Texas, California, Tennessee, and Louisiana. Visitors to endemic areas are only rarely infected, with only a handful of cases being recorded in intrepid travelers spending time in traditional housing in rural areas. The range of reservoir hosts and species of triatomine bugs transmitting infection is wide.

Parasites may also be transmitted by blood transfusion (see later), vertically from mother to child by breastfeeding, organ transplant, and rarely by sexual transmission. Several outbreaks in Brazil have been reported after contamination of food by triatomine bugs and their feces. Laboratory infection by accidental ingestion or inoculation of parasites is well recorded.

Fig. 158.13 DISTRIBUTION OF CHAGAS DISEASE. Human infection is endemic in parts of Central and South America from the Andes to the Atlantic coast and as far south as the latitude of the River Plate (Río de la Plata), shown here in green. Two major intergovernmental programs were started in 1991 to eliminate domestic vectors by a combination of spraying residual insecticides in houses, the use of insecticidal paints, and the deployment of fumigant canisters. The countries covered in the two initiatives, the second of which started in 1997, are shown in the figure. The latter program instituted universal blood screening to avoid transmission from infected blood donors. Remarkable progress has been made. Transmission (by the major vector *Triatoma infestans*) was eliminated in Uruguay by 1997 and in Chile by 1999. Major reductions in transmission but, to date, not complete control have also been reported in other endemic countries. (Southern Cone Initiative; Andean and American Initiative areas.)

Parasitology

T. cruzi parasites are from the order Kinetoplastida and family Trypanosomatidae, existing as infective trypomastigotes in the bloodstream of vertebrate hosts. These organisms are fusiform cells, 10 to 20 μm in length, with a distinctive large posterior kinetoplast containing mitochondrial DNA. They can enter phagocytes, muscle and nerve cells, and a wide variety of other cell types and here transform to oval amastigotes 2 to 5 μm in diameter. They multiply by fission, and amastigotes develop into mature trypomastigotes released on rupture of the cell to begin a new cycle of invasion and multiplication.

Slender, highly motile and broader, less motile trypomastigotes have been distinguished, which may be relatively more infective for host cells and insects, respectively. The species of triatomine bugs that commonly transmits disease is able to cause extensive infestation of simple mud-and-wattle thatched houses in rural Latin America,²¹⁵ where Chagas disease is a disease of poverty associated with poor housing. These bugs are infected by circulating trypomastigotes after taking a blood meal on sleeping victims. In the midgut, trypomastigotes transform into epimastigotes and multiply by fission before migrating to the hindgut, where they develop into metacyclic

Fig. 158.14 *TRYPANOSOMA RANGELI*. *T. rangeli* is a long, slender trypanosome also transmitted by reduviid bugs from wild animals to humans. It is readily distinguished by its shape from *Trypanosoma cruzi* in blood films and appears to be nonpathogenic to humans.

trypomastigotes, adherent to the epithelium of the rectum. These infective forms are excreted into the feces, and people are infected by rubbing this infected material from the bug into the skin or conjunctival membranes. In the human host, multiplication into macrophages is followed by rapid dissemination of trypomastigotes into the blood and hence to tissues. The genome sequence of *T. cruzi* has stimulated a plethora of comparative and genomic approaches to the study of the parasite.^{216,217}

Trypanosoma rangeli Infections

The nonpathogenic trypanosomes can be transmitted directly to people by the bite of the triatomine bugs, and they exist only as circulating trypomastigotes. No tissue amastigotes exist. Circulating organisms are sparse, but sometimes diagnosis can be made by careful microscopic examination of the distinctive morphology of these organisms in blood smears. The anterior position of the nucleus and small kinetoplast distinguish it from *T. cruzi* (Fig. 158.14). The antibodies produced to *T. rangeli* cross-react with those from *T. cruzi* and hence cause false-positive serologic test results for *T. cruzi*. However, the species may be differentiated by xenodiagnosis or molecular genetics in specialized laboratories.²¹⁸ The importance of recognizing this nonpathogenic infection is to avoid unnecessary treatment for *T. cruzi*.

Pathology

There is a wide variation in the pathogenicity of isolates and some regional variation in the clinical spectrum of acute and chronic illness. Molecular typing has demonstrated considerable heterogeneity of *T. cruzi* isolates, although the association between strains of parasite and the outcome of infection are unclear. Clearly the organism must have many mechanisms of the immune evasion to cause chronic infections in a high proportion of individuals. Some of these have been elegantly defined, including resistance to activation of the alternate pathway of complement, specific mechanisms of entering the host cells, and evasion of intracellular killing by the oxidative burst and lysozymes. Both CD4⁺ and CD8⁺ T cells are important for killing *T. cruzi*-infected cells, and IFN- γ has shown to be important to controlling disease, whereas transforming growth factor- β and IL-10 enhance parasite replication (for review, see Dutra et al²¹⁹).

End-organ damage occurs after tissues have been infected by *T. cruzi* amastigotes, but the mechanisms leading to extensive cell damage are not clear. After multiplication, tissue amastigotes form pseudocysts in the heart with little or no inflammatory reaction,

although occasionally acute myocarditis with focal hemorrhage and inflammation may lead to heart failure. As the disease progresses, the inflammatory response is increased and is associated with increased tissue damage. There may be an autoimmune component to this inflammatory response, but the precise pathogenesis is poorly understood.²²⁰ In the heart, chronic myocarditis leads to a decline in cardiac function. In late-stage disease, amastigotes can be found in almost all organs. Acute myocarditis with focal hemorrhage and inflammation may also lead to heart failure. Involvement of the brain, meninges, liver, lymph nodes, and spleen is common. Damage to the muscle walls and intramural nerve plexus in the esophagus and colon leads to dilation of these structures in the later phases of the disease.

Clinical Features

In about half the patients, a granuloma (or chagoma) occurs where parasites have been inoculated. The tender erythematous papule becomes keratotic and later heals, forming a hyperpigmented scar. When the conjunctiva are inoculated, the extensive unilateral periorbital edema may be prolonged (Romaña sign).

The severity of the acute illness is variable and ranges from asymptomatic infection or a mild febrile illness to a severe, potentially fatal illness with cardiac failure and meningoencephalitis in a minority of cases. Myalgia, generalized lymphadenopathy, hepatosplenomegaly, headaches, facial or generalized edema, vomiting, diarrhea, and anorexia are common features of the acute disease. The disease may be worse in children. The acute illness typically resolves in 4 to 8 weeks. Chagas disease must be distinguished from typhoid fever, VL, brucellosis, toxoplasmosis, and malaria in cases of chronic, febrile illness in endemic areas.

Chronic Disease

The acute phase of *T. cruzi* infection is followed by a variable latent or indeterminate phase with no clinical symptoms. Indeed, patients may never present with signs of end-organ damage. However, up to one-third of clinically infected patients may develop cardiac involvement and show right bundle branch block, atrioventricular conduction abnormalities, and/or abnormal T and Q waves. The patient may experience palpitations, chest pain, edema, and dizziness or syncope or dyspnea. The heart is enlarged, and intramural thrombus may cause sudden death.

In a further minority of chronically infected patients, the gastrointestinal tract is infected with abnormal motility of the esophagus and colon, leading to dysphagia and/or severe constipation. Occasionally, other hollow organ systems may be affected.

Pregnancy and Congenital Infection

In pregnant women, Chagas disease can cause spontaneous abortion, premature birth, intrauterine growth retardation, and stillbirth. Congenital infection occurs in 1% to 2% of women with chronic infection. Prompt diagnosis of circulating parasites in neonates at risk for congenital Chagas disease is essential to beginning early treatment. It is recognized that infection can also be transmitted by breastfeeding. Most children are asymptomatic, but 10% to 20% of children have a mild systemic illness with hepatosplenomegaly. More severely affected newborn children have pneumonitis, meningoencephalitis, and diffuse dermal granulomas. Petechiae, purpura, and a generalized bleeding tendency may occur.²²¹

Immunocompromised Patients

The disease may recrudesce after chemotherapy for malignant disease, immunosuppressive therapy, or after organ transplant. The clinical disease may be fulminating with obvious parasitemia. Irregular

erythematous indurated lesions have been described during *T. cruzi* recrudescence after solid-organ transplant. Here tissue amastigotes can be demonstrated by fine-needle aspiration.

HIV

Coinfection with *T. cruzi* and HIV has been reported from urban centers in Brazil. *T. cruzi* develops in end-stage disease with CD4⁺ T-cell counts of less than 400/ μ L. Patients may be severely ill, the majority with meningoencephalitis and often with a space-occupying lesion. Typically the CSF shows a mild lymphocytosis (<100 cells/ μ L). Parasites may be seen in the blood and occasionally the CSF. Cardiac involvement and heart failure are common.

Hematologic and Laboratory Features

A mild, normocytic, normochromic anemia is typical of acute illness. The pathogenesis of the anemia and contributions of hemolysis and bone marrow depression have not been studied in humans, but in experimental infections in mice, uncontrolled infection and TNF- α can be shown to contribute to depressed hematopoiesis. A modest lymphocytosis and increases in liver and muscle enzymes may be present. Nonspecific electrocardiographic changes, first-degree heart block, and cardiomegaly suggest early myocardial involvement.

Hematologic abnormalities are not usually found in the late stage of disease, in which cardiomyopathy with cardiac failure, rhythm disturbance, and angina and systemic emboli from intramural thrombus may occur. Trials of systemic anticoagulation have not been conducted.

Diagnosis

Microscopy

During the acute phase of the disease, motile trypanosomes can be identified in wet preparations or buffy coat preparations using concentration methods and detailed morphologic examination, including Giemsa-stained, gently prepared thick and thin films to avoid damage to parasites (Fig. 158.15). Trypanosomes can be aspirated from the chagoma in the acute phase of disease and visualized in a wet

Fig. 158.15 *TRYPANOSOMA CRUZI* IN HUMAN BLOOD FILM. The causative agent occurs in blood films, characteristically as short C-shaped or S-shaped trypomastigotes with a prominent kinetoplast. It is otherwise monomorphic.

preparation of needle aspirates. Parasites may occasionally be found in lachrymal fluid.

Sensitivity is increased by the concentration methods described for *T. brucei* earlier. Organisms may also be sought in centrifuged serum after blood has clotted or by centrifugation after lysis of RBCs with 0.8% ammonium chloride. Trypomastigotes can also be detected in other specimens, including CSF, bone marrow, pericardiac fluid, and tissue biopsy specimens. Organisms must be distinguished from the morphologically similar nonpathogenic *T. rangeli* (see Fig. 158.14 and earlier).

After the acute phase, circulating parasites are not visible, although inoculation of blood into susceptible animals (xenodiagnosis), in vitro culture, or molecular methods may demonstrate patent infection. Parasitemia may be obvious in immunocompromised patients in the chronic phase of disease.

Xenodiagnosis

Infection of laboratory triatomine bugs by a seropositive patient is more sensitive than morphologic examination in chronically infected patients. It is also possible to infect susceptible laboratory animals. However, these techniques are available only in specialized centers in Latin America.

In Vitro Culture

Epimastigotes can be cultured using blood agar (NNN) medium or other media such as Schneider insect medium. After 4 weeks or more of culture at 26°C, epimastigotes may be detected.^{222,223}

Serology

Serologic testing is a sensitive method of detecting infection after the acute phase. In Latin America, a number of commercial assays are available using crude epimastigote lysates in a variety of different formats. Serologic tests have used IFAT and ELISA using crude antigen prepared from in vitro cultures of epimastigotes. These tests must be carefully controlled with appropriate positive or negative sera. Chronically infected patients usually give a positive test result if titers are greater than 1 : 80.²²⁴ These have a sensitivity and specificity of more than 95%. These antibodies may cross-react with antibodies to malaria, leishmaniasis, syphilis, and some autoimmune conditions. ELISA should be used in conjunction with a confirmatory test such as Western blot.

In South and North America, a number of companies market ELISA-based assays using recombinant antigens, synthetic peptides, or a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuen strain *T. cruzi* trypomastigotes (total trypomastigote excretory-secretory antigens [TESAs]). These assays may provide more rapidly available and cheaper tests without loss of sensitivity and specificity (see Trypanosomiasis as a Transfusion-Transmitted Infection section for further discussion).

Serologic testing may be useful in the evaluation of people who may have been exposed to Chagas disease, pregnant women, and patients about to undergo immunosuppressive treatment or to receive chemotherapy or who have been diagnosed with HIV or other immunosuppressive illness. Children born to seropositive women will have maternally derived IgG anti-*T. cruzi* antibodies but demonstrate IgM anti-*T. cruzi* antibodies if congenitally infected.²²⁵

Molecular Diagnosis

Amplification of *T. cruzi*-specific sequences by PCR is potentially the most widely applicable, sensitive, and specific method for detecting parasites. A number of assays have been developed, based on the application of repetitive sequences in kinetoplast DNA. A

meta-analysis has suggested that PCR is not more sensitive than ELISA for detection of *T. cruzi* in chagasic patients. The recommendation is to use two serologic tests, which may be supplemented by PCR-based assays in the immunocompromised patient, in whom seroconversion may not occur in patent infection.²²⁶

Treatment

The detailed treatment of Chagas disease is beyond the scope of this chapter. Treatment of the acute, intermediate, and chronic phases requires expert supervision because parasitologic cure is achieved in only half the cases and monitoring progress requires specialist testing and evaluation and where necessary treatment of end-organ damage. The current and potential future chemotherapy^{227–229} have recently been reviewed.

Nifurtimox is a synthetic nitrofurantoin that inhibits pyruvic acid synthesis by inhibition of lactic dehydrogenase. It is given for 30 to 120 days at 3 to 5 mg/kg three times per day. The most serious side effects are peripheral neuropathy, mental disturbance (including psychosis), and hemolytic anemia associated with G6PD.

Benznidazole is widely available in Latin America and is given at 5 mg per kilogram of body weight per day for 60 days. Severe hematologic complications are common, and bone marrow depression is a serious side effect. Thrombocytopenia may be severe, and neutropenia may progress to agranulocytosis. Other serious complications include photosensitivity, neuropathy, and weight loss.²³⁰

Supportive therapy is required for heart failure and acute meningoencephalitis. Surgery may be required for alleviation of esophageal and chronic dysfunction. In the absence of effective or simple therapy, control of triatomine bugs and an improvement in the housing stock are essential to prevent and control disease.

American Trypanosomiasis as a Transfusion-Transmitted Infection

Chagas disease may occur as a transfusion-transmitted infection and represents a real threat to the safety of the blood supply in endemic areas. It is estimated that 1.5% to 50% of contaminated units cause infection in recipients, a wide range that may reflect the stage of infection in the donor, the type and processing of the component, and the immune status of the recipient.²³¹

In endemic areas, seropositivity is high, reaching 50% in some areas of Bolivia and 1% to 2% in major areas in Brazil. Control of blood transfusion-transmitted infection is part of the World Health Organization strategy for control of Chagas disease.^{232–234} Serologic screening, tests using synthetic peptide antigens, or a mixture of recombinant antigens to detect anti-*T. cruzi* antibodies in chronically infected blood donors are more than 95% sensitive.^{235,236} These serologic tests, replacing those based on crude antigens, have allowed improved coverage of screening of blood donors throughout Latin America and in the United States.^{237,238}

It is possible to treat blood with gentian violet (0.25 g/L for 24 hours at 4°C) or with methylene blue to kill circulating organisms. It has also been shown that amotosalen or riboflavin plus ultraviolet A photochemical inactivation technology is effective in inactivating *T. cruzi* in platelet concentrates and plasma.^{238,239} In addition, prophylactic benznidazole can be given to immunosuppressed patients receiving blood products in endemic areas.

Outside Latin America, Chagas disease is an occasional cause of transfusion-transmitted infection, mainly in immunosuppressed patients. It is possible that minor infections are not recognized in healthy individuals. Clearly the high rates of seropositivity in individuals from endemic areas suggest that recent immigrants may easily transmit the disease.

In the United States the overall seropositive rate among blood donors is 1:250,000, with local incidence rates reaching 1:7500 or greater in Los Angeles and Miami.²³¹ These rates are probably underestimates because immigration from endemic areas has recently

increased. Surveys of blood donors in France have shown seropositivity of *T. cruzi* can be detected by PCR in about half the seropositive donors and remain viable for at least 20 days, surviving cryopreservation and thawing. *T. cruzi* has been reported to be transmitted after organ transplant^{240,241} and after blood transfusion in seven patients who were immunosuppressed.^{242–246}

Donors can be excluded by a medical questionnaire eliciting obvious symptoms of acute or chronic disease. Prospective studies have shown these questionnaires would miss many infected donors,^{247,248} including those infected congenitally.²⁴⁹ Nevertheless, in Europe screening for anti-*T. cruzi* antibodies is targeted at at-risk blood donors who originate from an endemic area, donors with mothers originating from such an area, and individuals who have lived in or traveled to endemic areas. In France the seropositivity in these selected donors was 1:32,000.²⁵⁰

In the United States new tests have been requested by the Food and Drug Administration to combat this threat. A radioimmuno-precipitation assay (RIPA) is the most sensitive method to detect anti-*T. cruzi* antibodies,²⁵¹ although RIPA cross-reactivity has been reported in patients with VL.²⁵² It is unsuitable for mass screening, however. An ELISA based in a concentrated extract of excretory-secretory antigens from either Brazil or Tulahuén strain *T. cruzi* trypomastigotes (TESAs)^{253,254} had an overall sensitivity of 100% and specificity of more than 94%, and a prototype *T. cruzi* lysate-based ELISA has been developed that appears to be 97.7% sensitive and 100% specific.²⁵¹

It is only to be hoped that sensitive screening tests are consistently applied to reduce transmission of Chagas disease by blood products in endemic and nonendemic countries. On a more general note, it is encouraging that the initiatives to control *T. cruzi* infection across Latin America are showing real evidence of success.^{213,255}

BABESIOSIS

Babesiosis is an intraerythrocytic infection caused by parasites from the order Piroplasmida and the family Babesiidae. It was first observed as causing parasitic inclusions in erythrocytes of cattle in Romania by Victor Babes at the end of the 19th century.²⁵⁶ The infection is zoonosis transmitted by hard-bodied ticks and causes fever and hemolytic anemia. Several distinct *Babesia* spp. cause disease in different geographic areas.^{257,258}

There are two well-defined *Babesia* species that cause human infection. *Babesia microti* is a parasite of small rodents in the northeastern United States and is spread by nymphs, larvae, and adult forms of the hard-bodied ixodid ticks (*Ixodes dammini*). Infection of the white-tailed deer by ticks allows multiplication and spread of the infected ticks. Infections can be transferred to humans by all forms of the tick after prolonged feeding. The infection is therefore most common in people vacationing or working in forested areas of the northeastern United States. The northeastern US offshore islands of Nantucket, Martha's Vineyard, Block Island, and Shelter Island are foci of the disease, but it also occurs in eastern states, particularly Connecticut, Rhode Island, Delaware, and New York State, as well as upper Midwestern states. Hundreds of cases have been recorded since the first identified case in 1969. Visitors and workers in endemic areas should avoid tick bites by using appropriate clothing and repellents.

In Europe, *Babesia divergens* and the morphologically indistinguishable parasite *Babesia bovis* are transmitted to humans by ticks (*Ixodes ricinus*) from cattle. Fewer than 50 cases have been recorded. European cases of *B. microti* and *Babesia canis* infection have also been reported.

A handful of cases of infections with *Babesia duncani* in the western United States have been reported. These organisms are morphologically indistinguishable from *B. microti* but are distinguished by molecular methods. The MO1-type piroplasm caused illness in an index case in Missouri in 1992, and the WA1-2 and CA1-5 piroplasms caused disease in eight cases reported in Washington State and California.^{259,260} A further *B. microti*-like organism, *B.*

venatorum, has caused infection in a small series of older men who had undergone splenectomy for a lymphoproliferative disease.²⁶¹ The same organism has been isolated in a much larger series of patients from China.²⁶²

B. microti and *B. duncani* have been transmitted by blood and platelet transfusions.²⁶⁰ Transplacental infection by *B. microti* has also been reported.

Parasitology

Parasites appear to be introduced into the bloodstream, where they invade erythrocytes. There they multiply by asexual fission to produce two to four merozoites. These infective forms are released after lysis of the erythrocyte and begin another cycle of invasion multiplication. Parasites are cleared by macrophages. The contribution of antibodies and cell-mediated immune response has not been defined, although *B. bovis* expresses clonally variant antigens on the surface of infected erythrocytes.²⁷

Clinical Features

The North American *B. microti* infections have an incubation period of several weeks, and after infection by blood transfusion, clinical symptoms have taken from 17 days to many months to become manifest.^{263–265} The spectrum of clinical disease is wide. *B. microti* may cause asymptomatic infection or present with a mild flulike illness in most cases in people with normal immune and splenic function.²⁶⁶ The cardinal manifestations are fever and hemolytic anemia. Splenectomy, old age, and immunosuppression, including HIV, may increase the risk for more severe clinical disease.^{267–269} The disease may progress to adult respiratory distress syndrome (ARDS), disseminated intravascular coagulation, or renal failure.²⁶² Patients who have had a splenectomy should avoid exposure to ticks in forested areas where the disease is transmitted.

B. divergens in Europe predominantly causes symptomatic infection in people who have had a splenectomy.^{270,271} Here, the case fatality rate is on the order of 50%. However, symptomatic disease does also occur in immunocompetent individuals.²⁷²

Patients present with high fever, often with chills and sweats, jaundice, fatigue, malaise, headache, arthralgia, and myalgia. Gastro-

intestinal disturbances are common, and people may complain of dark urine secondary to hemoglobinuria. In some cases the disease progresses with respiratory failure secondary to ARDS, disseminated intravascular coagulation, and renal failure requiring the appropriate supportive care.²⁷³ Such severe cases resemble severe malaria in nonimmune persons, and it has been suggested that the pathophysiology, like in malaria, includes adhesion and sequestration of infected erythrocytes and the release of proinflammatory cytokines. These diseases may be confused with falciparum malaria, leptospirosis, or viral hepatitis. In pregnancy, acute babesiosis may mimic the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count).²⁷³

Hematologic and Laboratory Features

The hematologic features of the disease are dominated by substantial intravascular hemolysis.²⁵⁷ Physical examination shows pallor, jaundice, and mild hepatosplenomegaly.

The laboratory findings are those of a compensated intravascular hemolytic anemia and thus feature low hemoglobin and haptoglobin levels, increased reticulocyte count and serum lactate dehydrogenase, and hemoglobinuria and proteinuria. Moderate thrombocytopenia is common.^{265,274} Electron microscopy suggests uninfected erythrocytes are damaged during infection and so likely to be cleared more rapidly than normally.²⁷⁵ The white blood cell count is usually decreased with atypical lymphocytosis and occasional evidence of hemophagocytosis. However, leukocytosis may occur, particularly in *B. divergens* infections.

The direct Coombs test result is frequently positive for both C3 components and IgG. Polyclonal hypergammaglobulinemia is seen, and levels of C3 and C4 are reduced in acute infection. Liver function tests show raised indirect bilirubin and mildly raised transaminase levels.

Diagnosis

The blood films stained with Giemsa or Romanowsky stain show ringlike intraerythrocytic parasites. Morphology is variable, and ring, rod, and ameboid forms of *Babesia* parasites may be seen (Fig. 158.16).²⁷⁶ Occasionally, multiple intraerythrocytic forms can be

Fig. 158.16 BABESIA PARASITES. Human infection with species of piroplasm transmitted by the bite of the tick *Ixodes ricinus* infected from cattle is a rare occurrence. Infection in normal people with this piroplasm may give rise to a self-limiting fever and parasitemia, as in the case of infection with the rodent parasite *Babesia microti* on the northeastern seaboard of the United States via the tick *Ixodes scapularis* (A). Heavy red-cell infection may develop, however, in splenectomized patients, leading to fatal hemolytic anemia. This patient died as a result of an infection acquired from the cattle parasite *Babesia divergens* in Scotland (B). Other species of *Babesia* that occasionally infect humans, for example, the WA1, CA1, and MO1 isolates from the United States, are distinguished by molecular means.

seen, linked to form a tetrad or, colloquially, a “Maltese cross.” However, at low parasitemia, *Babesia* parasites may easily be mistaken for ring-stage forms of *P. falciparum*. Moreover, false-positive sightings of *Babesia* spp. may be caused by platelets, nonspecific stain deposit overlying erythrocytes, or indeed other intraerythrocytic inclusions.

Parasitemias are variable, and in *B. microti* infections may be low or transient.²⁶⁶ In symptomatic infection, parasitemias typically range from less than 1% to 10% and rarely much higher, more than 70%, in severe infections. Low-level parasitemias may be detected by inoculation of the blood into susceptible animals, including the golden hamster (*Mesocricetus auratus*), but this is not routinely available.

An IFAT using crude antigen is available in the United States through the Division of Parasitic Diseases at the Centers for Disease Control and Prevention.²⁷⁷ Titers greater than 1:64 are regarded as positive and have been reported to be 88% to 96% sensitive and 90% to 100% specific.

PCR analysis is the most useful method of detecting or confirming low levels of parasitemia, and it can also be used to monitor treatment. Real-time PCR assays target the *Babesia* 18S rRNA gene and, with use of a fluorescent probe, can distinguish *B. microti* from *B. duncani*.^{278,279} PCR tests may be positive in the absence of positive serology in immunocompromised patients and/or those patients who have received rituximab, whereas serology for *Babesia* spp. may be positive in the absence of positive microscopy or positive PCR tests in asymptomatic individuals who were infected but who have cleared the infection spontaneously.

Treatment

Many *B. microti* infections are self-limiting, and therapy is used for moderate or severe disease.^{257,280–282} The combination of atovaquone and azithromycin is the treatment of choice for mild to moderate illness, whereas clindamycin and quinine and exchange transfusion are indicated for severe disease.

B. divergens infections are often fatal in splenectomized patients, and therapy is based on somewhat limited experience. Three cases have been treated successfully with large-volume exchange transfusions (two to three blood volumes) and intravenous clindamycin and oral quinine.²⁸³ This regimen of clindamycin and intravenous and oral quinine gives the best chance of success in the absence of randomized controlled trial evidence.

Exchange transfusion has been suggested as a useful adjunctive treatment if the parasitemia rises to greater than 10% and/or in severely ill patients. *B. divergens* infections can run a rapidly progressive course, and early exchange transfusion should be considered. A prolonged course of treatment may be required in immunocompromised patients.²⁸⁴ The parasite and hemoglobin levels should be regularly monitored during treatment.

Serologic testing and PCR testing of seropositive cases may be helpful in making a diagnosis. An indirect IFAT is available for *B. divergens* and *B. microti*. The IFAT titer is usually greater than 1:64 in acute infection. The reported sensitivity of the *B. microti* IFAT is 88% to 96%, and its specificity is 90% to 100%. Antimalarial antibodies may cross-react in this test.

Babesia and Transfusion-Transmitted Infection

Babesia infection poses a substantial and increasing threat to the blood supply. Between 150 and 170 cases of transfusion-transmitted babesiosis have been reported from 1979 to 2009, with 12 recorded fatalities.^{285–287} There are no approved serologic screening tests for donors, and prevention of transfusion-transmitted babesiosis in the United States requires screening donors about a previous history of babesiosis and excluding patients with fever and a low hematocrit level. The scale of infection can be gauged from surveys of blood donors in the northeastern United States, where 1% to 2% of donors in some panels are seropositive for *Babesia*.²⁸⁸ In the United Kingdom,

a conservative approach has been taken, and all donors who have visited the northeastern United States between May and October are excluded, in addition to the standard criteria of screening out febrile and/or anemic donors.

EOSINOPHILIA

Eosinophilia may be caused by a wide variety of systemic diseases and parasitic infections. The association with parasitic disease is through part of the Th2 T-cell response stimulated by helminths (worms), filaria, and cestodes. In general, protozoan infections, such as malaria, amebiasis, and giardiasis, are not associated with eosinophilia. However, case reports do exist suggesting that isosporosis due to infection with *Isospora belli*, toxoplasmosis, and infection with *Dientamoeba fragilis* can cause eosinophilia.

The rise in absolute eosinophil count depends on the degree of tissue invasion and is therefore modest with tapeworms and adult roundworms resident in the bowel but much higher where invasion occurs, for example, with *Toxocara canis* or filaria. Some parasites, such as ascariasis (roundworms) and clonorchiasis, have migratory larval stages.

The differential diagnosis of eosinophilia in those who have lived in tropical areas is therefore wide. Evaluating the patients must begin by establishing the degree of eosinophilia (minimal, $<1 \times 10^9/L$; moderate, 1 to $3 \times 10^9/L$; high, $>3 \times 10^9/L$), the relation to travel (where necessary), and the presence of symptoms. A wide range of systemic diseases are associated with eosinophilia, and the eosinophil count may be high in drug allergy, pulmonary infiltrate with eosinophilia, and vasculitides.

Eosinophilia in Travelers

Evaluating the cause of eosinophilia in travelers to tropical areas where many parasitic diseases are endemic requires a systematic approach to narrow down likely possibilities by considering existing systemic diseases that may cause eosinophilia (particularly allergy, drug ingestion and autoimmune disease, vasculitis, or arthritis); the areas visited; duration of stay; and history of exposure to soil-transmitted nematodes, freshwater potentially infected with schistosomiasis, and rural areas where loiasis, onchocerciasis, and hydatid disease may be contracted.

Physical examination may show subcutaneous swellings associated with filaria or hepatosplenomegaly consistent with schistosomiasis, hydatid disease, or toxocara. Laboratory examination requires a stepwise approach, given the breadth of the differential diagnosis (Table 158.4). The details of specific parasitologic tests are beyond the scope of this chapter, and detailed investigation would certainly require consultation with colleagues in infectious diseases.

Some parasitic causes of eosinophilia may not be diagnosed during the incubation period, because larval stages of nematode worms may cause eosinophilic drug migration, but eggs will not be excreted in stools for many months. Moreover, filarial infections do not produce detectable parasites in blood or skin for many months after exposure.

In immunocompromised patients or those about to receive a diagnosis, eosinophilia may be crucial, given the risks of giving immunosuppressive therapy such as chemotherapy or hematopoietic stem cell or solid organ transplant to a patient with a chronic parasitologic infection. Patients with undiagnosed eosinophilia and possible exposure to *Strongyloides* should be given an empirical course of treatment.

OTHER PARASITIC DISEASES

Many parasitic diseases cause some minor hematologic disturbance. A few may present with distinct hematologic features or indeed syndromes.

Filariasis

Lymphatic filariasis is caused by *Wuchereria bancrofti* and *Brugia malayi*. Infection with *W. bancrofti* occurs throughout the tropics, but by far the majority of cases are in Asia. The distribution of *B. malayi* is more restricted to China, Southeast Asia, and Southern India. The male and female adult worms live in the lymphatics, and the female worm releases a vast number of microfilariae, each 250 to 300 μm in length. Microfilariae develop but do not appear to multiply in the mosquito.

Infection may present with lymphangitis; often recurrent and unlike bacterial infections, the inflammatory features may spread distally. Over time, lymphatic obstruction may cause hydrocele, lymphedema (if severe elephantiasis), chyluria, and tropical pulmonary eosinophilia. *B. malayi* causes neither hydrocele nor chyluria.

Filariasis is most easily diagnosed by finding microfilariae in peripheral blood in a wet preparation. Motile microfilariae can be seen under low power and may be concentrated by centrifugation or filtration using a 3- μm filter. They are speciated in thin or thick films

by their nuclear distribution and sheath characteristics (Fig. 158.17), and the two pathogenic species must be distinguished from the nonpathogenic species *Mansonella perstans* and *Mansonella ozzardi*, which do not have sheaths. Circulating *W. bancrofti* antigens can also be detected in the circulation by ELISA or immunochromatographic methods. Adult worms can sometimes be imaged by ultrasound. Filarial DNA from all species can be detected by PCR. Serologic testing is unhelpful because many people become exposed without developing clinical symptoms.

The worms cause marked or severe eosinophilia (see later) with counts greater than $1 \times 10^9/\text{L}$. Migration of worms through the lungs may exacerbate the eosinophil count and cause minor respiratory symptoms and fluctuating radiologic signs. Other causes of tropical pulmonary eosinophilia are the worms (helminths) *Ascaris*, *Strongyloides*, *Schistosoma*, and *Toxocara*. Of these organisms causing pulmonary symptoms and signs, filariasis alone is responsive to diethylcarbamazine. Albendazole and ivermectin may also be used against filarial infection.

Toxoplasmosis

Toxoplasmosis may cause a mild illness or a more prolonged course with constitutional symptoms, atypical lymphocytes, and thrombocytopenia. Congenital toxoplasmosis as a result of infection acquired during pregnancy is a cause of neonatal thrombocytopenia, where it may be accompanied by cerebral calcification, hepatitis, and pneumonitis. In immunocompromised patients, new or reactivated toxoplasmosis may cause severe disease, including encephalitis, pneumonitis, and hepatitis. Thrombocytopenia is frequently accompanied by anemia and leukopenia.

Amebiasis

Amebiasis causes hypochromic, microcytic anemia, both as a result of chronic blood loss and as an anemia of chronic disease in which disease progresses to formation of a liver abscess. Neutrophilia accompanies severe tissue damage caused by perforation of the bowel or a liver abscess, or it may be present in a secondary bacterial infection. Sometimes a leukemoid reaction with high white blood cell count and extreme left-shifted myeloid cells can be seen. Prolonged and/or extensive liver damage may cause prolongation of the prothrombin time.

Giardiasis

Acute giardiasis causes folate deficiency through malabsorption of folate in the small intestine. Chronic infection can cause vitamin B₁₂ deficiency because ileal absorption of the vitamin is impaired.

Hookworm Infection

Adult hookworms attach themselves to the lining of the small bowel and take blood meals. The accumulated blood loss may be extensive because worms consume 2.0 mL (*Necator americanus*) or 0.5 mL

TABLE 158.4 Approach to Investigation of Eosinophilia in a Returning Traveler

History	Allergy Drugs and vitamins (L-tryptophan) Regions, localities, and duration of exposure
Physical examination	Skin, subcutaneous tissues Liver/spleen Signs of other systemic disease
Initial investigations	Full blood count and differential white blood cell count Stool examination for ova and parasites ($\times 3$) Urine analysis Examination of midday urine for ova and parasites ($\times 3$) (in those who have traveled to Africa or the Middle East)
Further investigations as suggested by travel and exposure from history	As suggested by travel and exposure from history <i>Strongyloides</i> culture and serologic testing Duodenal aspirate (strongyloidiasis, hookworm) Serologic testing (schistosomiasis, filariasis) Day/night blood films (filariasis)
Further studies if suggested by history and physical examination	Skin snips (onchocerciasis) Chest x-ray examination (hydatid cyst, tropical pulmonary eosinophilia, paragonimiasis) Soft tissue x-ray examination (cysticercosis) Sputum examination for ova and parasites (paragonimiasis) Abdominal ultrasound examination (hydatid cyst) Cystoscopy with or without biopsy (schistosomiasis) Rectal snips (schistosomiasis)

Fig. 158.17 MICROFILARIA (*BRUGIA MALAYI*) ON THICK (A) AND THIN FILMS (B). The species is determined by the nuclear distribution and sheath characteristics.

(*Ancylostoma duodenale*) of blood each day. These infections are a common contributing factor to iron deficiency anemia in children, in whom infection is acquired by eating or walking barefoot on larva-infected soil. The disease is usually diagnosed by finding excreted eggs in stool samples, and treatment is with albendazole.

Tapeworm Infection

The fish tapeworm (*Diphyllobothrium latum*) is a rare cause of vitamin B₁₂ deficiency. This tapeworm is transmitted in the Far East by eating raw or partially cooked fish. Infection has to be extensive and causes vitamin B₁₂ deficiency; however, such cases are rare, even in endemic areas.

Schistosomiasis

Schistosoma haematobium causes blood loss in urine. Infection is acquired by swimming in freshwater, where cercariae from the infected snail host enter the skin and migrate to the blood vessels of the bladder. Chronic blood loss is a cause of iron deficiency anemia in children in endemic areas, but infection is likely to be diagnosed at an early stage in travelers because of the striking symptoms of painless hematuria. Treatment is with praziquantel.

FUTURE DIRECTIONS

Parasitic diseases present many problems for global health. They cause a wide spectrum of hematologic abnormalities, and in endemic areas, a broad knowledge of the parasitic disease is vital for everyday practice. In nonendemic areas, there are a few situations where the diagnosis or management of these diseases may fall within the remit of hematologists and hematology laboratories, particularly malaria and the diagnosis of anemia, cytopenias, eosinophilia, and hepatosplenomegaly. Here, a high index of suspicion is often needed for the diagnosis to be made. A good travel history is crucial to establishing exposure to parasitic disease and to prompt the search for the appropriate organisms. Several parasitic diseases pose a threat for the safe supply of blood, and the problems of screening of these infections are far from solved. Beyond everyday practice, the pathophysiology and prevention of these diseases pose major challenges for biomedical research and public health.

HEMATOLOGIC PROBLEMS IN THE SURGICAL PATIENT: BLEEDING AND THROMBOSIS

Iqbal H. Jaffer, Mark T. Reding, Nigel S. Key, and Jeffrey I. Weitz

Surgical patients often present unique challenges to the consulting hematologist. They may develop hemostatic disorders ranging from unexpected bleeding to pathologic thrombosis, both of which can be potentially life threatening. Consultation may be sought to assess preoperative bleeding risk and/or to recommend strategies to prevent postoperative thrombosis. The hematologist may be called upon to assist in the management of patients with a previous history of bleeding or thrombosis and in those with unexplained bleeding or thrombosis in the perioperative period. This chapter will review: (1) the preoperative evaluation of bleeding risk; (2) strategies to aid intraoperative hemostasis; (3) the management of patients with hemostatic abnormalities or those taking long-term oral anticoagulation; and (4) the perioperative prevention of venous thromboembolism (VTE).

PREOPERATIVE EVALUATION OF HEMOSTATIC RISK

History

Preoperative evaluation of hemostatic risk begins with a carefully taken history. Particular attention should be directed at specific bleeding symptoms and any history of bleeding associated with surgical procedures, including circumcision, tonsillectomy, and dental extractions. For women, it is important to inquire about a history of menorrhagia or excessive bleeding associated with childbirth. A detailed family history and record of medication use, including nonprescription medications, should be obtained. In adults, an interview to assess for the presence or absence of bleeding symptoms has a high discriminating power when used in a screening situation, where no bleeding disorder is suspected, but may be less discriminatory for those referred for specialty evaluation.¹ In the pediatric population, the medical history may be less reliable as a screening method because of fewer previous hemostatic challenges.²

Obtaining an adequate bleeding history may be complicated by the fact that even in the absence of hemostatic defects, many people consider their bleeding to be excessive. Surveys of healthy individuals frequently report excessive nosebleeds (5%–39%), gingival bleeding (7%–51%), easy bruising (12%–24%), menorrhagia (23%–44%), postpartum bleeding (6%–23%), and bleeding following dental extraction (up to 13%) and tonsillectomy (up to 11%).^{1,3,5} Thus a thorough search for objective confirmation of reported symptoms is essential. Also, a constellation of bleeding symptoms, rather than any single symptom, is most helpful in suggesting the presence and etiology of an underlying bleeding disorder.

Coagulation Testing

The need for routine coagulation testing before surgical or invasive procedures remains controversial. Those in favor of testing point to the asymptomatic nature of some hemostatic abnormalities that may cause surgical bleeding and the occasional failure to obtain a detailed history.^{5,7} A prospective study of preoperative screening in children before tonsillectomy found history and laboratory screening to have high specificity but a low positive-predictive value for perioperative

bleeding.⁶ Another study found that perioperative blood loss in adult cardiothoracic surgery patients could be predicted with a model, which included the bleeding time, prothrombin time (PT), and platelet count.⁸ Given the variety of potential hemostatic defects however, no simple screening system will identify all patients at increased risk for bleeding. Those against routine laboratory testing⁹ point to retrospective studies indicating that they rarely detect unexpected bleeding disorders^{10,11} and emphasize the problems associated with evaluation of false-positive results. A literature review found insufficient evidence to conclude that an abnormal PT/international normalized ratio (INR) predicts bleeding during invasive procedures.¹² A retrospective review of the value of preoperative determination of the platelet count, PT, and activated partial thromboplastin time (aPTT) in 828 patients undergoing major noncardiac surgery found that only 2% had abnormal results, and most were expected on the basis of history and physical examination.¹³ Furthermore, abnormal laboratory test results and intraoperative blood loss or postoperative bleeding complications were not related. This is not surprising given the lack of studies using an evidence-based approach to determine the degree of abnormality in the PT/INR or aPTT at which invasive procedures may be unsafe.¹⁴ A number of prospective studies have also concluded that routine laboratory screening tests in asymptomatic patients are not predictive of perioperative or postoperative bleeding.^{15–19} Thus in the absence of historical risk factors or physical examination findings suggestive of an underlying bleeding tendency, the likelihood of an unsuspected, clinically significant congenital or acquired coagulopathy is low enough that routine laboratory screening is not warranted, particularly for those undergoing low-risk procedures.²⁰ The British Committee for Standards in Haematology recently issued guidelines reiterating this position: indiscriminate coagulation testing before surgical or invasive procedures is a poor predictor of bleeding risk and is not recommended in the absence of a positive personal or family bleeding history.²¹

There are a variety of reasons why routine coagulation tests such as the PT/INR and aPTT may be poorly predictive of underlying coagulopathy and bleeding risk.²¹ First, these tests were designed to measure time to clot formation in artificial in vitro assays and do not reliably depict the global hemostatic situation in vivo (see [Liver Disease](#) section). More importantly, the PT/INR and aPTT may be insensitive to mild but clinically relevant bleeding disorders such as von Willebrand disease or mild hemophilia. Conversely, they may detect conditions such as factor XII deficiency or a lupus anticoagulant that do not increase the risk for bleeding.

The platelet function analyzer (PFA-100) has been developed for rapid, quantitative in vitro global testing of platelet function.^{22,23} The clinical sensitivity (94%–95%) and specificity (88%–89%) of this instrument are virtually identical to platelet aggregometry.²⁴ Although some have suggested that the PFA-100 could be used for screening for primary hemostatic defects, such testing has limitations.²⁵ The PFA-100 has high sensitivity for detection of moderate-to-severe von Willebrand disease and severe platelet defects, such as Glanzmann thrombasthenia and Bernard-Soulier syndrome, but it has poor sensitivity for detection of milder platelet disorders such as storage pool disease, Hermansky-Pudlak syndrome, and primary secretion defects.²⁶ Although the PFA-100 is most useful when a hemostatic defect is clinically likely, in such cases additional testing

TABLE 159.1 Risk for Bleeding With Surgical or Invasive Procedures

Risk	Type of Procedure	Examples
Low	Nonvital organs involved, exposed surgical site, limited dissection, percutaneous access	Lymph node biopsy, dental extraction, cataract extraction, most cutaneous surgery, laparoscopic procedures, coronary angiography
Moderate	Vital organs involved, deep or extensive dissection	Laparotomy, thoracotomy, mastectomy, major orthopedic surgery, pacemaker insertion
High	Bleeding likely to compromise surgical result, bleeding complications frequent	Neurosurgery, ophthalmic surgery, cardiopulmonary bypass, prostatectomy or bladder surgery, major vascular surgery, renal biopsy, bowel polypectomy

TABLE 159.2 Preoperative Hemostatic Evaluation

Routine Screening Surgical Risk	Approach
Low	History only
Moderate or high	History, PT/INR, aPTT, platelet count
Consultation History	
Negative or minimal for bleeding	PT/INR, aPTT, platelet count, biochemical profile, complete blood count with differential, review of peripheral smear
Suggestive of bleeding disorder	Add to above as indicated: platelet function tests, von Willebrand antigen, ristocetin cofactor, factor VIII, factor IX, factor XI, factor XIII assays

aPTT, Activated partial thromboplastin time; INR, international normalized ratio; PT, prothrombin time.

is usually necessary to establish a specific diagnosis.²⁵⁻²⁷ If clinical suspicion is high, further testing is indicated even with normal PFA-100 results.²⁶ Thus the PFA-100 should not be used for general unselected screening.²⁷

Although some studies have demonstrated the ability of the PFA-100 to predict recurrent ischemic events following percutaneous coronary interventions²⁸ and coronary artery bypass graft surgery,²⁹ such testing does not predict bleeding in patients undergoing cardiac or hip fracture surgery.³⁰⁻³²

Notwithstanding the controversy about the value of preoperative laboratory screening, it is reasonable to personalize the approach to preoperative evaluation depending on the hemostatic risk of the proposed surgery or invasive procedure (Tables 159.1 and 159.2). A hemostatic history should always be obtained, and no laboratory testing is required in patients undergoing procedures at low risk for bleeding. For procedures associated with a high risk of bleeding, screening could include a PT/INR, aPTT, and determination of the platelet count.

In practice, hematologists are rarely consulted for routine screening because surgeons have adopted approaches based on their own training and local practice patterns. Instead, consultation is sought because of a history suggestive of a bleeding disorder or because an abnormal test result is found on screening. If a referral is requested because of an abnormal screening test, the abnormality needs to be identified. However, regardless of the reason for the referral, the history is of central importance and must include a thorough review

of any bleeding episodes, including results of prior hemostatic testing, as well as careful attention to the family history. The physical examination should focus on evidence of bleeding and on identifying systemic disorders such as hepatic or renal disease. If the history of bleeding is negative or minimal, appropriate laboratory testing would include a PT/INR, aPTT, and a biochemical profile to evaluate hepatic and renal function. A complete blood count and examination of the peripheral blood smear are useful to identify myeloproliferative disorders, gray platelet syndrome, or thrombocytopenia. If the history is suggestive of a hemostatic abnormality, a full evaluation is indicated and additional specific testing is usually required because von Willebrand disease; mild deficiencies of factors VIII, IX, and XI; severe factor XIII deficiency; platelet function defects; and fibrinolytic abnormalities may not be identified by global screening tests (see Table 159.2).

HEMOSTATIC AGENTS

A variety of hemostatic agents are available and may be useful for the prevention or treatment of bleeding in the surgical patient. These agents work through a variety of mechanisms to facilitate hemostasis, including enhancement of primary hemostasis, enhancement of thrombin generation and fibrin formation, and inhibition of fibrinolysis.³³ However, it is important to note that there is a paucity of safety data involving hemostatic agents because most trials have been designed to assess therapeutic efficacy rather than potential complications, including thrombosis.^{33,34} The use of desmopressin, topical hemostatic agents, antifibrinolytic agents, and recombinant factor VIIa (rFVIIa) will be discussed here. Blood products (platelets, fresh-frozen plasma, and cryoprecipitate) and factor VIII and IX concentrates are discussed elsewhere (Chapters 112 and 115–117).

Desmopressin

Desmopressin (1-deamino-8-D-arginine vasopressin, or DDAVP) is a synthetic analogue of the antidiuretic hormone arginine vasopressin. Intravenous, subcutaneous, or intranasal administration of DDAVP results in transient increases in plasma concentrations of factor VIII and von Willebrand factor as a result of their release from vascular endothelium.³⁵ Peak levels (typically two to four times baseline) are achieved 30–60 min after intravenous and 60–90 min after subcutaneous or intranasal administration.³⁶ Doses may be repeated at intervals of 12–24 hours, but tachyphylaxis may occur after three or four doses,³⁷ limiting further usefulness of DDAVP. Expression of glycoprotein Ib (GPIb) and GPIIb/IIIa on the platelet membrane is also enhanced after DDAVP administration.³⁸ DDAVP is the treatment of choice for patients with mild hemophilia A or type 1 von Willebrand disease who require low-risk surgical procedures. Moderate- or high-risk procedures usually require administration of clotting factor concentrates.³⁷ DDAVP may also be useful for patients with congenital or acquired platelet function disorders.^{36,38,39}

DDAVP does not reduce blood loss or transfusion requirement after cardiopulmonary bypass surgery.^{40,41} Worrisome also is the fact that a metaanalysis shows a 2.4-fold increase in perioperative myocardial infarction in cardiac surgery patients treated with DDAVP.⁴¹ Thus the routine use of DDAVP in cardiac, orthopedic, or other elective surgical procedures is not recommended.^{34,42} A more recent metaanalysis of 38 randomized placebo-controlled trials that included nearly 2500 surgical patients found that DDAVP slightly reduced blood loss (by approximately 80 mL) and transfusion requirements (by approximately 0.3 units) but did not reduce the proportion of patients receiving transfusions.⁴³ Although the authors acknowledged that the clinical impact of the reduced transfusion requirement is questionable, they felt this could not be ignored because of the low cost of DDAVP. The incidence of thromboembolic events in the DDAVP and placebo groups was similar (5.4% and 4.6%, respectively), but they pointed out that identification of harm from DDAVP

is limited by study design and that the safety concerns remain unresolved.⁴³ Nonetheless, certain subgroups of patients, such as those with platelet dysfunction, may derive benefit.^{38,42-44} Because of the small but important risk for myocardial infarction,⁴⁵ DDAVP should be used with caution in any surgical patient with a history of or risk factors for coronary artery disease.

Topical Hemostatic Agents

Topical hemostatic agents can be grouped into several categories: physical agents (bone wax, Ostene), absorbable agents (gelatin foams, oxidized cellulose, microfibrillar collagen), biologic agents (thrombin, fibrin sealants, platelet gel), synthetic agents (polyethylene glycol hydrogels, cyanoacrylates, glutaraldehyde cross-linked albumin), and hemostatic dressings.⁴⁶ A thorough discussion of the currently available products, including mechanisms of action, specific advantages and disadvantages, and recommendations for their use is provided in a recent comprehensive review.⁴⁶ A brief overview of the different types of topical hemostatic agents follows.

Physical Agents

Bone wax and alkylene oxide copolymers (Ostene) control hemorrhage by occluding bleeding channels on cut bone surfaces, and are often used in cardiac and orthopedic surgery. Ostene is preferred because it does not impede bone growth and is eventually absorbed. Both can increase the risk for local infection.⁴⁶

Absorbable Agents

Gelatin foams are derived from animal products and provide a physical matrix upon which clotting occurs. These products expand to double their volume, an attractive feature for use in penetrating wounds, but potentially problematic if used near nerves or in confined spaces.⁴⁶

Oxidized cellulose is derived from wood pulp. It provides a physical matrix for initiation of clotting and has excellent handling characteristics. By lowering surrounding pH, oxidized cellulose exerts an antimicrobial effect, but this property not only limits its use with biologic agents such as thrombin that are pH sensitive, but also can contribute to local inflammation.⁴⁶

Microfibrillar collagen is derived from bovine components. It contributes to hemostasis by promoting platelet adherence and activation and is effective in controlling wide-spread parenchymal bleeding. Consequently, it can be useful even in the face of heparin therapy, although it is less effective in the setting of thrombocytopenia.⁴⁶

Biologic Agents

Thrombin derived from bovine plasma was used for more than 40 years as a topical hemostatic agent in surgical patients. However, bovine thrombin can trigger the formation of antibodies that cross-react with human thrombin, leading to hemorrhagic complications.⁴⁷⁻⁴⁹ Because of these issues, plasma-derived and recombinant forms of human thrombin were developed. A phase III randomized, double-blind trial found that the efficacy and safety of recombinant human thrombin and bovine thrombin were comparable, but there were fewer immunologic complications with recombinant human thrombin.⁵⁰

Fibrin sealants are topical hemostatic agents composed of purified virally inactivated human fibrinogen and human thrombin. Some products also add human factor XIII to induce fibrin crosslinking and antifibrinolytic agents to prevent clot breakdown.⁵¹ The components of fibrin sealants are supplied in separate chambers of a dual-syringe delivery device that combines them at the time of administration. The final steps of the coagulation cascade are reproduced, resulting in formation of a stable fibrin clot. These products are particularly effective for controlling oozing from raw surfaces.⁴⁶

Platelet gel combines microfibrillar collagen and thrombin with patient-derived plasma that contains fibrinogen and platelets. Like fibrin sealants, the product is applied using a dual-chamber syringe device. The presence of platelets improves clot strength and provides growth factors, but the need for centrifugation of patient blood and processing before use is a disadvantage.⁴⁶

Synthetic Agents

Cyanoacrylates are liquid monomers that rapidly polymerize in the presence of water and bind adjacent surfaces together. Octyl-2-cyanoacrylate is useful for closing small wounds or incisions and provides good cosmetic results.⁴⁶

Polyethylene glycol hydrogel can be sprayed onto tissues, where it rapidly forms a cross-linked polymer matrix and serves as a sealant that inhibits cell ingrowth and adhesion formation. It is useful for preventing pericardial adhesions and as a mechanical sealant for vascular reconstructions in situations where swelling and expansion are not a concern.⁴⁶

Glutaraldehyde cross-linked bovine albumin is primarily used to seal sutures or staple lines in complex cardiovascular procedures. However, because it can restrict tissue growth, it should not be used circumferentially around developing structures, particularly in children.⁴⁶

Hemostatic Dressings

Progress in the field of topical hemostatic agents over the last decade has expanded into the development of hemostatic dressings. Several products containing combinations of gauze and lyophilized fibrinogen and thrombin, chitin, and chitosan (polysaccharides found in arthropod skeletons and produced by fermenting algae), and mineral zeolite are available. In general, the use of hemostatic dressings is still under investigation, primarily by the military and emergency first responders.⁴⁶

Antifibrinolytics

Antifibrinolytic agents include the synthetic lysine analogues 6-aminohexanoic acid (aminocaproic acid) and 4-(aminomethyl) cyclohexanecarboxylic acid (tranexamic acid), and the serine protease inhibitor, aprotinin. Although both types of antifibrinolytic agents have been used in managing surgical bleeding, the lysine analogues are available in oral forms that facilitate their use in other clinical situations as well.

Aminocaproic Acid and Tranexamic Acid

Both aminocaproic acid and tranexamic acid bind reversibly to the lysine binding sites on plasminogen, thereby attenuating its capacity to bind to fibrin, which is essential for its activation by plasminogen activators.³⁶ Although tranexamic acid is approximately 10 times more potent than aminocaproic acid and has a longer half-life, both drugs have similar hemostatic effects.⁵²

Because the oral form of tranexamic acid was not commercially available in the United States for a number of years, aminocaproic acid became the lysine derivative of choice for oral delivery. Aminocaproic acid is commonly used to treat mucosal hemorrhage (menorrhagia, epistaxis, dental bleeding) in patients with congenital coagulopathies and is also effective for prevention of oral bleeding in those who require dental work while receiving long-term oral anticoagulant therapy.

Although aminocaproic acid is sometimes used to treat bleeding in patients with thrombocytopenia, randomized controlled trials are lacking. The use of antifibrinolytic drugs in patients with gastrointestinal bleeding is reasonable given the high concentration of

fibrinolytic enzymes in the digestive tract, and a metaanalysis found reductions in recurrent bleeding, need for surgery, and mortality.⁵³ However, improvements in the efficacy of other medical and endoscopic treatments have limited the use of these drugs in this setting, although they are still useful for some patients with underlying bleeding disorders.³⁶ The urinary tract is also rich in plasminogen activators, and some clinical trials comparing tranexamic acid or aminocaproic acid with placebo in patients undergoing prostatectomy have shown reduced blood loss, but not a reduced need for transfusion or decreased mortality.³⁶

The largest experience with aminocaproic acid in surgical patients is in those undergoing cardiac and orthopedic surgery. Older meta-analyses have consistently shown that prophylactic treatment of cardiac surgery patients with aminocaproic acid results in a 30%–40% reduction in postoperative bleeding, without an increase in thromboembolic complications.^{41,54–56} Similar results have been shown with tranexamic acid.³⁸ Other metaanalyses have shown that aminocaproic acid and tranexamic acid are effective in reducing surgical blood loss but have yielded inconsistent results in their capacity to reduce transfusion requirements.^{42,57} A wide variety of dosing schedules may partly explain these heterogeneous results.⁴² A recent meta-analysis showed that both agents were effective in reducing blood loss and transfusion requirements in those undergoing cardiac surgery.⁵⁸

A number of studies have demonstrated that antifibrinolytic agents reduce blood loss in orthopedic surgery. A meta-analysis of 43 randomized controlled trials in total hip and knee arthroplasty, spine fusion, musculoskeletal infection, or tumor surgery found that aprotinin and tranexamic acid significantly reduced the number of patients requiring transfusion, with a dose-effect relationship suggested for tranexamic acid.⁵⁹ A meta-analysis of 11 clinical trials involving total hip replacement found that the use of tranexamic acid significantly reduced intraoperative blood loss and transfusion requirements, without any increase in VTE or other complications.⁶⁰ A recent double-blind, randomized, placebo-controlled trial demonstrated that intraoperative treatment with tranexamic acid was also effective for reducing the need for transfusion in patients undergoing retropubic prostatectomy.⁶¹ Therefore many centers routinely administer tranexamic acid to patients undergoing elective joint arthroplasty to reduce blood loss and decrease the need for transfusion, and some centers also use it in patients undergoing urologic procedures.

Antifibrinolytics, particularly tranexamic acid, have also been studied in the treatment of trauma patients, in whom 30% of deaths are attributed to hemorrhage.⁶² A landmark trial, Clinical Randomisation of an Antifibrinolytic in Significant Haemorrhage 2 (CRASH-2), evaluated the safety and efficacy of tranexamic acid in the setting of trauma.⁶³ This randomized, placebo-controlled, multinational trial that included more than 20,000 trauma patients demonstrated a significant reduction in all-cause mortality and death because of bleeding in the treatment group. More severely injured patients and those treated within 3 hours of injury derived the greatest benefit, and there was no difference in the rate of vascular occlusive events between the two groups.⁶³ Tranexamic acid is now incorporated into trauma clinical practice guidelines and treatment protocols.⁶⁴

Two randomized controlled trials have shown that high-dose tranexamic acid significantly reduces surgical blood loss and transfusion requirements in liver transplant recipients.^{65,66} A metaanalysis identified 23 studies with a total of 1407 liver transplant patients who received aminocaproic acid, tranexamic acid, or aprotinin compared with each other or with controls/placebo. This review found that tranexamic acid and aprotinin reduced transfusion requirements without any increased risk for hepatic artery thrombosis, VTE, or perioperative mortality.⁶⁷

Aminocaproic acid and tranexamic acid are not without risks. There are case reports of thrombosis associated with both aminocaproic acid and tranexamic acid. However, no significant increase in thrombotic complications has been observed when the drugs have been used in patients undergoing cardiac, liver transplantation, or orthopedic surgery.^{37,39,59,61,68} Furthermore, when used in doses exceeding 80 mg/kg, tranexamic acid has been associated with convulsive seizures in patients undergoing cardiac surgery.^{66,69}

Aprotinin

Aprotinin is a polypeptide extracted from bovine lung that inhibits the action of serine proteases, including plasmin and kallikrein.³⁷ In addition to its antifibrinolytic activity, aprotinin is also thought to preserve platelet function and have antiinflammatory effects, both of which may be mediated by inhibition of protease-activated receptors expressed on platelets, vascular endothelium, and neutrophils.⁶⁸

The bulk of clinical experience with aprotinin was in cardiac surgery. In a large number of trials prophylactic administration of aprotinin improved hemostasis and reduced requirements for transfusion of red blood cells, platelets, and fresh-frozen plasma in patients undergoing cardiopulmonary bypass.^{35,39,43} A large metaanalysis of such trials demonstrated decreased mortality with aprotinin and a reduced incidence of repeat thoracotomy, without any increased risk for perioperative myocardial infarction.⁴² Furthermore, another metaanalysis showed a lower incidence of stroke in cardiac surgery patients treated with high-dose aprotinin.⁷⁰

Although there is abundant evidence that aprotinin reduces blood loss and transfusion requirements in cardiac surgery patients, an observational study in patients undergoing elective coronary revascularization surgery revealed that aprotinin increased the risk of renal failure, myocardial infarction, heart failure, stroke, or encephalopathy. In that study, aminocaproic acid and tranexamic acid reduced blood loss to a similar extent as aprotinin without an increase in adverse events. The same investigators subsequently reported that aprotinin use was associated with increased long-term mortality after coronary artery bypass graft surgery.⁷¹ A second observational study confirmed the increased risk of postoperative renal dysfunction, without the associated elevated risk of myocardial or cerebrovascular events however.⁷²

A database analysis of over 30,000 children undergoing congenital heart operations found no difference in postoperative mortality, need for dialysis, or length of stay in patients who received aprotinin versus those who did not.⁷³ The Blood Conservation Using Antifibrinolytics in a Randomized Trial (BART) randomly assigned 2331 cardiac surgery patients to aprotinin, tranexamic acid, or aminocaproic acid. The study was terminated early because of an excess of deaths in the aprotinin group, and the drug was subsequently withdrawn from the market in both Europe and the United States. Although the European Medicines Agency subsequently lifted this ban in 2012, the use of aprotinin is limited, and tranexamic acid is preferred.

Recombinant Factor VIIa

rFVIIa is licensed in the United States only for the prevention and treatment of bleeding in hemophilia patients with factor VIII or factor IX inhibitors, patients with acquired hemophilia, and in those with congenital factor VII deficiency. This drug is believed to induce hemostasis at local sites of tissue injury through enhancement of thrombin generation on the surface of thrombin-activated platelets.⁷⁴ rFVIIa also activates thrombin activatable fibrinolysis inhibitor, which in turn stabilizes the clot by inhibiting fibrinolysis.⁷⁵ The use of rFVIIa in the management of hemophilia and factor VII deficiency is reviewed in [Chapters 135–137](#).

rFVIIa is often used for a variety of off-label indications, such as to control refractory bleeding after surgery or major trauma and to prevent bleeding in surgeries where blood loss is expected to be excessive (see box on [Off-Label Use of rFVIIa](#)). A prospective, multicenter, randomized, controlled trial that included 143 patients with blunt trauma and 134 patients with penetrating trauma found that in the group with blunt trauma, three successive doses of rFVIIa significantly decreased red blood cell transfusion (mean reduction of 2.6 units) and decreased by approximately half the number of patients requiring massive transfusion (more than 20 units of red blood cells).⁷⁶ Although similar trends were observed in the patients with penetrating trauma, the differences were not statistically significant. In spite of the reduction in the need for blood products, there was no survival benefit. After these initial encouraging reports of the use

A 56-year-old man has undergone aortic arch replacement for an aortic dissection. During the procedure he underwent circulatory arrest for 35 min, with a lowest recorded temperature of 18°C. His total bypass time was 225 min. After rewarming, there was considerable bleeding and he received 10 units of packed red blood cells, 8 units of fresh frozen plasma, 4 pooled units of platelets, and 20 units of cryoprecipitate. He was transferred from the operating room to the intensive care unit in stable condition.

A consultation is made to the hematologist 1 hour later because of excessive drainage (>500 mL) from his chest tubes.

Important information to consider:

- likelihood of surgical bleeding versus coagulopathy
- current temperature
- evidence of clotting within the chest tubes
- current coagulation studies (if available)
- hemodynamic status

Upon discussion with the surgeon and intensive care unit team, it is noted that the temperature is 35.5°C, there is little clot in the chest tubes, and he requires hemodynamic support with epinephrine and norepinephrine. His recent coagulation studies reveal an INR of 1.8, an aPTT of 48 s, a thrombin time of 59 s, and a fibrinogen level of 2.5 g/L.

Possible treatments:

1. warming blanket
2. protamine sulfate 50 mg by slow intravenous infusion: for heparin rebound
3. calcium gluconate 1–2 g intravenous bolus: for excessive citrate (from blood products)
4. blood products (using a warming line)
5. consider rFVIIa: 40–80 mcg/kg

Interpretation: The likelihood is that despite the extensive transfusion, the combination of a prolonged time on bypass and cooling to 18°C has resulted in a coagulopathy. This is further evidenced by the prolongation of the coagulation tests and the lack of visible clots within the chest tubes. Although items 1–3 are important as adjunctive therapies, they are unlikely to be sufficient on their own. The utility of further blood products in this situation cannot be understated, because in order for rFVIIa to work effectively, it relies on the presence of underlying substrate, which is effected by judicious use of blood products. Although the use of rFVIIa in this scenario is off-label, its use is justified when the surgeon feels that the likelihood that bleeding is too diffuse to be stopped by surgical intervention and is likely caused by coagulopathy.

of rFVIIa in trauma patients, questions regarding optimal dosing and timing of administration remained. In an attempt to address these issues, the Western Trauma Association Multi-Center Trials Group conducted a case registry of 380 adult trauma patients who received adjunctive rFVIIa for hemorrhage control.⁷⁷ This registry was unable to define a precise role for rFVIIa in traumatic bleeding. However, a pH of less than 7.2, platelet count of less than 100,000/ μ L, and blood pressure less than or equal to 90 mmHg were each found to be predictors of poor response to rFVIIa, suggesting that correction of shock, acidosis, and thrombocytopenia should precede the use of rFVIIa in bleeding trauma patients.⁷⁷ The CONTROL trial, which randomized 560 actively bleeding trauma patients to rFVIIa or placebo, found no differences in overall mortality, organ system failure, or adverse events in either group.⁷⁸ Thus although initial reports were encouraging, there is currently insufficient evidence to support a role for the routine use of rFVIIa in the setting of trauma.

The use of rFVIIa in cardiac surgery is controversial. Because perioperative bleeding is a major cause of morbidity and mortality, there is off-label use of rFVIIa in this patient population.⁷⁹ A number of case reports and uncontrolled case series in both adult and pediatric populations have suggested that rFVIIa is effective in decreasing blood loss and transfusion requirements in patients with intractable bleeding after cardiopulmonary bypass. However, in the absence of data from well-designed clinical trials demonstrating efficacy and with the current widespread use of tranexamic acid in such patients, rFVIIa is rarely used in this setting.

rFVIIa has been used in a variety of other surgical settings with divergent results. Although a trial in patients undergoing retropubic prostatectomy demonstrated a greater than 50% reduction in surgical

blood loss with a single intraoperative dose of rFVIIa,⁸⁰ rFVIIa resulted in little or no reduction in blood loss in a patients without cirrhosis undergoing partial hepatectomy.^{81,82} Overall therefore, the published experience of rFVIIa in noncardiac surgery is still too limited and subject to bias to draw meaningful conclusions.⁸³

Neurosurgical patients are distinct from other groups in that rather than treating massive hemorrhage, the goal is to treat relatively small bleeds within a closed space where even mild or modest benefit may result in significantly better outcomes.⁸³ A randomized, placebo-controlled study of 399 patients with intracerebral hemorrhage suggested that treatment with rFVIIa within 4 hours after the onset of symptoms limited growth of the hematoma, reduced mortality, and improved functional outcomes at 90 days, albeit with a small increase in the frequency of thromboembolic events.⁸⁴ In a subsequent larger trial in patients with intracerebral hemorrhage, rFVIIa failed to improve mortality and disability at 90 days.⁸⁵ Therefore rFVIIa should not be used for this indication.

The primary safety concern with the off-label use of rFVIIa is thrombosis. In hemophilia, the risk for thrombosis is estimated to be less than 1%.^{86,87} In contrast, the risk is much higher with off-label use. Both arterial and venous thromboembolic events have been reported, and thromboembolic events were the probable cause of death in the majority of the reported fatalities. Half of the thromboembolic events occurred within 24 hours of the last dose of rFVIIa, and many occurred within 2 hours.⁸⁸ Therefore off-label use of rFVIIa should be restricted to cases where there are no alternatives.

MANAGEMENT OF PATIENTS WITH HEMOSTATIC ABNORMALITIES

Patients with known hemostatic abnormalities are often referred before surgery for assessment of bleeding risk and recommendations regarding perioperative management. The approach to these patients should be according to the following considerations: (1) evaluation of the risk for bleeding associated with the specific surgery or procedure (see Table 159.1); (2) careful consideration of the need for surgery and its urgency; greater risks are warranted for correction of life-threatening conditions than for elective procedures; (3) recognition of the nature and severity of the patient's hemostatic abnormality and the ability to correct it; and (4) consideration of the duration of replacement that will be required, with appreciation of potential bleeding that may be associated with events in the postoperative period such as removal of sutures and deep drains, and the need for postoperative rehabilitation. The following sections discuss perioperative management of some common coagulation abnormalities; the management of congenital factor deficiencies and von Willebrand disease are discussed elsewhere in this text (see Chapters 135, 137, and 138).

Thrombocytopenia

Thrombocytopenia is one of the most common acquired hemostatic abnormalities, and the availability of platelet transfusion makes consideration of both emergency and elective surgery reasonable even in severely thrombocytopenic patients. The best index of bleeding risk in thrombocytopenic patients is the platelet count. In nonsurgical patients a threshold platelet count of 10,000/ μ L is widely used for prophylactic transfusions, yet there is inadequate scientific evidence to determine the platelet count below which the risk for surgical bleeding is increased.^{89,90} The American Society of Anesthesiologists Task Force on Blood Component Therapy concluded that prophylactic platelet transfusion in surgical patients is usually indicated when the count is below 50,000/ μ L and is rarely indicated when the count is above 100,000/ μ L.⁸⁹ Clinical trials addressing this issue are still lacking.⁹¹ For low-risk surgery, a single transfusion to increase the platelet count to more than 50,000/ μ L followed by close observation may suffice, whereas transfusion to maintain the platelet count at greater than 50,000/ μ L for moderate-risk surgery and greater than

100,000/ μ L for high-risk surgery is usually appropriate. The optimal duration of postoperative platelet support has not been carefully studied, but even for moderate- or high-risk surgery, platelets may be needed for less than 1 week because they are principally required for primary hemostasis. The platelet count should be monitored closely during the postoperative period, with the expectation that platelet survival will be shortened by infection, fever, or bleeding. In addition, platelet transfusion may be indicated for surgical patients despite an apparently adequate count in the presence of known or suspected platelet dysfunction, antiplatelet therapy, and microvascular bleeding.

When thrombocytopenia is caused by increased platelet destruction (e.g., immune thrombocytopenic purpura), prophylactic platelet transfusion is largely ineffective and is indicated only for active, serious bleeding. In preparation for surgery, therapy with steroids and/or intravenous γ -globulin often will increase the platelet count to a satisfactory level so that transfusion is not needed. Rho(D) immunoglobulin (WinRho[®]) may also be useful in this setting.

Platelet Dysfunction

Patients with platelet dysfunction represent a large group for whom preoperative consultation is sought, typically because of an abnormal bleeding history or the discovery of a prolonged bleeding time or other laboratory assessment of platelet function with a normal platelet count. Drugs are the most common cause of acquired platelet dysfunction. Many commonly used types of medications, including aspirin and other nonsteroidal antiinflammatory drugs, antibiotics, antidepressants (selective serotonin reuptake inhibitors), cardiovascular drugs, and newer antiplatelet agents, including ADP receptor, GPIIb/IIIa or protease-activated receptor antagonists, can cause platelet dysfunction. Ethanol as well as certain foods and herbal supplements can also inhibit platelets; a careful history is therefore essential. Any drugs that interfere with platelet function should be reviewed before surgery and an assessment of their ongoing use be carefully considered.

A number of medical conditions can cause acquired platelet dysfunction. The etiology may be fairly obvious in cases of renal or liver disease, myeloproliferative disorders, leukemia, myelodysplastic syndromes, or dysproteinemia, but consideration of undiagnosed intrinsic platelet defects (storage pool disease or platelet release defects) or von Willebrand disease may be necessary. Treatment of the underlying disease is the most effective approach, if possible. If not, platelet transfusion may be indicated, but the dose required to achieve hemostasis is difficult to predict and depends in part on the severity of the underlying platelet abnormality. As discussed earlier, treatment with DDAVP may be appropriate in selected patients. The exact mechanism of action of DDAVP in acquired platelet dysfunction is not well understood, but one study suggests that DDAVP interacts directly with platelets and exerts a priming effect on platelet aggregation stimulated by ADP or collagen.³² Expression of GPIIb and GPIIb/IIIa on platelet membranes is also enhanced following administration of DDAVP.³⁹

Renal Disease

Impaired hemostasis has long been recognized in patients with chronic renal failure and is discussed in greater detail in [Chapter 154](#). The pathogenesis is multifactorial but is due in large part to alterations in platelet function.⁹³ Anemia also contributes to platelet dysfunction in chronic renal failure. Red blood cells release ADP, which in turn inactivates vascular prostacyclin, an inhibitor of platelet function.⁹⁴ Correction of anemia, now routinely accomplished through the use of recombinant erythropoietin, also improves the rheologic factors that facilitate platelet interaction with the vessel wall. An increase in hematocrit, whether by the use of erythropoietin or transfusion, is accompanied by significant shortening of the bleeding time and improvement of platelet adhesion.⁹⁵ In addition to platelet dysfunction and altered balance between mediators of normal

endothelial function, the pathophysiology of uremic bleeding is complicated by the comorbidities in this patient population, such as vascular disease and hypertension, and the medical treatment of those conditions.⁹⁶

Liver Disease

Hemostatic alterations in patients with acute or chronic liver disease (see [Chapter 153](#)) are complex and involve both procoagulant and anticoagulant pathways.^{97,98} Although patients with liver disease are typically felt to have deficient hemostasis, this concept has been challenged in the recent literature.⁹⁹ These patients are not “autoanticoagulated”, as often assumed. In fact, they are not protected from and may even be at increased risk for thrombosis, particularly in the portal venous system.¹⁰⁰⁻¹⁰² The presence of genetic thrombophilic mutations may further increase this risk.⁸² The procoagulant tendency associated with chronic liver disease^{103,104} suggests that prophylaxis against VTE may be warranted in high-risk situations.⁹⁹ However, the perceived bleeding risk often limits the use of prophylaxis,¹⁰⁵ and appropriately designed pharmacologic clinical studies are clearly needed.¹⁰⁰

Patients with severe decompensated liver disease and markedly abnormal coagulation test results are at increased risk for bleeding, and surgery should be avoided except as a lifesaving measure. In evaluating hemostasis in patients with less severe disease, the PT/INR and aPTT may be good indicators of decreased synthesis of clotting factors and vitamin K deficiency, but they are poor predictors of bleeding risk. Several studies have shown the failure of the PT/INR and aPTT to predict bleeding after liver biopsy.^{106,107} Similarly, preoperative hemostatic testing has generally not been shown to be useful for predicting bleeding during liver transplantation.¹⁰⁸ A study in patients with liver disease found that INR values in the range of 1.3–2.0 generally correspond to levels of factors II, V, and VII that are adequate for hemostasis.¹⁰⁹ A preoperative platelet count is needed to identify thrombocytopenia, and some assessment of platelet function may be useful to determine whether platelet function is abnormal in the setting of a normal or near-normal platelet count. A thrombin time or fibrinogen level should also be performed to evaluate for dysfibrinogenemia. Tests for fibrinogen/fibrin degradation products, D-dimer, euglobulin clot lysis time or thromboelastography may be useful in evaluating for disseminated intravascular coagulation (DIC) or accelerated fibrinolysis.

In patients with mild liver disease and mild-moderate INR prolongation (<2.0), serious surgical bleeding is unlikely in the absence of other hemostatic abnormalities, and prophylactic intervention is rarely required for low- or moderate-risk surgery. For high-risk surgery or for patients with markedly abnormal coagulation tests, transfusion of fresh-frozen plasma is the most commonly used approach for correcting the coagulation abnormality, although prospective studies demonstrating the value of fresh-frozen plasma administration in this setting are lacking. There are, however, guidelines that caution against the indiscriminate use of plasma before invasive procedures.¹¹⁰ It should be noted that the PT of fresh-frozen plasma is approximately 15 s, which corresponds to an INR of 1.5, so complete correction of the PT/INR is unlikely to be achieved.¹¹¹ Administration of platelets should be considered for more severe degrees of thrombocytopenia, although recovery will be decreased in the presence of splenomegaly. Administration of DDAVP may be useful for correcting abnormal platelet function in some cases.¹¹² Intravenous administration of 5–10 mg vitamin K will usually shorten the PT/INR if vitamin K deficiency is a contributory factor. Antifibrinolytic agents also may be useful for the reduction of perioperative hemorrhage in patients with liver disease.

INTRAOPERATIVE AND POSTOPERATIVE BLEEDING

Patients with excessive bleeding during or after surgery require rapid evaluation and treatment. The first step is to distinguish between

“surgical” and “coagulopathic” causes of bleeding. Failure to surgically control bleeding vessels at the operative site is the most frequent cause of postoperative bleeding and is suggested by evidence of hemorrhage restricted to the operative site and manifesting as an expanding hematoma, excessive blood in surgical drains, or saturated wound dressings. Conversely, coagulopathic bleeding is suggested by slower “oozing” at the operative site in addition to evidence of bleeding outside the operative field that may be seen as petechiae, purpura, or bleeding at sites of venipuncture, urinary or vascular catheters, or nasogastric and endotracheal tubes.¹¹³ In addition to careful physical examination, laboratory tests, including PT/INR, aPTT, and platelet count, are an essential part of the evaluation. Other useful tests may include a fibrinogen level, and a test for fibrin degradation products or D-dimer and thromboelastography to search for evidence of DIC or increased fibrinolysis. The peripheral blood smear should also be reviewed to examine platelet morphology and number, and to identify possible red blood cell fragmentation that may occur in DIC. The possibility of a preexisting hemostatic abnormality that may have been missed before surgery should also be considered.

When evaluating coagulation test results in surgical patients, changes that normally occur in response to surgery must be considered. These vary depending on the extent of tissue dissection and the duration of the procedure. Consumption and hemodilution from crystalloid and blood product infusion can lead to acute reductions of coagulation factors and platelets during surgery and in the initial postoperative period. This is typically followed by changes resulting from the acute-phase response, including increases in fibrinogen and factor VIII levels, and the platelet count during the first postoperative week.¹¹⁴

Alterations in coagulation factor levels that occur during surgery and in the initial postoperative period can limit the reliability of the PT/INR and aPTT in evaluating the bleeding surgical patient. Clinical practice guidelines have consistently recommended transfusion of fresh-frozen plasma if the PT/INR and aPTT results are prolonged more than 1.5-fold compared with the mean reference range.¹¹⁵⁻¹¹⁷ However, there are differing opinions on the utility of coagulation studies to guide transfusion practices,^{118,119} and prospective studies are needed.

Coagulopathy Associated With Massive Blood Loss/Transfusion

Massive bleeding (loss of one or more blood volumes in a 24-h period) may occur in the setting of severe trauma or major surgery and requires aggressive fluid resuscitation and transfusion of blood products. The mechanisms involved in the coagulopathy that accompanies massive transfusion have not yet been fully elucidated but are multifactorial in nature.¹²⁰ Similar to chronic liver disease, procoagulant, anticoagulant, profibrinolytic, and antifibrinolytic factors are all affected, resulting in a complex coagulopathy. Impaired thrombin generation is compensated in part by reduction in the activity of antithrombin and other protease inhibitors. Fibrinogen levels can fall rapidly and are proportional to the degree of hemodilution. Antifibrinolytic protein levels are decreased, rendering clots more susceptible to lysis.¹²¹ In addition to a dilutional coagulopathy, other complications, including consumptive coagulopathy, hypothermia, electrolyte abnormalities (because of citrate intoxication), and acid-base disturbances, may also develop.¹²¹

In patients without a preexisting coagulopathy, replacement of approximately 1.5 blood volumes is the threshold for the development of dilutional coagulopathy.¹²² At that point, PT/INR, aPTT, fibrinogen level, and platelet count should be determined. If the PT/INR or aPTT is prolonged greater than 1.5-times control, the fibrinogen level is below 100 mg/dL, or the platelet count is reduced to 50,000–70,000/ μ L, clinical coagulopathy is suspected and appropriate blood product administration is indicated, particularly if additional blood loss is expected. The same coagulation parameters should be measured again with the replacement of each additional half-blood volume (i.e., 5–6 units of red blood cells).¹²³

Over the last several years, there has been an increased emphasis on more aggressive blood component therapy, driven by data from both military and civilian trauma populations.¹²⁴⁻¹²⁷ These studies have demonstrated that higher ratios (approaching 1:1) of plasma and platelets to red blood cells are associated with improved outcomes in massively transfused patients. Patients receiving less than massive transfusion may also benefit from higher plasma-to-red blood cell ratios.¹²⁸ Furthermore, maintaining an adequate fibrinogen level is essential for successful management of dilutional coagulopathy.¹²¹ Appropriate and timely management for these patients needs to be facilitated in order to avoid prolonged hypotension, acidosis, and tissue-level ischemia, all of which can predispose to the development of DIC (Chapter 139).

Cardiopulmonary Bypass

Cardiopulmonary bypass is associated with unique hemostatic changes. Perfusion through the extracorporeal membrane oxygenator has profound effects on platelets and clotting factors: platelet count, hematocrit, and levels of coagulation and fibrinolytic factors are reduced to approximately 50% of baseline after starting bypass and remain reduced throughout the procedure, with the exception of factor V, which may be further reduced to less than 20%.¹²⁹⁻¹³¹ These changes may be caused in part by exposure to artificial surfaces and also by a tissue factor–dependent pathway related to surgical trauma.¹³² Cardiopulmonary bypass results in significant platelet dysfunction¹³³ reflected by release of α -granule contents, the generation of platelet microparticles, abnormal ex vivo platelet aggregation test results, and a transient prolongation of the bleeding time.^{130,131,133,134} In addition to quantitative and qualitative platelet function defects, cardiopulmonary bypass also results in platelet activation, which may trigger thrombotic and inflammatory complications.¹³⁴ Patients with acute coronary syndrome (who may be candidates for urgent cardiac surgery) are sometimes given GPIIb/IIIa inhibitors, which may further impair platelet function. If surgery cannot be delayed, consideration of prophylactic platelet transfusions may be required.¹³⁵ Inadequate neutralization of heparin with protamine sulfate after cardiopulmonary bypass may result in a prolonged aPTT and thrombin time with a normal reptilase time, and is an indication for administration of additional protamine sulfate. The use of DDAVP, antifibrinolytic drugs, and rFVIIa to reduce the hemorrhagic complications of cardiac surgery was discussed earlier. Fibrinogen concentrate has also been shown to reduce blood loss and transfusion requirements during cardiac surgery.¹³⁶

Orthotopic Liver Transplantation

In addition to the complex coagulopathy of end-stage liver disease, orthotopic liver transplantation is accompanied by major alterations in hemostasis. The surgical procedure itself can be divided into three stages, each with its own profile of coagulation abnormalities.¹³⁷ Bleeding during the preanhepatic stage, while the host liver is surgically isolated, is due primarily to the patient's preexisting coagulopathy and is determined by the severity of the underlying liver disease. Excessive fibrinolysis may be encountered during this stage in 10%–20% of those with cirrhosis. The anhepatic stage begins with surgical removal of the liver. Bleeding during this stage is primarily hemostatic because of DIC and excessive fibrinolysis.¹³⁸ As the donor liver is reperfused, the postanhepatic stage begins, and serious bleeding is often encountered as a result of a combination of hyperfibrinolysis, metabolic acidosis, hypothermia, electrolyte abnormalities, and sometimes impaired cardiac function.^{138,139}

The multifactorial nature of the coagulopathy associated with orthotopic liver transplantation requires a combination of therapeutic interventions. In addition to transfusion of blood products, other hemostatic agents such as DDAVP and antifibrinolytics may be useful and were discussed earlier. There has also been much interest in the use of rFVIIa, and some randomized, placebo-controlled trials have been

completed, but questions about optimal dosing, cost-effectiveness, and safety remain to be fully answered. Furthermore, it is still questionable whether rFVIIa should be used prophylactically in liver transplantation patients outside of a prospective clinical trial.¹⁴⁰

PERIOPERATIVE ANTICOAGULATION MANAGEMENT

Hematologists are frequently consulted for advice on the perioperative management of patients who are taking oral anticoagulants. Important considerations to be taken into account include: (1) the bleeding risk associated with the surgery; (2) the underlying indication for anticoagulant therapy; (3) in the case of secondary antithrombotic prophylaxis, the remoteness of the most recent thrombotic event; (4) other comorbid conditions that may increase the risk for thrombosis and/or the potential consequences of thrombosis while oral anticoagulation is temporarily interrupted; and (5) the half-life of the anticoagulant agent. Regarding the first point, experience has accumulated in recent years suggesting that many relatively minor procedures can be carried out without any interruption of warfarin or direct oral anticoagulant (DOAC) therapy.¹⁴¹ These include minor dental procedures (single or multiple extraction, endodontic procedure), cataract removal, minor dermatologic procedures, and low-risk endoscopy procedures. Audits have suggested that discontinuation of anticoagulation is excessively frequent in these situations and discordant with guidelines.¹⁴² Apart from the risk for thromboembolism, the inappropriate use of bridging therapy also places patient at risk for bleeding complications. Suggested management strategies are summarized in Table 159.3.

Traditionally, patients on chronic oral anticoagulation with warfarin were admitted to hospital several days before surgery for “bridging” anticoagulation, at which time warfarin was discontinued and dose-adjusted unfractionated heparin (UFH) was administered by continuous infusion. The short half-life of UFH allows it to be safely discontinued approximately 4–6 hours ahead of the procedure. This was followed by the use of LMWH in place of UFH.^{143–145} LMWH has the advantage that in most patients with normal renal function, no monitoring is required, so that therapy can be administered in the outpatient setting. In addition, the risk for heparin-induced thrombocytopenia is less with LMWHs.¹⁴⁶ However, the longer half-life (generally in the range of 4–6 hours) necessitates withdrawal of these agents at least 12 hours (for prophylactic doses) or 24 hours (for full therapeutic doses) preoperatively, although even then significant circulating anticoagulant activity may remain in the plasma.¹⁴⁷ A recent randomized trial suggests that bridging with LMWH does not reduce the risk of thromboembolic events and increases the risk of bleeding in patients with atrial fibrillation.¹⁴⁸ Although these results have changed practice, it is important to note that atrial fibrillation patients with prior stroke were underrepresented in the study.

Temporary interruption of warfarin is often required for more major surgery. Even with a normal diet, 4–5 days should be allowed for full or near-full reversal of warfarin when it is being targeted to an INR of 2.0–3.0. A more rapid reversal over 24–36 hours can be achieved if necessary by administration of a small oral dose of vitamin K1 (1.0–2.5 mg).^{149,150} Large doses of vitamin K1 (>10 mg) are generally unnecessary for this purpose and will lead to prolonged refractoriness to warfarin after it is reinitiated. Although frequently used, subcutaneous administration of vitamin K1 is associated with highly variable absorption and should be avoided. Intravenous vitamin K1 has the advantage of more rapid INR reversal compared with the oral route,¹⁵¹ but it should be administered slowly to avoid anaphylactoid reactions. Urgent reversal of oral anticoagulation before surgery may call for the administration of fresh-frozen plasma, although large volumes (15–20 mL/kg) are usually required to reverse the INR, and indeed complete normalization cannot usually be achieved. Furthermore, the effect is relatively short-lived because of the short half-life (approximately 6 hours) of transfused factor VII. Therefore concomitant vitamin K1 administration is required to ensure maintenance of adequate hemostasis. Prothrombin complex

TABLE 159.3 Perioperative Management Strategies for Patients on Chronic Oral Anticoagulant Therapy

Clinical Situation	Suggested Anticoagulation Management
Low bleeding-risk surgery (dental, cataract, skin)	- Consider reducing dose of warfarin to achieve INR ≤ 2.0 - Consider holding dose of DOAC until after the procedure
Low thrombotic risk Aortic valve prosthesis without other thrombotic risk factors ^a or AF with low stroke risk or VTE >3 months previously	- Stop warfarin 4–5 days prior to surgery, safe to operate when INR ≤ 1.5 - Hold DOACs for 5 half-lives – dabigatran for 3–4 days, rivaroxaban, apixaban, edoxaban for 2–3 days - Restart warfarin in evening of the day of surgery after hemostasis secured; restart DOACs on postoperative day 3 or 4 - Start prophylactic LMWH on the morning of the day after surgery and continue until INR >1.8 or full dose of DOACs resumed
Moderate thrombotic risk Mitral or multiple valve prostheses or Aortic prosthesis with risk factors for thrombosis or AF at high stroke risk or VTE within past 3 months	- Stop VKA 5 days before surgery - Begin twice-daily LMWH in therapeutic doses starting 3 days before surgery with last dose at least 12 h prior to surgery - Hold DOACs for 5 half-lives – dabigatran for 3–4 days, rivaroxaban, apixaban, edoxaban for 2–3 days; no bridging - Restart warfarin in evening of the day of surgery after hemostasis secured; restart DOACs on postoperative day 3 or 4 - Start prophylactic LMWH on the morning of the day after surgery and continue until INR >1.8 or full dose of DOACs resumed

^aRisk factors include caged-ball or single tilting-disk valve, AF, history of stroke/transient ischemic attack/other embolic event, left ventricular failure, underlying hypercoagulable state, including cancer.

AF, Atrial fibrillation; DOAC, direct oral anticoagulant; INR, international normalized ratio; LMWH, low-molecular-weight heparin; VKA, vitamin K antagonist (i.e., warfarin); VTE, venous thromboembolism.

concentrate (PCC; 25–50 units/kg) is preferred over plasma to control hemorrhage in warfarin-treated patients with active bleeding.^{150,152} These concentrates are manufactured by fractionation of pooled plasma and contain the vitamin K–dependent factors II, VII, IX, and X. However, it is important to be aware that there is significant heterogeneity among these agents, with some (three-factor PCC) having a low concentration of factor VII, which may leave the INR prolonged following administration.¹⁵³

In recent years, DOACs, oral anticoagulants that directly inhibit thrombin or factor Xa, have been licensed for the prevention of stroke and systemic embolism in patients with atrial fibrillation and for prevention and treatment of VTE (see Chapter 149). A working knowledge of the respective elimination half-lives of these agents is important in deciding when and if to discontinue before elective procedures. In addition, an appreciation of the dominant mechanism(s) of clearance that may affect the elimination half-life is essential (Table 159.4). In general, when the procedure is considered to be more than minor, and the aim is to have negligible amounts of drug (<10%) in the circulation at the time of surgery, the drug should be discontinued at a time before surgery equivalent to four to five half-lives. This would imply 2–3 days (48–60 hours) for dabigatran and 1–2 days

TABLE 159.4 Comparison of the Features of the Direct Oral Anticoagulants

	Dabigatran	Rivaroxaban	Apixaban	Edoxaban
Target	Thrombin (IIa)	Factor Xa	Factor Xa	Factor Xa
Active Drug	No	Yes	Yes	Yes
Onset Time (h)	0.5–2	2–4	3–4	1–3
Half Life (h)	12–17	5–13	~12	9–11
Renal Excretion (%)	80	33	27	50
Reversal Agent	Idarucizumab 5 g IV bolus	PCC	PCC	PCC

IV, Intravenous; PCC, prothrombin complex concentrate.

for rivaroxaban, apixaban, and edoxaban.¹⁵⁴⁻¹⁵⁶ In the setting of urgent surgery, dabigatran can effectively be reversed with a 5 g bolus of idarucizumab.¹⁵⁷⁻¹⁵⁹ Reversal agents for rivaroxaban, apixaban and edoxaban are not yet available. PCC can be considered in such patients.^{160,161}

PERIOPERATIVE THROMBOPROPHYLAXIS

VTE is the most common cause of preventable death in hospitalized patients. Thromboprophylaxis in medical patients is discussed in Chapter 142. In surgical patients, the risk of postoperative VTE depends on the type of surgery and patient factors. Patients undergoing nonorthopedic surgery have a variable risk of postoperative VTE, whereas those undergoing major orthopedic procedures are at high risk. Therefore the two groups are discussed separately.

Nonorthopedic Surgery

In patients undergoing nonorthopedic surgery, the risks of VTE are grouped into four categories: very low (<0.5%), low (~1.5%), moderate (~3%), and high (~6%).¹⁶² In both the very low- and low-risk groups, guidelines recommend that patients be managed with early ambulation and mechanical methods of prophylaxis using intermittent pneumatic compression devices. In the moderate- and high-risk groups, guidelines recommend pharmacologic thromboprophylaxis with LMWH.¹⁶² LMWH is preferred over low-dose UFH because its use is associated with a reduced risk of heparin-induced thrombocytopenia.¹⁶³ Although LMWH is usually given only while the patient is hospitalized, extended prophylaxis for at least 4 weeks is recommended for patients undergoing abdominal or pelvic surgery for cancer. If the risk of bleeding is deemed to be too high to enable pharmacologic thromboprophylaxis, such as in patients undergoing neurosurgery or spinal surgery, intermittent pneumatic compression devices should be used until the bleeding risk subsides.¹⁶²

Orthopedic Surgery

Patients undergoing orthopedic surgery are at high risk for postoperative VTE because they are relatively immobile after surgery and because manipulation of the lower limb vascular structures may disrupt the vascular endothelium.¹⁶⁴ Therefore patients undergoing hip or knee arthroplasty or surgery for hip fracture are all categorized as high risk. Accordingly, postoperative pharmacologic prophylaxis is recommended and the choices in patients undergoing hip or knee arthroplasty include the DOACs, LMWH, or dose-adjusted warfarin; aspirin is also included as an option in preference to no prophylaxis. The DOACs have not been extensively evaluated in patients undergoing surgery for hip fracture, and LMWH is more commonly used in these patients.¹⁶⁵ In patients undergoing knee arthroplasty,

guidelines recommend that prophylaxis be continued for at least 10–14 days after surgery and in those undergoing hip arthroplasty or surgery for hip fracture, prophylaxis should be continued for at least 35 days.¹⁶⁵ In general, patients undergoing arthroscopic surgery with no prior history of VTE do not require pharmacologic prophylaxis.¹⁶⁵

SUMMARY

The management of surgical or trauma patients in the perioperative period can be challenging because of the variability of procedures, risks inherent within the patient and/or procedure, and the limitations of time and acuity of the situation. A thorough history of bleeding or thrombosis events and a comprehensive medication record, coupled with appropriate use of coagulation studies, hemostatic agents and/or blood products, and collaboration with surgical or trauma teams can lead to improved outcomes for patients. Ongoing research into the management of these patients will likely aid clinical decision-making into the future.

THE SPLEEN AND ITS DISORDERS

Nathan T. Connell, Susan B. Shurin, and Fred Schiffman

Galen described the spleen as the “organ of mystery,” with functions related to mood and good or ill humors. It was not until the 18th century that the spleen’s relationship to the immune and hematologic systems was appreciated. The complexities of splenic function continue to be the focus of research and observation. Although many of its functions overlap with or can be assumed by other organs, it is an important regulator of immune function and hematologic homeostasis. The spleen efficiently phagocytoses erythrocytes, recycles iron, recognizes and destroys pathogens, and induces adaptive immune responses. An appreciation for the subtleties of its anatomy and function is important for the physician evaluating patients with many hematologic, immunologic, hepatic, and infectious diseases.

NORMAL SPLENIC ANATOMY AND FUNCTION

Embryology

The spleen arises from the mesoderm and, by the ninth week of gestation, layers of the left dorsal mesogastrium condense with the appearance of blood vessels. Sheaths are formed around arterioles by reticular cells and fibers.¹ Macrophages are present and develop phagocytic function by the end of the first trimester. Lymphocytes appear during the fourth month, and a formal delineation between red and white pulp can be identified by the sixth month. Germinal centers do not develop during fetal development, but primitive inactive follicles are evident at birth. In mice, the homeobox gene *Tbx1* (formerly known as *Hox11*), which controls the genesis of the splanchnic mesodermal plate, is essential for development of the spleen.² Both the basic helix-loop-helix transcription factor capsulin and the Wilms tumor suppressor 1 (*WT1*) gene are necessary for formation of the spleen. The genetic basis for development of the human spleen is less well understood. The spleen is capable of supporting hematopoiesis during fetal life and, in a variety of pathologic states, postnatally. The circulation of primitive hematopoietic stem cells in peripheral blood during prenatal life through birth makes it difficult to distinguish hematopoiesis arising from stem cells in the spleen as opposed to the incidental presence of hematopoietic cells within the circulation.

Anatomy

The spleen is the body’s largest filter of the blood.^{3,4} Located directly below the diaphragm and adjacent to the stomach, it is covered by a fibrous capsule with blood vessels, lymphatics, and nerves coated by peritoneal mesothelium. The splenic artery arises from the celiac axis, enters the capsule at the hilum, and branches into trabecular arteries. The trabecular arteries then branch into central arteries and enter the white pulp. The periarterial lymphatic sheath consists of a cuff of T lymphocytes, plasma cells, and macrophages around the central arteries. As the arteries branch, the sheath narrows. B-lymphocyte clusters appear in follicles along the periarterial lymphatic sheath at arterial branch points (Fig. 160.1).

The components of the white pulp are connected by a reticular network and supporting stromal cells. On the cut surface of the normal spleen, white pulp is visible as white nodules approximately 1–2 mm in diameter, although their size varies with age and antigenic stimulation. The nodules are fully developed at birth, increase in size during childhood (especially following immunizations and

infections), peak during puberty, and involute in adulthood. Uninfected adults with an intact immune system usually do not show evidence of germinal centers. The secondary germinal center is comprised of a mantle zone of B lymphocytes surrounding the follicle. Antigen trapping and processing take place in the marginal zone of the white pulp.

The red pulp of the spleen consists of vascular sinuses, the cords of Billroth, and the terminal branches of the penicilliary arteries (Fig. 160.2). Vascular sinuses are lined with CD8⁺ littoral endothelial cells that resemble endothelial cells with long processes and a basement membrane with ring fibers that attach to macrophage-derived dendritic processes. No tight junctions or interdigitations connect the cytoplasmic processes. Intact leukocytes, erythrocytes, and platelets are able to squeeze through the potential spaces between these cells and between the ring fibers (Fig. 160.3). Processes of the reticular cells of the cords of Billroth are outside the sinus walls. Endothelial cells line pulp veins but not the cords.

The reticular structure of the spleen facilitates its immune response. Venous sinus endothelial cells contain a plasma membrane-associated network of stress fibers composed of actin and myosin-like filaments. These filaments may cross the plasma membrane and insert into the mesh-like basement membrane. As the fibers tense, they create fenestrations through which erythrocytes must pass if they hope to continue their journey. With age, erythrocytes lose the ability to deform their shape and navigate the pathways created by these fibers and will not be able to continue into the circulation. The limitation is similar for erythrocytes containing parasitic infections. This mechanism, combined with mannose receptors and Toll-like receptors, helps the infrastructure of the spleen play a role in the host’s overall immune response.

Circulation of blood through red pulp lined with endothelial-like littoral cells represents a rapid and closed circulation. Circulation into the cords is slower and open, thereby permitting the macrophages lining the cord to remove damaged or aged cells.

Accessory spleens are present in up to a third of the population and result from failure of precursor cells to fuse during embryologic development. Usually, they receive blood flow from the splenic artery and are located near the spleen, but they can be distant and mistaken for a tumor when noted on imaging studies or physical examination. Accessory spleens may develop similar conditions as the spleen proper and should be considered within the differential diagnosis for patients who have continued abnormalities after splenectomy.

Functions

The functions of the spleen and their anatomic locations are summarized in Table 160.1. Correlation with anatomy and histology are shown in Fig. 160.4

The Red Pulp

Splenic macrophages dominate the function of the red pulp and are responsible for filtering blood, removing bacteria, and recycling iron.

Removal of Damaged and Aged Formed Elements

The venous system of the red pulp enables it to filter whole blood, removing senescent erythrocytes and other blood cells. Arterial

Fig. 160.1 ORGANIZATION OF THE HUMAN SPLEEN PRESENTED SCHEMATICALLY. See text for description of blood flow and cell distribution. TABLE 160.1

Functions of the Spleen

Category	Function	Effector Cells/Areas
Clearance/ Filtration	Antibody-mediated clearance Culling and pitting	Macrophages Reticular meshwork
Immune Response		
Marginal zone	Interaction of antigens with effector cells Antigen processing Immune recognition	Monocytes, lymphocytes Macrophages T cells (periarteriolar sheath)
White pulp	Immunoregulation, antibody production Antigen processing, preservation	B cells (lymphoid follicles) Macrophages
Red pulp	Phagocytosis	Macrophages, monocytes, neutrophils
Hematologic		
	Hematopoiesis	Cords and sinuses
	Storage of erythrocytes, platelets, leukocytes	Reticular meshwork, red pulp
	Finishing/polishing of erythrocytes	Reticular meshwork, macrophages
Hemostasis		
	Production of factor VIII, von Willebrand factor	Endothelial cells

Fig. 160.2 DIAGRAM OF THE SPLENIC ARTERY. Arterial blood pools in the splenic cords before entering the splenic sinuses and returning to systemic circulation. (Used, with permission, from Emerson SG: *Hematopoiesis: The development of blood cells*. In Schiffman FJ, editor: *Hematologic pathophysiology*, Philadelphia, 1998, Lippincott-Raven, p 12.)

blood is delivered to the cords of the red pulp through an open system of reticular fibers, fibroblasts, and macrophages without an endothelial lining. Blood then passes from the cords into the efferent venous sinuses, which are lined with endothelial-like littoral cells with a discontinuous structure. Stress fibers extend beneath the basal plasma membrane and run parallel to the axis of the littoral cells. These cords direct the blood into sinuses through slits modulated in size by the stress fibers. In many animals, the stress fibers and splenic capsule are contractile, giving the spleen the ability to serve as a reservoir of red cells while reducing blood viscosity at rest. In humans, however, there is no evidence that the spleen serves such a function or is capable of significant changes in volume with rest and exercise. To return to the circulation, cells must pass through the slits between venous sinus littoral cells (see Fig. 160.3), the size

of which may be controlled in part by actin and myosin filaments within the stress fibers in the basal portion of endothelial cells. This surface is believed to be an important site for the culling and pitting of aged or damaged cells.

Compared with when they are young and have a healthy metabolic reserve, older erythrocytes and platelets are unable to tolerate the hostile splenic environment. The spleen has a pH between 6.8 and 7.2, is hypoxic (partial pressure of oxygen $[P_{O_2}]$: 54 mmHg), and hypoglycemic (glucose concentration approximately 60% of that in venous blood). With age, damaged enucleated cells undergo changes in complex membrane carbohydrates, which facilitate recognition by splenic macrophages and removal from the circulation. *Culling* describes the destruction of erythrocytes: the normal removal of aging cells or the removal of damaged cells in pathologic states. Most

Fig. 160.3 ORGANIZATION OF THE SPLENIC SINUSES. Erythrocytes and leukocytes are scrutinized as they squeeze through the reticular fibers of endothelial cells to enter the splenic sinuses. The fenestrate contract and relax according to sympathetic stimuli to regulate cell passage. (Used, with permission, from Emerson SG: *Hematopoiesis: The development of blood cells*. In Schiffman FJ, editor: *Hematologic pathophysiology*, Philadelphia, 1998, Lippincott-Raven, p 13.)

Compartment	Histology	Structure	Function	Cell
White pulp			Adaptive response (antigen specific) consequent to interaction between antigen-presenting cells (dendritic cells or marginal zone B lymphocytes) and B lymphocytes or T lymphocytes	PALS (T-cell dependent) Small CD4 ⁺ T lymphocytes Dendritic cells B lymphocytes Macrophages Plasma cells Follicle (B-cell dependent) B lymphocytes or plasma cells Dendritic cells

platelets and leukocytes are not removed by the spleen as they age but adhere to vessel walls and migrate into tissues where they die. *Pitting* refers to the removal of inclusions from within erythrocytes, which are then released back into the circulation. The erythrocyte membrane is in close apposition to the macrophage membrane so that aged or damaged glycoproteins, antibody, or complement on the surface of the cell are easily recognized and activate phagocytosis. Particulate matter—Howell-Jolly bodies, Heinz bodies, Pappenheimer bodies, and malarial and other parasites—are removed and the cell returned to the bloodstream. If membrane-containing adsorbed antibody is present, it is removed and the remainder of the cell is released with changes in shape and volume. Internal vesicles near the erythrocyte membrane appear as if they were on the surface of the cell and are termed *pits* or *pocks*. The spleen also normally removes these, with the polished erythrocyte returned to the circulation. The lack of this polishing function can be used to assess splenic dysfunction as the number of pits or pocks per erythrocyte is increased when the spleen fails to remove them.

Recycling of Iron

Macrophages in the liver and spleen are important for recycling iron as erythrocytes are phagocytized and hydrolyzed in the phagolysosome. Degradation of hemoglobin releases heme, which is catabolized into biliverdin, carbon monoxide, and ferrous iron (Fe^{2+}). Iron is then either released as a low-molecular-weight species for rapid reuse or stored as ferritin. As ferritin accumulates, it aggregates into hemosiderin. Iron-laden macrophages are a feature of iron overload states in both the liver and spleen. Erythrocytes that are destroyed intravascularly release hemoglobin that binds to haptoglobin. CD163 on the surface of splenic macrophages mediates endocytosis of circulating hemoglobin and haptoglobin-bound hemoglobin.

Iron is released from stores in splenic macrophages in response to the erythropoietic drive expressed by the bone marrow. The precise mechanisms are not well understood. Uptake of iron is mediated in most cells by a divalent cation transporter, the natural resistance-associated macrophage protein 2 (NRAMP2), in recycling endosomes that express the transferrin receptor. NRAMP2 transports ferritin into the cytoplasm across the endosomal membrane. In addition to the more widely expressed NRAMP2, macrophages and monocytes express NRAMP1, which was initially described as an iron-transporting protein affecting resistance to intracellular pathogens. A third molecule involved in iron metabolism in the spleen is lipocalin-2, which is secreted by macrophages and other myeloid cells when activated by exposure to bacterial metabolites. Lipocalin-2 binds to bacterial siderophores and sequesters iron from microorganisms. These and other related molecules tightly link the iron-recycling and host-resistance functions of the red pulp of the spleen.

Antibody Production

After stimulation and differentiating in the follicles of the white pulp, antigen-specific plasmablasts and plasma cells lodge in the red pulp, where they are closer to macrophages. A similar translocation occurs in lymph nodes, where plasmablasts migrate to the medullary cords. This translocation occurs after upregulation of expression of CXC-chemokine receptor 4 (CXCR4), which binds CXC-chemokine ligand 12 (CXCL12) expressed in red pulp.

The White Pulp

The lymphoid region of the spleen incorporates multiple components of the immune system that are organized to enhance recognition and/or response to pathogens.⁵ The white pulp contains lymphoid sheaths around branching arterial vessels, similar to the structure of lymph nodes. Specific chemokines attract B and T cells to their appropriate domains. The periarteriolar lymphatic sheath contains T cells that interact with dendritic cells and circulating B cells. T cells and dendritic cells are attracted to the periarteriolar lymphatic sheath through CC-chemokine ligands 19 and 21. Clonal expansion of activated B cells occurs in follicles. B-cell migration to follicles requires CXCL13.

Expression of all these homeostatic chemokines is reduced when signaling through the lymphotoxin receptor or tumor necrosis factor (TNF)- α receptor 1 is absent, which results in disorganization of the domains of the white pulp.

Marginal Zone

Similar to the migration of leukocytes across endothelial barriers in inflammation, leukocytes leave the bloodstream and enter the white pulp in the marginal zone of the spleen via the function of G protein-coupled receptors. The marginal zone is an area for cells in transit as well as home to resident cells with complex interactions. Marginal zone metallophilic macrophages form an inner ring close to the white pulp, marginal zone macrophages form an outer ring, and dendritic cells and B cells are located between the two sets of macrophages. Both trafficking and retention of dendritic cells and B cells involve complex interactions with integrins and other adhesion molecules.

Innate Immunity

The spleen is important in the recognition of antigens, in the production of antibodies, and in the clearance of opsonized and nonopsonized particles from the bloodstream (see Table 160.1). The spleen structure facilitates monitoring of the contents of the blood, with blood flowing through the marginal zone directly along the white pulp. The white pulp is involved in adaptive immunity, whereas the marginal zone is involved in both innate and adaptive immunity (Table 160.2).

Trapping and processing antigens is a major function of the marginal zone. Macrophages are abundant here and the spleen captures more than 5% of the cardiac output (greater than 250 mL/min), which allows a large volume of blood to be immunologically scrutinized. Antigens penetrate the germinal center where T lymphocytes predominate. Processing of carbohydrate antigens is a special function of splenic marginal zone lymphocytes. Marginal zone macrophages express lectin receptors and scavenger molecules.

Splenic macrophages are more sensitive to small amounts of opsonic antibody or complement present on the surface of particles than are macrophages in the liver, lung, or bone marrow. In the absence of a spleen, individuals may fail to remove bacteria with limited opsonic coating, and the production of antigen-specific immunoglobulin (Ig) M is impaired. An asplenic individual has defective recognition of carbohydrate antigens, defective production of IgM early during infection, and defective removal of lightly opsonized particles—all crucial components of response to an invasive infection with encapsulated organisms.

Marginal zone B lymphocytes are sensitive to detection of blood-borne pathogens and rapidly differentiate into either antigen-presenting cells (APCs) or IgM-producing plasma cells. After activation in the marginal zone, some B cells migrate into the white pulp, where they function to activate naive CD4^+ T cells.

Similarly, blood-borne dendritic cells activated in the marginal zone migrate into the white pulp. This process appears to be important in control of certain parasitic infections. For example, in *Leishmania donovani* infection, the spread of infection is inversely proportional to the upregulation or downregulation of CCR7 expression on activated dendritic cells and migration of APCs into the white pulp. In human immunodeficiency virus (HIV)-positive patients with low CD4^+ T-cell counts (less than 300 cells/ μL), there is evidence that IgM memory B-cell depletion might be a risk factor for pneumococcal disease. Effective antiretroviral therapy appears to reverse this depletion, in turn decreasing the risk for pneumococcal infection.

Adaptive Immunity

Although the white pulp is both anatomically and functionally similar to lymph nodes, all cells enter the white pulp via the marginal zone rather than through high endothelial venules and afferent lymphatic vessels, exposing them to an environment highly sensitive

TABLE 160.2**Innate Immune Pattern Recognition Receptors That Are Highly Expressed on Splenic Phagocytic Cells^a**

Name	Abbreviation	Function	Splenic Cells Expressing	Recognizes or Affects	Pathogens Recognized
Toll-like receptor networks	TLR	Pattern recognition of pathogen-associated molecular patterns	Marginal zone macrophages Dendritic cells	Lipopolysaccharide Flagellin Double-stranded RNA	Multiple bacteria, especially gram negative
Natural resistance-associated macrophage protein-1	NRAMP1	Solute carrier family 11 (proton-coupled divalent metal ion transporters); phagolysosomal function	Macrophages	Lysosomal targeting	<i>Mycobacterium tuberculosis</i> <i>Mycobacterium avium</i> <i>Mycobacterium leprae</i>
Natural resistance-associated macrophage protein-2	NRAMP2	Proton-dependent cation transporter; iron absorption	Macrophages (apical duodenal cells, erythroid cells)	Impairs bacterial gene expression, protein synthesis	<i>Brucella</i> spp.
Sialic acid-binding Ig-like lectin-1; sialoadhesin	SIGLEC1, CD169	Immunoglobulin superfamily	Splenic and peritoneal macrophages Many hematopoietic cells	Mannose	<i>Streptococcus pneumoniae</i>
Specific intercellular adhesion molecule 3-grabbing nonintegrin related 1	SIGNR1, CD209b	ICAM3-binding nonintegrin homologue, mannose receptor	Dendritic cells	Polysaccharide antigens, ManLAM	Fungi, other pathogens
Macrophage receptor with collagenous structure	MARCO	Type 1 scavenger	Marginal zone macrophages	Lipopolysaccharide	<i>Staphylococcus aureus</i> <i>Escherichia coli</i>

^aThese receptors contribute to resistance to infection with pathogens in the absence of prior exposure, specific immune responses, or surface opsonic immunoglobulin or complement.

ICAM, Intercellular adhesion molecule; ManLAM, mannoseylated lipoarabinomannan; RNA, ribonucleic acid.

to detection of blood-borne pathogens. Circulating dendritic cells capture bacteria from the blood and transport them to the spleen, where they mediate the initial differentiation of B cells to plasmablasts or APCs. Activated APCs entering the white pulp activate T cells, resulting in changes in receptor expression that enable them to migrate to the edge of B-cell follicles. Contact with activated T cells induces an isotype switch in follicular B cells, which then migrate to the red pulp and marginal zones or remain in splenic germinal centers. The white pulp of the spleen is the largest mass of lymphoid tissue in the body. The B lymphocytes, which ultimately produce antibodies, predominate in the nearby germinal centers and mantle zones. These areas all increase in size and activity with immunization or infection. The complex interaction between the cells in close apposition, autocrine, and paracrine signaling, and migration of cells into, within, and ultimately out of the spleen, contributes to the extraordinary repertoire of innate and adaptive immunity within the organ. Changes in splenic architecture are quite dramatic with septicemia, the most marked being depletion of splenic B-cell areas that occurs during overwhelming enterococemia. Bacterial virulence factors appear to contribute to depletion of B- and T-cell areas.

Hematopoiesis

Active hematopoiesis can be seen in the fetal spleen throughout the second trimester, decreasing during the third trimester. Erythropoiesis and megakaryocytopoiesis predominate, with myelopoiesis present to a lesser extent. As hematopoiesis transitions from the hepatic phase into the bone marrow, it becomes less evident within the fetal spleen. The spleen is not normally a site of hematopoiesis in postnatal life in humans, but it is a rich source of hematopoietic stem cells and can support hematopoiesis in a number of pathologic states. Extramedullary hematopoiesis is a significant cause of splenomegaly primarily in bone marrow disorders (e.g., myelofibrosis or osteopetrosis) and chronic hemolytic anemias (e.g., thalassemia). The stromal cells of the spleen appear to be capable of supporting hematopoiesis and may produce the C-KIT ligand, as do marrow stromal cells. When splenic hematopoiesis occurs, the erythrocytes and platelets that circulate

tend to be less mature than when hematopoiesis occurs in the bone marrow, which suggests that egress from the spleen is easier than from the marrow.

Stem Cells

In higher mammals, including primates, the resident stem cells are capable of restoring hematopoietic and immunologic function after lethal irradiation.⁶ Recently the spleen has been shown to be a source of multipotent stem cells in humans as well as other animals. These stem cells have been shown to contribute to the regeneration of multiple types of tissue, including pancreatic islet cells, bone, cranial nerves, and salivary glands. In addition, undifferentiated splenic monocytes assembled in clusters in the cords of the subcapsular red pulp have been shown to accumulate in injured myocardial tissue.⁷ These stem cells are considered to have limited potential to undergo malignant transformation.

Storage of Cells

The normal adult human spleen contains 20–40 mL of blood and does not serve as a reservoir for blood or erythrocytes. However, in many conditions associated with splenomegaly, especially portal hypertension, the pulp cords widen to create an organ with more storage volume. Vascular pooling of blood and formed elements occurs, regardless of the underlying cause of the splenomegaly. Platelets and granulocytes, however, are normally stored in the red pulp of the spleen. As much as one-third of the total platelet mass may be stored in the spleen and released when cytokines affecting platelet adhesiveness are released. The lack of musculature in the human splenic capsule prevents the distention and contraction that occur in many animals, such as dogs, although the spleen appears to contract in divers during periods of breath-hold apnea. Platelet counts and granulocyte counts rise significantly after splenectomy, then fall. The circulating masses of these cell pools are chronically increased postsplenectomy, which may contribute to an increased incidence of atherosclerosis years after splenectomy.

EXAMINATION OF THE SPLEEN

Maneuvers for examination of the spleen involve inspection, percussion, and palpation, but their sensitivity and specificity vary based on patient factors (such as body habitus) and operator skill.⁸ The pretest probability of splenomegaly, based on associated historical and clinical data, influences the positive-predictive value of finding splenomegaly on physical examination. If the pretest probability of splenomegaly is less than 10%, then physical examination maneuvers are inadequate for determining the presence or absence of splenomegaly. For those patients with a greater than 10% pretest probability of splenomegaly (for instance, patients with suspected infectious mononucleosis), the examination begins with inspection and then percussion of Traube's space—defined by the sixth rib superiorly, the anterior axillary line, and the costal margin. For adequate examination of the spleen, the patient must be fully supine, relaxed, with arms adjacent to the trunk. Dullness to percussion in Traube's space should be followed by palpation. Beginning in the right iliac fossa, the examiner's hand gently advances toward the left upper quadrant. This minimizes the likelihood that a grossly enlarged spleen will be missed, and the lower pole and medial border should be easily appreciated. If the spleen cannot be felt with this approach, the left hand of the examiner is placed on the left flank, lifting the lower part of the rib cage to displace the spleen medially toward the examiner's right hand. The splenic notch should be felt in the inferior medial border. Rotating the patient into the right lateral decubitus position while still recumbent may make it easier to palpate the spleen. The spleen should move with deep inspiration. The degree of enlargement is usually measured in centimeters below the costal margin. Depending on the position of the spleen within the abdomen, it may be difficult to appreciate even significant enlargement. Normal splenic size in an adult is up to 250 g and up to 13 cm in its long axis. Up to half of spleens weighing 600–750 g are not palpable. Greater degrees of splenomegaly are easier to appreciate on physical examination. In terms of sensitivity and specificity, there does not appear to be a difference between examination in the supine position and examination in the right lateral decubitus position, although both of these parameters are dependent on the experience of the examiner.

Up to 15% of normal children and 3% of young adults have palpable spleens without evidence of illness. The spleen involutes with age, and a spleen that is palpable in an older person is unlikely to be a normal variant and more likely to be associated with clinical disease.

Due to various abnormalities, the spleen may not be located in its usual anatomic position. It may migrate from its normal abdominal position to the left mid-abdomen or even the left lower quadrant.⁹ While a rare finding, this highlights the need to pay particular attention to the lower abdomen when palpating for the spleen.

IMAGING OF THE SPLEEN

Radionuclide scintigraphy assesses anatomic and functional aspects of the spleen. The most common procedure is a liver-spleen scan in which technetium-99m (^{99m}Tc) sulfur colloid is injected intravenously and taken up by hepatic and splenic macrophages. It is the phagocytic activity of macrophages, rather than the presence of the spleen itself or any aspects of lymphoid function, that is assessed. A dynamic ^{99m}Tc scan can also assess the distribution of blood within the portal system and suggest the presence of portal hypertension. Infusion of ^{99m}Tc-labeled or Indium-111-labeled platelets with scintigraphy to determine their relative distribution in the liver and spleen has been used with considerable, but not absolute, success to predict the clinical efficacy of splenectomy in patients with immune thrombocytopenia purpura (ITP).

Ultrasonography readily shows the size, shape, and several aspects of splenic anatomy, including the presence of cysts and abscesses. The procedure is noninvasive, painless, of low cost, avoids radiation exposure for patients, and is a good screening study when the spleen is thought to be enlarged. In 95% of the normal population, the long axis of the spleen measures less than 12 cm on ultrasound

examination. Accessory spleens tend not to be well visualized on routine ultrasonography. In the hands of a skilled operator, endoscopic ultrasound-guided biopsy permits accurate diagnosis of lesions as small as a centimeter or less, which compares well with results obtained using computed tomography (CT). High-frequency sonography has significantly better resolution and can visualize both nodularity within the spleen, which occurs in childhood as immunity is acquired, and accessory spleens and splenosis after splenic rupture or trauma.

CT imaging has the advantage of showing the anatomy and some aspects of splenic function. Contrast material in the gastrointestinal tract helps delineate splenic tissue when it impinges on this system. Intravenous contrast material is required to delineate splenic lesions whose density is the same as normal splenic tissue. Abscesses have a rim of contrast agent enhancement.

CT can be used to estimate the volume of the spleen. Accessory spleens have the same attenuation as a normal spleen, which is somewhat less than that of liver. Accessory spleens are usually located in the gastrosplenic ligament near the hilum. Subcapsular and intrasplenic hematomas and splenic lacerations are clearly seen on CT. Leukemias and many inflammatory diseases produce diffuse splenomegaly, while granulomas and infarcted areas eventually calcify. Cysts, abscesses, and some malignancies may have a homogeneous pattern on CT scan. Although not replacing other methods of staging, splenic enlargement on CT may direct follow-up studies and indicate prognosis.

In addition to imaging the spleen, CT can be used to direct therapeutic interventions. Abscesses, hematomas, and cysts can be drained (see box on [Management of Splenic Cysts](#)). As long as portal pressures are normal and vascular lesions have been adequately excluded, thin-needle aspiration under CT guidance is generally a safe intervention. CT scanning of the abdomen, performed as part of the initial emergency department evaluation of patients with abdominal trauma, may avert hospital admission and prevent exploratory laparotomy.¹⁰

Magnetic resonance imaging (MRI) is useful for identifying vascular lesions, which would otherwise require angiography, and splenic infections. It is more difficult to image the contents of the upper abdomen with MRI than with CT because of respiratory motion. With more rapid imaging technology, MRI has gained considerable utility for imaging infectious and vascular lesions of the spleen. Hepatosplenic candidiasis and other infections to which immunocompromised patients are susceptible can be identified noninvasively with modern MRI technology.

Through the use of T2* sequences MRI imaging of the spleen allows quantitative measurement of iron burden in organs that accumulate iron, although the liver and heart are more commonly imaged for this purpose.¹¹

Positron emission tomography (PET) scanning using ¹⁸F-2-deoxyglucose is used in the diagnosis, staging, and monitoring of both non-Hodgkin and Hodgkin lymphoma. It is more sensitive than

Management of Splenic Cysts

A 37-year-old woman with no past medical history comes in for evaluation of early satiety and left shoulder pain. She reports that she feels full after only a few bites of any meal and sometimes becomes nauseated and vomits. Physical examination is remarkable for an enlarged, nontender spleen. Imaging shows a large splenic cyst.

- Many conditions can lead to cyst formation in the spleen including parasitic infections, trauma, hemangiomas, and polycystic kidney disease.
- Asymptomatic nonparasitic cysts may be observed with careful attention and plan for intervention should they become symptomatic, rupture, or become infected.
- Symptomatic cysts may require percutaneous drainage with radiologic guidance or sometimes surgical procedures including partial or total splenectomy.
- Parasitic cysts should be treated in consultation with infectious disease specialists as the particular parasitic infection, radiologic appearance, and patient comorbidities will guide choice of therapies.

CT scanning for identifying nodal disease and superior to both lymphangiography and CT scanning at imaging the spleen. The availability of more sensitive, specific, and less toxic approaches to imaging permits more precise staging of Hodgkin lymphoma without the complications of splenectomy (Fig. 160.5).^{12,13}

The role of PET scanning is expanding in other disorders as whole-body PET scanners and appropriate small-molecule markers for individual diseases are more widely available. Imaging studies in small-animal models are very promising; splenic involvement can be identified with high sensitivity in mice.

TESTS OF SPLENIC FUNCTION

The peripheral blood smear may be the most sensitive tool for identification of functional or anatomic hyposplenism. The presence

of Howell-Jolly bodies, which are nuclear remnants normally removed by the spleen, is an excellent indicator of hyposplenism (Fig. 160.6). These are rarely seen until the spleen is largely non-functional or overwhelmed by other phagocytic functions, such as extravascular hemolysis. Newborn infants commonly have visible Howell-Jolly bodies, and splenic function appears to be at least somewhat impaired in the first week of life. Pappenheimer bodies (siderotic granules normally removed by the spleen) are often seen in hyposplenic states, particularly when a component of hemolysis exists. Erythrocyte morphologic features reflect the lack of membrane polishing by the spleen, with the presence of acanthocytes and target cells. Granulocyte and platelet numbers are increased during asplenic states, including splenic infarction and surgical splenectomy.

To confirm suspected hyposplenism, the simplest test is a count of pitted or pocked erythrocytes. Fixation in 0.5%–1.0% glutaraldehyde

Fig. 160.5 POSITRON EMISSION TOMOGRAPHY SCANNING TO IMAGE AREAS OF INVOLVEMENT IN HODGKIN DISEASE. (A) Pretreatment imaging showing the spleen (large mass in left upper quadrant with arrow) and activity in the kidney and bladder (arrowheads). (B) The same patient after three cycles of chemotherapy. The arrow now points to normal activity in the myocardium not seen previously and arrowheads point to persistent urinary tract activity. The spleen is particularly well imaged on PET scan. (Used, with permission, from Friedberg JW, Chengazi V: PET scans in the staging of lymphoma: Current status, *Oncologist* 8:438, 2003.)

Fig. 160.6 RED BLOOD CELL FINDINGS IN HYOSPLENISM. (A) Red blood cells with Howell-Jolly bodies. (B) Nucleated red blood cell. (C) Cells with Pappenheimer bodies. Red blood cells with Howell-Jolly bodies are seen in patients with hyposplenism. The cytoplasmic inclusions (A) are nuclear remnants that are usually round and stain similar to the nucleus of a nucleated red blood cell (B). They occur normally during red cell maturation but are typically removed by a normal spleen. Their presence in the blood indicates less-than-normal splenic function. Pappenheimer bodies (C), which can also be seen in hyposplenism, are siderotic granules that are irregular in shape and frequently multiple.

and examination under interference optics should reveal endocytic vesicles containing hemoglobin, ferritin, and remnants of mitochondria. These form in mature erythrocytes and are normally removed by the functioning spleen. The number of pitted cells (not the number of pits per cell) is inversely proportional to splenic function, with normal persons having less than 2% pitted cells.¹⁴ The absence of Howell-Jolly bodies on a peripheral blood smear cannot be used as evidence of adequate splenic immune function.¹⁵

ASPLENIA AND HYPOSPLENIA

Congenital asplenia may be an isolated lesion or associated with severe cyanotic congenital heart disease and bilateral right-sidedness. Life-threatening cardiac lesions, including transposition of the great vessels, pulmonary artery atresia or stenosis, septal defects, anomalous venous drainage, and a single atrioventricular valve, are components of bilateral right-sidedness. The liver is central, and both lungs have three lobes. The peripheral blood smear shows Howell-Jolly bodies and other signs of hyposplenism. There is considerable variation in the anatomic and functional findings, and it is difficult to predict with accuracy the degree of splenic dysfunction on the basis of the anatomy alone. Children who survive the cardiac difficulties in the neonatal period have a significant incidence of sepsis secondary to a variety of organisms.

Polysplenia is associated with bilateral left-sidedness. Dextrocardia, bilateral superior venae cavae, septal defects, and anomalous pulmonary venous return are associated cardiac lesions. Both lungs have two lobes, the liver is midline, and bowel malrotation is common. The splenic tissue is divided into two to nine masses. The peripheral blood smear usually does not suggest hyposplenism, and no clear association with an increased risk for infection has been documented.

Asplenia occurring without heart disease is less likely to be detected before an infection develops than when associated cardiac lesions bring the patient to medical attention. Some of these patients also have *situs inversus*. Isolated cases of asplenia discovered after death of an otherwise healthy adult or child from overwhelming sepsis with encapsulated organisms have been reported. Familial instances of congenital asplenia are likely to be instances of genetic abnormalities (e.g., *Hox11/Tlx1*), but these have not yet been documented. Examination of a blood smear for Howell-Jolly bodies is a simple procedure and may be lifesaving in the rare patients affected with these disorders.

If Howell-Jolly bodies are observed on the blood smear of an otherwise healthy person, imaging should be performed to assess for the presence of a spleen. Immunization with polysaccharide vaccines and early intervention with antibiotics for apparent infection may prove lifesaving for these individuals. Because approximately 20% of invasive pneumococcal infections in these patients are nonvaccine strains, a high degree of vigilance remains essential, even with more widespread immunization of healthy children.

ACQUIRED HYPOSPLENISM

Infarction in Sickle Cell Disease

The course of sickle cell disease is marked by progressive dysfunction of multiple organs over many years, and one of the earliest organs to be affected is the spleen. Serial measurements of the numbers of pitted erythrocytes in patients with sickle cell disease demonstrate that splenic dysfunction develops progressively over the first few years of life in the major sickle syndromes (Figs. 160.7 and 160.8). The hypoxic, acidotic, hypoglycemic environment of the spleen creates optimal conditions for tactoid formation and for sickling of the poorly deformable erythrocytes, which then block splenic blood vessels and infarct the tissues. Splenic environmental conditions that enhance acidosis or hypoxia, or additional erythrocyte membrane or enzyme abnormalities that promote irreversible sickling, increase splenic infarction. The hyposplenism is reversible with transfusion for

Fig. 160.8 POKED ERYTHROCYTES IN THE SICKLE HEMOGLOBINOPATHIES. (Used, with permission, from Sills R, Oski FA: RBC surface pits in the sickle hemoglobinopathies. *Am J Dis Child* 133:526, 1979.)

at least the first few years of life but becomes irreversible with progressive damage to blood vessels by 6 years of age in patients with sickle cell disease.

Splenic sequestration is a manifestation of the infarctive process of sickling in the spleen that extends to involve larger veins.

Distensible splenic tissues results in pooling of a large amount of blood, whereas the venous drainage is occluded by sickled hypoxic erythrocytes. Patients with sickle cell disease who have not yet had multiple episodes of infarction and whose spleens have not undergone fibrosis are susceptible to this syndrome. Unlike the chronic process of smaller vessel infarction, the acute splenic sequestration crisis can be life threatening because a large amount of blood can collect in the highly distended spleen. The tendency for recurrence and the potential for fatal outcome have resulted in the common recommendation for splenectomy in a patient who has had one severe splenic sequestration crisis, or more than one less severe crisis. Occlusion of venous drainage also occurs in the liver, but the less distensible capsule of the liver and the options for venous drainage through the portal system make this less likely to be life threatening.

Immunologic and Autoimmune Diseases

Poor phagocytic function of the spleen is associated with impaired function of the Fc receptors on splenic macrophages in a variety of immunologic, rheumatic, and inflammatory disorders. Among those disorders in which hyposplenism has been clearly defined and associated with a risk for infection are systemic lupus erythematosus, rheumatoid arthritis, sarcoidosis, systemic vasculitis, ulcerative colitis, celiac disease, amyloidosis, chronic graft-versus-host disease, mastocytosis, and congenital and acquired immunodeficiency. The diseases themselves and the immunosuppressive therapies that are used in their management may contribute to the risk for infection in these conditions. Immunization with polysaccharide antigens and recognition of the risk of bacterial infection are important steps in reducing the risks of splenic hypofunction.

Splenomegaly and the production of autoantibodies such as antiplatelet or antiphospholipid antibodies, are features of the acquired immunodeficiency syndrome (AIDS). In the late stages of AIDS, atrophy of lymphoid follicles and depletion of T-cell-dependent areas are common. It is not clear that impairment of phagocytic function is a component of splenic atrophy in AIDS.

Therapy-Induced Splenic Hypofunction

Radiation therapy affects splenic function depending on the dose administered. In general, phagocytic cells are not affected by irradiation, but lymphoid cells are extremely sensitive. B-cell function is nearly ablated with as little as 500 cGy. T-cell lymphoblastogenesis is eliminated by administration of 3000 cGy. With doses of 2000 cGy, splenic hypofunction is usually transient because the macrophages and splenic stroma are not affected, and circulating B and T lymphocytes can repopulate the splenic follicles. Permanent splenic hypofunction may develop with doses of 4000 cGy or higher. The risk for infection is significant after such therapy.

Corticosteroid therapy impairs the affinity of the Fc receptors of splenic macrophages for opsonized IgG and decreases the adhesiveness of granulocytes and monocytes. This results in an acute pharmacologic splenectomy, even at commonly administered therapeutic dosages. The function of the Fc receptors on hepatic, pulmonary, and bone marrow macrophages is far less affected than that of splenic macrophages. The acute rise in platelet count or hemoglobin values seen with corticosteroid therapy in ITP or warm autoimmune hemolytic anemia is due to decreased clearance of sensitized cells. With prolonged therapy, the production of antibodies by splenic lymphocytes is also affected, and splenic function continues to be impaired.

Intravenous IgG appears to decrease the phagocytic function of the spleen by binding to Fc receptors and impeding their recognition of opsonized particles. This is a transient effect because the Fc receptors are internalized and recycled, and opsonic function returns to normal within 2–3 weeks. Occupancy and impairment of function of Fc receptors is also seen with administration of anti-IgD to Rh-positive patients, which induces a transient hemolytic anemia.

Reticuloendothelial blockade, or occupancy of these receptors, refers to the impaired ability of the spleen to recognize and remove other IgG-coated particles, including bacteria, in the presence of these agents.

SPLENOMEGALY AND HYPERSPLENISM

An enlarged spleen is not a disease state in itself but usually indicates some underlying pathologic state.¹⁶ The processes run the gamut from minor to life threatening, from congenital disorders to those at the end of life. It is useful to approach the differential diagnosis of splenomegaly by considering the processes that may cause splenic enlargement and then to focus on the specific diagnoses within those categories. The spleen may be enlarged as a result of infiltration, hypertrophy of normal elements (macrophages and lymphoid components), extramedullary hematopoiesis, inflammatory or immunologic processes, and systemic or portal congestion (see box on [Timing of Return to Contact Sports in Athletes Who Have Had Infectious Mononucleosis](#)). The degree of splenomegaly correlates well with involvement of the spleen in many malignant disorders, such as Hodgkin disease. Rarely, anatomic abnormalities will cause splenomegaly. Splenomegaly is important to investigate because it is frequently the presenting finding of a serious disorder whose earlier recognition and treatment may prevent significant long-term morbidity and mortality. The diseases associated with splenomegaly are detailed in [Table 160.3](#). Patients with splenomegaly do not necessarily have hypersplenism, and patients with hypersplenism may indeed have normal-sized spleens, such as those seen in ITP.

Hypersplenism refers to nonimmune, indiscriminate destruction of the formed elements of the blood by a spleen that is usually enlarged, affected by portal hypertension, or both. The bone marrow is hyperplastic, and the peripheral blood cell counts are decreased because of destruction of mature formed elements. Splenectomy corrects the cytopenia. Any of the formed elements of the blood—erythrocytes, neutrophils, or platelets—can be affected alone or in combination. Splenic hypertrophy in cirrhosis is due to an increase in splenic macrophages and their activity. Because the normal function of splenic macrophages is to remove senescent cells, this is an exaggeration of a physiologic process.

Hypersplenism develops in patients who receive chronic transfusions, and there are several components that contribute to the development of hypersplenism. The antigenic load of allogeneic transfused cells stimulates the immune system. Additionally, transfused cells have shorter survival than normal red cells (mean of 60 instead of 120 days, unless specially prepared neocytes are used), which increases the work of splenic macrophages. Finally, iron

Timing of Return to Contact Sports in Athletes Who Have Had Infectious Mononucleosis

An 17-year-old male high school student is diagnosed by his primary care physician with infectious mononucleosis. The patient is concerned about the upcoming soccer season and wants to be able to start training with the team in 4 weeks.

- More than half of patients with infectious mononucleosis develop splenomegaly within the first 14 days of illness.
- Most reports of splenic rupture in the setting of infectious mononucleosis occur in the first 21 days of illness.
- There is a paucity of data to support imaging the spleen to document resolution of splenomegaly before returning to contact sports.
- Noncontact sports may be safely resumed after at least 21 days from the onset of initial symptoms and contact sports should be safe in most cases after at least 28 days. Infectious mononucleosis-associated splenic rupture has been reported as far as 7 weeks after symptom onset.
- The timing of return to sports and the risks should be discussed with the patient, especially if the patient may not have returned to baseline after prolonged fatigue.

TABLE 160.3
Causes of Splenomegaly

Primary Process	Pathogenesis	Examples
Anatomic	Developmental abnormalities	Cysts, pseudocysts, hamartomas, peliosis, hemangiomas
Hematologic	Hemolysis	Intrinsic (membrane, enzyme, hemoglobin disorders), extrinsic (immune)
	Extramedullary hematopoiesis	Myeloproliferative diseases/ myelodysplasias, myelofibrosis, osteopetrosis
Infectious	Bacteria	Acute and chronic systemic infection, abscesses, subacute bacterial endocarditis
	Mycobacteria	Miliary tuberculosis
	Spirochetes	Syphilis, Lyme disease, leptospirosis
	Viruses	Epstein-Barr virus; cytomegalovirus; human immunodeficiency virus; hepatitis A, B, C
	Rickettsia	Rocky Mountain spotted fever, Q fever, typhus
	Fungi	Disseminated candidiasis, histoplasmosis, South American blastomycosis
	Parasites	Malaria, babesiosis, toxoplasmosis, <i>Toxocara canis</i> , <i>Toxocara cati</i> , leishmaniasis, schistosomiasis, trypanosomiasis
Immunologic	Collagen vascular diseases	Felty syndrome, systemic lupus erythematosus, mixed connective tissue disorder, systemic vasculitis, Sjögren syndrome, systemic mastocytosis
	Immunodeficiency	Common variable immunodeficiency
Neoplastic	Primary malignancies	Lymphomas, leukemias
	Metastatic malignancies	Breast, lung, skin, colon
Infiltrative	Storage diseases	Gaucher disease, Niemann-Pick disease, GM ₁ gangliosidosis, glycogen storage disease type IV, Tangier disease, Wolman disease, mucopolysaccharidoses, hyperchylomicronemia types I and IV
Congestive	Portal hypertension	Intrahepatic cirrhosis, extrahepatic cirrhosis (Budd-Chiari syndrome)
	Systemic	Congestive heart failure
	Local	Splenic vein thrombosis

overload causes hemosiderosis of both the spleen and the liver, so that portal hypertension may develop and further increase splenic pathology. Hypersplenism increases the transfusion requirement in patients who are already transfusion dependent.

Interestingly, spleen status at the time of allogeneic hematopoietic stem cell transplantation affects outcomes. Patients with splenomegaly have delayed engraftment while those with prior splenectomy have early engraftment and no difference in mortality.¹⁷ The increased risk in infection may be mitigated by the high-intensity setting in which stem cell transplantation occurs.

SPLENECTOMY

Indications and Timing

Splenectomy should be performed for clinical indications rather than for specific diagnoses. In many instances, removal of the spleen will improve the condition of patients with hemolytic anemia due to intrinsic disorders of erythrocyte membranes and enzyme disorders, and of those with chronic conditions, such as storage diseases and portal hypertension. Specific clinical indices that require intervention should be identified, and parameters that can be used to identify clinical improvement (usually an increase in peripheral blood cell counts, growth, or energy level) should be determined before the procedure is performed. For patients with inherited erythrocyte membrane or enzyme disorders, such as hereditary spherocytosis or pyruvate kinase deficiency, marked reticulocytosis indicating significant metabolic energy required for erythropoiesis, somatic growth failure, or lack of exercise tolerance would be potential indications for splenectomy. Avoidance of formation of gallstones, formerly often considered an indication for splenectomy when a diagnosis of hereditary spherocytosis was made, is less important today because minimally invasive surgical procedures have improved the management of cholelithiasis. Patients with storage disorders such as Gaucher disease often develop splenomegaly and hypersplenism, and subsequent cytopenias requiring intervention. As new therapies are developed, such as eliglustat for Gaucher disease and ruxolitinib for primary myelofibrosis, these patients experience a significant reduction in spleen size and increase in quality of life, which may mitigate the need for splenectomy.^{18,19}

The clinical benefit to be obtained from splenectomy should at least balance, and preferably outweigh, the potential long-term risks of postsplenectomy septicemia, an increased risk for thrombosis, and the shift of storage cells from the spleen to other organs, such as the bone marrow, where they may do more harm in the absence of the spleen. Not all patients with hemolytic anemias require splenectomy. If such patients develop an aplastic crisis due to parvovirus B19 infection while their spleens are intact, they may require a transfusion. Many patients with mild chronic hemolysis and well-compensated anemia may be better off with their spleens remaining intact. Patients with ITP should undergo surgical splenectomy when the risks of bleeding or of medical therapies (such as long-term corticosteroids or the anti-CD20 monoclonal antibody rituximab) are such that the benefits of splenectomy exceed the risks. The introduction of thrombopoietin mimetics for treatment of chronic ITP has further delayed or eliminated the need for splenectomy in many patients. The indications for splenectomy are different in adults than in children, and are affected by the presence of underlying disorders, such as systemic lupus erythematosus and HIV. In an attempt to avoid immunologic consequences of a total splenectomy, several centers are performing partial splenectomies for hereditary spherocytosis, although in some cases a second procedure is later required.²⁰

Splenectomy for sickle cell disease is usually performed for splenic sequestration that is severe, persistent, or recurrent. In some sickle syndromes, the spleen does not autoinfarct in childhood, and persistent splenomegaly may increase the degree of anemia. The risk for subsequent development of gallstones should be considered in patients with hemoglobinopathies and other hemolytic anemias so that cholecystectomy can be performed simultaneously, if deemed indicated.²¹

The timing of splenectomy (when it is to be performed) should again be chosen to minimize risks and maximize benefits. Immunity to carbohydrate antigens, such as those in the cell walls of encapsulated organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b, develops over the first 2–3 years of life. When splenectomy can be delayed until the patient is at least 2 and preferably more than 5 years of age, specific immunity and response to administered polysaccharide vaccines will improve host defenses and lessen the risk for postsplenectomy sepsis. When patients have a disease, such as Gaucher disease, or hemolytic anemia

predisposing to iron overload, such as thalassemia, the presence of the spleen as a preferential site for the storage of harmful cellular breakdown products may protect other organs from damage. Delaying splenectomy until a clear clinical indication is present will balance risks and benefits to an optimal degree. The recently developed oral substrate inhibitor, eliglustat, has shown promising success in reducing splenomegaly in patients with Gaucher disease.¹⁸ As this drug is studied further, it is possible that splenectomy may not be needed as often.

Surgical Options

When splenectomy is clearly indicated, acute complications are rarely a consideration in the decision to perform surgery. Nevertheless, advances in surgical procedures have minimized the short-term risks of the procedure itself and of postoperative complications such as intestinal obstruction from adhesions. Subtotal splenectomy can be performed when total splenectomy is not desirable, such as for the removal of a cyst, a pseudocyst, or tumors, after trauma, or for Gaucher disease. Wedge resection with mattress sutures and cyanoacrylate adhesives and microfibrillar collagen omental packs have greatly improved partial splenectomy procedures in the past decade. Laparotomy is required when extensive peritoneal adhesions are present and for removal of massively enlarged spleens. A sufficiently large incision to permit full visualization and mobilization is essential when the spleen is very large or when inspection is a major part of the surgical procedure. A retroperitoneal approach is useful when the spleen is not massively enlarged but needs to be fully removed, such as when cytopenias are the indication for the procedure. This approach shortens the postoperative recovery time and avoids induction of peritoneal adhesions.

Minimally invasive procedures have become standard for most splenectomies. Laparoscopy is now the procedure of choice for splenectomy. Although the operative time is significantly greater than for laparotomy, the postoperative recovery time, risk for damage to the pancreas, likelihood of developing a subphrenic abscess and peritoneal adhesions postoperatively, and nutritional and metabolic challenges to the patient are considerably reduced. Laparoscopic splenectomy can be performed even in thrombocytopenic patients. The outcome of laparoscopic splenectomy in ITP is affected by the experience and skill of the surgeon and by the patient's obesity. Prolonged presurgical use of corticosteroids may induce obesity and impair tissue healing, resulting in a higher risk for complications from laparoscopic splenectomy than when splenectomy is performed before adverse drug effects develop. In the case of massive splenomegaly, splenic morcellation may be necessary prior to laparoscopic retrieval.

Appreciation of the risk for postsplenectomy septicemia and refinements in noninvasive, accurate radiologic monitoring techniques have led to more conservative approaches to splenic injury. Nonoperative management has increased over time and has an acceptable mortality and complication rate in selected patients, although early discharge may put patients at risk for the later complications.²² Noninvasive imaging and minimally invasive surgical procedures have greatly affected these trends. After traumatic rupture, splenic tissue may regenerate as both micro- and macroscopic ectopic implants in the peritoneal cavity, a process termed *splenosis*. Although splenosis appears to be partially protective against overwhelming postsplenectomy infection in animals, its protective value in humans is not known and may depend on the adequacy of splenic tissue perfusion. If poorly vascularized, the ectopic splenic tissue may not provide adequate contact between macrophages and the antigens of the infecting organism. It is generally valuable to attempt preservation of splenic function when possible after traumatic rupture. Some surgeons attempt to induce splenosis when traumatic splenectomy is unavoidable, in the hope of minimizing late complications.

As the late complications of splenectomy are better appreciated, surgeons have become increasingly creative at performing procedures

that preserve or restore splenic function. Even large cysts that were indications for splenectomy until recently have been managed with spleen-conserving procedures, such as partial or total cyst removal, which can often be performed laparoscopically.²³ Pancreatic surgery often requires sacrifice of the spleen; however, increasing numbers of procedures are being performed with salvage of the spleen.

Splenic transplantation is being used as a means of developing immune tolerance, as well as a means of reducing the risk for infection following organ transplantation.²⁴ Allograft spleen has been transplanted within multivisceral grafts with only minimal graft-versus-host disease. To date there are more animal than human data, and it is unclear how large an impact this approach will have on visceral, especially small-bowel and pancreatic, allotransplantation.²⁵ If protection against infection is the main consideration, an intact spleen is superior to a repaired or autotransplanted spleen, whereas accessory spleens and splenosis may be only marginally better than asplenia.¹⁵

Complications After Splenectomy

Acute complications in the perioperative period include rupture of the spleen, the development of a subphrenic abscess, and injury to the pancreas during the operative procedure. In a healthy patient, the immediate risk of splenectomy is limited. The degree of splenomegaly greatly affects the risk for rupture and pancreatic injury. The technical difficulty of performing a splenectomy is much greater when the spleen is massively enlarged than when the spleen is small. Once the arterial supply is ligated, rupture of the spleen is rarely a problem. The splenic hilum is retroperitoneal, so if the spleen is very large, mobilization to gain access to the splenic artery and vein can be difficult. After recovery from surgery, intestinal obstruction due to formation of peritoneal adhesions is a complication that, if it is to occur at all, usually occurs within the first few months.

Two late complications of splenectomy give the greatest concern: overwhelming postsplenectomy septicemia and atherosclerotic heart disease. Both of these complications may develop many years after the splenectomy (Fig. 160.9). The precise risk is not known, and preventive interventions are probably underused because patients may not be aware of the risks of splenectomy performed early in life.

Postsplenectomy septicemia is rare but may be rapidly lethal. In the absence of protective levels of opsonic IgG antibodies produced in the spleen, hepatic and pulmonary macrophages are unable to effectively clear organisms from the bloodstream. Organisms that

Fig. 160.9 THE INTERVAL FROM SPLENECTOMY TO POSTSPLENECTOMY SEPSIS. Of the total ($n = 288$), 3.1% occurred more than 20 years after splenectomy. PSS, Postsplenectomy sepsis. (Used, with permission, from Lutwick LI: *Infections in asplenic patients*. In Mandell GL, Bennett JE, Dolin R, editors: *Principles and Practice of Infectious Diseases*, ed 7, Philadelphia, 2009, Churchill Livingstone.)

enter the bloodstream and would ordinarily be removed by splenic macrophages are able to evade recognition by macrophages whose Fc and C3b receptors appear to be less avid than those of splenic macrophages. Circulation of the blood through the liver and lung is more rapid than through the spleen, and there is little opportunity for macrophages to recognize organisms with surfaces containing little IgG and only small amounts of C3bi. The important filtration function of the venous sinus endothelial cells is absent following splenectomy. The generation of cytokines, including TNF- α and bacterial endotoxins, leads to cardiovascular collapse and shock. It is difficult to rescue an asplenic patient once shock develops, even with effective antibiotic therapy. The risk that this will happen varies with the indication for splenectomy (Table 160.4) and the patient's medical condition. Factors that impair host defenses significantly increase the risk for infection. These include deficient opsonins (hypogammaglobulinemia and specific antibody-production deficiency), reticulo-endothelial blockade related to increased phagocytic activity of macrophages in other organs, impaired antigen processing or recognition (AIDS, lymphoma, other malignancies, and some collagen vascular diseases), neutropenia, and high iron load (thalassemia). The tetrapeptide tuftsin, primarily produced in the spleen, enhances the phagocytic activity of monocytes and neutrophils; its absence in asplenic patients appears to contribute to depressed neutrophil function and the subsequent increased risk for infection.

Patients at the lowest risk for overwhelming postsplenectomy sepsis are those in whom splenectomy cures the underlying problem, such as isolated ITP, hereditary spherocytosis, and trauma. Patients undergoing splenectomy for trauma have a 50-fold greater risk for subsequent septic death than trauma patients with intact spleens, whereas the risk in patients with sickle cell disease is increased 350-fold over that of the general population, and other authors report the risk to be 600 times greater. Similar to use of hemodialysis to attempt to replace the function of the kidney, work is ongoing to devise an artificial spleen as a mechanical way to filter pathogens from the blood.

An increased risk for vascular complications may result from splenectomy. Acute portal vein thrombosis occurs within 2 months of splenectomy in 5%–37% of patients, which is probably the result of local surgical factors. The surgical approach seems to affect the rate of postsplenectomy portal and splenic vein thrombosis, with a laparoscopic approach and morcellation associated with a higher rate of thrombosis compared with open splenectomy (55% vs. 19%, respectively). Patients with thalassemia and prior splenectomy appear to also have an increased incidence of venous thromboembolism beyond the portal venous system. In addition, splenectomy appears to be a risk factor for the development of pulmonary hypertension. Vascular events after splenectomy are likely multifactorial in origin, being attributed to a combination of hypercoagulability, platelet activation, activation of endothelium due to the persistence of particulate matter, and damaged cells in the bloodstream.

Atherosclerosis that develops many years after splenectomy in patients with hereditary spherocytosis or hereditary stomatocytosis

may be related to subsequent thrombocytosis that leads to enhancement of plaque formation. Statistically, the increased risk for atherosclerosis is not particularly high, but for individuals with other risk factors such as hypertension, diabetes, high levels of cholesterol or homocysteine, heterozygous protein C or S deficiency, or factor V Leiden, splenectomy may pose a more significant risk. Although no human data are currently available in this area, some studies have suggested that the spleen might be involved in lipid metabolism in both rats and rabbits.

Prevention of Complications

Postsplenectomy Sepsis

The major risk for postsplenectomy sepsis is infection with encapsulated organisms such as *Staphylococcus pneumoniae*, *H. influenzae* type b, and *N. meningitidis*, which require opsonization for effective phagocytosis. Polysaccharide vaccines are available for all three bacteria.^{26,27} The highest risk period for children is in the first 2 years of life, when their ability to mount an antibody response to purified polysaccharides has not developed completely, so protein-conjugated vaccines are now in widespread use. This has significant potential benefit for patients when asplenia is not recognized, because they might then be immunized as part of their routine care. The antibody responses to vaccines, especially the conjugated vaccines, differ in IgG subclasses from those produced following natural infection. Overwhelming postsplenectomy sepsis and death from sepsis in functionally hyposplenic patients should be preventable.²⁸ It is recommended that immunization be done at least 14 days prior to the anticipated splenectomy in order to optimize antigen recognition and processing, and induce more effective immunity. If emergency splenectomy is performed, it is recommended that vaccination be postponed until at least 14 days postsplenectomy to avoid the transient immune suppression often seen with general anesthesia and surgery (see box on [Vaccination of a Patient Scheduled for Elective Versus Emergency Splenectomy](#)). Adults are generally presumed to be immune to *H. influenzae* type b and may receive the 23-valent pneumococcal polysaccharide vaccine (PPSV23) and meningococcal vaccines alone. Reimmunization for children is recommended 2–5 years after initial immunization. Splenectomized adults should be revaccinated with the PPSV23 once after 5 years, whereas meningococcal revaccination should occur every 5 years. Recently, the Advisory Committee on Immunization Practices clarified recommendations that adult patients who are vaccine naive receive the pneumococcal conjugate vaccine (PCV13) followed 8 weeks later by the pneumococcal polysaccharide vaccine (PPSV23). Because these recommendations change with experience and vaccine use, it is wise to consult current guidelines for individual patients. The US Centers for Disease Control website should be consulted for the most up-to-date recommendations. Additional organisms to consider in postsplenectomy sepsis include *Escherichia coli*, *Pseudomonas aeruginosa*, and *Capnocytophaga canimorsus*.²⁹ There are fewer data on the efficacy of prophylactic antibiotics for asplenic patients, except for

TABLE 160.4

Incidence of Postsplenectomy Sepsis

Indication for Splenectomy	Cumulative Incidence of Bacterial Sepsis (%)
Trauma	1.5
Hematologic disorders	3.4
Portal hypertension	8.2
Hodgkin disease	10
Sickle cell disease	15
Thalassemia	25

Data from Gorse GJ: The relationship of the spleen to infection. In Bowlder AJ, editor: *The spleen: Structure, Function, and Clinical Significance*, New York, 1990, Van Nostrand Reinhold, p 269, with permission.

Vaccination of a Patient Scheduled for Elective Versus Emergent Splenectomy

A 50-year-old man with refractory ITP is scheduled for splenectomy. Having heard there is a risk for different types of infection after splenectomy, he asks about what he can do to reduce his risk.

- Patients scheduled for elective splenectomy should receive the following at least 14 days prior to the procedure:
 - *Streptococcus pneumoniae* vaccine
 - *Haemophilus influenzae* vaccine
 - *Neisseria meningitidis* vaccine
 - Consider administration of the influenza vaccine as influenza is a risk factor for secondary bacterial infection.
- If the procedure is done emergently, wait at least until the 14th postoperative day.

young children with sickle cell disease, in whom antibiotics should be initiated as soon as the diagnosis is established. Present recommendations are that twice-daily oral penicillin V potassium or amoxicillin be continued in sickle cell patients until 5 years of age or 3 years postsplenectomy. High-risk patients with surgical or functional asplenia, including those with diagnoses of thalassemia, Hodgkin disease, other malignancies, immunodeficiency disease, or chronic graft-versus-host disease, should receive prophylactic antibiotics unless specific contraindications exist. Patients who have a history of pneumococcal postsplenectomy sepsis may be considered candidates for life-long daily prophylaxis as well. Whether or not such patients receive prophylactic antibiotics, and regardless of their immunization status, they may develop overwhelming infections with other organisms, including gram-negative organisms and *Staphylococcus aureus*. Some experts recommend that at the time of febrile illness, asplenic patients take immediate antibiotics at home before quickly traveling to an emergency room for evaluation. There are no randomized trials to guide therapy and experts have recommended the use of amoxicillin-clavulanate, cefuroxime axetil, or extended-spectrum fluoroquinolones. Updated recommendations should be consulted for specific circumstances.

The single most important measure to prevent postsplenectomy septicemia is education of the patient, family, and physician. Recognition of the risk, the institution of appropriate preventive measures, and the rapid administration of antibiotics to a patient who is showing signs of infection (fever and chills) can be lifesaving.

Atherosclerosis

The magnitude of the risk for development of atherosclerosis is not clear.^{9,30} Appropriate preventive measures include identifying and minimizing concurrent risk factors, such as obesity, dietary patterns, a sedentary lifestyle, and the presence of other hereditary factors that would predispose to thrombosis. Low-dose aspirin could be considered, but no data exist regarding its efficacy in this situation.

CONCLUSIONS AND FUTURE DIRECTIONS

Although very little novel information has emerged about clinical aspects of splenic function in recent years, appreciation of many subtleties of splenic function and advances in supportive care in several fields have had significant impacts on the management of disorders of the spleen. Better education and more effective immunizations have helped prevent serious complications related to splenic disorders. Advances in imaging and surgery have transformed the diagnosis and management of congenital and traumatic splenic disorders.

Enhanced understanding of the complexity of communication interaction between the cells of the immune and hematopoietic system has improved our appreciation of the molecular, cellular, system, and network basis for clinical observations about splenic function. The ability of splenic macrophages, in concert with dendritic cells and B cells, to recognize and ingest a variety of microorganisms—even in patients without previous exposure to the pathogens—provides great insight into the reasons that the spleen provides protection against a variety of very specific infections. More detailed understanding of the impact of the splenic microenvironment on cellular functions, the role of stromal infrastructure on the ability of cells to interact with and respond to invading pathogens, and the integration of components of the immune system has contributed to an appreciation of clinical observations about the role the spleen plays in normal biology. The intersection of hematopoiesis, recycling of aging cells, and iron metabolism is most clearly demonstrated in the spleen.

Although not necessary to life under baseline circumstances, the contribution of the spleen to homeostasis under stress is considerable. Ongoing efforts to preserve and manage splenic function will continue to benefit from enhanced appreciation of the underlying biology.

HEMATOLOGY IN AGING

Andrew S. Artz and William B. Ershler

Although most classifications consider patients “older” once their age exceeds 65 or 70 years, age-related changes are not discrete. A central tenet of gerontology (the study of normal aging) is that biologic measures show increased variation with advancing age, but age-related variations are of insufficient magnitude to result in disease per se. Hematologic conditions in older adults have unique features and frequently require a modified approach relative to younger adults. Anemia in older adults with advancing age is one of the most common hematologic problems associated.

EPIDEMIOLOGY

Aging

The median life expectancy continues to rise throughout the world. In the United States, the Centers for Disease Control and Prevention estimates life expectancy at 77.9 years for children born in 2007. The proportion and absolute number of older adults is increasing, and life expectancy of adults who have reached an advanced age may be considerable. Accordingly, we advocate estimating life expectancy for older adults who have hematologic conditions, by using several calculators available online (e.g., <http://eprognosis.ucsf.edu>).¹

Anemia Definition

Historically, criteria for diagnosing anemia in older and younger adults used by the World Health Organization (WHO) were hemoglobin (Hb) threshold levels below 13 g/dL for men and less than 12 g/dL for women.² It was widely recognized that these criteria required modification, and Beutler and Waalen³ evaluated two large databases to develop population-based threshold levels, defining the fifth percentile as the lower limit of normal after excluding anemia-causing conditions, as shown in Table 161.1.

Anemia Prevalence

Most reports of anemia prevalence use the historical WHO threshold levels of less than 13 g/dL of Hb for men and less than 12 g/dL for women. For adults 65 years and older, the prevalence of anemia is around 10%–11% and rises to 20%–25% for those 85 years and older, and 50% for those in nursing homes.^{4,5}

Race/ethnicity also influences anemia prevalence. Studies from Europe and Japan^{4,6} indicate a fairly similar anemia prevalence in older adults, whereas African-Americans have lower median Hb values and a threefold higher prevalence of anemia.⁵ A substantial portion of African-Americans with lower Hb levels have the α -thalassemia trait, with one or two deletions contributing to the degree of anemia.

Neutropenia and Thrombocytopenia

The incidence of thrombocytopenia, defined as a platelet count below $150 \times 10^9/L$, does not appreciably change with age with an average

reduction of $19 \times 10^9/L$ in those 70–90 years of age.^{7,8} A study of Sardinian villages revealed an increasing incidence of thrombocytopenia with aging, approaching 6% in the seventh decade and 8% for octogenarians.⁹ Interestingly, neutropenia (less than $1.5 \times 10^9/L$) appears less common with advancing age, such that the prevalence in community-dwelling older adults 75 years and older has been approximated at 0.5%.

PATHOBIOLOGY

Hematopoietic Changes With Aging

The study of older adults illustrates an overriding paradox, that although aging alone does not cause clinically significant cytopenias, aging predisposes to reduced hematopoietic reserves and to diseases, both of which increase the tendency to encounter significantly lower blood counts in older adults. Major hematopoietic changes occurring with aging are listed in Table 161.2.

The attention to the hematopoietic system must be understood in the context that organ systems are integrated to maintain homeostasis. For example, decreased bone mass and heightened systemic inflammation may adversely influence hematopoiesis. Whether hematopoietic perturbations are linked to a global decline or the factors promoting functional decline of marrow function cannot be easily deciphered. Reduced neutrophil responses to granulocyte colony-stimulating factors have long been appreciated as predisposing to infection with advancing age, but this occurs in the setting of a decline in immune function that occurs with aging.

Clonal Hematopoiesis and Aging

Myeloid bias has emerged as a hallmark of hematopoiesis and advancing.¹⁰ Impairment of the lymphoid compartment may explain immune deficits that occur with aging, and at the same time, an increased number of myeloid progenitors likely influences the markedly higher rate of myeloid malignancies in older individuals. The discovery of several mutations involving *DNMT3A* and *TET2*, commonly found in preleukemic hematopoietic stem cells, has formed a critical link to understanding the pathway of hematopoietic changes associated with aging that result in hematologic malignancy.^{11,12} The observation of *TET2* mutations in women with clonal hematopoiesis by X-chromosome inactivation lends support to the presence of a preleukemic state in the hematopoietic compartment in some older patients.¹³

A series of studies employing whole-exome sequencing have compellingly demonstrated a strong link of advancing age and the emergence of blood cell mutations associated with hematologic malignancies.^{14–16} Specifically, 10% of individuals 70 years and older and up to 18% in those 90 years and older have clonal expansion of cells bearing these mutations, most frequently *DNMT3A* and *TET2*. The incidence of hematologic malignancies, particularly myeloid malignancies, rises about 10-fold in the presence of a detectable mutation.^{15,16} However, screening for somatic mutations cannot be recommended, as even in older adults the rate of hematologic malignancy for those with evidence of clonal hematopoiesis is approximately 0.5%–1% per year.¹⁵

TABLE 161.1 Anemia Definitions

Group	Hemoglobin (g/dL)
Men, 60 Years or Older	
White	13.2
Black	12.7
Women, 50 Years or Older	
White	12.2
Black	11.5

Adapted from Beutler E, Waalen J: The definition of anemia: what is the lower limit of normal of the blood hemoglobin concentration? *Blood* 107:1747, 2006.

TABLE 161.2 Hematopoietic Changes Associated With Advancing Age

Diminished bone marrow cellularity
Reduced CD34 ⁺ cell mobilization to G-CSF administration in healthy donors
Decreased stem cell telomeres
Reduced hematopoietic cell proliferative capacity
Increased numbers of hematopoietic stem cells
Reduction in lymphocyte function
Reduced response to vaccination
Development of unexplained anemia

G-CSF, Granulocyte colony-stimulating factor.

Fig. 161.1 CATEGORIZATION OF PRIMARY ANEMIA ETIOLOGY OR UNEXPLAINED ANEMIA IN THE ELDERLY IS SHOWN. Others include hemolysis, 4; alcohol, 3; hypothyroidism, 1; vitamin B₁₂ deficiency, 1; medication, 1. *ACI*, Anemia of chronic inflammation; *CKD*, chronic kidney disease; *Heme Malig*, hematologic malignancy; *IDA*, iron-deficiency anemia; *Oth*, other; *Thal*, thalassemia trait. (From Artz AS, Thirman MF: *Unexplained anemia predominates despite an intensive evaluation in a racially diverse cohort of older adults from a referral anemia clinic*. *J Gerontol A Biol Sci Med Sci* 66:925, 2011.)

Anemia

Although anemia is not a normal finding in older adults, the prevalence increases markedly from the seventh decade to the ninth decade of life.⁵ For the majority, anemia is related to an underlying cause such as iron deficiency/bleeding, chronic disease/inflammation, or renal insufficiency.⁵ An intensive hematologic evaluation of anemia in older adults reveals a wider range of causes than previously appreciated, including 5%–10% with hematologic neoplasms.^{17,18} Nevertheless 30%–40% of anemic adults lack a discernible cause despite a thorough investigation, and this has become commonly termed *unexplained anemia in the elderly* (Fig. 161.1). Our recommended approach for anemia in older adults differs from that for younger adults (see box on *Evaluating Anemia in Older Adults*). Unexplained anemia has been associated with somatic mutations by whole-exome sequencing.¹⁶

Evaluating Anemia in Older Adults

Anemia in older adults is a common finding and frequently results in a request for hematology consultation.

To define anemia, we apply the Beutler and Waalen criteria in [Table 161.1](#) but also evaluate hemoglobin trajectories over time based on remote laboratory values when available. Based on the fact that the average hemoglobin level declines in older adults about 1 g/dL over 15 years or more,¹⁹ we consider a decline of 1 g/dL in less than 5 years or 2 g/dL over 10 years significant, and this also supports the need to pursue a complete evaluation.

To elicit symptoms, both the patient and family members and caregivers are asked about functional changes (walking, naps, activity level) and the duration (weeks, months or years). Because the etiology of anemia can be multifactorial, we routinely perform the same panel on most patients: complete blood count, white blood cell differential, red blood cell indices, reticulocyte count, smear review, serum ferritin, serum iron, total iron-binding capacity, serum creatinine (and estimated renal function), vitamin B₁₂, and thyrotropin levels. Mean corpuscular volume is helpful but imperfect. We also have found high C-reactive protein (i.e., >10 mg/L) consistent with an inflammatory process and high serum erythropoietin (above the reference range) suspicious for iron deficiency, hematologic malignancy, or hyperproductive anemias. Folate levels are rarely useful in countries practicing universal dietary supplementation. The remainder of the laboratory tests will be performed as indicated.

A ferritin level of less than 50 ng/mL prompts a complete evaluation of the cause of iron deficiency. At a minimum, we embark on an oral iron trial and fecal guaiac tests for blood (not immunohistochemistry). We recommend endoscopic gastrointestinal evaluation generally, especially for more significant or unexplained iron deficiency and in individuals with a longer life expectancy. Other measures exist for diagnosing iron deficiency, such as reticulocyte hemoglobin concentration, serum transferrin receptor, or intravenous iron trials. We also empirically treat if vitamin B₁₂ levels are below 200 pg/mL with oral vitamin B₁₂ at 1000 µg for 8–12 weeks. If there is no response, we discontinue therapy.

A bone marrow examination follows if any of the following are present: unexplained requirement for red blood cell transfusion therapy, unexplained mean corpuscular volume of 97 fL or greater, thrombocytopenia below 120 × 10⁹/L, neutropenia below 1000 × 10⁹/L, or a suspicious peripheral smear. If the bone marrow is nondiagnostic and the sample adequate, we repeat the marrow examination at the time of clinical progression.

When the anemia has no established cause, a hemoglobin level less than 2 g below the age- and race-adjusted normal values above, and hemoglobin trajectory is stable, we follow up with blood cell counts every 6 months and then annually.

Leukopenia and Thrombocytopenia

The causes of thrombocytopenia and neutropenia are vast. Although the causes of cytopenias are not unique to older adults, the possibility of more than one cause should not be overlooked.

CLINICAL MANIFESTATIONS

In the industrialized countries, the detection of cytopenias is often encountered after routine laboratory testing or accompanies minor or nonspecific symptoms. Especially for anemia, one may not be able to disentangle anemia symptoms from other conditions that coexist or underlie the anemia (e.g., rheumatoid arthritis). Although fatigue may be the most obvious symptom of anemia, the potential signs and symptoms are protean. Patients frequently attribute fatigue to “growing old.” Observational studies demonstrate a clear association between mild hemoglobin reduction (e.g., less than 14 g/dL for women and less than 15 g/dL for men) and reduced quality of life, strength, and mobility. Signs and symptoms may also direct one toward a cause, such as a pica suggesting iron deficiency or weight loss directing the clinician toward a systemic illness.

Specific hemoglobin thresholds do not permit one to validate symptoms because patients have different levels of reserve and organ function, pace of hemoglobin fall, and underlying causes for the anemia. A more rapid pace of hemoglobin decline is at least as important in provoking symptoms relative to anemia severity.

Neutropenia and Thrombocytopenia

Because of immune alterations associated with aging, one expects older adults at a given degree of neutropenia to suffer more infections and/or more serious infections. For example, not only do older adults have a greater probability of developing neutropenia, they also have a heightened risk for life-threatening complications.²⁰ Thrombocytopenia in older adults increases bleeding risks compared with younger adults, best illustrated in chronic autoimmune thrombocytopenic purpura.^{21,22}

LABORATORY MANIFESTATIONS

Diagnosis

The use of age-adjusted norms remains quite controversial, because normal aging itself has only a small impact on normal values. For cytopenias, blood counts are mandatory for diagnosis, to establish severity, and to guide the etiologic evaluation. For anemia, we advocate applying the hemoglobin thresholds provided in Table 161.1. Thresholds to define neutropenia and thrombocytopenia should not differ from younger adults.

Laboratory Evaluation for Anemia

See box on [Evaluating Anemia in Older Adults](#). Review of the blood smear can be enormously useful, if not simply to exclude a high-risk hematologic disorder.

Bone Marrow Evaluation

Although a bone marrow examination may be invaluable in excluding serious marrow-related conditions, all cytopenias in older adults do not warrant a bone marrow examination. We favor delaying bone marrow examination until recovery from acute events unless a high-grade hematologic malignancy that would warrant immediate treatment is suspected. Mild fluctuations of counts, particularly within the range found over years, without other evidence of a hematologic malignancy may allow one to safely defer a bone marrow examination. Metaphase cytogenetics and whole-exome sequencing mutational panels are routinely performed. Specific fluorescence in situ hybridization (FISH) panels can be considered based on the level of suspicion of a hematological malignancy.

DIFFERENTIAL DIAGNOSIS

It is important to distinguish true and clinically important findings from false or transiently low values by having serial blood counts and/or a review of the peripheral smear.

In addition to causes delineated in Table 161.3, other causes specific for anemia in older adults include unexplained iron deficiency/blood loss, hemolysis, and androgen deprivation.

PROGNOSIS

The underlying condition driving the hematologic abnormality usually dictates prognosis. Even a mildly low hemoglobin concentration is an independent adverse prognostic factor in older adult patients, even in those 85 years and older.

THERAPY

To the extent possible, the underlying illness should be treated. Particularly for anemia, the cause often remains obscure or the underlying illness may not be amenable to therapy. We favor diagnostic and therapeutic trials of iron or vitamins for a defined period of 3 months and discontinuing if ineffective. We reserve intravenous iron for severe anemia to avoid red blood cell transfusions or after clear failure of an adequate oral iron trial. One must be attuned to fluctuations, normal variation, or confounding factors in assessing response. For example, anemia following hospitalization may reflect phlebotomy, dilution, and an acute inflammatory response. The anemia may improve over months following hospitalization without therapy.

For unexplained anemia, caution should be exercised in employing erythropoiesis-stimulating agents because of concerns for toxicity. Polypharmacy remains a frequent problem in older adults and may either cause hematologic abnormalities or adversely interact with the detected blood abnormality. The primary physician, once prompted, may determine many medications are unnecessary and can simply be discontinued.

For older adults with an established hematologic malignancy for which aggressive therapy may be entertained, a detailed assessment may guide decision-making (see box on [Assessment of Older Adults With Hematologic Malignancies](#)).

FUTURE DIRECTIONS

The biology of aging is increasingly being better understood and may allow recognition of those at risk prior to overt malignancy. Although interventional trials among older persons remain challenging, the growing number of older and often relatively healthy adults mandates efforts to study older adults to define standards of clinical practice.

TABLE 161.3 Differential Diagnosis for Common Causes of Cytopenias in Older Adults

Cytopenia of one or more lineages
Hematologic neoplasm
Vitamin B ₁₂ deficiency
Autoimmune disorder
Consumptive coagulopathy
Systemic inflammation
Alcohol
Splenomegaly
Thyroid dysfunction
Human immunodeficiency virus

Assessment of Older Adults With Hematologic Malignancies

Optimal treatment for a hematologic condition in an older patient must be measured in terms of both efficacy and anticipated toxicity. Assessing the patient's reserve before treatment promotes tailoring treatment and provides an objective baseline assessment.

For all adults over 60 years, we screen for age-associated vulnerabilities. Cataloging comorbid conditions and assessing performance status (PS) plays a central role. PS alone provides only a crude estimate of tolerance to treatment. We find insufficient data to recommend a specific comorbidity tool or index. However, the Charlson comorbidity index or hematopoietic cell transplantation–comorbidity index have been validated in the context of certain diseases and their treatments, and thus may be invaluable in specific situations.

The PS and comorbidity index should be complemented by screening for other vulnerabilities, particularly in those older patients for whom intensive therapy is under consideration. Limitations in the following domains also suggest vulnerability:

- Instrumental activities of daily living, which are the skills required to live independently in the community (e.g., transportation, paying bills, shopping)
- Poor caregiver support
- Cognition
- Age 70 years and older

One should directly question patients about perceived problems for the recommended treatment. Patients will often relay difficulties not recognized by a standard medical examination (e.g., caring for an ill spouse, limited prescription coverage, and poor perceived health). More formal screening instruments are available and useful if familiarity can be achieved (e.g., Vulnerable Elders Survey-13).

Knowledge of disease response rates for older adults allows further individualization of treatment decisions. Responses to imatinib for chronic-phase chronic myeloid leukemia do not differ substantially by age, whereas acute myeloid leukemia induction results in lower responses, shorter disease-free survival, and greater toxicity relative to younger adults.

Although disease-based therapy exists along a spectrum, we generally divide therapy into low-intensity, intermediate-intensity, or high-intensity therapy. High-intensity treatment entails strategies such as AML induction and allogeneic hematopoietic stem cell transplantation owing to high rates of early death for patients with health limitations. We typically reserve high-intensity therapy for patients with a preserved PS and controlled comorbid conditions. We recommend that a patient with any vulnerability on screening undergo a more comprehensive geriatric assessment, if available, before curative-intent intensive therapy. Clinics focusing on issues and research in geriatric oncology are becoming available, and identifying experts (physician and nonphysician) in aging with an interest in oncology is invaluable. They often can connect patients with resources for specific problems (e.g., home care, transportation, financial help, assisted living).

Intermediate-intensity therapy such as CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone)-like regimens and fludarabine plus cyclophosphamide may produce manageable toxicity-related morbidity in older patients, but they remain efficacious and can be administered safely to those with a PS of 2 or better. Demethylating agents span the gap between low- and intermediate-intensity therapy. Low-intensity therapies, such as imatinib or supportive care alone, generally require only a reasonable nondisease life expectancy of more than a couple of months and can be given with an ECOG PS of 3 or less.

We strongly encourage a family meeting before initiating treatment at which goals and expectations are clearly discussed and support from all available caregivers enlisted. Not only will insights be gained into the available support system, but communicating to the entire team harmonizes goals for providers and patients alike. Standard guidelines for infectious disease prophylaxis and growth factor support should be supplemented with plans to address limitations found in the initial assessment.

- D-dimer
- PFA-100
- Platelet aggregometry

This appendix is intended to provide useful supplemental information to clinicians in selecting, obtaining, and interpreting certain key laboratory tests relevant to hematology. The most appropriate reference range for a particular test is dependent on the specific testing methods employed (including reagents and instrumentation), patient age and gender, testing conditions, preanalytical variables, and other concurrent medical conditions. The listed reference ranges thus provide only a rough guide to differentiating normal from abnormal results. Clinicians are encouraged to seek out the most applicable and appropriate reference range for a particular test, preferably using reference data that are specific to the performing laboratory and the patient population being tested. Although the tables listed herein provide some age-specific information, caution is particularly emphasized in interpreting results obtained from testing infants and children.

Estimated Blood Volumes (Includes Plasma Volume, Red Blood Cell Mass)

The red cell volume, plasma volume, and total blood volume are calculated from hematocrit (packed cell volume) and isotope dilution after reinjection of red cells labeled with a radioactive isotope. Performance of a red cell mass determination is occasionally indicated in the investigation of polycythemia to differentiate primary or secondary polycythemia (elevated red cell mass) from relative polycythemia (normal red cell mass). Table 162.1 provides typical reference ranges.

Total blood volume can also be estimated by calculation†:

$$\text{Total Blood Volume for Males} = [0.3669 \times (\text{Height in Meters})^3] + [0.03219 \times (\text{Weight in Kilograms})] + 0.6041;$$

$$\text{Total Blood Volume for Females} = [0.3561 \times (\text{Height in Meters})^3] + [0.03308 \times (\text{Weight in Kilograms})] + 0.1833.$$

*Previously collated by Donald L. Yee, Catherine M. Bollard, and Sharon M. Geaghan.

†From Nadler SB, Hidalgo JU, Bloch T: Prediction of blood volume in normal human adults. *Surgery* 51:224, 1962.

INTERPRETIVE COMMENTS

Complete Blood Count (Red Blood Cell) Parameters

Summary points	- Used to identify anemia or polycythemia (RBC count, hemoglobin, hematocrit) - RBC indices (MCV, MCH, MCHC, RDW) can characterize anemia according to RBC size and degrees of hemoglobinization and anisopoikilocytosis
Methodology	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia or polycythemia
Reference range	Table 162.2
Interpretation	- Anemia (low hemoglobin, hematocrit, RBC count) - Microcytic, hypochromic: iron deficiency (often with high RDW), thalassemia (typically normal RDW but can be high, high RBC count), sideroblastic anemia (may be dimorphic RBCs on peripheral smear), some cases of anemia of chronic disease, hyperthyroidism - Normocytic, normochromic: aplastic anemia, anemia of chronic disease, renal disease, hemolysis, bone marrow infiltration, drugs, lead poisoning, myelodysplastic syndrome - Macrocytic: vitamin B₁₂ or folate deficiency, liver disease, antimetabolite drugs, inherited bone marrow failure, some cases of aplastic anemia, myelodysplastic syndrome, hemolysis with high reticulocyte count, hypothyroidism, alcohol - Polycythemia (high hemoglobin, hematocrit) - Primary: polycythemia vera, altered erythropoietin receptor - Secondary: pulmonary disease, high-affinity hemoglobin, tumor related
Related tests	- Peripheral smear review, reticulocyte count, bone marrow aspiration/biopsy, tests of renal and hepatic function, hemoglobin fractionation/electrophoresis - Microcytic, hypochromic anemias: iron studies, lead level (children), hemoglobin fractionation/electrophoresis - Macrocytic anemias: vitamin B₁₂, folate, homocysteine, methylmalonic acid - Normocytic anemias: markers of hemolysis (reticulocyte count, haptoglobin, indirect bilirubin, LDH) - Polycythemia: family history, <i>JAK2</i> mutation testing, erythropoietin level
Interfering substances	Clotted or hemolyzed sample, cold agglutinin, lipemia, marked turbidity

EDTA, Ethylenediaminetetraacetic acid; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell; RDW, red blood cell distribution width.

Red Blood Cell Distribution Width

Summary points	- Measures variability of red blood cell size (anisocytosis) - Reported as either CV, SD, or both
Methodology	Automated hematology analyzer
Specimen requirements	Whole blood: EDTA
Indications	Evaluation of anemia
Reference range	RDW-CV: 11%–15% (based on adults) ^a
Interpretation	- Elevated with increased variability in red blood cell size and shape; normal with more uniform, red blood cell size - Hypochromic microcytic anemia - Usually elevated with iron deficiency, hereditary sideroblastic anemia, thalassemia intermedia and major, and red blood cell fragmentation - Normal with anemia of chronic disease and thalassemia minor - Normocytic or macrocytic anemia - Usually elevated in folate or vitamin B₁₂ deficiency, mixed iron and folate or vitamin B₁₂ deficiency, some hemoglobinopathies, myelofibrosis, acquired sideroblastic anemia, immune hemolytic anemia, and cold agglutinins - Usually normal in anemia of chronic disease, some hemoglobinopathies, hemorrhage, hereditary spherocytosis, and bone marrow failure - RDW-CV = (SD of red cell volume/MCV)(100) reported more commonly than the RDW-SD - RDW-SD less influenced by MCV and may be more accurate assessment of variability in red blood cell size - Reference range will vary with the instrument used—check with laboratory
Related tests	RBC, Hgb, Hct, MCV, MCH, MCHC, peripheral blood smear
Interfering substances	Hemolyzed or clotted specimen
References	Briggs C: Quality counts: New parameters in blood cell counting. <i>Int J Lab Hematol</i> 31:277, 2009. ^aEvans TC, Jehle D: The red blood cell distribution width. <i>J Emerg Med</i> 9:71, 1991.

CV, Coefficient of variation; EDTA, ethylenediaminetetraacetic acid; Hgb, hemoglobin; Hct, hematocrit; MCH, mean corpuscular hemoglobin; MCHC, mean corpuscular hemoglobin concentration; MCV, mean corpuscular volume; RBC, red blood cell count; RDW, red blood cell distribution width; SD, standard deviation.

Reticulocyte Count (Absolute and Percentage)

Summary points	- Used to assess erythroid production - In setting of anemia, can aid in distinguishing between destructive process (hemolysis) and marrow production problem
Methodology	Automated hematology analyzer, flow cytometry
Specimen requirements	Whole blood: EDTA
Indications	Differential diagnosis of anemia (destruction versus marrow production problem); evaluate marrow response to anemia; monitor response to therapy (treatment of nutritional anemias, post immunosuppressive therapy for aplastic anemia, post growth factor therapy, post chemotherapy, or bone marrow transplant)
Reference range	Table 162.3
Interpretation	- Elevated with marrow response to anemia, implying decreased RBC life span (hemolysis), marrow recovery (post injury, chemotherapy, or bone marrow transplant), or response to treatment (immunosuppressive therapy in aplastic anemia, nutritional replacement in iron, B₁₂, or folate deficiency) - Decreased (or inadequately elevated) in nutritional anemias, marrow suppression (infections, toxic exposures, malignancy), marrow failure - Corrected reticulocyte count (absolute reticulocyte count/reticulocyte maturation time) and RPI [reticulocyte percentage $\times$ (hematocrit/45) $\times$ (1/reticulocyte maturation time)] adjust for the degree of anemia and account for reticulocyte maturation time in assessing appropriateness of the marrow response
Related tests	Absolute count more meaningful than percentage in some settings (aplastic anemia) Complete blood count, reticulocyte hemoglobin, immature reticulocyte fraction, mean reticulocyte volume, corrected reticulocyte count, RPI, direct antiglobulin test, markers of hemolysis
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; RBC, red blood cell; RPI, reticulocyte production index.

Immature Reticulocyte Fraction

Summary points	- Indicator of marrow response to anemia - May be useful to follow engraftment after bone marrow transplant
Methodology	Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, differential diagnosis of anemia, assess marrow response to anemia, after marrow injury, chemotherapy, growth factor treatment, or bone marrow transplant
Reference range	Table 162.4
Interpretation	- Decreased in marrow failure or suppression states, increased with marrow response to anemia - Increased levels after bone marrow transplant appear to correlate with engraftment and precede other cell counts
Related tests	Complete blood count, reticulocyte count, reticulocyte hemoglobin, mean corpuscular volume reticulocyte
Interfering substances	Clotted or hemolyzed sample
Reference	Piva E, Brugnara C, Chiandetti L, et al: Automated reticulocyte counting: State of the art and clinical applications in the evaluation of erythropoiesis. <i>Clin Chem Lab Med</i> 48:1369, 2010.

EDTA, Ethylenediaminetetraacetic acid.

Reticulocyte Hemoglobin Equivalent (Ret-He)

Summary points	- May be useful in early detection of iron deficiency - CHr is a similar but not identical parameter; whether Ret-He or CHr is reported depends on the hematology analyzer used
Methodology	Can be used to monitor response to therapy Automated hematology analyzer—flow cytometric method
Specimen requirements	Whole blood: EDTA
Indications	Suspected anemia, assessment of iron status, differential diagnosis of anemia, assess response to growth factor therapy
Reference range	Table 162.5
Interpretation	- Decreased in iron deficiency and may be decreased in thalassemia - Decreased levels in renal failure may suggest functional iron deficiency
Related tests	Complete blood count, reticulocyte count, immature reticulocyte fraction, mean corpuscular volume reticulocyte, iron studies
Interfering substances	Hemolyzed or clotted specimen
References	Brugnara C, Mohandas N: Red cell indices in classification and treatment of anemias: from M.M. Wintrobe's original 1934 classification to the third millennium. <i>Curr Opin Hematol</i> 20:222, 2013. Piva E, Brugnara C, Chiandetti L, et al: Automated reticulocyte counting: State of the art and clinical applications in the evaluation of erythropoiesis. <i>Clin Chem Lab Med</i> 48:1369, 2010.

CHr, Reticulocyte hemoglobin content; EDTA, ethylenediaminetetraacetic acid; Ret-He, reticulocyte hemoglobin equivalent.

Haptoglobin

Summary points	• Binds free hemoglobin in plasma • Haptoglobin-hemoglobin complex removed by reticuloendothelial system • Often used to evaluate for intravascular hemolysis but has low sensitivity and specificity • Acute-phase reactant
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Evaluation of hemolysis, especially intravascular
Reference range	Table 162.6
Interpretation	• Levels low in neonates and young infants, severe extravascular hemolysis, liver disease, massive tissue hemorrhage, and congenital deficiency states • High levels occur with pregnancy, steroids, estrogen, and acute-phase responses. Preexisting high levels may mask hemolysis
Related tests	Plasma-free hemoglobin concentration, LDH, bilirubin, reticulocyte count
Interfering substances	Lipemia
Reference	Owen JA, Better FC, Hoban J: A simple method for the determination of serum haptoglobins. <i>J Clin Pathol</i> 13:163, 1960.

EDTA, Ethylenediaminetetraacetic acid; LDH, lactate dehydrogenase.

Hemoglobin F and Hemoglobin A₂

Summary points	• Hemoglobin F is composed of two α and two γ chains—the dominant hemoglobin during gestation and early infancy • Hemoglobin A₂ is composed of two α and two δ chains—a normal minor hemoglobin in adulthood • Hemoglobin A₂ present at very low levels at birth, gradually increasing to adult levels over the first 1–2 years of life
Methodology	Gel electrophoresis or high-performance liquid chromatography
Specimen requirements	Whole blood: EDTA
Indications	• Assess for β-thalassemia (including trait) or other hemoglobinopathy • Evaluate for bone marrow failure syndromes or juvenile myelomonocytic leukemia (elevated hemoglobin F); evaluate patients being treated with hydroxyurea for hemoglobin F response (e.g., sickle cell anemia)
Reference range	Tables 162.7 and 162.8
Interpretation	• Hemoglobin F is elevated in β-thalassemia, $\delta\beta$-thalassemia, hereditary persistence of fetal hemoglobin, sickle cell anemia, other hemoglobin disorders, some bone marrow failure syndromes, and juvenile myelomonocytic leukemia • Hemoglobin A₂ is elevated in β-thalassemia, unstable β-chain variants, megaloblastic anemia, thyrotoxicosis • Hemoglobin A₂ is decreased in $\delta\beta$-thalassemia and at times in iron deficiency, lead poisoning, anemia of chronic disease, sideroblastic anemia, and hypothyroidism • Infants with suspected β-thalassemia disorders may require repeat testing at 6 months to 1 year of age to reliably evaluate hemoglobin A₂ levels
Related tests	Complete blood count, peripheral smear review, molecular diagnostic testing for β -chain mutations

EDTA, Ethylenediaminetetraacetic acid.

Sickle Cell Screen (Hemoglobin S Solubility Test)

Summary points	• Rapid test to evaluate for the presence of hemoglobin S >30% • Also known as a <i>sickle prep</i> or by the brand name of a commonly used test kit—<i>Sickledex</i>
Methodology	Differential solubility
Specimen requirements	Whole blood: EDTA, some laboratories accept heparin or ACD anticoagulants
Indications	Suspected hemoglobin S disorder
Reference range	Negative
Interpretation	• Positive when hemoglobin S >30%, negative when hemoglobin S <20% • Hemoglobin S between 20% and 30% may be positive or negative • False positive with cryoglobulinemia, multiple myeloma, dysglobulinemia, certain rare hemoglobinopathies (C Harlem or C Georgetown); false negative with severe anemia, high hemoglobin F, infants under 6 months • Recent transfusion may give false-positive or false-negative results • Does not distinguish between sickle cell trait and sickle cell disease or compound heterozygotes for hemoglobin S and another hemoglobinopathy • Positive results should be confirmed by another method
Related tests	Hemoglobin fractionation/electrophoresis
Interfering substances	Hemolyzed sample
References	Lange RD, Minnich V, Moore CV: Effect of oxygen tension and of pH on the sickling and mechanical fragility of erythrocytes from patients with sickle cell anemia and sickle cell trait. <i>J Lab Clin Med</i> 37:789, 1951. Nalbandian RM, Nichols BM, Camp FR Jr, et al: Dithionite tube test—a rapid, inexpensive technique for the detection of hemoglobin S and non-S sickling hemoglobin. <i>Clin Chem</i> 17:1028, 1971.

ACD, Acid citrate dextrose; EDTA, Ethylenediaminetetraacetic acid.

Ferritin

Summary points	- Ferritin concentration reflects body iron stores; decreased in iron deficiency, increased in iron overload - Useful in distinguishing between iron deficiency anemia and anemia of chronic disease, thalassemia minor - Assessment of iron deficiency may be confounded by infection, inflammation, malignancy, and liver disease, all of which raise ferritin concentration - More sensitive and reliable than serum iron, transferrin (total iron-binding capacity), and transferrin saturation for detecting iron deficiency - Is an acute-phase reactant
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency or iron overload
Reference range	Table 162.9
Interpretation	- Levels are age and gender dependent. Levels in adult females are generally lower than in adult males, but following menopause progressively approach those of males - Levels elevated with iron overload, Gaucher disease, acute hepatitis, malignancies, hemophagocytic lymphohistiocytosis, other highly inflammatory states
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Interfering substances	Antianimal antigen antibodies

Soluble Transferrin Receptor

Summary points	- Transferrin receptor derived mainly from erythroid marrow cells - Reflects iron status independent of concurrent inflammation
Methodology	Immunoassay
Specimen requirements	Lithium heparin or plain tube
Indications	Assess for iron deficiency, especially in setting of inflammation
Reference range	Table 162.10
Interpretation	- Levels decreased with erythroid hypoplasia states, increased with increased iron demand (erythroid hyperplasia [hemolysis, recent blood loss, thalassemia], iron deficiency) - Unaffected by inflammation or liver disease - African Americans and individuals at high altitude may have slightly higher values
Related tests	Iron, transferrin (total iron-binding capacity), transferrin saturation, ferritin
Interfering substances	Lipemia

Total Iron-Binding Capacity, Transferrin Saturation

Summary points	- Transferrin—the major iron transporter protein in plasma - TIBC—often measured as transferrin concentration, especially in pediatrics, because of smaller specimen volume required for children - One molecule of transferrin can bind two molecules of iron - TIBC and transferrin concentration—typically elevated in iron deficiency due to increased transferrin gene expression - Transferrin saturation—calculated as serum iron concentration divided by the iron-binding capacity; low in iron deficiency, elevated in iron overload
Methodology	Immunoassay and calculation
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, and acute iron poisoning (transferrin saturation elevated in the latter)
Reference range	Table 162.11
Interpretation	- Pregnancy and oral contraceptives increase transferrin concentration, leading to low transferrin saturation - Acute-phase response can decrease transferrin and TIBC - Spuriously high TIBC can occur with acute hepatitis and after iron dextran injection
Related tests	Iron, ferritin, soluble transferrin receptor
Interfering substances	Lipemia

TIBC, Total iron-binding capacity.

Iron

Summary points	- Reflects recent iron ingestion and absorption - Undergoes circadian variation - Less reliable than ferritin for assessing iron deficiency
Methodology	Spectrophotometry
Specimen requirements	Lithium heparin or plain tube
Indications	Assess suspected iron deficiency, iron overload, acute iron poisoning, iron absorption (iron challenge test)
Reference range	Table 162.12
Interpretation	- Acute-phase response, malignancy, and ascorbate deficiency can decrease iron concentration, whereas liver disease, ineffective erythropoiesis, and aplastic and sideroblastic anemias can increase it - For oral iron challenge testing, an increase of at least 100 µg/dL 1–4 h after ingestion of 65 mg elemental iron is thought to indicate adequate absorption
Related tests	Ferritin, transferrin (total iron-binding capacity), transferrin saturation, soluble transferrin receptor
Reference	Cook JD: Diagnosis and management of iron-deficiency anaemia. <i>Best Pract Res Clin Haematol</i> 18:319, 2005.

Erythropoietin

Summary points	- Glycoprotein hormone secreted mostly by kidney but also liver - Level varies inversely with hematocrit, stimulated by hypoxia - May be secreted by certain tumors, leading to polycythemia - Results obtained with one method may differ significantly from those obtained with another—any serial testing over time should be performed using the same test method
Methodology	Immunoassay
Specimen requirements	Lithium heparin, EDTA, or plain tube
Indications	Can differentiate primary (decreased concentration) from secondary erythrocytosis (elevated), but testing may be problematic given the broad overlap between the two groups. Levels are usually increased in anemia except in chronic renal failure patients, in whom levels may be used to monitor erythropoietin therapy
Reference range	Adult values approximately 3–16 milli-International Unit/mL; Table 162.13
Interpretation	Normal or low levels with primary polycythemia; elevated levels with most forms of secondary polycythemia
Interfering substances	Lipemia
Reference	Cotes PM, Doré CJ, Yin JA, et al: Determination of serum immunoreactive erythropoietin in the investigation of erythrocytosis. <i>N Engl J Med</i> 315:283, 1986.

EDTA, Ethylenediaminetetraacetic acid.

Folate (RBC or Serum/Plasma)

Summary points	- Folate—commonly assessed in setting of macrocytic anemia along with vitamin B₁₂ (should be done concurrently) - RBC folate less sensitive to short-term dietary changes than serum folate; more reflective of tissue folate stores, more specific for folate deficiency - Folate deficiency usually nutritional in origin or due to inadequate intake in the setting of increased demand (pregnancy, hemolytic anemias, liver disease)
Methodology	Immunoassay
Specimen requirements	RBC: whole blood: EDTA; protect from light for RBC Serum: plain or serum separator tube (fasting state preferred)
Indications	Macrocytic or megaloblastic anemia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms or dementia
Reference range	Table 162.14
Interpretation	- Decreased in nutritional deficiencies (pregnancy, alcoholism, older adults), antimetabolite therapy (methotrexate, for example), rarely due to inherited metabolic disorders - May be decreased in vitamin B₁₂ (cobalamin) deficiency - Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B₁₂ deficiency in patients who have borderline levels of either - Homocysteine—elevated in both folate and vitamin B₁₂ deficiency - MMA—elevated in vitamin B₁₂ but not folate deficiency
Related tests	Vitamin B ₁₂ , homocysteine, MMA, complete blood count
Interfering substances	Excessive light exposure before testing, hemolysis, lipemia
Reference	Kaferle J, Strzoda CE: Evaluation of macrocytosis. <i>Am Fam Physician</i> 79:203, 2009.

EDTA, Ethylenediaminetetraacetic acid; MMA, methylmalonic acid; RBC, red blood cell.

Vitamin B₁₂ (Cobalamin)

Summary points	- Commonly assessed in setting of macrocytic anemia along with folate (should be done concurrently to avoid undiagnosed vitamin B₁₂ deficiency) - Deficiency often due to inadequate gastric absorption (pernicious anemia, gastric bypass) or lack of small bowel reabsorption (malabsorption, Crohn disease, small intestinal surgery) - Nutritional deficiency uncommon but strict vegans are at risk (vitamin B₁₂ available only from animal sources); also seen in alcoholics, older adults, malnutrition - Elevated vitamin B₁₂ may accompany severe disease states and warrants consideration of additional evaluation
Methodology	Immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Macrocytic or megaloblastic anemia, pancytopenia, workup of possible nutritional deficiencies or myelodysplastic syndrome, unexplained neurologic symptoms or dementia, hypersegmented neutrophils on peripheral smear
Reference range	Table 162.15
Interpretation	- Low levels diagnostic of deficiency; pregnancy lowers vitamin B₁₂ level - Follow-up testing for low levels to diagnose pernicious anemia: parietal cell antibodies, antiintrinsic factor antibodies - Additional testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B₁₂ deficiency in patients with borderline levels of either - Homocysteine—elevated in both folate and vitamin B₁₂ deficiency - MMA—elevated in vitamin B₁₂ but not folate deficiency - High vitamin B₁₂ may accompany solid neoplasms, hematologic malignancy, liver or kidney disease, functional B₁₂ deficiency, and autoimmune lymphoproliferative syndrome
Related tests	Folate, homocysteine, MMA, complete blood count, parietal cell antibodies, antiintrinsic factor antibodies, serum gastrin
Interfering substances	Excessive light exposure before testing, hemolyzed sample
References	Andres E, Serraj K, Zhu J, et al: The pathophysiology of elevated vitamin B ₁₂ in clinical practice. <i>Q J Med</i> 106:505, 2013. Kaferle J, Strzoda CE: Evaluation of macrocytosis. <i>Am Fam Physician</i> 79:203, 2009.

MMA, Methylmalonic acid.

Homocysteine

Summary points	Used in differentiating vitamin B₁₂ from folate deficiency, evaluating hereditary metabolic disorders, and assessing cardiovascular risk
Methodology	Liquid chromatography—tandem mass spectrometry, stable isotope dilution analysis, quantitative enzymatic
Specimen requirements	Plain, EDTA, heparin, or serum separator tube (fasting state preferred)
Indications	Suspected B ₁₂ or folate deficiency with equivocal initial testing (folate, vitamin B ₁₂ level), disorder of methionine metabolism, assess cardiovascular or prothrombotic risk
Reference range	Table 162.16
Interpretation	- Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B₁₂ deficiency in patients with borderline levels of either - Homocysteine—elevated in both folate and vitamin B₁₂ deficiency - MMA—elevated in vitamin B₁₂ but not folate deficiency - Levels decrease with vitamin supplementation - May be elevated due to age, medications, smoking, renal disease, poor nutrition, thyroid disease, MTHFR 677C→T polymorphism - Serum/plasma should be separated quickly from red blood cells to prevent false elevations - Recent consumption of high-protein meal may falsely elevate level
Related tests	Folate, vitamin B ₁₂ , MMA, complete blood count, methionine, plasma amino acids, urine organic acids
Reference	Refsum H, Smith AD, Ueland PM, et al: Facts and recommendations about total homocysteine determinations: An expert opinion. <i>Clin Chem</i> 50:1:3, 2004.

EDTA, Ethylenediaminetetraacetic acid; MMA, methylmalonic acid.

Methylmalonic Acid

Summary points	Used in differentiating vitamin B₁₂ from folate deficiency and evaluating hereditary metabolic disorders
Methodology	Liquid chromatography—tandem mass spectrometry
Specimen requirements	Plain, EDTA, heparin, or serum separator tube; urine levels may also be measured
Indications	Suspected vitamin B ₁₂ or folate deficiency with equivocal initial testing (folate, vitamin B ₁₂ level), metabolic disorder (methylmalonic acidemia)
Reference range	Table 162.17
Interpretation	- Testing for pathway intermediates homocysteine and MMA can help distinguish between folate and vitamin B₁₂ deficiency in patients with borderline levels of either - Homocysteine—elevated in both folate and vitamin B₁₂ deficiency - MMA—elevated in vitamin B₁₂ but not folate deficiency - Elevated in vitamin B₁₂ deficiency, renal failure, thyroid disease, bacterial overgrowth of small bowel - Markedly elevated levels in a child suggest hereditary metabolic disorder but must be confirmed
Related tests	Folate, vitamin B ₁₂ , homocysteine, complete blood count
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; MMA, methylmalonic acid.

Osmotic Fragility

Summary points	- Used in differential diagnosis of hemolytic anemia - Usually increased osmotic fragility with hereditary spherocytosis - Increased osmotic fragility can be seen in other conditions with increased spherocytes and other hematologic disorders
Methodology	Lysis of erythrocytes in gradient of hyposmolar solutions; degree of hemolysis commonly measured by spectrophotometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Hemolytic anemia, suspected hereditary spherocytosis
Reference range	Normal curves generated by individual laboratories; patient results are plotted against a normal curve
Interpretation	- Patients with hereditary spherocytosis will show increased lysis of red blood cells in hyposmolar solutions compared with normal controls - Increased osmotic fragility also seen in other causes of spherocytosis (autoimmune hemolytic anemia, posttransfusion), other hematologic disorders (pyruvate kinase deficiency, G6PD deficiency, hereditary stomatocytosis, hereditary pyropoikilocytosis), Rh-null phenotype - Decreased osmotic fragility seen in sickle cell disease, thalassemia, iron deficiency - Normal test does not exclude hereditary spherocytosis (the most fragile cells may have already lysed) —repeat testing at time when patient is at baseline state and hematologically stable may be useful as may perform test with incubation overnight (increases sensitivity) - Measurements taken either immediately or after incubation for 24 h at 37°C enhance assay sensitivity - Results may vary depending on patient age, gender, medication history, and presence or absence of active hemolysis
Related tests	Flow cytometry for band 3 using EMA is more sensitive and specific for hereditary spherocytosis and related hereditary disorders than osmotic fragility
Interfering substances	Flow cytometry for band 3 using EMA, peripheral smear, direct antiglobulin test, complete blood count
References	Hemolyzed specimen, specimen age may falsely increase background hemolysis (laboratory may require submitting concurrent sample from normal nonrelative to control for this)
	King MJ, Zanella A: Hereditary red cell membrane disorders and laboratory diagnostic testing. <i>Int J Lab Hematol</i> 35:237, 2013.
	Park SH, Park CJ, Lee, BR, et al: Comparison study of the eosin-5'-maleimide binding test, flow cytometric osmotic fragility test, and cryohemolysis test in the diagnosis of hereditary spherocytosis. <i>Am J Clin Pathol</i> 142:474, 2014.

EDTA, Ethylenediaminetetraacetic acid; EMA, eosin-5'-maleimide; G6PD, glucose-6-phosphate dehydrogenase.

Leukocyte Counts (Absolute and Percentage)

Summary points	- Also called <i>WBC count and differential</i> - Part of complete blood count
Methodology	Automated hematology analyzer—flow cytometric or impedance methods, may use myeloperoxidase staining for granulocytes, differential may be performed by automated or manual methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected infection, hematologic disorder, or immune deficiency
Reference range	Table 162.19
Interpretation	- Results can vary with time of day, hormonal status, ethnicity (e.g., lower neutrophil counts in persons of African descent) - With infection, total white blood cell (leukocyte) count often elevated, but may be normal or low - Predominance of neutrophils with left shift (immature myeloid precursors) suggests bacterial infection or sepsis but nonspecific; also seen with physical or emotional stress, growth factor treatment - Predominance of lymphocytes and/or monocytes suggests viral or atypical bacterial infection - Eosinophilia suggests allergy, drug effect, or invasive parasitic infection - Abnormal cells suggest leukemia, lymphoma, or myelodysplastic syndrome but can also be seen after growth factor treatment - Low counts suggest marrow suppression due to infection, medication, autoimmunity, toxic exposure, metabolic disorder, bone marrow failure, myelodysplastic syndrome, leukemia, or immune deficiency - Generally, automated differentials are more accurate, but a manual differential may be indicated if abnormal or immature cells are present
Related tests	Manual differential, peripheral smear, lymphocyte subsets
Interfering substances	Clotted or hemolyzed sample

EDTA, Ethylenediaminetetraacetic acid; WBC, white blood cell.

Lymphocyte Subsets

Summary points	B-, T-, and NK-cell subsets used to diagnose and characterize immunodeficiency along with other lymphocyte function testing
Methodology	Flow cytometry
Specimen requirements	Whole blood: EDTA or heparin
Indications	Suspected or known immune deficiency; monitor status of HIV disease or immunomodulatory/immunosuppressive therapy
Reference range	Table 162.20
Interpretation	- Absolute declines in lymphocyte subsets can aid diagnosis and characterization of immune deficiencies: primarily B cell, T cell, or combined - T- and B-cell subsets may decline with immunomodulatory or immunosuppressive therapy - Absolute CD4 counts—monitored in patients with HIV; may define therapy thresholds or risks for specific pathogens - Results may vary with diurnal rhythm
Related tests	Complete blood count, lymphocyte mitogen testing, lymphocyte antigen response testing, antigen-specific IgG/IgM titers after vaccination, PPD testing for delayed type of hypersensitivity response
Interfering substances	Hemolyzed sample, lipemia

EDTA, Ethylenediaminetetraacetic acid; HIV, human immunodeficiency virus; Ig, immunoglobulin; NK, natural killer; PPD, purified protein derivative.

Immunoglobulin A

Summary points	- Important component of mucosal immunity—dimeric form in mucosal secretions, monomeric form in serum - IgA deficiency may occur asymptotically and may or may not confer increased infection risk - Elevated levels may be seen in monoclonal gammopathies or in setting of chronic inflammation or infection (liver disease, collagen vascular disease, autoimmune disease, chronic infections) leading to polyclonal gammopathy
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (recurrent infections), monoclonal gammopathy, isolated IgA deficiency, anaphylactic transfusion reaction to plasma
Reference range	Table 162.21
Interpretation	- Decreased with immune deficiency, celiac disease, some autoimmune diseases, medications, protein loss (nephrotic syndrome, protein-losing enteropathy), non-IgA monoclonal gammopathy - Increased in polyclonal hypergammaglobulinemia, monoclonal gammopathies, infections (tuberculosis, sepsis), chronic liver disease, collagen vascular disease, autoimmune disease, IgA nephropathy - Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgM, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe specimen turbidity, microbial contamination
Reference	Woof JM, Kerr MA: The function of immunoglobulin A in immunity. <i>J Pathol</i> 208:270, 2006.

Ig, Immunoglobulin.

Immunoglobulin E

Summary points	• Important in immune response to deep parasitic (nematode) infections • Important mediator of allergic response; level often elevated in patients with bronchial asthma or atopic dermatitis
Methodology	Nephelometry, immunoassay
Specimen requirements	Plain or serum separator tube
Indications	Suspected allergic disease; monitoring allergic bronchopulmonary aspergillosis
Reference range	Table 162.22
Interpretation	• Low levels in hypogammaglobulinemia and selective IgE deficiency • Elevated levels in allergic diseases, deep parasitic infections, malignancy, drug allergy, immune deficiency, some infections and inflammatory disorders; rarely monoclonal IgE gammopathies • IgE measurement has limited value in diagnosing atopy given large overlap between atopic and nonatopic individuals • Normal levels do not exclude allergy
Related tests	IgA, IgG
Interfering substances	Lipemia, other causes of extreme turbidity, microbial contamination
References	Bacharier LB, Geha RS: Regulation of IgE synthesis: The molecular basis and implications for clinical modulation. <i>Allergy Asthma Proc</i> 20:1, 1999. Hamilton RG, Adkinson NF Jr: Clinical laboratory assessment of IgE-dependent hypersensitivity. <i>J Allergy Clin Immunol</i> 111:S687, 2003.

Ig, Immunoglobulin.

Immunoglobulin G

Summary points	• Largest fraction of serum immunoglobulins; important component of secondary humoral immunity • Elevation seen in monoclonal gammopathies and many polyclonal infectious or inflammatory conditions
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency (primary or secondary) or monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 162.23
Interpretation	• Polyclonal elevations seen in hypergammaglobulinemia, chronic liver disease, collagen vascular diseases, autoimmune diseases, some infections • Monoclonal elevations seen in monoclonal gammopathies (plasma cell dyscrasias); confirmed by serum protein electrophoresis with immunofixation • Decreased in immune deficiencies, hypogammaglobulinemia, states of protein loss (protein-losing enteropathy, nephrotic syndrome), some malignancies, medications • Normal IgG levels do not exclude humoral immunodeficiency—further functional studies (assessment of antibody response post vaccine administration) and/or IgG subclasses may be required if high degree of clinical suspicion • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgM, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination

Ig, Immunoglobulin.

Immunoglobulin G Subclasses

Summary points	• IgG subclass deficiencies are uncommon but may be associated with recurrent bacterial infections • Total serum IgG may be normal, even with a subclass deficiency
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected humoral or combined immune deficiency with normal total serum IgG levels, recurrent respiratory or sinus infections. Testing IgG subclasses has a limited role for assessment of antibody-mediated immune function in patients with recurrent sinusitis and respiratory infections
Reference range	Table 162.24
Interpretation	• Decreased levels in hypogammaglobulinemia • Most frequent abnormality: IgG2 deficiency or combined IgG2-IgG4 deficiency. IgG2 deficiency may be associated with IgA deficiency in patients with chronic respiratory infection • Decreased IgG3 levels may be seen in primary immunodeficiencies (Wiskott-Aldrich syndrome) and type 1 diabetes mellitus • 70% of serum IgG is IgG1—selective IgG1 deficiency is rare • Significance of decreased IgG4 in absence of IgG2 deficiency uncertain
Related tests	IgG, IgM, IgA
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Reference	Maguire G: Are there any clinical indications for measuring IgG subclasses? <i>Ann Clin Biochem</i> 39:374, 2002.

Ig, Immunoglobulin.

Immunoglobulin M

Summary points	• Important component of adaptive humoral immune response as initial antibody type produced after antigen exposure • Measurement of antigen-specific IgM and IgG can be useful in the diagnosis of recent or previous infection • Most common monoclonal immunoglobulin subtype elevated in Waldenström macroglobulinemia; associated with hyperviscosity syndrome
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected immune deficiency, monoclonal gammopathy, assess response to immunization or recent or previous infection when antigen-specific IgM and IgG are tested
Reference range	Table 162.25
Interpretation	• Elevated in polyclonal hypergammaglobulinemia, chronic liver disease, collagen vascular disease, autoimmune disease, some infections, some immune deficiencies, monoclonal gammopathy (lymphoplasmacytic lymphoma and Waldenström macroglobulinemia), cryoglobulinemia • Decreases in immune deficiencies, hypogammaglobulinemia, chronic protein loss (protein-losing enteropathy, malnutrition), some malignancies • Reference intervals may vary with methodology and patient ethnicity
Related tests	IgG, IgA, lymphocyte subsets, serum protein electrophoresis with immunofixation
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination

Ig, Immunoglobulin.

Immunoglobulin Light Chains

Summary points	• Measurement of free light chains is done for diagnosis and monitoring of amyloid, nonsecretory myeloma, and light chain myeloma • Kappa/lambda ratio is critical—excess of kappa versus lambda or excess of lambda versus kappa light chains is consistent with a plasma cell dyscrasia
Methodology	Nephelometry
Specimen requirements	Plain or serum separator tube
Indications	Suspected monoclonal gammopathy, amyloidosis, other plasma cell dyscrasia
Reference range	Table 162.26
Interpretation	Elevated free light chain with either kappa or lambda light chain restriction consistent with amyloidosis or another plasma cell dyscrasia
Related tests	Urine free light chains, urine protein electrophoresis with immunofixation, serum protein electrophoresis with immunofixation, serum immunoglobulin levels (IgG, IgA, IgM)
Interfering substances	Lipemia, other causes of severe turbidity, microbial contamination
Comments	May be more sensitive than serum protein electrophoresis with immunofixation for diagnosis of light chain disease

Ig, Immunoglobulin.

Complement Fractions C3 and C4

Summary points	• Used to measure complement activation or deficiency • C3 and C4, measured together, examine both classical and alternative complement pathways
Methodology	Nephelometry, quantitative immunoturbidimetric, radioimmunodiffusion, electroimmunodiffusion
Specimen requirements	Plain or serum separator tube
Indications	Measure activity in collagen vascular diseases (systemic lupus erythematosus), complement deficiency, immune complex disease, glomerulonephritis, hereditary angioedema
Reference range	Table 162.27
Interpretation	• Reduced C4 with or without reduced C3 implies classical pathway activation as seen in lupus, immune complex disease, hereditary angioedema due to C1 inhibitor deficiency, chronic liver disease • Reduced C3 with normal C4 implies activation by the alternative pathway (e.g., sepsis) • Elevated C3 and/or C4 implies an acute-phase response • Primary deficiency is rare and requires functional assay
Related tests	Total complement CH50, C1q inhibitor
Interfering substances	Lipemia, microbial contamination
Reference	Wen L, Atkinson JP, Giclas PC: Clinical and laboratory evaluation of complement deficiency. <i>J Allergy Clin Immunol</i> 113:585, 2004.

Platelet Count and Mean Platelet Volume

Summary points	Used to assess integrity of hematopoietic and hemostatic systems
Methodology^a	Automated hematology analyzer—flow cytometric or impedance methods
Specimen requirements	Whole blood: EDTA
Indications	Suspected thrombocytopenia or thrombocytosis
Reference range	Table 162.28
Interpretation	- Thrombocytopenia - Primary marrow process: infiltration by tumor or fibrosis, bone marrow failure, marrow suppression (drugs, toxins, infections), myelodysplasia - Secondary consumptive or destructive process: immunologic destruction, hypersplenism, microangiopathy, disseminated intravascular coagulopathy - Thrombocytosis - Primary: essential thrombocythemia - Secondary: acute-phase reactant, splenectomy, iron deficiency - MPV may increase in destructive processes when larger, immature platelets prevail - MPV is elevated in hereditary macrothrombocytopenia (Bernard-Soulier syndrome, MYH9 disorders) and ITP - MPV is low in Wiskott-Aldrich syndrome
Related tests	Peripheral smear, complete blood count, platelet aggregometry
Interfering substances	Clotted or hemolyzed sample; difficult or prolonged collections may activate platelets and artifactually decrease the count

^aPlatelet count may also be estimated by peripheral smear review (count platelets in five fields using a 100× oil-immersion lens, take the average count, and multiply by 15,000) or manually counted using phase contrast microscopy and a hemocytometer. Automated methods using a hematology analyzer are usually more accurate and preferred.

EDTA, Ethylenediaminetetraacetic acid; ITP, immune thrombocytopenic purpura; MPV, mean platelet volume; MYH9, myosin heavy chain 9.

Immature Platelet Fraction

Summary points	- Similar to reticulated platelet count by flow cytometry, but available on automated hematology analyzers - Analogous to reticulocyte count for erythropoiesis, IPF assesses rate of thrombopoiesis, can help distinguish decreased marrow production versus peripheral destruction as likely cause of thrombocytopenia
Methodology	Automated hematology analyzer—flow cytometric method using light scatter and fluorescence dyes that stain RNA
Specimen requirements	Whole blood: EDTA
Indications	Aid in differential diagnosis of thrombocytopenia, assess marrow response after marrow injury, chemotherapy, or bone marrow transplant
Reference range	Table 162.29
Interpretation	- Increased with increased platelet production as seen in thrombocytopenia due to peripheral destruction (ITP, TTP; assuming normally functioning marrow) - Rise in IPF occurs with marrow engraftment posttransplant; precedes a rise in platelet count by a couple of days - Normal or decreased with impaired thrombopoiesis (bone marrow failure, suppression)
Related tests	Increased in patients with macrothrombocytopenia
Interfering substances	May be artifactually elevated with platelet clumping
References	Platelet count, mean platelet volume, complete blood count Clotted or hemolyzed specimen Briggs C: Quality counts: New parameters in blood cell counting. <i>Int J Lab Hematol</i> 31:277, 2009. Miyazaki K, Koike Y, Kunishima S, et al: Immature platelet fraction measurement is influenced by platelet size and is a useful parameter for discrimination of macrothrombocytopenia. <i>Hematology</i> 20:587, 2015.

EDTA, Ethylenediaminetetraacetic acid; IPF, immature platelet fraction; ITP, immune thrombocytopenic purpura; RNA, ribonucleic acid; TTP, thrombotic thrombocytopenic purpura.

Coagulation Screening Tests (PT, aPTT, Fibrinogen)

Summary points	- PT, aPTT used to screen for coagulation factor deficiency and monitor anticoagulation; fibrinogen detects hypofibrinogenemia, dysfibrinogenemia - PT elevated with deficiencies of extrinsic and common pathway factors (PT expressed as INR when used to monitor oral anticoagulant therapy) - aPTT elevated with deficiencies of intrinsic and common pathway factors and inhibitors (heparin, lupus anticoagulant, specific factor inhibitors)
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected coagulation factor deficiency, monitor anticoagulation
Reference range	Table 162.30
Interpretation	- Reference ranges dependent on reagents and instrumentation, requiring laboratory-specific and population-specific ascertainment (e.g., aPTT is normally prolonged during neonatal period) - PT and aPTT vary in their sensitivity to deficiency of individual coagulation factors—PT tends to be least sensitive to FII, aPTT to FIX - Normal aPTT does not exclude mild but clinically significant factor deficiency (especially hemophilia B and von Willebrand disease) - Prolonged PT suggests deficiency of one or more factors (fibrinogen, II, V, VII, X) or presence of a coagulation inhibitor - Prolonged aPTT suggests deficiency of one or more factors (fibrinogen, II, V, VIII, IX, X, XI, or other contact pathway factors) or presence of inhibitor such as lupus anticoagulant or heparin (consider heparin contamination in specimen drawn from a heparinized line) - Prolonged PT and aPTT suggests vitamin K deficiency, liver disease, disseminated intravascular coagulation, common pathway factor deficiency - Isolated prolonged PT (normal aPTT) suggests FVII deficiency - Shortening of aPTT may reflect elevated FVIII level (caused by inflammation) - Spurious prolongation of tests with polycythemia, partially filled collection tube, prolonged storage or warming, clotted specimen
Related tests	Coagulation factor levels (fibrinogen, factors II, V, VII, VIII, IX, X, XI, other contact pathway factors), lupus anticoagulant, mixing studies

aPTT, Activated partial thromboplastin time; FII, factor II; FIX, factor IX; FVII, factor VII; FVIII, factor VIII; INR, international normalized ratio; PT, prothrombin time.

Coagulation Factor Levels (Fibrinogen, II, V, VII, VIII, von Willebrand Factor, IX, X, XI, Contact Pathway Factors)

Summary points	- Choice of which specific factor(s) to measure driven by clinical scenario and screening test results (e.g., isolated prolonged PT suggests FVII deficiency, isolated preoperative aPTT suggests measurement of at least FVIII, FIX, and FXI, to assess bleeding risk) - Low von Willebrand factor may not result in abnormal screening test results
Methodology	Clot detection
Specimen requirements	Citrate
Indications	Suspected coagulation factor deficiency, especially as suggested by prolonged coagulation screening test and subsequent mixing study that corrects, assessment of risk factors for thrombosis (e.g., high FVIII), monitoring of factor-replacement therapy in patients with coagulopathy
Reference range	Tables 162.30 and 162.32
Interpretation	- No definitive threshold for what constitutes hemostatically adequate factor level, but criteria for diagnosing mild factor deficiency often set at 40%–50% - Fibrinogen, FVIII, and von Willebrand factor are acute-phase reactants - Factor deficiency may be due to reduced production (hereditary factor deficiency, liver disease, vitamin K deficiency), increased consumption (disseminated intravascular coagulation), or specific inhibitor (FVIII) - Acquired deficiency of multiple factors occurs with liver disease, vitamin K deficiency (including vitamin K-antagonist therapy or toxicity), disseminated intravascular coagulation—FV, FVII, and FVIII may aid in distinguishing between these - Rare inherited combined factor deficiencies exist (combined FV/FVIII, vitamin K-dependent factors) - With exception of FXI, contact factor deficiencies (FXII, high-molecular-weight kininogen, prekallikrein) may cause prolonged aPTT but are not associated with increased bleeding risk - Vitamin K-dependent and contact factors are physiologically low in early infancy - FV and FVIII are particularly labile, with potential for spuriously low levels—carefully consider abnormally low levels in clinical and laboratory context and assess need for repeat/confirmatory testing
Related tests	Specific factor inhibitor testing, lupus anticoagulant, mixing studies

aPTT, Activated partial thromboplastin time; FIX, factor IX; FV, factor V; FVII, factor VII; FVIII, factor VIII; FXI, factor XI; FXII, factor XII; PT, prothrombin time.

Natural Anticoagulants (Antithrombin, Protein C, Protein S, Tissue Factor Pathway Inhibitor)

Summary points	- Severe deficiency associated with severe thrombotic complications or lethality - Acquired deficiencies more common than inherited - Therapeutic repletion may be indicated in some deficiency states
Methodology	Chromogenic (functional) or immunoassay (antigenic)
Specimen requirements	Citrate
Indications	Assessment of thrombotic risk, diagnosis of severe anticoagulant deficiency states, anticoagulant therapy monitoring (antithrombin status with heparin therapy), assessment of repletion need with concentrate (AT, PC)
Reference range	Tables 162.31 and 162.32
Interpretation	- Levels lower in early infancy and may be reduced in acute thrombosis, consumptive coagulopathy, liver disease - Estrogen, heparin, and asparaginase therapy, nephrotic syndrome associated with decreased AT - PC, PS vitamin K dependent—levels reduced with deficiency and vitamin K antagonist exposure - PS decreased in setting of inflammation, coexisting activated PC resistance (factor V Leiden), pregnancy, estrogen therapy, sickle cell anemia, nephrotic syndrome - No definitive threshold for what levels constitute adequate levels protective against thrombosis, but levels below approximately 70% often considered abnormal
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia

AT, Antithrombin; PC, protein C; PS, protein S.

D-Dimer

Summary points	- Fibrin degradation byproduct of fibrinolytic process after cross-linking by FXIII - Used as biomarker in thrombosis, disseminated intravascular coagulation - Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Methodology	Immunoassay
Specimen requirements	Citrate or EDTA
Indications	Assessment of possible venous thromboembolism, risk stratification for recurrent thrombosis, evaluation of disseminated intravascular coagulation
Reference range	Table 162.33
Interpretation	- Elevated with recent fibrin formation and subsequent fibrinolysis (assuming normal fibrinolytic function) - Elevated with inflammation, malignancy, surgery, recent trauma, bleeding, liver disease, pregnancy - Varied assay methods without clear standardization—reference values specific to method and population critical to interpretation
Related tests	Thrombophilia evaluation, anticoagulation monitoring tests
Interfering substances	Hemolyzed sample or lipemia
Reference	Adam SS, Key NS, Greenberg CS: D-dimer antigen: Current concepts and future prospects, <i>Blood</i> 113:2878, 2009.

EDTA, Ethylenediaminetetraacetic acid; FXIII, factor XIII.

PFA-100

Summary points	- Widely available method measuring time to platelet plug formation under high shear and in presence of platelet agonists (epinephrine and ADP) - Suboptimal sensitivity and specificity for platelet function disorders and von Willebrand disease
Methodology	Automated aspiration of whole blood
Specimen requirements	Citrate
Indications	Assessment of primary hemostasis
Reference range	Table 162.34
Interpretation	- Determination of site-specific reference ranges recommended—longer closure times have been reported - Prolonged closure times with more severe von Willebrand disease and platelet dysfunction but also with anemia, thrombocytopenia, and antiplatelet therapy - Specimen agitation and delayed time to assay may give spurious results
Related tests	Platelet aggregometry, von Willebrand disease testing
Interfering substances	Antiplatelet therapy and other drugs

ADP, Adenosine diphosphate.

Platelet Aggregometry

Summary points

- “Gold standard” for measuring platelet function
- Poor interlaboratory standardization of sample collection methods, agonists, agonist concentrations, parameters of interest and other methodologic aspects can limit interpretability
- Test availability often limited to specialized hemostasis laboratories due to significant technical and quality control requirements

Methodology

Turbidometric or impedance

Specimen requirements

Citrate

Indications

Assessment of platelet function

Reference range

Laboratory dependent; control specimen often required

Interpretation

- Common agonists include ADP, arachidonic acid, collagen, epinephrine, ristocetin, thrombin; pattern of aggregation and presence or absence of primary or secondary waves help to define certain rare, inherited but well-characterized platelet function disorders (e.g., Glanzmann thrombasthenia, Bernard-Soulier syndrome)
- Other less specific abnormalities seen in acquired disorders: uremia, myeloproliferative neoplasms, myelodysplastic syndromes, dysproteinemia, liver disease, cardiopulmonary bypass, drug effect

Related tests

PFA-100, VerifyNow assay

Interfering substances

Antiplatelet therapy and other drugs

ADP, Adenosine diphosphate.

14–19 years	0.06–0.33	0.06–0.33

^aFrom Soldin SJ, Brugnara C, Gunter KC, et al: *Pediatric Reference Ranges*, ed 2, Washington, DC, 1997, AACC Press, pp 100, 101, 143.

^bFrom Lockitch G, Halstead AC, Wadsworth L, et al: Age- and sex-specific pediatric reference intervals for zinc, copper, selenium, iron, vitamins A and E, and related proteins. *Clin Chem* 34:1625, 1988. Study was based on healthy children; children with anemia, microcytosis, and thalassemia syndromes were excluded. Values represent the 0.025th to 0.975th fractiles.

^cNo significant differences between males and females; range derived from combined data.

^dTransferrin saturation calculated from iron (μmol/L)/total iron-binding capacity. Transferrin, transferrin saturation, and total iron-binding capacity results may be misleading in patients receiving iron therapy. Note that the lower reference limits for serum iron and transferrin saturation in this study are below the limits used to define acceptable levels for nutritional health for these two analytes (see O'Neal RM, Johnson OC, Schaefer AE: Guidelines for the classification and interpretation of group blood and urine data collected as part of the National Nutritional Survey. *Pediatr Res* 4:103, 1970).

TABLE 162.12 Serum Iron Reference Values

Age	Male Subjects		Female Subjects	
	μg/dL	μmol/L	μg/dL	μmol/L
1–30 days	32–112	5.7–20.0	29–127	5.2–22.7
31–365 days	27–109	4.8–19.5	25–126	4.5–22.6
1–3 years	29–91	5.2–16.3	25–101	4.5–18.1
4–6 years	25–115	4.5–20.6	28–93	5.0–16.7
7–9 years	27–96	4.8–17.2	30–104	5.4–18.6
10–12 years	28–112	5.0–20.0	32–104	5.7–18.6
13–15 years	26–110	4.7–19.7	30–109	5.4–19.5
16–18 years	27–138	4.8–24.7	33–102	5.9–18.3

Data were collected from hospitalized patients; 2.5th to 97.5th percentile values adapted from the Hoffman technique. Specimens from more than 100 patients in each age-group were analyzed by radioimmunoassay.

TABLE 162.13 Erythropoietin Reference Values in Infants and Children**Serum Erythropoietin Levels in Term Infants During the First Year of Life^a**

Days After Birth	Erythropoietin (Milli-International Unit/mL)	Hemoglobin (g/dL)	RBC (×10 ⁶ /μL)
0–6	33.0 ± 31.4 (11)	15.6 ± 2.2 (11)	4.51 ± 0.74 (11)
7–50	11.7 ± 3.6 (7)	12.8 ± 1.1 (5)	3.92 ± 0.35 (5)
51–100	21.1 ± 5.5 (13)	11.4 ± 1.0 (10)	4.09 ± 0.51 (10)
101–150	15.1 ± 3.9 (5)	11.2 ± 1.1 (3)	4.21 ± 0.31 (3)
151–200	17.8 ± 6.3 (6)	–	–
>201	23.1 ± 9.7 (10)	11.8 ± 0.8 (9)	4.57 ± 0.24 (9)

^aValues are expressed as means ± SD; parentheses enclose number of specimens. Patients were not transfused and weighed 2500 g or more. From Yamashita H, Kukita J, Ohga S, et al: Serum erythropoietin levels in term and preterm infants during the first year of life. *Am J Pediatr Hematol Oncol* 16:213, 1994.

Plasma Erythropoietin Reference Ranges in Children^b

Age (Years)	Number	Male Subjects	Number	Female Subjects
1–3	122	1.7–17.9	97	2.1–15.9
4–6	89	3.5–21.9	76	2.9–8.5
7–9	79	1.0–13.5	80	2.1–8.2
10–12	98	1.0–14.0	90	1.1–9.1
13–15	100	2.2–14.4	148	3.8–20.5
16–18	66	1.5–15.2	77	2.0–14.2

^bValues are expressed in milli-International Unit/mL. Data were obtained from a total of 1122 hospitalized and outpatient children ages 1–18 years, using a commercially available enzyme-linked immunosorbent assay methodology. Values are 2.5th to 97.5th percentiles.

From Krafte-Jacobs B, Williams J, Soldin SJ: Plasma erythropoietin reference ranges in children. *J Pediatr* 126:601, 1995.

TABLE 162.16 Homocysteine Reference Values in Infants and Children

Age	Median (μmol/L)	Range (μmol/L)
Newborn ^a	5.2	0.8–10.9
4 days ^b	6.22	5.0–7.48
6 weeks–6 months ^b	7.47	6.1–9.22
1–10 years ^b	5.24	4.68–5.97
10.5–15 years ^b	6.52	5.7–7.75
15.5–19 years ^b	7.75	6.61–9.12

^aData from blood spots from 200 normal newborns using tandem mass spectrometry. Data from Turgeon CT, Magera MJ, Cuthbert CD, et al: Determination of total homocysteine, methylmalonic acid, and 2-methylcitric acid in dried blood spots by tandem mass spectrometry. *Clin Chem* 56:1686, 2010.

^bData from cross-sectional study of 700 children; range in interquartile. Data from Monsen AL, Refsum H, Markstad T, et al: Cobalamin status and its biochemical markers methylmalonic acid and homocysteine in different age groups from 4 days to 19 years. *Clin Chem* 49:2067, 2003.

TABLE 162.17 Reference Values for Methylmalonic Acid

Age	Median (Range) $\mu\text{mol/L}$
Newborn ^a	0.6 (0.2–2.0)
4 days ^b	0.29 (0.24–0.39)
6 weeks–6 months ^b	0.78 (0.36–1.51)
1–10 years ^b	0.13 (0.11–0.17)
10.5–15 years ^b	0.17 (0.13–0.22)
15.5–19 years ^b	0.14 (0.12–0.18)
Adult ^c	<0.4

^aData from blood spots from 200 normal newborns using tandem mass spectrometry, median value, and range given. Data from Turgeon CT, Magera MJ, Cuthbert CD, et al: Determination of total homocysteine, methylmalonic acid, and 2-methylcitric acid in dried blood spots by tandem mass spectrometry. *Clin Chem* 56:1686, 2010.

^bData from cross-sectional study of 700 children; range in interquartile. Data from Monsen AL, Refsum H, Markestad T, et al: Cobalamin status and its biochemical markers methylmalonic acid and homocysteine in different age groups from 4 days to 19 years. *Clin Chem* 49:2067, 2003.

^cData from Bjørke Monsen AL, Ueland PM: Homocysteine and methylmalonic acid in diagnosis and risk assessment from infancy to adolescence. *Am J Clin Nutr* 78:7, 2003.

TABLE 162.18 Red Cell Glycolytic Intermediate Metabolites in Normal Adults, Term Infants, and Premature Infants^a

Metabolite	Normal Adults (n = 10)	Term Infants (n = 10)	Premature Infants (n = 11)
Glucose-6-phosphate	24.8 ± 9.8	45.2 ± 8.7	66.8 ± 34.8
Fructose-6-phosphate	5.4 ± 1.0	9.9 ± 2.3	20.5 ± 8.9
Fructose-1,6-diphosphate	4.6 ± 1.0	3.8 ± 0.7	3.6 ± 0.8
Dihydroxyacetone phosphate	4.9 ± 3.5	11.9 ± 5.0	18.6 ± 10.7
Glyceraldehyde-3-phosphate	2.6 ± 0.7	1.9 ± 1.6	6.5 ± 3.2
3-Phosphoglycerate	61.6 ± 12.4	58.2 ± 14.4	47.5 ± 14.2
2-Phosphoglycerate	4.3 ± 1.8	4.9 ± 1.6	4.4 ± 2.5
Phosphoenolpyruvate	8.8 ± 2.6	7.6 ± 2.9	7.4 ± 3.0
Pyruvate	73.5 ± 33.1	70.4 ± 32.3	78.4 ± 4.15
2,3-Diphosphoglycerate	4423 ± 1907	3609 ± 800	3152 ± 2133

Units per 100 mL of red blood cells.

^aPremature infants had birth weight below 2200 g and gestational age of less than 37 weeks and were clinically healthy at the time of investigation.

Reproduced with permission from Oski FA: Red cell metabolism in the newborn infant. V. Glycolytic intermediates and glycolytic enzymes. *Pediatrics* 44:84, 1969; Beutler E: G6PD deficiency. *Blood* 84:3613, 1994.

TABLE 162.19 Reference Ranges for Leukocyte Counts in Children and Adults^a

	Total Leukocytes		Neutrophils ^b			Lymphocytes			Monocytes		Eosinophils	
Age	Mean	Range	Mean	Range	%	Mean	Range	%	Mean	%	Mean	%
Birth	18.1	9.0–30.0	11.0	6.0–26.0	61	5.5	2.0–11.0	31	1.1	6	0.4	2

21 years	7.4	4.5–11.0	4.4	1.8–7.7	59	2.5	1.0–4.8	34	0.3	4	0.2	3

^aNumbers of leukocytes are in thousands per cubic millimeter, ranges are estimates of 95% confidence limits, and percentages refer to differential counts. Neutrophils include band cells at all ages and a small number of metamyelocytes and myelocytes in the first few days of life.

^bNormal ranges vary slightly depending on automated analyzer used. The total leukocyte count is used to convert percentage values to absolute counts. Some automated hematology analyzers provide a full or limited differential.

From Dallman PR: Blood-forming tissues. In Rudolph AM, editor: *Pediatrics*, ed 16, New York, 1977, Appleton-Century-Crofts, p 1178.

Basophils^c

Absolute range	3–100/mm ³
Percentage range	0.10–1.47%

^cData based on 668 normal individuals ages 5–74 years; range reflects 2.5th to 97.5th percentiles; counts obtained using a Hemalog D cytochemical automated counter. From Simmons A, Leaverton P, Elbert G: Normal laboratory values for differential white cell counts established by manual and automated cytochemical methods (Hemalog D™). *J Clin Pathol* 27:55, 1974.

For each assay the first two rows show mean and boundaries including 95% of the population. The next row shows the number of individual samples.

^aDenotes values that are significantly different from adult values ($p < .05$).

AT, Antithrombin; PC, protein C; PS, protein S; TFPI, tissue factor pathway inhibitor.

Data from Monagle P, Barnes C, Ignjatovic V, et al: Developmental haemostasis: Impact for clinical haemostasis laboratories. *Thromb Haemost* 95:362, 2006.

TABLE 162.32 Comparison of Selected Coagulation Factor Values in Newborns^a

Study	Fibrinogen (mg/dL)	Factor II (units/mL)	Factor VIII (units/mL)	Factor IX (units/mL)	Factor XII (units/mL)	Antithrombin (units/mL)	Protein C (units/mL)
Term							
Hathaway and Bonnar (1987) and Manco-Johnson et al (1988) ^b	240 (150)	0.52 (0.25)	1.5 (0.55)	0.35 (0.15)	0.44 (0.16)	0.56 (0.32)	0.32 (0.16)
Andrews et al (1987, 1988) ^c	283 (177)	0.48 (0.26)	1.0 (0.50)	0.53 (0.25)	0.53 (0.20)	0.63 (0.25)	0.35 (0.17)
Corrigan (1992) ^d	246 (150)	0.45 (0.22)	1.68 (0.50)	0.40 (0.20)	0.44 (0.16)	0.52 (0.20)	0.31 (0.17)
Preterm							
Hathaway and Bonnar (1987) and Manco-Johnson et al (1988) ^b	300 (120)	0.45 (0.26)	0.93 (0.54)	0.41 (0.20)	0.33 (0.23)	0.40 (0.25)	0.24 (0.18)
Andrews et al (1987, 1988) ^c	243 (150)	0.45 (0.20)	1.1 (0.50)	0.35 (0.19)	0.38 (0.10)	0.38 (0.14)	0.28 (0.12)
Corrigan (1992) ^d	240 (150)	0.35 (0.21)	1.36 (0.21)	0.35 (0.10)	0.22 (0.09)	0.35 (0.10)	0.28 (0.12)

Note: In summary, plasma levels of the vitamin K-dependent factors (including proteins C and S), contact factors, and antithrombin are decreased at birth.

^aData are expressed as mean and lower limit of normal (in parentheses). Preterm, 30–36 weeks' gestational age.

^bData from Hathaway W, Bonnar J: *Hemostatic disorders of the pregnant woman and the newborn infant*, New York, 1987, Elsevier Science; Manco-Johnson M, Marlar R, Jacobson L, et al: Severe protein C deficiency in newborn infants. *J Pediatr* 113:359, 1988.

^cData from Andrews M, Paes B, Milner R, et al: Development of the human coagulation system in the full-term infant. *Blood* 70:165, 1987; Andrews M, Paes B, Milner R, et al: Development of the human coagulation system in the healthy premature infant. *Blood* 72:1651, 1988.

^dData from Corrigan JJ Jr: Normal hemostasis in fetus and newborn: Coagulation. In Polin RA, Fox WW, editors: *Fetal and neonatal physiology*, Philadelphia, 1992, WB Saunders, pp 1368-1371; From Hathaway W, Corrigan J: Report of Scientific and Standardization Subcommittee on Neonatal Hemostasis. *Thromb Haemost* 65:323, 1991.

TABLE 162.33 D-Dimer Reference Values in Infants, Children, and Adults

	Day 1	Day 3	1 Month–1 Year	1–5 years	6–10 years	11–16 Years	Adults
D-dimer	1.47 ^a 0.41–2.47 20	1.34 ^a 0.58–2.74 23	0.22 0.11–0.42 20	0.25 ^a 0.09–0.53 40	0.26 ^a 0.1–0.56 39	0.27 ^a 0.16–0.39 21	0.18 0.05–0.42 32

^aDenotes values that are significantly different from adult values ($p < .05$). Data from Monagle P, Barnes C, Ignjatovic V, et al: Developmental haemostasis: Impact for clinical haemostasis laboratories. *Thromb Haemost* 95:362, 2006. First two rows show mean and boundaries including 95% of the population. The next row shows the number of individual samples.

TABLE 162.34 PFA-100 Closure Times in Healthy Neonates, Children, and Adults

	Collagen/Epinephrine (s)	Collagen/ADP (s)
Term neonates ($n = 17$)	81 (61–108)	56 (48–65)
Children ($n = 57$)	117 (83–163)	91 (72–111)
Adults ($n = 31$)	106 (82–142)	85 (67–111)

ADP, Adenosine diphosphate.

From Carcao MD, Blanchette VS, Dean JA, et al: The Platelet Function Analyzer (PFA-100): A novel in-vitro system for evaluation of primary haemostasis in children. *Br J Haematol* 101:70, 1998. Mean and ranges given as 5th to 95th percentiles.

Fast answers and trusted evidence

Drive better outcomes with a clinical search engine that makes it easier to find and apply relevant knowledge.

Fast

Anticipates your query, recognizing concepts and offering shortcuts

Complete

Draws relevant answers from a wide range of current, comprehensive content across 30+ medical and surgical specialties

Convenient

Accessible at the patient's bedside or on the go, making it easy to discover, share, and apply content anywhere

Trusted

Content from Elsevier, the name healthcare professionals worldwide rely on
