Complications of HCT are one of the major barriers to the wider application of transplantation for a variety of diseases. Currently, only one in four adult HCT recipients survives to 1 year post-HCT without experiencing a major complication.⁴⁹ The impact of newer transplantation modalities, including the use of NMA or RIC regimens, alternative donor transplantation with UCB, and incorporation of immune-based therapies within transplantation regimens, on early and late complications are areas of current investigation. Better tools to predict the risk of post-HCT complications and nonrelapse mortality are needed as well. Genomic and proteomic approaches to HCT complications are being investigated to monitor and predict complications. Although they are some years from use in clinical practice, these approaches could have many potential applications in transplantation, including prediction of risk for complications and GVHD, refining donor selection, and utilization of pharmacogenomic data to individualize conditioning regimens and immunosuppression. Each of these facets represent areas of ongoing vigorous research to improve the safety and effectiveness of HCT.

TRANSFUSION MEDICINE

This page intentionally left blank

HUMAN BLOOD GROUP ANTIGENS AND ANTIBODIES

Connie M. Westhoff, Jill R. Storry, and Beth H. Shaz

Pretransfusion testing includes ABO and Rhesus (Rh) type and antibody screening to determine whether a patient has an unexpected red blood cell (RBC) antibody. If the antibody screen is positive, an identification panel is performed to identify the specificity of the antibody. Unexpected antibodies can be clinically significant causing hemolysis (i.e., acute or delayed hemolytic reaction) after transfusion of RBCs carrying the reciprocal antigen, or can be insignificant. The clinical significance of an antibody is assessed by correlating the serologic information with clinical experiences reported in the literature and with the patient's medical history. Notably, the majority of clinically significant antibodies (outside the ABO system) are in response to RBC antigen exposure either through transfusion or pregnancy. Other antibody characteristics that are used to predict clinical significance include immunoglobulin (Ig) class and *in vitro* characteristics such as strength of reactivity and titer; however, no foolproof method exists to predict the clinical significance. For antibodies with well-known clinical significance, antigen-negative blood is selected for transfusion. Predicting clinical significance is more difficult when a patient has an antibody to a novel or rare high-prevalence antigen and requires a transfusion but antigen-negative blood is not available.

ERYTHROCYTE BLOOD GROUP ANTIGENS

Erythrocyte blood group antigens are polymorphic, inherited, carbohydrate, or protein structures located on the surface of the RBC membrane. There are more than 300 blood group antigens, most of which are included in 36 different blood group systems (Table 110.1). The protein antigens are primarily located on integral transmembrane proteins, but a few are on glycosylphosphatidylinositol (GPI)-linked proteins (Fig. 110.1). Some antigens are carbohydrates attached to proteins or lipids, some require a combination of a specific portion of protein and carbohydrate, and a few antigens are carried on proteins that are adsorbed from the plasma. Many of the proteins carrying blood group antigens reside in the erythrocyte membrane as complexes with other proteins.

Recognition of a new blood group antigen begins with discovery of an antibody. When an individual whose RBCs lack an antigen is exposed to RBCs that possess the antigen, he or she may mount an immune response and produce antibodies that react with the antigen. Depending on the characteristics of the antibody and the number and topology of antigens in the RBC membrane, the interaction *in vivo* between antibody and antigen may result in removal of antibody-coated RBCs by the reticuloendothelial system or in hemolysis if complement is activated.

In blood group testing, most assays are designed to detect antibody-antigen binding with clumping of the RBCs ("agglutination") as the detectable endpoint. The ability to detect and identify blood group antigens and antibodies has contributed significantly to current safe supportive blood transfusion practice, to the appropriate management of pregnancies at risk for hemolytic disease of the fetus and newborn (HDFN), and to management of hematopoietic progenitor cell and solid organ transplantation.

Terminology

Some blood group systems bear the family surname in which the antibody was first discovered (Kell, Kidd, Duffy, etc.), with abbreviations to indicate antigens (K/k, Jk^a/Jk^b, Fy^a/Fy^b, etc.). Others have

been given letter designations (A, B, D, M, N, etc.). A committee for terminology of RBC surface antigens and alleles, organized by the International Society of Blood Transfusion (ISBT), works to standardize terminology of new blood group antigens and the coding alleles.

DNA-Based Typing for Blood Group Antigens

The majority of genes encoding blood group antigens have been identified and cloned, and the molecular basis of most blood group antigens has been determined.^{1,2} Details concerning the alleles associated with blood group antigens are found on the ISBT nomenclature and the Blood Group Antigen Gene Mutation Database (BGMUT) websites (www.ncbi.nlm.nih.gov/gv/mhc/xslcgi.cgi?cmd=bgmute/home; www.isbtweb.org/working-parties/red-cell-immunogenetics-and-blood-group-terminology/). Knowledge of the genes has advanced understanding of the structure and function of the components carrying antigens and resulted in an appreciation of diseases associated with loss of expression of some blood groups, for example, null phenotypes (Table 110.1). Of importance, knowledge of the gene has made it possible to perform DNA analyses to predict the serologic phenotype, to determine gene dosage (zygosity), to perform noninvasive fetal typing, and to type for numerous blood group antigens in a single assay.

Although the simple hemagglutination test remains the principal assay for RBC antigen typing for ABO and Rh, antibody screen, and compatibility testing; genotyping for minor blood group antigens has become commonplace in several clinical situations (Table 110.2). These include determination of the extended blood group phenotype in patients who are multiply transfused, which avoids false typing because of contaminating donor RBCs and aids determination of antibody specificity. This approach is also preferred in patients with strongly direct antiglobulin test (DAT)-positive RBCs, as well as for typing for antigens when no serologic reagents are available and for fetal typing from amniocytes or from free DNA present in the maternal plasma. In these instances^{2a} and others (Table 110.2), hemagglutination is not helpful and genomic analysis is a useful adjunct to routine testing. More recently, genotyping is useful in patients treated with daratumumab (anti-CD38) because treatment results in panreactivity on antibody screening (all cells being reactive). High-throughput genotyping systems have enabled blood centers to screen donors for a large number of antigens in a single assay.

Blood Group Antibodies

The common causes of immunization against blood group antigens are transfusion, pregnancy, transplantation, or occasionally, practices such as sharing needles. "Naturally occurring" antibodies are not a result of RBC exposure; rather, a response to microbes encountered by way of the digestive tract and other mucosal surfaces regularly (e.g., anti-A, anti-B,) or sometimes (e.g., anti-M, -P, -P^b, -P1, -Le^a, -Le^b, -I, -IH) which result in production of antibodies with these specificities. These are the most common antibodies present in children and nontransfused male patients, and are primarily IgM. These multivalent IgM antibodies directed to carbohydrate antigens optimally bind and directly agglutinate to RBCs at temperatures below 37°C. Most are not clinically significant (outside of ABO).

TABLE 110.1
Blood Group Systems, Antigens, Expression, and Disease Associations

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (null phenotype)	Present in Other Tissue	Disease Association	Function
ABO (001)	<i>ABO</i>	Glycosyl-transferases Type II ^a (354 AA)	Carbohydrate	A, B, AB, A1 (group O)	Secretions, platelets, broad tissue distribution	Altered in some hematologic disorders, leukemia	Glycosylation
MNS (002)	<i>GYPA (MN)</i> <i>GYPB (Ss)</i>	Type I (131 AA) Type I ^a (72 AA)	GPA GPB	M, N, S, s, U, Vw; M ^k M ^k lack GPA and GPB; En(a-) lack GPA; S-s-U- lack GPB	Renal endothelium and epithelium	Decreased <i>Plasmodium falciparum</i> invasion May be receptor for <i>Escherichia coli</i> microbes	Negative charge on sialic acid; receptor for microbes
P (003)	<i>A4GALT</i>	Galactosyl-transferase Type II (353 AA)	Carbohydrate	P1, Pk (P1-, PP1Pk-)	Lymphocytes, granulocytes, monocytes, platelets	Receptor <i>E. coli</i> and <i>Parvovirus-B19</i> Miscarriage	Glycosylation
Rh (004)	<i>RHD</i> <i>RHCE</i>	Multipass—12 spans (417 AA)	RhD RhCE	D, C, E, c, e, G, VWS (R _{hnull} syndrome)	RBC-specific	Hemolytic anemia; stomatocytosis Reduced expression and mosaicism in hematologic malignancies	Structural link to underlying cytoskeleton
Lutheran (005)	<i>LU</i>	Type I IgSF (597 AA) (557 AA)	Lutheran glycoprotein B-CAM	Lu ^a , Lu ^b , Lu ³ , Au ^a , Au ^b (recessive Lu(a-b-))	Broad tissue distribution Not on lymphocytes, granulocytes, monocytes or platelets	Increased expression possibly involved in vasoocclusion in sickle cell disease	Possibly adhesion; may mediate intracellular signaling Binds to laminin
Kell (006)	<i>KEL</i>	Type II (732 AA)	Kell glycoprotein	K, k, Kp ^a , Kp ^b , Ku, Js ^a , Js ^b (K ₀ or K _{null})	Broad tissue distribution Bone marrow, fetal liver, testes, brain, heart, skeletal muscle	Depressed in McLeod syndrome (see XK)	Cleaves big endothelin 3 to ET-3 (a potent vasoconstrictor)
Lewis (007)	<i>FUT3 (LE)</i>	Not endogenous to RBCs Type II (361 AA)	Carbohydrate Adsorbed from plasma	Le ^a , Le ^b , Le ^{ab} , Le ^{ah} , ALe ^b , BLe ^a (Le(a-b-))	Saliva and body fluids, Blood cells, GI, skeletal muscle, kidney, adrenal	Increased expression in fucosidosis	Fucosyl transferase
Duffy (008)	<i>ACKR1 (FY)</i>	Multipass—7 spans (338 AA)	Fy glycoprotein	Fy ^a , Fy ^b , Fy3, Fy6 (FY(a-b-))	Broad tissue distribution Endothelial and epithelial cells, Purkinje cells, colon, lung, spleen, thyroid, thymus, kidney	<i>Plasmodium vivax</i> receptor RBC null-resistant to <i>P. vivax</i>	Chemokine receptor
Kidd (009)	<i>SLC14A1 (JK)</i>	Multipass—10 spans (389 AA)	Kidd glycoprotein	Jk ^a , Jk ^b , Jk3 (Jk(a-b-) or Jk _{null})	Kidney: vasa recta endothelium Renal medulla	Urine concentrating defect	Urea transport
Diego (010)	<i>SLC4A1 (DI)</i>	Multipass—14 spans (911 AA)	Band 3, AE1	Di ^a , Di ^b , Wr ^a , Wr ^b , (1 reported—transfusion dependent; predicted to be incompatible with life)	Kidney: intercalated cells of distal and collecting tubules	Southeast Asian ovalocytosis, hereditary spherocytosis, renal tubular acidosis	Anion transport CO ₂ /HCO ₃ ⁻ exchange
Yt (011)	<i>ACHE (YT)</i>	GPI-linked (557 AA)	Acetylcholinesterase	Yt ^a , Yt ^b	Brain, muscle, nerves	Absent from PNH III RBCs	Enzymatic
Xg (012)	<i>MIC2 (XG1)</i>	Type I (180 AA) (163 AA)	Xg ^a glycoprotein	Xg ^a	The antigen may be restricted to RBC, but CD99 has broad tissue distribution		Adhesion molecule

Scianna (013)	ERMAP (SC)	Type I (475 AA)	ERMAP	Sc1, Sc2, Sc3, Rd (Sc -1, -2, -3)	Possible adhesion
Dombrock (014)	ART4 (DO)	GPI-linked (314 AA)	Do glycoprotein; ART 4	Do ^a , Do ^b , Gy ^a , Hy, Jo ^a (Gy(a-))	Enzymatic
Colton (015)	AQP1 (CO)	Multipass—6 spans (269 AA)	Aquaporin	Co ^a , Co ^b , Co3 (Co(a-b-))	Water transport
Landsteiner-Wiener (016)	ICAM4 (LW)	Type I IgSF (241 AA)	LW glycoprotein ICAM-4	LW ^a , LW ^b , LW ^{ab} (LW(a-b-))	Ligand for integrins
Chido/Rodgers (017)	C4A, C4B (CH/RG)	Not endogenous to RBC (1191 AA)	C4A; C4B	Ch1, Ch2, Rg1	Part of the complement cascade
H (018)	FUT1(H)	Fucosyl-transferase Type II (365 AA)	Carbohydrate	H (Bombay O _h)	Glycosylation
Kx (019)	XK (XK)	Multipass—10 spans (444 AA)	XK glycoprotein	Kx (McLeod)	Transport; possible neuro-transmitter
Gerbich (020)	GYPC (GE)	Type I (128 AA) (107 AA)	GPC GPD	Ge2, Ge3, Ge4 (Leach phenotype)	Structural Interacts with protein 4.1 and p55
Cromer (021)	CD55 (CROM)	GPI-linked (347 AA)	DAF	Cr ^a , Tc ^a , Tc ^b , Tc ^c , Dr ^a , Es ^a , IFC (Inab)	Complement regulation; binds C3b; disassembles C3/C5 convertase
Knops (022)	CR1 (KN)	Type I (1998 AA)	CR1	Kn ^a , Kn ^b , McC ^a , SI ^a , Yk ^a , KCAM (no nulls reported)	Complement regulation; binds C3b and C4b; mediates phagocytosis
Indian (023)	CD44 (IN)	Type I (341 AA)	Hermes antigen	In ^a , In ^b	Binds hyaluronic acid; mediates adhesion of leukocytes
Ok (024)	BSG (OK)	Type I IgSF (248 AA)	Basigin	Ok ^a	Possible adhesion
RAPH (025)	MER2	Multipass—4 spans (253 AA)	CD151	MER2 (Raph-)	Absence associated with renal disease and kidney failure

TABLE 110.1 Blood Group Systems, Antigens, Expression, and Disease Associations—cont'd

ISBT System Name (Number)	Gene Name	Predicted Topology (Number of Amino Acids [AA])	Component Name	Principal Associated Blood Group Antigens (null phenotype)	Present in Other Tissue	Disease Association	Function
JMH (026)	<i>SEMA-L</i> (JMH)	GPI-linked (656 AA)	Semaphorin 7A	JMH		Absent from PNHIII RBCs	Adhesion molecule
I (027)	<i>GCNT2</i>	N-acetyl-glucosaminyl-transferase type II (400 AA)	Carbohydrate	I (I- or i adult)	Broad tissue distribution	Cataracts in Asians	Glycosylation
Globoside (028)	<i>B3GAL T1</i>	N-acetyl-galactosaminyl-transferase type II (331 AA)	Carbohydrate (G _b ₄ , globoside)	P (P-), P ^k and p	Broad tissue distribution Placenta (trophoblasts and interstitial cells)	Receptor <i>E. coli</i> and <i>Parvovirus-B19</i> Spontaneous abortion	Glycosylation
GIL (029)	<i>AQP3 (GIL)</i>	Multipass—6 spans (292 AA)	AQP3	GIL (GIL-)	Board tissue distribution Kidney, prostate, GI tract, spleen, skin, eye		Glycerol/ water/ urea transport
RHAG (030)	<i>RHAG</i>	Multipass—12 spans (409 AA)	Rh-associated glycoprotein	RHAG1 or Duclos, RHAG2 or OI ^a , RHAG3 or DL, RHAG4 (Rh _{null} regulator)	RBC-specific but homologs RhBG, RhCG in kidney, liver, skin, GI tract	Hereditary overhydrated stomatocytosis	Ammonia transport
FORS (031)	<i>GBGT1</i>	Type II (347 AA)	Carbohydrate	FORS1	Broad tissue distribution		Glycosyltransferase
JR (032)	<i>ABCG2</i>	Type III – 6 spans (655 AA)	ATP-binding cassette sub-family G member 2	Jr ^a (Jr(a-))	Broad tissue distribution. High in placenta, seminal vesicles.	Gout; multidrug resistance in cancer	Urate exporter; porphyrin hemostasis
LAN (033)	<i>ABCB6</i>	Type III – 6 spans (842 AA)	ATP-binding cassette sub-family B member 6, mitochondrial	Lan (Lan-)	Broad tissue distribution	Dyschromatosis universalis hereditaria; Microphthalmia	Binds heme and porphyrins. Important in heme synthesis
VEL (034)	<i>SMIM1</i>	Type 1 (78 AA)	SMIM1	Vel (Vel-)	RBCs, salivary glands, testis		Not known
CD59 (035)	<i>CD59</i>	GPI-linked (128 AA)	CD59 glycoprotein	CD59.1 (CD59.1-)	Broad tissue distribution; Soluble form in plasma	Hemolytic anemia, with or without polyneuropathy	Complement regulation; inhibits MAC complex
AUG	<i>SLC29A1</i>	Type III – 11 spans (456 AA)	Equilibrative nucleoside transporter 1	At ^a (At(a-))	Broad tissue distribution	Pseudo gout in the null phenotype	Nucleoside transmembrane transporter

^aType I, protein with a single pass through the RBC lipid bilayer with its amino terminus to the outside of the cell; type II, protein with a single pass through the RBC lipid bilayer with its amino terminus to the inside of the cell. AEI, Anion exchanger 1; AQP^a, aquaporin; C4, fourth component of complement; CGD, chronic granulomatous disease; CR1, complement receptor 1; CSF, colony-stimulating factor; CNS, central nervous system; DAF, decay-accelerating factor; ERMAP, erythrocyte membrane-associated protein; GPA, glycoprotein A; GPB, glycoprotein B; GPC, glycoprotein C; GPD, glycoprotein D; GI, gastrointestinal; GPI, glycosylphosphatidylinositol; GU, genitourinary; ICAM4, intercellular adhesion molecule 4; IgSF, immunoglobulin super family; ISBT, International Society of Blood Transfusion; PNH, paroxysmal nocturnal hemoglobinuria; RBC, red blood cell; SLE, systemic lupus erythematosus.

Fig. 110.1 MODEL OF BLOOD GROUP PROTEINS IN THE RED BLOOD CELL MEMBRANE. Schematic representation of the red blood cell (RBC) molecules that carry blood group antigens and the predicted structure. These include carbohydrates, single and multipass proteins, and GPI-linked proteins in the RBC membrane. AQP-1 (aquaporin-1), COOH (carboxyl group), CR1 (complement receptor 1), DAF (decay-accelerating factor), ERMAP (erythrocyte membrane-associated protein), GPA (Glycophorin A), GPB (glycophorin B), GPC (glycophorin C), GPD (glycophorin D), GPI (glycosylphosphatidylinositol), ICAM-4 (intercellular adhesion molecule 1), LW (landsteiner-wiener), Rh (rhesus), RhAG (Rh-associated glycoprotein).

TABLE 110.2 Uses of DNA-Based Genotyping Assays for Transfusion Medicine

Type patients who have been recently transfused
Type patients who are being treated with monoclonal antibody therapy, for example anti-CD38
Type RBCs coated with immunoglobulin
Type patients with AIHA (to select antigen-negative RBCs for transfusion and absorption of autoantibodies when searching for underlying alloantibodies)
Type RBCs when commercial antisera are not available
Type for numerous blood group antigens in a single assay
Identify weak D and partial D (to determine candidate for Rh immune globulin or avoid use of limited Rh-negative donor supply)
Resolve blood group typing discrepancies
Determine paternal zygosity for <i>RHD</i> and HPA
Type fetus to determine risk for HDFN or NAIT

AIHA, Autoimmune hemolytic anemia; HDFN, hemolytic disease of the fetus and newborn; HPA, human platelet antigen; NAIT, neonatal alloimmune thrombocytopenia; RBC, red blood cell.

Exceptions occur if the antibody is reactive at 37°C and/or has an IgG component. Antibodies that are considered not to be clinically significant unless the antibody reacts in tests performed at 37°C include those to A1, P1, M, N, Lu^a, Le^a, Le^b, I, IH, and Sd^a antigens.

In contrast, antibodies occurring following immunization to protein antigens such as those in the Rh, Kell, Kidd, and Duffy blood

group systems are primarily of the IgG isotype that react at 37°C and are detected by the indirect antiglobulin test (IAT). These bivalent antibodies optimally bind to, but do not directly agglutinate, RBCs at 37°C. The addition of an antiglobulin reagent (i.e., antihuman IgG (AHG), also known as Coombs serum) is required to induce RBC agglutination. Most of these are clinically significant antibodies, with the exception of antibodies to Knops (Kn), Chido/Rodgers (Ch/Rg) and JMH systems (Table 110.3 summarizes the Ig class and clinical significance associated with alloantibodies; see also box on [Indirect Antiglobulin Test and Direct Antiglobulin Test](#)).

Antibodies recognizing antigens in the ABO system are by far the most clinically significant and are present in nearly all individuals who lack the antigen (they typically appear by 4 months of age). Other clinically significant antibodies occur in the following approximate order, from the most to the least commonly encountered in transfusion practice: anti-D, anti-K, anti-E, anti-c, anti-Fy^a, anti-C, anti-Jk^a, anti-S, and anti-Jk^b. Clinically significant antibodies occur in approximately 3% of transfused patients³ but have a higher incidence of 35% to 55% in patients undergoing chronic transfusion.⁴⁻⁸ The frequency of antibody production depends on the antigen immunogenicity and prevalence of the antigen in a population.

Compatibility Procedures and Location of Antigen-Negative Blood

Manual tube, solid phase, or gel-column methods based on agglutination of RBCs are the most common serologic assays performed in transfusion medicine laboratories.

TABLE 110.3**Characteristics of Some Blood Group Alloantibodies (Listed in Approximate Order of Clinical Significance)**

Antibody Specificity	IgM	IgG	Clinical	
			Transfusion Reaction	HDFN
ABO	Most	Some	Immediate; mild to severe	Common; mild to moderate
H in Bombay	Most	Some	Immediate; mild to severe	Rare; mild
Rh	Some	Most	Immediate/delayed; mild to severe	Common; mild to severe
RhAG	Rare	Most	Immediate/delayed; mild to severe	Mild to severe
Kell	Some	Most	Immediate/delayed; mild to severe	Mild to severe

Xg ^a	Rare	Most	None	None

^aMost examples of these antibodies are both IgM and IgG.

^bSeldom hemolysis of fetal cells but high incidence of recurrent spontaneous abortions.

IgG, Immunoglobulin G; IgM, immunoglobulin M; HDFN, Hemolytic disease of the fetus and newborn; Rh, rhesus; RhAG, Rh-associated glycoprotein.

ABO

Commercially available mouse monoclonal anti-A and anti-B are used to determine ABO type, and these reagents directly agglutinate RBCs at room temperature. To confirm the RBC ABO reactivity, the plasma is tested for the presence of the corresponding agglutinins by testing with commercially available group A1 and group B RBCs. In both tests, agglutination is macroscopically visible.

Rhesus

Patient and donor RBCs are routinely tested for the presence of the D antigen in the Rh system. Reagents containing monoclonal anti-D that directly agglutinate D-positive (Rh-positive) RBCs suspended in saline at room temperature are commonly used for testing. Testing by a method that detects expression of a weak D antigen on RBCs is required for donors, but additional testing for weak D is optional when testing patient samples. Exceptions include typing the RBCs of a newborn when the mother is D-negative to determine whether she is a candidate for Rh immune globulin (RhIG) (see box on [Rh Immune Globulin](#)).

Antibody Screening

Patient plasma is incubated at 37°C with commercially available reagent RBCs of known antigen type. After incubation, unbound antibodies are removed by washing with saline, and an antiglobulin reagent containing either AHG, or a mixture of AHG and antihuman complement is added. Column agglutination technology is now widely used and eliminates the requirement to wash unbound IgG. If the antibody screen is positive, the specificity of the antibody is determined by testing the plasma against a panel of different group O reagent RBCs (usually 10) varying in antigen phenotype (termed antibody identification).

Compatibility Testing

Once a patient is actively immunized to an RBC antigen and produces a clinically significant alloantibody, the patient is considered immunized for life and should be transfused with antigen-negative RBCs, even if the antibody is no longer detectable. Patients with passively acquired antibody (e.g., neonates with maternal antibody; recipients of plasma and platelet products or RhIG) need to be

Indirect Antiglobulin Test and Direct Antiglobulin Test

The indirect antiglobulin test (IAT) is used to detect alloantibodies in patient sera in vitro following incubation at 37°C and includes antibody screening and identification and crossmatching with donor red blood cells (RBCs). IAT is also sometimes used for antigen typing to detect RBCs coated with antibody following incubation with reagent antisera. After incubation, unbound antibodies are removed by washing with saline and an antiglobulin reagent containing either antihuman IgG (AHG) or a mixture of AHG and monoclonal antihuman complement is added. Differential agglutination suggests the presence of antibodies to one or more specific RBC antigens while agglutination of all cells suggests the presence of an antibody to a high-prevalence antigen or the presence of an autoantibody.

The direct antiglobulin test (DAT) is used to detect the presence of antibody or complement (or both) on the surface of RBCs in vivo such as autoantibodies coating the patient's cells in warm autoimmune hemolytic anemia, cold hemagglutinin disease, or alloantibodies coating the patient's cells in immediate or delayed transfusion reactions, or hemolytic disease of the fetus and newborn. Patient RBCs obtained in ethylenediaminetetraacetic acid, to prevent in vitro complement deposition on the RBCs, are washed with saline and then incubated with a commercial antiglobulin reagent containing AHG or antihuman complement or a mixture of the two. Antiglobulin reagents containing anti-IgM or anti-IgA are available in specialized centers to detect coating of RBCs by antibodies of these isotypes.

Rh Immune Globulin

Rh immune globulin (RhIG) is a human plasma-derived hyperimmunoglobulin product consisting of IgG antibodies to D antigen that is administered to D-negative pregnant women who are at risk for D sensitization. RhIG is administered (1) at 28 weeks gestational age, (2) when there is a risk for fetal maternal hemorrhage through amniocentesis, trauma, or other procedures, and (3) postpartum in the case of a known or potential D-positive newborn or fetus. If the Rh(D) typing of a pregnant woman is discrepant with prior results, or typing reactions are weaker than expected, or if variable reactivity is seen, RHD genotyping should be considered to guide RhIG prophylaxis and selection of blood for transfusion.

RhIG is sometimes administered outside of pregnancy to D-negative patients who receive D-positive blood products, most commonly whole blood derived platelet products. This is primarily considered for females of childbearing potential when the formation of anti-D has serious consequences. Because the risk for D alloimmunization from whole blood derived platelet transfusion is less than 4%, and even less for apheresis platelets, the majority of D-incompatible platelets are given without RhIG administration. RhIG in significantly higher doses is used to treat immune thrombocytopenic purpura (ITP) in patients who are D-positive and have not been splenectomized.

For prevention of D-sensitization in the United States, 300 µg are routinely administered, but dosing is increased if there is evidence of large fetal-maternal hemorrhage (300 µg for every 15 mL of RBC exposure or 30 mL of whole blood exposure). The dose is calculated based on the estimated volume of D-positive fetal RBCs from Kleihauer-Betke or flow cytometry, which is more precise. RhIG dosing calculators are available. RhIG should be given within 72 hours, which was the time period for the original studies, but should not be withheld if not administered within this time period. Adverse events to low doses used to prevent D immunization include fever, chills, and pain at the injection site. Rarely, hypersensitivity reactions are noted. RhIG doses used to treat ITP are substantial: 50 µg/kg for hemoglobin values ≥10 g/dL and 25–40 µg/kg when hemoglobin is 8–10 g/dL. Adverse events include possible anemia, hemolysis, disseminated intravascular coagulopathy, and rarely, death (Chapter 131).

transfused with antigen-negative RBCs only while the passive antibody is present. Selection of blood for transfusion to patients with alloantibodies requires typing of donor units for the corresponding antigen to identify antigen-negative units and crossmatch of the selected units with the patient's plasma. Antigen-negative units are provided by, or can be located by, most donor centers. Provision of

TABLE 110.4

Approaches to Supplying Red Blood Cell Products to Prevent Alloimmunization in Patients With Sickle Cell Disease or Other Transfusion-Dependent Anemia

- Phenotype or genotype for clinically significant antigens before transfusion
- Provide antigen-matched blood for C, E, and K prophylactically
- Provide blood negative for the major antigens that the patient lacks after the patient makes an antibody

antigen-negative blood will to some extent depend on the prevalence of the target antigen(s) in the donor population. Transfusion service staff are vital for communication between the patient's physician and/or consultant transfusion medicine specialist to determine the immediate and ongoing transfusion needs of the patient and to ensure that antigen-negative blood is available. Understanding the risks and benefits of transfusion are important, as well as understanding the potential clinical significance of the antibody and the urgency of transfusion. When a patient's antibody is directed at a high-prevalence antigen, it is important to test siblings in the quest for compatible blood and to urge the patient to donate blood for long-term storage when clinical status permits. In hemolytic anemia because of warm-reactive autoantibodies, compatibility may be difficult to demonstrate. In this scenario, the important issue is to be sure that there are no clinically significant alloantibodies underlying the warm reactive autoantibodies. Donor RBCs antigen-matched with the patient for clinically significant blood group antigens should be considered in lieu of transfusion with "least incompatible" blood to minimize alloimmunization.

Prevention of Alloimmunization

Transfusion management of patients who require chronic transfusion therapy, in particular patients with sickle cell disease can be challenging.^{9–11} Many programs attempt to reduce or prevent alloimmunization by transfusion of RBCs that are prophylactically antigen-matched, typically for C, E, and K,¹² and some match for additional antigens. Some centers match for extended antigens once the patient makes an antibody (Table 110.4). The goal is to prevent hemolytic or delayed transfusion reactions, which are known to be underreported because they can manifest as a sickle cell crisis and may result in decreasing the transfusion interval.

Blood Group Disease Association

The absence of some blood group antigens and their carrier molecules can result in disease. For example, an absence of the Rh and Rh-associated glycoprotein (RhAG) proteins causes stomatocytosis¹³ and anemia, termed *Rh_{null} syndrome*. The absence of Xk protein is associated with the *McLeod syndrome*, which is associated with myopathy and neurodegeneration. RBCs and white blood cells from patients with leukocyte adhesion deficiency II (also known as *congenital disorder of glycosylation type II*) lack antigens that are dependent on fucose. The RBCs have the Le(a–b–) Bombay phenotype and the white blood cells lack sialyl-Le^x, which explains the high white blood cell count and infections in these patients. Hemagglutination is a simple test that can be used to diagnose these syndromes. In patients with paroxysmal nocturnal hemoglobinuria, a proportion of the RBCs will lack antigens carried on GPI-linked proteins. Other associations between blood group antigens and diseases are summarized in Table 110.1.

Diseases associated with antibodies to blood group antigens include hemolytic disease of the newborn, warm autoimmune hemolytic anemia, cold hemagglutinin disease, and paroxysmal cold hemoglobinuria. Hemagglutination is a valuable aid in diagnosis of these conditions.

of group O red cells and AB plasma products is an option. In blood donors, if very weak expression of A or B antigens on the RBCs is not detected, the major risk is that they may be transfused to a patient whose antibodies may cause accelerated destruction of the transfused cells.

Rare Bombay (O_h) phenotype RBCs, first reported in Bombay (Mumbai), India, lack H antigen and, consequently, A and B antigens. Other variants with weak H expression on RBCs, with or without H in secretions, also occur (para-Bombay) and have been reviewed.¹⁶ Of clinical relevance, potent anti-H with the same hemolytic potential as anti-A and anti-B can be produced by Bombay individuals. Anti-H is often found in para-Bombay individuals but is generally not a potent antibody. HDFN caused by anti-H has not been reported.

Acquired B antigen is a rare phenomenon that results from the action of bacterial deacetylase, an enzyme that can remove an acetyl group from the A-terminal sugar, *N*-acetylgalactosamine. Galactosamine is similar to galactose, the B-specific terminal residue, and anti-B reagents can cross-react with the deacetylated structure. Acquired B can occur in individuals suffering from gram-negative infections of gastrointestinal origin or carcinoma and can be clinically significant if a patient's blood group is misinterpreted and group AB blood is transfused. Other polyagglutinable states (e.g., T, Tn, Tk) are detected by naturally occurring antibodies found in the serum of most people; these can be identified by a panel of lectins.

A or B antigen expression can weaken in patients with acute leukemia or stress hematopoiesis or, occasionally, during pregnancy. Chromosomal deletions or lesions that involve the *ABO* locus can result in the loss of transferase expression in the leukemic cell population. A decrease in A or B antigen expression, when found without a hematologic disorder, can be prognostic of a preleukemic state.

Genes and Enzymes The *ABO* gene was cloned in 1990 following purification of A transferase; since then, over 200 different alleles have been described.¹⁷ There are only four amino acid differences between A and B transferases in the catalytic domain, two of which (Leu-266Met and Gly268Ala) are primarily responsible for the substrate specificity. The group O phenotype results from mutations in *ABO* that cause a loss of glycosyltransferase activity. The most common group O allele (*ABO***O1*) results from a single nucleotide deletion near the 5' end of the gene that causes a frameshift and early termination with no active enzyme production. The rare B(A) and cis-AB phenotypes have both A and B enzyme activity from a single allele caused by variant glycosyltransferases that have a combination of A-specific and B-specific residues.

The fucosyltransferases required for H synthesis are encoded by two closely linked genes on chromosome 19, *FUT1* (or H) and *FUT2* (or *Se* for secretor), which have different substrate specificity and expression in tissues. Homozygosity for defective *FUT2* alleles is responsible for the common nonsecretor phenotype in which A, B, and/or H antigen are not present in secretions. Individuals homozygous for null alleles at both the *FUT1* and *FUT2* loci have the Bombay phenotype (see earlier section).

ABO and Transplantation As tissue antigens, ABO antigens are important in solid organ transplantation. Recipient antibodies will react with antigens on the transplanted organ and complement activation at the surface of endothelial cells can result in rapid destruction and hyperacute rejection. However, successful transplantation across ABO barriers is possible, particularly with blood group A_2 to O and with current immunosuppressive and pretreatment regimens including removal of ABO antibodies.¹⁸ Allogeneic hematopoietic stem cell transplantations are routinely performed regardless of ABO compatibility, but occasionally initial hemolysis or pure red cell anemia because of persisting anti-A or anti-B titers in the recipient can result.

Antibodies Anti-A and anti-B are found in the sera of individuals who lack the corresponding antigens. They are produced in response to environmental stimulants, such as bacteria. These antibodies are

produced after birth, reaching a peak at 5–10 years of age, and declining with increasing age. The antibodies are mostly IgM and can activate complement, which in conjunction with the high density of ABO antigen sites on RBCs, are responsible for the severe, life-threatening transfusion reactions that may result following ABO-incompatible transfusions. In contrast, HDFN caused by ABO antibodies is usually mild because (1) placental transfer is limited to the fraction of IgG anti-A and anti-B found in maternal serum, (2) ABH antigens are not fully developed on fetal RBCs because of a lack of fully branched carbohydrate chains, and (3) tissue ABH antigens provide additional targets for the antibodies.

Platelets have intrinsic A, B, and H antigens; thus ABO incompatibility can decrease the posttransfusion platelet increment, but this is often not of clinical significance.¹⁹ However, platelets from donors with an A_2 phenotype lack both A and H antigens. Approximately 20% of group A platelets would be from A_2 donors and would be appropriate for “universal” use. Platelets from A_2 donors may also be a superior product for patients undergoing A/O major mismatch allogeneic progenitor cell transplantation.²⁰

Potent anti-H (along with anti-A and anti-B) found in O_h (Bombay) individuals will destroy transfused RBCs of any ABO group, so these individuals must be transfused only with H– RBCs. In contrast, anti-H identified in individuals with low expression of H antigen, notably A_1B and A_1 , is usually IgM, reacts only at lower temperatures, and is thus clinically insignificant.

Other Carbohydrate Blood Group Systems

As for all glycoconjugate structures, sequential enzymatic action is required to build other carbohydrate antigenic epitopes, and the genetic background of all these involves different glycosyltransferase loci.

The null p phenotype, P_2^k and P_1^k , are of clinical interest because of potent naturally occurring antibodies that are present in plasma of individuals whose RBCs lack the glycolipid-based antigens $P1/P/P^k$, $P1/P/PX_2$, or P/PX_2 , respectively. In analogy with the ABO blood group system, antibodies of IgM and IgG class (anti- $PP1P^k$, anti- $P1PPX_2$, or anti- PPX_2) are made against the missing antigens. Although the incidence of the null phenotypes is only 5–10 per million, they have attracted considerable interest because of their relationship to disease and as receptors for pathogens. Women with p and P^k phenotypes suffer a high incidence of spontaneous abortion, a phenomenon most likely caused by destruction of the placenta by anti-P. In addition, anti-P and anti- P^k cause hemolytic transfusion reactions if antigen-positive RBCs are transfused. Transient autoanti-P, produced following a viral infection, causes paroxysmal cold hemoglobinuria and lysis of autologous P-positive RBC. P antigen (also known as *globoside*) is the cellular receptor for the parvo-B19 virus that causes erythema infectiosum (fifth disease) in children, sometimes complicated by severe aplastic anemia because of lysis of early erythroid precursors. P-fimbriated *Escherichia coli* expresses both P-binding and P^k -binding molecules at the tips of their pili, a finding with implications for uropathogenicity. Individuals lacking P, or P^k and P, appear to be naturally resistant to these bacterial and viral infections. In contrast to anti-P and anti- P^k , it should be noted that anti-P1 is a cold-reactive agglutinin that seldom has clinical importance. The clinical importance of anti- PX_2 made by P^k individuals is unclear.

Lewis antigens are fucosylated glycolipids that are synthesized by nonerythroid cells, circulate in plasma, and are passively adsorbed onto RBC. Antibodies to Lewis can be made by individuals with the Le(a–b–) phenotype. These antibodies are of IgM class and seldom cause any clinical problems. Lewis antibodies are commonly found in pregnant women.

The i and I antigens are nonterminal epitopes on linear and branched carbohydrate structures, respectively, carrying ABH antigens at their terminal ends. During the first years of life, linear chains are modified into branched chains, resulting in the appearance of I antigens. The i phenotype is very rare among adults, but it is the

normal state on RBCs from fetuses and infants. The gene encoding the I-branching β -1,6-*N*-acetylglucosaminyltransferase (*GCNT2*) has three alternative forms of exon 1 with common exons 2 and 3. Mutations in exon 2 or exon 3 silence *GCNT2* and give rise to the form of the *i* phenotype that is associated with cataracts in Asians. Mutations in exon 1C silence the gene in erythrocytes (but not in other tissues) and lead to the *i* phenotype without cataracts.

Alloanti-I made by a person with the rare *i* adult phenotype can be clinically significant and cause destruction of transfused I-positive RBCs. However, the sera of all I-positive individuals contain autoanti-I that is clinically benign and reactive only at or below room temperature. In contrast, cold hemagglutinin disease is characterized by a high titer of complement-fixing monoclonal anti-I, which causes in vivo hemolysis and hemolytic anemia. The titer and thermal range of autoanti-I is often increased following infection with *Mycoplasma pneumoniae*. If transfusion cannot be avoided, donor RBCs should be transfused through a blood warmer.

The FORS1 blood group antigen is a rare low prevalence antigen that is A-like in that it is defined by a terminal *N*-acetylgalactosamine and was first recognized as a weak A subgroup. The antigen has been defined as Forssman antigen, commonly found on the RBCs of nonprimate mammals, and arises from a gain-of-function mutation in the *GBGT1* pseudogene. The clinical relevance of anti-FORS1 found naturally occurring in the plasma of most individuals is not known.

Protein Blood Groups

Rhe, Rhe-associated glycoprotein, and LW Blood Group Systems

The Rh system is second only to the ABO system in importance in transfusion medicine. Rh antigens, especially D, are highly immunogenic; thus in most countries, blood for transfusion is tested and labeled with the D antigen type (Rh-positive or Rh-negative) and D-recipients are transfused with D-RBC products.

Three systems for naming Rh antigens have been used. Two are shown in Table 110.5, which indicates the incidence of the common Rh haplotypes present in different ethnic groups. The Fisher-Race nomenclature was based on the premise that there were three closely linked genes (D, C/c, and E/e), whereas the Wiener nomenclature (Rh-Hr) was based on the belief that a single gene encoded multiple factors (antigens). Although it is now well established that two genes, *RHD* and *RHCE*, encode the Rh proteins, the Fisher-Race (D, C/c, and E/e) terminology is often preferred for written communication; for spoken communication, a modified version of the Wiener nomenclature is preferred. Uppercase *R* indicates that D antigen is present and use of a lowercase *r* (or “little r”) indicates that it is absent. The

C or c and E or e antigens carried with D are represented by subscripts: 1 for Ce (R_1), 2 for cE (R_2), 0 for ce (R_0), and Z for CE (R_z). The presence of these antigens without D is represented by a superscript: prime for Ce (r'), double-prime for cE (r''), and γ for CE (r^γ). This terminology allows one to convey the common Rh antigens (the phenotype) with a single term. The third system of numeric designations is not widely used in the laboratory, with a few exceptions (Rh17, Rh32, Rh33).

Genes, Proteins, Antigens, and Phenotypes The Rh proteins are designated RhD (encoded by *RHD*), which carries the D antigen, and RhCE (encoded by *RHCE*), which carries the CE antigens (either ce, cE, Ce, or CE). RhD differs from the various forms of RhCE by 32–35 amino acids. RhD and RhCE are not glycosylated but form a complex in the RBC membrane with RhAG (Rh-associated glycoprotein). Other proteins present in the Rh-complex are CD47 (an integrin-associated protein), LW, and glycophorin B. The Rh-complex also associates with band 3 (the anion exchanger) as a macrocomplex in the membrane.

The D-negative (Rh-negative) phenotype is prevalent in whites (15%–17%), less common in African blacks (3%–5%), and rare in Asians (<0.1%). The absence of D in Europeans is primarily caused by a deletion of the *RHD* gene. African blacks and rare D-negative whites and Asians carry a *RHD* gene that is silenced by a variety of molecular events.³

RBCs with weak D have D antigen but at lower levels than normal because of one or more amino acid changes that are often predicted to be in the intracellular or transmembrane regions of RhD. The RBCs do not lack, or have altered, epitopes of D. Many individuals with a serologic weak D phenotype have weak D types 1, 2, and 3 by *RHD* genotyping, and individuals with these genotypes can safely receive D-positive blood and do not make clinically significant anti-D.^{21,22}

Partial D antigens (previously called *D categories* or *D mosaics*) are caused either by point mutations in *RHD* that encode amino acid changes that alter D epitopes, or by replacement of *RHD* nucleotides or exons by the equivalent part of *RHCE* that result in loss of D epitopes. RBCs with a partial D antigen may have strong or weak reactivity with anti-D. Because patients with partial D antigens can make anti-D directed to the D epitopes that are altered or absent, they ideally should receive D-negative blood and women of childbearing potential are candidates for Rh immune globulin. In practice, many type as D-positive and are recognized only after they make anti-D. However, in the United States monoclonal D typing reagents licensed by the Food and Drugs Administration for patient testing classify partial DVI phenotypes as D-negative in direct testing, and as D-positive by IAT. *RHD* genotyping is very useful to distinguish weak D phenotypes from partial D to guide selection of blood for transfusion and prevent D alloimmunization and to avoid unnecessary Rh immune globulin injection (see box on **Weak or Variable D Typing**).

TABLE 110.5 Prevalence of the Principal Rhesus Haplotypes

Fisher-Race Haplotype	Modified Weiner Haplotype	Incidence (%)		
		White	African Black	Asian
Rh-Positive				
DCe	R ₁	42	17	70
DcE	R ₂	14	11	21
Dce	R ₀	4	44	3
DCE	R _z	<0.01	<0.01	1
Rh-Negative				
ce	r	37	26	3
Ce	r'	2	2	2
cE	r''	1	<0.01	<0.01
CE	r ^y	<0.01	<0.01	<0.01

Weak or Variable D-Typing

Clinically significant D-sensitization potentially results in a pregnancy with a fetus at risk for hemolytic disease of the fetus and newborn and hemolytic transfusion reactions if transfused with D-positive red blood cells (RBCs). Individuals with RBCs that express a partial D antigen are at risk for D-sensitization, whereas those with weak D antigen are usually not at risk. These cannot be distinguished by serologic reactivity, because either may present as weak or moderately positive or give variable results with anti-D reagents. Particularly in the prenatal setting, *RHD* genotyping should be done to distinguish weak D from partial D. Women with weak D expression, particularly weak D types 1, 2, and 3, are not at risk for clinically significant D-sensitization and therefore are not candidates for RhIG prophylaxis. In contrast, individuals with partial D, lack D epitopes and have produced clinically significant anti-D and should receive RhIG prophylaxis. *RHD* genotyping avoids unnecessary treatment with RhIG and excess use of Rh-negative blood in patients with weak D antigen.

Several phenotypes, including D[−], Dc[−], and DC^w−, have an enhanced expression of D antigen and no, or variant, CE antigens. They are caused by replacement of portions of *RHCE* by *RHD*. The RhD sequences in RhCE, along with a normal RhD, explain the enhanced D and account for the lack, or reduced expression, of CE antigens. Immunized individuals with these CE-depleted phenotypes can make antibodies to high-prevalence Rh antigens.

C and c antigens differ by four amino acids, but only residue Ser103Pro is predicted to be extracellular. E and e differ by one amino acid, Pro226Ala. The RhD and various combinations of RhCE proteins (ce, Ce, cE, and CE) are typical for the majority of white transfusion recipients. However, Rh proteins in other ethnic groups often carry additional polymorphisms, particularly in individuals of African descent, and this fact often complicates transfusion in patients with sickle cell disease. For example, the RBCs of more than 30% of blacks are VS+ because of a Leu245Val substitution in Rhce, and expression of this antigen is associated with variant expression of e antigen. Many other amino acid changes in Rhce, as well as in RhD, are associated with production of Rh antibodies in patients with sickle cell disease. RH genotyping by DNA methods allows enhanced Rh antigen matching of patients and donors and is particularly important in patients who present with Rh antibodies reacting with all, or the majority, of cells tested.

The Rh_{null} phenotype is very rare and occurs on two genetic backgrounds: the “regulator” type, caused by mutations in *RHAG*, which encodes an Rh-associated glycoprotein, and the “amorph” type, caused by mutations in *RHCE* on a D[−] (deleted *RHD*) background. Rh_{null} RBCs are stomatocytic, fragile, and associated with anemia. *RHAG* is involved in maintenance of cation balance in RBCs.¹³

Antibodies Most Rh antibodies are IgG and do not activate complement. As a result, primarily extravascular hemolysis, rather than intravascular hemolysis, occurs in transfusion reactions involving Rh antibodies. The antibodies are almost always caused by RBC immunization from pregnancy or transfusion and usually persist for years. Anti-D can cause severe hemolytic transfusion reactions and HDFN, but the incidence of anti-D has decreased with the prophylactic use of Rh immune globulin. Most Rh antibodies should be considered as having the potential to be clinically significant for HDFN and hemolytic transfusion reactions. If serum antibody levels fall below detectable levels, subsequent exposure to the antigen characteristically produces a rapid secondary immune response. Autoantibodies in the sera of patients with warm autoimmune hemolytic anemia, as well as in some cases of drug-induced autoimmune hemolytic anemia, appear to demonstrate relative specificity to high-prevalence Rh antigens, although specificity for other members of the Rh complex have not been ruled out (see box on [Transfusion Management of Patients With Warm Autoimmune Hemolytic Anemia](#)).

RHAG Blood Group System

RhAG glycoprotein, encoded by *RHAG*, is highly similar to the RhD and RhCE proteins. It carries four blood group antigens: two of high prevalence (RHAG1 and 3) and two of low prevalence (RHAG 2 and 4). Antibodies to RHAG4 cause HDFN. RhAG is important for erythrocyte ion balance in RBCs and is required for the expression of RhD and RhCE proteins forming the core of the Rh-complex.

LW Blood Group System

Rh and LW are independent blood group systems but have a phenotypic relationship. In adults, D-positive RBCs have a stronger expression of LW antigen than D-negative RBCs, and anti-LW can be confused with anti-D. Transient loss of LW antigens from RBCs has been described in pregnancy and in patients with diseases, particularly Hodgkin disease, lymphoma, leukemia, sarcoma, and other forms of malignancy. Loss of LW antigens is usually associated with the production of antibodies that appear to be alloanti-LW.

Kell and Kx Systems

The Kell glycoprotein is highly folded through multiple intrachain disulfide bonds and is covalently linked to the XK protein in the RBC

Transfusion Management of Patients With Warm Autoimmune Hemolytic Anemia

Patients with warm autoimmune hemolytic anemia may present with jaundice, fatigue, and anemia, or they may show no overt clinical manifestations. The antibody screen and antibody identification panel will show all red blood cells (RBCs) positive (panagglutinin) with anti-IgG in the indirect antiglobulin test. The autocontrol (patient's own plasma and RBCs) will also be positive.

History: A transfusion history should be obtained to differentiate these results from a hemolytic transfusion reaction or hemolysis because of an alloantibody.

DAT: A direct antiglobulin test should be performed with anti-IgG and anti-C3. In clinically significant hemolysis, the DAT is usually strongly positive.

Eluate: If patient has been recently transfused (3–4 months), an eluate should be prepared from the patient cells to remove the antibody(ies); the eluate should be tested to determine specificity. The eluate is usually reactive with all cells when tested by the IAT with anti-IgG.

Phenotype or genotype: Type the patient's RBCs for minor blood group antigens (Cc, Ee, K, Jka/b, Fya/b, Ss) if the patient has not been recently transfused. When possible, IgM typing reagents are used because the patient's own antibody-coated RBCs may result in false-positive typing. Some laboratories are able to remove the IgG from the RBCs and perform a phenotype, but alternatively, genotyping for minor blood group antigens including Do^{a/b} antigens (there is no serologic reagent) can be performed.

Adsorption: Adsorb the serum autoantibody onto the patient's own RBCs to test for underlying alloantibody if the patient has not been recently transfused (3–4 months). If the patient has been recently transfused or if the low hematocrit results in insufficient autologous RBCs, perform alloadsorption with well-characterized RBCs (usually three with known antigen profiles). Test the adsorbed serum for underlying alloantibodies.

Crossmatch: Perform with neat and with adsorbed plasma.

Crossmatch performed with neat plasma will usually be incompatible.

Communication: Inform ordering physician of reactivity and of delay in receiving crossmatched RBCs. Provide emergency-release RBCs if patient's clinical situation warrants. Inform the physician that the patient may hemolyze transfused RBCs similar to hemolysis of his or her own RBCs.

Transfusion: Consider providing RBC units negative for minor antigens that the patient also lacks. Consider matching for Cc, Ee, K, Jka/b, Fya/b, Ss (and Doa/b if possible). This potentially enables RBC units to be available before completion of the antibody identification testing. Transfusion with antigen-matched units potentially allows continued transfusion without need for autoadsorption or alloadsorption unless signs and symptoms of RBC destruction occur or there is a change in reactivity in antibody screening or the DAT.

membrane. Kell is highly polymorphic because of single amino acid substitutions in the glycoprotein that account for 35 of 36 antigens described to date. The K antigen is remarkably immunogenic even though it differs from wild-type (k, small k) by only one amino acid, and it appears that loss of an N-glycan exposes the peptide, thereby rendering it immunogenic.

Inherited weak expression of Kell antigens, termed *K_{mod}* phenotype, occurs with amino acid changes in the protein, with Kp^a in cis, and in the McLeod phenotype.²³ Transient depression of Kell system antigens may also occur in autoimmune hemolytic anemia, in microbial infections, and was reported in two cases of idiopathic thrombocytopenia purpura. The lack of Kell antigens (the K₀ or K_{null} phenotype) is caused by multiple different gene defects.

HDFN caused by anti-K can result in severe neonatal anemia, and unlike anti-D, maternal antibody titers and amniotic bilirubin levels are not good predictors of the severity of the disease. Kell antigens are expressed very early during erythropoiesis, and anti-K has been shown to suppress erythropoiesis in vitro. This may explain the low level of bilirubin observed in cases of neonatal anemia; thus Doppler

screening of the fetal middle cerebral artery peak systolic velocity is used to monitor anemia. Other unusual consequences of Kell antibodies include risk for fetal thrombocytopenia and neutropenia.

McLeod Syndrome This uncommon syndrome is associated with the loss of expression of Kx protein caused by mutations and deletions in the *XK* gene.²³ The syndrome, which is X-linked and manifests only in males, may be underdiagnosed. The physical characteristics, which often develop only after the fourth decade of life, include muscular and neurologic problems. A minority of patients with chronic granulomatous disease also have the McLeod phenotype as a result of X-chromosome deletions encompassing both genes. Carrier females have two populations of RBCs (one of the McLeod phenotype and one of normal phenotype).

Duffy Blood Group System

The Duffy (*FY*), previously known as *DARC* now designated *ACKR1* for atypical chemokine receptor, glycoprotein is a promiscuous chemokine receptor found on RBCs and on endothelial cells in the kidney and brain that binds a family of chemotactic and proinflammatory peptides from the CXC (IL-8, MGSA) and the CC (RANTES, MCP-1, MIP-1) classes. The physiologic role of *FY* is clear, but on RBCs the receptor may allow RBCs to act as scavengers for excess chemokines. *FY* is also a receptor to which *Plasmodium vivax* merozoites can bind to invade RBC and cause malaria.

Antigens The Fy^a and Fy^b antigens differ by a single amino acid (Gly42Asp) located on the N-terminal extracellular domain of the *FY* glycoprotein and is responsible for the common $Fy(a+b-)$, $Fy(a-b+)$, and $Fy(a+b+)$ phenotypes. The null $Fy(a-b-)$ phenotype is rare in most ethnic groups, but it is common in people of African and Arabian origins. The null phenotype most often results from a mutation in the promoter region of *FY* that disrupts a binding site for the erythroid transcription factor GATA-1 and results in loss of *FY* on RBCs.²⁴ Because the erythroid promoter controls expression only in erythroid cells, *FY* expression in other tissues is unaffected. All individuals of African origin with a mutated GATA box to date have been shown to carry *FYB* and therefore Fy^b is expressed on nonerythroid tissues. This explains why $Fy(a-b-)$ individuals make anti- Fy^a but not anti- Fy^b . $Fy(a-b-)$ caused by a mutated GATA box on an *FYA* allele has been found in Papua New Guinea, another malaria-endemic region.

Antibodies *FY* antigens are much less immunogenic than Rh and K. Anti- Fy^b is less common than anti- Fy^a , and both antibodies can cause delayed hemolytic transfusion reaction (DHTR) and rarely HDFN. Anti- $Fy3$ is made by $Fy(a-b-)$ individuals who are exceptions to above, and it is speculated they may lack *FY* protein on all cells.

Kidd Blood Group System

The Kidd (*JK*) blood group protein was implicated in urea transport when RBCs lacking the antigens were shown to resist lysis in 2 M urea. The protein is present in RBCs and kidney medulla and is a constitutive urea transporter, but failure to express Kidd does not result in an overt clinical syndrome; the only observed manifestation is a reduced capacity to concentrate urine.²⁵

Antigens The Jk^a and Jk^b antigens differ by a single amino acid (Asp280Asn) and are responsible for the common $Jk(a+b-)$, $Jk(a-b+)$, and $Jk(a+b+)$ phenotypes. The $Jk(a-b-)$ or Jk_{null} phenotype is uncommon and occurs with greater incidence in Polynesians, Asians, and Finns. Many different molecular changes in both *JKA* and *JKB* alleles have been shown to abolish expression of the Kidd blood group protein. Weakly expressed variants of Jk^a and Jk^b antigens are also not uncommon.

Antibodies *JK* antibodies are responsible for at least one-third of cases of DHTR. The antibodies often drop to undetectable levels or react only with cells that are homozygous for the antigen and escape

detection in the sensitized patient's serum before transfusion. *JK* antibodies only rarely cause HDFN, and if they do, it is typically not severe. Anti- $Jk3$, sometimes referred to as anti- Jk^{ab} , is produced by $Jk(a-b-)$ individuals, and rare donors must be located for transfusion.

MNS System

M and *N* antigens are carried on alternative forms of glycophorin A (GPA), whereas *S* and *s* antigens are carried on alternative forms of glycophorin B (GPB). *M/N* and *S/s* are homologous proteins encoded by adjacent genes and consequently show linkage disequilibrium in inheritance of the antigens. The MNS system is highly polymorphic and most of the 49 antigens are the result of amino acid substitutions or rearrangements between *GYP A* and *GYP B*. Persons who are *S-s-* are usually of African origin. They either also lack the high-prevalence *U* antigen arising from a deletion of *GYP B* or express variant weak *U* antigen as a result of an altered form of *GYP B*.

Antibodies Anti-*S*, anti-*s*, and anti-*U* are usually IgG and can be clinically significant antibodies. Anti-*M* and anti-*N* can be naturally occurring, may be reactive at room temperature or below, and are often clinically insignificant.

Other Protein Antigens

Antibodies to antigens in the following systems are less common than those described earlier in this chapter, and information regarding their general clinical significance is summarized in Table 110.3.

Lutheran System

Lutheran (*Lu*), along with Secretor, provided the first example of autosomal linkage in humans, the first example of autosomal crossing over, and the first indication that crossing over in humans is more common in females than in males. The *Lu* system consists of four antithetical pairs of antigens and 16 independent high-prevalence antigens. The $Lu(a-b-)$ phenotype is rare, but in the majority of individuals, it is caused by heterozygosity for silencing mutations in the *EKLF/KLF1* gene.²⁶ *KLF1* is a transcription factor that regulates many erythroid-specific genes, and the expression of antigens in other blood group systems (e.g., *Kn*, *In*) is also affected. In one family, heterozygosity for a mutation in the *GATA1* gene was shown to be responsible for the $Lu(a-b-)$ phenotype.

Antibodies Antibodies in this system are rarely encountered because the antigens are not highly immunogenic. They are usually IgG and give characteristic agglutinates surrounded by unagglutinated RBCs. They can cause mild transfusion reactions, but do not typically cause HDFN. Anti-*Lu3* is found in the serum of immunized people of the rare recessive $Lu(a-b-)$ phenotype, and the antibody is usually IgG and may cause DHTR or HDFN. Blood with the $Lu(a-b-)$ phenotype should be used for transfusion of patients with these antibodies.

Diego System

The Diego (*Di*) blood group antigens are on Band 3 anion transport protein (AE1), one of the most abundant erythrocyte glycoproteins. AE1 forms complexes with many other proteins in the cell membrane and is important for RBC stability. The Diego blood group system contains three antithetical pairs of antigens and 16 low-prevalence antigens. Di^b antigen has a prevalence of greater than 99.9%, but Di^a is rare in most populations. Exceptions include South American Indians (Di^a occurs in 54% of this population) and North American Indians, approximately 12% of whom are $Di(a+)$.

Antibodies *Di* antibodies are usually IgG and do not bind complement. These antibodies have caused DHTR (usually delayed) and HDFN. Autoantibodies to band 3 are common in patients with warm autoimmune hemolytic anemia.

Yt Blood Group System

The Yt system was named in 1956 when an antibody was found in the serum of patient whose last name was Cartwright. Yt^a occurs with a prevalence of more than 99% in random blood samples, and Yt^b is found with a prevalence of approximately 8%, except in Israelis, in whom it has a prevalence of 20% or higher.

Antibodies Yt antibodies usually are IgG and do not bind complement. These antibodies have caused DHTR but not HDFN.

Scianna Blood Group System

The Scianna (Sc) antigens are expressed by the RBC adhesion protein, erythrocyte membrane-associated protein. Sc1 is a high-prevalence antigen (prevalence ≈99.9%), and Sc2 is a low-prevalence antigen (1%); there are five other Scianna antigens.

Antibodies Sc antibodies are usually IgG, and some bind complement. These antibodies have not caused DHTR, and although they have caused a positive DAT in cord RBCs, they have not caused HDFN. Several examples of autoanti-Sc1 have been reported, some reactive in tests using patient serum but not plasma. Autoanti-Sc3-like antibodies have been described in one patient with lymphoma and in one patient with Hodgkin disease whose RBCs had suppressed Sc antigens.²

Dombrock Blood Group System

Dombrock (Do) antigens are carried on a GPI-linked glycoprotein that is a member of the mono-ADP-ribosyltransferase family, although Do has no demonstrable enzyme activity on the RBC. The Do blood group system consists of two antithetical antigens, Do^a and Do^b, and eight other antigens of high prevalence. The null phenotype is Gy(a-).

Antibodies Do^a and Do^b antigens are poor immunogens, and anti-Do^a and anti-Do^b are rarely found as single specificities. Antibodies in the Do system are usually IgG and do not bind complement. These antibodies have caused DHTR and a positive DAT but no clinical HDFN.

Colton Blood Group System

The Colton (Co) antigens are carried on aquaporin-1 (AQP-1), the first water channel protein characterized in mammals, and are also found in the kidney. The function of AQP-1 in RBCs may be to rehydrate rapidly after shrinking in the hypertonic environment of the renal medulla. Co^a has a prevalence of 99.9%, its antithetical antigen Co^b has a prevalence of 10%, and Co3 and Co4 are present on all RBCs except those of the very rare Co(a-b-) null phenotype. Co4 is a high prevalence antigen, the absence of which has been seen in three families only. Apparently healthy probands with the Co(a-b-) phenotype and AQP-1 deficiency have RBCs with an 80% reduction in the ability to transport water. The residual water transport in these RBCs may be through another member of the water channel protein family, AQP-3, which transports water, glycerol, and urea, and carries the blood group antigen GIL.

Antibodies Antibodies in the Co system are usually IgG and some bind complement. The antibodies have caused DHTR and HDFN.

Gerbich Blood Group System

The Gerbich system antigens are carried on glycophorin C (GPC) and glycophorin D (GPD). There are six high-prevalence antigens and five low-prevalence antigens. The two glycoproteins are products of the *GYPC* gene. The gene consists of four exons, and the smaller GPD is generated by the use of an alternative translation initiation site.

Antibodies The antibodies may be immune or naturally occurring. Most are IgG and some of these bind complement. Some antibodies may be IgM. Although some antibodies have caused DHTR, others

have been benign. Anti-Ge3 has caused HDFN, and similar to Kell antibodies, the disease is associated with severe anemia. Clinical HDFN associated with anti-Ge2 has not been reported, but the antibodies have been eluted from DAT-positive cord RBCs.

Cromer Blood Group System

The Cromer (Cr) antigens are carried on decay-accelerating factor (DAF, CD55), a complement control protein attached to the RBC membrane through GPI-linkage. Cr is a system of two sets of antithetical antigens (Tc^a/Tc^b/Tc^c and WES^a/WES^b), 16 high-prevalence antigens, and three low-prevalence antigens. The Cr(a-) phenotype is the least rare of the negative phenotypes, and with the exception of one Spanish-American woman, all people with Cr(a-) RBCs are black. Most of the other phenotypes are exceedingly rare.

Antibodies Antibodies in the Cr system are usually IgG and do not bind complement. The antibodies have caused mild DHTR but not HDFN.

Knops Blood Group System

The Kn blood group antigens are carried on complement receptor 1 (CR1). Kn^a, Sl^a, and McC^a antigens are fairly common and have a similar prevalence (>90%) in different populations; however, Sl^a is present on RBCs of 98% of whites, but on only 60% of African Americans. Typing for Kn system antigens can be challenging because the low level of expression on the RBCs in some disease processes gives false-negative results. RBC CR1 is important in the processing of immune complexes, binding them for transport to the liver and spleen for removal from the circulation. The CR1 copy number per RBC (and thus antigen strength) is reduced in SLE, cold agglutinin disease, paroxysmal nocturnal hemoglobinuria (PNH), hemolytic anemia, insulin-dependent diabetes mellitus, acquired immunodeficiency syndrome, some malignant tumors, and any condition associated with increased clearance of immune complexes. CR1 (the Sl^a antigen in particular) may act as a receptor for the malarial parasite *Plasmodium falciparum*; thus the Sl(a-) phenotype may provide selective advantage.

Antibodies Antibodies in the Kn system are usually IgG, and they do not bind complement. The antibodies do not cause DHTR or HDFN, and once identified, they can usually be ignored for clinical purposes. Identification may be complicated by the fluctuation of antigen expression on RBCs. In the Kn system, anti-Kn^a is the most common antibody in whites, and anti-Sl^a is the most common in African Americans.

Indian Blood Group System

The antigens of the In system are carried on CD44. CD44 has a diverse range of biologic functions involving cell-cell and cell-matrix interactions in cells other than RBCs. It is an adhesion molecule in lymphocytes, monocytes, and some tumor cells. CD44 binds to hyaluronate and other components of the extracellular matrix and is also involved in immune stimulation, as well as signaling between cells. In^b is a common antigen, and In^a is rare in white persons but has a prevalence of 4% in Indians, 10% in Iranians, and nearly 12% in Arabs.

Antibodies Antibodies in the Indian system are usually IgG and do not bind complement. Some antibodies may directly agglutinate RBCs, but the reactivity is greatly enhanced by the IAT. These antibodies have caused decreased RBC survival and a positive DAT in the neonate but not HDFN. A severe DHTR caused by anti-In^b has been reported.

Chido/Rodgers Blood Group System

Although the Ch and Rg antigens are readily detected on RBCs, they are located on the fourth component of complement (C4), which becomes bound to RBCs from the plasma. In complement activation through the classic pathway, C4 becomes bound to the RBC membrane and undergoes further cleavage; ultimately, a tryptic fragment,

C4d, remains on the RBC. This C4d glycoprotein carries the Ch/Rg blood group antigens. The antigens are stable in stored serum or plasma, and the phenotypes of this system are most accurately defined in plasma by agglutination inhibition tests.

Antibodies Antibodies in the Ch/Rg system are usually IgG, do not activate complement, and are considered benign. Considerable variation may be common in the reaction strength obtained with different RBC samples. Although these antibodies do not generally cause DHTR, they have caused anaphylactic reactions. The antibodies have not caused HDFN.

Jr Blood Group System

The Jr^a antigen is carried on ABCG2, a member of the ATP-binding cassette family of multipass membrane proteins. The protein is broadly distributed and is a high-affinity urate transporter. It is also involved in porphyrin transport and in multidrug resistance in some cancers. The Jr(a⁻) phenotype is the null phenotype and Jr(a⁻) individuals lack the protein. Many different mutations have been identified for this phenotype although it is more common among the Japanese (where it is associated with gout) and the Roma population in Europe.

Antibodies Anti-Jr^a are usually IgG, do not activate complement and do not generally cause DHTR or HDFN, however two cases of severe HDFN have been reported.

Lan Blood Group System

Lan too, is carried by an ATP-binding cassette protein, in this case ABCB6, a protein that is widely expressed. It is highly expressed in fetal liver and upregulated during erythropoiesis. ABCB6 is important in heme synthesis and transports heme and porphyrins into the mitochondria. The Lan⁻ phenotype is the null phenotype and it arises from many different molecular backgrounds but is not associated with a disease phenotype. Lan antigen expression is variable on erythrocytes.

Antibodies Anti-Lan are generally IgG and do not bind complement but have caused mild to severe DHTR and mild HDFN.

Vel Blood Group System

The Vel blood group antigen is dependent on the SMIM1 protein for expression and a 17-bp mutation in the *SMIM1* gene accounts for the vast majority of Vel⁻ individuals and absence of SMIM1. The protein is widely expressed but more highly expressed on erythrocytes, salivary glands, and testes, although its function is unknown. Vel antigen expression is variable on RBCs.

Antibodies Anti-Vel are often a mixture of IgM and IgG and readily bind complement. While HDFN caused by anti-Vel is rare, the antibodies can cause severe hemolytic transfusion reactions.

CD59 Blood Group System

An antibody in the plasma of a young patient with CD59 deficiency qualified CD59 as a blood group antigen. CD59 is a GPI-linked protein on the erythrocyte and is important in complement regulation. It inhibits the formation of the membrane attack complex (MAC) by specifically binding to C8 and C9. Like other GPI-linked proteins, it is absent from the erythrocytes of PNH patients and its absence is the underlying cause of hemolysis.

Antibodies Only one example of the antibody has been reported. It was clinically benign although a positive DAT was observed following one of the transfusions.

Augustine Blood Group System

The blood group system Augustine (symbol AUG; number 036) was recently assigned to the equilibrative nucleoside transporter 1 protein (SLC29A1; ENT1) after it was identified as the carrier of the At^a antigen. The At(a⁻) phenotype in individuals of African origin is

defined by an amino acid polymorphism on SLC29A1 (p.Glu391Lys), while the At(a⁻) members of a rare family affected by bone malformation lacked the protein due to an inactivating mutation in the *SLC29A1* gene: c.589+1G>C. The antigen defined by the antibody produced by the null phenotype was named AUG1, and the antigen defined by the amino acid Glu391 (At^a) was named AUG2.²⁷

Antibodies. Anti-At^a are mostly IgG although may contain IgM. While HDFN due to anti-At^a is rare, the antibodies can cause severe hemolytic transfusion reactions.

PRINCIPLES OF RED BLOOD CELL TRANSFUSION

Yen-Michael S. Hsu, Paul M. Ness, and Melissa M. Cushing

The clinical practice of transfusion medicine has evolved substantially since the discovery of the ABO system around 1900. Two technologic advances set the stage for clinical practice through blood component therapy. First, the introduction of a safe and effective anticoagulant-preserved solution (suggested by Loutit and Mollison) allowed for the preservation of blood products. Second, in the mid-1960s, the introduction of plastic blood bags by Walter and Murphy, combined with the ability to store blood for extended periods, created opportunities to use transfusions in varied clinical settings. With these discoveries, the era of modern component therapy began. In 2011, approximately 13.8 million units of whole blood/red blood cells (RBC) were transfused in the United States; whole blood transfusions accounted for only 0.15% of total transfusions. This chapter reviews appropriate RBC transfusion practice in a variety of clinical settings, the clinical implications of RBC storage, the pathogenesis of red cell alloimmunization, and existing and emerging alternatives to allogeneic RBC transfusions.

RED BLOOD CELL COMPONENTS

Modern transfusion medicine practice aims to provide the specific component of the blood required, rather than whole blood: red cells for oxygen-carrying capacity, plasma for coagulation proteins, and platelets for microvascular bleeding. The component therapy approach allows for optimal use of a limited community resource (Table 111.1). Today, the clinician wishing to increase the patient's oxygen-carrying capacity is more likely to use an RBC concentrate than whole blood, although there may still be situations in which whole blood, if available, is appropriate. For particular clinical applications, several modifications can be made to RBC products to render them leukocyte or plasma depleted. RBCs can also be frozen for long-term storage.

Whole Blood

A unit of whole blood is collected in citrate phosphate dextrose adenine (CPDA)-1 anticoagulant, giving it a shelf-life of 35 days and a volume of approximately 510 mL (450 mL of blood plus 63 mL of CPDA-1). Within 24 hours of collection, the granulocytes are dysfunctional, and several plasma coagulation factors including factors V and VIII have fallen. Although clinicians have been taught that whole blood stored at 4°C has no functional platelets, evolving studies have demonstrated *in vitro* that platelet quantities and function are maintained for 10–14 days after collection, leading to new interest in the use of whole blood for resuscitation.

Whole blood has the advantage of correcting simultaneous deficits in oxygen-carrying capacity and blood volume. Therefore, whole blood is useful in the management of trauma or in surgical cases involving extensive blood loss. In this setting, whole blood has two distinct advantages: (a) it provides colloid osmotic pressure and coagulation factors not supplied by crystalloid solutions and (b) it does not expose the recipient to RBCs and plasma from different donors.

The goal of using whole blood for all cases of concomitant RBC and volume deficit is difficult to achieve in practice. Most indications for whole blood transfusion are now well managed exclusively with

blood component therapy, but the use of fresh whole blood has persisted in military settings. In the civilian setting, the simultaneous need for volume and oxygen-carrying capacity can usually be met by combining red cells with crystalloid or colloid solutions. In massive transfusions, however, this clinical axiom is being questioned, and current approaches are designed to minimize crystalloid exposure. In some cases of trauma and cardiovascular surgery, platelet transfusion may be indicated to combat microvascular bleeding from dilutional thrombocytopenia or bypass-associated platelet dysfunction. The transfusion of platelets usually supplies the equivalent of several units of relatively fresh plasma so that there is often no reason for further donor exposure by the administration of thawed plasma.

There has been recent renewed interest in fresh whole blood for patients with severe coagulopathy and shock. Few prospective trials have compared fresh whole blood with component therapy. The potential advantages for fresh whole blood are a relative increase in hemoglobin (Hb) concentration, coagulation factors, and platelets compared with component therapy. In addition, fresh products avoid some of the negative effects of storage and processing. A Food and Drug Administration (FDA) approved platelet-sparing leukocyte reduction filter is available for fresh whole blood. However, the use of fresh whole blood is limited due to the lack of published randomized controlled studies on specific indications and the demonstration of significant clinical benefits. The methods to achieve adequate pathogen removal and the determination of optimal storage conditions for whole blood products are the subjects of active investigations.

Increasingly studies in trauma patients have demonstrated a benefit to the early use of increased ratios of plasma and platelets to RBCs, including the PROPPR study that found there was a significant reduction in the time to hemostasis and a reduction in death by exsanguination within 24 hours for patients receiving a 1:1:1 ratio of RBC:plasma:platelets versus a 2:1:1 ratio. Whole blood transfusion is also being looked at as an alternate approach to provide trauma patients with early plasma and platelets.

Red Blood Cells

RBCs (also referred to as *packed RBCs* or *RBC concentrates*) are obtained from anticoagulated whole blood after removal of most of the platelet-rich plasma for the production of frozen plasma or platelets, or both. At most blood centers, the RBCs are then mixed with 100 mL of an additive nutrient solution that extends the storage period to 42 days and results in flow properties similar to those of whole blood.

RBCs are the product of choice for the correction of an isolated defect in oxygen-carrying capacity, as in cases of chronic anemia. In addition, RBCs rather than whole blood are used for the emergent transfusion of patients of unknown ABO type. The use of concentrated group O RBCs without plasma containing anti-A and anti-B can minimize potential hemolysis of the recipient's red cells.

Leukocyte-Reduced Red Blood Cells

Leukocyte-reduced RBCs (LRRCs) can be prepared by a variety of methods, resulting in differing degrees of white blood cell (WBC)

TABLE 111.1 Red Blood Cell (RBC) Components: Characteristics and Indications

Component	Characteristics	Indications
Whole blood	High volume; good flow	Combined red cell/volume deficit (massive hemorrhage; exchange transfusion)
RBCs	Lower volume Higher hematocrit	Red cell deficit
Leukocyte-reduced RBCs	Good flow in AS-1	Prevention of febrile reactions Reduction of alloimmunization Reduction of immunomodulatory effects
Washed RBCs	Plasma depletion Must use within 24 hours	Prevention of severe allergic reactions Prevention of anaphylaxis in IgA deficiency
Frozen RBCs	Long-term storage Plasma and leukocyte depletion Must use within 24 hours of thawing	Rare donor unit storage Autologous storage for postponed surgery

Ig, Immunoglobulin.

removal. Currently, the most widely used method of leukoreduction is filtration that can be performed either in the laboratory or at the bedside. The various filters on the market result in greater than 99% leukocyte reduction while depleting less than 10% of the red cells. Blood bags with in-line filters allow prestorage leukoreduction.

The major indication for the use of LRRCs is the prevention of the febrile nonhemolytic transfusion reaction, the most common adverse effect of transfusion, particularly in multiply transfused patients or multiparous females. These reactions are believed to be mediated by antibodies directed against leukocyte antigens (human leukocyte antigen, HLA, or granulocyte-specific antigens). Depletion of leukocytes to less than 5×10^6 has been shown to prevent, or at least ameliorate, such reactions in most patients. Increasing evidence suggests that cytokines play a role in causing these reactions. Because cytokines may be released from leukocytes during storage, prestorage leukoreduction procedures are the preferred mode of leukoreduction.

A second important indication for LRRCs is the mitigation of alloimmunization to HLA antigens that can adversely affect post transfusion platelet increments and the search for HLA-compatible donors for stem cell and solid organ transplantations. This approach will be effective only if leukoreduced platelets are also used. According to current AABB standards, the total leukocyte number must be less than 5×10^6 when intended for this purpose. With the introduction of third-generation leukoreduction filters for both RBCs and platelets, this goal is achievable. A multicenter study known as TRAP showed that the use of leukoreduction filters for platelet products significantly decreased the rate of alloimmunization, but did not completely eliminate the problem.

A third indication for the use of LRRCs is to prevent transfusion-transmitted cytomegalovirus (CMV). CMV is found in low copy numbers outside of cells, and leukoreduced blood components are considered CMV safe. RBCs that are either leukoreduced or from CMV seronegative donors are associated with 1% to 1.5% CMV-transmission failure rates, and thus some institutions use the “belt and suspenders” approach of providing leukoreduced RBCs from a CMV seronegative in their vulnerable populations.

A final indication for the use of LRRCs is to prevent Transfusion Related Immunomodulation (TRIM), which is of particular concern in the postoperative period. A large metaanalysis previously demonstrated that patients who receive a blood transfusion are more likely to experience a postoperative infection than patients not transfused.

This effect has been found to be dose-dependent and is thought to be mediated by suppressing the patient's immune function. The mechanism of TRIM has yet to be defined, but multiple theories have been proposed. It has been suggested that immunologically active WBCs or soluble biologic response modifiers released from WBCs during storage down regulate the recipient's immune function. Alternative theories suggest that soluble mediators circulating in allogeneic plasma may have an immune modulatory effect. Universal leukoreduction has been found by some studies, but not by others, to mitigate the immunomodulatory effect of allogeneic transfusions.

Washed Red Blood Cells

RBCs are washed using isotonic saline solutions by either automated or manual techniques. Automated techniques are more efficient, but there is always some degree of RBC loss with each wash cycle. When the washing is performed in an open system, the resulting product must be transfused within 24 hours because of concerns over potential bacterial contamination.

The primary aim of washing is to remove plasma proteins, although some leukocytes and platelets are removed simultaneously. The major indication for washed RBCs is the prevention of severe allergic transfusion reactions, most likely mediated by recipient IgE antibodies against donor plasma proteins. Washing is recommended when reactions are severe and refractory to steroid and antihistamine administration. In IgA-deficient patients who have preformed antibody to IgA, the exposure to IgA-containing plasma can cause anaphylaxis. Therefore, high volume cell washes may be required to prepare cellular components for transfusion in IgA-deficient patients.

Irradiated Red Blood Cells

RBCs are irradiated with either gamma-ray or x-ray technology with a minimum dose of 25 Gy not exceeding 50 Gy. Red cells expire 28 days after irradiation or on the original expiration date, whichever is sooner. A method is used to ensure that irradiation has occurred with each batch. The primary aim of irradiation is to prevent the rare, but often fatal risk of transfusion-associated graft-versus-host disease (TA-GVHD) by the abrogation of the proliferative potential of donor T lymphocytes. GVHD can occur after the transfusion of immunologically competent donor lymphocytes, usually to an immuno-incompetent recipient. Ultraviolet light activated nucleic acid cross-linking techniques have also been shown to effectively inactivate T lymphocytes; however, currently, the FDA has not approved it as an acceptable alternative to gamma or x-ray irradiation to prevent TA-GVHD. Some patient populations with indications for irradiated products include neonates, patients with hematologic malignancies, stem cell transplant recipients, and patients with congenital immune deficiencies. There is still much debate among experts regarding which additional patient populations may be at risk for TA-GVHD. It has been suggested that a policy of universal blood component irradiation could prevent TA-GVHD in patients with currently unsuspected risks, including advanced age, unrecognized immune deficiencies in the recipient, or unsuspected donor-recipient immune similarities. Pathogen reduction is a term that refers to one of several methods to reduce the risk of blood-borne pathogens. If efficacious systems to apply pathogen reduction to red cell components by induction of DNA/RNA cross-linking become approved, another advantage would be the inactivation of white cells, which would eliminate the need for gamma irradiation to prevent TA-GVHD.

Frozen Red Blood Cells

RBCs can be frozen (with glycerol used as a cryoprotective agent) and stored in liquid nitrogen or mechanical freezers. The required

concentration of glycerol depends on the rate and the temperature of freezing. The freezing process destroys other blood constituents, except for a small percentage of immunocompetent lymphocytes. RBCs are prepared for transfusion by thawing and washing away the glycerol using a series of progressively less hypertonic crystalloid solutions, allowing glycerol to diffuse gradually from the cells to prevent hemolysis. The cells are resuspended in an isotonic saline solution containing glucose. The extensive washing removes approximately 99.9% of the plasma as well as cellular debris.

RBCs can be stored in the frozen state up to 10 years with good viability. After thawing and washing, storage is typically limited to 24 hours because of the open system. Frozen cells have been shown to maintain prefreezing adenosine triphosphate (ATP) and 2,3-diphosphoglycerate (DPG) levels. To maintain these factors at high levels, the standard is to freeze within 6 days of collection. When it is necessary to freeze older units, rejuvenation with a solution containing pyruvate, glucose, phosphate, and adenine has provided excellent results. The major indication for frozen RBCs is the stockpiling of rare donor units for patients who have developed alloantibodies. Some patients with rare phenotypes can make autologous donations that can be frozen for later use. Cells from autologous donors can be frozen if more units are required than can be collected in the 42-day liquid storage period or if surgery is postponed. Because of the high cost and cumbersome nature of freeze-thaw procedures, other uses of frozen RBCs are somewhat difficult to justify.

APPROPRIATE TRANSFUSION PRACTICE IN VARIOUS CLINICAL SETTINGS

The response to RBC transfusion varies from patient to patient. In the absence of increased red cell destruction or sequestration, one unit of RBCs can be expected to increase the Hb level by 1 g/dL or the hematocrit level by approximately 3%. This rise is usually not fully realized until approximately 24 hours after transfusion, when the plasma volume has had time to return to normal. On the basis of a half-life of approximately 57.7 days for donor red cells, Mollison and associates calculated that an average-sized adult requires 24 mL of RBCs per day to maintain a given hematocrit level, assuming no red cell production. Patients with red cell aplasia require approximately 2 units of RBCs every 2 weeks.

Several factors can adversely affect the survival of transfused red cells. Hemolysis, caused by either immune-mediated red cell damage or mechanical trauma, shortens the survival of transfused cells, much as it shortens the survival of the patient's own cells. Hypersplenism can lead to initial sequestration as well as increased destruction of red cells. Continued blood loss is another obvious cause of suboptimal response to transfusion. It should also be emphasized that transfusion suppresses erythropoiesis, so that the net result of transfusion may be less than expected if transfusions are administered on a chronic basis.

Chronic Anemia

As a rule, signs and symptoms attributable to anemia are unlikely to develop at a Hb level of greater than 7 or 8 g/dL. When the anemia is of gradual onset, the body's compensatory mechanisms for maintaining oxygen delivery to the tissues come into play. Both cardiac output and intracellular 2,3-DPG increase, and thus, oxygen unloads at a lower oxygen saturation of Hb. When chronic anemia is due to red cell destruction, the healthy bone marrow responds by increasing erythropoiesis up to sixfold.

RBC transfusion more commonly provides symptomatic support rather than definitive therapy for anemia. Transfusion should be used only when there is no definitive treatment for the underlying cause, or when the severity of the anemia and the clinical manifestations in the patient make it impossible to wait for the effects of the treatment to be realized.

Generalizations about RBC transfusion indications and practices are difficult to make and are usually inappropriate. The clinical

impact of anemia varies depending on its pathogenesis, rate of onset, the presence or absence of accompanying hypovolemia, and, most importantly, the individual patient. The Hb level at which a given individual manifests the signs and symptoms of anemia relates, in part, to underlying health status, cardiorespiratory reserve, and tissue oxygen demand.

Perioperative Period

Many generalizations have been made about the appropriate transfusion management of acute blood loss, often with little hard data to support the arguments. One rule of thumb is that blood loss of 10% or less of total blood volume requires no replacement therapy at all; loss of up to 20% can be replaced exclusively with crystalloid solutions; and loss of greater than 25% generally requires RBC transfusion to restore oxygen-carrying capacity, along with crystalloid and sometimes colloid solutions to restore intravascular oncotic pressure to achieve adequate perfusion. For years, the threshold of 10 g/dL of Hb had been used as the gold standard for the RBC transfusion trigger during the perioperative period, but 7 g/dL is now more commonly used. Each case must be evaluated individually on the basis of clinical signs and symptoms, rather than on the basis of laboratory values. If the cardiovascular system is healthy and the degree of hypoperfusion is not significant, good tissue oxygenation can be maintained at much lower Hb levels. A National Institutes of Health consensus conference suggested that many surgical patients do not need transfusion unless the Hb level falls to less than 7 g/dL. Given that RBC transfusion should be tailored to individual needs, the question arises as to whether there is any readily available, objective measurement that can be used to determine how low the Hb level can safely be allowed to fall before RBC transfusion is initiated.

Global hemodynamic parameters do not always correlate with microvascular perfusion. Assessment of tissue oxygenation at the microvascular level would help evaluate the effectiveness of a red cell transfusion, evaluate the effect of red cell storage on end-organ perfusion, and provide data about when to transfuse. Several general methods are available to evaluate the microcirculation and include direct assessment using image techniques and indirect methods of assessment, such as measures of microvascular oxygen availability and function. Direct assessment can be performed using laser Doppler flowmetry, imaging of the microcirculation, intravital microscopy, orthogonal polarization spectral imaging, and sidestream dark-field imaging. Assessments of oxygen availability include oxygen electrodes, reflectance spectrophotometry, and near-infrared spectroscopy. The techniques described are currently considered research tools and are not available in routine clinical practice. Many have yet to prove reliable and reproducible in the clinical setting. Further, some are only useful in specific organ systems and do not reflect the global oxygenation of the patient. To be useful at the bedside, a technique must be technically simple, rapid and noninvasive without large interoperator variation. Such a device has yet to become available.

The Society of Thoracic Surgeons and the Society of Cardiovascular Anesthesiologists published clinical practice guidelines that identified six variables that increased a patient's risk of postoperative blood transfusion: advanced age, low preoperative red cell volume, preoperative antiplatelet or antithrombotic drugs, reoperative or complex procedures, emergency operations, and noncardiac patient comorbidities. The report recommended developing institution-specific protocols to screen for high risk patients and apply blood conservation interventions, such as erythropoietin or antifibrinolytic administration, intraoperative blood salvage or normovolemic hemodilution, and institution-specific blood transfusion algorithms supplemented with point-of-care testing. In 2015, the American Society of Anesthesiologists published a practice guideline for perioperative blood management that emphasizes the preoperative patient assessment and encourages greater utilization of pharmacologic agents and point of care testing-directed transfusion algorithms to minimize blood transfusion.

Randomized clinical trials have evaluated the effects of different transfusion thresholds in distinct clinical settings; however the thresholds used in the studies differ widely. Many of the studies found no difference in outcome. Most studies were not powered to adequately evaluate clinically important outcomes. Few studies included more than 100 patients. The Transfusion Requirements in Critical Care trial included 838 intensive care unit (ICU) patients who were randomized to a restrictive transfusion strategy (transfused at Hb 7 g/dL) or liberal strategy (transfused at 10 g/dL). The 30-day mortality was slightly lower in the restrictive group (18.7% versus 23.3%), but not significantly lower. The FOCUS trial, a 2600 patient, multicenter randomized trial designed to determine whether patients with cardiovascular disease or risk factors undergoing surgical repair of the hip benefit from a lower (<8 g/dL) or liberal transfusion trigger (transfused at 10 g/dL), has recently been completed. The results showed that liberal transfusion did not reduce mortality or in-hospital morbidity in this patient cohort. Other studies have now been published in the ICU, in sepsis, and in upper gastrointestinal (GI) bleeding that support the use of conservative transfusion triggers. On the other hand, there is a need for studies of transfusion triggers in patients with cardiac ischemia or in neurosurgery where clinicians have been reluctant to adopt conservative red cell triggers.

Red Blood Cell Transfusion in Neonates

In neonates it is convenient to consider periodic, small-volume transfusion separately from massive transfusion situations. The trigger for transfusion and the optimal type of component are very different in these two settings. The potential adverse effects may be quite distinct.

Low-volume RBC transfusion is rarely indicated in full-term infants unless acute blood loss has occurred at birth or an intrauterine situation has led to prenatal anemia. In contrast, premature infants are frequent recipients of transfusions. In the intensive care setting, the premature infant is subjected to frequent blood sampling, and iatrogenic anemia may necessitate transfusion. Anemia of prematurity is also a well-recognized entity; premature infants have a slightly lower Hb value at birth. In addition, the postnatal decline in Hb occurs earlier and is more pronounced in premature infants. The mechanism for anemia of prematurity appears to involve a relatively lower output of erythropoietin in response to a given degree of anemia. This phenomenon is attributed in part to the fact that the liver, rather than the kidney, is the major site of erythropoietin production in these infants. Although some practitioners have considered this degree of anemia to be physiologic, the benign nature of this condition remains controversial.

Another debate among neonatologists concerns the triggers for RBC transfusion, as in what clinical signs and symptoms are valid reflections of poor tissue oxygenation. Congestive heart failure and severe pulmonary disease are generally accepted indications for transfusion, but recurrent apnea, tachypnea, tachycardia, and failure to thrive are also used as transfusion triggers. In recent times, the rate of transfusion and the donor exposure rate of premature infants have consistently declined. These changes, however, reflect improvements in patient care (e.g., microtesting methods resulting in less iatrogenic blood loss; the use of surfactant resulting in decreased respiratory distress and the use of a single unit to supply one infant over a longer period) rather than being attributable to changes in the transfusion trigger. The prolonged use of single units has become possible with the advent of the sterile docking technology that preserves the full shelf-life of the unit of RBCs, as well as with the accumulating evidence that fresh blood is not necessary for low-volume transfusions in neonates because supernatant potassium and decreased pH are not of concern in this setting. Two recent studies have provided additional information about the relative risks and benefits of using restrictive rather than more liberal criteria for very low birth weight infants. One study showed that a liberal transfusion practice resulted in more infants receiving transfusion but conferred little evidence of

benefit. The other study showed a lower risk of apnea and major brain injury for the liberal transfusion arm of the study. Therefore, the safest transfusion trigger in the preterm infant still remains unclear, and further studies are indicated. Most institutions assess the clinical situation and consider the postnatal age and whether a neonate has oxygen requirements when determining the need for a RBC transfusion.

The dose of a RBC transfusion in a neonate can vary by institution between 5 and 20 mL/kg. Few studies have assessed the optimal dose in this patient population and further studies are needed. Paul et al compared 10 and 20 mL/kg and found that the larger volume did not cause impaired pulmonary function. Wong et al demonstrated extra transfusion episodes could be avoided with 20 mL/kg versus 15 mL/kg, without any additional risk to the patient. Many transfusion services now routinely use RBCs stored in additive solutions for low volume RBC transfusion and thus prefer a dose of 20 mL/kg to account for the lower hematocrit of an additive unit.

Finally, several trials of erythropoietin therapy in premature infants have been undertaken. The administration of relatively high-dose erythropoietin has been shown to raise Hb levels and reticulocyte counts in healthy premature infants, but the effect in sicker neonates is unclear. Although transfusion exposure was decreased, the significance of this observation is diminished, given the promise of new strategies for limiting transfusions and donor exposure. The high cost and the increased risk of retinopathy associated with erythropoietin treatment does not justify its use in this patient population.

In the case of massive transfusion, the situation differs. There have been marked increases in massive transfusion in recent years in full-term as well as premature infants. Hemolytic disease of the newborn remains a prominent indication for exchange transfusion; however, the recent use of intravenous immune globulin to decrease red cell antibody levels in newborns has decreased the necessity of this procedure. The two triggers for exchange are (a) rapidly rising levels of unconjugated bilirubin that may lead to kernicterus and permanent central nervous system damage and (b) congestive heart failure secondary to severe anemia. Whole blood exchange transfusion is especially beneficial in cases of hemolytic disease of the newborn because it clears the bilirubin, the offending antibody, and the antibody-coated red cells before lysis, while providing a source of red cells lacking the offending antigen. A two-blood-volume exchange is commonly performed by using a fresh unit of blood concentrated to a final hematocrit level of approximately 50%. In cases of hyperbilirubinemia resulting from other causes (e.g., that associated with liver immaturity in premature infants), phototherapy is the treatment of choice because its effects are usually more sustained, and exchange transfusion is used only for cases of marked elevations. Extracorporeal membrane oxygenation and open-heart surgery are two other situations that the neonate may be exposed to large volumes of allogeneic RBCs. The extracorporeal membrane oxygenation circuit requires a prime with RBCs, as do many of the types of extracorporeal circuits used for cardiopulmonary bypass.

Although accumulating evidence supports the safety of using RBC units of any age and with any preservative solution for low-volume transfusions in neonates, the same transfusion policies may not apply to massive transfusion. Newborn physiology is unique in several ways that may have implications for massive transfusion therapy. The newborn does not handle metabolites in a mature fashion. Renal immaturity may lead to problems in clearing potassium or acid from stored RBCs, and the immature liver may not catabolize citrate efficiently. These problems are accentuated and protracted in the premature infant. To address the concern about potassium load, fresh (<7 days old) or washed RBCs are often used, although the necessity of this practice is actively debated. Fresh blood may also be preferred because of its higher 2,3-DPG levels and better red cell integrity. The citrate problem is probably best handled by using slow infusion rates, because the use of bicarbonate or calcium replacement to counteract the acid load or calcium-chelating effects of citrate is controversial. Finally, the use of RBCs stored in the newer preservative solutions (CPDA-1, Adsol, Nutricel, Optisol) is avoided

by some authorities because of the risk of renal damage and renal stones due to adenine metabolites. If CPD RBCs are not available, the additive solution can be removed and the cells washed. RBCs preserved in additive solutions also have a lower hematocrit level that must be taken into account in making calculations for exchange transfusion.

The humoral and cellular immune systems of the neonate are immature, especially in the premature infant. There is a small but real risk of transfusion-induced GVHD in premature infants receiving RBC transfusions and in the fetus undergoing intrauterine transfusion. Irradiation of RBCs should be performed in both settings. Another risk of transfusion in low birth weight (<1500 g) premature infants is the development of clinical CMV infection in infants of CMV-seronegative mothers. CMV safe blood, either CMV seronegative or leukoreduced, should be provided to these infants. Some retrospective studies have suggested that other rare RBC transfusion-associated complications in this particularly vulnerable patient group include necrotizing enterocolitis and intraventricular hemorrhage. However, a causal relationship has yet to be established through clinical studies.

Novel ideas to prevent anemia and decrease donor exposure in premature infants and other neonates include delayed cord clamping, cord milking, umbilical vein blood sampling from the delivered placenta, and autologous cord blood transfusion. One review of 10 delayed cord clamping studies, and demonstrated lower transfusion requirements in the delayed versus early clamped group. However, a randomized controlled trial by Strauss et al found no difference in transfusion needs between delayed and early clamped groups. A few studies have looked at autologous cord blood transfusions in neonates. One study found that the amount of blood harvested was insufficient to cover all transfusions in low birth weight infants. In addition, studies have demonstrated that blood processing problems, bacterial contamination, and costs are all barriers to the routine collection and autotransfusion of cord blood.

Red Blood Cell Transfusion in the Allogeneic Hematopoietic Stem Cell Transplantation Recipient

Red cell engraftment is usually the last phase of hematopoietic recovery after stem cell transplantation; therefore, RBC transfusion is common during the posttransplantation period. As hematopoietic stem cells and progenitor cells lack ABO antigens, the transplantation outcome is not significantly affected by the red cell antigen/antibody incompatibility between the donor and the recipient. However RBC transfusion requirements and blood product selection can vary significantly depending on the type of ABO incompatibility. The phenotyping of non-ABO/Rh red cell antigens from the donor and recipient is not required in the absence of a positive red cell antibody screen in the recipient. Patients with an autologous stem cell transplant have less RBC transfusion requirements when compared with patients receiving allogeneic stem cell transplantation.

In the setting of allogeneic stem cell transplantation, there are four major categories of ABO antigen matching: full compatibility, minor incompatibility, major incompatibility, and bidirectional incompatibility. In addition, Rh type must be taken into consideration. Rh positive recipients with Rh negative donors should receive Rh negative RBCs, but Rh negative recipients with Rh positive donors may receive Rh positive RBCs. Apheresis platelets and plasma may be given without regard to Rh. The blood product selection algorithm is shown in (Table 111.2). Minor incompatibility is defined as the presence of blood group antibodies in donor plasma (e.g., group O donor to group A recipient). In minor incompatible stem cell transplantation, the incompatible plasma in the donor stem cell product may result in some hemolysis of the recipient's endogenous RBCs during the early phase of the posttransplantation period. Minor incompatibility is occasionally complicated by passenger lymphocyte syndrome, where transient hemolysis may occur if donor-derived lymphocytes in the stem cell graft remain viable and form blood group-specific antibodies, which are incompatible with the recipient's

TABLE 111.2 Transfusion After ABO Incompatible Hematopoietic Stem Cell Transplantation

ABO Group			Product Selection

RBC, Red blood cell.

red cells. Typically, passenger lymphocyte syndrome involves ABO incompatibility, but hemolysis resulting from serologic incompatibility in other blood group systems has been reported. If hemolysis increases a few days after transplantation, passenger lymphocyte syndrome should be considered. Once the donor is engrafted and incompatible recipient red cells are removed, donor red cells will have normal survival in the recipient. Major incompatibility is defined by the presence of blood group antibodies in recipient plasma (e.g., group A donor to a group O recipient). Major ABO incompatible transplantation may result in pure red cell aplasia (PRCA) due to persisting incompatible ABO antibody targeting the donor's engrafting erythropoietic precursors expressing ABO antigens. Although there may be no evident hemolysis, the donor red cell engraftment could be further delayed and result in prolonged RBC transfusion support. Finally, bidirectional incompatibility is defined as the presence of incompatible ABO antigens and antibodies contributed by both donor and recipient (e.g., group A donor to group B recipient). Bidirectional incompatible transplants may cause the problems associated with both minor and major ABO incompatible transplants. To predict the severity of these complications and provide management, an ABO antibody titer can be performed on either the stem cell product or the recipient. However, titers do not correlate perfectly with the clinical outcomes. When a high titer incompatible ABO antibody is discovered in a minor incompatibility, the stem cell product can be plasma-reduced to avoid an immediate hemolytic reaction. Occasionally, in major incompatibilities, plasma exchange can be considered if the recipient has a high level of incompatible ABO antibody to prevent hemolysis at the time of transplant or PRCA.

RED BLOOD CELL PRESERVATION AND STORAGE

The first key to the storage of blood is a stable, minimally toxic anticoagulant with preservative properties. During the early 1900s, it was recognized that citrate met these criteria. Citrate is slightly more toxic than heparin, especially when given rapidly and in large amounts, but citrate has preservative action that heparin lacks. Citrate has the added advantage of not causing systemic anticoagulation in the recipient.

The other factor essential for long-term storage is a mechanism to maintain cell viability and function. Freshly transfused RBCs have a good survival rate in the recipient's circulation, with a destruction rate approximately equal to that of the recipient's own cells: 1% per day.

Discoveries during the past two decades have raised clinical concern regarding the efficacy and risk of RBC transfusion. Changes within the RBC and its supernatant during RBC storage have been associated with reduced tissue oxygenation and other adverse effects in patients receiving RBC components stored for extended periods. The biochemical, structural, and functional changes are collectively termed the red cell storage lesion. The alterations found with the storage lesion along with the clinical implications will be discussed in this section.

BIOCHEMICAL CHANGES ASSOCIATED WITH RED BLOOD CELL STORAGE

Adenosine Triphosphate Levels

ATP levels appear to be a major determinant of red cell viability. The drop in cellular ATP levels during storage has been correlated with increased cell rigidity and with loss of membrane lipid, leading to decreased red cell life span. For this reason, most efforts to extend RBC storage have focused on ways to maintain intracellular ATP levels. First, dextrose was introduced into the citrate solution (citrate-phosphate-dextrose [CPD]: 21 day shelf life), and then adenine was added (CPDA-1: 35 day shelf life). Three additive solutions containing additional dextrose and adenine (Nutricel, or AS-3) or dextrose and adenine plus mannitol (Adsol, or AS-1) and (Optisol, or AS-5) allow extension of the maximum storage time to 42 days (Table 111.3). The majority of today's RBC supply is stored in an additive solution.

2,3-Diphosphoglycerate Levels

Stored RBCs must also maintain their capacity to deliver oxygen. It was not until 1967 that the central role of 2,3-DPG in releasing oxygen from oxyhemoglobin was recognized. Attention was then focused on ways to maintain high levels of 2,3-DPG in stored RBCs. The first anticoagulant introduced on a large scale, acid citrate-dextrose, was ineffective because of its low initial pH; however, the subsequently developed CPD, with its higher initial pH and slower fall in pH, was superior. CPDA-1 and additive solutions have not further improved 2,3-DPG maintenance. Although 2,3-DPG depletion of stored RBCs is known to decrease oxygen delivery, the clinical significance of this finding is unclear. 2,3-DPG levels in stored RBCs are rapidly regenerated in vivo, rising to greater than 50% of normal within several hours and to normal within 24 hours of transfusion. Although a patient with normal cardiac status should be able to compensate by increasing cardiac output to maintain normal oxygen delivery until 2,3-DPG levels are regenerated, an improvement in 2,3-DPG preservation in stored RBCs is still desirable.

TABLE 111.3 Biochemical Changes in Stored Red Blood Cells

Variable	CPDA-1	CPDA-1	Adsol	Fresh	35 Days	35 Days
In vivo survival (at 24 hours) (%)	100	<71.0	<88.0			
pH	<7.5	<6.7	<6.7			
ATP (% initial)	100	<45.0	<76.0			
2,3-DPG (% initial)	100	<10.0	<10.0			
Plasma K ⁺ (mEq/L)	5.1	<78.5	<49.0			

CPDA-1, Citrate phosphate dextrose adenine-1; DPG, 2,3-diphosphoglycerate. Data from Zuck TF, Bensinger TA, Peck CC, et al: The in vivo survival of red cells stored in modified CPD with adenine: Report of a multi-institutional cooperative effort. *Transfusion* 17:34, 1977; and Moore GL, Peck CC, Sohmer RR, Zuck TF: Some properties of blood stored in anticoagulant CPDA-1 solution: A brief summary. *Transfusion* 21:135, 1981.

Citrate

Infusion of large volumes of blood with citrate anticoagulant over a short period may cause plasma citrate levels to reach the toxic range. The primary concern is the cardiovascular effects of hypocalcemia caused by chelation of calcium by citrate. The risk of citrate toxicity is exacerbated by liver dysfunction or liver immaturity. Despite these theoretical considerations, there is little documented evidence of clinical citrate toxicity, which can usually be prevented by slower infusion. If large amounts of blood have to be infused over a very short period, administration of calcium gluconate can be considered, but whether the benefits justify the risk is controversial.

Potassium

Another issue with prolonged storage is the excess potassium in the RBC supernatant that could potentially cause cardiac arrhythmias. At a storage temperature of 4°C, the red cell sodium-potassium pump is essentially nonfunctional, and intracellular and extracellular levels gradually equilibrate. In addition, hemolysis results in increased potassium in the supernatant. However, because the total volume of plasma in RBC concentrates is low (approximately 70 mL), the total potassium burden is only approximately 5.5 mEq at product expiration. Practically speaking, the potassium load is rarely a clinical problem except in the setting of preexisting hyperkalemia and renal failure in adults. In children with rapid or massive transfusions, hyperkalemic cardiac arrest is more commonly recognized. In these situations, fresher units of RBCs or washed RBCs can be used.

Di(2-ethylhexyl)phthalate

Since their introduction in the 1960s, plastic blood bags used for storing RBCs have been made from polyvinylchloride containing the lipophilic plasticizer di(2-ethylhexyl)phthalate (DEHP), which confers pliability. The safety of DEHP has been questioned for years owing to its tendency to leach from the bag and to be present at levels of 50–70 mg/L in stored RBCs. The storage of RBCs in bags made of polyvinyl chloride plasticized with DEHP has caused more recent concern because of the reported association between DEHP exposure and impaired development of the male genital tract. One of the benefits of using DEHP for RBC storage is the prevention of hemolysis. DEHP leaches out from the plastic bag and intercalates and stabilizes the red cell membrane. Shorter storage lessens the load of DEHP delivered to the recipient. Although there are potential replacement plasticizers, DEHP is most commonly used since the exposure to DEHP through transfusion is generally felt to be less than other environmental exposures.

Storage Length of Red Blood Cells

Current Status

The current expiration time of an RBC unit stored in an additive solution is 42 days. The allowable storage time is regulated by the FDA and requires: 1) the recovery of at least 75% of red cells transfused twenty-four hours after infusion, and 2) less than 1% hemolysis, both at the end of the storage limit. There is no criterion based on the clinical ability of transfused red cells to oxygenate tissue. The 2011 National Blood Collection and Utilization Survey reported that the mean age of RBC units at transfusion was 17.9 days.

Many variables affect the age of a specific RBC unit at transfusion. The blood group of the unit will impact the length of storage. Group O units tend to be issued quickly due to their universal compatibility; as a result, Group O units are often issued with a shorter age. Group B and AB tend to be stored the longest. Transfusion service policies will also affect the overall age of RBC units at the time of transfusion. Busy tertiary care hospitals tend to transfuse some of the oldest units

since they may receive units returned from smaller community centers who did not expect to use them before their outdate. Hospitals that have blood refrigerators outside the blood bank tend to age units in the refrigerators because it is cumbersome to rotate the units out frequently. Hospitals with high crossmatched to transfused ratios also tend to have older units on their shelves.

Red Blood Cell Storage Lesion

The RBC storage lesion includes all the changes that occur to blood components during blood bank storage. The lesion includes biochemical and structural changes to the red cell, as well as changes that occur in the storage supernatant. The structural changes include red cell membrane loss that leads to the reversible evolution of the shape of the red cell from a biconcave disc to a spherocytocyte. After this stage, further red cell membrane loss becomes irreversible, and microvesicles are produced. Red cell vesicles are quickly cleared by macrophages due to exposed negatively charged lipids. The infusion of a large amount of red cell vesicles during a RBC transfusion may overwhelm the reticuloendothelial system and cause a proinflammatory and prothrombotic response. The shape changes are also associated with a rheologic effect, including increased viscosity and reduced flow within the capillaries, leading to decreased tissue perfusion. Many of the biochemical and structural changes, aside from vesiculation, are reversible when the RBCs enter human circulation where pH, ATP levels, and 2,3 DPG levels are normal.

Older red cells become more susceptible to oxidative damage, although this change generally occurs at a lower rate during *in vitro* conditions than *in vivo* due to the lower storage temperature. However, during a transfusion the human circulation is confronted by a bolus of equally damaged RBCs that may overwhelm the reticuloendothelial system. The work of Hod and Spitalnik emphasized that up to 25% of transfused RBCs with prolonged storage are cleared within 24 hours. The rate of delivery of heme-iron to the reticuloendothelial system may abruptly increase as much as 60-fold after transfusion of even a single unit of RBCs. This can surpass the rate of uptake by transferrin and produce circulating nontransferrin bound iron that may in turn lead to the myriad of problems associated with iron overload.

Irradiated cells are exposed to additional oxidative stress that can damage red cell protein and lipid. WBCs in the component also break down during storage and release proteases and lipases. Lysophospholipids and glycosidases are produced. Glycosidases may remove sialic acid and other sugars from the red cell membrane and can cause increased binding of stored red cells to endothelial cells and potentially contribute to endothelial inflammation. Increased lysophospholipids, such as platelet activating factor, have been found in units that have caused TRALI.

Clinical Relevance of the Red Cell Storage Lesion

Retrospective or prospective observational studies in many diverse patient populations have suggested numerous adverse events that may be associated with prolonged RBC storage, including increased risk for mortality, postoperative infection, multiorgan failure, deep venous thrombosis, or increased length of stay in the ICU or hospital. The observational studies on this topic have a number of significant limitations. First, larger volumes of RBC transfusion predict worse outcomes. Patients who are transfused larger volumes are statistically more likely to receive older RBCs. Second, confounding factors may not be recognized and, as a result, are discounted in nonrandomized studies. Third, individual methodologies in the presently available studies have varied markedly. Some studies have looked at the effect of mean storage age of all units transfused on outcome and some have broken storage time into categorical groups (i.e., is storage less than 14 days safer than storage beyond 14 days). In addition, studies have not used a single definition for "older" units; some have defined older units as greater than 14 days, greater than 21 days, or greater than

28 days. The definitions of age have not been based on either clinical or microcirculatory relevance or related to the feasibility and practicality of blood collection. Most studies have been designed for convenience and feasibility; a red cell storage age study with a definition of an older RBC unit as greater than 14 days of storage is achievable given current hospital inventories. Fourteen days is close to the average age of RBCs stored in a blood bank, but from a blood collection and inventory management perspective, an expiration time of 14 days would be disastrous for both hospitals and blood collection facilities. Authorities have argued that studies should be designed to measure storage age differences between lengths of storage that would actually be achievable given current inventory levels and difficulties in donor recruiting.

Published studies have focused on three patient groups that consume large numbers of RBC components: cardiac surgery, trauma, and critical care patients. A publication on the effect of RBC storage age on hematopoietic transplant recipients has also been recently published.

The Age of RBCs in Premature Infants study, a double-blinded study evaluating the effectiveness of RBCs stored no longer than seven days versus standard-issue RBCs in 377 neonates requiring transfusions has been published. The primary outcome revealed that using fresh blood of less than 7 days old did not improve the clinical outcome of these vulnerable premature infants. Recently, the Red Cell Storage Duration Study evaluated 1098 patients undergoing complex cardiac surgical procedures who were likely to require RBC transfusion. Patients were randomized to receive RBC units stored for either 10 or fewer days or 21 or more days. The median storage times of the transfused RBCs were 7 days versus 28 days for the two groups. RBC storage duration was not associated with a change in the Multiple Organ Dysfunction Score (MODS) or the 28-day mortality. Adverse events did not differ between the groups, except that hyperbilirubinemia was more common in the older storage age group.

The Age of Blood Evaluation study investigated the effect of leukoreduced RBCs stored 7 days or less versus leukoreduced standard-issue RBCs on 90-day all-cause mortality. Investigators enrolled 2430 adult participants receiving their first RBC unit in an intensive care unit. The study found that fresh versus standard-issue red cells did not decrease 90-day mortality among critically ill adults. Most recently, the Age of Blood in Children in Pediatric Intensive Care Units trial has been initiated to examine the effect of transfusing less than 7-day old blood (versus standard-issue age) in over 1500 pediatric ICU patients requiring transfusion. The primary outcome is new or progressive MODS.

Although the randomized prospective trial seems to be the only option to determine the clinical consequences of the RBC storage lesion, conducting a well-designed trial is not an easy task. Limited blood bank inventories to supply the longer and shorter storage duration arms, difficulty in consenting patients, and difficulty in selecting outcome measures to study have made creating the ideal study a formidable challenge.

The published studies evaluating whether adverse clinical consequences are associated with prolonged RBC storage have yet to satisfactorily answer this important question in all patient populations. The current RBC inventory almost always meets hospital needs with a 42 day RBC expiration period but is not currently equipped to meet the needs of a less than 7 day inventory, or even a less than 21 day inventory. Although it is logical to expect that there is a limit to RBC storage, beyond which the risks of transfusion outweigh the benefits of transfusion, none of the randomized studies described above is designed to determine this limit.

Animal studies have been able to provide additional information about the safety of RBCs stored for longer amounts of time than the clinical trials in humans. Natanson et al found that older blood (42 days of storage) increases the risk of transfusion (survival and multiple organ injury) in canine subjects with infection. In addition, in critically ill dogs with infection, they showed a favorable risk-to-benefit ratio for washing older blood. However, fresh blood (7 days of storage) was superior to older blood, whether washed or not.

RED CELL ALLOIMMUNIZATION

Overview

RBCs have over 300 blood group antigens that are capable of mounting humoral responses in antigen-naïve transfused recipients. Direct exposure to nonself red cells from allogeneic blood transfusion, circulating fetal red cells in pregnant females, or even occasionally stem cell/organ transplantation can cause red cell alloimmunization. In addition, recent studies have shown that indirect immune modulation mediated via proinflammatory factors in stored RBCs, a proinflammatory state in the host (e.g., endothelial damage or higher turnover rate of red cells in patients with chronic transfusion), and passive transfer of WBC antibodies (anti-HLA and anti-HNA) are associated with a higher risk of RBC alloimmunization. Matzinger's Danger Theory/Model further proposes that nonself antigen exposure with local danger signals from injured cells can synergize immune responses. Therefore, red cell alloimmunization represents an intricate yet complex interplay between transfused allogeneic RBCs and host immunity.

The humoral response can be categorized into two phases. The primary response occurs immediately when foreign antigen activates B lymphocytes leading to the high-affinity mutation selection process. This process allows the activated B cells to proliferate and differentiate into memory/plasma B cells that produce a specific antibody against the antigen. Although, the initially generated antibody may not lead to significant hemolysis of sensitized red cells. Upon reexposure to the same antigen (e.g., transfusing an individual who had preformed antibody but at an undetectable level), the second phase of the immune response (anamnestic response) can lead to rapid and robust antibody production from the pregenerated antigen-specific memory/plasma B cells. This response often causes clinically significant hemolysis that may even lead to a fatality in these transfused individuals. In the blood bank, a process is in place to prevent clinically significant hemolysis in transfused patients with preformed red cell alloantibody. There are two isotypes of red cell antibodies that are routinely evaluated in the blood bank. Immunoglobulin M (IgM) is a pentavalent antibody that appears during the early phase of antibody generation. It is primarily restricted to the intravascular compartment, can fix complement on the transfused red cells with cognate antigens, and could result in intravascular hemolysis. On the contrary, IgG antibody is produced mostly by memory/plasma B cells that can migrate to the extravascular compartment (e.g., amniotic fluid, tissues, etc.). Due to its capacity to move between compartments, it is commonly associated with extravascular hemolysis and fetal hemolysis.

Individuals at Risk

Both the immunogenicity and quantity of foreign red cell antigens are critical determinants of alloimmunization. Therefore, frequent transfusion exposure and transfusion across different ethnic groups are the most common factors associated with alloimmunization. This issue is of great concern in patients with transfusion dependent hemoglobinopathies [e.g., sickle cell disease (SCD) and thalassemia] and PRCA (e.g., Diamond-Blackfan anemia). In particular, SCD is associated with rapid sequestration of defective red cells and endothelial damage. The discrepancy in the prevalence of certain red cell antigens, such as in the Rh system (DCCeE) and Kell (K1), between blood donors (mostly Whites) and SCD patients (mostly African descent) significantly contributes to the increase in red cell alloimmunization rate compared with the general population. Interestingly, by molecular genotyping, it was found that SCD patients have a high frequency of polymorphisms that can result in red cell alloimmunization even when serologically matched red cells are transfused. In addition, the endothelial damage and chronic inflammatory state associated with SCD have been hypothesized to cause synergy in red cell alloimmunization. Genetic factors predisposing SCD patients to red cell alloimmunization have been studied, and patients with HLA-B35 have a sixfold higher likelihood of making red cell alloantibodies compared

with SCD patients lacking HLA-B35. GWAS studies currently being pursued may clarify the role of genetic factors. Interestingly, the rate of alloimmunization was not proportionally observed in patients receiving massive transfusion with uncrossmatched RBCs. This observation may be due to transient immunosuppression in the setting of severe physiologic stress or by immune modulation due to the overwhelming amount of foreign RBCs transfused. This phenomenon was also shown in pediatric SCD patients receiving RBC exchange. On rare occasions, solid organ transplant can also be a source of red cell alloimmunization as it may expose the recipient to residual donor red cells with foreign antigens, despite immediate saline perfusion to rinse the organ of blood. Clinical hemolysis may be observed, but severe hemolytic complications are more likely a result of passenger lymphocytes that are capable of mounting an anamnestic response to antigen-positive recipient red cells (Passenger Lymphocyte Syndrome). From knowledge gained through observational studies, the risk of red cell alloimmunization seems to be associated with both red cell exposure and host immune responses. However, the complete pathophysiology still remains to be determined.

Molecular Pathophysiology

The exact cause of human RBC alloimmunization under myriad clinical circumstances is multifactorial and difficult to accurately identify. Thus, reductionist animal model based studies will be needed to investigate the mechanisms and identify the specific etiologies of this clinical entity. Given the well-defined genetic background, ready availability of a large number of participants, ability to adapt to many genetic manipulations, and largely conserved lineage-specific genes in the mouse immune system, mouse models are ideal to investigate this complex clinical entity. For example, transgenic human Rh, Kell, and Duffy antigen-expressing mice have been generated to study the interaction with their cognate alloantibodies. In addition, human hemolytic disease of the fetus and newborn (HDFN) associated with alloantibody against the Kell antigen has been closely recapitulated in pregnant transgenic Kell mice. Unlike the HDFN associated with alloantibody against the RhD antigen that can be prevented with administration of Rh immune globulin, HDFN associated with alloantibody against the Kell antigen still lacks effective prevention. Therefore, this anti-Kell mouse model will be useful in revealing the mechanism of alloimmunization against the Kell antigen.

There is a high red cell alloimmunization rate in SCD patients. The transgenic murine model of SCD revealed that the sickle cell genetic mutation alone was not sufficient to independently cause RBC alloimmunization. This study further suggests the critical roles of environmental factors involved in this immune response. Indeed, other mouse model studies have found that viral analog-induced inflammation (e.g., polyinosinic polycytidylic acid, or poly:IC) can independently enhance RBC alloimmunization. Furthermore, experimental mice transfused in the absence of inflammation developed immune tolerance against the transfused foreign red cell antigens as compared with control mice in the presence of poly:IC. This observation is supported by the fact that most transfused individuals without infections do not make alloantibodies to nonself red cell antigens. Also, exogenous inflammatory factors accumulated during RBC storage (storage lesion) were found to enhance sensitization to foreign RBCs leading to a more than 10-fold increase in alloantibody production. This concept has not yet been tested in prospective controlled clinical trials.

While animal models are able to provide the reductionist view of red cell alloimmunization and can serve as a platform to study the mechanism of red cell alloimmunization, the study conclusions may have limited general applicability. For example, the transgenic SCD mouse model has inherent differences in disease manifestations (e.g., massive splenomegaly, large vessel vasculopathy, etc.) that are not observed in human SCD patients. In addition to the interspecies genetic variation, the homogeneous nature of the experimental mouse's genetic background may not fully capture the true pathophysiology of red cell alloimmunization in the human population.

Nevertheless, mouse models provide a molecular view of the disease pathogenesis and generate many new hypotheses to further elucidate the mechanism of red cell alloimmunization.

Red Blood Cell Alloimmunization Mitigation Strategies

Blood transfusion is one of the most common therapies provided in a hospital, and millions of blood products are transfused every year worldwide. Therefore, a carefully planned strategy to prevent red cell alloimmunization is urgently needed. Reducing red cell alloimmunization can occur in three areas: blood collection/manufacturing, hospital transfusion services, and through patient care. At the blood center, prestorage leukoreduction can effectively remove more than 99.99% of the original WBCs. This process minimizes the inflammatory or “danger” signals infused into recipients at the time of foreign red cell antigen exposure and thus may reduce subsequent alloimmunization. Some blood centers have also begun to provide non-ABO red cell antigen typing on RBC units to minimize transfusing RBCs with mismatched red cell antigens. Clinical interventions have also been proposed to reduce red cell alloimmunization risk. Surgical splenectomy was shown in mouse models and observed in transfusion-dependent patients (e.g., thalassemia) to reduce the alloimmunization rate; however, this procedure is not as effective if the initial antigen exposure occurred prior to spleen removal. Since sickle cell patients develop asplenia at early ages, this finding may also not be relevant to the high incidence of alloimmunization in sickle cell anemia. Immunosuppression can also theoretically retard the red cell alloimmunization rate. However, one must consider the adverse clinical impact of these drugs. More studies on drug types and dosages are needed to refine this strategy. Finally, blood bank practice plays a daily pivotal role in preventing red cell alloimmunization in hospital patients. Molecular/genetic typing can permit red cell antigen matching at a higher resolution and precision than traditional serologic red cell antigen typing. This additional testing is particularly helpful in patients with hemoglobinopathies or high titer warm autoantibodies, who are especially vulnerable to red cell alloantibody formation. In the current climate of medical care, patients often do not receive care at the same institution; therefore blood bank results may not fully and accurately transfer between hospitals. Recently, the National Patient Antibody Registry was developed to address this issue. By integrating patient test results from hospital blood banks and blood centers within a region or across the nation, this shared database not only reduces blood issuing time, but can also facilitate the selection of antigen-matched RBCs to prevent or mitigate alloimmunization. Collectively, the approaches described above to reduce alloimmunization were derived from clinical trials, observational studies, and studies using mouse-models. As many of these approaches incur additional cost and effort, a validated cost-effective strategy is needed to further improve patient care and reduce red cell alloimmunization. In view of the high costs of finding antigen negative blood and the fact that many patients with sickle cell anemia do not become alloimmunized, another strategy that remains reasonable until antigen negative blood becomes more cost effective is to monitor patients carefully and switch to antigen matching after the first detection of a red cell antibody

ALTERNATIVES TO ALLOGENEIC RED CELL TRANSFUSIONS

There are many alternatives to standard allogeneic red cell transfusions for a patient requiring elective surgery (Table 111.4). Potential alternatives include banking autologous units before the surgery, acute normovolemic hemodilution, pharmacologic therapies (i.e., erythropoietin or fibrinolysis inhibitors), perioperative salvage, virally inactivated donor red cells, or blood substitutes. All current options have their own unique benefits and drawbacks, and some of these alternatives are not yet available. In cases where an emergency transfusion is needed, the first three options would not be possible as they

**TABLE
111.4**

Alternatives to Standard Allogeneic Transfusions

Hemodilution
Intraoperative autologous transfusion
Perioperative blood salvage
Lower transfusion trigger
Pharmacologic therapies
Pathogen inactivation
Red Cell Substitutes
Stem cell derived RBCs

all require significant planning. Only virally inactivated components and red cell substitutes (both of which are still works in progress) would be available for unanticipated transfusion needs.

Autologous Blood Transfusion

Advantages of Autologous Blood Transfusion

The substitution of autologous blood components for those collected from other (allogeneic) donors eliminates transfusion-transmitted diseases such as viral hepatitis and acquired immunodeficiency syndrome. Immunologic complications related to the transfusion of foreign cells, including hemolysis and febrile reactions to WBCs, are also prevented. Other advantages, though possible, are less clearly established. For example, erythropoiesis may be sufficiently stimulated in the repeatedly bled autologous donor to hasten recovery from postoperative anemia. Intraoperatively salvaged red cells are spared the acquired membrane defects (“storage lesion”) and 2,3-DPG deficiencies of refrigerated red cells.

An important drawback to these techniques is their increased expense in contrast to the simpler allogeneic transfusions they replace. In addition, the availability of autologous components may result in their use in situations where transfusion might not have otherwise been considered. Patients with suboptimal compensatory erythropoiesis and donation-induced anemia at the time of surgery are also more likely to be given transfusions. Based upon the current level of viral safety in blood components in the developed world, the use of autologous blood has dropped significantly from times when viral testing was not available or reliable.

Preoperative Autologous Blood Collection

The typical volunteer allogeneic blood donor is allowed to give one unit of blood no more than once every 8 weeks, to prevent iron deficiency. However, provided that bone marrow erythropoiesis can be stimulated and satisfactory iron supplies maintained, blood can be collected as frequently as once a week from an autologous donor. Although the shelf-life of refrigerated RBCs is limited to 42 days, frozen storage for up to 10 years is possible at less than 65°C using glycerol as a cryopreservative.

From a cardiovascular standpoint, phlebotomy is well tolerated by a variety of seemingly high-risk donors, including the elderly, children, pregnant women, and patients with coronary artery disease. By contrast, anemia frequently develops during the donation interval and limits the number of autologous units that can be collected. In addition to marginal iron stores, erythropoietin levels often do not increase during the donation interval, probably because the hematocrit level of most donors is not allowed to fall to less than 30%. This situation may be improved by the administration of the recombinant growth hormone erythropoietin to autologous donors. The use of preoperatively donated autologous blood has also been reported for a variety of surgical procedures, including radical prostatectomy; hysterectomies and other gynecologic procedures; colorectal, biliary, and gastric surgery; orthopedic surgery, and neurosurgery. Since

many of these procedures are now performed using laparoscopy or other techniques to limit blood loss, the demand for predeposit autologous transfusion support has fallen in recent years.

Autologous blood has been safely collected from women during pregnancy for use during childbirth. Nevertheless, the transfusion rate at delivery is quite low (<2.5% in many institutions) and most autologous donations are unused. Long-term (frozen) storage of autologous RBCs in the absence of a planned transfusion episode is largely ineffective and expensive.

Intraoperative Blood Salvage

Cell salvage occurs in three phases: collection, washing, and reinfusion. RBCs are collected from the operative field using a dedicated double lumen suction device. One lumen suctions blood from the operative field and the other lumen adds heparinized saline to the salvaged blood. The anticoagulated blood then passes through a filter and is collected in a reservoir. If less than 1 L of blood is collected, further processing is foregone and the collected blood is discarded.

In most circumstances the contents in the bag can be washed to remove free Hb, surgical irrigation solutions, and other debris. Instruments are available that include both a reservoir for collecting salvaged blood and a centrifugal washer. Large aliquots (>500 mL) can be fully washed in as little as 3 minutes. As a result of this speed, autologous blood salvage has become practical in situations in which blood loss may be extremely rapid, such as trauma or liver transplantation.

The hematocrit level of unwashed blood is typically low because of dilution from irrigating surgical fluids and some degree of mechanical hemolysis. Free Hb levels are sometimes greater than 1000 mg in unwashed blood, and hemoglobinemia and hemoglobinuria may occur after the transfusion, although renal sequelae are surprisingly low. Despite this evidence of red cell injury, the survival rate of ⁵¹Cr-labeled salvaged cells is normal in most patients studied.

There are many potential complications associated with cell salvage, such as nonimmune hemolysis, air embolus, febrile nonhemolytic transfusion reactions, mistransfusion, coagulopathy, and contamination with drugs. Transfusion of salvaged blood has resulted in coagulation abnormalities, including hypofibrinogenemia, prolonged prothrombin time and partial thromboplastin time, elevated fibrin degradation products, and thrombocytopenia. These coagulation abnormalities most likely reflect the characteristics of the salvaged blood itself, which, after exposure to serosal surfaces, becomes deficient in coagulation factors and platelets and, in the case of unwashed blood, has high levels of fibrin degradation products (Table 111.5).

Fat, fibrin, bone fragments, and microaggregates often contaminate salvaged autologous blood. However, infusion of unwashed blood has not been proved harmful in either animals or humans, possibly because routine blood filters remove most particulate material. Other contaminants, such as heparin, topical antibiotics, hemostatic agents, and biologic substances such as tissue enzymes, can be at least partially removed by washing. Complete removal of bacteria is also not possible, even when the salvaged blood is washed with antibiotics. Thus, collection of blood from a contaminated site (e.g., with intestinal contents) is usually considered to be contraindicated;

in fact, manufacturers contraindicate the use of cell salvage in cases where there is potential contamination of salvaged blood with enteric contents. However, in recent years this viewpoint has been reconsidered as studies have found that autotransfusion of microbiologically contaminated salvaged blood have demonstrated no adverse outcomes or increase in postoperative infectious complications. Tumor cells have been found in blood salvaged during cancer operations, and thus many practitioners consider cancer another contraindication. Others believe that filtration would remove salvaged tumor cells.

Approximately one-half the blood lost during surgery can be salvaged. The rest is usually irretrievably absorbed in drapes and sponges or damaged during collection. The use of salvaged autologous blood has been associated with a 50% reduction in allogeneic blood use in orthopedic procedures such as spinal surgery and hip replacement, and is also effective in vascular surgical procedures such as aortic reconstruction. Autologous salvage has been a useful adjunct in the treatment of some Jehovah's Witnesses whose literal acceptance of the Bible includes abstention from routine allogeneic blood transfusions.

Both the canister systems and RBC processors used to collect intraoperative autologous blood can also be used to collect postoperative blood drainage, such as that from the mediastinum after open heart surgery, from the knee or hip after orthopedic procedures, or from the peritoneal cavity after hepatic injury. Because blood salvaged from a serosal cavity has little residual fibrinogen and platelets, clotting is not a problem, and the addition of anticoagulants is usually unnecessary. Shed mediastinal blood after open-heart surgery contains high levels of cardiac muscle enzymes, especially creatine kinase, as well as lactate dehydrogenase from hemolyzed RBCs. Therefore, reinfusion of shed blood results in elevated levels of both enzymes that can confound the diagnosis of myocardial infarction (MI) in the postoperative period. Reinfusion of shed mediastinal blood has been shown to reduce the need for allogeneic transfusions.

Hemodilution

The collection of autologous blood during surgery for later reinfusion at the end of the procedure was first suggested in open-heart operations, in which it was hoped that a supply of platelets undamaged by exposure to the membrane oxygenator might reduce the incidence of coagulopathies. Hemodilution itself reduces RBC loss: a patient with a hematocrit level of 45% and 2 L blood loss during surgery loses roughly 900 mL of RBCs, but one with a hematocrit level of 20% from hemodilution loses only 400 mL of RBCs. Hemodilution is less expensive to accomplish than preoperative autologous blood donation and may be the only option available when surgery is performed in other than elective settings. Proponents claim that the induced anemia may even be beneficial to the patient, in that oxygen delivery at a hematocrit level of 30% is enhanced by an increased cardiac output resulting from the decreased blood viscosity. Other advantages of hemodilution over predeposit autologous transfusion are the provision of fresh red cells along with plasma and platelets that may be important in maintaining hemostasis.

Reductions in allogeneic blood needs have been reported after marked intraoperative hemodilution (after the hematocrit is lowered

**TABLE
111.5**

Autologous Blood Salvage Systems^a: Characteristics of Collected Blood

System	Hardware	Software	Hematocrit	Free Hemoglobin	Platelet Count	Coagulation Factors	Fibrin Degradation Products
Collection without washing	Rigid plastic container	Plastic bag	Low (25%)	Very high (200 mg%)	Low (100,000/mm ³)	Low (35–75%)	High (300 mg%)
Collection followed by washing	Integral or separate blood cell processor	Disposable plastic bowl and tubing	High (60%)	Low (<50 mg%)	Very low (10,000/mm ³)	Absent (0%)	Absent (0%)

^aTypical results of laboratory tests are shown. Transfusion of large volumes of salvaged blood results in similar alterations in these tests in the recipient.

Data from Noon GP: Intraoperative autotransfusion. *Surgery* 84:719, 1978; and Silva R, Moore EE, Bar-Or D, et al: The risk: benefit ratio of autotransfusion-comparison to banked blood in a canine model. *J Trauma* 24:557, 1984.

by 50%). More modest hemodilution (e.g., removal of 2 units of blood at the beginning of surgery) is also beneficial, according to some investigators but the amount of red cells saved is small. Furthermore, one group has provided evidence that hemodilution may jeopardize patients at risk of ischemic myocardial injury. More research is needed to establish the safety, efficacy, and ideal protocols for this form of blood conservation. The availability of blood substitutes may facilitate augmented hemodilution for some patients who are expected to have large volumes of blood loss or who refuse blood transfusions.

BLOOD SUBSTITUTES

The search for blood substitutes began when our early scientific ancestors tested alternatives to human blood, including animal blood, milk, and wine. Modern research into the use of animal blood includes the work by Amberson et al, who reported the successful use of a bovine hemosylate for exchange transfusions in cats and dogs. Further work revealed that human and bovine hemosylates caused renal dysfunction in human recipients. The suspected cause of this nephrotoxicity was the stromal lipid component of the RBC membrane. The logical next step in the search for the ideal substitute was the development of stroma-free Hb (Hb tetramer). Unfortunately, in 1978 Savitsky et al demonstrated renal dysfunction, hypertension, and abdominal pain using stroma-free Hb in healthy volunteers. It was hypothesized that these adverse events were due to the instability of the Hb tetramer. Since then, efforts have been made to produce stabilized products with desirable oxygen off-loading characteristics and extended intravascular retention times.

Today, the United States blood supply is increasingly safe and has sufficient capacity to meet most patient needs. There is room for considerable improvement, however, in supply levels and risk reduction. The shrinking donor pool (owing to lack of willingness and/or ability) and the increasing transfusion requirements of an aging population may lead to shortage of blood products. The threat of new and emerging infections results in the vulnerability of human-derived oxygen carriers. The continuous battle against emerging infectious diseases underscore the risk of a tainted blood supply and depletion of transfusion resources. Theoretically, the ideal red cell substitute would solve both of these issues (Table 111.6). There have been many attempts to develop red cell substitutes in the past, but no product has been able to fulfil all of the above criteria or meet the Food and Drug Administration's requirements of purity, potency, and safety. There is no licensed red cell substitute available.

RED BLOOD CELL SUBSTITUTES

It is important to differentiate between "blood substitutes" and red cell substitutes. Red cell substitutes are oxygen carriers and do not replace all components and functions of blood, for example,

TABLE 111.6 The Ideal Red Cell Substitute

Delivers oxygen (and maybe enhances delivery)
Does not transmit disease
Does not have immunosuppressive effects
Available in abundant supply
Universally compatible (no need to type and crossmatch)
Prolonged shelf-life and stable at a range of temperatures
Similar in vivo half-life to the RBC
Available at a reasonable cost
Easy to administer
Able to access all areas of the human body (including ischemic tissue)
Effective on room air or ambient conditions

RBC, Red blood cell.

coagulation factors and WBCs. There are two main categories of oxygen carriers that show promise as RBC substitutes: perfluorocarbons (PFCs) and Hb-based oxygen carriers (HBOC).

Perfluorocarbons

PFCs are chemically and biologically inert artificial fluorinated organic fluids that are immiscible in water and have a high solubility for oxygen. The amount of dissolved oxygen in PFC is linearly related to the ambient oxygen tension, unlike Hb; gas molecules are not chemically bound to PFCs but are absorbed and released by simple diffusion. Products require oxygen inhalation by the patient, as the oxygen delivery capacity is less than 30% of normal blood. PFC has been shown to reduce the need for RBC transfusion, but has been associated with an increase in stroke rates. Although some PFCs are still being investigated, there are no major trials ongoing and no licensed products in the United States.

Hemoglobin-Based Oxygen Carriers

As RBCs age and degrade, the stroma and unmodified Hb released can lead to various adverse effects in the transfused recipients. Therefore, the HBOC that were most recently in clinical development were stroma-free and engineered to produce desirable oxygen dissociation characteristics as well as an adequate in vivo half-life with minimal toxicities. Stroma-free Hb has a very high oxygen affinity compared with native Hb in a RBC because of a lack of 2,3-DPG. Furthermore, the Hb tetramer is such a small molecule that the kidney rapidly removes it.

Four different methods have been suggested to avoid toxicities: stabilization, polymerization, conjugation, and Hb vesicles. HBOC can be prepared from different Hb sources (e.g., bovine RBCs or recombinant Hb harvested from bacteria/yeasts). However, the safety concerns of using Hb from nonhuman sources, such as the potential for transmitting diseases, immunogenicity, and toxicities have not been fully addressed. While one of the commercially available HBOCs (e.g., Bovine-derived Oxyglobin, HBOC-301) is approved for veterinary use, there is no HBOC product approved for clinical use although several products are in clinical development phases. All faced significant challenges in proving their safety and efficacy in early and late phase clinical trials. A large metaanalysis by Natanson et al identified 16 randomized controlled trials in which adult patients received HBOCs therapeutically. The analysis reviewed the association between HBOCs and the risk of MI and mortality in clinical trials. The study included five different HBOCs in the analysis and reported a 30% increase in risk of death and threefold increase in risk of MI when all HBOC trials were pooled. The metaanalysis has been criticized for including trials of varying methodologies performed on heterogeneous patient populations in different settings with different controls. The authors of the metaanalysis criticized the United States government oversight, as well as the transparency and timeliness in reporting the results of the HBOC clinical trials. The editorial that accompanied the publication in the Journal of the American Medical Association made a recommendation that further phase III trials of HBOCs should not be conducted until the mechanisms and potential toxicities are better understood. The effects may be due to the interaction of Hb and nitric oxide, a concern not fully appreciated in the early days of blood substitute research, but potentially addressed by the expansion of knowledge about NO and mitigating its effects. Although some HBOCs are still being investigated, there are no major trials ongoing and no licensed products in the United States.

Potential Clinical Applications

RBC substitutes have many potential applications. One of the most compelling needs would be the use for rapid resuscitation during military and civilian traumas. In developing a specific plan to avoid

the consequences of blood unavailability after national disasters involving large-scale injuries, blood substitutes could play a key role as an immediate treatment option. In addition to these acute emergency situations, there is a wide range of less urgent applications where oxygen carriers might provide a viable solution to difficult situations, including supporting solid organ perfusion during transport/storage, augmenting perioperative hemodilution, transfusion of patients who refuse human blood components because of religious beliefs (e.g., Jehovah's Witnesses), transfusion of patients with rare blood types or antibodies to high incidence antigens, organ preservation for transplant surgery, transfusion in patients with autoimmune hemolytic anemia in whom it is difficult to detect underlying antibodies, and reducing alloimmunization risk in patients receiving frequent transfusions. Since blood transfusion therapy is not available to handle some of these indications, there remains an unmet medical need for a safe and efficacious RBC substitute.

Red Blood Cells Derived From Stem Cells

Due to the threat of future blood shortages, the possible shortening of RBC storage, and unlikely availability of RBC substitutes in clinical use, a new source of RBCs is needed. Blood substitutes will not answer this need in the near future. The generation of RBCs derived from stem cells could meet this need, and this method is currently under intense development by researchers worldwide.

Umbilical cord blood is an accessible source of stem cells with proliferative capacity; however, the proliferation is not infinite, requiring a system of production in batches. Neildez-Nguyen et al first reported the possibility of converting umbilical cord stem cells into erythroid progenitors that can continue to mature into terminally differentiated RBCs in vivo. Giarratana et al subsequently demonstrated that adult mobilized hematopoietic stem progenitor cells can also be differentiated into RBCs and found that the survival of the cultured RBCs was similar to that of native RBCs. Under optimized expansion and differentiation conditions, Giarratana et al reported that they were able to generate 4 to 30 million RBCs from one hematopoietic stem progenitor cell obtained from apheresis donors. While this expansion scheme could be adequate to generate clinically useful transfusable RBCs, it may not justify the donor risks (e.g., G-CSF–mobilized apheresis collection) for the sole purpose of RBC production. Stem cells cultured from umbilical cords would necessitate the use of cord blood banks and would still be dependent on human donation. Alternatively, embryonic stem cells and induced pluripotent stem cells (iPSCs) can be obtained, generated, then maintained indefinitely in culture, thus providing an unlimited source of cells. Like embryonic stem cells, iPSCs are capable of in vitro self-renewal and differentiation into cell types from all germ layers. However, they possess an advantage over embryonic cells in that they pose no ethical dilemma and can be selected based on known phenotypes. Researchers have been able to demonstrate that iPSCs can differentiate into terminally mature and fully functional red cells.

A number of challenges must be overcome before we have an unlimited supply of clinical grade RBCs. The ideal choice for the initial cell type (e.g., hematopoietic stem cell, erythroblast, etc.) remains to be determined. The method of reprogramming the cells must be established to avoid the risk of potential mutation and tumor development (although this is less of an issue for red cells as they are enucleate and can be safely irradiated) while still ensuring the functionality of the end product. Finally, the use of GMP conditions for mass production within a reasonable amount of time and at a reasonable cost seems to be the greatest hurdle to date. The current challenges in utilizing iPSCs to generate RBCs are the inefficiency in erythroid commitment and the suboptimal cellular amplification. A number of strategies are under development to solve this crucial problem. Until mass amplification is possible, the iPSCs could be developed, not as an unlimited supply, but as a source of cells expressing a rare blood group used to treat alloimmunized patients with rare blood types. Currently, the available methods for ex vivo manufacturing of RBCs for clinical use are expensive and unrealistic.

CLINICAL CONSIDERATIONS IN PLATELET TRANSFUSION THERAPY

Richard M. Kaufman

PLATELET COLLECTION AND MANUFACTURING

Platelet components are either prepared from whole blood donations (platelet concentrates) or, more commonly, are collected by apheresis (single donor platelets). In the United States, whole blood-derived platelet concentrates are made using the platelet-rich plasma (PRP) method. First, a whole blood unit is separated by gentle centrifugation (slow spin) into red blood cells (RBCs) and PRP. The PRP is then centrifuged a second time (hard spin) to isolate one platelet concentrate plus one unit of plasma. Each platelet concentrate contains approximately 5.5×10^{10} platelets suspended in a plasma volume of approximately 50 mL. In Europe and Canada, the alternate buffy coat method is used to produce platelet concentrates. Platelets are stored at room temperature under continuous gentle agitation for up to 5 days. To prepare an adult dose of platelets for transfusion, four to six platelet concentrates are pooled together.

Apheresis platelet units are collected from a single platelet donor by continuous flow centrifugation using an automated device. A high volume of whole blood is processed through the machine, and the platelets are retained in a sterile collection bag. According to AABB (formerly, the American Association of Blood Banks) standards, an apheresis platelet unit should contain a minimum of 3×10^{11} platelets,¹ a dose that is approximately equivalent to five pooled platelet concentrates. Current devices allow many different combinations of blood products to be collected during a single apheresis donation, such as 1 unit of platelets plus 1 unit of RBCs. Apheresis platelet units generally contain less than 1×10^6 white blood cells (WBCs) per unit; thus, they meet the current AABB definition for leukoreduced blood products ($<5 \times 10^6$ WBCs/unit).¹ Although apheresis platelets cost more to produce than whole blood-derived platelet concentrates, they have become increasingly popular. In the United States in 2011, approximately 2 million therapeutic doses of platelets were provided as apheresis platelets, and only 200,000 equivalent doses were administered as whole blood-derived platelet concentrates.²

Apheresis platelets provide limited advantages over whole blood-derived platelet concentrates. Radiolabeling studies indicate that apheresis platelets circulate longer in vivo than pooled concentrates, most likely reflecting gentler handling and less platelet activation during collection. Recipients of apheresis platelets are exposed to fewer donors per transfusion (1 donor versus 4–6 as with a pool of platelet concentrates), so in principle, apheresis platelets should pose a lower risk of viral transmission than whole blood-derived platelets. However, given that the per-unit transfusion-transmission risks for HIV and hepatitis C virus have been reduced to less than 1 per 1,000,000,³ the viral safety advantage of apheresis platelets over whole blood-derived platelets is marginal. Data from surveillance culture studies suggest that apheresis platelets may be less likely than platelet concentrates to become contaminated with bacteria. At one time, it was predicted that apheresis platelets would be less likely than pooled concentrates to provoke platelet alloimmunization by virtue of exposing recipients to fewer unique donor human leukocyte antigens (HLAs). This hypothesis was not confirmed empirically, however. Although they express surface HLA class I antigens, platelets appear to be rather poor immunogens. HLA alloimmunization to platelets primarily appears to be triggered by contaminating WBCs within a

platelet unit. Thus, alloimmunization is not platelet dose dependent, and simply providing leukoreduced platelet units prevents most cases of immune-mediated platelet refractoriness.⁴ When platelet refractoriness does occur, it is often in multiparous women, who were initially sensitized to foreign (paternal) HLA antigens in previous pregnancies.⁵

PROPHYLACTIC PLATELET TRANSFUSION

Most platelet units are transfused to prevent bleeding in nonbleeding patients, rather than to treat active bleeding. Before 1960, platelet transfusions were not widely available, and death from hemorrhage was common among patients with leukemia who received chemotherapy. In 1962, Gaydos and colleagues⁶ published a seminal study demonstrating a relationship between platelet count and likelihood of bleeding. After this study was published, prophylactic platelet transfusion rapidly became standard practice. Notably, based on their data, no specific platelet transfusion trigger was suggested by the authors. Regardless, a platelet count of 20,000/ μ L was widely adopted at the time as the standard prophylactic platelet transfusion trigger.

Later studies suggested that a lower transfusion trigger would be as effective as a trigger of 20,000/ μ L. Slichter and Harker,⁷ for instance, performed RBC radiolabeling studies in thrombocytopenic patients who were not receiving platelet transfusions. They demonstrated that only patients with platelet counts below 5000/ μ L had significantly elevated fecal RBC loss.⁷ Years later, several clinical studies directly challenged the 20,000/ μ L trigger. Platelet transfusion triggers of 10,000/ μ L versus 20,000/ μ L were compared directly in three randomized prospective studies of patients with acute leukemia.^{8–10} These studies, as well as a nonrandomized prospective trial,¹¹ did not show an increased incidence of bleeding when a trigger of 10,000/ μ L is used. Most recently, the Platelet Dosing (PLADO) trial demonstrated that the risk of bleeding among patients with hypoproliferative thrombocytopenia only increased at platelet counts below 6000/ μ L.¹² As shown in Fig. 112.1, the risk of spontaneous bleeding was equivalent between platelet counts of 6000/ μ L and 80,000/ μ L.

Severe hemorrhage in the setting of therapy-related hypoproliferative thrombocytopenia is now quite rare. Given the substantial changes in both chemotherapy and the supportive care of patients with hematologic malignancy that have occurred over the past several decades, two randomized controlled trials recently examined whether routine platelet prophylaxis still provides a clinical benefit. In the study by Wandt and colleagues,¹³ patients receiving chemotherapy or undergoing autologous hematopoietic stem cell transplantation (HSCT) were randomly assigned to receive platelet transfusions only when bleeding occurred, or standard prophylactic platelet transfusions for a morning platelet count at or below 10,000/ μ L. Grade 2 or higher bleeding occurred in 42% of patients receiving therapeutic platelet transfusions only, versus 19% in patients receiving platelet prophylaxis ($p < .001$). There were significantly more intracerebral hemorrhages in the no-prophylaxis group (7% versus 2%, $p = .01$), and there were two deaths due to bleeding in the no-prophylaxis group compared with zero in the prophylaxis group. In the Trial of Prophylactic Platelets,¹⁴ a similar population of patients

Fig. 112.1 RELATIONSHIP BETWEEN PLATELET COUNT AND SPONTANEOUS BLEEDING AMONG PATIENTS WITH THERAPY-INDUCED HYPOPROLIFERATIVE THROMBOCYTOPENIA. The percentage of days that adult or pediatric patients with hematologic malignancy enrolled in the PLADO trial had grade 2 or higher bleeding is shown as a function of morning platelet count. The 95% confidence intervals are shown as dashed lines. The bleeding risk was equivalent for platelet counts between 6000 and 80,000/ μ L.¹²

was randomized to no prophylactic platelet transfusions or routine prophylaxis. Grade 2 or higher bleeding occurred in 50% of patients in the no-prophylaxis group versus 43% in the prophylaxis group ($p = .06$ for noninferiority.) There were no deaths due to bleeding in this study. In both trials, bleeding occurred more frequently among patients being treated for acute leukemia versus autologous stem cell transplant recipients. Overall, the results of these trials support the continued use of prophylactic platelet transfusions for patients with hematologic malignancy and therapy-induced hypoproliferative thrombocytopenia.¹⁵

Prophylactic Platelet Dosing

There are currently thought to be two distinct clearance mechanisms for platelets. Most platelets undergo senescence after circulating in the peripheral blood for 8 to 10 days. But there is also evidence for a second clearance route in which there is a fixed daily loss of platelets that occurs independent of platelet age. Platelets exiting the circulation via this second route are postulated to function in maintaining vascular integrity. In principle, a low dose of platelets could be used to meet this daily requirement. This hypothesis was tested directly by the 2010 PLADO trial. A total of 1272 patients undergoing HSCor chemotherapy were randomly assigned to receive low-, medium-, or high-dose platelets for a morning count of 10,000/ μ L or lower. The risk of spontaneous bleeding was not increased until patient platelet counts fell to 5000/ μ L or lower. No differences were observed in bleeding rates among the three treatment groups, supporting the concept that few platelets are required to maintain hemostasis. Although significantly fewer total platelets were transfused to patients in the low-dose group, platelet transfusions were required more frequently.¹²

Prophylactic Platelets for Invasive Bedside Procedures

To date, there have been no large randomized trials evaluating the need for platelet prophylaxis before invasive bedside procedures such as lumbar puncture. However, retrospective data provide reassurance that moderate thrombocytopenia does not pose a serious risk for performing such procedures. Howard et al¹⁶ reviewed the records of 956 consecutive pediatric patients with newly diagnosed acute

lymphoblastic leukemia who underwent lumbar puncture. No serious hemorrhagic complications were observed after 5223 lumbar punctures, including 170 procedures that were done when the platelet count was 11,000 to 20,000/ μ L. The authors concluded that prophylactic platelet transfusion was unnecessary in patients with platelet counts above 10,000/ μ L. Lumbar punctures were performed in only 29 patients with platelet counts of 10,000/ μ L or less, making it difficult to assess the risk of bleeding in patients with very low platelet counts. A similar, albeit much smaller, retrospective study examined the same issue in adult patients with acute leukemia.¹⁷ No hemorrhagic complications were observed after 195 lumbar punctures, including 35 that were done with platelet counts of 20,000 to 30,000/ μ L. With very limited data published data available on severely thrombocytopenic adults, AABB has suggested 50,000/ μ L as a minimum safe platelet count for lumbar puncture in adult patients. For central venous catheter placements, AABB has suggested 20,000/ μ L as a minimum safe platelet count, based on multiple observational studies.¹⁵ Relatively few studies have been published to date addressing the question of a safety minimum platelet count for other types of bedside procedures (thoracentesis, paracentesis, etc.)

Prophylactic Platelets for Major Surgical Procedures

There are currently no data from randomized trials addressing the question of what constitutes an adequate platelet count before surgery. Retrospective studies, though, suggest that patients with platelet counts of 50,000/ μ L or higher are not at excess bleeding risk during surgery. Bishop and colleagues¹⁸ reported a series of 95 patients with acute leukemia who underwent 130 surgical procedures with platelet counts of less than 50,000/ μ L. Intraoperative blood loss exceeded 500 mL in only 7% of cases. No relationship was seen between the preoperative platelet count and surgical blood loss. These data suggest that prophylactic platelet transfusions need not be administered before surgery when the preoperative platelet count is at least 50,000/ μ L. This rule of thumb is thought to apply to most types of surgery (cardiac, orthopedic, and so on). For a few types of surgeries, however, requiring a higher platelet count (70,000–100,000/ μ L) is traditional, although no published data currently exist either to support or refute this approach. These settings include neurosurgery, retinal surgeries, and other procedures in which the risk is not that the patient may exsanguinate but rather that even a minor bleed

might cause clinically significant damage in a vulnerable vital structure such as the brain.

ADVERSE EFFECTS OF PLATELET TRANSFUSION

Infectious Risks

Platelets are associated with essentially the same range of infectious pathogens as other blood components, but septic transfusion reactions caused by bacterially contaminated units comprise a unique risk of platelet transfusion. Over time, improvements in donor screening virtually eliminated the risk of transfusion transmission of hepatitis B virus, hepatitis C virus, and HIV. The risk of septic transfusion reactions remained fairly constant over this same time period, so eventually, platelet bacterial contamination became, by default, the most frequent infectious risk of transfusion. Unlike other blood components, which are stored either refrigerated or frozen, platelets are stored at room temperature. The reason is that if platelets are refrigerated before transfusion, they are cleared rapidly from the recipient's circulation.¹⁹ Although room temperature storage allows transfused platelets to circulate in vivo, it has the downside of promoting bacterial growth. Because of this risk, platelet storage is ordinarily limited to only 5 days, making platelet inventory management extremely challenging.

In the 1990s, numerous studies demonstrated that contaminating bacteria, usually representing skin flora from the donor, could be cultured out of approximately 1 of 3000 platelet units. Clinically apparent septic transfusion reactions were thought to occur after approximately 1 of 25,000 platelet transfusions, although there is considerable uncertainty around this point estimate. In response to the issue, AABB developed the following standard:

5.1.5.1 The blood bank or transfusion service shall have methods to limit and detect or inactivate bacteria in all platelet components. Standard 5.6.2 applies [skin disinfection].¹

How this standard is being met varies by facility. Many blood collection centers have begun routinely culturing platelet units using an automated culture system. The BacT/ALERT system (BioMerieux), used by many centers, works by continuously monitoring for bacterial production of CO₂ within culture bottles. Platelet units are sampled on the day after collection. The samples are cultured for a period of time, typically 24 hours, and if the cultures fail to produce abnormal levels of CO₂, the product is released into inventory. Overall, culture-based bacterial screening appears to have decreased, but not eliminated, the risk of septic reactions.²⁰ Rapid, point-of-issue tests that can be used to test the sterility of a platelet unit just before issue have also been developed, but are not widely used due to issues of logistics and cost. Reducing the bacterial risk further may ultimately require alternative approaches, such as pathogen reduction.²¹ Pathogen inactivation systems, using photoactivated reagents such as amotosalen or riboflavin plus ultraviolet (UV) light, can provide up to 6 logs of killing of spiked virus or bacteria within 1 unit of platelets. Such systems have been used in Europe and elsewhere, and in 2015, a pathogen reduction system for platelets and plasma was licensed for use in the U.S.²²

Allergic and Febrile Nonhemolytic Transfusion Reactions

The typical RBC unit contains approximately 20 mL of plasma. Platelet units contain far more plasma, approximately 200 mL on average. There are multiple potential adverse effects associated with this large plasma content. Indeed, in the PLADO trial, higher platelet doses were associated with significantly increased risk of transfusion-related adverse events.²³ Febrile nonhemolytic reactions, defined as an increase in temperature of more than 1°C, are the most common reactions seen after platelet transfusion. In a classic study, Heddle and

colleagues²⁴ demonstrated that the plasma component of platelet units, rather than the cellular component, causes most reactions. Cytokines that accumulate during product storage have been implicated. Allergic transfusion reactions are the second most-common type of adverse event associated with platelet transfusion.²³ Allergic reactions to blood products occur when the recipient has a preexisting allergy to a plasma protein component. Allergic reactions range from mild, uncomplicated urticarial reactions (most common) to full-blown anaphylaxis. Platelet Additive Solution (PAS) platelet units are those in which a preservative solution replaces most of the residual plasma. Using PAS platelets has been shown to reduce the risk of allergic reactions.²⁵

ABO and Hemolytic Reactions to Platelets

Whenever possible, platelet units are assigned so as to match the donor plasma with recipient RBC type. For example, a type A patient would ordinarily receive type A or AB platelets, which do not contain anti-A antibody. When platelet inventories are constrained, however, it is common for blood banks to issue ABO-incompatible platelets. For example, a type A patient might receive type O platelets, containing anti-A. The passive transfusion of donor anti-A or anti-B to a patient usually does not cause adverse sequelae. Rarely, however, hemolysis may be observed. Most often, this occurs with units from type O donors, who occasionally have high titer anti-A, anti-B, or anti-A,B antibody. In a typical type O adult, the titer of circulating anti-A is on the order of 128 to 256. Some donors, however, have anti-A titers of 10,000 or higher. Recipients of products from donors with high-titer anti-A (and less frequently, anti-B) rarely do have clinically apparent hemolysis, and a small number of fatalities have been reported.²⁶ This is considered to be a low-risk event, but it may be on the rise in the United States because of the increased number of single-donor apheresis platelet units used. One strategy to deal with this issue is to measure the anti-A/B titer on all platelet donors; components exceeding a threshold titer are assigned to type-specific recipients. An alternate strategy is to reduce the load of plasma in a platelet unit before transfusing the unit to a non-ABO-identical recipient, either by washing or concentrating the unit, or by using a PAS unit (above.)

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is an acute respiratory distress syndrome associated with the transfusion of any plasma-containing blood component, including platelets.²⁷ Most cases of TRALI appear to be precipitated by the passive transfusion of donor anti-HLA or (less commonly) anti-neutrophil antibody. It is believed that products containing higher volumes of plasma such as fresh-frozen plasma (FFP) and apheresis platelets carry a higher risk of TRALI. Approximately one-third of female blood donors have circulating anti-HLA antibody because of prior sensitization during pregnancy. To help mitigate against the risk of TRALI, many countries, including the United States, now produce FFP from the blood of male donors only. Although this strategy has been relatively easy to apply to FFP production, female platelet donors are still needed to ensure an adequate platelet supply. A variety of strategies are being implemented to screen female platelet donors for anti-HLA antibody and to defer women who are antibody positive.

D Sensitization

The Rh(D) antigen is the most immunogenic RBC protein antigen. More than 80% of individuals who are D-negative will form anti-D after a single D-positive RBC transfusion. Anti-D is associated with both hemolytic transfusion reactions and hemolytic disease of the fetus and newborn. For this reason, it is standard practice to provide D-negative individuals exclusively with D-negative RBC units.

Platelet units contain a small number of contaminating RBCs. In the case of whole blood-derived platelet concentrates, approximately 0.3 to 0.5 mL RBCs may be present. In contrast, current apheresis platelets contain far fewer RBCs (≈ 0.0002 to 0.0007 mL per unit). When possible, D-negative platelet units are given to D-negative recipients. However, inventory constraints often force blood banks to issue D-positive platelet products to D-negative recipients. Transfusion of such units is associated with a low but nonzero risk of sensitization and formation of anti-D. D sensitization can be prevented by administering Rh immune globulin, as is done to prevent fetomaternal Rh sensitization in D-negative mothers of D-positive children. The risk of sensitization is very low among D-negative immunocompromised patients transfused with D-positive platelets (e.g., HSCT patients).²⁸ In this setting, the value of Rh immune globulin (RhIG) prophylaxis appears to be low.

PLATELET REFRACTORINESS

Causes of Refractoriness to Platelet Transfusion

Platelet refractoriness is defined as an inappropriately low platelet increment after repeated platelet transfusions. It can be caused by nonimmune or immune factors (Table 112.1). The most commonly reported nonimmune causes of platelet refractoriness include fever, sepsis, bleeding, splenomegaly, and disseminated intravascular coagulation. In a small subset of cases, platelet refractoriness is immune mediated. Platelets express HLA class I antigens, ABO antigens, and several platelet-specific antigens. Any of these molecules may potentially serve as an immune stimulus in a transfusion recipient. Whereas antibodies directed against HLA molecules are responsible for most cases of immune-mediated platelet refractoriness, antibodies to the human platelet antigens (anti-HPA) are less frequently implicated.

Diagnosis of Platelet Refractoriness

Because fewer than half of all platelet-refractory patients have demonstrable anti-HLA or antiplatelet antibodies, evaluation of both an immediate response to platelet transfusion and an 18- to 24-hour posttransfusion platelet survival is needed to help establish the cause of platelet refractoriness. Platelet counts obtained from 10 minutes to 1 hour after transfusion that repeatedly fail to demonstrate a corrected count increment of more than $5000/\mu\text{L}$ usually indicate immune-mediated platelet refractoriness. If the 10-minute to 1-hour posttransfusion platelet count shows a reasonable increment but the platelet count falls back to baseline by 18 to 24 hours, a nonimmune mechanism of refractoriness may be presumed (see Table 112.1). In cases of suspected immune-mediated refractoriness, HLA antibody screening (panel reactive antibody [PRA]) provides valuable supporting evidence that allosensitization has occurred.²⁹ A patient with a PRA greater than 70% may be considered to be “severely immunized” and a good candidate for HLA-matched platelets (below).

Detection of Anti-Human Leukocyte Antigen Antibodies

Several assays are available to detect the presence of anti-HLA class I antibodies in the serum of alloimmunized patients. Years ago, the most commonly used test was the lymphocytotoxicity assay (LCA). The results of the LCA correlate well with the response to platelet transfusion. However, this assay does not detect anti-HLA antibodies that do not activate complement. The anti-HLA antibodies can also be detected using an HLA-specific solid-phase enzyme-linked immunosorbent assay, glycoprotein-specific monoclonal antibody-specific immobilization of platelet antigens, or flow cytometric detection of antibody binding to beads coated with purified HLA antigens. The flow cytometry-based methodology has significantly improved sensitivity over LCA and, similar to solid-phase assays, it can detect both complement-fixing and noncomplement-fixing antibodies.

Anti-HPA antibodies
ABO mismatch
Drug-dependent antibodies

HLA, Human leukocyte antigen; HPA, human platelet antigen.

Detection of Antiplatelet Antibodies

The most commonly used methods for detection of anti-HPA antibodies are solid-phase assays using purified platelet antigens for detection of antibody specificity. However, testing for anti-HPA antibodies is not typically performed in the workup of platelet refractory patients, mainly because the importance of these antibodies in causing clinical refractoriness is not well established.

Prevention of Alloimmunization

Although they express HLA class I antigens, platelets themselves are fairly weak immunogens. It has been shown that contaminating leukocytes in platelet products are primarily responsible for stimulating HLA antibody formation in platelet transfusion recipients. Thus removing WBCs from blood products (leukoreduction) is an essential means of preventing alloimmunization and subsequent platelet refractoriness. The definitive study showing this was the Trial to Reduce Alloimmunization to Platelets (TRAP study)⁵ that compared alloimmunization rates in 530 newly diagnosed patients with acute myeloid leukemia randomized to receive unmodified, pooled platelet concentrates (control); filtered, pooled platelet concentrates (F-PC); filtered single-donor apheresis platelets (F-AP); or UV-B-irradiated pooled platelet concentrates (UVB-PC). Anti-HLA antibodies were detected in 45% of control participants compared with 17% to 21% of patients receiving modified platelets. A total of 13% of control group patients became platelet refractory versus only 3% in the F-PC group, 4% in the F-AP group, and 5% in the UVB-PC group.

Management of Platelet-Refractory Patients

When platelet refractoriness has been demonstrated, several strategies may facilitate achieving therapeutic platelet increments in vivo (Table 112.2). A trial of ABO-matched, fresh (1–2 days old) platelets may be helpful. In cases of immune-mediated refractoriness, a trial of HLA-matched platelets, antigen-negative platelets, or cross-matched platelets should be considered. The basic principles for selection of HLA-matched platelets are outlined in Table 112.3. In most cases, alloimmune refractory patients will show some degree of response to HLA-matched platelets. Because of the high degree of polymorphism of the HLA loci, it is often not possible to find perfect HLA-A and HLA-B locus matches, leading to the use of platelets mismatched at one or more loci (Table 112.4). In general, transfusion of grade A- or BU-matched platelets can result in an increase in platelet count that is superior to platelet increment obtained using either cross matched platelets or platelets with different degrees of HLA mismatching (BX, C, or D). An additional step that may help in finding compatible

TABLE 112.2 Management of the Platelet-Refractory Patient

Obtain 10-minute to 1-hour posttransfusion platelet count on two occasions.

If there is an appropriate increment in platelet count after a single platelet transfusion, continue to transfuse random platelets and treat nonimmune factors associated with decreased platelet survival such as sepsis and DIC, discontinue offending drugs, and so on.

If the 10-minute to 1-hour posttransfusion platelet counts demonstrate no platelet increment (or only a marginal increment), obtain the patient's HLA type and screen the patient for the presence of anti-HLA antibodies (panel reactive antibody test).

While awaiting HLA antigen typing and antibody screening results, consider transfusion of "fresh" (<3 days old) ABO-matched platelets.

If PRA shows less than 20% reactivity, continue with "fresh" ABO-matched random platelets.

If PRA shows more than 20% reactivity, obtain anti-HLA antibody specificity. Use the recipient's HLA typing information to locate grade A or B matched platelet units for transfusion. Avoid transfusion of platelets containing antigens against which the recipient has antibodies. Consider recruiting recipient's family for platelet donation.

Transfusion of cross match-compatible platelets is an option if there is a poor response to grade A- or B-matched platelets or if the recipient has antibodies to platelet-specific antigens.

All HLA-matched or cross-matched platelet units must be irradiated before transfusion to prevent transfusion-associated GVHD.

DIC, Disseminated intravascular coagulation; GVHD, graft-versus-host disease; HLA, human leukocyte antigen; PRA, panel reactive antibody.

TABLE 112.3 Traditional Platelet Selection Guidelines for Refractoriness Caused by Alloimmunization

ABO antigens are expressed on platelets. Consider transfusion of ABO-matched platelets while awaiting the recipient's HLA type and antibody specificity.

Platelet matching for the recipient's HLA-A and HLA-B antigens is important.

Platelet matching for the recipient's HLA-C antigens is not essential. Determine the antigen specificity of recipient's antiplatelet antibodies and try to transfuse antigen negative platelets.

Some HLA antigens may be weakly expressed on platelets. Consider giving platelets mismatched for those antigens (e.g., HLA-B12 and its splits B44, B45).

If HLA-matched platelets are unavailable, consider transfusion of platelets mismatched for HLA antigens that are serologically cross-reactive with the recipient's HLA antigens.

If platelets mismatched for serologically cross-reactive antigens are not effective, matching for HLA-associated antigen systems such as Bw4/Bw6 may be helpful.

HLA, Human leukocyte antigen.

platelets is flow cytometric detection of anti-HLA antibody specificity using single HLA antigen-coated beads. This information can be used to find donors that may be HLA mismatched with the recipient, but whose platelets lack the antigens to which the patient has specific antibodies. Furthermore, family members may be considered as platelet donors in addition to the available pool of HLA-matched volunteer donors. As an alternative to HLA antigen matching, patients may benefit from receiving donor platelets that are cross match compatible with the patient's serum. The major benefit of cross matching is a potentially larger pool of donors that would have been excluded by strict HLA antigen matching. Also, platelet cross matching may be helpful in cases of refractoriness caused by antibodies directed against platelet-specific antigens.³⁰

TABLE 112.4 Grades of Human Leukocyte Antigen–Matched Platelets

Match Grade	Description
A	4-antigen match (donor and recipient match at both HLA-A and HLA-B loci)
B1U	1 antigen unknown or blank (e.g., donor is: A2, –; B5, 27)
B1X	1 cross-reactive group ^a
B2UX	1 antigen blank and 1 cross-reactive ^a
C	1 mismatched antigen present
D	≥2 mismatched antigens present
R	Random

^aThe clusters of human leukocyte antigen (HLA) that share antigenic epitopes can be classified into cross-reactive antigen groups. Antibodies recognizing one HLA molecule within the group cross-react with other members of the same group.

Adapted from Brecher ME, editor: *Technical manual*, ed 15, Bethesda, MD, 2005, American Association of Blood Banks.

The most challenging cases are the rare instances involving immune-refractory patients who are actively bleeding and HLA-matched platelets or cross matched platelets are either ineffective or unavailable. In such cases, patients are typically transfused with repeated doses of random HLA-incompatible platelets during hemorrhagic episodes. The efficacy of this practice is unclear.

HUMAN LEUKOCYTE ANTIGEN AND HUMAN NEUTROPHIL ANTIGEN SYSTEMS

Ena Wang, Sharon Adams, David F. Stroncek, and Francesco M. Marincola

This chapter reviews human leukocyte antigen (HLA) and human neutrophil antigen (HNA) systems. A general background of the structure, function, and nomenclature of both systems and their relevance in clinical hematology is presented. Analysis of HLA gene products is applied in clinical settings (1) to select compatible donor-recipient pairs for transplantation, (2) to select HLA-compatible single-donor platelet products for thrombocytopenic patients refractory to standard transfusion of random pooled platelets, (3) to screen for genetic factors that may contribute to the prevalence of diseases, and (4) for forensic purposes in which the identity of individuals may contribute to solving legal disputes or criminal investigations. In addition, we discuss new applications that have broadened the relevance of HLA in the area of immune pathology. HLA phenotypes determine the suitability of patients for epitope-specific immunization. Tetrameric HLA/epitope complexes (tHLA) allow enumeration of antigen-specific T-cell responses. Furthermore, molecular identification of T-cell epitopes associated with distinct diseases and characterization of the communication between immune effector cells through HLA–HLA ligand interactions extend the relevance of HLA to biologic fields. These biologic fields encompass natural killer (NK) and cytotoxic T-cell function, antigen recognition in the context of infection, autoimmunity, graft-versus-neoplasia (GVN) effect, and autologous cancer rejection. Finally, the recognition that polymorphism extends to other protein families relevant to immune pathology including cytokines, their receptors, and killer cell-inhibitory receptors has broadened the significance of immunogenetics beyond HLA. Thus this chapter emphasizes the importance of viewing human pathologic conditions through the kaleidoscopic complexity of human polymorphism.

GENETICS, STRUCTURE, AND FUNCTION OF HUMAN LEUKOCYTE ANTIGEN MOLECULES

HLAs embrace a family of genes clustered in the short arm of chromosome 6 as the human version of the major histocompatibility complex (MHC), initially identified in mice as responsible for graft rejection between genetically unrelated strains (transplantation antigens).¹ Credit for the description of the human MHC goes to three individuals. In 1952, Jean Dausset observed that serum of individuals who had received several transfusions contained hemagglutinins (HAs) specific to the donors' leukocytes. In 1958, Rose Payne noted that the only requirement for the development of HAs against leukocytes was a history of previous transfusion or pregnancy and concluded that these antibodies were directed against antigens on the surface of circulating leukocytes. This conclusion was concomitantly and independently confirmed by Jon van Rood, who observed that multiple pregnancies immunize mothers against leukocytes leaked from the fetus into the mother's circulation. Based on these discoveries, the term *human leukocyte antigen* was subsequently adopted.² It should be clarified, however, that this historical name is misleading. HLA molecule expression is neither limited to leukocytes nor do they display, in natural conditions, antigenic behavior. In fact, several are expressed by most somatic cells, and, rather than being antigens, they chaperone protein bioproducts to the cell surface for recognition by

T cells. There is, however, some substance to the name, because HLAs, by virtue of being densely packed on the cell surface, are exposed to recognition in a foreign environment such as allotransplantation or xenoinfusion performed to induce anti-HLA antibodies as diagnostic reagents.

ORGANIZATION OF THE HUMAN LEUKOCYTE ANTIGEN GENES

HLA genes constitute a string of coding sequences that regulate the expression of molecules with similar but not identical function. Residing in a region that spans approximately 4000 kilobases of the short arm of chromosome 6 (Fig. 113.1),³ HLA contains several genes and pseudogenes characterized by sequence homology and functional similarity. Of them, 47 are officially recognized by the World Health Organization (WHO) nomenclature committee and include classic HLA class I and class II genes associated with antigen processing such as proteasomal units PSMB8 and PSMB9, or peptide transport TAP1 and TAP2.⁴ Both HLA and HLA-associated genes can be physically grouped into three subregions according to chromosomal location. In centromeric to telomeric direction, the first is HLA class II region comprising the α - and β -chains of HLA-DR, HLA-DQ, HLA-DP, HLA-DM, and HLA-DO as well as TAP and PSMB. Sandwiched between the class II and class I region, class III region encodes for functionally unrelated genes such as complement components, heat shock proteins, and tumor necrosis factor. The reason for their genetic link to the HLA complex is unknown, but their immunologic function seems more than coincidental. The class I region is mostly telomeric and includes HLA-A, HLA-B, and HLA-C loci; the non-classic HLA-E, HLA-F, and HLA-G loci; and several pseudogenes.

General terminology separates HLA genes into classic and non-classic. Classic HLA genes have been well characterized and are clearly associated with presentation of antigen to immune cells. They are further subdivided into class I (HLA-A, HLA-B, HLA-C) and class II (HLA-DR, HLA-DQ, and HLA-DP). In general, HLA class I and II genes have very similar structure and function.^{5,6} They contain six to eight exons coding for functionally distinct domains (Fig. 113.2). The first exon encodes a leader sequence; the following exons (exons 2 to 4) are highly polymorphic and encode extracellular domains responsible for peptide binding and T cell-antigen receptor (TCR) engagement. Because they are exposed on the cell surface, these domains are also responsible for alloreactivity. The last exons encode a conserved transmembrane and small intracellular domains whose functions are unclear.

Only the heavy chain of HLA class I is encoded in the MHC region. Genes encoding HLA-A, HLA-B, and HLA-C contain three exons coding for α_1 , α_2 , and α_3 extracytoplasmic domains, one transmembrane, and three cytoplasmic domains (Fig. 113.3). The associated class I light chain, β_2 -microglobulin, is encoded on chromosome 15.⁷ By contrast, the HLA class II molecule is composed of a heterodimer of an α -chain and β -chain encoded in the MHC region. Although the genetics are different, the protein product is structurally similar to HLA class I, with two helices resulting in the antigen-presenting part of the molecule (Fig. 113.4).

Fig. 113.1 PHYSICAL MAP OF THE HUMAN LEUKOCYTE ANTIGEN (HLA) GENETIC COMPLEX, ILLUSTRATING THE CLUSTERS OF GENES ACCORDING TO THE CLASS OF ENCODED GENE PRODUCTS. The symbol ψ represents four DRB pseudogenes, designated 7, 8, and 9. Other pseudogenes are shown in *gray*.

Fig. 113.2 ORGANIZATION OF CLASS I AND II MAJOR HISTOCOMPATIBILITY COMPLEX (MHC) GENES. 5'UT and 3'UT, Untranslated regions in the 5' and 3' ends of the gene; α , β , exons encoding extracellular domains. CY, Exon encoding cytoplasmic tail; L, leader sequence; TM, transmembrane exon. (From Germain RN, Malissen B: *Analysis of the expression and function of class-II major histocompatibility complex-encoded molecules by DNA-mediated gene transfer*. Annu Rev Immunol 4:281, 1986.)

All DR molecules use DRA for α -chains but can use alleles coded by DRB1, DRB3, DRB4, or DRB5 for β -chains. DP, DQ, DM, and DO molecules are the product of DPA1 and DPB1, DQA1 and DQB1, DMA and DMB, and DOA and DOB genes, respectively. HLA DRB1 locus is expressed in all HLA haplotypes (the set of HLA alleles derived from the same parental chromosome and therefore genetically linked). However, only one other HLA DR locus is present in each individual chromosome. Thus each haplotype can have either DRB5 (DR1 haplotype); DRB3, DRB4, or DRB5 loci

(DR2 haplotype); DRB4 locus (DR4 and DR7 haplotype); or none (DR8 and DR10 haplotype).³

INHERITANCE AND LINKAGE DISEQUILIBRIUM

Because of their proximity within a short chromosomal distance, HLA genes are inherited en bloc from each parent unless a recombinant event occurs. Thus each HLA haplotype behaves as a unit and is transmitted through generations according to mendelian principles. Because there are four possible genotypes (two from each parent), the probability of genotypic identity between two siblings is 25%. Most HLA phenotypically identical siblings are also HLA genotypically identical, because the genetic pool of derivation is restricted to the parents. In 2% of cases, recombinant HLA haplotypes (a set of genes derived partially from two chromosomes through recombination) deviate from this rule.

The occurrence of HLA haplotypes within a population with a frequency higher than expected from the prevalence of individual alleles is called *linkage disequilibrium*. In large populations, gene frequencies achieve equilibrium within a few generations unless selective pressure influences individuals' survival and mating capacity (Hardy-Weinberg principle). In equilibrium, gene prevalence is maintained based solely on its frequency. Thus, assuming that there were 18, 36, and 8 alleles for the HLA-A, HLA-B, and HLA-C loci, respectively (number of alleles known when this example was described²), theoretically $18 \times 36 \times 8 = 5184$ HLA class I allelic combinations or haplotypes would be possible. Adding HLA class II genes to the calculation yields an astronomical number, making the identification of two HLA-matched individuals unlikely. However, individual alleles occur with different frequency, and an allele that occurs with high frequency is predominant in a given population, such as HLA-A2 in whites and A24 or A11 in Asians.⁸ Because predominant alleles come with the related haplotype, most theoretical permutations never occur, and the chances of identifying matched individuals are much higher than theoretically possible.

Fig. 113.3 THREE-DIMENSIONAL CONFIGURATION OF HLA-A2, MODELED FROM X-RAY CRYSTALLOGRAPHIC STUDIES. *HLA*, Human leukocyte antigen. (From Bjorkman PJ, Saper MA, Samraoui B, et al: *Structure of the human class I histocompatibility antigen, HLA-A2*. *Nature* 329:506, 1987.)

STRUCTURE OF THE HUMAN LEUKOCYTE ANTIGEN CLASS I AND II

The structure of HLA molecules and their relationship with their natural ligand, the TCR, has been well characterized by crystallography.^{9–11} HLA molecules are heterodimer glycoproteins belonging to the immunoglobulin superfamily with common features (Fig. 113.4). This includes two α -helical domains protruding toward the extracellular milieu. Between them lies a flat surface formed by β -sheet structures that contributes to the formation of a groove accommodating peptides generated from intracellular (HLA class I) or extracellular proteins (HLA class II) (Fig. 113.5). The helices/peptide complex is exposed for TCR recognition. Because HLA polymorphism is clustered within the α -helices and β -sheets domains, peptides display variable affinity for distinct HLA alleles.^{12,13} It has been proposed that a given peptide can bind to closely related alleles, and HLA superfamilies with similar binding characteristics have been described.^{14–16} However, peptide binding to related but distinct HLA alleles is associated with conformational dissimilarity caused by differential interaction with variant residues in the binding groove.¹⁷ The TCR interaction with HLA required for productive engagement spans a surface including the peptide and portions of the α - and β -helix.^{11,18–20} This double requirement of interaction between TCR and HLA/peptide complex represents the structural basis for HLA restriction. Degenerate and promiscuous TCR recognition of peptides presented by distinct HLA alleles within the same superfamily has also been described.²¹ Although this concept holds in general, several exceptions can be expected because single amino acid variants in the HLA molecule may disallow binding of a peptide or may not be permissive to TCR engagement.^{22–24}

The binding affinity of a given peptide for an HLA allele can be predicted through algorithms that compile available information to identify amino acid residues that fit distinct pockets of the HLA groove.^{13,25} Several algorithms implement this information with experimental testing based on the refolding capability of HLA heavy chains exposed to known peptide sequences in the presence of β_2 -microglobulin and/or their dissociation rates (see www.bimas.dcrf.nih.gov or www.uni-tuebingen.de/uni/kxi). This is based on the principle that the affinity of a peptide for a given HLA promotes that stability of the noncovalent assembly of heavy chain with β_2 -microglobulin.^{13,26} Finally, peptide binding can be shown by direct elutriation from purified HLA heavy chains.^{12,27}

Fig. 113.4 SCHEMATIC DIAGRAM OF HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS I AND CLASS II MOLECULES POINTING TO THEIR STRUCTURAL SIMILARITY. In both HLA classes, two immunoglobulin-type domains reside close to the cell membrane (α_3 and β_2m for class I and α_2 and β_2 for class II). The other two domains project toward the extracellular milieu with α -helices (α_1 and α_2 for class I and α_1 and β_1 for class II) and a platform of parallel β -sheets that form a peptide-binding groove.

Fig. 113.5 SCHEME OF THE PEPTIDE GROOVE OF A HUMAN LEUKOCYTE ANTIGEN (HLA) CLASS I MOLECULE, FORMED BY THE α_1 AND α_2 DOMAINS AT THE SIDE AND THE β -SHEETS AT THE BOTTOM. The view is looking down on the vertically oriented molecule: the T-cell receptor point of view. (From Bjorkman PJ, Saper MA, Samraoui B, et al: Structure of the human class I histocompatibility antigen, HLA-A2. *Nature* 329:506, 1987.)

Beyond the interactive component of the HLA molecule with TCR, other domains act as coreceptors for the TCR. CD8⁺ cytotoxic T cells bind to the α_3 -domain of HLA class I through CD8, whereas CD4⁺ T cells interact with HLA class II-specific domains. Although the coreceptor-TCR interaction is not an absolute requirement in most cases, it determines HLA class I or II restriction of individual T cells.²⁸ Specific to HLA class I is the assembly with β_2 -microglobulin on stabilization in the presence of high-affinity peptides derived from the cleavage of intracellular proteins (endogenous pathway of antigen presentation).²⁹ Most peptides derive from degradation of self-protein in the cytosol by proteasomes (PSMB) and other proteases.³⁰ Soluble peptides (9 to 10 amino acids long) are then chaperoned into the endosomal compartment by transporter molecules associated with antigen processing (TAP1 and TAP2). Within this compartment, they bind to heavy chains according to each individual's HLA phenotype. The binding and stability of the HLA-peptide complex depends on the affinity of each peptide for a particular allele. If the stability is sufficient, the peptide-loaded HLA migrates to the cell surface. Intracellular pathogens produce proteins that are also degraded by proteasomes into peptides that compete with self-peptides for binding to HLA class I molecules. Thus the function of the endogenous pathway of antigen presentation is to provide information to the extracellular compartment of intracellular events. In physiologic conditions, only self-peptides are presented, and therefore minimal interactions occur with circulating T cells. During infection, pathogen-derived peptides signal cellular infection to T cells, whereas antibodies that cannot cross the cell membrane remain insensitive to intracellular pathogens. Several pathogens, such as cytomegalovirus (CMV), can interfere with this process as well as with reduction of HLA/peptide density on the cell surface and, consequently, diminished T-cell recognition.^{31,32} This escape mechanism can be counteracted by the host through increased susceptibility of virally infected cells to NK cell-mediated cytotoxicity.³³ Reciprocally, viruses can evade NK cells and escape recognition by modulating HLA expression.³⁴⁻³⁶

HLA class II molecules bind to longer peptides derived from the metabolism of molecules endocytosed from the extracellular compartment (exogenous pathway of antigen presentation).²⁹ This is a specialized process used by professional antigen-presenting cells such

as macrophages and dendritic cells. HLA class II molecules are assembled within the endosomal compartment where they are composed of a heterotrimer. This includes the α - and β -chains plus a short invariant chain that stabilizes the molecule by occupying its groove while chaperoning its migration to the endosomal compartment where exogenous antigen is processed. Upon uptake, the exogenous antigen undergoes limited proteolysis in the membrane-bound acidic endosomal compartment (MHC class II peptide-loading compartment, MIIC). Upon entering the MIIC, the pre-HLA class II complex is degraded, and antigenic peptides are loaded with the help of the nonclassical HLA-DM molecule.³⁷

EXPRESSION OF HUMAN LEUKOCYTE ANTIGEN MOLECULES

There are genetic and structural differences between the two classes of HLA alleles. The most striking difference is functional, because HLA class I molecules are expressed by most nucleated cells with the exception of germinal cells, whereas HLA class II molecules are expressed mainly by specialized antigen-presenting cells.^{38,39} HLA class I molecules are also expressed by platelets.⁴⁰ They are responsible for refractoriness after multiple transfusions and sufficiently, though minimally, expressed by reticulocytes to be targets of alloantibodies during hemolytic transfusion reactions.⁴¹⁻⁴⁵ HLA class II proteins are expressed constitutively by cells associated with the initiation of the immune response, such as monocytes, macrophages, and B cells,⁴⁶ or by immune cells activated by cytokines during inflammation. Thus HLA class I molecules instruct the host about the condition of individual cells as potential targets for CD8⁺ cytotoxic T cells responsible for clearing the organisms of altered cells. HLA class II molecules initiate immune responses by taking up pathogen components and presenting them to CD4⁺ helper T cells, which can in turn initiate humoral and facilitate cellular immune responses.

Expression of HLA alleles is sensitive to environmental conditions and can be modulated by cytokines among which interferons play a major role.⁴⁷ This is particularly important for HLA-B and HLA-C normally expressed at a lower density than HLA-A, but are more sensitive to cytokine induction.^{48,49} In addition, HLA class II molecules can be expressed by most cells following cytokine stimulation.^{50,51} Thus the ability of cells to present antigen in association with HLA is strongly influenced by the surrounding environment. This might explain why chronic inflammation induced by alloreactions during graft-versus-host disease (GVHD) may facilitate the presentation of tumor-specific antigens by tumor cells with consequent development of GVN effect. In addition, it might explain how systemic administration of proinflammatory cytokines such as interleukin (IL)-2 may stimulate immune responses by increasing the antigen-presenting ability of cells within the tumor microenvironment.⁵²

HUMAN LEUKOCYTE ANTIGEN POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

A striking characteristic of the HLA system is its extreme polymorphism.⁵³ By chance, most individuals are heterozygote and therefore carry two different alleles for each HLA gene that, being codominant, are equally expressed on the cell surface. Because everybody carries three HLA class I (-A, -B, and -C) and three HLA class II (-DR, -DQ, and -DP) genes, most individuals (with the exception of homozygotes) express six different HLA class I and six different HLA class II molecules on the surface of their cells. This has important functional implications, because HLA polymorphism is clustered in domains of the HLA molecule associated with peptide binding and interaction with the TCR. Thus most individuals have a broad repertoire of molecules capable of presenting different pathogen components to immune cells leading to the belief that HLA polymorphism improves the chances of a given species of surviving infection.⁵⁴ This paradigm is difficult to demonstrate in human pathologic conditions

in which the natural history of infectious diseases rarely correlates with HLA phenotype. An exception is the strong association between HLA-B*5701 and lack of progression to acquired immunodeficiency syndrome of individuals infected with human immunodeficiency virus (HIV).⁵⁵ Associations have been observed between HLA phenotype and predisposition for nasopharyngeal carcinoma.^{56,57} This is of particular interest because nasopharyngeal carcinoma is a virally induced cancer against which T cells can mediate immune surveillance. HLA associations have also been described with less consistency than other virally driven tumors, such as cervical carcinoma,⁵⁸ or immunogenic tumors, such as melanoma.^{59,60}

The difficulty in demonstrating conclusive associations between infectious disease and HLA in humans could be caused by the successful implementation of antigen presentation through a broad repertoire of HLA genes that could compensate for each other in limitations in antigen presentation. Chickens carry a single MHC locus, and their susceptibility to infection appears to be clearly related to MHC. For instance, Kaufman et al.⁵⁴ have shown that chickens carrying a particular Bf (the only MHC class I gene in chickens) allele are fully protected from Rous virus-induced sarcomas, because this allele (B-f12) can bind several antigenic peptides from its proteins. On the contrary, chickens homozygous for B-f4 are killed by the same infection, because this allele cannot bind peptides from sarcoma virus proteins.⁵⁴

HLA polymorphism is the basis of alloimmunization because most individuals are likely to have different HLA molecules on the surface of their cells. Hundreds of HLA alleles have been identified through high-resolution typing, making the chances of two individuals having identical HLA phenotypes extremely low. Thus partial mismatches are commonly accepted in transplantation cases and are at the root of hyperacute, acute, and chronic rejections. Hyperacute rejection is caused by preformed antibodies against donor HLA alleles in patients presensitized by multiple transfusions.⁶¹ Acute and chronic rejection result from a combination of humoral and cellular immune reactivity toward HLA alleles of the donor.^{62,63} In addition to allo-sensitization, HLA alleles can mediate GVHD whereby hematopoietic cells derived from the grafted tissue recognize and reject the host tissues. They do this by identifying polymorphisms of intracellular proteins of the host [minor histocompatibility antigens (mHags)] presented in association with donor-recipient matched HLA alleles.

NONCLASSIC MHC AND MHC CLASS I CHAIN-RELATED MOLECULES

Besides the three ubiquitously expressed highly polymorphic classic HLA class I molecules, humans encode three relatively conserved nonclassic, selectively expressed (HLA-E, HLA-F, and HLA-G) MHC class I genes (also known as MHC-Ib). These evolved at different rates in primates reflecting differential involvement in the modulation of immune responses.^{4,64,65} In addition, these molecules are characterized by unique patterns of transcription, protein structure, and immunologic function.⁶⁶

The MHC class I-related chain genes (MICA and MICB) are located within the MHC region and are characterized by high polymorphism (more than 50 alleles so far identified).⁶⁷ The molecules encoded by these genes do not appear to bind peptides or associate with β_2 -microglobulin. Their polymorphic variants are not concentrated around the peptide-binding groove, yet they seem to have functional significance, because most mutations are nonsynonymous, suggesting selective pressure as a driving force. Their tissue distribution is restricted to epithelial and endothelial cells and fibroblasts. It appears that MIC genes modulate the function of NK and CD8⁺ T cells by binding the NKG2D stimulating receptor.⁶⁸ Also, MIC genes have been implicated in transplant rejection because alloantibodies against them are often found in transplant recipients that may exert complement-mediated cytotoxicity against endothelial cells from the graft.

Other unusual MHC-like molecules are present in the genome and have disparate functions, including presentation of lipid antigens

(CD1), transport of immunoglobulins (Fc receptor), and regulation of iron metabolism (hemochromatosis gene product).⁶⁹ Contrary to classic MHC class I genes that are constitutively expressed, nonclassic MHC and MIC gene expression is dependent on stimulation by proinflammatory cytokines.⁷⁰ In addition, two nonclassic MHC class II proteins (HLA-DM and HLA-DO) have been described as mediators of peptide exchange by stabilizing empty MHC class II molecules.³⁷ Finally, it is possible that several nonclassic MHC molecules whose function is to present peptides to lymphocytes may be present throughout the genome. Because of their limited polymorphism, however, these genes may have evolved to serve specialized presentation functions.⁷¹

Characterized by low polymorphism, the regulation of HLA-G expression follows a nonclassic behavior. Aberrant cytokine-responsive regulatory sequences may be responsible for its predominant expression by trophoblasts that do not express other HLA proteins.⁷²⁻⁷⁵ It may also account for its low levels in a variety of human tissues.⁷⁶ Lack of responsiveness to common immunostimulatory pathways (NF- κ B, interferon- γ , or CIITA) is most pronounced in HLA-G cells and is shared by other nonclassic MHC such as HLA-E.⁷⁷ Also, HLA-G is expressed in a variety of cancers.⁷² It is hard to know what the relevance of HLA-G expression is, because it can occur in various membrane-bound or soluble isoforms with distinct functional characteristics.⁷² Functional isoforms that include the α -1 and α -2 domains bind and present peptides from cytoplasmic proteins.⁷⁸ Because of the minimal polymorphism, however, the repertoire of peptides presented is likely to be limited, suggesting that peptide binding is necessary to stabilize the molecule rather than being involved in antigen presentation.

Functionally, HLA-G is thought to modulate the function of NK cells through interactions with their inhibitory receptors.⁷⁹ In addition, the HLA-G leader sequence contains a peptide that can bind and stabilize the expression of HLA-E, which, in turn, inhibits NK cells.⁸⁰ Because the HLA-G–derived leader peptide has the strongest affinity for HLA-E (among all HLA class I molecules), it is likely that HLA-G is a powerful direct and indirect inhibitor of NK cells, reducing the risk for cardiac rejection or inducing immune escape of cancer cells.^{72,81} Although much has been published about the immunoregulatory role of HLA-G, its true function remains unknown, principally because of discordant findings reported by various groups.⁷⁴ With the goal of achieving consensus, a workshop was recently organized to standardize methods of analysis of HLA-G.⁶⁶

HLA-E is minimally polymorphic,⁴ binds hydrophobic peptides from other HLA class I leader sequences, and interacts with CD94/NKG2 lectin-like receptors present predominately on NK and partially on CD8⁺ T cells.⁸²⁻⁸⁵ The peptide binding is highly specific and stabilizes the HLA-E protein, allowing its migration to the cell surface. Thus surface density of HLA-E is an indirect reflection of the number of HLA class I alleles expressed by a cell.⁸⁶ The interaction of HLA-E with CD94/NKG2 protects HLA-E–expressing cells from killing. Cells damaged by viral infection or neoplastic degeneration may lose HLA class I expression. As a backup mechanism of protection, reduced HLA class I expression results in decreased expression of HLA-E, leading to vulnerability to NK cells.⁸⁷ Some viruses express mimic peptides that bind and stabilize HLA-E so that, although classic MHC molecules are downregulated, HLA-E expression is maintained, allowing the pathogen to simultaneously escape CD8⁺ T- and NK-cell killing.⁸⁸

The function of HLA-F remains enigmatic. Its transcriptional regulation is closest to classic HLA molecules in that it can be induced by NF- κ B, interferon regulatory factor-1, and class II trans-activator.⁸⁹ However, contrary to classic HLA molecules, HLA-F is predominantly empty, mostly intracellular, with a restricted pattern of expression.⁹⁰ Its tissue distribution appears to be limited to B cells, therefore it is mostly found in lymphatic organs.⁹⁰ Structural studies suggest that HLA-F is a peptide-binding molecule and may reach the cell surface under favorable conditions when a suitable peptide is present.⁹¹ Once on the cell surface, HLA-F may interact with the effector-cell receptors IL-T2 and IL-T4, as suggested by HLA-F tetrameric complexes-binding studies.⁹¹ Thus it is possible that in specific yet

unknown conditions, HLA-F may modulate the function of immune effector cells similarly to HLA-E and HLA-G.

NON-HUMAN LEUKOCYTE ANTIGEN POLYMORPHISM AND ITS CLINICAL SIGNIFICANCE

Although this chapter is dedicated to HLA, it would be incomplete without mentioning the increasingly recognized polymorphisms of other immune modulators. The significance of non-HLA polymorphism is evidenced by the development of GVHD in the presence of HLA identical matching among relatives. As recently summarized,⁹² three general areas of polymorphism are being investigated: NK cell-receptor genes, mHags, and cytokines. Over the last decade, much progress has been made in identifying the mechanisms of action of NK cells. A major breakthrough was made in the discovery of HLA class I-specific inhibitory receptors and in the role they play in the regulation of NK function with consequent effects on the eradication of hematologic malignancies, prevention of graft rejection, or induction of GVHD.⁹³ NK cells recognize HLA molecules via killer immunoglobulin-like receptors (KIRs). The regulation of NK cell function by KIRs is further discussed in [Chapter 22](#). KIRs are glycoproteins encoded by at least 17 different genes located on chromosome 19q13.4.⁹⁴ All human KIR genes derive from a gene encoding three immunoglobulin (Ig)-like domains (D0, D1, and D2) and a long cytoplasmic tail. However, the KIRs genes are diverse and may encode either two or three Ig-like domains and either a long or short cytoplasmic tail ([Table 113.1](#)). The long cytoplasmic tails contain one or two immunoreceptor tyrosine-based inhibition motifs.⁹⁵ Although KIR molecules with long cytoplasmic tails inhibit NK cytotoxicity, those with short tails do not. The names given to KIR genes are based on the molecule that they encode. The first digit corresponds to the number of Ig-like domains in the molecule and a *D* denotes domain. The *D* is followed by either an *L* for long cytoplasmic tail or *S* for short cytoplasmic tail or *p* for a pseudogene. The last digit indicates the number of the KIR gene.⁹⁶

Expression of KIR in individual NK cells is complex because NK cells may express several members of the KIR family. The number of KIR genes in each haplotype varies among individuals. The most common haplotype is known as group A, and is made up of six genes (2DL1, 2DL2 or 2DL3, 3DL1, 3DL2, 2DS4, and 2DL4). Various KIR genes can recognize different HLA-A, HLA-B, and HLA-C molecules. HLA-C antigens can be divided into two groups based on polymorphisms at amino acid positions 77 and 80 of their class I heavy chains. One group has asparagine (Asn) at position 77 and lysine (Lys) at 80 and the other has serine (Ser) at 77 and Asn at 80. Some KIRs recognize HLA-C antigens with Asn 77 and Lys 80, whereas other KIRs recognize HLA-C antigens with Ser 77 and Lys 80. The polymorphism at position 80 is most important. Another group of KIR reacts with HLA-B antigens that carry specific combinations of amino acids at positions 77 and 83 of the heavy chain that

forms HLA-Bw4. Because a single KIR can interact with multiple HLA class I alleles, KIR recognition of HLA class I molecules is degenerate. Another NK inhibitory receptor (CD94-NKG2A) recognizes the nonclassical HLA-E molecule. In addition, each of the KIR genes is extensively polymorphic.

Because the genes for KIR, HLA, and CD94-NKG2A are located in separate chromosomes, they segregate independently and consequently individuals can carry genes for KIR for which there is no correspondent HLA ligand.⁹⁷ As HLA-E is expressed in all individuals, NK cells that bear the CD94-NKG2A receptor are not alloreactive. Because the specificity of KIR for their ligands is broad and each individual carries several KIRs, it is likely that in most cases all NK cells of a given person express at least one KIR that is specific for a self-HLA class I allele. Thus in autologous settings, NK cells kill only aberrant cells that have lost HLA class I expression. By contrast, NK cells can kill allogeneic cells that do not express HLA class I alleles recognized by their KIR. Thus, by knowing the KIR repertoire of a given transplant recipient and the HLA type of the donor, it would theoretically be possible to predict the likelihood of an NK-mediated alloreaction. Importantly, it appears that alloreactive NK cells undergo proliferation on exposure to the stimulatory cells and therefore can preferentially expand in the presence of allogeneic tissue. NK cells also express activating receptors that are responsible for their lytic activity. Although the identity of the ligands for these receptors has not been identified, it is possible that they are expressed primarily by activated or proliferating cells. It is therefore possible that during the inflammatory process induced in allogeneic conditions, normal cells can become activated by cytokines and express ligands, which are responsible for NK activation in the absence of HLA class I molecules reactive with the inhibitory receptors.⁹³ The relevance of KIR in transplantation has been well studied in the context of haploidentical hematopoietic transplantation. In this case, several combinations are possible: NK cells from the graft express KIRs that do not interact with the donor's HLA (graft-versus-host alloreactivity). It seems that the presence of graft-versus-host reactive NK cells associated with incompatibilities between donor and recipient (especially HLA-C families) has favorable effects on the outcome of acute myeloid leukemia.⁹⁸ Alternatively, a good match may be present between graft NK and host HLA as well as between host NK and graft HLA. In such a case, no alloreactivity occurs. Finally, the graft's HLA type may be unsuitable for the host's NK repertoire, and the host's reactivity may lead to graft rejection. Alloreactive grafted NK cells seem to prevent GVHD while inducing GVN.⁹³

Like HLA, KIR genes are polymorphic, and their variability is clustered in positions likely to affect the overall structure of the molecule. The relevance of KIR gene polymorphism in the outcome of hematopoietic stem cell transplantation (HSCT) is unclear. It appears that the risk for GVHD is highest in the context of unrelated HSCT when the recipient KIR genotype is included in the donor KIR genotype.⁹⁹ These results show that compatibility between KIR genotypes themselves may influence the outcome of HSCT.

The mHags are represented by polymorphic molecules whose peptides containing variant sequences are presented by HLA alleles. They have been shown to be targets of cytotoxic T cells, which can lyse leukemia cells.^{98,100} In addition, some mHags are selectively expressed by neoplastic cells.¹⁰¹ At present, little is known about the identity of mHag epitopes in the context of various HLA types and their significance in the development of GVHD and GVN.

Cytokines are another large family of molecules associated with antigen recognition, graft rejection, and GVHD. Their polymorphism is becoming an important area of investigation in the context of transplantation, autoimmunity, and cancer.¹⁰² Polymorphic sites reside in regulatory regions so that genetic variants are associated with high or low production of a given cytokine rather than differences in its function. A Web site compiles information about cytokine polymorphism (www.bris.ac.uk/Depts/PathAndMicro/services/GAI/cytokine4.htm). Although no consensus has been achieved yet, several studies have shown associations between various cytokine genotypes and propensity toward disease and transplant outcome. These studies have been summarized elsewhere.^{92,103} A strong

TABLE 113.1 HLA Class I Alleles Recognized by Different Killer Immunoglobulin-Like Receptors

KIR	HLA Class I Allele	Amino Acid Sequence Motif
P58.1 (KIR2DL1)	HLA-C2, HLA-C4, HLA-C5, HLA-C6	Asn 77, Lys 80
P58.2 (KIR2DL2/3)	HLA-C1, HLA-C3, HLA-C7, HLA-C8	Ser 77, Asn 80

association was recently noted between a low IL-10 producer genotype and a tendency to develop melanoma and prostate cancer.^{104,105}

HUMAN LEUKOCYTE ANTIGEN NOMENCLATURE

The history of the HLA system nomenclature was summarized by Sir Walter Bodmer who, together with Ruggero Ceppellini, was primarily involved in its development.¹⁰⁶ It began as HL-A, for *human leukocyte locus A*. With the recognition that HLA molecules are encoded by more than one locus, the A came to stand for *antigen* and a locus designation was added after HLA (i.e., HLA-A, HLA-B, HLA-C, HLA-D, etc.).² From then on, the WHO has updated nomenclature on a quarterly basis. The most recent update was assigned in January 2015, as seen in Table 113.2.⁴ At present, two systems are used. An immunologically defined nomenclature is based on the identification of HLA antigens on the surface of leukocytes. Therefore HLA phenotypes described by immunologic methods are

conventionally called *HLA antigens*.¹⁰⁷ The second system is based on the molecular identification of nucleotide sequences in genomic deoxyribonucleic acid (DNA), and results are conventionally referred to as *HLA alleles*. Because molecular typing has higher resolution, it has gained increasing popularity.

IMMUNOLOGICALLY DEFINED HUMAN LEUKOCYTE ANTIGEN NOMENCLATURE

Immunologically defined nomenclature follows this rule: HLA separated by a hyphen from a capital letter identifying the locus encoding distinct HLA class I (-A, -B, -C) or class II (-DR, -DQ, -DP) antigens. The letter is followed by a number that identifies a serologic family of alleles sharing epitopes recognized by alloantibodies or alloreactive cytotoxic T cells. With improved understanding of the molecular genetics of the HLA region, various appendages have been removed from the HLA nomenclature. For instance, the letter *w* was used to

**TABLE
113.2**

Name of Genes in the HLA Region Considered by the WHO Nomenclature Committee

Name	Previous Equivalents	Molecular Characteristics	No. of Alleles January (2015)
HLA-A	–	Class I α -chain	3107
HLA-B	–	Class I α -chain	3887
HLA-C	–	Class I α -chain	2623
HLA-E	E, “6.2”	Associated with class I 6.2-kBa Hind III fragment	17
HLA-F	F, “5.4”	Associated with class I 5.4-kBa Hind III fragment	22
HLA-G	G, “6.0”	Associated with class I 6.0-kBa Hind III fragment	50
HLA-H	H, AR, “12.4”, HLA-54	Pseudogene association with class I 5.4-kBa Hind III fragment	12
HLA-J	cda 12, HLA-59	Pseudogene association with class I 5.9-kBa Hind III fragment	9
HLA-K	HLA-70	Pseudogene association with class I 7.0-kBa Hind III fragment	6
HLA-L	HLA-92	Pseudogene association with class I 9.2-kBa Hind III fragment	5
HLA-X	–	Class I gene fragment	0
HLA-DRA	DR α	DR α -chain	7
HLA-DRB1	DR β I, DR1B	DR β I determining specificity for DR1, DR2, DR3, etc.	1726
HLA-DRB2	DR β II2	Pseudogene with DR β -like sequence	1
HLA-DRB3	DR β III, DR3B	DR β 3 determining DR52, Dw24, w25, -26 specificity	59
HLA-DRB4	DR β IV, DR4B	DR β 4 determining DR53 specificity	15
HLA-DRB5	DR β V, DR5B	DR β 5 determining DR52, Dw24, w25, -26 specificity	21
HLA-DRB6	DRB σ , DRB σ	Pseudogene found in DR1, DR2, and DR10 haplotypes	3
HLA-DRB7	DRB ψ 1	Pseudogene found in DR4, DR7, and DR9 haplotypes	2
HLA-DRB8	DRB ψ 2	Pseudogene found in DR4, DR7, and DR9 haplotypes	1
HLA-DRB9	M 4.2 β exon	Pseudogene isolated fragment	1
HLA-DQA1	DQ α 1, DQ1A	DQ α -chain as expressed	54
HLA-DQB1	DQ β 1, DQ1B	DQ β -chain as expressed	780
HLA-DOA	DNA, DZ α , DO α	DO α -chain	12
HLA-DOB	DO β	DO β -chain	13
HLA-DMA	RING 6	DM α -chain	7
HLA-DMB	RING 7	DM β -chain	13
HLA-DPA1	DP α 1, DP1A	DP α -chain as expressed	33
HLA-DPB1	DP β 1, DP1B	DP β -chain as expressed	520
TAP1	ABCB2, RING4	ABC (ATP-binding cassette) transporter	12
TAP2	ABCB3, RING 11	ABC (ATP-binding cassette) transporter	12

Data from Marsh SGE, Albert AD, Bodmer WF, et al: Nomenclature for factors of the HLA system, 2010. *Tissue Antigens* 75:291, 2010.

indicate a provisional assignment, and this has been discontinued, but it is occasionally added to HLA-C antigen nomenclature to distinguish it from complement genes; DP and DW also maintained this letter to reinforce the dependency of their immune identification predominantly through cellular techniques. Finally, HLA-Bw4 and HLA-Bw6 retain the *w* to emphasize that the public epitopes are shared by several HLA-B and some HLA-A antigens. More recently, a bridge between immunologic and molecular nomenclature has been proposed whereby HLA antigens that encompass a single gene product can be assigned a two-digit numeric extension corresponding to the molecular nomenclature for that allele.¹⁰⁸

SEQUENCE-DEFINED ALLELIC NOMENCLATURE

The 10th International Histocompatibility Workshop recommended in 1987 a sequence-based nomenclature to describe alleles not distinguishable by immunologic methods.¹⁰⁸ Since then, the number of HLA alleles has rapidly increased. As of January 2015, a total of 13,023 alleles for HLA exist. This is a drastic increase from the original numbers established in 2003. Other designations are summarized in Table 113.2. HLA designates molecules belonging to the human MHC followed by the locus (-A, -B, etc.). Alleles are then identified after an asterisk (*). Each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons. The length of the allele designation is dependent on the sequence of the allele and that of its nearest relative. All alleles receive at least a four digit name that corresponds to the first two sets of digits, longer names are only assigned when necessary. The digits before the first colon describe the type, which often corresponds to the serologic antigen carried by an allotype. The next set of digits are used to list the subtypes, numbers being assigned in the order that the DNA sequences have been determined. Alleles whose numbers differ in the two sets of digits must differ in one or more nucleotide substitutions that change the amino acid sequence of the encoded protein. Alleles that differ only by synonymous nucleotide substitutions (also called silent or noncoding substitutions) within the coding sequence are distinguished by the use of the third set of digits. Alleles that only differ by sequence polymorphisms in the introns or in the 5' or 3' untranslated regions that flank the exons and introns are distinguished by the use of the fourth set of digits.¹⁰⁹ A four-digit number is used when the first two digits refer to the original serologic family (e.g., HLA-A2 serologically would be HLA-A*02). Often numbers are missing because an original assignment was revoked (e.g., this is why there is no HLA-A*24:01). When silent mutations are identified (variation in nucleotide sequence that does not translate into changes in amino acid sequence), the name of the allele remains identical, but another two digits are added to designate a variant that has no functional significance. New sequences are submitted to European Molecular Biology Laboratory (EMBL; www.ebi.ac.uk/Submissions/index.html), GenBank (www.ncbi.nlm.nih.gov/Genbank/index.html), or DNA Data Bank of Japan (DDBJ; <http://www.ddbj.nig.ac.jp/submission-e.html>).

Requirements for new allele naming were described by Marsh et al.⁴ The WHO committee also made recommendations about naming alleles with aberrant expression such as HLA-G isoforms and KIR. Some alleles are identifiable at the genomic level but are not translated into protein (pseudogenes). These are indicated by the addition of an *N* (for null) following the numerical designation of the allele. Mutations inducing a reduction of expression are marked by *L* (low expression). An *S* denotes alleles expressed as soluble secreted molecules, such as HLA-B*44:02:01:02S characterized by an intronic variant that disallows the expression of the transmembrane domain of the HLA molecule and is therefore only in soluble form. Differential splicing of HLA-G leads to production of membrane-bound and soluble forms, which are respectively denoted by a lowercase *m* or *s* before HLA. Limited cytoplasmic expression is denoted by *C* and aberrant expression by *A*. Finally, KIR polymorphism will be classified by a new system that is in preparation.^{4,97,110} A nomenclature system for cytokine polymorphism has not yet been developed.¹¹¹

HUMAN LEUKOCYTE ANTIGEN TYPING IN CLINICAL HEMATOLOGY AND DETERMINATION OF COMPATIBILITY HLA TYPING

Originally HLA typing was done primarily in support of transplantation or transfusion needs with the purpose of identifying histocompatibility through the best match between donor and recipient. Allosensitization of recipients previously exposed to heterologous cell products is tested by identifying alloreactive antibodies in serum, and crossmatch procedures are performed to grade compatibility of candidate donor-recipient pairs. In addition, HLA testing has been applied to identify links between a given disease and the genetic makeup of its carriers.¹¹² Strong associations are exemplified by birdshot uveitis (a disease occurring exclusively in HLA-A29 individuals),¹¹³ type 1 diabetes and other autoimmune diseases,^{114–116} or long-term survival of HIV-infected individuals.⁵⁵ These studies evaluated the role that genetic background may have contributed over environmental factors.^{112,117} HLA associations are thought to be caused by the differential ability of distinct alleles to present immunogenic epitopes^{113,115} or by the close linkage to the HLA class III region where potent immunomodulators such as tumor necrosis factor- α are located.¹¹⁸ It has also been suggested that HLA associations may be predictors of immune responsiveness of cancer to immune therapy.⁶⁰ However, such associations have remained quite difficult to reproduce.¹¹⁹ HLA typing is requested for enrollment of patients into and interpretation of immunization protocols,²⁴ because specific HLA-epitope combinations require high-resolution typing.^{22,120}

Serologic testing takes advantage of fetomaternal sensitization. In mammals, the progeny carries a full haplotype of paternal origin, and pregnant women may develop antibodies against the paternal haplotype. Maternal serum samples are collected at term and characterized by testing their ability to kill HLA-bearing repository cell lines of known phenotype in the presence of complement (complement-dependent cytotoxicity [CDC]).¹²¹ CDC is used for HLA typing by exposing circulating cells expressing HLA class I (most cells) and class II (predominantly B cells) antigens from the individual (to be typed to previously characterized sera or monoclonal antibodies).¹²² Conversely, already typed repository cell lines are used in CDC to identify alloantibodies in sera of sensitized individuals. The fraction of cell lines killed by the sera roughly grades the intensity of allosensitization or panel reactive antibody (PRA) reactivity. Some antibodies activate complement and kill with poor efficiency, known as the *cytotoxicity-negative absorption-positive (CYNAP) phenomenon*.¹²³ As judged by cytotoxicity testing, CYNAP may underestimate allosensitization. By modifying CDC with the addition of antihuman antibodies suitable for complement activation, CYNAP can be circumvented (augmented CDC). In this case, however, relatively innocuous antibodies can cause overestimation of clinically relevant allosensitization.¹²⁴

Other methods identify alloantibodies, including immobilization of HLA molecules on solid surface to capture soluble antibodies and flow cytometry using a spectrum of microbeads loaded with known HLA alleles.^{125–129} An interlaboratory comparison of serum screening for HLA-antibody determination suggested that enzyme-linked immunosorbent assay and flow cytometry yield higher PRA activity values compared with CDC or augmented CDC.^{125,127} However, the study suggested a lack of consistency among participant laboratories, leaving the question of which method most accurately defines clinically relevant allosensitization unsolved, and a panel of various methods may be most informative.⁷²

CDC is declining in interest in the United States because most laboratories are switching to easier-to-handle and higher-resolution molecular methods. However, immunologic methods remain valuable to characterize functional aspects of HLA because molecular methods cannot define whether an HLA allele is expressed nor, at least until recently,¹³⁰ grade allosensitization. Thus it is likely that immunologic methods will continue to complement molecular methods in the future.¹³⁰

The usefulness of conventional serologic typing of HLA antigens has been limited by the availability of allele-specific sera. Most

important, because antibodies identify structural differences on the surface of HLA molecules, variants caused by nucleotide polymorphism in nonexposed areas such as the peptide-binding groove of the HLA heavy chain are not detectable. However, these differences are of functional significance because they determine the specificity and affinity of peptide binding and T-cell recognition of self and allogeneic target cells.^{23,131–133} DNA-based typing directly determines the sequence,¹³⁴ and its resolution is limited only by the number of allele-specific probes used to identify an ever-growing number of alleles (see www.anthonynolan.com/HIG/index.htm). Various polymerase chain reaction (PCR)-based methods have been described, among which sequence-specific primer and sequence-specific oligonucleotide probe-based methods are the most universally used.^{134–137} The rich nature of HLA has led to proportionally increasing complexity of the assays used to cover all possible alleles. As a consequence, accurate HLA typing for donor and recipient matching in transplantation has become increasingly complex and burdensome. In addition, because of the important role that HLA molecules play in antigen presentation and the stringency of the relationship between epitope and associated HLA allele, high-resolution typing is increasingly requested for appropriate enrollment of patients into immunization protocols aimed at the enhancement of T-cell responses.¹³⁸ Therefore high-resolution HLA typing is increasingly in demand in clinical and experimental settings.

Although oligonucleotide-based methods could theoretically discriminate any known polymorphic site, they have two major limitations. First, they require a specific PCR reaction for each allele investigated. Because each individual has only two alleles for each locus, a disproportionately large number of PCR reactions must be performed to cover all possible polymorphisms to identify the two borne by the individual tested. Because both methods are based on specific interactions with known oligonucleotide sequences unique to a particular allele, they cannot identify unknown polymorphisms unless the variation occurs within the region spanned by one of the oligonucleotides used in the assay. Because of these limitations, interest is growing for definitive typing methods that yield conclusive information about the identity of the alleles typed. The most comprehensive method is sequence-based typing. Unfortunately, its use has been limited by the cost of equipment and reagents and by the high level of expertise and time required for the interpretation of each typing. More recently, high-throughput, robotic, sequence-based typing has been developed that allows sequencing of hundreds of genomic fragments each day.^{139–141} However, even sequence-based typing has some technical limitations. Some combinations of HLA class I and class II

alleles result in ambiguous allele combinations that require additional testing for resolution.¹⁴² Finally, new methods based on high-density array technology are being developed that may allow extensive typing of known and unknown polymorphisms on microchips.^{143,144}

High-resolution methods yield high-resolution information of an individual's HLA type. However, the wealth of information is counterbalanced by increased difficulty in identifying suitable HLA alleles during donor-recipient pairing or accrual into immunization protocols restricted to specific HLA-epitope combinations. Thus, at present, clinicians are faced with the daunting task of applying high-resolution typing results of unclear relevance to clinical settings.¹⁴⁵

TESTING FOR ALLOSENSITIZATION AND DETERMINATION OF COMPATIBLE RECIPIENT-DONOR PAIRS

Any cell-containing product transfused or transplanted between different individuals should be compatible in an ideal situation. Yet, in most cases, histocompatibility is not prospectively sought. Thus patients with multiple exposures to blood products often become reactive to various antigens, including HLA. Transplant candidates often develop prior alloreactivity following transfusion of platelet concentrates contaminated with leukocytes, even though the incidence of allosensitization is much less because of leukodepletion of blood products. Alloreactivity must be documented before transplantation, because alloreactive patients can still undergo transplantation, provided that the donor has no mismatched HLA antigens reacting with the patient's antibodies. Patients who have received repeated platelet transfusions may become allosensitized and consequently refractory to further transfusions unless HLA-compatible platelets are used. Obviously the best compatibility consists of identical matching. It is often impossible to identify a perfectly matched unrelated donor, particularly in the case of rare HLA types. Thus other strategies are adopted to identify the best possible match or compatible mismatch. Selection of unrelated donor-recipient pairs is carried out through typing with serologic, cellular, and molecular methods.¹⁴⁶ The chances of identifying compatible donors based on full or partial HLA matching have become increasingly low with the increasing resolution of the typing methods.¹⁴⁵ To broaden compatibility, matching criteria of donor-recipient pairs are based on shared public epitopes assigned to cross-reactive groups (CREGs)¹⁴⁷ or shared amino acid polymorphisms defined through sequence information (Table 113.3).¹⁴⁸ The

TABLE 113.3 Population Frequencies of Major Cross Reactive or Determinants Present on HLA-A and HLA-B Gene Products

preexistence of alloantibodies restricts the identification of compatible donors even further. Highly sensitized recipients with PRA activity exceeding 85% of tested specificities (generally between 30% and 60%) represent a particularly challenging group.¹⁴⁹ An alternative approach to the exclusion of alloreactive determinants is the inclusion of acceptable antigen mismatches expressed in a panel of cells that give negative reactions with the recipient sera,¹⁵⁰ which extends the repertoire of possible donors. All these are fundamental tools for the identification of nonrelated, not fully matched donor-recipient pairs. Unfortunately, even these compromises often fail to identify a suitable match.

Duquesnoy¹⁴⁹ described a molecularly based algorithm to identify histocompatible pairs called *HLAMatchmaker*. This method focuses on the structural basis of HLA class I polymorphism so that compatible HLA mismatches can be identified without extensive serum screening. This algorithm is based on the principle that short amino acid sequences (triplets) characterizing polymorphic sites of the HLA molecules are critical components of allosensitizing epitopes. Such amino acids reside in the α -helices and β -loops of the heavy chain. Because each HLA molecule expresses a characteristic string of these determinants, it is possible to characterize each molecule according to the linear sequence of amino acid triplets present on its surface. Based on the reasonable assumption that none of the triplets present in the HLA repertoire of the recipient is self-immunogenic, it is possible through a process of electronic recombination to identify donors with HLA alleles different from the recipient's but containing exclusively shared triplets. These HLA alleles will be compatible, because they do not contain any epitope absent in the recipient.

In theory, a large number of triplets could occur if polymorphisms were randomly distributed. However, most HLA molecules span conserved domains, and only a total of 142 different polymorphic triplets designate serologically defined HLA-A, HLA-B, and HLA-C antigens.¹⁴⁹ Triplet polymorphism can occur in 30 locations on HLA-A, 27 in HLA-B, and 19 in HLA-C chains. Because the *HLAMatchmaker* algorithm includes interlocus comparison, it is possible to accumulate the information into a single database. Among the 142 polymorphic triplets, 29 are polymorphic for one class I locus but monomorphic for another class I locus. Such polymorphic triplets cannot be immunogenic because they are always present on the patient's own HLA antigens, whereas the remaining 113 triplets have immunogenic potential. With this algorithm, it is possible to significantly broaden the number of molecularly matched HLA alleles and significantly increase the chances of identifying a compatible donor, particularly in those cases in which the recipient has a rare HLA phenotype. In addition, *HLAMatchmaker* considers triplets that are present in the panel cells that give negative reactions with the recipient's serum. These negative panel cells can be expected to share antigens with the patient's, but other HLA antigens may be present and contain mismatched triplets apparently not immunogenic for that patient. Such triplets are therefore acceptable and can be added to the algorithm for the identification of possible donors. Thus *HLAMatchmaker* assesses HLA compatibility at a molecular level by determining whether or not a triplet in a given position of a mismatched HLA antigen is also found in the same position in any of the recipient's own HLA-A, HLA-B, and HLA-C molecules. A shared triplet in the same position on a mismatched HLA antigen cannot elicit a specific antibody response in that patient. Preliminary verification of the algorithm in a series of high-PRA renal patients suggested that this is a proper strategy at least in highly sensitized renal transplantation candidates waiting for unrelated donors.^{150,151} *HLAMatchmaker* is also effective at selecting an optimal HLA-typed platelet component for alloimmunized thrombocytopenic patients.¹⁵²

A new version of *HLAMatchmaker* considers so-called *eplets* and is based on the structural definitions of functional epitopes on well-characterized protein antigens that have been complexed with an antibody.¹⁵³ Eplets represent amino acid residue configurations within a 3- to 3.5-Å radius of each polymorphic residue on the HLA molecular surface. Many eplets correspond to triplets, but eplets represents a more complete repertoire of structurally defined epitopes.

THE HUMAN LEUKOCYTE ANTIGEN MOLECULES AS ANTIGENS AND HLA ALLOIMMUNIZATION

By no means are HLA molecules antigenic in physiologic condition (with the exception of maternofetal alloimmunization). However, because of their high density on the surface of cells, they can become highly immunogenic in the nonphysiologic event in which cells from different individuals are exposed to another person's immune system. The mechanism or mechanisms leading to allosensitization are believed to follow two pathways. The first pathway mimics the one followed during most immune reactions in which antigen is up-taken by antigen-presenting cells and presented to autologous lymphocytes (indirect pathway). In this case the donor's HLA molecules are processed into peptides through the exogenous pathway of antigen presentation and presented to autologous T cells as linear peptides.^{154,155} This pathway is believed to be responsible for the development of alloantibodies as well as T-helper cell responses, but its role in the development of cytotoxic T-cell responses remains unclear. Because this pathway depends on the presentation of donor HLA molecules by recipient HLA alleles, it may explain why the humoral response to HLA class I allodeterminants correlates with the HLA phenotype of the responder.¹⁵⁶ The indirect pathway of HLA allorecognition has been associated with allograft rejection.¹⁵⁷ Because the function of HLA molecules is to present antigenic determinants to T cells, it could be easily envisioned how minor changes in their structure could be misinterpreted as antigenic epitopes. Intact HLA molecules residing on the surface of donor cells are a perfect target for T cell-mediated allorecognition (direct pathway) either through the direct cytotoxic effect of T cells against target cells or by the activation of helper T cells through HLA class II engagement, leading to stimulation of antibody-mediated immune responses.¹⁵⁸

Humoral responses mediated most frequently by IgM are predominant in the sensitization to infrequent allogeneic exposure because they require smaller amounts of antigenic material. T-cell responses become more manifest in the context of transplantation in which the persistence of the allogeneic stimulus allows the expansion and sustenance of alloreactive cytotoxic T cells. Antibodies and TCR have different requirements for their engagement, which means epitopes recognized by T cells and antibodies are different. Antibodies require interaction with a small structure, including a limited number of amino acids; thus any sequence combination on the surface of an HLA allele not present in the individual exposed to the alloreaction may represent an epitope. T cells have much lower binding affinity for their ligand and require a complete interaction with the peptide as well as the α - and β -helices of the HLA class I heavy chain.¹¹ Although several B-cell epitopes recognized by antibodies can be identified in a given HLA molecule, generally the whole HLA molecule is necessary for T cell-dependent allorecognition. Definition and topographic mapping of epitopes defined by serologic or cellular methods has revealed distinct regions of hypervariability in the α -1 and α -2 domains of the class I heavy chains and in the α -1 and β -1 domains of class II molecules.¹⁵⁹ Two types of antibody-defined epitopes can be identified according to their frequency among HLA alleles. Private epitopes are almost, but not totally unique for a single serologically defined HLA antigen and are used for typing. These epitopes are generally shared by all molecular alleles present in that given family, and fine differences among alleles within a general family cannot be distinguished by antibodies. Public epitopes are more widely distributed and cluster distinct serologic families into groups. These epitopes bear an immunodominant character. Immune sera that identify public epitopes have been considered predictive of major CREGs with the idea that alloreactivity among patients belonging to the same CREG may be less likely (Table 113.3). The predictive value of CRECs in transplant outcome or platelet transfusion results, however, remains to be demonstrated.

Not all patients who have been exposed to alloantigens develop alloantibodies, and in fact, exposure to low doses of donor-specific HLA antigens through donor transfusion may have a beneficial effect

on graft survival.¹⁶⁰ Obviously, the degree of compatibility in the context of allosensitization may vary according to the degree of mismatch between donor and recipient. In addition, alloantibodies are one aspect of alloreaction that does not take into account cellular responses. These have been more difficult to document, although they are likely to play an important role in the context of acute transplant rejection. Several hypotheses have been discussed about the reason or reasons for the capriciousness of allosensitization, including the presence of regulatory immune responses or cytokine-mediated immunosuppression. Currently the mechanism modulating the quality and quantity of alloimmunity remains elusive, and different aspects of this algorithm are discussed ad hoc in this chapter, with particular attention to molecularly defined algorithms for the prediction of histocompatibility.^{130,149,161,162}

Clearly, HLA matching is beneficial in patients undergoing renal transplantation. An analysis of more than 150,000 recipients receiving transplants in different centers participating in the Collaborative Transplant Study showed that a complete mismatch (6 HLA-A+B+DR) had a 17% lower survival expectation than no mismatch ($p < .0001$).¹⁶³ Matching was particularly beneficial in patients with highly reactive preformed alloantibodies. The same study suggested that high-resolution matching based on molecular typing improved graft survival. Similar results were observed in cases of cardiac transplantation in which HLA matching yielded significantly better results ($p < .0001$). This is particularly important because donor hearts are currently not allocated according to HLA match in most centers. In cases of liver transplantation, HLA matching was not beneficial.¹⁶⁴

Donor-specific hyporesponsiveness has been particularly well documented in the context of renal allotransplantation and may limit the need for immunosuppression. A recent randomized study suggested that pretransplant donor transfusions improved the survival of cadaver kidney grafts in patients receiving modern immunosuppressive regimens, but the mechanism remains unclear.^{165,166} Although most centers currently do not implement deliberate blood transfusions, the usefulness of this approach needs to be investigated further.

Approximately 5% to 10% of platelet transfusions are given to patients who have been previously exposed to HLA class I-expressing heterologous cells and are reactive to HLA antigens. Such patients are refractory to random-donor platelets and must be given HLA-matched or semi-matched platelet apheresis components.⁴¹⁻⁴⁴ However, a provision of HLA-matched platelets does not always improve platelet recovery and survival. Possibly, the ineffective platelet transfusion is in part caused by unrecognized HLA mismatches between the donor and recipient resulting from the low-resolution methods used for typing, thus higher resolution methods have been advocated. It is currently controversial whether or not molecularly based HLA typing confers an advantage over serologic typing, and this principle was recently questioned in the context of hematopoietic cell transplantation.^{167,168}

HUMAN LEUKOCYTE ANTIGEN AS A FUNCTIONAL MEDIATOR OF GRAFT-VERSUS-HOST DISEASE AND/OR GRAFT-VERSUS-NEOPLASIA EFFECT

Allogeneic or syngeneic HSCT is used predominately for the treatment of hematologic malignancies¹⁶⁹⁻¹⁷¹ and other hematologic disorders such as aplastic anemia,¹⁷² thalassemia,¹⁷³ or myelodysplastic syndrome.¹⁷⁴ This strategy can induce long-term disease-free survival in chronic myelogenous leukemia patients.^{169,171} The objective of HSCT in cases of malignancy is to cure the patient by eradication of the neoplastic cells with myeloablative chemotherapy followed by restoration of hematopoiesis through the transplantation of normal hematopoietic stem cells derived from HLA-compatible normal donors. This strategy is characterized by the insurgence of an immune reaction toward the host's normal cells (GVHD) that is often associated and preferentially targets neoplastic cells (GVN

effect).¹⁷⁵⁻¹⁸⁵ Both the GVHD and the GVN effect occur in the presence of a full HLA match; thus the HLA molecules are not targets of allosensitization themselves, but present polymorphic molecules expressed by the recipient's cells recognized by the grafted immune cells.

GRAFT-VERSUS-HOST DISEASE

GVHD represents the alloimmune reaction of donor lymphocytes against normal cells of the recipient. GVHD occurs predominantly in association with HSCT compared with other types of transplants because the hematopoietic transplant is enriched with immune cells. Myeloablative therapy is generally administered before transplantation and, as a consequence, in most cases prevents graft rejection. GVHD is a major complication of HSCT, and a fine balance between GVHD and graft rejection is maintained by modulating the level of posttransplantation immunosuppression.¹⁷⁹ In addition, other major disturbances associated with HSCT, such as overwhelming infection, leukemia, or tumor relapse, and other regimen-related morbidities are strongly influenced by the treatment of GVHD. With the advent of nonmyeloablative HSCT for the treatment of nonhematologic diseases such as solid tumors, GVHD has reached a predominant role because of its close association with GVN effect.

T-cell depletion has been advocated for the prevention of GVHD by decreasing the probability of cellular and humoral alloresponses.^{186,187} This strategy decreases the occurrence of GVHD but is associated with an increased risk for graft rejection and tumor or leukemia relapse.¹⁷⁹ In fact, Weiden et al¹⁸⁸ observed that survivors of severe acute GVHD had a significantly lower incidence of tumor relapse compared with patients who did not experience GVHD. This association appeared mandatory, and it was believed that the beneficial GVN reaction was inseparable from GVHD.

The risk for GVHD increases with genetic distancing between donor and recipient. Thus recipients of transplants from HLA-identical twins have a lesser chance of developing GVHD than recipients of transplants from HLA-unrelated donors and from donors with only a partial HLA match.^{189,190} Interestingly, although the genetic closeness between donor and recipient appears to decrease the risk for GVHD, it also decreases the therapeutic benefit, with increased chances of tumor relapse.

GRAFT-VERSUS-NEOPLASIA EFFECT

It was originally observed that a beneficial collateral effect of GVHD was the rejection of neoplastic cells by the donor immune system in the context of hematologic malignancies (graft-versus-leukemia effect).¹⁸³ It was rapidly recognized that the graft-versus-leukemia effect could play a powerful therapeutic role in the treatment of refractory malignant disorders, including some solid tumors (graft-versus-tumor effect).¹⁸⁰ Because the biology and clinical principles underlining the two effects are likely similar, for simplicity, in this chapter we coin a unifying term: *graft-versus-neoplasia effect*. Indeed, there is a perception that the GVN reaction is the most potent form of tumor immunotherapy currently in clinical use. Its mechanism of action is still poorly understood. T cells definitely play a fundamental role in the initiation and maintenance of the alloreaction toward neoplastic cells.¹⁹¹ A sevenfold increase in the chance of relapse was noted in patients with chronic myelogenous leukemia who received a T cell-depleted HSCT as compared with a subset of patients who had received a T cell-depleted HSCT but did not develop GVHD.^{186,187} This result suggested that GVHD is a biologic entity different from the GVN effect. In addition, on leukemia relapse, administration of donor lymphocyte infusion could reinduce clinical remission.¹⁹² Finally, leukemia-specific CD8⁺ T cells have been identified in circulating lymphocytes at the time of leukemia regression.¹⁹³ NK cells play an additional role in mediating this phenomenon, and clinical data suggests that mismatch of NK receptor and ligands during

allogeneic HSCT can be used to enhance the GVN effect.^{93,194} Appreciation of the GVN effect has led to the development of nonmyeloablative stem cell transplants designed to immunosuppress the host to a level sufficient to permit engraftment of the donor immune cells to generate GVN without inducing the serious complications associated with myeloablation.¹⁷⁹ The GVN effect has gained popularity in the last decade to the point that allogeneic-based immunotherapeutic approaches have been advocated for several nonhematologic malignancies.¹⁷⁹ The rationale is largely based on the assumption that the immune cell repertoire capable of recognizing cancer cells in the allogeneic context is broader than in the autologous system. Donor T cells can target not only tumor-specific antigens but also allelic variants of these antigens; mHag; and, in the case of HLA-mismatched transplants, HLA antigens disparate from the donor expressed by the tumor cells.^{195–197} Although there are several theories about how the GVN effect occurs, it remains unclear why allo-T cells have a better chance of targeting tumor cells in an allogeneic context as compared with the natural insurgence of antitumor immunity described for several solid tumors.

HUMAN LEUKOCYTE ANTIGEN AND T CELL-DIRECTED IMMUNIZATION

The last decade has witnessed remarkable progress in the identification and mapping of T-cell epitopes for various infectious diseases and cancer. In particular, progress was made in mapping HLA-associated epitopes for HIV, CMV, and Epstein-Barr virus.^{198–201} In addition, the molecular identification of tumor-associated antigens has yielded a large number of epitopes that could be used to immunize against neoplasia.²⁰² A comprehensive discussion of these topics is beyond the scope of this chapter, but we address a few points framing the relevance of HLA in the context of T cell-directed immunization (viral specific T cells).

The identification of T-cell epitopes led to two major areas of clinical investigation. The first is active-specific immunization to prevent or treat ongoing infections or cancer. The second is the harvest and in vitro expansion of immunization-induced T cells for adoptive transfer. In general, active immunization has proved successful in inducing epitope-specific T cells easily detectable among circulating lymphocytes.^{120,203–205} However, often the immunization-induced enhancement of T-cell function is not associated with clinical improvement. Although the reason for the clinical ineffectiveness of immunization-induced T cells is unclear, it has been postulated that they may be quantitatively or qualitatively inadequate for eradicating disease.^{203,206} Therefore a second strategy is being pursued whereby the number of antigen-specific T cells is amplified in vitro for autologous or donor-derived adoptive transfer. This second strategy has met some promising success in the context of ganciclovir-resistant CMV infection,²⁰⁷ Epstein-Barr virus–induced posttransplantation lymphoproliferative disorders,²⁰⁸ and metastatic melanoma.²⁰⁹

Whether delivered as a primary form of therapy or to prime in vivo T cells for further ex vivo expansion, epitope-specific vaccination encounters the major limitation of a stringent requirement for HLA allelic association. Although super families of HLA alleles may share epitopes,^{14,16} in practical terms, clinically relevant HLA-epitope associations are restricted to few peptide-allele combinations for a given protein.²² Patients considered for enrollment in immunization protocols are best served by high-resolution HLA typing to exclude subtypes with unproven immunogenic potential for a given epitope. To bypass the stringent HLA requirements demanded by epitope-specific vaccination, whole-antigen delivery is suggested. This is based on the assumption that the epitope repertoire of a protein can be adjusted to distinct HLA phenotypes by a cellular process of self-selection naturally coupling peptides to HLA according to binding affinity. Although theoretically indisputable, in practice, the truth of this assumption depends on the efficiency with which individual molecules are processed and presented in association with distinct HLA alleles. Even in these settings, high-resolution typing is desirable

because it allows accurate interpretation of immunization results by allowing a comparison between the detailed genetic makeup of the individual receiving the vaccine and his or her antigen-specific immune response. It is likely that in the future HLA laboratories will receive increasing demands for high-resolution, definitive typing for appropriate patient enrollment and for subsequent interpretation of immune responses.

MONITORING IMMUNE RESPONSES WITH TETRAMERIC HUMAN LEUKOCYTE ANTIGEN-PEPTIDE COMPLEXES

A growing understanding of the molecular immunology of T-cell interactions with HLA/epitope complexes in the context of infectious disease, virally induced malignancies, and spontaneous tumors as well as interest in their treatment with T cell-directed vaccines has generated more attention to the issue of using accurate methods to quantify ex vivo the extent of antigen-specific immune responses.²¹⁰ The most commonly used assays available for the enumeration of antigen-specific T cells include tHLA; intracellular fluorescence-activated cell sorter staining for cytokine expression on cognate stimulation; detection of cytokine release by enzyme-linked immunospot assay; and quantitative real-time PCR, recently reviewed by Keilholz et al.²¹¹ tHLAs are complexes of four HLA molecules combined with a specific peptide and bound to a fluorochrome (Fig. 113.6). These complexes bind to complementary TCR and identify antigen-specific T cells,²¹² measuring cellular responses against specific epitopes with sensitivity as low as 1 in 5000 CD8⁺ T cells. To synthesize tHLA molecules, soluble HLA heavy chains containing a biotinylation site and recombinant β_2 -microglobulin are synthesized and purified. They are then refolded in the presence of the specific epitope, and the monomer is isolated by gel filtration and is biotinylated. Fluorescent streptavidin is added to induce tetramerization. An aliquot of tetramers is added to the peripheral blood mononuclear cells together with other antibodies for a more detailed characterization of antigen-specific T cells.²⁰⁶ Analysis is performed using a flow cytometer. Because of the specificity of vaccines, the patient's HLA type and specific peptide must be identified and synthesized to provide the adequate tetramer. Pentameric HLA/peptide complexes have recently become available and in some laboratories have replaced the use of tHLA.

Analysis of tHLA offers many potential advantages over other T-cell assays. This method is quantitative and enables an estimation of the avidity between TCR and peptide-loaded HLA class I molecules. tHLA staining does not kill the labeled cells, allowing sorting of subpopulations by flow cytometry for additional analysis or expansion for adoptive transfer. With tHLA, specific T cells can be analyzed from blood samples without the prerequisite of in vitro culture, and all specific cytotoxic T lymphocytes are detected, regardless of their functional status.^{203,206,213}

HUMAN LEUKOCYTE ANTIGEN SUMMARY

The relevance of HLA in clinical pathology has broadened from its role as a predictor of allosensitization to a mediator of GVHD and GVN. The understanding of action mechanisms in various nonclassic HLA genes as well as KIR has opened a new field. The study examining the function of the innate immune response in the context of transplantation and other immunopathologies is a result of this. Together with HLA, immunogenetics is rapidly growing, driven by the realization that polymorphism is the hallmark of human immunopathology as it spans mHag, KIR, cytokines, and their receptors. Each of these is interwoven in an intricate array of interdependent functions that cannot be discounted. Modern methods should be able to adopt high-throughput systems for the parallel assessment of all these variables when addressing the genetic makeup of an individual in correlation with the natural or therapeutic history of his or her disease. The comparison of donor and recipient protein profiling and cytokine polymorphism may offer insights

Fig. 113.6 SCHEMATIC REPRESENTATION OF THE MECHANISM OF BINDING OF TETRAMERIC PEPTIDE/HUMAN LEUKOCYTE ANTIGEN COMPLEXES (tHLA) TO ANTIGEN-SPECIFIC T CELLS. (A) Binding of tHLA to T-cell receptor. The tHLA consists of four HLA/peptide complexes identical to the ones recognized by the T cell on the surface of live cells. Each HLA molecule is modified to contain one biotin molecule that serves as a bridge for binding to tetraivalent streptavidin molecules fluorescently labeled. (B) Actual fluorescence-activated cell sorter analysis result of CD8⁺, tHLA-positive T cells. (Modified from Monsurro V, Nargosen D: Immunotracking of specific cancer vaccine CD8 lymphocytes. *ASHI Q* 26:100, 2003.)

into the rejection mechanism when matched-donor grafts are used. Finally, the increased use of T cell-directed immunization is driving renewed interest in high-resolution typing of HLA molecules to allow a more accurate interpretation of clinical and immunologic results. In the coming years, there will be an abundance of data generated from various methods for next generation sequencing. Utilization of this data will have a tremendous impact on understanding the clinical and immunologic implications in regards to HLA. This data will require an enormous effort with bioinformatics at the forefront.

HUMAN NEUTROPHIL ANTIGENS AND THEIR CLINICAL SIGNIFICANCE

Lalezari et al described the first granulocyte antigens.^{214,215} These antigens were designated *N* for neutrophil. Each antigen system was described alphabetically, and each allele was described numerically in order of discovery. They identified NA1 in 1966 and its allele, NA2, in 1972.^{214,215} Reports of several other granulocyte antigens followed.

A new nomenclature was established in 1998 by the International Society of Blood Transfusion Working Party (Table 113.4).²¹⁶ In this nomenclature, antigen systems are referred to as *human neutrophil antigens*, or HNA. The antigen systems—that is, the polymorphic forms of the immunogenic proteins—are indicated by integers, and specific antigens within each system are designated alphabetically by date of publication. Alleles of the coding genes are named according to the Guidelines for Human Gene Nomenclature. Neutrophil antigens NA1 and NA2 became HNA-1a and HNA-1b, respectively, and NB1 became HNA-2. The serology, biochemistry, molecular biology, and clinical significance of these antigens are reviewed here.

THE HNA-1 ANTIGEN SYSTEM

Expression of HNA-1 Antigens

HNA-1 antigens are expressed only on neutrophils. HNA-1 antigens are located on the low-affinity Fc- γ receptor IIIb (Fc γ RIIIb), CD16.^{217–220} Fc γ RIIIb, HNA-1a, HNA-1b, HNA-1c, and HNA-1d

TABLE 113.4

International Society of Blood Transfusion Nomenclature

Antigen System	Antigens	Location	Former Name	Alleles
HNA-1	HNA-1a	Fc γ RIIIb, CD16	NA1	FCGR3B*01
	HNA-1b	Fc γ RIIIb, CD16	NA2	FCGR3B*02
	HNA-1c	Fc γ RIIIb, CD16	SH	FCGR3B*03
	HNA-1d	Fc γ RIIIb, CD16		FCGR3B*02

HNA-3	HNA-3a	CTL-2	5b	SLC44A2*01
HNA-4	HNA-4a	CD11b (CR3)	Mart(a)	ITGAM*01
HNA-5	HNA-5a	CD11a (LFA-1)	Ond(a)	ITGAL*01

CR3, C3bi receptor; gp, glycoprotein; HNA, human neutrophil antigen; LFA-1, leukocyte function-associated antigen-1.

antigens are expressed on all segmented neutrophils, approximately one-half of neutrophilic metamyelocytes, and approximately 10% of neutrophilic myelocytes.²²¹ Neutrophil expression of Fc γ RIIIb and HNA-1 antigens are diminished by the treatment of neutrophils with stimulants such as complement component C5a and chemotaxin F-met-leu-phe or granulocyte colony-stimulating factor (G-CSF). Soluble Fc γ RIIIb is present in plasma, and it has the same HNA-1 polymorphisms found on neutrophils. Fc γ RIIIb released from granulocytes is the source of the soluble Fc γ RIIIb and HNA-1 antigens.²²²

Biochemistry

Fc γ RIIIb is a glycoprotein with 233 amino acids and is glycosylphosphatidylinositol (GPI) anchored.^{217–220} Its molecular weight is 50 to 80 kDa, and the glycoprotein has *N*-linked carbohydrate side chains. The HNA-1a form of Fc γ RIIIb is 50 to 65 kDa, while the HNA-1b form of Fc γ RIIIb is 65 to 80 kDa, and the heterozygous form is 50 to 80 kDa. Differences in *N*-glycosylation account for the differences in molecular mass.

TABLE 113.5 Nucleotide Differences Between the Genes Encoding the HNA-1a, HNA-1b, and HNA-1c Antigens of Fc γ RIIb Base Pair Position

HNA, Human neutrophil antigen.

Molecular Biology

Fc γ RIIb and the HNA-1 antigens are encoded by the FCGR3B gene located on chromosome 1q23-24 within a cluster of two families of Fc γ R genes, FCGR2, and FCGR3. The FCGR3 family is made up of FCGR3A and FCGR3B. FCGR3B is highly homologous to FCGR3A, which encodes Fc γ RIIIa. Only four nucleotides differ between FCGR3B and FCGR3A (Table 113.5). The most important difference between the two genes is a C to T change at 733 in FCGR3B that creates a stop codon. As a result, FCGR3A has 21 more amino acids than FCGR3B, and FCGR3A is a transmembrane rather than GPI-anchored glycoprotein. Fc γ RIIIa is not recognized by antibodies specific to HNA-1 antigens, but the similarities between FCGR3A and FCGR3B complicate genotyping of HNA-1 alleles.

HNA-1a, HNA-1b, HNA-1c, and HNA-1d Polymorphisms

The neutrophil-specific HNA-1 antigen system is made up of four alleles, HNA-1a, HNA-1b, HNA-1c, and HNA-1d.²²³ (Table 113.4). The gene frequencies of the alleles vary widely among different racial groups. Among whites, the frequency of the gene encoding HNA-1a, FCGR3B*01, is between 0.30 and 0.37, and the frequency of the gene encoding HNA-1b, FCGR3B*02, is from 0.63 to 0.70.²²⁴⁻²²⁸ In Japanese and Chinese populations, the FCGR3B*01 gene frequency is from 0.60 to 0.66, and the FCGR3B*02 gene frequency is from 0.30 to 0.33.^{217,218,221,225-228} The frequency of the gene encoding HNA-1c, FCGR3B*03, also varies among racial groups. FCGR3B*03 is expressed by neutrophils in 4% to 5% of whites and 25% to 38% of African Americans.²²⁹

The FCGR3B*01 gene differs from the FCGR3B*02 gene by only five nucleotides in the coding region, at positions 141, 147, 227, 277, and 349 (Table 113.5).²¹⁷⁻²²⁰ Four of the nucleotide changes result in changes in amino acid sequence between the HNA-1a and HNA-1b forms of the glycoprotein. The fifth polymorphism at 147 is silent. The glycosylation pattern of the protein differs between the two antigens because of two nucleotide changes at bases 227 and 277. The HNA-1b form has six N-linked glycosylation sites, while the HNA-1a form has four glycosylation sites.

The gene encoding the HNA-1c form of Fc γ RIIb, FCGR3B*03, is identical to FCGR3B*02 except for a C to A substitution at nucleotide 266 resulting in an alanine to aspartate change at amino acid 78 of Fc γ RIIb (Table 113.5).²²³ In many cases, FCGR3B*03 exists on the same chromosome with a second or duplicate FCGR3B gene.^{223,230}

Antibodies to HNA-1d have recently been described in two cases of neonatal immune neutropenia. The antigen HNA-1d is also encoded by FCGRB*02.²³¹

Fc γ RIIb Deficiency

Blood cells from patients with paroxysmal nocturnal hemoglobinuria lack the GPI-linked glycoproteins, and their granulocytes express

reduced amounts of Fc γ RIIb and the HNA-1 antigens.²²⁰ Genetic deficiencies of granulocyte Fc γ RIIb and HNA-1 antigens have also been reported. With inherited deficiency of Fc γ RIIb, the FCGR3B gene is deleted along with an adjacent gene, FCGR2C.^{224,232} Among white patients the incidence of individuals homozygous for FCGR3B deletion is about 0.1%.^{233,234} However, among Africans and African Americans the incidence is much higher; in one study, 3 of 126 Africans were found to be FCGR3B deficient,²²⁹ and, in another, 1 of 53 was found to be FCGR3B deficient.²²⁷

Function of HNA-1 Antigens

The low-affinity Fc- γ receptors link humoral immunity to cellular immune function; specifically, Fc γ Rs on effector cells recognize cytotoxic IgG molecules and immune complexes containing IgG molecules. Polymorphisms in Fc γ RIIb affect neutrophil function. Neutrophils that are homozygous for HNA-1b have a lower affinity for IgG3 than granulocytes homozygous for HNA-1a.²³⁵ Neutrophils from people who are homozygous for HNA-1b phagocytize erythrocytes sensitized with IgG1 and IgG3 anti-Rh monoclonal antibodies and bacteria opsonized with IgG1 at a lower level than granulocytes homozygous for HNA-1a.^{236,237}

Clinical Relevance of Fc γ RIIb Deficiency

Despite the important role of Fc γ RIIb in neutrophil function, deletion of the entire Fc γ RIIb gene does not cause major clinical problems, and most people with Fc γ RIIb deficiency are healthy. However, too few patients have been studied to identify a slight increase in susceptibility to infection or autoimmune disease due to Fc γ RIIb deficiency.

THE HNA-2 ANTIGEN SYSTEM

HNA-2 is an isoantigen without allelic variation. It was first described in 1971 by Lalezari et al and was known as NB1.²³⁸ Monoclonal antibodies specific to HNA-2 have been clustered as CD177.

Expression of HNA-2

HNA-2 is expressed only in neutrophils, neutrophilic metamyelocytes, and myelocytes.^{221,239} HNA-2 is unique in that it is expressed in subpopulations of neutrophils. The mean size of the HNA-2-positive subpopulation of neutrophils is 45% to 65%.²⁴⁰⁻²⁴² The expression of HNA-2 is greater on neutrophils from women than men.^{241,243} The size of the HNA-2-positive subpopulation of neutrophils from women is approximately 60%, compared with approximately 50% for men. Neutrophil expression of HNA-2 is greater in pregnant women than in healthy female blood donors.²⁴³ The surface expression of HNA-2 is slightly upregulated by treatment with the

chemotactic peptide F-met-leu-phe.²⁴⁰ The administration of G-CSF to healthy patients for several days increases the proportion of neutrophils expressing HNA-2 to near 90%.²⁴⁴

CD177 Glycoprotein Biochemistry

The glycoprotein carrying HNA-2a, CD177, was previously known as the NB1 glycoprotein. It is located on neutrophil plasma membranes and secondary granules^{240,245} and is linked to the plasma membrane via a GPI anchor.²⁴⁰ Although some GPI-anchored proteins are shed by F-met-leu-phe-treated neutrophils, CD177 is not, nor is soluble CD177 glycoprotein present in plasma.²⁴⁰ The molecular weight of CD177 is 58 to 64 kDa, and it contains *N*-linked carbohydrate side chains.^{240,245}

Molecular Biology

The gene encoding CD177 is located on chromosome 19q13.31, and its coding region consists of 1311 base pairs that code for a protein of 416 and a signal peptide of 21 amino acids.^{246,247} The predicted protein has two cysteine-rich domains, three potential *N*-linked glycosylation sites, and a potential ω -site for attachment of the GPI anchor.²⁴⁷ This gene belongs to the Ly-6 snake toxin superfamily. Other genes in this family include urokinase-type plasminogen activator receptor (uPAR; CD87) and decay-accelerating factor (CD59).

Polymorphisms

HNA-2 is expressed in neutrophils by approximately 97% of whites, 95% of African Americans, and 89% to 99% of Japanese.^{241,248–250} HNA-2-negative neutrophil phenotype is caused by a CD177 transcription defect.²⁵¹ HNA-2 genes from two women with HNA-2-negative neutrophils who produced HNA-2a-specific alloantibodies have been studied, and CD177 complementary DNA (cDNA) sequences were present in both women.²⁵¹ The HNA-2-negative phenotype was the result of different off-frame insertions at the RNA level, resulting in CD177 glycoprotein deficiency in neutrophils.²⁵¹

Clinical Relevance of HNA-2 Antigens

The rare women who produce HNA-2-specific alloantibodies and who lack NB1 glycoprotein are healthy. The expression of HNA-2 is reduced in neutrophils from people with paroxysmal nocturnal hemoglobinuria and chronic myelogenous leukemia,²³⁹ but it is unknown whether this has any clinical significance. CD177 mRNA is overexpressed by neutrophils from patients with polycythemia rubra vera and essential thrombocytosis.^{252,253} The role of CD177 in neutrophil function is unknown. In some studies HNA-2 may have a role in the adhesion of neutrophils to endothelial cells.²⁵⁴

HNA-3 ANTIGEN SYSTEMS

The HNA-3 antigen system has one antigen, HNA-3a, which was previously known as 5b. HNA-3a is expressed by neutrophils, lymphocytes, platelets, endothelial cells, kidney, spleen, and placental cells. HNA-3a has a gene frequency of 0.66.²⁵⁵ HNA-3a is located on the Choline Transporter-like protein-2 (CTL-2) and is encoded by SLC44A2. The HNA-3a phenotype is due to a nucleotide polymorphism that results in an arginine rather than a glutamine at position 154 of CTL-2.^{256,257} Several cases of transfusion-related acute lung injury (TRALI) have been associated with transfusion of plasma containing anti-HNA-3a.^{258,259}

HNA-4 AND HNA-5 ANTIGEN SYSTEMS

HNA-4 and HNA-5 antigens are located in the β_2 -integrins. Each antigen system contains only a single antigen, HNA-4a and HNA-5a, respectively. HNA-4a antigen was previously known as Mart(a). HNA-4a has a phenotype frequency of 99.1% in white patients. HNA-4a has been located on the α_M chain (CD11b) of the C3bi receptor (CR3) and is caused by a single nucleotide substitution of G to A at position 302 of the gene ITGAM.²⁶⁰ The substitution is predicted to result in an arginine to histidine polymorphism at amino acid 61.

A second polymorphism of the β_2 -integrins, HNA-5a, was first described as Ond(a). HNA-5a was found to be expressed on the α_L integrin unit, leukocyte function-associated antigen-1 (LFA-1) (CD11a), and is caused by a G to C single nucleotide substitution at position 2446 of the gene ITGAL. This change predicts an amino acid change of arginine to threonine at amino acid 766.²⁶⁰

CLINICAL SIGNIFICANCE OF ANTIBODIES TO NEUTROPHIL ANTIGENS

Alloimmune Neonatal Neutropenia

During pregnancy, mothers can become alloimmunized to neutrophil antigens. Maternal IgG directed to neutrophils can cross the placenta and destroy the neonate's neutrophils. Maternal alloimmunization to neutrophil antigens can occur in utero and affect the first child. Most neonates experience isolated neutropenia, but the cytopenias are self-limiting and resolve as the antibody is cleared. The alloimmunized mothers produce and carry the antibodies; but the antibodies do not react with the mother's blood cells or tissues, and they have normal neutrophil counts. Antibodies to neutrophil-specific antigens HNA-1a, HNA-1b, and HNA-2 most commonly cause neonatal alloimmune neutropenia (Table 113.6).^{255,261} Antibodies to HNA-1c and HNA-3a rarely cause alloimmune neonatal neutropenia. Mothers with Fc γ RIIIb deficiency have produced Fc γ RIIIb-specific antibodies that caused neonatal neutropenia.^{233,255,261}

Newborns with alloimmune neutropenia are usually asymptomatic. Most often, the neutropenia is detected in the first week of life when the neonate becomes febrile or develops an infection and a neutrophil count is performed. Typically the counts are 0.100 to $0.200 \times 10^9/L$. Some neonates have normal neutrophil counts the first day of life, but they become neutropenic on their second day.²⁶¹ White blood cell count, platelet count, and hemoglobin level are usually normal; but eosinophilia or monocytosis may be present. If a bone marrow biopsy is performed, it often shows normal numbers of erythroid progenitors and megakaryocytes with hyperplasia of myeloid progenitors.

TABLE 113.6 Specificities of Antibodies in Alloimmune Neonatal Neutropenia

Antigen	N = 18 ²¹¹ (%)	N = 48 ²⁵³ (%)
HNA-1a	28	10
HNA-1b	22	8
Fc γ RIIIb	0	8
HNA-2a	11	2
HNA-3a	0	2
Unknown	0	15
HLA class I ²⁵¹	11	54
Negative	28	38

HLA, Human leukocyte antigen; HNA, human neutrophil antigen.

The clinical course is quite variable. An occasional infant is asymptomatic, but almost all affected children have an infection. The most common infections are umbilicus infections, skin infections, abscesses, and respiratory tract infections. Less commonly, infants experience otitis media, urinary tract infections (UTIs), and gastroenteritis. Serious infections such as sepsis, pneumonia, and meningitis can occur. The duration of the neutropenia may be as short as a few days or as long as 28 weeks.²⁶¹ The mean duration of neutropenia is about 11 weeks.²⁶¹

For an asymptomatic child, no immediate treatment may be required. Prompt and aggressive antibiotic treatment of children with fevers or other signs of infections is indicated. Intravenous immunoglobulin has a limited role in the treatment of neonatal alloimmune neutropenia. Approximately half the patients treated have a transient increase in count lasting only a few days. The use of G-CSF to treat alloimmune neutropenia has also had mixed results. The administration of G-CSF elevates the neutrophil count in some but not all neonates.²⁶¹

AUTOIMMUNE NEUTROPENIA OF CHILDHOOD

Autoimmune neutropenia has been well described in children.²⁶²⁻²⁶⁵ Typically the onset of the autoimmune neutropenia of children begins at 8 months of age, but children between 1 and 36 months of age can be affected. Most studies found that neutrophil counts recover spontaneously by the age of 5 years, with a median of 13 to 20 months of neutropenia.²⁶²⁻²⁶⁵

In most cases, children presented with severe neutropenia, having neutrophil counts less than $0.5 \times 10^9/L$. Monocytosis has been reported to occur in up to 38% of patients. Results of bone marrow biopsies in affected patients usually show normal to hypercellular marrow with a decreased number of mature granulocytes. Febrile episodes and infections, including bacterial skin infections, otitis media, respiratory tract infections, and UTIs, are common. Life-threatening complications are rare.

Antibodies to neutrophils can be detected in up to 98% of affected patients. If antibody specificity is identified, the antibodies are almost always specific to epitopes located on FcγRIIIb. The antibodies are directed to HNA-1a in 10% to 46% of patients, to HNA-1b in 2% to 3% of patients, and rarely to FcγRIIIb epitopes expressed by granulocytes from all donors.^{262,265}

Autoimmune neutropenia has been treated with corticosteroids, intravenous immunoglobulin, and G-CSF. Approximately half the patients responded to intravenous immunoglobulin, but neutrophil counts remained elevated for only 1 week.²⁶² Almost all the patients responded to G-CSF and 75% to corticosteroids, and neutrophil counts remained elevated as long as the drugs were given.

TRANSFUSION REACTIONS

Antibodies to neutrophil and HLA antigens can cause febrile nonhemolytic transfusion reactions and TRALI. Before the widespread transfusion of leukocyte-reduced blood components, approximately 0.5% of transfusions were associated with febrile nonhemolytic transfusion reactions, and leukocyte antibodies are a common cause of these reactions. These febrile reactions are caused by the interaction of leukocyte antibodies in the transfusion recipient with leukocytes contained in the transfused blood components. These reactions can be prevented by the use of components that have been filtered to remove leukocytes.

A more serious type of transfusion reaction associated with leukocyte antibodies is the acute noncardiac pulmonary edema, or TRALI. This entity is characterized by acute respiratory distress that usually occurs within 4 hours after a transfusion. These reactions are characterized by dyspnea, hypoxia, and bilateral pulmonary infiltrates on chest radiograph without cardiomegaly or pulmonary vascular congestion. The mortality rate associated with TRALI is approximately 5%.²⁶⁶ Of patients with TRALI, 80%

have rapid resolution of pulmonary infiltrates and return of arterial blood gas values to normal within 96 hours after the initial respiratory insult. However, pulmonary infiltrates have persisted for at least 7 days after the transfusion reaction in 17% of TRALI patients.

TRALI has been associated with both neutrophil and HLA antibodies. Antibodies reported in these reactions include HNA-1a, HNA-1b, HNA-2, HNA-3a, and HLA class I and II antibodies. Most of these cases involve the passive transfusion of the offending antibody in donor plasma, as contrasted with the reactivity of the recipient's antibody with donor leukocytes to cause febrile nonhemolytic reactions. Retrospective studies involving antibodies to HNA-3a have implicated blood components from single donors with anti-HNA-3a in several TRALI cases.²⁵⁸

NEUTROPHIL ANTIGENS SUMMARY

Five neutrophil antigen systems, HNA-1, HNA-2, HNA-3, HNA-4 and HNA-5 have been well described. HNA-1 antigens are located on FcγRIIIb, and antibodies to these antigens are frequently implicated in autoimmune and alloimmune neutropenia. HNA-2 is located on CD177 glycoprotein, and antibodies to HNA-2 are found in patients with alloimmune and autoimmune neutropenia. Antibodies to HNA-3a are rare; but relative to other neutrophil antibodies, may be more frequently associated with cases of TRALI. The significance, if any, of HNA-4a and HNA-5a antibodies is uncertain.

PRINCIPLES OF NEUTROPHIL (GRANULOCYTE) TRANSFUSIONS

Ronald G. Strauss

Current leukapheresis technology and donor management/stimulation permit collection of large numbers of several types of blood leukocytes (e.g., neutrophils, hematopoietic progenitors/stem cells, and lymphocytes) from either healthy donors (allogeneic use) or patients (autologous use)—who often are stimulated with recombinant cytokines such as granulocyte colony-stimulating factor (G-CSF)—to be used for transfusion and transplantation or for further processing (e.g., ex vivo expansion and genetic manipulation). Polymorphonuclear neutrophils (PMNs) are granulocytic leukocytes that are collected from healthy donors and issued as a standard blood component (granulocytes, pheresis). This chapter analyzes the use of neutrophil (i.e., granulocyte) transfusions (GTX) as an adjunct to antimicrobial drugs in the treatment and prevention of progressive infections in patients with severe neutropenia or PMN dysfunction.

Life-threatening infections with bacteria, yeast, or other fungi continue to be a consequence of severe neutropenia ($<0.5 \times 10^9/\text{L}$ blood PMNs), most commonly occurring after intense chemotherapy or hematopoietic progenitor cell (HPC) transplantation, and disorders of PMN dysfunction such as chronic granulomatous disease. The most frequent clinical situation today is neutropenic fever and infection following intense chemotherapy or HPC transplantation given to treat hematologic malignancies. Neutropenic infections cause considerable morbidity, occasionally are fatal, and add considerable cost to the management of these patients. However, because of improved antifungal prophylaxis and therapy immediately following HPC transplantation, severe fungal infections often occur later after neutrophil engraftment (i.e., due primarily to long-standing immunodeficiency, not to severe neutropenia), and neutrophil transfusions (GTX), of course, are not warranted during this later time in the posttransplant period. Thus the number of patients with severe fungal infections, for whom GTX previously were considered, has decreased, further questioning the need in some physicians' opinions for GTX therapy.

Previous attempts to prevent infections in severely neutropenic patients by transfusing PMN concentrates (i.e., prophylactic GTX) achieved only questionable success. Although rates of certain infections were significantly reduced by prophylactic GTX, many adverse effects, such as pulmonary infiltrates and cytomegalovirus infections, were reported, and GTX were expensive. Thus prophylactic GTX have gained little support over the years. Similarly, use of therapeutic GTX to resolve existing infections has not gained lasting acceptance, despite many reports, including randomized clinical trials, documenting significant benefit for some patients. This lack of enthusiasm for GTX can be explained by the continuing development of new and very effective antimicrobial drugs to prevent and treat infections and by the availability of recombinant hematopoietic growth factors and peripheral blood hematopoietic progenitor cell (PBHPC) transfusions—both of which hasten patient recovery from myelotoxic therapy and, thereby, shorten the period of severe neutropenia and consequent risk of neutropenic infections.

Historically, PMN concentrates were collected for transfusion from unstimulated donors or those stimulated only with corticosteroids, and contained woefully inadequate numbers of PMNs. Currently, very large numbers of PMNs can be collected from normal donors using G-CSF plus corticosteroid (i.e., dexamethasone) marrow stimulation followed by large-volume leukapheresis, during which several liters (e.g., 7 L) of donor blood are processed. In this chapter

the historical and modern experiences with GTX are reviewed, and the current technology of PMN collection is discussed.

THERAPEUTIC GTX FOR NEUTROPENIC INFECTIONS: HISTORICAL EXPERIENCE

The historical experience with GTX will be critically reviewed because it provides the underpinnings for continued interest in this mode of therapy, despite its lack of universal acceptance over the 40 or so years since publication of the first controlled trials. In the third edition of this book, 34 papers were reviewed that reported the therapeutic use of GTX—collected before the advent of G-CSF donor stimulation—in severely neutropenic patients ($<5 \times 10^9/\text{L}$ blood PMNs), and only a summary of their findings will be presented here to lay the basis for modern GTX therapy.

Results of the historical studies were tabulated (Table 114.1) according to the index infection that prompted GTX therapy. Patients were counted only once (e.g., patients with septicemia were listed only in the septicemia group, even if they had another infection, such as pneumonia). As an exception, all patients with invasive fungal infections were counted together because it was impossible to accurately separate sepsis, pneumonia, sinusitis, and so forth into distinct categories. All patients given GTX for a designated type of infection were enumerated in the “Treated” column. The treated patients, those for whom the actual course and mortality of the index infection could be clearly documented, were enumerated again in the “Evaluable” column. GTX therapy was considered successful if so stated by the authors. Combining data from multiple reports of varying experimental design, admittedly, is of limited value for drawing firm conclusions, and it was done simply to document the surprising breadth of historical reported experience.

To obtain more definitive information regarding efficacy of historical GTX (i.e., collected without G-CSF), the seven controlled studies were analyzed in more detail.^{1–7} In these seven studies, the response of infected neutropenic patients to treatment with GTX plus antibiotics (study group) was compared with that of comparable patients given antibiotics alone and evaluated concurrently (control group). The design, size, and results of these seven studies are presented in Tables 114.2 and 114.3. Despite the limited donor stimulation and somewhat primitive leukapheresis technology, three of the seven studies reported a significant overall benefit for GTX.^{4–6} In two additional studies,^{1,3} overall success was not demonstrated for GTX, but certain subgroups of patients were found to benefit significantly. Thus some measure of success for GTX was evident in five of the seven controlled studies. However, this success was counterbalanced by four studies that were negative in some respect—two totally^{2,7} and two partially negative.^{1,3}

An explanation of these inconsistent results is evident on critical analysis of the adequacy of GTX support (see Table 114.3). Patients in the three successful trials received relatively high doses of PMNs (generally $\geq 1.7 \times 10^{10}/\text{day}$).^{4–6} Donors were selected to be both erythrocyte and leukocyte compatible. By contrast, the four controlled studies yielding negative results can legitimately be criticized. Two of the four studies with negative conclusions used PMNs collected by filtration leukapheresis for some patients.^{1,3} It is now known that such PMNs are defective, and they are no longer transfused. In the negative studies using PMNs collected by centrifugation

leukapheresis,^{2,3,7} the dose was extremely low (0.41 to 0.56×10^{10} per concentrate). As another factor, investigators in two of the four negative studies^{1,7} made no provision for the possibility of leukocyte alloimmunization, because donors were selected solely on the basis of erythrocyte compatibility. Finally, control subjects responded reasonably well to antibiotics alone in three of the four negative studies,^{1,3,7} suggesting that some patients fared so well with conventional treatment that they had no apparent need for additional therapeutic modalities.

These impressions from the seven controlled GTX trials have been analyzed by formal meta-analysis,⁸ with conclusions that the dose of PMNs transfused and the survival rate of the nontransfused control subjects were primarily responsible for the differing success rates of the historical studies. In clinical settings in which the survival rate of nontransfused control subjects was low, study subjects benefited from receiving adequate doses of GTX, prompting the authors to suggest that severely neutropenic patients with life-threatening infections should be considered to receive GTX given in adequate doses.⁸

THERAPEUTIC GTX FOR NEUTROPENIC INFECTIONS: MODERN EXPERIENCE

Bacterial, yeast, and other fungal infections occur frequently in patients with severe neutropenia or PMN dysfunction, and when these infections fail to promptly respond to antimicrobial drugs, they pose a major challenge for which modern therapeutic GTX offer a possible answer. Recipients of HPC transplants—particularly marrow transplant patients—often become severely neutropenic and exhibit PMN dysfunction shortly after transplant. Importantly, they manifest defective cellular and humoral immunity for months after transplantation. Altered immunity is particularly profound when the HPC

graft is T-lymphocyte depleted to diminish graft-versus-host disease. Hence all types of infection pose a threat, with yeast and other fungal infections being major problems. In a series of 1186 marrow transplant patients, 10% developed a noncandidal fungal infection, with only 17% of infected patients surviving. When the marrow graft is depleted of T lymphocytes, the rate of infection is increased twofold to sevenfold above that occurring with standard bone marrow transplantation.

Data are insufficient to determine the proper role of GTX in treating yeast or other fungal infections (which are the most difficult to treat). Historical case reports, experimental studies in animals, and experience in treating patients with chronic granulomatous disease have supported the efficacy of GTX in fungal infections. In contrast, a large historical clinical study reported that GTX collected without G-CSF donor stimulation were of no benefit in treating yeast or other fungal infections in 87 bone marrow transplant patients, 50 of whom received GTX. Although this study was a retrospective review with several shortcomings, it is supported by the disappointing finding of the poor response of invasive/tissue fungal infections in neutropenic patients to even modern GTX in some reports.

At this time, two randomized clinical trials of therapeutic GTX collected after G-CSF donor stimulation have been reported, but fail to clearly establish the efficacy or potential toxicity of modern GTX. Their shortcomings will be discussed. Because the randomized trials fail to provide definitive information, five case reports (Table 114.4) and six uncontrolled studies of multiple patients (Table 114.5) will be reviewed to provide as much information as possible for making clinical decisions.^{9–19}

Clarke et al⁹ and Catalano et al¹¹ each reported single patients (see Table 114.4) with aplastic anemia undergoing HPC transplantation and with fungal infections that responded favorably to strikingly different doses of PMNs. Similarly, Ozsahin et al¹² and Bielorai et

TABLE 114.4 Case Reports of Modern Therapeutic Granulocyte Transfusions Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor–Stimulated Donors in Neutropenic Patients

Investigators	PMNs $\times 10^{10}$ per Each GTX	Stimulation	Leukapheresis	Outcomes

TABLE 114.5 Groups of Neutropenic Patients Treated With Modern Therapeutic Granulocyte Transfusions Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor–Stimulated Donors

Investigators	PMNs $\times 10^{10}$ per Each GTX	Stimulation	Leukapheresis	Outcomes
Hester et al ¹⁰	4.1	G-CSF 5 $\mu\text{g/kg}$	Pentastarch 7 L processed	60% (9 of 15) success with yeast (4 patients) and other fungus (11 patients)
Grigg et al ¹⁵	5.9 ^a	G-CSF 10 $\mu\text{g/kg}$	Dextran 10 L processed	100% (3 of 3) success with bacterial infection 0% (0 of 5) success with progressive fungus 67% (2 of 3) success with stable fungus
Peters et al ¹⁶	3.5a	G-CSF 5 $\mu\text{g/kg}$ or Prednisolone	Hetastarch 6.4 L processed	82% (14 of 17) success with bacterial infection 54% (7 of 13) success with fungal infection
Price et al ¹⁷	8.2	G-CSF 600 $\mu\text{g/kg}$ plus Dexamethasone 8 mg	Hetastarch 10 L processed	100% (4 of 4) success with bacterial infection 0% (0 of 8) success with invasive fungus 57% (4 of 7) success with yeast infection
Lee et al ¹⁸	5.1–10.6	G-CSF 5 $\mu\text{g/kg}$ and/or Dexamethasone 3 mg/m^2	Pentastarch 6–10 L processed	40% (10 of 25) success with multiple-organism infections
Hubel et al ¹⁹	4.6–8.1	G-CSF 600 mg/kg with or without Dexamethasone 8 mg	Hetastarch or pentastarch 10 L processed	55% (unrelated donor) success with bacterial infection 75% (family donor) success with bacterial infection 0% (unrelated donor) success with yeast infection 40% (family donor) success with yeast infection 15% (unrelated donor) success with fungal infection 25% (family donor) success with fungal infection

^aAssumptions made because PMN dose expressed $\times 10^{10}$ unclear in these reports. PMN dose calculated using values for range of leukocytes collected, percentage of collected cells being myeloid, and volume of units collected (Grigg et al). Dose calculated that would be given to a 70-kg recipient for Peters et al.

G-CSF, Granulocyte colony-stimulating factor; GTX, granulocyte transfusions; PMN, neutrophil.

al¹³ each reported single patients (see Table 114.4) with chronic granulomatous disease and fungal infections that responded favorably to GTX during the transplantation period. Bielorai et al¹⁴ reported a single patient with acute leukemia and sepsis with progressive, antibiotic-resistant bacteria whose infection cleared slowly with GTX.

Hester et al¹⁰ transfused 15 patients with hematologic malignancies and infections (see Table 114.5). PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Although GTX were successful in most patients, it was not possible to distinguish responses of yeast versus other fungal infections. Lee et al¹⁸ transfused 25 patients with hematologic malignancies, many of whom were infected with multiple organisms. PMNs were collected from donors stimulated with G-CSF alone (67% of donors), G-CSF plus dexamethasone (25% of donors), or dexamethasone alone (8% of donors). Of patients with sepsis, 50% (2 of 4) responded favorably, and 38% (8 of 21) of patients with progressive localized infections responded favorably. Grigg et al¹⁵ transfused 11 patients (see Table 114.5). Eight patients had hematologic malignancies and progressive infections, five of the eight

undergoing progenitor cell transplantation and three receiving chemotherapy. Three additional patients who were undergoing progenitor cell transplantation had stable fungal infections. PMNs were collected from donors stimulated only with G-CSF and selected without regard for leukocyte compatibility. Success was excellent for bacterial and stable fungal infections but was quite poor for progressive fungal infections with organ dysfunction, a troubling pattern reported by others.¹⁷

Peters et al¹⁶ transfused 30 patients (see Table 114.5) with hematologic disorders—18 undergoing HPC transplantation. PMNs were collected from donors stimulated with G-CSF or prednisolone and selected without regard for leukocyte compatibility. The exact PMN dose transfused is uncertain because values from 0.9×10^{10} to 14.4×10^{10} can be calculated from data reported, and it was impossible to distinguish the success of GTX from G-CSF–stimulated versus prednisolone-stimulated donors. However, the outcome of bacterial infections appeared to be superior to that of fungal infections.

Price et al¹⁷ transfused 19 patients (see Table 114.5) with hematologic malignancies, 16 who had received HPC transplants and three

who were pretransplantation recipients. PMNs were collected from donors stimulated with G-CSF and dexamethasone. Although donors were selected without regard for leukocyte compatibility, recipients were documented not to exhibit evidence of leukocyte alloimmunization at study entry. Bacterial infections responded well, and yeast infections responded modestly. Despite very high PMN doses, success for other invasive fungal infections was dismal.

Hubel et al¹⁹ expanded the study of Price et al¹⁷ to a total of 74 patients (see Table 114.5) with HPC transplants. Controls were 74 historical patients not given GTX. Donors were either family members or unrelated individuals stimulated with G-CSF with or without dexamethasone. Comparative favorable responses varied with family versus unrelated donors but were approximately 70% for bacterial, 50% for yeast, and 20% for other fungal infections, values similar to the historical control patients not given GTX.

The report of Safdar et al²⁰ did not lend itself to presentation in Table 114.5 because many aspects of the patients and their infections are quite heterogeneous. The study was a case-control retrospective analysis of 491 cancer patients with candidemia—29 given GTX and 462 not. Donors were stimulated with G-CSF plus dexamethasone, and GTX were given either daily or on alternate days. Not all patients were evaluable, but unexpectedly only 35% of patients given GTX resolved their infections versus 67% of those not given GTX ($p < .001$).

No firm conclusions can be drawn from these somewhat anecdotal and very heterogeneous reports of modern therapeutic GTX, but on the basis of these preliminary findings, bacterial infections appeared to respond well to modern GTX, relatively mild yeast and other fungal infections responded modestly well, whereas, serious and/or invasive fungal infections with tissue damage often resisted even the large doses of PMNs transfused with modern GTX.^{15–17} Accordingly the precise role of modern therapeutic GTX, collected from donors stimulated with G-CSF plus corticosteroids, was addressed by two randomized clinical trials.

As background for judging the quality and recognizing the shortcomings of the randomized trials, modern therapeutic GTX is defined as PMNs collected from donors stimulated with G-CSF, preferably combined with dexamethasone, by means of centrifugation leukapheresis using an erythrocyte-sedimenting agent, while processing large volumes of donor blood. An ideal PMN collection should include: (1) 300–480 μg G-CSF given subcutaneously plus 8 mg dexamethasone given orally to the donor approximately 12 hours before leukapheresis begins; (2) hetastarch plus concentrated citrate infused throughout the entire leukapheresis procedure at a ratio of 1 part hetastarch to 12 to 14 parts donor blood; and (3) processing of 8 to 10 L of donor blood. The goal should be to transfuse 6 to 8 $\times 10^{10}$ neutrophils per GTX, with a lower limit of 4×10^{10} .

Two randomized clinical trials have been reported, but both have shortcomings or flaws that preclude firm guidelines for clinical practice. The first published randomized clinical trial of modern GTX provided no definitive guidelines for transfusion practices²¹ because of problems including: (1) lack of completion due to poor enrollment; (2) donors stimulated only with G-CSF and not dexamethasone resulting in relatively low PMN doses for individual GTX; and (3) GTX were given every other day, not daily, resulting in low PMN doses for the overall course of GTX. Thus the trial failed to test efficacy of modern “high-dose” GTX.²¹

The second and most recent randomized clinical trial (RING),²² like the first trial, was stopped before completion due to slow enrollment and, accordingly, failed to provide definitive guidelines for clinical practice. RING is a multicenter (14 clinical sites in the United States) randomized clinical trial in which 114 infected neutropenic (<500 neutrophils/ μL blood) patients were randomly allocated to treatment either with daily GTX collected from donors stimulated with G-CSF plus dexamethasone plus antibiotics ($n = 56$) or with antibiotics alone ($n = 58$). The primary endpoint was composite, consisting of survival at 42 days after randomization plus a favorable microbial response determined by a blinded adjudication panel.

Results by intention-to-treat analysis (i.e., all subjects enrolled into the two arms, regardless of whether or not they received the therapy

dictated for each arm) were nearly identical ($p > .99$) with 42% in the GTX arm versus 43% of controls having a favorable response. Similarly, by per-protocol analysis (i.e., only patients actually treated as intended), results were not different ($p = .64$), with 49% favorable in the GTX arm versus 41% of controls. No differences in success rates were noted when subsets of subjects were analyzed per specific type of infection (i.e., bacteremia, fungemia, invasive/tissue bacterial infections, or invasive/tissue fungal infections).

Although results appeared to be “negative” (i.e., no advantage for GTX), 32% of patients in the GTX arm received less than the intended dose of PMNs/granulocytes. When patients actually given the intended “high-dose” GTX were compared with those given the unintended lower doses of GTX, the “high-dose” GTX patients had significantly higher success rates ($p = .01$). Specifically the success rate was 58% for 26 patients given at least three GTX with an average dose per transfusion of at least 5×10^{10} compared with 11% success for 9 patients receiving lower leukocyte doses.

The reasons for the poor PMN/granulocyte doses given in the RING trial could not be determined, but the findings suggest that the potential benefits of high-dose GTX still remain a possibility, provided high-dose GTX (at least 4×10^{10} neutrophils per transfusion) are actually given.²² The findings also demonstrate that the collection of quality neutrophil/granulocyte concentrates requires expertise and careful quality assessment to consistently provide a product with any hope of benefit.

As a case in point, in a retrospective review of patients with invasive *Fusarium* infections, 11 patients with severe neutropenia and failure to respond to antifungal drugs received a median of seven GTX containing a mean of 6.84×10^{10} granulocytes per GTX.²³ Ten of eleven patients (91%) had a favorable response, compared with an expected response of $<50\%$ when antifungal drugs are given without GTX. Over 98% of donors were unrelated community donors who were given 480 μg G-CSF subcutaneously plus 8 mg dexamethasone orally, 12–18 hours and 12 hours before leukapheresis, respectively. Seven liters of donor blood were processed by continuous-flow leukapheresis using 500 mL of 6% hetastarch and anticoagulated with 30 mL of 46.7% trisodium citrate at a hetastarch to donor blood ratio of 1:12 throughout the procedure.

Conclusions regarding the role of modern therapeutic GTX at this time are as follows. The use of G-CSF plus dexamethasone to stimulate PMN donors has brought GTX therapy into a new era, as it is now possible to collect relatively large numbers of PMNs (granulocytes) ($>4 \times 10^{10}$). However, definitive quality data to provide firm guidelines for clinical practice remain elusive. Randomized clinical trials have proven extremely difficult to complete because of poor and/or slow patient enrollment and the lack of dependable neutrophil/granulocyte leukapheresis products. There are strong hints that transfusing $>4 \times 10^{10}$ neutrophils/granulocytes daily to severely neutropenic infected patients may be beneficial and, despite lack of definitive proof of efficacy, should be considered in clinical settings where severely neutropenic patients suffer significant morbidity and/or mortality from infections.

THERAPEUTIC GTX IN INFANTS AND CHILDREN

Children with severe neutropenia due to marrow failure during chemotherapy or HPC transplantation suffer infections similar to those of adult patients, and the principles for therapeutic GTX are comparable to those discussed in the previous section. Accordingly, they will not be reiterated other than to note that GTX, generally, are transfused infrequently with doses of PMNs/granulocytes decreased commensurate with smaller body size. Alternatively, it may be wise to transfuse an entire standard leukapheresis collection to provide very high doses of PMNs, assuming the overall condition of the patient permits the large volume of the GTX.

An indication for GTX is severe infection occurring in children with congenital disorders of PMN dysfunction, who have adequate numbers of blood PMNs, but are susceptible to serious infection because their PMNs fail to kill pathogenic microorganisms. Patients

with severe forms of PMN dysfunction are relatively rare, and no randomized clinical trials have been reported to establish the efficacy of therapeutic GTX in their management. Firm recommendations about the use of GTX to treat patients cannot be made. However, several patients with chronic granulomatous disease, complicated by progressive life-threatening fungal infections, have been reported to benefit. Because of the possibility of alloimmunization to leukocyte and red blood cell antigens plus the other risks of allogeneic transfusions, such as pulmonary reactions and transfusion-transmitted infections, therapeutic GTX are recommended only for progressive infections that cannot be controlled with antimicrobial drugs. Because of lifelong problems with infections, prophylactic GTX are impractical.

Neonates (infants within the first month of life) are another group of patients who may suffer life-threatening bacterial infections caused, at least in part, by PMN dysfunction and neutropenia—absolute or relative (i.e., normal neonates exhibit a physiologic neutrophilia compared with normal PMN counts in older children and adults)—consequently, absolute blood PMN counts as high as $3.0 \times 10^9/L$ might prompt consideration of GTX in neonates.²³ Although four of six controlled trials assessing the efficacy of therapeutic GTX in neonatal sepsis found a significant benefit for GTX, this form of therapy is rarely used today. Accordingly, they will not be discussed further.

PROPHYLACTIC GRANULOCYTE TRANSFUSIONS IN NEUTROPENIC PATIENTS

Based on historical reports, prophylactic GTX were of marginal value. In 12 reports, benefits were few, whereas risks and expenses were substantial. However, some measure of success was found in 7 of 12 studies; the remaining 5 studies failed to show a benefit for prophylactic GTX. In none of these 5 negative studies were large numbers of PMNs obtained from matched donors and transfused daily. In a situation analogous to that for the negative therapeutic GTX trials, the failure of prophylactic GTX might be explained, at least in part, by inadequate transfusions.

The role of modern prophylactic GTX (i.e., from G-CSF-stimulated donors) has not been established by definitive clinical trials. However, two factors suggest possible success: (1) because of the rapid recovery from myeloablation, hastened by peripheral blood HPC transplantation plus treatment of patients with recombinant growth factors such as G-CSF, the period of severe neutropenia may be as short as 1 week; and (2) this relatively brief period of severe neutropenia might literally be eliminated by transfusing large doses of PMNs collected from donors stimulated with G-CSF plus corticosteroids. A few studies have begun to explore this possibility (Table 114.6).

Adkins et al²⁴ transfused 10 allogeneic marrow recipients with PMNs collected from their human leukocyte antigen (HLA)-matched sibling marrow donors (see Table 114.6). Leukapheresis was performed on days 1, 3, and 5 posttransplant, and GTX were infused.

Recipients were given 7.5 $\mu g/kg$ G-CSF every 12 hours until blood PMNs were greater than or equal to $1.5 \times 10^9/L$. Recipient blood PMNs were maintained at greater than $1.5 \times 10^9/L$ throughout the 5 days of posttransplant GTX. By comparison, a historical group of control recipients treated with G-CSF, but no GTX, exhibited lower mean blood PMN counts of less than $0.5 \times 10^9/L$ posttransplant. Prophylactic GTX seemed promising in this setting and perhaps would have been even more effective (i.e., higher recipient blood PMN counts and fewer infections) if given daily.

In another study, Adkins et al²⁵ transfused 23 autologous peripheral HPC recipients with PMNs collected from first-degree relative donors (see Table 114.6). Leukapheresis was performed on posttransplant days 2, 4, 6, and 8, and GTX were infused. Recipients were given 5 $\mu g/kg$ G-CSF daily until the blood PMN count was greater than or equal to $1.5 \times 10^9/L$. Recipients were studied for the effects of lymphocytotoxic antibodies (i.e., leukocyte alloimmunization) on GTX effectiveness. The 15 recipients who did not exhibit lymphocytotoxic antibodies during the 10-day study period experienced a mean of 4.1 febrile days and required 7.3 days of antibiotics. Values for the eight recipients with lymphocytotoxic antibodies were less desirable—6.3 febrile days and 10.5 days of antibiotics. Rates of documented infections were not reported.

No firm conclusions can be drawn from these reports of modern prophylactic GTX because (1) no nontransfused control subjects were included, (2) few patients were studied, and (3) most patients were given GTX every other day, rather than daily—possibly providing a lower-than-optimal dose of PMNs. Modern prophylactic GTX appear promising, but their efficacy, potential adverse effects, and economic analysis await definition by randomized clinical trials.

ALTERNATIVE OR ADDITIVE MEASURES TO GRANULOCYTE TRANSFUSIONS

Patients with severe neutropenia, particularly those undergoing intense chemotherapy or HPC transplantation, exhibit a variety of abnormalities in multiple body defense mechanisms, most of which cannot be corrected by GTX. Consequently infections that occur in these patients often occur after the period of severe neutropenia and accordingly do not respond to GTX. To bolster body defenses, a number of additional therapies have been evaluated, two of which are the use of recombinant myeloid growth factors (i.e., cytokines) and intravenous immunoglobulin (IVIg). A critical analysis of the biology and clinical use of these agents is beyond the scope of this chapter.

AUTHOR'S APPROACH TO THERAPEUTIC GTX

1. Consider for severe bacterial, yeast, or other fungal infection in a neutropenic patient ($<0.5 \times 10^9$ PMNs/ μL blood) when the infection progresses despite optimal antimicrobial therapy.

TABLE 114.6 Modern Prophylactic Granulocyte Transfusion Studies Using Neutrophils Collected From Granulocyte Colony-Stimulating Factor-Stimulated Donors in Hematopoietic Progenitor Cell Transplant Recipients

Investigator	PMNs × 10 ¹⁰ per Each GTX	Stimulation	Leukapheresis	Outcomes
Adkins et al ²⁴	4.1 (day 1)	G-CSF 5 µg/kg × 5	Hetastarch	60% (6 of 10) afebrile
	5.1 (day 3)	Days posttransplant	7 L processed	40% (4 of 10) febrile
	6.1 (day 5)		Days 1, 3, and 5	3 culture positive
Adkins et al ²⁵	5.6 (day 2)	G-CSF 10 µg/kg	Hetastarch	Reduction of fever and antibiotics if no leukocyte antibodies
	7.0 (day 4)		7 L processed	
	8.5 (day 6)		Days 2, 4, 6, and 8	
	9.9 (day 8)			

G-CSF, Granulocyte colony-stimulating factor; GTX, granulocyte transfusions; PMN, neutrophil.

2. Collect PMNs (4 to 8×10^{10}) from allogeneic blood donors, as follows:
 - a. Stimulate neutrophilia by giving the donor 300 to 480 μg G-CSF subcutaneously plus 8 mg dexamethasone orally 12 hours (± 4 hours) before beginning leukapheresis;
 - b. Process 10 L of donor blood using a continuous-flow blood separator with citrated hydroxyethyl starch solution infused throughout the entire collection.
3. Transfuse one granulocyte concentrate (4 to 8×10^{10} PMNs) daily until bone marrow recovery (blood PMNs $> 1.0 \times 10^9/\text{L}$ without granulocyte transfusion) or clinical resolution of infection.

TRANSFUSION OF PLASMA AND PLASMA DERIVATIVES: PLASMA, CRYOPRECIPITATE, ALBUMIN, AND IMMUNOGLOBULINS

Matthew S. Karafin, Christopher D. Hillyer, and Beth H. Shaz

Plasma and its derivatives are well-established clinical resources, but cost risk of infectious disease transmission, although rare, and other adverse effects mandate their appropriate use. Even to this day however, much still remains to be clarified regarding the appropriate clinical use of plasma products. The 2015 National Institute of Health-National Heart Lung and Blood Institute State of the Science Symposium revealed that significant and fundamental gaps in our knowledge regarding the most predictive clinical hemostatic tests (i.e., viscoelastic versus traditional coagulation tests), best products (i.e., frozen versus liquid plasma), new products (i.e., freeze dried plasma), and appropriate clinical indications/protocols for plasma product use remain. Plasma can be separated from red blood cells (RBCs) through centrifugation of whole blood at the time of collection, or can be collected by apheresis as a single product or as a by-product of platelet or RBC apheresis. Plasma can be processed into derivatives through cold ethanol fractionation (method of Cohn). In this chapter, the features and uses of plasma products, which include fresh frozen plasma (FFP), plasma frozen within 24 hours of phlebotomy (FP24), thawed plasma, liquid plasma, solvent detergent treated plasma (SD-plasma), pathogen-reduced/ inactivated plasma as well as plasma derivate, including cryoprecipitate-reduced plasma, cryoprecipitate, albumin, intravenous immunoglobulin (IVIg) and intramuscular immunoglobulin (Ig) are discussed. The use of plasma-derived clotting factor concentrates as well as coagulation factor concentrates that are genetically engineered as therapy for specific clotting factor deficiencies are discussed in [Chapter 120](#).

PLASMA PRODUCTS

Plasma is the acellular, fluid compartment of blood and it consists of 90% water, 7% protein and colloids, and 2% to 3% nutrients, crystalloids, hormones, and vitamins. The protein fraction contains the soluble clotting factors: fibrinogen, factor XIII, von Willebrand Factor (vWF), factor VIII primarily bound to its carrier protein vWF, and the vitamin K-dependent coagulation factors II, VII, IX, and X. Clotting proteins are the constituents for which transfusion of plasma is required. Plasma products include FFP, FP24, thawed plasma, SD-plasma, and pathogen reduced/inactivated plasma which can be used interchangeably. Notably, FFP and FP24 are both termed FFP in some countries outside of the United States.

FFP and FP24

Plasma frozen at -18°C or colder within 8 hours of donation (6 hours with the use of some storage bags after apheresis collection) can be labelled as FFP. This product may be stored up to 1 year before use, at which time it is thawed at 37°C over 20 to 30 minutes. A second type of frozen plasma, the most commonly used in the United States, is FP24 plasma. FP24 is frozen at -18°C or colder within 24 hours of collection. The difference between FFP and FP24, using historic data, is a reduction in the following factors: fibrinogen 12%, factor V 15%, factor VIII 23%, and factor XI 7%. More recently, a direct comparison between FFP and FP24 mean factor activity immediately postthaw revealed the following changes in activity levels: factor II

0%, factor V +1%, factor VII -16% , factor VIII -15% , factor IX +6%, factor X 0%, vWF antigen activity +34%, vWF:ristocetin cofactor activity +22%, fibrinogen +29 mg/dL, antithrombin 0%, protein C -19% , and protein S -5% . A disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13) activity level is also equivalent in FFP, FP24, and cryoprecipitate-reduced plasma (discussed later). All of the factors evaluated in this study reveal that FP24 immediately postthaw had activities above the minimum activity required for safe surgical hemostasis (factor II 97%, factor V 86%, factor VII 89%, factor VIII 66%, factor IX 88%, factor X 94%, vWF:Ristocetin cofactor activity 123%, fibrinogen 309 mg/dL). Therefore, studies support that FFP and FP24 can be used interchangeably.

Thawed Plasma

Coagulation factors are also well maintained in thawed FFP and FP24 stored at 1°C to 6°C for up to 5 days, termed thawed plasma. Studies show that during 5 days of storage, most clotting factors, including ADAMTS13, remain stable. However, there is evidence that activity levels fall significantly for factors V, VII, and VIII. A review by Eder and Sebock revealed that at day 5, factor V, VII, and VIII activity levels fell from day 1 on average by 16%, 20%, and 41%, respectively, if the FFP was derived from whole blood, and 9%, 4%, and 14%, respectively, if the FFP was derived via apheresis. Although some recent evidence suggests that thrombin generation may be slower in 5-day-old thawed plasma, the decrease in clotting factor activity for both FFP and FP24 is generally not considered to be of clinical significance, as the mean factor activity levels for 5-day-old thawed plasma remain above the minimum activity required for safe surgical hemostasis (on average, FFP: factor V 67%, factor VII 70%, factor VIII 43%; FP24: factor V 59%, factor VII 77%, factor VIII 48%). Stored thawed plasma improves patient care and is more cost-effective than frozen plasma because there is no preparation time required. This difference consequently results in a decreased turn-around time, and a substantially reduced wastage rate.

Liquid Plasma

Liquid plasma is produced from whole blood within 5 days of the whole blood expiration date. Liquid plasma is maintained at 1°C to 6°C and stored for up to 26 days. It is deficient in labile clotting factors (i.e., factor V, VIII). It is used primarily for immediate treatment of acutely bleeding patients, especially where reversal of the effects of warfarin is required, as the vitamin K-dependent factors FII, FVII, F IX, and FX are relatively stable under these storage conditions. Liquid plasma remains rarely used in the United States, but studies in Europe demonstrate at least comparable efficacy to FFP in urgent situations.

Freeze-Dried Plasma (Lyophilized Plasma)

Freeze-dried plasma is produced and pooled from 10 or fewer apheresis plasma donors. The plasma undergoes a cryodesiccation process

to form a 215 g powder in a sterile bottle. The plasma is then rehydrated for use via 200 mL of sterile water with soft agitation. While not in use yet in the United States (but used in Europe), the product is being actively investigated for use in military situations. Early studies suggest that the product is safe and efficacious for treatment of war injuries.

Cryoprecipitate-Reduced Plasma

Cryoprecipitate-reduced plasma, also known as cryosupernatant or cryoreduced-plasma, is the remaining supernatant after the removal of cryoprecipitate from FFP, which is subsequently refrozen. This product is deficient in factor VIII, factor XIII, vWF, fibrinogen, and fibronectin. Cryoprecipitate reduced plasma is only indicated in the treatment of patients with thrombotic thrombocytopenic purpura (TTP), and thus cannot be used interchangeably with thawed plasma, FFP, or FP24. It can be thawed and stored for up to 5 days at 1°C to 6°C termed, thawed plasma cryoprecipitate reduced.

Solvent-Detergent Plasma (SD-Plasma)

SD-plasma is a product manufactured from ≤ 2500 pooled plasma products that has been treated with solvent (tri- η -butyl phosphate)/detergent (triton X-100) to inactivate lipid-enveloped viruses (HIV, hepatitis B, hepatitis C). The product is distributed in 200 mL containers, frozen at -18°C with a shelf life of 1 year. The coagulation factor levels are comparable to FFP and FP24, and SD-plasma has less viability between units. SD-plasma was recently approved by the U.S. Food and Drug Administration (FDA), and has the added advantage of a substantially reduced risk of transfusion-related acute lung injury (TRALI) and has a lower rate of allergic reactions.

Pathogen-Reduced/Inactivated Plasma

Other pathogen-reduction methods have been developed including amotosalen photochemical treatment with ultraviolet (UVA) light, which has recently been FDA approved. Riboflavin-treated plasma with UVA light and methylene blue-treated plasma have also been developed, but these have not yet been FDA approved, but are approved in Europe. Studies in Europe show that these methods are also quite effective at reducing the risk of viral contamination, but are deficient in some clotting factors, such as fibrinogen and factor VIII (approximately 80% retention in comparison with control plasma).

Recovered and Source Plasma (Plasma for Manufacture)

There are plasma products that are not used for transfusion, but are used for further manufacturing into plasma derivatives. These products include recovered plasma (liquid plasma and “plasma”) that are derived from whole blood and are sent to a manufacturer from a collection facility through a “short supply agreement”. Liquid plasma, as noted previously, is defined as plasma that is separated from whole blood at any time during storage at 1°C to 6°C, up to 5 days after the whole blood expiration date. “Plasma” is defined as liquid plasma that is frozen at -18°C or colder with a frozen shelf life of 5 years. Source plasma, a FDA licensed product, is collected by apheresis which is intended for further manufacturing. The Plasma Protein Therapeutics Association promotes safe collection and manufacturing practices of plasma derivatives. Source plasma can be collected more frequently under special donor programs; the donors can be compensated for their time, and can be collected in an open or closed system. Source plasma is frozen immediately in the United States and within 24 to 72 hours in Europe.

Indications

Most guidelines consistently support plasma transfusions for correcting multiple acquired coagulation factor deficiencies, as seen in liver failure or disseminated intravascular coagulopathy (DIC), massive transfusion, reversal of warfarin effect, and certain indications as a replacement fluid in therapeutic plasma exchange (Table 115.1). However, according to one recent metaanalysis, there are no published or ongoing trials regarding the optimal transfusion strategy for these indications. As there are currently no evidence-based laboratory value “triggers” for plasma administration, any recommendation needs to be carefully weighed against the patient’s presence, or risk, of bleeding.

Plasma is typically indicated when prothrombin time (PT) and/or partial thromboplastin time (PTT) are greater than 1.5 to 1.7 times normal paired with the presence of bleeding or anticipated bleeding. The justification for these current recommendations is that there is compelling evidence that plasma transfusions are ineffective in correcting mild to moderate abnormalities of coagulation screening tests. One study demonstrated that fewer than 15% of patients with a pretransfusion PT between 13.1 and 17.0 seconds had some correction after plasma transfusion, and less than 1% completely normalized. Another study found that minimally prolonged international normalized ratios (INRs) decreased with treatment of the underlying disease alone, and that the addition of plasma did not statistically change the INR over time. On the other hand, marked reductions in substantially elevated coagulation studies can occur with relatively modest plasma transfusion volumes. This variable response to plasma can be largely explained because of the nonlinear, exponential relationship between clotting factors activity levels and coagulation test results (Fig. 115.1).

Audits of recent transfusion practices have consistently demonstrated that plasma product use is inappropriately high. Recent estimates suggest up to 83% (reported range: 10–83%) of plasma transfusions are not administered according to published guidelines. The most commonly cited reason for plasma administration is a preprocedural elevation in coagulation studies. This indication is not evidence-based, especially when the coagulation abnormality is mild-moderate. Moreover, plasma should not be used as a volume expander or as a source of nutrients. Clinical situations where plasma transfusions may be beneficial are further defined in the following sections.

Liver Failure

Patients with liver failure may develop low levels of the vitamin K-dependent clotting factors (factors II, VII, IX, and X). These

TABLE 115.1 Indications for Plasma Product Transfusion Indicated

Disseminated intravascular coagulation
Liver failure
Massive transfusion
Multiple acquired coagulation factor deficiency
Plasma infusion or exchange for thrombotic thrombocytopenic purpura and other thrombotic microangiopathies, diffuse alveolar hemorrhage, and catastrophic antiphospholipid syndrome
Rapid reversal of warfarin effect when prothrombin complex concentrate is not available
Replacement of an inherited single plasma factor deficiency for which no coagulation factor concentrate exists
Not Indicated
Burns
Immunodeficiency
Source of nutrients
Volume expansion
Wound healing

Fig. 115.1 RELATIONSHIP BETWEEN FACTOR ACTIVITY LEVELS AND COAGULATION STUDIES. The general relationship between the concentration of coagulation factors and the result of PT and INR studies. The normalization of modest elevations in the INR required much larger volumes of plasma than would be expected and modest doses of plasma can result in marked changes in the INR when markedly elevated. The cause of this phenomenon can be explained by the nonlinear, exponential, relationship between coagulation factor concentration and standard coagulation test results. As shown earlier, small increases of coagulation factors correlate with marked changes in coagulation studies when coagulation factors are depleted. The opposite is true when the coagulation factors are at higher concentrations. *INR*, International normalized ratio; *PT*, prothrombin time. (Adapted from Levi M, Toh CH, Thachil J, Watson HG: *Guidelines for the diagnosis and management of disseminated intravascular coagulation*. Br J Haematol 145:24–33, 2009).

patients develop a prolonged PT/INR, PTT, and thrombin time. Fibrin split products may also be elevated in these patients, and in later stages, the fibrinogen level may be decreased. Prolongation of the PT and PTT has been correlated with both an increased risk of bleeding and mortality in these patients. Moreover, hemorrhage, most often secondary to an anatomic lesion, may be complicated by the coagulopathy resulting from these abnormalities. Patients with orthotopic liver transplantation complicated by preexisting severe liver disease and liver disease with DIC are two such examples that may require large plasma volumes.

While elevations in coagulation tests are correlated with the incidence of bleeding in these patients, growing evidence now suggests that the PT and PTT are, in themselves, poor predictors of surgical bleeding. The reason for this lack of association may be twofold. First, PT and PTT values do not correlate well with plasma factor activity levels. One study identified that up to 50% of patients with abnormal coagulation tests had coagulation activity levels considered sufficient for adequate thrombus formation. Moreover, studies demonstrate that mild abnormalities in these coagulation tests do not correct—even with infusion of large quantities of plasma, because of the mathematical difficulty of infusing normal levels of factors into mildly deficient blood to get enough plasma to decrease the PT/PTT (see Fig. 115.1). Second, the lack of increased/excessive bleeding noted in some patients with liver disease and elevated coagulation tests may be caused by a parallel reduction in anticoagulant proteins, such as proteins C and S. Therefore, patients with liver disease may not bleed as much as expected because they retain a homeostatic balance between coagulant and anticoagulant proteins.

A growing body of evidence suggests that the use of plasma in the context of severe liver disease and perioperatively during liver transplant does not significantly improve outcome. One study demonstrated that appropriate plasma transfusions did not significantly alter thrombin generation in cirrhotic liver patients. Another study demonstrated in 293 patients who received plasma transfusions during hepatectomy that there was no significant difference in complication

rate or postoperative liver function tests between those who received plasma from those who did not. Two other studies showed a poor correlation between number of plasma transfusions, PT and PTT values, and number of RBCs transfusions needed during liver transplantation. Lastly, a randomized control trial revealed that intranasal desmopressin was both less expensive and as effective as plasma transfusions for liver disease patients with an INR between 2.0 and 3.0 undergoing minor surgery.

As a result of these studies, authorities now suggest that the use of plasma be more limited in liver disease and hepatectomy patients. The transfusion of plasma in these patients should be guided by a combination of clinical assessment, the evidence and degree of bleeding, and by coagulation test results. Plasma products are currently not recommended prophylactically before a surgical challenge or liver biopsy in these patients. However, as noted previously, plasma transfusions may be considered when the PT/PTT is greater than 1.5 to 1.7 times normal, or if the INR is 2.0 or greater when the risk of bleeding is considered high.

Massive Transfusion

Massive transfusion is generally defined as receiving 10 or more units of RBCs within 24 hours (or one blood volume). Trauma patients may arrive at the hospital with a prolonged PT (termed acute trauma induced coagulopathy, early trauma induced coagulopathy, or acute coagulopathy of trauma). Early trauma induced coagulopathy is associated with increased mortality and increased use of blood products. Trauma patients can also develop a secondary coagulopathy, termed the lethal triad, secondary to dilutional coagulopathy, acidosis and hypothermia. The dilutional coagulopathy is secondary to the administration of crystalloid and RBCs without coagulation factor support. Studies have shown that the early use of plasma and platelets in trauma patients undergoing massive transfusion appears to decrease the incidence of secondary coagulopathy (lethal triad) and improve survival in these patients. In addition, the early administration of tranexamic acid has been shown to reduce mortality in bleeding patients.

Some experts have previously argued that plasma should be used only in the context of abnormal coagulation studies in a massively bleeding patient. However, recent studies have shown that this may not be the most effective approach. Because of the rapidity required to treat severely bleeding patients, standardized hospital-based massive transfusion protocols providing predetermined transfusions of RBCs, plasma, cryoprecipitate, and platelets are in use and have been associated with improved survival. Further, massive transfusion protocols identify who is responsible for different aspects of the patient's care, what laboratory tests should be ordered and when, and what blood products should be prepared and at what intervals. Some protocols are laboratory based while others have preset blood product volumes and ratios, and lastly, some integrate both. Importantly, hospitals develop these protocols using a multidisciplinary team, defining quality measures with periodic review to adjust the protocol based on new evidence and data.

The optimal ratio of RBCs and plasma in the context of massive transfusion is under active investigation. Multiple studies in both the military and civilian literature have shown a reduction in morbidity and mortality with a transfusion ratio of 1 unit of plasma for every 1 to 3 RBC units transfused in the context of severe posttraumatic bleeding. The Prospective Observational Multicenter Major Trauma Transfusion (PROMMTT) study demonstrated that clinicians generally are transfusing patients with a blood product ratio of 1:1:1 or 1:1:2 (plasma:platelet:RBC) and that early transfusion of plasma (within minutes of arrival to a trauma center) was associated with improved 6-hour survival after admission. The recently published Pragmatic, Randomized Optimal Platelet and Plasma Ratios trial was designed to compare the effectiveness and safety of a 1:1:1 transfusion ratio with a 1:1:2 transfusion ratio in patients with trauma who were predicted to receive a massive transfusion. This randomized clinical trial found no overall difference in survival based on

transfusion ratio, but did find that those who were randomized to receive more plasma (1:1:1 ratio) achieved hemostasis more frequently. Consequently, data support no advantage of 1:1:1 versus 1:1:2, and further study comparing 1:1:2 versus 1:1:3 is needed.

Questions regarding best practice still remain. One European group has suggested that the use of prothrombin complex concentrate (PCC) and fibrinogen concentrates, instead of plasma, provide a safer alternative for massive transfusion patients. The increased use of whole blood, as an alternative to using the 1:1:1 component ratio, is being studied and has been shown to have similar efficacy in pilot trials. Other studies are investigating the early use of cryoprecipitate and the use of concentrated and/or lyophilized plasma. The optimal blood type for emergency plasma transfusions is also under active investigation. During the initial resuscitation phase of these patients, the patient's blood type is often unknown. Emergency release plasma, traditionally group AB, is used until blood typing has been completed, and the plasma used can be switched to the patient's identified ABO type. The theoretic advantage in using group AB plasma is its lack of anti-A and anti-B antibodies, thus theoretically avoiding the risk of acute hemolytic transfusion reactions. However, since AB plasma is the least common type of plasma, there is a possibility of shortages. Studies now support the use of group A plasma in massive support situations as the universal product, and have so far shown no increased risk to the recipient and no substantial effect on clinical outcomes. Some provide low titer, typically defined as less than 1:100, group A plasma while other do not titer group A plasma. Since patients typically receive group O RBCs and about 80% of the population is group O or group A, the risk of hemolysis is low.

In the recent past, trauma patients would be provided primarily crystalloid and albumin, followed by component transfusion therapy based on specific transfusion "triggers." A hemoglobin less than 8 g/dL for RBCs, a PT greater than 1.5 times normal for plasma, a platelet count less than 50,000/ μ L for platelet transfusions, and a fibrinogen less than 100 g/dL for cryoprecipitate were often used. These "triggers" have now been incorporated as part of some massive transfusion protocols as algorithms to guide therapy. In these protocols, component therapy is guided by rapid and regular laboratory value correlation. To improve the speed by which one can address coagulation abnormalities, some protocols now use thromboelastography (TEG) or other point-of-care tests. TEG technology provides a dynamic and global assessment of the coagulation process, and can provide rapid assessments of the patient's platelet function, coagulation cascade, and fibrinolysis. The mechanism underlying TEG technology and the interpretation of TEG data are beyond the scope of this chapter. Currently, sufficient data are lacking to universally recommend the use of TEG in massive transfusion protocols.

Massive transfusion in other conditions, such as liver, cardiac, or orthopedic surgery and obstetric hemorrhage, likely have a different pathophysiology and thus transfusion management of these patients may be different than trauma patients. Studies exploring the use of massive transfusion protocols in these situations are lacking, but institutions should have policies in place for rapid availability of blood products and laboratory testing.

Disseminated Intravascular Coagulation

DIC may be secondary to sepsis, liver disease, hypotension, surgery-associated hypoperfusion, trauma, obstetric complications, leukemia (usually promyelocytic), or underlying malignancy. Successful treatment of the underlying cause is paramount. Recent guidelines suggest, based on low quality evidence, that plasma therapy should not be initiated based on abnormal laboratory results alone. Rather, patients with DIC and bleeding, those requiring an invasive procedure, and those at risk for bleeding complications should be given plasma in amounts sufficient to correct or ameliorate the coagulopathy or hemorrhagic diathesis. Large volumes of plasma are often necessary to correct the coagulation defect in these patients. However, in

patients with severe liver disease, bleeding, and DIC, plasma infusions often fail to normalize the PT and PTT.

Rapid Reversal of Warfarin Effect

Warfarin inhibits the hepatic synthesis of vitamin K-dependent clotting factors (factors II, VII, IX, and X) by blocking the recovery of the form of vitamin K that is active in the carboxylation of these proteins. Warfarin therapy induces functional deficiencies of these factors, which correct within 48 hours after the discontinuation of warfarin if diet and vitamin K absorption are normal.

The use of plasma in the context of warfarin anticoagulation is well established, but is becoming less relevant because of the availability of four factor PCC. Recent randomized control trials comparing PCC with plasma have demonstrated a similar clinical efficacy between the two products, but superior rate of INR normalization for those who receive PCC. Plasma is generally not indicated for warfarin reversal when the patient is not bleeding and when the patient has an INR <9, as vitamin K administration corrects the coagulopathy in 12 to 18 hours. In patients anticoagulated with warfarin who have active bleeding, require emergency surgery, or have serious trauma, however, the deficient clotting factors can be immediately provided by PCC, or plasma transfusions. Plasma use may not be optimal in all situations of warfarin-induced bleeding, though, as large volumes of plasma might be required for adequate warfarin reversal, and lengthy infusion times, especially in those who are volume sensitive, might delay needed surgical intervention.

Consequently, four factor PCC, which was approved for use by the FDA in April 2013, should be chosen as the first-line therapy for rapid reversal of life or limb threatening warfarin anticoagulation. For nonemergent or nonthreatening reversal, vitamin K can be administered. Studies have shown that PCC can reverse a warfarin-induced coagulopathy faster with lower mortality and less volume overload than plasma or vitamin K alone. Also, INR levels need to be closely followed to ensure warfarin reversal is sustained.

Thrombotic Thrombocytopenic Purpura and Other Thrombotic Microangiopathies

In patients with TTP, plasma exchange (TPE) with plasma as the replacement fluid is life-saving. Plasma infusion or exchange is also critical in the treatment of individuals who have congenital TTP. TPE has decreased the mortality of TTP from over 90% to less than 10% (see Chapter 134). Six randomized control trials have demonstrated that TPE is most effective in patients who have an autoantibody to ADAMTS13. This is caused by both the removal of a patient's plasma containing the inhibitor coupled with the addition of donor plasma containing the functional vWF-cleaving protease. The FDA has also approved the use of cryoprecipitate-reduced plasma for refractory TTP, defined as those who are unresponsive to plasma exchange with FFP. Some authorities advocate the use of cryoprecipitate-reduced plasma as a first-line therapy for TTP, as these products have a lower level of vWF than FFP, a comparable ADAMTS13 activity, and lower amounts of ADAMTS13–larger vWF multimer complexes. However, the most recent multicenter prospective randomized trial comparing exchange transfusion with plasma and cryoprecipitate reduced plasma for the initial treatment of TTP demonstrated equal efficacy between plasma and cryoprecipitate-reduced plasma for the initial therapy in TTP.

Standard therapy involves daily TPE with plasma replacing 1.0 to 1.5 plasma volumes until the platelet count is above $150 \times 10^9/L$, and lactate dehydrogenase is near normal for 2 to 3 consecutive days. Treatment should be initiated immediately or at least within 24 hours of diagnosis, and if TPE is not available to initiate treatment, plasma infusions can be used until TPE is available. The total number of treatments required is variable and is based on each individual's clinical response, but studies have shown that the median number of TPEs needed to establish hematologic recovery is about 7 to 8.

TPE is not indicated in the treatment of individuals with diarrhea associated hemolytic uremic syndrome (HUS) (also termed thrombotic microangiopathy, Shiga toxin mediated) unless there are severe neurological symptoms. Seven randomized control trials were performed evaluating the efficacy of TPE for typical cases of HUS. These trials found that the use of plasma was not superior to supportive therapies alone. TPE with plasma replacement fluid, however, is currently indicated in diarrhea-negative (atypical) HUS (aHUS), which is caused by a number of inherited and sporadic conditions that lead to the uncontrolled activation of the alternative complement system (i.e., deficiency or autoantibody to complement factor H). A complete discussion of aHUS is beyond the scope of this chapter. Typically, all patients diagnosed with aHUS are empirically treated with TPE or plasma transfusions until underlying disease or mutation is further defined, which then determines treatment. TPE has been theoretically proposed to effectively remove the potentially causative autoantibody or mutated circulating complement regulator, while replacing absent or defective complement regulators. The reported clinical response varies depending on the underlying cause, however. For some causes of aHUS, plasma infusion can be initiated. Recently, Eculizumab, a humanized monoclonal antibody against C5, has been shown to be an effective alternative treatment for some causes of aHUS (see [Chapter 134](#)).

TPE with plasma replacement may also be indicated in other thrombotic microangiopathies. Some medications cause thrombotic microangiopathies that require plasma exchange. Current examples include ticlopidine and clopidogrel, and potentially cyclosporine or tacrolimus. Lastly, TPE with plasma may also be used in the treatment of thrombotic microangiopathy associated with stem cell transplantation.

Plasma as replacement fluid, either partially or completely, for TPE is used in other diseases with risk of hemorrhage caused by the resulting coagulopathy, such as diffuse alveolar hemorrhage, liver failure, and perioperatively.

Prophylactic Use of Plasma

Studies have shown that prophylactic administration of plasma to nonbleeding recipients with abnormal coagulation studies (i.e., PT, aPTT, INR) is unlikely to produce a clinical benefit and unnecessarily exposes the patient to the risks of plasma transfusion. Moreover, systematic reviews of whether a prolonged PT or aPTT even predicts bleeding found no significant difference in the risk of bleeding between patients with a prolonged PT or aPTT and those with normal clotting parameters in the setting of bronchoscopy, central vein cannulation, angiography, or liver biopsy. Despite this ambiguity, a number of randomized control trials and metaanalyses have evaluated the efficacy of the prophylactic use of plasma products to reduce the risk of bleeding. One trial, the Northern Neonatal Nursing Initiative Group Trial, randomized 776 neonates, and evaluated whether plasma transfusion prophylaxis could prevent intraventricular hemorrhage in comparison with volume expanders (gelofusine or dextrose-saline). In a second large randomized clinical trial, 275 patients were randomized to see whether plasma transfusions could prophylactically prevent bleeding in acute pancreatitis patients. Neither large study showed clinical benefit of prophylactic plasma use. In one systematic review, 55 other randomized clinical trials were reviewed and evaluated. Only 17 of these 55 involved a control group that did not receive plasma. Overall, like the two largest studies, the results of these randomized control trials failed to show evidence for the efficacy of prophylactic plasma use across multiple clinical and laboratory outcomes. Similarly, a second metaanalysis evaluated 25 independent studies of minor surgical procedures and found that there was no significant difference in bleeding risk between those who did and did not have a coagulopathy. Despite this evidence, current recommendations still indicate that a pretransfusion INR of ≥ 1.5 to 1.7 be used as a transfusion trigger, as the prophylactic use of plasma is theoretically justified when the clinical risk of bleeding is greater than potential harms of using plasma.

Dosage

One unit of plasma derived from a unit of whole blood contains 200 to 280 mL. When plasma is collected by apheresis, as much as 800 mL can be obtained from one individual ("jumbo" plasma units), but the majority of units clinically used have a volume around 250 mL. On average, there is 0.7 to 1 unit/mL of activity of each coagulation factor per milliliter of plasma and 1 to 2 mg/mL of fibrinogen. The appropriate dose of plasma may be estimated from the plasma volume, the desired increment of factor activity, and the expected half-life of the factor being replaced (i.e., factor VII has a half-life of only 4–6 hours, and thus plasma doses should be repeated every few hours if replacing factor VII in a patient with factor VII deficiency). Alternatively, the plasma dosage may be estimated as 10 to 15 mL/kg, and ideally should be ordered as the number of milliliters to be infused. The frequency of administration depends on the clinical response to the infusion and correction of laboratory parameters. Moreover, plasma infusions should be given as close to the time as it is needed to allow for its maximum hemostatic effect if given preprocedure. A recent one-year evaluation of 10 U.S. hospitals revealed that the current median dose of plasma was 2.0 units with 15.2% receiving only 1 unit. The median weight-adjusted plasma dose was only 7.3 mL/kg with only 29% of doses being at least 10 mL/kg and 15.5% being 15 mL/kg. Based on these findings, a large proportion of patients in the United States are likely being underdosed.

Compatibility

Plasma is screened for unexpected RBC antibodies during product testing and should be ABO-type compatible for transfusion (see later). Notably, group AB plasma is universally compatible with all patients and group O plasma is only compatible with patients with group O RBCs.

Plasma Product ABO Type				
Patient ABO type	O	A	B	AB
O	Yes	Yes	Yes	Yes
A	No	Yes	No	Yes
B	No	No	Yes	Yes
AB	No	No	No	Yes

Yes = compatible blood types

No = incompatible blood types

Adverse Events

Plasma transfusion is associated with a number of infectious and noninfectious adverse events. Transfusion transmitted diseases traditionally include HIV, hepatitis B, and hepatitis C ([Chapter 120](#)), which are currently rare. Noninfectious risks include allergic reactions, TRALI, transfusion-associated circulatory overload (TACO), and hemolytic reactions ([Chapter 119](#)).

Transfusion-Related Acute Lung Injury

TRALI is noncardiogenic pulmonary edema associated with the transfusion of blood products. TRALI is usually caused by neutrophil and pulmonary endothelial activation, usually caused by transfused donor white cell antibodies, including human leukocyte antigen (HLA) antibodies and human neutrophil antigen (HNA) antibodies. These donor antibodies react with the recipient's white cells in the pulmonary vasculature causing leukoagglutination, activation of the

complement cascade, cytokine release, and pulmonary edema. Approximately 5% of TRALI is caused by the opposite mechanisms, which are recipient white cell antibodies against transfused donor white cells. Nonimmune mechanisms are also postulated to mediate TRALI, including bioactive lipids and CD40 ligand.

TRALI is the most common cause of transfusion-associated mortality in the United States and is usually associated with transfusion of blood products containing large volumes of plasma containing white blood cell antibodies. Patients at higher risk include those with shock, chronic alcohol abuse, positive fluid balance, higher peak airway pressure, and current smoker. Signs and symptoms appear within 2 to 6 hours of transfusion and include respiratory distress with dyspnea, tachypnea, hypoxia, fever, tachycardia, and hypotension. Bilateral pulmonary infiltrates on chest x-ray may be seen with no evidence of left atrial hypertension. In cases of suspected TRALI, the transfusion should be discontinued. Medical management is primarily supportive, commonly with supplemental oxygen and endotracheal intubation, if needed. Diuresis is not indicated, and the role of steroids is unclear. The majority of patients improve within 2 days, although TRALI has a 5% to 25% mortality rate.

Multiple strategies have been implemented to reduce the risk of TRALI and have resulted in a substantial decline in its incidence. First, donors implicated in prior TRALI reactions are deferred from further blood donation. Second, multiparous female donors can be tested for HLA and HNA antibodies, and blood products with high volume plasma (i.e., plasma and apheresis platelets) are not made from those with high-titer antibodies. Third, plasma supplied to hospitals for transfusion can be only from male donors while the female plasma is diverted for fractionation. Currently, these strategies have reduced the risk of TRALI from 1:4000 to 1:12,000 without significantly reducing blood product availability.

Allergic Reactions

Allergic transfusion reactions occur when preformed recipient antibodies bind to transfused allergens. Allergic transfusion reactions occur in approximately 1% to 3% of plasma transfusions. Anaphylactic reactions occur in approximately 1 in 20,000 to 1 in 50,000 transfusions. The majority of allergic transfusion reactions are mild. Mild reactions consist of urticaria with or without generalized pruritus or flushing. More severe symptoms include hoarseness, stridor, wheezing, dyspnea, hypotension, gastrointestinal symptoms, and shock. Mild reactions can be treated with antihistamines, while more severe reactions can be treated with epinephrine, H1-receptor antagonists, and steroids.

Anaphylactic reactions may be secondary to anti-IgA, usually found in rare patients with IgA deficiency (0.13% of the population). Patients who have severe allergic reactions should be tested for IgA deficiency and the presence of anti-IgA. If anti-IgA is identified, the patient should receive plasma products from IgA-deficient donors or washed RBC and platelets products.

Premedication with antihistamine is used to mitigate allergic transfusion reactions and is indicated in patients who have multiple prior or moderate allergic reactions. Unlike platelet products, however, which can be washed or concentrated before administration, there are currently no other preventative measures, other than premedication, to diminish the risk or severity of allergic reactions in plasma transfusion recipients. Consequently, oral premedication with antihistamines can be given 30 to 60 minutes before a transfusion, while intravenous premedication can be given 10 minutes before a transfusion in patients with a history of allergic reactions to plasma products.

Transfusion-Associated Circulatory Overload

TACO results from vascular fluid volume overload following the transfusion of blood products, and is most common in very young or elderly patients with cardiac dysfunction or positive fluid balance.

TACO is also likely underdiagnosed and underreported. Studies show that the mean age of patients who develop TACO range from about 70 to 85 years. Additional known risk factors for TACO include larger volumes of transfusion, greater plasma transfusion volume, and a faster transfusion rate. The incidence of TACO is unknown, but it is increasingly recognized clinically. Studies have reported the incidence to range from 1 in 356 to 1 in 10,000 blood products transfused or 1% to 8% of transfusion recipients, depending on the study population and data collection methodology, and are currently associated with a mortality rate of 5% to 15% in the United States.

Symptoms include dyspnea, orthopnea, cough, chest tightness, cyanosis, hypertension, and headache. Symptoms usually present at the end of transfusion but may occur up to 6 hours posttransfusion. Diagnosis is based on the presence of cardiogenic pulmonary edema. Management includes discontinuing transfusion, diuretic therapy, oxygen supplementation, and sitting the patient upright. Avoiding rapid transfusion can prevent TACO, unless clinically indicated. Transfusions should be administered slowly, usually 1 mL/kg/h, particularly in patients at risk for TACO.

CRYOPRECIPITATE

Cryoprecipitate is prepared from 1 unit of FFP thawed at 4°C. The precipitate is then refrozen and stored at -18°C or colder for 1 year. Cryoprecipitate, volume of 10 to 15 mL, contains 80 to 100 units of factor VIII, 100 to 250 mg of fibrinogen, and 50 to 60 mg of fibronectin as well as vWF and factor XIII.

Cryoprecipitate takes 10 to 15 minutes to thaw at 30°C to 37°C, and then requires pooling before infusion. Prepooled (pooled before storage) cryoprecipitate products are now available, easing the burden of preparation on the transfusion services. Once pooled and thawed, cryoprecipitate is maintained at 20°C to 24°C and outdates in 4 hours (6 hours if unpooled or pooled in a closed system).

Indications

Cryoprecipitate is used predominantly to treat bleeding associated with fibrinogen deficiency (Table 115.2). Cryoprecipitate should not be used to treat factor XIII, vWF, and factor VIII deficiencies, as virally inactivated factor concentrates are available. Human fibrinogen concentrate is also available and FDA approved, which is primarily used for congenital fibrinogen factor deficiency in the United States and broader indications in Europe. Like plasma, recent studies also indicate that actual administered doses of cryoprecipitate vary widely, suggesting inconsistent practice and uncertainty over the evidence informing optimal use. One large audit, for instance, demonstrated that across 25 Canadian hospitals and 4370 units of cryoprecipitate transfusions, only 24% of transfusions were considered clinically appropriate, and 34% of cryoprecipitate transfusions were deemed inappropriate according to published national guidelines (i.e.,

**TABLE
115.2**

Administration of Cryoprecipitate

Indicated

Congenital afibrinogenemia if fibrinogen concentrate unavailable
Dysfibrinogenemia
Factor XIII deficiency
Fibrinogen deficiency
Massive transfusion
Reversal of thrombolytic therapy

Possibly Indicated

Amniotic fluid embolism (used as last resort to replace depleted fibronectin)
Snake bites
Uremic bleeding

Transfusion Medicine Advisory Group of British Columbia, Canada Guidelines for cryoprecipitate transfusion).

Fibrinogen Deficiency

Fibrinogen deficiency is the primary indication for cryoprecipitate transfusion. The deficiency may be caused by congenital afibrinogenemia or dysfibrinogenemia, severe liver disease, DIC, or massive transfusion. Patients with the later indications often have concomitant decreases in clotting factor levels and require the coadministration of plasma products. It is important to obtain fibrinogen measurements because levels less than 100 mg/dL cause prolongation of the PT and PTT, despite adequate clotting factor replacement. Very low levels of fibrinogen occur during liver transplantation (<100 mg/dL), where transfusion support with cryoprecipitate is vital.

A specific purified human fibrinogen concentrate is now available, and may represent a safer alternative for direct fibrinogen replacement in isolated fibrinogen deficiencies, such as inherited hypofibrinogenemia. Fibrinogen concentrates undergo viral inactivation and have a standardized fibrinogen content; these are used preferentially over cryoprecipitate in some countries, but studies have not demonstrated a clinical benefit over cryoprecipitate. In the United States, fibrinogen concentrate is FDA approved for treatment of bleeding in patients with congenital fibrinogen deficiency.

Fibrin Glue/Sealant

Fibrin glue/sealant results from the mixture of a fibrinogen source (from plasma, platelet-rich plasma, or allogeneic/autologous cryoprecipitate) with a thrombin source (bovine, human, or recombinant). The enhanced local hemostasis achieved by the sealant product is through the action of thrombin on fibrinogen. "Fibrin glue" is a non-FDA-approved thrombin/preparation, and it has been widely used in Europe many years. Fibrin and thrombin sealants are FDA-approved alternatives to fibrin glue and are advantageous over locally made fibrin glues, because of standard dosing. Fibrin and thrombin containing glues/sealants can be used for multiple surgical purposes, including as a topical hemostat (creating a blood clot to halt bleeding), as a sealant (agents to prevent leakage of potentially nonclotting fluids, i.e., cerebrospinal fluid), or as an adhesive (bonds different tissues together). Multiple fibrin or thrombin containing products are now FDA approved for use.

The safety profile of each product differs depending on the product components and source. Bovine thrombin has been reported to cause anaphylaxis (because of bovine allergies), coagulopathy through formation of antibodies to factor V or II, and rarely death caused by severe systemic hypotensive reactions. Consequently, bovine products have an FDA mandated black-box warning on their package inserts. Pooled human plasma sources have the potential risk of viral or prion disease transmission. Reports indicate that hepatitis A and parvovirus B19 are particularly difficult to remove from these products despite current cleansing and filtration methods, and it is recommended that patients be counselled about this risk. Recombinant products, while eliminating the risk of infectious transmission or antibody formation, may also cause allergic reactions because of the hamster or snake proteins used to manufacture the product. Lastly, autologous fibrin clot preparations have been used, although the infectious risks (e.g., HIV and hepatitis) associated with the use of heterologous fibrin glue are eliminated by replacement with the autologous source, but are resource intensive. Given the current safety of the blood supply, the infectious risks are extremely low, particularly for pathogen inactivated products.

Alternatively, albumin mixed with glutaraldehyde has been used to form both an effective sealant and adhesive. The FDA has currently approved an albumin-based product to seal large blood vessel anastomoses and to reattach layers of the aorta in the context of an aortic dissection. Other successful reported uses include as

a sealant in breast cancer surgery, and to reduce air leaks in lung volume reduction procedures. Side effects of this compound can be significant, however, and include nerve and muscle necrosis, sinoatrial node damage, calcium metabolism abnormalities, mucosal and skin irritation, adhesive emboli, limitation of aortic growth, and pseudoaneurysms.

Uremic Bleeding

Abnormal bleeding is a common complication of uremia and is primarily caused by platelet dysfunction and defective interaction with endothelium. Use of cryoprecipitate as a source of vWF has been speculated to correct the platelet dysfunction. However, cryoprecipitate has been shown not to affect platelet aggregation in vitro, but does shorten the bleeding time. In 1980, a single study published in the *New England Journal of Medicine* led to the widespread, but temporary, use of cryoprecipitate for the treatment of uremic bleeding. Since that time, variable response reports have been published. Numerous alternative strategies are currently available for the prevention and treatment of uremic type bleeding including dialysis, erythropoietin, RBC transfusion, desmopressin, and conjugated estrogens, and, as such, cryoprecipitate is now rarely used in the prevention or treatment of uremic bleeding.

Massive Transfusion

While most studies regarding massive transfusion evaluate the use of platelets and plasma, some studies suggest that regular doses of cryoprecipitate may also help improve survival. In general, the current use of cryoprecipitate in massive support is not standardized and the use is based on theoretic efficacy. According to the recently published PROMMTT study, there are wide differences (7–82%) in the use of cryoprecipitate at U.S. level 1 trauma centers, and inclusion of cryoprecipitate in massive transfusion protocols vary significantly. Specifically, some PROMMTT sites used cryoprecipitate after a certain number of RBC units infused, while others used fibrinogen triggers, such as 100 mg/dL. While the PROMMTT study found no significant differences in mortality between those that did and did not receive cryoprecipitate, other studies have shown benefit. One study found that a high transfusion ratio involving cryoprecipitate in 214 massive transfusion patients resulted in improved 30-day survival (66% versus 41%). Another key study found that maintaining a ≥ 0.2 g fibrinogen/RBC (10 units of cryoprecipitate used for every 10 units of RBCs) unit ratio resulted in significantly higher survival rates (76% versus 48%). Lastly, military trauma patients in the MATTERS II study who received a combination of cryoprecipitate and Tranexamic acid had the lowest observed mortality despite high injury severity scores (odds ratio, 0.34). While a small randomized feasibility study has been performed (CRYOSTAT trial), and demonstrated that cryoprecipitate can be prepared early during trauma resuscitation, larger randomized prospective clinical trials are still needed. Consequently, while still under investigation, current data tentatively support the use of cryoprecipitate in the context of massive transfusion protocols, however cryoprecipitate remains indicated in the treatment of hypofibrinogenemia. See box "Severe Maternal Hemorrhage."

Dosage

The dosage of cryoprecipitate is calculated on the basis of the amount of fibrinogen present in 1 unit of cryoprecipitate, the plasma volume, and the desired increment. The difficulty in determining the correct amount to administer is primarily caused by variability in the fibrinogen content of cryoprecipitate, secondary by variability in donors and component processing and preparation. The goal of therapy should be to maintain the measured fibrinogen at greater than 100 mg/dL, although increasing studies and some consensus recommendations

Severe Maternal Hemorrhage

Major obstetric hemorrhage is a leading cause of maternal morbidity and mortality, and is preventable and/or treatable. Significant obstetric hemorrhage is defined as active bleeding >1000 mL within the 24 hours following birth that continues despite the use of initial measures including first-line uterotonic agents and uterine massage. Early assessment and aggressive treatment of postpartum hemorrhage (PPH) are important for reducing morbidity and mortality rates. A critical first step in managing PPH is rapid recognition that clinically significant bleeding has occurred, with effective communication of the situation to the appropriate team members, both clinical and laboratory staff. Subsequent measures include immediate resuscitation with definitive action to arrest the bleeding (obstetric, surgical, and/or hematologic) and ongoing assessment and monitoring of the response to treatment. In these cases, blood ordering protocols specific to obstetric patients may be helpful. A massive transfusion protocol, similar to that seen in acute trauma patients ensures sustained availability of blood products while the bleeding remains uncontrolled. Unique to maternal hemorrhage, hypofibrinogenemia is an important predictor for the later development of severe bleeding. Consequently, point-of-care technologies, such as thromboelastography and rotational thromboelastometry, in addition to fibrinogen levels can identify decreased fibrin clot quality during PPH, which correlate with low fibrinogen levels and can assist in transfusion management. Early administration of 1 to 2 g tranexamic acid is also recommended, followed by an additional dose in cases of ongoing bleeding. Early fibrinogen replacement using an appropriate dose of cryoprecipitate may also be beneficial in these cases.

have revised target levels to at least 150 to 200 mg/dL, or a TEG Maximum clot firmness (MCF) reading of 6 to 8 mm. It is estimated that a dose of 8 to 10 units of cryoprecipitate will increase the fibrinogen in a 70 kg adult by 50 to 70 mg/dL, but how this dose affects a TEG is unclear. Dosing frequency should be determined based on clinical and laboratory responses, as factor XIII and fibrinogen are very stable proteins. Specifically, the half-life of fibrinogen is 4 days, and factor XIII has a half-life of 9 days.

Compatibility

Cryoprecipitate can contain minimal anti-A and/or anti-B antibodies and, as such, ABO and D compatibility is not necessary for most adult and pediatric patients.

Adverse Events

Cryoprecipitate has similar adverse event risk as other blood products, including transfusion-transmitted diseases, hemolytic reactions and allergic reactions. Since it contains less plasma and no leukocytes, febrile and allergic reactions are less likely to occur.

ALBUMIN

Albumin, an important plasma protein, contributes primarily to the maintenance of plasma colloid oncotic pressure; it is also involved in the transport of numerous substances, such as unconjugated bilirubin, various hormones, and drugs. Albumin also has an established role in acid-base function, free radical scavenging, is antiapoptotic, anti-thrombotic, and has positive and negative effects on vascular integrity. The human body content of albumin is 4 to 5 g/kg, and is responsible for 80% of the osmotic pressure of human plasma. Albumin is clinically available in four forms: 5% solution in saline; 25% solution in distilled water; albumin conjugated with polyethylene glycol; and purified protein fraction, which is 5% total protein (88% albumin and 12% globulins). These products are heat-treated and albumin has not been documented to transmit infectious diseases (single outbreak occurred with albumin transfusion-associated hepatitis B with purified protein fraction in 1973).

**TABLE
115.3**

Administration of Albumin

Indicated

After large-volume paracentesis
Nephrotic syndrome resistant to potent diuretics
Ovarian hyperstimulation syndrome
Volume/fluid replacement in plasmapheresis

Possibly Indicated

Adult respiratory distress syndrome
Cardiopulmonary bypass pump priming
Fluid resuscitation in shock/sepsis/burns
Neonatal kernicterus/hyperbilirubinemia
To reduce enteral feeding intolerance

Not Indicated

Correction of measured hypoalbuminemia or hypoproteinemia
Nutritional deficiency, total parenteral nutrition
Preeclampsia
Red blood cell suspension
Simple volume expansion (surgery, burns)
Wound healing

Investigational

Cadaveric renal transplantation
Cerebral ischemia
Stroke

Common Usages

Cardiopulmonary bypass, pump priming
Extensive burns
Hypotension
Intraoperative fluid requirement exceeding 5–6 L in adults
Labile pulmonary, cardiovascular status
Liver disease, hypoalbuminemia, diuresis
Nephrotic syndrome, proteinuria, and hypoalbuminemia
Plasma exchange
Premature infant undergoing major surgery
Protein-losing enteropathy, hypoalbuminemia
Resuscitation
Serum albumin <20 g/dL

Indications

A decrease in measured plasma albumin is found in many situations, including chronic liver disease, chronic renal failure, sepsis, malignancy, burns, critical illness, severe head trauma, and hemorrhage, and is often, in itself, not a clinically significant concern. Mild edema arising from hypoalbuminemia does not require albumin therapy. However, inadequate synthesis, as seen in severe liver disease and severe malnutrition, or excessive loss, as seen in nephrotic syndrome and protein-losing enteropathy, can lead to significant hypoalbuminemia with intravascular volume depletion, anasarca, ascites, and pleural effusions. Hypoalbuminemia is associated with poor clinical outcome in some studies, yet correction of low serum albumin levels in critically ill patients does not improve outcome measures such as mortality, duration of intensive care unit (ICU) and hospital stay, or mechanic ventilation. Historically, albumin had a broader use (i.e., nutritional support, correction of hypoalbuminemia, volume replacement), but recent studies support its benefit in fewer situations, including nephrotic syndrome resistant to potent diuretic therapy, after large-volume paracentesis, and in ovarian hyperstimulation syndrome (OHSS) (Table 115.3).

Intravascular Volume Expansion

As noted, albumin provides the majority of plasma colloid oncotic pressure. Infused albumin provides colloid oncotic pressure; however, 50% of the infused protein is lost to the extravascular fluid

compartment within 4 hours. Crystalloid may also provide volume expansion and is more quickly redistributed into total body fluids. Studies investigating the use of albumin in various situations including volume expansion during and after surgery, as priming solution in cardiopulmonary bypass, or in maintaining colloid oncotic pressure, found no clinical benefit compared with controls. In 1998, the Cochrane Injuries Group performed a systematic review of randomized control trials in albumin treatment of critically ill patients and concluded that there was no evidence that albumin use for volume expansion reduces mortality in patients. They also suggested that albumin increases mortality, but this conclusion was not confirmed in later randomized control trials or subsequent metaanalyses. The SAFE trial found in 6997 patients across 16 ICUs that there was no difference in survival between those ICU patients who received albumin versus normal saline. In another randomized study, the SAFE trial investigators found that albumin use was associated with a trend toward better outcomes in patients with severe sepsis 2-year postrandomization. A smaller prospective study further revealed that albumin was at least equivalent to plasma in clinical endpoints (perioperative/postoperative RBC transfusions, postoperative blood loss, duration of ICU stay, major complications) as a plasma expander in the context of pediatric craniofacial surgeries. One conclusion from these prospective randomized trials is, contrary to previous reports, the use of albumin is at least clinically equivalent to saline or plasma for intravascular volume resuscitation in some clinical settings. Moreover, the Italian Society of Transfusion Medicine and Immunohematology recently recommended that albumin may be useful for hypovolemia in some patients with hemorrhagic shock, patients undergoing major surgery, such as cardiac surgery, patients with severe burns, and patients postliver transplant when crystalloids and other colloids did not provide adequate clinical benefit.

Hypoalbuminemia

Low serum albumin is an independent predictor of morbidity and mortality in many clinical settings. However, correction of low serum albumin levels in ill patients does not improve outcome measures such as mortality. However, two randomized controlled studies showed that correction of hypoalbuminemia did improve respiratory, cardiovascular, and central nervous system function. Current guidelines support the use of albumin to correct hypoalbuminemia for patients with ascites, large volume paracentesis, hepatorenal syndrome, and spontaneous bacterial peritonitis. Recent studies with albumin infusions have also been done in end-stage liver disease patients for hypoalbuminemia. However, results are less encouraging, with studies indicating no additional benefits or reduction in morbidity.

Cirrhosis

The use of albumin in cirrhotic patients dates to before 1950. In this setting, albumin was recommended for temporary improvement in hyponatremia, spontaneous bacterial peritonitis, or prevention of the complications associated with paracentesis, including volume shifts and hyponatremia, as noted earlier. Several studies demonstrated that after large-volume paracentesis (>5 L), hyponatremia and renal insufficiency were improved with albumin infusion compared with other volume-expanding agents. Moreover, a single randomized control trial of albumin use in cirrhotic patients with spontaneous bacterial peritonitis revealed that albumin administration with antibiotics resulted in reduced mortality and a reduced risk of renal failure in comparison with antibiotic use alone.

Nephrotic Syndrome

Albumin has been used to increase colloid oncotic pressure with the intention of increasing diuresis via increasing vascular pressure at the level of the glomerulus. Several studies have shown that albumin use

in this context have resulted in no clinical benefit. However, other studies have suggested that albumin use is associated with increased hypertension, respiratory distress, and electrolyte abnormalities. Consequently, the current recommended use of albumin for nephrotic syndrome patients is limited to patients in whom diuretic therapy is poorly tolerated or ineffective or in those with massive ascites or anasarca.

Ovarian Hyperstimulation Syndrome

OHSS is usually a result of iatrogenic administration of human chorionic gonadotrophin (hCG) to induce ovulation. OHSS is typified by enlarged ovaries which release vascular endothelial growth factor that can result in increased capillary permeability. This, in turn, leads to a fluid shift out of the intravascular compartment to the abdominal/pleural spaces resulting in ascites and hypovolemia. In the most severe form, the patient can develop tense ascites, oliguria, dyspnea, hemodynamic instability, and thromboembolism. Treatment includes fluid restriction, analgesics, and close monitoring; occasionally hospitalization may be necessary.

Mild OHSS occurs in approximately one-third and moderate-severe in approximately 5% of women receiving exogenous hCG. Increased risk of OHSS includes young age, low body weight, polycystic ovarian syndrome, high dose hCG, high or rapid rise in estradiol level, and previous history of OHSS. In addition, the risk is proportional to the number of developing follicles and number of oocytes retrieved. Moderate-severe OHSS can be mitigated by closely monitoring women during treatment and subsequently withholding or reducing hCG administration when there is a large number of intermediate size developing follicles present or when estradiol levels are elevated.

In 2011, the Cochrane collaboration systematically reviewed eight randomized clinical trials of albumin administration in OHSS, and concluded that there is only a borderline statistically significant decrease in the incidence and severity of OHSS when albumin was administered during oocyte retrieval in high-risk women. In contrast, the metaanalysis further revealed that the use of hydroxyethyl starch (HES) resulted in a markedly decreased incidence of severe OHSS. In addition, [Bellver et al.](#) published a large randomized trial that demonstrated no difference in moderate-severe OHSS when 40 g of albumin was administered after the retrieval of 20 or more oocytes. Only one (nonrandomized) study to date has compared human albumin and 6% HES. This study concluded in 16 patients with severe OHSS that patients who received HES had a higher urine output, needed less abdominal paracentesis and drainage of pleural effusions, and had a shortened hospital stay than patients who received albumin. Therefore, while still clinically used, albumin may be inferior to other therapies in the prevention of OHSS.

Therapeutic Apheresis

Albumin is the replacement fluid of choice for many apheresis indications. Albumin reduces the risk of adverse events during apheresis procedures by reducing the risk of viral transmission, allergic reactions, and TRALI in comparison to plasma use (see plasma section). Albumin can also be used in combination with saline during apheresis procedures, but excessive use of saline results in hypotensive reactions. Albumin is also indicated if large (>15% of the total blood volume) blood volumes are removed to prevent hypotensive reactions in other therapeutic apheresis procedures (leukapheresis, plateletpheresis).

While albumin is generally well tolerated in therapeutic apheresis patients, albumin use can result in significant hypotension, bradycardia, and flushing in patients receiving angiotensin converting enzyme inhibitor (ACE) therapy. ACE inhibitors prevent the patient's ability to metabolize bradykinins that are present in the albumin and activated during the apheresis procedure. In patients taking ACE inhibitors, symptoms can be prevented by using plasma, or halting ACE inhibitor use and delaying the start of apheresis therapy.

Emerging Indications

Serum albumin has been shown to be a free radical scavenger. Because of this function, some have recommended albumin as an adjuvant therapy in patients with sepsis. There are no confirmed data on the benefits of albumin therapy in this patient population, however. In other conditions associated with systemic inflammation such as acute lung injury or acute respiratory distress syndrome, albumin therapy use was found to improve oxygenation and hemodynamic status.

Dose

The volume and speed of administration should be determined by the patient's volume status, condition, and response to the product. In an adult, the total daily dose should not exceed the theoretical amount present in normal plasma (2g/kg/day), in the absence of acute hemorrhage. In the pediatric population, albumin dose again depends on the patient's condition, but 0.5 to 1.0 g/kg/dose with a maximum dose of 6 g/kg/day could be used as a general guideline. Albumin 5% is oncologically equivalent to normal human plasma. Albumin 25% provides less infusion volume per amount of albumin and is usually administered to patients with fluid or sodium intake restriction. Albumin 25% expands the blood volume by 3.5 times by drawing fluid into the intravascular space.

Adverse Effects

Albumin is a plasma derivative used widely and associated with rare adverse reactions. Allergic reactions, including urticaria, may be encountered. Changes in vital signs (heart rate, blood pressure, respiration rate), nausea, emesis, and fever/chills have also been rarely reported. Volume overload and dilutional anemia as well as hypocalcemia may occur. Albumin has not been associated with transfusion-transmitted diseases.

INTRAVENOUS IMMUNOGLOBULIN

IVIg is prepared by fractionation of large pools of human plasma. There are numerous preparations available in the United States and throughout the world. Subcutaneous preparations of Ig are also now available. Each preparation is slightly different and has theoretic advantages and disadvantages and specific licensed indications. Ideally, IVIg should contain each IgG subclass; retain Fc receptor activity; have a normal half-life; demonstrate virus neutralization, opsonization, and intracellular killing; and have antibacterial capsular polysaccharide antibody. Furthermore, vasoactive impurities should be absent, and no transmissible infectious agents should be present. The uses of IVIg have been extensively reviewed and the number of theoretical and accepted uses for IVIg is rapidly expanding.

Indications

IVIg is indicated for replacement of Igs or for its immunomodulatory effects. Currently, there are six FDA approved indications for IVIg treatment: primary immunodeficiency, pediatric HIV infections, secondary immunodeficiency in chronic lymphocytic leukemia (CLL), idiopathic thrombocytopenic purpura (ITP), Kawasaki disease, and allogeneic stem cell transplantation in patients older than 20 years of age. Some of the FDA indications are no longer applicable, such as in patients with CLL and HIV, given better medications. IVIg is also considered first-line therapy for multiple other conditions, such as Guillain-Barré syndrome, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), neonatal alloimmune thrombocytopenia (NAIT), posttransfusion purpura (PTP), myasthenia gravis and stiff-person syndrome (Table 115.4). An exhaustive review of all the known established and investigational uses for IVIg cannot be

reasonably summarized in this chapter. For further information, some excellent reviews are cited in the reference section. A brief summary of some of the more well-established uses of IVIg are presented in the following section.

Primary Immunodeficiency Syndromes

Primary congenital immunodeficiency syndromes have been treated with intramuscular Ig for the past 30 years. The use of intramuscular Ig has certain disadvantages: delayed absorption, delivery of inadequate amounts because of small muscle mass, and pain at the injection site. IVIg overcomes these disadvantages, and used prophylactically in patients with primary immunodeficiency has been demonstrated to reduce the number of febrile and infectious episodes as well as improve survival rate. IVIg use in IgG subclass deficiencies is also beneficial.

Chronic Lymphocytic Leukemia

CLL may be associated with hypogammaglobulinemia and complications of repeated bacterial infections. IVIg decreases the incidence and severity of bacterial infections in CLL patients with hypogammaglobulinemia and has become accepted prophylactic therapy.

Bone Marrow Transplantation

The use of prophylactic IVIg or cytomegalovirus (CMV)-IVIg in CMV-negative bone marrow transplant recipients during the first 100 days posttransplant has been demonstrated to reduce the incidence of symptomatic CMV-associated disease, including CMV interstitial pneumonia, in some trials. Because of the high cost of this treatment and the increasing use of prophylactic ganciclovir, IVIg is currently not indicated for the prophylaxis of CMV infections in bone marrow transplant recipients. In established CMV-interstitial pneumonia, IVIg in combination with ganciclovir has been shown to reduce the mortality rate and has become the recommended treatment modality. Its role in preventing severe graft-versus-host disease is unclear. Prolonged IVIg therapy during graft-versus-host disease prevention may suppress humoral immunity recovery.

Pediatric Human Immunodeficiency Virus Infection

The defects in humoral and cellular immunity observed in children with HIV infection predispose them to life-threatening bacterial infections. Studies previously demonstrated that the administration of IVIg to HIV-infected children could reduce the incidence and severity of bacterial infections as well as the frequency of hospitalization. More recently, studies have now shown that IVIg does not improve outcome, likely because of improved medications for HIV and HIV-associated infections.

Idiopathic Thrombocytopenic Purpura

IVIg and Rh immune globulin are routinely and effectively used in the treatment of acute and chronic ITP. IVIg significantly raises the platelet count within 5 days in adults with chronic ITP and in children with acute ITP. The mechanism of action of IVIg in ITP is unknown; one postulation is Fc receptor blockade decreases the removal of antibody-coated platelets. Other proposed mechanisms include suppressed antiplatelet antibody synthesis, increased antiviral immunity, and blockage by antiidiotypic antibodies. In general, IVIg induces responses in most patients within 1 to 2 days. Responses are of variable duration and are rarely sustained, although maintenance therapy may be of some value. IVIg may be effective in chronic ITP refractory to corticosteroids or splenectomy; and may show greater efficacy in conjunction with corticosteroids.

TABLE 115.4 Administration of Intravenous Immunoglobulins

Indicated Ataxia-telangiectasia Chronic inflammatory demyelinating polyneuropathy Chronic lymphocytic leukemia Common variable immunodeficiency Cytomegalovirus-interstitial pneumonia after bone marrow transplantation Guillain-Barré syndrome Graft-versus-host disease after bone marrow transplantation Hemolytic disease of the fetus and newborn Idiopathic thrombocytopenic purpura Immunoglobulin G subclass deficiency Inflammatory myopathies (refractory dermatomyositis and polymyositis) Myasthenia gravis Mucocutaneous lymph node syndrome (Kawasaki disease) Neonatal alloimmune thrombocytopenia Parvovirus infection Pediatric human immunodeficiency virus infection Persistent deficit in antibody production after bone marrow transplantation Posttransfusion purpura Primary immunodeficiency syndromes Secondary hypogammaglobulinemia Severe combined immunodeficiency Stiff-person syndrome Wiskott-Aldrich syndrome X-linked agammaglobulinemia	Solid organ transplantation (kidney) Systemic lupus erythematosus (refractory, severe, active) Thrombocytopenia refractory to platelet transfusion Vasculitis (refractory to standard therapy)
Possibly Indicated Antiphospholipid syndrome in pregnancy Autoimmune hemolytic anemia (warm type unresponsive to prednisone) Factor VIII inhibitors (refractory) Graves ophthalmopathy Immune neutropenia Multiple myeloma (stable disease, high risk for infections) Pemphigus	Investigational Acquired von Willebrand disease Amyotrophic lateral sclerosis Burn patients Chronic fatigue syndrome Chronic human parvovirus B19 infection Chronic idiopathic pericarditis Chronic pain syndromes Congestive heart failure Dilated cardiomyopathy Graft-versus-host disease Human immunodeficiency virus infection Immune-mediated aplastic anemia Inflammatory bowel disease Intractable childhood epilepsy Multiple sclerosis Myocarditis Necrotizing fasciitis Neonatal sepsis Neonatal hemochromatosis Postpartum cardiomyopathy Prevention of nosocomial postoperative infections Prophylaxis in transplant recipients against cytomegalovirus infection Recurrent unexplained spontaneous abortions Rheumatoid arthritis Sepsis and septic shock Toxic epidermal necrolysis/Stevens-Johnson syndrome Toxic shock syndrome

Although IVIg has shown equal efficacy with corticosteroids in pediatric acute ITP and in 75% of adults with chronic ITP, because of the transient responses and high cost, its use is justified only in clinical situations requiring rapid elevation of platelet count or if standard therapy has failed. IVIg is, therefore, indicated in acute bleeding episodes or before urgent surgery, including splenectomy; in patients at high risk of intracranial hemorrhage; and in those in whom corticosteroids are contraindicated or ineffective. IVIg has also been used to treat ITP during pregnancy, postinfectious thrombocytopenia, ITP associated with HIV infection, and neonatal thrombocytopenia. Intravenous anti-D immune globulin (also known as Rh immune globulin) has demonstrated efficacy in Rh-positive, nonsplenectomized individuals with ITP. It has been suggested that the mechanism of action may involve a shift in the immune-mediated destruction from platelets to the antibody-coated RBCs ([Chapter 131](#)).

Kawasaki Disease

The mucocutaneous lymph node syndrome (Kawasaki disease) has been treated with aspirin with or without concomitant IVIg administration. Coronary artery aneurysm, a serious complication of this disease, was significantly reduced in the IVIg-treated group. However, in a multicenter retrospective survey of all children treated with Kawasaki disease, persistent or recrudescence fever after their first course of IVIg was associated with a statistically significant risk of treatment failure. Furthermore, IVIg retreatment in those patients with persistent fever after IVIg treatment failure was approximately 60%. Current randomized trials are now being done to compare the efficacy of newer, and perhaps better, therapies, such as infliximab (anti-tumor necrosis factor α). To date, these randomized control

studies show that infliximab is at least as safe and as efficacious as IVIg in these refractory patients. One retrospective review has even suggested that infliximab might result in faster resolution of fever and fewer days of hospitalization in comparison with IVIg. While studies are still ongoing, IVIg may soon be replaced by alternative therapies in this refractory patient population.

With regard to the pathogenesis of Kawasaki disease, decreased peripheral blood lymphocyte apoptosis has been demonstrated. Therefore, the effect of IVIg in Kawasaki disease has been postulated to partially reverse inhibited lymphocyte apoptosis.

Solid Organ Transplantation

The presence of high-titer reactive antibodies against incompatible graft HLA or ABO antigens increases the risk of early solid organ, antibody-mediated, graft rejection and mortality, especially in kidney and cardiac transplants. For some patients who have HLA antibodies to undergo transplantation, these antibodies must be removed or decreased. While morbidity and mortality can be reduced by selecting an adequately cross-matched donor, IVIg with or without plasma exchange has also been shown to decrease sensitization of incompatible antigens in patients awaiting renal and cardiac transplantations. In addition, IVIg with or without plasma exchange is used in the treatment of biopsy-proven antibody-mediated rejection. One review discussed three randomized control trials which investigated the use of IVIg for renal transplantation and revealed a trend in improvement in desensitization rates and a statistically significant decrease in time to transplant for patients treated with IVIg, superior graft survival rate in kidney transplant patients desensitized with IVIg, and a lower rate of recurrent acute rejection with IVIg in comparison to OKT3

(murine monoclonal antibody to CD3 antigen of human T cells). Consequently, current consensus renal transplant guidelines indicate IVIg is a useful treatment modality for desensitization of patients with HLA antibodies and in patients with acute rejection.

Randomized trials have not yet been performed for ABO incompatible kidney transplants, heart, liver, or lung transplants. Moreover, there is a paucity of data for transplant outcomes, and current studies have small numbers without data on donor specific antibody levels. Current guidelines assert that there is insufficient evidence to make a recommendation for or against the routine use of IVIg for desensitization in these transplants.

Aplastic Anemia Secondary to Parvovirus

Parvovirus B19 infection can result in severe anemia and reticulocytopenia, especially in immunocompromised individuals or individuals with sickle cell disease or thalassemia, and the use of IVIg is considered first-line therapy in the treatment of these patients (typical dose 0.5 g/kg weekly for 4 weeks).

Chronic Inflammatory Demyelinating Polyradiculoneuropathy

CIDP is a chronic disorder resulting in demyelination of peripheral nerves that result in weakness and sensory changes. Equivalent outcomes have been observed in the treatment of CIDP with IVIg (reported dose 400 mg/kg/day for 5 days, once each month, or 1 g/kg/day for 2 days, once each month), TPE, or glucocorticosteroids. The decision as to which treatment to use is made on an individual basis balancing the risks and benefits of each treatment modality.

Dermatomyositis

Dermatomyositis is a chronic inflammatory disorder that results in progressive weakness and rash. IVIg (typical dose 2.0 g/kg per month administered over 2–5 days) results in improved muscle strength and neuromuscular symptoms.

Guillain-Barré Syndrome (Acute Inflammatory Demyelinating Polyneuropathy)

Guillain-Barré syndrome is an acute demyelinating peripheral neuropathy affecting both motor and sensory nerves. IVIg (typical dose 400 mg/kg/day for 5 days or 1.0 g/kg/day for 2 days or 2.0 g/kg as a single dose) is likely equivalent to TPE in improving disability and shortening the time to improvement.

Hypogammaglobulinemia Associated With Multiple Myeloma

Multiple myeloma is a monoclonal B-cell (plasma cell) disorder with clinical symptoms arising as a result of plasma cell infiltration of the bone marrow, monoclonal Ig in the blood and urine, and immunosuppression. IVIg has shown to be beneficial in preventing serious infections in plateau-phase multiple myeloma or other hematologic malignancy, where the patients have hypogammaglobulinemia, at doses of 0.4 g/kg every 4 weeks, with subsequent dosing adjusted based on trough levels.

IgM Paraproteinemic Demyelinating Neuropathy

Paraproteinemic demyelinating neuropathy is a chronic disorder resulting in decreased sensory and motor function, similar to CIDP,

in association with monoclonal Igs. One placebo-controlled trial demonstrated that IVIg may improve short-term morbidity, but the remainder of the available evidence is mixed. The use of IVIg for this condition has recently fallen out of favor with current consensus groups.

Inclusion Body Myositis

Inclusion body myositis is an inflammatory myopathy resulting in chronic muscular weakness. Randomized trials using IVIg appear to result in short-term improvement in strength scores and improved swallowing in patients with inclusion body myositis, and are equivalent to treatment with glucocorticosteroids in one small clinical study. The use of IVIg for this condition has also recently fallen out of favor with current consensus groups because of the lack of known sustained benefit for patients with this condition.

Lambert-Eaton Myasthenic Syndrome

Lambert-Eaton myasthenic syndrome results from antibodies to the neuromuscular junction, leading to autonomic dysfunction. One randomized control trial reveals that IVIg significantly improves generalized central and peripheral muscle strength and decreases serum calcium channel antibody titers. A total dose of 2.0 g/kg given over 2 to 5 days is a recommended initial treatment.

Multifocal Motor Neuropathy

Multifocal motor neuropathy is a chronic progressive disorder resulting in primarily hand weakness. IVIg is now considered a first-line treatment for this condition, and improved strength can be seen at a dose of 2.0 g/kg over 2 to 5 days.

Multiple Sclerosis

Multiple sclerosis is a chronic progressive or relapsing and remitting disorder characterized by brain white matter demyelination. There are two published metaanalyses, and several randomized controlled clinical trials in patients with relapsing-remitting multiple sclerosis using a wide range of IVIg doses that demonstrate the success of IVIg in reducing the number of exacerbations and disability in patients with relapsing-remitting multiple sclerosis in comparison with placebo. However, no studies to date have compared IVIg with standard therapies, and one clinical trial (PRIVIG trial) has raised doubt that IVIg is effective as a routine treatment. Consequently, IVIg is considered a viable second-line option for those patients who fail, decline, or are unable to tolerate standard immunomodulatory therapies such as β -interferon and glatiramer acetate.

Myasthenia Gravis

Myasthenia gravis is a chronic neurologic autoimmune disorder characterized by weakness and fatigue upon repetitive skeletal muscle use, which improves with rest. IVIg has been used successfully as a short-term measure for acute severe exacerbations of myasthenia gravis at a dose of 2.0 g/kg given over 2 to 5 days, and appears comparable with TPE. A definitive randomized control trial comparing the two treatment modalities has not been done, however.

Neonatal Alloimmune Thrombocytopenia

NAIT is a rare condition that results from maternal platelet alloantibodies against the fetal/neonatal platelets resulting in neonatal/fetal

thrombocytopenia. Studies evaluating the use of IVIg for NAIT are limited, but unlikely to improve because of the rarity of the condition. The treatment of NAIT during pregnancy is maternal administration of 1.0 g/kg IVIg weekly as a first-line therapy beginning at 20 weeks of gestational age with the use of glucocorticosteroids, or 2.0 g/kg weekly if steroids are not used. Once at 32 weeks of gestation, the IVIg dose is increased to 2.0 g/kg weekly with corticosteroids. Moreover, the neonate may need to receive IVIg and platelet transfusions after delivery to increase fetal platelet counts to prevent intracerebral hemorrhage at a dose of 1.0 g/kg (Chapter 131).

Hemolytic Disease of the Fetus and Newborn

Hemolytic Disease of the Fetus and Newborn (HDFN) results from maternal RBC alloantibodies binding to fetal/neonatal RBCs and may result in hemolysis, leading to anemia or hydrops fetalis and death depending on the severity. Two metaanalyses reveal that IVIg significantly reduces the need for exchange transfusions in patients with HDFN. IVIg is now consequently recommended at a dose of 0.5 to 1.0 g/kg to treat newborns with HDFN if there is established jaundice and a rising total serum bilirubin despite phototherapy. In addition, maternal IVIg infusion (with or without therapeutic plasma exchange) has been used in severe cases of HDFN where treatment must occur before the ability to perform intrauterine transfusions.

Posttransfusion Purpura

PTP is a rare complication of transfusion resulting in acute, profound thrombocytopenia, secondary to platelet antibodies that destroy both transfused and autologous platelets. While the evidence evaluating the effect of IVIg in these patients is limited to multiple case reports, the available evidence suggests that IVIg should be a first-line therapy for this condition. PTP treatment with IVIg at a dose of 2 g/kg over 2 days or 0.4–0.5 g/kg daily for 5 days can result in a rapid increase in platelet count.

Sepsis and Septic Shock in Adults

The use of IVIg in adult patients with bacterial sepsis or septic shock is potentially beneficial. One randomized control trial revealed that in ICU patients with intraabdominal sepsis and shock, IVIg with antibiotics was superior to antibiotics with albumin in improving patient survival. Encouraging results have also been identified in patients receiving IVIg for streptococcal toxic shock syndrome, but further studies are currently needed.

Stiff-Person Syndrome

Stiff-person syndrome is a neurologic disorder associated with truncal and limb rigidity and heightened sensitivity. One small randomized control trial suggests that IVIg could play a positive role in improving stiffness and sensitivity symptoms. Currently, IVIg is considered a second-line therapy for those who fail or cannot tolerate GABA (glutamic acid decarboxylase)-ergic medications. A dose of 2.0 g/kg given over 2 to 5 days is the current recommended starting dose.

Dosage

The dosage and frequency for IVIg varies significantly depending on the age of the patient and the clinical indication. Many typical dosages were described in the preceding section. In general, patients require 200 to 800 mg/kg intravenously every 3 to 4 weeks to achieve adequate IgG levels if immunodeficient (usually 500 mg/dL) and

needing protection against infection. Initially, serial IgG level determination may allow the physician to individualize the dose and schedule. These are affected by the recovery, half-life, redistribution, and catabolism of IVIg, which vary from product to product and patient to patient. Patients with ITP are usually initially treated with 400 to 1000 mg/kg daily for 2 to 5 consecutive days with a maximum dose of 2.0 g/kg. Maintenance doses of 400 to 1000 mg/kg/dose every 3 to 6 weeks is recommended in some patients (particularly children) based on clinical response and platelet count. Kawasaki disease is treated with 2.0 g/kg as a single dose in combination with aspirin. Currently, direct comparisons between different IVIg formulations or brands are lacking, and so evidence-based recommendations cannot be made along these lines.

Adverse Effects

Infusions of IVIg should be started slowly and patients should be closely monitored. If the initial rate (0.5 mL/kg/h) is well tolerated, the rate can be increased gradually, but not more than eightfold. That said, initial and maximum infusion rates vary by IVIg product, and product inserts should be consulted prior to selecting an appropriate infusion rate. Fever, headache, nausea, vomiting, fatigue, backache, leg cramps, urticaria, flushing, elevation of blood pressure, and thrombophlebitis may be seen. Adverse events have been reported in 2% to 10% of infusions. IgA-deficient patients may have IgG anti-IgA antibodies, which can cause anaphylactic reactions. This complication is rare and may be avoided by using products with a lower concentration of IgA. Aggregated IgG may produce chills, nausea, flushing, chest tightness, and wheezing. Rarely, IVIg preparations contain RBC antibodies that can produce hemolysis or interfere with serologic evaluations, including RBC compatibility testing. IVIg treatment will produce a false positive direct antiglobulin test, and sometimes positive hepatitis and CMV serologies. Serum sickness can also occur. Lastly, high-dose IVIg therapy has been associated with thrombosis, reversible acute renal failure, TRALI, and aseptic meningitis. Improved manufacturing processes currently in place render IVIg free of enveloped and nonenveloped viruses.

HYPERIMMUNE IMMUNOGLOBULIN PRODUCTS

Hyperimmune globulins are concentrated immune globulins with specificity for an antigen, or group of antigens. These products are manufactured in a similar manner to that used for IVIg product production. However, donors for these specific products are unique in that they have high titers for the Ig specificity of interest. The donor high titers can be achieved via natural immunity, prophylactic immunization, or target immunization, depending on the antibody of interest. These products are generally used to provide passive immunity for a variety of conditions that are described in more detail in the following sections (Table 115.5).

TABLE 115.5

Hyperimmune and Intramuscular Immunoglobulins

Antithymocyte globulin
Botulism immunoglobulin
Cytomegalovirus immunoglobulin
Hepatitis A immunoglobulin
Hepatitis B immunoglobulin
Rabies immunoglobulin
Respiratory syncytial virus immunoglobulin
Rh(D) immunoglobulin
Tetanus immunoglobulin
Vaccinia immunoglobulin
Varicella-zoster immunoglobulin
Western equine encephalitis immunoglobulin

Antithymocyte Globulin

Antithymocyte globulin is a purified concentrated globulin made from hyperimmune serum of horses immunized with human T lymphocytes. Antithymocyte globulin is used in renal transplant patients as an adjunct therapy in the treatment of graft rejection. It is also used in patients with aplastic anemia who are not candidates for bone marrow transplantation.

Hyperimmune Immunoglobulin

Hyperimmune globulin is used to prevent the development of specific clinical disease or alter its symptomatology. Hepatitis B Ig is used to provide passive immunity to hepatitis B virus associated with needle stick exposure or sexual contact with hepatitis B surface antigen-positive individuals, postliver transplantation for prevention of recurrence, and prevention of hepatitis B vertical transmission. Other hyperimmunoglobulins include botulism, CMV, hepatitis A, rabies, respiratory syncytial virus, tetanus, vaccinia, and varicella-zoster virus Igs.

Rh Immunoglobulin

Rh Ig has two primary indications: prevention of D antigen alloimmunization and treatment of ITP. Rh Ig is given to D-negative mothers after potential exposure to fetal D-positive RBCs, such as after abortion or amniocentesis, as well as at 28-weeks gestational age, and postpartum if the child proves to be D positive. The therapeutic effect is thought to be caused by antibody feedback with T-cell suppression of the B-cell clone responsible for the formation of anti-D antibody. Rh Ig can also be given to prevent immunization in D-negative individuals given D-positive blood products, such as platelets.

Rh Ig is dosed to adequately prevent D immunization. In the United States, 300 µg are administered after event resulting in maternal-fetal hemorrhage, 28 weeks and postpartum. Doses are increased for evidence of large maternal-fetal hemorrhage (300 µg for every 15 mL of RBC exposure). This dosing is also used in the prevention of D alloimmunization after receipt of RBC containing blood product. Rh Ig should be given within 72 hours after RBC exposure. Adverse events to low doses, such as those used to prevent D immunization include fever, chills, and pain at the injection site. Rarely, hypersensitivity reactions are noted. See box “Weak, Partial D, and Rh Ig Use” for more information.

Weak, Partial D, and Rh Ig Use

Clinically significant D sensitization potentially results in a pregnancy with a fetus at risk for hemolytic disease of the fetus and newborn and hemolytic transfusion reactions if transfused with D-positive red blood cells. In rare cases, as a result of a mutation in the *D* gene, a person may have amino acid substitutions affecting a part of the normal D protein that changes the antigen on the external aspect of the red cell. These patients are described as having “partial D.” When someone with partial D is exposed to blood from someone with a normal form of D, they may make an antibody against the portions of the D antigen that they lack. Individuals with red blood cells that express a partial D antigen are thus at risk for D-sensitization and may benefit from Rh Ig administration to prevent D sensitization. Mutations which result in fewer “normal” D antigens on a red cell are known as having a “weak” D. Those with weak D antigens are usually not at risk for D sensitization because they have a normal D protein, and thus do not require Rh Ig administration. Partial and weak D antigens cannot be distinguished by serologic reactivity, because either may present as weak, moderately, or strongly positive or give variable results with anti-D reagents. Particularly in the prenatal setting, RhD genotyping can be done to distinguish weak D from partial D to help determine need for Rh Ig administration.

Rh Ig doses are substantially higher for the treatment of ITP: 50 µg/kg for hemoglobin ≥ 10 L/dL and 25 to 40 µg/kg when hemoglobin is 8 to 10 g/dL. Rh Ig use in ITP is indicated in D-positive patients with intact spleen. Adverse events at high doses of Rh Ig include hemolysis, DIC, and rarely death (Chapter 131).

PREPARATION OF PLASMA-DERIVED AND RECOMBINANT HUMAN PLASMA PROTEINS

David B. Clark

The development of large-scale methods for the preparation of human plasma proteins began more than 70 years ago, soon after the outbreak of World War II. The US Armed Forces issued an urgent request to the medical community for 300,000 units of human whole blood or plasma, which appeared to be an impossibly large amount at the time. Thinking that albumin could be used instead of plasma, Dr. Edwin J. Cohn of Harvard Medical School drew together a task force of investigators who developed methods for the fractionation of plasma based on differential precipitation of various proteins with ethanol. Although albumin was the only product distributed during the war, the remaining plasma fractions were carefully preserved, and other preparations, including fibrinogen and immunoglobulins, were soon developed. This was the beginning of the plasma fractionation industry.

PLASMA FRACTIONATION

Beginning in the post-World War II era and continuing to the present, major improvements have occurred in the preparation of human plasma protein products. Most large-scale manufacture of plasma-derived products is still based on modifications of the original method developed by Cohn's group supplemented by more selective purification techniques to produce a wide variety of products. In addition, genetic engineering technology has allowed recombinant human plasma proteins to be produced in cell culture systems and transgenic animals. This chapter describes current methods and future directions for the preparation of plasma-derived and recombinant human plasma proteins for clinical use, primarily for products available in the United States.

Plasma is estimated to contain approximately 10,000 different proteins, most of which have yet to be identified. One of the unique features of plasma fractionation is the ability to produce multiple products from a single raw material. Plasma for fractionation is derived from two sources, either directly by plasmapheresis, termed *source plasma*, or as a byproduct of whole blood donation, termed *recovered plasma*. The plasma is usually shipped frozen as individual units from local blood or plasma collection centers to a central processing plant.

At the plant, sufficient units to produce typically 2000–3000-L pools are thawed slowly at 1° to 5°C to produce cryoprecipitate, a cold-insoluble fraction that contains significant amounts of factor VIII, von Willebrand factor (vWF), fibrinogen, fibronectin, and factor XIII, along with a number of other proteins present in smaller quantities. The cryoprecipitate is usually recovered by centrifugation. The cryo-supernatant or cryo-poor plasma may be treated with a chromatographic media to capture the factor IX complex or antithrombin (AT) before it enters the Cohn process. There it goes through a series of precipitations as the ethanol concentration is increased in steps from 8% to 40% at specific combinations of pH, ionic strength, protein concentration, and cold temperature. The precipitates and supernatants are separated either by the traditional continuous-flow centrifugation or in large-scale filter presses. The method provides both relatively pure fractions containing albumin and immunoglobulins, which need minimal additional processing, as well as fractions enriched in other proteins, which are used as the

starting materials for further purification. Fig. 116.1 shows a schematic of the ethanol process.

The first precipitate, fraction I at 8% alcohol, contains factor VIII, fibrinogen, and other poorly soluble proteins. Fractions II and III are precipitated together and contain the immunoglobulins, which are separated in a subsequent series of precipitations to produce fraction II, essentially pure immunoglobulins. Because many of the fraction I proteins are removed in the cryoprecipitate, some manufacturers do not produce a separate fraction I. Instead they collect a combined fraction I + II + III. Fraction IV, produced from the supernatant of fraction (I +) II + III, is sometimes produced in two subfractions. Fraction IV-1 contains the vitamin K-dependent (VKD) clotting factors, AT and α_1 -proteinase inhibitor (API), whereas fraction IV-4 contains transferrin, haptoglobin, and some of the albumin. Fraction V is almost pure albumin.

PRODUCT SAFETY

Ensuring the safety of plasma products depends on a complex system that starts with donor selection and carries all the way through to the patient receiving the product. The system is highly redundant so that a failure in one area may be compensated for by another.

Donor Selection, Screening, and Testing

Gone are the days when anyone could be a donor, with prisons and mental hospitals providing much of the country's plasma. Plasma collection centers screen their potential donors rigorously, both for medical history and any social behaviors that might put them at risk of infection. Plasma products licensed in the United States are only produced from plasma collected from US donors in US Food and Drug Administration (FDA)-licensed establishments.

Every donation is tested for a number of different viral diseases by a battery of tests, again with redundancy. Sensitive antigen and antibody tests are followed by NAT testing (nuclear amplification or nucleic acid testing, a form of polymerase chain reaction), which can detect extremely small numbers of virus particles. Because of the "window period" between the time a donor is infected and the time antibodies or viruses can be detected in his or her plasma, most manufacturers also hold donations for at least 60 days until a donor has returned for a repeat donation. If the repeat donation still tests negative, there is a high likelihood that the first donation is safe. In addition to FDA oversight, many manufacturers and collection agencies belong to the Plasma Protein Therapeutic Association (PPTA), which has strict quality regulations to help ensure the safety of donated plasma.

Viral Inactivation and Removal Processes

Maximizing the safety of the incoming plasma is only the first step. Viral inactivation and removal methods are now incorporated into all purification processes. One of the early methods, still used today, is pasteurization of albumin; otherwise, except for donor screening

Fig. 116.1 SCHEMATIC OF A TYPICAL PLASMA FRACTIONATION PROCESS. The *dashed lines* show optional steps. *API*, α_1 -Proteinase inhibitor; *AT*, antithrombin; *FIX*, factor IX; *FVIII*, factor VIII; *PPF*, plasma protein fraction; *vWF*, von Willebrand factor.

and testing, most other early products had no antiviral treatment. That all changed with the AIDS crisis in the early 1980s, when many in the hemophilia community became infected with HIV from clotting factor concentrates.

Since then, many viral inactivation and removal methods have been developed, including various types of heat treatment, solvent and detergent treatment, and nanofiltration. Manufacturers have also realized that many of their purification methods remove viruses, which works well as long as they take steps to protect the processed products from recontamination. Many of those steps also remove prions, the agents of the transmissible spongiform encephalopathies.

The bottom line is that modern plasma-derived products are extremely safe, as shown both theoretically and by actual experience over the past 30 years. Still, many patients and physicians prefer recombinant products because of their perceived greater safety in terms of the future unknown, emergent virus.

PLASMA PRODUCTS

The following sections provide information about the plasma-derived and recombinant plasma protein products available in the United

States in 2015. Additional details, including manufacturing and viral reduction methods, are listed in the tables for most products. The manufacturing methods were taken from the prescribing information sheets provided with each product and from the published literature. However, most manufacturers consider their processes proprietary, so some descriptions are not very detailed.

Fresh-Frozen Plasma

Whole plasma is still used to treat various conditions, including as a source of coagulation proteins that are not available in purified form and for replacement of significant blood loss. Plasma from a single donor that has been separated from the red blood cells, placed in a freezer within 8 hours after phlebotomy, and stored at -18°C or less is labeled as fresh-frozen plasma. *Fresh-frozen plasma* undergoes essentially the same donor screening and donation testing as plasma for fractionation and has a low risk of infectious disease transmission. In addition, INTERCEPT plasma was recently licensed by FDA as a viral-inactivated plasma for treatment of thrombotic thrombocytopenic purpura. The INTERCEPT process uses a psoralen, amotosalen, and ultraviolet light to inactivate viruses.

Albumin and Plasma Protein Fraction

Albumin remains one of the major products of human plasma fractionation. Literally tons of albumin have been isolated and millions of units have been infused. Albumin, recovered in very pure form in fraction V, is pasteurized in the final vial for 10 hours at 60°C with sodium acetyltryptophanate and sodium caprylate added as stabilizers.

Albumin is a commodity product, with little to distinguish one manufacturer's product from another's. There are small differences in purity, but those are only clinically relevant in rare cases. Three albumin products are manufactured in the United States: *albumin (human) 25% solution*, *albumin (human) 5% solution*, and *plasma protein fraction (human)* or PPF. In albumin (human), more than 96% of the protein content must be albumin. PPF, obtained by coprecipitating fraction IV-4 with fraction V, has a lower purity of greater than 83% albumin. PPF is more economical to produce than albumin, but the rapid infusion of PPF has been associated with hypotensive episodes.

Immune Globulins and Hyperimmune Globulins

Since the early 1950s, immune globulin products have been prepared from Cohn fraction II + III by the method developed by Oncley, a collaborator of Cohn. The Oncley process uses additional ethanol precipitations to remove lipoproteins, immunoglobulins A and M (IgA and IgM), and other plasma proteins, leaving fraction II, which contains purified immunoglobulin G (IgG). Whereas immune globulin is prepared from the plasma of unselected normal donors, hyperimmune globulins are prepared from the plasma of donors with high antibody titers against specific antigens [e.g., rho(D), hepatitis B, rabies, and tetanus]. These donors may be identified during convalescent periods after infection or transfusion, or they may be specifically immunized to produce the desired antibodies. The immune globulin products are listed in [Tables 116.1](#) and [116.2](#).

Intravenous Immune Globulin Concentrates

The original immune globulin concentrates, initially termed *immune serum globulin* and currently *immune globulin (human)*, were administered by the intramuscular route, with the associated problems of limited injectable volume, poor bioavailability, and discomfort at the injection site. Intravenous (IV) injection of immune globulin (human) causes serious clinical reactions, which are attributed to complement-activating aggregates in these products.

To overcome these limitations, *immune globulin intravenous (human)* (IGIV) products were developed using a variety of methods to remove or inactivate anticomplementary aggregates. Today most intramuscular immune globulin usage is limited to hyperimmune products. Although immune globulin products tend to be self-protecting from viral transmission because of the large pools of antibodies they contain, infections have occurred, and as a result all manufacturers have incorporated viral inactivation or removal steps in their production processes.

The development of IGIV has permitted the administration of much higher doses, with a subsequent expansion in immunoglobulin therapy. Although immune globulin products were originally also considered commodity products, the increased usage has led manufacturers to distinguish their products in various ways. As shown in the tables, products are available in both lyophilized and liquid forms, with various strengths and purities. IgA content and product formulation are also distinguishing factors.

Subcutaneous Immune Globulin Concentrates

The first patient treated for primary immune deficiency was actually given subcutaneous injections of immunoglobulins, but as described

above, intramuscular and later IV injection became the preferred methods. Recently, however, two immune globulin concentrates for subcutaneous injection have been marketed, Hizentra and HyQvia. HyQvia is also formulated with recombinant hyaluronidase to improve dispersion and absorption of the immune globulins in subcutaneous infusion. These products are intended for patients who have problems with IV infusion.

COAGULATION FACTOR CONCENTRATES

Transfusion of whole blood was shown in the mid-1800s to curtail bleeding in patients with hemophilia, and by 1940, bleeding episodes were being routinely treated with plasma. However, large amounts of plasma were needed, and this method of therapy could not provide normal levels of coagulation factors without producing hypervolemia. The development of more highly purified plasma-derived coagulation factor concentrates and more recently of recombinant concentrates has resulted in dramatic increases in the quality of life and life expectancy for patients with hemophilia. Hemophilia treatment is a large market, and the development of improved coagulation factor concentrates continues to be a major focus of research.

Factor VIII Concentrates

Factor VIII is the protein that is missing or defective in patients with hemophilia A. Factor VIII concentrates, generically termed *antihemophilic factor (human)* or AHF, for the treatment of hemophilia A have evolved from cryoprecipitates to very high-purity plasma-derived products to recombinant products. The various AHF concentrates available in the United States are listed in [Table 116.3](#).

Cryoprecipitate

In a landmark discovery for hemophilia A treatment, cryoprecipitate was discovered in the mid-1950s to contain much of the factor VIII activity of the original plasma. By 1965, single-donor cryoprecipitate with factor VIII concentrations five to 30 times that of plasma became widely available for use in the treatment of patients with hemophilia A. Single-donor cryoprecipitate is still available from many blood banks but does carry a risk of viral transmission.

Intermediate- and High-Purity Antihemophilic Factor Concentrates

The development of AHF concentrates purified approximately 3000-fold over plasma was the next significant advance in the treatment of hemophilia A. Cryoprecipitate was used as the starting material, and a variety of methods were developed to remove fibrinogen, immunoglobulins, and other contaminating proteins. These were the mainstay of hemophilia A treatment for many years and are still available, their chief advantage being lower cost. Some of these products are also indicated as a source of vWF, which circulates in a complex with factor VIII. Products purified 5000-20,000-fold over plasma were subsequently developed using various chromatographic methods, but they have primarily been supplanted by immunoaffinity-purified products in the United States.

Immunoaffinity-Purified Concentrates

The next major advance in the preparation of AHF concentrates was the use of murine monoclonal antibodies (mAbs) immobilized on a chromatographic column for the purification of factor VIII. Factor VIII concentrates partially purified by conventional means are applied to an immunoaffinity column that binds either factor VIII directly or the factor VIII/vWF complex. The columns are washed extensively to remove unwanted proteins and then eluted with a solution that

TABLE 116.1 Immune Globulin Products^a

Generic Name	Manufacturer or Distributor	Brand Name (Product Form)	Purity IgA Content	Production Methods (Formulation) ^b	Virus Inactivation or Removal Methods
Immune globulin (human)	Grifols Therapeutics	GamaSTAN S/D (15%–18% solution)	≥96% GG IgA: N/A	CEF (glycine)	PS, S/D, TSE
Immune globulin intravenous (human)	Baxter Healthcare	Gammagard S/D (lyophilized)	≥90% GG IgA <2.2 µg/mL	CEF, IEC (albumin, glycine, glucose, and PEG)	PS, S/D

disrupts the antibody binding. A final chromatography step removes the harsh elution solutions as well as any mAb that might have leached off the column to produce a factor VIII concentrate that is essentially pure before the addition of albumin as a stabilizer.

Recombinant Antihemophilic Factor Concentrates

One of the remarkable early accomplishments of molecular biology was the elucidation of the structure of factor VIII, its molecular cloning, and the successful production of two recombinant human factor VIII products, Recombinate and Kogenate. Additional recombinant factor VIII products have followed. Because proper

posttranslational processing is essential for factor VIII functionality, the products are produced in mammalian cells, either baby hamster kidney (BHK) cells or Chinese hamster ovary (CHO) cells. A newer product, Eloctate, is produced in human embryonic kidney (HEK) cells. Recombinant factor VIII is purified by various types of chromatography.

One of the major driving forces for development of recombinant products is viral safety; they are seen as inherently safer because they are not produced from plasma. However, the first generation of recombinant products used animal-derived proteins and sera in their cell culture media and in the production of the mAbs used for purification, plus human albumin to stabilize the products in the final vial, all potential sources of viral contamination. With this in

mind, manufacturers went still further to develop recombinant products completely free of human- and animal-derived proteins, both in their production processes and in their formulations. Most current production methods for recombinant products also incorporate viral inactivation or removal procedures for an added measure of safety.

One of the potential benefits of recombinant technology is the ability to design completely new proteins that do not occur in nature, ones that potentially perform better or are easier to produce than their natural counterparts. The factor VIII molecule is a multidomain complex consisting of a heavy chain with A1, A2, and B domains and a light chain consisting of A3, C1, and C2 domains. Previous research had shown that the B domain is not necessary for coagulant activity, so a B domain-deleted product, ReFacto, was developed. Eliminating the B domain, which is highly glycosylated, increased the expression of the molecule as much as 20-fold over full-length factor VIII. Xyntha was later introduced as an updated version of ReFacto with an improved manufacturing process.

Many hemophilia A patients are on prophylactic treatment regimens that require infusions every other day to maintain an increased factor VIII level in the bloodstream. To reduce the frequency of

infusions, a number of manufacturers are developing factor VIII molecules that have longer lifetimes in circulation. They are all taking the approach of connecting factor VIII to another molecule that has a longer half-life such as albumin or an immunoglobulin fragment. The first product to reach the market is Eloctate, which is a recombinant fusion protein of factor VIII and the Fc fragment of an immunoglobulin molecule. Eloctate reduces the frequency of infusions from every other day to once every 3–5 days.

Another new product, Obizur, is a recombinant porcine factor VIII that is indicated for patients with acquired hemophilia A. Antibodies against human factor VIII often do not react to porcine factor VIII, but the porcine molecule is active in the human coagulation process.

Factor IX Concentrates

Factor IX is the protein that is missing or defective in patients with hemophilia B. Two types of plasma-derived factor IX concentrates are available today: factor IX complex, which contains significant amounts of the other VKD clotting factors, and coagulation factor

TABLE
116.4Factor IX and Other Coagulation Factor and Anticoagulant Concentrates^a

Generic Name	Manufacture or Distributor	Brand Name	Specific Activity ^b	Production Methods	Virus Inactivation or Removal Methods
Factor IX complex	Baxter Healthcare Grifols Biologicals	Bebulin Profilnine	2 4	CP, IEC CP, IEC	PS, VHT, NF PS, S/D, NF
Prothrombin complex concentrate (human)	CSL Behring	Kcentra	N/A	CP, IEC, AS, CPA	PS, PST, NF
Coagulation factor IX (human)	CSL Behring Grifols Biologicals	Mononine AlphaNine SD	≥190 ≥150	CP, IEC, IAC, HIC CP, IEC, BCA, AC	PS, CT, NF PS, S/D, NF
Coagulation factor IX (recombinant)	Pfizer Baxter Healthcare	BeneFIX Rixubis	≥200 ≥200	CHO, IEC, AC, IMAC CHO, CHR	NF S/D, NF

Protein C concentrate (human)	Baxter Healthcare	Ceprotin	N/A	CP, CEF, IAC, IEC	PS, P80, VHT

Various forms of filtration and ultrafiltration are common in production processes, so those steps are not listed.

^aThese products were marketed in the United States in 2015. Data were obtained from manufacturers, distributors, and available literature.

^bIU-factor IX/mg of total protein.

AA, Autocatalytic activation; AC, affinity chromatography; AH, aluminum hydroxide adsorption; AS, ammonium sulfate precipitation; AT, antithrombin; BCA, barium citrate adsorption; BHK, baby hamster kidney cell culture; CHO, Chinese hamster ovary cell culture; CHR, chromatography (specific method not available); CP, cryoprecipitation; CPA, calcium phosphate adsorption; CEF, cold ethanol fractionation; CT, chemical treatment; HEK, human embryonic kidney cell culture; HIC, hydrophobic interaction chromatography; HT, heat treatment; IAC, immunoaffinity chromatography; IEC, ion-exchange chromatography; IMAC, immobilized metal affinity chromatography; IU, international units; N/A, not available or not applicable; NF, nanofiltration; P80, polysorbate 80 treatment; PAC, Protein A chromatography; PPTN, precipitation; PS, purification steps; PST, pasteurization (heat treatment in solution); SA, surface activation; S/D, solvent/detergent; TGM, transgenic goat milk; TSE, validated for removal of transmissible spongiform encephalopathies; VHT, vapor heat treatment; YST, yeast cell culture.

IX (human), a preparation substantially free of these other proteins. Recombinant factor IX products are also available. The factor IX concentrates available in the United States are listed in Table 116.4.

Factor IX Complex Concentrates

The VKD proteins are serine proteases that include clotting factors II, VII, IX, and X and the anticoagulants protein C and protein S. Because of their similar structures, they tend to co-purify by most of the methods used to isolate them from plasma. Thus, the original factor IX products for treatment of hemophilia B were mixtures of the VKD proteins called *factor IX complex*. Because the protein in highest concentration in these products is prothrombin (factor II), they have also been identified as *prothrombin complex concentrates* (PCCs).

The VKD proteins were originally adsorbed from either cryo-poor plasma or fraction IV-4 using tricalcium phosphate. Later, ion exchange chromatography resins were used with cryo-poor plasma with the advantage that the supernatant plasma can then be further fractionated by the Cohn method for the production of immune globulins, albumin, and other products with little loss in yield.

Coagulation Factor IX Concentrates

With the widespread use of factor IX complex, it became apparent that serious thromboembolic episodes and acute myocardial infarction were major complications of its infusion, especially when used in large quantities for extended periods, such as for surgical procedures and in patients with liver disease. The cause of the

thrombogenicity has not been conclusively determined, but the problem led to the development of more highly purified concentrates that are essentially free of the other VKD clotting factors. These products are designated *coagulation factor IX (human)*. Of the two products available in the United States, Mononine is prepared by immunoaffinity chromatography using a mAb to factor IX, and AlphaNine SD is purified by heparin affinity chromatography. These preparations have proven to be largely nonthrombogenic in clinical use.

Recombinant Factor IX Concentrates

Recombinant coagulation factor IX products have also been developed. They are produced in cell culture by mammalian cells and are purified using several chromatography steps. As with the latest generation AHF products, they are produced without human or animal proteins and include viral inactivation/removal steps to eliminate any viruses that might be present.

Manufacturers are also developing factor IX products with longer half-lives in circulation. The first to be marketed, Alprolix, is a recombinant fusion protein of factor IX bound to the Fc portion of an immunoglobulin molecule. The longer half-life reduces the frequency of prophylactic infusions from about once every third day to once a week or longer.

OTHER COAGULATION AND ANTICOAGULANT CONCENTRATES

Now that the risk of infection has essentially been eliminated, the major complication in hemophilia treatment is the development of

inhibitors, neutralizing antibodies directed against factor VIII or factor IX. There are two primary means of treating bleeding in inhibitor patients, both based on administration of activated clotting factors.

Factor IX complex was known to be somewhat effective in preventing bleeding in inhibitor patients, possibly because it contains small amounts of activated clotting factors. Based on that information, two activated factor IX complex products were developed, one of which, FEIBA, is still available. FEIBA, which is named for factor eight inhibitor bypassing activity, is generically named *anti-inhibitor coagulant complex* and is indicated for inhibitor treatment in both hemophilia A and B.

The hypothesis that administration of activated clotting factors can bypass inhibitors also led to the development of NovoSeven, a recombinant activated factor VII concentrate. NovoSeven has been extensively studied and is currently the most widely used option for inhibitor treatment, especially for patients who have never been exposed to plasma-derived products. However, both FEIBA and NovoSeven do carry a risk of thromboembolic complications. FEIBA and NovoSeven are listed in [Table 116.4](#).

von Willebrand disease (vWD), caused by missing or abnormal vWF, is actually the most common inherited coagulation disorder. vWF is a large protein that circulates in a complex with factor VIII. It stabilizes factor VIII in the bloodstream but also has coagulation functions of its own. Several intermediate-purity viral-inactivated AHF concentrates that contain significant amounts of vWF are also indicated for replacement therapy for vWD. These vWF/AHF concentrates are listed in [Table 116.3](#).

Fibrinogen is the final protein in the coagulation cascade. It is cleaved by thrombin to form fibrin, a protein that naturally self-associates to form a clot. RiaSTAP is a plasma-derived concentrate for replacement therapy in fibrinogen-deficient patients that is made from the concentrated fibrinogen in cryoprecipitate. Interestingly, fibrinogen was also one of the first plasma products developed, but it was soon taken off the market because it almost universally transmitted viral infections. RiaSTAP is pasteurized (heat treated) in solution for 20 hours at 60°C, twice as long as the typical treatment for pasteurized plasma products. Significant viral removal has also been demonstrated for its purification process, and the resulting product is considered safe. RiaSTAP is listed in [Table 116.4](#).

Factor XIII does not participate directly in the coagulation cascade but instead stabilizes the final clot by cross-linking the fibrin molecules. Factor XIII deficiency is rare and is characterized by weak clots prone to rebleeding. Before the availability of factor XIII concentrates, patients were usually treated with plasma or cryoprecipitate, both of which carry a risk of viral infection. Plasma-derived Corifact is purified from cryoprecipitate and employs a unique process step using Vitacel, a wheat-based vegetable fiber, to remove fibrinogen, after which the factor XIII is further purified by ion-exchange chromatography. Tretten is a recombinant version of the A subunit of factor XIII, a deficiency of which is the usual cause of factor XIII deficiency. Tretten is produced in yeast and purified by chromatography. Tretten and Corifact are listed in [Table 116.4](#).

Anticoagulant Concentrates

Antithrombin III, now generally just called AT, is an anticoagulant. As its name suggests, it inhibits thrombin (activated factor II), but it also inhibits the activated forms of factors IX, X, XI, and XII. It belongs to the serpin family named for their activity as serine protease inhibitors. Heparin is a cofactor that increases the native activity of AT significantly, from 500- to 1000-fold for factor Xa inhibition up to 1 million-fold for factor IXa inhibition. The affinity of AT for heparin is also used to purify the protein by affinity chromatography on an immobilized heparin column. Thrombate III, the only plasma-derived product currently on the US market, is purified by heparin affinity chromatography from Cohn fraction IV-1. ATryn, a recombinant AT, was the first recombinant human plasma protein produced in transgenic animals to be approved anywhere. It is made in the milk

of transgenic goats and also purified by heparin affinity chromatography. The two available AT concentrates are listed in [Table 116.4](#).

Protein C is a serine protease with a structure similar to clotting factors II, VII, IX, and X, but it is an anticoagulant that cleaves activated factors V and VIII. Patients deficient in protein C are susceptible to thrombosis. One plasma-derived protein C concentrate, Ceprotin, is available. Ceprotin is listed in [Table 116.4](#).

Fibrin Sealant and Thrombin

Fibrinogen and thrombin are also used as topical hemostatic agents, together as fibrin sealant, and as standalone thrombin concentrates. The fibrin sealant and thrombin products available in the United States are listed in [Table 116.5](#).

Fibrin sealant uses the clot-forming reaction of thrombin and fibrinogen to form a physiologic glue or sealant that has become widely used in surgical procedures. All three fibrin sealant products on the US market are made from human plasma-derived fibrinogen and thrombin. Fibrinogen is purified directly from cryoprecipitate followed by further purification steps. ARTISS and TISSEEL contain a plasmin inhibitor, synthetic aprotinin, which is used to delay clot lysis. EVICEL contains a more highly purified fibrinogen component that has minimal plasmin activity and therefore does not contain a clot lysis inhibitor. Both fibrinogen preparations contain residual factor XIII for clot stabilization, and additional factor XIII is recruited from the patient's bloodstream during use. Fibrin sealant is also the basis of two patches or bandages that are used to promote clotting.

Thrombin is produced from prothrombin (factor II) purified from the factor IX complex captured by ion exchange from cryosupernatant plasma. Prothrombin is autocatalytically activated to thrombin in the presence of calcium. Both the fibrinogen and thrombin components are also treated for viral inactivation and removal. Three standalone thrombin products are also available for use in promoting topical hemostasis. For years, bovine thrombin was the standard of care for such use; however, research has suggested that it may have been responsible for postsurgical hemostatic problems in some patients. The cause was apparently contamination with bovine factor V, against which some patients developed antibodies that cross-reacted with their own human factor V. Most bovine thrombin products were taken off the market, but Thrombin-JMI, the sole remaining bovine product, was instead further purified to reduce bovine factor V to undetectable levels. A plasma-derived human thrombin product, EVITHROM, was also developed, which is the same thrombin used in EVICEL fibrin sealant.

The recombinant human thrombin product, RECOTHROM, is another example of a bioengineered protein. The VKD clotting factors contain a domain called the Gla region that is rich in a unique amino acid, γ -carboxyglutamic acid (Gla). The posttranslational modifications required to produce the Gla residues are a rate-limiting step in the production of all of the VKD proteins in cell culture. Presence of the Gla region is absolutely necessary for the function of most of the clotting factors but not for thrombin. Therefore, the Gla-less molecule prethrombin-1 is produced in CHO cells, with a significant increase in production rate. Prethrombin-1 is activated to thrombin using a proprietary enzyme system. RECOTHROM behaves similarly to human and bovine thrombin in clinical use.

PLASMA PROTEINASE INHIBITORS

The proteinase inhibitors that are present in human plasma play critical roles in the regulation of the coagulation, fibrinolytic, complement, and kinin cascade systems. Most of these inhibitors have similar amino acid and structural properties and are members of the serpin superfamily of proteins. AT, an anticoagulant, was discussed earlier. Two other proteinase inhibitors, API and C1 esterase inhibitor, are also available for treatment of deficient patients. These concentrates are listed in [Table 116.6](#).

TABLE 116.5**Fibrin Sealants and Thrombin Concentrates^a**

Generic Name	Manufacturer/Distributor	Brand Name (Product Format)	Production Methods	Virus Inactivation or Removal Methods
Fibrin sealant (human)	Baxter Healthcare	Artiss (frozen solutions in prefilled syringe)	FC: CP, OS TC: IEC, CA	FC and TC: PS, VHT, S/D
	Omrix/Ethicon	Evicel (frozen solutions)	FC: CP, AH, HIC, AC TC: CP, IEC, CA	FC: S/D, PST TC: S/D, NF
Fibrin sealant (Tisseel)	Baxter Healthcare	Tisseel (lyophilized or frozen solutions)	FC: CP, OS TC: IEC, CA	FC and TC: PS, VHT, S/D
Fibrin sealant patch	Omrix/Ethicon	Evarrest (lyophilized absorbable patch)	FC: CP, AH, HIC, AC TC: CP, IEC, CA	FC: S/D, PST TC: S/D, NF

Various forms of filtration and ultrafiltration are common in production processes, so those steps are not listed.

^aThese products were marketed in the United States in 2015. Data were obtained from manufacturers, distributors, and available literature.

AC, Affinity chromatography; AH, aluminum hydroxide adsorption; AS, ammonium sulfate precipitation; BP, bovine plasma; CA, calcium activation; CHO, Chinese hamster ovary cell culture; CHR, chromatography (specific method not available); CP, cryoprecipitation; CTA, citrate activation; EA, enzymatic activation; FC, fibrinogen component; GBL, ground bovine lung tissue; GI, gamma irradiation; HIC, hydrophobic interaction chromatography; IEC, ion-exchange chromatography; MHA, magnesium hydroxide gel adsorption; NF, nanofiltration; OS, other steps, not specified; PPTN, precipitation; PS, purification steps; PST, pasteurization (heat treatment in solution); S/D, solvent/detergent; TA, thromboplastin activation; TC, thrombin component; TSE, validated for removal of transmissible spongiform encephalopathies; VHT, vapor heat treatment.

α_1 -Proteinase Inhibitor

α_1 -Proteinase inhibitor (human), also known as α_1 -antitrypsin, was the first of the serpins to be isolated and characterized. Although the protein was originally named for its antitrypsin activity, its primary physiologic function appears to be the inhibition of neutrophil elastase in the lung. API replacement therapy is indicated for chronic treatment of individuals with hereditary deficiency. However, even with four products available, the supply is tight because of the limited amount ultimately available from plasma. One issue is the poor efficiency of IV administration. It is estimated that only approximately 2% of the infused API ends up in the lung. Studies have suggested that aerosol delivery of API directly into the lungs by inhalation would be efficacious and could replace IV administration because of its lower cost and greater convenience. API is also a good candidate for recombinant production.

C1 Esterase Inhibitor

C1 esterase inhibitor (human) acts as a regulator in the complement and fibrinolytic systems and as an inhibitor of factor XIIa and kallikrein. Its name comes from its inhibition of the complement proteins C1r and C1s. Patients deficient in C1 esterase inhibitor are at risk for attacks of hereditary angioedema. Two plasma-derived C1 esterase inhibitor concentrates are licensed in the United States. RUCON-EST, a recombinant product produced in transgenic rabbits, was also licensed recently. The products are listed in Table 116.6.

FUTURE DIRECTIONS

New Plasma-Derived Concentrates

With licensure of a number of new products in the past few years, including protein C, vWF, factor XIII and C1 esterase inhibitor, the

United States is catching up with Europe and other parts of the world. Concentrates of factor VII and factor XI are also available elsewhere. Several other proteins in plasma would be potentially useful as therapeutic products, including butyrylcholinesterase for reversal of succinylcholine-induced apnea and treatment of cocaine overdose and other coagulation factors and inhibitors, such as factors X and XII and protein S. However, the prevalence of deficiency disorders of these proteins is small, so they would be true orphan drugs with limited markets. There are also potential improvements that can be made to current plasma-derived and recombinant concentrates. In addition to enhanced purification and viral clearance methods, products can be made more user friendly.

Alternate delivery systems could also potentially improve the utility of many products. Delivery of clotting factors by inhalation, ingestion, and subcutaneous injection has been explored. As mentioned earlier, several studies have looked at aerosol delivery of API. Production of fibrin sealant in a powder form that could be sprinkled on a wound has also been studied.

Recombinant Plasma Protein Concentrates

Almost all plasma proteins licensed for human use have been cloned and expressed in biologically active forms in animal cells in the laboratory, and several have been developed into licensed products, as described earlier. The main advantages of recombinantly produced proteins include freedom from human viruses and a potentially unlimited supply. AT and C1 esterase inhibitor have already been produced in the milk of transgenic animals, and others such as API, which are required in relatively large amounts, are also candidates. Transgenic cows, goats, pigs, and sheep can produce large quantities of human proteins, typically 1–10 g/L in milk. In contrast, the animal cell culture systems routinely used for production of the types of plasma proteins described here produce substantially less protein, typically 0.01–0.1 g/L.

Recombinant proteins can also be produced in modified forms that may give them advantageous new properties such as increased

TRANSFUSION THERAPY FOR COAGULATION FACTOR DEFICIENCIES

Elizabeth Roman, Peter J. Larson, and Catherine S. Manno

This chapter reviews products available to treat deficiencies of plasma coagulation proteins. The development of blood component therapy and subsequently protein concentrates that are enriched in particular coagulation factors and other proteins made possible the effective treatment of bleeding episodes in patients with hemophilia and other diatheses. In the 1940s, a collaborative effort funded by the US government was undertaken among protein scientists with the goal of rapidly developing a method to isolate albumin from human plasma to provide a lyophilized intravascular volume expander for use in the military. As part of this effort, Dr. Edwin Cohn developed an ethanol fractionation procedure that was amenable to large-scale manufacture.¹ Building on the foundation of the Cohn fractionation procedure (see [Chapter 116](#)), the first coagulation factor concentrates were developed in the mid-1960s and provided a safer and more effective treatment for patients with the X-linked coagulation deficiencies, hemophilia A and B. Given the limited human plasma resource as a raw material for production of all but a few coagulation protein concentrates, manufacturers of human plasma-based products attempt to derive the maximum yield from each pool of plasma. Manufacturers of plasma-derived products strive to maximize the therapeutic potential of pooled human plasma by deriving more products from these processes.

Development of recombinant products was fueled by infectious disease transmission through human plasma-derived products. Currently licensed products are produced in mammalian cell culture to optimize necessary posttranslational modifications required for biologic activity. These recombinant expression processes are complicated and expensive. Transgenic recombinant technology has been explored as a way to decrease or eliminate reliance on the human plasma resource and the technically rigorous production of recombinant proteins using mammalian cell culture methods.

Recombinant technology has made significant progress recently in the evolution of long-acting factor VIII and IX preparations, which are effective in preventing as well as treating bleeding episodes; however, the progress has been more significant in the extension of the factor IX half-life. By conjugation to fusion protein (immunoglobulin Fc) the half-lives of these coagulation proteins have been extended. This has had a great impact on the daily life of patients with hemophilia who use factor concentrate as prophylaxis, as extending the factor half-life has reduced the burden of numerous weekly infusions, while maintaining factor efficacy.

In addition, this new era holds vast promise in gene therapy for factor IX deficiency. Enhancing a patient's ability to produce even a modest increase in factor levels could transform the individual from a severe to moderate hemophilia patient, eliminating the need for routine prophylactic therapy and reducing the number of spontaneous or trauma-related bleeding episodes.

HEMOPHILIA A AND B

The hemophilias are X-linked disorders caused by deficiencies of either factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease). The genes for these coagulation factors are located in close proximity on the long arm of the X chromosome. Whereas hemophilia A affects 1:5000 males,

hemophilia B affects 1:30,000. This difference in incidence is roughly correlated with the size of the genes, and more than 30% of cases arise from spontaneous mutations.

The major morbidity of the severe hemophilias A and B is arthropathy, a result of recurrent joint bleeding developing over the course of years in those with inhibitors or those who are untreated or undertreated. The major cause of hemorrhagic mortality is bleeding into critical closed spaces (e.g., intracranial).² Central nervous system (CNS) bleeding occurs in 3% to 14% of patients, and mortality from CNS hemorrhage ranges from 20% to 50%³⁻⁵ with neurologic sequelae (including seizures, motor impairment, or mental retardation) observed in 40% to 50% of survivors.³ CNS bleeding episodes occur predominantly in patients with severe disease (<1% factor level).³ A more detailed discussion of the hemophilias and the molecular biology of factors VIII and IX can be found in [Chapter 135](#).

TRANSFUSION THERAPY FOR HEMOPHILIA A AND B

History of Transfusion for Hemophilia

Transfusion was first proposed by Schönlein and his student Hopf in 1832 as a treatment for “bleeders” who were suffering from exsanguinating hemorrhage, and these two were likely the first to have used the term *Haemophilie* to describe the disease.^{6,7} The first effective transfusion-based intervention for hemophilia is credited to Samuel Lane who, in 1840, infused 10–12 ounces of fresh human blood into a 12-year-old boy with postoperative hemorrhage after eye surgery for correction of a squint.⁸ Subsequently, a variety of interventions, using the infusion of human and animal blood and blood derivatives, were used in the therapy of hemorrhage in patients with congenital bleeding diatheses ([Table 117.1](#)). Citrated plasma was first used in 1923 for the treatment of hemophilia by Feissly in a father-to-son transfusion.⁹ Development of modern blood banking in the 1930s and expansion of transfusion during and after World War II allowed for more widespread use of whole blood and subsequently frozen plasma in the treatment of hemophilia. Because of limited availability, the use of whole blood and components of whole blood for the treatment of hemophilia and other diseases was initially confined to larger metropolitan areas. In addition, volume constraints associated with the quantity of whole blood or plasma needed to achieve therapeutic levels of coagulation limited their usefulness.¹⁰

The advent of modern transfusion therapy for hemophilia came with the observation that the cold-insoluble precipitate remaining after thawing of frozen plasma at 4°C contains high concentrations of factor VIII.³² Application of this procedure to the separation of components of whole blood¹⁹ allowed for the production of a reduced-volume blood product known as *cryoprecipitate*. Cryoprecipitate derived from a single whole blood collection contains approximately 125 units of factor VIII and quickly replaced frozen plasma as the therapy of choice for the treatment of bleeding episodes in hemophilia A in the 1960s. The availability of cryoprecipitate made the treatment of bleeding episodes by patients in their homes, rather than at a hospital, a reality. In addition, the development of quantitative assays for factor VIII¹⁵ and for factor IX¹⁴ meant that the

two diseases could now be distinguished and effects of transfusion therapy on circulating levels of factors could be more accurately assessed.

Before the discovery of plasma cryoprecipitate, significant advances had been made in the fractionation of plasma using ethanol,¹ glycine,³³ polyethylene glycol,²⁰ a combination of glycine and polyethylene glycol,²¹ and calcium or barium^{17,22,34} to precipitate plasma proteins. These techniques, in conjunction with cold precipitation of frozen plasma, laid the groundwork that resulted in the production of the first factor VIII and factor IX concentrates for clinical use.^{21,22} These concentrates could be lyophilized and stored at temperatures up to 4°C with extended stability. Infusion of factor concentrates resulted in high circulating levels of factor VIII and factor IX without the complication of volume overload and paved the way for intensive infusion therapy for serious and life-threatening bleeding complications such as intracranial, retroperitoneal, and retropharyngeal hemorrhages and major surgery. Because they were produced from large pools of single plasma donations (>1000), initial concentrates were nearly universally contaminated with viral pathogens such as hepatitis B and non-A, non-B hepatitis (hepatitis C).³⁵ Initial attempts to attenuate viral transmission using pasteurization and dry heat, instituted by manufacturers in the late 1970s and early 1980s,^{23,36} were found to limit the transmission of hepatitis B. Eventually, these techniques were found to inactivate the human immunodeficiency virus (HIV).^{24,37,38} Before the widespread application of these techniques, however, the majority of patients with severe hemophilia treated with concentrates between 1978 and 1985 were infected with HIV and hepatitis C virus. This tragic consequence of infusion therapy helped fuel the development of modern strategies to reduce the risk of viral transmission by products derived from human plasma. These strategies include (1) careful screening of potential donors for risk factors leading to infection with transfusion-transmissible infections, (2) more vigilant surveillance of the blood donor base for the appearance of new pathogens, (3) development and implementation of testing specific for markers of infectious agents, (4) purification strategies that reduce viral load in final products, and (5) physical and chemical viral inactivation methods to treat infusible products. Finally, development and refinement in techniques of molecular biology in the 1970s and 1980s resulted in the cloning of the genes for many plasma proteins, including factor VIII and factor IX.^{39–41} Within the next decade, the production and licensure of biologically active recombinant factor VIII and factor IX products had become a reality.^{29,42–44} Concentrates of these recombinant products have been shown to be effective and have not been associated with the transmission of pathogens. Further development of recombinant products centered on the removal of all human and animal proteins in the production and formulation of products to further reduce the risk of their inadvertent contamination with emerging pathogens, such as variant prions,^{45,46} and newly discovered agents, such as hepatitis G virus and other transfusion transmitted viruses.^{47,48} In addition, episodic supply constraints incurred in the manufacture of recombinant proteins in mammalian cell culture systems resulting in supply shortages of recombinant factor VIII⁴⁹ have led to greater interest in transgenic production of human plasma proteins compared with mammalian cell culture. With transgenic systems, raw material from which the protein of interest is purified (milk, plant tissue) can be produced in abundance.

Attenuation of Pathogens in Blood-Derived and Other Biologic Products

The development of factor VIII and factor IX concentrates in the 1960s improved the life expectancy of patients with hemophilia from approximately 11 years (before effective transfusion therapy) to nearly normal.⁵⁰ Experience with these first-generation concentrates, however, showed that they invariably transmitted the viral agents responsible for hepatitis B and hepatitis C,³⁵ which are associated with chronic hepatitis with attendant morbidity and mortality, including cirrhosis and hepatocellular carcinoma. Although efforts

were being directed at methods to attenuate these known hepatitis viruses during the late 1970s and early 1980s,^{23,36} HIV contaminated the human blood supply. More than 70% of patients in many countries and 30% to 40% of hemophilia patients worldwide were infected with HIV.^{51–54} More recently, concern about the prion agents responsible for transmissible spongiform encephalopathies such as Creutzfeldt-Jakob disease (CJD), variant CJD, and bovine spongiform encephalopathy, as well as newly identified viral agents in the blood supply,^{47,48} have reinforced the need for continued surveillance and further refinements in the production of products for the treatment of hemophilia. This attention has also been focused on recombinant products because some currently licensed products use added human or animal protein in fermentation or as stabilizers during purification or formulation. Table 117.2 lists agents that are potential contaminants of human plasma. Other viruses such as cytomegalovirus and human T-lymphotropic virus type I are transmissible primarily by cellular blood products.

Although ideal, the absolute removal of infectious agents in transfusable products may be unattainable and in fact may be unnecessary because the primary goal is to make them noninfectious. Practically, this can be accomplished by reducing the levels of the contaminating agent below the level of infectivity. The most relevant agents, viruses and prions, are small and therefore difficult to separate from protein components of plasma. Some pathogens are resistant to currently used methods of inactivation. In addition, as exemplified by HIV and prions, new agents may periodically emerge in the human population by crossing species barriers. Unless detected rapidly, newly emerging agents have the potential for global dissemination, especially if they are transmitted by transfusion of contaminated blood products. Despite these limitations, the safety of infusible products derived from human or animal sources (which includes cultured mammalian cells expressing recombinant protein) can be optimized by reducing the initial viral load in the source material (human plasma, culture medium, or transgenic material). With human plasma, this is accomplished by screening to limit potentially infected donors, by removal and inactivation of infectious agents, and by prospective surveillance of all products and recipients of products that potentially may become contaminated. Progress continues in technology to reduce virus transmission; nanofiltration, an example of this, allows for more than 4–6 log reduction of viruses through size exclusion by filtering the solution through membranes with extremely small pore size (15–40 nm) and without denaturing

plasma proteins.⁵⁵ Nonenveloped viruses such as hepatitis A and parvovirus B19, both smaller than 30 nm, can be effectively removed by nanofiltration. Benefix (Pfizer) undergoes nanofiltration.

Current discussions in the medical, health economic, and patient communities center around achieving an appropriate balance between safety and costs given that plasma-derived products on the market today are extremely safe with regard to pathogen transmission.⁵⁶

Infusion Regimens and Dosing for Hemophilia

The mainstay of therapy for hemophilia involves the treatment of bleeding episodes with the infusion of products capable of replacing the missing factor VIII or IX. This so-called on-demand therapy is effective in staunching hemorrhage but not before tissue damage has occurred. Bleeding is especially destructive in the synovium, where a vicious cycle develops in which the initial bleed results in a proliferative inflammatory response and hypertrophy of synovial tissues that then become more susceptible to further trauma and bleeding. The result in the short term is repeated bleeds into the same joint, resulting in what is referred to as a “target joint,” and eventually chronic joint destruction or hemophilic arthropathy. Patients with chronic arthropathy often require surgical intervention, including synovectomy, debridement, joint replacement, or even joint fusion.

With the availability of factor concentrates that allowed for the attainment of high plasma levels of factor VIII or IX, prophylactic therapy became possible. This approach was pioneered by Swedish treaters who have demonstrated that the use of prophylactic regimens,⁵⁷ wherein trough factor levels are maintained at greater than 1% of normal, reduces the incidence of arthropathy and CNS hemorrhage.⁵⁶ Greater availability of virally safe factor concentrates has allowed for the initiation of prophylactic regimens in early childhood. This “primary” form of prophylaxis has become the standard of care in developed countries. For prophylaxis, the National Hemophilia Foundation Medical and Scientific Advisory Council recommends infusion of factor VIII 25–50 U/kg 3 times a week or every other day for hemophilia A and factor IX 40–100 U/kg 2 or 3 times a week for hemophilia B.⁵⁸ Prophylaxis is not universally practiced, however, owing to the high cost of factor concentrates, the requirement for frequent intravenous (IV) infusion, and the need for placement of central venous catheters in some patients, especially small children, to obtain IV access. The cost of factor makes primary prophylaxis

TABLE 117.3 Dosing Regimens for Bleeding and Prophylaxis in Hemophilia

Site	Factor Level (%)	Dose Hemophilia A (U/kg)	Dose Hemophilia B (U/kg)	Duration of Treatment	Comments
Joint	30–70	15–35	30–70	1–3 d	Splinting, temporary splinting, no weight bearing
Life threatening (e.g., intracranial, retropharyngeal, retroperitoneal)	80–100	40–50	80–100	1–14 d	Antifibrinolytic therapy with retropharyngeal bleeds
Soft tissue	30–50	15–25	30–50	2–5 d	Higher levels can be used for compartment syndrome
Surgery	80–100	40–50	80–100	10–14 d (or shorter for minor procedures)	Significant blood loss can occur into large muscles of the lower extremity and the iliopsoas
Oral	20–50	10–25	20–50	1–2 d	Antifibrinolytic therapy
Gastrointestinal ^a	30–100	15–50	30–100	2–3 d	Should be evaluated for source
Genitourinary ^b	30–50	15–25	30–50	1–2 d	Avoid antifibrinolytic therapy
Prophylaxis ^c	50	25	50	qod or 3×/wk	Steroids may be useful

^aDepending on severity.

^bPainless spontaneous hematuria often requires no treatment other than fluid intake. Persistence requires treatment and evaluation.

^cUse of a schedule of 25 U/kg qod and a dose of 40 U/kg with an interval of 2 days between the next dose may increase compliance by decreasing infusions to three per week.

qod, Every other day.

and even on-demand treatment prohibitive to more than 60% of the hemophilia patients in the world.⁵⁹

To understand how prophylaxis is currently being instituted in the United States, a survey of hemophilia treatment centers was conducted: 62 centers responded, and 32% (or 20 centers) initiated prophylaxis on a once-weekly schedule, 21% (13 centers) on a twice-weekly schedule, and 47% on a thrice-weekly schedule.⁶⁰ This survey demonstrated the diversity in practice and deviation from the recommendation from the National Hemophilia Foundation. Alternative schedules for prophylaxis have been investigated. For example, the Canadian Hemophilia Primary Prophylaxis Study, a small, prospective, multicenter study, evaluated a tailored prophylaxis regimen in 25 patients with severe hemophilia A; patients were started at 50 U/kg once a week and were escalated to 30 U/kg twice weekly and then 25 U/kg on alternate days if one of the three situations occurred: development of a target joint, four bleeds in 3 months, or five or more bleeds occurred into any one joint. This seemed to be well tolerated, resulting in 1.2 bleeds per year while maintaining good joint function; long-term follow-up of tailored prophylaxis is needed, but it may be a cost-effective and central line-sparing option.⁶¹

Dosing regimens for the treatment of bleeding episodes in hemophilia have also evolved paralleling the availability of high-concentration pathogen-safe replacement products. Although no universal regimen for “on-demand” treatment has been established, certain trends prevail. In general, for nonlife-threatening bleeding episodes, the goal of therapy is to achieve a plasma factor VIII or IX level of between 30% and 100%. For life-threatening bleeds or prophylaxis for surgical procedures, the goal is a level of 100% to be maintained by repeated bolus infusions or continuous infusion for a duration of 10–14 days or longer, depending on the severity of the bleed or surgical intervention.

The majority of prophylaxis regimens aim at achieving a trough factor level of approximately 1%. Primary prophylaxis, instituted in

young children, is aimed at preventing any joint bleeding episodes that would eventually result in chronic arthropathy. Secondary prophylaxis refers to limited or prolonged periods of prophylactic therapy, instituted after a serious bleed or the development of repeated bleeding into a single joint (target joint); tertiary prophylaxis entails initiation of prophylaxis subsequent to the onset of joint disease. A prospective randomized trial evaluating the safety and efficacy of a preemptive approach using once-weekly dosing before the first bleed to reduce inhibitor formation is currently in the planning stages.⁶²

To prevent the development of a target joint and chronic arthropathy, many hemophilia treatment centers have recently adopted a regimen of two, three, or more infusions after a hemarthrosis (aggressive on-demand treatment). Specific dosing regimens for bleeding episodes have been developed by treaters and treatment centers. Although slight variations in indications and target plasma levels of factor VIII and factor IX among treatment centers exist, representative dosing regimens are similar and are presented in Table 117.3.^{63–65}

Venous Access in Hemophilia Patients

Parents of young hemophilia patients are taught how to administer factor preparations through a butterfly needle until the patient is old enough to be taught to self-infuse. Alternatively, visiting nurse services obtain peripheral access for some patients. Factor administration via peripheral veins can be very challenging in infants and in patients who require frequent IV therapies, such as those with inhibitors; therefore, more permanent venous access is required in some patients. Options for venous access include externally tunneled or fully implantable catheters or arteriovenous fistulas (AVFs).⁶⁶ Hemophilia practitioners differ in their approach to venous access; one survey indicated that central venous access devices are widely used in 89%

of centers and avoided in 11%.⁶⁰ Complications such as infections and thrombosis limit the life of a device and add to the morbidity of the patient. From a metaanalysis of 48 studies, the incidence of infection was 0.66 per 1000 catheter-days. A multivariate analysis of these data showed that the presence of an inhibitor was associated with an increased risk of infection; additionally, they demonstrated that the risk of infection with a fully implantable device was one-third that of an external device.⁶⁷ In one prospective study of catheter-related deep venous thrombosis (DVT) in boys with hemophilia, 69% of children had a DVT when screened and 81% at the 2-year rescreening.⁶⁸ One study of 38 hemophilia patients confirmed that AVF is feasible, with complications in 34% of the patients; this group suggests that in patients with inhibitors, AVF should be considered the first line for venous access because they frequently require long-term, daily administration of factor.⁶⁹ In deciding on which approach to IV access for a patient, practitioners should address the risks and benefits of each type of device on an individual basis. Use of central catheters is attended by the risks of catheter-induced septic and thrombotic complications.⁷⁰ With longer acting products becoming available and the potential for more convenient modes of administration (subcutaneous), the need for semi-permanent vascular access devices will decrease over time.

TREATMENT OF HEMOPHILIA

Products Available for Treatment of Factor VIII Deficiency

Products available for the treatment of bleeding episodes or prophylaxis against bleeding in patients with mild or moderate hemophilia A include DDAVP (1-deamino 8-D arginine vasopressin), a vasoactive peptide that stimulates release of stored factor VIII, and infusible products containing exogenous factor VIII protein. These may be blood components, concentrates purified from blood plasma, or concentrates containing recombinant factor VIII protein.

DDAVP

The preferred product for treatment of patients with mild or moderate hemophilia A is the synthetic octapeptide DDAVP, a vasopressin analog. DDAVP causes a release of factor VIII (and von Willebrand factor [vWF]) from endothelial cells, raising plasma factor VIII by approximately threefold (range, 2–12-fold) in patients with hemophilia in whom the disease is caused by decreased production or secretion of a functional protein or a protein that has decreased activity. To be effective, DDAVP relies on a partial quantitative deficiency of factor VIII; thus, patients with severe hemophilia will not benefit from its use if the causative mutation results in no synthesis, secretion, or a nonfunctional protein. In a retrospective study assessing response to a DDAVP challenge in mild or moderate hemophilia, 57% of patients with mild hemophilia had a positive response, and several who failed the initial challenge had a response after a mean of 6 years, increasing the response rate to 71% in the mild group.⁷¹ The response to DDAVP in an individual patient is typically reproducible, and an effective response must be documented before its routine use or as prophylaxis for bleeding in surgical procedures (see box on 1-Deamino 8-D Arginine Vasopressin Trial). IV and intranasal preparations are available. The IV product has been used in a subcutaneous route of administration. The intranasal preparation more easily allows a patient to administer the compound on an as-needed basis in a home therapy regimen. The phenomenon of tachyphylaxis, the decreased effectiveness of repeated doses of the same compound, occurs after several, typically three, consecutive doses.

Injectable DDAVP (Sanofi Aventis) is available in 4 µg/mL. The recommended dose is 0.3 µg/kg, mixed in 30 mL normal saline (for children <10 kg, 10 mL normal saline), infused IV slowly over 30 minutes. This dose can be repeated after 12–24 hours. DDAVP nasal

1-Deamino 8-D Arginine Vasopressin Trial

1. Collect citrated plasma from the patient immediately before DDAVP infusion for testing with the postinfusion blood specimen.
2. Administer DDAVP IV (0.3 µg/1 kg) in 25–50 mL normal saline.
3. Wait approximately 30 minutes after the infusion, carefully observing the patient for possible adverse side effects (increased blood pressure, facial flushing, signs or symptoms of hyponatremia).
4. Collect post-DDAVP infusion specimen in sodium citrate at 60, 120, and 240 minutes.
5. Compare the pre- and post-DDAVP factor VIII and vWF:Ag levels to confirm a therapeutic response, threefold increase from baseline (for mild or moderate hemophilia, response is defined as twofold increase in factor VIII: C levels or an absolute level above 0.31 U/mL at 1 hour).⁷¹

spray Stimate (CSL Behring) is available in a metered-dose pump that delivers 0.1 mL (150 µg) per activation (spray). The dose is one activation for patients weighing less than 50 kg and two activations in separate nostrils for those weighing more than 50 kg. In general, only three consecutive doses of DDAVP should be used unless otherwise advised by an experienced hemophilia treater. Because DDAVP is a vasopressin analog, there is a risk of fluid retention with its use. Changes in fluid balance can result in hyponatremia and seizures, especially when DDAVP is used in individuals on nonfluid-restricted or salt-restricted diets (e.g., elderly or very young patients or surgical patients undergoing fluid replacement with solutions with concentrations <0.9% sodium). For this reason, DDAVP is not recommended for children younger than 2 years of age. Caution is advised with the use of DDAVP in patients at risk for arterial thrombosis because there have been reports of myocardial infarction and cerebral thrombosis with its use.⁷²

Factor VIII Concentrates

In developed countries, the current standard of care for the treatment and prevention of bleeding episodes in patients with severe hemophilia A and in patients with mild or moderate disease who do not respond to DDAVP is the infusion of recombinant human factor VIII. Recovery of recombinant factor VIII ranges from 1.5% to 2.5% IU/kg so that dosing assumes a rise in plasma factor VIII activity of 2% for every 1 IU/kg infused. Available concentrates are optimized to enhance viral clearance during purification and undergo one or more viral inactivation steps during manufacture. Plasma-derived factor VIII concentrates, treated with multiple purification and viral inactivation steps, are also available and have an excellent recent record of safety.

Intermediate- and High-Purity Plasma-Derived Concentrates

Intermediate-purity plasma-derived concentrates are prepared from cryoprecipitated plasma or fresh-frozen plasma (FFP), from which factor VIII is further purified using precipitation, gel permeation, ion exchange, or affinity chromatography, often in combination. Specific factor VIII coagulant activity in these products ranges from 2 to more than 100 IU/mg of protein, and many of the methods used also copurify significant amounts of vWF, making them useful for the treatment of some patients with von Willebrand disease (vWD; see later discussion on treatment of vWD). More highly purified plasma-derived concentrates are produced using heparin ligand or immunoaffinity purification methods and have specific activities ranging from 140 to greater than 3000 IU/mg. To stabilize the factor VIII molecule, the majority of these products are formulated by adding human albumin before lyophilization.

Recombinant Factor VIII Products

Highly purified recombinant factor VIII concentrates have been licensed in North America, Europe, and Japan since the early 1990s. These are either full-length or B domain-deleted molecules (the B domain is not required for activity in coagulation) that are expressed in mammalian cell culture (Chinese hamster ovary or baby hamster kidney cell lines) and are purified using immunoaffinity techniques. The development of these recombinant products was fueled primarily by concerns regarding safety of the human blood donor pool and the viral epidemics that occurred within the hemophilia population with the use of early plasma-derived products. As with highly purified plasma-derived factor VIII concentrates, the first-generation recombinant products are formulated with added albumin as a stabilizer. "Second generation" products (Kogenate FS, Bayer, Refacto, Pfizer) have been developed that stabilize the factor VIII molecule with nonprotein excipients.^{73–75} Third-generation products (Advate, Baxter, Xyntha, Pfizer) do not have human proteins or other additives in the cell culture or as a stabilizer. Recombinant production methods that do not rely on the human plasma resource theoretically should provide for unlimited supply.

The first long-acting recombinant factor VIII product, Eloctate, Biogen Idec, synthesized in a human embryonic kidney cell line, was US Food and Drug Administration (FDA) approved in June 2014. It is a B domain-deleted factor VIII covalently linked to human immunoglobulin G1; this Fc fusion protein has extended the half-life of factor VIII: in adults, almost 20 hours, 12–17 years old almost 16.5 hours, 6–11 years old about 14.5 hours and 2–5 years old, 12 hours.⁷⁶ Almost all of the patients (99%) receiving Eloctate for 6 months have been able to use the product every 3 days or longer to maintain a factor VIII level 1% to 3%.⁷⁶ Eloctate, Biogen Idec, has been used on demand, for prophylaxis and in the perioperative setting. For prophylaxis, Biogen Idec recommends 50 IU/kg every 4 days and suggests personalizing the dose based on response, 25–65 IU/kg at 3–5 day intervals.⁷⁶ The package insert also indicates that children less than 6 years old, may require more frequent or higher doses (up to 80 IU/kg).⁷⁶ For minor and moderate bleeds, Eloctate 20–30 IU/kg can be given every 24–48 hours; however in children less than 6 years old, Eloctate should be given every 12–24 hours.⁷⁶ For major bleeding episodes, Eloctate 40–50 IU/kg should be given every 12–24 hours and in children less than 6 years old, Eloctate should be given every 8–24 hours.⁷⁶ Many other long-acting factor VIII products are currently under investigation.

Novel Direction for Factor VIII Deficiency

In a phase I, dose escalating study, ACE910, Roche, a humanized bispecific antibody which binds both IXa and X, essentially mimicking how factor VIII functions, was given to patients with severe hemophilia with ($n = 11$) and without inhibitors ($n = 7$); this unique agent was given subcutaneously weekly and was well tolerated.⁷⁷ Further testing is needed but the possibility of a weekly subcutaneous injection would be life altering for patients with factor VIII deficiency, both with and without inhibitors.

Gene Therapy for Factor IX Deficiency

A landmark paper was published in December 2011 describing a phase 1 trial of the first six patients with severe factor IX deficiency who received one peripheral IV injection of an adeno-associated virus (AAV) expressing a factor IX gene, at three different doses. This vector was selected as it does not intercalate into the host genome and a capsid of AAV serotype 8 was added to avoid immunogenicity. Another advantage of using this serotype is the propensity for it to home to the liver. Sixty-seven percent of the patients in the trial no longer needed prophylaxis and the other 33% needed less factor. Patients who received the highest dose experienced a transient elevation of the alanine aminotransferase, between week 7 and 10, which resolved with prednisolone; this effect correlates with finding

AAV8-capsid specific T cells in the peripheral blood.⁷⁸ These authors recently published an update on the long-term outcome of 10 men (22–64 years old) treated with gene therapy using the AAV8 construct; the additional four patients received the high dose of the vector and had on average 5% factor IX levels, with a decrease in bleeding episodes, sustained over 4 years.⁷⁹

Plasma/Cryoprecipitate

In communities where virally inactivated factor VIII concentrates are not available, cryoprecipitate provides an effective alternative to therapy with concentrates for hemophilia A and vWD patients. Cryoprecipitate is a small-volume product (10–15 mL) enriched in factor VIII, vWF, fibrinogen, fibronectin, and factor XIII. Dosing can be calculated assuming approximately 80–150 IU of factor VIII per bag of cryoprecipitate (derived from a 450-mL single whole blood donor collection unit). Thus, a typical 1750-IU dose (50% correction for a 70-kg patient) would require between 10 and 21 bags or units. The limitations of cryoprecipitate therapy are (1) lack of a viral inactivation step in manufacture of the component and (2) lack of convenience, because multiple units must be pooled into a large volume (≈ 70 –100 mL) for infusion. FFP and whole blood provide less desirable alternatives because adequate therapy with both of these products suffers from the limitations described for cryoprecipitate, and their use often results in intravascular volume overload. Solvent/detergent (S/D)-treated FFP product is available in some countries. ABO group-specific S/D plasma is prepared by S/D treatment (TNBP and Triton $\times 100$) of a pool of up to 2500 donors. After removal of the solvent and detergent components, 200-mL aliquots are refrozen for infusion.

Products Available for Treatment of Factor IX Deficiency

Factor IX Concentrates

As with replacement therapy for factor VIII deficiency, intermediate- and high-purity products derived from plasma for the treatment of factor IX deficiency are available, as well as a single recombinant factor IX product. All of these concentrates also undergo at least one viral inactivation or exclusion step in manufacture. The volume of distribution of factor IX is approximately twice the plasma volume. This can be explained in part by the affinity of factor IX for type IV collagen present in the extracellular matrix.⁸⁰ Recovery of factor IX after infusion is therefore approximately 1%/IU/kg. The recovery observed with recombinant factor IX is approximately 20% lower than that observed with plasma-derived factor IX.⁸¹ This is likely caused by differences in posttranslational modifications between recombinant factor IX and plasma-derived factor IX.

Intermediate-purity factor IX products are generally purified from plasma using anion-exchange chromatography or calcium or barium precipitate adsorption. These methods select for proteins that contain highly negatively charged epitopes. The vitamin K-dependent (VKD) coagulation factors, by virtue of their gamma-carboxyglutamic acid-rich domains, are such proteins; thus, these techniques copurify varying amounts of the other VKD coagulation factors, factor VII, factor X, and prothrombin with factor IX. Hence, the products are referred to as *prothrombin complex concentrates* (PCCs). The levels of vitamin K proteins in these products vary and can be obtained from the manufacturer. In addition, the PCCs are contaminated with trace amounts of activated forms of VKD factors. The presence of these activated factors is the likely explanation for thromboses that have occurred with the use of these intermediate-purity products, typically in the setting of postoperative immobility or hepatic dysfunction.⁸² To minimize the risk of thrombosis with the use of PCCs, it is advisable to achieve a peak factor IX level no higher than 50%.⁸³ Some clinicians add small amounts of heparin to infusions of these products to prevent thrombosis, and some manufacturers have formulated PCCs with heparin or antithrombin III.

High-purity factor IX products are produced from plasma using techniques of ligand affinity or immunoaffinity chromatography and typically have specific activities greater than 150 IU/mg. Three single high-purity recombinant factor IX products have been licensed in the United States (Alphanine, Grifols; Mononine, CSL Behring; and BeneFIX, Wyeth). Because specific products have different recovery results, consulting the package insert and performing recovery studies are recommended; for example, 1 IU BeneFIX/kg will increase the circulating activity of factor IX by 0.8 ± 0.2 and 0.7 ± 0.3 IU/dL in adults and pediatric (younger than 15 years old) patients, respectively.⁸⁴ Also, the initial dose of BeneFIX should be given under direct medical supervision because the potential for an allergic reaction is significant.⁷⁷ Thrombotic complications have not been reported with these high-purity products; some thrombotic events have been associated with continuous administration, which is not an approved method.⁷⁷ In patients with a history of allergy and inhibitors, an irreversible nephrotic syndrome has been reported during immune tolerance induction.⁸⁵

In communities where factor IX concentrates are not available, plasma may provide a means of replacing factor IX in hemophilia B patients during bleeding episodes. Each unit of FFP derived from a 450-mL whole blood collection contains approximately 200 IU of factor IX. Replacement to therapeutic levels of factor IX with FFP is difficult because of the complication of volume overload. In some areas, S/D plasma provides a virally inactivated alternative to FFP.

The first long-acting recombinant factor IX product, Alprolix, Biogen Idec, synthesized in a human embryonic kidney cell line and purified by nanofiltration was FDA approved in March 2014. This factor IX is covalently linked to human immunoglobulin G1; this Fc fusion protein has extended the half-life of factor IX: in adults, almost 86.5 hours, 12–17-years old about 83.5 hours, 6–11 years old about 72 hours and 2–5 years old almost 66.5 hours.⁸⁶ Some patients with factor IX deficiency may only need factor IX three times a month with this product. It should be noted that kaolin-based assays may underestimate the factor IX level.⁸⁶

Other Useful Adjuncts for Treatment of Bleeding in Hemophilia A and B

The antifibrinolytic agents tranexamic acid and ϵ -aminocaproic acid (EACA) (Amicar, Xanodyne Pharmaceuticals) are sometimes used in conjunction with clotting factor replacement therapy or DDAVP in the treatment of bleeding that occurs with hemophilia and other bleeding disorders. These agents interact with the lysine-binding site of plasminogen and enhance its activation. The more important effect of lysine analogs is that their occupancy of this site inhibits binding of the zymogen, plasminogen, to fibrin, which is necessary for full fibrinolytic activity. Antifibrinolytics are useful in the setting of mucosal bleeding and may substantially reduce the need for clotting factor concentrates in the setting of oral mucosal bleeding with tooth extractions. These agents are administered preoperatively and continued postoperatively until wound healing occurs. Although tranexamic acid is more potent, it is less readily absorbed when given orally. Tranexamic acid is administered at 25 mg/kg orally or 10 mg/kg IV preoperatively, and therapy can be continued postoperatively using oral rinses with a 5% solution. EACA is used at a dose of 100 mg/kg preoperatively followed by 100 mg/kg every 6 hours either orally or IV (maximum dose, 24 g/day). Dosing of EACA should be reduced in patients with renal insufficiency.

INHIBITORS OF FACTOR VIII AND FACTOR IX

A major complication in the treatment of patients with hemophilia is the development of inhibitory antibodies against the infused factors that interfere with factor activity. Rarely, antibodies may develop that do not affect activity but increase clearance of factor VIII or factor IX. The incidence of factor VIII inhibitors is approximately 30%, and inhibitors typically develop within the first 20 exposures to replacement therapy.^{87,88} Well-designed prospective studies of the use of recombinant factor VIII in previously untreated patients revealed

that many of these inhibitors are low titer and transient in nature.^{42,43} Patients with low-titer, transient inhibitors can be managed with increased doses of factor VIII. Inhibitors to factor IX occur less frequently; with an estimated incidence of approximately 1% to 3%.⁸⁹ Patients with factor IX antibodies may have anaphylactic reactions when treated with high-purity products.^{90,91}

Patients with high-titer inhibitors to either factor VIII or factor IX do not usually achieve hemostasis after factor replacement and thus present a treatment challenge. Treatment of patients who develop inhibitors involves two approaches: (1) acute treatment of bleeding episodes and (2) immune tolerance induction therapy, whereby the patient is treated frequently (often daily) with factor VIII or factor IX in an effort to suppress the production of inhibitors by the immune system (similar to allergic desensitization therapy).

Treatment of acute bleeding episodes can be accomplished by two methods. For patients with low-titer inhibitors (<5 Bethesda units [BU], a laboratory measurement of inhibitor activity), hemostasis can be accomplished with large doses of factor VIII or factor IX (e.g., as high as 200 IU/kg given at frequent intervals) in an effort to neutralize or “override” the circulating inhibitor. A neutralization approach is usually ineffective for patients with high-titer inhibitors (>5–10 BU) and is expensive because of the large amounts of factor required. These patients and patients with low-titer inhibitors who fail to respond to override therapy can be treated using products that act to “bypass” the inhibitor. The only current bypass agents include activated prothrombin complex concentrates (FEIBA, Baxter Bioscience) (aPCC), which contain factors VII, X, and prothrombin in addition to factor IX that enhance production of thrombin generation by activating the coagulation pathway at points further down than the factor VIIIa/factor IXa step. FEIBA is used as first-line treatment of bleeding episodes in patients with inhibitors by some treaters even though the concentrate is derived from human plasma.

Recombinant activated factor VII (rFVIIa) (NovoSeven, Novo Nordisk) product was licensed in Europe and the United States with an indication for use as a bypass agent in the treatment of inhibitors in patients with hemophilia A and hemophilia B, as well as for bleeding and perioperative management in Glanzmann thrombasthenia, who are refractory to platelet transfusion. Another recombinant VII product, AryoSeven (Aryogen), which is biosimilar to NovoSeven is available and was shown to be as effective in the management of acute bleeding episodes.⁹² The dose of rFVIIa is 90 μ g/kg. Recombinant activated factor VIIa is administered every 2 hours compared with every 8–12 hours for PCCs or aPCCs. Thrombosis has also been reported with the use of rFVIIa^{93,94} and PCCs.⁹⁵

Despite the success achieved with immune tolerance induction regimens (80%–90%),⁹⁶ “bypass” agents are still needed in patients undergoing tolerization because an interval potentially as long as 2–3 years exists between the time that induction is initiated and the inhibitor is suppressed. Bleeding episodes that occur before achievement of tolerance usually require treatment with one or other of the bypassing agents.

Recently, Leissinger et al⁹⁷ demonstrated in hemophilia A patients with high-titer inhibitors the superiority of prophylactic thrice-weekly FEIBA (Baxter) at 85 U/kg over on-demand therapy. In a prospective, randomized, crossover study with a 3-month washout between the two arms, which were each 6 months, the prophylaxis regimen prevented progression of joint disease in high-titer inhibitor patients; and is now recommended for prophylaxis in high-titer inhibitor patients (see box [Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX](#)).

Treatment of life-threatening bleeds in the context of a high-titer inhibitor represents a significant challenge. The effect of nonfactor VIII concentrates (bypass agents), when the inhibitor titer is greater than 10 BU (precluding the use of factor VIII), is difficult to monitor in the laboratory because plasma factor levels do not reflect hemostasis. Adjunctive therapies are frequently used in this setting to lower the titer of the antibody to allow for treatment of the patient with factor VIII concentrates. Aggressive regimens are used in which circulating antibodies are depleted using plasmapheresis or staphylococcal protein A immunoabsorption, and reduction of antibody

Treatment of Life-Threatening Bleeding Episodes in Patients With Inhibitors Against Factor VIII or Factor IX

Concentrates

1. Factor VIII containing concentrates in high doses (as high as 150–200 IU/kg) if inhibitor titer is low (<5–10 BU). High-dose continuous infusion of factor VIII (≈ 10 IU/kg/hour) after a high-dose bolus may be useful.
2. Recombinant factor VIIa. Dose is 90 μ g/kg (or a dose up to 320 μ g/kg) administered every 2 hours. Risk of thrombosis exists with this product.
3. Activated PCCs at a dose of 50–75 IU/kg every 8–12 hours. Risk of thrombosis exists with this product.

Immunomodulation

1. Antibody depletion
 - a. Plasmapheresis
 - b. Extracorporeal immunoadsorption of plasma (staphylococcal protein A column therapy and other methods)
2. Suppression of antibody production
 - a. High-dose steroids (equivalent of prednisone 80 mg/day)
 - b. Cyclophosphamide (10–15 mg/kg load and 2–3 mg/kg/day)
 - c. Intravenous immunoglobulin (1 g/kg daily for 2 days)
 - d. More aggressive regimens that may include vincristine, azathioprine, cyclosporine, or interferon- γ

Conservative Measures

1. Immobilization
2. Compression
3. Local application of hemostatic agents
4. Antifibrinolytics
5. Avoid venipunctures, intramuscular injections, arterial puncture, and lumbar punctures
6. Avoid use of medications that inhibit platelet function (ASA, NSAIDs)
7. DDAVP may be effective in some patients with low-titer inhibitors

ASA, aspirin; BU, Bethesda unit; NSAIDs, nonsteroidal antiinflammatory drugs; PCC, prothrombin complex concentrate.

production is attempted using immunomodulatory agents such as steroids, cyclophosphamide, and IV infusion of immunoglobulin G (IgG).^{98–101} These strategies for acutely reducing antibody titers are also used by some hemophilia treaters at the outset of immune tolerance induction. In a phase II trial, Leissinger et al evaluated the safety and efficacy of rituximab, without concurrent immune tolerance induction (ITI), to reduce high-titer inhibitor levels in hemophilia A patients,¹⁰² although the study was designed to enroll 43 patients, only 23 were enrolled and the Data Safety Monitoring Board closed the study because of poor accrual over 4 years. Three of 16 (18.8%) had a major response (inhibitor titer <5 BU) and one with a minor response (initial inhibitor titer <5 BU but increased after factor VIII exposure).¹⁰³ Several case reports or series of patients with severe hemophilia have demonstrated a greater advantage from rituximab when used in conjunction with ITI.^{104,105} In a recent review of inhibitor eradication with rituximab, Franchini and Mannucci concluded that the combination of ITI with rituximab in mild to moderate hemophilia is likely to be more beneficial¹⁰⁶ than when used without simultaneous factor VIII. Also, rituximab has been used successfully in the setting of acquired hemophilia A, mostly with concurrent immunosuppression.¹⁰⁵

VON WILLEBRAND DISEASE

vWD is an autosomal dominant bleeding disorder first described by Erik von Willebrand in 1926, who named this bleeding diathesis *pseudohemophilia*. vWD is relatively common, with a prevalence of up to 2% of the general population.¹⁰⁷ The penetrance and severity of the disease vary depending on the type of vWD (type 1, 2, or 3); the specific mutation; the number of affected genes; the patient's blood type; and numerous drug, hormonal, and stress-related

parameters. These factors, particularly the subtype of vWD and the patient's response to DDAVP, influence the recommended treatment for acute bleeding episodes or for prophylaxis against bleeding.

Although the disease had been described in the 1920s, the primary defect had earlier been attributed to either platelets or the vessel wall. An understanding of the missing protein in vWD and its relationship to factor VIII was not appreciated until the 1950s. Correction of the defect with transfusion of plasma, but not with platelet concentrates alone, defined the disease as one involving a missing plasma protein factor (vWF), not a platelet or vessel wall defect.¹⁰⁸ A correlation between vWD and factor VIII activity had previously been observed—the observation that a plasma fraction from patients lacking factor VIII (hemophilia A) could correct the defect in vWD in addition to the autosomal inheritance pattern, which helped further differentiate hemophilia A from vWD.¹⁰⁸ A more detailed discussion of clinical features and pathophysiology of vWD and the molecular biology of vWF can be found in [Chapter 138](#).

Transfusion Therapy for von Willebrand Disease

The specific treatment for vWD varies with the bleeding symptoms and signs and with the individual diagnostic subtype of vWD (see [Chapter 138](#)). Treatment is guided further by laboratory results indicating the potential success of increasing vWF with DDAVP and the clinical experience with a particular patient and his or her natural biologic family members who have vWD. When possible, attempts should be made to treat the patient without exposing him or her to plasma-derived products.

Nonprotein-Based Treatment

DDAVP is a synthetic octapeptide homolog of vasopressin that results in the release of stored vWF from Weibel Palade bodies of the endothelium (see section on treatment of hemophilia A). DDAVP is often effective for type 1 disease and may be useful in certain patients with type 2 disease. It is not appropriate for use in patients with type 3 disease in whom no stores of vWF exist. Before the use of DDAVP, a DDAVP trial should be conducted to document its efficacy in an individual patient. The trial is performed as described for hemophilia A. The phenomenon of tachyphylaxis is also observed when DDAVP is used to treat vWD. For bleeding that does not respond to DDAVP or in patients in whom a poor response is observed with DDAVP, other modalities (typically protein based) must be used.

As described for hemophilia A, the antifibrinolytic agent EACA or tranexamic acid are often administered in the setting of dental surgery to inhibit fibrinolysis. Care should be taken when these agents are administered in patients with a predisposition to thrombosis.

Estrogens upregulate vWF synthesis and may be useful especially in women. Therapy with estrogens should also help ameliorate menorrhagia in affected symptomatic patients.

Plasma-Protein-Based Therapy

Factor VIII Concentrates

Some intermediate-purity factor VIII concentrates are manufactured from plasma using methods that copurify significant amounts of vWF. Many of the products listed in [Table 117.4](#) contain vWF. Humate-P (ZLB Behring), Alphanate (Grifols USA), and Wilate (Octapharma), which is 1:1 vWF:RCo/factor VIII, are currently licensed for the treatment of vWD. Others, including Koate-DVI (Talecris Biotherapeutics), have been tested in vitro and in vivo for their potential use in therapy for vWD.^{109–111} The multimeric pattern of VWF in these concentrates varies, and no product has the pattern of multimers that is present in normal plasma.¹¹⁰ Because many of these products are effective clinically, the importance of these differences in multimer pattern remains to be determined. In addition,

TABLE 117.4 Other Coagulation Deficiencies

Factor	Incidence	Inheritance	Chromosome	Half-Life	Target Plasma Level	Treatment Product ^a
I (fibrinogen)	1–2/10 ⁶		4	2–4 days	50–100 mg/dL	Concentrates
Afibrinogen		AR				Cryoprecipitate
Hypofibrinogen		AR or AD				
Dysfibrinogen		AR or AD				
II (prothrombin)	<1/10 ⁶	AD	11	3 days	30%	PCCs Plasma
V	1/10 ⁶	AR	1	36 hours	25%	Plasma
VII	2/10 ⁶	AR	13	3–6 hours	25%	rFVIIa Concentrates PCCs Plasma
X	2/10 ⁶	AR	13	40 hours	10%–25%	PCCs Plasma
XI		AR or AD	4	80 hours	20%–40%	Concentrates Plasma
XIII	<1/10 ⁶	AR	1.6	9 days	5%	Concentrates Cryoprecipitate Plasma

^aProducts are listed in order of viral safety.

AD, Autosomal dominant; AR, autosomal recessive; PCC, prothrombin complex concentrates.

Data from Cohen AJ and Kessler: Treatment of inherited coagulation disorders. *Am J Med* 99:675, 1995.

when using multiple doses of these products, factor VIII and vWF:RCo should be monitored because there is an increased risk of thrombotic events with the accumulation of factor VIII.

von Willebrand Factor Concentrates (Plasma Derived and Recombinant)

Several chromatography-purified plasma-derived concentrates enriched in vWF have been studied by manufacturers in Europe.^{112,113}

Preliminary reports suggest that these are amenable to viral inactivation steps and may be effective both in vitro and in vivo.¹¹⁰ To date, none of these have been developed as widely licensed products. Recombinant vWF (BAX 111, Baxter) which is albumin- and plasma-free and synthesized in Chinese hamster ovaries has been developed. In patients with severe vWD, a phase 3 multicenter trial of recombinant vWF (BAX 111, Baxter), given alone or with Advate, Baxter was effective in treating all 22 patients with bleeding episodes; no thrombosis or inhibitors occurred during the study.¹¹⁴ A biologic license application was submitted to the FDA for BAX111.

Cryoprecipitate

Cryoprecipitate was the mainstay of plasma-based therapy for bleeding in patients with vWD until the availability of virally inactivated intermediate-purity factor VIII concentrates with preserved functional vWF protein. These factor VIII concentrates are the products of choice for the treatment of bleeding in patients with types 1 and 2 vWD who are unresponsive to DDAVP and for bleeding in patients with type 3 vWD. Owing to the small potential for viral contamination of cryoprecipitate, manufacture of which does not include steps to inactivate viral pathogens, cryoprecipitate is currently indicated only when virally safe concentrates containing vWF are unavailable.

ACQUIRED FACTOR VIII AND VON WILLEBRAND FACTOR DEFICIENCY

Antibodies that inhibit the activity of factor VIII can develop in previously normal patients. Most of these patients have no underlying disease; however, factor VIII antibodies can arise in the setting of autoimmune disorders or in the postpartum period. Although approximately one-third of inhibitors disappear spontaneously, the mortality rate among affected patients is significant.

In adults, acquired vWD is a rare autoimmune disorder that can occur in association with other autoimmune disorders or lymphoproliferative disease. Antibody may interact with the epitopes on

vWF required for its normal activity or result in increased clearance of antibody–vWF complexes.

In children, acquired vWD is extremely rare but has been reported in the context of Wilms tumor, hypothyroidism, and congenital heart disease and some medications; with treatment of the underlying disorder, vWF normalizes.

Treatment

Therapy for those patients with relatively high inhibitor titers (>5 BU) includes bypassing agents (FEIBA or rFVIIa) to stop bleeding and immunosuppression to reduce inhibitor levels. Plasmapheresis or immunoadsorption can be used to reduce the circulating levels of inhibitors. Immunosuppressive agents and IV IgG are useful adjuncts to abrogate production of the autoantibody. DDAVP can also be effective in some patients with low-titer inhibitors. Unlike inhibitors that develop with hemophilia A, exposure to factor VIII usually does not result in increased antibody titers.¹¹⁵ Conservative measures to control hemorrhage should also be used in conjunction with the above, including immobilization and compression, topical or local hemostatic agents, and antifibrinolytic therapy. The use of venipunctures, intramuscular injections, and drugs with platelet inhibitory activity should be minimized or avoided.

OTHER COAGULATION PROTEIN DEFICIENCIES

Approximately 15% of inherited bleeding disorders are caused by deficiencies of coagulation factors other than factor VIII, factor IX, or vWF. Inherited deficiencies of fibrinogen and factors II, V, VII, X, XI, and XIII may result in bleeding, requiring treatment. The genes for these factors are not located on the X chromosome; thus two gene defects are typically required for symptomatic disease. Consanguinity is frequent in affected kindreds. The characteristics of these deficiencies are presented in Table 117.4. Hereditary deficiencies of factor XII, prekallikrein, and high-molecular-weight kininogen have not been described to result in bleeding diatheses.

The mainstays of therapy for these disorders are cryoprecipitate (for fibrinogen deficiency) and plasma. In some countries, concentrates enriched in the missing protein have been available. An S/D-treated pooled plasma product is also available in some regions. Pooled S/D-treated plasma has the advantage over FFP in that it is

virally inactivated but has the drawback of exposing the patient to a large number of donors (2500) with each dose.

Fibrinogen Deficiency

Bleeding disorders can result from low to absent levels of fibrinogen (hypofibrinogenemia or afibrinogenemia) or a protein with abnormal function (dysfibrinogenemia). The inheritance pattern for the former is autosomal recessive and for the latter is autosomal dominant. Dysfibrinogenemias can result in bleeding or hypercoagulability. The gene for fibrinogen is located on chromosome 4. Because fibrinogen is required for the formation of a fibrin clot, it is surprising that afibrinogenemic patients survive gestation and birth. Diagnosis is made when patients present with bleeding from the umbilical stump, intracranial hemorrhage, or mucosal bleeding. Hemarthroses can occur but are less common than observed with the hemophilias. Wound healing may be delayed. Increased incidence of fetal wastage in patients with afibrinogenemia and hypofibrinogenemia is observed, and term gestation is rarely achieved without replacement of fibrinogen.^{116–118} Because the substrate for clot formation, fibrinogen, is missing or deficient, the prothrombin time (PT), activated partial thromboplastin time (aPTT), thrombin clotting time (TCT), and coagulation assays that have fibrin formation as their end points are all prolonged. Replacement of fibrinogen is accomplished with cryoprecipitate with a goal of achieving a plasma level between 50 and 100 mg/dL and at least 60 mg/dL for maintenance of pregnancy.¹¹⁸ Each bag of cryoprecipitate contains approximately 200 to 300 mg of fibrinogen. The biologic half-life of fibrinogen is between 2 and 4 days. Virally inactivated, highly purified fibrinogen concentrates are available in Europe, China, and Japan (Japan Green Cross, Aventis, LFB) and in the United States, RiaSTAP, CSL Behring is available. These fibrinogen concentrates offer many advantages over cryoprecipitate, including: viral inactivation, standardized fibrinogen content, smaller infusion volume and expedited time to treat the patient as reconstitution is swift, since it is stored as a lyophilized powder, and there is no need for cross-matching.¹¹⁹ Adverse reactions to treatment include the development of fibrinogen antibodies; allergic reactions; and, paradoxically, thrombosis.

Prothrombin Deficiency

Congenital prothrombin deficiency is a rare autosomal recessive disorder estimated to be present at a rate of 0.5 cases per million. Disease has been described with both homozygous and heterozygous defects (including compound heterozygotes). No reports of a prothrombinemia appear in the literature, suggesting that complete lack of the protein is incompatible with normal development. Hemorrhagic symptoms include bruising; hemarthroses; intracranial, mucosal, and deep tissue bleeding; and menorrhagia.¹²⁰ Correlation between bleeding and prothrombin levels is poor. Both the PT and the aPTT are prolonged, and the thrombin time is normal. Treatment of prothrombin deficiency includes plasma at a dose of 15–25 mL/kg followed by 3 mL/kg every 12–24 hours to achieve levels of approximately 30%. The half-life of prothrombin is approximately 3 days. PCCs contain prothrombin and other VKD factors and can be used to treat prothrombin-deficient patients who are undergoing major surgery or life-threatening bleeds. Caution should be exercised because these have been associated with thrombosis.

Factor V Deficiency

Inherited deficiency of factor V occurs in fewer than 1:1,000,000 people with an autosomal recessive inheritance pattern (homozygous or compound heterozygous), resulting in factor V levels less than 20%. Symptoms include bleeding from the umbilical stump and mucous membranes, ecchymoses, menorrhagia, postpartum bleeding, and intracranial hemorrhage. Hemarthroses can occur but are

less common than with severe hemophilia. Correlation between bleeding and factor V levels is poor. No factor V–enriched plasma concentrates are available. Because factor V is in the common pathway of coagulation, in deficiency states, both the PT and the aPTT are prolonged. Treatment of bleeding involves the infusion of plasma at 15–20 mL/kg with a goal of achieving levels of 20%. The half-life of factor V is approximately 36 hours. Because platelets contain stored factor V,¹²¹ they have been used to treat bleeding. Platelet infusion may result in the production of platelet-specific antibodies.

Factor VII Deficiency

Factor VII deficiency occurs in approximately 1:500,000 people; it is autosomal recessive and of the rare inherited coagulation disorders, factor VII deficiency is the most common. Severe bleeding occurs with levels below 1%, and symptoms in severely affected patients are similar to those observed with severe hemophilia. Intracranial hemorrhage may occur in up to 16% of cases and in neonates after vaginal delivery. The PT is prolonged, but the aPTT and thrombin time are normal. PCCs contain factor VII and may provide a benefit over plasma because they are virally inactivated. As with the use of these products for factor VIII and factor IX inhibitors, thrombosis has been reported. Several plasma-derived factor VII concentrates (LFB, Baxter and PFL) have been developed and have been used to treat congenital deficiency. Recombinant activated factor VII concentrate is effective in the treatment of bleeding with a congenital factor VII deficiency.^{122–125} This can be used at a dose of 10–40 µg/kg every 4–6 hours.¹²⁶ Inhibitors to factor VIIa have developed in patients with congenital factor VII deficiency.¹²²

Factor X Deficiency

Congenital deficiency of factor X is a rare condition resulting from homozygous or compound heterozygous defects in the autosomal genes for factor X located on chromosome 13. Bleeding is correlated with factor X levels, and symptoms include epistaxis, menorrhagia, hemarthrosis, intracranial or gastrointestinal hemorrhage, hematuria, and umbilical cord bleeding. Because factor X is a component of prothrombinase (the first step in the common pathway), diagnosis is suggested by both a prolonged PT and a prolonged aPTT but a normal TCT. Treatment is with plasma products (FFP or S/D-treated plasma) at approximately 15–25 mL/kg followed by 5 mL/kg every 24 hours with a goal of plasma factor X activity levels of 20%. PCCs can be used; however, they contain variable amounts of factor X. As with the use of PCCs for other indications, the risk of thrombosis is increased. Currently, a Phase III, multicenter study to investigate the pharmacokinetics, safety, and efficacy of a high purity factor X (Bio Products Laboratory) in patients with moderate to severe factor X deficiency was completed and results are not yet available.¹²⁷

Factor XI Deficiency

Congenital factor XI deficiency (sometimes called hemophilia C) is an autosomal disorder with a recessive pattern of inheritance and is particularly common in Ashkenazi Jews in whom two specific mutations account for the approximately 8% prevalence of an abnormal factor XI gene.^{123,124} The factor XI gene is located on chromosome 4. Bleeding symptoms are variable and include postsurgical or traumatic bleeding or heavy menses in women. Spontaneous hemorrhage and musculoskeletal bleeding are not typical of the disorder, and these characteristics distinguish this disorder from hemophilia A and B. Plasma levels of factor XI do not correlate with bleeding symptoms unlike the factor levels in hemophilia A and B. The aPTT is prolonged with factor XI deficiency; PT and thrombin time are normal. Patients with factor XI deficiency are usually treated before surgical procedures with a goal of factor XI levels between 30 and 45 U/dL.¹²³ Plasma (FFP and S/D-treated plasma) provides the mainstay of

therapy, and dosing takes into consideration the long half-life of 60–80 hours; however, some patients may have difficulty tolerating the large fluid volume of FFP. Although the half-life of factor XI in S/D plasma is comparable to that of FFP, decreased levels of factor XI in the product ($\approx 30\%$ – 50%) have been reported.¹²⁵ Especially in those patients with absent factor XI protein, inhibitors have developed after exposure to factor XI products. Two virally reduced or inactivated factor XI concentrates have been developed using affinity chromatography or cation-exchange chromatography.¹²⁸ These two concentrates, licensed in France (Hemoleven, LFB Biomedicaments France) and England (FXI concentrate Bio Products Laboratory), are not available in the United States, although the factor XI concentrate from France can be obtained through compassionate use in the United States.¹²⁹ Both concentrates have been demonstrated to be effective, but there have been reports of thromboembolic complications with their use, presumably because of contaminant activated factor IX. Both products are now formulated with antithrombin and heparin, but caution is advised with their use in elderly patients and in patients with preexisting cardiovascular disease. In addition, because of thromboembolic risk, when using factor XI concentrates, antifibrinolytics should not be used concurrently. Doses should not exceed 30 U/kg and peak factor XI should not exceed 70 U/dL.¹²⁶

Because bleeding occurs in patients with factor XI deficiency more often in settings in which fibrinolysis is more active (oral mucosa, urinary tract), antifibrinolytic agents can be useful adjuncts in the treatment of such bleeding episodes or used as sole agents to prevent bleeding with dental procedures. Fibrin glue can provide a useful adjunct or be used solely in topical bleeding (dental extractions, circumcisions). DDAVP has been reported as useful for the prevention of surgical bleeding in factor XI deficiency.¹³⁰ The mode of effect of DDAVP is unclear but is likely caused by the coexistence of mild vWF deficiency.

Factor XIII Deficiency

Factor XIII is a transglutaminase that catalyzes the cross-linking of γ -glutamyl and ϵ -lysyl groups of fibrin monomers, stabilizing the forming clot by decreasing its susceptibility to fibrinolysis. Inherited deficiency of factor XIII is autosomal recessive and results from defects in the genes for the two subunits of factor XIII located on chromosome 1 (B subunit) and chromosome 6 (A subunit). The majority of reported defects involve the A subunit. Umbilical bleeding in homozygotes may be observed at birth. Soft tissue bleeds, hemarthroses, excessive intracranial bleeding (relative to other coagulation deficiencies), pseudotumors, and bleeding during surgery are observed in affected patients. Surgery is also complicated by poor wound healing. Affected male patients may have oligospermia, and female patients may have recurrent miscarriages. Coagulation screening test results (PT, aPTT, and TCT) are normal. Solubility of clots is increased with factor XIII deficiency; thus, the diagnosis can be made by incubating clots in the presence of solubilizing agents such as 5 M urea or 1% to 2% chloroacetic acid. This qualitative test fails to detect mild and moderate deficiency; therefore, it is not recommended to perform quantitative factor XIII testing when suspecting a deficiency. Factor XIII has a long half-life (9–15 days). Previously, FFP (2–3 mL/kg) or cryoprecipitate (1 bag/10–20 kg) were the only options for treating patients with factor XIII deficiency. However, in February 2011, the first plasma-derived factor XIII concentrate (Corifact, CSL Behring) was approved by the FDA for prophylaxis; this concentrate is given intravenously to maintain a trough level of 5% to 20% with the initial recommended dose being 40 IU/kg every 28 days.¹³¹ Because of the long half-life of factor XIII, replacement can be used on a prophylactic basis (dosing every 3–4 weeks) to prevent intracranial hemorrhage and other bleeding episodes. The United Kingdom Haemophilia Centre Doctors' Organisation's current guidelines recommend lifetime prophylaxis for those patients with a severe factor XIII deficiency and a personal or family history of bleeding.¹²⁶ Dosing with factor XIII concentrate is 10–75 IU/kg every 4–6 weeks, with lower doses for prophylaxis and higher doses

for the treatment of bleeding episodes, as well as escalating the dose throughout pregnancy.¹²⁶

A recent, international, multicenter, phase III study of recombinant FXIII-A2 in patients 1–77 years old demonstrated that 35 IU/kg monthly can safely be used as prophylaxis in patients with congenital factor XIII A-subunit deficiency, irrespective of age; this product cannot be used for patients with a B-subunit deficiency.¹³²

OTHER PLASMA-DERIVED PROTEIN CONCENTRATES

As discussed in Chapter 116, plasma fractionation processes also allow for the isolation of plasma components other than the coagulation proteins. Immunoglobulins are isolated by a variety of techniques from the Cohn fraction II–III. α_1 -Antitrypsin and antithrombin are produced from fraction IV. As with other VKD proteins, protein C may be isolated from Cohn fraction II.

Anticoagulant Proteins (Protein C and Antithrombin)

Brief mention should be made of plasma-derived concentrates enriched in protein C and recombinant antithrombin III. These products have been used for a variety of indications, but both are licensed for the treatment of congenital deficiencies that result in thrombosis. Protein C concentrate has also been used in the treatment of purpura fulminans with meningococcemia. Antithrombin in combination with defibrotide has been used for the successful treatment of veno-occlusive disease in patients who develop this complication after undergoing bone marrow transplantation,¹³³ heparin resistance in patients undergoing cardiopulmonary bypass, extracorporeal membrane oxygenation (ECMO) and sepsis. In addition, antithrombin has been used in patients with acute lymphoblastic leukemia who are receiving asparaginase. Early studies showed some efficacy in using activated protein C to treat sepsis.¹³⁴ However, a recent update of a Cochrane review reported that in five randomized controlled trials, including 5101 patients, activated protein C did not decrease the risk of death and was associated with an increased risk of bleeding.¹³⁵ Its utility for other indications is not yet known.

Immunoglobulins

The use of immunoglobulins (both IV and hyperimmune products) for a variety of diseases is discussed elsewhere in this book.

α_1 -Protease Inhibitor (Antitrypsin)

α_1 -Protease inhibitor (or antitrypsin) concentrates (Prolastin, Bayer Healthcare LLC; Aralast, Baxter Biosciences; Zemaira, ZLB-Behring) are available for the prophylactic treatment of people with congenital deficiency of α_1 -antitrypsin. α_1 -Antitrypsin inhibits neutrophil elastase, which is thought to be responsible for the alveolar damage resulting in emphysema. These replacement products, administered IV, are presumed to act to delay the progression of congenital emphysema associated with this protease inhibitor deficiency.

FUTURE DIRECTIONS

Virally safe plasma-derived concentrates have been developed that are enriched in a variety of coagulation and other proteins. Initially, refinements in techniques of plasma fractionation formed the basis for the development of these concentrates as an improvement over the use of blood component therapy (whole blood, plasma, and cryoprecipitate). Plasma-derived protein concentrates were first developed for the treatment of the more common hemophilias A and B. Subsequent refinements were made to reduce and then eliminate the transmission of viral and other pathogens present in the human

plasma pool while increasing product purity. Techniques in molecular biology and heterologous expression of mammalian proteins have allowed for the production of some proteins, most notably factor VIII and factor IX, without reliance on the limited plasma resource. These plasma-derived and recombinant concentrates have supplanted the use of plasma or cryoprecipitate for the treatment of some congenital and acquired deficiencies of soluble plasma factors and have decreased or eliminated the attendant risks of allergic reactions, volume overload, and pathogen transmission. For patients on home infusion regimens, protein concentrates also have the benefit of increasing patient convenience because infusion volumes are small relative to blood component therapy. Although the development of high-purity, virally safe concentrates to treat other plasma protein deficiencies that are currently treated with blood components is technically feasible, such development is limited by the very small numbers of patients with these disorders. In the future, the development of products produced in transgenic animals holds the promise of producing large quantities of recombinant proteins, thus making available more of these lifesaving products for use clinically. Long-acting factor products have now been approved and may improve quality of life while reducing the number of weekly infusions and limiting the need for venous access devices. Novel delivery methods for factor VIII deficiency, such as weekly subcutaneous injections are being explored. Profound progress has been made in terms of a curative treatment, gene therapy for factor IX deficiency. This is a most promising time for the management of patients with hemophilia and rare inherited factor deficiencies.

HEMAPHERESIS

Sandhya R. Panch and Harvey G. Klein

Therapeutic bloodletting is an ancient therapy, fashionable, albeit unproved, and practiced well into the 19th century. About the time that scientific skepticism began to temper the widespread use of therapeutic phlebotomy, a new technique for blood removal, apheresis, appeared in the research laboratory.¹ The term *apheresis*, derived from a Greek verb meaning “to take away or withdraw,” was coined to describe removal of one component of blood with return of the remaining components to the donor. Like phlebotomy, apheresis was used first to treat patients but later became more important for collecting blood components for transfusion. Increasingly, apheresis techniques are used to collect cell populations from the peripheral blood of healthy donors and patients for purposes of hematopoietic stem/progenitor cell (HPC) transplantation and immune cell therapies. Annually in the United States, about 1.9 million units of red blood cells (RBCs), 2.5 million units of platelets, and 2500 granulocyte doses are collected by apheresis and more than 50,000 units of peripheral blood-hematopoietic stem and progenitor cells (PB-HSPC) and therapeutic cellular therapy products are collected at hospital and blood center apheresis facilities.²

PRINCIPLES OF APHERESIS

The principal objective of apheresis is efficient removal of some circulating blood component, either cells (cytapheresis) or some plasma solute (plasmapheresis). For most disorders the treatment goal is to deplete the circulating cell or substance directly responsible for the disease process. Apheresis can also mobilize cells and plasma components from tissue depots. For example, lymphocytes may be mobilized from the spleen and lymph nodes of some patients with chronic lymphocytic leukemia (CLL), and low-density lipoproteins (LDLs) can be removed from tissue stores in patients with familial hypercholesterolemia. The apheresis procedure itself mobilizes CD34⁺ cells from extravascular depots in peripheral blood-hematopoietic stem and progenitor cells (PB-HSPC) donors, resulting in collection of more than twice as many CD34⁺ cells than estimated based on preapheresis peripheral blood cell counts (Fig. 118.1). Apheresis may have other, less obvious effects. Lymphocyte depletion may modify immune responsiveness in some disease states, possibly by disturbing the control mechanisms of cellular immune regulation. Plasmapheresis enhances splenic clearance of immune complexes in certain autoimmune disorders. When therapeutic effect is judged by clinical improvement rather than by efficiency of solute removal, apheresis is more often a helpful adjunct than a form of first-line therapy.

Several mathematical models formulated for different clinical conditions describe the kinetics of apheresis. Removal of most blood constituents follows a logarithmic curve (Fig. 118.2). This model assumes that the substance removed is neither synthesized nor degraded substantially during the procedure, remains within the intravascular compartment, and mixes instantaneously and completely with any plasma replacement solution. When the goal of plasmapheresis is to supply a deficient substance, for example, the cleavage ADAMTS13 in the treatment of thrombotic thrombocytopenic purpura (TTP), replacement follows logarithmic kinetics similar to those developed for solute removal. From Fig. 118.2, it is evident that removal of 1.5–2.0 volumes will reduce an intravascular substance by approximately 80% and that processing larger volumes results in little additional gain. Specific cell removal with centrifugal

automated cell separators depends on the number of cells available, the volume of blood processed, the efficiency of the particular instrument, and the separation characteristics of the different cells. Most commercially available instruments remove platelets and lymphocytes extremely efficiently. Granulocytes and other mononuclear cells, including HPCs from peripheral blood, cannot be cleanly separated from other cells by standard centrifugal apheresis equipment (Fig. 118.3). Optimal harvesting of these cells requires special techniques such as stimulating the donor with corticosteroids or cytokines and adding sedimenting agents to enhance cell separation.

Whereas this model accurately estimates removal of cells and large proteins such as fibrinogen and immunoglobulin (Ig) M, removal of smaller solutes such as IgG and albumin-bound drugs is less efficient. Transfer of these moieties from the extravascular to the intravascular compartment depends both on diffusion along a concentration gradient and on active transport. The rate of clearance can be calculated using diffusion coefficients, sieving coefficients, and lymphatic flow rate, although in practice this degree of accuracy is rarely necessary.

TECHNOLOGY AND TECHNIQUES

The plasmapheresis technique that originated in the animal laboratory required manual resuspension of RBCs and posed a substantial risk of microbial contamination of the components being reinfused. With the introduction of sterile, disposable, interconnected plastic blood bags, plasmapheresis became relatively safe and easy. However, manual apheresis proved too inefficient and labor intensive for collecting large component volumes and raised concerns that the separated units of RBCs might be reinfused accidentally into the wrong donor or patient. The introduction of automated online blood cell separators solved these problems. Automated apheresis instruments use microprocessor technology to draw and anticoagulate blood, separate components either by centrifugation or by filtration, collect the desired component, and recombine the remaining components for return to the patient or donor. The equipment contains disposable plastic software in the blood path and uses anticoagulants containing citrate or combinations of citrate and heparin that do not result in clinical anticoagulation of the patient or donor. Most instruments function well at blood flow rates of 30–80 mL/min and can operate from peripheral venous access or from a variety of multilumen central venous catheters. Newer therapeutic apheresis devices are smaller and more automated, allowing for implementation of more safety functions and improved portability.

Because the ideal method for treating disorders mediated by abnormal plasma components is to remove the offending substance selectively, a variety of online filtration and column adsorption techniques have been introduced or proposed. Ligands bound to a column matrix may be relatively nonspecific chemical sorbents, such as charcoal or heparin, or specific ligands, such as monoclonal antibodies and recombinant protein antigens. Two such columns are commercially available: one using staphylococcal protein A and the other using negatively charged dextran sulfate cellulose beads. Staphylococcal protein A has high affinity for the Fc portion of IgG1, IgG2, and IgG4 and for immune complexes containing these IgG subtypes. This column is approved for use in therapeutic apheresis procedures for patients with chronic immune thrombocytopenia and selected adult patients with rheumatoid arthritis. The dextran sulfate cellulose

Cell type	Blood concentration			Cell content			Apparent volume of distribution	
	Initial	End	% change ^a	Blood ^b	Product ^c	Fraction ^d	Liters	No. of blood volumes

^b Estimated initial content in peripheral blood

^c Total product content

^d Total product content divided by estimated initial content in peripheral blood. L, liters. CD34 cell concentration in $10^9/L$, CD34 cell content $\times 10^8$ cells.

Fig. 118.1 TWENTY HEALTHY MOBILIZED DONORS UNDERWENT EITHER A SINGLE LARGE VOLUME LEUKAPHERESIS PROCEDURE OF 25 L OR TWO CONSECUTIVE-DAY SMALLER VOLUME PROCEDURES OF 15 L EACH. In both study groups, more than twice as many CD34 cells were collected than the estimated total content of these cells in the peripheral blood before apheresis, providing evidence for the existence of a large extravascular pool of peripheral blood stem cells, which becomes accessible to collection by leukapheresis. (Modified from Bolan CD, Carter CS, Wesley RA, et al: *Prospective evaluation of cell kinetics, yields and donor experiences during a single large-volume apheresis versus two smaller volume consecutive day collections of allogeneic peripheral blood stem cells*. Br J Hematol 120:801, 2003, by permission of the authors.)

Fig. 118.2 RELATIONSHIP BETWEEN VOLUMES REMOVED BY APHERESIS AND PERCENTAGE OF THE TARGET COMPONENT REMAINING. The relation is valid for blood volumes during red blood cell exchange or for plasma volumes during plasmapheresis if the target solute remains primarily within the intravascular compartment.

columns selectively remove LDL, very-low-density lipoprotein, and lipoprotein, and have proved effective in managing patients with homozygous hypercholesterolemia who have not responded to diet and cholesterol-lowering drug therapy (Fig. 118.4). A similar technique, heparin-induced extracorporeal lipoprotein precipitation, uses low pH and negatively charged heparin to precipitate lipoproteins and remove the precipitate by filtration online (H.E.L.P. Plasmat Futura, Braun Medical). Apheresis technology has also been adapted for extracorporeal phototherapy of patient leukocytes (photopheresis) to treat cutaneous T-cell lymphoma and to modulate the pathologic immune response in graft-versus-host disease (GVHD), solid organ transplant, and autoimmune diseases (see later discussion).

Fig. 118.3 SCHEMATIC DISTRIBUTION OF CELLS AT THE COLLECTION PORT OF A CENTRIFUGAL CELL SEPARATOR. The number and percentage of each cell type collected can be varied by adjusting the site of collection along the interface or by changing centrifugal force, blood flow rate, or rate of cell removal.

Therapeutic Cytopheresis

Common indications for therapeutic cell removal are listed in Table 118.1. Most of these procedures entail simple apheresis of the patient's peripheral blood with diversion for discarding the affected RBC, white blood cell (WBC), or platelet fraction. Special apheresis technologies have been approved, such as photopheresis devices, that divert a cell fraction that is photochemically treated in the extracorporeal circuit and returned to the patient's circulation, and

Fig. 118.4 TWO-STAGE THERAPEUTIC PLASMAPHERESIS. Plasma is separated from cells by filtration and then passed through parallel adsorption columns to remove low-density lipoproteins from a patient with homozygous familial hypercholesterolemia.

TABLE 118.1

Common Indications for Therapeutic Cytophoresis

Erythrocytapheresis

Acute complications of sickle cell disease
Prophylaxis for recurrent stroke
Frequent severe pain crises
Hyperparasitemia (malaria, babesiosis)
Hemochromatosis

Leukapheresis

Leukemia with hyperleukocytosis syndrome
Cutaneous T-cell lymphoma (photopheresis)
Peripheral blood stem cell collection

Plateletpheresis

Symptomatic thrombocytosis

apheresis immunoabsorption columns, which selectively remove immunoglobulins in the plasma by binding to a solid matrix.

Erythrocytapheresis

RBC exchange (erythrocytapheresis) is used most often to manage or prevent the acute vasoocclusive complications of sickle cell disease. Compared with manual exchange transfusion, mechanical cell separators offer the advantages of speed and ease and reduce the risks of rapid blood volume alteration and increased blood viscosity that may occur with simple transfusion. Automated procedures can be performed with all centrifugal instruments, and programmed procedures allow accurate prediction of target hemoglobin (Hb) concentration and percent HbA at the conclusion of the procedure. A single volume exchange will remove about two-thirds of the circulating cells.

Sickle cell anemia occurs in individuals who are homozygous for a single mutation in codon 6 of the β -globin gene, resulting in

substitution of a single amino acid. Although the defect appears simple, the pathophysiology of the vasoocclusive crises is complex, involving Hb polymerization, change in cell shape, adhesion to endothelial cells, dysregulated nitric oxide homeostasis, and release of free Hb and inflammatory cytokines.³ Clinical manifestations vary from patient to patient. The rationale behind exchange transfusion involves improving tissue oxygenation, reducing hemolysis, and preventing microvascular sickling by diluting the patient's abnormal RBCs, simultaneously correcting anemia and favorably altering whole blood viscosity and rheology. No clinical data support a single optimal level of HbA; however, as few as 30% of transfused cells markedly decrease blood viscosity. At mixtures of 50% or greater, resistance to membrane filterability approaches normal. In nonemergency situations, such levels can often be achieved with a simple transfusion regimen. For simple and exchange transfusions, raising the level of HbA to between 60% and 70% while lowering the level of HbS to 30% is generally efficacious, although even higher levels of HbA are often used to treat an ongoing crisis. Clinical indications for exchange transfusion in patients with sickle cell anemia remain controversial, with limited controlled study data available. Simple transfusion has been shown to improve renal concentrating ability and splenic function in young sickle cell patients; exchange transfusion improves exercise tolerance and reverses the periodic oscillations in cutaneous blood flow associated with this disease. Such observations have encouraged the use of exchange transfusion for acute complications of sickle cell disease such as acute chest syndrome, priapism, cerebrovascular accident, and hepatic and retinal infarction. Exchange transfusion for sickle cell patients has also been used for prophylaxis during pregnancy and before surgery, although prophylactic transfusion in these settings remains controversial. The only randomized trial of transfusion during pregnancy has shown that prophylactic transfusion sufficient to reduce the incidence of painful crises did not reduce other maternal morbidity or perinatal mortality. The risk of intrauterine growth restriction may be reduced by prophylactic exchange transfusion; however, the study is limited by the retrospective observational nature of the data. In a randomized study of patients with sickle cell disease undergoing surgery, a conservative simple transfusion regimen (to increase the Hb level to 10 g/dL) was as effective as an aggressive regimen (to lower the HbS level to <30%) with respect to perioperative complications not related to transfusion. The patients in the aggressive regimen group received twice as many units of blood, had a proportionally increased RBC alloimmunization rate, and had more hemolytic transfusion reactions. A subsequent trial has confirmed that preoperative transfusion is associated with decreased perioperative complications in patients with sickle cell disease who are scheduled to undergo low-risk and medium-risk surgeries.⁴

Transfusion prophylaxis is now clearly indicated for children at high risk for stroke. A randomized controlled study demonstrated a risk reduction of 90% in the patients who were maintained at levels of 30% or less HbS by simple or exchange transfusion. This result confirms earlier experience and indicates that in this group of children with sickle cell anemia, transfusion therapy should begin before the first event and continue indefinitely. A second trial addressed whether transfusion could be safely discontinued to avoid the cumulative long-term risks of iron overload and RBC alloimmunization. After 10 months of randomization, half of the patients who discontinued transfusion had developed central nervous system abnormalities, including reversion to abnormal transcranial Doppler findings and a small number of strokes, necessitating early termination of the trial. For chronic management, repeated erythrocytapheresis may be preferable to simple transfusion for patients at high risk for stroke who have developed iron overload to levels associated with organ damage. Exchange transfusion, although relatively safe and convenient, carries all the complications of RBC transfusion. Patients are exposed to a large number of donors and are at a small but significant risk of contracting hepatitis and other blood-borne infections. As many as 33% of all patients develop alloantibodies, and life-threatening delayed hemolytic transfusion reactions have been reported. In addition, an immunohematologic study of multiply

transfused sickle cell patients shows that 85% of heavily transfused patients are alloimmunized to human leukocyte antigens (HLAs), platelet-specific antigens, or both. Most centers avoid inducing nonhemolytic transfusion reactions and HLA alloimmunization by using leukocyte-depleted RBCs. Extended RBC phenotyping at diagnosis and provision of phenotypically matched blood, when practical, can reduce the risk of RBC alloimmunization and associated hemolytic transfusion reactions. Despite the removal of RBCs during exchange, most patients remain in positive iron balance, although iron accumulation is slow and chelation is rarely required to prevent transfusional hemosiderosis.

Other indications for RBC exchange are rare. The procedure has been used for patients with overwhelming RBC parasitic infections, such as severe and complicated malaria and babesiosis. In malaria, exchange transfusion may have at least three beneficial effects. An automated exchange rapidly decreases the concentration of circulating parasites while improving the rheologic properties of the blood by replacing the infected RBCs. The exchange may also reduce levels of proinflammatory cytokines and may help sustain life until conventional therapy and natural immunity take effect. Although the efficacy of this therapy has not been evaluated by controlled trials, prospective studies and review of published cases suggest the use of erythrocytapheresis for parasitemia greater than 10% to 15% or even less in selected patients such as those with cerebral malaria or pulmonary edema. Case reports document RBC exchange in such diverse conditions as carbon monoxide poisoning and glucose-6-phosphate dehydrogenase (G6PD)-deficient hemolysis.

Automated RBC removal with volume replacement (isovolemic hemodilution) can be performed rapidly and safely in polycythemic subjects. This maneuver should be reserved for polycythemic patients with an urgent clinical indication to lower the hematocrit (e.g., evolving thrombotic stroke) for which standard single-unit manual phlebotomy might be inadvisably slow. Automated double RBC apheresis technology has more recently been used to treat individuals with hereditary hemochromatosis. This procedure removes excess iron more rapidly than manual phlebotomy and is well received by patients because it lowers the frequency of clinic visits (Fig. 118.5).⁵

Fig. 118.5 ONE TWIN WAS TREATED WITH MANUAL PHLEBOTOMY (T1) AND THE OTHER WITH DOUBLE RED BLOOD CELL APHERESIS (T2). In the same time period, ferritin levels declined more rapidly and to lower levels in the twin treated with double red blood cell apheresis. DRCA, Double red blood cell apheresis. (Unpublished data from Bolan CD, Leitman SF, with permission of the authors.)

Leukapheresis

Therapeutic leukapheresis has been used most successfully to help manage patients with acute leukemia and extremely high WBC numbers, so-called acute hyperleukocytic leukemia (AHL). When the fractional volume of leukocytes (leukocrit) exceeds 20%, blood viscosity increases and leukocytes can interfere with pulmonary and cerebral blood flow and compete with tissue for oxygen in the microcirculation. Investigations of the expression and function of adhesion receptors in leukemic cells and the role of adhesion molecules in leukocyte-induced acute lung injury in sepsis suggest that the pathophysiology of leukostasis in AHL may also be related to interactions between leukemic blasts, platelets, and endothelial cells mediated by locally released adhesion molecules. A single-volume leukapheresis procedure generally reduces the WBC count by 20% to 50%, depending on the differing sedimentation characteristics of the specific blast cell population. Ordinarily, leukapheresis is initiated in a patient with acute myeloid leukemia (AML) or in the accelerated phases of chronic myeloid leukemia (CML) when the blast count exceeds 100,000/mm³ or when rapidly rising blast counts are higher than 50,000/mm³, especially when evidence of central nervous system or pulmonary symptoms appears. The threshold for initiation of leukapheresis in patients with acute lymphocytic leukemia (ALL) is generally higher (WBC count >200,000/mm³). Leukostatic syndromes do not occur when concentrations of well-differentiated lymphocytes exceed even several million/mm³.

Although leukapheresis is effective in reducing the number of circulating blasts, the evidence for clinical benefit is anecdotal. Case reports and small series describe dramatic improvement of patients with evolving strokes and respiratory insufficiency, but the absence of a randomized controlled trial necessitates reliance on retrospective studies. Leukapheresis may reduce early death (ED) rates but does not improve the overall survival of patients with AML.⁶ Trials reporting reduction in ED should be interpreted with caution. Because one retrospective cohort study associated leukapheresis with a poorer outcome attributed to a delay in commencing chemotherapy,⁷ it seems imprudent to delay other immediate measures for treatment of patients with AHL (infusion of intravenous [IV] fluids, administration of hydroxyurea, and uricosuric medication, urinary alkalization, correction of coagulopathy and thrombocytopenia) while awaiting leukapheresis.

Mechanical cytoreduction for managing other leukemic processes has limited value. Although repeated leukapheresis has adequately reduced the WBC count in a series of patients with CML, the median patient survival rate was not significantly different from that of similar patients treated with conventional chemotherapy. Chronic leukapheresis can provide acceptable control of the peripheral WBC count in clinical situations such as pregnancy, when cytotoxic agents may best be avoided, but cytoreduction alone does not appear to alter the course of CML. In a small series of gravid patients leukapheresis in combination with interferon has successfully controlled the disease until therapy with tyrosine kinase inhibitors could be initiated after delivery.⁸ Early studies of patients with CLL suggested short-term clinical benefit of leukapheresis, but long-term support of patients when the disease is refractory to chemotherapy does not appear to prolong life.

Lymphocyte removal by apheresis has also been used to modify immune responsiveness in patients with autoimmune diseases and to enhance solid organ allograft survival and reverse solid organ graft rejection. Evidence of clinical efficacy in these situations is sparse. Removal of large numbers of lymphocytes over a period of a few weeks can suppress peripheral lymphocyte counts in patients with rheumatoid arthritis for up to 1 year and can alter skin test reactivity and lymphocyte mitogen responsiveness to a variety of stimulants. Selected patients experience a modest but significant reduction in disease activity; however, the subset of patients who may derive substantial benefit from this therapy is difficult to identify. Because leukocytes are a major source of inflammatory cytokines implicated in the pathogenesis of inflammatory bowel diseases (IBD), nonpharmacologic methods for selective leukoreduction have been developed

to treat these chronic, relapsing, lifelong disorders. Although IBD respond to a variety of drug regimens, leukapheresis may have a role as a “steroid-sparing” intervention for patients who develop toxicity from long-term steroid use. Cellsorba removes leukocytes by extracorporeal filtration. Granulocyte-monocyte apheresis (Adacolumn) selectively adsorbs cells through columns filled with cellulose beads.⁹ Clinical trials using Adacolumn technology have promising results in the treatment of ulcerative colitis, with remission rates in excess of 70% compared with conventional medical therapy. These studies should be interpreted with caution given their high risk of bias and the inclusion of predominantly Japanese patients, which may limit how the results apply to populations with different genetic and environmental factors.¹⁰ The optimum course of therapy is yet to be defined. Recent trials have investigated the safety and efficacy of procedures varying from weekly to a daily basis.¹¹

Extracorporeal Photopheresis

Photopheresis, although not strictly a “cell removal” procedure, is considered “apheresis” as it involves automated extracorporeal photopheresis (ECP) treatment that includes leukapheresis, extracorporeal photoactivation with 8-methoxypsoralen (8-MOP), a light-sensitizing agent, and ex vivo ultraviolet A irradiation. The treated leukocyte fraction (Fig. 118.6) delivering the light-sensitizing agent directly to the extracorporeal leukocyte fraction avoids any potential toxicity from oral administration of 8-MOP. The mechanism of action of photopheresis is unproved, but may involve induction of apoptosis of pathogenic T lymphocytes and induction of a dendritic cell-mediated cytotoxic T-cell response. This therapy has minimal toxicity and is highly effective in the treatment of patients with advanced cutaneous T-cell lymphoma. Patients who present with the erythrodermic disease form and circulating malignant cells have the best clinical response. Photopheresis is typically performed once or twice a month. Symptomatic patients with a higher circulating tumor burden benefit from a more intense regimen.¹² More recently, the major use of this technology involves modulation of immune rejection of transplanted organs and management of GVHD after stem cell transplantation in patients who do not respond to standard immunosuppressive therapy. In steroid-refractory acute GVHD, ECP is thought to enhance regulatory T-cell activity, likely inhibiting the cytotoxic T-cells implicated in the pathogenesis of this condition. Response rates in steroid refractory acute GVHD in pediatric and adult patients range from 52% to 100%. Based on these promising results, trials evaluating the utility of ECP as a GVHD preventive strategy are currently underway. Patients with chronic extensive GVHD have also been treated, with responses observed in approximately two-thirds of the steroid-dependent patients, with cutaneous, oral, and ocular forms of the disease. Treatment which is more aggressive than the traditional bimonthly schedule may be required. A response may facilitate a reduction in immunosuppression (“steroid sparing”) with continued photopheresis based on results from a randomized phase II trial.¹³ In chronic visceral GVHD, where a clear benefit is yet to be established, consideration for treatment should include the logistic challenges of frequent hospital visits and the prolonged need for central venous catheter care and/or transfusion support.

Acute rejection in cardiac transplantation occurs in 25% of recipients in the first year. In 30% to 50% of cases, acute rejection is T-cell mediated. Prospective studies have shown benefit of photopheresis in prevention of rejection. In the case of lung transplant, chronic rejection is manifest as bronchiolitis obliterans syndrome (BOS), presenting as progressive dyspnea and airflow limitation. In a recent prospective nonrandomized study, the rate of decline in lung function stabilized within 6 months of starting ECP therapy compared with rates of FEV₁ (forced expiratory volume in the first second of expiration) which were worsening at baseline. Rates of retransplantation were lower and survival was higher among patients who received ECP treatment. Patients with cystic fibrosis and those with longer interval to BOS development since transplant were less likely

Fig. 118.6 OVERVIEW OF A PHOTOPHERESIS PROCEDURE. (1) Vascular access is achieved by placement of a peripheral intravenous line or through a temporary central venous catheter. Whole blood is withdrawn from the patient, mixed with an anticoagulant solution, and pumped to a centrifuge, where it is separated into plasma, red blood cell, and mononuclear cell (buffy coat) fractions by elutriation. (2) After the collection of each mononuclear cell fraction, the uncollected red blood cells and plasma are pumped from the plasma/return bag through a blood filter and returned to the patient. (3) The mononuclear cell fractions are mixed with 8-methoxypsoralen and then (4) pumped through a sterile cassette surrounded by ultraviolet A (UVA) bulbs, resulting in a controlled rate and amount of UVA exposure. (5) The treated cell fraction is filtered and returned to the patient.

to respond to therapy.¹⁴ Of the substantial number of autoimmune disorders for which ECP therapy has been studied, data from small randomized trials have shown benefit in systemic sclerosis (improvement is skin and joint disease severity), and in Crohn disease (steroid-sparing effect). No significant benefit was demonstrated in type I diabetes or in multiple sclerosis (MS).¹⁵ The acute adverse effects of photopheresis include photosensitivity, low-grade fever, and transient hypotension. Anemia and iron deficiency caused by incomplete reinfusion of RBCs may occur in patients undergoing repeated photopheresis. In patients with inadequate peripheral venous access requiring central venous catheter placement, infection, bleeding, and recurrent clotting are risk factors.

Plateletpheresis

Therapeutic plateletpheresis is generally reserved for patients with myeloproliferative disorders and hemorrhage or thrombosis associated with an increase in circulating platelets. Many centers consider using plateletpheresis when the patient's peripheral platelet count is greater than $10^6/\text{mm}^3$, although no consistent relationship between the level of platelet elevation and the occurrence of symptoms has

been found, and no generally accepted assay of platelet dysfunction predicts which patients are at risk. A single cytopheresis procedure can lower the platelet count by 30% to 50%. Plateletpheresis can have dramatic effects for selected patients such as those with evolving digital gangrene. Attempts to maintain thrombocytopenic patients at normal platelet counts by cytopheresis alone have not been successful; more practical long-term chemotherapy should be instituted concurrently. Because most patients with thrombocytosis do not develop symptoms, including patients with myeloproliferative disorders, prophylactic plateletpheresis seems unwarranted regardless of the platelet count. One possible exception involves pregnant patients with essential thrombocythemia who may be at increased risk of first trimester abortion; Periodic plateletpheresis has been used in a limited series, with weekly procedures necessary to reduce the circulating platelet number until delivery.

THERAPEUTIC PLASMAPHERESIS

Common clinical indications for therapeutic plasmapheresis are outlined in Table 118.2. Most procedures are performed for treatment of immunologic and hematologic disorders. A course of plasmapheresis generally consists of five to seven exchanges of 1–1.5 plasma volumes each, either daily or with an interval of 1–2 days between procedures; the course of therapy varies depending on the specific disease indication and rate and duration of response.

Several expert committees have published practice guidelines for using plasmapheresis in a wide variety of disease states.¹⁶ Some of the least controversial indications for plasmapheresis are supported by small series of uncontrolled cases that rely on some objective clinical or laboratory measurement of patient improvement.

Hematologic Indications

Two of the most common indications for plasmapheresis are treatment of TTP and treatment of clinical syndromes associated with paraproteinemias. Plasma exchange with fresh-frozen plasma (FFP) replacement has been estimated to improve survival rates of patients with TTP from 10% to more than 75%. Comprehensive reviews of the clinical and laboratory evaluation and treatment of patients with suspected TTP, including management with plasma exchange therapy, have been published.¹⁷ Treatment usually involves daily single-volume plasma exchange with both frequency and duration of treatment

guided by clinical response and continued until the platelet count is above 150,000/ μ L and lactate dehydrogenase is near normal for 2–3 consecutive days. The persistence of schistocytes on the peripheral blood smear does not preclude weaning or discontinuation of treatment. Typically, patients should respond within 2 or 3 days of beginning treatment. In desperately ill and deteriorating patients, escalating the intensity of plasma exchange to twice daily may be necessary.¹⁸ Despite initial reports of improved response rates in certain patients, recent experience suggests that the use of cryoprecipitate-poor plasma may not be more effective than the use of standard FFP as a specific replacement fluid for plasma exchange in patients with TTP. The effectiveness of plasma exchange in this setting may derive from removal of antibody to or replacement of the von Willebrand factor–cleaving zinc metalloprotease, ADAMTS13. However, patients with clinical features of TTP and only moderate ADAMTS13 deficiency or even normal activity may respond to plasma exchange. Plasma exchange for hematopoietic progenitor cell transplant recipients exhibiting clinical features of TTP, now generally referred to as transplantation-associated thrombotic microangiopathy (TAM), has proved far less efficacious. This syndrome likely differs in pathogenesis from classic TTP in many aspects, including the absence of severe ADAMTS13 deficiency, the spectrum of clinical symptoms, and the lack of evidence of systemic microthrombus formation. Furthermore, plasma exchange has been unsuccessful in reversing most cases of TAM. Finally, atypical hemolytic uremic syndrome (aHUS), a rare form of thrombotic microangiopathy with high mortality, may be difficult to distinguish clinically from TTP in adults. aHUS results from uncontrolled complement activation, does not respond at all to plasma therapies, and is instead treated with eculizumab to block the terminal complement complex.

Small, uncontrolled studies and extensive clinical experience support the use of plasmapheresis as an adjunctive therapy for patients with paraproteinemia and hyperviscosity syndrome and with some paraproteinemias in the absence of hyperviscosity. Waldenström macroglobulinemia manifests as a lymphoplasmacytic lymphoma with a monoclonal IgM protein in the plasma. Because IgM is a large molecule and resides predominantly in the intravascular space, as little as one apheresis procedure will result in improvement in symptoms. Recurrence of symptoms and rising plasma viscosity will determine the need and frequency of repeated exchanges. Comprehensive reviews describing the rationale and treatment schedules for plasmapheresis in patients with a variety of paraproteinemias, including cryoglobulinemia and Waldenström macroglobulinemia have been published.

Low-Density Lipoprotein Apheresis and Other Metabolic Disease Indications

Evidence that cutaneous lesions and vascular lesions regress in individuals with familial hypercholesterolemia as LDL levels are controlled by plasmapheresis has encouraged the use of apheresis column absorption procedures in patients with homozygous disease and in poorly controlled heterozygous patients. LDL apheresis removes apolipoprotein B–containing lipoproteins from the blood by a variety of techniques, including dextran sulfate cellulose adsorption, immunoadsorption, and heparin-induced extracorporeal precipitation. Short-term safety and efficacy have been demonstrated. Patients have now been treated successfully for several years; however, additional experience with this therapy will be required to prove long-term benefit for refractory hypercholesterolemia and coronary artery disease for heterozygotes in particular.¹⁹ In 36 homozygous children in two studies, 20% to 22% developed new aortocoronary lesions or showed progression of existing lesions while on apheresis despite impressive reductions in mean LDL cholesterol.^{20,21} Side effects such as malaise, shivering, and pain at the phlebotomy site are common but mild, and the treatments are generally well tolerated. Patients with severe hypertriglyceridemia are at risk of developing acute pancreatitis. Plasma exchange appears to reduce recurrent episodes by an average 67% but requires continuation of medical therapy.

TABLE 118.2 Common Indications for Therapeutic Plasmapheresis

Hematologic Diseases (Including Blood Cell–Specific Autoimmune Diseases)
Thrombotic thrombocytopenic purpura
Idiopathic thrombocytopenic purpura (immunoabsorption)
Hyperviscosity
Posttransfusion purpura
Cold agglutinin syndrome
ABO-mismatched marrow transplant (recipient)
Autoimmune Diseases
Cryoglobulinemia
Rheumatoid arthritis (immunoadsorption, lymphoplasmapheresis)
Myasthenia gravis
Goodpasture syndrome
Guillain-Barré syndrome
Chronic inflammatory demyelinating polyneuropathy
Metabolic Diseases
Homozygous familial hypercholesterolemia (selective adsorption)
Refsum disease
Other
Drug overdose and poisoning

Fig. 118.7 PLASMA EXCHANGE TO REMOVE PLASMA NEUTRAL GLYCOLIPIDS IN A PATIENT WITH FABRY DISEASE. The plasma lipid recovery curve appears to be biphasic, reflecting initial reequilibration from tissue stores and subsequent new synthesis of that glycolipid.

Simple plasma exchange may be used in patients with other inherited metabolic diseases, such as Refsum disease. The frequency of exchange depends primarily on total body burden, rate of synthesis, and plasma concentration of the solute to be removed (Fig. 118.7). Less evidence exists to support a role for repeated treatments in these diseases.

Immune Disease Indications and Immunoabsorption Therapies

Plasma exchange appears to have at least a temporary adjunctive role in managing some rheumatic diseases and other immune disorders characterized by circulating autoantibodies. Early success was reported in patients with Goodpasture syndrome, a disorder characterized by a specific pathogenic autoantibody directed against the renal glomerular and pulmonary alveolar basement membrane. Plasmapheresis has demonstrated similar success in myasthenia gravis, pemphigus, and Eaton-Lambert syndrome. Although nonselective plasma exchange has been used in a variety of other rheumatic diseases such as systemic lupus erythematosus (SLE) and rheumatoid vasculitis, with the exception of treatment of patients with Goodpasture syndrome (in which plasma exchange is considered first-line adjuvant therapy), such use remains unproved and should be reserved for circumstances in which a vital organ or life itself is endangered. Selective leukapheresis by Adacolumn technology in a series of patients with SLE has shown clinical benefit, but trial interpretation is limited by the uncontrolled nature and small size.

In some immune disorders, such as immune thrombocytopenic purpura (ITP) and immune inhibitors to coagulation proteins, plasma exchange may be helpful during a catastrophic event, but in general, benefit of nonselective plasma exchange therapy is not established.

Plasma exchange appears to be a useful therapeutic option in renal transplant patients threatened with refractory humoral rejection and is now widely used to overcome ABO and HLA incompatibilities between renal transplant patients and their only available donors. Several studies have shown successful reversal of acute humoral rejection mediated by HLA-specific donor antibody using a combination of plasmapheresis and IV immune globulin (IVIg), which is superior to high dose IVIg alone.²² A conditioning regimen consisting of

pretransplant plasmapheresis, immunosuppressive medications, and low-dose cytomegalovirus immune globulin effectively reduces donor-specific antibody and isoagglutinin titers with and without posttransplant splenectomy and anti-CD20 treatment. The strength of donor-specific antibodies is also important and can be determined by titration, but greater sensitivity and specificity may be obtained using Luminex flow-bead technology. Patients with strong HLA antibodies have increased mean bead fluorescence and were more likely to have acute rejection; however, the introduction of peritransplantation apheresis reduced acute rejection from 66% to 7%.²³

Plasma exchange has also been used to treat patients with focal segmental glomerulosclerosis, both for primary disease refractory to standard immunosuppressive therapy and for treatment of patients with recurrent disease after renal transplantation.

Two immunoabsorption columns have been approved in the United States for removal of autoantibodies to factor VIII or factor IX (Immunosorba staphylococcal protein A–agarose column) and treatment of ITP and rheumatoid arthritis (Prosorba staphylococcal protein A–silica column). Several case series describe the use of immunoabsorption for patients with immune inhibitors to factor VIII or factor IX. A phase III, multicenter, sham-controlled randomized study of staphylococcal protein A column immunoabsorption shows a significant increase in clinical response in adult patients with longstanding rheumatoid arthritis. Sparse published evidence exists to support the use of immunoabsorption therapy in patients with chronic ITP refractory to standard medical management.

Plasmapheresis is effective first- or second-line therapy in selected patients with certain neurologic disorders. Controlled clinical trials of plasmapheresis have demonstrated efficacy in at least two of the polyradiculoneuropathies. In Guillain-Barré syndrome, plasmapheresis should be considered when patients are unable to walk independently or require mechanic ventilation. However, IVIg alone may be equally effective and is more readily available.¹⁶ Periodic plasmapheresis may be necessary in patients with a chronic inflammatory demyelinating neuropathy. Because the long-term prognosis varies, plasmapheresis may be used in conjunction with steroids and IVIg. Rapid deterioration may occur upon discontinuation.

MS is a relapsing and progressive disorder with demyelination of the central nervous system white matter. Patients who present with acute fulminant demyelination may benefit from early plasma exchange, particularly when they fail to respond to high-dose corticosteroids.²⁴ The majority of patients have a relapsing-remitting form of the disease, and plasmapheresis may be of benefit. Unfortunately, for chronic progressive forms of MS, plasma exchange has consistently been shown to be ineffective.

REPLACEMENT FLUIDS FOR PLASMA EXCHANGE

The success of therapeutic apheresis procedures seldom depends on the composition of the replacement solution that is used; the single exception is TTP (discussed in the previous section). With therapeutic plasmapheresis for most other disorders, the primary function of the replacement solution is to maintain intravascular volume. Additional requirements include restoration of important plasma proteins, maintenance of colloid osmotic pressure, maintenance of electrolyte balance, and preservation of trace elements lost during a prolonged course of plasmapheresis procedures. In moderately well-nourished patients, homeostatic mechanisms normally obviate the need for precise plasma replacement, and 5% albumin in normal saline or combinations of albumin and crystalloid are usually sufficient. Commonly used is 60% to 80% replacement by colloid, with the crystalloid component consisting of a combination of normal saline and an anticoagulant. Patients with clinical conditions such as hypotension, hypoalbuminemia, or preexisting coagulopathies should receive solutions prepared specifically to meet their individual requirements. Routine supplementation with calcium, potassium, or immunoglobulins is unnecessary. However, for large-volume apheresis procedures to collect PB-HSPC, IV calcium supplementation is beneficial (discussed in the following section). Because less than 500 mL is removed

TABLE 118.3 Bone Marrow Versus Cytokine Stimulated Peripheral Blood Stem Cells as Graft Source of Choice for Hematopoietic Stem Cell Transplantation

Disease Category	Recipient Age Group	Type of Donor	Preferred Graft Source (Unstimulated BM vs. Cytokine Stimulated PB HSPC)
Nonmalignant (e.g., severe aplastic anemia)	All ages	Sibling	BM HSPCs
Malignant	Pediatric	Sibling	BM HSPCs
Malignant	Adult	Sibling	PB or BM HSPCs (PB HSPCs preferred in high-risk leukemia)
Malignant	Adult	Matched unrelated donor	PB or BM HSPCs (PB HSPCs preferred if high graft failure risk; BM HSPCs if high cGVHD risk, prior immunosuppression)

BM, Bone marrow; cGVHD, chronic graft-versus-host disease; HSPC, hematopoietic stem and progenitor cell; PB, peripheral blood.

during most cell collection procedures and therapeutic cell depletions, no volume replacement beyond the anticoagulant and saline priming solution is required. Problems of decreased availability and high cost of albumin have led some centers to develop protocols for alternatives to plasma-derived volume expanders, such as hydroxyethyl starch (HES), for full- or partial-volume replacement with plasma exchange. One center has used a combination of 3% HES and 5% albumin mixture successfully, but patients did experience mild adverse events more frequently than did historical control subjects.²⁵ Although such solutions are generally well tolerated, extensive replacement with HES in patients undergoing longer courses of plasmapheresis, especially those with impaired renal function, can result in diffuse tissue accumulation of the larger starch molecules (acquired lysosomal storage).

HEMATOPOEITIC STEM CELL COLLECTION

Blood cell separators developed for hemapheresis are used to collect peripheral blood cells for cellular therapy. The most common application of apheresis technology for cell therapy indications is the collection of HPCs from peripheral blood after administration of recombinant hematopoietic growth factor or chemotherapy, or both, to “mobilize” large numbers of HPCs into the circulation. The collected mononuclear cell fraction contains a subset of progenitor cells that, on infusion, can home to and reconstitute the bone marrow in patients who receive ablative radiation or chemotherapy, or both. Similarly, donor leukocytes obtained from leukapheresis procedures may be used for donor lymphocyte infusion or subject to further processing for immunotherapy.

Peripheral Blood Hematopoietic Stem and Progenitor Cells

Pluripotent HPCs, and quite possibly primordial hematopoietic stem cells capable of reconstituting the bone marrow and the immune system, have long been known to circulate in the peripheral blood. Numerous studies have confirmed the potential for rapid and durable engraftment of peripheral blood hematopoietic stem and progenitor cells (PB HSPCs) mobilized into the circulation by hematopoietic growth factors harvested by large-volume leukapheresis procedures and subsequently administered to patients with marrow aplasia after high-dose chemotherapy. The concentration of hematopoietic stem and progenitor cells in the peripheral blood can be increased by the administration of cytokines such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) and by the administration of chemotherapy. CD34⁺ hematopoietic cell numbers in the peripheral blood generally rise 20- to 40-fold (from 1–3 cells/ μ L to 40–70 cells/ μ L) after administration of G-CSF alone, and they increase 100- to 1000-fold when chemotherapy rebound is enhanced by administration of G-CSF. Efforts to define optimal collection conditions have been

limited by the lack of a standardized assay; however, time and level of increase of donor peripheral blood WBC and CD34⁺ cell counts after administration of mobilizing agents have proved to be useful indicators. Despite ongoing problems with interlaboratory standardization, flow cytometric analysis of cells labeled with a fluorochrome-conjugated CD34 antibody are used for “real-time” decision making about the timing and adequacy of PB HSPC collections. Several prestimulation donor variables are important. Increasing age, white ethnicity, and female gender are associated with significantly lower post-G-CSF CD34⁺ cell counts, which would favor younger males as donors when high cell doses are required.²⁶

Several clinical scale devices for CD34⁺ cell enrichment of leukapheresis collections by immunoabsorption or immunomagnetic techniques are available. This “positive selection” of CD34⁺ hematopoietic cells also results in reduced numbers of cells that do not express the CD34 antigen, such as T lymphocytes. T-cell–reduced products may confer a lower risk of GVHD, and the ability to produce apheresis products enriched for CD34⁺ cells facilitates graft manipulations for experimental cell therapies such as ex vivo expansion of CD34⁺ cells. However, some studies suggest a higher incidence of engraftment failure and possibly delayed immune reconstitution in certain patient populations when transplants are performed with highly purified CD34-selected, T-cell–depleted products.

Over the last decade, PB HSPCs have surpassed bone marrow HSPCs as the predominant graft source in the clinical setting for various hematopoietic stem cell transplants. PB HSPCs are the graft of choice in 99% of conditions where autologous transplants are indicated. For allogeneic transplants, especially which use stem cells from matched unrelated donors or in pediatric transplants, bone marrow stem cells still remain the popular graft source. PB HSPC transplants result in higher rates of clinically significant chronic GVHD in these situations. Table 118.3 provides a summary of comparisons of bone marrow versus PB HSPCs in different types of allogeneic stem cell transplants.

From a donor perspective, the discomfort and inconvenience of multiple-day cytokine administration may be a significant deterrent. Most donors experience some degree of malaise and bone pain, and some donors require hospitalization for more serious adverse reactions to G-CSF administration. However, a large prospective trial of the National Marrow Donor Program found intensity and duration of pain in the pericollection period (during G-CSF administration before apheresis among PB HSPC donors and following bone marrow biopsy procedure in bone marrow HSPC donors) was similar for persons undergoing HSPC collection by either apheresis or bone marrow biopsy. Further, 3% of bone marrow donors reported ongoing low-grade site pain after 6 months of completing the procedure whereas recovery was complete for PB HSPC donors by this time. Risk factors for worse toxicities, including older age, female gender, and obesity were similar among bone marrow and PB HSPC donors.²⁷ While concerns remain regarding the hypothetical long-term effects of exposure of healthy donors to growth factors, another recent prospective study with more than 20,000 donor-years of follow-up, showed no evidence of increased risk for cancer, autoimmune illness, and

stroke in donors receiving G-CSF.²⁸ Splenic enlargement occurs commonly, and several instances of splenic rupture have been reported. Citrate toxicity is a common complication of PB-HSPC collections; although usually mild and transient, it may be severe and even life-threatening in some individuals (see previous section). Venous access requires large-bore multilumen catheters, and these appear particularly susceptible to clotting, especially when patients receive recombinant cytokine stimulation. Hemorrhage, especially in thrombocytopenic patients, is another potentially severe complication of central venous catheter placement.

Some patients who have received multiple prior cycles of chemotherapy and a small proportion of normal healthy donors, referred to as “poor mobilizers,” fail to respond adequately to mobilization regimens. In this circumstance, Plerixafor, a reversible CXCR4 antagonist that can block the adhesion of HPCs to the bone marrow stroma can enhance collections by releasing these cells into the circulation. In a randomized controlled trial, the combination of G-CSF and Plerixafor resulted in a significantly higher proportion of patients with non-Hodgkin lymphoma achieving their target cell dose in fewer apheresis days.²⁹ Similar success is achieved with multiple myeloma patients achieving a 4.8-fold increase peripheral blood CD34 cell count compared with 1.7-fold with G-CSF alone. Emerging evidence indicates that Plerixafor may be administered “just-in-time” to rescue collections for patients who mobilize poorly with G-CSF alone. While the optimum circumstances and timing for administration have not yet been determined, some guidelines recommend addition of Plerixafor for circulating CD34⁺ cell counts fewer than $20 \times 10^6/L$ on two consecutive days accompanied by increasing WBCs.³⁰

COMPLICATIONS OF THERAPEUTIC APHERESIS

Automated apheresis is a minimal-risk procedure for normal healthy blood and plasma donors. The current generation of blood cell separators is remarkably reliable and equipped with sensitive detection and alarm systems to alert the operator to potential problems. Nevertheless, serious morbidity and rare deaths have been associated with therapeutic procedures. In most reports, deaths are related to either complications associated with the use of central venous access catheters or to cardiac and respiratory problems in patients who were critically ill before apheresis; in the latter, the contributory role of the apheresis procedure is often questionable. The most common adverse effects of therapeutic apheresis are citrate-induced hypocalcemia, allergic reactions (usually to donor plasma or other blood components), vasovagal reactions, and hypovolemia. If transient paresthesia and mild vasovagal events are excluded, approximately 5% of all therapeutic apheresis procedures have medical complications. The frequency of adverse reactions is influenced by the experience of the operator and the nature of the patient population being treated. Expected and predictable effects of therapeutic apheresis include alterations in laboratory parameters caused by removal and dilution by replacement fluids. A 5% to 15% decrease in Hb and hematocrit, a 20% to 30% decrease in platelet count, and mild transient increase in leukocyte count are commonly observed. Significantly but transiently abnormal coagulation test results are often observed (recovery generally occurs within 48 hours after a single-volume exchange procedure), as well as clinically insignificant decreased levels of other plasma proteins after serial plasma exchange procedures. The most common adverse effect of both donor and therapeutic apheresis procedures is symptomatic hypocalcemia caused by infusion of calcium-chelating citrate ions in the anticoagulant, and if used as replacement fluid, anticoagulated donor plasma. Hypocalcemia is usually manifested by mild perioral or acral paresthesia, or both, requiring no intervention other than slowing the reinfusion rate. The benefit of oral calcium supplements in this setting is questionable, although the practice is widespread. Hyperventilation may exacerbate the symptoms of hypocalcemia. More severe citrate toxicity is uncommon; signs may range from involuntary carpopedal spasm, nausea, and vomiting to frank tetany with spasm in other muscle groups, including life-threatening laryngospasm and grand mal seizure.

Severe toxicity is most commonly experienced by small patients, particularly women, when the blood flow rate is rapid and the procedure is prolonged beyond a few hours. Symptoms correlate inversely with the level of ionized calcium. Extremely low concentrations of ionized calcium are encountered routinely in therapeutic procedures that process more than 15 L of blood. Acute severe hypocalcemia leading to fatal cardiac arrhythmia has been reported in patients who have undergone apheresis. Controlled infusions of 10% calcium gluconate or calcium chloride are effective in the management of these complications. Because metabolism of citrate occurs predominantly in the liver and kidney, patients with conditions affecting these organs are at increased risk for severe citrate reactions. Studies of therapeutic plasma exchange procedures and of PB-HSPC donations performed with and without calcium gluconate or calcium chloride infusion show the effectiveness of continuous calcium infusion for the prevention of mild to moderate citrate toxicity (Fig. 118.8). A study of plateletpheresis donors documented sustained effects of citrate infusion on bone metabolism demonstrated by changes in alkaline phosphatase, osteocalcin, parathyroid hormone, and 1,25-dihydroxyvitamin D levels, suggesting the potential for long-term effects on bone metabolism in these donors. Magnesium, another divalent cation, is also bound by citrate. Despite decreases in serum ionized magnesium levels to 39% below baseline, clinical effects are not typically observed even during large-volume leukapheresis procedures. The most severe allergic complications occur when plasma is used as the replacement solution, and this risk increases with repeated exposure. Allergic reactions to ethylene oxide, an agent used in the sterilization of plastic disposable equipment, have been reported. IV diphenhydramine is usually effective in managing allergic reactions; premedication with steroids and precautions against anaphylaxis may be necessary for sensitized individuals. Atypical (hypotension and flushing) and anaphylactic reactions have been reported in patients receiving angiotensin-converting enzyme inhibitors undergoing different apheresis procedures, including immunoadsorption with staphylococcal protein A columns. These medications should be discontinued for at least 24 hours before apheresis. Unlike

Fig. 118.8 LEVELS OF IONIZED CALCIUM ARE MARKEDLY LOWER IN PROCEDURES PERFORMED WITHOUT PROPHYLACTIC CALCIUM INFUSION AND REMAIN BELOW THE REFERENCE RANGE 90 MINUTES AFTER COMPLETION OF APHERESIS. Dotted lines indicate upper and lower limits of the reference range. Open symbols represent procedures without prophylactic calcium; solid symbols represent those with calcium infusion. Dashed lines between 180 minutes and end-procedural values (End) reflect varying procedure duration. *iCa*, Ionized calcium. (From Bolan CD, Cecco SA, Wesley RA, et al: Controlled study of citrate effects and response to i.v. calcium administration during allogeneic peripheral blood progenitor cell donation. *Transfusion* 42:935, 2002, used by permission).

donors undergoing apheresis for donation of RBCs, platelets, or plasma, donors undergoing apheresis for collection of therapeutic granulocytes are stimulated with steroids and G-CSF before donation. The well-known association of long-term steroid treatment and posterior subcapsular cataracts is likely irrelevant in the context of short-term steroid stimulation for donor granulocyte mobilization. However, an increased number posterior subcapsular cataracts has been detected in three separate studies including an analysis of 100 granulocyte donors compared with age-matched plateletpheresis donors, suggesting that granulocyte donors may be at increased risk for cataract formation. Repeated steroid stimulation for granulocyte collection warrants regular ophthalmologic examination and close follow up.³¹ Serious complications indirectly associated with therapeutic apheresis include adverse consequences of large-needle vascular access; namely, retroperitoneal or pericardial hemorrhage, phlebotomy site aneurysm formation, pneumo- or hemothorax, thrombosis, nerve damage, and infection. A retrospective review of 381 therapeutic plasma exchange procedures at one institution reported an approximately 1% incidence of severe complications, all of them related to central venous catheters (see box on [Patient Management Issues for Therapeutic Apheresis](#)).

Patient Management Issues for Therapeutic Apheresis

Important issues to consider when preparing a patient for therapeutic apheresis, for monitoring the patient during the procedure, and for managing the patient after removal from the apheresis device include:

Preparation

- Volume considerations: Calculate volume to be processed or exchanged; order replacement solutions; assess patient volume status. A blood prime may be necessary for children who weigh less than 25 kg.
- Vascular access: Assess need for apheresis line placement. Note that not all large catheters are suitable for apheresis procedures.
- Medications: Evaluate impact of medications (Coumadin, platelet inhibitory agents, angiotensin-converting enzyme inhibitors) and indications to suspend certain medications. Albumin-bound medications may be depleted by apheresis.
- Cell counts: Patient may require transfusion for preprocedure anemia or thrombocytopenia.
- Electrolytes: Assess risks for citrate toxicity; order calcium replacement solutions if indicated.

Procedure

- Volume considerations: Monitor replacement fluids (saline-to-albumin ratio). Rapid infusion of refrigerated solutions may cause hypothermia.
- Vascular access: Observe for impaired, intermittent, or obstructed flow. Kinked tubing can result in hemolysis.
- Medications: Limitations on blood or citrate flow rate caused by symptomatic citrate-induced hypocalcemia may necessitate addition of anticoagulant to the final apheresis product or inclusion of heparin in the anticoagulant regimen.
- Cell counts: Consider the impact of very high or low cell counts on device settings and procedure efficiency.
- Electrolytes: Continually monitor for adverse citrate effects; bolus or continuous intravenous calcium administration may be required.

Postprocedure Management

- Volume considerations: Review net volume balance and consider additional infusion or administration of diuretic if needed.
- Vascular access: The decision to remove the apheresis catheter should include the possibility of additional apheresis or procedures; monitor for complications associated with maintenance or removal of venous catheter.
- Medications: Determine when to restart medications; consider the impact of transiently reduced coagulation factor levels.
- Cell counts: The patient may require transfusion for postprocedure thrombocytopenia; monitor cumulative red blood cell and platelet loss after repeated procedures.
- Electrolytes: Assess for imbalance postprocedure with attention to ionized calcium and magnesium as indicated by symptoms.

PEDIATRIC HEMAPHERESIS

Therapeutic apheresis in pediatrics poses a particular challenge. The indications for apheresis in children are limited by a lack of clinical trial data. Therefore the evidence for therapy in many diseases is extrapolated from trials in adults despite differing patient physiology and an age-dependent presentation and natural history of the disease. For example, hemolytic uremic syndrome is more common in children and responds to supportive care; at the other end of the spectrum of this disease, TTP is more common in adults and necessitates plasma exchange.

Similarly the mechanics of apheresis were developed for adults and therefore designed for their larger circulating blood volume. Therefore depending on the size of the child, modifications to the apheresis procedure may be necessary. Central venous catheters are required in most circumstances because the caliber of peripheral venous access is too small to permit adequate blood flow.

Technical Aspects

In pediatric apheresis, maintenance of isovolemia is essential to prevent circulatory compromise, particularly in an acutely ill child who may have some degree of cardiac or renal impairment. The beginning and end of the apheresis procedure involves negative and positive intravascular fluid shifts, respectively. Typically, this has negligible impact on an adult's circulation but can represent a substantial proportion of the total blood volume (TBV) of an infant. The volume of the patient's blood required to fill the apheresis circuit at the start of the procedure is the extracorporeal volume (ECV). Symptomatic hypovolemia becomes increasingly likely as ECV exceeds 15% of TBV. An ECV of 400 mL represents 8% of the TBV of a 70-kg patient but may be as much as 35% for a 15-kg infant. Modification of the apheresis procedure is necessary for safe management in infants and small children.

In adults, the apheresis circuit is primed with saline, which is then diverted to the collection or waste bag. One option permits return of saline prime to the patient, which may be useful for larger children. For children who weigh less than 25 kg, a prime with RBCs is often necessary to prevent intravascular volume depletion and severe anemia. Upon completion, fluids remaining in the apheresis circuit, typically returned to the adult patient, are not returned in pediatrics to avoid a positive fluid shift causing fluid overload.

PEDIATRIC APHERESIS

Pediatric therapeutic apheresis accounts for about 10% of all apheresis procedures performed. The majority of apheresis procedures in children are erythrocytapheresis for patients with sickle cell disease and mononuclear cell collections for HPCs to be used in conjunction with high-dose chemotherapy. Leukapheresis is performed in symptomatic leukostasis in acute leukemias, but may not be beneficial as prophylaxis in hyperleukocytosis. Indications for ECP and LDL-apheresis follow guidelines discussed earlier. In solid organ rejection, both ECP and therapeutic plasma exchange (TPE) have been used as adjunct treatment modalities with sparse data thus far. As in adults, TPE is shown to be efficacious in acute and chronic demyelinating neuropathies and in severe refractory myasthenia gravis. TPE may also benefit children with rare neurologic disorders; pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection and Sydenham chorea (SC) are autoimmune neuropsychiatric disorders that occur rarely after infection with group A β -hemolytic streptococcal infections. Circulating immune factors may contribute to the pathogenesis of these diseases. These conditions respond to IVIg and plasmapheresis. In a small randomized study, 50% of patients with SC also responded to plasmapheresis, and although superior to corticosteroids, treatment with IVIg had the best response, with 72% of patients having a reduction in symptoms of chorea. Small pediatric studies have demonstrated benefit of

TPE specifically in recurrent focal segmental glomerulosclerosis, especially when it occurs post renal transplantation. It has been attempted with marginal success in severe refractory vasculitides such as Henoch-Schönlein purpura, Kawasaki disease and ANCA-associated vasculitides.³²

TRANSFUSION REACTIONS TO BLOOD AND CELL THERAPY PRODUCTS

William Savage

A *transfusion reaction* can be defined broadly as any untoward clinical event that is the consequence of infusing a blood or cell therapy product. Transfusion reactions are classified by how close to transfusion they occur (timing), how much morbidity is caused (severity), how strong the causal association of the event is with transfusion (imputability), and how closely the reactions fit a consensus definition of a transfusion reaction type. Every year, approximately 40 fatalities attributable to transfusion are reported to the US Food and Drugs Administration (FDA).

It is important to recognize that many transfusion reactions can mimic pathology unrelated to transfusion. The differential diagnosis of any untoward clinical event should always consider adverse sequelae of transfusion, even when transfusion occurred weeks earlier. This chapter will review the presentation, mechanisms, and management of transfusion reactions (Table 119.1). Approximate risks of selected transfusion reactions are shown in Fig. 119.1.

HEMOLYTIC TRANSFUSION REACTIONS

Hemolytic transfusion reactions are caused by the immune-mediated clearance of transfused red blood cells (RBCs). Immune-mediated hemolysis can be classified clinically according to the timing of the reaction (acute or delayed) and mechanistically by site of hemolysis (intravascular with terminal complement activation or extravascular with phagocytosis in liver and spleen, Table 119.2).^{1,2} Although hemolytic transfusion reactions are mechanistically considered immune-mediated in most cases, thermal, osmotic, infectious, and mechanical destruction of RBCs also can lead to acute hemolysis.

ACUTE INTRAVASCULAR HEMOLYTIC TRANSFUSION REACTIONS

Acute hemolytic reactions are those that occur typically during or immediately after incompatible RBCs are transfused into a patient who already possesses the corresponding antibody. ABO-incompatible RBC transfusion is the prototypical example of an acute, intravascular hemolytic transfusion reaction. ABO antibodies are spontaneously occurring immunoglobulin (Ig) M and IgG antibodies to foreign A and B blood group antigens. IgM antibodies efficiently fix complement after binding to ABO-incompatible RBCs and are responsible for initiating the hemolytic and inflammatory cascades that cause a clinically significant acute intravascular hemolytic transfusion reaction. Such a reaction could occur, for example, after transfusion of A RBCs into an O recipient who has significant amounts of circulating anti-A (see box titled “Acute Hemolytic Transfusion Reaction”). Acute hemolytic reactions can also occur with incompatible plasma transfusion. Because of limited platelet inventories, platelet components with incompatible plasma to the recipient are frequently transfused, for example an O platelet with anti-A transfused into an A recipient. This plasma incompatibility (i.e., minor incompatibility) can occasionally result in acute, ABO-incompatible hemolytic reactions.

Factors that determine the severity of hemolysis include the antibody titer, antibody avidity, antibody subtype, antigen density on the RBC membrane, and volume and rate of incompatible blood

transfused. Transfusing as little as 30 cm³ of incompatible blood can be fatal, and there is a direct relationship between increasing volumes of incompatible blood transfused and mortality.

In IgM-mediated ABO-incompatible transfusion reactions, activation of the complement cascade generates anaphylatoxins C3a and C5a, which lead to capillary leak, hypotension, and phagocyte and mast cell activation. Furthermore, the deposition of C3b on the RBC membrane increases extravascular hemolysis. Excessive terminal complement activation results in C5b-9 membrane attack complexes overwhelming complement regulatory factors on the RBC membrane leading to osmotic lysis. Plasma heme also induces renal vasoconstriction through nitric oxide scavenging.

In addition to complement components, cytokines also play a role in the clinical syndrome, including fever. For example, interleukin (IL)-1 β , IL-6, and tumor necrosis factor (TNF)- α have pyrogenic activity; IL-8 is a neutrophil chemotactic and activating factor. These four cytokines have been generated in various in vitro models of intravascular hemolysis and IgG-mediated RBC incompatibility. TNF- α induces tissue factor expression on endothelium while decreasing thrombomodulin, which contributes to disseminated intravascular coagulation (DIC). TNF- α also promotes endothelin production, which promotes renal vasoconstriction. The clinical variability of hemolytic transfusion reactions is explained in part by the relative balance of cytokine production in the transfusion recipient. Factors that increase the circulating levels of proinflammatory cytokines and chemokines often result in more severe reactions.

An acute intravascular hemolytic transfusion reaction is a medical emergency. Initial clinical symptoms can include fever and chills, shortness of breath, chest pain, dizziness, and back or flank pain. Some patients report feeling anxiety or pain or warmth ascending from the site of infusion. Often the first sign of an immediate hemolytic transfusion reaction is fever. Therefore RBC transfusions must be stopped and evaluated by blood bank testing when fever develops ($\geq 1^\circ\text{C}$). The transfused incompatible RBCs undergo complement-mediated osmotic lysis, producing hemoglobinemia and hemoglobinuria. Cardinal signs of an acute intravascular hemolytic transfusion reaction are the presence of red plasma (hemoglobinemia) and red/dark urine (hemoglobinuria). Acute transfusion reactions can quickly progress to shock and acute renal failure. Many patients, curiously even anephric patients, often complain of lower back pain. It is speculated that this symptom is caused by ischemic muscle pain or vasospasm, rather than by kidney pain from developing renal failure.

Laboratory tests for hemolysis can be useful if there is clinical ambiguity about the type of reaction and useful for guiding ongoing management of severe hemolytic reactions. Because most ABO-incompatible transfusion reactions are caused by errors in safety systems, an important initial evaluation is confirmation of blood incompatibility and determination of where an error occurred. There may be a systemic error that could put other patients at risk. Laboratory findings include hemoglobinuria, hemoglobinemia, and a haptoglobin level that is low to undetectable. During the hemolytic episode, the bilirubin (especially indirect bilirubin) usually increases only modestly (2–3 mg/dL) if the patient has normal liver function. Because of the lysis of RBCs, levels of lactate dehydrogenase (LDH) may rise markedly. If the patient shows no signs of cardiovascular instability and if hemostatic and renal function is unchanged at least

24 hours after the incompatible transfusion, the episode can be considered to be over, with serious sequelae unlikely. The direct antiglobulin test (DAT) becomes positive in an immune hemolytic reaction (if tested before all the incompatible RBCs are destroyed). Preparation of an antibody eluate is often necessary to identify the presence of an offending IgG antibody. An elution is a procedure that chemically separates the bound antibody from the RBCs and concentrates it so that it may be identified.

Initial therapy consists of immediately stopping the transfusion, administering intravenous fluids, cardiorespiratory support, and ensuring a brisk diuresis. Increasing renal blood flow is the best way to prevent acute oliguric renal failure. Usually, 0.9% NaCl is infused to maintain a urine output of 100 mL/hour for approximately 24 hours. Diuresis can be achieved with loop diuretics or mannitol. Mannitol, if chosen, must be used with caution; if acute tubular necrosis (ATN) occurs before mannitol infusion, pulmonary edema may occur as a result of the acute increase in intravascular volume secondary to fluid expansion. Maintaining hydration and diuresis can be complicated in the setting of heart failure and underlying renal disease. The mechanisms responsible for the beneficial effect of increased renal blood flow likely include increased clearance of free hemoglobin and a return of more physiologic control of renal vasodilation. Creatinine and blood urea nitrogen (BUN) should be monitored; dialysis may be necessary for treatment of oliguric acute renal failure. Support of blood pressure and respiration may require the use of vasopressors, bronchodilators, or intubation. DIC can occur in severe cases. The prothrombin time, activated partial thromboplastin time, and fibrinogen level should be monitored (see box on [Workup of an Acute Intravascular Hemolytic Transfusion Reaction](#)).

Hyperhemolysis is a specific type of acute intravascular hemolysis of bystander RBCs that do not express the antigen to which an immune-mediated hemolysis is directed. Hyperhemolysis occurs in

TABLE 119.1 Types of Acute Transfusion Reactions

Reaction Type	Presenting Signs and Symptoms
Acute hemolytic	Fever, chills, dyspnea, vomiting, hypotension, tachycardia, infusion site pain, back pain, hemoglobinuria, hemoglobinemia, indirect hyperbilirubinemia, renal failure, DIC
Febrile reaction	Fever, chills, rigors
Allergic	Urticaria, pruritus, flushing, angioedema, dyspnea, bronchospasm stridor, hypotension, tachycardia, abdominal cramping
Hypervolemic	Dyspnea, tachycardia, hypertension, headache, jugular venous distention
Septic	Fever, chills, hypotension, tachycardia, vomiting
Transfusion-related acute lung injury	Dyspnea, hypoxemia, fever, hypotension

TABLE 119.2 Hemolytic Transfusion Reactions: Serologic Presentation

Type	Antibody Detectable Initially	Primary Antibody Type	Degree of Complement Binding	Example
Acute intravascular	Yes	IgM	Full (C1-9)	ABO system
Acute extravascular	Yes	IgG	None/partial	Rh system
Delayed intravascular	No	IgG	Full (C1-9)	Kidd system
Delayed extravascular	No	IgG	None/partial	Duffy system

Acute Hemolytic Transfusion Reaction

A 15-year-old blood group O male with sickle cell disease presents for routine simple transfusion for primary prevention of stroke. He has no history of red blood cell (RBC) alloimmunization and his pretransfusion compatibility testing shows a negative screen for RBC alloantibodies. Seven minutes into the transfusion, the patient reports not feeling well. He quickly develops chills, abdominal pain, flank pain, and pain at the infusion site. The transfusion is stopped. Vital signs show a 15-mm Hg drop in systolic blood pressure from baseline value, pulse of 130, and a temperature increase from afebrile pretransfusion to 38.9°C. Gross hematuria is seen in a subsequent urine sample. Reinspection of the blood unit shows that it is group A and labeled with the name of the child receiving blood in the infusion chair next to him. The patient is transferred to the emergency room where he is evaluated for renal failure and DIC.

Recognition of the signs and symptoms at an acute hemolytic transfusion reaction are paramount for transfusion safety. Stopping transfusion at the first sign of incompatibility, usually fever, is critical for preventing severe sequelae. Although almost all febrile reactions to blood transfusion are not caused by blood incompatibility, it is impossible to exclude this possibility at the bedside. All transfusion reactions need to be reported to the blood bank to exclude incompatibility.

Fig. 119.1 APPROXIMATE RISK OF VARIOUS TRANSFUSION COMPLICATIONS. *FNHTR*, Febrile nonhemolytic transfusion reaction; *PTP*, posttransfusion purpura; *t-GVHD*, transfusion-associated graft-versus-host disease; *TRALI*, transfusion-related acute lung injury.

Workup of an Acute Intravascular Hemolytic Transfusion Reaction

If an acute transfusion reaction occurs:

1. Stop blood component infusion immediately.
2. Maintain intravenous access with a suitable crystalloid or colloid solution.
3. Maintain an adequate airway.
4. Monitor/maintain blood pressure and heart rate. Monitor renal status (blood urea nitrogen, creatinine, volume status).
5. Give a diuretic or institute fluid diuresis, or both.
7. Obtain blood and urine studies for the transfusion reaction workup.
8. Blood bank workup of suspected transfusion reaction:
 - Check paperwork and identification to ensure correct blood component was transfused to the correct patient.
 - Observe plasma for hemoglobinemia.
 - Perform direct antiglobulin test.
 - Repeat compatibility testing (crossmatch).
 - Repeat other serologic testing as needed (ABO, Rh).
 - Analyze urine for hemoglobinuria.
9. Monitor coagulation status (prothrombin time, activated partial thromboplastin time, fibrinogen).
10. Monitor for signs of hemolysis (lactate dehydrogenase, bilirubin-total/direct, haptoglobin).

the setting of sickle cell disease with transfusion, acute malarial infection, passenger lymphocyte syndrome, paroxysmal nocturnal hemoglobinuria, and select cases of autoimmune hemolytic anemia. Petz and colleagues proposed the term *sickle cell hemolytic transfusion reaction syndrome* to describe the constellation of hemolysis, sickle cell pain crisis, reticulocytopenia, severe anemia, RBC transfusion leading to accelerated hemolysis, and lack of a clear serologic reason for hemolysis. Hyperhemolysis is frequently fatal because transfusion exacerbates hemolysis and the primary treatment for severe anemia (RBC transfusion) makes anemia worse. Recognition of this syndrome is therefore critical because treatment should shift from transfusion to administering erythropoietin, glucocorticoids, and intravenous immunoglobulin (IVIg), which have been used successfully in case series.

ACUTE EXTRAVASCULAR HEMOLYTIC TRANSFUSION REACTION

In an extravascular hemolytic transfusion reaction, complement is either not fixed at all or is fixed only to C3b. In either situation, because of the nature of the antigen-antibody reaction, complement activation with fixation of the C5b-9 complex does not occur. This presentation is commonly associated with Rh antibodies, but can be seen with any number of non-ABO antigen-antibody complexes. The presence of IgG bound to the RBCs or C3b fixation results in an extravascular reaction because the antibody-coated cells are cleared by IgG receptors in the spleen or C3b receptors in the liver. In these circumstances, RBC lysis does not occur in the intravascular space. Because of the lack of generation of C3a or C5a, an extravascular hemolytic transfusion reaction does not usually present as a clinical emergency. It is characterized by a positive DAT caused by recipient RBC alloantibodies binding to the incompatible circulating donor RBCs. Moreover, an increase in indirect bilirubin, an increase in LDH, a decrease in hematocrit, a decrease in haptoglobin, and an increase in colorless urine urobilinogen can occur, but hemoglobinuria and hemoglobinemia are rarely present. The patient typically remains clinically stable. Renal failure, shock, and hemostatic abnormalities, such as DIC, are rarely seen unless the amount of incompatible blood infused is excessive. However, patients often have a low-grade fever.

When an extravascular hemolytic transfusion reaction is suspected, the diagnostic test of choice is a DAT with an eluate. The eluate is performed to identify the antibody coating the RBCs. The positive DAT result reflects the patient's antibody (or antibodies) coating the

incompatible donor RBCs. Because this is not an autoantibody, the patient's own RBCs are not involved in the reaction.

Typically an acute extravascular hemolytic transfusion reaction requires no special therapeutic intervention if the volume of incompatible blood transfused is relatively low. The patient characteristically recovers in a few days as the incompatible donor RBCs are cleared from the circulation. If the volume of incompatible blood transfused was high, hemolysis can quickly lead to a severe anemia. Communication with the blood bank is key to identifying how many units of incompatible units were transfused.

Extravascular acute reactions may occur if the patient's preexisting alloantibody was missed by the blood bank during the antibody screening process, if a wrongly labeled sample was used, if the unit of blood was labeled for the wrong patient, or if the unit was hung on the wrong patient.

DELAYED HEMOLYTIC REACTIONS

The pathogenesis of a delayed hemolytic transfusion reactions (DHTR) is similar to that described for acute hemolytic reactions. However, in DHTRs, the patient develops hemolysis 3–10 days after the transfusion as an anamnestic antibody response to a blood antigen previously known to the patient's immune system through transfusion, pregnancy, or hematopoietic stem cell transplantation (HSCT). Delayed hemolytic reactions occur more slowly than acute reactions and are less likely to present as a clinical emergency. Hemoglobinuria and hemoglobinemia can occur but are less pronounced than with an acute intravascular reaction. This is probably because of the gradual increase in antibody, as well as the fact that most DHTRs are caused by antibodies not efficient at activating complement. The need for intervention is much less likely than with an acute hemolytic transfusion reaction, but hematologic and renal monitoring are prudent.

DHTRs are the most common presentation of transfusion-associated immune hemolysis. DHTRs often involve the Rh system. Patients present with a fever, a falling hematocrit, and the development of a positive DAT with an eluate demonstrating a new RBC alloantibody. Because these reactions are typically mild in nature, they are usually addressed with supportive care only. In patients with sickle cell disease, DHTRs can precipitate vasoocclusive crises, autoantibody production, or hyperhemolysis. It is prudent to take a transfusion history in people with sickle cell disease who present with new complications.

One final note regarding the serologic evaluation of a transfusion reaction: posttransfusion testing may be complicated and difficult to interpret because of the possibility of autoantibodies or the involvement of medications. In such circumstances, referral to the pretransfusion specimen is often helpful. In cases of more complex evaluations, consultation with an expert serologist is recommended to detect and identify new alloantibodies in the patient's plasma, which may be responsible for a hemolytic transfusion reaction.

FEBRILE NONHEMOLYTIC TRANSFUSION REACTIONS

A febrile nonhemolytic transfusion reaction (FNHTR) is suspected when a transient temperature rise of 1°C to over 38°C or more occurs during or after transfusion and when no other cause for the fever can be identified.³ In addition to fever, FNHTRs are often associated with rigors and chills. In fact, rigors and chills can also manifest without a concomitant fever, an atypical or "afebrile" FNHTR. In these cases, temperature increases may be masked by antipyretic premedication.

Evidence supports two mechanisms of FNHTR: antileukocyte antibodies and a storage lesion of released cytokines. Cytotoxic or agglutinating antibodies having human leukocyte antigen (HLA) specificity, neutrophil specificity, or platelet specificity may be present in the recipient's plasma and react against antigens present on transfused donor lymphocytes, granulocytes, or platelets. Conversely, donor plasma may contain the offending antibody that can react with

the corresponding cellular antigens in the recipient's blood. Leukocyte-derived cytokines IL-8, IL-1 β , and IL-6 accumulate in platelet products in particular and induce fever. IL-1, through prostaglandin PGE₂ synthesis, is thought to stimulate the thermoregulatory center of the hypothalamus to produce fever. Other mediators such as macrophage inflammatory proteins (e.g., MIP-1) may also participate in the febrile response, but this reaction is not mediated through prostaglandin synthesis. CD154 (CD40 ligand) derived from platelets is also involved in febrile reactions by inducing cyclooxygenase-2 and PGE₂. Leukoreduction is less effective at preventing FNHTRs to platelets than to red cell components because of platelet-derived biologic response modifiers. Nevertheless, studies show that generation of cytokines during storage is directly proportional to the leukocyte count of the unit and the duration of storage.

The frequency of febrile reactions for a nonleukoreduced unit has been estimated to be 6.8 per 100 units RBCs transfused and 2.2 per 100 units platelet transfused. With the advent of prestorage leukoreduction, these risks have been decreased to about 0.09–1.1 per 100 units RBCs transfused and 0.04–1.56 per 100 units platelet transfused. Reactions are most commonly seen in recipients who have been exposed to multiple white cell or platelet antigens. Patients with bone marrow failure (primary or chemotherapy-induced) are at risk as a result of frequent transfusions, as are multiparous women who may have received multiple exposures during pregnancy and childbirth. These groups of patients can form multiple HLA-, granulocyte-, or platelet-specific antibodies that will react with white cells or platelets upon subsequent exposure.

The workup of a febrile reaction must be undertaken promptly, because fever may also be the first sign of other, more severe reactions, including acute hemolysis or sepsis. A hemolytic transfusion reaction may be ruled out by reconfirming the ABO and Rh type of the patient and the donor unit, repeating crossmatching to confirm patient-donor compatibility, evaluating the results of the pretransfusion and posttransfusion DATs, evaluating the serum for hemolysis, and rechecking the accuracy of paperwork. The posttransfusion DAT should yield negative findings, because FNHTRs do not involve RBC alloantibodies.

As laboratory testing is being completed, the workup should include bedside patient evaluation. Fever and chills may be attributable to drugs or underlying diseases, or they may be associated with infection or inflammation. Neutropenic fever often complicates the clinical picture in patients undergoing myeloablative chemotherapy, a population of patients likely to undergo repeated RBC or platelet transfusions. Blood cultures of the patient and the blood product should be considered, especially if the patient has high fever or shows signs of sepsis (see later text and box for a more in-depth discussion of [septic transfusion reactions](#)). The difficulty lies in knowing when to order blood cultures, because there is a false-positive incidence as a result of contamination during culturing. It is not routine to identify the specificities of HLA, platelet, or granulocyte antibodies that could cause FNHTRs. Accordingly the diagnosis of an FNHTR is usually made as a diagnosis of exclusion without isolating an identifiable antibody.

Fever from an FNHTR usually responds to antipyretics, including aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), and acetaminophen. Aspirin and NSAIDs should be avoided in thrombocytopenic patients because of their inhibitory effects on platelet cyclooxygenase, including inhibition of transfused platelets. Diphenhydramine is not indicated for treatment or prevention of febrile reactions.

For patients with no history of febrile reactions, routine premedication is unnecessary. Most patients do not experience subsequent FNHTRs. Those with a history of clinically significant FNHTRs may be premedicated with acetaminophen or an NSAID. Those patients with severe reactions despite premedication may require more intensive pharmacotherapy, including corticosteroids 1–2 hours before transfusion. Patients with severe rigors can be treated with meperidine. Febrile reactions after granulocyte transfusions and, less frequently, after platelet transfusions can be so severe that hypotension may occur.

Septic Transfusion Reaction

A 29-year-old woman in week 38 of pregnancy received a unit of apheresis platelets prophylactically in clinic for a chronic bone marrow failure syndrome of unclear etiology. During the infusion, she developed flank pain and coughing. The transfusion was stopped and the patient was admitted. She became febrile to 39.3°C 90 minutes after transfusion. Blood cultures from the patient and bag grew *Staphylococcus aureus* within 12 hours.

Blood transfusion is common in people with bone marrow failure, either primary or secondary to myeloablative chemotherapy. These patients are also often neutropenic, have central venous catheters, and/or are taking immunosuppressive medications. Despite these underlying risk factors, transfusion should always be considered a potential source of bacteremia. It is critical to always consider blood components as a source of infection. There are usually other components manufactured from the same collection, and the blood bank must quarantine them before release to another patient. It is only when the blood bank is notified of a suspected septic reaction that this is possible. Yomtovian and colleagues prospectively cultured all platelets issued from a large hospital blood bank and found contaminated units similar to other reported rates (~1:2000). When they relied on passive reporting of septic reactions from clinicians, the incidence fell to zero, only to increase back to baseline once active culturing of platelets resumed.

Prevention of febrile reactions also relies on the use of leukocyte-depleted blood components. Several leukocyte depletion techniques are available. Prestorage leukocyte depletion filters are the most common method used for preventing febrile reactions. They remove up to 4 logs (99.99%) of leukocytes, often lowering the level of white cells in a unit of blood from 10⁹ to 10⁵. They also are useful for preventing or delaying the onset of HLA alloimmunization and preventing cytomegalovirus transmission. For these reasons, leukoreduction is universal in many centers. Cell washing or use of frozen deglycerolized RBCs can remove up to 95% of contaminating white cells. Individuals with a history of recurrent, severe febrile reactions should have notations made in their blood bank record to ensure future use of leukocyte-reduced components.

ALLERGIC TRANSFUSION REACTIONS

Allergic transfusion reactions complicate up to 3% of all transfusions. The allergic manifestations occur on a spectrum of severity. They can include flushing, urticaria, pruritus, angioedema, hypotension, bronchospasm, stridor, abdominal pain, and emesis. Anaphylaxis is a systemic immediate hypersensitivity reaction, which can be defined as allergic signs and symptoms in skin/mucosa and at least one other organ system (cardiovascular, respiratory, gastrointestinal). Shock is the most ominous manifestation of anaphylaxis, but bronchospasm and upper airway angioedema are more common manifestations (see box titled "[Management and Prevention of Allergic Transfusion Reaction](#)").

Allergic transfusion reactions manifest as other IgE-mediated, immediate hypersensitivity reactions. The incidence is associated with the plasma content of the product, so it is thought that a plasma protein is responsible for many reactions. Examples of IgG or IgE with specificity to IgA, haptoglobin, and C4 have been described. There are several reports of allergic transfusion reactions to autologous transfusion, suggesting that a storage lesion may be responsible for some reactions. Passive transfer of IgE with allergen exposure in the recipient is a mechanism that has been described for food and antibiotic-mediated allergic transfusion reactions, but these are uncommon.

Mast cells are the primary allergic effector cells for immediate hypersensitivity reactions; basophils may play a secondary role. Mast cells and basophils can be activated by cross-linking cell surface high-affinity IgE receptors or via IgE-independent mechanisms, such as complement receptor binding by C5a. Upon activation, histamine is released immediately, as it is stored preformed in granules. Platelet

Management and Prevention of Allergic Transfusion Reaction

A 34-year-old man with thrombotic thrombocytopenic purpura has been receiving daily 60 mg prednisone and daily plasmapheresis for 8 days without complication. Halfway through the ninth procedure, the patient rapidly develops severe angioedema of the face and tongue, stridor, wheezing, and diffuse flushing and urticaria. Tachycardia develops with stable blood pressure. A code is called and the patient is administered oxygen, 0.5 mg epinephrine intramuscularly, albuterol nebulizer, diphenhydramine, ranitidine, and methylprednisolone. Symptoms resolve over the next 12 hours without the need for escalated respiratory support. The patient receives another 3 weeks of plasma exchanges with two sporadic minor allergic reactions (focal urticaria and pruritus only).

Among chronically transfused patients, most will have none or only one allergic transfusion reaction. Even among the minority of patients with recurrent reactions, most transfusions will not result in another reaction, including anaphylactic reactions. Most cases of anaphylaxis are idiosyncratic to a specific unit and do not recur, as in this case. Nevertheless, when platelet and red blood cell components are subsequently needed, plasma reduction is prudent because anaphylaxis can recur in a minority of patients. Screening for IgA deficiency can identify the rare cases of anaphylactic reactions caused by severe deficiency. Severe haptoglobin deficiency can occur in Asian populations. Nevertheless, even among fatal anaphylactic reactions, IgA deficiency is not present in most cases.

The medications used in the previous case are effective at treating allergic reactions, but not preventing them, according to randomized controlled trial and observational evidence. Because most transfusions do not result in an allergic transfusion reaction, clinicians sometimes have the confounded belief that adding premedications after a reaction prevented subsequent reactions, when no additional reaction was to occur, anyway. Histamine H1 and H2 receptor blockers are readily accessible in nearly all transfusion settings and can readily be administered if allergic symptoms develop. Patients often do not like the wide array of side effects associated with premedication, particularly diphenhydramine. As in the earlier case, the small subset of patients with severe or highly recurrent reactions, premedication is reasonable to consider on subsequent transfusions to mitigate symptoms that are more likely to occur than with unselected patients.

activating factor, a potent arachidonic acid derivative that mediates anaphylactic shock, is produced rapidly, along with a variety of other eicosanoids, for example, leukotrienes.

Over 90% of allergic transfusion reactions occur during infusion. When allergic symptoms develop, transfusion should be stopped and the patient given 25–50 mg of diphenhydramine. The transfusion may resume, but only if the symptoms resolve and the patient feels well. A mild allergic reaction (urticaria and pruritus) during a blood transfusion usually does not progress to a more severe anaphylactic reaction after infusion of additional blood from the same unit. The severity of allergic transfusion reactions is not directly related to volume infused or infusion rate.

Most patients never experience an allergic transfusion reaction, and for those who have one, it is usually isolated. Even among the minority of patients with recurrent reactions, most transfusions are tolerated well. Patients who have had more than one mild allergic reaction may continue to receive routine units. Washed RBCs or plasma-reduced platelets can be used to prevent severe, recurrent reactions; however, washing cellular products compromises component quality. Washing RBCs leads to accelerated in vitro hemolysis. Washing platelets increases platelet activation and lowers posttransfusion platelet count increments. Platelets collected in platelet additive solution and pooled, solvent detergent plasma are relatively new products that have been shown to reduce the incidence of allergic transfusion reactions. Leukocyte depletion or microaggregate filters are of no value.

There is no evidence that antihistamine premedication prevents allergic transfusion reactions, although antihistamines do mitigate symptoms when they occur. Studies in healthy volunteers support a synergistic role for treating histamine-mediated reactions with both H1 and H2 receptor antagonists, for example, diphenhydramine and

ranitidine, respectively. Corticosteroids, provided in advance of a transfusion, also may be useful in patients with serious recurrent reactions.

Most anaphylactic transfusion reactions are idiopathic. Case reports describe moderate or severe anaphylactic reactions in patients who are severely IgA deficient (<0.05 mg/dL) and have anti-IgA antibodies. The generalizability of this mechanism is low. Most cases of fatal anaphylaxis are not related to IgA deficiency, and most severely IgA-deficient people tolerate transfusions well. Thus, patients with incidental IgA deficiency may receive routine blood components, and IgA/anti-IgA testing should be reserved for patients with anaphylactic reactions. Quantitative haptoglobin can also be considered as a screening test, as rare cases of haptoglobin deficiency are associated with anaphylactic reactions.

HYPOTENSIVE TRANSFUSION REACTION

A less recognized, but severe acute transfusion reaction is isolated hypotension during or immediately following a blood product infusion. For adults, the definition includes a drop in systolic blood pressure greater than 30 mmHg to below 80 mmHg, and it is most likely when hypotension occurs within minutes of the start of the transfusion and resolves quickly after the transfusion is stopped. This type of transfusion reaction was initially reported after transfusion of platelets administered through some types of bedside leukoreduction filters. Later it was also reported in other types of blood products including plasma and RBCs. The pathogenesis of this syndrome appears to be related to the activation of the contact pathway (prekallikrein converting to kallikrein) induced in plasma by the negatively charged surface of some leukoreduction filters. Kallikrein activation stimulates the conversion of high-molecular-weight kininogen to bradykinin. Notably these reactions have also been reported in cases where leukoreduction filters were used before storage, indicating that bradykinin generation may occur via pathways other than via bedside filtration. The syndrome is often more severe in patients already taking angiotensin-converting enzyme (ACE) inhibitors. ACE is identical to kininase II, which is responsible for degrading bradykinin. Blockage of the kininase II degradation of bradykinin by ACE inhibitors results in a prolonged bradykinin half-life and a reaction that can be very severe. Two surgical settings that may pose increased risk of hypotensive reactions include (1) procedures involving the prostate, because another kallikrein gene family member, *hK2*, can generate bradykinin, and (2) cardiac bypass surgery because the pulmonary vasculature is an important site for kinin metabolism.

INFECTIOUS COMPLICATIONS OF TRANSFUSION

Transfusion-transmitted diseases are discussed in detail in [Chapter 120](#). A focus on the clinical presentation of acute reactions is presented here.

Bacterial contamination of stored blood can pose grave risks to the recipient. Bacteria can enter the blood collection bag during venipuncture as a result of inadequate skin preparation, during component preparation, or through the collection of blood from a donor with an occult infection or asymptomatic bacteremia. Platelet concentrates, stored at room temperature, have the highest risk of bacterial contamination. Many reports describe fatal septic transfusion reactions caused by platelet components containing a variety of species, including *Pseudomonas*, *Salmonella*, and *Staphylococcus*. Bacteria that grow well at refrigerated blood bank temperatures (1°C to 6°C), including *Pseudomonas*, *Yersinia*, *Enterobacter*, and *Flavobacterium*, are organisms commonly associated with a contaminated unit of RBCs. Units of blood that are contaminated need not be obviously discolored, malodorous, or clotted; it is extremely difficult to determine by simple visual inspection whether a unit is contaminated.

Patients who receive a unit of contaminated blood may develop fever, rigors, skin flushing, abdominal cramps, myalgias, DIC, renal failure, hypotension, and cardiac arrest. These reactions may be

immediate, or there may be a delay of several hours before the symptoms become apparent. Especially for gram-positive bacteria, a reaction to infusion of a contaminated unit may not be distinguishable from an FNHTR. Shock in a septic transfusion reaction is attributable to endotoxin produced by gram-negative bacteria. Septic transfusions differ from acute hemolytic reactions most notably by the absence of characteristic hemoglobinuria and hemoglobinemia.

For a patient who appeared well and suddenly develops rigors, fever, and/or shock during an infusion, an infected component should be considered. Blood infusion should be stopped the moment any transfusion reaction is suspected, and appropriate samples should be sent to the blood bank for a DAT, hemolysis check, and bacterial culture. Broad-spectrum antibiotics should be started immediately if infusion of contaminated blood is suspected and continued until the culture results are reported. It is also important to consider a bacterially contaminated blood component when a patient presents with signs of bacteremia several hours after a transfusion is completed. Gram-positive bacteria, which are the most common bacterial contaminants in platelet components, are less likely to cause shock, and presentation of signs and symptoms of infection may be delayed by several hours.

Because of the decrease in viral transmission by blood transfusion, septic transfusion reactions now account for a significant portion of the transfusion-related infections in the United States. Data from the Bacterial Contamination of Blood study showed that from 1998 to 2000, the rate of transfusion-transmitted bacteremia was 9.98 per million single-donor platelets, 10.64 per million pooled platelets, and 0.21 per million RBC units; the rate of fatal reactions was 1.94 per million single-donor platelets, 2.22 per million pooled platelets, and 0.13 per million RBC units, respectively. To decrease the likelihood of a septic unit of platelets being transfused, the expiration date of units of platelet concentrate has been limited to a 5-day outdate. To further reduce the risk for bacterial transmission through platelet transfusion, platelet concentrates must be tested for bacterial contamination. There are two bacterial detection systems approved by the FDA for screening of blood components. Since the implementation of the mandatory bacterial testing for platelets, FDA data indicate that the mortality associated with septic transfusion reactions in the United States has decreased, although the risks for septic transfusion reaction have not been eradicated.

Viral and parasitic transmission through transfusion does not lead to acute reactions. Rather, subacute infectious syndromes present days to months after transfusion. As with bacteremia, it is important to always consider transfusion as an infectious source. A full description of the infectious agents transmissible through transfusion are surveyed in the following chapter.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Transfusion-related acute lung injury (TRALI), is the leading cause of transfusion-related death reported to the FDA. For the period of 2009–2013, 38% (72 of 190) of reported fatalities to the FDA were caused by TRALI. Symptoms of TRALI range from mild dyspnea to severe noncardiogenic pulmonary edema, with symptoms and signs that include dyspnea, oxygen desaturation, respiratory failure, chills, fever, and hypotension. Most patients require oxygen support, and many require mechanical ventilation. TRALI, by definition, develops within 6 hours of starting a transfusion, but typically reactions occur within 2 hours. Because the pulmonary edema is noncardiogenic, there is no elevation in cardiopulmonary pressures. The chest radiograph may reveal pulmonary edema pattern (bilateral infiltrates), but should not show vascular congestion. Copious amounts of fluid are produced in the lungs, as is characteristic of hypervolemia; however, the noncardiogenic reaction usually follows infusion of volumes of blood too small to produce fluid overload. It is often postulated that TRALI consists of a “two-hit” event, the first “hit” being an underlying clinical condition that leads to the sequestration and priming of neutrophils in the lung tissue, and the second being the transfusion of blood products containing anti-HLA or anti-HNA (human neutrophil antigen) antibodies

that activate the neutrophils in the lung parenchyma, leading to edema. Complement and monocyte activation with aggregation of white blood cells also may occur when leukoagglutinins present in the recipient react with leukocytes contained in the infused donor blood. As a result of the leukocyte antigen-antibody reaction, the activated leukocytes express adhesive molecules on their surface (CD11/CD18), which then permit leukocytes to attach to pulmonary endothelial cells and migrate to the interstitial space between the pulmonary capillaries and the alveolar epithelium. Once in the interstitial space, neutrophils degranulate and through enzymatic digestion produce capillary dehiscence that results in fluid filling the alveolar sacs. Pulmonary leukostasis with pulmonary edema thus occurs as a result of microvascular occlusion and capillary leakage. Complement-activated granulocytes also produce oxygen radicals that damage pulmonary endothelial cells, resulting in a further increase in pulmonary vascular permeability and additional passage of fluid into alveolar spaces. It has been reported that aged blood products may accumulate bioactive lipids and soluble mediators, such as CD40L, that hamper the chemokine scavenging ability of erythrocytes as a result of reduction in the expression of the Duffy antigens, and this may represent a second hit in the two-hit model. Rodent model systems for TRALI have also been described, and some of these models suggest a role for platelets in TRALI. Work is ongoing to elucidate the different mechanisms leading to this syndrome, which may be a final common pathway from a variety of initiating insults.

Because TRALI is hard to distinguish from fluid overload without central cardiovascular pressure measurements, it is often not straightforward to diagnose. When a patient shows signs of noncardiogenic pulmonary edema, the infusion should be immediately stopped, as it should be with all other reactions. These HLA/neutrophil antigen-antibody reactions are usually donor-specific and should not recur with a unit from a different donor.

Treatment is supportive (Table 119.3). Donors who are implicated in TRALI reactions should be permanently deferred from blood donation. Hence reporting of these reactions to the blood bank is important so that implicated donors can be identified and tested. Antileukocyte antibodies are most likely present in blood donors who are multiparous women. The exclusion of these donors has proven to be effective. Using male-only plasma started in the 2000s and led to a reduction in TRALI fatalities by more than half.

TABLE 119.3 Transfusion-Related Acute Lung Injury

Onset	Within 6 hours of start of transfusion, usually within 2 hours
Frequency	1 : 10,000 transfusions
Signs and symptoms	Hypoxemia, fever, hypotension, tachypnea, dyspnea, diffuse pulmonary edema,
Pathogenesis	HLA/granulocyte-specific antibodies (usually of donor origin) reacting with recipient leukocytes or directly with endothelium. Lysophosphatidylcholines that accumulate during component storage can activate neutrophils in an antibody-independent manner.
Diagnosis	Chest radiograph; blood gases; post/pretransfusion NT-BNP ratio <1.5; blood for HLA or antineutrophil antibodies
Differential diagnosis	Fluid overload; septic transfusion; anaphylaxis; unrelated acute lung injury
Treatment	Stop transfusion. Provide respiratory support (administer O ₂ , intubation may be needed), support blood pressure, no evidence supporting glucocorticoids or diuretics.

HLA, Human leukocyte antigen; NT-BNP, N-terminal brain-natriuretic peptide.

TRANSFUSION-ASSOCIATED CIRCULATORY OVERLOAD

Transfusion-associated circulatory overload (TACO) results from hydrostatic transudate accumulation in the lungs and should be considered in patients who, during a blood infusion, develop sudden onset of dyspnea, jugular venous distention, tachycardia, congestive heart failure, or other signs of fluid overload. Unless there is severe hemorrhage or life-threatening shock, blood should not be infused rapidly, because the acute expansion of a patient's intravascular volume may exceed the capacity of the cardiovascular and renal systems to compensate, resulting in fluid overload. Likewise, rapidly transfusing an anemic patient who is euvoletic may cause harm. This caveat applies to transfusion of any blood component. Patients with compromised cardiopulmonary status may not tolerate acute blood volume expansion and may develop right- or left-sided heart failure. This is especially true for infants, the elderly, and people with renal failure.

If TACO is suspected, the transfusion should be stopped and the patient's blood volume reduced by diuretics. If there is a concern that the patient may not tolerate infusion of a full unit of blood or component within the 4-hour period allotted for infusion of blood components, the blood bank often can divide the product into smaller portions, which can be transfused in aliquots. As a general guide, infusions in nonbleeding adults should occur at less than 2–3 mL/kg/hour. The rate should be lowered to 1 mL/kg/hour for patients at risk for fluid overload. For a blood component of 300 mL with a typical 4-hour expiration, a 75-kg adult would receive the component at 1 mL/kg/hour if transfused over 4 hours. Diuretics may be given to patients with compromised cardiopulmonary status before transfusion. Diagnostically, if the patient improves with diuretics, it is suggestive of TACO.

The initial stages of transfusion-induced hypervolemia may be difficult to distinguish from hemolytic transfusion reaction, FNHTR, allergic reaction, or TRALI. The absence of hemoglobinuria and hemoglobinemia and the absence of a positive posttransfusion DAT result distinguish the reaction from one caused by immune hemolysis. Likewise, the absence of fever, chills, or urticaria should help distinguish TACO from the febrile or allergic types of reactions. The clinical use of laboratory testing such as N-terminal probrain natriuretic peptide (NT-proBNP) may aid in the diagnosis; when NT-proBNP is at least 50% higher posttransfusion than pretransfusion levels, NT-proBNP is sensitive and specific for TACO and makes other diagnoses in the differential less likely. TRALI is less likely when NT-proBNP is elevated.

Transfusion-Associated Graft-Versus-Host Disease

Transfusion-associated graft-versus-host disease (t-GVHD) occurs when immunologically competent lymphocytes are introduced into a host who cannot destroy the donor lymphocytes. The immunocompetent donor lymphocytes engraft, host HLA antigen is presented to donor lymphocytes, and the activated lymphocytes attack host tissues. t-GVHD occurs after transfusion of nonirradiated cellular blood components, especially when the blood donor and recipient share HLA antigens. t-GVHD has a much higher fatality rate than HSCT-related GVHD because the donor lymphocytes produce recipient bone marrow aplasia in addition to typical liver, gut, and skin manifestations of acute GVHD. In GVHD after bone marrow transplantation, the bone marrow is of donor origin, and bone marrow aplasia does not occur.

Posttransfusion GVHD is fatal in more than 90% of cases, primarily because of aplasia of the recipient's bone marrow. It often occurs 8–10 days after transfusion with marked pancytopenia, as well as gut, skin, and liver GVHD. The signs and symptoms include nausea, vomiting, anorexia, fever, diarrhea, liver dysfunction, and erythroderma. Patients often die of infection and hemorrhage within 3–4 weeks. There is no effective treatment, with the possible exception of bone marrow transplantation, if posttransfusion GVHD is recognized early and a suitable donor can be found in a short time.

Risk Groups for Transfusion-Associated Graft-Versus-Host Disease^a

Congenital T-cell defects (known or suspected)
Immunologic immaturity (fetus or premature infant)
Intrauterine transfusion
Neonates undergoing intrauterine exchange transfusion or extracorporeal membrane oxygenation
Solid organ and hematopoietic stem cell transplant
Lymphoma and hematologic malignancy
Solid tumors
Fludarabine
Haplotype sharing between donor and recipient
Transfusions from blood relatives
Human leukocyte antigen-matched platelets
Granulocyte transfusions

^aRisks not identified for human immunodeficiency virus infection/acquired immunodeficiency syndrome or aplastic anemia (except in setting of bone marrow transplantation or immunosuppressive therapy).

Reports have shown that haploidentical directed donor units of blood may produce fatal posttransfusion GVHD even in immunocompetent recipients. The use of irradiated blood (2500 cGy) is thus recommended in clinical situations in which posttransfusion GVHD is considered possible, such as when patients receive directed blood transfusions from their relatives. Leukocyte-reduction filters should not be used as prophylaxis against GVHD, because the number of leukocytes needed to produce the disease is not known. Case reports of fatal GVHD in patients who received leukoreduced, but not irradiated, blood have been published. GVHD continues to be a rare, but extremely serious, complication of blood transfusion. From 2009 to 2013, two fatalities from transfusion-associated GVHD were reported to the FDA. There is no clear evidence that prophylactic irradiation is indicated for patients with human immunodeficiency virus infection (see box on [Risk Groups for Transfusion-Associated Graft-Versus-Host Disease](#)). Of note, irradiation of RBCs causes membrane damage, permitting slow leakage of potassium and hemoglobin extracellularly. Nevertheless, rather than track which patients need irradiated blood, many centers provide universal irradiation of RBC components without adverse sequelae.

Posttransfusion Purpura

Posttransfusion purpura (PTP) is a rare and self-limiting thrombocytopenia occurring 5–10 days posttransfusion in patients lacking a specific platelet antigen, usually HPA-1a (also called PLA1, GPIIIa, CD61). These patients often have a history of sensitization with prior transfusions or pregnancies. Indeed, about 85% of cases occur in women. After resensitization by transfusion, patients can develop potent antibodies against the platelet-specific antigen that they are lacking but which is present on donor platelets. These platelet antibodies often have a high titer and can fix complement. As a result, the transfused platelets and the patient's own platelets are also destroyed through the adsorption of the antigen or immune complexes on their own platelets. A concurrent autoimmune process may also involve destruction of the recipient's own platelets, as shown in one case report of a positive antibody against the patient's own platelets. The thrombocytopenia can be marked with a platelet count falling below 10,000/μL. The onset is sudden, although self-limited, and usually resolves in 2 weeks. This severe thrombocytopenia can help distinguish PTP from heparin-induced thrombocytopenia, which can also be considered in the differential diagnosis when thrombocytopenia develops 5–10 days after combined heparin exposure and blood transfusion, for example, major surgery. In patients who already have thrombocytopenia, diagnosing PTP can be difficult, especially when the patient already has immune-mediated platelet destruction. PTP can be considered if platelet refractoriness continues despite transfusion of HLA-matched platelets. IVIg appears to be an effective treatment, although plasma exchange, steroids, and

splenectomy may also be useful. Patients with acute bleeding and needing platelet support should receive platelets without the platelet-specific antigen, if possible. If random donor platelets are given, patients can develop severe reactions, including allergic reactions. Recurrence of PTP is rare.

Hypothermia

Hypothermia can occur with rapid infusion of large quantities of refrigerated (1–6°C) blood, such as in cases of rapid and massive transfusions. Rapid infusion of blood (1 unit every 5 minutes) may lower the temperature of the sinoatrial node to less than 30°C, at which point ventricular fibrillation may occur. Hypothermia also induces coagulopathy, possibly attributed to inefficient enzymatic activity below physiologic temperatures. Use of warming devices may reduce the incidence of coagulopathies associated with major trauma and also help to overcome cardiac complications. Most transfusions need not be given this rapidly. For routine transfusion, blood does not have to be warmed. Indeed, overwarming a unit of blood can cause RBC thermal injury and produce hemolysis, DIC, or shock.

If blood is to be warmed, the temperature must be monitored and kept below a level that could cause hemolysis. Usually, this is less than 42°C. Heating blood under running hot tap water or heating in a microwave device is unacceptable.

Electrolyte Toxicity

Citrate, a component of the preservative solution used in blood storage, functions as an anticoagulant by chelating calcium and interfering with the coagulation cascade. Rapid transfusion of citrated blood is associated with a drop in ionized calcium levels. Citrate-containing blood products, however, are routinely infused without any problem because the citrate is rapidly metabolized to bicarbonate. In patients with normal liver function, citrate infusion is unlikely to produce reactions. Mild to severe citrate toxicity can be seen, however, in individuals undergoing therapeutic apheresis when citrate is infused to anticoagulate blood flowing through the instrument and large volumes of citrated RBCs or plasma are simultaneously reinfused.

The effects of hypocalcemia range from mild circumoral paresthesias to frank tetany. However, severe citrate toxicity, even with massive transfusion, is rare. More commonly, the reaction is mild and self-limiting and can be treated by merely slowing the rate of reinfusion. If prolonged QT intervals or signs of tetany are seen, calcium can be administered. Calcium need not be infused routinely, even after large-volume blood transfusions. However, it is prudent to monitor calcium status in patients undergoing massive transfusion and patients at risk for hypocalcemia arising from citrate toxicity. Under no circumstances should calcium be added to a unit of blood or a line used for blood infusion because it would recalcify the unit and cause clots to form. In addition to the effects on calcium, the metabolism of citrate also can result in a metabolic alkalosis because of the generation of large amounts of bicarbonate.

Citrate also chelates magnesium, so correction of the hypocalcemia may require infusion of magnesium, as well. Actual clinical complications of transfusion-induced hypomagnesemia, however, have not been well documented other than in cases of apheresis.

Hyperkalemia caused by infusion of stored blood is a rare occurrence. Although hyperkalemia is often thought to be a problem in massive transfusion, development of hypokalemia is of greater concern. With storage, leakage of potassium from RBCs to the extracellular fluid occurs. However, after infusion the RBCs reverse the biochemical storage lesion by restoring the Na-K ATP membrane pump, and intracellular potassium levels are restored. As the citrate is metabolized to bicarbonate, the blood becomes alkalotic, contributing to hypokalemia. In massive transfusion, it is not uncommon for this to result in the need for administration of potassium. Depending on the storage solution, the potassium content in the

supernatant of an RBC unit can reach 7 mEq at the end of storage. Neonates and children can receive transfusions of up to 20 mL/kg RBC for routine transfusions over 3–4 hours without concern for hyperkalemia. For large volume transfusions or transfusion in the setting of hyperkalemia, fresher or washed RBC components can be requested. As there is increased potassium leakage from RBCs after exposure to 25 Gy of radiation to prevent posttransfusion GVHD, a maximum 28-day shelf life from the day of irradiation is imposed on this blood component.

Iron Overload

Iron loading from RBC transfusion is not categorized as a transfusion reaction, but it is a common adverse consequence of chronic RBC transfusion. One milliliter of RBCs at a hematocrit of a typical RBC unit contains approximately 0.75 mg of iron. A unit of blood with 300 mL of RBCs thus contains approximately 225 mg of iron, and 4 units of blood contain ~1 g of iron, roughly the amount stored in the bone marrow. Men and nonmenstruating women lose only approximately 1 mg of iron each day. Continued use of transfusion therapy in individuals with a hemolytic anemia, such as those with thalassemia or sickle cell disease, in which iron is not lost from the body but is recycled, can thus result in the accumulation of excessive tissue stores of iron. Over long periods, the iron that is stored in parenchymal cells results in oxidative injury and organ failure, particularly in the heart, liver, and endocrine organs. Iron chelation therapy is now widely used to mitigate positive iron balance. The availability of oral iron chelators such as deferasirox and deferoxamine provides expanded access to iron chelation therapy.

Air Emboli

Since the replacement of evacuated glass bottles by plastic blood bags, the risk for air embolism from phlebotomy or transfusion has virtually disappeared from transfusion practice. Air, however, still may be infused into patients by the roller pumps contained in various transfusion devices, especially apheresis machines and intraoperative salvage machines. All such devices currently manufactured, however, contain air-in-line sensors. However, any operators using this equipment must be well trained and remain alert to the potential risk for air embolization at all times while the patient is being treated. Patients who receive air intravenously experience acute cardiopulmonary insufficiency. The air tends to lodge in the right ventricle, preventing blood from entering the pulmonary circulation. Acute cyanosis, pain, cough, shock, and arrhythmia may occur, and death may result unless immediate action is taken. The patient should be placed head-down on the left side; this may displace the air bubble from the pulmonary valve. Use and removal of central lines may also pose a risk for air embolism.

Complications Associated With Massive Transfusion

Massive transfusion is variably defined as the transfusion of one whole blood volume within 24 hours, 4 units of RBCs in 1 hour with anticipation of more blood needed, or transfusion of 50% of total blood volume in 3 hours. Common problems associated with massive transfusion include coagulopathy, hypothermia, and metabolic abnormalities.

Coagulopathy of massive transfusion is multifactorial and can have devastating consequences. Classically the coagulopathy associated with massive transfusion was thought to be attributable solely to consumption of factors owing to ongoing hemorrhage and/or dilution owing to the large volume of fluids and RBCs typically infused. However, the understanding of hemostasis in massive transfusion now includes a form of coagulopathy that occurs *before* coagulation factors and platelets are consumed. Early coagulopathy, described primarily in the setting of trauma, is driven by tissue hypoperfusion and increased fibrinolysis. Early coagulopathy is not

**TABLE
119.4****Common Hematopoietic Stem Cell Infusion Reactions**

Types	Presentations	Treatment and Prevention
DMSO toxicity	Halitosis, nausea, vomiting, flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely neurologic toxicity, such as syncope and transient encephalopathy	Antihistamine Antiemetics Limiting DMSO infusion volume
Minor ABO mismatch	Delayed hemolysis (1–2 weeks post HSC infusion)	Plasma depletion of HSC product RBC transfusion support compatible with donor and recipient Monitor for hemolysis RBC exchange with donor- and recipient-compatible blood if massive hemolysis
Major ABO mismatch	Hemolysis at the time of infusion Delayed RBC engraftment	Limiting the infusion of incompatible RBC Hydration Monitor for RBC engraftment Modify immunosuppression Plasmapheresis to remove isohemagglutinins if significant RBC engraftment delay

DMSO, Dimethyl sulfoxide; HSC, hematopoietic stem cell; RBC, red blood cell.

likely to respond to traditional transfusion therapy and may only be resolved with restoration of circulatory capacity and inhibition of fibrinolysis.

Despite enhancements in understanding of early coagulopathy, platelet/coagulation factor dilution and consumption still remain outstanding problems in the setting of massive transfusion. Patients undergoing large-scale transfusion must be regularly monitored for hematocrit, platelet count, prothrombin time, activated partial thromboplastin time, and fibrinogen. Reasonable goals to promote hemostasis in the setting of massive transfusion are to maintain (1) hematocrit >25%, (2) platelets >50,000/ μ L, (3) international normalized ratio (INR) <1.7, and (4) fibrinogen $\geq$ 100–150 mg/dL. Therefore it is imperative that clinicians provide more than just RBCs to massively bleeding patients. To ensure a more appropriate provision of plasma and platelet products, many facilities have developed protocols consisting of preset numbers of RBC, fresh frozen plasma (FFP), and platelet units that are immediately issued upon requests for massive transfusion. Such protocols, developed in conjunction with surgical and trauma services, can drastically improve the efficiency of blood product provision in the setting of massive transfusion. Although massive transfusion protocols are useful tools to combat coagulopathy, controversy remains regarding the numbers of plasma and platelet products that should be provided to patients transfused with large volumes of RBCs. Trials and reports from military trauma centers have promoted use of protocols based around a 1:1:1 ratio of RBC/plasma/platelets units. Data from combat theaters suggest that such ratios are successful in avoiding the coagulopathy of massive transfusion and ultimately lead to improved survival. Despite these data, it is unclear whether such approaches are relevant to noncombat, civilian hospitals, which frequently issue massive transfusions for wide-ranging indications such as surgical complications, large gastrointestinal or retroperitoneal hemorrhages, or blunt trauma. A 2015 randomized controlled trial (PROPPR Trial) compared 1:1:1 and 2:1:1 RBC/plasma/platelet transfusion protocols in civilian trauma patients. Results showed an absolute difference of 4% lower 24-hour and 30-day mortality in the 1:1:1 group, but the difference was not statistically significant.

Complications Associated With Hematopoietic Stem Cell Infusion

Hematopoietic stem cells (HSCs), the most widely used cell therapy products, may be derived from bone marrow, peripheral blood, and

cord blood. As with blood transfusions, the infusion of HSCs carries the risk of the same types of transfusion reactions. However, additional risks are associated with HSC infusion, such as those related to cryopreservatives. In general, infusions of cryopreserved cells are more likely to cause reactions, as they contain higher concentrations of lysed RBCs and granulocytes than other blood products. For most reactions, it is difficult to identify the causative agent. Moreover, because of the irreplaceable nature of HSC products, higher risks may be tolerated. Only those reactions that are unique or more problematic for HSC infusions are discussed in this section. A summary of the reactions is given in [Table 119.4](#).

Dimethyl Sulfoxide Toxicity

The most common reactions to HSC have been attributed to dimethyl sulfoxide (DMSO), the most widely used cryopreservative. A variety of symptoms are associated with DMSO infusion and are generally dose-dependent. A garlic odor commonly accompanies DMSO infusion, and nausea and vomiting are often reported. Additional DMSO-related symptoms include flushing, coughing, chest tightness, dyspnea, abdominal pain, hypotension, hypertension, cardiac toxicity (such as bradycardia and other arrhythmias), and rarely, neurologic toxicity (such as syncope and transient encephalopathy). Some cases of DMSO toxicity are thought to arise from the release of histamine. Agents such as diphenhydramine have been used for the treatment and prevention of DMSO-related toxicity. Antiemetic agents such as prochlorperazine have been useful for ameliorating nausea and vomiting. Most clinical services have protocols in place to limit the volume of DMSO that can be infused, such as setting an upper infusion limit of 1 g/kg/day, dividing HSC infusion doses, or washing HSC products to remove DMSO (this, however, may result in cellular loss).

Red Blood Cell Engraftment and Hemolysis

Although mismatched ABO and non-ABO blood groups do not prevent successful HSCT, these antigens (and their corresponding antibodies) can create problems during the transplant period. When considering incompatibilities within the ABO system, three scenarios are possible: (1) antibodies present in the recipient interact with incompatible cells present in the graft (major incompatibility), (2) antibodies present in the plasma portion of the graft mediate

hemolysis of recipient RBCs (minor incompatibility), or (3) antibodies present in both the recipient and the donor interact with incompatible RBCs (bidirectional, or two-way, incompatibility). It has been shown that both major and bidirectional ABO incompatibility can delay stem cell engraftment. In such cases, anti-A and/or B antibodies suppress RBC precursors expressing these antigens, leading to reticulocytopenia and prolonged anemia. In the most severe form of this process, HSC recipients can develop pure RBC aplasia, a condition wherein bone marrow shows a virtual absence of immature erythroid elements more than 3 months posttransplantation. In cases of either delayed engraftment or pure RBC aplasia, patients are dependent on RBC transfusions for prolonged periods of time.

Another risk factor associated with HSC infusion is the possibility for RBC hemolysis. Both ABO and non-ABO antibodies are capable of mediating RBC lysis. In such conditions, preformed antibodies in either the recipient or HSC plasma can cause accelerated clearance of incompatible RBCs by either intra- or extravascular mechanisms. Presentation of hemolytic transfusion reactions immediately after HSC infusion is no different from that of typical transfusion reaction. Policies and protocols should be in place to prevent postinfusion HSC-related hemolysis—for example, plasma depletion of HSC products (in cases of minor mismatch and bidirectional ABO incompatibility), limiting the infusion of incompatible RBCs (in cases of major mismatch and bidirectional ABO), hydration of patients, and prospective monitoring for hemolysis.

Although delayed hemolysis is rarely clinically significant in major ABO-mismatched HSC transplant, clinically significant delayed hemolysis is commonly reported in minor and bidirectional ABO-incompatible HSC transplants. As a result of donor lymphocyte engraftment, typically occurring 1–2 weeks after HSC infusion, donor ABO antibodies can cause hemolysis of residual recipient RBCs. This delayed hemolysis is typically clinically evident with decreased hemoglobin, increased indirect bilirubin, increased LDH, and decreased haptoglobin, and patients often require RBC transfusion. Sometimes the hemolysis can be acute and massive and result in multiorgan failure and death. Thus it is important to monitor patients closely for anemia and hemolysis after minor and bidirectional ABO-incompatible HSC infusion, especially in the first two weeks post-HSC infusion. Timely support and treatments such as RBC exchange with donor type blood can be provided for massive hemolysis.

Infectious Complications

As a result of an underlying bacteremia during collection, or contamination through collection, processing, storage, thawing, and sampling, some HSC products may harbor microbial organisms capable of mediating septic reactions during or immediately after HSC infusion. Such reactions may manifest with fever, tachycardia, hypotension, nausea, or vomiting. Patients experiencing such symptoms should be treated with broad-spectrum antibiotics to cover both gram-positive and gram-negative organisms. Bone marrow collections have a higher contamination rate than apheresis HSC collections, although typically with coagulase negative *Staphylococcus aureus* and *Propionibacterium acnes* that grow only with extended culture.

Fortunately, bacterial contamination of an HSC unit is often known well in advance of an actual HSC infusion because HSC products are typically cultured at the time of collection and processing. As such, clinical teams can be prepared for such reactions. In such circumstances, preventative measures include provision of pre-infusion antibiotics to cover the documented organism(s) and close patient surveillance during and after infusion. One additional option would be to avoid infusion of a contaminated unit altogether. This is possible if a patient has multiple, separate HSC products available for infusion. Clinical and transplant teams can preferentially infuse noncontaminated HSC units first, saving the contaminated unit as a “last resort” should the graft fail.

Other Infusion Complications Related to Hematopoietic Stem Cell Products

In addition to the problems related to DMSO and ABO mismatches, other adverse reactions sometimes occur with the use of HSC products. Nausea and vomiting are frequently reported with infusion of freshly collected HSC products such as fresh marrow. Fever and chills are commonly seen with cryopreserved HSC; these have been speculated to be caused by the cellular debris and cytokines contained in HSC products. Antipyretics and steroid premedication may be used for prevention. Severe adverse reactions to HSC infusion (such as cardiac arrest and neurologic symptoms, including loss of consciousness and seizure) have been linked to high granulocyte counts in HSC products.

Respiratory problems are increasingly being recognized as an important cause of morbidity and mortality in the setting of HSC infusion. Although many of these are late-onset problems (e.g., infectious complications associated with immunosuppression occurring days or weeks after transplantation), some pulmonary issues will arise acutely during HSC infusion. The National Marrow Donor Program (NMDP) issued a report in 2010 regarding seven patients who experienced hypertension, chest pain, and decreased oxygen saturation after infusion of cord blood. Even though no clear-cut cause-effect relationship was established, some recommendations were made, including minimizing thaw to infusion time, filtering HSC products with standard 150–250- μ m blood filters, avoiding very high infusion rate, and others. In addition, the classic pulmonary complications encountered during HSC infusion may resemble TRALI in that they are associated with dyspnea, hypoxemia, a low-grade fever, and bilateral pulmonary infiltrates, all occurring within a short time after initiation or completion of infusion. Some authors have attributed these problems to a noncardiogenic capillary leak syndrome that appears to be independent of cardiac function, similar to the proposed pathophysiology of TRALI.

Patients demonstrating signs or symptoms of respiratory distress during HSC infusion must be treated aggressively. The first response should be to stop the HSC infusion and provide immediate respiratory support. The provision of corticosteroids or other immunosuppressive agents is not likely to be of benefit for such reactions. It may also be prudent to investigate whether the patient's symptoms are related to circulatory overload rather than arising from noncardiogenic pulmonary edema. This distinction may be assisted by measuring plasma levels of brain-natriuretic peptide (BNP). If BNP is elevated, then the patient's symptoms may be attributable, in part, to volume overload.

National Healthcare Safety Network

The National Healthcare Safety Network (NHSN) is a national program of combined governmental and private sector agencies designed to evaluate and track transfusion reactions and other adverse effects associated with infusion of blood products and derivatives. Similar programs exist in other countries, including the United Kingdom (Serious Hazards of Transfusion, SHOT), the Netherlands (Transfusion and Transplantation Related Incidents in Patients, TRIP), and Canada (Transfusion Transmitted Injuries Surveillance System, TTISS). Hemovigilance systems in other countries have established efficacy of safety interventions, for example, reduction in TRALI using male-only plasma donors, and they can identify emerging threats to transfusion safety, especially when events are uncommon and are detectable only when large numbers of outcomes are evaluated in aggregate.

The Hemovigilance Module, the first protocol release of the Biovigilance Component of NHSN, was developed through a public-private partnership between the Centers for Disease Control and Prevention (CDC) and subject-matter experts convened by AABB. The Hemovigilance Module is designed for transfusion services staff in health care facilities to monitor recipient adverse reactions and quality-control incidents related to blood transfusion.

The Hemovigilance Module provides standard criteria and definitions to participating facilities to report adverse events related to blood transfusion that will result in aggregate data suitable for trend analyses and benchmarking. Participating facilities can analyze their data independently within NHSN and will be able to compare their data with national aggregate rates through NHSN in the future.

The following transfusion reaction categories are used to identify types of adverse events related to blood transfusion:

- Allergic
- Acute hemolytic
- Delayed hemolytic
- Delayed serologic
- Febrile nonhemolytic
- Hypotensive
- Posttransfusion purpura
- Transfusion-associated circulatory overload (TACO)
- Transfusion-associated dyspnea
- Transfusion-associated graft-versus-host disease
- Transfusion-related acute lung injury (TRALI)
- Transfusion-transmitted infection

Transfusion reactions are further classified by their severity and imputability—that is, the likelihood that the reaction is attributable to infusion of the blood product being investigated. Protocols, forms, and enrollment information are available online (<http://www.cdc.gov/nhsn/PDFs/Biovigilance/BV-HV-protocol-current.pdf>).

TRANSFUSION-TRANSMITTED DISEASES

Susan L. Stramer and Roger Y. Dodd

Adverse reactions following blood transfusion reflect immunologic, pathophysiologic, and microbiologic events. This chapter presents information about transfusion-associated viral, bacterial, parasitic, and prion infections and discusses a number of emerging agents. Transfusion-transmitted infection risk mitigation through blood donor screening and blood testing strategies are presented.¹ The boxed discussions provide insights into interventions aimed at reducing risk from known and emerging threats and new technologies for reducing or eliminating microbial contamination. Red cell, platelet, and plasma transfusion represent important therapeutic modalities for appropriately selected patients. Awareness of the hazards of transfusion and the rate at which these events occur should enable physicians to better determine the benefit/risk ratios when prescribing transfusions.

HEPATITIS VIRUSES

The hepatitis viruses can be classified according to their predominant modes of transmission, parenteral and enteric, with the parenterally transmitted agents, hepatitis B virus (HBV) and hepatitis C virus (HCV) dominating concerns about transfusion transmission because many individuals unknowingly infected with these agents become asymptomatic chronic carriers and may make blood donations.

Parenterally-Transmitted Hepatitides

Hepatitis B

HBV is a deoxyribonucleic acid (DNA) virus in the family *Hepadnaviridae*. The infectious virion is occasionally referred to as the Dane particle and has surface and core components, surface antigen (HBsAg), and core antigen (HBcAg), respectively. Epitopes on the viral surface provide a basis for epidemiologic studies and consist of the HBsAg “a,” d/y, and w/r determinants. However, this approach is being replaced by genotyping and DNA sequencing methods. Recombinant vaccines containing the “a” determinant confer protective immunity to a high proportion of vaccinees and are dramatically altering the incidence and prevalence of HBV infection in the general population where they are in wide use and consequently also impact the frequency of HBV infection in the donor population.

The average incubation period (the time from infection to liver enzyme elevation and symptomatic hepatitis) is 59 days (range, 5 to 12 weeks) but may be as long as 6 months. Symptoms, which occur in 30% to 50% of infected persons age 5 years and older, include fatigue, anorexia, nausea, vomiting, jaundice, dark urine, light stools, arthralgias, rashes, vasculitis, and glomerulonephritis. The risk for progression to chronic infection is inversely related to age at infection. HBV infection becomes chronic in more than 90% of infants, 25% to 50% of children 1 to 5 years of age, and fewer than 5% of older children and adults. Approximately 5% of the US population has serologic evidence of prior HBV infection (antibodies against HBcAg [anti-HBc] reactive). From the mid-1980s through 2013, with increasing immunization in early childhood, the incidence of acute HBV infection has decreased. In 2013 41 states reported HBV infections to the US Centers for Disease Control and Prevention (CDC) of which approximately 3000 were acute cases, or 1 case per 100,000

population, and an additional 12,400 were chronic hepatitis (www.cdc.gov/hepatitis/statistics, Viral Hepatitis—Statistics and Surveillance). It is estimated in the United States that approximately 12 million persons are infected, with 5000 deaths each year resulting from hepatitis B and its complications.

Based largely on data from parenteral exposures of health care workers, HBV is 100 times more infectious than human immunodeficiency virus (HIV) and 10 times more infectious than HCV. The predominant mode of transmission to adults and adolescents is through sexual contact. Forty percent have infected partners, 15% are males having sex with other males, injecting drug users account for 14% of cases, and one-third have no identifiable risk. A recent study of risk factors in blood donors found to be infected with HBV found that of 292 infected donors surveyed, the characteristics most frequently associated with infection were living abroad or having immigrated to the United States (51% vs. controls at 6%), a family member infected with hepatitis (15% vs. 2%), having been in a jail or detention for 3 nights or more (19% vs. 5%) and having taken illegal drugs (20% vs. 12%).²

HBsAg is detectable in blood approximately 4 weeks (30 to 60 days) after infection. Subsequently, immunoglobulin M (IgM) anti-HBc antibodies appear coincident with symptom onset. High viral titers (10^{10} genomes/mL) present at that time decline subsequently. HBsAg persists transiently in acute infections for up to 4 months (average 63 days). More recent data using extremely sensitive HBsAg assays for blood donation screening show the mean period of HBsAg duration to be 43 days.³ Antibodies against HBsAg (anti-HBs) develop subsequently and are generally thought to protect against reinfection although recent studies on blood donors have identified a few breakthrough cases of infection. These cases were mainly caused by HBV genotypes differing from that of the vaccine strain and were mild and self-limited.⁴ Such donations were not detected by HBsAg blood donation screening but required more sensitive HBV DNA screening.

Some anti-HBc-positive and HBsAg-negative individuals have circulating HBV DNA, and this pattern defines so-called occult HBV infection (OBI). In rare cases, OBI may be accompanied by anti-HBs, usually at levels below 200 mIU per mL. Donors with OBI may transmit HBV via blood transfusion, but the frequency of such infection is low, and seems to be absent if anti-HBs is present.⁵ Although anti-HBs usually confers immunity to reinfection, sufficient virus remains in the liver to transmit HBV following liver transplant from anti-HBs-positive donors through reactivation under intense immunosuppression.

Blood donors in the United States are currently queried for a history of hepatitis and risks associated with hepatitis and screened for HBsAg, anti-HBc and HBV DNA. It should, however, be noted that the FDA has eliminated the requirement to ask about a history of viral hepatitis, effective May 2016.⁶ The detection of HBV DNA is performed by nucleic acid testing (NAT) in minipools of 6–16 donations each as now required per Food and Drug Administration (FDA) Guidance, Use of Nucleic Acid Tests on Pooled and Individual Samples from Donors of Whole Blood and Blood Components, including Source Plasma, to Reduce the Risk of Transmission of Hepatitis B Virus (www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/default.htm, October 2013) and made final in updates to the Code of Federal Regulations.⁶ The risk for HBV transmission per unit in the United States has

TABLE 120.1 Risk for Transfusion-Transmitted Diseases in the United States

Pathogenic Agent or Disease	Average Estimated Risk Per Unit
Hepatitis A	Rare
Hepatitis B	1 per 765,000–1,006,000
Hepatitis C	1 per 1,149,000
Human immunodeficiency virus	1 per 1,467,000
Human T-lymphotropic viruses 1, 2	1 per 4,364,000
Cytomegalovirus	Infrequent
Parvovirus B19	Rare
West Nile virus	Rare
Malaria	0–3 cases per year
Babesiosis	1 per 18,000 in highly endemic regions; 1 per 100,000 endemic regions overall
Chagas disease	20 transfusion-associated cases reported
Creutzfeldt-Jakob disease	4 vCJD transfusion-associated cases reported
Bacterial contamination:	
Red cells	1 per 30,000
Septic reactions	1 per 500,000–1 per 10,000,000
Platelets	1 per 3000–1 per 8000
Septic reaction	1 per 100,000
Emerging infections:	
Arboviruses including dengue viruses, chikungunya and Zika viruses	Risk unknown
Pandemic influenza viruses (H5N1, H1N1)	

vCJD, Variant Creutzfeldt-Jakob disease.

recently decreased substantially as a result of very sensitive HBsAg testing, the implementation of NAT, and a recent decline in the incidence of HBV infection among donors undoubtedly because of universal vaccination (Table 120.1).^{3,4,7} Before NAT implementation, most contemporary HBV transfusion-transmitted infections were attributable to blood donations from asymptomatic donors during acute infection preceding the development of detectable HBsAg. Early in infection, HBV replicates relatively slowly with a doubling time of approximately 2.6 days. The current window period between infection and the detection of HBV DNA by NAT ranges from 30 to 38 days depending on the infectious dose, which, early in infection, is estimated to be between 1 and 10 copies per mL.⁸ Since the implementation of HBV NAT in the United States, there have been no documented cases of breakthrough HBV transfusion transmissions. The per unit residual risk is estimated to be 1 per 843,000 to 1 per 1,208,000, depending on which infectious dose is used for this calculation.⁷

There is evidence that some HBsAg assays will not detect all HBsAg and HBc gene variants of HBV. Because all blood donations are screened by HBV NAT, HBsAg, and anti-HBc, it is unlikely that any mutant strain of HBV would go undetected in the United States. Among 12.8 million blood donors to the American Red Cross during 2009–11, 1 per 9337 were infected with HBV. Of these, 1090 were positive for HBsAg, with or without HBV DNA (1 per 11,736), and only 5 were identified solely by NAT in minipools (1 per 2.55 million).⁷ However, more recent data, also from the American Red Cross, demonstrate the HBV DNA detection rate of

seronegative donations by NAT to be 1 per 600,000 donations. NAT on individual donation aliquots has the potential to reduce the risk for transfusion-transmitted HBV further by detecting newly infected donors slightly earlier than the HBsAg tests licensed for blood donor screening, but the additional cost of individual donation-NAT in the United States would be high with very little to no demonstrable clinical benefit.

Hepatitis D

Hepatitis D virus (HDV) was originally called the delta agent. It is a defective ribonucleic acid (RNA)-containing passenger virus that requires active synthesis of HBsAg to act as a “helper” for assembly of HDV virions. As many as 10% of HBV infections are accompanied by HDV worldwide. Its prevalence is very low in the United States but higher in injection drug users. HDV superinfection of chronic HBV carriers is associated with worsened chronic sequelae and with fulminant hepatitis. Screening for HBV acts synergistically to prevent transfusion-associated HDV cases by identifying donors that are co-infected with HBV and HDV. There has never been a HBV-HDV-related transfusion transmission reported.

Hepatitis C

HCV is an RNA virus in the family *Flaviviridae*, genus *Hepacivirus*. There are six genotypes that share similar epidemiology, pathogenesis, and natural histories. In the United States, genotypes 1, 2, and 3 cause 75%, 10%, and 10% of infections, respectively. Genotype 1 responds relatively poorly to traditional treatment regimens using pegylated interferon combined with oral doses of ribavirin compared with genotypes 2 and 3; the overall cure rate for all genotypes using this regimen was no better than 40% to 50%. Recently approved HCV protease inhibitors are materially improving these rates. Two new oral regimens of Harvoni and Viekira Pac are now the standard of care in the United States, and result in a sustained virologic response of greater than 90% (www.cdc.gov/hepatitis/statistics, Viral Hepatitis—Statistics and Surveillance).

HCV is distinguished by a low rate of recognized acute infection and by a high rate of chronic infection, with substantial morbidity and mortality over long periods of observation as a result. In the United States there are an estimated 3.2 million chronic infections.

The most common source of HCV acquisition is injection drug use. The prevalence of HCV in US adults (20 to 59 years old) with any history of illegal injection drug use is greater than 45%. Other risks include blood transfusion before donor serologic screening began in 1990, a high lifetime number of sex partners, exposure in health care settings, including through dialysis, among infants born to HCV-infected mothers, and tattoos in unregulated settings. In a large series, 15% to 30% of patients report no risk factors. Vertical transmission occurs to 3% to 7% of infants of mothers with active infections. In contrast to HBV, sexual transmission is an inefficient route of infection and much less often reported, but was found to be the most likely mode of transmission of HCV among HIV-infected men who have sex with men (MSM) in New York City. In 2012 CDC recommended that individuals born during 1945–1965 have one-time HCV screening since among all persons living with HCV infection, about 75% were born during this time. Such individuals have a 3% prevalence, which is five times higher than the prevalence seen in adults born in other years. Among blood donors, 0.03% have confirmed-positive HCV test results. There have been studies on risk factors among HCV-infected blood donors, and despite policies requiring deferral of injection drug users, such use is the most common risk factor.^{2,9} Of 316 blood donors followed who were HCV-confirmed positive, risks identified via a retrospective questionnaire revealed risks versus control donors of illegal drug use (37% vs. <1% for controls), followed by jail or detention (57% vs. 5%), history of a blood transfusion before screening (18% vs. 7%), and living in a household with someone having hepatitis (15% vs. 2%).

At most 20% to 30% of newly infected persons develop recognizable symptoms during acute HCV infection. Some 20% of infected individuals clear their infection over a relatively short initial period, remaining antibody positive but RNA negative. Chronic infection develops in 75% to 85% of persons infected after 45 years of age and in 50% to 60% of those infected as children or young adults. Chronic HCV infection progresses to cirrhosis in 15% to 30% over 30 years of observation. Hepatocellular carcinoma occurs in 1% to 4% per year in those with cirrhosis. HCV is among the most prevalent causes of chronic hepatitis, cirrhosis, and primary liver cancer in the developed world and is the most common indication for liver transplantation in the United States, resulting in around 2400 procedures annually.

A single positive anti-HCV result cannot distinguish between acute and chronic HCV infection or between current or cleared infection. In 2012 laboratory criteria for the confirmation of anti-HCV reactivity were modified to add one specific assay including RNA detection, using a supplemental anti-HCV assay (as available) or a single value above a specific threshold on the screening test.¹⁰ The risk for posttransfusion HCV infection declined progressively with the introduction of surrogate markers for non-A, non-B hepatitis in the 1980s (alanine aminotransferase [ALT] and anti-HBc) and of serologic testing for HCV antibodies in May 1990, followed sequentially by improved serologic testing and NAT. The seronegative-window period for the first-generation HCV antibody test extended to 6 months from infection, but was reduced to 82 and 70 days with second- and third-generation assays, respectively. NAT further reduced the window period to approximately 7 days. The risk per unit declined from an estimated 1 per 276,000 units to 1 per 1,935,000 units.¹¹

Like HBV, in the United States, testing for HCV RNA has used NAT in small minipools combining aliquots from 16 to 24 donations (currently 6 to 16). Loss of test sensitivity because of sample pooling was tolerable given the rapid increase or burst of HCV viremia before antibody seroconversion (estimated doubling time of 10.8 hours in that period during the 40–50-day window period) and the high titer of viremia that remains preceding antibody seroconversion. However, the rest of the world (except the United States, Canada, the United Kingdom and most of Germany) has implemented NAT for screening individual donation samples intended for transfusion. The HCV RNA yield by NAT in seronegative donations using data from the American Red Cross is 1 per 225,000 donations.

As an alternative to NAT assays, enzyme immunoassays (EIAs) have been developed that detect HCV HbCag in serum or plasma, either as an individual analyte in parallel with antibody assays or as HCV antigen-antibody combination assays. These tests reduce the preseroconversion-window period and were adopted in some developing countries. They are less sensitive than HCV NAT and are not approved for blood donor screening in the United States.¹² Since the implementation of NAT, reports of transfusion-transmitted HCV are virtually nonexistent.

The high seroprevalence of HCV at the onset of serology screening in the early 1990s, the prolonged interval between infection and clinical manifestations, and the relatively high rate of HCV clinical sequelae prompted blood collection facilities and hospitals to conduct “look-back” notification of previous recipients of blood given by donors found on subsequent donations to be HCV infected. Look-back was subsequently made mandatory in companion rules from FDA and the Centers for Medicare and Medicaid Services. In general, HCV look-back programs found half or fewer of targeted transfused individuals alive, but were able to find both seropositive and RNA-positive recipients who were unaware of their status.

Enterically Transmitted Hepatitides

Hepatitis A

The hepatitis A virus (HAV), a nonenveloped picornavirus, genus *Hepatovirus*, is transmitted predominantly by the fecal-oral route,

with an average incubation period of 28 days (range, 15 to 50 days) with signs or symptoms persisting for less than 2 months. The incidence of HAV infection in the United States fell by 76% between 1997 and 2003 after the recommendation for targeted immunization of members in high-risk communities. Populations at risk include those in areas where extended community outbreaks occur and children living in states that have high and intermediate rates of disease, staff and residents of closed communities, close personal contacts of cases, the staff and parents of children in day-care centers, and those with common-source exposure to infected food or water. For many sporadic cases there is no recognized source. HAV is self-limited with no chronic carrier state, but approximately 10% to 15% of infected individuals develop a more prolonged or relapsing illness. It is the most frequent cause of hepatitis among children under 11 years of age.

Transfusion-related transmission, although rare, is caused by a blood donation from a recently infected, asymptomatic, viremic individual. The peak viremia occurs 2 weeks before onset of jaundice or elevation of hepatocellular enzymes and persists for a median period of 42 days (range, up to 59 days). The virus is quite resistant to many inactivation procedures, including the pathogen-reduction procedures being developed for cellular blood components (e.g., licensed psoralens or investigational riboflavin, both with ultraviolet [UV] irradiation) and fresh-frozen plasma (solvent/detergent and methylene blue). Transmission by clotting-factor concentrates treated with the solvent/detergent pathogen-reduction process occurred in the 1990s, but not thereafter. Plasma for further manufacture is routinely screened for HAV RNA by pooled NAT.

An indefinite deferral for a clinical history of viral hepatitis after age 11 years has been required in the United States (regardless of the specific viral agent). Because most viral hepatitis in the United States before 11 years is HAV, with its relatively brief and self-limited viremia, individuals with a history of hepatitis before the age of 11 are allowed to donate on the assumption they had HAV. As pointed out previously, the FDA has now issued new rules for donor suitability that do not require questioning for a history of viral hepatitis.⁶ A 120-day deferral is recommended after exposure to HAV during community outbreaks to prevent transfusion transmission. Screening for HAV is not done for donation of blood for transfusion.

Hepatitis E

The hepatitis E virus (HEV) is a small, nonenveloped single-stranded RNA virus in the *Hepeviridae* family. HEV was first recognized in the 1980s in Afghanistan among soldiers with unexplained hepatitis. There is a single serotype but at least four genotypes with differing geographic distributions and epidemiologic patterns. Genotypes 1 and 2 are generally associated with large, water-borne (fecal-orally transmitted) outbreaks in less developed tropical countries. Illness is usually self-limited but can be lethal in pregnant women, their fetuses, and patients with chronic liver disease. Genotypes 3 and 4 appear to be animal viruses that result in zoonotic infection of humans, most often through consumption of inadequately cooked pork products. Genotype 3 seems to be widely distributed and is present in developed countries, whereas genotype 4 seems to be more common in certain Asian countries. Transfusion-related transmission, mostly of serotype 3, has been well-documented in Japan, France, England, the Netherlands, and Spain.¹³

Recent studies suggest a wide range of seroprevalence rates, but some of the variability may be attributable to the differences in performance characteristics of the tests used and some to dietary habits. Most studies indicate a cohort effect, with prevalence rates increasing with age. Transfusion infectivity is logically associated with the presence of detectable viral RNA in the plasma and the frequency of this finding varies between 1 in 1000 to 1 in 10,000 donations.

In a large study in England,¹⁴ 225,000 donations were tested and 79, or 1 in 2848, were found to be positive when tested for HEV RNA. For 43 of these, recipient tracing was possible and 18 (42%) showed evidence of transfusion-transmitted infection. In contrast, in

a smaller, blinded study in the United States, 7.7% of donors were anti-HEV positive and only two of approximately 19,000 were RNA positive; recipient follow-up was not possible.¹⁵ A current broader concern is the finding that highly immunosuppressed patients (such as solid-organ transplant recipients) do develop chronic HEV infections with long-term clinical sequelae, although these have not been specifically linked to infection via transfusion.

Non-A-E Hepatitis

Cases of posttransfusion hepatitis only rarely if ever occur but there remains speculation that undiscovered hepatitis agents exist. A small but consistent percentage of community-acquired hepatitis cases test negative for known hepatitis viruses, some cirrhosis is classified as “cryptogenic,” an etiologic agent for hepatitis-associated aplastic anemia eludes description, and the cause of some cases of acute liver failure remains elusive. Several candidate agents have been proposed as non-A-E hepatitis viruses. None of these agents have been shown to be pathogenic and are instead likely commensal and nonpathogenic.

GBV-C (initially called hepatitis G virus) is a flavivirus with no confirmed disease association that is transmitted parenterally, including frequently from transfusion. Of interest, GBV-C infection may delay progression of disease in those co-infected with HIV, which has led to studies of the interactions of these viruses.¹⁶

From 1% to 4% of US blood donors are viremic compared with 15% to 20% of injection drug users who have detectable GBV-C RNA. Infection occurs frequently among those infected with HCV and HIV. More people have antibodies against the E2 envelope protein, in the absence of RNA, suggesting viral clearance. GBV-C has not been shown to cause liver disease or other morbidity, and hence there is no consideration of donor screening at this time. GBV-C is now referred to as a human pegivirus. A second human pegivirus has recently been described associated with HCV likely as a result of an acute parenteral co-infection event, but again, has not been associated with hepatitis or any pathology. This virus was identified by next generation sequencing.¹⁷ Likely other such commensal agents will continue to be identified by use of sophisticated molecular techniques.

The torque teno virus (TTV) complex is a genetically diverse group of nonenveloped DNA viruses in the family *Circoviridae*, which was discovered in 1997. They cause viremia, and they are transmitted by transfusion, but they cause no recognized liver disease or other clinical illness.

SENV virus (SENV), another member of the *Circoviridae*, was described using degenerate polymerase chain reaction (PCR) primers while working with TTV. After an initial report associating SENV variants in two patients with transfusion-associated non-A-E hepatitis, subsequent epidemiologic studies have failed to link SENV with clinical hepatitis.

RETROVIRAL INFECTION

Human Immunodeficiency Virus

The HIVs type 1 and type 2 (HIV-1 and HIV-2) are retroviruses of the family *Retroviridae*, genus *Lentivirus*, and the etiologic agents of the acquired immunodeficiency syndrome (AIDS). They are enveloped viruses with two linear, positive-sense RNA molecules, 9.2 kb in length. The predominant transmission mechanisms are sexual, perinatal, and parenteral. An acute retroviral syndrome may be seen around 21 days after infection, although this period may range from 5 to 70 days and may involve fever, lymphadenopathy, and rash. If untreated, the incubation period for full-blown AIDS is measured in years. Molecular characterization divides HIV-1 into three groups: group M (main), group O (outliers), and group N (non-M/O). Group M subtype B infections predominate in the United States; only 3% of HIV-positive blood donors have non-B strains. Very rare

group O infections have been detected in the United States among patients who were born, lived, or had sexual contact in endemic regions of West and Central Africa. HIV-2 infected persons in the United States are rare (less than 1% of HIV cases diagnosed annually) and have, for the most part, been infected after heterosexual transmission from West African emigrants or residents. HIV-2 disease requires a longer time to evolve and is less severe than that from HIV-1. There have been five confirmed cases of HIV-2 infection among blood donors in the United States.

In 2010 CDC estimated a total of 1.2 million people in the United States 13 years or older are living with HIV infection, or 1 per 300 Americans, with over 10% of those unaware of their infection. The highest number of new infections occurs in those 25 to 34 years old with about 50,000 new infections per year and about half of those in African-American males, most of whom are MSM. MSM continue to bear the greatest burden of HIV infection among all race and ethnic groups. Although MSM represent 4% of the US population, in 2010 MSM accounted for nearly 80% of all new HIV infections in males and over 60% of all new HIV infections. Antiretroviral therapy for HIV treatment has improved dramatically since the advent of combination therapy in 1996, even against multidrug resistant viruses. HIV-associated morbidity and mortality have significantly been reduced so that HIV treatment has converted HIV infection to a chronic, versus a fatal disease.

Antibody testing of blood donors detects both HIV-1 and its variants and HIV-2.¹⁸ Antibody testing for HIV-1 began in 1985, with the addition of HIV-2 in 1992 (although HIV-1 tests before that time detected most HIV-2 infections arising from over 60% sequence homology between the two viruses) and for HIV-1 group O in 2006.

Both serologic testing and NAT are performed on every blood donation. First-generation antibody tests had a window period (time between infection and detection) of 45 days on average, but has decreased significantly as tests became more sensitive leading to less than a 20-day window period. HIV-1 NAT, implemented in 1999 (in duplex tests with HCV performed in pools of 6–16 donations) detects RNA at a minimum concentration of approximately 5 copies per milliliter (50% lower limit of detection) leaving about a 9-day window period of risk in which an infected donor could donate and not be detected by any test in current use. Rare genetic variants of HIV may escape NAT detection when nucleotide sequence changes affect NAT primer or probe binding sites, but the vast majority of these infections will be detected serologically. Further, tests are now designed to detect two or more separate sequences representing different viral regions. Currently, the frequency of confirmed-positive test results for antibodies to HIV is 0.26 per 10,000 donations. Almost all of these are also RNA-positive as the finding of an infected donor with low-level RNA levels is very rare (on the order of 2%). One donation per 900,000 is confirmed positive for RNA in the absence of antibody (NAT yield).¹¹

To interdict donations in the window period between exposure and test positivity, each blood donor is asked at each donation about exposure risks using questions developed in the early to mid-1980s, subsequent to the first reports of AIDS in hemophiliacs and transfusion recipients. These initial interventions targeted blood donations from homosexually active men and injection drug users, substantially reducing the transmission risk between 1983 and 1985. Five clusters of transfusion transmissions have been documented subsequent to the introduction of NAT, three before 2002 and one in 2008.^{8,19} It is of interest to note that in two cases, although the transfused plasma component transmitted HIV, the corresponding red cell component did not. Modeling suggests a residual risk for HIV transmission persists at approximately one transmission per 1.5 million donations, because NAT cannot detect HIV infection during the immunosilent 9-day eclipse phase between infection and test reactivity. Processing and quarantine procedural errors do not now appear to be a risk for transmission of HIV via transfusion. Fourth-generation tests combine HIV-1/2 antibody and HIV antigen detection and detect almost 90% of infections detected by NAT. Their role is expanding worldwide even in countries that use HIV-1 NAT. In 2014 the CDC published

revised guidelines for laboratory diagnosis of HIV infection (<http://dx.doi.org/10.15620/cdc.23447>).²⁰

Recent studies have shown that the predominant risk factors for HIV infection among 149 male infected blood donors surveyed retrospectively continues to be a history of MSM behavior (62% in cases vs. 2% in controls) or of a male having sex with an HIV-positive individual (26% in cases and none in controls). Of note, 50% of MSM activity occurred within the last 12 months. Although in the past, injection drug use was also a prominent risk factor, this has decreased in prominence (24% in cases vs. 5% in controls).²

In 2015 the US FDA formally reconsidered the original policy of permanent lifetime deferral of MSM even once since 1977 and have now issued Guidance permitting donation by those who have not engaged in MSM in the prior year, thus reducing the deferral period to 1 year, in common with a number of other countries, including Australia²¹ and the United Kingdom (www.fda.gov/BiologicsBloodVaccines/GuidanceComplianceRegulatoryInformation/Guidances/default.htm, Revised Recommendations for Reducing the Risk of Human Immunodeficiency Virus Transmission by Blood and Blood Products, Dec 2015).

Most consider the blood supply in the developed world to be at its highest historical safety level. This reflects incremental improvements in donor selection and history screening, blood testing, and process control that span four decades. For years, blood collection professionals and government regulators formulated blood safety policy decisions in an apparent aim to achieve zero-risk blood supply. In part, this reflects the perceived delayed response of the transfusion

medicine community in the early 1980s to the emergence of human immunodeficiency virus (HIV) in the blood supply and the recognition of the scope and severity of post-transfusion non-A, non-B hepatitis (subsequently hepatitis C [HCV]) following that. It reflects also the “dread fear” associated with transfusion-associated HIV. This reaction is seen when devastating, unpredictable, and stigmatizing events threaten potential victims who have little ability to escape the risk. This fear was validated by numerous transfusion-related HIV cases. It was amplified by widely publicized lawsuits, indictments, and criminal convictions of health ministers and policy makers in the 1980s and 1990s (*l'affaire du sang contaminé* in France addressing HIV and Canada's Royal Commission of Inquiry on the Blood System into blood collection agencies' response to non-A, non-B hepatitis risk) (Fig. 120.1). (See box on [Blood Safety Decision Making](#).)

Human T-Lymphotropic Virus-1 and Virus-2

Human T-lymphotropic virus-1 (HTLV-1) and HTLV-2 are closely related deltaretroviruses with 60% to 70% sequence homology and shared tropism for T-lymphocytes. In contrast to HIV, HTLV is rarely present in cell-free plasma and shows little active replication in infected humans. HTLV-1 is distributed worldwide, with endemic foci in southern Japan, the Caribbean, certain parts of South America, Africa, the Middle East, and Melanesia. HTLV-2 is endemic among Amerindians in both North and South America and African Pygmies. An epidemic of HTLV-2 infections has occurred over the past 40 to

Blood Safety Decision Making

Not surprisingly, from the 1980s until now, donor deferrals and blood-testing interventions have been rapidly, successively, and additively implemented for emerging and theoretical risks. Collection facilities introduced antibody testing to the HBcAg of HBV (anti-HBc) and ALT testing as surrogates for non-A, non-B hepatitis, HIV-1 p24 antigen testing, then NAT for hepatitis C and HIV and subsequently HBV, extensive deferrals for the risks attending transmissible spongiform encephalopathies (TSEs), NAT for West Nile virus (WNV), and antibody testing for *Trypanosoma cruzi*. The cost-benefit estimates for some of these interventions exceeded by orders of magnitude generally accepted thresholds but did not deter their adoption. In general, the implementation of these measures was undertaken by the blood providers, but at the time of writing, it is unlikely that this reactive approach can be sustained in the current health care–reform environment and in the face of declining funding for blood providers, at least in the United States.

Application, after HIV entered the blood supply, of a stringent form of the precautionary principle (originally promulgated for environmental protection, not transfusion safety) pushed decision making toward avoidance of all risks. The precautionary principle promotes implementation of measures to mitigate risk even if evidence of a risk is incomplete. It is supposed to be tempered by proportionality; that is, any measures adopted are to be proportional to the risk and with those used in similar circumstances, but some have argued that this has not been the case with blood safety measures, at least by the metric of cost-benefit. Nevertheless, although in potential conflict with evidence-based decision making, this approach resonated with policy advocates charged with transfusion safety. In contrast, when the risk for transfusion transmission of variant Creutzfeldt Jakob (vCJD) disease (the human form of bovine spongiform encephalopathy, BSE) emerged as theoretical, modeling was used to balance the perceived risk against the impact of extensive donor deferrals on the adequacy of the blood supply and to arrive at a policy decision. Some argue that the magnitude of risk does not justify the stringency of the donor deferral policy, given the small risk in a country that was not BSE endemic or lacked any BSE-contaminated materials in their food supply, but the process was the first to attempt to balance risk with adequacy. Subsequently, vCJD was shown to be transfusion transmissible.²²

Hemovigilance programs, such as the Serious Hazards of Transfusion (SHOT) in the United Kingdom and others in Canada, France, and a

smaller program in the United States, have emerged, supplying evidence about a much broader range of transfusion hazards than just infections. For example, a data-driven decision to minimize plasma transfusions from potentially alloimmunized female donors resulted in a dramatic reduction in transfusion-related acute lung injury (TRALI) in the United Kingdom, and studies in the United States have reproduced this finding.

These systems provide an opportunity for monitoring the risks and benefits of new initiatives, (e.g., proactive pathogen reduction). Pathogen-reduction processes (see box on [Pathogen Reduction](#)) offer the opportunity to abrogate most of the residual risk for all of the historically important transfusion-transmitted viral infections, bacterial contamination of platelets, babesiosis and malaria contaminated red cells, WNV infections, and Chagas disease. Pathogen reduction could eliminate the often lengthy, reactive, iterative paradigm of emergence of a new pathogen in the population, recognition of a material threat to transfusion recipients, development of donor-deferral strategies followed by development and refinement of test systems that has characterized our historical approach. Critically, broadly active pathogen-reduction processes offer a layer of protection against unsuspected emergence of new agents.²³ If already in use, they would need only to be validated as active against a new agent or appropriate model agents. The challenge with this approach is broad-based availability (all components) and wide-scale acceptance, the impact on product quality, and the potential long-term toxicities that may not be apparent in premarketing clinical trials or implementation to date.^{24–26}

More recently, as cost pressures for health care increase, transfusion professionals are questioning whether the zero-risk paradigm remains relevant. A consensus conference held in Toronto in October 2010 addressed concerns about “safety at any cost” and inconsistent decision-making practices affecting the blood supply. This initiative has led to a definitive effort to establish a framework for risk-based decision-making under the direction of the Alliance of Blood Operators (www.allianceofbloodoperators.org/abo-resources/risk-based-decision-making/rbdm-framework.aspx). The process involves risk identification, risk assessment, risk management, and risk communication, along with an assessment of risk tolerance, in the context of full and open communication with stakeholders.²⁷ Risk will never be zero, and there is now a realization that cost considerations,²⁸ politics, ideology, and public opinion cannot be ignored.

Pathogen Reduction

Pathogen-reduction technology (PRT) offers a proactive strategy to address new threats; these technologies involve physical, chemical, and photochemical treatments of blood components to inactivate or decrease viral, bacterial, and parasite infectivity.^{23,25}

Beginning in the 1980s, heat treatment, nanofiltration, and solvent/detergent treatment eliminated or reduced viral transmission in products derived from large-scale plasma fractionation such as albumin, immunoglobulin, and hemostatic factor concentrates.

In the past two decades, attention turned to whole blood–derived components: frozen plasma, platelets, and red cells. For these, PRT utilizes solvent-detergent, ultraviolet (UV) and methylene blue and visible light treatment for plasma; amotosalen (psoralen) and UVA light, and riboflavin (vitamin B₂) and UVB and UVA light for plasma and platelets; and riboflavin/UV light and S303 (a labile alkylating compound) for whole blood or red cells. Many European countries use PRT for platelets and plasma. Amotosalen/UVA-treated plasma and platelets (Intercept, Cerus Corporation) and solvent-detergent plasma (OctaPlas, OctaPharma) are FDA-approved and available in the United States. Because solvent-detergent does not inactivate nonenveloped viruses, OctaPharma screens all incoming units in pools to prevent the introduction of HAV, HEV and B19. Breakthrough HEV infections have been described with Intercept-treated plasma in France.

Amotosalen/UVA (Intercept, Cerus) and riboflavin/UV (TerumoBCT) have advanced furthest in investigation in North America. They provide significant antiviral activity against all agents for which tests are performed currently, human immunodeficiency virus (HIV), hepatitis B and C viruses (HBV and HCV), human T-lymphotropic virus (HTLV), West Nile virus (WNV), the parasite, *Trypanosoma cruzi*, and cytomegalovirus, but the two methods appear to differ in their inactivation capacity. PRT also inactivates agents causing bacterial contamination of platelets; inactivates white blood cells to prevent transfusion-associated graft-versus-host disease; decreases formation and release of cytokines during storage, reducing febrile, nonhemolytic transfusion reactions; and abrogates white blood cell–induced alloantibody (e.g., human leukocyte antigen [HLA] antibody) formation mitigating alloimmune platelet refractoriness. Intercept-treated plasma (as mentioned) and platelets are FDA approved and available in the United States; clinical studies on pathogen-inactivated red cells (Cerus) and whole blood (TerumoBCT) are ongoing.

Methylene blue and visible light inactivate pathogens in plasma by targeting nucleic acids. However, this alters fibrinogen structure. Because it damages cell membranes, methylene blue is not used for platelets or red cells. It is not effective against hepatitis A or parvovirus and is not recommended for use in the treatment of thrombotic thrombocytopenic purpura.

Amotosalen/UVA targets nucleic acids. Platelets treated with these technologies have somewhat lower 1-hour post-transfusion corrected-count counts.²⁶ In clinical trials, mild and moderate bleeding frequency is increased, but not severe bleeding complications; the time between transfusions and the total number of platelet transfusions have not generally been different. Pulmonary toxicity similar to transfusion-related acute lung injury (TRALI) has been reported in clinical trials and in animal model experiments in which UV light has been implicated. Previous clinical trials in red blood cells (RBCs) were halted because of asymptomatic immunoreactivity against the red cell neoantigens believed to be the result of treatment, and are being resumed with a reformulated process. Preliminary reports suggest riboflavin/UV causes functional impairment in red cells stored nearest the 42-day expiration. Although, there have been discussions about the potential for adverse reactions to treated products, extensive reviews of European data do not support the additional concern. Nevertheless, initial implementation of the Intercept platelet technology will be accompanied by Phase 4 studies in the United States.

Interest in PRT remains high because it reduces sepsis-related platelet transfusion complications and will eliminate the need for complex testing procedures to reduce bacterial risk related to contaminated platelets; inactivates parasites such as *Babesia microti*, and *Plasmodium falciparum*; mitigates risks associated with recognized emerging pathogens such as dengue, chikungunya, and Zika viruses; and proactively decreases threats from unknown, emerging pathogens. It should be noted that inactivation capabilities differ greatly between the various technologies, and each must be evaluated for its intended use.

50 years among intravenous drug users in the United States, Brazil, and Europe. Transmission of both HTLV-1 and HTLV-2 occurs by parenteral exposures, sexual contact, and by vertical transmission from mother to child during pregnancy and breastfeeding.

Diseases associated with HTLV-1 infection include adult T-cell leukemia/lymphoma (ATL), HTLV-associated myelopathy/tropical spastic paraparesis (HAM/TSP), lymphocytic pneumonitis, uveitis, polymyositis, and arthritis. HTLV-2 does not appear to cause hematologic malignancy but has been associated with HAM/TSP and linked to a higher rate of common infections such as acute bronchitis, pneumonia, and urinary tract infections, suggesting a subtle immunomodulatory effect of the virus.²⁹

ATL occurs in only 1% to 5% of infected persons following a latent period of decades. The illness is characterized by malignant lymphocytosis and leukemia, lymphadenopathy, hepatomegaly, abnormal liver function test results, splenomegaly, skin lesions, bone lesions, and hypercalcemia. HAM/TSP occurs in approximately 2% of individuals infected with HTLV-1 and HTLV-2. Patients with transfusion-associated HAM/TSP develop neurologic symptoms rather more rapidly, at a median of 3.3 years after transfusion. This illness is characterized by slowly progressive chronic spastic paraparesis, lower limb weakness, urinary incontinence, impotence, sensory disturbances, low back pain, hyperreflexia, and impaired vibration sense.

Blood donor screening for HTLV-1 antibodies began in 1988, and more sensitive combination HTLV-1/2 assays that detect close to 100% of HTLV-2 infections were introduced in 1998. The prevalence of HTLV confirmed-positive donors decreased approximately 10-fold during the 1990s to the current value of 0.004%. The rate is threefold higher in female compared with male donors. Incident infections are rare in repeat donors, an observation that has led to one-time testing of donors in some European countries, but an incidence of 3 per million donor years of follow up is felt by some to be too high for adoption of this strategy in the United States. Cell-free components such as plasma and cryoprecipitate do not transmit HTLV, and less than 30% of infected cellular components transmit. The residual risk for transfusion-associated HTLV infection using contemporary serologic testing is approximately 1 per 2.4 million donations, but since the initiation of testing using these contemporary tests, there has not been a breakthrough HTLV infection by transfusion. The contribution of blood-donor serologic testing to this low residual risk is confounded by the effect of effective leukoreduction that reduces HTLV-1 copy numbers in red blood cell (RBC) concentrates by up to 6 logs, to below the infectious dose of 10⁷ to 10⁸ infected cells per unit (one of a number of arguments used in support of universal leukoreduction of blood components).

The deferral, notification, and counseling of healthy blood donors after a repeatedly reactive screening test for HTLVs has been problematic, and tens of thousands have been affected since screening started. The vast majority of such tests are false positive, a licensed confirmatory test is now available and will greatly improve this situation.

HUMAN HERPESVIRUS INFECTIONS

Human herpesviruses (HHVs) are enveloped, structurally complex double-stranded DNA viruses that cause common infectious diseases. Primary infection is followed by lifelong carrier states and the possibility of reactivation. They are classified in three subfamilies, *Alphaherpesvirinae*, *Betaherpesvirinae*, and *Gammaherpesvirinae*, of which the latter two contain the herpesviruses that are of greatest concern from a transfusion medicine standpoint. Members of the *Alphaherpesvirinae* subfamily, herpes simplex viruses (HSVs) and varicella-zoster virus (VZV), are rarely, if ever, associated with transfusion-transmitted infections. Transfusion-transmitted cytomegalovirus (CMV) is well recognized. Transmissions of Epstein-Barr virus (EBV) and HHVs 6–8 by blood are virtually nonexistent in the United States because of the use of primarily leukocyte-depleted (leukoreduced) blood products.

Fig. 120.1 VARIOUS SAFETY MEASURES INTRODUCED DURING THE PAST THREE DECADES OF ENHANCED TRANSFUSION SAFETY. The x-axis displays costs associated with these advances per quality-adjusted life-year. Hepatitis C virus seroscreening saves costs. Estimates for platelet bacterial culturing and human immunodeficiency virus p24 antigen testing are not available. *ALT*, Alanine aminotransferase; *anti-HBc*, antibodies against HBcAg; *HBV*, hepatitis B virus; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *HLTV*, human T-lymphotropic virus; *NAT*, nucleic acid testing; *QALY*, quality-adjusted life-year; *T. cruzi*, *Trypanosoma cruzi*.

TABLE 120.2 Patients Benefiting From Cytomegalovirus Risk-Reduced Blood Components^a

Infants <1200 g with CMV-seronegative mothers
Seronegative autologous and allogeneic (CMV-seronegative donors) stem cell transplant recipients
Seronegative stem cell transplant candidates
Seronegative recipients of seronegative solid organ transplants
Seronegative pregnant women
Fetuses receiving intrauterine transfusions
Immunosuppressed patients receiving granulocyte transfusions
HIV-seropositive/CMV-seronegative patients

^aCMV risk-reduced components include CMV-seronegative and leukocyte-reduced components.
CMV, Cytomegalovirus; HIV, human immunodeficiency virus.

Cytomegalovirus

CMV, a betaherpesvirus, infects a wide range of cell types, including leukocytes of the monocyte-macrophage lineage and their progenitors. In the United States, in the population-based National Health and Nutrition Examination Survey (NHANES) III study, 58.9% of individuals more than 5 years old were seropositive, indicating prior CMV infection. Prevalence increases with age and is dependent on race/ethnicity and other demographic factors. The prevention of transfusion-transmitted CMV infection has depended on the use of “CMV safe” blood including a combination of leukoreduced and CMV-seronegative blood. There is, however, some evidence that acute infection may result in plasma viremia and thus the potential for transfusion infectivity.

Primary CMV infection in immunocompetent individuals is usually community acquired, often asymptomatic or associated with a mild, self-limited infectious mononucleosis syndrome. After virtually all infections, latent virus persists permanently in cellular reservoirs, allowing lifelong reactivation, and in the setting of transfusion or transplantation, the potential for viral transmission via nonleukoreduced cellular blood products, and allografts.

In immunosuppressed patients, CMV infection can cause severe morbidity and mortality from pneumonitis, hepatitis, gastroenteritis, retinitis, and other inflammatory conditions. CMV infection in low-birth-weight infants is associated with sepsis-like syndromes, respiratory distress, and liver and bone marrow dysfunction. Their infections can be acquired in utero, from breast milk, or from transfusion. Reported infant morbidity varies considerably but can approach 50% of seronegative low-birth-weight infants receiving unscreened, nonleukoreduced blood. CMV-seronegative marrow transplant patients are also susceptible to CMV infection; but the adoption of routine monitoring for CMV antigen or nucleic acid in transplant recipients and of preemptive antiviral therapy have decreased this risk. Seronegative solid organ transplant recipients are also susceptible to symptomatic transfusion-transmitted CMV infections. CMV-seronegative, HIV-infected patients are another group at risk for transfusion-transmitted primary CMV infection. The historical risk for CMV infection in immunosuppressed recipients receiving CMV-unscreened, nonleukoreduced blood components varies from 13.5% to 53.3%. The residual risk for CMV infection in seronegative, immunocompetent patients who receive nonleukoreduced cellular blood components unscreened for presence of CMV antibodies is approximately 1%. CMV transmission strictly attributable to blood is rare to nonexistent with the combination of leukoreduction and CMV antibody screening. CMV antibody screening will be replaced by pathogen reduction methods in the future.

Current practice in the United States is diverse. In a meta-analysis of 11 controlled trials in allogeneic marrow transplantation, 12 of 829 recipients of seronegative units versus 24 of 878 receiving leukoreduced but unscreened units developed CMV infections.³⁰ Pooling of data from three studies of seronegative or leukoreduced components, in comparison with CMV unscreened components, demonstrated statistically identical 93.1% and 92.3% reduced risks of CMV

infection, respectively. Thus most clinicians consider leukoreduction and CMV seronegative blood to be equivalent; however, clinicians caring for neonates are more likely to require serologic screening. American Association of Blood Banks (AABB) recommends that each institution review its internal policies for blood use in patients vulnerable to CMV infection. Table 120.2 lists patient populations for whom use of “CMV risk-reduced” components, that is, CMV seronegative, leukoreduced, or both, are thought to be beneficial. The failure of clinicians to recognize recipients requiring CMV-safe transfusion and to request such components is an argument that has been advanced in support of universal prestorage (versus bedside) leukoreduction.

CMV DNA blood donation screening by NAT may be considered an additional risk reduction measure for donors with seronegative window-period infections. However, current NAT assays would be expected to be equivalent to serologic screening in detecting latently infected blood donors. Any consideration of additional testing is complicated by the absence of randomized studies using contemporary leukoreduction methods and by our lack of understanding of the clinical impact of transfusion-transmitted CMV in an era of CMV monitoring and treatment. But with the advent of pathogen reduction measures the need for any CMV donor screening will become obsolete.

EPSTEIN-BARR VIRUS (HHV-4)

EBV, a gammaherpesvirus, is the causative agent of heterophile antibody-positive infectious mononucleosis and is etiologically associated with Burkitt lymphoma, nasopharyngeal carcinoma, and posttransplant lymphoproliferative disease. Transfusion transmission of the virus is unusual because more than 90% of the adult population is infected, and second infection is prevented by host virus-specific cytotoxic T-lymphocytes, capable of lysing EBV-infected B lymphocytes when viral peptides are expressed on the lymphocyte surface. Rare cases of transfusion-transmitted EBV presenting as infectious mononucleosis have been described in immunocompetent recipients and in immunosuppressed patients following solid organ transplantation. Aggressive EBV-associated lymphoproliferative disorders have been observed in patients with immune injury after cord blood stem cell transplantation but have not been documented following transfusion. B lymphocytes are the likely source of transfusion-transmitted EBV infection, so leukoreduction is an attractive strategy to prevent infection in transfusion recipients. Nonclinical studies suggest that leukoreduction is capable of removing detectable EBV DNA from platelet concentrates and RBCs.

Kaposi Sarcoma Herpesvirus (HHV-8)

HHV-8 is a gammaherpes virus causally linked to Kaposi sarcoma, primary effusion lymphoma, and multicentric Castleman disease. It is highly cell-associated with lymphocytes and monocyte-macrophages. Although generally spread person to person, including sexually, it has been shown to be transmitted by transplantation. There is convincing evidence of HHV-8 transmission by transfusion in sub-Saharan Africa, where the seroprevalence of HHV-8 among blood donors is 40%, and fresh, nonleukoreduced blood transfusions are commonly used. The seroprevalence of HHV-8 among US blood donors has been reported to be as high as 20% to 25%, but a multicenter study using well-characterized antibody tests on donations from five representative US regions estimated a seroprevalence of only 3.5% and showed no evidence of viremia by PCR. The possibility has been raised that transfusions in the United States have transmitted HHV-8, but subsequently reported studies comparing transfused patients with untransfused controls are not suggestive. Similar to what has been established for CMV infection, it is assumed that widespread leukoreduction in the United States mitigates the risk for HHV-8 transmission by transfusion, but this has not been proven.

Other Herpesviruses (Herpes Simplex, Varicella-Zoster Virus, Human Herpesviruses 6 and 7)

Infection with these viruses is very common to ubiquitous. From 50% to 80% of the adult population is seroreactive to HSV-1 and/or HSV-2, up to 95% for VZV, more than 90% for HHV-6, and 70% to 90% for HHV-7. Primary infection is followed by lifelong latency for all HHVs, and reactivation from latency is described for all. There is no credible evidence of transfusion transmission of HSVs (causing orolabial and genital herpes and herpes encephalitis), VZV (chickenpox and shingles), or HHV-6 or HHV-7 (exanthem subitum or roseola infantum, multiorgan dissemination with reactivation in immunocompromised hosts).

Viremia occurs during both primary and reactivation infection with HSV and VZV, but transmission by blood has never been reported for these viruses. Although the lymphocyte association of HHV-6 and HHV-7, like CMV and EBV, suggests the possibility of transfusion transmission, well-documented case reports or series are not available. Case reports of HHV-6 transmission by hematopoietic stem cells used molecular methods to detect integrated donor HHV-6 DNA in engrafted donor cells and appear to represent transmission of latently infected cells rather than of active infection. Furthermore, transplant recipients may reactivate preexisting latent infection, thereby confounding the evaluation of potential transfusion transmission. HHV-6 and HHV-7 are highly leukocyte associated after primary infection, and leukoreduction would be expected to be effective by analogy to human CMV; however, cell-free viremia can be found during primary infection.

PARVOVIRUS

Human parvovirus B19 (erythrovirus) is a 19- to 23-nm-diameter nonenveloped, single-stranded DNA virus from the family *Parvoviridae*, as are adeno-associated viruses, human parvovirus 4 (PARV4), PARV5, and bocaviruses. B19 has at least three genotypes. Genotype 1 infections appear predominantly in the United States and Europe. Genotype 2 infections appear confined to those born before 1973, and genotypes 3a and 3b infections occur in parts of West Africa. Infection with B19 is ubiquitous, with 50% of high school children demonstrating seropositivity, increasing to 90% in older adults. Approximately three-quarters of transfusion recipients have B19 IgG antibodies. Natural transmission occurs through the respiratory route most commonly and transplacentally to the fetus in up to 30% of women infected during pregnancy. Transfusion of blood and blood components, plasma derivatives, and organ transplantation are minor routes. In women infected during weeks 9 to 20 of pregnancy, fetal death occurs in 10% to 15% from hydrops fetalis. The low observed incidence of infection in transfusion recipients results from prior infection and immunity, co-infusion of neutralizing antibodies, and possibly because very high viral loads are uncommon in donor blood.

Parvovirus B19 causes erythema infectiosum, or fifth disease, oligoarthritis, and neurologic and myocardial infections. Following acute infection, viral replication leads to extremely high-titer viremia that declines at the time of IgM seroconversion approximately 9 days following infection. B19 may persist in bone marrow, liver, tonsils, and skin of healthy persons with no recognized clinical significance, and low levels of B19 DNA have been amplified from the blood of healthy people for several years after primary infection. The virus is highly tropic for erythroid progenitor cells using the P-blood group antigen, or globoside, as its receptor, causing aplastic crises in patients with sickle cell anemia, other inherited hemolytic diseases, and conditions associated with decreased RBC survival, malaria, and HIV/AIDS. Acute infection impairs erythropoiesis for 7 to 10 days, with complete cessation for 3 to 7 days, resulting in hemoglobin decreases. Persistent infection, causing red cell aplasia, occurs in those who fail to develop neutralizing antibodies to the viral capsid protein 1. In these patients, the virus continues to circulate at high titer, greater than 10^{12} International Units (IU) or equivalent genome copies per

mL. Patients at risk for persistent infection include those receiving chemotherapy and immunosuppression, organ transplant recipients, and those with HIV. Infection in these groups tends to respond favorably to intravenous immunoglobulin infusions.

B19 virus-impaired erythropoiesis appears to be multifactorial. B19 viral nonstructural protein 1 (NS1) mediates apoptosis via an 11-kDa protein that perturbs signal transduction and induces apoptosis. B19 viral DNA activates Toll-like receptor 9 inhibiting cell growth and is toxic for infected cells.

Blood and plasma-derivative transmission involves donations during the transient 1- to 2-week high-titer viremic period. The prevalence of B19 viremia has been reported as 0.003% to 0.84% in blood and plasma donors. In a study involving more than 12,100 B19 DNA-tested blood donations, given to surgical patients with a 78% pretransfusion B19 IgG seroprevalence, no B19 transmissions occurred from transfusions containing less than 10^6 IU per mL.³¹ Hence most blood transfusion recipients are believed to be at low risk for an infectious exposure. However, careful studies in Japan have demonstrated some transmissions from components with comparatively low viral loads of around 10^5 IU per mL.^{32,33}

By contrast, recipients of plasma-derived products made from manufacturing pools of thousands of donations have a significant risk because the virus survives partitioning, ethanol fractionation, and other anti-infective measures applied to derivatives, and a single high-titer viremic donation can overcome the neutralizing activity of antibody in the pool. Recipients of coagulation concentrates are at highest risk, whereas those of intravenous immunoglobulin and albumin are less so based on cohort studies of prevalence. In one report, 14% of viremic plasma donors had titers between 10^4 and 10^7 IU per mL, and one in 13,000 had titers greater than 10^7 . In observational studies, seroconversion occurred among recipients of plasma derivatives with high titers, $10^{7.5}$ to $10^{8.5}$ IU per mL, treated with the solvent/detergent pathogen-reduction technique, suggesting that the protective effect of neutralizing anti-B19 antibodies is exceeded in the presence of high viral loads (see box on [Pathogen Reduction](#)). Since B19 is a nonenveloped virus, solvent/detergent pathogen-reduction treatment is ineffective in preventing B19 transmission in hemophilia patients receiving factor concentrates. Freeze-drying and dry-heat treatment (80°C [176°F] for 72 hours) inactivate more than 4.7 logs B19, but this is not always sufficient to prevent transmission. Currently, plasma derivative manufacturers use “in-process” NAT to identify and remove source (from paid and volunteer donors) and recovered (from volunteer whole blood donors) plasma units with the objective to assure that manufacturing pools have parvovirus B19 DNA titers no greater than 10^4 IU per mL. Approximately 1 per 10,000 plasma units is withheld from further processing. For volunteer whole blood donors, 1 per 6000 to 1 per 16,000 have titers greater than 10^6 IU per mL. Because individual whole-blood donations rarely cause recognized parvovirus infection, testing of single red cell units, platelets, or plasma for transfusion for B19 DNA is not currently required, although some advocate use of B19-tested blood components for those potentially at risk, including pregnant women, neonates, those with reduced RBC survival, and immunocompromised patients.

Of note, PARV4 and PARV5 have been detected in pooled plasma derivative samples, but the clinical significance is not known; limited clinical disease associations have been described.³⁴

WEST NILE VIRUS

WNV is a mosquito-borne lipid-enveloped RNA virus in the Japanese encephalitis complex of the family *Flaviviridae*. Transmitted bird-to-bird primarily by culicine mosquito vectors, human infections occur incidentally. The first cases were identified in the West Nile district of Uganda in 1937. Subsequently, outbreaks occurred in the Middle East, South Africa, and Europe. The first North American cases appeared in New York City in 1999. Starting in July 2000, WNV cases spread to the Mid-Atlantic States. This was followed in the next 3 years by transcontinental dissemination. During the summer of

2002, a model suggesting a significant risk for WNV infection in blood donors was published,³⁵ and then four recipients of organ allografts from a single donor developed neuroinvasive WNV infection. Infection of the organ donor was traced to donor blood transfused before death from trauma. Transfusion transmission was documented in 23 recipients in 2002³⁶ against a background of 2946 cases of WNV-meningoencephalitis (WNME). These events provoked a multidisciplinary effort, successfully engaging the blood community, the manufacturers of blood donor-screening NAT platforms, and public health officials and regulators to develop and deploy, under an investigational new drug (IND) exemption, high-throughput screening tests in the 10 months before the 2003 transmission season began. WNV test implementation represents the benchmark for responsiveness to a serious emerging transfusion-transmitted infection in the United States.^{37,38}

In 2003 2946 WNME were reported and 714 healthy blood donors tested WNV RNA positive. In 2004 case reports declined in the Northeast but extended westward into Arizona and Southern California. In 2005 more than 1300 WNME cases were reported, with approximately 25% occurring in California, relatively high activity in South Dakota, Nebraska, Louisiana, and Illinois, and low activity in the Northeast. In 2006 over 400 WNV RNA-positive blood donors were identified. Subsequently WNV activity was reported in Washington State for the first time, and high rates of infection were noted in Idaho, California, Nebraska, Illinois, Louisiana, and the Dakotas. By 2011 fewer than 150 blood donors tested positive with the highest frequencies in New York, Texas, Arizona, and California. The frequency of both WNME cases and RNA-positive blood donors continues to vary by year and remain unpredictable. In total from 2002–2014, nearly 19,000 cases of WNME have been recorded with 4355 RNA-positive blood donors identified, which are related in magnitude by year.³⁹

WNV RNA is believed to appear 1 to 3 days after a bite of an infected mosquito. In contrast to HIV and HCV, peak WNV levels are low (maximum observed 720,000 copies/mL, median 3500 copies/mL compared with 10^5 to 10^7 copies for HIV and HCV). In cohort studies of blood donors with positive WNV RNA tests, only 29% to 61% (retrospectively) describe any symptoms before or after donation consistent with WNV infection, compared with 3% to 20% of those not infected, demonstrating that the donor history is neither sensitive nor specific enough to prevent transfusion transmission.⁴⁰ Testing for antibodies also will not prevent transmission because IgM antibodies appear a median of 14 days and IgG antibodies a median of 17 days after infection and infectivity disappears rapidly with the development of antibody. These data explain the selection of WNV NAT for the testing strategy. To maximize efficiency, donation samples are tested in minipools containing aliquots from 6 to 16 donors, as is done for HCV, HBV, and HIV.

Despite minipool NAT, six transfusion-associated WNV cases occurred during 2003. The implicated donors were antibody-negative and had low-level RNA that escaped detection in the minipool (i.e., diluted) samples. At the end of 2003 an observation was made, even before the documentation of these transfusion transmissions, that the viral load in some donor samples is too low for detection by minipool NAT. Consequently, strategies have been developed to switch from minipool-NAT to NAT on individual donation aliquots in areas experiencing high WNV activity.⁴¹ In total, following the 23 cases of transfusion-transmitted WNV documented before the initiation of donation NAT screening, an additional 14 have been reported, most related to donations having only low-levels of RNA; the last was in 2016. All implicated donations, except one in 2002, have been IgM negative. Blood centers must remain vigilant for appropriate conversion to individual donation-NAT for this strategy to be effective.

DENGUE VIRUSES

This mosquito-borne infection is of great interest as an emerging pathogen with the potential to spread by transfusion. Forty percent of the world's population lives in areas with risk for dengue, including

many areas visited by US travelers. It has spread rapidly in Latin America and the Caribbean since the 1980s. Dengue is endemic in Puerto Rico, the US Virgin Islands, and American Samoa, and there have been outbreaks in Hawaii, Texas, and Florida during the last 10 years. Dengue is caused by four related flaviviruses spread person to person by *Aedes aegypti* and *Aedes albopictus*, which are present in 16 and 35 US states, respectively. Over 2.3 million dengue clinical cases occurred in the Americas during 2015.

Most infections are asymptomatic, but illness ranges from undifferentiated fever to classic break-bone fever and severe dengue (dengue hemorrhagic fever and dengue shock syndrome). An approximately 7-day viremia is a feature of both asymptomatic and symptomatic infection, and asymptomatic blood donors from Hong Kong, Singapore, Brazil, and Puerto Rico have transmitted dengue to blood recipients in seven clusters. Although such reports are limited, compared with the high rates of vector-borne infection, there is no systematic surveillance for transfusion-transmitted dengue and its recognition in the face of widespread outbreaks is problematic.⁴² RNA-positive, asymptomatic donors have been identified in Brazil, Central America, and Puerto Rico using NAT and antigen detection tests. Rates of donor RNA positivity in Puerto Rico are comparable to those found in US donors during the most active WNV seasons.^{43,44} A recent study in Brazil documented transfusion transmission; however, when patient charts of those donors who received an RNA-positive unit and were shown to be infected were compared with control recipients who did not receive an RNA-positive unit, there was no reported increase in clinical illness.⁴⁵ This further illustrates the difficulty in identifying transfusion-transmitted dengue among severely ill patients who are frequently transfused.⁴⁴

In the absence of significant outbreaks of locally-transmitted dengue in the continental United States, transfusion risk relates mainly to return of infected, asymptomatic or presymptomatic travelers to the United States from endemic areas. A 3- to 14-day incubation period precedes symptom onset. Deferral for travel to malarious areas (1 year for a US resident) offers some protection, but a large proportion of dengue-affected areas frequently visited from the United States are malaria-free and donor-travelers to those areas could potentially introduce the virus into the community and the blood supply. Careful surveillance and a high index of suspicion when sustained febrile illness occurs following transfusion are required to recognize transfusion-related dengue. Preliminary data on travelers from the United States to dengue-endemic destinations that are malaria-free suggest that 2- to 4-week deferral for travel to dengue-affected areas may have a greater adverse impact on blood donation than current malaria deferrals. To date, however, there are no instances of transfusion-transmitted dengue in the continental United States that are attributable to donor exposure through travel. The conditions for sustained spread of dengue exist in large areas of the United States: a source of infection from travelers and immigrants; a susceptible population; and competent vectors. Whether the recently identified outbreaks in the United States will continue or increase, and whether sustained transmission will begin is unknown. Transfusion-transmitted dengue has been identified by one group as one of the three highest-priority emerging infections posing a potential threat to transfusion recipients in the United States and Canada and has been the subject of discussions at the FDA's Blood Products Advisory Committee (see box on [Emerging Infections](#)).

CHIKUNGUNYA VIRUS

Chikungunya virus is another tropical arbovirus transmitted by *Aedes* spp. mosquitoes. It is a togavirus of the alphavirus group and, although first recognized in Africa has been notably responsible for explosive outbreaks in the islands of the Indian Ocean and has most recently spread to the Caribbean, where more than 1.7 million clinical cases were reported from the end of 2013 to the middle of 2015, including RNA positivity in blood donors.⁵¹ Although there have been no reported cases of transmission by transfusion, the similarity of early infection to that of dengue has resulted in significant concern.

Emerging Infections

The experiences with human immunodeficiency virus (HIV), new variant Creutzfeldt-Jakob disease (vCJD), and West Nile virus (WNV) have made it clear that planning for the emergence of new pathogens that may threaten the blood supply is critical in order to shorten the interval from emergence to mitigation. To that end, the characteristics of pathogens likely to enter the blood supply must be understood. These include the ability of the agent to establish an asymptomatic blood-borne phase, to survive under contemporary processing and storage conditions, to establish infection by the intravenous route, and to cause significant morbidity in a transfusion recipient.

Using these characteristics and a review of contemporary literature, the Transfusion Transmitted Diseases Committee of the American Association of Blood Banks (AABB), from 2005 to 2009 produced a compendium of infectious agents that might become relevant to transfusion medicine and attempted to prioritize those that were identified.⁴⁶ A series of 68 fact sheets was developed. The fact sheets provide transfusion medicine professionals and clinicians with an overview of the agents' phylogeny, epidemiology, clinical characteristics, and interventions that might be useful to protect the safety of the blood supply. Three agents were included in the highest priority stratum: *Babesia* sp., dengue viruses, and the vCJD prion; a section on each is included in this chapter. The fact sheets are freely available online, cover many of the agents discussed in this chapter, and have been updated when required (www.aabb.org/tm/eid/Pages/eidpostpub.aspx).

Since the original publication, several new monographs have been added, reflecting an ongoing "horizon-scanning" initiative designed to alert the medical community to potential threats. These include yellow fever and the yellow fever vaccine viruses after the latter was transmitted to blood recipients when recent vaccine recipients failed to divulge that information during blood donation. Other fact sheets have been updated and rereleased to capture relevant new information (see box on [Xenotropic Murine Leukemia Virus-Related Virus](#)). The availability of these materials to the transfusion medicine and general medical communities is meant to increase awareness that unexpected infections in transfusion recipients should trigger consideration of that source and to provide background allowing the rational consideration of approaches to avert and minimize their spread.⁴⁷

Xenotropic Murine Leukemia Virus-Related Virus

The alleged association of the gammaretrovirus xenotropic murine leukemia virus-related virus (XMRV) with chronic fatigue syndrome/myalgic encephalomyelitis (CFS/ME) is paradigmatic of the difficulties inherent in the real-time assessment of potential and emerging transfusion-transmissible infections. A group of CFS/ME patients and controls were evaluated using polymerase chain reaction (PCR), virus isolation, serology, and immunohistochemistry.⁴⁸ Evidence of the virus's presence was strongly associated with the clinical diagnosis, culturable virus was found in plasma, and the issue of transfusion transmission was appropriately raised.

Multiple subsequent studies from other groups over the ensuing 2 years failed to confirm the presence of XMRV in a variety of populations. Several publications suggested that PCR contamination underlies some positive results; however, data now indicate that XMRV arose as a recombinant of two murine leukemia viruses during passages in nude mice, leading to the conclusion that the initial findings were an artifact.⁴⁹ With these findings, the original publication was retracted. The absence of transfusion transmission and of the agent were also demonstrated in studies on the donor pool.⁵⁰ The amount of research and resulting publications on this recombinant laboratory-generated virus were simply another lesson in caution that is required prior to claims of a viral agent being a human pathogen, or in this case, being the result of recombinant contamination.

Notably, French authorities responded to the outbreak in La Réunion by halting local collection of red cells (providing for the island's needs by supplying blood from the French mainland) and by implementation of limited NAT and the use of pathogen reduction for platelets.⁵² Other precautions that have been used have been to strengthen requirements of postdonation information from donors (a process that is enhanced by the high [50%–80%] frequency of symptoms

among infected subjects), along with deferrals for residence in affected areas. Chikungunya symptoms are similar to those of dengue, but without the impact upon the circulatory system. Arthralgia is, however, a prominent symptom and may be prolonged. Routine testing is not currently available.

ZIKA VIRUS

Zika virus is another tropical arbovirus of the flavivirus group. Again, first recognized in Africa, it has been circulating in the Pacific islands at relatively modest levels. In 2007 the first human outbreak was recognized on the island of Yap in Micronesia with subsequent spread in 2013 to French Polynesia.⁵³ Testing performed in Polynesia showed 2.8% of presenting donors to have Zika virus RNA. Within 2015 Zika virus and associated disease emerged in Brazil and has now spread to beyond other South and Central American countries, Mexico, and the Caribbean including travel-associated cases in the United States.⁵⁴ A particular concern is that the infection seems to be associated with an unexpectedly high and troubling incidence of microcephaly, a neurologic developmental abnormality.^{55,56} Increases have been noted, particularly in Brazil, where it is believed that the increase is a consequence of maternal infection and transmission to the developing fetus. In addition, during the outbreak in Polynesia, a 20-fold increase in the number of reported Guillain-Barré syndrome cases were reported; a similar increase is also being noted in Brazil. Other than mosquito transmission, like dengue, transfusion transmission has been reported. Unlike the other mosquito-borne viruses, Zika appears to be sexually transmitted (and can be recovered from urine and semen).⁵⁷ The World Health Organization has called a public health emergency of international concern to increase surveillance and vector control and to expedite the development of diagnostics, treatment, and vaccine development. Given the similarity to and relationship with dengue, there are concerns about the spread of Zika virus and local transmission in the continental United States. Most recently (August 2016), the implementation of universal, individual donation NAT for Zika virus RNA has been required for all blood collected in the United States.

PANDEMIC INFLUENZA A

There was interest in the transfusion safety implications of influenza A even before the swine origin A-H1N1 pandemic of 2009–2010.⁵⁸ Viremia in donors, and the potential for infection of recipients were discussed during meetings of an AABB pandemic influenza planning task force as early as 2008, based on old literature demonstrating the virus in the blood of experimentally infected volunteers and case reports of viral dissemination during human infection with highly pathogenic avian A-H5N1 virus. Subsequent studies have failed to identify influenza viruses in donors drawn in US communities during periods of high seasonal influenza activity or in donors with the onset of influenza-like illness immediately following donations.⁵⁹ The current consensus is that pandemic influenza is not likely a threat to blood recipients, but that disruption of the blood supply in a severe pandemic is a more important possibility, requiring careful advance planning.

BACTERIAL CONTAMINATION

Bacterial contamination of red cell and platelet components occurs primarily as a result of the inability to achieve complete skin disinfection at the donor phlebotomy site, where bacterial populations survive in skin appendages below the accessible surface and contaminate skin plugs made by the phlebotomy needle and enter the blood bag. Transient asymptomatic bacteremia at the time of blood donation, a break in technique during pooling the contents of or sealing blood containers, disruption of blood bag integrity or its contamination during manufacturing are other rare sources. Bacterial

proliferation occurs more rapidly in platelet concentrates stored at room temperature than in red cells maintained at 4°C (39.2°F).

The rate of bacterial contamination in allogeneic platelets was estimated at 1 per 1000 to 3000 units with life-threatening septic reactions occurring in one per 15,000 to 100,000 recipients before routine implementation of culture-based tests to detect bacteria in apheresis platelets in 2004. These tests reduced contamination rates to approximately 1 per 5000 to 8500 platelet units. Clinical septic reactions occur in approximately 30% of recipients receiving contaminated platelets. Bacterial contamination was responsible for 33 of 267 (12%) of transfusion-related deaths reported to the FDA from 2005 to 2009.⁶⁰ In subsequent reporting periods (2008–2012 and 2010–2014) bacterial contamination of platelets (primarily *Staphylococcus aureus* and *Serratia marcescens*) were responsible for 13 of 198 (7%) and 11 of 176 (6%) recipient fatalities (www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/ReportaProblem/TransfusionDonationFatalities/). The downward trend is undoubtedly caused by interventions that have been put into place (increased attention to arm scrub, improved antiseptic solutions used, sample diversion of the first 40 mL or so containing the skin plug and bacterial testing). Only acute hemolytic reactions and TRALI are responsible for more fatalities in the referenced reporting periods. However, there is consensus that these reactions are badly underrecognized and underreported. Culturing fails to detect 50% to 75% of contaminated units. This undetected contamination occurs largely because minimal bacterial levels, present when cultures are obtained, yield culture aliquots without bacteria. Subsequently the few bacteria remaining in the blood bag can grow out during storage, producing transfusions with significant bacterial levels. To minimize this, collection facilities generally hold apheresis platelets for approximately 24 hours after collection before sampling for culture to allow low bacterial inocula to proliferate, improving the sensitivity of culture. As mentioned, improved skin antisepsis and diversion for laboratory testing of the first 40 mL of blood, which contains the skin plug, provide further reduction of contamination rates, transfusion reactions, and fatality rates by lowering the bacterial load that otherwise would enter the final component container.

Septic transfusion reactions should be suspected when one or more of the following occur within 1 to 4 hours of transfusion: temperature elevations greater than 1–2°C (1.8–3.6°F), chills and rigors, tachycardia more than 120 beats per minute or an increase of 40 beats per minute, or an increase or fall in systolic blood pressure of greater than 30 mmHg. Additional signs and symptoms can include nausea, vomiting, diarrhea, bleeding, oliguria, or septic shock. Septic transfusion reactions may be confused with hemolytic transfusion reactions, febrile, nonhemolytic transfusion reactions, or TRALI.

Platelet concentrates contaminated with *Staphylococcus aureus*, *Serratia marcescens*, *Staphylococcus epidermidis*, *Escherichia coli*, and *Streptococcus* species account for most of clinically recognizable reactions. *Propionibacterium acnes* is a frequent culture isolate from platelets during storage when an anaerobic culture is also performed but is not believed to be responsible for a significant number of reactions. A clinically relevant case of *Clostridium perfringens*, another anaerobe, has been reported.⁶¹ The bacterial dose in platelet concentrates and species virulence correlate with the clinical outcome. Bacterial concentrations greater than 10⁵ colony-forming units (CFU)/mL are more likely to result in severe reactions or fatalities. Alternatively, low concentrations, 10⁴ or fewer CFU/mL of skin organisms, frequently elicit no reaction. Endotoxin elaboration by gram-negative organisms is associated with the most severe reactions, but the vast majority of gram-negative organisms are easily detected by bacterial culture.

In addition, bacteria grow at variable rates. *S. epidermidis* grows slowly, and *P. acnes* requires on average 3 days for detection. Because collection agencies continue bacterial culturing until the platelet unit expiration date or detection of growth, there is further opportunity to intercept released platelets that have not been transfused and to alert physicians about the potential risk for bacterial contamination in cases where the units have been administered. However, the vast

majority of septic reactions are associated with false-negative culture tests because of sampling insufficiency as noted earlier. The overall rate of bacterial contaminated apheresis platelets is 1 per 5000 and for septic transfusion reactions is 1 per 107,000 distributed components.⁶¹

Before the mid-1980s, platelet concentrates were stored for 7 days. Following reports of septic reactions, the shelf life was reduced to 5 days to decrease the interval during which bacteria could proliferate. In the United States, blood suppliers distributed platelets from 2005 to 2008 with a 7-day shelf life following enrollment in an FDA-mandated postmarket surveillance study (Post Approval Surveillance Study of Platelet Outcomes, Release Tested [PASSPORT]) that included testing for bacterial contamination by a sensitive culture method. Initial experience suggested that extended platelet storage coupled with bacterial testing substantially decreased platelet loss from outdating. However, the PASSPORT study found 1 per 4329 tested platelet products with negative bacterial cultures had bacterial growth when tested at the end of storage, 7 days later.⁶² Septic transfusion reactions occurred in approximately 1 per 25,000 platelet transfusions; some following infusion of 3-day stored platelets, most with those stored 4 days or longer, leading to reinstatement of the 5-day platelet shelf life.

Alternative methods for detecting bacterial contamination include point-of-release testing in the hospital transfusion service. Considered a supplement to culture-based testing, this assay can be used shortly before issuing platelets for transfusion to detect units missed by early culture. This rapid qualitative immunoassay tests for the presence of conserved bacterial antigens (gram-negative lipopolysaccharide and gram-positive lipoteichoic acid). In one report using this test, 1 per 3000 platelet doses contained gram-positive organisms when issued 3 or more days after collection.⁶³ Other methods, under development for mitigating septic platelet events, include microcolorimetry, bacterial spore biosensors, real-time PCR, flow cytometry, and detection of other bacterial cell wall constituents. Pathogen-reduction technology using licensed psoralens (Intercept) or riboflavin plus UV light provides an opportunity for inactivating multiple pathogens before they can proliferate. Again, however, not all technologies inactivate different bacterial isolates with the same efficiency.

RBC bacterial contamination rates approximate 1 per 30,000 units with adverse clinical outcomes occurring in 1 per 500,000 transfusions and fatalities occurring at a rate of 1 per 10 million. Most septic reactions occur in units stored for 4 weeks or longer, reflecting the delayed growth of bacteria at 4°C (39.2°F).

Bacteria isolated from contaminated red cell units include *S. marcescens*, *E. coli*, *Pseudomonas* species (especially *Pseudomonas fluorescens*), and *Yersinia enterocolitica*. The latter two are psychrophilic and known to proliferate in the cold. Gram-positive skin saprophytes account for most of the organism-contaminating platelet concentrates, with the remaining attributed to gram-negative organisms associated with occult bacteremia.

Immediate recognition of a platelet or red cell septic reaction and immediate discontinuation of the transfusion, supportive care, and antibiotic administration are the mainstays of therapy. Prevention relies on careful donor selection and scrupulous adherence to aseptic techniques and precautions from component collection, processing, transport, and storage to transfusion at the bedside. The Gram stain reveals bacteria in platelet concentrates contaminated with more than 10⁵ to 10⁶ CFU/mL.

A proportion of donors of platelet units contaminated with *Streptococcus bovis* or *Streptococcus infantarius* have been found to have colonic polyps or colon cancer.

the discovery of the Australia antigen almost two decades later. More than 100 transfusion syphilis cases were published before World War II, and many more certainly occurred. The last alleged case of transfusion-transmitted syphilis in the United States, however, was in 1966. Since then, hundreds of millions of components have been transfused in this country without another recognized case. There are multiple explanations for the disappearance of transfusion-transmitted syphilis in addition to improvements in testing: (1) the dramatic decline in the incidence of early syphilis in the United States over the decades, more than an order of magnitude, reducing the reservoir of donors able to transmit; (2) the end of direct donor-to-recipient transfusion combined with the loss of viability of *Treponema pallidum* in stored blood—the latter attributed to poor survival in refrigerated RBCs and to the high oxygen tension in platelets stored at higher temperatures; (3) the ubiquitous administration of antibiotics for trivial to serious viral, bacterial, and noninfectious clinical syndromes, especially to those sick enough to be transfused; (4) donor deferral for behavioral correlates of syphilis risk (e.g., male sex with males, occurrence of recent sexually transmitted infection in donors, exchange of drugs or money for sex, injection drug use); (5) passive surveillance for transfusion-transmitted syphilis compounded by the failure of recognition by physicians (who may have never seen syphilis, venereal or otherwise); and (6) donor illness during spirochetemia severe enough to prevent their presentation to donate blood or causing deferral. The relative contributions of each of these factors are unquantified.

Most blood collection facilities screen donors with an automated test for detecting treponemal antibodies (e.g., *T. pallidum* hemagglutination assay and *T. pallidum* particle agglutination assay; treponemal antibody confirmatory test usually follows using a variety of methods such as enzyme-linked immunosorbent assay (ELISA) or fluorescent treponemal antibody, absorbed (FTA-abs) test; most blood centers further test donors with treponemal antibody reactivity using a nontreponemal test (e.g., rapid plasma reagin [RPR]) to stage the reactivity as recent or past. Approximately 50% of donors with confirmed positive treponemal test results have evidence of a treated syphilis infection. Donations with reactive syphilis tests are generally discarded. Blood centers defer donors with positive treponemal confirmatory tests; donors may be reentered (regardless of their nontreponemal test results) 12 months after completion of treatment for syphilis. Treponemal and nontreponemal false positivity occurs in healthy donors caused by cross-reactivity with a wide variety of infectious diseases other than syphilis, in those with high-titer human leukocyte antigen (HLA) antibodies, after some immunizations, with autoimmune disease and other chronic inflammatory disease, and have increasing prevalence with increasing age.

Most true treponemal antibody positives are the “serologic scar” of remote (often treated) infection and pose no risk to blood recipients. A recommendation to discontinue donor screening for syphilis was made in 1985 but not acted upon initially because of the perception that testing might be functioning as a surrogate for HIV or other transfusion-transmissible viruses.⁶⁴ This hypothesis has been rejected, but, because the role of syphilis testing in the elimination of transfusion syphilis is unclear, syphilis testing continues even though it has no apparent value. Although small PCR studies of reactive donors have been universally negative, rabbit inoculation studies using samples from confirmed reactive donors will likely be required to eliminate syphilis testing, and it seems unlikely the resources will be found to do a study of the required size.

Lyme Disease

Borrelia burgdorferi is the spirochete that causes Lyme disease, the most frequent tick-borne infection in North America and Europe. The agent was discovered in 1977 during investigations of an arthritis cluster in Connecticut children. Cases reported in the United States doubled between 1992 and 2006 to almost 20,000. Geographic distribution of cases is highly focused, with the majority of reported

SPIROCHETE INFECTIONS

Syphilis

US blood banks first screened donors with a serologic test for syphilis in 1938, and screening has been a regulatory requirement since 1958. It was the first test mandated for US donors and stood alone before

cases occurring in 10 northeast and north central states. *Ixodes scapularis*, the black-legged tick, transmits *B. burgdorferi* in those areas, and *Ixodes pacificus*, the western black-legged tick, transmits the infection along the Pacific coast. The ticks feed predominantly in late spring and early summer during the nymph stage. Emergence has been associated with environmental changes that increase deer and rodent reservoir populations and changing residential patterns putting humans in more intimate contact with the tick vectors. Rodents are the reservoir. Although deer are not infected, they transport and maintain the ticks. Birds may also play a role in transporting the vector ticks.

The characteristic erythema chronicum migrans (“bull’s-eye”) rash is present in 70% to 80% of cases within 30 days of infection. The wide variety of clinical findings includes malaise, fatigue, headache, myalgias, large joint arthralgias and arthritis, and neurologic and cardiac signs and symptoms. These may not immediately suggest Lyme disease in the absence of a typical rash or known tick exposure. Serologic testing supports the clinical diagnosis. Unfortunately, poor specificity is recognized with many screening methods, and a two-step approach using a sensitive EIA or immunofluorescence assay (IFA) followed by a confirmatory, more specific, immunoblot is recommended by the CDC.

B. burgdorferi spirochetemia occurs in 44% of patients with clinical Lyme disease and peaks 7 to 10 days after tick bite. The spirochete can survive in red cells, platelets, and frozen plasma for at least the duration of their routine storage. Transfusion transmission of *B. burgdorferi* has been demonstrated in a murine model. Despite these observations, no human transfusion-associated cases have been reported. This may reflect the relatively short spirochetemic phase and low levels of organisms, as well as deferral of donors with non-specific illness or signs and symptoms of Lyme borreliosis. Although there are no official standards or guidance, it would be prudent for individuals with a history of Lyme disease to be deferred until well and treatment has been completed.

Other Tick-Borne Bacteria

The rickettsia that cause human monocytic ehrlichiosis (HME) and human granulocytic anaplasmosis (HGA; formerly human granulocytic ehrlichiosis) are intracellular bacteria that survive in stored blood. *Ehrlichia chaffeensis* causes HME and is transmitted to humans by Lone Star tick (*Amblyomma americanum*) bites. Most cases occur in the south central and southeastern United States. *Anaplasma phagocytophilum* causes HGA and occurs predominantly in the northeastern and upper midwestern areas of the United States. *I. scapularis* and *I. pacificus* (the Lyme borreliosis vector) transmit the organism. Signs and symptoms include fever, chills, and headache, often associated with thrombocytopenia, leukopenia, and increased liver enzyme levels. Intracellular aggregates of microcolonies of bacteria referred to as morulae appear in monocytes in the HME, and inclusions appear in granulocytes in HGA. Seroprevalence studies in blood donors in Wisconsin and Connecticut report 0.5% to 3.5% seropositivity for *A. phagocytophilum* antibodies. At least nine cases of transfusion-transmitted HGA from asymptomatic donors have been recognized after nonleukoreduced RBC transfusion; however, cases have occurred as well following leukoreduction including one from apheresis platelets.⁶⁵ Both *Ehrlichia* and *Anaplasma* spp. are white blood cell-associated, and it has been suggested that leukoreduction may mitigate their impact. The infectivity of *Orientia tsutsugamushi*, the rickettsial agent of scrub typhus, is reduced by up to 10⁵ by filtration leukoreduction, but infectious *E. chaffeensis* survived in refrigerated red cells and could be isolated from the packed RBCs after filtration.

In a study of heavily tick-exposed military recruits in Arkansas, which included a look back to 10 blood recipients of units from soldiers infected with *E. chaffeensis* and *Rickettsia rickettsii* (the agent of Rocky Mountain spotted fever [RMSF]), no clinical illness occurred in recipients. One possible RMSF seroconversion was reported. There is a single case report of transfusion-associated RMSF

that involved a donor developing symptoms 3 days postdonation. The recipient developed symptoms 6 days posttransfusion.

PARASITIC INFECTIONS

Malaria

Five *Plasmodium* species (*Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium knowlesi*) and occasionally others cause the protozoan disease malaria. In 2008 243 million cases occurred worldwide, with most in sub-Saharan Africa. Other endemic areas include parts of Asia and South America and more limited areas in Mexico, Central America, and the Caribbean. Of 1478 imported cases in the United States in 2009, 735 were acquired in Africa, 142 in Asia/Western Pacific, and 103 in the Americas.⁶⁶ West Africa accounted for most cases associated with Africa, and Honduras, Haiti, and Guyana for most of the cases from the Americas. During 2009 only two cases were acquired in Mexico, both *P. vivax*. In 2003 eight autochthonous infections occurred in Palm Beach, Florida; but none subsequently. Vectorial transmission, overwhelmingly the most common route, is by the bite of an infected female *Anopheles* mosquito. *Anopheles* mosquitoes generally feed between dusk and dawn, thereby limiting the risk to tourists who usually visit malaria areas during daylight hours. Almost three-quarters of those who acquired malaria were visiting friends or relatives in endemic areas. Missionaries and business travelers represent fewer than 20% of infected US citizens. Leisure travelers make up the small remainder.

P. falciparum accounts for 40% to 46% of US cases detected recently, *P. vivax* 11% to 20%, and *P. malariae* and *P. ovale* approximately 2% each. For the remainder, most are undetermined with a few mixed-species infections. *P. knowlesi* has not yet been reported.

Seventy percent of imported cases in the United States occur among returning travelers who were visiting friends or relatives, ethnically and racially distinct from the majority population of the United States (where malaria is not endemic), who return to their homelands (countries where malaria is endemic) to visit friends or relatives. The region of origin is very relevant to measures designed to prevent malaria transmission by transfusion because many of these individuals are semiimmune and therefore can be parasitemic while asymptomatic. In contrast, donors without malarial immunity who travel to endemic areas and become infected are nearly always symptomatic when they are parasitemic and would not be accepted as blood donors. Malaria symptoms occurred within 1 month of arrival in the United States in 84% of those infected with *P. falciparum* and 56% of those with *P. vivax* in 2009. The latter represents almost all cases of relapsing malaria. No acute onsets involving the four most frequent *Plasmodium* species occurred at an interval greater than 1 year.

One hundred transfusion cases have been recognized and reported in the United States since 1963. Since 1999 there have been 19 (0 to 3 per year) including one in 2007, none in 2008, two in 2009 and one each in 2010 and 2011; from 2012–2015, no cases have yet to be reported. In the majority of the 100, the case would have been prevented had the extant donor deferral criteria been appropriately applied.

The incubation period for transfusion-associated malaria ranges from 8 to 90 days. *P. falciparum* has the shortest time, mean 17 days (range, 8 to 36 days) and *P. malariae* the longest, mean 50 days (range, 8 to 90 days). Most cases involved RBC or whole-blood transfusion, although a few transmissions from platelet transfusions have occurred, presumably related to RBC contamination. Transmission from frozen plasma has not been reported.

Current strategies for reducing the low risk for transfusion transmission in the United States involve deferral of residents of nonendemic areas who have traveled to malaria-endemic regions during the previous 12 months, those with residence in endemic areas for 3 years since their last potential exposure in such regions, and those with a history of malaria for 3 years after resolution. Apart from incomplete

elicitation of malaria risk history, residual risk remains because transfusion transmissions of *P. falciparum*, *P. vivax*, and *P. ovale* have been reported 13, 27, and 7 years, respectively, after departure from malarious areas. Because *P. malariae* infection can persist for more than 70 years without symptoms, elimination of transfusion-induced malaria is a practical impossibility. At this time, licensed in vitro screening for at-risk donors using antibody tests, antigen detection, or NAT are unavailable in the United States. It is not clear that the limited commercial potential of assays to be used on a relatively small fraction of donors will justify the investment required to pass the stringent regulatory requirements of a blood donor screening assay. Donor deferral guidelines have been modified in 2014 to reduce the loss of more than 60,000 potential donors with travel to areas of Mexico where the malaria risk is minimal.⁶⁷

Babesiosis

Babesia species that infect humans include *Babesia microti*, *Babesia duncani* (previously WA1 type), *Babesia divergens* (limited primarily to Europe), *B. divergens*-like (MO1 and EU1), and *Babesia venatorum*. *B. microti*, an intraerythrocytic protozoan, causes most human infections. The white-footed mouse, *Peromyscus leucopus*, serves as the reservoir and the deer or black-legged tick, *I. scapularis* (also the vector of Lyme borreliosis and HGA), as the vector. Transmission follows bites from infected ticks, primarily nymphs, from May through early September. The defined transmission period has less relevance for transfusion transmission because asymptomatic blood donors can be infected chronically.⁶⁸ Most cases occur in Massachusetts and its coastal islands, Rhode Island, Connecticut, New York, New Jersey, Wisconsin, and Minnesota; these states are considered the seven endemic states. This geographic range has expanded recently, attributed to expansion of white-tailed deer, *Odocoileus virginianus*, populations. Although not a competent host, deer provide a blood meal and transportation for adult ticks to new areas.

The vast majority of both vectorial and transfusion-associated *Babesia* cases involve *B. microti*. *B. duncani* infections include those previously designated WA1. *B. divergens* cases occur predominantly in Europe. The incubation period varies from 1 to 9 weeks. The severity of illness associated with *Babesia* infections relates more to the infected individual's immune status than the *Babesia* species. The very young, older adults, persons who have had a splenectomy, and those with hereditary hemolytic disorders are at greatest risk for morbidity and mortality. Approximately one-third of infected subjects remain asymptomatic, and parasitemia may persist for more than 2 years. Typical symptoms resemble malaria and include fever, headache, chills, sweats, and arthralgia, myalgia, malaise, nausea, diarrhea, and hemolytic anemia. Parasitemia levels vary from 1% to 2% in otherwise healthy hosts to 85% in immunocompromised and asplenic patients. Case fatality rates approximate 5%.

Case reports of transfusion-associated *Babesia* infections include red cell units stored for up to 42 days. *Babesia* transmission has been reported following transfusion of cryopreserved red cells, and four cases involve whole blood-derived platelet transfusions presumably contaminated with red cells. At least 159 transfusion-associated *B. microti* cases have occurred, primarily in endemic regions, but cases in nonendemic states reflect the interstate movement of both blood components and blood donors and highlight the high index of suspicion required to recognize cases.⁶⁹ More than three-quarters of the reports occurred during the past decade. The all-cause mortality rate approaches 19%. *Babesia* represented the highest number of reported transfusion-related fatalities to the FDA from any single microbial infection in the periods of 2008–2012 and again in 2010–2014 including 8 of 21 (38%) and 4 of 15 (27%), respectively. The total number of transfusion-related fatalities in these periods was 198 and 176, respectively (www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/ReportaProblem/TransfusionDonationFatalities/). There are three reports of transfusion-transmission involving *B. duncani*, and single cases have been reported from Japan (*B. microti*-like) and Germany.

Babesiosis has been made a nationally notifiable infection in 2011 and included in the nascent biovigilance network of the National Healthcare Safety Network, so more accurate measurements of transfusion risk may become available in the future. In 2011–2013 up to 29 states reported a total of 3857 cases nationally of which 95% occurred in seven states in New England and the upper Midwest and increased to 98.5% in nine states (adding New Hampshire and Maine) (<http://www.cdc.gov/mmwr/preview/mmwrhtml/mm6127a2.htm>). Transfusion-transmission risk estimates in endemic states have occurred with the advent of investigational testing and are about 1 per 18,000 red cell units transfused in the highly endemic states of New England to an overall risk of approximately 1 per 100,000 units throughout the all nine endemic states mentioned (including New Hampshire and Maine, where an increasing number of transfusion-related cases have been reported).

Febrile patients must be queried for a transfusion history and babesiosis considered when transfusion has occurred. Diagnostic laboratory evaluation includes blood smear examination, which requires differentiation of *Babesia* sp. from *Plasmodium* infections. Tetrad or “Maltese cross” forms are diagnostic for *Babesia* but occur infrequently. Diagnostic testing most frequently involves indirect IFA testing for identifying persons with low-level parasitemia such as patients with chronic infections but remains positive for up to 5 years after resolution or cure of babesiosis. PCR testing is more sensitive for detecting acute infections before seroconversion.

In the absence of an FDA-licensed test, mitigation of transfusion transmission involves deferral of potential donors with a history of *Babesia* infection. Questioning donors about tick exposure or tick bite has no predictive value as a donor-screening question. Investigational testing most widely uses IFA and PCR to screen donations. One US blood center's screening program screens red cell units intended for immunosuppressed patients considered at highest risk for *Babesia* infection complications such as neonates, pediatric patients with sickle cell disease, and pediatric oncology patients. However, when cases of transfusion-transmitted babesiosis are carefully studied, such groups only represent about half of those who have developed transfusion-transmitted babesiosis. The same investigational assays (IFA and PCR) are being used together by another system in highly endemic regions for screening of red cells units. Retrospective studies have demonstrated the feasibility and suitable performance characteristics of the combination of these tests, yielding a combined specificity of 99.8%⁷⁰ and demonstrating an absence of transfusion transmission by screened units. Donor prevalence in endemic areas is 0.3%. Currently this program only screens enough units to supply those hospitals requesting babesia-screened blood. An attractive alternative to testing is the eventual development of red cell or whole blood pathogen-reduction technologies.

Leishmaniasis

Phlebotomine (Old World) and *Lutzomyia* (New World) sand-fly bites transmit *Leishmania* infections to humans in most of the tropical and subtropical world. *Trypanosomatidae* of various species cause visceral infection also known as kala-azar (*L. donovani*, *L. infantum*, and others). Additional species are involved in cutaneous and mucocutaneous infections (*L. tropica*, *L. major*, *L. mexicana*, *L. braziliensis*, and others given a variety of local names). In addition, transplacental, sexual, and transfusion transmissions occur.⁷¹ The promastigote form of the parasite resides in the gastrointestinal tract of sand flies and is inoculated into humans through a skin bite. In humans, promastigotes are phagocytosed by monocytes, where they transform into amastigotes that reproduce and reside in macrophages and the reticuloendothelial system. Organisms in monocytes and free amastigotes are released during refrigerated storage, transform back into extracellular promastigotes, and mediate transfusion transmission. *L. tropica* also survives in monocytes contained in frozen red cell preparations and in platelet concentrates stored at room temperature. At least 10 cases of transfusion-associated leishmaniasis attributed to *L. donovani* have been reported in endemic areas, mostly in young children or

neonates. A probable case of platelet transfusion–transmitted *L. donovani* was reported in India. A presumed case of transfusion-transmitted *L. mexicana* in a renal transplant recipient was mistakenly diagnosed as Chagas disease because of serologic cross-reactivity between *Trypanosoma cruzi* and *Leishmania*. *L. infantum* DNA was amplified from 6% of peripheral blood mononuclear cells of blood donors with *Leishmania* antibodies in the Balearic Islands. Several animal model studies also demonstrate transmission by blood transfusion.

Asymptomatic infections occur frequently in healthy donors exposed in endemic areas, and the organisms may circulate in peripheral blood more than 1 year following exposure. Foxhounds infected with *Leishmania* species have been found in 18 US states and two Canadian provinces, but transmission has not extended to humans.

Following reports of *L. tropica*–related viscerotropic leishmaniasis in veterans of Operation Desert Storm, between August 1990 and December 1992, those serving in that theater of operations were deferred from blood donation for 1 year. The deferral period reflected the development of fever, malaise, abdominal pain, and intermittent diarrhea up to 7 months after return to the United States. *L. tropica* was found in the bone marrow of seven patients and in the lymph nodes in one. When intracellular amastigotes were seen in the peripheral blood of the one patient in whom this was studied following reports of cutaneous and visceral leishmaniasis among troops involved in the Afghanistan and Iraq wars, a similar 1-year deferral following departure from Iraq and Afghanistan was implemented. The military continues to enforce lifetime deferral for any clinical history of *Leishmania* infection.

The possibility of transmission to humans during military deployment and travel and the large number of military personnel returning from Iraq and Afghanistan raise concerns about future transfusion transmission. To date, there are no cases of transfusion-transmitted leishmaniasis in the United States. The widespread use of leukoreduction filters likely has a beneficial role because these filters reduce both intracellular and extracellular parasite concentrations by 3 to 4 logs.

Toxoplasmosis

Toxoplasmosis is caused by the obligate intracellular protozoan parasite *Toxoplasma gondii*, whose usual host is the domestic cat. The parasite is transmitted by exposure to cat feces, by eating raw or undercooked pork, goat, lamb, beef, or wild game, and congenitally. In the NHANES from 1999–2004, 24.8% of foreign-born US residents age 12 to 49 years of age, compared with 8.2% of US–born residents, had serologic evidence of infection; approximately 50% of those with antibody harbor parasites in tissue. Transfusion-associated disease has been described in immunocompromised patients receiving granulocyte concentrates from donors with chronic myelocytic leukemia who would not qualify as blood donors currently. One possible transfusion-related case involves a platelet transfusion. Red cells and frozen plasma transmission have not been reported.

Chagas Disease

The protozoan parasite *Trypanosoma cruzi* causes Chagas disease. The infection is widespread in Latin America; approximately 8 to 10 million people are affected. Humans become infected when bitten by *Trypanosoma cruzi*–infected insects of the *Reduviidae* family (triatomine, assassin, kissing, or chinch bugs). Congenital transmission from mother to fetus, organ transplantation, blood transfusion, and ingestion are recognized routes as well. Once infection occurs, low-level, intermittently detectable parasitemia usually persists for life. Treatment with benznidazole or nifurtimox can reduce the risk for chronic sequelae, but neither of these drugs is FDA approved and access to only one of these is through an IND with the CDC. Treatment is most effective during the acute stage of infection. At least 18 mammalian species in the United States serve as reservoirs, including armadillos, opossums, and raccoons, and vectors are present

in the lower two-thirds of the country, but autochthonous vector transmission is rare but has been increasingly reported especially in rural areas of Texas. CDC estimates at least 20 states have had isolation of the insect vector and 17 states with the mammalian reservoir. An estimated 300,000 people in the United States and Canada are estimated to be infected with *T. cruzi*; most are immigrants from Latin America. *T. cruzi* organisms remain viable in whole blood stored at refrigerator temperatures for 18 days, for longer than 8 months in citrated blood samples stored at room temperature, and following freezing and thawing. In South America, early data suggested that approximately 13% to 49% of recipients of fresh whole blood from parasitemic donors become infected. There has been concern that additional transfusion-associated Chagas disease cases will occur as immigration increases to the United States from Central and South America.

American trypanosomiasis, or Chagas disease, consists of an acute phase that varies from asymptomatic to manifestations that include fever, skin rash, and conjunctivitis with edema around the eyelids, lymphadenopathy, and hepatosplenomegaly. The acute phase usually resolves in 4 to 8 weeks unless severe myocarditis or meningoencephalitis intervenes. The latter is associated with fatal outcomes. Intracellular *T. cruzi* amastigotes remain in cardiac and skeletal muscle following the acute phase. Following an indeterminate stage of undetermined duration, chronic disease occurs in 20% to 30% of infected patients, manifesting as cardiac disease (initially conduction and left ventricular wall abnormalities), megacolon, or achalasia. Diagnosis is made on clinical and serologic grounds most often. Xenodiagnosis, hemoculture, and nucleic acid amplification tests are also available.

Risk factors for transfusion-transmitted *T. cruzi* infection include birth or residence in endemic regions such as Central America, South America, or Southeastern Mexico; living in dwellings with palm leaf–thatched roofs or mud walls, where vector insects reside; oral intake of contaminated foodstuffs; and receipt of unscreened blood transfusions in Latin America. Among donors who lived in poor housing or received a blood transfusion in endemic areas, 3% to 4% had *T. cruzi* antibodies. One study, conducted in California in the 1990s, found that 1 per 340 blood donors had a risk factor for Chagas disease. A large survey conducted from 1994 to 1998 in Los Angeles and Miami among immigrant blood donors from endemic areas found *T. cruzi* seroprevalence rates of 1 per 7500 and 1 per 9000, respectively. However, none of the 18 recipients in this survey who received blood from a seropositive donor, and who were available for testing, had evidence of infection.

A look-back study involving blood donations in Mexico made before determining the donors were *T. cruzi*–seropositive, found four of nine recipients of subsequently determined seropositive whole blood or platelets to be seropositive.

Since 1987, 30 years before testing started in the United States and Canada, seven cases of transfusion-associated Chagas disease were reported in those countries; symptoms developed 2 to 3 months after transfusion. In six cases, platelets were the implicated component; and the unit in the seventh case was not identified. In each of the six cases, the implicated donor emigrated from a *T. cruzi*–endemic region (Bolivia, Mexico, Paraguay, and Chile) between 16 and 33 years before the implicated donation. *T. cruzi* may separate with platelets, or room-temperature storage may favor parasite survival. In addition, acute Chagas disease has been reported in organ transplant recipients. More recently, two transfusion-related infections were identified in the United States as a result of recipient tracing (look-back) studies (but these represented fewer than 1% of all studied individuals exposed to transfusion of blood from infected donors; see later). Additional transfusion-associated cases have been reported from Spain, all derived from donors who had emigrated from South America for a total of 20 cases ever documented when combining all reported transfusion-associated cases from the United States, Canada and Spain, the countries with the highest immigration rates from Latin America.⁷²

The assumed increasing prevalence of *T. cruzi*–infected blood donors with immigration into the United States from Latin America,

the reports of transfusion-associated cases, and some autochthonous infections triggered efforts to mitigate the risk for transfusion-transmitted Chagas disease in the United States. Questioning donors about region of birth or extended stay and transfusion in Chagas-endemic areas could interdict 75% of infected donors but would result in deferral of large numbers of noninfected donors. Leukoreduction decreases *T. cruzi* transmission in a mouse model by 50% to 70%, consistent with *Leishmania* and the rickettsia *Anaplasma*. Pathogen-reduction techniques successfully decrease *T. cruzi* viability in plasma and cellular products.

Serologic screening, used for many years in Latin America, was chosen as the preferred strategy for the United States. The first serologic test for screening blood donors, based on a *T. cruzi* whole-parasite lysate, achieved FDA licensure in December 2006, and voluntary screening commenced in early 2007. Approximately 1 per 30,000 donations showed confirmed reactive serologic results, a lower prevalence than estimated. In 2010 the FDA licensed a second assay that uses chimeric recombinant antigens and in 2011, a licensed supplemental test using the same antigen constructs was FDA licensed. Seropositive donors are overwhelmingly immigrants from *T. cruzi*-endemic countries with asymptomatic chronic infections, although a small number of seropositive donors may have acquired the infection in the United States via vertical transmission from infected immigrant mothers, or very rarely by autochthonous vectorial transmission. From the investigation of antibody-positive donors lacking any immigration or maternal risk factors, autochthonous transmission has been estimated to occur at the rate of 1 per 354,000 donors.⁷³

Look-back studies involving recipients of prior donations from those found positive for *T. cruzi* antibodies on a subsequent donation showed rates of transfusion transmission much lower than predicted. Only two occurred (0.8%), both from the same apheresis platelet donor born in Argentina, among 253 recipients tested. In light of these findings, testing donors is now required only once rather than at each donation.⁷⁴ Concern that those tested once might contract *T. cruzi* during travel or within the United States seems unfounded in that no seroconversions have been observed in more than 4 million blood donors during 6 million person-years of follow up. The unexpectedly low rate of transmission may relate to differences in blood component processing and storage in the United States compared with Latin America (absence of the transfusion of fresh whole blood), some underrepresentation of platelet donors in the look backs completed to date, or other biases. Although all donors are asked a question about having a history of Chagas disease, with the advent of sensitive testing, the question has no residual value and has been removed from the donor history questionnaire according to FDA rules.⁷⁵

TRANSMISSIBLE SPONGIFORM ENCEPHALOPATHIES

The transmissible TSEs (prion diseases) are rare, lethal neurodegenerative diseases generally accepted to be caused by nucleic acid-free proteins called PrP^{TSE}, as distinguished from the normal cellular protein, PrP^C. The existence of additional factors has not been excluded, but current consensus supports the involvement of infectious proteins. PrP^{TSE} is an abnormal conformation of PrP^C that induces transformation (recruitment) of additional PrP^C to PrP^{TSE}, resulting in deposits of insoluble aggregates in central nervous system tissue followed by progressive dementia and other characteristic neurologic findings. Classic Creutzfeldt-Jakob disease (CJD) is diagnosed at a rate of approximately one case per million population per year worldwide. It occurs as sporadic CJD, vertically transmitted familial diseases caused by germline mutations in the human *PRNP* gene (e.g., fatal familial insomnia and Gerstmann-Sträussler-Scheinker syndrome), iatrogenically transmitted infection (e.g., from dura mater implantation, contaminated surgical equipment, injection of human pituitary-derived growth hormone, or corneal transplant) and can be spread horizontally (Kuru associated with consumption of human brain during ritual cannibalism is of historical interest).

There are no documented cases of transfusion transmission of sporadic CJD, the familial or iatrogenic forms, and cohort studies of intensively transfused patient groups have failed to establish any epidemiologic association in both the United Kingdom and the United States.^{22,76} In an ongoing look-back effort, no cases of CJD have been observed among 461 recipients (of whom 85 were still alive as of December 31, 2008) of blood components from 40 donors subsequently diagnosed with CJD. A case-control study of CJD patients, compared with control patients with CJD ruled out, found a fivefold increased risk for CJD with a history of transfusion more than 10 years before TSE onset, but the authors recognized critical sources of bias in their methods and their findings are unconfirmed. Nevertheless, as a result of the iatrogenic transmissions and long incubation period of the disease (as demonstrated in growth hormone transmissions), concern arose in the mid-1990s that CJD transmission could occur from asymptomatic donors to transfusion or derivative recipients. This theoretical risk resulted in lifetime donor deferral requirements for iatrogenic exposure to or a family history of classic CJD.

Like classic CJD, vCJD is a fatal, degenerative neurologic disease. It occurs in younger patients than classic CJD and has distinctive clinical, radiographic, histopathologic, and biochemical features. The first reports of vCJD from the United Kingdom were published in 1996. The etiologic agent is the same prion that causes BSE or “mad cow disease.” Transmission of the BSE prion to humans occurred by consumption of beef and other bovine products containing infectious neural or reticuloendothelial tissue. In the United Kingdom the vCJD epidemic followed a massive epidemic of BSE in the 1980s and 1990s. The latter was traced to the recycling of material from dead sheep and cattle (offal) into feed for cattle. This practice was banned in 1988, and the vCJD outbreak subsided after a peak of 28 cases in 2000. The number of new vCJD diagnoses in the United Kingdom rose steadily in the first few years after 1995 from 3 in 1995 to 28 in 2000, but decreased since then to 5, 5, 5, 1, 3, 3, and 2 from 2005 to July 2011, by which time 175 (172 deaths, 3 living) definite or probable cases of vCJD had been reported in the United Kingdom. An additional 49 cases have been diagnosed elsewhere, mostly in France and several other European countries. A few cases have been identified outside Europe, including 3 cases in the United States (2 associated with exposure in the United Kingdom and 1 in Saudi Arabia), 2 from Canada, and 1 each from Japan, Taiwan, and Saudi Arabia. Most but not all of the patients with non-European cases had more than 6 months’ exposure in the United Kingdom during the BSE epidemic. Although it appears that the vCJD outbreak is waning (and is much smaller than initially feared), concern persists that there could be a second wave of the epidemic caused by delayed onset of the disease in infected individuals. This is based in part on observations of abnormal prion protein accumulation in random surgical tissue samples in the United Kingdom, which may represent preclinical vCJD disease. In one retrospective study, 3 of 12,674 appendectomy and tonsillectomy specimens from persons 20 to 29 years of age were positive. Furthermore, a critical polymorphism at codon 129 of the PrP^C gene coding for methionine or valine leads to variation in the susceptibility to and incubation period of human TSEs. All of the clinical cases reported to date are methionine homozygotes. Because only 37% of the general British population is homozygous for methionine, and are maximally susceptible to vCJD, a larger population (52%) of heterozygotes and valine homozygotes (11%) may be at risk for asymptomatic infection in a prolonged incubation period.

Four transfusion-transmitted infections with the vCJD prion have been reported in the United Kingdom. Although they may have developed vCJD independent of transfusion, this possibility is regarded highly unlikely based on epidemiologic and statistic considerations. Three of the four cases were diagnosed with clinical vCJD 6.5, 7.8, and 9 years after receiving nonleukocyte reduced RBCs or a blood component from two different donors who developed clinical symptoms of vCJD 40 and 21 months after donating. These three with symptomatic disease were homozygous for methionine at codon 129. The fourth case was heterozygous (methionine/valine) and had

no clinical signs or symptoms of vCJD at death from unrelated causes, but had abnormal prion protein aggregates in lymphoid (but not neural) tissues at autopsy and was considered to have preclinical infection. Five years before death the recipient received nonleukocyte reduced RBCs from a donor who developed clinical vCJD 18 months after donating. These four cases represent 6% of the 67 UK recipients who received blood components from 18 different donors subsequently diagnosed with vCJD (and an estimated 23% of exposed methionine homozygotes). In light of these cases and animal transfusion experiments, TSE transmission and disease from transfusion is no longer regarded as a theoretical event.²² A single case reports a potential epidemiologic link between exposure to plasma derivatives and transmission of the agent to a recipient.

Prion-removal strategies (e.g., affinity filters) remain under evaluation, especially in the United Kingdom, but none is expected to be suitable for consideration for use in the United States in the immediate future. There are currently no blood donor-screening tests for vCJD, leaving risk mitigation dependent on removal of donors that could have asymptomatic infection. Initially, primarily on the basis of the prominent distribution of vCJD prion in reticuloendothelial tissue compared with classic prion protein (PrP^C), on subsequent reports of animal and human infection by transfusion, and then on the early observation that nearly all cases of vCJD were associated with potential exposure in the United Kingdom or to UK bovine products, the FDA adopted and has modified donor-deferral policies sequentially since 1999.⁷⁷ The first called for indefinite deferral of donors who had spent more than 6 months in the United Kingdom from 1980 to 1996, before control of the food chain and of recipients of bovine insulin from the UK. Models predicted that this would remove approximately 90% of the risk at a “cost” of deferring approximately 5% of otherwise eligible donors. These were subsequently expanded to include US military personnel and their dependents who spent certain durations on bases in the European Union where UK beef was imported during the BSE epidemic and recipients of transfusions in the United Kingdom and France during the peak risk periods of their BSE epidemics. Experience at US blood centers has largely confirmed the donor loss predictions of the FDA models.

Chronic wasting disease (CWD) of deer and elk is prevalent at rates as high as 15% in cervid populations in multiple areas of the United States and Canada. Concern has been expressed that, given the popularity of hunting, there may be risk for exposure to and infection with the CWD prion during handling or consumption of infected animals. Apparent clusters of classic CJD in hunters have been alleged, but on full evaluation have not been shown to have a relationship to the CWD agent. There is currently no plan to intervene for this theoretical risk in hunters who donate blood beyond hygienic measures when handling cervids or their tissues.

FUTURE DIRECTIONS

The residual risk for transmitting HIV, HBV, and HCV is less than 1 per million units transfused, an extremely low rate. In contrast, platelet septic events are reported at a frequency of 1 per 100,000 units. Transmission of known, emerging infectious agents such as dengue, Zika virus, *B. microti*, and those currently unrecognized remain problematic. Continued safety of the blood supply requires constant vigilance, early detection, reporting of untoward events, and excellent communication and cooperation between those providing blood components and those prescribing them.

PEDIATRIC TRANSFUSION MEDICINE

Cassandra D. Josephson and Steven R. Sloan

A variety of neonatal and pediatric patients require blood component transfusions. This chapter focuses on aspects of blood-bank laboratory testing, blood products and components, transfusion indications, and potential adverse events that are specifically relevant to neonates and children.

PEDIATRIC BLOOD BANKING

Blood and Blood Components

Several different blood components, including whole blood, reconstituted whole blood, red blood cells (RBCs), platelets, plasma, and cryoprecipitated antihemophilic factor (CRYO) may be available from a blood bank for transfusion. Recently, additional components have become available in the United States. They are photochemically-treated INTERCEPT platelets and plasma, and solvent detergent-treated plasma, Octaplas. The availability of specific component types varies between blood suppliers.

- Whole blood is infrequently used and may not be available from a particular blood bank or blood supplier, but it may be available on request and is used by some pediatric cardiac surgery services. Whole blood contains all RBCs, plasma, platelets, and an anticoagulant preservative solution containing citrate, phosphate, dextrose, and possibly adenine.
- RBC units mostly contain RBCs but also contain some plasma and a preservative solution. Most RBC units contain an additive preservative solution that includes some combination of adenine, dextrose, and mannitol. Additive solutions are safe for relatively small (≤ 20 mL/kg) transfusions. There are concerns over the safety of these additives given in large transfusions to neonates, and their safety in this setting has never been proven in a randomized clinical trial. In view of this concern, some hospital blood banks provide nonadditive RBC units or wash additive units intended for large transfusions to neonates. Because many blood centers provide only additive RBC units to hospital blood banks and washing an RBC unit takes approximately 1 hour, blood banks have been unable to supply RBC units without additives in many situations. Thus many institutions now have significant experience transfusing large volumes of additive RBC units to neonates and have not noticed any problems.
- Two general types of platelet units are available in the United States, although any one blood bank or hospital may stock only one of these types. These two types, whole blood–derived platelets (platelets) and platelets collected by apheresis (pheresis platelets), differ in their size. A platelet unit contains approximately 5.5 to 10×10^{10} platelets in about 50 mL, whereas a pheresis platelet unit contains at least 3×10^{11} platelets in about 200 mL. It is often easier to use platelet units for small children because pheresis platelets usually need to be aliquoted to provide the correct dose. However, many blood centers exclusively provide only one type of platelet component. Recently, two modifications of platelet components were approved in the United States, although these had been in use in other countries for several years.
 - Platelets that have undergone pathogen inactivation using the INTERCEPT Blood System (Cerus Corporation, Concord, CA) which mixes amotosalen HCl, a synthetic psoralen compound that intercalates with nucleic acid and, on activation with ultraviolet (UV) light, cross-links pathogen and white blood cell DNA, inhibiting replication.¹ Almost all of the amotosalen, a potential carcinogen, is removed during processing. However, INTERCEPT platelets are contraindicated for neonatal patients treated with phototherapy devices emitting wavelengths <425 nm due to potential erythema from interaction between UV light and amotosalen.
 - Platelets stored in a Platelet Additive Solution (PAS). PAS platelets contain very little plasma, which reduces the risk of allergic reactions and transfusion-related acute lung injury (TRALI), but also lowers the dose of coagulation factors contained in the platelet component.
- Plasma is frozen to retain functional plasma proteins including clotting factors. Depending on the timing of freezing and thawing, the component may be called fresh frozen plasma (FFP) or another name. However, all of these plasma components contain all the necessary clotting factors. Two pathogen-inactivated plasma products, that had been available in several countries, are now available in the United States:
 - INTERCEPT (Cerus Corporation, Concord, CA) treated plasma using the same system as described above.
 - Octaplas (Octapharma, Hoboken, NJ) is a filtered pooled plasma product that is subjected to solvent/detergent treatment to inactivate lipid-enveloped viruses.² Its safety and efficacy in pediatric patients has not been evaluated which would be important in neonates whose coagulation system regulation differs from adults. Specifically, Octaplas contains low concentrations of protein S and α_2 -antiplasmin, two inhibitors of the coagulation system that are present in low concentrations in neonates.^{3,4}
- Cryoprecipitate is prepared from plasma and contains high concentrations of fibrinogen.
- Because pediatric patients require smaller doses of blood components, they often require only a portion of a component.
- RBCs are stored refrigerated and hence can be prepared in aliquots as needed if the blood bank has the necessary equipment. Alternatively the blood center can collect RBC units into a collection system in which additional bags are attached for dispensing aliquots. Whole blood is also stored refrigerated, but its use is very limited and it is almost never prepared in aliquots.
- All platelet components are stored at room temperature under constant agitation and can be prepared in aliquots when needed in the blood bank if the blood bank has the necessary equipment and supplies. However, 1 unit of whole blood–derived platelets does not contain many doses, even for infants, and most blood banks do not aliquot them.
- All plasma products are stored frozen, and are not generally aliquoted after thawing. However, many blood centers will prepare plasma aliquots before freezing.
- Because even small infants rarely require less than 1 unit of cryoprecipitate, this component is rarely prepared in aliquots.

Directed Donations

Families often prefer to donate blood for their children using a process known as directed donations, and some blood banks

permit this. If this is done without medical reason, it offers no benefit and there are potential risks. Although directed donors need to go through the same screening and infectious disease testing process as all allogeneic blood donors, some studies suggest that directed donors have a slightly higher risk for infectious disease transmission.

In addition, directed donors may be a poor choice for immunologic reasons. For example, if a neonate has alloimmune thrombocytopenia or anemia, the pathologic antibody is a passively acquired maternal antibody directed against inherited paternal antigens. In this case, blood donated by the father would be recognized by the antibody in the baby's circulation and cleared just as the neonate's own platelets or erythrocytes are cleared. Another example in which immune concerns make directed donors a poor choice involves transplants. Some patients may require a future tissue or bone marrow transplant, and blood relatives often serve as the best donors for such transplants. However, prior transfusions from relatives may sensitize the patient's immune system to antigens present on the tissues of blood relatives, complicating those potential tissue or bone marrow transplants.

TECHNICAL CONSIDERATIONS/MECHANICAL DEVICES

Smaller pediatric patients require small transfusions administered at slow rates. Aliquots of components often need to be prepared. This can be performed by collecting blood into collection bags interconnected with sterile tubes or by attaching additional containers to a standard blood component by using a sterile docking device that produces a sterile weld between two separate tubing sets.

Blood components must be filtered to remove microaggregates before transfusion. For an adult patient, this is normally accomplished by transfusing the component through a filter contained within the blood administration set. These standard blood administration sets are not ideal for transfusing small patients because 20 to 40 mL of the component is lost in the dead space of the administration set. Pediatric microaggregate filters with much smaller dead space are available.

For nonbleeding patients, blood components are generally transfused at a rate of no more than 5 mL/kg/h. For infants, this corresponds to a lower rate than can be regulated by most standard infusion pumps. Hence these transfusions are usually performed using syringe pumps, with the blood component aliquot being transferred to a syringe for the transfusion. Often the blood bank prepares aliquots of a blood component through a pediatric microaggregate filter directly into a syringe, eliminating the need for bedside microaggregate filtration.

TRANSFUSION MEDICINE: GENERAL INDICATIONS AND DOSING

Indications for RBC Transfusion in Neonates, Children, and Adolescents

Neonates Less Than 4 Months Old

RBC transfusions are more commonly administered to hospitalized neonates than any other pediatric patient age-group, and RBCs are the component most often transfused in this population. Symptomatic anemia is the major indication for simple transfusion and an RBC transfusion should be considered when the venous hemoglobin is less than 13 g/dL in the first 24 hours of life or when a neonate has lost approximately 10% of his/her blood volume. A transfusion dose of 10–15 mL/kg of RBCs should yield an increase in the neonate of 2–3 g/dL of hemoglobin after transfusion.

Two randomized clinical trials of premature infants in neonatal intensive care units, examining restrictive versus liberal RBC transfusion practices, had conflicting results.^{5,6} Therefore most guidelines

TABLE 121.1

Guidelines for Transfusion of Red Blood Cells in Infants Less Than 4 Months of Age

1. Hematocrit <20% with low reticulocyte count and symptomatic anemia (tachycardia, tachypnea, poor feeding)
2. Hematocrit <30% and
 - a. On <35% oxygen hood, or
 - b. On oxygen by nasal cannula, or
 - c. On continuous positive airway pressure and/or intermittent mandatory ventilation on mechanical ventilation with mean airway pressure <6 cm of water, or
 - d. With significant tachycardia or tachypnea (heart rate >180 beats per minute for 24 hours or respiratory rate >80 breaths per minute for 24 hours)
 - e. With significant apnea or bradycardia (more than six episodes in 12 hours or two episodes in 24 hours requiring bag and mask ventilation while receiving therapeutic doses of methylxanthines), or
 - f. With slow weight gain (<10 g/day observed over 4 days while receiving >100 kcal/kg/day)
3. Hematocrit <35% and
 - a. On >35% oxygen hood, or
 - b. On continuous positive airway pressure/intermittent mandatory ventilation with mean airway pressure >6–8 cm of water
4. Hematocrit <45% and
 - a. On extracorporeal membrane oxygenation (ECMO), or
 - b. With congenital cyanotic heart disease

RBC, Red blood cell.

are based on experience rather than evidence-based medicine (Table 121.1). An ongoing study (<http://clinicaltrials.gov/01702805>) has the promise of providing definitive evidence to inform RBC transfusion practice in this population.⁷ One prospective randomized clinical trial found equivalent clinical outcomes in neonates transfused with fresh RBCs stored for less than 7 days as those transfused with standard-issue RBCs with a mean age of 14.6 days, although some have criticized the generalizability of the study results.^{8,9}

Older Infants, Children, and Adolescents

RBC transfusion indications for infants older than 4 months and for young children are similar to those of adults. However, there are several noteworthy differences between children and adults: total blood volume, ability to tolerate blood loss, and age-specific hemoglobin levels (Table 121.2). In infants, RBC transfusions are primarily given for surgical losses, anemia of chronic diseases, and malignancies. Infants inherently have lower hemoglobin levels than adults and remain asymptomatic at lower hemoglobin concentrations, especially if the anemia occurs gradually. Even with these physiologic differences, general transfusion-trigger guidelines for pediatric intensive care unit patients are similar to those for adults, with a transfusion trigger of 7 g/dL of hemoglobin for hemodynamically stable patients being shown to be safe for these patients.¹⁰ This threshold has also been found to be safe for hematopoietic progenitor cell (HPC) transplant patients.¹¹ The usual dose of RBCs is 10 to 15 mL/kg. There is no evidence that pediatric patients benefit from transfusion of RBCs of a particular age, although it is currently the subject of a multicenter study (<http://clinicaltrials.gov/01977547>).

Platelets

Platelet transfusion support in pediatric patients is usually intended as a prophylactic strategy to prevent bleeding (Table 121.3). The prophylactic platelet transfusion thresholds in premature infants are

TABLE 121.2 Guidelines for Transfusion of Red Blood Cells in Patients More Than 4 Months of Age

- Emergency surgical procedure in patient with significant postoperative anemia
- Preoperative anemia when other corrective therapy is not available
- Intraoperative blood loss $\geq 15\%$ total blood volume
- Hematocrit $< 24\%$
 - In perioperative period, with signs and symptoms of anemia
 - While on chemotherapy/radiotherapy
 - Chronic congenital or acquired symptomatic anemia
- Hematocrit $< 21\%$, hemodynamically stable patients > 3 days old in the pediatric intensive care unit
- Acute blood loss with hypovolemia not responsive to other therapy
- Hematocrit $< 40\%$ and
 - With severe pulmonary disease
 - On ECMO
- Sickle cell disease and
 - Cerebrovascular accident
 - Acute chest syndrome
 - Splenic sequestration
 - Aplastic crisis
 - Recurrent priapism
 - Preoperatively when general anesthesia is planned (target hemoglobin 10 mg/dL)
- Chronic transfusion programs for disorders of RBC production (e.g., β -thalassemia major and Diamond-Blackfan syndrome unresponsive to therapy)

ECMO, Extracorporeal membrane oxygenation; RBC, red blood cell.

TABLE 121.3 Guidelines for Transfusion of Platelets in Neonates and Older Children**Platelet Count $< 150,000/\mu\text{L}$**

- Platelet count 5000–10,000/ μL with failure of platelet production
- Platelet count $< 30,000/\mu\text{L}$ in neonate with failure of platelet production
- Platelet count $< 50,000/\mu\text{L}$ in stable premature infant
 - With active bleeding, or
 - Before an invasive procedure with failure of platelet production
- Platelet count $< 100,000/\mu\text{L}$ in sick premature infant
 - With active bleeding, or
 - Before an invasive procedure in patient with DIC

Without Thrombocytopenia

- Active bleeding with qualitative platelet defect
- Unexplained excessive bleeding during cardiopulmonary bypass
- Patient receiving ECMO with
 - Platelet count $< 100,000/\mu\text{L}$
 - Higher platelet counts and bleeding

Modified from Roseff SD, Luban NLC, Manno CS. Guidelines for assessing appropriateness of pediatric transfusion. *Transfusion* 42:1398, 2002 and Wong CC, Luban NLC: Intrauterine, neonatal, and pediatric transfusion. In: Mintz PD, editor: *Transfusion therapy: Clinical principles and practice*, ed 2. Bethesda, MD, 2005, AABB Press, p 159.

quite controversial and based primarily on expert consensus rather than evidence-based medicine. In sharp contrast to adults, who rarely develop spontaneous severe bleeding until their platelet counts fall below 10,000/ μL , preterm infants with other complicating illnesses may bleed at higher platelet counts. The increased risk may be secondary to (1) lower levels of plasma coagulation factors, (2) natural anticoagulants that potentiate thrombin inhibition, (3) intrinsic or extrinsic platelet dysfunction, and (4) increased vascular fragility. Platelet counts and function in older children are similar to those of

TABLE 121.4 Guidelines for Transfusion of Frozen Plasma and Cryoprecipitate in Neonates and Older Children**Frozen Plasma**

- Support during treatment of DIC
 - Replacement therapy
 - When specific factor concentrates are not available, including but not limited to, antithrombin, protein C or S deficiency, and factor II, factor V, factor X, and factor XI deficiencies
 - During therapeutic plasma exchange when FFP is indicated (cryoprecipitate-poor plasma, plasma from which the cryoprecipitate has been removed)
 - Reversal of warfarin in an emergency situation, such as before an invasive procedure with active bleeding
- Note: Frozen plasma is not indicated for volume expansion or enhancement of wound healing

Cryoprecipitate

- Hypofibrinogenemia or dysfibrinogenemia with active bleeding
- Hypofibrinogenemia or dysfibrinogenemia, undergoing an invasive procedure
- Factor XIII deficiency with active bleeding or undergoing an invasive procedure in the absence of factor XIII concentrate
- Limited directed-donor cryoprecipitate for bleeding episodes in small children with hemophilia A (when recombinant and plasma-derived factor VIII products are not available)
- In the preparation of fibrin sealant
- von Willebrand disease with active bleeding: Cryoprecipitate is used in von Willebrand disease only when both of the following are true:
 - 1-Deamino-8-D-arginine vasopressin is contraindicated, not available, or does not elicit response
 - Virus-inactivated plasma-derived factor VIII concentrate (which contains von Willebrand factor) is not available

DIC, Disseminated intravascular coagulation; FFP, fresh frozen plasma.

adults, and the indications for platelet transfusions do not differ from the indications for adults.

Frozen Plasma and Cryoprecipitate

Frozen plasma is used in preterm and term infants most commonly to treat multiple factor deficiencies or vitamin K deficiency, a condition that can occur in infants not prophylactically given vitamin K after birth, especially if the mother ingested certain drugs during pregnancy such as warfarin, cephalosporins, or some anticonvulsants (Table 121.4). Dosing for all pediatric patients is 10 to 15 mL/kg. This should result in an increase in all factor activity of 15% to 20% unless there is a marked consumptive coagulopathy. As mentioned previously, solvent detergent–treated plasma, Octaplas, may not be safe for neonates as it has low concentrations of protein S and α_2 -antiplasmin.

Cryoprecipitate is used primarily to treat disorders resulting from a decrease in or dysfunction of fibrinogen or factor XIII deficiency. These indications are similar to those for adults. Children should receive 1 to 2 units of CRYO/10 kg patient weight. One unit or less of cryoprecipitate is usually sufficient to achieve hemostatic levels in infants and premature infants. The expected rise in fibrinogen should be 60 to 100 mg/dL.

Granulocytes

Granulocytes, whose efficacy, especially at low doses, is unproven, may be indicated for neutropenic children with infections unresponsive to standard antimicrobial therapy.¹² In addition, children with granulocyte dysfunction (e.g., chronic granulomatous disease [CGD]) severe infections may also benefit from granulocyte transfusions.

However, patients with CGD are at significant risk for developing anti-HLA antibodies from granulocyte transfusions, which can render granulocyte transfusions ineffective and can complicate possible future hematopoietic cell transplants.¹³

TRANSFUSION MEDICINE: INDICATIONS IN UNIQUE PEDIATRIC POPULATIONS

Hemolytic Disease of the Fetus and Newborn

Hemolytic disease of the fetus and newborn (HDFN) occurs when the mother's immune system recognizes a foreign, paternally inherited antigen on fetal erythrocytes. The incidence of HDFN dramatically declined after the introduction of Rh immune globulin to prevent sensitization of the mother to RhD. Although introduction of Rh immune globulin has prevented most cases of HDFN due to RhD sensitization, it has not totally eliminated HDFN due to RhD or reduced HDFN due to other antibodies.

Most significant cases of HDFN are due to antibodies recognizing antigens other than ABO system antigens. These antibodies should be detected in the blood-bank antibody screen of the blood specimen of the pregnant or postpartum woman. Also necessary for diagnosis, the corresponding antigens would be present on fetal or newborn erythrocytes, or predicted to be present on fetal erythrocytes based on molecular testing of fetal DNA. The direct antiglobulin test (DAT) of the fetal or newborn's erythrocytes is usually positive, although it can be negative in transfused patients. Although antibody titers can be used to help predict the severity of the disease during pregnancy, they are generally not useful in the newborn. After birth, the severity of the anemia and the resulting hyperbilirubinemia serve as markers for the severity of HDFN. Rates of rise in bilirubin level are most helpful in determining whether an exchange transfusion will be necessary, with increases of 8 to 13 $\mu\text{mol/L/h}$ despite phototherapy indicating that exchange transfusion will likely be necessary.¹⁴

RBCs transfused in utero to the fetus need to be compatible with the ABO type of the fetus and mother and hence are usually blood group O. They need to lack the antigen(s) to which the mother has made antibodies, and they need to be crossmatch compatible with her serum. The RBCs should be irradiated to prevent transfusion-associated graft-versus-host disease (TA-GVHD), and cytomegalovirus (CMV) safe to minimize the risk for transfusion-transmitted CMV. Relatively fresh RBCs also are usually chosen for these transfusions.

Reconstituted whole blood is usually used for neonatal exchange transfusions. The blood is prepared by removing most of the preservative solution from an RBC unit and adding plasma, usually so that the final hematocrit is 40% to 45%.

Neonatal Alloimmune Thrombocytopenia

The pathophysiology of neonatal alloimmune thrombocytopenia (NAIT) is similar to that of HDFN in that both involve immune-mediated attack and destruction of fetal and neonatal blood cells by the mother's immune system. Unlike HDFN, NAIT often affects a woman's first pregnancy. In addition, the antigens involved are due to polymorphisms on platelet-specific proteins. Although a variety of antigens can be implicated, the human platelet antigen-1 (HPA-1) protein is most frequently implicated in whites, with approximately 70% to 80% of cases being due to women who lack the HPA-1a antigen making antibodies against HPA-1a that is expressed on fetal platelets.¹⁵ When NAIT is suspected, maternal serum can be tested for antibodies to platelet antigens, and the parent's or patient's platelet antigens can be determined by molecular means in which their platelet antigens are indirectly determined from their DNA. An affected infant or fetus may require platelet transfusions. Although random platelets may be of some transient benefit, antigen-negative units are best. Maternal platelets lack the antigen, but because the plasma contains the pathogenic antibody, the platelet unit should be

washed before transfusion. Alternatively, antigen-negative units may be available. Indeed, major blood centers usually have HPA-1a-negative units available.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) is an intervention in which whole blood is removed from the patient's venous circulation and circulated through a machine to remove carbon dioxide and replenish oxygen before being returned to the patient. This prolonged intervention is reserved for patients with more than 80% mortality risk and those who have been unresponsive to conventional ventilator support and medical treatment but still potentially can recover. In neonates and children, ECMO has become a lifesaving therapy in the treatment of multiple disorders; Table 121.5¹⁶ lists indications for ECMO support in neonates and children. Standardized guidelines for transfusion practice have not been established, resulting in individualized centers establishing their own criteria. In order to prevent thrombosis and platelet activation in the extracorporeal circuit which is comprised of extensive tubing, patients are anticoagulated, usually with heparin, resulting in a significant risk of bleeding.¹⁷ Bleeding during ECMO is a common complication and may be caused by any of the following factors necessary for operating the ECMO circuit or resulting from the thrombogenic surface of the circuit: (1) systemic heparinization, (2) platelet dysfunction, (3) thrombocytopenia, (4) other coagulation defects, and (5) nonendothelial cell surface lining the circuitry. It is recommended that hospital transfusion services and ECMO staff be in close communication to agree on local protocols to ensure safe, efficient, and consistent care (Table 121.6 provides an example protocol from one institution).¹⁶ Blood products for ECMO are typically ABO and Rh specific and crossmatch compatible for priming. The RBC units for priming circuits are typically relatively fresh, irradiated, and CMV seronegative and/or leukoreduced.

Trauma

Hemorrhagic shock requiring massive transfusion can occur in children. Prothrombin time (PT), activated partial thromboplastin time (aPTT), and platelet count abnormalities upon emergency room admission are strongly associated with mortality.¹⁸ Transfusion management of a pediatric trauma patient often must be guided by the patient's estimated blood loss and associated signs and symptoms, such as hypotension or tachycardia, and bleeding. A prospective study found that a ratio of 1:1:1 of RBC to plasma to platelet units transfused did not decrease overall mortality but decreased hemorrhagic deaths in trauma patients.¹⁹ The use of such a massive transfusion strategy has not been rigorously tested in pediatric patients.

TABLE 121.6 Blood Product Protocols for Extracorporeal Membrane Oxygenation

Clinical Scenario	Urgency	Products	Blood Groups	Storage
Cardiac arrest	5–10 min	2 units RBCs	O-negative RBCs	<14 days, AS
ECMO circuit disruption	5–10 min	2 units RBCs	O-negative RBCs	<14 days, AS
Progressive septic shock, nonneonate	30 min	2 units RBCs	O-negative RBCs or type specific	<10 days, any preservative
Neonate transferred for ECMO	1–2 hr	2 units RBCs 1 unit FFP 1 unit platelets	O-negative RBCs AB plasma	<10 days, CPD or CPDA-1
Cardiac ICU	30–60 min	2 units RBCs	Type specific	<7 days, AS
Gradual respiratory or cardiac failure on conventional support	Hours-days	2 units RBCs	Type specific	<10 days, CPD

AS, Additive solution unit is acceptable; CPD, citrate phosphate dextrose; CPDA-1, citrate phosphate dextrose adenine; ECMO, extracorporeal membrane oxygenation; FFP, fresh frozen plasma; ICU, intensive care unit; RBC, red blood cell.

Modified from protocols developed at The Children's Hospital of Philadelphia. Friedman DF, Montenegro LM: Extracorporeal membrane oxygenation and cardiopulmonary bypass. In: Hillyer CD, Strauss RG, Luban NLC, editors: *Handbook of pediatric transfusion medicine*, London, 2004, Elsevier Academic Press, p 181.

Although some have advocated adopting similar protocols for pediatric trauma centers, this has occurred in only a few places, most likely because there are little data on transfusions in pediatric trauma patients.²⁰

Hemoglobinopathies

In patients with sickle cell disease (SCD), chronic transfusion therapy has been shown to reduce the risk for both primary and secondary stroke, by decreasing the hemoglobin S content of the patient's blood, as well as achieving a reduction in sickling, suppression of erythropoiesis, and preventing an increase in blood viscosity.^{21,22} The risk for recurrent stroke has been reduced to less than 10% if hemoglobin levels are maintained between 8 and 9 g/dL and hemoglobin S levels below 30%. Simple or partial-exchange transfusion therapy can achieve this goal when performed approximately every 3 to 4 weeks. Chronic erythrocytapheresis has also been used for this therapy with an added mission to mitigate iron overload complications. Chronic transfusion treatment for stroke most times is an indefinite therapy, that is, once the patient is placed on it, cessation is not possible because it has been shown to lead to recurrent stroke.²¹ Table 121.2 describes other indications for patients with SCD needing either simple or chronic RBC transfusion therapy. Products for patients with SCD should be screened at a minimum for hemoglobin S and should be leukocyte reduced to reduce the risk for febrile nonhemolytic transfusion reactions and to reduce the risk for human leukocyte antigen (HLA) alloimmunization resulting in platelet refractoriness that can complicate possible stem cell transplantation.

In children with SCD, it also is useful to prevent alloimmunization to minor RBC antibodies because in most children with severe SCD, RBC transfusion is the only therapy available to treat the multiple manifestations of SCD. Overall the SCD patient has higher rates of alloimmunization than other chronically transfused patient groups. The antibodies most frequently produced are against common Rh, Kell, Duffy, and Kidd system antigens. Some sickle cell treatment centers perform thorough phenotype analysis of a patient's red cells before initiating transfusion therapy. This testing helps to reduce the rate of alloimmunization by allowing preferential selection of phenotypically similar units.²³ However, particularly for patients who are not yet alloimmunized, this process remains controversial because phenotypically compatible units may be difficult to obtain and expensive.²⁴ One common protocol followed for nonalloimmunized patients is pretransfusion phenotypic matching for C, E, and K antigens to reduce the incidence of alloimmunization. Once a patient has developed a red cell antibody, some centers extend matching to additional red cell antigens (Fy, Jk, S) to prevent further alloimmunization. However, care must be taken with some of these

strategies as recent studies have found no benefit in alloimmunization rates by providing Rh-matched RBC units from minority donors.²⁵ The benefits of RBC transfusion therapy in SCD disease must constantly be weighed against the costs (e.g., iron overload, RBC alloimmunization, and increased donor exposure risks). As a result of these issues, some clinicians have proposed that a clinically successful course of transfusions that maintains the hemoglobin S below 30% could, after several years, be transitioned to a strategy of more limited transfusions with a hemoglobin S target of 40% to 50% to reduce the risks for iron overload.²¹ Patients with SCD may also be at risk for delayed hemolytic transfusion reactions, the development of autoantibodies, and "hyperhemolytic" syndrome, a phenomenon in which a patient hemolyzes both the native and transfused erythrocytes following RBC transfusion. The mechanism is not well characterized.

Thalassemia

Thalassemia with severe anemia is usually treated with chronic transfusion therapy to improve tissue oxygenation and suppress extramedullary erythropoiesis in the liver, spleen, and bone marrow. This approach mitigates many of the complications caused by the ineffective erythropoiesis. In contrast to chronic transfusion regimens used to treat SCD, most β -thalassemia major patients requiring chronic transfusion therapy start at a very young age. The treatment goals in this population are characterized by (1) increasing oxygen-carrying capacity by anemia correction, (2) preventing progressive hypersplenism, (3) suppression of endogenous erythropoiesis, and (4) reduction of gastrointestinal absorption of iron.²⁶ The target hemoglobin levels are usually 8 to 9 g/dL, where normal growth and development can occur in these patients. Supertransfusion protocols aim for higher target hemoglobin levels (11 to 12 g/dL) to reduce organomegaly from extramedullary hematopoiesis. Iron overload is a complication of this RBC transfusion protocol that cannot be prevented and must be treated with chelation therapy beginning early in childhood. In a recent report from the Centers for Disease Control and Prevention on transfusion complications in thalassemia patients in the thalassemia network in the United States from 2004–2012, iron-induced multi-organ dysfunction from transfusion was common despite chelation. Transfusion-transmitted disease pathogens were found in almost one-quarter of those patients monitored and almost 50% of patients experienced transfusion reactions including allergic, febrile nonhemolytic, and hemolytic. RBC alloimmunization was found in 19% of all patients with the most common antigens being E, Kell, and C. Years of transfusion was found to be the strongest predictor of alloantibody formation.²⁷ Phenotypic-matching protocols are used in some locations to prevent RBC alloimmunization,

but data supporting or refuting this practice are scant and further research is needed.

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia in children occurs predominantly in young children, with a median age of 3.8 years, and 53% are associated with other immunologic diseases, according to one study in which 74% of the cases had both immunoglobulin G (IgG) and C3d on their surface.²⁸ Like adult cases, most cases of autoimmune hemolytic anemia in children have antibody reactivity to all RBCs from all donors.

Children also may develop autoimmune hemolytic anemia associated with a Donath-Landsteiner antibody, which is rarely seen in adults. Classically the Donath-Landsteiner antibody is associated with paroxysmal cold hemoglobinuria, a disease in which patients developed paroxysms of hemoglobinuria following exposure to cold temperatures.²⁹ However, some children with a Donath-Landsteiner antibody develop symptoms of anemia that are not obviously associated with exposure to cold. The syndrome often develops following an infection such as a respiratory infection.

The Donath-Landsteiner antibody is an IgG antibody that binds erythrocytes, usually recognizing the P antigen, at cold temperatures (<20°C [68°F]) and fixes early components of complement. The fixed complement does not cause significant hemolysis at cold temperatures, but upon warming, the entire complement complex binds and lyses the erythrocytes. Initial testing in the blood bank may be entirely normal or may reveal a positive DAT for C3. The Donath-Landsteiner antibody can be detected only by special testing in which the patient's plasma is incubated with erythrocytes in cold temperatures followed by warm temperatures.

Hematopoietic Cellular Transplant Patients

Transfusion support for HPC transplant patients is similar to that for adult patients, although there are few published studies on transfusion of pediatric HPC transplant patients. RBC transfusions are often not needed in these patients whose hemoglobin level is at least 7 g/dL.¹¹ No studies in the modern era have been published on platelet transfusions in these patients, but use of a transfusion trigger of 10,000 platelets/ μ L, like that used for adults, seems reasonable for those patients without a significant bleeding risk other than thrombocytopenia.

Apheresis

Pediatric apheresis is used for many of the same indications as for adults. However, additional aspects need to be considered in treating pediatric patients. Many children require vascular access through a central vein because the peripheral veins of many children are too small. In addition, peripheral access requires patients to remain seated or reclining with limited arm movement for the procedure duration, and younger patients are often unable to comply with this given that procedures usually last at least 2 hours. During the procedures, children are susceptible to symptomatic hypocalcemia from citrate anticoagulation. For this reason, some pediatric centers use heparin to anticoagulate patients, although prophylactic cation replacement can successfully prevent most symptoms in pediatric apheresis patients.³⁰ Apheresis procedures subject the patient to volume shifts, which are usually a loss of less than 200 mL of fluid during the procedure and a gain of up to 300 mL at the end of the procedure. The actual fluid shifts depend on the machine, the procedure, and the parameters for that procedure. In some cases, the volume shifts may be too large to be safe for the patient. In these cases, most machines can be primed with 5% albumin, an RBC unit, or reconstituted whole blood. Using a prime solution, it is possible to minimize fluid shifts so that the patient is effectively volume neutral for the

entire procedure. Procedures to accomplish this are usually only available at centers that perform apheresis on relatively large numbers of pediatric patients.

Special Processing and Prevention of Adverse Events in Pediatric Patients

Special processing of blood products is performed more frequently for children than for adults. This is especially true for the preterm infant population, specifically in very low-birth-weight (VLBW) infants weighing less than 1500 g and extremely low-birth-weight infants weighing less than 1000 g.

Leukocyte-Reduced Blood Components

Leukoreduced cellular blood products are used in greater than 80% of blood components transfused to children in the United States. The rationale behind the use in pediatric patients has primarily been extrapolated from adult studies. In general, leukoreduction reduces transmission of CMV,³¹ decreases HLA alloimmunization,³² and decreases the frequency of febrile nonhemolytic transfusion reactions. The benefits of leukoreduction for neonates differ from the benefits for older patients. While neonates younger than 4 months of age rarely develop transfusion reactions and rarely become HLA alloimmunized, some neonates, especially premature infants, are at risk for transfusion-transmitted CMV.³¹ Additionally, one study of premature infants found that implementation of universal leukoreduction was associated with decreased incidences of retinopathy, prematurity, and bronchopulmonary dysplasia, and decreased length of hospitalization.³³

Cytomegalovirus-Seronegative Blood Components

Some immunosuppressed pediatric patients, including premature infants, are at risk of significant disease from CMV infection. Transfusion-transmitted CMV can occur because many healthy blood donors have been infected at some point and their leukocytes harbor the virus. Approaches to reduce the risk of transfusion transmission of CMV include transfusion of blood components that test negative for antibodies to CMV (CMV seronegative), are leukoreduced, or both. Although each of these approaches is highly effective, none of these approaches provides zero risk of transfusion-transmitted CMV since blood from donors who were recently infected can lack antibodies to CMV and can contain cell-free virions that are not removed by leukoreduction. The risk of transfusion-transmitted CMV in VLBW infants (<1500 g) is less than 1% when the units are leukoreduced and CMV seronegative.³⁴ This approach has not been directly compared to using only CMV seronegative or using only leukoreduced units. However, results from older studies found that the residual risk for transfusion-transmitted CMV in adults from CMV seronegative blood components to be between 1% and 3% but current risks are likely lower, and one study found no infants acquiring transfusion-transmitted CMV from transfusion of CMV seronegative blood components.³⁵ Leukoreduction is also very effective, reducing the rate of transfusion-transmitted CMV to less than 1% in immunosuppressed patients of all ages.³⁶ Some have recommended the combined approach of using leukoreduced CMV seronegative units for prevention of transfusion-transmitted CMV for some of the most at-risk patients.³⁷ Despite confidence in the safety of using CMV seronegative units, it may not be practical and cost effective to rely on CMV seronegative donors as they often constitute less than or equal to one-half of the blood donor pool.

Irradiation

Mortality rates associated with TA-GVHD are as high as 80% to 90%, with no effective treatments. As a result, identifying neonates

and children who are immunosuppressed is paramount, so irradiation of cellular components can be performed to prevent this noninfectious serious hazard of transfusion. There are differing expert opinions and practices, and local protocols based on patient populations, available equipment, and best practices at each institution should be followed. The following patients should receive irradiated cellular blood components: (1) premature infants with birth weight less than 1200 g, (2) any child with known or suspected cellular immune deficiency (e.g., severe combined immunodeficiency), (3) any child with significant immunosuppression due to chemotherapy or radiation treatment, (4) any child who receives blood components from blood relatives, and (5) any child who receives HLA-matched or crossmatched platelet components.

Washing

Washing removes the supernatant from RBC or platelet units and is usually performed to reduce the risk of allergic reactions related to plasma. For very young children, washing may also be performed to reduce the concentration of extracellular potassium or to remove anticoagulant-preserved solutions. Washing can also be used to remove pathologic antibodies from a donor unit. Most donor units lack such antibodies. However, if maternal RBC or platelet units are used to treat her newborn with HDFN or neonatal alloimmune thrombocytopenic purpura, respectively, then her plasma would contain the pathogenic antibodies and the units should be washed prior to transfusion. Indeed, because maternal blood contains pathologic antibodies in these settings, its use for these patients is not generally recommended. However, a maternal component may be used because it may be the only component available that lacks the antigen recognized by her antibodies.

Volume Reduction

Volume reduction, involving removal of plasma, is primarily used for patients who cannot tolerate the volume of a blood component transfusion, such as some infants with compromised cardiac function. However, it may also be employed for infants and children who receive ABO-mismatched platelet transfusions, because several deaths have been reported in the literature of children who have received out-of-group platelets (e.g., O platelet pheresis to A recipient).³⁸ Not all blood banks volume-reduce such platelets.

Reconstitution of RBCs for Neonatal Exchange Transfusion

During a neonatal exchange, the infant's whole blood is replaced with reconstituted whole blood prepared from type-compatible RBCs and plasma. Typically, RBCs less than 5 to 7 days old are used to minimize the concentration of extracellular potassium and, theoretically, provide transfused RBCs that will have maximal *in vivo* benefit, although this has never been demonstrated. Because of theoretical concerns associated with large volumes of RBC additives transfused to premature infants, nonadditive units are sometimes selected or additives are removed from the RBCs prior to reconstitution. Most blood banks also provide RBC units that are negative for sickle hemoglobin to avoid the rare potential of intravascular sickling. RBC units should be leukoreduced, CMV seronegative, or both to reduce the incidence of transfusion-transmitted CMV. The RBC unit should also be irradiated to prevent TA-GVHD if the infant is considered at risk of this by local criteria. If irradiated, the RBC or reconstituted whole blood should be irradiated just before the exchange to minimize liberation of potassium from intracellular stores. Alternatively the RBC unit can be irradiated prior to volume reduction or washing. The glucose load during an exchange transfusion can be high due to the fact that banked plasma contains added dextrose and because glucose is added to RBC preservative solutions.

Hence glucose levels should be monitored during the first few hours of the exchange.

The goal of most exchanges is to exchange twice the blood volume of the neonate. The volume needed can be calculated based on the fact that the blood volume of a neonate ranges from 100 mL/kg for the most premature to 85 mL/kg for term infants. Usually, one RBC unit is sufficient for a two-volume exchange. The reconstituted whole blood should have a hematocrit of approximately 40% to 50% and must be adequately mixed to maintain the intended hematocrit throughout the exchange transfusion.

The reconstituted whole blood should be transfused through a standard filter and an inline blood warmer. In general, no more than 5 mL/kg of body weight or 5% of the infant's blood volume is to be removed and replaced during a 2–5 minute cycle. The exchange should be performed at a slow pace, so as to not cause sudden hemodynamic changes that can result in cerebral blood flow shifts in intracranial pressure, precipitating an intraventricular hemorrhage.³⁹ A double-volume exchange transfusion typically takes 1.5 to 2 hours.

HEMOSTASIS AND THROMBOSIS

This page intentionally left blank

OVERVIEW OF HEMOSTASIS AND THROMBOSIS

James C. Fredenburgh and Jeffrey I. Weitz

Hemostasis preserves vascular integrity by balancing the physiologic processes that maintain blood in a fluid state under normal circumstances and prevent excessive bleeding after vascular injury. Preservation of blood fluidity depends on an intact vascular endothelium and a complex series of regulatory pathways that maintain platelets in a quiescent state and keep the coagulation system in check. In contrast, arrest of bleeding requires rapid formation of hemostatic plugs at sites of vascular injury to prevent exsanguination. Perturbation of hemostasis can lead to bleeding or thrombosis. Bleeding will occur if there is failure to seal vascular leaks either because of defective hemostatic plug formation or because of premature breakdown of the plugs. In contrast, thrombosis may occur if prothrombotic stimuli are unregulated.

Thrombosis can occur in arteries or veins and is a major cause of morbidity and mortality. Arterial thrombosis is the most common cause of acute coronary syndromes, ischemic stroke, and limb gangrene, whereas thrombosis in the deep veins of the leg leads to postthrombotic syndrome and pulmonary embolism, which can be fatal.

Most arterial thrombi form on top of disrupted atherosclerotic plaques, because plaque rupture exposes thrombogenic material in the plaque core to the blood.¹ This material then triggers platelet aggregation and fibrin formation, which results in the generation of a platelet-rich thrombus that temporarily or permanently occludes blood flow. Temporary occlusion of blood flow in coronary arteries may trigger unstable angina, whereas persistent obstruction causes myocardial infarction. The same processes can occur in the cerebral circulation, where temporary arterial occlusion may manifest as a transient ischemic attack, and persistent occlusion can lead to a stroke. Likewise, critical limb ischemia can occur if there is superimposed thrombosis on ruptured atherosclerotic plaques in the major arteries supplying blood to the lower extremities.

In contrast to arterial thrombi, venous thrombi rarely form at sites of obvious vascular disruption. Although they can develop after surgical trauma to veins, or secondary to indwelling venous catheters, they usually originate in the valve cusps of the deep veins of the calf or in the muscular sinuses, where there is stasis.² Sluggish blood flow in these veins reduces the oxygen supply to the avascular valve cusps. Hypoxemia induces endothelial cells lining the valve cusps to become activated and express adhesion molecules onto their surfaces. Tissue factor-bearing leukocytes and microparticles adhere to these activated cells and induce coagulation. Impaired blood flow exacerbates local thrombus formation by reducing clearance of activated clotting factors. These responses constitute the three axes of the Virchow triad associated with development of thrombosis: stasis, hypercoagulability of the blood, and activation or disruption of the endothelium. Calf vein thrombi that extend into the proximal veins of the leg can dislodge and travel to the lungs to produce pulmonary embolism.³

Arterial and venous thrombi contain platelets and fibrin, but the proportions differ. Arterial thrombi are rich in platelets because of the high shear on this side of the circulatory system. In contrast, venous thrombi, which form under low shear conditions, contain relatively few platelets and consist mostly of fibrin and trapped red blood cells. Because of the predominance of platelets, arterial thrombi appear white, whereas venous thrombi appear red.

The antithrombotic drugs used for prevention and treatment of thrombosis target components of thrombi and include antiplatelet drugs, which inhibit platelets; anticoagulants, which attenuate

coagulation; and fibrinolytic agents that induce fibrin degradation (see [Chapter 149](#)). With the predominance of platelets in arterial thrombi, strategies to inhibit or treat arterial thrombosis focus mainly on antiplatelet agents, although in the acute setting, strategies often include anticoagulants and fibrinolytic agents. When arterial thrombi are occlusive and rapid restoration of blood flow is imperative, mechanical and pharmacologic methods enable thrombus extraction, compression, or degradation. Although rarely used for this indication, anticoagulants can also prevent recurrent ischemic events after acute myocardial infarction. Anticoagulants are the mainstay for prevention and treatment of venous thromboembolism because fibrin is the predominant component of venous thrombi (see [Chapter 142](#)). Antiplatelet drugs are less effective than anticoagulants because of the limited platelet content of venous thrombi. Selected patients with venous thromboembolism benefit from fibrinolytic therapy—for example, patients with massive or submassive pulmonary embolism achieve more rapid restoration of pulmonary blood flow with systemic or catheter-directed fibrinolytic therapy than with anticoagulant therapy alone. Certain patients with extensive deep vein thrombosis in the iliac and/or femoral veins may also have a better outcome with catheter-directed fibrinolytic therapy and/or mechanical thrombus extraction in addition to anticoagulants (see [Chapter 143](#)).

This chapter provides an overview of hemostasis and thrombosis by highlighting the processes involved in platelet activation and aggregation, blood coagulation, and fibrinolysis.

HEMOSTATIC SYSTEM

The major components of the hemostatic system are the vascular endothelium, platelets, and the coagulation and fibrinolytic systems.

Vascular Endothelium

A monolayer of endothelial cells lines the intimal surface of the circulatory tree and separates the blood from the prothrombotic subendothelial components of the vessel wall (see [Chapter 123](#)). As such, the vascular endothelium encompasses about 10^{13} cells and covers a vast surface area. Rather than serving as a static barrier, the healthy vascular endothelium is a dynamic organ ([Fig. 122.1](#)) that actively regulates hemostasis by inhibiting platelets, suppressing coagulation, promoting fibrinolysis, and modulating vascular tone and permeability.⁴ Defective vascular function can lead to bleeding if the endothelium becomes more permeable to blood cells, if vasoconstriction does not occur, or if premature degradation of hemostatic plugs reopens repaired vasculature.

Platelet Inhibition

Endothelial cells synthesize prostacyclin and nitric oxide and release them into the blood.⁴ These agents not only serve as potent vasodilators but also inhibit platelet activation and subsequent aggregation by stimulating adenylate cyclase and increasing intracellular levels of cyclic adenosine monophosphate (cAMP). In addition, endothelial cells express CD39 on their surfaces, a membrane-associated ecto-adenosine diphosphatase (ADPase). By degrading adenosine

Fig. 122.1 THE ANTITHROMBOTIC FUNCTIONS OF THE ENDOTHELIUM. The healthy endothelium has (a) antiplatelet activity because of synthesis and release of prostacyclin and nitric oxide (NO) and expression of CD39, a membrane-associated ectoADPase; (b) anticoagulant activity because of heparan sulfate proteoglycan-mediated activation of antithrombin and expression of thrombomodulin (TM) and endothelial protein C receptor (EPCR), which are involved in protein C activation, and surface-bound tissue factor pathway inhibitor (TFPI); and (c) profibrinolytic activity because of release of tissue and urokinase-type plasminogen activator (t-PA and u-PA, respectively).

diphosphate (ADP), which is a platelet agonist, CD39 attenuates platelet activation.

Anticoagulant Activity

Intact endothelial cells play an essential part in the regulation of thrombin generation through a variety of mechanisms. Endothelial cells produce heparan sulfate proteoglycans, which bind circulating antithrombin and accelerate the rate at which it inhibits thrombin and other coagulation enzymes. Tissue factor pathway inhibitor (TFPI), a naturally occurring inhibitor of coagulation, binds heparan sulfate on the endothelial cell surface.⁵ Administration of heparin or low-molecular-weight heparin (LMWH) displaces glycosaminoglycan-bound TFPI from the vascular endothelium, and released TFPI may contribute to the antithrombotic activity of these drugs.

Endothelial cells regulate thrombin generation by expressing thrombomodulin and endothelial cell protein C receptor (EPCR) on their surfaces. Thrombomodulin binds thrombin and alters this enzyme's substrate specificity such that it no longer acts as a procoagulant but becomes a potent activator of protein C (see [Chapter 127](#)). Activated protein C serves as an anticoagulant by degrading and inactivating activated factor V and factor VIII (factor Va and VIIa, respectively), key cofactors involved in thrombin generation. Protein S acts as a cofactor in this reaction, and EPCR enhances this pathway by binding protein C and presenting it to the thrombin–thrombomodulin complex for activation. In addition to its role as an anticoagulant, activated protein C also regulates inflammation and preserves the barrier function of the endothelium.⁶

Fibrinolytic Activity

The vascular endothelium promotes fibrinolysis by synthesizing and releasing tissue-type and urokinase-type plasminogen activator (t-PA and u-PA, respectively), which initiate fibrinolysis by converting plasminogen to plasmin (see [Chapter 126](#)). Endothelial cells in most vascular beds synthesize t-PA constitutively and release it in response to stimuli such as thrombin or bradykinin. In contrast, perturbed endothelial cells produce u-PA in the settings of inflammation and wound repair.

Endothelial cells also produce type 1 plasminogen activator inhibitor (PAI-1), the major regulator of both t-PA and u-PA. Therefore net fibrinolytic activity depends on the dynamic balance between the release of plasminogen activators and PAI-1. Fibrinolysis localizes to the endothelial cell surface because these cells express annexin II, a coreceptor for plasminogen and t-PA that promotes their interaction. Therefore healthy vessels actively resist thrombosis and help maintain platelets in a quiescent state.

Vascular Tone and Permeability

In addition to synthesizing potent vasodilators, such as prostacyclin and nitric oxide, endothelial cells also produce a group of counter-regulatory peptides known as endothelins that induce vasoconstriction. Endothelial cell permeability is influenced by the connections that join endothelial cells to their neighbors. Macromolecules traverse the endothelium via patent intercellular junctions, by endocytosis, or through transendothelial pores. Vasodilatation, severe thrombocytopenia, and high doses of heparin can increase endothelial permeability, which may contribute to bleeding. Activated protein C may also contribute to the barrier function of the endothelium.

Platelets

Platelets are anucleate cellular particles released into the circulation after programmed fragmentation of bone marrow megakaryocytes (see [Chapter 124](#)). Because they are anucleate, platelets have limited capacity to synthesize proteins. Consequently, platelet protein composition is determined by the parent cell as well as by those factors endocytosed from the circulation. Thrombopoietin, a glycoprotein synthesized in the liver and kidneys, regulates megakaryocytic proliferation and maturation as well as platelet production. Once they enter the circulation, platelets have a life span of 7 to 10 days.

Damage to the intimal lining of the vessel exposes the underlying subendothelial matrix. Platelets home to sites of vascular disruption and adhere to the exposed matrix proteins (see [Chapter 125](#)). Adherent platelets undergo activation and not only release substances that recruit additional platelets to the site of injury, but also promote thrombin generation and subsequent fibrin formation ([Fig. 122.2](#)). A potent platelet agonist, thrombin amplifies platelet recruitment and activation. Activated platelets then aggregate to form a plug that seals the leak in the vasculature.⁷ An understanding of the steps in these highly integrated processes helps pinpoint the sites of action of antiplatelet drugs and rationalizes the utility of anticoagulants for the treatment of arterial thrombosis and venous thrombosis.

Adhesion

Platelets adhere to exposed von Willebrand factor (vWF) and collagen, originating from endothelial cells and the subendothelium, respectively. The platelet monolayer promotes thrombin generation and subsequent fibrin formation. These events depend on constitutively expressed receptors on the platelet surface, $\alpha_2\beta_1$ and glycoprotein (GP) VI, which bind collagen, and GPIb α and GPIIb/IIIa ($\alpha_{IIb}\beta_3$), which bind vWF. The platelet surface is crowded with receptors, but those involved in adhesion are the most abundant: every

Fig. 122.2 SITES OF ACTION OF ANTIPLATELET DRUGS. Aspirin inhibits thromboxane A_2 (TXA_2) synthesis by irreversibly acetylating cyclooxygenase-1 (COX-1). Reduced TXA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block $P2Y_{12}$, a key ADP receptor on the platelet surface; whereas ticagrelor is a reversible inhibitor of $P2Y_{12}$. Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and von Willebrand factor (vWF) binding to activated glycoprotein (GP) IIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting protease activated receptor-1 (PAR-1), the major thrombin receptor on platelets.

platelet has about 40,000 to 80,000 copies of GPIIb/IIIa and 25,000 copies of GPIb α . Receptors cluster in cholesterol-enriched subdomains, which render them more mobile, thereby increasing the efficiency of platelet adhesion and subsequent activation (see Chapter 125).

Under low shear conditions, such as in the venous circulation, collagen can capture and activate platelets on its own. Captured platelets undergo cytoskeletal reorganization that causes them to flatten and adhere more closely to the damaged vessel wall. Under high shear conditions in the arterial system, however, collagen and vWF must act in concert to support optimal platelet adhesion and activation. vWF synthesized by endothelial cells and megakaryocytes assembles into multimers that range from 550 to over 10,000 kDa. When released from storage in the Weibel-Palade bodies of endothelial cells or the α -granules of platelets, most of the vWF enters the circulation, but the vWF released from the abluminal surface of endothelial cells accumulates in the subendothelial matrix, where it binds collagen via its A3 domain. This surface-immobilized vWF can simultaneously bind platelets via its A1 domain. In contrast, circulating vWF does not react with unstimulated platelets. This difference in reactivity likely reflects vWF conformation; circulating vWF is in a coiled conformation that prevents access of its platelet-binding domain to vWF receptors on the platelet surface, whereas immobilized vWF assumes an elongated shape that exposes its A1 domain. Shear forces at sites of vascular injury also unfold vWF, thus contributing to the abundance of platelets in arterial thrombi. In this extended conformation, large vWF multimers serve as the molecular glue that tethers platelets to the damaged vessel wall with sufficient strength to withstand higher shear forces.⁸ Large vWF multimers

provide additional binding sites for collagen and heighten platelet adhesion because platelets have more vWF receptors than collagen receptors. Adhesion to collagen or vWF results in platelet activation, the next step in platelet plug formation.

Activation and Secretion

Adhesion to collagen and vWF initiates signaling pathways that result in platelet activation. These pathways induce cyclooxygenase-1 (COX-1)-dependent synthesis and release of thromboxane A_2 , and trigger the release of ADP from storage granules. Thromboxane A_2 is a potent vasoconstrictor, and like ADP, locally activates ambient platelets and recruits them to the site of injury. This process results in expansion of the platelet plug. To activate platelets, thromboxane A_2 and ADP must bind to their respective receptors on the platelet membrane. The thromboxane receptor (TP) is a G protein coupled-receptor that is found on platelets and on the endothelium, which explains why thromboxane A_2 induces vasoconstriction as well as platelet activation.⁹ ADP interacts with a family of G protein-coupled receptors on the platelet membrane. Most important of these is $P2Y_{12}$, which is the target of the thienopyridines, but $P2Y_1$ also contributes to ADP-induced platelet activation, and maximal ADP-induced platelet activation requires activation of both receptors. A third ADP receptor, $P2X_1$, is an adenosine triphosphate (ATP)-gated calcium channel. Platelet storage granules contain ATP as well as ADP; ATP released during the platelet activation process may contribute to the platelet recruitment process in a $P2X_1$ -dependent fashion.

Fig. 122.3 ACTIVATION OF PROTEASE-ACTIVATED RECEPTOR (PAR)-1 BY THROMBIN. Thrombin (IIa) binds to the amino terminus of the extracellular domain of PAR-1 where it cleaves a specific peptide bond. Cleavage of this bond generates a new amino-terminal sequence of Ser-Phe-Leu-Leu-Arg (SFLLR) that acts as a tethered ligand and binds to the body of the receptor, thereby activating it. Thrombin then dissociates from the receptor. Analogues of the first five or six amino acids of the tethered ligand sequences, known as thrombin receptor agonist peptides, can independently activate PAR-1.

Although TP and the various ADP receptors signal through different pathways, they all trigger an increase in the intracellular calcium concentration in platelets. This in turn induces shape change via cytoskeletal rearrangement, granule mobilization and release, and subsequent platelet aggregation. Activated platelets promote coagulation by cycling phosphatidylserine from the inner membrane bilayer to the outer layer. Surface exposure of this anionic phospholipid is essential for assembly of coagulation factor complexes (see [Chapter 126](#)). Once assembled, these clotting factor complexes trigger a burst of thrombin generation and subsequent fibrin formation. In addition to converting fibrinogen to fibrin, thrombin amplifies platelet recruitment and activation, thus promoting expansion of the platelet plug. Thrombin binds to protease-activated receptors types 1 and 4 (PAR1 and PAR4, respectively) on the platelet surface and cleaves their extended amino-termini, thereby generating new amino-termini that serve as tethered ligands that bind internally and activate the receptors ([Fig. 122.3](#)). Whereas low concentrations of thrombin cleave PAR1, PAR4 cleavage requires higher thrombin concentrations.¹⁰ Cleavage of either receptor triggers platelet activation.

In addition to providing a surface on which clotting factors assemble, activated platelets also promote fibrin formation and subsequent stabilization by releasing factor V, factor XI, fibrinogen, and factor XIII (see [Chapter 125](#)). Thus there is coordinated activation of platelets and coagulation, and the fibrin network that results from thrombin action helps anchor the platelet aggregates at the site of injury. Activated platelets also release adhesive proteins, such as vWF, thrombospondin, and fibronectin, which augment platelet adhesion at sites of injury, as well as growth factors, such as platelet-derived growth factor (PDGF) and transforming growth factor-beta (TGF- β), which promote wound healing. Platelet aggregation is the final step in the formation of the platelet plug.

Aggregation

GPIIb/IIIa mediates platelet-to-platelet linkages that result in the formation of clumps of platelets. On nonactivated platelets, GPIIb/

IIIa exhibits minimal affinity for its ligands. Upon platelet activation, GPIIb/IIIa undergoes a conformational transformation, which reflects transmission of inside-out signals from its cytoplasmic domain to its extracellular domain.¹¹ This transformation enhances the affinity of GPIIb/IIIa for its ligands, fibrinogen, and, under high shear conditions, vWF (see [Chapter 125](#)). Cryptic Arg-Gly-Asp (RGD) peptide sequences located in fibrinogen and vWF, as well as a platelet-binding Lys-Gly-Asp (KGD) sequence in fibrinogen, mediate their interaction with GPIIb/IIIa. When subjected to high shear, circulating vWF elongates and exposes its platelet-binding domain, which enables its interaction with the conformationally activated GPIIb/IIIa. Similarly, initial binding to GPIIb/IIIa leads to a conformational change in fibrinogen that unmasks additional binding sites. Divalent fibrinogen and multivalent vWF molecules serve as bridges and bind adjacent platelets together. Once bound to GPIIb/IIIa, fibrinogen and vWF induce outside-inside signals that augment platelet activation and result in the activation of additional GPIIb/IIIa receptors, creating a positive feedback loop. Because GPIIb/IIIa acts as the final effector in platelet aggregation, it is a logical target for potent anti-platelet drugs (see [Chapters 130 and 149](#)). Fibrin, the ultimate product of the coagulation system, tethers the platelet aggregates together and anchors them to the site of injury.

Coagulation

Coagulation results in the generation of thrombin, which converts soluble fibrinogen to fibrin. Coagulation occurs through a series of concerted activation steps, wherein a nascent protease activates an inactive enzyme precursor (zymogen); a process that is repeated in a cascade-like fashion. The principal enzyme complexes are composed of a vitamin K-dependent enzyme and a non-enzyme cofactor assembled on anionic phospholipid membranes in a calcium-dependent fashion (see [Chapter 126](#)). Because each enzyme complex activates a substrate that becomes the enzyme component of the subsequent complex, a small stimulus can produce a robust response. Initially the small amount of thrombin generated activates

Fig. 122.4 COAGULATION SYSTEM. Coagulation occurs through the action of discrete enzyme complexes, which are composed of a vitamin K–dependent enzyme and a non-enzyme cofactor. These complexes assemble on anionic phospholipid membranes in a calcium-dependent fashion. Vascular injury exposes tissue factor (TF), which binds factor VIIa to form extrinsic tenase. Extrinsic tenase activates factors IX and X. Factor IXa binds to factor VIIIa to form intrinsic tenase, which activates factor X. The contact system also leads to activation of factor IX in response to exposure of anionic surfaces. Factor Xa binds to factor Va to form prothrombinase, which converts prothrombin (II) to thrombin (IIa). Thrombin then converts soluble fibrinogen into insoluble fibrin.

non-enzyme cofactors and platelets. The activated platelets then provide an anionic surface on which the coagulation complexes assemble to promote rapid thrombin generation. The three predominant enzyme complexes involved in thrombin generation are extrinsic tenase, intrinsic tenase, and prothrombinase, named for their substrates, factor X and prothrombin (Fig. 122.4).

Coagulation can be divided into three phases: initiation, propagation, and termination.^{12,13} These phases reflect the exquisite control over thrombin activity necessary to effect hemostasis. The initiation phase, which is predominantly mediated by extrinsic tenase, is responsible for generating the initial burst of thrombin required for platelet and coagulation factor activation. The propagation phase is largely mediated by intrinsic tenase and is responsible for the explosive thrombin generation necessary to sustain the coagulant response. The termination phase, which is mediated by numerous protease inhibitors, ensures that thrombin generation is localized and finite. Each of the activation complexes exhibits similar composition, assembly, and regulation.

Because initiation and propagation reactions require a membrane surface for assembly of factors, cells play a key role in coagulation. Tissue factor exposure on monocytes and extravascular cells and platelet membrane capacitation are recognized key steps. However, other cells also make important contributions. For example, damaged endothelium appears to support coagulation because mice deficient

in PAR4, the major thrombin receptor on mouse platelets, still exhibit significant thrombus formation after laser injury. Red blood cells also bind to damaged endothelium and express procoagulant phospholipids on their surface, thereby providing additional sites for assembly of coagulation complexes. In addition, activated neutrophils extrude web-like structures known as neutrophil extracellular traps (NETs). Composed of nuclear DNA, histones, and metalloproteases, NETs promote coagulation by binding and activating platelets, trapping red blood cells, and activating the contact pathway. Thus cells contribute to coagulation at numerous sites in the cascade.

Extrinsic Tenase

This complex forms upon exposure of tissue factor–expressing cells to the blood.¹⁴ Tissue factor exposure occurs after atherosclerotic plaque rupture because the core of the plaque is rich in macrophages and other cells that express tissue factor. Denuding injury to the vessel wall also exposes tissue factor constitutively expressed by subendothelial fibroblasts and smooth muscle cells. In addition to cells in the vessel wall, circulating monocytes and monocyte-derived microparticles (small membrane fragments) also provide a source of tissue factor. When tissue factor–bearing monocytes or microparticles bind to platelets or other leukocytes and their plasma membranes fuse,

tissue factor transfer occurs. By binding to adhesion molecules expressed on activated endothelial cells or to P-selectin on activated platelets, these tissue factor-bearing cells or microparticles can initiate or augment coagulation. This phenomenon likely explains how venous thrombi develop in the absence of obvious vessel wall injury.

Tissue factor is an integral membrane protein that serves as a receptor for factor VIIa. Blood contains trace amounts of factor VIIa, which has negligible activity in the absence of tissue factor.¹⁴ Although tissue factor is present on cell surfaces, it is proposed to exist in an encrypted, inactive form. The decryption step is thought to occur by a disulfide bond rearrangement catalyzed by protein-disulfide isomerase and exposure of phosphatidylserine on the outer membrane surface. Factor VIIa binds tissue factor in a calcium-dependent fashion to form the extrinsic tenase complex, which is a potent activator of factors IX and X. Once activated, factor IXa and factor Xa serve as the enzyme components of intrinsic tenase and prothrombinase, respectively. Because sufficient levels of factor Xa and thrombin are formed in response to exposure of tissue factor, the extrinsic tenase complex is considered the essential mediator of the initiation phase.

Intrinsic Tenase

Factor IXa binds to factor VIIIa on anionic platelet or cell surfaces to form the intrinsic tenase complex.¹⁵ Factor VIII circulates in blood in complex with vWF. Thrombin cleaves factor VIII and releases it from vWF, converting it to its activated form. Activated platelets express binding sites for factor VIIIa. Once bound, factor VIIIa binds factor IXa in a calcium-dependent fashion to form the intrinsic tenase complex, which then activates factor X. The loss in catalytic efficiency of intrinsic tenase that occurs with a deficiency of factors VIII or IX in hemophilia A and B, respectively, highlights their importance. Absence of the membrane or factor VIIIa almost completely abolishes enzymatic activity, and the catalytic efficiency of the complete complex is 10⁶-fold greater than that of factor IXa alone.¹⁵ Because intrinsic tenase activates factor X at a rate 50- to 100-fold faster than extrinsic tenase, it plays a critical role in the amplification of factor Xa and subsequent thrombin generation. Thus intrinsic tenase is crucial to the propagation phase of coagulation.

Contact Pathway

The contact pathway is so named because initial identification of its constituents (factors XII, XI, IX, and kallikrein), required contact with artificial agents such as ellagic acid or silica for activation. For this reason, the contact pathway lost prominence when the physiologic tissue factor pathway was identified. Current thinking is that tissue factor exposure represents the sole pathway for activation of coagulation and thus the contact system is unimportant for hemostasis because patients deficient in factor XII, prekallikrein, and high-molecular-weight kininogen do not have bleeding problems (see [Chapter 126](#)). Although patients with severe deficiency of factor XI can bleed after trauma or surgery, spontaneous bleeding is uncommon, and the plasma level of factor XI does not reliably predict the propensity for bleeding (see [Chapter 137](#)). The capacity of thrombin to feedback and activate platelet-bound factor XI may help to explain this phenomenon. It also is possible that platelet-derived factor XI may be more important for hemostasis than circulating factor XI.

We cannot ignore the contact pathway, however, because catheters and other blood-contacting medical devices, such as stents or mechanical valves, likely trigger clotting through this mechanism. Factor XII bound to charged or artificial surfaces undergoes a conformational change that results in its activation. Factor XIIa converts prekallikrein to kallikrein in a reaction accelerated by high-molecular-weight kininogen, and factor XIIa and kallikrein both feed back to activate additional factor XII. Factor XIIa propagates coagulation by activating factor XI and generating factor XIa, the predominant activator of factor IX ([Fig. 122.5](#)). (See box on [Emerging Role of the Contact Pathway](#))

Emerging Role of the Contact Pathway

The contact pathway has emerged as an important player in thrombosis. It has long been recognized that the contact pathway is dispensable for hemostasis because of the lack of a bleeding diathesis in patients with hereditary deficiency of factor XII, prekallikrein, or high-molecular-weight kininogen and the mild bleeding diathesis with factor XI deficiency relative to deficiencies of factor VIII or factor IX. However, until recently, the role of the contact pathway remained elusive. The pathway was ignored for several decades because its activators were mainly nonphysiologic substances such as kaolin or ellagic acid, compounded by the observation that thrombin could activate factor XI, providing a potential physiologic bypass for the contact system as the activator of intrinsic tenase.

The renaissance in our understanding of the important contribution of the contact pathway to thrombus stabilization and propagation occurred as a result of the identification of new physiologic activators, the attenuated thrombosis after venous or arterial injury observed in mice deficient in factor XII or XI, and the development of contact pathway-specific inhibitors. Reports that factor XI-deficient mice were protected from arterial injury-induced thrombosis to the same extent as factor IX-deficient mice, but did not experience bleeding, provide a clear demarcation between hemostasis and thrombosis. The role of the contact pathway in thrombosis gained credibility with the observation that mice lacking factor XII were also resistant to clot formation at sites of vascular injury. However, the physiologic mechanism for activation of the pathway remained unclear until studies showed that nuclear material released from neutrophils in the form of neutrophil extracellular traps, nucleic acids, and inorganic polyphosphates released from activated platelets or microorganisms, activated coagulation in a contact pathway-dependent fashion. With a valid association between the contact pathway and physiologic activators, investigation into the role of the contact pathway in thrombosis exploded.

Renewed interest in the contact pathway has spurred investigation of factors XI and XII as targets for new antithrombotic drugs. Agents targeting factors XI and XII include biological inhibitors, antibodies, small molecule inhibitors, and aptamers. Another approach is to reduce factor levels by inhibiting protein expression through the use of antisense oligonucleotides (ASO). This approach has been successfully applied to factor XI, where administration of an ASO reduced postoperative thrombosis in patients undergoing total knee arthroplasty, without an increase in bleeding. Similar interest in targeting the contact pathway is directed at device-related thrombosis. Thrombosis is a major cause of failure of blood-contacting medical devices, a problem that can lead to life-threatening complications including pulmonary embolism, coronary occlusion, and stroke. and activation of the contact pathway by the artificial surface is thought to be the primary cause. Therefore the contact pathway has emerged as an attractive target for development of agents that reduce thrombosis with little impact on hemostasis.

In addition to its role in device-related thrombosis, the contact pathway may also contribute to the stability of arterial and venous thrombi.¹⁶ NETs, and DNA and RNA released from damaged cells in atherosclerotic plaques, activate factor XII, and mice given DNA- or RNA-degrading enzymes exhibit attenuated thrombosis at sites of arterial injury. Polyphosphates released from activated platelets also activate factor XII, and may provide another stimulus for contact pathway activation. Mice deficient in factor XII or factor XI form small unstable thrombi at sites of arterial or venous damage, suggesting that factor XII and factor XI contribute to thrombogenesis (see [Chapter 137](#)). There is mounting evidence that the same is true in humans. Thus patients with unstable angina have increased plasma levels of factor XIa which could reflect activation by factor XIIa, although activation by thrombin remains a possibility. The best evidence for the importance of the contact system comes from the results of a phase II study that demonstrated that knock down of factor XI with an antisense oligonucleotide in patients undergoing elective knee arthroplasty reduced the risk of postoperative venous thromboembolism to a greater extent than enoxaparin. Furthermore, the thrombi that did form in patients with low levels of factor XI were very small in size, consistent with the role of factor XI in thrombus growth. Therefore the contact system is not only an important driver

Fig. 122.5 CONTACT SYSTEM. Factor XII (XII) is activated by contact with negatively charged surfaces. XIIa converts prekallikrein (PK) to kallikrein (K), which can feed back to activate more XII. Likewise, XIIa also can feed back to amplify its own generation. About 75% of circulating PK is bound to high-molecular-weight kininogen (HK), which localizes it to anionic surfaces and promotes PK activation. XIIa propagates clotting by activating XI, which then activates IX. The resultant IXa assembles into the intrinsic tenase complex, which activates X to initiate the common pathway of coagulation. Thrombin can feed back activate factor XI to further propagate coagulation.

of thrombosis in blood-contacting medical devices but may also contribute to thrombus propagation in situations where tissue factor initiates coagulation, such as after major surgery.

Prothrombinase

Being the only physiologic producer of thrombin, the prothrombinase complex is essential for hemostasis. Factor Xa binds to factor Va, its activated cofactor, on anionic phospholipid membrane surfaces to form the prothrombinase complex. Activated platelets release factor V from their α -granules, and this platelet-derived factor V may play a more important role in hemostasis than its plasma counterpart.¹⁷ Whereas plasma factor V requires thrombin activation to exert its cofactor activity, the partially activated factor V released from platelets already exhibits substantial cofactor activity. Activated platelets express specific factor Va binding sites on their surface, and bound factor Va serves as a receptor for factor Xa. The catalytic efficiency of factor Xa activation of prothrombin increases by 10^5 -fold when factor Xa incorporates into the prothrombinase complex.¹³ Prothrombin binds to the prothrombinase complex, where it undergoes conversion to thrombin in a reaction that releases prothrombin fragment 1.2 (F1.2). Plasma levels of F1.2, therefore, provide a marker of prothrombin activation. Prothrombin is the most abundant coagulation factor, and the efficiency of activation generates high local levels of thrombin.

Termination

Because thrombin clots fibrinogen, activates cells and platelets, and mediates anticoagulant and antifibrinolytic processes, it is imperative to regulate its activity and location. Thus the termination phase plays a critical role in balancing the procoagulant forces. Two principal

inhibitors modulate coagulation: TFPI and antithrombin. TFPI, which is located on platelets and microvascular endothelial cells, inhibits factor VIIa in a factor Xa-dependent manner. TFPI effectively halts tissue factor-mediated initiation of coagulation, but not before sufficient factor Xa is generated to propagate clotting. The high levels of thrombin produced during the amplification phase are controlled by antithrombin. This serine protease inhibitor (serpin) also inactivates other coagulation proteases, including factors VIIa, IXa, Xa, and XIa. Although antithrombin is abundant, it exhibits only moderate inhibitory activity, except in the presence of cell-associated glycosaminoglycans, such as heparan sulfate. This is the biochemical basis for use of heparin as an anticoagulant (see Chapter 149). Further regulation of thrombin generation is mediated by the protein C anticoagulant pathway which is catalyzed by thrombin. These processes ensure that thrombin generation is localized and limited. Sufficient thrombin is produced, however, to ensure that coagulation occurs.

Fibrin Formation

Thrombin converts soluble fibrinogen into insoluble fibrin. Fibrinogen is a dimeric molecule, each half of which is composed of three polypeptide chains, the A α , B β , and γ chains. Numerous disulfide bonds covalently link the chains together and join the two halves of the fibrinogen molecule (Fig. 122.6). Electron micrographic studies of fibrinogen reveal a trinodular structure with a central E domain flanked by two D domains. Crystal structures show symmetry of design with the central E domain, which contains the amino termini of the fibrinogen chains, joined to the lateral D domains by coiled-coil regions.

Fibrinogen circulates in a soluble form. Thrombin binds to the amino termini of the A α and B β chains of fibrinogen, where it cleaves specific peptide bonds to release fibrinopeptide A and fibrinopeptide B and generates fibrin monomer (Fig. 122.6). Because they are products of thrombin action on fibrinogen, plasma levels of these fibrinopeptides provide an index of thrombin activity. Fibrinopeptide release creates new amino termini that extend as knobs from the E domain of one fibrin monomer and insert into preformed holes in the D domains of other fibrin monomers. This creates long strands known as protofibrils, consisting of fibrin monomers noncovalently linked together in a half-staggered, overlapping fashion.¹⁸

Noncovalently linked fibrin protofibrils lack tensile strength.¹⁸ The stability of the fibrin network is enhanced by platelets and procoagulant cells.¹⁹ Platelets not only bind fibrin via GPIIb/IIIa and promote formation of a dense fibrin network, but they also release factor XIII. By covalently cross-linking α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin in a calcium-dependent fashion and renders it relatively resistant to physical strain and degradation. Factor XIII circulates in blood as a heterodimer consisting of pairs of A and B subunits. The active and calcium binding sites on factor XIII are localized to the A subunit. Platelets contain large amounts of factor XIII in their cytoplasm, but platelet-derived factor XIII consists only of the A subunits (see Chapter 125). Both plasma and platelet factor XIII are activated by thrombin.

Hemostasis depends on the dynamic balance between the formation of fibrin and its degradation. The fibrinolytic system mediates fibrin breakdown.

Fibrinolytic System

Fibrinolysis initiates when plasminogen activators convert plasminogen to plasmin, which then degrades fibrin into soluble fragments. Blood contains two immunologically and functionally distinct plasminogen activators, t-PA and u-PA. t-PA mediates intravascular fibrin degradation, whereas u-PA binds to a specific u-PA receptor (u-PAR) on the surface of cells, where it activates cell-bound plasminogen. Consequently, pericellular proteolysis during cell migration and tissue remodeling and repair are the major functions of u-PA.²⁰

Fig. 122.6 FIBRINOGEN STRUCTURE AND CONVERSION OF FIBRINOGEN TO FIBRIN. A dimeric molecule, each half of fibrinogen is composed of three polypeptide chains, A α , B β , and γ . Numerous disulfide bonds (*lines*) covalently link the chains together and join the two halves of the fibrinogen molecule to yield a trinodular structure with a central E domain linked via the coiled-coil regions to two lateral D domains. To convert fibrinogen to fibrin, thrombin cleaves specific peptide bonds at the amino (NH₂) termini of the A α and B β chains of fibrinogen to release fibrinopeptide A (FPA) and fibrinopeptide B (FPB), thereby generating fibrin monomer. Fibrin monomers polymerize to generate protofibrils arranged in a half-staggered overlapping fashion. By covalently cross-linking α and γ chains of adjacent fibrin monomers, factor XIIIa stabilizes the fibrin network and renders it resistant to degradation.

Regulation of fibrinolysis occurs on a number of levels (see [Chapter 127](#)). The substrate of the fibrinolytic system, fibrin, serves a transient but essential stimulatory role that subsides as it degrades. The serpins, PAI-1, and to a lesser extent, PAI-2, inhibit the plasminogen activators, whereas α_2 -antiplasmin inhibits plasmin. Endothelial cells synthesize PAI-1, which inhibits both t-PA and u-PA, whereas monocytes and the placenta synthesize PAI-2, which specifically inhibits u-PA. Thrombin-activatable fibrinolysis inhibitor (TAFI) also modulates fibrinolysis and provides a link between fibrinolysis and coagulation.²¹ Thrombosis can occur if there is impaired activation of the fibrinolytic system, whereas excessive activation leads to bleeding. Therefore a review of the mechanisms of action of t-PA, u-PA, and TAFI is worthwhile.

Mechanism of Action of Tissue-Type Plasminogen Activator

t-PA, a serine protease, contains five discrete domains: a fibronectin-like finger domain, an epidermal growth factor (EGF) domain, two kringle domains, and a protease domain. Synthesized as a single-chain polypeptide, t-PA is converted into a two-chain form by plasmin.

Single- and two-chain forms of t-PA convert plasminogen to plasmin. Native Glu-plasminogen is a single-chain polypeptide with a Glu residue at its amino-terminus. Plasmin cleavage near the amino-terminus generates Lys-plasminogen, a truncated form with a Lys residue at its new amino terminus.²⁰ t-PA cleaves a single peptide bond to convert single-chain Glu- or Lys-plasminogen into two-chain plasmin, composed of a heavy chain containing five kringle domains and a light chain containing the catalytic domain. Because its open conformation exposes the t-PA cleavage site, Lys-plasminogen is a better substrate than Glu-plasminogen, which assumes a circular closed conformation that renders this bond less accessible.

t-PA has little enzymatic activity in the absence of fibrin, but its activity increases by at least three orders of magnitude when fibrin is present. This increase in activity reflects the capacity of fibrin to serve as a template that binds t-PA and plasminogen and promotes their interaction. t-PA binds to fibrin via its finger and second kringle domains, whereas plasminogen binds fibrin via its kringle domains. Kringle domains are triple loop-like structures that bind Lys residues on fibrin and other proteins. As fibrin undergoes degradation, more Lys residues are exposed, which provide additional binding sites for t-PA and plasminogen. Consequently, degraded fibrin stimulates t-PA activation of plasminogen more than intact fibrin.

α_2 -Antiplasmin, another serpin, rapidly inhibits circulating plasmin by docking to its first kringle domain and then inhibiting the active site.²⁰ Because plasmin binds to fibrin via its kringle domains, plasmin generated on the fibrin surface resists inhibition by α_2 -antiplasmin. This phenomenon endows fibrin-bound plasmin with the capacity to degrade fibrin. Factor XIIIa cross-links small amounts of α_2 -antiplasmin onto fibrin, which prevents premature fibrinolysis.¹⁹

Like fibrin, endothelial cells bind t-PA and plasminogen and markedly promote activation by colocalization of enzyme and substrate. Cell-surface binding is mediated by receptors such as annexin II, gangliosides, and α -enolase, as well as an orphan transmembrane protein expressed with a carboxy-terminal lysine residue. Plasminogen binds to exposed lysine residues on these receptors via its kringle domains. Lipoprotein a, which also possesses kringle domains, impairs cell-based fibrinolysis by competing with plasminogen for cell-surface binding. This phenomenon may explain the association between elevated lipoprotein a levels and atherosclerosis.

Mechanism of Action of Urokinase-Type Plasminogen Activator

Synthesized as a single-chain polypeptide, single-chain u-PA (scu-PA) has minimal enzymatic activity. Plasmin converts scu-PA into a two-chain form that is enzymatically active and capable of binding u-PAR, the u-PA receptor on cell surfaces. Further cleavage at the amino-terminus of two-chain u-PA yields a truncated, lower-molecular-weight form that lacks the u-PAR binding domain.

Two-chain forms of u-PA readily convert plasminogen to plasmin in the absence or presence of fibrin.²⁰ In contrast, scu-PA does not activate plasminogen in the absence of fibrin, but it can activate fibrin-bound plasminogen, because plasminogen adopts the readily activatable open conformation. Like the higher-molecular-weight form of two-chain u-PA, scu-PA binds to cell surface u-PAR, where plasmin can activate it. Many tumor cells elaborate u-PA and express u-PAR on their surface. As with fibrin and plasminogen receptors, colocalization of the reactants greatly promotes activation. Plasmin generated on these cancer cells endows them with the capacity for metastasis because plasmin readily degrades components of the extracellular matrix and activates growth factors and other degradative proteases.

Mechanism of Action of TAFI

TAFI, a procarboxypeptidase B-like molecule synthesized in the liver, circulates in blood in a latent form where thrombin bound to thrombomodulin can activate it to TAFIa (see Chapters 126 and 127). Unless bound to thrombomodulin, thrombin activates TAFI inefficiently.²¹ TAFIa attenuates fibrinolysis by cleaving Lys residues from the carboxy termini of chains of degrading fibrin, thereby removing binding sites for plasminogen, plasmin, and t-PA, attenuating activation, and promoting inhibition. TAFI links fibrinolysis to coagulation because the thrombin-thrombomodulin complex not only activates TAFI, which attenuates fibrinolysis, but also activates protein C, which mutes thrombin generation.

TAFIa has a short half-life in plasma because the enzyme is unstable.²¹ Genetic polymorphisms can result in synthesis of more stable forms of TAFIa. Persistent attenuation of fibrinolysis by these variant forms of TAFIa may render patients susceptible to thrombosis.

DISORDERS OF HEMOSTASIS OR THROMBOSIS

A physiologic host defense mechanism, hemostasis focuses on arrest of bleeding by forming hemostatic plugs composed of platelets and fibrin at sites of vessel injury. In contrast, thrombosis reflects a pathologic process associated with intravascular thrombi that fill the lumens of arteries or veins.

TABLE 122.1 Comparison of the Features of Disorders of Primary, Secondary, or Tertiary Hemostasis

Features	Primary	Secondary	Tertiary
Components involved	Platelets, vWF, and vessel wall	Coagulation	Fibrinolysis factors
Site of bleeding	Skin and mucocutaneous and soft tissues	Muscles, joints, and deep tissues	Wounds and genitourinary tract
Physical findings	Petechiae and ecchymoses	Hematomas and hemarthroses	Hematuria and menorrhagia
Timing of bleeding	Immediate	Delayed	Delayed
Inheritance	Autosomal dominant	Autosomal or X-linked recessive	Autosomal recessive

vWF, von Willebrand factor.

TABLE 122.2 Disorders of Primary Hemostasis

Components Affected	Causes
Platelets	Quantitative or qualitative platelet disorders
vWF	Inherited or acquired deficiency or dysfunction of vWF
Vessel wall	Vasculitis or abnormalities of connective tissue supporting the vasculature

vWF, von Willebrand factor.

Hemostatic Disorders

Bleeding can occur if there is abnormal platelet plug formation and/or reduced thrombin generation and subsequent fibrin clot formation at the site of vascular injury; disorders of primary and secondary hemostasis, respectively. Bleeding also can occur if the platelet/fibrin clot is prematurely degraded because of excessive fibrinolysis; a disorder of tertiary hemostasis. The features distinguishing disorders of primary, secondary, and tertiary hemostasis are outlined in Table 122.1. Hemorrhagic disorders can be inherited or acquired, and the clinical and laboratory evaluation of such disorders is detailed in Chapters 128 and 129, respectively.

Disorders of Primary Hemostasis

Platelet plug formation, the first step in the arrest of bleeding at sites of injury, requires three key components (a) an adequate number of functional platelets, (b) vWF, the molecular glue that mediates platelet adhesion to the damaged vessel wall even in the face of high shear, and (c) a normal blood vessel that constricts in response to injury (Table 122.2). Because the platelet plug provides the first line of defense against bleeding, patients with disorders of primary hemostasis often present with immediate bleeding after injury, and petechiae (pinpoint hemorrhages) may be noted. In addition to skin bleeding, mucocutaneous bleeding, which may manifest as epistaxis, bleeding gums, or hematochezia, is common as is excessive menstrual bleeding in women (see Chapter 128).

Disorders of primary hemostasis may be inherited or acquired.²² Thrombocytopenia or congenital or acquired disorders of platelet function are common causes of bleeding. Thrombocytopenia can be the result of decreased production, which can occur because of failure, infiltration, or fibrosis of the bone marrow (see Chapters 29 and 30), increased platelet destruction, or abnormal distribution because of platelet pooling in the spleen (see Chapter 132). Increased

destruction of platelets can occur via immune mechanisms, such as immune thrombocytopenic purpura (ITP), alloimmune thrombocytopenia, posttransfusion purpura, and drug-induced thrombocytopenia (see [Chapter 131](#)), or nonimmune mechanisms, which include microangiopathic disorders, such as thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (see [Chapter 134](#)), as well as consumption because of activation of coagulation, such as occurs with disseminated intravascular coagulation (see [Chapter 139](#)).

Platelet function disorders include disorders of platelet (a) adhesion, such as von Willebrand disease (see [Chapter 138](#)) and Bernard-Soulier syndrome (see [Chapter 125](#)); (b) thromboxane synthesis; (c) secretion, such as alpha or dense granule deficiency or aspirin-like secretion defects; (d) aggregation, such as Glanzmann thrombasthenia (see [Chapter 125](#)); or (e) procoagulant activity (Scott syndrome) where the platelets fail to support clotting factor complex assembly (see [Chapter 126](#)). Acquired disorders of platelet function can occur in patients taking drugs that impair platelet function, such as aspirin or nonsteroidal antiinflammatory drugs, or in patients with uremia, paraproteins or myelodysplastic or myeloproliferative disorders (see [Chapter 130](#)).

Bleeding can also occur with inflammation or malformations of the blood vessels or abnormalities of the connective tissue supporting the blood vessels. Inflammatory disorders include Henoch-Schönlein purpura (see [Chapter 152](#)) and the vasculitis that occurs with paraproteins or cryoglobulins or in patients with systemic lupus erythematosus or other immune disorders.²³ Hereditary hemorrhagic telangiectasia is an inherited disorder associated with malformations of the capillaries. Telangiectatic vessels can often be seen in the oral and nasal cavities of patients with this disorder and bleeding episodes, primarily from the nose and gastrointestinal tract, are common. Abnormalities of the connective tissue matrix supporting the blood vessels include Marfan syndrome, Ehlers-Danlos syndrome, and pseudoxanthoma elasticum.²⁴ Patients with these disorders frequently report easy bruising.

Disorders of Secondary Hemostasis

Secondary hemostasis depends on rapid generation of sufficient amounts of thrombin to generate a fibrin mesh that not only consolidates the platelet aggregates that form at sites of vascular injury, but also is stable enough to provide a barrier that prevents leakage of blood from the damaged blood vessel.¹⁹ Secondary hemostasis can be compromised by (a) impaired thrombin generation because of congenital or acquired deficiencies of coagulation factors or cofactors or intake of drugs that inhibit one or more steps in the coagulation pathways, (b) congenital or acquired fibrinogen deficiency or dysfunction, and/or (c) impaired cross-linking of fibrinogen because of congenital or acquired deficiency of factor XIII ([Table 122.3](#)).

Examples of inherited deficiencies of coagulation factors include hemophilia A and B, deficiencies of factor VIII and factor IX, respectively (see [Chapter 135](#)). Because of redundancy in the coagulation system, only patients with a factor VIII or factor IX level less than 1% have severe disease characterized by spontaneous bleeding or

bleeding with minimal trauma. Those with factor levels between 1% and 5% have an intermediate phenotype, whereas patients with factor VIII or IX levels above 5% usually have mild disease and bleed only with trauma or surgery. The frequency of bleeding episodes in patients with severe hemophilia can be reduced with prophylactic administration of the appropriate factor concentrate; such treatment is also administered to hemophiliacs with overt bleeding, or in preparation for surgery or other major interventions. Long-lasting factor VIII and IX molecules have been developed to reduce the frequency of factor replacement. The half-lives of these recombinant full-length or truncated proteins have been prolonged by conjugating them to hydrophilic polymers such as polyethylene glycol or by fusing them with albumin or the Fc fragment of IgG₁. Conjugation to polyethylene glycol protects the proteins from proteolytic degradation, whereas fusion technology creates new recycling pathways that diminish natural protein breakdown (see [Chapter 136](#)). Management of hemophilia becomes more complicated if patients develop inhibitory antibodies that attenuate or abolish the activity of the infused factor.

Congenital deficiencies of prothrombin (factor II), factors V, VII, X, or XI (hemophilia C), or fibrinogen are less common causes of bleeding (see [Chapter 137](#)). In contrast, deficiencies of components of the contact pathway—factor XII, high-molecular-weight kininogen, and prekallikrein—are not associated with bleeding. The clinical and laboratory evaluation of such patients is detailed in [Chapters 128 and 129](#), respectively, whereas their treatment is outlined in [Chapter 115](#).

Acquired deficiencies of coagulation factors can result from decreased synthesis due to severe liver disease, vitamin K deficiency or intake of drugs that interfere with vitamin K metabolism, consumption because of excessive activation of coagulation (e.g., disseminated intravascular coagulation; see [Chapter 139](#)), or accelerated clearance due to adsorption by paraproteins or amyloid (see [Chapters 86 and 87](#)) or to autoantibodies that shorten the half-life or attenuate or abolish clotting factor activity.

Congenital disorders of fibrinogen include absence or low levels of fibrinogen (afibrinogenemia and hypofibrinogenemia, respectively) or synthesis of a dysfunctional protein (dysfibrinogenemia). Acquired disorders of fibrinogen include decreased synthesis or production of an abnormal fibrinogen, increased fibrinogen consumption or the presence of inhibitors that interfere with fibrin polymerization, such as paraproteins, autoantibodies, particularly in patients with systemic lupus erythematosus or other immune disorders or elevated levels of fibrin(ogen) degradation products.

Stabilization of fibrin requires cross-linking of the α and γ chains of adjacent fibrin monomers to yield a polymer that is resistant to premature breakdown. Factor XIIIa, a transglutaminase, performs this function by catalyzing the condensation of lysine residues on one chain with glutamic acid residues on another chain.²⁵ Congenital or acquired deficiency of factor XIII can impair cross-linking, resulting in bleeding. The hallmarks of severe factor XIII deficiency include umbilical stump bleeding in the neonatal period (see [Chapter 150](#)), intracranial hemorrhage with little or no trauma, recurrent soft tissue hemorrhages, and, in females, recurrent spontaneous miscarriages.

Disorders of Tertiary Hemostasis

Tertiary hemostasis depends on the generation of plasmin, which degrades fibrin and restores blood flow in damaged vessels. Premature lysis of fibrin in hemostatic plugs can lead to bleeding; this can occur systemically or can be localized ([Table 122.4](#)). Systemic fibrinolysis that occurs in the absence of activation of coagulation, so-called primary hyperfibrinolysis, is rare but can occur with inherited deficiency of PAI-1 or α_2 -antiplasmin, the inhibitors of the plasminogen activators and plasmin, respectively, advanced liver disease, and some snake bites. More commonly, systemic hyperfibrinolysis is secondary to activation of coagulation by procoagulants such as tissue factor (e.g., in patients with metastatic cancer) or artificial surfaces (e.g., in cardiopulmonary bypass surgery or with cardiac assist devices). Examples of localized hyperfibrinolysis include menorrhagia or hematuria after prostatectomy triggered by excessive plasmin generation

TABLE 122.3 Disorders of Secondary Hemostasis

Components Affected	Causes
Coagulation factors	Congenital deficiency, autoantibodies, increased consumption, or drugs that attenuate thrombin generation or thrombin activity
Fibrinogen	Decreased production; increased consumption or synthesis of an abnormal protein Impaired fibrin polymerization because of fibrin(ogen) degradation products or paraproteins
Fibrin cross-linking	Congenital or acquired factor XIII deficiency

TABLE 122.4 Disorders of Tertiary Hemostasis

Component Affected	Causes
Plasminogen activators	Increased t-PA or u-PA release in the GU tract or other tissues
Plasmin	Deficiency of PAI-1 or α_2 -antiplasmin, resulting in an increased plasmin concentration
Plasminogen activation	Enhanced plasminogen activation secondary to activation of coagulation by procoagulants, such as cancer cells, artificial surfaces, or snake venoms

GU, Genitourinary; PAI-1, plasminogen activator inhibitor 1; t-PA, tissue plasminogen activator; u-PA, urokinase-type plasminogen activator.

induced by the high concentrations of t-PA and u-PA in the uterus and genitourinary tract, respectively.

Thrombotic Disorders

Thrombosis may occur in arteries, in the chambers of the heart, or in the veins. Factors contributing to thrombosis in these sites include endothelial injury or activation, reduced blood flow, and hypercoagulability of the blood, the so-called Virchow triad.

Arterial Thrombosis

Most arterial thrombi occur on top of disrupted atherosclerotic plaques. Plaques with a thin fibrous cap and a lipid-rich core are most prone to disruption. Erosion or rupture of the fibrous cap exposes thrombogenic material in the lipid-rich core to the blood and triggers platelet activation and thrombin generation. The extent of plaque disruption and the content of thrombogenic material in the plaque determine the consequences of the event, regardless of whether it occurs in the cerebral circulation (see Chapter 145), the coronary circulation (see Chapter 146), or the major arteries of the legs (see Chapter 148), but host factors also contribute. Breakdown of regulatory mechanisms that limit platelet activation and inhibit coagulation can augment thrombosis at sites of plaque disruption.

Decreased production of nitric oxide and prostacyclin by diseased endothelial cells can trigger vasoconstriction and platelet activation. Proinflammatory cytokines lower thrombomodulin expression by endothelial cells, which promotes thrombin generation, and they stimulate PAI-1 expression which inhibits fibrinolysis.

Products of blood coagulation contribute to atherogenesis, as well as to its complications (see Chapter 144). Microscopic erosions in the vessel wall trigger the formation of tiny platelet-rich thrombi.²⁶ Activated platelets release PDGF and TGF- β , which promote a fibrotic response. Thrombin generated at the site of injury not only activates platelets and converts fibrinogen to fibrin, but also activates PAR-1 on smooth muscle cells and induces their proliferation, migration, and elaboration of extracellular matrix. Incorporation of thrombi into plaques promotes plaque growth, and decreased endothelial cell production of heparan sulfate—which normally limits smooth muscle proliferation—contributes to plaque expansion.²⁶ The multiple links between atherosclerosis and thrombosis have prompted the term atherothrombosis (see Chapter 144).

Intracardiac Thrombosis

Thrombi can form in the left ventricle after transmural myocardial infarction or with an aneurysm or dyskinetic ventricle, or in the left atrial appendage, particularly in patients with atrial fibrillation (see Chapter 147). Damage to the endothelium after myocardial

infarction and abnormal blood flow are the major triggers for left ventricular thrombus formation. With rapid atrial fibrillation, there also is stasis and turbulent blood flow in the left atrial appendage, which is a long, blind-ended trabeculated pouch.²⁷ This may lead to localized activation of endothelial cells and subsequent loss of their anticoagulant phenotype, a process amplified by adhesion of leukocytes and subsequent elaboration of proinflammatory cytokines. The generation of thrombin creates a local hypercoagulable state that likely promotes thrombus formation on the abnormal endothelium. Embolization of these thrombi to the brain is a common cause of ischemic stroke and the major cause of mortality and morbidity in patients with atrial fibrillation.

Venous Thrombosis

The causes of venous thrombosis include those associated with hypercoagulability, which can be genetic or acquired, and the mainly acquired risk factors, such as advanced age, obesity, or cancer, which are associated with immobility (see Chapters 140 and 142). Inherited hypercoagulable states and these acquired risk factors combine to establish the intrinsic risk of thrombosis for each individual.² Superimposed triggering factors, such as surgery, pregnancy, or hormonal therapy, modify this risk, and thrombosis occurs when the combination of genetic, acquired, and triggering forces exceed a critical threshold.²⁸

Some acquired or triggering factors entail a higher risk than others. For example, major orthopedic surgery, neurosurgery, multiple trauma, and metastatic cancer (particularly adenocarcinoma) are associated with the highest risk; prolonged bed rest, antiphospholipid antibodies (see Chapter 141), and the puerperium are associated with an intermediate risk; whereas pregnancy, obesity, long-distance travel, or the use of oral contraceptives or hormonal replacement therapy are mild risk factors. Up to half of patients who present with venous thromboembolism before the age of 45 have inherited hypercoagulable disorders—so-called thrombophilia (see Chapter 140)—particularly those whose event occurred in the absence of risk factors or with minimal provocation, such as after minor trauma or a long-haul flight or with estrogen use.²⁹

TREATMENT OF DISORDERS OF HEMOSTASIS AND THROMBOSIS

By the midpoint of the 20th century, two major anticoagulant drugs had been discovered, characterized, and given to humans for prevention or treatment of thrombotic disorders. Heparin and vitamin K antagonists, such as warfarin, dominated treatment regimens for decades. In the same era, determination of their mechanisms of action and dosing was aided by the discovery of the main players of the coagulation system, resulting from the development of sensitive functional assays to monitor their activity. Heparin and warfarin still represent effective members of the anticoagulant armamentarium; however, detailed understanding of the biochemistry and cell biology of hemostasis has directly contributed to the development of new therapies. Heparin derivatives with more predictable pharmacokinetics have improved therapy and reduced complications (see Chapter 149). Small molecule, direct inhibitors of thrombin and factor Xa have been developed as non-vitamin K antagonist (or direct) oral anticoagulants, such as dabigatran, rivaroxaban, apixaban, and edoxaban, that are replacing conventional therapies (see Chapter 149). The resurgence of interest in the contact system as a potential mediator of thrombosis has led to the investigation of factors IX, XI, and XII as new targets for therapy. Likewise new antiplatelet agents that antagonize activation or aggregation steps are being used in conjunction with aspirin to prevent and treat arterial thrombosis (see Chapter 146). On the hemostasis side, regimens to treat bleeding disorders include administration of factors VIIa, VIII, or IX, and prothrombin complex concentrates (see Chapters 135, 136, and 137). The new agents and treatment regimens highlight the therapeutic benefit that has resulted from our detailed understanding of hemostasis and thrombosis.

THE BLOOD VESSEL WALL

Marianne A. Grant and Aly Karsan

The vasculature plays a major role in conveying and distributing hematopoietic cells, nutrients, gases, metabolites, and various chemical mediators.¹ The interior of the vessel wall is lined by the endothelium, comprising more than 1012 endothelial cells, covering a surface of approximately 500 m² and weighing approximately 1 kg in total.^{2,3} The endothelium forms a continuous monolayer at the interface between blood and tissue. Thus it contributes significantly to sensing and transducing of signals between blood and tissue, trafficking of hematopoietic cells, and maintenance of a nonthrombogenic surface permitting flow of blood. Normally quiescent with cell turnover measured on the order of years, endothelial cells have a remarkable capacity to proliferate and vascularize tissues in physiologic (menstrual cycle) and pathologic (tumorigenesis, diabetic retinopathy) situations.⁴ The endothelium is critical for initiating and potentiating the inflammatory response. The pathogenesis of several disorders, such as atherosclerosis, hypertension, diabetic angiopathy, and microangiopathic hemolytic anemias, involves dysfunction of the endothelial lining. The complexity and the vast array of its functional responses have led to the description of the endothelium as a distributed organ.⁵ This chapter provides a conceptual framework of the structure and development of the vessel wall and the physiologic functions of the endothelium as it relates to the hematopoietic system.

STRUCTURE OF THE VESSEL WALL

The circulatory system has traditionally been divided into the macrovasculature (vessels >100 µm in diameter) and the microvasculature.⁶ The arterial system transports blood to tissues, resists changes in blood pressure proximally, and regulates blood flow distally. Veins return blood to the heart and act as capacitance vessels because they contain approximately 70% of the total blood volume. Venules with luminal diameters less than 50 µm are structurally similar to capillaries.⁶ Capillaries and microvessels in general are particularly important in the exchange of gases, macromolecules, and cells between blood and tissue. Although large vessels play an important role in maintaining vascular tone, a significant proportion of peripheral resistance arises from the capillaries.⁷ Capillary endothelial cells also have a metabolic role, as in the conversion of angiotensin and hydrolysis of lipoproteins. Finally, sprouting of new vessels is initiated in the microvasculature.

Macrovasculature

Large vessels are composed of three layers: intima, media, and adventitia.^{6,8} The intima comprises the endothelium and the subendothelium. The endothelial cells of large vessels contain a distinct rod-shaped organelle, measuring approximately 3 µm × 0.1 µm, called the Weibel-Palade body.⁹ Ultrastructural studies indicate the presence of a single membrane around the Weibel-Palade body with tubular structures within. This organelle contains von Willebrand factor (vWF), and P-selectin has been reported to be present on the surrounding membrane.^{10–12} The abluminal face of the endothelium rests on a basement membrane, which supports the endothelial cell and can act as a secondary barrier against the extravasation of blood.² The subendothelial matrix contains occasional smooth muscle cells and scattered macrophages. Both smooth muscle cells and endothelial

cells contribute to the extracellular matrix (ECM) of the intima, along with ECM components including elastin and collagen.^{13,14} In large vessels, the media is separated from the intima by a layer of elastin, the internal elastic lamina. Diseases associated with mutations in elastin include supravalvular aortic stenosis,^{15,16} Williams syndrome,¹⁷ and autosomal dominant cutis laxa.¹⁸ The medial layer is composed primarily of concentric layers of smooth muscle cells and their secreted matrix, which is a complex mix of glycoproteins and proteoglycans. This layer is responsible for the structural integrity of the wall and for maintaining vascular tone. Mutations of the fibrillin-1 gene, a microfilament protein in elastic fibers, result in disruption of the media in Marfan syndrome.¹² Defects of type III collagen can cause aortic rupture in patients with Ehlers-Danlos syndrome type IV.¹⁴ An attenuated band of elastic fibers, the external elastic lamina, separates the adventitia from the media. The adventitia is composed of loose connective tissue, and the outer portion of the media contains an ECM scaffold containing fibroblasts, small nerves, progenitor cells, lymphatic vessels, and nutritive blood vessels, the vasa vasorum. The adventitia has been recognized as a dynamic environment, important in the growth, disease, and repair of the artery. The external limit of the adventitial layer is loosely defined and becomes continuous with the surrounding connective tissue of the organ.^{6,8}

Microvasculature

Capillaries and postcapillary venules are composed of two cell types: endothelial cells and pericytes.¹⁹ Pericytes and endothelial cells are invested with a basement membrane and, depending on the vascular bed, variable amounts of matrix separate the two cell types. Both cell types contribute to secretion of basement membrane proteins, demonstrating that pericyte–endothelial interaction plays a key role in basement membrane formation, maintenance, and remodeling. Long pericyte processes extend over the abluminal surface of the endothelial cell,²⁰ and reciprocal extensions of the endothelial cell make contact with the pericyte. At distinct points in the basement membrane, pericytes and endothelial cells form specialized junctions with each other. Adherens junctions connect the cytoskeleton of pericytes and endothelial cells, mediating contact inhibition through contractile forces. Gap junctions between the cytoplasm of pericytes and endothelial cells enable communication through the passage of metabolites and ionic currents.²¹ A variety of functions have been ascribed to the pericyte, including^{19,22,23} (1) a contractile function, which regulates blood flow; (2) multipotential capabilities resulting in differentiation to adipocytes, osteoblasts, phagocytes, and smooth muscle cells; and (3) regulation of capillary growth. The best evidence probably exists for the last function. In animal models^{24,25} and human disease (diabetic microangiopathy, hemangiomata),²⁶ a lack of pericytes is associated with microaneurysms and disordered microvasculature. In addition, there is a temporal correlation between pericyte contact and cessation of vessel growth in wound healing,²⁷ and pericyte contact suppresses endothelial cell migration and proliferation in vitro.¹⁹

Endothelial Structure and Function

In contrast to circulating blood cells and vascular smooth muscle cells but similar to epithelial cells, the endothelium exhibits polarity

manifested by the asymmetric distribution of cell surface glycoproteins and by the unidirectional secretion of some ECM proteins and chemical mediators.^{28,29} Although in cultured endothelial cells an apical–basal polarity is established before confluence, intercellular junctions may have a role in maintaining the asymmetry *in vivo*.^{28,30}

Four types of intercellular junctions between adjacent endothelial cells have been described^{30,31}: tight junctions, gap junctions, adherens junctions, and syndesmos. Their distribution varies along the vascular tree, with tight junctions occurring more frequently in the larger arteries and brain vasculature, correlating with a more stringent requirement for permeability control. The molecular structure of endothelial tight junctions is similar to that of epithelial cells, consisting of a network of fibrils, with the integral membrane components composed of occludin, claudin-5, and junctional adhesion molecules (JAMs), which associate with various structural and signaling proteins on the cytoplasmic face.³² The distribution of gap junctions tends to follow that of tight junctions. Connexin 37, connexin 40, and connexin 43 are gap junction proteins that have been detected in endothelial cells. Gap junctions mediate communication between adjacent endothelial cells, and between endothelial cells and pericytes or smooth muscle cells; they also contribute to the endothelial barrier and vascular integrity. Adherens junctions are formed by transmembrane glycoproteins called cadherins, which make the link between cell-to-cell contacts and the cytoskeleton. Several different types of cadherins are expressed in endothelial cells. The endothelial-specific cadherin vascular endothelial cadherin (VE-cadherin [cadherin-5]) is expressed on virtually all types of endothelium.³¹ Similar to other cadherins, VE-cadherin forms homotypic contacts with VE-cadherin on adjacent cells. Within the cell, VE-cadherin complexes with catenins, which, through other proteins, contact the actin cytoskeleton. Homotypic engagement of VE-cadherin results in density-dependent inhibition of endothelial proliferation, which appears to be mediated by association of vascular endothelial growth factor receptor 2 (VEGFR-2) with VE-cadherin, thereby sequestering VEGFR-2 at the membrane and preventing its internalization into signaling compartments.³³ The structure of the fourth type of junction, the syndesmos, is not well elucidated.

Other membrane proteins that are located at interendothelial junctions include platelet endothelial cell adhesion molecule 1 (PECAM-1), which may be important in directing the formation of junctions, nectins, JAMs, endothelial cell-selective adhesion molecule (ESAM), and the integrins (particularly $\alpha 2\beta 1$ and $\alpha 5\beta 1$).^{34,35} In addition to the functions listed previously, intercellular contacts are important in maintaining cell survival.³⁶

On the luminal side, endothelium is exposed to blood elements and, under pathologic conditions, to circulating molecules such as cytokines and bacterial products. Engagement of endothelial receptors by these humoral factors activates a well-described series of responses, including the recruitment and transmigration of leukocytes and changes in endothelial cell coagulant activity (see [The Endothelium as a Nonthrombogenic Surface](#) section). Biomechanical forces resulting from pulsatile blood flow have been shown to mediate striking changes in endothelial morphology and metabolism. Vessels must withstand three types of physical forces: radial distension (tension), longitudinal stretch, and tangential shear stress. In response to flow (shear stress), endothelial cells reorganize their cytoskeletal architecture, rearrange focal contacts at the basal surface, and align in the direction of flow.^{37–39} Some endothelial cell responses following exposure to physical forces occur within seconds, such as activation of potassium channels and increased release of nitric oxide (NO), resulting in vasodilation. Other endothelial cell responses to flow are related to changes in gene expression and occur after a delay of a few hours. Elements in the promoters of various adhesion molecule and growth factor genes have been shown to contain sequences that respond to shear stress (in a positive or negative fashion) and have been referred to as the *shear stress response element*.^{37–39}

Endothelial cells vectorially secrete certain ECM proteins to the abluminal face. The matrix molecules that are secreted by endothelium include several types of collagen, elastin, fibronectin, laminins, and proteoglycans (e.g., heparan sulfate and dermatan sulfate). The exact

composition of the subendothelium varies with location in the vascular tree, age, and disease states.^{2,14,40} Endothelial cells bind to the ECM via heterodimeric cell surface glycoproteins—the integrins—which link and integrate matrix proteins to the cytoskeleton at sites referred to as *focal contacts*.⁴¹ The integrins detected in resting endothelium include $\alpha 6\beta 1$, $\alpha 5\beta 1$, $\alpha 2\beta 1$, and $\alpha v\beta 3$.⁴² Interestingly, endothelial cells express integrins on luminal as well as abluminal surfaces.⁴² The ECM serves several important functions: (1) it serves as a barrier to macromolecules in the event of disruption of the endothelium; (2) it sequesters growth factors and mediates their high-affinity binding to endothelial cells (e.g., heparan sulfate binds to fibroblast growth factor [FGF]); and (3) it acts as a counterstructure for the binding of endothelial cell integrins.^{14,40,43} This binding of endothelial cells to the ECM serves at least four purposes: (1) Whereas certain matrix molecules provide a physical scaffold, others act as haptotactic agents, inducing endothelial cells to migrate.¹⁴ (2) Clustering of integrins at focal adhesion contacts by certain matrix molecules can transduce survival or differentiation signals by causing phosphorylation of various proteins and lipids.⁴³ Whereas fibronectin and vitronectin provide survival signals, laminins appear to signal differentiation.^{44–46} (3) By maintaining cell shape, integrin-mediated cell spreading provides an antiapoptotic signal independent of direct integrin-initiated signal transduction.⁴⁷ (4) By anchoring the cell, the matrix provides a mechanism whereby blood flow at the luminal surface of the endothelium creates shear stress, which also transmits signals to cells.³⁷

Endothelial Heterogeneity

Despite their common features, quiescent endothelial cells *in vivo* represent a widely heterogeneous population, with their phenotype depending on vessel caliber and location. Exposure to different physical forces (e.g., arteries vs. veins) and the different functions served by vessels of different caliber are reflected in different endothelial phenotypes.⁴⁸ However, study of the molecular basis of the heterogeneity of these different populations is just beginning. Experiments using serial analysis of gene expression and *in vivo* delivery of phage display peptide libraries have revealed organ- and tumor vasculature-specific molecules that will help to elucidate the molecular basis of endothelial heterogeneity.^{49–51} Within the microvasculature is a structural heterogeneity of capillaries, depending on the organ supplied. Even within a single organ, endothelial cells exhibit different phenotypes, depending on their functional role. When microvessels from different organs are harvested and cultured *in vitro*, they lose some of their distinctive characteristics with progressive passaging. Some specialization of the different endothelial cells can be retained if they are cocultured with cells or matrix from the organ from which they are derived. Thus matrix proteins, soluble factors from the organ, or heterotypic contacts with parenchymal cells or pericyte or smooth muscle cells are believed to be important factors in specifying endothelial cell phenotype.⁵² Conversely, emerging evidence indicates that endothelial cells in turn provide instructive morphogenic cues during organogenesis and in adults.⁵³ Specific examples of microvessels found in hematopoietic tissues are discussed in the following sections. Endothelial cells from veins and arteries and from capillaries of different organs demonstrate heterogeneity at structural, functional, and molecular levels.⁵⁴ Intriguingly, phenotypic heterogeneity also exists between neighboring endothelial cells exposed to the same extracellular environment. In the case of endothelial-restricted vWF expression, heterogeneity denoted by mosaic vWF expression proved dynamically regulated by bistable transitions in the DNA methylation status of the vWF promoter, suggesting novel stochastic phenotype switching potentials in endothelial microenvironments.⁵⁵

High Endothelial Venules

Lymphocyte migration into secondary lymphoid sites, such as lymph nodes, Peyer patches, and chronically inflamed nonlymphoid tissues, occurs at specialized postcapillary venules called *high endothelial*

venules (HEVs).⁵⁶ The endothelial cells of these venules (HEV-ECs) exhibit a plump or cuboidal morphology (hence the name high endothelial venule), display intense biosynthetic activity, and are encircled by a continuous thick basal lamina formed from ECM components produced by surrounding pericyte-like cells called *fibroblastic reticular cells*. HEV-ECs are composed of free ribosomes, multivesicular bodies, well-developed Golgi apparatus, tissue-specific adhesion molecules, and chemokines.⁵⁷ They secrete a thick glycocalyx, of which a proportion is glycosylation-dependent cell adhesion molecule 1, a ligand for L-selectin.⁵⁸ CD34 is another HEV “addressin” on peripheral lymph node endothelial cells. Endothelium of mesenteric lymph nodes and Peyer patches express mucosal addressin cellular adhesion molecule 1 (MAdCAM-1) as a ligand for L-selectin and $\alpha 4\beta 7$ integrin. HEV-EC express additional L-selectin ligands grouped together as peripheral node addressins (PNAd) including glycosylation-dependent cellular adhesion molecule 1 (GlyCAM-1),⁵⁹ endomucin,⁶⁰ and nepmuin.⁶¹ Expression of these different addressins may recruit specific subpopulations of lymphocytes to different lymphoid tissues (i.e., they facilitate the “homing” of lymphocytes). Several other proteins, including the chemokine receptor DARC (Duffy antigen receptor for chemokines) and the antiadhesive matrix protein Hevin, have been identified as being preferentially expressed by the high endothelial venule.⁶² Tight junctions are present at intermittent spots, and extensive overlap between the membranes of adjacent cells prevents macromolecules from interendothelial transit. However, when lymphoid cells transit to the high endothelial venule, there is a temporary breach in the barrier.⁵⁸ Evidence suggests that the high endothelial venule not only plays a critical role in homing and recruitment of immune cells, but also can influence the outcome of the immune response.⁶³

Bone Marrow Sinuses

Much less is known about the bone marrow (BM) sinuses than about the high endothelial venule. The BM sinus endothelial cell is flat, in contrast to that of the high endothelial venule, with loose interdigitated junctions and the basal lamina is discontinuous. It has been suggested that hematopoietic cells traverse pores present at attenuated areas of the endothelium rather than move by an interendothelial route.⁶⁴ Clearly, the BM sinus endothelial cell is specialized given the regulated egress of cells from the BM. For example, if a red blood cell (RBC) that still is nucleated begins to enter the circulation, the body of the cell is allowed to cross and is released as a reticulocyte, while the nucleus is retained extravascularly. The adventitial reticular cell (similar to a pericyte) is also thought to play an important role in controlling hematopoietic cell egress.⁶⁵ Stromal cell–derived factor 1 (SDF-1; also called CXC-chemokine ligand [CXCL]12) and chemokine receptor CXC-chemokine receptor (CXCR)4 interactions are essential for stem cell homing, mobilization, and transendothelial migration into the BM.^{66,67} SDF-1 activates the integrins lymphocyte function-associated antigen 1 (LFA-1 [$\alpha L\beta 2$]), very late antigen 4 (VLA-4 [$\alpha 4\beta 1$]), and very late antigen 5 (VLA-5 [$\alpha 5\beta 1$]). Whereas vascular cell adhesion molecule 1 (VCAM-1), which is expressed on BM endothelial cells (and spleen endothelial cells in the mouse), appears to be the major BM addressin for hematopoietic progenitor cells expressing VLA-4, intercellular adhesion molecule 1 (ICAM-1) binds LFA-1.^{67,68} Endothelial selectins also have been implicated in promoting hematopoietic stem and progenitor cell homing to the BM.⁶⁹ Factors such as CD44, cytoskeletal rearrangement, and matrix metalloproteinases (MMPs) are other key players in the homing process related to the endothelium.⁶⁷ The BM endothelium is also involved in regulating hematopoiesis (see [Relationship Between Vascular Development and Hematopoiesis](#) section).

VASCULAR DEVELOPMENT AND DIFFERENTIATION

The human embryo develops a vascular system by the third week, when its nutritional needs are no longer met by diffusion.⁷⁰ Vascular

development proceeds in several ways. Vasculogenesis is the process whereby blood vessels form *de novo* from the differentiation of mesodermal precursors. Angiogenesis is the outgrowth of new capillaries from preexisting vessels and is thought to be the major mode of new vessel development in the adult. Arteriogenesis, or collateral development, is the rapid enlargement of preexisting collateral arterioles after occlusion of a supply artery. Lymphangiogenesis is the development of lymphatic vessels, which are required for transportation of extravasated lymph and lymphoid cells. Finally, in some neoplasms, tumor cells rather than endothelial cells form vascular channels or a portion of some vessels, a process termed *vasculogenic mimicry*.⁷¹ A similar nonendothelial cell lining of vascular channels can be created by placental cytotrophoblasts forming hybrid fetal–maternal vessels in the endometrium.⁷¹

Vasculogenesis

Vasculogenesis in the yolk sac proceeds initially by the differentiation of mesodermal cells into angioblasts.⁷² Angioblasts are vascular cells that express some, but not all, endothelial markers. These cells arise from mesodermal cells resting on the endoderm (splanchnopleuric mesoderm) but not from the mesoderm adjacent to the ectoderm (somatopleuric mesoderm). Thus it is believed that whereas the endoderm positively regulates vascular development, the ectoderm negatively regulates vasculogenesis. Organs that are primarily of ectodermal origin (e.g., brain and kidney) are vascularized by angiogenesis and not by vasculogenesis. The mesodermal cells migrating outward from the endoderm form primitive structures termed *blood islands*. Whereas the cells at the center of the blood island are hematopoietic precursors, those arranged peripherally are angioblastic precursors. Vasculogenesis within the embryo begins shortly after that in the yolk sac, again in close association with endoderm.⁷³ However, except for a region on the ventral aspect of the embryonic aorta, intraembryonic vascular development occurs in solitary angioblasts rather than blood islands. Angioblasts differentiate *in situ* and form primary capillary plexuses with lumens, or they migrate and fuse with other angioblasts or capillaries. Fusion of angioblasts or blood islands results in the formation of a capillary plexus that undergoes extensive remodeling over the developmental period.⁷²

Vasculogenesis in the Adult

Although initially said to occur primarily in the embryo, vasculogenesis may also play a role in promoting vascular development in adults. The identification of circulating BM-derived vascular precursors and the demonstration that these precursors can integrate into the vasculature at sites of angiogenesis describe an adult form of *de novo* vessel development.⁷⁴ Two distinct BM-derived precursors with the ability to differentiate into vascular cells have been identified: (1) accumulating evidence points to a single precursor, the hemangioblast, which can differentiate into either hematopoietic or endothelial cells,⁷⁵ and (2) a multipotent nonhematopoietic adult progenitor cell, which is thought to represent a BM mesenchymal stem cell (BM-MSC). When injected intravenously into adult mice, these MSCs differentiate into vascular cells, hematopoietic cells, and several epithelial cell types.^{76,77} Once seeded on a synthetic graft, BM-MSCs differentiate into both smooth muscle and endothelial cells *in vivo*.⁷⁸ Both types of multipotential precursor populations express CD133, a cell surface marker that is lost upon further maturation.⁷⁹ However, only the hemangioblast expresses CD34. Whether MSCs are able to circulate and thus contribute to neovascularization outside the BM remains to be shown. Various stresses, including neoplasia, sepsis, burns, and trauma, have been suggested to induce mobilization of BM-derived endothelial precursors, which express CD133, CD34, and VEGFR-2.⁷⁹ Cytokines that reportedly induce mobilization of BM-derived endothelial precursors include VEGF-A and granulocyte macrophage colony-stimulating factor (GM-CSF),⁷⁹ as well as SDF-1, which stimulates mobilization of CXCR4+ BM cells, including

hematopoietic stem cells (HSCs) and EPCs.^{80,81} Recent data have implicated IL-8 as a regulator in mobilizing EPCs into the peripheral circulation by binding both CXCR1 and CXCR2.⁸² The contribution of BM-derived vascular precursors to angiogenic vessels in tumors is highly variable, depending on the study, the model used, and the tumor cell type used.⁸³ The degree of endothelial precursor incorporation into the angiogenic vasculature is highly controversial; several groups suggest negligible, if any, involvement by distant precursors.⁸³ The problem arises in part from the poor definition of a circulating endothelial precursor cell. Many, if not all, of the markers used to define this rare cell population are shared with hematopoietic stem or progenitor cells, and the distinction between the endothelial and hematopoietic precursor has not been rigorously addressed in the majority of studies. More recent work has suggested that BM-derived, perivascular CD11b+ hematopoietic cells secreting angiogenic cytokines have been misidentified as endothelial precursor cells.^{84,85}

Angiogenesis

In a normal adult, angiogenesis occurs primarily in the female reproductive system. However, angiogenesis is a process that has a major impact in several pathologic situations. Probably the best known and studied example of pathologic neovascularization occurs during tumor progression. Angiogenesis also is important in chronic inflammation, ischemia, and wound healing.

Capillary sprouts from the existing microvasculature form secondary to an inciting stimulus that results in increased vascular permeability, accumulation of extravascular fibrin, and local proteolytic degradation of the basement membrane.^{86–88} Endothelial cells overlying the disrupted region become “activated,” change shape, and extend elongated processes into the surrounding tissue. Filopodia extending from the specialized endothelial cells at the tip of the vascular sprout guide the migration of the nascent vessel.⁸⁹ Directed migration toward the angiogenic stimulation results in the formation of a column of endothelial cells. Just proximal to the migrating tip of the column is a region of proliferating endothelial cells. These proliferating cells cause an increase in the length of the sprout. In the region of proliferation, up to 20% of endothelial cells may enter the cell cycle. This is in marked contrast to quiescent endothelium, of which less than 0.01% of cells are cycling. Proximal to the proliferative zone, the endothelial cells undergo another shape change, adhere tightly to each other, and begin to form a lumen. Evidence suggests that endothelial lumina arise through the formation and fusion of intracellular vacuoles.⁹⁰ Secondary sprouting from the migrating tip results in a capillary plexus, and fusion of individual sprouts at their tips closes the loop and circulates blood into the vascularized area. Activated macrophages and platelets, by secreting growth factors, cytokines, proteases, and protease inhibitors, can influence all phases of the angiogenic process.⁹¹

The morphologic features described are characteristic of sprouting angiogenesis. Another mechanism of angiogenesis, “intussusceptive microvascular growth,” refers to vascular network formation by insertion of interstitial tissue columns, called *tissue pillars* or *posts*, into existing vascular lumen and subsequent growth of these columns, resulting in partitioning of the vessel lumen. Periendothelial cells, including pericytes and myofibroblasts, which invade the pillar core stabilize the structure in association with collagen fibrils. The mechanisms of intussusceptive angiogenesis are less well described, but hemodynamic factors appear to be involved.⁹²

Recruitment of Periendothelial Cells

Whether formed by vasculogenesis or angiogenesis, maturation of new vessels requires recruitment of smooth muscle cells or pericytes to reestablish vessel integrity. Periendothelial cells provide structural support, assist in production of the ECM, provide contractile function so as to modulate vessel caliber, and maintain the cells in a quiescent state. Genetically altered mice that fail to invest their vessels

with pericytes develop microaneurysms.²⁴ In embryos, periendothelial cells are thought to be derived from locally available mesenchymal cells as endothelial cells invade organ rudiments. Local derivation of periendothelial cells may be one mechanism that allows for tissue-specific phenotype of the vasculature.¹⁹ Evidence suggests that embryonic endothelial cells may transdifferentiate into vascular smooth muscle cells.⁹³ Evidence also indicates that some periendothelial cells are derived from the neural crest during embryogenesis and from BM-derived precursors in adults.^{94–97} Although some studies have shown pericytes to be potential antivascular targets for tumor therapy,^{96,98} other work has suggested that pericytes act to limit tumor metastasis.⁹⁹

Extracellular Matrix

It is thought that whereas interstitial collagens (e.g., collagen I) and provisional plasma-derived fibronectin–fibrin matrices stimulate endothelial tubular morphogenic events, laminin-rich matrices lead to endothelial differentiation and stabilization events.⁹¹ Mice deficient in fibronectin die during embryogenesis and show vascular defects. Type I collagen-deficient mice die of circulatory failure just before birth. Although most tumor vessels are covered by basement membrane, this layer has multiple structural abnormalities consistent with ongoing vascular activation in tumors.¹⁰⁰ ECM proteins or their proteolytic fragments have been shown to inhibit angiogenesis.

Dissolution of the underlying matrix by MMPs and heparanases allows endothelial cells to migrate at the initiation of angiogenesis.^{101,102} Matrix-bound growth factors are also released as a consequence of ECM degradation. The balance between positive and negative regulators is the basis of tight control in this process. Tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), by generating plasmin, can activate collagenases and other MMPs. Plasminogen activator inhibitors (PAIs) may block angiogenesis at this step. Action of the MMPs is required for angiogenesis, and the tissue inhibitors of MMPs regulate their function.¹⁰³

Cell Adhesion Molecules

Of the various classes of cell adhesion molecules involved in angiogenesis, the integrins have been the most studied.^{14,104,105} Although it is universally accepted that integrins and integrin ligands function in angiogenesis, their exact actions remain unclear. In particular, substantial controversy surrounds the role of $\alpha_v\beta_3$ integrin.^{14,104,106} Immunohistochemical studies localize this integrin to the tips of sprouting vessels. Neutralizing antibodies abrogate angiogenesis and induce vascular cell apoptosis in vivo, and inhibitory peptides or peptidomimetics blocking adhesive functions of integrin $\alpha_v\beta_3$ inhibit angiogenesis in a variety of animal models.¹⁰⁷ However, mice lacking α_v show extensive angiogenesis, and mice and humans (Glanzmann thrombasthenia) lacking β_3 integrin also show normal angiogenesis. Notwithstanding the discrepancies outlined, preclinical studies have validated $\alpha_v\beta_3$ and potentially other integrins ($\alpha_v\beta_5$, $\alpha_1\beta_1$, $\alpha_2\beta_1$, $\alpha_5\beta_1$, $\alpha_6\beta_4$) as therapeutic antiangiogenic targets, and clinical trials with combination therapy are currently in progress.¹⁰⁸ One of the integrin receptors for fibronectin, $\alpha_5\beta_1$, has been shown to be necessary for vascular development, and $\alpha_2\beta_1$ seems important for the formation of tubes by endothelial cells in vitro. However, there likely is a dynamic regulation of β_1 integrins during angiogenesis because constitutive activation of this integrin inhibits endothelial sprouting in vitro and angiogenesis in vivo.¹⁰⁹ The junctional proteins VE-cadherin and PECAM-1, and possibly JAM-1, are expressed early in development and have a role in assembling the vasculature.^{33,110,111}

Guidance Molecules

Similar to the nervous system, the vascular system forms a highly ordered, branching network. The ordering of this patterned network

is dependent on multiple attractive and repulsive cues, many of which are common to both the nervous and vascular systems.^{112,113} Tip cells express a distinctive profile of genes with substantially higher expression compared with stalk cells of molecular markers including platelet-derived growth factor (PDGF)-B, VEGFR-2, uncoordinated (Unc)5b, Delta-like (Dll)4, and VEGFR-3. Whereas VEGF165 acts as an attractive cue to the tip cell of the endothelial sprout, Netrin-1 signals to Unc5b on the vasculature act as a repulsive cue. Netrin-4 can also bind Neogenin, which in turn recruits and activates Unc5b to mediate repulsion. Other guidance pathways implicated in vascular patterning and angiogenesis are ephrinB2–EphB4, plexinD1–semaphorin, and Slit–Robo interactions, as well as the neuropilins. Patterning and specification of small arteries along peripheral nerves in the skin of the embryonic limb involves nerve-derived VEGF; in other situations, neuronal patterning is dependent on the vasculature.^{114,115} Thus the congruent patterning of the neural and vascular systems likely is caused by use of common signals and may require cross-talk between the two systems.

Remodeling, Regression, and Apoptosis

Even though the vasculature is laid down before circulation begins, hemodynamic forces are important for maintenance and remodeling. Most of the vessels laid down during vasculogenesis regress or are remodeled. After neovascularization (e.g., during wound healing), the vessels regress when no longer needed. A chronic decrease in blood flow results in narrowing of the vessel lumen. This change in vessel caliber is dependent on an intact and functional endothelium.¹¹⁶ Remodeling, which involves loss of some vessels as well as changes in

lumen diameter and wall thickness, requires both cell death and proliferation (as well as remodeling of the ECM). In addition to survival signals transmitted by integrins, shear stress is important for endothelial survival and vessel healing after injury.^{117–119} Oxygen tension is important in vascular maintenance. Hypoxia increases levels of VEGF, which provides signals for vessel maintenance and neovascularization.¹²⁰ Hyperoxia, on the other hand, inhibits VEGF expression, which leads to regression and death of retinal vessels.¹²¹ In some models, regression of vessels occurs by apoptosis of vascular cells.^{122,123} Endothelial cells express several antiapoptotic molecules to maintain viability when quiescent and when stressed.^{124,125} Most likely, an intricate balance between cell death and proliferation is maintained by activators and inhibitors of both processes.

Role of Ligand–Receptor Interactions

Numerous factors regulate vascular development and differentiation in a positive or negative fashion. Some of the key molecules and their receptors are discussed here. A model for vascular development is shown in Fig. 123.1.

Inducers of Angiogenesis

Fibroblast Growth Factors

The role of FGFs in vascular development remains murky.^{126–128} Because of possible functional redundancy in the numerous family members, assigning specific roles to the various members of the FGF family has been difficult. Evidence suggests that FGF receptors signal

Fig. 123.1 MODEL FOR VASCULAR DEVELOPMENT. The role of secreted proteins and membrane receptors in vascular development is highlighted, but other factors such as cell adhesion molecules and extracellular matrix components also contribute significantly. *Ang*, Angiopoietin; *EC*, extracellular; *ECM*, extracellular matrix; *FGF2*, fibroblast growth factor 2; *PDGF*, platelet-derived growth factor; *PEC*, periendothelial cell (smooth muscle cell, pericyte); *TF*, tissue factor; *TGFβ*, transforming growth factor-β; *VEGF*, vascular endothelial cell growth factor; *VEGFR*, vascular endothelial cell growth factor receptor.

an inductive pathway by upregulating VEGFR-2 in differentiating mesoderm before vascular morphogenesis.^{128–130} FGF2 may induce neovascularization in adults indirectly through activation of the VEGF–VEGFR pathway.¹³¹

Vascular Endothelial Growth Factors

Eight members of the VEGF family have been identified^{186,126,128,132–137}: VEGF-A (also called vascular permeability factor), VEGF-B, VEGF-C, VEGF-D, VEGF-E (a viral ortholog), VEGF-F, VEGF-b, and placental growth factor. Three members of the receptor tyrosine kinase family^{126,135,136}—VEGFR-1 (flt-1), VEGFR-2 (flt-1/KDR), and VEGFR-3 (flt-4)—respond differentially to individual members of the VEGF family. In addition, the coreceptors for VEGF, neuropilin 1 and neuropilin 2, have been identified on arterial and venous endothelial cells, respectively. Neuropilin 1 is a coreceptor for VEGFR-2 that enhances binding of the VEGF-A isoform VEGF165 to VEGFR-2.¹³⁵ VEGF-A functions as a homodimer. However, it also heterodimerizes with VEGF-B and placental growth factor, and it has a crucial dose-dependent effect on vasculogenesis.^{86,126,128,135,136} Whereas VEGF-A binds VEGFR-1 and VEGFR-2, VEGF-C binds VEGFR-2 and VEGFR-3. Whereas placental growth factor specifically activates VEGFR-1, VEGF-E binds only VEGFR-2.^{128,135,136} Lack of VEGFR-2 prevents the development of endothelial cells and a hematopoietic system because cells lacking VEGFR-2 do not reach the correct location to form blood islands.¹³⁸ Mice that have been rendered deficient for VEGFR-1 have normal hematopoietic progenitors and abundant endothelial cells, but they do not form capillary tubes or functional vessels.¹³⁹ Both VEGFR-2- and VEGFR-1-deficient mice die at an early embryonic stage, as do neuropilin 1- and neuropilin 2-deficient mice. In von Hippel-Lindau disease, development of hemangioblastomas may be caused by stabilization of VEGF mRNA.¹⁴⁰ VEGF is also believed to play a key role in propagating tumor angiogenesis. Whereas tip cell migration has been shown to be dependent on a gradient of VEGF-A, endothelial proliferation in the lengthening vascular stalk is dependent on the absolute concentration of VEGF-A, although both processes require VEGFR-2.⁸⁹ Finally, injection of VEGF is capable of relieving limb ischemia by the generation of collateral vessels.⁸⁸ Whereas VEGF appears to collaborate with the angiopoietins (Angs) to stimulate vascular development, VE-cadherin acts to temper the VEGF response.³³

Angiopoietins

The Ang family of secreted glycoproteins comprises four members: Ang1 to Ang4. All four bind to Tie2, a receptor tyrosine kinase.^{141–144} Whereas Ang1 and Ang4 act as agonists of Tie2, Ang2 and Ang3 function as antagonists of Tie2.¹⁴⁴ However, the action of Ang2 is context dependent, and in some environments, it may behave as an agonist.¹⁴⁴ Binding of Ang1 to Tie2 results in tyrosine phosphorylation of Tie2 and promotes endothelial cell survival but not proliferation.^{141,144} Early in development, Ang1 is found mainly in the myocardium surrounding the endocardium, but it also becomes expressed in the mesenchyme surrounding developing vessels.¹⁴¹ Disruption of either Ang1 or its receptor Tie2 in the mouse results in embryonic lethality because of similar defects.^{142,145} These mice die at a slightly later stage than do VEGFR-deficient mice. Although endothelial cells are present, they have a lack of vascular complexity and a scarcity of periendothelial cells. Reciprocal interactions between the endothelial cells and surrounding matrix and mesenchyme appear to be disrupted. An activating Tie2 mutation in humans causes vascular malformations that show a disproportionate number of endothelial cells compared with smooth muscle cells, resulting in dilated, tortuous vascular channels in certain tissues.¹⁴⁶ Mice engineered to overexpress Ang2 specifically in their vasculature show embryonic lethality and vascular defects that are reminiscent of those seen in Ang1- or Tie2-null embryos.¹⁴³ In one proposed model, Ang1–Tie2 coupling mediates vascular maturation by sustaining endothelial cell–periendothelial cell–matrix interactions and may be involved in maintaining endothelial cell quiescence. Because Ang2 is found only at sites of vascular remodeling, Ang2 loosens matrix contacts, thus allowing access and responsiveness to angiogenic factors such as

VEGF.^{143,144} In the absence of growth factors, disruption of the vessel architecture by Ang2 may result in vascular cell apoptosis and vessel regression. However, Ang2-deficient mice are born alive, and the major defect appears to be lymphatic development.¹⁴⁴ Thus despite major advances, the data are conflicting. The response of endothelial cells to the angiopoietins likely is context dependent and endothelial cell type specific.¹⁴⁴

Tie1 is a receptor tyrosine kinase that exhibits structural similarities to Tie2. A ligand for Tie1 has not yet been identified.^{126,147} Disruption of the Tie1 gene in mice results in lethality at a much later point in development; Tie1-null mice may survive up to birth.^{145,148} Tie1^{-/-} mice die of hemorrhage and edema, implicating Tie1 in signaling the control of fluid exchange across capillaries and in maintenance of vessel integrity under hemodynamic stress. Chimeric mice that express Tie1^{-/-} and Tie1^{+/-} endothelial cells show underrepresentation of Tie1^{-/-} cells in vessels primarily derived by angiogenesis but not in embryonic vessels derived by vasculogenesis, suggesting a differential function for Tie1 in angiogenesis.¹⁴⁹ Evidence also implicates a role for Tie1 in combination with Ang1 in establishing vascular polarity.¹⁵⁰

Platelet-Derived Growth Factors

The PDGF family is composed of four chains. PDGF-A and PDGF-B can associate in a homodimeric or heterodimeric fashion.¹⁵¹ Similarly, the receptors α and β are receptor tyrosine kinases that can form homodimers or heterodimers. PDGF-BB can bind the receptors PDGFR- $\beta\beta$ or PDGFR- $\alpha\beta$, but PDGFR- $\beta\beta$ binds only PDGF-BB and not PDGF-AA or PDGF-AB.¹²⁶ Mice that are null for PDGF-B die perinatally of renal, hematologic, and cardiovascular abnormalities.¹⁵² The large vessels and heart of these mice are dilated, and microvessels exhibit microaneurysms because of a lack of pericytes.^{24,152} PDGFR- β knock-out mice do not show an overtly abnormal cardiovascular phenotype, but generation of chimeric mice demonstrates that PDGFR- β ^{-/-} cells are underrepresented in all muscle lineages (smooth, cardiac, and skeletal).^{153,154} Thus it appears that PDGF-BB elaborated by the endothelial cell provides a signal to recruit mesenchymal periendothelial cells as part of the maturation process of vascular morphogenesis. Two novel PDGF chains, PDGF-C and PDGF-D, have been identified.¹⁵⁵ PDGF-CC can bind PDGFR- $\beta\beta$ or PDGFR- $\alpha\beta$, exhibits greater mitogenicity of mesenchymal cells than does PDGF-AA, and promotes wound repair. PDGF-DD activates PDGFR- $\beta\beta$ and possibly PDGFR- $\alpha\beta$. PDGF-DD expression has been found to be elevated in the serum of patients with various types of tumors and has been shown to have transforming and angiogenic activity.¹⁵⁵

Transforming Growth Factors β

Members of the transforming growth factor- β (TGF β) family are multifunctional homodimeric peptides with diverse effects on cell proliferation, migration, differentiation, adhesion, and expression of cell adhesion molecules and ECM.^{126,156,157} They are secreted as inactive precursors. After being activated, they transmit signals to cells by binding heteromeric complexes of type I and type II serine/threonine kinase receptors. In most cell types, the type I receptor engaged by TGF β is activin receptor-like kinase 5 (ALK5). However, in endothelial cells, TGF β can bind and signal through ALK5 and ALK1.¹⁵⁸ Contact between endothelial cells and periendothelial cells is required for production of active TGF β .¹⁹ Mice lacking TGF β or TGF β receptor type II exhibit similar defects in vasculogenesis and hematopoiesis.^{156,157} Endothelial proliferation is not affected, but poor contacts between endothelial cell and mesothelial layers in embryos of TGF β ^{-/-} mice result in a disorganized and reduced vascular network lacking capillary tubes. Mutations in two TGF β receptors, ALK1 and the accessory TGF β receptor endoglin, have been linked to the vascular disorder hereditary hemorrhagic telangiectasia.¹⁵⁸ Disruption of TGF β signaling likely plays a role in the telangiectasia seen in this disorder.

Notch

The Notch family is composed of four receptors (Notch1 through Notch4) and five ligands (Jagged1 and Jagged2 and Delta-like 1 [Dll1], Dll3, and Dll4). Ligand engagement results in a series of

proteolytic clips that release the Notch intracellular domain, which then translocates to the nucleus where it effects transcriptional activation via the DNA-binding protein CSL (also called *RBP-1* or *CBF1*).¹⁵⁹ Gene targeting studies have revealed a critical role for Notch1, Dll1, Dll4, and Jagged1 in vascular development and remodeling.¹⁵⁹ Dll4–Notch1 signaling between endothelial cells within the angiogenic sprout serves to restrict tip cell formation in response to VEGF.^{160–162} Consequently, inhibition of Dll4 in adult mice results in increased endothelial proliferation, sprouting, and branching and increased tumor vascularity.^{163,164} However, the vasculature is disorganized and poorly perfused; thus Dll4 blockade inhibits tumor growth in several models.^{163,164}

Coagulation Factors

Tissue factor (TF) is a member of the cytokine receptor superfamily. In addition to its role in initiating coagulation as a cofactor for factor VII, TF may be involved in intracellular signaling. TF knock-out mice have abnormalities of their large vessels and microvasculature secondary to defects in mesenchymal cell and periendothelial cell accumulation and function.²⁵ Elevated TF expression in various tumors and the associated angiogenic endothelium has been reported.¹⁶⁵ Expression of mutant oncogenes (*K-ras*, *EGFR*) or tumor suppressor genes (*PTEN*, *p53*) leads to increased TF expression and activity, and this may link tumor angiogenesis and the hypercoagulable states manifested in cancer.¹⁶⁵ Abnormal development of the vasculature also affects 50% of mice that are deficient in factor V. The affected mice die in utero, and the 50% embryonic lethality is similar to that observed in thrombin receptor–deficient mice that die without obvious coagulation defects.¹⁶⁶ Factor V–dependent generation of thrombin may be important for early vascular development by signaling through the thrombin receptor.¹⁶⁷ Thrombin can promote angiogenesis through a mechanism that is independent of fibrin formation.^{167,168} Studies have suggested that thrombin can stimulate release of angiogenic factors (e.g., VEGF-A) from tumor cells and platelets, as well as induce VEGFR-2 on endothelial cells.¹⁶⁸ In addition, APC and protein C inhibitor have been shown to contribute not only to the regulation of hemostasis but also to cell inflammation, proliferation, apoptosis, tumor biology, and angiogenesis.¹⁶⁹ Regarding angiogenesis, APC increases proliferation of vascular endothelial cells and angiogenesis by APC receptor-mediated activation of mitogen-activated protein kinase, phosphatidylinositol 3-kinase, and endothelial nitric oxide synthase (eNOS) pathways.¹⁷⁰

Clinical trials have revealed that treatment with low-molecular-weight heparins improves the survival time of cancer patients receiving chemotherapy, an effect that appears to be independent of the anticoagulant properties of the low-molecular-weight heparins.^{171,172} Although antiangiogenic effects of specific heparanase-generated fragments of unfractionated heparins have been demonstrated in vitro, the mechanism of the antitumor effect remains to be defined.

The potential involvement of fibrinolytic factors in angiogenesis has been mentioned. Interestingly, fragments 1 and 2 of prothrombin have been reported to inhibit angiogenesis, and various other fragments of coagulation and fibrinolytic proteins also may inhibit angiogenesis.¹⁷³

Other Factors

Various other families of ligand–receptor pairs play a role in angiogenesis. They include ephrin–Eph, Wnt–frizzled, neuropilin–semaphorin, slit–Robo, and sonic hedgehog–patched/smoothed. Various chemokines have been shown to modulate angiogenesis in either a positive or negative fashion.

Inhibitors of Angiogenesis

As with the angiogenesis inducers, multiple factors have been reported to negatively regulate vascular morphogenesis.^{88,173} Of interest is a class of endogenous angiogenesis inhibitors that are fragments of larger proteins that have little or no angiogenesis-related activity in their intact form. They include fragments of ECM proteins such as

fibronectin, collagen type IV $\alpha 3$ chain (tumstatin), and collagen type XIII (endostatin), as well as coagulation protein fragments such as plasminogen (angiotatin) and antithrombin.¹⁷³ The mechanism of action of these protein fragments depends on the particular polypeptide, but the functional effect usually is inhibition of endothelial proliferation or induction of apoptosis.^{173–175} Other endogenous inhibitors include interferons, chemokines, and interleukin-12 (IL-12).

More than 100 compounds are in clinical trials attempting to cause regression of tumors by inhibiting angiogenesis.¹⁷⁶ These compounds can be broadly divided into those that act directly by targeting the angiogenic endothelial cell and those that act indirectly by targeting activators of angiogenesis. The latter category includes targeting of oncogenes (e.g., mutant EGFR or Her2) because many aberrantly activated oncogenes have been shown to induce expression of angiogenic factors. The first clear-cut evidence of efficacy in clinical trials of an angiogenic inhibitor for tumor therapy came from regimens directed against the VEGF pathway (e.g., bevacizumab).^{177,178} Because of the short improvement in overall and progression-free survival with the addition of VEGF inhibitors over standard chemotherapy, it is likely that heterogeneity and inherent instability of tumor cell populations result in the selection of malignant cells that feed their vasculature through factors other than VEGF. In this regard, use of indirect angiogenic inhibitors still suffers from the likelihood of tumors becoming resistant to the therapy.

Whether the mechanism of action of these inhibitors is truly caused by the abrogation of a functional vascular supply is an open question. VEGF inhibitors “normalize” the aberrant, leaky tumor vasculature. Other than in renal cancer, VEGF inhibitors have shown effect only when used in combination chemotherapy regimens, which has led to the proposal that VEGF pathway inhibition improves vessel functionality and perfusion, thus facilitating delivery of chemotherapeutic agents.^{177,178} VEGF–VEGFR signaling also acts in an autocrine fashion within some tumor cell populations, raising the possibility that positive outcomes may have as much to do with direct tumor kill as with an antiangiogenic effect. Finally, as with organogenesis, the vasculature may provide a juxtacrine or paracrine role in supporting tumor viability and proliferation independent of the provision of a circulatory system for delivery of nutrients and oxygen.⁵³

Some of the more common side effects observed with use of VEGF-A inhibitors were not predicted a priori but may be understandable in retrospect. For instance, hypertension and arterial thrombosis are common side effects. Two possible reasons may explain the hypertensive side effect. One is that VEGF directly activates eNOS and thus may be responsible in part for basal production of NO.¹⁷⁹ Another potential explanation is that podocyte-derived VEGF is required for proper glomerular function throughout life.⁵³ Heterozygous loss of podocyte VEGF results in hypertension and proteinuria in adult mice.⁵³ Given that proteinuria is also commonly seen in patients treated with VEGF inhibitors, the latter explanation would tie two of the side effects seen. The reasons for arterial thrombosis are less obvious. Because arterial circulation is more dependent on VEGF, it is possible that arterial endothelial apoptosis serves as a nidus for localized activation of coagulation and platelet aggregation. Apoptotic endothelial cells have been shown to increase thrombin-generating capacity and bind to unactivated platelets and leukocytes.^{180–182}

More recently, the use of PDGF inhibitors to target pericytes has been shown to be a potentially effective antiangiogenic strategy, particularly in combination with antiendothelial (anti-VEGF) molecules.^{96,98} “Metronomic” or low-dose, frequent scheduling of traditional cytotoxic agents also is reported to have an antiangiogenic effect and has proven efficacious in animal studies.¹⁸³ Antivasculogenic therapy directed against recruitment of BM-derived vascular precursors may have a role in future cancer therapeutic regimens, but thus far the evidence is weak at best.⁷⁹

Arteriogenesis

Arteriogenesis is a term coined to distinguish the development of collateral vessels in adults from the process of angiogenesis.^{184,185}

Remodeling of a preexisting collateral arteriole is thought to be caused by flow-induced changes secondary to occlusion of a supply artery. The consequent increase in shear stress through the collateral arteriole activates endothelial cells, resulting in monocyte recruitment and infiltration into the media. Elaboration of various cytokines, growth factors, and proteases from monocytes and endothelial cells causes matrix degradation, smooth muscle cell proliferation, and rapid enlargement of the preexisting arteriole. Factors thought to promote arteriogenesis include FGF-2, placental growth factor, PDGF-BB, TGF β 1, monocyte chemoattractant protein 1, and GM-CSF.^{185,186}

Lymphangiogenesis

The lymphatics comprise a low-flow, low-pressure system that collects extravasated fluid from the tissues and transfers it back to the venous system via the thoracic duct. Lymphatic vessels also serve an immune function by transporting lymphoid and antigen-presenting cells to lymphoid organs.¹⁸⁷ Lymphatic vessels share features with blood vessels, but they also exhibit differences. Lymphatic vessels develop shortly after blood vessels and may arise de novo from precursor mesenchymal cells (lymphangioblasts) in a process akin to vasculogenesis.¹⁸⁸ Alternatively, other studies suggest that specific venous endothelial cells differentiate to lymphatic endothelium in response to signals that have yet to be determined.¹⁸⁹ VEGF-C and VEGF-D, by activating VEGFR-3 and Ang2 potentially through Tie2 activation, are growth factors necessary for lymphatic vessels.¹⁹⁰ The α 9 β 1 integrin and matrix interacting protein CCBE1 are necessary for proper lymphatic development, and the homeobox transcription factor Prox1 appears to induce transdifferentiation of venous to lymphatic endothelial cells.^{189–191} The earliest described regulator of early lymphatic endothelial cell specification is Sox18 (sex determining Region Y Box 18), a transcriptional regulator of Prox1 expression. Lymphedema can be caused by congenital defects, parasitic (filariasis) or neoplastic obstruction, or surgical resection. Congenital lymphedema (Milroy disease) is linked to inactivating mutations of VEGFR-3.¹⁸⁷ Whether lymphatic vessel density in human tumors correlates with disease progression is not clear, but in animal models, induction of lymphangiogenesis by VEGF-C or VEGF-D promotes lymph node metastasis.¹⁸⁷

Relationship Between Vascular Development and Hematopoiesis

Hematopoietic cells and endothelial cells are intertwined in several ways. First, there is the likely existence of a common precursor (see [Vasculogenesis](#) section earlier). Second, the endothelium is intimately involved in hematopoiesis, having a supportive role structurally and nutritionally. Finally, the endothelium organizes the controlled egress and ingress of hematopoietic cells in hematopoietic and other tissues. The last issue is covered in the Interaction of Blood Cells With the Vessel Wall section.

BM stromal cells secrete cytokines, produce ECM, and are in direct cellular contact with hematopoietic cells, thereby providing a microenvironment suitable for hematopoietic proliferation, differentiation, and self-renewal.¹⁹² Many studies demonstrate the supportive role of endothelium in hematopoiesis.^{193–195} The physical proximity of endothelium and hematopoietic precursors within the BM and the requirement of blood cells to transit BM endothelium to reach the circulation is presumptive evidence of an important role for endothelium. BM endothelial cells constitutively express high levels of IL-6, stem cell factor, granulocyte colony-stimulating factor (G-CSF), and granulocyte macrophage colony-stimulating factor (GM-CSF).¹⁹³ Both yolk sac and BM endothelial cells support long-term proliferation and differentiation of hematopoietic cells in vitro.¹⁹³ BM endothelial cell expression of notch ligand jagged supports long-term notch-dependent HSC proliferation and renewal.¹⁹⁶ However, endothelial cells also have been reported to inhibit hematopoiesis.¹⁹⁷

Significant evidence now indicates that hematopoietic stem and progenitor cells are not randomly distributed in the BM, but rather are spatially and possibly physically associated with the endosteum and the blood vessels.¹⁹⁵ Functional differences between the osteoblastic and vascular niches have been described. It has been suggested that whereas the osteoblastic niche maintains quiescence of HSCs, stem and progenitor cells that are activated for differentiation and mobilization reside at the vascular niche.¹⁹⁴ Translocation of megakaryocyte progenitors to the vicinity of the BM sinuses is sufficient to induce megakaryocyte maturation and platelet production.¹⁹⁵ However, a study has identified CXCL12 (SDF-1)–abundant reticular cells that are located in close proximity to the sinusoidal endothelium as well as the endosteum.¹⁹⁸ The authors confirmed that the CXCL12–CXCR4 signaling axis is required for maintenance of HSCs in the BM, and these findings raise the possibility that the vascular and osteoblastic niches may not be that different.¹⁹⁸ In all likelihood, endothelial cells and osteoblasts, in concert with other stromal cells, provide a finely tuned system to modulate hematopoiesis in the BM such that differentiation, proliferation, and self-renewal occur in a regulated fashion.

Human endothelial cells have been reported to express receptors for IL-3, stem cell factor, erythropoietin, and thrombopoietin, and show functional responses to IL-3 and erythropoietin.^{199–201} The shared responses to growth factors, combined with the importance of macrophages in angiogenesis and the production of cytokines by monocytes and macrophages, suggest that hematopoietic cells play a reciprocal role in maintaining the endothelium.

PHYSIOLOGIC FUNCTIONS OF THE ENDOTHELIUM

The Endothelium as a Barrier

The microvessels (capillaries and postcapillary venules) act as the exchange vessels of the circulation. However, as with other endothelial functions, vessel permeability is dependent on the type of vessel and its location. Movement of lipophilic and low-molecular-weight hydrophilic substances between blood and tissue is virtually unimpeded, but the vessels are selectively permeable to macromolecules. This semiselective barrier is necessary to maintain the fluid balance between intravascular and extravascular compartments, yet antibodies, hormones, cytokines, and other molecules must have access to the interstitial space for the initiation and potentiation of various processes, including inflammation, immune response, and wound repair.

Movement of macromolecules across the vessel wall is governed by (1) hydrostatic and oncotic pressure gradients; (2) physicochemical properties of the molecule, such as size, shape, and charge; and (3) properties of the barrier. The barrier of the vessel wall is formed by the cellular components, endothelial cells, and pericytes, as well as by the charge and compactness of the matrix components, glycocalyx, and basement membrane. Macromolecules can pass either directly through the endothelial cell (transcellular path) or between adjacent endothelial cells (paracellular path). Surprisingly, the mechanisms of macromolecular movement remain controversial, and data generated by physiologists, morphologists, and cell biologists have not been consolidated into a model that satisfies the findings of the different groups.²⁰²

To explain cellular transport in endothelium, physiologists have proposed the existence of two sets of “pores” based on experiments measuring the movement of dextran and other macromolecules: a small pore of radius 3–5 nm for transport of water and small hydrophilic molecules, and a large pore of radius 25–60 nm for macromolecular transport.^{202–204} Although water mainly moves across the continuous endothelium via the paracellular route, a significant proportion ($\leq 40\%$) can traverse the endothelium via the transcellular route by water-transporting membrane channels, the aquaporins.²⁰⁵ Macromolecular transport into cells can proceed by receptor-mediated systems, such as clathrin-coated pits, in which the molecules usually are targeted to the lysosome, but may be transported through

Fig. 123.2 OVERVIEW OF ENDOTHELIAL FUNCTION IN COAGULATION. ADP, Adenosine diphosphate; AMP, adenosine monophosphate; AT, antithrombin; ATP, adenosine triphosphate; EPCR, endothelial protein C receptor; 5'-Nuc, ecto-5'-nucleotidase; NO, nitric oxide; P2Y, purinergic receptor 1; PAI-1, plasminogen activator inhibitor 1; PC, protein C; PGI₂, prostaglandin I₂ (prostaglandin); PS, protein S; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; t-PA, tissue plasminogen activator; vWF, von Willebrand factor.

the cell. Alternatively, molecules can be moved across the cell by plasmalemmal vesicles or caveolae, which are abundant in capillary endothelial cells. Caveolae are 50–100-nm membrane invaginations that can participate in transcytosis as well as in the translocation of glycosylphosphatidylinositol-linked proteins into the cytoplasm and in transmembrane signaling.²⁰⁶ Because of the known leakiness of tumor microvasculature, investigators have studied these microvessels and identified a structure designated the vesiculovacuolar organelle.²⁰⁷ These organelles are grape-like clusters of interconnecting uncoated vesicles and vacuoles that span the entire thickness of vascular endothelium, thereby providing a potential transendothelial connection between the vascular lumen and the extravascular space.²⁰⁷ Interestingly, their function is enhanced by injection into normal skin of VEGF, which is known to increase the permeability of vessels.²⁰⁷ Localization of caveolin to vesiculovacuolar organelles suggests that this structure is a fusion of caveolae.²⁰⁷

During inflammation, binding of neutrophils to the endothelium results in the generation of oxidants that can mediate endothelial cell injury and increase permeability.²⁰⁸ Upon adhesion of neutrophils to the endothelium, leukocyte CD18 (β2 integrin)-mediated signals trigger the release of the neutrophil cationic protein called *heparin-binding protein/CAP37/azurocidin*, which in turn induces formation of gaps between endothelial cells and macromolecular efflux.²⁰⁹ Thrombin, an inflammatory mediator, can increase endothelial permeability by several mechanisms resulting from activation of its receptor on endothelial cells.^{210–212} First is an increase in transcellular vesicular permeability. Second is increased paracellular permeability that results from phosphorylation of endothelial cell nonmyosin light chains and contractile activity generated by movement of actin and myosin filaments past each other. The contraction and retraction of endothelial cells are accompanied by “loosening” of intercellular junctions and focal integrin contacts with the ECM. Finally, thrombin may alter the repulsive effect of the negatively charged glycocalyx. An increase in paracellular permeability may result from alteration of cell–cell contacts present at tight junctions and adherens junctions secondary to posttranslational modification of components of these junctions such as claudins and VE-cadherin.²⁰² Pericyte contractility also has been hypoth-

esized as a mechanism for increasing permeability in inflammatory states.²¹²

The Endothelium as a Nonthrombotic Surface

The molecular mechanisms of hemostasis and thrombosis are addressed in Chapters 115 and 116 and 118–120. This section places the endothelium in the appropriate context in these processes. An overview of endothelial cell contributions to the anticoagulant and procoagulant states is shown in Fig. 123.2. Normal unperturbed endothelium presents a nonthrombotic surface to the circulation by inhibiting platelet aggregation, preventing the activation and propagation of coagulation and enhancing fibrinolysis.^{213–217} These activities are accomplished by both passive and active processes. Conversely, when injured or under inflammatory conditions, the endothelium may become procoagulant.

When in close proximity to endothelial cells, platelets become unresponsive to agonists. This inhibition of platelet aggregation is accomplished by secretion of prostacyclin (prostaglandin I₂ [PGI₂]) and NO, and by surface expression of an ecto-adenosine phosphatase (ADPase)/CD39/nucleoside triphosphate diphosphohydrolase (NTPDase-1).^{216,218} Prostacyclin is synthesized mainly by vascular endothelial and smooth muscle cells as a product of arachidonic acid metabolism. It inhibits platelet activation, secretion, and aggregation, as well as monocyte interactions with endothelial cells. It also causes vascular smooth muscle cell relaxation. NO similarly has a wide range of functions, including inhibition of platelet adhesion, activation, and aggregation. Most of the NO released from endothelial cells is elaborated abluminally, where it acts on the smooth muscle cell to cause vasodilation. However, some NO may enter the lumen and thereby diffuse into platelets. Prostacyclin and NO can act synergistically to reverse platelet aggregation.²¹⁶ The released platelet agonist, ADP, can be inactivated by endothelial membrane-associated CD39.²¹⁸ Metabolism of ATP and ADP to adenosine monophosphate (AMP) by CD39 eliminates platelet recruitment and returns platelets to their resting state. Adenosine, which is generated by hydrolysis of AMP by ecto-5'-nucleotidase, acts to inhibit platelet aggregation and cause

vasodilation. ATP/ADP can stimulate purinoreceptors on endothelial cells, resulting in synthesis and release of PGI₂ and NO.²¹⁹

Endothelial cells use three main pathways to inhibit thrombin generation and limit coagulation^{213,215,220,221}:

1. Antithrombin system: Heparan sulfate proteoglycans are secreted onto the luminal surface of endothelial cells and into the subendothelium. Heparan sulfates are capable of binding and activating antithrombin III, thereby accelerating inactivation of several procoagulant serine proteases, including thrombin, factor Xa, and factor IXa.
2. Protein C²²²: Thrombomodulin on the surface of endothelial cells binds thrombin. This coupling inhibits the coagulant properties of thrombin and increases its affinity for protein C, which it cleaves and activates. Activation of protein C by the thrombin–thrombomodulin complex is augmented by its binding to the endothelial cell protein C receptor. Protein S, which is thought to be synthesized primarily by the endothelial cell, acts as a cofactor for protein C but itself also has anticoagulant properties. Independent of the presence of activated protein C, free protein S is able to inhibit the prothrombinase and intrinsic tenase complexes and interact directly with factors Va and VIIIa.
3. Tissue factor pathway inhibitor (TFPI)²²³: TFPI is a Kunitz-type serine protease inhibitor that modulates TF-initiated coagulation. TFPI binds to and directly inhibits the TF–factor VIIa–factor Xa complex. It is mainly produced by and bound to endothelial cells, likely to surface glycosaminoglycans. There is also a plasma pool bound to low-density lipoprotein.

If coagulation occurs despite the many anticoagulant mechanisms, endothelial cells also provide proteins to promote fibrinolysis.²¹⁵ Endothelium is a major source of t-PA.^{224,225} Approximately 40% of t-PA is bound to its inhibitor, PAI-1, which is also secreted by endothelial cells. Stresses such as exercise, acidosis, hypoxia, shear forces, increased venous pressure, and thrombin cause release of t-PA,^{224,225} and presumably activate plasminogen. Receptors for plasminogen and t-PA are present on the endothelial cell surface, allowing for effective localized production of fibrinolytic activity.

Although intact endothelium is necessary to maintain blood in a fluid state and inhibit coagulation under normal conditions, injured endothelium can rapidly downregulate its anticoagulant functions and become procoagulant even without overt vascular damage as occurs with trauma or surgery. Further tissue injury or vascular pathology also leads to exposure of the underlying matrix, which is procoagulant by virtue of its binding to and activation of platelets. Endothelial cells that have been induced to undergo apoptosis *in vitro* become procoagulant. Apoptotic endothelial cells expose phosphatidylserine on their surface and downregulate their anticoagulant properties. Apoptotic endothelial cells and vascular smooth muscle cells also increase thrombin formation in recalcified citrated plasma, and apoptotic endothelial cells show increased adhesion to unactivated platelets.^{180,181,226} Thrombosis resulting from procoagulant changes induced by endothelial apoptosis could contribute to the pathogenesis of diverse diseases.²²⁷

Even without endothelial death, perturbation of the vascular lining by inflammatory mediators could tip the balance such that the endothelium converts from a nonthrombogenic to a procoagulant surface because of downregulation of anticoagulant properties as well as induction of procoagulant properties. For example, the setting of acute inflammation is associated with increased release of vWF, platelet-activating factor, and fibronectin, all of which may potentiate thrombus formation. Tumor necrosis factor (TNF), IL-1, and lipopolysaccharide can increase the expression of PAI-1 in endothelial cells with downregulation or no change in t-PA levels, thereby impairing fibrinolysis. TNF, IL-1, and lipopolysaccharide also have been shown to downregulate thrombomodulin as well as to induce expression of TF on cultured endothelial cells. However, whether endothelial cells express TF on their luminal surfaces *in vivo* is controversial.²²⁸ More recently, circulating microparticles generated by leukocytes and vascular cells have been shown to be a source of blood-borne TF and

to contribute to coagulation.²²⁹ Although most microparticles probably are derived from platelets and monocytes, endothelial-derived microparticles may be an important source of circulating TF under conditions of drastic activation.^{229,230}

Control of Vascular Tone

Control of vascular tone is orchestrated primarily by a balance between endothelium-derived vasodilators (NO, PGI₂, and endothelium-derived hyperpolarizing factor [EDHF]) and vasoconstrictors (endothelin-1 [ET-1], thromboxane (TXA₂) and superoxide). In addition to inhibiting platelet aggregation, NO and PGI₂ act as vasodilators.^{231,232} NO is produced by conversion of L-arginine to L-citrulline by NO synthase (NOS). Three forms of NOS exist: a constitutive NOS in neuronal tissue; an inducible enzyme found in macrophages and other cells that plays a role in NO-induced cytotoxicity; and a constitutively active endothelial form, NOSIII (eNOS).²³³ The inducible form of NOS also is present in endothelial cells and may be responsible for the uncontrolled vasodilation seen in septic shock.²³³ Injection into the forearm of L-arginine analogues that inhibit NOS causes substantial vasoconstriction. Conversely, eNOS-deficient mice are hypertensive, suggesting that NO release is crucial for maintaining basal vasodilation.^{231,232} The major physiologic stimulus for continuous production of NO *in vivo* is shear stress. The action of NO on platelets (antiaggregatory), endothelial cells, and smooth muscle cells (relaxation) is caused by activation of guanylyl cyclase and formation of cyclic guanosine 3',5'-cyclic monophosphate. Whereas NO is quite unstable, the formation of S-nitrosothiols in the presence of oxygen and thiols provides a stable reservoir of NO.²³⁴ Hemoglobin is an avid scavenger of NO, which may account for the vasoconstriction observed with administration of cell-free, hemoglobin-based RBC substitute.²³⁵ Physiologically, however, S-nitrosohemoglobin acts as a regulator of blood flow. Deoxygenation is accompanied by an allosteric change in S-nitrosohemoglobin that releases the NO group, relaxing blood vessels to bring blood flow in line with local oxygen requirements.²³⁶

Prostacyclin (PGI₂), on the other hand, does not appear to have as global a role in vasodilation as does NO. PGI₂ is synthesized mainly by endothelial cells and acts locally at sites of injury. It may counterbalance the vasoconstriction induced by the platelet-produced arachidonic acid metabolite thromboxane A₂ (TXA₂). Most PGI₂ is released lumenally, where it has an antiplatelet effect. Whereas PGI₂ transduces a cellular signal by increasing the levels of cyclic AMP (cAMP), TXA₂ signals via the phosphoinositol pathway and lowering of cAMP levels. Synthesis of prostaglandins is catalyzed by the action of cyclooxygenases (COX-1 and COX-2) on arachidonic acid. Aspirin inhibits COX irreversibly in both platelets and endothelial cells. However, the clinical effect is seen primarily in platelets for two reasons.^{232,233} One reason is that platelets, being nonnucleated, cannot synthesize new COX, but endothelial cells can. Therefore TXA₂ synthesis recovers only when new platelets enter the circulation, but COX production by endothelial cells restores PGI₂ levels within a few hours. The second reason is that platelets encounter orally administered aspirin before it is deacetylated by the liver and diluted by the venous circulation. The important balance in the activity of PGI₂ and TXA₂ to homeostasis in the healthy vessel becomes evident when using selective COX-2 inhibitors to reduce inflammation, which decreases the production of PGI₂ without affecting the production of TXA₂ resulting in vasoconstriction and platelet aggregation unopposed by PGI₂, and increased risk for cardiac events.

Early experimental evidence suggested that endothelial cells release other relaxing factors (i.e., EDHF), which act by increasing the membrane potential of smooth muscle cells. Hyperpolarization of isolated coronary arteries occurs in the presence of an arginine analogue, a NOS inhibitor, and indomethacin, a COX inhibitor, suggesting that EDHF, NO, and prostanooids contribute differentially to relaxation in human coronary arteries.²³⁷ The nature of EDHF is unclear, but it encompasses different biologic mechanisms. These mechanisms involve an increase in intracellular calcium

concentration, the opening of calcium-activated potassium channels, and the hyperpolarization of endothelial cells, resulting in an endothelium-dependent hyperpolarization of smooth muscle cells.²³⁸ Smooth muscle cell hyperpolarization may occur through direct myo-endothelial electrical coupling or through accumulation of potassium ions in the intercellular space. Findings suggest that EDHF represents cytochrome P450-linked arachidonate metabolites in some blood vessels but also lipoxygenase derivatives and hydrogen peroxide.²³⁸

ET-1 is a 21-amino acid peptide, released preferentially at the abluminal surface of endothelial cells, that exhibits potent vasoconstrictor activity.^{239,240} Of the three known ETs, only ET-1 is produced by endothelial cells. At least two receptors (ET-A and ET-B) bind to all three ETs. Whereas ET-A is abundantly expressed on smooth muscle cells, ET-B is predominantly expressed on endothelial cells. The vasoconstrictor activity of ET-1 is preferentially mediated by ET-A receptors on smooth muscle cells. Engagement of ET-B on endothelial cells by ET-3 may paradoxically cause a transient vasodilation. Little evidence indicates that ET-1 plays a role in essential hypertension, but it might contribute to pregnancy-induced hypertension and may play a role in reperfusion injury after ischemia.²⁴⁰ ET-1 does appear to play a role in pulmonary arterial hypertension, and the dual ET receptor antagonist bosentan and ET-A antagonist ambrisentan have been approved for treatment of this disease.^{241,242}

Another seemingly important regulator of vascular tone is the superoxide anion.^{231,243} The source of this free radical may be the endothelium itself or inflammatory cells that have been recruited to sites of injury or inflammation. Interaction of superoxide radicals and NO produces peroxynitrite and reduces the concentration of NO. Peroxynitrite can oxidize low-density lipoprotein (LDL) and deleteriously modify other proteins, thereby causing endothelial dysfunction. Increased production of superoxide inhibits synthesis of PGI₂ but not that of TXA₂.²⁴³

The endothelium expresses angiotensin-converting enzyme at its surface; this enzyme converts angiotensin I to angiotensin II, a potent vasoconstrictor. The interaction among ET, angiotensin II, and α -adrenergic agonists in the pathogenesis of hypertension is complex.²⁴⁴ An altered balance of the vasoactive substances described in this section has been proposed to cause endothelial dysfunction and the attendant vascular pathology observed in atherosclerosis, hypertension, and diabetes mellitus. Alteration of vascular function in these diseases then may perpetuate endothelial dysfunction and, consequently, worsen disease.

Interaction of Blood Cells With the Vessel Wall

Leukocytes

In the absence of any inflammatory stimulus, neutrophils circulate freely and do not interact significantly with the endothelium. This contrasts with continuous, low-level physiologic traffic of monocytes and lymphocytes across the vessel wall. Monocytes emigrate from the bloodstream to develop into tissue macrophages that may exhibit tissue- or organ-specific functions. To maintain immune surveillance of tissue, lymphocytes recirculate between blood and lymphatics, gaining entrance to the latter at the high endothelial venule of postcapillary venules in lymphoid tissue.

Intravital microscopic studies have established a sequence of events involved in leukocyte emigration at extravascular sites of inflammation. Under conditions of flow, leukocytes first tether to and then roll along the endothelium of postcapillary venules adjacent to the site of inflammation. Some of the rolling leukocytes are activated and adhere firmly. The adherent leukocytes migrate along the endothelial surface and diapedese between endothelial junctions to enter the extravascular tissue. These steps in emigration tethering, rolling, activation, firm adhesion, and diapedesis also are involved in lymphocyte emigration at high endothelial venules. They result from the interaction of distinct leukocyte and endothelial receptors in an adhesion cascade (Fig. 123.3; see Chapter 16).^{245,246} Rolling is observed only under flow conditions and is the consequence of shear

forces acting on the leukocyte and adhesive interactions between selectin receptors and their glycoconjugate counterstructures.²⁴⁷ It is initiated primarily by activation of the endothelium by extravascular stimuli such as bacterial-derived products or by endogenous mediators produced by the endothelium or cells in tissue. Early on, rolling is mediated by endothelial P-selectin, which is rapidly translocated from Weibel-Palade bodies to the luminal surface, and L-selectin on leukocyte microvilli. E-selectin is involved only at later time points because it is not constitutively expressed by endothelium but rather is induced over hours by *de novo* synthesis.

For leukocytes to circulate freely, their integrin receptors must be minimally adhesive, but they also must be able to increase binding rapidly at sites of inflammation. After being tethered to endothelium by selectin interactions, leukocyte integrin receptors are activated by endothelial membrane-expressed platelet-activating factor, endothelial membrane-bound chemokines, or locally secreted chemoattractants. Activation of leukocyte integrins involves changes in receptor affinity or affinity-independent receptor clustering,²⁴⁸ which promotes firm adhesion to endothelial ligands, which are members of the immunoglobulin gene superfamily (IgSF). These IgSF ligands are constitutively expressed (ICAM-1, ICAM-2), further upregulated (ICAM-1), or induced (VCAM-1) by inflammatory mediators (Table 123.1). Although these activation-dependent increases in leukocyte integrin binding to endothelial IgSF ligands are necessary for shear-resistant firm adhesion, subsequent leukocyte migration over the endothelium requires reversible adhesion caused by cyclic modulation of receptor avidity.²⁴⁹

There are several caveats regarding the current multistep model of initial selectin-mediated rolling and subsequent integrin-mediated firm adhesion.²⁵⁰ First, selectin-mediated rolling is not a prerequisite for emigration under conditions of reduced flow, as might occur at sites of inflammation.²⁵¹ Second, the model was developed from observations in the systemic microcirculation, where leukocyte emigration occurs in postcapillary venules under relatively low shear forces. However, selectins do not appear to play a major role in neutrophil emigration in the pulmonary microcirculation, where emigration occurs predominantly in capillaries,²⁵² or in the liver microvasculature, where leukocytes emigrate primarily in sinusoids.²⁵³ Third, under some conditions leukocytes are able to tether and roll via receptors other than selectins and α 4 integrins (e.g., CD44²⁵⁴ or VAP-1²⁵⁵). Finally, several other adhesion pathways have been implicated in leukocyte adhesion to endothelium *in vitro*, and their roles in the adhesion cascade *in vivo* remain to be defined.²⁵⁰

When adherent, leukocytes migrate upon the endothelial luminal surface. Upon encountering an intercellular junction, some leukocytes diapedese between endothelial cells (paracellular pathway), enter extravascular tissue, and then migrate to the site of inflammatory or immune reaction.^{256,257} This process of transendothelial migration uses leukocyte integrin interactions with endothelial IgSF ligands²⁵⁸ and several junctional proteins, including PECAM-1 (CD31),²⁵⁹ JAM-1,²⁶⁰ CD99,²⁶¹ CD99L2,²⁶² ESAM,²⁶³ PVR,²⁶⁴ and CD47.²⁶⁵ Diapedesis involves signaling by the leukocyte to the endothelial cell that triggers opening of endothelial cell junctions.²⁶⁶ Although leukocyte migration is primarily paracellular (i.e., through endothelial cell-cell junctions), under certain circumstances, leukocytes may emigrate directly through the body of an endothelial cell (transcellular pathway).²⁶⁷

Leukocyte recruitment is terminated by several mechanisms. Whereas E-selectin and P-selectin are removed from the endothelial cell surface by endocytosis,²⁶⁸ L-selectin is cleaved from leukocytes by a membrane protease.²⁶⁹ Decay of cytokine, chemokine, or chemoattractant generation leads to gradual resolution of endothelial adhesion molecule expression and integrin activation. Locally expressed mediators, such as NO,²⁷⁰ TGF β ,²⁷¹ and Fas ligand,²⁷² also inhibit further leukocyte adhesion to endothelium.

The adhesion molecules involved in leukocyte trafficking from bloodstream to tissue have emerged as important therapeutic targets. Extensive preclinical studies showed that blockade of leukocyte or endothelial adhesion molecules was efficacious in diverse disease models,²⁷³ prompting the development of adhesion antagonists for

Fig. 123.3 ADHESION CASCADE. Under conditions of flow, leukocytes first tether to endothelial ligands and then roll along the vessel wall. Tethering is mediated predominantly by interaction of P-selectin and L-selectin with their cognate glycoconjugate ligands. P-selectin binds to SLe^x and sulfate residues expressed on PSGL-1. L-selectin binds to an uncharacterized ligand(s) on inflamed endothelium and to sulfated SLe^x-like moieties on PNA^d and MAdCAM-1 and sialomucin nephrin on high endothelial venules. E-selectin, α₄β₁ (very late antigen 4 [VLA-4]), and α₄β₇ stabilize rolling initiated by P-selectin and L-selectin. E-selectin recognizes SLe^x on PSGL-1 and other glycoproteins or glycolipids. After tethering and rolling, leukocyte integrin receptors are activated, most often by chemoattractants (e.g., chemokines) via G protein-coupled receptors. After activation, integrin receptors engage endothelial immunoglobulin gene superfamily ligands to promote firm adhesion. Leukocyte α_Lβ₂ (leukocyte function antigen 1 [LFA-1]) binds to ICAM-1 and ICAM-2, α_Mβ₂ (macrophage 1 [Mac-1]) to ICAM-1, α₄β₁ (VLA-4) to VCAM-1, and α₄β₇ to MAdCAM-1. The adherent leukocyte then migrates across endothelium to interendothelial junctions, where it diapedes between endothelial cells via leukocyte integrin receptors and their endothelial immunoglobulin gene superfamily ligands as well as endothelial junctional proteins such as CD31 (PECAM-1), CD99, CD99L2, ESAM, and JAM-1. *ESAM*, endothelial cell-selective adhesion molecule; *ICAM*, intercellular adhesion molecule; *IgSF*, immunoglobulin gene superfamily; *JAM-1*, junctional adhesion molecule 1; *MAdCAM*, mucosal addressin cell adhesion molecule; *PNA^d*, peripheral node addressin; *PSGL*, P-selectin glycoprotein ligand; *PVR*, poliovirus receptor; *SLe^x*, sialyl Lewis X; *VCAM*, vascular cell adhesion molecule 1.

clinical trials in a variety of diseases. However, results were disappointing overall, with many unsuccessful clinical trials of various adhesion antagonists in multiple disease indications.^{274,275} Moreover, the report of progressive multifocal leukoencephalopathy, a rare viral infection of the CNS, in several patients treated with the α₄-integrin antagonist natalizumab²⁷⁶ highlights the risks of targeting molecules that are pivotal in host defense and repair as well as in disease. Nevertheless, the potential of antiadhesion therapy is demonstrated by the approval of two integrin antagonists: efalizumab for treatment of psoriasis²⁷⁷ and natalizumab for treatment of multiple sclerosis.²⁷⁸

Platelets

Similar to neutrophils, unactivated platelets do not interact with unperturbed endothelium. After a vascular injury that produces

endothelial denudation or retraction, platelets rapidly adhere to the exposed subendothelium. As discussed in greater detail in [Chapters 115 and 116](#), at high shear rates this initial adhesion does not require platelet activation and involves platelet glycoprotein Ib/V/IX (GPIb-V-IX) binding to vWF in the subendothelial matrix and platelet GPVI binding to collagen in the injured arterial wall. Platelet activation occurs after adhesion, leading to platelet spreading mediated by integrin receptors binding to matrix components and aggregation mediated by fibrinogen binding to GPIIb/IIIa (αIIbβ₃).

Evidence indicates that platelets can bind directly to activated endothelium *in vivo* via endothelial P-selectin²⁷⁹ and PECAM-1²⁸⁰, and to roll on venular endothelium via interaction of platelet GPIbα and endothelial P-selectin.²⁸¹ Platelets have been shown to bind to high endothelial venules *in vivo* via platelet P-selectin.²⁸² *In vitro* platelets can adhere to intact endothelium via a platelet GPIIb/IIIa-dependent bridging mechanism involving platelet-bound adhesive

TABLE 123.1 Endothelial Cell Activation^a

Agonist	Response
Thrombin	Secretion of vWF, P-selectin, TFPI, and PDGF Synthesis of PAF, IL-8, IL-6, and E-selectin
IL-1 β , TNF- α , LPS	Synthesis of adhesion molecules (ICAM-1, VCAM-1, E-selectin), chemokines (IL-8, MCP-1), cytokines (IL-6, CD40), procoagulant proteins (TF, PAI-1, t-PA, u-PA), and cytoprotective molecules (A1, IAP) Downregulation of anticoagulant proteins (TM)
Reduced/disturbed shear stress	Increased expression of proinflammatory genes (e.g., VCAM-1, ICAM-1, MCP-1)
VEGF	Decreased eNOS activity Increased expression of cytoprotective genes (A1, MnSOD), Ang2, COX-2

^aSelected agonists and responses. Many other stimuli (e.g., lipoproteins, hypoxia, microbes, and microbial products) have been reported to upregulate or downregulate various endothelial responses. Ang, Angiotensin; A1, Bcl-2 homologue; COX-2, cyclooxygenase 2; eNOS, endothelial nitric oxide synthase; IAP, inhibitor of apoptosis protein; ICAM, intercellular adhesion molecule; IL, interleukin; LPS, lipopolysaccharide; MCP, monocyte chemoattractant protein; MnSOD, manganese superoxide dismutase; PAF, platelet-activating factor; PAI, plasminogen activator inhibitor; PDGF, platelet-derived growth factor; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin; TNF, tumor necrosis factor; t-PA, tissue plasminogen activator; u-PA, urokinase-type plasminogen activator; VCAM, vascular cell adhesion molecule; VEGF, vascular endothelial growth factor; vWF, von Willebrand factor.

proteins and the endothelial cell receptors ICAM-1, α V β 3 integrin, and GPIb α .²⁸³ Platelet adhesion to intact endothelium via these various pathways may contribute to thrombus formation in the circulation and may provide a link between thrombosis and inflammation in diseases such as atherosclerosis.²⁸⁴ Platelet–endothelial interactions also may contribute to the pathogenesis of thrombotic thrombocytopenic purpura. Normally, ultra-large vWF remains attached to endothelium via P-selectin until it is cleaved by the plasma metalloproteinase a disintegrin and metalloproteinase with thrombospondin (ADAMTS-13). Failure of this mechanism in thrombotic thrombocytopenic purpura because of a deficiency of ADAMTS-13 may lead to spontaneous platelet adhesion to endothelium and microvascular thrombosis.²⁸⁵

Red Blood Cells

Plasmodium falciparum–infected and sickled RBCs interact significantly with endothelium, and these adhesive interactions are thought to play an important role in the pathogenesis of human diseases.

Among the human malarial parasites, only *P. falciparum* modifies the surface of the parasitized RBCs so that asexual parasites and gametocytes are able to adhere to the vascular endothelium.^{286,287} Binding of trophozoite- and schizont-infected RBCs to endothelium not only allows the parasite to escape destruction in the spleen, but also may contribute to the pathogenesis of cerebral malaria.^{287,288} Multiple endothelial adhesion receptors have been implicated in mediating cytoadherence of infected RBCs, including P-selectin, ICAM-1, VCAM-1, and CD36.²⁸⁹

Binding of young sickled RBCs to postcapillary endothelium with secondary trapping of poorly deformable, often irreversibly sickled cells is thought to be an important pathogenic factor in vasoocclusive events.²⁹⁰ Several interactions between sickle RBC receptors and endothelial ligands have been described, including α 4 β 1/VCAM-1,²⁹¹ α 4 β 1/Lutheran blood group (basal cell adhesion molecule)²⁹²; and ICAM-4/ α V β 3.²⁹³ The adhesive proteins thrombospondin and vWF promote adhesion by serving as bridging factors between various sickle RBC and endothelial adhesion molecules. In addition to direct

adhesion to endothelium, sickle RBC binding to adherent leukocytes has been proposed as a mechanism for sickle cell vascular occlusion.²⁹⁴ As with leukocyte adhesion to endothelium in inflammatory and immune disease, drugs targeting sickle RBC adhesive interactions with endothelial cells or leukocytes may prove useful in preventing or treating vasoocclusive crises.

Endothelial Cell Activation and Dysfunction

Although once viewed as a passive barrier between blood and tissue, the endothelium now is evident to be a dynamic and heterogeneous organ that responds to diverse stimuli, ranging from coagulation proteins and cytokines to hemodynamic forces and growth factors. Activation of endothelial cells induces a complex proinflammatory and prothrombotic phenotype as well as expression of certain cytoprotective genes (see Table 123.1).^{295,296} Multiple transcription factors, particularly nuclear factor- κ B²⁹⁷ and early growth response 1,²⁹⁸ regulate these responses.²⁹⁵ Endothelial activation undoubtedly is an important event in host defense and repair, but it also may contribute to the pathogenesis of diverse diseases, ranging from sepsis²⁹⁹ to atherosclerosis.³⁰⁰

Endothelial dysfunction is characterized by a reduction in the bioavailability of vasodilators, particularly NO, leading to impairment of endothelium-dependent vasodilation, or by an increase in endothelium-derived contracting factors.³⁰¹ Endothelial dysfunction is prominent in atherosclerosis but also has been described in diabetes, preeclampsia, hypertension, uremia, and other diseases. In a broader sense, endothelial dysfunction encompasses proinflammatory and procoagulant changes as well as apoptotic cell death.^{227,302,303}

A number of noninvasive approaches for assessing endothelial function in vascular diseases have been developed. Endothelial vasodilatory responses can be evaluated by high-resolution ultrasound measurement of flow-mediated vasodilation or by plethysmography of changes in forearm blood flow during reactive hyperemia.³⁰⁴ Endothelial activation can be assessed in plasma by circulating markers such as soluble endothelial adhesion molecules (e.g., sVCAM-1, sICAM-1, sE-selectin) and endothelial coagulation proteins (e.g., vWF and thrombomodulin)³⁰⁵ or endothelial microparticles.³⁰⁶ Circulating endothelial cells reflect significant vascular damage or cell death.³⁰⁷

MEGAKARYOCYTE AND PLATELET STRUCTURE

Joseph E. Italiano, Jr. and John H. Hartwig

Platelets are small anucleate fragments that are formed from the cytoplasm of megakaryocytes and have a characteristic discoid shape. To assemble and release platelets, megakaryocytes become polyploid by endomitosis and follow a maturation program that results in the conversion of the bulk of their cytoplasm into multiple long processes called *proplatelets*. To produce its quota of 1000–2000 platelets, a megakaryocyte may protrude as many as 10–20 proplatelets, each of which begins as a blunt protrusion that over time thins and branches repeatedly. Platelets form selectively at the ends of proplatelets. As platelets develop, their content of granules and organelles is delivered to them in a stream of individual particles moving from the megakaryocyte cell body to the nascent platelet buds at the proplatelet tips. Platelet formation can be arbitrarily divided into two phases. The first phase takes days to complete and requires megakaryocyte-specific growth factors. Massive nuclear proliferation to 16–32N and enlargement of the megakaryocyte cytoplasm occur as the platelet is filled with cytoskeletal proteins, platelet-specific granules, and sufficient membrane to complete the platelet assembly process. The second phase is relatively rapid and can be completed in hours. During this phase, megakaryocytes generate platelets by remodeling their cytoplasm first into proplatelets, then preplatelets, which undergo fission to generate discoid platelets.

MEGAKARYOCYTE DEVELOPMENT

Endomitosis

Hematopoietic stem cells, which are endowed with the genetic capacity to differentiate into multiple lineages, are induced down the pathway to become megakaryocytes by their exposure to certain growth factors.¹ Megakaryocytes become polyploid (i.e., 4N, 16N, 32N, 64N) through repeated cycles of DNA replication without cell division.^{2–5} Normally ploidy ranges from 4 to 64 times the haploid DNA complement, but the majority of cells fall within three ploidy classes (8N, 16N, and 32N), with 16N being dominant (Fig. 124.1).^{6,7} Ploidy number appears to be a predetermined event, possibly signifying genetic diversity among megakaryocyte populations. Megakaryocyte polyploidization results in a functional gene amplification whose likely function is an increase in protein synthesis.⁸ This process, called *endomitosis*, is a shortened mitosis caused by a block in late anaphase.^{9,10}

Whereas cells undergoing diploid mitoses proceed through cytokinesis and complete abscission division, megakaryocytes exhibit regression of the cleavage furrow and reenter G₁ as polyploid cells.¹ During polyploidization of megakaryocytes, the nuclear envelope breaks down, and an abnormal spherical mitotic spindle forms. The spindle has attached chromosomes that align from a position equidistant from the spindle poles. Sister chromatids segregate and move toward their respective poles (anaphase A). However, the spindle poles fail to move apart and do not undergo the microtubule-driven separation typically observed during anaphase B. Individual chromatids are not moved to the poles, and subsequently a single nuclear envelope encapsulates the entire set of sister chromatids.^{9,10} In most cell types, checkpoints and feedback controls ensure that DNA replication and cell division are tightly coupled. Megakaryocytes appear to be an exception to this rule, indicating they have managed to deregulate this process. Proposed mechanisms for regulating endomitosis include a reduction in mitosis-promoting factor^{11,12} or decreased

expression of cyclin B.^{12–15} Cyclins appear to play a critical role in directing endomitosis. Cyclin D3 is overexpressed in the G₁ phase of maturing megakaryocytes,¹⁶ but a triple knockout of cyclins D1, D2, and D3 in mice does not appear to affect megakaryocyte development.¹⁷ In contrast, cyclin E-deficient mice exhibit a profound defect in megakaryocyte development.¹⁸ The molecular programming involved in endomitosis is characterized by the mislocalization or absence of at least two critical regulators of mitosis: the chromosomal passenger proteins Aurora-B/AIM-1 and survivin. AIM-1, a serine/threonine kinase in the Aurora family that is implicated in mitosis, is downregulated as megakaryocyte polyploidization occurs, suggesting its loss may lead to the abortive mitosis and polyploidization.^{19,20} However, while Aurora kinase A is required for hematopoiesis, it is dispensable for mouse megakaryocyte endomitosis and differentiation.²¹ Whereas deletion of the APC/C cofactor Cdc20 causes mitotic arrest and severe thrombocytopenia, lack of the kinases Aurora-B, Cdk1, or Cdk2 does not affect endomitosis of megakaryocytes or platelet counts. Deletion of Cdk1 forces a change to endocycles without mitosis, whereas polyploidization in the absence of cdk1 and cdk2 occurs in the presence of aberrant replication events. Notably, ablation of these kinases rescues defects in Cdc20 null megakaryocytes. The observations suggest that endomitosis can be functionally replaced by alternative polyploidization mechanisms *in vivo*. One explanation for endomitosis could be inhibition of microtubule-based forces in anaphase B. Spindle pole separation during anaphase B is believed to be powered by the sliding of antiparallel interdigitating microtubules past each other²² mediated by the mitotic kinesin-like protein 1. This protein localizes at regions of overlapping microtubules during anaphase B and studies *in vitro* indicate that it can slide microtubules past each other.²³ Therefore lack of spindle pole separation during endomitosis may result from failure of megakaryocytes to undergo normal spindle orientation and/or the absence of signals that localize or activate a kinesin motor molecule that provides force for sliding.

Cytoplasmic Maturation

Megakaryocytes, the largest of the hematopoietic cells, undergo a pronounced cytoplasmic maturation to attain their large volumes (15,000 fL). Cytoplasmic maturation begins during endomitosis and increases considerably after all DNA amplification has ended (Fig. 124.2). Megakaryocytes enlarge dramatically as they mature, reaching sizes of 100–150 μm in diameter in culture and in bone marrow. During this process, the megakaryocyte cytoplasm rapidly fills with platelet-specific proteins, organelles, and membrane systems that ultimately are subdivided and packaged into platelets (Fig. 124.3). Their cytoplasmic space expands and, except for the most cortical regions, becomes densely filled with internal membranes that subsequently serve as the repository for the plasma membrane to be regurgitated for coating proplatelets as they extend.²⁴ This internal membrane system, which is one of the most striking features of mature megakaryocytes, has been referred to as the *demarcation membrane system* (DMS). The DMS, first described by Yamada in 1957, consists of an extensive, tortuous, branching network of membrane channels composed of flattened cisternae and tubules. Initially, the DMS was proposed to play an essential role in platelet formation by defining preformed “platelet territories” or “platelet fields” within the megakaryocyte cytoplasm.^{26,27} Release of individual

Fig. 124.1 POLYPLOID MEGAKARYOCYTES IN THE BONE MARROW. Large polyploid megakaryocytes are seen in the bone marrow on a typical hematoxylin- and eosin-stained slide and are recognized by their abundant pink cytoplasm and large nuclei (A). The degree of polyploidization is difficult to determine. Rarely, megakaryocytes can be seen in mitosis (B), and when chromosomes are aligned in metaphase plates, the high ploidy level become quite apparent. In the mitotic figure illustrated, the megakaryocyte is a 16N form with eight 2N metaphase plates.

Fig. 124.2 SUMMARY OF THE MAJOR EVENTS THAT LEAD TO PLATELET FORMATION AND RELEASE FROM MEGAKARYOCYTES. Hematopoietic stem cells are converted into megakaryocytes by exposure to the specific growth factor TPO. TPO initiates a maturation program that amplifies the megakaryocyte DNA and leads to synthesis of platelet-specific proteins. In particular, cytoskeletal elements, membrane systems, and receptor proteins are made in bulk, and the megakaryocyte becomes filled with platelet-specific granules. Platelet production begins when microtubules aggregate in the cell cortex, and one pole of the megakaryocyte spontaneously elaborates pseudopodia. These begin as large blunt pseudopodia, which subsequently thin and branch into proplatelets. The branching reaction is dependent on a localized assembly of actin and is inhibited by drugs that disrupt actin filaments. Platelets are assembled primarily at the ends of the proplatelets. Intracellular organelles are delivered to the platelet buds along microtubule tracks in the shafts. Platelets are released from the ends of proplatelets. FOG, Friend of *GATA1*; *GATA1*, GATA binding protein 1; *TPO*, thrombopoietin.

Fig. 124.3 PLATELET PRODUCTION IN THE MEGAKARYOCYTE. (A) Immature polyploid megakaryoblast with little differentiation. (B) Megakaryocyte with early Golgi zone. (C) Early platelet production in cytoplasm. (D) Late-stage megakaryocyte with abundant internal membranes, organelles, and platelet-specific proteins. (E) Early formation of demarcation membranes.

platelets was postulated to occur by massive fragmentation of the megakaryocyte cytoplasm along DMS fracture lines between these fields. However, studies demonstrating that platelets are primarily assembled and released from proplatelet ends (see [Platelet Formation](#) later in this chapter) are inconsistent with this notion and indicate instead that the DMS functions predominantly as a membrane reserve for proplatelet formation.²⁴ Direct visualization of mature DMSs containing phosphatidylinositol 4,5-bisphosphate suggests that it is the source of proplatelet membranes.² Studies by Eckly et al²⁸ have begun to provide insights into how the DMS forms and matures. To develop the DMS, the megakaryocyte plasma membrane enfolds at specific sites to generate a perinuclear pre-DMS. Next, the pre-DMS is expanded into its mature form by material added from Golgi-derived vesicles and by endoplasmic reticulum-mediated lipid transfer. This structural description is in line with studies on platelet glycosyltransferases, which arrive early in the forming DMS and eventually make their way to the megakaryocyte and platelet surface.²⁹ Thus far only a handful of proteins have been identified to participate in DMS formation based on alteration in its structure in certain knockout mouse models. Membrane-deforming proteins that use F-BAR domains to curve membranes or use GTP as an energy source to bud vesicles from membranes appear to be necessary for normal megakaryocyte maturation and platelet release. Gross disruptions in DMS structure are found in megakaryocytes isolated from either filamin A knockout, pascin2 knockout, dynamin 2 knockout, or Cdc42 interacting protein 4 (CIP4) knockout mice. CIP4 is an F-BAR protein that induces membrane tubulation and localizes to membrane lipids via its BAR domain and interacts with the Wiskott-Aldrich syndrome protein (WASP).³⁰ CIP4^{-/-} mice have mild thrombocytopenia with a 25% decrease in platelet counts. While megakaryocyte numbers and ploidy are normal in CIP4^{-/-} knockout mice, megakaryocytes isolated from these mice are less effective in producing proplatelets in vitro.

Dynamins are highly conserved large mechanochemical GTPases involved in endocytosis and vesicle transport, and mutations in dynamin 2 have been associated with thrombocytopenia in humans. Dynamin-2-dependent endocytosis is required for megakaryocyte development in mice.³¹ Filamin connects α GPIb α to the actin cytoskeleton and binds pascin2, a molecule that deforms membranes. Pascin 2 has an F-BAR and SH3 domain that binds dynamin and N-WASP. Pascin2 plays an important role in organizing internal membranes during megakaryocyte development and platelet production.

Maturing megakaryocytes, like other granulated cells, contain an abundance of ribosomes and rough endoplasmic reticulum, where

protein synthesis occurs. During this phase of megakaryocyte development, the cytoplasm fills with cytoskeletal proteins, platelet-specific receptors and secretory granules, and normal cellular organelles such as mitochondria and lysosomes.

One of the hallmark features of the mature megakaryocyte is its abundance of platelet-specific secretory granules. The two specific granules destined for platelets are α -granules and dense granules. α -Granules, the more abundant and larger of the two (200–500 nm in diameter), contain proteins that enhance platelet adhesion, promote cell-cell interactions, regulate angiogenesis, and stimulate vascular repair. α -Granules store matrix proteins and contain glycoprotein receptors in their membranes (Fig. 124.4A). The bulk of cellular P-selectin and a portion of $\alpha_{IIb}\beta_3$ and the glycoprotein Ib/IX/V complex, a receptor for von Willebrand factor (vWF), are expressed in the membranes of α -granules. Adhesion molecules within the granules include vWF, fibrinogen, fibronectin, vitronectin, and thrombospondin. α -Granule proteins can be derived from different sources. Some proteins, such as α -thromboglobulin and vWF, are synthesized by megakaryocytes. However, fibrinogen, also a major component of α -granules, is not synthesized by megakaryocytes and is taken up from plasma by an endocytic mechanism requiring fibrinogen binding to $\alpha_{IIb}\beta_3$. Although little is known about the intracellular trafficking of proteins in megakaryocytes, experiments using cryosectioning and immunoelectron microscopy suggest that multivesicular bodies are an essential intermediate stage in the formation of platelet α -granules. During megakaryocyte development, large ($\approx 0.5 \mu\text{m}$) multivesicular bodies undergo a gradual transition from granules containing 30–70-nm internal vesicles to granules containing secretion concentrates.

The second and smaller type of platelet granule is the dense granule. Platelets contain relatively few dense granules, which are approximately 150 nm in diameter. Dense granules have electron opaque cores and function primarily to recruit additional platelets to sites of vascular injury. Dense granules contain soluble activating agents, such as serotonin and ADP, as well as divalent cations. When the megakaryocyte reaches a certain point of maturation, proplatelet production begins, and granules are sent into the proplatelets destined for platelets.

REGULATION OF MEGAKARYOCYTE DEVELOPMENT

The development of megakaryocytes and the process of platelet biogenesis occur within a complex bone marrow environment where both cytokines and adhesive interactions play an essential role.

Fig. 124.4 MICROTUBULE DYNAMICS DURING PROPLATELET FORMATION. (A) Visualization of plus-end microtubule assembly in living megakaryocytes expressing end-binding protein 3 (EB3)-green fluorescent protein (GFP). First frame from the time-lapse sequence (B) of a living megakaryocyte that was retrovirally directed to express EB3-GFP. The cell body (CB) is at the right of the micrograph, and proplatelets (PP) extend to the left. EB3-GFP labels growing microtubule plus ends in a characteristic “comet” staining pattern that has a bright front and a dim tail. (B) The kymograph shows movement over time. Images are every 5 seconds. EB3-GFP comets undergo bidirectional movements in PP, demonstrating that microtubules are organized as bipolar arrays. Some EB3-GFP comets move toward the tip and are highlighted in *green*; others that move toward the cell body are highlighted in *red*. (C) Distribution of α -granules in megakaryocytes and PP projections visualized by fluorescence microscopy. α -Granules are stained with Alexa 568 (*red*)-labeled anti-von Willebrand factor antibodies. The proplatelets have been co-stained with Alexa 488 (*green*) anti-tubulin antibodies to highlight the microtubules.

Megakaryocytes are imprisoned within the subendothelial layer of the bone marrow sinuses where development and platelet biogenesis are regulated at multiple levels by several cytokines. Thrombopoietin (TPO), which is synthesized in bone marrow and the liver, is the principal regulator of thrombopoiesis. TPO also plays a central role in hematopoietic stem cell survival and proliferation. Circulating levels of TPO induce proliferation and maturation of megakaryocyte progenitors by binding to the c-Mpl receptor and signaling induction. TPO regulates all stages of megakaryocyte development, from the hematopoietic stem cell stage through cytoplasmic maturation. TPO increases platelet production by increasing both the number and size of individual megakaryocytes. c-Mpl activation is regulated by a complex array of signaling molecules that turn on specific transcription factors (see [Transcriptional Regulation of Platelet Formation](#) later in this chapter) to drive megakaryocyte proliferation and maturation. Although TPO appears to function as the main regulator of megakaryocyte development, it is not exclusive in this action. The

cytokine stem cell factor, granulocyte-macrophage colony-stimulating factor, FLT ligand, interleukin (IL)-3, IL-6, IL-11, and erythropoietin also can regulate megakaryocyte development but appear to function mainly in concert with TPO. Mice that lack TPO or its receptor c-Mpl have approximately 15% of the normal platelet count. The discovery of TPO in 1994 and the development of primary megakaryocyte or mouse embryonic stem cell cultures that can be induced to faithfully reconstitute platelet formation has provided systems for studying megakaryocytes in the act of making platelets in vitro. Megakaryocytes isolated from mouse fetal liver and incubated with TPO for 4–5 days mature into huge polyploid cells that are capable of generating and releasing large numbers of platelets. In a similar fashion, mouse embryonic stem cells can be induced to mature into large polyploid megakaryocytes in the presence of stromal cells and TPO, IL-6, and IL-11. This process requires 10–12 days, during which the conversion of embryonic stem cells into hematopoietic stem cells very likely occurs in the first half of the time period and

the maturation of hematopoietic stem cells into proplatelet-producing megakaryocytes in the second half. Human embryonic stem cells can be coaxed to differentiate into mature megakaryocytes,³ although the process takes several more days in culture. Recently, platelets have been generated from induced human pluripotent stem cells in culture using a doxycycline-controlled c-MYC expression vector.⁴

PLATELET FORMATION

Proplatelets and the Cytoskeletal Mechanics of Platelet Formation

The discovery of TPO and the development of megakaryocyte cultures that reconstitute platelet formation *in vitro* have allowed visualization of megakaryocytes in the act of forming platelets.⁵ The actual mechanical process of platelet production begins when mature megakaryocytes start to elaborate proplatelets (see Fig. 124.2 and Fig. 124.5). This process is distinguished by the erosion of one pole of the megakaryocyte cytoplasm (see Fig. 124.5). Multiple thick pseudopodia are extended and subsequently elongate to yield thin tubules. As these slender tubules grow, they branch repeatedly and develop periodic densities along their length that impart a beaded appearance.^{5,6} The first insight into the cytoskeletal mechanics of platelet formation dates from the work of Tablin and colleagues, who showed that proplatelet formation is dependent on microtubules; that is, proplatelet elaboration is inhibited by microtubule poisons. Microtubule poisons are effective because the extension of proplatelets from the megakaryocyte is mediated by the assembly of microtubules and their reorganization into cortical bundles. Cortical bundles align in the shafts of proplatelets, and proplatelet elongation is driven by sliding movements between overlapping microtubules composed of these bundles.⁷ The microtubule bundles form loops at the end of each proplatelet, and ultimately a single microtubule is rolled into a coil at the proplatelet end to define the platelet territory. Cytoplasmic tubulin in solution is an $\alpha\beta$ dimer that reversibly polymerizes into microtubules, which are long, hollow cylinders with an outer diameter of 25 nm. Several studies reveal an essential role in platelet biogenesis for β_1 tubulin, a divergent and lineage-specific β tubulin that is a major component of the megakaryocyte proplatelet cytoskeleton and marginal microtubule coil of the platelet. β_1 Tubulin, which is expressed exclusively in platelets and megakaryocytes during the late stages of megakaryocyte development, is essential for the production of normal numbers of platelets, as well as for the discoid shape of platelets. The evidence supporting the role of β_1 tubulin in these processes comes from several sources. First, mRNA subtraction between wild-type and NF-E2–deficient megakaryocytes identifies β_1

tubulin as a downstream effector of the megakaryocyte transcription factor NF-E2 that is absent in NF-E2–deficient megakaryocytes. Second, genetic elimination of the β_1 -tubulin gene in mice results in thrombocytopenia.⁶ Third, megakaryocytes isolated from β_1 -tubulin knockout mice fail to form proplatelets *in vitro* and instead extend only a small number of blunt protrusions.

The first event that signals proplatelet production is the consolidation of microtubules into large bundles at the megakaryocyte cortex that subsequently are reorganized into parallel bundles in the shafts of the proplatelets (Fig. 124.6).⁸ Microtubule bundles are thick near the body of the megakaryocyte as they enter the proplatelet shaft but become progressively thinner along the shaft, such that only 5–10 microtubules remain at the end of the proplatelet. Of note, the microtubule bundles that run down the proplatelet shaft make characteristic U turns in the tips and reenter the shaft, forming teardrop-shaped structures (Fig. 124.7). This creates a bipolar orientation of bundles near the proplatelet tip, a geometry required to explain the bidirectional granule and organelle traffic observed in proplatelets. The looped arrangement of microtubules in proplatelet tips also constrains the elongation mechanism used to grow proplatelets because of an insufficient number of free microtubule ends to nucleate this reaction.

Direct visualization of microtubule dynamics in living megakaryocytes using green fluorescent protein (GFP) technology has provided insights into how microtubules orient to power proplatelet elongation (see Fig. 124.4A,B). End-binding protein 3 (EB3), a microtubule plus end-binding protein associated only with growing microtubules, fused to GFP was retrovirally expressed in murine megakaryocytes and used as a marker to localize microtubule plus ends and to follow plus end dynamics.⁷ Immature megakaryocytes without proplatelets use a centrosomal-coupled microtubule nucleation/assembly reaction, which appears as a prominent starburst pattern when visualized with EB3-GFP. Microtubules assemble only from the centrosome and grow outward into the cell cortex, where they turn and run parallel to the cell edges. Just before proplatelet production begins, however, centrosomal assembly ends and microtubules release and consolidate into the cortex as bundles. Fluorescence time-lapse microscopy of living, proplatelet-producing megakaryocytes expressing EB3-GFP reveals that as proplatelets elongate, microtubules assemble continuously throughout the entire proplatelet. EB3-GFP studies also reveal that microtubules polymerize in both directions in proplatelets—that is, toward both the tips and cell body—demonstrating that microtubules composing the bundles have a mixed polarity. The cytoplasmic Ran-binding protein, RanBP10, is a β_1 -tubulin-binding protein that appears to regulate the assembly of proplatelet microtubules.⁹ Even though microtubules are continuously assembling at their plus ends in proplatelets, polymerization *per se* does not provide the force for proplatelet elongation. First, the rates of microtubule polymerization

Fig. 124.5 FORMATION OF PROPLATELETS BY A MOUSE MEGAKARYOCYTE. Time-lapse sequence of a maturing megakaryocyte showing the events that lead to elaboration of proplatelets *in vitro*. (A) Platelet production begins when the megakaryocyte cytoplasm starts to erode at one pole (arrow). (B) The bulk of the megakaryocyte cytoplasm has been converted into multiple proplatelet processes that continue to lengthen and form swellings along their length. These processes are highly dynamic and undergo bending and branching. (C) Once the bulk of the megakaryocyte cytoplasm has been converted into proplatelets, the entire process ends in a rapid retraction that separates the released proplatelets from the residual cell body.

Fig. 124.6 STRUCTURE OF PROPLATELETS. (A) Differential interference contrast image of proplatelets elaborated by mouse megakaryocytes in culture (bar = 5 μm). (B) Staining of proplatelets with Alexa 488 antitubulin immunoglobulin G reveals that the microtubules line the shaft of the proplatelet and form loops at the proplatelet tips (bar = 5 μm). (C, D) Organization of microtubules in the tips of proplatelets. (C) Microtubules form bundles in the proplatelet shafts (bar = 2 μm). (D) Microtubules loop in the proplatelet ends and reenter the proplatelet shafts (bar = 0.2 μm).

(average 10.2 $\mu\text{m}/\text{min}$) are approximately 10-fold faster than the proplatelet elongation rate. Second, proplatelet elongation continues when microtubule polymerization is blocked with drugs that inhibit net assembly, suggesting an alternative mechanism for proplatelet elongation. Third, proplatelets possess an inherent microtubule sliding mechanism. Cytoplasmic dynein, a minus-end microtubule molecular motor protein, localizes along the microtubules of the proplatelet and appears to directly contribute to microtubule sliding because inhibition of dynein through disassembly of the dynactin complex prevents proplatelet formation. Microtubule sliding can be reactivated in detergent-permeabilized proplatelets. Adenosine triphosphate, which is known to support the enzymatic activity of microtubule-based molecular motors, activates elongation in permeabilized proplatelets that contain dynein and its regulatory complex dynactin. More recent analysis has indicated six types of behaviors that characterize the elaboration of proplatelets: elongation, branching, pausing, fusions, fragmentations, and retractions. While the average elongation rate for proplatelets over time is 1 $\mu\text{m}/\text{min}$, extension normally occurs in bursts and pauses. Burst rates greatly exceed the average rates, and under flow rates of less than 30 $\mu\text{m}/\text{min}$ have been observed. These rates correlate well with the sliding rates of microtubules within the bundles. Fluorescence recovery after photobleaching studies have demonstrated that microtubule sliding drives proplatelet elongation and is dependent on cytoplasmic dynein.³² Thus dynein-facilitated microtubule sliding appears to be the key event driving proplatelet elongation.

Nascent platelets assemble at the bulbous ends of proplatelets, as defined by the rolling of a single microtubule into a coil having the

same diameter as the coil found in the mature platelet. Given that maturation of the platelet is limited to these sites; efficient platelet production requires a large number of proplatelet ends. Megakaryocytes use a unique mechanical process to repeatedly bifurcate the shafts of the proplatelet, thereby amplifying the number of ends. To accomplish this task, the shaft of elongating proplatelets is bent on itself and a new proplatelet grows out of the bend; a process that results in bifurcation of the shaft. Whereas proplatelet elongation is mediated by microtubules, actin mediates the bending and branching of proplatelet shafts. Actin filament assemblies decorate branch points, and agents that disrupt actin assembly, such as the cytochalasins, abolish proplatelet branching. One possibility is that proplatelet bending and branching are regulated by the actin-based molecular motor myosin. Myosin II is an ATPase motor that makes up 2%–5% of the total platelet protein. Myosin II binds to actin filaments and generates force for contraction. Each myosin has two heads and a long, rod-like tail whose function is to permit the molecules to assemble into bipolar filaments. Of interest, a mutation in the tail domain of the nonmuscle myosin heavy chain A gene in humans results in several disorders, including May-Hegglin anomaly, Sebastian syndrome, and Fechtner syndrome. These rare autosomal platelet disorders are characterized by thrombocytopenia with giant platelets. Recent findings have implicated myosin IIA in restricting proplatelet production until megakaryocytes attain full maturity. The loss of myosin IIA function through targeted gene disruption in mice, through dominant inhibitory mutations in humans, or by manipulation of cultured megakaryocytes appears to accelerate proplatelet production. Consequently, platelet production is inefficient and

Fig. 124.7 MEMBRANE SKELETON OF THE PROPLATELET. Representative electron micrographs of the detergent-insoluble proplatelet cytoskeleton. Proplatelets were permeabilized with 0.75% Triton X-100, 5 μ M phalloidin, and 0.1% glutaraldehyde. Examination through electron microscopy reveals that the plasma membrane of the proplatelet tube is supported by a fibrous membrane skeleton that is similar in structure to the membrane skeleton of mature platelets. (A) This low-magnification field shows that an intact membrane skeleton laminates the underside and extends along the entire length of proplatelets (bar = 1 μ m). (B) High-magnification, three-dimensional electron micrograph of the proplatelet membrane skeleton reveals a lattice-like network of elongated filamentous strands, similar in nature to the spectrin-based network in red blood cells and platelets. The membrane skeleton continuously laminates the underside of the proplatelet. A cytoplasmic bridge is shown (left) linking to a swelling (right) (bar = 200 nm).

produces platelets that vary extensively in shape, content, and diameter. These findings also suggest that the Rho-ROCK-myosin light chain pathway regulates myosin IIA.

Because proplatelets elongate, but do not branch in the presence of the actin-disrupting drug cytochalasin B, it is unexpected that the deletion of certain actin-associated proteins from the megakaryocyte lineage leads to macrothrombocytopenia. It seems likely that removal of actin-modulating proteins alters and/or increases filamentous actin and that the cytoskeletal structure appears to have a dominant inhibitory effect on proplatelet production and release. The absence of the cytoplasmic actin crosslinking protein Filamin A in conditional knockout mice whose megakaryocyte lineage lacks Filamin A results in macrothrombocytopenia in which platelet counts are reduced by 80%–90%.³³ Conditional knockout mice lacking the actin turnover protein cofilin-1 in the megakaryocyte lineage also contain giant platelets with a platelet count reduced by 60%–80% of normal. In

contrast, mice lacking the actin turnover protein ADF have normal platelet counts and morphology.³⁴ On the other hand, when ADF^{-/-} mice are crossed with cofilin-1 knockout mice, platelet production is severely reduced and morphologies of platelets are highly variable. Mice that contain megakaryocytes that specifically lack profilin 1, a small protein that promotes actin filament assembly, have macrothrombocytopenia with reduced platelet counts.³⁵ Profilin-null platelets have a thickened microtubule coil with hyperacetylated microtubules, and in some ways, the profilin 1 knockout phenotype is similar to the behavior of platelets in Wiskott-Aldrich syndrome, or in WASp knockout mice. Defective proplatelet production has also been observed in mice in which the small regulatory GTPases Rho, Cdc42, and Rac have been deleted in the megakaryocyte lineage.^{36,37}

In addition to playing an essential role in proplatelet elongation, the microtubules lining the shafts of proplatelets serve a secondary function: transport of membrane, organelles, and granules into proplatelets and assembling platelets at proplatelet ends (see Fig. 124.4C). Organelles are sent individually from the cell body into the proplatelets, where they move bidirectionally until they are captured at proplatelet tips.¹⁴ Immunofluorescence and electron microscopic studies indicate that organelles are intimately associated with microtubules, and actin poisons do not diminish organelle motion. Thus movement appears to involve microtubule-based forces. Bidirectional organelle movement is conveyed in part by the bipolar arrangement of microtubules within the proplatelet because kinesin-coated latex beads move in both directions over the microtubule arrays of permeabilized proplatelets. Of the two major microtubule motors, kinesin and cytoplasmic dynein, only the plus end-directed kinesin is localized in a pattern similar to organelles and granules, and is likely responsible for transporting these elements along microtubules. It appears that two mechanisms of organelle and granule movement are involved in platelet assembly: first, organelles and granules travel along microtubules, and second, the microtubules themselves slide bidirectionally in relation to other motile filaments, indirectly moving organelles along proplatelets in a piggyback manner.

Although the roles of microtubules and actin filaments in proplatelet development have been extensively studied, our understanding of the function of the membrane skeleton has only recently been established. High-resolution electron microscopy reveals that proplatelets have a dense spectrin-based membrane skeleton similar in structure to that of mature blood platelets. Nonerythroid spectrin subunits, α -II and β -II spectrin, are predominantly expressed in mouse megakaryocytes, proplatelets, and platelets, but erythroid α -I and β -I spectrin isoforms are also expressed (see Fig. 124.6).¹⁵ Assembly of spectrin tetramers is required for development of the DMS and proplatelet elaboration because expression of a spectrin tetramer-disrupting construct in megakaryocytes inhibits both processes. Furthermore, integration of this spectrin-disrupting construct into a permeabilized proplatelet system quickly destabilizes proplatelets, resulting in massive blebbing and swelling. Spectrin tetramers also stabilize the barbell-like shapes found in the penultimate stage in platelet production (see later). Taken together, these studies suggest a role for spectrin in different steps of megakaryocyte development through its participation in the formation of demarcation membranes and in the maintenance of proplatelet structure.

Platelet Maturation at the Proplatelet Tip

Platelet maturation at proplatelet tips ends when a single microtubule detaches from the microtubule bundle and is rolled into a coil. To complete construction of mature platelets, once the fundamental cytoskeletal components have been delivered to and assembled in the platelet buds, the buds must fill with their organelle and granule content.

Granules are sent to nascent platelets on the microtubule tracks of the proplatelets. The concentration of this cargo in the platelet occurs by an end-trapping mechanism as granules and organelles, which enter the nascent platelet, continue to move in the tip but do not return to the proplatelet shaft.

Release of Mature Platelets

Details of how mature platelets release from the proplatelet tips are beginning to come into focus. In vitro, maturation of proplatelets ends in a rapid retraction that separates a variable portion of the proplatelets from the residual cell body, leaving behind a naked, denuded nucleus (see Fig. 124.5C). Activation of apoptotic pathways in the cell body has been shown to be coincident with this event. Junt and colleagues have used intravital fluorescence microscopy to visualize proplatelet production in the opened cranial marrow cavity of living mice.¹⁶ Yellow fluorescent protein (YFP)-labeled megakaryocytes were seen to protrude proplatelets and release megakaryocyte fragments into the marrow sinusoids of living mice. Notably, these anucleate fragments typically exceed platelet dimensions, suggesting that platelet morphogenesis continues in the circulation. In line with these observations, we have recently identified a previously unrecognized intermediate stage in platelet formation and release, which we termed the *preplatelet*.¹⁷ Preplatelets are defined as discoid cells (3–10 μm) that retain the capacity to convert into barbell-shaped proplatelets and undergo fission into platelets. The conversion of preplatelets to barbell proplatelets is powered by microtubule-based forces. It is likely that the microtubule motors that drive proplatelet extension are involved in aspects of platelet release, as well as in the process of microtubule coiling. Sliding of an uncoiled portion of the microtubule relative to the rigid microtubule bundle in the proplatelet tip would provide a simple mechanism to effect platelet release and would explain the variable morphology of the small but reproducible percentage (<5%) of dumbbell-shaped platelets that are present in blood. Recently, it was demonstrated that individual human platelets have the innate capacity to duplicate and form new cell bodies that undergo fission into platelets.¹⁸ The morphologic similarities between platelets that form new cell bodies and preplatelets are striking. Whether or not newly released platelets exhibit a preplatelet phenotype, which allows them to form barbell-shapes and divide again, is not clear.

Location of Platelet Release

Megakaryocytes are produced in the bone marrow, and some undergo fragmentation into platelets in this location. It has been suggested that, by extending into the bone marrow sinusoids, proplatelets provide a mechanism for extension into the bone, allowing release of platelets directly into the circulation.^{19,20} Megakaryocytes have been identified in intravascular sites within the lung, leading to a theory that some platelets are formed from their parent cell in the pulmonary circulation.

Transcriptional Regulation of Platelet Formation

Megakaryocyte development and platelet formation are controlled by the coordinated action of transcription factors that specifically turn on the genes of megakaryocyte precursors or suppress the expression of genes that support other cell types.²² Gene-targeting studies in mice have identified several genes that are crucial for megakaryocyte development and platelet formation. Leading the list of transcription factors that play an essential role in megakaryocyte maturation and platelet biogenesis is the basic leucine zipper heterodimer NF-E2. NF-E2 is a protein composed of a ubiquitously expressed 18–20-kDa small-Maf subunit and a p45 subunit that is restricted to erythroid and megakaryocytic lineages. Although NF-E2 was postulated to be a transcription factor that specifically drove the expression of genes essential for erythropoiesis, mice lacking p45 NF-E2 do not exhibit defects in erythropoiesis. Instead, mice deficient in the p45 subunit or two of the small-Maf subunits die of hemorrhage shortly after birth because of a complete lack of circulating platelets. Although megakaryocytes undergo normal endomitosis and proliferate in response to TPO, mice deficient in p45 NF-E2 produce increased numbers of megakaryocytes that are larger than normal, contain fewer granules,

exhibit a highly disorganized DMS, and fail to generate proplatelets in vitro, a phenotype indicative of a late block in megakaryocyte maturation. Therefore NF-E2 appears to control the transcription of a limited number of genes involved in cytoplasmic maturation and platelet formation. Shivdasani and colleagues generated a subtracted cDNA library enriched in transcripts downregulated in NF-E2 knockout megakaryocytes. Using this approach, these investigators have started to identify the downstream targets of NF-E2 and to analyze their role in the terminal stages of megakaryocyte differentiation. Putative transcriptional targets of NF-E2 include β_1 tubulin, thromboxane synthase, and proteins that regulate inside-out signaling via $\alpha_{IIb}\beta_3$ integrin. The zinc finger protein GATA1 is also a transcription factor that plays a critical role in driving the expression of genes essential for megakaryocyte maturation. However, unlike NF-E2, which appears to drive the later stage of megakaryocyte development, *GATA1* functions at multiple stages of development. Initially, GATA proteins were thought to regulate red blood cell maturation because genetic disruption of the *GATA1* gene in mice results in embryonic lethality secondary to a block in erythropoiesis. However, several more recent observations also implicate *GATA1* as a regulator of megakaryocyte differentiation. First, forced expression of *GATA1* in the early myeloid cell line 416b induces megakaryocyte differentiation. Second, Shivdasani and colleagues used targeted mutagenesis of regulatory elements within the *GATA1* locus to generate mice with a selective loss of *GATA1* in the megakaryocyte lineage. These knockdown mice expressed sufficient levels of *GATA1* in erythroid cells to circumvent the embryonic lethality caused by anemia. *GATA1* deficiency in megakaryocytes leads to severe thrombocytopenia. Platelet counts are reduced to approximately 15% of normal, and the small numbers of circulating platelets are round and larger than normal. These mice have increased numbers of small megakaryocytes that exhibit an accelerated rate of proliferation. The small cytoplasmic volume of *GATA1*-deficient megakaryocytes typically contains an excess of rough endoplasmic reticulum, very few platelet-specific granules, and an underdeveloped or disorganized DMS, suggesting that maturation of megakaryocytes is arrested in *GATA1*-deficient megakaryocytes.

A family with X-linked dyserythropoietic anemia and thrombocytopenia due to a mutation in *GATA1* has been described. A single-nucleotide substitution in the N-terminal zinc finger of *GATA1* inhibits the interaction of *GATA1* with its essential cofactor, friend of *GATA1* (FOG). Although megakaryocytes in affected family members are abundant, they are unusually small and exhibit several abnormal features, including an abundance of smooth endoplasmic reticulum, an underdeveloped DMS, and a lack of granules. These observations suggest an essential role for the *FOG1-GATA1* interaction in thrombopoiesis. Genetic elimination of FOG in mice unexpectedly resulted in specific ablation of the megakaryocyte lineage, suggesting a *GATA1*-independent role for FOG in the early stages of megakaryocyte development; therefore *GATA1* and FOG are required for megakaryocyte generation from a common bipotential progenitor.

Several knockout mice also indicate a role for additional transcription factors in megakaryocyte development. Mice carrying a null mutation in *Fli-1*, a member of the ETS family of winged helix-turn-helix transcription factors that bind purine-rich sequences in gene promoters, exhibit defects in megakaryocyte development. Megakaryocytes cultured from mice lacking *Fli-1* contain reduced numbers of α -granules, disorganization of the demarcation membranes, and a reduction in size. Mice lacking the hematopoietic zinc finger (Hzf) protein, a transcription factor that is predominantly expressed in megakaryocytes, have reduced numbers of α -granules in megakaryocytes and platelets. Therefore Hzf may regulate the transcription of genes involved in the synthesis of α -granule components and/or their packaging into α -granules. SCL, a basic helix-loop-helix transcription factor initially identified in a subset of human T-cell leukemia with multilineage characteristics, also appears to be critical for megakaryopoiesis. Results of deletion of SCL in mice indicate that this transcription factor is required for proper erythroid and megakaryocyte development.

PLATELETS

Structure of the Resting Platelet

Megakaryocyte development culminates in the release of mature discoid platelets having dimensions of approximately $3.0 \times 0.5 \mu\text{m}$ and a cytoplasmic volume of 7 fL.²³ The evolutionary explanation for the discoid shape of the platelet is unknown. Discoid shape may permit more efficient flow or dispersion of clot-promoting elements or may simply reflect the microtubule-based mechanism by which platelets are produced. In humans, platelets, once released from the ends of proplatelets, normally circulate for 7–10 days. Given that nearly 1 trillion platelets circulate in an adult human, each day an adult produces approximately 100 billion platelets.

The precise morphology of newly released platelets is unknown. However, when released into the circulation or maintained in culture, platelets have a very reproducible structure. Although they are heterogeneous in size, presumably because of changes in size as they age, platelets have discoid shapes with flat, featureless surfaces (Fig. 124.8A and Fig. 124.9A) that are interrupted only by pit-like openings into the open canalicular system (OCS). The OCS is an extensive system of internal membrane conduits that serves as a passageway to the outside world into which granular contents are released. It also is a reservoir of plasma membrane, membrane receptors, and proteins. For example, approximately 30% of the thrombin receptors are

localized in the OCS of the resting platelet, awaiting movement to the surface when the cells are activated. Although contiguous with the plasma membrane, not all proteins on the cell surface can enter the OCS. Factors controlling movement into the OCS remain to be defined but likely depend on the actin cytoskeleton. Entry restriction, however, occurs at the necks of OCS infoldings. The third function of the OCS is to serve as a source of redundant plasma membrane for cell spreading. OCS membrane initially is disgorged to the surface following cell activation. When cells are activated in solution, much of this membrane is subsequently reabsorbed into the remnants of the OCS.

A small thin zone of cytoplasm separates the plasma membrane of the resting platelet from a marginal microtubule coil and the general intracellular space, which contains all inclusion bodies and the internal cytoskeleton of the cell. This zone is filled with the spectrin-based membrane skeleton (see Fig. 124.9A). Beneath this zone sits a microtubule coil. Then follows the cytoplasmic space, which is filled with filaments of actin that embed granules, organelles, the OCS, and other specialized membrane systems such as smooth endoplasmic reticulum.

Platelets actively recruit other blood-borne cells to areas of vascular damage by releasing mediators packaged in intracellular granules (described earlier in Cytoplasmic Maturation) that initiate secondary homeostatic interactions and that express a “sticky” apical surface after the platelets adhere. In the resting platelet, granules

Fig. 124.8 COMPARISON OF THE STRUCTURE OF NORMAL MOUSE PLATELETS (A, C, D) WITH THOSE LACKING β_1 TUBULIN (B, E, F). (A) Electron micrograph of a resting mouse platelet sectioned through its thin axis. The cut plane reveals the microtubule coil (MC) at the cell periphery. The inset shows a high-magnification cross-section through the MC of the resting platelet. The microtubule is wound 11 times in this platelet, forming the coil. The cytoplasmic space embeds mitochondria (MT), α -granules (α -G), and dense granules (DG). Spaces created by the open canalicular system (OCS) are apparent. (B) Electron micrograph of a thin section through a platelet isolated from a mouse lacking β_1 tubulin (bar = $0.2 \mu\text{m}$). Platelets from these animals are spherical (E) and have only a rudimentary microtubule coil (inset). In this platelet the microtubule is twisted twice. (C) Differential interference contrast image of resting platelets shows them to be flat discs. (D) MC of the resting mouse platelet. Staining of fixed mouse platelets with Alexa 488 antitubulin immunoglobulin G (IgG) reveals the MC. This coil resides at the periphery of the platelet. (E) Differential interference contrast image of platelets lacking β_1 tubulin. (F) Staining of fixed mouse β_1 -tubulin-deficient platelets with Alexa 488 antitubulin IgG reveals the coil is defective and bent in a number of places throughout the platelets. (C–F are the same magnification; bar = $5 \mu\text{m}$.)

Fig. 124.9 STRUCTURE OF THE RESTING HUMAN BLOOD PLATELET AND ITS ACTIN-BASED CYTOSKELETON. (A) Composite illustrating the major actin cytoskeletal layers of the resting platelet. *Plasma membrane*: The plasma membrane of the resting cell is flat and featureless, except for periodic invaginations that lead into the open canalicular system (OCS) (arrows). *Membrane skeleton*: The plasma membrane of the platelet is supported by a submembranous spectrin-based skeleton. This network is composed primarily of spectrin molecules, which are tetramers with actin binding sites at the ends. Actin filament ends dock on spectrin to complete the network. The association between spectrin and F actin is promoted by adducin. *Actin cytoskeleton*: As discussed earlier, the spectrin network is both directly and indirectly attached to the underlying actin filaments. Filament ends interconnect spectrin molecules, whereas the filamin links run from the filament sides to the plasma membrane receptor (GPIIb/IIIa)₂V. The cytoplasmic space has a dense filling of actin filaments. Actin filaments from the cell center radiate outward. As the filaments approach the plasma membrane, they turn and run in parallel with it. The actin filaments have been decorated using myosin subfragment 1 (S1), which gives them a twisted cable-like appearance in frozen samples. Myosin S1 labeling reveals the polarity of the actin filament. “Pointed” and “barbed” ends are definable. The ends of actin filaments are bound by the ends of spectrin molecules on the edges of the membrane network (arrowhead). A microtubule coil composed of a single long microtubule resides just beneath the plasma membrane at the periphery of the thin axis of the platelet (not shown) (bar = 0.5 μm). (B) Schematic showing the structural features of the resting blood platelet cytoskeleton. Resting cells have discoid shapes. Structural elements that support this shape are (1) a marginal microtubule coil, (2) a spectrin-based membrane skeleton, and (3) a rigid network of cross-linked cytoplasmic actin filaments (only a small number of the actin filaments have been added to this illustration so that they will not obscure the rest of the structures in the cell). Platelets have a specialized membrane skeleton composed of spectrin, actin, and many associated proteins. Spectrin tetramers (200 nm long and 5 nm wide) have actin filament-binding sites at each molecular end. The membrane skeleton is held in compression between the plasma membrane and the cytoplasmic actin by filamin connections from the sides of actin filaments to the cytoplasmic tails of GPIIb/IIIa subunit of the membrane glycoprotein complex that binds to von Willebrand factor (GPIIb/IIIa)₂V complex. Greater than 98% of the barbed ends of actin filaments are capped by adducin and capZ in the resting platelet.

are juxtaposed together and are in intimate association with the membranes of the OCS. The release reaction of platelet granules differs from that of other cells. Granules rarely fuse with the plasma membrane; instead they exocytose into the OCS. Platelets also contain lysosomes and a few mitochondria, which are easily identified under the electron microscope by their internal system of membrane cristae.

Cytoskeleton of the Resting Platelet

Although both microtubule- and actin-based forces have been considered in the elaboration and branching of proplatelets, respectively, it is the integration of the microtubule and actin cytoskeletal elements that uniquely defines the shape of the mature platelet. One of the most distinguishing features of the resting platelet is its marginal microtubule coil (see Fig. 124.8). αβ-Tubulin dimers assemble into microtubule polymers under physiologic conditions. In resting

platelets, tubulin is equally divided between dimer and polymer fractions. In many cell types, αβ-tubulin subunits are in a dynamic equilibrium with microtubules such that reversible cycles of assembly-disassembly of microtubules are observed. Microtubules are long, hollow polymers (24 nm in diameter) that are responsible for many types of cellular movements, such as segregation of chromosomes during mitosis and transport of organelles across the cell. The microtubule ring of the resting platelet, initially characterized in the late 1960s by White and Krivit, was described as a single microtubule approximately 100 μm long and is coiled 8–12 times inside the periphery of the platelet. However, recent work suggests that the marginal band is highly dynamic and consists of multiple microtubules with mixed polarity that undergo constant assembly and disassembly.²⁴ This may accommodate the shrinkage of microtubule coil diameters that occurs with aging of platelets. Antagonistic microtubule motors appear to keep the marginal microtubule coil in its resting state.³⁸ The primary function of the microtubule coil is to maintain the discoid shape of the resting platelet. Disassembly of

platelet microtubules with drugs such as vincristine, colchicine, or nocodazole causes platelets to become round and to lose their discoid shape. Cooling the platelets also causes disassembly of the microtubule coil and loss of the discoid shape. Mice lacking β_1 tubulin, the major hematopoietic β -tubulin isoform, produce platelets that lack their characteristic discoid shapes and have defective marginal bands. Genetic elimination of β_1 tubulin in mice results in thrombocytopenia with circulating platelet counts below 50% of normal. β_1 -Tubulin-deficient platelets are spherical in shape, apparently due to shortened marginal bands with fewer coilings. Whereas normal platelets possess a marginal band that consists of 8–12 coils, β_1 -tubulin knockout platelets contain only 2–3 coils. A human β_1 -tubulin functional substitution (AG→CC) inducing both structural and functional platelet alterations has been described. Of note, the Q43P β_1 -tubulin variant was found in 10.6% of the general population and in 24.2% of 33 unrelated patients with undefined congenital macrothrombocytopenia. Electron microscopy revealed enlarged spherocytic platelets with a disrupted marginal band and structural alterations. Platelets with the Q43P β_1 -tubulin variant showed mild platelet dysfunction with reduced ATP secretion, attenuated thrombin receptor-activating peptide (TRAP)-induced aggregation, and impaired adhesion to collagen under flow conditions.⁵ A more-than-doubled prevalence of the β_1 -tubulin variant was observed in healthy subjects not undergoing ischemic events, raising the possibility that the variant confers an evolutionary advantage and a protective cardiovascular role.

Actin is the most abundant of all the platelet proteins, with 2 million molecules expressed per platelet. Of these molecules, 800,000 assemble to form the 2000–5000 linear actin polymers that exist in the resting cell (see Fig. 124.9A). The remainder of the actin is maintained in storage as a 1:1 complex with β_4 thymosin, which can be converted to filaments during platelet activation to drive cell spreading. All evidence indicates that the filaments of the resting platelet are interconnected at various points into a rigid cytoplasmic network because platelets express high concentrations of actin cross-linking proteins, including filamin and α -actinin.⁷ Both filamin and α -actinin are homodimers in solution. Three filamin genes are located on chromosomes 3, 7, and X. Filamin A (X) and filamin B (3) are expressed in platelets. Filamin A is expressed at levels more than 10-fold higher than that of filamin B. Filamin subunits are elongated strands composed primarily of 24 repeats, each approximately 100 amino acids in length and folded into immunoglobulin G-like β -barrels. Each strand has an N-terminus actin-binding site that shares homology with other actin-binding proteins, two rod domains that are end-to-end assemblies of the repeat units, interrupted by two hinge domains between repeats 15 and 16, and 23 and 24, and a C-terminus self-association site (Fig. 124.10B). Subunits assemble to form V-shaped bipolar molecules—that is, the self-association site is the vertex of the V, and the actin-binding sites are on the free ends. Inclusion of the first hinge in filamin depends on alternative RNA splicing. Filamin now is recognized to be a prototype “scaffolding

Fig. 124.10 INTERACTION OF FILAMIN A WITH THE VON WILLEBRAND FACTOR RECEPTOR. (A) Model showing the orientation of filamin A when interacting with the GPIIb α chain of the vWFR and cytoplasmic actin filaments. For tight binding of filamin A to vWFR, both GPIIb α chains of the receptor must be engaged by a single filamin A molecule. (B) Ribbon diagram showing the interface between filamin A repeat 17 and the filamin A binding region of the GPIIb α tail (residues 556–577). Critical residues that provide the lock-and-key interaction between the two domains are indicated. GPIIb α , glycoprotein Ib α ; vWFR, von Willebrand factor receptor.

molecule” that collects binding partners and localizes them adjacent to the plasma membrane. Partners bound by filamin members include the small GTPases, RalA, Rac, Rho, and Cdc42, with RalA binding in a GTP-dependent manner; the exchange factors Trio and Toll; kinases such as PAK1; phosphatases; and transmembrane proteins. Most partner proteins are bound within the C-terminus portion of filamin.

Central to the structural organization of the resting platelet is an interaction between filamin and the cytoplasmic tail of the GPIIb α subunit of the GPIIb-IX-V complex.²⁷ The second rod domain (repeat 17) of filamin has a binding site for the cytoplasmic tail of GPIIb α . The interaction between filamin A and GPIIb α occurs at the atomic level. Repeat 17 of filamin A has a groove between certain β -sheet strands that forms a pocket for the GPIIb α tail (see Fig. 124.10). Binding between filamin A and GPIIb α is driven by entropic forces, and the alignment and specificity are provided by large residues that create a lock-and-key fit between the two molecules. Whereas the interaction between one filamin A subunit and GPIIb α has an affinity of approximately 10 μ M, high-affinity binding (10 nM) occurs when each filamin A subunit in a molecule and both GPIIb α chains in a vWF receptor are engaged. Studies have shown that the bulk of platelet filamin (>90%) is in complex with GPIIb α . This interaction has three consequences. First, it positions filamin's self-association domain and associated partner proteins at the plasma membrane while dangling filamin's actin binding sites into the cytoplasm. Second, because a large fraction of filamin is bound to actin, it aligns the GPIIb-IX-V complexes on the surface of the platelet over the underlying filaments (see Fig. 124.9B). Third, because the filamin linkages between actin filaments and the GPIIb-IX-V complex pass through the pores of the spectrin lattice, it restrains the molecular movement of the spectrin strands in this lattice and holds the lattice in compression. The filamin-GPIIb α connection is essential for the formation and release of discoid platelets by megakaryocytes; platelets lacking this connection are large and fragile and are produced in low numbers. However, the role of the filamin-vWF receptor connection in platelet construction is unknown. Because a low number of Bernard-Soulier platelets form and release from megakaryocytes, it can be argued that this connection is a late event in the maturation process and is not required for platelet shedding. Both filamin and GPIIb α are synthesized early, but linkage between the two may not occur until later, perhaps as late as the final stages of platelet shedding. Bernard-Soulier patients have an autosomal recessive bleeding disorder characterized by low platelet count with giant platelets, underscoring the importance of the filamin-GPIIb α connection in stabilizing the membrane skeleton in platelet biology.

Aside from the erythrocyte, the platelet is the only cell whose membrane skeleton has been visualized at high resolution. Like the erythrocyte, the platelet membrane skeleton is a self-assembly of elongated spectrin strands (see Fig. 124.9) that interconnect through binding to actin filaments. Platelets express approximately 2000 spectrin molecules. Although considerably less is known about how the spectrin-actin network forms and is connected to the plasma membrane in the platelet relative to the erythrocyte, certain differences between the two membrane skeletons have been identified. First, the spectrin strands composing the platelet membrane skeleton interconnect using the ends of long actin filaments instead of short actin oligomers. These ends arrive at the plasma membrane originating from filaments in the cytoplasm. Hence the spectrin lattice is assembled into a continuous network by its association with actin filaments. Second, tropomodulins are not expressed at sufficiently high levels, if at all, to have a major role in capping the pointed ends of the platelet actin filaments. Instead, biochemical experiments have revealed that a substantial number ($\approx$ 2000) of these ends are free in the resting platelet. Third, although little tropomodulin protein is expressed, α adducin and γ adducin are abundantly expressed and appear to cap many of the barbed ends of the filaments composing the resting actin cytoskeleton. Adducin is a key component of the membrane skeleton, forming a triad complex with spectrin and actin. Capping of barbed filament ends by adducin also serves the function of targeting them to the spectrin-based membrane skeleton because

the affinity of spectrin for adducin-actin complexes is greater than for either actin or adducin alone. Platelet glycoproteins involved in attaching spectrin to the membrane remain to be defined.

MOLECULAR BASIS OF PLATELET FUNCTION

Margaret L. Rand and Sara J. Israels

The primary physiological role of platelets is to support hemostasis at sites of vascular injury by forming a plug that arrests blood loss (Fig. 125.1). Normally, disc-shaped platelets circulate in the bloodstream without adhering to the endothelium of the vessel wall. When the endothelium is damaged, platelets adhere to the exposed subendothelial collagen and, at high shear, to collagen-immobilized von Willebrand factor (VWF). Platelet adhesion at the site of vessel wall damage initiates activation events via intracellular signaling pathways that trigger (1) reorganization of the actin cytoskeleton that results in a shape change from discs to irregular spheres with filopodia, and enables platelet spreading to increase surface contact; (2) secretion of dense granule and α granule contents, including ADP from the dense granules; (3) formation and release of second messengers including thromboxane A_2 (Tx A_2); and (4) exposure of phosphatidylserine (PS) on the platelet surface, thereby creating a procoagulant activated platelet surface for assembly of coagulation factor complexes that accelerate the generation of thrombin. Platelet agonists, including ADP, Tx A_2 , and thrombin, bind to their specific membrane receptors, initiating signaling pathways that convert integrin $\alpha IIb\beta_3$ from a low-affinity resting state to a high-affinity activated state capable of binding its ligands. Divalent fibrinogen and multivalent VWF function as bridges between $\alpha IIb\beta_3$ on adjacent activated platelets, resulting in aggregation and plug formation. This series of platelet responses is essential for the hemostatic function of platelets, and when impaired by congenital or acquired defects, bleeding can occur. However, if these same events take place on a ruptured atherosclerotic plaque, they can lead to the formation of a platelet-rich thrombus that can occlude the arterial lumen and lead to ischemia.

This chapter addresses the molecular basis of platelet activation and primary hemostatic plug formation. Significant progress has been made in defining the molecular mechanisms that govern platelet responses, facilitated by the study of patients with congenital defects of platelet function and/or number, and by the study of genetically modified animals. Recently, the field of platelet biology has expanded to encompass the platelet's role in inflammation, host defense and tumor progression.¹⁻³ What we have learned about the molecular mechanisms of platelets in the setting of hemostasis and thrombosis is now being applied in new areas to address new questions.

MOLECULAR BASIS OF PLATELET ADHESION

Substrates for Platelet Attachment and Spreading

Platelet plug formation is initiated by contact of circulating platelets with proteins in the subendothelial extracellular matrix (ECM). Normal endothelium maintains an effective barrier that prevents circulating platelets from contact with these ECM proteins. In addition to the physical barrier, endothelial cells actively inhibit platelet activation by release of nitric oxide, prostacyclin, and enzymes (CD39/CD73) involved in the metabolism of ADP.⁴ At sites of vascular injury, where endothelium is lost or damaged and the ECM becomes exposed to flowing blood, platelets come into close contact with ECM adhesive proteins that promote initial attachment and subsequent activation.

The subendothelial matrix can be viewed as a dynamic and mutable interface that provides multiple substrates to support platelet

adhesion (Table 125.1). These substrates include collagens,⁵ immobilized VWF,⁶ fibronectin,⁷ laminin,⁸ and thrombospondin-1.⁹ Plasma proteins fibrinogen,¹⁰ vitronectin,¹¹ and circulating VWF also interact with platelets after binding to matrix components. The roles of collagen and VWF are well defined, while the contributions of other adhesive proteins to the initial attachment of platelets are less well established. Studies of mice deficient in individual matrix proteins have been useful in determining the contribution of these proteins to the integrated function of the ECM in the formation, growth, and stabilization of the platelet plug.

Shear rates in flowing blood, which vary depending on vessel caliber, influence the contribution of specific matrix proteins. At low shear, platelets can be captured by collagens, but at higher shear rates ($>1000\text{ s}^{-1}$), VWF becomes critical in ensuring efficient platelet attachment via the receptor glycoprotein (GP)Ib α (Fig. 125.2A) (see section on Platelet Adhesion Receptors). VWF, secreted from endothelial cells and recruited from plasma, binds to type VI collagen in the vascular matrix via the VWF A1 domain, and to types I and III collagen in both superficial and deeper layers of the matrix via the VWF A3 domain.¹²

Collagen types I, III, and VI exposed at sites of vascular injury are key substrates for direct platelet adhesion. Collagen is a fibrillar protein made up of tropocollagen monomers packed into units of five to generate microfibrils.¹³ Collagens have motifs that are not only recognized by VWF, but also by the platelet collagen receptors $\alpha 2\beta 1$ and GPVI^{5,14} (see section on Platelet Adhesion Receptors). At low shear, collagen can function independently of VWF to capture platelets at the matrix surface. However, under high shear, collagen and VWF, with their respective receptors, function in concert.^{12,15}

Platelet adhesion is supported by other substrates in the matrix, and by plasma proteins that interact with the matrix. It is likely that these proteins fine-tune the primary hemostatic response depending on the site or severity of the injury. Plasma proteins including fibronectin,^{7,16} vitronectin,¹¹ and fibrinogen (and its polymerized product fibrin), matrix protein laminin⁸ and platelet α granule protein thrombospondin-1⁹ all support platelet adhesion in experimental systems. It is likely that most of these proteins play an ancillary role in vivo via mechanisms that include enhancing VWF immobilization in the matrix (laminin), protecting large VWF multimers from degradation (thrombospondin-1), or bridging between platelet receptors and matrix collagen (fibronectin).

Platelet Adhesion Receptors

Nomenclature

The individual adhesive proteins serve as ligands for specific receptors on the platelet surface (Table 125.1). Several nomenclature systems have been used to identify the membrane glycoproteins of the platelet, such that the same receptor may have multiple designations. The original and still widely used system designates the membrane glycoproteins according to their electrophoretic mobility upon sodium dodecyl sulfate polyacrylamide gel electrophoresis; protein separation is on the basis of molecular weight, with higher molecular-weight proteins migrating more slowly. Glycoproteins were designated as GPI, II, III, and so on, with GPI having the highest molecular weight. With greater resolution techniques, additional glycoproteins were

Vitronectin	$\alpha \nu \beta 3$ GPIIb-IIIa ($\alpha \text{IIb}\beta 3$)
Laminin	$\alpha 6\beta 1$

^aAlternative name for receptor is given in brackets.

identified, hence the subdivision designations, e.g., GPIa, GPIb, GPIc; GPIIa, GPIIb. Many of the membrane glycoproteins on the platelet surface exist as noncovalent complexes, e.g., GPIa-IIa, GPIb-IX-V, GPIIb-IIIa.

In addition to the GP nomenclature system, the $\alpha\beta$ integrin nomenclature system is used. Several of the platelet membrane glycoproteins are members of the integrin family of adhesion receptors (see later), e.g., GPIa-IIa is $\alpha 2\beta 1$, GPIIb-IIIa is $\alpha \text{IIb}\beta 3$. Some glycoproteins also have cluster of differentiation (CD) designations, e.g., CD41 for GPIIb and CD61 for GPIIIa. Finally, some receptors have been named based on their function (e.g., the fibrinogen, fibronectin, and vitronectin receptors). Although functional designations can be appropriate from a descriptive standpoint, at least two different membrane glycoproteins on platelets serve as receptors for vitronectin and fibronectin (see Table 125.1), and several are receptors for collagen (see later). Beyond creating nomenclature complexity, redundancy of platelet receptors endows the platelet with the capacity to form multiple contacts with a single matrix constituent. Thus, a

single ligand may initiate several distinct functional responses by engaging different receptors.

The Integrin Family of Adhesion Receptors

Integrins are members of a superfamily of broadly distributed adhesion receptors that mediate cell-matrix and cell-cell interactions. They are composed of noncovalently associated α and β transmembrane polypeptide subunits with large extracellular domains and short cytoplasmic tails. Of the 18 known α subunits, platelets express five, and of the eight known β subunits, platelets express two, with a total of five different platelet integrins. It is estimated that half of the surface area of an activated platelet is occupied by integrin receptors. Many of the glycoprotein receptors on platelets that mediate cell-matrix adhesion are members of the integrin family (Table 125.1). $\alpha 2\beta 1$ is a receptor for subendothelial collagen (see later); $\alpha 5\beta 1$ for fibronectin; $\alpha 6\beta 1$ for laminin; $\alpha \text{IIb}\beta 3$ for fibrinogen, VWF, and fibronectin; and $\alpha \nu \beta 3$ for vitronectin. Of the integrins expressed on blood cells, $\alpha \text{IIb}\beta 3$ is the most narrowly distributed and is restricted predominantly to platelets and megakaryocytes. It not only plays a prominent role in cell-cell adhesion, i.e., platelet aggregation (see section on Molecular Basis of Platelet Aggregation), but in many other platelet responses, including the association of platelets with tumor cells, an interaction involved in tumor metastasis.

Role of GPIb-IX-V in Platelet Adhesion

GPIb-IX-V is a notable example of a major cell surface molecule involved in platelet adhesion that is not a member of the integrin family. GPIb is composed of an α (heavy) chain and two β (light) chains; the α and β chains both span the platelet membrane and are linked by disulfide bonds.¹⁷ GPIX and GPV are smaller single-chain transmembrane polypeptides that are noncovalently associated with GPIb, and all three subunits (members of the leucine-rich repeat protein superfamily) are necessary for the expression of the complex on the platelet surface. The GPIb α -GPIb β -IX-V complex has a

Fig. 125.2 ADHESION TO THE SUBENDOTHELIUM IS A MULTI-STEP PROCESS. (A) Collagen-bound VWF in the subendothelium undergoes a conformational change when exposed to arterial shear rates such that GPIb α of the GPIb-IX-V complex binds to the VWF A1 domain. These rapidly formed bonds are quickly broken and reestablished, causing platelet translocation, or rolling, along the subendothelium. (B) The translocation process slows platelet transit, allowing the signaling receptor GPVI to bind directly to collagen. (C) GPVI-mediated signal transduction pathways activate the integrin $\alpha 2 \beta 1$, enabling it to bind strongly to collagen. This final association between the platelet and collagen is stable and allows the platelet to adhere firmly to the subendothelium. GP, Glycoprotein; VWF, von Willebrand factor.

stoichiometry of 2:4:2:1 and exists in high copy number on the platelet surface (approximately 25,000 molecules per platelet) with the N-terminus of GPIb α being the major ligand-binding subunit of the complex. Platelet activation and aging are associated with shedding of glycocalicin, a large proteolytic N-terminal fragment of GPIb α that is cleaved by ADAM17 or other sheddases. The cytoplasmic tail of GPIb α binds to a number of proteins, including the signaling molecule 14-3-3 ζ and the cytoskeletal protein filamin A (an actin-binding protein)¹⁸ (see section on the [Platelet Cytoskeleton](#)).

GPIb-IX-V plays a major role in hemostasis and thrombosis as a receptor for immobilized VWF in the subendothelium. Plasma VWF does not interact with platelet GPIb-IX-V, but at the high shear rates that occur in the arterial microcirculation, a conformational change in VWF bound to subendothelial collagen exposes a GPIb α binding site in the A1 domain. Thus, GPIb-IX-V binds to subendothelial VWF; this interaction is reversible with fast on and off rates, which allows for translocation (rolling) of platelets on the surface (Fig. 125.2A).^{12,15} A polymorphism in the GPIb α gene leads to variable numbers of tandem repeats in the macroglycopeptide region of the protein between the ligand-binding region and the plasma membrane. The length of this region, which is determined by the number of

tandem 13 amino acid repeats (one to four), may have a role in regulating platelet adhesion to VWF.

In addition to serving as a receptor for VWF in the subendothelium, GPIb-IX-V is also a receptor for the soluble agonist thrombin (see section on [Soluble Agonist Receptors](#)). Other adhesive ligands for GPIb-IX-V include the counter-receptors P-selectin (CD62P), expressed on activated platelets and endothelial cells, and leukocyte integrin Mac-1 ($\alpha M \beta 2$), which is involved in the formation of platelet-leukocyte conjugates.¹⁸

Platelets from patients with Bernard-Soulier syndrome (BSS) lack GPIb-IX-V as a result of mutations in GPIb or GPIX that prevent the expression of the complex on the platelet surface. Decreased expression of GPIb-IX-V impairs platelet adhesion to the subendothelium and can result in a significant bleeding diathesis (see section on [Molecular Basis of Inherited Platelet Disorders](#)).

Collagen Receptors

Subendothelial collagen has long been recognized as an important initiator of platelet responses, serving as a substrate for platelet adhesion, which ultimately results in platelet aggregation. Three different receptors are involved in platelet responses to collagen: the GPIb-IX-V complex, which binds to collagen via VWF, and GPVI and $\alpha 2 \beta 1$ (GPIIa-IIIa), which directly bind to collagen.

GPVI, with approximately 4000–6000 copies per platelet, is a transmembrane protein member of the immunoglobulin superfamily and has two extracellular immunoglobulin domains. As an immunoreceptor tyrosine-based activation motif (ITAM)-coupled receptor, its cytoplasmic domain contains a proline-rich sequence that binds to tyrosine kinases involved in platelet signaling^{12,19} (see section on [Activation Pathways](#)). GPVI is noncovalently associated with the Fc receptor γ chain (FcR γ) dimer, which is required for GPVI surface expression. There is in vitro and in vivo evidence of shedding of GPVI from the surface of activated platelets by the action of ADAM17 and during platelet aging in the circulation. Deficiencies of GPVI can be associated with a mild bleeding diathesis (see section on [Genetic Basis of Inherited Platelet Function Disorders](#)).

$\alpha 2 \beta 1$, with approximately 2000 copies per platelet, is the major collagen-binding integrin on the platelet surface.^{12,20} It undergoes a conformational change to a high-affinity state to allow it to bind to collagen. Silent polymorphisms in the $\alpha 2$ gene control its expression level, with higher plasma membrane levels associated with enhanced adhesion to collagen in vitro and an increased risk of cardiovascular disease.

The adhesion of platelets to collagen is a complex, multistep process. An initial interaction of GPIb-IX-V with VWF in the subendothelium (see earlier) facilitates a direct, low-affinity interaction of GPVI with collagen (Fig. 125.2B). Binding of GPVI to collagen is a potent stimulus to intracellular signaling pathways (see section on [Activation Pathways](#)). As a result of this signaling cascade, $\alpha 2 \beta 1$ is activated to bind to collagen with high affinity (Fig. 125.2C), thereby forming a stable interaction. Alternatively, or in addition, low levels of constitutively activated $\alpha 2 \beta 1$ can initiate direct binding of platelets to collagen, thereby assisting GPVI to bind and to initiate activation signaling. At high shear, GPVI plays the major role in mediating stable adhesion, while at lower shear, $\alpha 2 \beta 1$ is more important.^{19,21}

CLEC2 Adhesion Receptor

CLEC2 is a transmembrane C-type lectin that was originally described as the receptor responsible for platelet activation by the snake venom rhodocytin, inducing signaling events similar to those initiated by GPVI (see section on [Activation Pathways](#)). CLEC2 contributes to thrombosis in mouse models,²² even though it does not have a ligand in the ECM. CLEC2 has now been recognized as the receptor responsible for platelet activation upon binding to the membrane glycoprotein podoplanin on lymphatic endothelial cells; this binding

and subsequent intracellular signaling regulates blood and lymphatic vascular separation during fetal development.²³

MOLECULAR BASIS OF PLATELET ACTIVATION

Soluble Agonist Receptors

The majority of agonist receptors on platelets are members of the superfamily of trimeric G protein-coupled receptors (GPCRs) that contain seven transmembrane spanning α-helices, four extracellular loops and domains, and four intracellular loops and domains. Upon binding of their ligands, intracellular signaling is initiated via G proteins (GTP-binding proteins) associated with the GPCRs at the inner plasma membrane, leading to diverse downstream responses (see section on [Activation Pathways](#)). The platelet GPCRs include receptors for thrombin, ADP, the arachidonate metabolite TxA₂, and epinephrine (Table 125.2).²⁴ Deficiencies or dysfunction of these GPCRs can result in bleeding diatheses ranging from mild to severe (see section on [Molecular Basis of Inherited Platelet Disorders](#)).

Thrombin Receptors

Thrombin receptors on platelets belong to the protease-activated receptor (PAR) family, GPCRs with a unique activation mechanism that involves cleavage of the N-terminal extracellular domain, thereby creating a new N-terminus that acts as a tethered ligand for the receptor. PAR1 and PAR4 are present on human platelets (PAR3 and PAR4 on mouse platelets); PAR1 is the high-affinity thrombin receptor (~2500 copies per platelet), responding to thrombin at nanomolar concentrations, and PAR4 is a lower affinity receptor.²⁵ After thrombin cleavage of the N-terminus of PAR1, the tethered ligand (peptide sequence: Ser-Phe-Leu-Leu-Arg-Asn; SFLLRN) undergoes a conformational change and forms an intramolecular complex with a region also on the N-terminal extracellular domain of the receptor, referred

to as ligand binding site-1. This triggers the G protein cycle of PAR1's associated G proteins. PAR4 is nonhomologous with PAR1 in both the peptide sequence of the tethered ligand (Gly-Tyr-Pro-Gly-Lys-Phe; GYPGKF) and its binding characteristics. Although PAR4 requires a higher concentration of thrombin for cleavage, once cleaved, it produces a more sustained signal than PAR1. GPIb-IX-V also possesses a high-affinity binding site for thrombin on GPIbα that facilitates PAR1 cleavage by thrombin.

ADP and ATP Receptors

ADP is an important primary platelet agonist and also amplifies other primary responses following its secretion from platelet dense granules. Platelets have two ADP receptors: P2Y1 and P2Y12, which are GPCRs that are coupled to different G proteins. ADP binding to P2Y1 (~150 copies per platelet), which is coupled to the α subunits of G_q and G_{12/13}, mediates a transient rise in intracellular calcium, and induces platelet shape change and rapidly reversible aggregation. ADP binding to P2Y12 (~600 copies per platelet), which is coupled to the α subunit of G_i, results in inhibition of adenylyl cyclase, decreased levels of cyclic AMP (cAMP) and enhancement of the aggregation and secretion responses produced by other agonists. Full aggregation responses to ADP in vitro require concurrent activation of both receptor pathways.²⁶

ATP is an antagonist of P2Y1 and P2Y12, but an activator of P2X1, a ligand-gated ion channel, that causes rapid influx of Ca²⁺ from the external milieu through the ion channel and amplifies responses to other agonists. The effects of ADP and ATP are modulated in vivo by CD39, a nucleoside triphosphate diphosphohydrolase (NTPDase-1) expressed by endothelial and vascular smooth muscle cells that hydrolyzes both ATP and ADP, thereby maintaining homeostasis and preventing inappropriate platelet activation.⁴

Thromboxane A₂ Receptor

In humans, the TxA₂ thromboxane/prostanoid (TP) receptor exists in two isoforms, the result of alternative splicing (TPα and TPβ). TPα is the dominant form expressed on platelets, with approximately 1000 copies per platelet.²⁷

Epinephrine Receptor

Epinephrine is a relatively weak agonist but plays a role in potentiating platelet activation by other agonists, manifested through its ability to inhibit cAMP formation. In humans, the epinephrine receptor is the α_{2A}-adrenergic receptor (~300 copies per platelet).

Activation Pathways

Once a subendothelial or soluble agonist binds to its receptor on the platelet surface, intracellular signaling pathways (detailed in [Fig. 125.1](#)) are set into motion. These signaling pathways result in reorganization of the cytoskeleton and platelet shape change, storage granule exocytosis, TxA₂ synthesis, PS surface exposure, and αIIbβ3 activation.

The signaling pathways, initiated by collagen binding to GPVI, and by thrombin, ADP, TxA₂, and epinephrine binding to their specific GPCRs, comprise a "molecular toolkit"²⁸ of signaling molecules, which will be considered briefly. The monomeric G proteins, also known as small (low molecular weight) GTPases, which regulate integrin activation and cytoskeletal reorganization, are described later in the sections [Molecular Mechanisms of Aggregation](#) and [Cytoskeletal Reorganization](#), respectively. Much has been learned about the signaling pathways from genetically modified mice. The reader is referred to comprehensive reviews of platelet signaling for more detail.²⁸⁻³⁵

Heterotrimeric G Proteins Are Early Response Elements for Most Soluble Platelet Agonists^{24,28}

The GPCRs for soluble platelet agonists are constitutively associated at the inner plasma membrane with specific heterotrimeric G proteins (consisting of α , β , and γ subunits) of the families G_q , $G_{12/13}$, and G_i (Table 125.2A). The receptor for the potent platelet inhibitory molecule, prostaglandin I_2 (PGI_2 ; prostacyclin) is also a GPCR and is coupled to G_s .

In the basal, resting state, GDP is bound to the α subunit of the G protein. Upon ligand binding, a GPCR acts as a guanine nucleotide exchange factor, promoting exchange of GDP for GTP on different classes of the α subunit. Sites on the α and $\beta\gamma$ subunits are thereby exposed, allowing for activation of effector molecules including the β isoform of phospholipase C (PLC- β), the γ isoform of phosphatidylinositol 3-kinase (PI3K), and a Rho-specific guanine nucleotide exchange factor, p115-RhoGEF (Table 125.2B). Adenylate cyclase is activated via G_s and inhibited by G_i . Intrinsic GTPase activity of the α subunit hydrolyzes the bound GTP to GDP, thus restoring the G protein to its resting conformation.

Protein Tyrosine Kinases Modulate Enzyme Activity and Allow for the Formation of Signaling Complexes^{28–30}

GPVI is the most potent signaling collagen receptor. Clustering of GPVI upon binding to collagen results in phosphorylation of its constitutively-associated FcR γ by tyrosine kinases of the Src family (Fyn and Lyn) that are associated with the cytoplasmic domain of GPVI. Phosphorylation of tandem ITAM motifs enables binding of Syk via Src homology 2 (SH2) domains. Activation of the tyrosine kinase Syk leads to the phosphorylation of the adaptor protein LAT, which serves as the platform for the assembly of a signalosome—a complex of multiple signaling enzymes and adaptor molecules (e.g., SLP 76, Btk, Gads, Gab1) within membrane lipid rafts. The signalosome serves as a membrane scaffold for phosphorylation/activation of effectors including phospholipase C- γ (PLC- γ) and the α , β , and δ isoforms of PI3K.

The platelet receptor platelet-endothelial cell adhesion molecule (PECAM)1 negatively regulates GPVI signaling by recruiting the tyrosine phosphatase SHP2, and reducing LAT signalosome assembly.

The signaling pathway initiated by binding of GPIb-IX-V to VWF is similar to that of GPVI in that both involve activation of PLC- γ via FcR γ , Fyn and Lyn, and Syk. Binding of platelets to podoplanin via CLEC2 also induces signaling events similar to those initiated through GPVI. However, rather than (tandem) ITAM phosphorylation, it involves hemi-ITAM phosphorylation.²⁹

Phospholipase C Is Responsible for the Hydrolysis of Membrane PI-4,5P₂²⁸

Activation of PLC, either the β -isoform (by thrombin, ADP, or TxA₂ via G_q) or the γ -isoform (by collagen, protein tyrosine kinases, and scaffold molecules) results in the hydrolysis of the minor inner plasma membrane leaflet phospholipid phosphatidylinositol-4,5-bisphosphate (PI-4,5P₂). The two second messengers that are formed, soluble inositol-1,4,5-trisphosphate (IP₃) and membrane-associated diacylglycerol (DAG), lead, respectively, to increased cytosolic Ca²⁺ concentrations and activation of protein kinase C (PKC), a serine/threonine kinase.

Phosphatidylinositol 3-Kinase Forms 3-Phosphorylated Phosphoinositides^{28,32}

Activation of PI3K isoforms, either the γ (via G_i) or the α , β , and δ (via the collagen signaling pathway), results in phosphorylation of

PI-4P and PI-4,5P₂ to yield PI-3,4P₂ and PI-3,4,5P₃, respectively. Inner membrane leaflet PIP₃ functions in signaling by interacting with Akt via binding motifs termed pleckstrin homology domains (PH), thereby activating Akt to function as a serine/threonine kinase.

Serine/Threonine Kinases Regulate the Activity of Other Proteins and Enable the Development of Signaling Complexes^{31,33}

PKC is a central protein kinase in the PLC signaling pathway that, upon activation by DAG and Ca²⁺, phosphorylates the serine and threonine residues of many platelet proteins, including pleckstrin. The serine/threonine kinase Akt is an effector of PI3K, activating Rap1B. PKC is important in platelet secretion and both PKC and Akt are involved in α IIB β 3 activation, resulting in aggregation.

Cytosolic Ca²⁺^{28,34}

An increase in the intracellular Ca²⁺ concentration ([Ca²⁺]_i) is a key event that triggers platelet activation and aggregation; Ca²⁺-dependent responses include shape change, secretion, procoagulant surface exposure, TxA₂ formation, and α IIB β 3 activation. The basal [Ca²⁺]_i is maintained at approximately 0.1 μ M and can increase to greater than 1 μ M with strong stimulation. The initial increase results from IP₃-mediated release of Ca²⁺ from the dense tubular system (DTS). Upon depletion of this Ca²⁺ pool, store-operated Ca²⁺ (SOC) influx occurs from the platelet exterior. Stromal interaction molecule 1 (STIM1), a protein in the DTS membrane, undergoes a conformational change when DTS Ca²⁺ is depleted, allowing it to bind and activate Orai1, the major SOC Ca²⁺-selective release-activated Ca²⁺ (CRAC) channel in the platelet plasma membrane.

Phospholipase A₂ Is Responsible for the Synthesis of TxA₂²⁸

An increase in [Ca²⁺]_i is one of the main triggers for activation of cytosolic phospholipase A₂ (cPLA2), resulting in the formation of the proaggregatory prostanoid TxA₂. cPLA2 hydrolyzes the polyunsaturated fatty acid arachidonate from the C2 position of inner plasma membrane leaflet phospholipids, and arachidonate is converted to the cyclic endoperoxide intermediates prostaglandin (PG)G₂ and PGH₂ by cyclooxygenase (COX)-1. Thromboxane synthase in the platelet cytosol metabolizes PGH₂ to TxA₂, which diffuses out of the platelet and is available to activate additional platelets via the TP receptor.

cAMP²⁸

Activation of adenylate cyclase via G_s increases the intracellular level of cAMP, which activates protein kinase A (PKA). This serine/threonine kinase is responsible for phosphorylating proteins including GPIIb β , filamin, myosin light chain (MLC), and Rap1B. Elevated levels of cAMP result in sequestration of intracellular Ca²⁺ in the DTS, and inhibition of cytoskeletal rearrangement, granule secretion, and aggregation. Inhibition of adenylate cyclase via G_i is important in facilitating activation of platelets by lowering cAMP concentrations that are raised above basal levels by PGI_2 produced by the endothelium.

Reorganization of the Actin Cytoskeleton

Platelet plug formation requires platelets to undergo a rapid change from their resting discoid shape to active forms spread over the damaged subendothelium that then recruit additional platelets by providing an enlarged surface area for platelet-platelet or

platelet-leukocyte interactions. The discoid shape of the circulating platelet is maintained by an internal cytoskeleton composed of polymers of actin and tubulin and their associated proteins (see also Chapter 124). Shape change requires the remodeling of the resting cytoskeleton and the assembly of new cytoskeletal fibers to transform the platelet into its activated configuration.

The Resting Platelet Cytoskeleton

The resting platelet cytoskeleton maintains cell shape and integrity as the platelet encounters the high shear forces of blood flow in small vessels. The spectrin-based membrane skeleton (similar but not identical to that of erythrocytes) forms a contiguous network with actin filaments to support platelet ultrastructure. Actin is the single most abundant platelet protein (2 million copies per platelet), forming 2000–5000 linear actin polymer filaments that are cross-linked to form a rigid cytoplasmic network. Cross-linking proteins include filamin A and B, and α -actinin. The interaction between filamin A/B and the cytoplasmic tail of the VWF receptor GPIb α provides structural stability and the major link between the plasma membrane and the actin cytoskeleton. Loss of this linkage in platelets deficient in either GPIb α (BSS) or filamin A results in loss of restraint of the spectrin lattice, swelling of the membrane skeleton, and large fragile platelets that are subject to rapid clearance from the circulation.¹⁵

Platelets contain a long microtubule wound 8–12 times into a coil that sits just beneath the plasma membrane, maintaining the discoid shape of the resting platelet. Microtubules are rigid polymers made up of $\alpha\beta$ -tubulin heterodimeric subunits. β 1-tubulin deficient mice have platelets that are spherical and fail to develop a discoid shape due to aberrant microtubule assembly.³⁶ A heterozygous human variant in β 1-tubulin, which may be present in as many as 10% of the general population, results in decreased levels of β 1-tubulin and a subset of spherocytic platelets.³⁷

Cytoskeletal Reorganization During Platelet Activation

The assembly and disassembly of the actin cytoskeleton allows platelets to spread. Following platelet activation, the platelet makes contact with the ECM, initially changing shape from disc to sphere and developing filopodia, followed by flattening and spreading of broad lamellae. Granules and organelles are relocated to the center of the cell. The filopodia are filled with long actin filaments originating in the center of the cell. Increases in $[Ca^{2+}]_i$ initiated by signaling through G_i result in activation of gelsolin, a multidomain protein with binding sites for Ca^{2+} , actin, and phospholipid. Ca^{2+} binding alters the conformation of gelsolin such that it binds and cleaves actin filaments, leading to disassembly of the resting actin cytoskeleton and allowing the platelet to change shape. Signaling via $G_{12/13}$ and p115-RhoGEF activates the small, monomeric G protein RhoA that is also involved in regulating actin filament formation and myosin contraction. For example, actin filaments are stabilized by the activation of Rho-activated kinase (p160ROCK) and LIM-kinase.

Assembly of the activated platelet cytoskeleton doubles the actin filament content of the platelet by exposing nucleation ends on existing actin filaments (the result of severing of filaments by gelsolin) or creating new nucleation sites (by the Arp 2/3 complex). The Arp2/3 complex is enriched in the periphery of the activated platelet where actin assembly is occurring, and the complex is activated by proteins associated with cell adhesion sites and by the Wiskott-Aldrich syndrome protein (WASP) family members.³⁸

Platelets are also the force-generating component of clot retraction. α IIB β 3 is tethered to underlying actin filaments in association with cytoplasmic proteins talin, filamin, paxillin, zyxin, α -actinin, and vinculin. Association of cytoplasmic myosin with actin provides the motor for the contractile force. Platelets contain nonmuscle

myosin IIA and IIB; myosin II is a hexamer made up of two heavy chains and four light chains. Assembly into bipolar filaments is the result of Ca^{2+} -activated phosphorylation of the 20-kDa MLCs by MLC kinase, enhanced by blocking MLC dephosphorylation through Rho kinase. *MYH9*-related disease is the result of mutations in the gene for nonmuscle myosin heavy chain IIA (NMMHC-IIA)³⁹ (see section on Molecular Basis of Inherited Platelet Disorders).

Secretion of Granules

Platelet activation leads to the release of a diverse list of molecules that stimulate or inhibit platelets or other blood and vascular cells, covalently modify the thrombus to affect its mechanical properties, regulate coagulation, contribute to cell adhesive events, and modulate wound healing, inflammation, and angiogenesis.

Most of the substances that are actively and selectively secreted from platelets are packaged in storage granules formed in megakaryocytes. Platelets contain three types of granules: dense (δ) granules, α granules, and lysosomal granules (Fig. 125.3A).

Dense Granules

Dense granules belong to the family of lysosome-related organelles (LROs) that also includes melanosomes, cytotoxic T-cell granules, and neutrophil azurophilic granules. Platelets contain three to eight dense granules, storing high concentrations of cations (Ca^{2+} , Mg^{2+} , K^+), polyphosphate, nucleotides (ADP, ATP, GTP), and bioactive amines (serotonin and histamine). These granules are innately dense when viewed by electron microscopy due to their Ca^{2+} content. Biogenesis of LRO complexes (BLOCs) are protein complexes that are critical in vesicle trafficking and dense granule formation.⁴⁰ Mutations in specific protein members of BLOCs 1, 2, and 3, or in the adaptor protein complex 3 (AP3) result in dense granule deficiency and associated LRO abnormalities in mice and in Hermansky-Pudlak syndrome (HPS) 1–9 in humans, characterized by mucocutaneous bleeding and oculocutaneous albinism⁴¹ (see section on Molecular Basis of Inherited Platelet Function Disorders).

α Granules

α Granules are unique to platelets and are the most abundant granule type: 50–80 granules per platelet, taking up 10% of the platelet volume. They contain a large number of proteins that are either synthesized by megakaryocytes or taken up from plasma by endocytosis. Genetic defects in *NBEAL2* and *VPS33B*, genes involved in α granule synthesis, result in α granule deficiency syndromes^{42–46} (see section on Molecular Basis of Inherited Platelet Disorders). Proteomic studies have demonstrated that there are more than 300 unique proteins released by α granules.⁴⁷ These proteins have diverse functions and can be classified as coagulants and anticoagulants (e.g., factors V and XI, antithrombin, protein S, plasminogen activator inhibitor-1); adhesion proteins (e.g., fibrinogen, VWF, thrombospondin-1); chemokines (e.g., CXC-chemokine ligand 4 [CXCL4; platelet factor 4], CXCL7 [β -thromboglobulin]); growth factors (e.g., epidermal growth factor, transforming growth factor- β); angiogenic factors (e.g., vascular endothelial growth factor, platelet-derived growth factor, angiostatin); and immune mediators (e.g., precursors of complement factors C3 and C4)⁴⁸ (Fig. 125.3A). There appears to be heterogeneity in the cargo protein content of subsets of α granules, with pro- and antiangiogenic proteins stored in distinct subsets and differentially released.⁴⁹ Membrane-bound proteins in α granules include integrins, immunoglobulin family receptors, leucine-rich repeat family receptors and tetraspanins. Most of these are also present on the resting platelet plasma membrane, but some, such as P-selectin (CD62P), are only expressed on the plasma membrane following granule exocytosis.⁴⁶

Lysosomal Granules

Platelets have small numbers of primary and secondary lysosomes that contain enzymes involved in degradation of proteins, carbohydrates, and lipids. These enzymes include cathepsins, elastase, collagenases, galactosidase, glucuronidase, and acid phosphatase.

Mechanism of Granule Secretion

The secretion of platelet granule contents occurs through mechanisms analogous to those required for the exocytosis of granules from neurons and mast cells. Platelet secretion is triggered by a variety of strong agonists such as thrombin. Induction of secretion by weak agonists (e.g., ADP) occurs when the cells are brought into close contact, such as during aggregation,⁵⁰ and is dependent on TxA₂ to amplify the effect of the primary agonist.

In most cells, exocytosis occurs when vesicles fuse with the plasma membrane and release their contents into the extracellular milieu. In platelets, granules clustered centrally by platelet shape change also fuse with one another and with the open canalicular system (OCS), a system of invaginations of the plasma membrane extending into the interior of the platelet; the granule contents diffuse to the external environment. Membrane fusion is driven by the soluble *N*-ethylmaleimide-sensitive factor (NSF) attachment protein receptors (SNAREs). Platelets have the three basic components of SNARE machinery: tSNAREs (target receptors associated with open canalicular system and plasma membrane), vSNAREs (vesicle-associated receptors associated with the granule membranes), and soluble regulators (including NSF and NSF-attachment proteins).^{48,51} vSNAREs including vesicle-associated membrane proteins (VAMPs) interact with syntaxin isoforms and synaptosomal-associated protein (SNAP)-23 on the target membranes to form four helix bundles

that bring the vesicular and target membranes into close proximity (Fig. 125.3B). SNARE function is tightly regulated by chaperone proteins. NSF regulates membrane interaction by disassembling SNARE complexes on the same membrane so that they are available to form complexes with proteins on opposing membranes. The Sec1/Munc proteins (Munc18a, b, and c, and Munc13-4) and Rab GTPases regulate granule docking,⁵¹ a preliminary step to granule membrane fusion (Fig. 125.3B).

Activation pathways involving intracellular Ca²⁺, Rab GTPase, and PKC isoforms regulate the SNARE complex interactions. PKC isoforms phosphorylate several of the SNARE proteins and their regulators including Munc18c, syntaxin 4, and SNAP-23. The PKC substrate pleckstrin is also a critical mediator of granule exocytosis; pleckstrin-deficient mice show markedly impaired platelet secretion.⁵²

The important role of granule releasates in hemostasis is underlined by the bleeding diathesis in people with granule deficiencies or defects of granule exocytosis. α Granules secrete fibrinogen and VWF, which mediate platelet-platelet and platelet-ECM interactions. Of the total VWF, 20% is contained in α granules, which are enriched in the most potent high-molecular-weight VWF multimers. ADP released from dense granules is essential for recruitment of additional platelets to the primary plug. Other mediators released from α granules play key roles in additional functions including wound repair, angiogenesis, and host defense. However, these modulators can also be pathogenic, contributing to the inflammatory response and atherosclerosis (Fig. 125.3A).

Procoagulant Surface Exposure and Microparticles

The phospholipids of the plasma membrane of resting platelets are asymmetrically distributed between the leaflets of the membrane bilayer, with choline-containing phospholipids predominating in the

Fig. 125.3 (A) PLATELET GRANULE CONTENTS RELEASED BY SECRETION. Examples of bioactive substances stored in platelet dense granules, α granules, and lysosomes.

1. Tethering

2. Docking

3. Fusion and Secretion

B

Fig. 125.3, cont'd (B) MOLECULAR CONTROL OF GRANULE SECRETION. This is a schematic diagram of steps in granule secretion. (1) Tethering: attachment of granules to the membrane cytoskeleton. (2) Docking: the engagement of vSNAREs on the granule membrane and tSNAREs on the target membrane to form a prefusion complex. In platelets, these docking proteins are VAMP8 on α granule and dense granule membranes, STX11/SNAP-23 complex on the plasma membrane and accessory proteins Munc13-4 and Munc18b/Munc18-2. (3) Fusion/secretion: involves the zippering of opposing SNAREs, applying force to fuse the granule and plasma membranes, resulting in release of the granule contents. Additional mediators of this active process include Rab GTPases, PKC, pleckstrin, Ca^{2+} , and NSF. β -TG, β -Thromboglobulin; CXCL, CXC-chemokine ligand; EGF, epidermal growth factor; GP, glycoprotein; IgG, immunoglobulin G; NSF, N-ethylmaleimide-sensitive factor; PAI-1, plasminogen activator inhibitor-1; PDGF, platelet-derived growth factor; PF4, platelet factor 4; PKC, protein kinase C; RANTES, regulated upon activation, normal T-cell expressed, and secreted; SNAP-23, synaptosomal-associated protein-23; SNARE, soluble N-ethylmaleimide-sensitive factor attachment protein receptor; STX11, syntaxin 11; TGF- β , transforming growth factor- β ; tSNARE, target SNARE; VAMP8, vesicle-associated membrane protein 8; VEGF, vascular endothelial growth factor; vSNARE, vesicle-associated SNARE; VWF, von Willebrand factor.

outer cytoplasmic leaflet, and the minor anionic aminophospholipid PS predominating in the inner. Platelet adhesion to collagen and stimulation with thrombin synergistically result in a loss of the asymmetry, or “scrambling,” of the membrane phospholipids, such that PS becomes exposed on the external plasma membrane leaflet.⁵³ PS translocated to the surface of activated platelets facilitates the assembly of the intrinsic tenase complex (factors VIIIa, IXa, and X) and prothrombinase complex (factors Va and Xa, and prothrombin), contributing to the burst of thrombin generation that occurs in the propagation phase of coagulation (see [Chapter 126](#)). Specifically, the negatively charged γ -carboxyglutamate (Gla) residues of the vitamin K-dependent factors, factors VII(a), IX(a), X(a), and prothrombin, mediate Ca^{2+} -dependent binding of the factors to negatively-charged PS. There is recent evidence that plasminogen also binds to PS-exposing platelets, thereby linking coagulation and fibrinolysis.⁵⁴

Exposure of PS on the platelet surface requires sustained increases in $[\text{Ca}^{2+}]_i$ via influx across the plasma membrane, and activation of phospholipid scramblase (see [Chapter 130](#), [Fig. 130.1](#)), which rapidly and nonspecifically transports phospholipids between the membrane leaflets. The transmembrane protein TMEM16F (anoctamin 6) has recently been shown to be essential for PS exposure,⁵⁵ but its specific role is not yet clear. Scott syndrome, a platelet disorder associated with a defect in PS exposure, is associated with mutations in *TMEM16F* (*ANO6*; see section on [Molecular Basis of Inherited Platelet Disorders](#)). There is heterogeneity in the platelet response to stimulation: only a proportion of activated platelets expose PS (this population of platelets is variously described as being procoagulant, superactivated, coated, or having Sustained Calcium-Induced Platelet [SCIP] morphology).⁵⁶ Coated platelets appear to overlap with the PS-exposing platelet population, being “coated” with covalently linked platelet secretion products (e.g., serotonin, fibrinogen, factor Va). Besides supporting thrombin generation, PS-exposing platelets are characterized by inactive $\alpha\text{IIb}\beta 3$ and a distinct balloon-like morphology with loss of internal organelles. In vitro, they are readily identified by annexin A5 or lactadherin binding. The pathway that leads to rapid PS exposure on activated platelets can be distinguished from a slower intrinsic apoptotic pathway, which involves caspase activation.⁵⁷

PS exposure is accompanied by blebbing of microparticles from the plasma membrane.⁵⁸ These small (0.1–1 μm diameter) vesicles not only express platelet membrane receptors such as $\alpha\text{IIb}\beta 3$ and GPIb–IX–V, but can also express activation markers such as CD62P. Platelet-derived microparticles are distinct from exosomes, which are smaller (40–100 nm) and are released from intracellular vesicles. Microparticles can support hemostasis; platelets from patients with the very rare bleeding disorder Castaman syndrome cannot generate microparticles. Circulating microparticles are considered to originate from megakaryocytes as well as from platelets. Increased circulating levels of microparticles have been reported in thrombotic conditions such as myocardial infarction, thrombotic thrombocytopenic purpura, sickle cell disease, and diabetes, immune-mediated conditions such as immune thrombocytopenia and heparin-induced thrombocytopenia, and in malignancy and inflammatory conditions. Microparticles formed by platelets activated via GPVI have been shown to contribute to the pathophysiology of rheumatoid arthritis, delivering IL-1 to synovial fibroblasts,⁵⁹ an example of how microparticles may play a role in platelet-cell communication by delivering bioactive molecules to target cells.

MOLECULAR BASIS OF PLATELET AGGREGATION

$\alpha\text{IIb}\beta 3$ and Molecular Mechanisms of Aggregation

Integrin $\alpha\text{IIb}\beta 3$ is the most abundant membrane protein on the platelet surface, with 40,000–80,000 copies per resting platelet, a very high receptor density for such a small cell. Platelet activation can produce an additional 10% increase in this number as a result of expression from internal pools, i.e., α -granule membranes. On resting platelets, $\alpha\text{IIb}\beta 3$ is in a low-affinity bent conformation that is unable

Fig. 125.4 MODEL SHOWING THE ACTIVATION OF $\alpha\text{IIb}\beta 3$. Signaling pathways induced by platelet agonists result in talin and kindlin binding to the cytoplasmic tail of $\beta 3$ and inside-out signaling such that the integrin is transformed from its low-affinity bent conformation on the resting platelet to its high-affinity extended conformation on the activated platelet. The extended conformation has the ligand binding site exposed, allowing for the binding of fibrinogen or von Willebrand factor, and thus for platelet aggregation. Binding of these ligands initiates outside-in signaling, triggering further intracellular signal transduction and platelet responses. This model is based on the crystal structure of the extracellular domain of $\alpha\text{v}\beta 3$, and the cytoplasmic tails on the nuclear magnetic resonance structure of $\alpha\text{IIb}\beta 3$. (Adapted, with permission, from Bledzka K, Smyth SS, Plow EF: Integrin $\alpha\text{IIb}\beta 3$. From *discovery to efficacious therapeutic target*. *Circ Res* 112:1189, 2013.)

to bind its ligands. Activation of $\alpha\text{IIb}\beta 3$ results in a change to a high-affinity, extended conformation ([Fig. 125.4](#)), allowing it to bind divalent fibrinogen or multivalent VWF which can bridge to other activated $\alpha\text{IIb}\beta 3$ molecules on adjacent platelets, mediating platelet aggregation. The N-terminal portion of $\beta 3$ contains three divalent cation-binding sites including the metal-ion dependent adhesion site (MIDAS); metal ions (Ca^{2+}) are required for ligand binding to $\alpha\text{IIb}\beta 3$. Absence or dysfunction of $\alpha\text{IIb}\beta 3$ on the platelet surface leads to Glanzmann thrombasthenia (GT), a disorder characterized by a moderate-to-severe bleeding diathesis and absent in vitro platelet aggregation responses to all agonists (see section on [Molecular Basis of Inherited Platelet Disorders](#)).

Activation of platelets with any of the agonists described in the preceding sections, including collagen, thrombin, ADP, and TxA_2 , results in the conversion of $\alpha\text{IIb}\beta 3$ from its resting to its activated state.⁶⁰ This transformation is a consequence of the intracellular signaling pathways set in motion when the agonist binds to its receptor (see section on [Activation Pathways](#)), leading to the final common pathway that results in aggregation; it occurs rapidly, on the order of seconds, after platelet exposure to an agonist. The signal is transmitted to the cytoplasmic tails of $\alpha\text{IIb}\beta 3$ and from the cytoplasmic tail through the transmembrane helices, ultimately inducing a change in the extracellular domain to render $\alpha\text{IIb}\beta 3$ competent to bind its ligands. The signaling process responsible for this transformation is referred to as “inside-out” signaling through $\alpha\text{IIb}\beta 3$.

Specifically, it is the agonist-induced increase in $[\text{Ca}^{2+}]_i$ and DAG formation that result in the final common pathway of integrin activation.⁶¹ Via the Ca^{2+} - and DAG-regulated guanine nucleotide exchange factor (CalDAG-GEFI), the small monomeric G protein (GTPase) Rap1 is activated and binds to Rap1-GTP-interacting adaptor molecule (RIAM); RIAM promotes binding of the cytoskeletal protein talin to the cytoplasmic domain of $\beta 3$. Talin cooperates with kindlin-3, which also binds to the cytoplasmic domain of $\beta 3$, to unclasp the complex between the αIIb and $\beta 3$ cytoplasmic tails. This leads to a dissociation of the transmembrane complex of the αIIb and $\beta 3$ subunits, inducing a conformational change in the extracellular

domains. The bent conformation of $\alpha\text{IIb}\beta 3$ is transitioned through intermediaries to an extended conformation that exposes the ligand-binding site (see Fig. 125.4) for fibrinogen and VWF.

Both fibrinogen and VWF bind to activated $\alpha\text{IIb}\beta 3$ via Arg-Gly-Asp (RGD) sequences. Fibrinogen contains two such sequences, RGD-Ser and RGD-Phe, in its A α chains, and VWF contains one in its C1 domain. The RGD sequence is a broadly used recognition code in cellular adhesive reactions; it is found on a variety of proteins, and it is recognized by several other integrin receptors. Fibrinogen has a second binding sequence for activated $\alpha\text{IIb}\beta 3$, -X-X-Lys-Gln-Ala-Gly-Asp-Val (XXXQAGDV), in the C-terminus of its γ -chains; evidence indicates that this sequence is the primary one by which fibrinogen binds to activated $\alpha\text{IIb}\beta 3$.⁶¹ While fibrinogen binding mediates platelet aggregation at low shear, it is VWF binding that mediates aggregation at high shear.⁶²

In turn, ligand binding induces conformational changes to activated $\alpha\text{IIb}\beta 3$, resulting in exposure of binding sites on the cytoplasmic tails of the integrin for cytoskeletal and signaling proteins, and activation of protein kinases and phosphatases. This “outside-in” signaling is important in platelet responses such as full platelet spreading, irreversible aggregation, and clot stability and retraction.^{28,61}

Upon aggregation, the close platelet-platelet contact facilitates binding of additional cell surface ligands on one platelet to cell surface receptors on adjacent platelets. Such binding can affect platelet activation and thrombus stability via initiation of intracellular signaling or formation of additional contacts between platelets. These ligand/receptor pairs include: ephrin/Eph kinase; semaphorin4D/CD72 (in humans) and a member of the plexin B family (in humans and mice); and growth-arrest specific gene 6 (Gas-6)/receptor tyrosine kinases Tyro3, Axl, and Mer.^{28,62}

Laboratory Evaluation of Aggregation

The in vitro aggregation response of platelets is most commonly assessed using aggregometry, considered to be the gold standard of platelet function testing.⁶³ In the aggregometer, platelet responses are measured in suspension, bypassing the initial adhesion response of platelets to the subendothelial ECM that occurs in vivo (see section on Platelet Adhesion). Optical or turbidometric aggregometry, now more often referred to as *light transmission aggregometry (LTA)*, was developed in the 1960s; in LTA, light transmission through a rapidly stirred suspension of platelets is recorded upon addition of a soluble agonist (Table 125.3). With all agonists except epinephrine, there is an initial, transient, small decrease in light transmission from baseline due to actin cytoskeleton reorganization and platelet shape change from discs to more rounded forms with extended filipodia. This is followed by a larger increase in light transmission as the platelets aggregate. Depending on the agonist and its concentration, platelets may deaggregate, indicated by a subsequent decrease in light transmission (Fig. 125.5).

In clinical laboratories, platelet-rich plasma (PRP), obtained by low-speed centrifugation of a whole blood specimen anticoagulated with citrate, is routinely used in LTA assessment of platelet function. Citrate lowers the plasma concentration of Ca^{2+} to the micromolar range, which is still sufficient for aggregation to occur. In research laboratories, LTA of platelets isolated from plasma and suspended in balanced salt solutions (e.g., Tyrode's solution) is often used. In this case, Ca^{2+} must be added to the suspending medium to allow aggregation to occur. LTA measures platelet aggregation under conditions of low shear, in which aggregation is dependent on fibrinogen binding to activated $\alpha\text{IIb}\beta 3$. This is in contrast with tests such as the Platelet Function Analyzer (PFA-100/200) (see Chapter 129), which measures aggregation under conditions of high shear (5000–6000 s^{-1}), in which aggregation is mediated by VWF binding to activated $\alpha\text{IIb}\beta 3$.

Some of the commonly used platelet agonists are listed in Table 125.3. Of particular physiological relevance are the platelet-derived aggregating agents—ADP, and the arachidonate metabolite TxA_2 —that provide a mechanism for stimulated platelets to recruit additional

TABLE 125.3 Agonists Used in the Laboratory Evaluation of Aggregation

Agonist	In vivo/In vitro Mechanism of Action
Thrombin receptor-activating peptide (TRAP) ^a	SFLLRN (Ser-Phe-Leu-Leu-Arg-Asn), the peptide sequence of the new N-terminus of PAR-1 after thrombin cleavage (binds to uncleaved PAR-1 in vitro)
ADP	Released from platelet dense granules; acts synergistically with many other agonists (binds to P2Y1 and P2Y12)
Arachidonate	Is metabolized by the cyclooxygenase pathway to TxA_2 which is released from stimulated platelets and is rapidly metabolized in plasma (TxA_2 binds to TP)
U46619	Stable TxA_2 mimetic (binds to TP)
Collagen	In subendothelial extracellular matrix (binds to GPVI and $\alpha 2\beta 1$)
Epinephrine ^b	A weak agonist that is not associated with platelet shape change and that potentiates other agonists; may allow for hormonal regulation of hemostasis (binds to α_{2A} -adrenergic receptor)
Ca^{2+} -ionophore	Directly mobilizes intracellular Ca^{2+} (does not bind to a receptor)
Ristocetin ^c	An antibiotic that changes the conformation of VWF, exposing the binding site for GPIIb α of the GPIIb-IX-V complex, allowing platelet agglutination by VWF

^aTRAP is used as a substitute for thrombin. Thrombin binds to GPIIb-IX-V and cleaves PAR-1 and PAR-4, but is not often used in the assessment of platelet aggregation in citrated platelet-rich plasma as it causes fibrin clot formation.

^bReduced response to epinephrine occurs in a proportion of healthy individuals due to natural variation in receptor density, and is not necessarily indicative of a platelet function disorder.

^cIn contrast with the other agonists that stimulate aggregation, an energy-requiring process, ristocetin induces platelet agglutination via VWF, a process that does not require platelets to be metabolically active.

ADP, Adenosine 5'-diphosphate; GP, glycoprotein; PAR, protease-activating receptor; TP, thromboxane/prostanoid; TxA_2 , thromboxane A_2 ; VWF, von Willebrand factor.

platelets to an aggregate in vivo. As described earlier, these agonists activate platelets by binding to specific receptors and triggering intracellular signaling pathways that ultimately converge to a set of common steps that permit the platelets to aggregate. Platelet aggregation, mediated by ligand binding to activated $\alpha\text{IIb}\beta 3$, is energy dependent, and can be distinguished on this basis from platelet agglutination induced by ristocetin (Table 125.3), mediated by VWF binding to GPIIb α of the GPIIb-IX-V complex, which does not require platelets to be metabolically active. Many preanalytical and analytical variables affect the results obtained by LTA and recommendations for clinical laboratory standardization have been published recently.^{64,65}

Platelet aggregation can also be measured by whole-blood aggregometry. This test measures platelet aggregation in diluted, anticoagulated whole blood as the change in impedance or resistance between two electrodes when platelets adhere to the electrodes and aggregate in response to soluble agonists (see earlier and Table 125.3). Whole-blood aggregometry has the advantages over LTA of requiring smaller blood volumes and less sample manipulation. Certain light transmission/whole-blood aggregometers also provide simultaneous measurements of dense granule secretion, specifically ATP release (using lumi-aggregometry).

The information gained from aggregometry has been extremely useful in the diagnosis of platelet function disorders, whether inherited or acquired.⁶⁴ However, aggregation as measured in vitro does

Fig. 125.5 AGGREGATION RESPONSES OF PLATELETS IN CITRATED PLATELET-RICH PLASMA STIMULATED WITH ADP. (Note that the micromolar concentration of Ca^{2+} in citrated platelet-rich plasma is sufficient to allow aggregation to occur.) The arrows indicate the addition of increasing concentrations of ADP from left to right. Following addition of the agonist, platelet shape change is observed as a slight decrease in light transmission, followed by an increase in light transmission as the platelets aggregate. The lowest concentration of ADP ($2.3 \mu\text{M}$; left) induces primary aggregation followed by deaggregation, as indicated by the subsequent decrease in light transmission. The intermediate concentration of ADP ($4.5 \mu\text{M}$; middle) induces primary aggregation followed by a secondary wave of aggregation; the secondary wave occurs due to thromboxane A_2 formation by the stimulated platelets and subsequent granule content exocytosis, including ADP. At the highest concentration of ADP ($9.1 \mu\text{M}$; right), there is fusion of the two phases of aggregation so that only a single wave of aggregation is apparent. (Adapted, with permission, from Rand ML, Leung R, Packham MA: Platelet function assays. Transfus Apher Sci 28:307, 2003.)

not always reflect platelet function in vivo; clinical bleeding and the aggregation response of platelets do not necessarily coincide. This disparity reflects, in part, the importance of platelet adhesion under flow conditions in hemostatic plug/arterial thrombus formation, an effect that is not detected by aggregometry.⁶² Tests that allow for measurement of adhesion of platelets to multiple surfaces under flow conditions at variable shear rates, and for measurement of multiple outcomes to characterize platelet responses will, in the future, provide additional information about platelet function.⁶⁶

MOLECULAR BASIS OF INHERITED PLATELET DISORDERS

Inherited platelet disorders are a heterogeneous group of bleeding disorders involving defects in platelet function and/or number (usually thrombocytopenia). The bleeding symptoms experienced by patients are primarily mucocutaneous, such as epistaxis, bruising, bleeding from the oropharynx or gastrointestinal tract, menorrhagia, and postpartum and surgical (including dental) bleeding; these symptoms can range from very mild to life threatening, depending on the disorder (severity may vary among individuals with the same disorder). The prevalence of these disorders is unknown, as there are no population-based data. While severe disorders such as GT and BSS are relatively easy to diagnose, rare, milder disorders are more difficult to characterize and it is likely that they are more common than previously appreciated.⁶⁷ Much has been learned about platelet development, structure and function, and the underlying

Platelet Aggregation Testing for the Diagnosis of Platelet Disorders

Platelet aggregometry is the mainstay in the work-up of platelet function disorders (PFDs). Abnormalities in aggregation tracings can point towards specific diagnoses and direct further testing.

Glanzmann Thrombasthenia

In this severe PFD in which there are quantitative or qualitative defects in integrin $\alpha\text{IIb}\beta 3$ (GPIIb-IIIa), the receptor to which fibrinogen/von Willebrand factor (VWF) binds on activated platelets, there is absent aggregation response to all agonists. However, agglutination in response to a high concentration of ristocetin occurs, as it is independent of $\alpha\text{IIb}\beta 3$.

Bernard-Soulier Syndrome

This disorder with defective surface expression of the adhesive VWF receptor GPIb-IX-V is characterized by a lack of agglutination to a high concentration of ristocetin. Note that in von Willebrand disease (VWD) there is an absent agglutination response to a high concentration of ristocetin because of deficient VWF.

Defects in Agonist/Adhesion Receptors

P2Y₁₂: a defect in this ADP receptor results in decreased and reversible aggregation responses to ADP. TP α : thromboxane A_2 (Tx A_2) receptor defects show decreased aggregation responses to arachidonic acid, collagen and the stable Tx A_2 mimetic U46619. GPVI: a defect in this collagen receptor is characterized by a decreased aggregation response to collagen.

Storage Granule Deficiencies/Secretion Defects

In these disorders, secondary aggregation responses to ADP, collagen, epinephrine, and arachidonic acid can be reduced, but it should be noted that secretion defects may be present with a normal aggregation profile. In dense granule disorders, secretion as measured by lumiaggregometry is decreased.

Platelet Type VWD/Type 2B VWD

These gain-of-function disorders in the VWF binding site of GPIIb α or in the GPIIb α binding site of VWF, respectively, are characterized by an abnormally increased agglutination response to a low concentration of ristocetin.

Effects of Antiplatelet Medications

Aggregation responses will also be affected by antiplatelet medications. For example, individuals taking aspirin or other nonsteroidal antiinflammatory drugs will have decreased responses to arachidonic acid, but not to U46619. Patients taking P2Y₁₂ receptor blockers, i.e., clopidogrel, prasugrel, ticagrelor, or cangrelor, will have decreased and reversible responses to ADP, depending on the extent of inhibition of the receptor.

genetic basis of specific disorders from the investigation of patients; indeed, the molecular defects in many of the disorders have now been identified (Fig. 125.6). Important insights have also been provided by characterization of mouse models in which platelet proteins have been altered genetically.⁶⁸ The reader is referred to comprehensive reviews of inherited disorders of platelets for more details.^{69–72}

Inherited Platelet Function Disorders

Inherited platelet function disorders encompass defects in: platelet adhesion, with deficiencies or dysfunction of receptors for subendothelial VWF or collagen; platelet activation, including deficiencies or dysfunction of receptors for soluble agonists, of cytoskeletal proteins, of signaling pathways, of dense and α granules, and of PS exposure; and platelet aggregation, with deficiencies or dysfunction of integrin $\alpha\text{IIb}\beta 3$. Most of the disorders described later have an autosomal recessive pattern of inheritance, and thus affected individuals have homozygous or compound heterozygous gene mutations. The disorders vary significantly in their severity, and some present with associated thrombocytopenia.

Abnormalities of Platelet Adhesion

*GP1b-IX-V*⁷³

In Bernard-Soulier syndrome (BSS), mutations in *GP1BA*, *GP1BB*, or *GP9* result in defective platelet surface expression of GPIb-IX-V, and thus a decreased ability of platelets to adhere to subendothelial VWF, as well as a decreased in vitro response of platelets to thrombin and ristocetin. Missense, nonsense, and frameshift alterations have been described^{69,74}; correlation of genotype with the moderate to severe bleeding phenotype in BSS is not apparent. The macrothrombocytopenia that occurs in BSS is discussed in the section Inherited Thrombocytopenias.

The autosomal dominant platelet-type VWD⁷⁵ is the result of gain-of-function mutations in the VWF binding site on GPIb α . Enhanced binding of plasma VWF to GPIb α leads to platelet agglutination and a bleeding phenotype. In vitro, enhanced agglutination to low-dose ristocetin is observed. Platelet-type VWD is clinically indistinguishable, but genetically distinguishable, from type 2B VWD, caused by gain-of-function mutations in the GPIb α binding site of VWF.

Collagen Receptors

There is wide variability in the platelet surface expression levels of GPVI and $\alpha 2\beta 1$ that is determined by specific haplotypes in *GP6* and *ITGA2*, respectively. While absence of $\alpha 2\beta 1$ expression has not been observed, there are several reports of patients with a mild bleeding phenotype associated with *GP6* mutations, leading to deficiencies in GPVI expression and decreased in vitro response of platelets to collagen.⁶⁹ Acquired GPVI deficiency can also occur, with ectodomain shedding (i.e., cleavage) of the receptor from the platelet surface in response to autoantibodies.

Abnormalities of Platelet Activation

Soluble Agonist Receptors

Rare patients have been described with defects in the gene for the ADP receptor P2Y₁₂ (*P2RY12*) or in the gene for the TxA₂ TP α receptor (*TBXA2R*). (There are no reports of patients with a deficiency in the P2Y₁ ADP receptor.) The defects mimic the effects of antiplatelet drugs: for *P2RY12*, clopidogrel, prasugrel, and ticagrelor that block P2Y₁₂; and for *TBXA2R*, aspirin, which blocks TxA₂ formation. As such, decreased platelet responses in vitro to ADP and the stable thromboxane mimetic U46619, respectively, are observed in these patients, who have a mild bleeding diathesis. There has been a recent first description of an inherited defect in *F2RL3*, the gene for the PAR4 thrombin receptor, which is associated with decreased expression levels of PAR4 and decreased in vitro platelet responses to thrombin.⁷⁶

Cytoskeletal Defects

These are discussed later in the section on [Inherited Thrombocytopenias](#).

*Dense Granules*⁷⁷

Hermansky-Pudlak syndrome is characterized by oculocutaneous albinism and platelet-dense granule deficiency.⁷⁸ The distinct HPS subtypes arise from defects in nine genes, *HPS1*, *AP3B1* (*HPS2*), and *HPS3-9*, the HPS protein products of which interact in BLOCs that are involved in dense granule biogenesis.⁴¹ Some subtypes are also associated with pulmonary fibrosis and granulomatous colitis. Patients with Chediak-Higashi syndrome have severe immunological defects in addition to oculocutaneous albinism and dense granule deficiency; they have mutations in the *LYST* gene, the product of which is a vesicular transport protein. These syndromic dense granule deficiencies are associated with mild-to-moderate bleeding; in vitro secretion responses as measured by lumiaggregometry are reduced.

Normal numbers of granules with decreased secretion responses are indicative of defective granule secretion processes. For example,

in vitro evidence of dense and α granule secretion defects with normal granule cargo are observed in some forms of familial hemophagocytic lymphohistiocytosis (FHL). Mutations for genes encoding SNARE proteins or their regulators have been identified: Munc13-4 (*UNC13D*) in FHL3,⁷⁹ and Munc18b/syntaxin binding protein 2 (*STXBP2*) in FHL5.⁸⁰

α Granules

The classic α granule deficiency, gray platelet syndrome, is discussed in the section Inherited Thrombocytopenias. Platelet α granules are also absent in the multisystem disorder arthrogryposis-renal dysfunction-cholestasis syndrome, which is lethal within the first year of life. Here, the gene defect is in *VPS33B*, which encodes a Sec1/Munc18 interacting protein considered to be involved in intracellular vesicular trafficking, or in *VIPAS39* (*VPS16B*), which encodes VPS33B-interacting protein. While α granules are present in platelets from patients with the autosomal dominant Quebec platelet disorder, their contents are proteolytically degraded by plasmin generated by urokinase-type plasminogen activator (u-PA), abnormally expressed due to tandem duplication of *PLAU*, the u-PA gene. Inappropriate fibrinolysis after platelet secretion results in symptoms of delayed bleeding after surgery or trauma; in vitro platelet responses to epinephrine are decreased.

Signaling Pathways

Patients have been identified with apparent congenital disorders in a variety of signaling pathways involving G proteins (G_q, G_s, G_i), cPLA₂, and PLC, PKC- θ , Ca²⁺ mobilization, TxA₂ formation (including COX-1 and thromboxane synthase deficiencies), and granule secretion. However, for the most part, the underlying genetic defects in these patients, who experience mild-to-moderate bleeding, remain unknown. An insertion mutation in the extra-large G α_x gene (*GNASXL*) has been associated with G α_x hyperfunction in platelets and a bleeding phenotype, neurological problems, and mild skeletal abnormalities. Mutations in *PLA2G4A* encoding cPLA2 and in *TBXAS1* encoding thromboxane synthase (Ghosal syndrome) have been described. Gain-of-function mutations in *STIM1* resulting in a CRAC channelopathy have been shown in the autosomal dominant Stormorken syndrome, which is characterized by a mild bleeding diathesis, thrombocytopenia, and, in resting platelets, elevated [Ca²⁺]_i and surface PS exposure. The York platelet syndrome,⁸¹ characterized by thrombocytopenia, ultrastructural abnormalities in platelet organelles, and deficiency of Ca²⁺ storage in dense granules, has also recently been reported to be a CRAC channelopathy due to gain-of-function mutations in *STIM1*.

PS Exposure

Scott syndrome, in which there is a defect in PS exposure and thus, platelet procoagulant activity, is associated with mutations in *TMEM16F* (*ANO6*); TMEM16F (anoctamin 6) is essential for Ca²⁺-dependent PS exposure, but its specific role is not yet clarified.⁸² Decreased thrombin generation results in a moderate-to-severe bleeding phenotype; in vitro platelet aggregation responses are not affected.

Abnormalities of Platelet Aggregation

$\alpha IIb\beta 3$ ⁸³

One of the best characterized platelet function disorders, Glanzmann thrombasthenia (GT), results from quantitative or qualitative defects of the fibrinogen/VWF receptor $\alpha IIb\beta 3$, and thus the inability of platelets to aggregate. The bleeding phenotype ranges from mild to life-threatening hemorrhage, and in vitro there are absent aggregation responses to all agonists, while ristocetin-induced agglutination is intact. Type I GT is defined as <5% surface-expressed $\alpha IIb\beta 3$; type II, as 5%–25%; and variant, as normal expression levels of a $\alpha IIb\beta 3$ complex that is nonfunctional. Approximately 200 mutations have been described in the *ITGA2B* and *ITGB3* genes, most commonly missense and nonsense mutations, and those involving splice mutations and small deletions and insertions with frame

shifts; genotype does not necessarily correlate with phenotype.⁸⁴ Rare mutations result in macrothrombocytopenia (see section on Inherited Thrombocytopenias).

Defects in the gene for kindlin-3 (*FERMT3*) or CalDAG-GEFI (*RASGRP2*) have been reported that prevent activation of α IIB β 3, with subsequent absence of platelet aggregation. Deficiency in kindlin-3 is the basis for leukocyte deficiency-III syndrome, a severe disorder that encompasses defective integrin β 2 function in leukocytes and associated susceptibility to infections and poor wound healing, as well as severe bleeding.

Inherited Thrombocytopenias

Inherited thrombocytopenias vary significantly in their severity, platelet morphology, and presence or absence of associated platelet dysfunction. There are approximately 20 human gene defects known to be associated with inherited thrombocytopenias. In terms of molecular mechanism, these can best be understood in the context of megakaryocyte differentiation, maturation, proplatelet formation, and platelet release (Fig. 125.6; see also Chapter 124).^{85,86}

Abnormalities of Megakaryocyte Differentiation

Defects in megakaryocyte maturation result in deficiency or absence of bone marrow megakaryocytes. Known defects include:

Congenital Amegakaryocytic Thrombocytopenia (CAMT)

This is an autosomal recessive disease caused by mutations in *MPL*, the gene for the thrombopoietin (TPO) receptor. Binding of TPO to its receptor activates multiple signaling pathways including JAK2/STAT, Ras/MAPK, and PI3K. TPO is essential for commitment and differentiation in megakaryocytes but also in the erythroid and granulocyte lineages, as patients with CAMT, although thrombocytopenic at birth, develop trilineage bone marrow hypoplasia in the first few years of life.⁸⁷

Thrombocytopenia with Absent Radii (TAR)

This is an autosomal recessive disorder characterized by absent radii and isolated thrombocytopenia, also present at birth. In contrast to CAMT, platelet counts improve with age and other cell lines are unaffected. The cause is a compound inheritance of a low-frequency single-nucleotide polymorphism and a rare null allele in *RBM8A*, a gene encoding the exon-junction complex subunit member Y14. This complex is involved in RNA processing and nuclear export. It is still unknown how this defect affects megakaryocyte maturation, although it may affect TPO signaling through its receptor.⁸⁸

Amegakaryocytic Thrombocytopenia with Radio-Ulnar Synostosis (ATRUS)

This is the result of heterozygous defects in *HOXA11*, a member of the *HOX* gene family of transcription factors involved in embryonic development. These patients have thrombocytopenia from birth that does not improve with time, associated with fusion of the proximal radius and ulna.⁸⁷

Abnormalities of Megakaryocyte Maturation

Defects in differentiation are associated with mutations in specific transcription factors. Some of these mutations are associated with an increased risk of myeloid malignancies and some are associated with additional functional platelet defects. They are characterized by immature or dysplastic bone marrow megakaryocytes.

Familial Platelet Disorder With Predisposition to Acute Myeloid Leukemia

Familial platelet disorder with predisposition to acute myeloid leukemia (FPD/AML) is the result of heterozygous mutations in

RUNX1 (also called *AML1* or *CBFA2*) that encodes the alpha subunit of the core-binding factor transcription complex. This complex regulates expression of genes involved in stem cell proliferation versus differentiation in hematopoiesis. The loss of this regulation predisposes to the development of myelodysplastic syndrome and AML in approximately 40% of individuals with germ-line *RUNX1* mutations. In some pedigrees, the thrombocytopenia is accompanied by abnormalities of granule structure or defects in granule secretion.⁸⁹

Paris-Trousseau Thrombocytopenia and Jacobsen Syndrome

Paris-Trousseau thrombocytopenia and Jacobsen syndrome are disorders caused by deletions in chromosome 11q23-ter, the severity of the syndrome, which includes cardiac and facial defects, depending on the size of the deletion. The loss of one copy of the transcription factor gene *FLII* results in macrothrombocytopenia, and platelets with abnormal α granules and internal membrane structure (see Chapter 124).⁸⁹

GATA-1-Related Thrombocytopenias

These are X-linked diseases associated with anemia, indicating this transcription factor's involvement in both megakaryocytic and erythroid maturation (see Chapter 124). Mutations in *GATA-1* that interfere with binding to its cofactor FOG1 result in dyserythropoietic anemia with thrombocytopenia and defects in α granule maturation.⁶⁹

ANKRD26-Related Thrombocytopenia

This is the result of point mutations in the 5'-UTR of *ANKRD26*, leading to gene overexpression, dysmegakaryopoiesis, and an increased risk of myeloid malignancies. Some affected individuals also have evidence of dysregulation of erythroid and myeloid maturation.⁹⁰

Gray Platelet Syndrome

Gray platelet syndrome (GPS) is the result of homozygous mutations in *NBEAL2*, a regulator of membrane dynamics and vesicle trafficking, affecting α granule development. The disorder is characterized by macrothrombocytopenia, absent platelet α granules, splenomegaly, and progressive bone marrow fibrosis.⁴²⁻⁴⁴ The *Nbeal2*^{-/-} mouse also shows evidence of abnormal megakaryocyte maturation.⁹¹ Recently, mutations in *GFI1B*, encoding a transcription factor involved in megakaryopoiesis and erythropoiesis, have been identified in association a phenotype similar to GPS. Affected individuals have macrothrombocytopenia and α granule deficiency, and some have erythrocyte abnormalities.⁹²

Abnormalities of Proplatelet Formation and Platelet Release

The central role of platelet cytoskeletal components and their interaction with surface membrane receptors in proplatelet formation and platelet production have been clarified by the identification of inherited defects in these molecules that are associated with thrombocytopenias.

MYH9-Related Disease

Previously referred to as the May-Hegglin, Sebastian, and Fechtner syndromes and Epstein anomaly, *MYH9*-related disease is the result of autosomal dominant mutations in *MYH9*, the gene that encodes NMMHC-IIA. NMM is involved in the generation of energy-driven skeletal forces involved in cytokinesis, cell motility, and shape change. Affected individuals have macrothrombocytopenia from birth, the result of branching defects in proplatelets. Branching increases the number of free proplatelet ends and the number of platelets released. There also appear to be defects in the timing of platelet release. Some *MYH9* mutations are also associated with leukocyte inclusions and the development of progressive renal dysfunction, sensorineural hearing loss, and cataracts.³⁹

ACTN1- and FLNA-Related Thrombocytopenias

These result from mutations in the genes that encode α -actinin or filamin A, both functioning as cross-linking proteins in the actin-based cytoskeleton. Filamin A is also critical in binding the cytoplasmic tail of GPIIb α to the filamentous actin network. Monoallelic mutations in either gene result in abnormalities of proplatelet formation and variable degrees of macrothrombocytopenia.⁸⁶

Wiskott-Aldrich Syndrome and X-linked Thrombocytopenia

Wiskott-Aldrich syndrome (WAS) and X-linked thrombocytopenia (XLT) are caused by mutations in the *WAS* gene. Mutations that result in nonexpression of WASp cause WAS that manifests as severe immune dysregulation, in addition to thrombocytopenia. XLT is caused by mutations that decrease expression of the normal protein. These syndromes have the unique characteristic of microthrombocytopenia. WASp is involved in regulation of actin polymerization; the defect in platelet production may be the result of ectopic platelet shedding by megakaryocytes.^{85,93}

Bernard-Soulier Syndrome

In addition to the functional adhesive defect (described in the section on Abnormalities of Platelet Adhesion), patients have thrombocytopenia and giant platelets. Abnormalities in proplatelet formation resemble those seen in mutations of cytoskeletal proteins, suggesting that the anchoring of the actin filament network by GPIIb α to the plasma membrane is a required part of this process, disrupted by deficiency of the GPIIb-IX-V transmembrane protein complex.^{15,86} Most heterozygotes do not have macrothrombocytopenia, but there are exceptions where specific mutations (e.g., p.A156V, the Bolzano mutation) or monoallelic BSS (e.g., Velo-Cardio-Facial syndrome) cause mild macrothrombocytopenia.

ITGA2B/ITGB3-Related Thrombocytopenias

These are rare macrothrombocytopenias with functional defects associated with specific monoallelic mutations in *ITGA2B* or *ITGB3* that are distinct from the mutations that cause GT, described previously. These mutations result in constitutive activation of α Ib β 3 and downstream effectors, defects in actin-myosin reorganization, and abnormalities of proplatelet formation.⁹⁴

TUBB1-Related Thrombocytopenia

This is caused by mutations in the gene for β 1-tubulin and is associated with platelets that are spherical rather than discoid, the result of abnormalities of the microtubule coil⁹⁵ (see also Chapter 124).

PRKACG-Related Macrothrombocytopenia

This is the result of a germ-line mutation in the gene encoding the γ -catalytic subunit of the cAMP-dependent protein kinase (PK), PKA. There is a defect in proplatelet formation and a low level of filamin A in megakaryocytes.⁹⁶

MOLECULAR BASIS OF BLOOD COAGULATION

Kathleen Brummel-Ziedins and Kenneth G. Mann

Blood is the principal vehicle delivering oxygen and nutrients to the various tissues and organs of the body. Blood flow and the integrity of the vasculature are essential to life itself. The hemostatic process has evolved to provide damage recognition and protection from blood loss after perforation of the vasculature while at the same time preventing the systemic activation of the clotting system. However, pathologic occlusions are associated with dysregulation of the intravascular system, resulting in venous or arterial thrombosis. The fine line between vascular occlusion and hemostasis is defined by the complex interplay between pro- and anticoagulant materials provided by the blood, the vasculature, and subvascular elements. The appropriate functions occur as a consequence of intense focal development and regulation of enzymatic activity at sites of vascular injury.

The development of the inventory of components involved in plasma clotting were initially based on the most abundant procoagulant plasma proteins, notably prothrombin and fibrinogen, and extended during the past century with the identification of genetic abnormalities that led to bleeding and deviations in laboratory tests that evolved as the inventory of congenital defects expanded. In some instances, laboratory test results indicating a defect in the procoagulant system were not mirrored by hemostatic pathology. In a similar fashion, the congenital defects associated with thrombosis led to the discovery of anticoagulant proteins in blood and vascular counterparts associated with their presentation and activation.

The functional connections between procoagulant “factors” were developed by mixing and matching plasmas associated with different hemostatic disorders. This inventory and its connectivity were ratified and expanded by experiments performed with transgenically mutated mice.

The dynamics of the plasma coagulation process as expressed are a consequence of the molar concentrations of the pro- and anticoagulant components in blood and the vasculature, and the kinetic processes associated with the dynamics of both the activation and functions of the various proteins associated with the process.

The initial result of the activation of the procoagulant hemostatic process is the formation of a fibrin–platelet plug that forms the temporary seal of the vascular perforation in hemostasis. The generation of an occlusive fibrin–platelet plug blocking further flow through an element of the vasculature is thrombosis. In both instances, the fibrin–platelet scaffold is ultimately removed and substituted by vascular repair, new cells, and connective tissue. In thrombosis, the platelet–fibrin plug is removed mechanically or by biochemical intervention to restore flow to the flow-starved vascular bed.

The elements of clotted fibrinogen–platelet plug are dissolved by the fibrinolytic system, a tightly regulated dynamic system involving enzyme activation, feedback regulation, and blockade by a potent series of inhibitors. Just as there is an interplay between the pro- and anticoagulant components that brings about a blood clot in hemostasis, similar mechanisms occur when blood clots are dissolved via the fibrinolytic process, which is essential for tissue repair. This chapter describes the components of the pro- and anticoagulant system and the pro- and antifibrinolytic system, and the interplay between these systems. The common feature of both systems is the focal presentation of activity that is dependent on the presentation of surface-bound enzymatic complexes that can cleave their respective substrates.

Blood coagulation can best be understood if viewed as a choreographed system that starts from an inventory of the key players, the relationship or connectivity of these players, and the dynamic catalytic processes. These processes together keep blood in a fluid state but

primed to react to vascular injury in an explosive manner. Therefore following sections describe the process of blood coagulation in terms of the inventory, the connectivity, and then the dynamics.

INVENTORY: PROCOAGULANT, ANTICOAGULANT, AND FIBRINOLYTIC PROTEINS, INHIBITORS AND RECEPTORS

Putting together an inventory of the blood coagulation components is still ongoing, but what we currently know to date began from initial observations that were made in the fifth century and recorded in the Babylonian Talmud. It was noted that if two male children died of bleeding after circumcision, the third should not be circumcised.¹ Over the centuries, many more hypotheses were made regarding what happens to blood when it escapes from the body.^{2,3} The realization that clots stem blood loss only occurred in the 18th century.^{2,3} The existence of thrombin, the key enzyme in blood coagulation, was recognized in the 19th century.^{2,4}

In 1905, Paul Morawitz proposed the classic theory of coagulation.⁵ He hypothesized that in the presence of calcium and thromboplastin, prothrombin was converted to thrombin, which in turn converted fibrinogen to the fibrin clot. These clotting factors were subsequently assigned Roman numerals, factor I (fibrinogen), factor II (prothrombin), factor III (thromboplastin; tissue factor membrane), and factor IV (calcium).⁶ As more coagulation factors were introduced, they were assigned consecutive Roman numerals. The activated forms are distinguished by a lower case “a” after their Roman numeral designation. Therefore the activated form of factor V becomes factor Va.

More complex descriptions of the coagulation system were as a “cascade” or “waterfall.” Macfarlane⁷ and Davie and Ratnoff⁸ proposed that in an intrinsic pathway, involving only plasma, blood coagulated by a sequence of events in which the reactions occurred in a defined series leading to fibrin clot formation. Over the past six decades, the Morawitz/Davie and Macfarlane pathways have been significantly expanded (Fig. 126.1). Each reaction shares a similar mechanism in which an inactive zymogen protein is converted to an active enzyme and each “enzyme” is a surface-bound multiprotein complex consisting of a surface, divalent calcium ions (Ca^{2+}), a protease, and a cofactor. Although some facets of these initial descriptions are still valid, the emerging concept of coagulation and fibrinolysis centers on a complex network of highly interwoven concurrent processes. Procoagulant and fibrinolytic events occur simultaneously with many positive- and negative-feedback loops regulating the processes.

To fully understand the multiple simultaneous processes that occur to effect a hemostatic response, we will first inventory the key procoagulant, anticoagulant, and fibrinolytic participants. The inventory sections discuss vitamin K–dependent protein family, cofactor proteins, the intrinsic accessory pathway proteins, endothelium, platelets, proteinase inhibitors, clot proteins, and fibrinolysis proteins.

The Vitamin K–Dependent Protein Family

Vitamin K–dependent proteins, synthesized in the liver, play a central role in blood coagulation through either procoagulant or anticoagulant mechanisms. The vitamin K–dependent protein family includes

three-dimensional shape. The domains of the vitamin K-dependent proteins are illustrated in Fig. 126.2. Several reviews have been written on vitamin K-dependent proteins.⁹⁻¹¹

Vitamin K is essential for the biosynthesis of these clotting factors by participating in the cyclic oxidation and reduction of the enzyme that converts 9-13 N-terminal glutamate residues to γ -carboxy glutamate (Gla; Fig. 126.2; see reviews listed in the References^{9,12-14}). This posttranslational modification to form Gla residues adds a net negative charge to the molecules that enables the vitamin K-dependent

TABLE 126.1**Procoagulant, Anticoagulant, and Fibrinolytic Proteins, Inhibitors, and Receptors**

Protein	Molecular Weight (kD)	Plasma Concentration		Plasma t _{1/2} (Days)	Clinical Phenotype Associated with Deficiency	Functional Classification
		(nmol/L)	(µg/mL)			
Procoagulant Proteins and Receptors						
Factor XII	80	500	40	2-3	None	Protease zymogen
HMW kininogen	120	670	80		None	Cofactor
LMW kininogen	66	1300	90			Cofactor
Prekallikrein	85/88	486	42			Protease zymogen
Factor XI	160	30	4.8	2.5-3.3	Sometimes bleeding	Protease zymogen
Tissue factor	44			N/A		Cell-associated cofactor
Factor VII	50	10	0.5	0.25	Bleeding (Occasionally thrombotic)	VKD protease zymogen
Factor X	59	170	10	1.5	Bleeding	VKD protease zymogen
Factor IX	55	90	5	1	Bleeding	VKD protease zymogen
Factor V	330	20	6.6	0.5	Bleeding ^a	Soluble procofactor
Factor VIII	285	1.1-1.5	0.3-0.4	0.3-0.5	Bleeding	Soluble procofactor
vWF	255	Varies	10		Bleeding	Carrier for factor VIII
Factor II	72	1400	100	2.5	Bleeding ^b	VKD protease zymogen
Fibrinogen	340	7400	2500	3-5	Bleeding ^c	Structural clot protein
Factor XIII	320	94	30	9-10	Bleeding	Transglutaminase zymogen
Anticoagulant Proteins, Inhibitors, and Receptors						
Protein C	62	65	4	0.33	Thrombotic	Proteinase zymogen
Protein S	69	300	20	1.75	Thrombotic	Inhibitory cofactor
Protein Z	62	47	2.9	2.5	Sometimes thrombotic	Inhibitory cofactor
Thrombomodulin	100	N/A	N/A	N/A		Cofactor/modulator
Tissue factor pathway inhibitor	40	1-4	0.1	minutes		Proteinase inhibitor
Antithrombin	58	2400	140	2.5-3	Thrombotic	Proteinase inhibitor
Heparin cofactor II	66	500-1400	33-90	2.5	Often thrombotic	Proteinase inhibitor
α ₂ -Macroglobulin	735	2700-4000	2-3000	<1 hour		Proteinase inhibitor
α ₁ -Proteinase inhibitor	53	28,000-65,000	1500-3500	6		Proteinase inhibitor
Endothelial protein C receptor						Receptor
Fibrinolytic Proteins, Inhibitors, and Receptors						
Plasminogen	88	2300	210	2.2		Proteinase zymogen
t-PA	70	0.07	0.005	<5 min		Proteinase zymogen
u-PA	54	0.04	0.002	5 min		Proteinase zymogen
TAFI	58	75	4.5	10 min	Thrombotic	Carboxypeptidase

proteins to interact with Ca^{2+} and a membrane surface.^{15,16} Blocking the formation of the Gla residues is the basis for anticoagulant therapy with coumarin (warfarin) derivatives, which are chemically similar in structure to vitamin K (Fig. 126.3). The Ca^{2+} binding association with this modification is also the basis for the anticoagulant activity of sodium citrate, a calcium chelator, found in the blue-top vacuum tubes used for clinical laboratory testing of clotting activity. The level of inhibition achieved with the same dose of warfarin varies among patients. Increased sensitivity to warfarin has been identified in patients when started after surgery.^{17,18} Factors affecting the level of anticoagulation include dietary intake of vitamin K; liver function; concomitant medications that either reduce or enhance the warfarin effect¹⁹; common polymorphisms in the vitamin K epoxide reductase complex subunit 1 (VKORC1), which is responsible for vitamin K reduction; and polymorphisms in CYP2C9, which affect warfarin metabolism (see reviews listed in the References^{20,21}). Therefore genotyping may be helpful to personalize starting doses of warfarin. Ultimately, proper monitoring of warfarin therapy is essential. This

is done using the prothrombin time (PT) with the assay sensitivity corrected using the international normalized ratio (INR).^{22,23}

The NH_2 -terminal Gla domains are followed by either a kringle domain in factor II or an epidermal growth factor-like domain (EGF) in factor VII, factor IX, factor X, protein C, protein S, and protein Z (see Fig. 126.2). Protein S is not a serine protease precursor and instead contains a thrombin-sensitive region before the EGF domain and a sex hormone-binding globulin-like domain (SHBG) in the COOH-terminus.²⁴ Protein Z contains a “pseudo catalytic domain” in the COOH-terminus and does not function as a serine protease enzyme.²⁵

Vitamin K-dependent protein complexes are essential for establishing hemostatic balance (Fig. 126.4). Each complex is composed of a serine protease enzyme, a cofactor that functions as a surface receptor or enhancer for the enzyme Ca^{2+} , and a negatively charged membrane surface provided by activated or damaged cells (e.g., endothelial cells, monocytes, and platelets). There are four vitamin K-dependent complexes: the extrinsic tenase complex (factor

Fig. 126.2 SCHEMATIC REPRESENTATION OF THE VITAMIN K-DEPENDENT PROTEINS. The vitamin K-dependent proteins can be divided into two classes, procoagulant (factors II, VII, IX, and X) and anticoagulant (protein C, protein S, and protein Z). The building blocks for these proteins include an NH₂-terminal Gla domain, consisting of nine to 13 Gla residues, followed by either an EGF-like domain in factor VII, factor IX, factor X, protein C, protein S, and protein Z, or a K domain in prothrombin. In protein S, a TSR precedes the EGF domain. Active sites are contained within the serine protease domain. Cleavage sites for the conversion of zymogens to their active forms are designated by *arrows*; activating proteases are placed in *boxes* above the *arrows*. Factor IX, factor X, and protein C are activated by proteolytic removal of an AP. Protein S, which is not a serine protease precursor, contains an SHGB at the COOH-terminus. Protein Z also contains a "pseudo catalytic domain" in the COOH-terminus and does not function as a serine protease. Disulfide bonds (-S-S-) critical to the integrity of the two-chain zymogens or active forms are presented. AP, Activation peptide; EGF, epidermal growth factor; K, kringle; SHGB, sex hormone-binding globulin-like domain; TSR, thrombin-sensitive region.

VIIa-tissue factor), the intrinsic tenase complex (factor IXa-factor VIIIa), the prothrombinase complex (factor Xa-factor Va), and the anticoagulant protein Case complex (thrombin-thrombomodulin).

When the serine protease is associated with its respective cofactor on an appropriate membrane surface with Ca²⁺, the specific reactions occur at a rate that is 10⁴–10⁹-fold faster than that of protease-substrate combination alone.²⁶ One way to visualize the importance of the assembly of these macromolecular complexes in the formation of the hemostatic plug is to note that if a healthy person takes 4 minutes for his or her blood to clot, then in the absence of membrane

and cofactor, blood clot formation would take approximately 3.8 years.

Cofactor Proteins

There are two categories of procoagulant cofactor proteins; the cell-bound cofactors (tissue factor and thrombomodulin) and the soluble plasma-derived procoagulant procofactors (factor V and factor VIII with its circulating carrier von Willebrand factor [vWF]).

Fig. 126.3 VITAMIN K-DEPENDENT PROCESS AND WARFARIN EFFECT. Schematic representation of the mechanism of γ -carboxy glutamate generation by a vitamin K-dependent reaction cycle to produce an active protein is illustrated. The regeneration of vitamin K hydroquinone by the vitamin K-dependent reductases is inhibited by warfarin.

Fig. 126.4 VITAMIN K-DEPENDENT COMPLEXES. Three procoagulant complexes (extrinsic tenase, intrinsic tenase, and prothrombinase) and one anticoagulant complex (protein Case) are illustrated. Each membrane complex consists of a vitamin K-dependent serine protease (factor VIIa [VIIa], factor IXa [IXa], factor Xa [Xa], or thrombin [IIa]) and a soluble or cell surface-associated cofactor (factor VIIIa [heavy and light chain VIII_H and VIII_L], factor Va [heavy and light chain V_H and V_L], tissue factor [TF], or thrombomodulin [TM]). Each serine protease is shown in association with the appropriate cofactor protein and zymogen substrate(s) on the membrane surface. The membrane serves as a scaffold for the coagulation reactants, enhancing the reaction rates by 10^4 – 10^5 -fold.

Cell-Bound Cofactors

Tissue Factor

Tissue factor is a transmembrane protein that functions as a nonenzymatic cofactor for factor VIIa in the extrinsic tenase complex²⁷ (see reviews listed in the References^{28,29}; Fig. 126.5A). In the absence of injury or inflammatory stimuli, tissue factor is not expressed on cellular surfaces in direct contact with circulating blood (see the review listed in the References³⁰). Presentation of tissue factor to the circulation is the event that triggers the primary procoagulant pathway of coagulation^{31–33} (see Fig. 126.1). There are no known mutations or deficiencies of human tissue factor, and tissue factor deletion in mice is lethal during embryonic development,³⁴ leading to the speculation that tissue factor is essential for life.

Tissue factor activity is primarily regulated by controlling its presentation. The commonly accepted sources of functional tissue factor are the subendothelium exposed upon vascular damage or monocytes stimulated by cytokines. However, there is controversy regarding the source and presentation of active tissue factor and whether functional tissue factor circulates in blood in healthy and pathologic states.^{35–40} Microparticle sources of blood-borne tissue factor are generally defined as submicron-sized cell-derived membrane fragments produced in response to activation or apoptosis. Their role in hemostasis is still debated.^{28,35,41,42}

Thrombomodulin

Thrombomodulin is a type 1 transmembrane protein constitutively expressed on the surface of vascular endothelial cells (see Fig. 126.5A). Thrombomodulin is a high-affinity receptor for all thrombin forms and acts as a cofactor for the thrombin-dependent activation of protein C.⁴³ The endothelial cell protein C receptor (EPCR) provides cell-specific binding sites for both protein C and activated protein C (APC).^{44–47} When bound to thrombomodulin, thrombin's procoagulant activities (e.g., its capacity to generate fibrin and activate factor V, factor VIII, factor XI, and platelets) are neutralized, and the rate of inactivation of thrombin by antithrombin is increased.^{48–50} The generation of APC by the thrombin–thrombomodulin complex leads to inactivation of the procoagulant cofactors factor Va and factor VIIIa, thus suppressing thrombin formation.^{51,52} Thrombin–thrombomodulin, or the “protein Case” (see Fig. 126.4) complex,

A

Cell-bound cofactors

B

Soluble plasma procofactors

Fig. 126.5 CELL-BOUND AND SOLUBLE COFACTOR STRUCTURES. (A) Cell-bound cofactors: tissue factor and thrombomodulin. Tissue factor is composed of an extracellular domain (residues 1–219), a transmembrane domain (residues 220–242), and a cytoplasmic domain (residues 243–263). Two disulfide bonds (–S–S–) and the sites of the three carbohydrate moieties (CHO) are identified by amino acid residue. One cysteine (C²⁴⁵) contains a thiol ester linkage to a fatty acid. Tissue factor, which is the cofactor for factor VIIa in the extrinsic tenase complex, is exposed on the subendothelial surface after injury. Thrombomodulin is an endothelial cell-surface glycoprotein composed of five distinct domains. These include a lectin-like domain (residues 6–149), a domain containing six EGF-like regions (residues 227–462), a small extracellular domain rich in threonine and serine residues (S⁴⁷² and S⁴⁷⁴ have been identified as sites of chondroitin sulfate adducts), a membrane-spanning region (residues 499–521), and a cytoplasmic tail (residues 522–557). There are nine known glycosylation sites (CHO) on the thrombomodulin molecule. Thrombomodulin functions as the cofactor in the protein Case complex and assists in the generation of activated protein C. (B) Soluble plasma procofactors: factor VIII and factor V. The linear domain structures (A₁–A₂–A₃–C₁–C₂) are illustrated with *horizontal arrows* bracketed by the beginning and ending amino acid number. Thrombin (IIa) and activated protein C cleavage sites are shown with *vertical arrows*. The B regions (factor V, residues 709–1545; factor VIII, residues 740–1689) are represented by the *crosshatched regions*. EGF, Epidermal growth factor.

also has an antifibrinolytic role via activation of the fibrinolysis inhibitor, thrombin-activatable fibrinolysis inhibitor (TAFI; see reviews listed in the References^{53–56}).

Thrombomodulin activity on the surface of endothelial cells is decreased by inflammatory cytokines,^{57,58} and this decrease may contribute to the hypercoagulation characteristic of inflammatory states.

Soluble Plasma Procofactors

Factor V

Factor V is a large single-chain glycoprotein (GP) that circulates in human plasma (see Table 126.1 and Fig. 126.5B) and is also contained in the α -granules of human platelets, with approximately 18%–25% of the total factor V found in platelets.⁵⁹ The procofactor

factor V is proteolyzed by α -thrombin to the active cofactor factor Va.⁶⁰ Factor Va functions both as a factor Xa receptor and positive modulator of factor Xa catalytic potential in the prothrombinase complex (see Fig. 126.4).⁶¹ Factor Va is proteolytically inactivated by APC.^{62,63} The importance of this regulatory mechanism is demonstrated by the “APC resistance” syndrome associated with factor V^{Leiden}.^{64,65} Individuals with factor V^{Leiden} have a G to A substitution at nucleotide 1691 in the factor V gene that results in an Arg⁵⁰⁶→Gln mutation at the protein level.⁶⁶ Factor Va^{Leiden} has normal cofactor activity as part of the prothrombinase complex. However, unlike normal factor Va, factor Va^{Leiden} is more slowly inactivated by APC. The Arg⁵⁰⁶→Gln mutation hinders the first step in the series of inactivating cleavages by APC. Cleaved factor Va^{Leiden} retains limited cofactor activity and continues to promote thrombin generation. The identification, role in coagulation, and overall importance of factor V in hemostasis have been described in numerous reviews.^{61,67}

Factor VIII

The soluble procofactor factor VIII, or antihemophilic factor (see Fig. 126.5B), circulates in plasma in complex with the large multimeric protein vWF.⁶⁸ vWF acts to regulate the plasma concentration of factor VIII. Factor VIII interaction with vWF requires the NH₂- and COOH-termini of the factor VIII light chain (A3, C1, and C2 domains), although a specific vWF binding site has been identified at residues 1673–1684 on the light chain.^{68–71} Factor VIII is activated by thrombin cleavage at three sites (Arg³⁷², Arg⁷⁴⁰, Arg¹⁶⁸⁹) to generate the heterotrimeric cofactor factor VIIIa.⁷² The vWF binding site is removed from the factor VIII protein by thrombin cleavage at Arg¹⁶⁸⁹. After forming, vWF-free factor VIIIa forms a complex with the serine protease factor IXa, Ca²⁺, and a membrane (provided by platelets), resulting in the intrinsic tenase (see Fig. 126.4). Factor VIIIa function is downregulated by the relatively rapid dissociation of the noncovalently associated A2 subunit, which is produced by the cleavages required for activation. Factor VIII is homologous (40% identity) to the procofactor factor V.⁷³

Deficiency of factor VIII, or hemophilia A, is a well-characterized bleeding disorder linked to the X chromosome.⁷⁴ Hemophilia A therefore occurs almost exclusively in males at a frequency of 1 in 5000 to 1 in 10,000 individuals.⁷⁵

von Willebrand Factor

vWF has several key roles in coagulation. It is synthesized in endothelial cells and also contained in the α -granules of human platelets.⁷⁶ vWF is a large adhesive GP that circulates in plasma as a heterogeneous mixture of disulfide-linked multimers that range in size from dimers ($M_r = 600,000$) to extremely large multimers of more than 20 million kDa. vWF has binding sites for factor VIII, heparin, collagen, platelet GPIIb, and platelet GPIIb–IIIa.^{77–90} vWF acts as the bridge between platelets to promote platelet aggregation. The primary platelet binding site for vWF is the GPIIb–IX–V receptor complex. GPIIb–IX–V is an active receptor on unstimulated platelets and serves to promote platelet aggregation and adhesion to vWF in the absence of platelet activation.⁹¹

vWF is a structural protein and is part of the subendothelial matrix. Endothelial cells secrete vWF multimers, which are larger than those found circulating in plasma.⁹² The function of these large multimeric forms of vWF is to bind to and agglutinate blood platelets under high shear conditions. These large multimers of vWF are degraded by a specific metalloprotease called a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS)-13.^{93–95} In familial and acquired thrombotic thrombocytopenic purpura, ultra-large vWF multimers are correlated with defective ADAMTS-13 activity.⁹⁶

ABO blood type has a significant influence on vWF levels, with individuals of types A, B, or AB blood having much higher levels of vWF than those with type O blood.^{97,98} vWF is also known for its role in ristocetin-induced platelet agglutination,^{99,100} which is the basis of clinical assays for von Willebrand disease, a fairly common disorder that is estimated to occur in 1%–2% of the general population (see Chapter 138).^{101–104} vWF is also an acute-phase reactant,

and vWF levels are elevated as a result of stress, pregnancy, or surgical trauma.^{105–108}

The Intrinsic Accessory Pathway Proteins

The designation “intrinsic accessory pathway” emerged as the relationship between genetic deficiencies and bleeding phenotypes was established (see Fig. 126.1). Deficiencies of proteins associated with the intrinsic or accessory pathway (factor XII, prekallikrein, and high-molecular-weight kininogen [HMWK]) are not ordinarily associated with excessive bleeding, even after surgical challenge.^{109–111} In contrast, deficiencies of the protein components of the extrinsic or primary pathway (prothrombin and factors V, VII, VIII, IX, and X) can lead to severe bleeding diatheses.^{112–116} The physiologic role of the accessory pathway is therefore not clearly understood.¹¹⁷

Although the intrinsic pathway proteins have no defined role in normal hemostasis, these accessory pathway factors are thought to play a key role in disseminated intravascular coagulation associated with the systemic inflammatory response syndrome^{118,119} and in the promotion of thrombus stability,^{117,120,121} and may be a new target to control pathologic coagulation.¹²² Also, the accessory pathway is important in cardiopulmonary bypass because of contact between blood components and synthetic surfaces.¹¹⁹ Recent evidence suggests that biologic activation of the contact pathway system may be accomplished through assembly of these proteins on endothelial cell membranes and that prekallikrein is activated by an endothelial cell membrane cysteine protease rather than by factor XII.^{123,124} Extracellular RNA derived from damaged or necrotic cells has also been found to participate in the activation of proteases of the contact pathway by providing a procoagulant cofactor template for factor XII- or XI-induced contact activation.¹²⁵ Polyphosphates, linear inorganic polymers of 60–100 phosphate residues, released from platelets have also been shown to activate fXII.¹²⁶

In principle, factor XI represents an intersection point for the two pathways. Individuals with factor XI deficiency (hemophilia C) have a variable bleeding phenotype upon surgical challenge,^{127,128} therefore establishing an essential role for factor XI in hemostasis. During the coagulation process, factor XIa formation appears to be catalyzed by thrombin as part of a positive-feedback loop stemming from thrombin generation.¹²⁹ Factor XIa then functions in the propagation phase of thrombin generation in association with the primary pathway by activation of factor IX.¹³⁰

Three proteins, factor XII, prekallikrein, and HMWK, are required for activity of the intrinsic or accessory pathway. Factor XII and prekallikrein are zymogens that are activated to generate serine proteases, and HMWK is a nonenzymatic procofactor (Fig. 126.6). The activation of this pathway *in vitro* is accomplished when factor XII autoactivates to factor XIIa upon exposure to foreign surfaces, including kaolin, dextran sulfate, and sulfatides.^{131–133} The substrates for factor XIIa, prekallikrein, and factor XI exist in noncovalent complex with HMWK and become activated to kallikrein and factor XIa, respectively.¹³⁴ Positive-feedback loops exist in which kallikrein cleaves HMWK, thereby releasing bradykinin and allowing more prekallikrein and factor XI to associate and activate.¹³⁵ This pathway is also negatively regulated by the cleavage of HMWK by factor XIa.¹³⁶

Proteinase Inhibitors

Proteinases, enzymes that hydrolyze peptide bonds, are found in a wide array of biologic systems, including the blood coagulation process (clot formation and fibrinolysis), digestive system, apoptotic cascades, and the immune system. To keep these systems in balance between activation and inhibition, a complex system of proteinase inhibitors has evolved. In blood, proteinase inhibitors constitute a significant percentage of circulating proteins. In general, proteinases that activate the coagulation and fibrinolytic cascades have highly defined substrate specificities. Coagulation is kept in check through

Fig. 126.6 SCHEMATIC REPRESENTATION OF THE ACCESSORY PATHWAY (INTRINSIC) PROTEINS. Factor XII, prekallikrein, kininogen, and factor XI are shown with their various domains depicted. Cleavage sites for activation are identified with an *arrow*, and with the specific amino acid residues of the site shown. Key interchain disulfide bonds (-S-S-) are included. For the kininogens, *horizontal arrows* indicate the amino acid residues defining heavy and light chain regions of the activated forms of the cofactors. Factor XI is illustrated as a monomer. *EGF*, Epidermal growth factor; *FXI*, factor XI; *HMW*, high molecular weight; *LMW*, low molecular weight; *PK*, prekallikrein.

the action of several specific and broad-spectrum proteinase inhibitors. Specific clot formation inhibitors are antithrombin, tissue factor pathway inhibitor (TFPI), heparin cofactor II, and protein C inhibitor. Together specific and broad-spectrum inhibitors function to localize, limit, and control hemostasis (see [Chapter 127](#)).

Antithrombin

Antithrombin is a member of the serpin proteinase inhibitory family and circulates in blood as a single-chain GP¹³⁷ (see [Table 126.1](#); [Fig. 126.7](#)). Congenital antithrombin deficiency exhibits an autosomal dominant pattern of inheritance, with an incidence of 1 in 2000 to 1 in 5000.¹³⁸ Individuals with this deficiency have partial expression of antithrombin and are prone to venous thromboembolic disease.¹³⁹ The complete absence of antithrombin is lethal.

Antithrombin has a broad spectrum of inhibitory activity, with most of its target proteases participating in the coagulation cascade (see [Fig. 126.1](#)). It is primarily an inhibitor of the serine proteases thrombin, factor Xa, factor IXa, factor VIIa–tissue factor, factor XIa, factor XIIa, kallikrein, and HMWK.^{140–142} Heparin and heparan sulfate potentiate these reactions, and heparin is used for the prevention and treatment of thrombosis. When antithrombin is complexed with heparin, its rate of inhibition of several coagulation proteases is accelerated by up to 10,000-fold. The general mechanism of inhibition involves reaction of the active site of the enzyme with a peptide loop structure (the reactive center loop) of antithrombin, forming a tight, equimolar (1:1) complex. Inactivation proceeds through covalent bond formation between antithrombin and the protease followed by inactivating structural rearrangements of both antithrombin and the protease.

Antithrombin also displays antiproliferative and antiinflammatory properties that primarily derive from its ability to inhibit thrombin. In addition, latent or cleaved forms of antithrombin have antiangiogenic activities.¹⁴³

Tissue Factor Pathway Inhibitor

TFPI, formerly called *extrinsic pathway inhibitor* or *lipoprotein-associated coagulation inhibitor*, is a multivalent Kunitz-type plasma proteinase inhibitor. It circulates in plasma as a heterogeneous collection of partially proteolyzed forms^{144–147} (see [Table 126.1](#) and [Fig. 126.7](#)). Up to 90% of circulating TFPI is found associated with lipoproteins, primarily low-density lipoprotein.^{144,148,149} Parenteral TFPI is cleared from the circulation mainly by the liver and has an unusually short half-life (minutes) compared with other proteinase inhibitors.

Many reviews of TFPI have been published.^{150–160} The importance of TFPI in blood coagulation is best illustrated through transgenic mice with complete TFPI deficiency; the deficiency is embryonic lethal.¹⁵⁴ However, this lethality in mice can be rescued by heterozygous or homozygous factor VII deficiency.¹⁶¹ This implies that diminishing the level of factor VII lessens the need for TFPI-mediated inhibition of the factor VIIa–tissue factor coagulation pathway during embryogenesis.¹⁶¹ Similarly, the combination of low normal TFPI with factor V Leiden is lethal.^{162,163} Mice with combined heterozygous TFPI deficiency and homozygous apolipoprotein E deficiency develop more extensive atherosclerosis burden,¹⁶⁴ raising the possibility that TFPI contributes to protection from atherosclerosis, as well as serving as a regulator of thrombosis.

TFPI is the principal stoichiometric inhibitor of the extrinsic factor tenase complex (factor VIIa–tissue factor).¹⁶⁵ Effective TFPI

Tissue factor pathway inhibitor**Antithrombin****Heparin cofactor II****Protein C inhibitor**

Fig. 126.7 SCHEMATIC REPRESENTATION OF SEVERAL PROTEINASE INHIBITORS. Tissue factor pathway inhibitor (TFPI) contains three Kunitz domains. TFPI inhibits the serine proteases FVIIa and FXa, shutting down the extrinsic pathway of coagulation. Kunitz 1 domain binds FVIIa, and Kunitz 2 domain binds FXa. The COOH-terminus of TFPI contains a basic region, the cell-binding domain, which binds to heparin. Antithrombin (AT) contains two intrachain disulfide bonds (-S-S-) in its NH₂-terminus and one in its COOH-terminus with a carbohydrate-rich domain (CHO) in between. The region of interaction between the active sites of target proteases and AT is illustrated (reactive center loop). Heparin binding occurs in the NH₂-terminus and enhances the rate of inhibition of serine proteases. Heparin cofactor II inhibits thrombin. Structurally, the inhibitor contains an NH₂-terminus hirudin-like region, a heparin or dermatan sulfate binding region, and a reactive center loop. The reactive site is shown at Leu⁴⁴⁴. Protein C inhibitor is a serine protease inhibitor that inhibits several proteases, including activated protein C, thrombin, and FXa. It is also a potent inhibitor of the thrombin-thrombomodulin complex. The reactive bond (Arg³⁵⁴) in the reactive center loop is shown. *FVIIIa*, Factor VIIa; *FXa*, factor Xa.

inhibition of the factor VIIa-tissue factor complex depends on the presence of factor Xa. Thus inhibition of the extrinsic factor tenase by TFPI occurs only after significant factor IXa and factor Xa formation. Inhibition by TFPI is achieved by formation of the stable quaternary, by tissue factor-factor VIIa-TFPI-factor Xa complex, and by formation of the factor Xa-TFPI complex directly.

Heparin Cofactor II

Heparin cofactor II is a member of the serpin family (see Fig. 126.7). The plasma concentration of heparin cofactor II is 0.5–1.4 $\mu\text{mol/L}$ ^{166,167} (see Table 126.1). Its plasma half-life is approximately 2.5 days. Similar to antithrombin, heparin cofactor II inhibits thrombin in a reaction that is accelerated more than 1000-fold by heparin.¹⁶⁸ However, unlike antithrombin, the only coagulation enzyme inhibited by heparin cofactor II is thrombin.¹⁶⁹ The rate of thrombin inhibition by heparin cofactor II in the absence or presence of heparin or heparin-like molecules is significantly slower than by antithrombin under similar conditions. Considering that the plasma concentration of heparin cofactor II is 25%–50% that of antithrombin and that low levels of heparin cofactor II are not strongly associated with

thrombosis,¹⁷⁰ the physiologic role of heparin cofactor II as a systemic thrombin inhibitor has been questioned.

In vitro, heparin cofactor II inhibition of thrombin is accelerated by dermatan sulfate proteoglycans synthesized by fibroblasts and vascular smooth muscle cells.¹⁷¹ Thus heparin cofactor II may be uniquely suited to regulate extravascular thrombin in areas of vascular endothelium disruption in which heparin cofactor II would be exclusively stimulated by dermatan sulfate in the subendothelium. In addition, heparin cofactor II may participate in regulation of acute inflammation and wound healing by harboring a peptide chemotactic for neutrophils and monocytes that is released by leukocyte proteolysis.¹⁷²

Heparin cofactor II may also have a role in protection from thrombosis during pregnancy. Increased levels of dermatan sulfate in the maternal and fetal circulation¹⁷³ along with increased levels of heparin cofactor II in pregnant women have been reported.^{174,175} Low levels of thrombin-heparin cofactor II complexes are detected in normal plasma samples; elevated levels were detected in patients with disseminated intravascular coagulation.¹⁷⁶ Although inherited deficiency of heparin cofactor II has been associated with thrombosis, this is not always the case.^{177–179}

Protein C Inhibitor

Protein C inhibitor is a member of the serine proteinase inhibitor family and is also known as *plasminogen activator inhibitor-3* (PAI-3). It circulates in blood at a concentration of 5 $\mu\text{g/mL}$ ^{180,181} (see Table 126.1 and Fig. 126.7) and is cleared from the circulation with a half-life of 1 day. When in complex with a target (e.g., APC), it is cleared from circulation with a $t_{1/2}$ of 20 minutes.¹⁸²

Protein C inhibitor is considered a nonspecific inhibitor in that its targets range from procoagulant (serine proteinases), anticoagulant, and fibrinolytic enzymes to plasma and tissue kallikreins, the sperm protease acrosin, and prostate-specific antigen.^{183,184} The major target of protein C inhibitor, as its name suggests, appears to be APC.^{182,185,186} Protein C inhibitor has been shown to regulate TAFI activation by inhibiting the thrombin–thrombomodulin complex.¹⁸⁷ Its importance as a dual regulator of coagulation and fibrinolysis remains unresolved.^{188,189} Other targets for protein C inhibitor include human plasma kallikrein,¹⁹⁰ factor XIa,¹⁹⁰ factor Xa, and thrombin. Because there are no documented patients with a deficiency to date, the actual function of protein C inhibitor in vivo has yet to be elucidated.

α_2 -Macroglobulin

α_2 -Macroglobulin is a nonspecific proteinase inhibitor that targets a broad spectrum of protease substrates. It is present in human plasma at concentrations ranging from 2 to 4 $\mu\text{mol/L}$ (2–3 mg/mL). α_2 -Macroglobulin can also be found at higher concentrations in extravascular fluids.¹⁹¹ This protease inhibitor can be produced in a variety of cells, including hepatocytes, fibroblasts, and macrophages.^{192,193} Human α_2 -macroglobulin circulates in plasma as a tetramer.^{191–198} α_2 -Macroglobulin has a unique mechanism of action, which accounts for its broad specificity. The initial step involves the “bait region” of α_2 -macroglobulin.¹⁹⁹ After proteolysis in this bait region, α_2 -macroglobulin undergoes conformational changes that trap the proteinase inside the molecule.¹⁹⁹ Consequently, α_2 -macroglobulin inhibits a broad range of proteinases. It is distinctive in its capacity to inhibit members from each of four mechanistic classes of proteinases (serine, cysteine, and aspartic proteinases, and metalloproteinases). α_2 -Macroglobulin functions as a secondary inhibitor of serine proteinases in plasma by inhibiting thrombin, kallikrein, and plasmin.^{200,201} It may also be important in preventing thromboembolic events when there is a congenital deficiency of antithrombin or acquired deficiency in sepsis.^{202,203} α_2 -Macroglobulin also inhibits various growth factors and cytokines, including transforming growth factor- α (TGF- α),²⁰⁴ interleukin (IL)-1 β ,²⁰⁵ IL-6,²⁰⁶ acidic fibroblast growth factor,²⁰⁷ basic fibroblast growth factor,²⁰⁷ tumor necrosis factor- α (TNF- α),²⁰⁸ and IL-2.²⁰⁹ Polymorphisms identified in α_2 -macroglobulin have been thought to play a role in Alzheimer disease.^{210–212} Overall, the biologic role of α_2 -macroglobulin in vivo is still being elucidated.

Reduced levels of α_2 -macroglobulin in humans have been observed in individuals with chronic obstructive lung disease²¹³ and metastatic cancer.²¹⁴ Complete deficiency has not been reported, suggesting that absence of α_2 -macroglobulin is incompatible with survival. Inactivation of the α_2 -macroglobulin gene in mice has no obvious phenotype, but the mice are resistant to endotoxin challenge.²¹⁵ It has been suggested that α_2 -macroglobulin serves as a neutralizer of TGF- α and an inducer of nitric oxide synthesis in mice.²¹⁶

Endothelium

Blood cells and the vasculature are crucial to normal hemostasis. Multiple processes involving components of the vessel wall, circulating platelets, and plasma protein moieties interact to maintain blood fluidity. These must be precisely choreographed to allow the vasculature to perform its myriad complex physiologic activities (Fig. 126.8). The endothelium, the thin layer of cells that lines the interior of blood and lymphatic vessels, plays a key role because of its strategic interface among organs, tissues, and circulating blood. The cells that form the endothelium are called *endothelial cells*, those in direct contact with blood are called *vascular endothelial cells*, and those in

direct contact with lymph are known as *lymphatic endothelial cells*. Vascular endothelial cells line the entire circulatory system (from the heart to the capillaries).

The endothelium varies in morphology and physiologic function in different parts of the vasculature. This complex cellular network not only provides a structural barrier to contain flowing blood but also regulates blood pressure, vascular tone, permeability, and processes involving other cells such as smooth muscle cells, leukocytes, and platelets, and deposits an intricate basement membrane and extracellular matrix.²¹⁷ In addition, the endothelium is involved in inflammatory and immune responses and angiogenesis.²¹⁸ Defects in vascular endothelium function, therefore, have profound physiologic implications. Excessive bleeding can result from structural abnormalities of the endothelial cell layer or supporting matrix. Impaired expression or secretion of PAI-1 by the endothelium likewise promotes bleeding through increased fibrinolytic activity.²¹⁹ Conversely, endothelial cells are also involved in mediating processes that promote atherosclerotic plaque formation and thrombotic pathologies.²²⁰

The early work of Ware and Seegers²²¹ identified the phospholipid requirements for coagulation. The biologic elements contributing to the phospholipid include damaged vascular tissue-activated platelets and inflammatory cells. The contributions of the membrane to the formation and expression of procoagulant complexes are essential. However, the nature of the membranes that support procoagulant reactions is poorly understood. Mechanically damaged cells can provide the anionic membrane bilayer inner leaflet phospholipids, which can support general procoagulant complex formation; however, more subtle cellular activation events also generate selective complex-forming sites on intact cells. Activated platelet membranes express individual binding sites for the factor IXa–factor VIIIa and factor Xa–factor Va complexes. Hemorrhagic pathology is therefore associated with thrombocytopenia and is also displayed in a rare disease, Scott syndrome, which appears to result from the improper presentation of these platelet binding sites.²²² Binding sites have also been reported on a number of peripheral blood cells, especially activated monocytes. The vascular endothelium itself can provide binding sites after stimulation by cytokine growth factors.²²³ The endothelium also provides the anticoagulant thrombomodulin, TFPI and heparan sulfate. The EPCR provides cell-specific binding sites for both protein C and APC.^{44,224} EPCR is downregulated by TNF- α .⁴⁴ Monocytes appear to express specific binding sites for APC that are distinct from the endothelial cell protein C receptor.²²⁵ The cell-expressed binding sites may be important in the antiinflammatory properties of APC.⁴⁶

A further consequence of damage to the endothelium is the release of pathologic quantities of vWF, which promote platelet aggregation and adhesion to the subendothelium, and thus the formation of potentially fatal thrombi. Endothelial dysfunction is also linked with hypertension, diabetes, obesity, and hyperlipidemia.

Platelets

Platelets, or thrombocytes, are vital to procoagulant events and contribute to the fibrinolytic process as well. They are small, irregularly shaped clear cell fragments, which are derived from megakaryocytes. The average lifespan of a platelet is approximately 5–9 days. Platelets are at the balance of bleeding or clotting events: when platelet numbers are low (thrombocytopenia), excessive bleeding can occur, and when platelet numbers are high (thrombocytosis), thrombosis can occur. Disorders that reduce the number of platelets but typically cause thrombosis instead of bleeding are heparin-induced thrombocytopenia and thrombotic thrombocytopenic purpura.

Similar to the endothelium, the undisturbed platelet presents a nonthrombogenic surface. Important components of platelet physiology are surface adhesion protein complexes and the platelet secretory granules: α -granules, lysosomes, and dense granules. Contents of the α -granules include procoagulant and adhesive proteins such as fibrinogen, fibronectin, thrombospondin, vWF, P-selectin, HMWK, platelet factor 4, osteonectin, factor V,⁵⁹ and factor XI.²²⁶ Other α -granule contents, α_1 -antitrypsin, protein S, TFPI, and platelet

Fig. 126.8 SCHEMATIC OF THE CHANGES THAT OCCUR TO THE ENDOTHELIUM UPON INJURY. Under normal conditions in the absence of injury or chemical stimulus (A), the *undisturbed endothelium* actively downregulates thrombin generation through production of TFPI, AT, protein S, heparan sulfate, TM, and dermatan sulfate. The *undisturbed endothelium* is also antifibrinolytic and secretes PAI-1. In the absence of a stimulus, the endothelium likewise prevents platelet activation, secretion, and aggregation through production of NO, prostacyclin, and the membrane-associated protein ectoADPase. When the *endothelium is disturbed* (B), the endothelium becomes procoagulant and accelerates thrombin formation by exposing or expressing anionic phospholipid (“PS”), TF, and factor V. The fibrinolytic response is modulated by the release of both antifibrinolytic and profibrinolytic molecules. u-PA and t-PA are profibrinolytic and serve to activate plasminogen; PAI-1 inhibits both enzymes and is antifibrinolytic. Platelet activation, secretion, and aggregation are also promoted under conditions in which the endothelium is disrupted. vWF in the subendothelial matrix is exposed, allowing platelets to attach to the surface of the vessel. P-selectin likewise promotes platelet attachment. AT, Antithrombin; NO, nitric oxide; PAI-1, plasminogen activator inhibitor-1; TFPI, tissue factor pathway inhibitor; TF, tissue factor; TM, thrombomodulin; t-PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator; vWF, von Willebrand factor.

inhibitor of factor XI, are involved in anticoagulant activities.^{227–229} The α -granule also contains proteins that mediate both pro- and antifibrinolytic processes. These proteins include plasminogen, α_2 -antiplasmin, factor XIII, and PAI-1.^{230–234} In the unstimulated platelet, the granule contents remain internalized and anionic phospholipid is sequestered in the inner leaflet of the plasma membrane. Prostaglandin I₂ (prostacyclin) and nitric oxide released from endothelial cells, the presence of CD39, and the inability of normal plasma vWF to bind spontaneously to the platelet surface are the inhibitory mechanisms that keep platelets unactivated.²³⁵

When the vascular system is perturbed, platelet plug formation occurs in stages. During the first stage, platelets adhere and are activated by exposure to collagen and vWF and other matrix components (Fig. 126.9). The cytoskeleton spreads and platelet–fibrinogen aggregates are formed and the contents of the granules are secreted.^{236–238} The activated platelets adhere to each other, endothelial cells, leukocytes, and components of the subendothelial matrix.²³⁹ The phosphatidyl serine-rich internal face of cell membranes are exposed and present a highly procoagulant surface to the circulation.²⁴⁰ In addition, activated platelets express specific receptors or binding sites for the assembly of the procoagulant multiprotein complexes (Fig. 126.10). There are approximately 3000 factor Va binding sites on the activated platelet

membrane.²⁴¹ Factor Va forms part of the receptor for factor Xa. Factor Xa is also reported to bind to effector cell protease receptor-1 (EPR-1) molecules expressed on activated platelets.^{241–244}

In the extension phase of platelet plug formation, where activated platelets accumulate on top of the initial monolayer of platelets bound to collagen, the presence of receptors on the platelet surface allows agonists such as thrombin, adenosine diphosphate, and thromboxane A₂ to recruit additional circulating platelets into the growing hemostatic plug (see Fig. 126.10). Subsequently, during the platelet plug formation perpetuation phase, close contacts between platelets promote the growth and stabilization of the hemostatic plug, in part through contact-dependent signaling mechanisms.²³⁵

Clot Proteins

A central event in blood coagulation is the conversion of soluble fibrinogen (factor I) to insoluble fibrin (see Fig. 126.1; see reviews listed in the References^{245,246}). Fibrinogen functions in hemostasis to stem blood loss. It serves as a molecular bridge to support interplatelet aggregation, and it is the precursor of fibrin, which is the main component of the protein scaffolding of the forming hemostatic plug.

Fig. 126.9 SCHEMATIC OF PLATELET ACTIVATION, SECRETION, AND AGGREGATION. Platelets have multiple functions in hemostasis. They serve as reservoirs of factor V, fibrinogen, vWF, PF4, and factor XI. Platelets also contribute a significant portion of the anionic phospholipid ("PS") necessary for membrane-dependent complex formation and function. In the unstimulated state, proteins and other molecules are sequestered in the platelet granules. Anionic phospholipid is found only in the inner leaflet of the platelet membrane and is not exposed to flowing blood. The GPIb-IX-V complex, which recognizes vWF, is an active receptor, but the GPIIb-IIIa receptor, which recognizes a variety of molecules, including fibrinogen and vWF, is not active. The GP Ib-IX-V receptor likely allows unstimulated platelets to attach to exposed subendothelial vWF, thereby promoting procoagulant events before platelet activation. Upon activation by a variety of agonists, platelets secrete granule contents, become activated and bind factor V/Va and factor XI/XIa, and expose anionic phospholipid. The GPII-IIIa receptor serves to link platelets to each other and the vessel wall. Collagen receptors, such as GPIa-IIa, promote both platelet activation and aggregation. *ADP*, Adenosine diphosphate; *GP*, glycoprotein; *PF4*, platelet factor 4; *vWF*, von Willebrand factor.

Platelet aggregation critically depends on fibrinogen binding to activated platelets via the platelet fibrinogen receptor GPIIb/IIIa as well as fibrin adhesion (see Fig. 126.10). Fibrinogen/fibrin also regulates thrombin activity by interactions that include the proteolytic cleavage by thrombin of fibrinopeptides^{247,248} to form a fibrin clot and thrombin exosite binding to fibrin, which potentially limits the diffusion of thrombin, thereby regulating clot propagation. The structure, stability, and duration of insoluble fibrin are controlled by an interplay between fibrin formation and fibrinolysis, which includes other molecular and cellular components.

The description of fibrinogen activation and fibrin assembly has been based on studies using citrated plasmas or purified proteins. The three main players in fibrinogen to fibrin conversion are the enzyme thrombin, the substrate fibrinogen, and the cross-linking transglutaminase factor XIII. Fibrinogen is composed of six polypeptide chains (two A α , two B β , and two γ chains) that form two symmetrical half molecules (three chains each) with the NH₂-termini cross-linked to each other. The outside two domains of fibrinogen are composed of the B β and γ chains, and designated as the D domain. The central domain that contains the NH₂-termini of all the chains

is designated as the E domain. From x-ray crystallographic data, fibrinogen has a trinodular structure aligned as D-E-D domains (Fig. 126.11).

The kinetics of fibrinogen cleavage by thrombin results in the hydrolysis of Arg-Gly bonds removing small, polar N-terminal fragments (fibrinopeptides [FPs]) from the NH₂-terminal of the A α and B β chains Fig. 126.11.^{249,250} Cleavage at the Arg-Gly bond of the A α chain releases FPA and forms fibrin I. The release of two FPA peptides exposes a site in the E domain that interacts with a site in the D domain to form overlapping fibrils. Subsequent cleavage of the Arg-Gly bond on the B β chain releases FPB to form fibrin II, presumably increasing lateral aggregation of the protofibrils.²⁵¹

An important enzyme for the structure and stability of the fibrin clot is transglutaminase factor XIIIa.²⁵²⁻²⁵⁴ Its function is to cross-link fibrin and other adhesive proteins, including integrin receptors, providing a stable network. Only the A α chain and the γ chain, which have donor (Gln) and acceptor (Lys) sites, participate in cross-linking of adjacent glutamyl and lysyl residues by factor XIIIa.^{251,255-257}

Fibrinogen is also required for competent inflammatory reactions. Fibrinogen is an acute-phase reactant whose levels increase during

Fig. 126.10 SELECTED PLATELET RECEPTOR TARGETS AND THEIR RESPECTIVE INHIBITORY AGENTS. When a platelet encounters a break in the endothelium, it encounters molecules that trigger its activation, such as collagen, TXA_2 , ADP, and thrombin. The ability of platelets to adhere, aggregate, respond to agonists, aid in coagulation, and bind fibrin are all processes mediated by the plasma membrane glycoproteins of the platelet. The platelet GPIbIX-V constitutes the receptor for vWF. GPIa/IIa mediates platelet-collagen interactions. GPIIb/IIIa is a receptor for fibrinogen. P2Y_{12} is a chemoreceptor for ADP. The $\alpha_2\text{A-AR}$ is expressed on platelets and binds the naturally occurring ligand epinephrine. COX-1 is responsible for the formation of prostaglandins and thromboxane. COX-1 converts arachidonic acid to PGG_2 . Aspirin irreversibly inhibits COX-1. $\alpha_2\text{A-AR}$, $\alpha_2\text{A}$ -adrenergic receptor; COX-1, cyclooxygenase-1; GP, glycoprotein; PGG_2 , prostaglandin G_2 ; TX, thromboxane; TXA_2 , thromboxane A_2 ; TXA_2R , thromboxane A_2 receptor; vWF, von Willebrand factor.

inflammation.^{258,259} In these situations, fibrinogen functions as a bridging molecule in cell-cell interactions.^{260,261} Fibrin and fibrinogen constitute a matrix that modulates cellular responses in a variety of cell types, including endothelial cells, epithelial cells, leukocytes, platelets, and fibroblasts. Cellular receptors that bind fibrinogen and fibrin include the integrins $\alpha_{\text{IIb}}\beta_3$, $\alpha_v\beta_3$, and $\alpha_5\beta_1$, and the cellular adhesion molecules intercellular adhesion molecule-1 and vascular endothelial cadherin.²⁶²⁻²⁶⁵

Fibrin clot-based assays have been extensively used in the clinical diagnosis of bleeding disorders. Two in vitro plasma tests, the PT^{266,267} and the activated partial thromboplastin time (aPTT),²⁶⁸ segregate the coagulation process into tissue factor-initiated or surface contact processes, respectively. The aPTT, which initiates coagulation by the introduction of a foreign surface, only examines the biologic constituents intrinsic to plasma. This assay is sensitive to isolated or combined deficiencies of factor XII, HMWK, prekallikrein, factor XI, factor VIII, factor IX, factor X, factor V, prothrombin, and fibrinogen. The PT assay is based on initiating coagulation via an extrinsic source of tissue factor (thromboplastin). The PT assay is sensitive to isolated or combined deficiencies of factor VII, factor X, factor V, prothrombin, and fibrinogen. Although these in vitro clotting assays help establish a basis for hemostasis, abnormal test results are not always mirrored by human pathology associated with bleeding or thrombosis.

Fibrinolysis Proteins

Clot formation is integrated with clot dissolution (fibrinolysis). Fibrinolysis, the elimination of blood clots, has two types, primary fibrinolysis and secondary fibrinolysis. Whereas primary fibrinolysis is a normal body process, secondary fibrinolysis is the breakdown

of clots caused by a medicine, a medical disorder, or some other cause.

The biochemical mechanisms of clot dissolution center on fibrin-specific activation of plasminogen to plasmin. The key proteins involved are plasminogen, the plasminogen activators tissue plasminogen activator (t-PA) and urokinase plasminogen activator (u-PA), and the inhibitors (PAI-1, α_2 -antiplasmin, and TAFIa). Plasminogen is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation (Fig. 126.12).²⁶⁹ The process of plasminogen activation can occur through three distinct pathways: (1) the intrinsic activator system (analogous to the contact system of blood coagulation), (2) the extrinsic activators (t-PA and u-PA), and (3) an exogenous activator system involving pharmacologic agents (fibrinolytic drugs). The primary pathway used in vivo appears to be the extrinsic pathway. However, both the intrinsic as well as exogenous activator systems can play important roles in human disease.

t-PA and u-PA, secreted by the endothelium, have unique structures and properties that affect the specificity and rate of plasmin generation (see Fig. 126.12).²⁷⁰ After being generated, plasmin digests fibrin in a pattern that produces a collection of degradation products, including fragment X, fragment Y, and the core fragments, fragments D and E. The first step in degrading fibrin is the removal of the α chains, thus exposing the coiled coils. As these coils are cleaved, different sized fragments are released.²⁷¹ Fibrinogen is represented as a trinodular structure (D-E-D domains) with each E domain and D domain separated by a coiled coil domain. Upon formation of fibrin cross-links occur between alternating molecules of fibrin at the D domain (D=D). Plasmin degrades fibrin, releasing various sized fragments, the smallest of which is the D=D or D-dimer ($M_r = 180,000$). The largest of these fragments is XXD, X=D-E-D, with a mass of 595,000.^{272,273} Elevated levels of D-dimer are found in the blood of patients with various thrombotic and thrombolytic disorders.²⁷⁴

Fig. 126.11 SCHEMATIC REPRESENTATION OF WHOLE-BLOOD FIBRIN FORMATION. At the start of clot formation, thrombin simultaneously acts on fibrinogen (D-E-D) and FXIII. A portion ($\approx 40\%$) of FPA is released from fibrinogen, and an initial clot is formed from the complementary overlap of the exposed sites between the E and D domains of adjacent fibrin molecules. fXIIIa simultaneously cross-links adjacent D domains (D=D). Thus the initial soluble fibrin clot is composed of fibrinogen, fibrin, and $\gamma\text{-}\gamma$ dimers with FPB still attached. The initial clot is continuously acted on by thrombin, releasing the remaining FPA and some of the FPB to yield a final clot with the majority of FPB still attached. The released FPB is selectively acted on by a CPB (potentially thrombin-activatable fibrinolysis inhibitor a), which cleaves the C-terminal arginine to produce des-Arg FPB. The significance of this cleavage is still unclear. *CBP*, Carboxypeptidase B-like enzyme; *FPA*, fibrinopeptide A; *FPB*, fibrinopeptide B; *FXIII*, factor XIII; *FXIIIa*, activated factor XIIIa. (From Brummel KE, Butenas S, Mann KG: *An integrated study of fibrinogen during blood coagulation*. J Biol Chem 274:22862, 1999, with permission.)

These circulating fragments are cleared by other proteases or by the kidney and liver.

Inhibitors of the Fibrinolytic System

Plasminogen activation in blood is primarily inhibited by PAI-1, which targets u-PA and t-PA. PAI-1 also has a role in tissue remodeling by interfering with vitronectin-dependent processes of cell adhesion and migration.²⁷⁵ Congenital deficiency of PAI-1 is rare, with homozygous individuals displaying abnormal bleeding in response to trauma.²⁷⁶ Platelets contribute to the fibrinolytic process by binding t-PA and plasminogen, and supporting plasmin generation. Increased levels of plasma PAI-1 delay fibrin removal by shortening the functional lifetime of plasminogen activators, thereby shifting hemostasis to a more thrombotic state.²⁷⁷

TAFI is a plasma zymogen with homology to procarboxypeptidases A and B (see Fig. 126.12).^{55,278–280} Activation of TAFI yields the exopeptidase (TAFIa) with carboxypeptidase B-like substrate specificity. TAFIa catalyzes the removal of basic amino acids (arginine, lysine) from the COOH-termini of polypeptides. The activation of many of the cofactors and zymogens of the coagulation and fibrinolytic cascades results in the generation of functional proteins with COOH-terminus arginine or lysine residues. COOH-terminus lysine residues that appear in fibrin fragments degraded with plasmin have been identified as the major substrates for TAFIa. The physiologic activator of TAFIa is the thrombin–thrombomodulin complex, thus defining TAFIa as a coagulation-dependent activity.²⁸¹ Because TAFIa functions as an attenuator of fibrinolysis,⁵³ an adequate rate of TAFIa

generation appears critical for the stabilization of the blood clot. Plasmas with specific deficiencies in the coagulation pathway exhibit reduced rates of thrombin production, decreased levels of TAFIa, and premature clot lysis.^{257,282,283}

Fibrinolytic drugs are often given after a myocardial infarct or ischemic stroke to dissolve the fibrin clot blocking the coronary or cerebral artery. Fibrinolytic drugs are also used in massive pulmonary embolism. Antifibrinolytics, such as aminocaproic acid (ϵ -aminocaproic acid) and tranexamic acid, are used as inhibitors of fibrinolysis.

CONNECTIVITY AND DYNAMICS IN HEMOSTASIS

In the healthy state, the hemostatic system is relatively quiescent, with the vascular endothelial cells, the blood, and the extravascular tissue functioning to maintain fluidity. Blood platelets remain in a quiescent state because of the endothelial cell lining of the blood vessel being an active anticoagulant that secretes small molecules and enzymes. The endothelium also provides constituent anticoagulant proteins, which inhibit the blood coagulation system. These vascular anticoagulant systems are both passive and dynamic in nature, and function in cooperation with plasma components. The blood supplies pro- and anticoagulant proteins in the plasma and platelets, which contribute to the coagulation reaction. If the endothelium becomes damaged, the pro- and anticoagulant levels become imbalanced, and cells that should remain in the blood can leak through blood vessels into adjacent body tissue, which triggers a response. The dimensions of the response are relevant to the injury. The extravascular compartment and blood interact to rapidly produce a vigorous local

Fig. 126.12 SCHEMATIC OF FIBRINOLYTIC PROTEINS. *Plasminogen* is the inactive precursor of the enzyme plasmin, which is the primary catalyst of fibrin degradation. The domain structure of human plasminogen is represented by Kringle domains (K1–K5), a catalytic domain, and the arrows indicate the sites of proteolytic cleavage by plasmin, elastase, and plasminogen activators (t-PA and u-PA). Disulfide bonds are illustrated by -S-S-. The t-PA molecule is a serine proteinase and consists of an A and B chain. The A chain consists of a fibronectin finger-like domain, an EGF-like domain, and two kringle domains. The K2 domain and the finger domain of t-PA are involved in the binding of t-PA to fibrin. The B-chain of t-PA contains the active site catalytic triad. Single-chain t-PA is an efficient plasminogen activator in the presence of fibrin and is converted to the two-chain form by cleavage of the peptide bond between R²⁷⁵ and I²⁷⁶. This cleavage is performed primarily by the action of plasmin during fibrinolysis. *Single-chain u-PA* (sc-uPA) is a serine protease and is an ineffective catalyst. Plasmin or plasma kallikrein can hydrolyze the K¹⁵⁸–I¹⁵⁹ peptide bond, converting sc-uPA into the fully active two-chain form (two-chain urokinase-type plasminogen activator). u-PA is composed of an EGF domain (EGF), a single kringle domain, a connecting peptide region, and the serine protease-type catalytic domain. *Thrombin-activatable fibrinolysis inhibitor* (TAFI): Activation of TAFI (TAFIa) yields an exopeptidase with carboxypeptidase B-like substrate specificity. TAFIa delays fibrinolysis by cleaving COOH-terminus Arg (R) or Lys (K) residues made available as a consequence of partial plasmin digestion of the fibrin clot. Removing these residues attenuates the self-amplifying mechanism of fibrin-based plasmin formation wherein partial plasmin proteolysis of fibrin increases the number of binding sites (COOH-terminal lysines) available for efficient plasminogen activation. TAFI contains an activation peptide region and a carboxypeptidase domain. It is activated by the thrombin–thrombomodulin complexes (IIa/TM) and plasmin–glycosaminoglycan complexes (Plm/GAG) by hydrolysis of the R⁹²–A⁹³ bond. EGF, Epidermal growth factor; *sc-uPA*, Single-chain u-PA; *t-PA*, tissue plasminogen activator; *u-PA*, urokinase plasminogen activator.

coagulation response, which attenuates blood loss and initiates the vascular repair process in four phases: initiation, propagation, termination, and elimination and fibrinolysis.^{284–286}

Initiation

If vascular injury occurs, a measured response is triggered in that the extent of damage regulates platelet and fibrin deposition. Activated platelets provide the membrane surfaces upon which coagulation enzymes can be anchored, assembled, and expressed. Therefore the activated platelet membrane provides both an initiating and limiting

component to the extent of a coagulation reaction.²⁸⁷ More vascular damage produces more anchored activated platelets, and more membrane allows the assembly of more coagulation enzymes, which ultimately results in increased fibrin formation.

When the vascular system is perturbed, the initial stages of the hemostatic response are triggered. The initial principal player is the extrinsic tenase complex (tissue factor–factor VIIa), which is composed of a cell membrane; tissue factor exposed by vascular damage or cytokine stimulation; Ca²⁺; and the serine protease plasma factor VIIa, which is already present in its active form at 1%–2% of the factor VII zymogen concentration^{53,288} (Fig. 126.13). Before binding to tissue factor, the plasma serine protease factor VIIa is essentially

Fig. 126.13 REGULATION OF THE DYNAMIC PROCOAGULANT RESPONSE. Initiation (A), propagation (B), and termination (C) of thrombin generation and the procoagulant response are illustrated. Four vitamin K–dependent complexes are shown: extrinsic tenase, intrinsic tenase, prothrombinase, and protein Case. The procoagulant response is regulated by the stoichiometric inhibitors AT and TFPI. AT inhibits thrombin, factor Xa, and factor IXa that are free in solution. TFPI inhibits both factor Xa and the factor VIIa–TF–factor Xa complex. APC generated from the protein Case complex (TM–thrombin [IIa]) inactivates factor Va and factor VIIIa by proteolysis of their heavy chains. Low levels of thrombin are required to initiate clot formation (initiation phase) and trigger the coagulation cascade response (propagation phase). The enzymes, cofactors, and inhibitors act together to generate a hemostatic response that can be divided into an initiation phase and a propagation and termination phase. During the initiation phase, factors X and IX are converted to their respective serine proteases factor Xa and factor IXa; low levels of thrombin are subsequently generated by factor Xa. This thrombin then can activate platelets and the procofactors factors V and VIII, which stimulate further thrombin generation during the propagation phase. Thrombin generation is attenuated by shutting down the initiation phase by means of the stoichiometric inhibitor of the extrinsic tenase complex, TFPI, followed by AT, which directly inhibits thrombin and factors Xa and IXa. APC, Activated protein C; AT, antithrombin; C, protein Case; TF, tissue factor; TFPI, tissue factor pathway inhibitor; TM, thrombomodulin. (From Mann KG: Coagulation explosion, Burlington, Vermont, 1997, Vermont Business Graphics, with permission.)

inert from the catalytic perspective and thus impervious to the abundant protease inhibitors in plasma.²⁸⁹ Factor VII also competes with factor VIIa for tissue factor binding, thus serving as a negative regulator that buffers the overall reaction.^{290,291} Factor VII-activating protease (FSAP) has also been shown to activate factor VII in the absence of tissue factor.^{292–294} The physiologic function of FSAP still is unclear, but most recently has been suggested to be involved in inflammation (see the review listed in the References²⁹⁵). The extrinsic tenase complex (tissue factor–factor VIIa) activates low levels of the zymogens factor X and factor IX to their respective serine protease enzymes factor Xa (≈ 10 pM) and factor IXa (≈ 1 pM).^{296,297} Factor X is the more efficient and abundant substrate.^{298,299}

The extrinsic tenase complex is under tight supervision by TFPI, which can bind both the complex and the product factor Xa (see Fig. 126.13).^{300,301} TFPI, present in low abundance in blood, is released from the vasculature by heparin.³⁰² If the initiating procoagulant stimulus is sufficient to overcome the level of this anticoagulant response, a threshold is exceeded and downstream complexes can be formed.

The limited amounts of factor Xa that escapes inhibition by TFPI and antithrombin bind to available membrane sites and can activate tiny amounts of prothrombin to thrombin (see Fig. 126.13).³⁰³ The time period in which factor Xa directly generates picomolar amounts of thrombin³⁰⁴ is referred to as the *initiation phase* of blood coagulation (Fig. 126.14). During the initiation phase, circulating blood cells

Fig. 126.14 SCHEMATIC OF THE DYNAMIC INTERACTION BETWEEN THE PROTEINS AND INHIBITORS OF FIBRINOLYSIS. Cross-linked fibrin formation is integrated with fibrin clot dissolution and degradation of its products. Two pathways are shown, intravascular fibrinolysis and extracellular matrix, separated by an endothelial cell layer. The enzymes (red circles), inhibitors (blue circles), zymogens (green boxes), and complexes (large yellow ovals) are illustrated in a simplified form to show this multicomponent process. The key proteins of the fibrinolytic system (left panel) are plasminogen, the plasminogen activator t-PA, PAIs, α_2 -AP and TAFI, and the transglutaminase FXIIIa. t-PA and plasminogen both bind to the fibrin surface, cross-linked by FXIIIa, where t-PA is an effective catalyst of plasminogen conversion to plasmin. Initially, plasmin proteolysis of fibrin generates new COOH-terminus lysine residues, which function as higher affinity binding sites for plasminogen, setting up an amplifying loop of plasminogen activation. Formation of activated TAFIa results in removal of the plasmin-generated COOH-terminus lysine residues, thus suppressing the rate of fibrin lysis. Opposing these events are antifibrinolytic mechanisms. Soluble and cross-linked α_2 -AP complexes with plasmin, rendering it inactive. PAI rapidly reacts with t-PA, thus reducing the concentration of the plasminogen activator. Fibrin degradation occurs by plasmin cleavage at the D-E-D domains of fibrin polymers to yield a variety of polymers as illustrated (for a definition of the D-E-D domain, see Fig. 126.11). Plasminogen can cross the endothelial cell layer and become converted to plasmin by the u-PA (right panel). Plasmin can convert latent MMPs (pro-MMPs) to their active form (MMPs). MMPs themselves can act in a positive-feedback mechanism to convert pro-MMPs to more MMPs, which ultimately degrade the extracellular matrix. Plasmin-mediated effects are inhibited by PAI and α_2 -AP. MMP-mediated effects are inhibited by TIMPs. α_2 -AP, α_2 -Antiplasmin; ECM, extracellular matrix; FXIIIa, activated factor XIII; MMP, matrix metalloproteinase; PAI, plasminogen activator inhibitor; t-PA, tissue plasminogen activator; TAFI, thrombin-activatable fibrinolysis inhibitor; TIMP, tissue inhibitors of metalloproteinases; u-PA, urokinase plasminogen activator.

and procoagulant proteins are activated,³⁰⁵ the procoagulant elements necessary for the full procoagulant response are generated, and a preliminary fibrin network is formed.³⁰⁶ Although this process is inefficient, this initial thrombin is essential for the acceleration of the process by serving as the activator of platelets through cleavage of protease-activated receptors (PAR1 and PAR4)³⁰⁷ and the activation of the procofactors factor V and factor VIII.¹²⁹ Thrombin also activates factor XI to factor XIa,¹³⁰ initiating the accessory pathway that enhances factor IX activation.³⁰⁸

In analyses of tissue factor–induced activation of the coagulation process in whole blood, the initial period of thrombin generation (based on levels of thrombin–antithrombin complexes) illustrates that most catalyst formation occurs before fibrin clot formation (see Fig. 126.14).³⁰⁵ The small amount of thrombin that is generated during the initiation phase is from the extrinsic factor tenase and is able to activate platelets,³⁰⁹ factor XIII,³¹⁰ factor V,³¹¹ and factor VIII³¹², and release some fibrinopeptide A and fibrinopeptide B²⁶³ from fibrinogen to form fibrin. Less than 2% of the final thrombin produced is required to achieve the activation of these catalysts produced in blood to form the initial clot. However, activation of the catalysts is essential to generate the bulk of thrombin (≈95%) that is formed during the propagation phase of the reaction. The aggregated platelets and fibrin resulting from thrombin formation are the principal components of the initial vascular plug formation. It has recently been shown that a fraction of red blood cells (≤1%) provide phosphatidyl serine–associated membrane receptors that can support the procoagulant complexes. These red blood cells are responsible for approximately 30% of all thrombin formation.³¹³

After cofactor factor VIIIa is formed, it combines on activated platelets with the serine protease factor IXa that was generated by the tissue factor–factor VIIa complex to form the intrinsic tenase complex (see Fig. 126.13). This complex is the major activator of factor X; it is 50-fold more efficient than factor VIIa–tissue factor in catalyzing factor X activation.^{299,314} The extrinsic tenase complex is under the control of TFPI.^{315,316} In the absence of factor VIII (hemophilia A) or factor IX (hemophilia B), the intrinsic tenase complex cannot be assembled; thus no amplification of factor Xa generation occurs. This is the principal defect observed in hemophilia^{317,318}; initial production of factor Xa by the tissue factor–factor VIIa complex is inadequate to efficiently stem blood flow.

Factor Xa combines with factor Va on the activated platelet membrane surfaces at specific receptor sites to form the prothrombinase complex; the principal generator of thrombin (see Fig. 126.13).^{319,320} This process serves as a major amplification loop of blood coagulation. The factor IXa and factor Xa constituent of prothrombinase and the intrinsic tenase complex are protected from inhibition by antithrombin and other plasma inhibitors when in the complexed form.

Propagation

When a sufficient stimulus is provided to overcome the antagonist–inhibitor threshold, the accumulating mass of activated platelets will support increasing intrinsic tenase and prothrombinase complex formation on their surfaces through specific platelet receptors, and the local inhibitor concentrations are overwhelmed (see Fig. 126.13). These platelet-bound catalysts execute the propagation phase of the reaction, during which massive amounts of thrombin are produced.³²¹ This phase of thrombin generation continues independent of the initially presented tissue factor as long as there is a continuous supply of blood to deliver new plasma procoagulant reactants, platelets, and fibrinogen to the site of perforation in the vascular endothelium.

Essential to the formation of the prothrombinase complex is the generation of factor Xa. Factor Xa is a unique regulatory enzyme in that it is formed through both the intrinsic tenase and the extrinsic tenase complexes. Under normal conditions, the concentration of factor Xa is the rate-limiting component of the prothrombinase complex. The other components of the complex, platelets (membrane

surface-binding sites), and the cofactor (factor Va) are activated rapidly to produce a surplus that is ready for action.³¹⁹ The coagulation mechanism can become sensitive to factor V or platelets when confronted with congenital deficiencies, thrombocytopenia, platelet pathology, or pharmacologic interventions.^{322,323}

The initial factor Xa is generated via the tissue factor–factor VIIa complex during the initiation phase. Additional factor Xa is then generated by the intrinsic tenase complex (factor IXa–factor VIIIa–membrane–Ca²⁺). Initially, the concentration of the factor VIIa–tissue factor complex is higher than the concentration of the factor VIIIa–factor IXa complex, which requires activation and assembly. As time progresses, the contribution of the intrinsic tenase complex to factor Xa generation exceeds that of the extrinsic tenase.³²⁴ The intrinsic tenase complex is kinetically more efficient and activates factor X at a 50–100-fold higher rate than the extrinsic tenase complex.^{299,325,326} The burst of factor Xa that is generated overcomes the levels of factor Xa inhibitors, such as TFPI, and achieves maximal prothrombinase activity and propagation of the procoagulant response.^{162,315} The bulk of thrombin (≈95%) is formed during the propagation phase after fibrin clot formation.^{305,327} Without the intrinsic tenase complex being formed, as occurs in hemophilia A or B, factor Xa is not generated in levels sufficient to produce the propagation phase of thrombin generation.^{317,328}

Because the presentation of a clot in a low tissue factor model depends on the generation of 10–30 nM thrombin,^{305,327} at high tissue factor concentrations, tissue factor–factor VIIa generates factor Xa rapidly and masks the contribution of the factor VIIIa–factor IXa complex in clot end point assays. This is the case for the PT^{266,267} in which the concentration of the initiator, thromboplastin (tissue factor and phospholipid), is chosen to produce a clot time of 11–15 seconds. This corresponds to a tissue factor concentration over 20 nM. In our whole-blood studies, a concentration of 5 pM tissue factor is used, which produces a clot time in the range of 5 minutes.^{305,327} Therefore in hemophilia A, the PT does not reflect a change in clot time in this well-established hemorrhagic disease. The major defect occurs after clot time, during the propagation phase of thrombin generation, which is dramatically decreased.^{317,321,329}

Termination

When blood flow has ceased because of the formation of a fibrin–platelet “dam,” the overwhelming concentration of inhibitors present in blood, including TFPI and antithrombin, heparin cofactor II, α₂-macroglobulin, α₁-antitrypsin, and protein C inhibitor, can “catch up” and inhibit the various reactants as they dissociate from their respective complexes (see Fig. 126.13).^{150,315,330–332}

In the intact vasculature surrounding the growing thrombus, procoagulant enzymes and cofactors escaping the wound site are rapidly quenched under normal circumstances by the stoichiometric and dynamic inhibitory systems of blood in cooperation with elements of the vascular endothelium. The free serine proteases (thrombin, factor IXa, and factor Xa) of the coagulation system in the plasma environment are rapidly inhibited by the surplus of antithrombin molecules. The reaction is accelerated by the interaction of antithrombin with heparan sulfate proteoglycans presented constitutively on the surface of vascular endothelial cells.³³³

Any thrombin escaping from the wound site may bind resident thrombomodulin molecules constitutively expressed by vascular endothelial cells. Thrombomodulin-bound thrombin is converted from a procoagulant enzyme to an anticoagulant enzyme.^{334,335} The thrombin–thrombomodulin complex (protein Case) activates protein C, which in turn downregulates the intrinsic factor tenase and prothrombinase procoagulants by cleaving factor VIIIa and factor Va, respectively. The rates of APC inactivation of factors Va and VIIIa are enhanced by protein S. TAFI is also activated by protein Case and serves to delay clot lysis (see reviews listed in the References^{53,336}). Cleavage of factor Va by APC and inhibition of thrombin generation also reduces thrombin–thrombomodulin–mediated TAFI activation.³³⁷

Fig. 126.15 SCHEMATIC OF THE DYNAMIC EVENTS DURING TISSUE FACTOR-INITIATED BLOOD COAGULATION. A cross-section of a blood vessel showing the luminal space, endothelial cell layer, and extravascular region is presented at the site of a perforation. The blood coagulation process in response is depicted in four stages. *Extrinsic tenase* complex, TF•VIIa; *prothrombinase* complex, Xa•Va; *intrinsic tenase*, VIIIa•IXa; AT–endothelial cell HS proteoglycan complex bound to thrombin or FXa, HS•AT•(IIa or Xa); protein C bound to TM–thrombin, TM•IIa•PC. *Stage 1.* Perforation results in delivery of blood, and with it circulating factor VIIa and platelets, to an extravascular space rich in membrane-bound TF. Platelets adhere to collagen and von Willebrand factor associated with the extravascular tissue, and TF binds factor VIIa, initiating the process of factor IX and factor X activation. Factor Xa activates small amounts of prothrombin to thrombin, which activates more platelets and converts factor V and factor VIII to factor Va and factor VIIIa. *Stage 2.* The reaction is propagated by platelet-bound intrinsic tenase and prothrombinase, with the former being the principal factor Xa generator. Initial clotting occurs and fibrin begins to fill in the void in cooperation with activated platelets. *Stage 3.* A barrier composed of activated platelets laden with procoagulant complexes and enmeshed in fibrin scaffolding is formed. The reaction in the now filled perforation is terminated by reagent consumption, attenuating further thrombin generation, but functional procoagulant enzyme complexes persist because they are protected from the dynamic inhibitory processes found on the intravascular face. *Stage 4.* View downstream of the perforation. Enzymes escaping from the plugged perforation are captured by antithrombin–heparan complexes, and the protein C system is activated by residual thrombin binding to endothelial cell TM, initiating the dynamic anticoagulant system. These intravascular processes work against occlusion of the vessel despite the continuous resupply of reactants across the intravascular face of the thrombus. AT, Antithrombin; PC, protein C; HS, heparan sulfate; TF, tissue factor; TM, thrombomodulin. (From Orfeo T, Butenas S, Brummel-Ziedins KE, Mann KG: *The tissue factor requirement in blood coagulation*. J Biol Chem 280:42887, 2005, with permission.)

When operating properly, this system of blood leakage attenuation displays the appropriate level of procoagulant required to obstruct blood loss but is precluded from systemic activation of the coagulation system. The converse to hemostasis occurs when the damaging insult for the vasculature is internal to the vessel lumen.³³⁸

Elimination and Fibrinolysis

The hemostatic or pathologic thrombus is structurally composed of aggregated platelets and cross-linked fibrin. The steps in thrombin generation of a cross-linked fibrin clot are shown diagrammatically in Fig. 126.11. Other plasma proteins and blood cells are also trapped within the clot. Clot formation is integrated with clot dissolution by plasmin to maintain hemostatic balance. The plasminogen system has two roles: t-PA generates plasmin at the fibrin surface and governs fibrin homeostasis, and u-PA binds to a cellular u-PA receptor (u-PAR) and generates pericellular plasmin, which plays an important role in tissue remodeling and cellular migration.^{339,340} The latter function is, to a great extent, mediated by plasmin activation of matrix metalloproteinases, which degrade ECM. t-PA and u-PA are secreted by vascular endothelial cells^{341,342} and are regulated by cellular cytokines and components produced during the clotting cascade, including thrombin.

In the absence of fibrin, t-PA is a poor enzyme.^{343,345} However, both t-PA and plasminogen bind to the fibrin surface with a resulting 100-fold enhancement in plasminogen activation. Thus t-PA activation of fibrinolysis is primarily initiated by and localized to fibrin.^{343,345} The digestion of fibrin by plasmin³⁴⁶ is seen in Fig. 126.14 and further described under the section **Fibrinolysis Proteins**.^{274,346–349}

Fibrinolysis is regulated primarily by PAI-1,^{350,351} PAI-2,³⁵² α_2 -antiplasmin, and TAFI.³⁵³ The antagonism between PAI-1 and the plasminogen activators u-PA and t-PA provides a threshold response of the fibrinolytic process in much the same way as the procoagulant–anticoagulant balance provides an activation threshold for the clotting process.^{354–357} α_2 -Antiplasmin is the primary inhibitor of plasmin.^{358–360} Plasmin, when bound through its lysine binding sites to fibrin, reacts more slowly with α_2 -antiplasmin than when free in solution because α_2 -antiplasmin interacts with plasma plasmin by binding to the lysine binding sites.^{358–362} In contrast, α_2 -antiplasmin, bound covalently by factor XIIIa to the A α chain of fibrin, blocks plasmin binding and appears to decrease plasminogen activation.³⁶³ TAFIa functions in vitro as an antifibrinolytic factor by suppressing the positive-feedback pathway of fibrinolysis.^{255,256,337}

The elimination phase begins the process of tissue repair by dissolving the fibrin–platelet clot generated in the earlier phases of hemostasis. The damaged vascular tissue not only requires plasmin to clear the fibrin clot, but also to initiate removal of damaged tissue to allow for cell migration into the injured area.^{364,365} Plasmin activates a variety of matrix metalloproteinases that degrade subendothelial matrix components and extricate the damaged tissue.^{365,366} These processes mark the beginnings of the final stages of the hemostatic response, repair, and regeneration.

The importance of the tight regulation of these processes is perhaps best illustrated by malfunctions of the hemostatic response. An inappropriate response can lead to one of two opposing but equally undesirable outcomes. Failure to form a sufficient hemostatic plug to arrest blood flow subsequent to vascular injury can result in pathologic hemorrhage. Excessive clot formation or failure to efficiently lyse a clot may result in thrombosis with consequent vascular obstruction. Under normal circumstances, the vascular endothelium together with the aforementioned positive- and negative-feedback loops within the procoagulant pathways prevent these negative outcomes by actively controlling the coagulation process until a triggering stimulus of sufficient magnitude threatens vascular integrity (Fig. 126.15). Initiation of the procoagulant response also initiates the fibrinolytic response simultaneously with repair and regeneration processes.

FUTURE DIRECTIONS

This chapter describes the process of blood coagulation (extrinsic and intrinsic pathway) by dividing it into sections based on procoagulant, anticoagulant, and fibrinolytic enzymes, cofactors, and inhibitors in the overall process of fibrin formation and fibrin dissolution. When all of the players are present, the overall process of blood coagulation and fibrinolysis is best described as a dynamic threshold-limited, complex, intertwined process that together promotes hemostasis.

ACKNOWLEDGEMENTS

We the authors would like to thank Matthew Gissel in the preparation of this chapter. The authors were supported by the NIH-DOD TACTIC study 1-UM-1-HL120877-2, the Systems Biology program ARO-W911NF-10-1-0376, and by the United States Naval Health Research Center contract W911QY-15-C-0027.

REGULATORY MECHANISMS IN HEMOSTASIS

James A. Huntington and Trevor P. Baglin

MAIN POINTS

- Hemostasis and thrombosis result from the localized production of thrombin.
- Thrombin is the final protease generated in the coagulation cascade of zymogen activation events.
- The regulation of hemostasis relies on maintaining the lumen of blood vessels (intravascular space) as an anticoagulant environment and the extravascular space as a procoagulant environment.
- The principal drivers of coagulation in the extravascular space are tissue factor (TF) and collagen.
- The procoagulant activity of von Willebrand factor (vWF) is controlled through limited proteolysis by ADAMTS13.
- Tissue factor pathway inhibitor (TFPI) limits the initiation of the coagulation cascade.
- The protein C pathway regulates propagation of the thrombin explosion.
- Antithrombin (AT) is a serpin (serine protease inhibitor) that neutralizes coagulation proteases in the absence and presence of heparin-like molecules.
- Hemostasis reflects the dynamic balance between coagulation and fibrinolysis; excessive fibrinolytic activity relative to thrombin generation may compromise hemostasis.

KEY EVENTS IN BLOOD COAGULATION

It is essential that blood remains fluid within the circulation, but that it clots rapidly when there is loss of vascular integrity. Hemostasis refers to the formation of a blood clot to limit blood loss into the extravascular space or hemorrhage outside the tissues. The term thrombosis refers to pathologic clot formation within the lumen of a blood vessel that impedes blood flow.

Blood coagulation is the result of a biologic amplification system in which plasma zymogens of serine proteases are converted into active enzymes (Fig. 127.1).^{1,2} Enzyme activation occurs in a sequential manner and is dependent on the assembly of enzyme–cofactor complexes on phospholipid membranes, principally on the surface of activated platelets (Fig. 127.2).³ The final event in the amplification process is the formation of the effector enzyme, thrombin. At each step in this process, specific protease inhibitors control the amount of enzyme generated while simultaneous regulatory mechanisms control the availability of phospholipid and the cofactor-dependent assembly of enzymatic complexes on the membrane of activated platelets.

Hemostasis is triggered by the exposure of extravascular tissue to certain protein and cellular components of blood. Nonendothelial cells express TF on their surface and collagen is present in the extracellular space. TF binds factor VIIa to initiate the coagulation cascade, and collagen binds platelets and initiates their activation. These events contribute synergistically to produce a large amount of thrombin from a small trigger.⁵ Thrombin ultimately converts soluble fibrinogen into an insoluble fibrin clot to form an impermeable platelet–fibrin barrier. This barrier is rapidly stabilized by platelet-dependent clot retraction and thrombin-mediated fibrin crosslinking

(through activation of factor XIII) and suppression of the fibrinolytic system (through activation of thrombin-activatable fibrinolysis inhibitor [TAFI]).

Both hemostasis and thrombosis are dependent on the action of thrombin. In order to maintain blood in a fluid state in the circulation but permit rapid coagulation when a blood vessel is ruptured it is necessary to regulate thrombin formation so that it occurs rapidly and is limited to sites of vascular injury. The regulation of thrombin generation is both spatial (compartmentalization) and temporal (kinetic). The traditional paradigm of blood coagulation is that hemostasis and thrombosis are inseparable, primarily due to their shared dependence on thrombin. There is now emerging evidence of dissociation between hemostasis and thrombosis, potentially due to subtle differences in the triggering or propagation of thrombin generation.^{6,7} However, the most important consideration is that hemostasis and thrombosis are distinct from a spatial perspective (extravascular versus luminal). Consequently, regulation of hemostasis relies principally on maintaining the lumen of blood vessels (intravascular space) as an anticoagulant environment and the extravascular space as a procoagulant environment.

THE ANTICOAGULANT INTRAVASCULAR SPACE

Blood Flow

The importance of blood flow as a regulatory mechanism is apparent from observations of arterial and venous thrombosis. The arterial system is a high-pressure, high-flow system and thrombosis typically occurs only in the presence of endothelial injury, for example atherosclerosis with plaque rupture or vasculitis. In contrast the venous system is a low-pressure, low-flow system, and venous thrombosis usually occurs in the absence of endothelial damage. Sluggish flow resulting from immobility or pooling of venous blood in valve pockets is an important contributory factor to venous thrombosis. Similarly, thrombus formation is common in atrial fibrillation where lack of coordinated contraction of the atria results in irregular blood flow (stasis) in the left atrial appendage.

Blood Components

Although the potential to convert from a liquid to a solid gel is an inherent property of blood, the components responsible for the phase change circulate in inactive states. The platelets are plate-like and inactive, with a membrane unable to bind clotting proteins and with receptors in inactive conformations. The proteases are all in inactive zymogen states, requiring cleavage of an activation peptide and the subsequent zymogen-to-protease conformational change typical of the chymotrypsin family of serine proteases.^{8,9} A possible exception to this is the small fraction of factor VII that circulates as factor VIIa; however, factor VIIa is still zymogen-like until it binds to TF to complete its activating conformational change.¹⁰ Clotting proteases that escape from the site of a clot into the blood are inhibited by a reservoir of inhibitory activity provided by a high (2.3 μM) concentration of the serpin, AT.¹¹

Fig. 127.1 THE HEMOSTATIC NETWORK OF ACTIVATION AND INHIBITION EVENTS. Clotting is initiated by the exposure of the subendothelial space containing tissue factor (TF)-expressing cells and collagen. TF binds to factor (f)VIIa (**boxed**) to form the extrinsic Xase complex. The fXa that is generated binds to fVa to form the prothrombinase complex, which then converts prothrombin to thrombin (fIIa). fIIa activates platelets through cleavage of PARs, converts fibrinogen to fibrin, activates fXIII, which cross-links the fibrin, and stimulates its own formation through activation of fV, fVIII and fXI. Inhibitors of coagulation include tissue factor pathway inhibitor (TFPI), antithrombin (AT) and activated protein C (APC) (**bold**).

Endothelium

Tight junctions between endothelial cells prevent exposure of blood components to the extravascular space, and their luminal surfaces are carpeted with negatively charged glycoproteins and proteoglycans that repel circulating platelets and keep them inert.¹² Other important regulators of platelet activation are secreted by endothelial cells: nitric oxide (NO) or endothelium-derived relaxing factor, prostacyclin (Pgl₂), and the ectonucleotidase, NTPDase-1 (CD39). NO and Pgl₂ are constitutively expressed, but secretion is stimulated by mechanical stimuli such as cyclic stretch and shear stress. These molecules regulate platelet activation by stimulation of inhibitory signaling pathways within platelets. NTPDase-1 suppresses platelet activation by hydrolyzing the platelet agonist ADP. Endothelial cells also express potent inhibitors of the clotting proteases, including TFPI, thrombomodulin, and glycosaminoglycans (GAGs), such as heparan sulfate and dermatan sulfate. TFPI directly inhibits the initiating complex of TF–factor VIIa–factor Xa; thrombomodulin binds to thrombin and converts it from a procoagulant into an efficient activator of the protein C pathway; and GAGs bind to and activate endogenous protease inhibitors (serpins), AT, protease nexin-1 (PN-1), and heparin cofactor II (HCII). GAG-associated AT inhibits factor IXa, factor Xa and thrombin, whereas PN-1 and HCII are specific for thrombin.

THE PROCOAGULANT EXTRAVASCULAR SPACE

Tissue Factor and Collagen

The principal drivers of coagulation in the extravascular space are TF and collagen.^{13–15} TF binds and allosterically activates factor VIIa to

generate sufficient factor Xa for a small amount of thrombin to be formed (Fig. 127.1). This thrombin can activate platelets by binding to GpIb α and cleaving protease-activated receptor (PAR) 1, thereby exposing phosphatidylserine on the platelet surface and setting the stage for the thrombin explosion.¹⁶ The principal procoagulant activity of collagen is to bind to platelet receptors, thereby tethering and accumulating platelets at the site of vascular damage. Exposed collagen also binds vWF (via its A3 domain) inducing a conformational change in the vWF A1 domain that enhances its affinity for GpIb α and leads to platelet adhesion and activation. The platelets contribute to hemostasis first by forming a platelet plug, through adhesion and aggregation, and then by contributing to coagulation by providing a catalytic surface that enhances thrombin generation. This catalytic activity, known as the platelet procoagulant response, results from exposure of negatively charged phospholipid (phosphatidylserine) on the platelet surface during the platelet activation process. These activated platelets are the structural foundation for the assembly of the macromolecular intrinsic tenase (factor VIIIa–factor IXa) and prothrombinase (factor Va–factor Xa) complexes (Fig. 127.2). These homologous enzymatic complexes are the “engines” of blood coagulation and are required for generating sufficient quantities of factor Xa and thrombin to form a stable thrombus. The anionic membrane helps to capture, orient and approximate the enzymes, cofactors and substrates involved in the biological amplification process of thrombin generation. The activation of factor X by the intrinsic tenase complex is 10⁹-fold faster than that by factor IXa alone, whereas the conversion of prothrombin to thrombin by the prothrombinase complex is 10⁶-fold faster than that by factor Xa alone (in the absence of membranes).¹⁷ The structure of the prothrombinase complex from the venom of the Australian eastern brown snake (*Pseudonaja textilis*) was recently published, allowing the generation of a detailed model

Fig. 127.2 ASSEMBLY OF THE CRITICAL HEMOSTATIC COMPLEXES OCCURS ON THE SURFACE OF SUBENDOTHELIAL CELLS AND PLATELETS. (A) All extravascular cell types express tissue factor (TF) on their surfaces so that clotting is initiated when they come into contact with blood. The factor VIIa–TF complex can activate factor VII, factor IX and factor X. The factor Xa created at this stage is thought to activate a small amount of thrombin (IIa) from prothrombin (II). (B) Thrombin can then bind to the platelets via the receptor GPIIb α and cleave protease-activated receptor (PAR) 1 to scramble the membrane bilayer and expose phosphatidylserine (red surface). The phosphatidylserine-rich surface of the activated platelet binds the circulating procofactors, factor VIII and factor V with high affinity. Thrombin activates these cofactors and continues to cleave PARs. (C) Activated platelets now serve as the template for the formation of the two “engines” of hemostasis, the intrinsic Xase complex (factor VIIIa and factor IXa) and the prothrombinase complex (factor Va and factor Xa), leading to the thrombin explosion. (Adapted from Huntington J: *Structural insights into the life history of thrombin*. In Tanaka K, Davie E, Ikeda Y, et al, editors: *Recent advances in thrombosis and hemostasis*, Japan, 2008, Springer, p 80–106,⁴ with permission.)

of the human orthologue.^{18,19} The components of the tenase and prothrombinase complexes are similar in sequence and structure, and it has always been assumed that they assemble in an analogous manner. However, how the very different substrates of factor X and prothrombin bind to their respective complexes has yet to be resolved.

THE REGULATORS OF COAGULATION

ADAMTS13

Platelet adhesion is an early event in hemostasis and is initiated primarily through vWF, which acts as a molecular bridge between exposed collagen and the GPIb/IX/V receptor on the platelet membrane.²⁰ vWF, a multidomain protein that forms large disulfide-linked multimers, is secreted from endothelial cells in a latent form that is unable to bind platelets. Binding to exposed collagen via the A3 domain in environments with high shear stress causes vWF to partially unfold, exposing the binding site for platelet glycoprotein receptor GPIb α , which is located in the A1 domain (Fig. 127.3A).²¹ The ease of unfolding, and therefore the procoagulant activity, is related to the size of the multimers, and this in turn is regulated by the multidomain metalloprotease ADAMTS13 (vWF-cleaving protease). Although ADAMTS13 circulates in a constitutively active state, its ability to cleave vWF is dependent on the unfolding of the A2 domain that harbors the scissile bond, Tyr¹⁶⁰⁵–Met¹⁶⁰⁶. Cleavage of ultralarge multimers of vWF by ADAMTS13 reduces the capacity of vWF to initiate platelet adhesion and spontaneous platelet aggregation. The importance of this regulatory mechanism is highlighted by the microvascular thrombosis that characterizes thrombotic thrombocytopenic purpura (TTP), a disorder associated with deficiency of ADAMTS13.²²

Tissue Factor Pathway Inhibitor

TFPI is an endogenous inhibitor of the extrinsic Xase complex.²³ It is expressed by endothelial cells in α and β isoforms generated by alternative splicing of its premessenger RNA (Fig. 127.3B). The α form is composed of three Kunitz domains (K1, K2, K3) followed by an unstructured basic C-terminal region. The first and second Kunitz domains inhibit factor VIIa and factor Xa, respectively. Inhibition is thought to be a two-step process with binding of factor Xa to K2 followed by binding of K1 to factor VIIa-TF. The third Kunitz domain does not possess inhibitory activity but binds to protein S, and the basic C-terminus binds to cell surface GAGs. The β -isoform consists of the first and second Kunitz domains and a glycoposphatidylinositol (GPI)-anchor on the C-terminus that tethers it to the surface of the endothelial cell that produced it. Endothelial cells secrete both α - and β -isoforms, but platelets only produce the soluble α isoform. The basic C-terminal tail of the α isoform has been shown to bind to an acidic stretch on factor Va that has been activated by factor Xa and on the partially activated factor V that is released from platelets.²⁴ However, that acidic stretch is missing in thrombin-activated factor Va, so the relevance of this interaction in normal clotting is unclear. Protein S binding to the K3 domain helps to localize TFPI α to cell surfaces and thus effects a cofactor activity, enhancing the rate of inhibition of factor Xa by 90-fold.²⁵

Serpins

The principal inhibitor of the coagulation proteases is the serpin, AT, also known as SERPINC1 and previously as ATIII.¹¹ Like all other members of the serpin family of protease inhibitors, AT utilizes a mousetrap-like mechanism whereby the protease (mouse) takes a bite of the reactive center loop (cheese), and before the protease can disengage, the serpin (trap) releases its stored energy through

a conformational change (snap) that crushes the protease.²⁶ AT circulates at about 2.3 μ M and acts to mop up luminal thrombin and factor Xa. A fraction of AT is associated with heparan sulfate on vascular endothelial cells, where it helps to confer an anticoagulant environment to intact vessels. Heparan sulfate binding also activates AT roughly 1000-fold toward its main targets, thrombin, factor Xa, and factor IXa. This is indeed how the structurally related GAG heparin asserts its therapeutic anticoagulant effect. About one-third of the chains of medicinal heparin (much less for heparan sulfate) contain a pentasaccharide sequence that binds AT with high affinity and induces a conformational change in AT. Low-molecular-weight heparins, including the synthetic pentasaccharide fondaparinux, accelerate inhibition of factor IXa and factor Xa, but have almost no effect on thrombin inhibition. This is because thrombin is insensitive to the conformational change in AT conferred by heparin binding, and instead requires long chains composed of at least 18 saccharide units to “bridge” AT to thrombin.²⁷ Factors IXa and Xa can also be bridged, but this is a secondary effect to the allosteric activation by heparins, and requires longer heparin chains than those needed for thrombin (36 or more saccharide units in length).²⁸ Other serpins play relatively minor roles in regulating clotting proteases, including heparin cofactor II (HCII or SERPIND1), which inhibits thrombin and is activated by dermatan sulfate and heparin; protease nexin-1 (PN-1 or SERPINE2), which is a specific thrombin inhibitor and is only found on cell surfaces bound to GAGs; and protein C inhibitor (PCI or SERPINA5), which is a promiscuous inhibitor of coagulation proteases and can be activated by GAGs to inhibit thrombin, factor Xa, factor XIa and the TF–factor VIIa complex.²⁹ The structures of most of these recognition complexes have been solved by x-ray crystallography.

Protein C Pathway

Protein C is activated by thrombin bound to thrombomodulin on the surface of endothelial cells.³⁰ Activation is more efficient when protein C binds to the endothelial cell protein C receptor (EPCR) via its Gla domain.³¹ Activated protein C (APC) is a physiologic anticoagulant that down-regulates thrombin generation by cleaving and inactivating factor Va and factor VIIIa, the cofactors of the prothrombinase and intrinsic Xase complexes, respectively; protein S acts as a cofactor for APC-mediated inactivation of factor Va and factor VIIIa by helping target APC to the negatively charged surface of activated platelets.³² Deficiency in protein C results in thrombophilia and its complete absence is associated with purpura fulminans.³³ The most common thrombophilic mutation is the Leiden mutation in factor V that reduces the rate of factor Va inactivation by APC.³⁴ Conversely, excessive APC activity is associated with bleeding.³⁵

Fibrinolysis

Fibrin is a key component of the hemostatic clot and is the primary target for plasmin, the effector protease of the fibrinolytic system. During healing of an injured vessel, the thrombus is lysed by plasmin. Plasmin is generated by plasminogen activators, principally tissue plasminogen activator (tPA). It is essential that tPA and plasmin activity are regulated to prevent hyperfibrinolysis.³⁶ The principle inhibitors of these enzymes are the serpins plasminogen activator inhibitor 1 (PAI-1) and antiplasmin. In addition, during hemostasis thrombin down-regulates fibrinolytic activity through activation of TAFI. However, hyperfibrinolysis may occur if there is excessive tPA or plasmin. Dysregulation and consequent hyperfibrinolysis occur in disseminated intravascular coagulation (DIC), liver disease, nephrotic syndrome and with some metastatic tumors. Very rarely, heritable deficiencies of PAI-1 or antiplasmin produce hyperfibrinolysis and a bleeding tendency. In addition, normal fibrinolysis may contribute to bleeding when there is inadequate thrombin generation, as in hemophilia.³⁶

Fig. 127.3 PRINCIPAL REGULATORS OF HEMOSTASIS. (A) von Willebrand factor (vWF) is a multidomain protein that circulates as large disulfide-linked multimers. A schematic of the monomer is shown in its latent state (*top*), where the platelet receptor binding site (GpIb) on the A1 domain and the ADAMTS13 cleavage site in the A2 domain are obscured. Binding of the A3 domain to collagen (*green cylinder*) in a high shear environment (*flow*) unfolds the A2 domain (*red*) exposing both cryptic sites: GpIb site (*yellow*) and ADAMTS13 cleavage site (*lightning bolt*). (B) The alpha and beta isoforms of tissue factor pathway inhibitor (TFPI) are shown (*schematics*). The alpha form is the predominant circulating form, and is composed of three Kunitz domains (K1, K2, and K3) and a basic C-terminus. K1 inhibits factor VIIa and K2 inhibits factor Xa. The beta isoform is devoid of the noninhibitory K3 domain and basic region, and ends with a C-terminal glycosylphosphatidylinositol (GPI)-anchor (*anchor*). This form is exclusively found on cell surfaces. (C) Serpins inhibit thrombin (IIa) and other serine proteases, often accelerated by the presence of endothelial cell glycosaminoglycans (GAGs). Inhibition leads to conformational changes in both the serpin and the protease, and in the case of AT and thrombin, results in release from GAGs for receptor-mediated clearance. (D) Endothelial cells also express the transmembrane protein thrombomodulin (TM), composed of six epidermal growth factor-like (EGF) domains. EGF domains 5 and 6 bind thrombin and support activation of protein C (PC). EPCR binding to the Gla domain of PC accelerates the reaction, and the presence of a chondroitin sulfate (CS) moiety on thrombomodulin increases its binding affinity for thrombin. CLINICAL APPROACH TO THE PATIENT WITH BLEEDING OR BRUISING

Catherine P.M. Hayward

Bruising and bleeding problems are common reasons for a hematology referral.¹ The management of an acute bleed (e.g., life-threatening hemorrhage from an acquired factor VIII inhibitor, an anticoagulant drug, or a postpartum hemorrhage) should be the first priority because diagnostic test results are often not immediately available. However, most assessments of bruising and bleeding symptoms are not urgent.

The assessment of bleeding or bruising can be challenging because some individuals without bleeding problems often experience bleeding symptoms (e.g., bruising with trauma, nosebleeds).¹⁻³ Furthermore, most individuals referred for assessment of bleeding or bruising will have experienced some bleeding symptoms that may or may not reflect an underlying bleeding disorder.³ Because many individuals referred to a hematologist for an evaluation for a bleeding disorder will be diagnosed with a bleeding disorder, there is a high pretest probability for a bleeding disorder among such patients.³

Some referrals for bleeding disorder assessment are for asymptomatic problems (e.g., abnormal coagulation tests caused by vitamin K deficiency, evaluation of a familial bleeding problem after diagnosis of other relatives). Mild bleeding symptoms (e.g., bruising, nosebleeds, possible abnormal bleeding with prior surgery) are more common than severe symptoms (e.g., severe bleed from anticoagulant therapy, life-threatening postpartum hemorrhage, joint bleed) among referred individuals. Sometimes the bleeding symptoms reflect an underlying bone marrow disorder (e.g., bleeding associated with thrombocytopenia caused by leukemia, or a platelet function defect induced by a myelodysplastic or myeloproliferative syndrome), which can develop as a complication of some inherited bleeding disorders (e.g., inherited thrombocytopenia caused by a RUNX1, ANKRD or FLI1 mutation). Some causes of bleeding, such as vitamin C deficiency (scurvy), are rare in developed countries. When considering possible causes of bleeding or bruising, it is important to identify symptoms that are of concern to the patient and/or the referring physician and to determine the extent of bleeding that the person has experienced.^{1,3} The next step is to formulate a differential diagnosis and plan for bleeding symptom management (e.g., control of menorrhagia), including strategies to minimize future bleeding risks from exposure to surgery and other invasive procedures.³

Fig. 128.1 provides a general guide to the steps involved in clinical assessment. Bleeding-history assessment tools provide a detailed framework to evaluate the medical history and to determine which symptoms should be considered more suspicious of an underlying bleeding problem.⁴⁻⁸ Bleeding-history assessment tools have been used to standardize and quantify bleeding for research purposes, and some have a reasonable utility for ruling out a bleeding disorder when performing an initial assessment for bleeding problems⁵ (see box on [Influences on Presenting Problems](#)). While a very high bleeding score is consistent with a bleeding problem,⁴⁻⁸ there is overlap of scores for individuals with and without bleeding problems.^{4,5,7,8} These tools provide evidence that some bleeding symptoms are uncommon unless there is a bleeding disorder (e.g., joint bleeds, bruises that are large or larger than an orange or that track downward).^{2,4,5,7,8} Nonetheless, further research is needed to determine the accuracy of recommended bleeding assessment tools for detecting a bleeding disorder at the time of bleeding disorder assessment (see box on [Case 1: Illustration of a Mild, Inherited Bleeding Problem](#)).

Some bleeding symptoms, such as menorrhagia or nosebleeds, are not specific to any particular type of bleeding problem.^{1,3,7} Bleeding

can be triggered or exacerbated by therapies for atherosclerotic disease (e.g., aspirin and/or P2Y12 inhibitors), venous thromboembolic disease (prophylaxis or treatment with anticoagulants), inflammatory states (e.g., treatment with prednisone or other glucocorticoids) and pain (prescription or nonprescription use of nonsteroidal antiinflammatory drugs).¹⁻³ Bruising can also reflect systemic or topical corticosteroid use and the effects of age- or sun-exposure related changes in the skin (i.e., senile purpura).^{1,3}

Without treatment, severe bleeding disorders typically cause abnormal bleeding with all major hemostatic challenges. On the other hand, bleeding may not occur with every challenge in persons with mild defects and lower bleeding risk (e.g., those with a 5- to 10-fold increased risk for bleeding). Age influences the bleeding history by increasing the likelihood of exposures to hemostatic challenges and the development of sequelae such as arthropathy in patients with severe hemophilia.^{6,7} A severe unexplained bleed with surgery may be considered suspicious of a bleeding problem. However, if the person reports that prior challenges did not result in bleeding, this narrows down the possibilities to a mild inherited bleeding disorder, an acquired bleeding disorder, an iatrogenic condition (e.g., bleeding while on anticoagulant therapy or a technical problem during surgery that caused bleeding) or a problem that is not related to a congenital or acquired bleeding disorder (e.g., a postpartum hemorrhage after a Caesarian section from uterine atony or retained products of conception). A bleeding disorder assessment needs to consider both familial and personal bleeding symptoms (see box on [Case 2: Illustration of The Importance of Assessing Both Personal and Familial Bleeding Problems](#)).

The timing of bleeding with challenges is evaluated to determine whether the bleeding problem reflects a common bleeding disorder, such as von Willebrand disease, a platelet function disorder, an undefined mucocutaneous bleeding problem, or a rarer cause, such as a defect or deficiency in a coagulation factor or fibrinolytic protein^{1,3} (see box on [Case 3: Illustration of the Importance of Assessing Bleeding Problems Over Time](#); see also boxes on [Cases 1 and 2](#)). Although patients will often know whether bleeding began on the day of a challenge, their recall of timing details is often better when procedures were done without general anesthesia (e.g., dental extractions, biopsies).^{1,3,7} Bleeding within a few hours or on the same day of a challenge (e.g., surgery or dental extraction) is most suggestive of a defect involving von Willebrand factor or platelets.^{1,3,7} Delayed bleeding (beginning 1 or more days after a challenge) is most suggestive of a coagulation or fibrinolytic defect (see boxes on [Cases 1 and 2](#)).^{1,3,7} However, the onset of some bleeding, such as postpartum hemorrhage, can be delayed in persons with von Willebrand disease or platelet function disorders.^{1,3,9-13} Postpartum bleeding may be absent or inconsistent in women with mild bleeding disorders because pregnancy increases the levels of some hemostatic proteins, including fibrinogen and von Willebrand factor. Bleeding during pregnancy after implantation is uncommon with most bleeding disorders, although it can be severe in individuals with bleeding disorders who develop placental abruption (e.g., from an untreated fibrinogen disorder or factor XIII deficiency). Intracranial bleeding in a child may suggest a severe defect or deficiency of factor XIII, a coagulation factor deficiency, or a fibrinolytic inhibitor, but other conditions should be considered if the diagnostic tests for these conditions are negative.

Fig. 128.1 STEPS TO EVALUATE BLEEDING AND BRUISING PROBLEMS.

Influences on Presenting Problems

When evaluating a bleeding history, it is important to recognize that the presenting problems are influenced by the following factors:

1. The nature and severity of the defect, and the presence of single or multiple risk factors for bleeding
2. Whether the bleeding problem is congenital or acquired
3. Antecedent exposure to hemostatic challenges (such as surgery, dental extraction, menses, and childbirth) and the risk for bleeding with each of these challenges
4. The presence of other medical problems (e.g., renal, hepatic, or thyroid disease), including anemia
5. Variability in the bleeding symptoms experienced by individuals without bleeding disorders (e.g., nosebleeds, bruising) and by individuals with known bleeding disorders, even within families with the same defect
6. Local factors (e.g., sun-damage to the skin, vascular lesions, diverticular disease, or cancerous lesions in the gastrointestinal tract) and the possibility of nonaccidental trauma
7. Treatments that increase the risk for bleeding (e.g., antiplatelet drugs, such as aspirin and nonsteroidal antiinflammatory drug used for pain control, anticoagulant therapy, etc.)
8. Whether treatments were used to prevent or control bleeding
9. Whether treatments prescribed for other reasons may have reduced bleeding (e.g., reduced menstrual bleeding while on oral contraceptives to prevent pregnancy)

EPIDEMIOLOGY

An understanding of the epidemiology of bleeding problems requires distinction between symptoms that rarely represent a pathologic condition and do not require investigation or therapy (e.g., isolated “easy bruising”, brief nosebleeds) and those that are

Case 1: Illustration of a Mild, Inherited Bleeding Problem

A 77-year-old man who is starting treatment for multiple myeloma was discovered to have a prolonged activated partial thromboplastin time. Review of his records indicated that the abnormality was present on a previous admission for spinal cord compression, which was treated with surgery. He required 4 units of packed red blood cells several days after this surgery because of delayed postoperative bleeding. There was no other bleeding history. He was found to have mild factor IX deficiency, unrelated to the myeloma, and his daughter proved to be a carrier of this defect.

Case 2: Illustration of the Importance of Assessing Both Personal and Familial Bleeding Problems

A 22-year-old woman was referred for evaluation of a possible platelet disorder. She had a history of menorrhagia (4 days out of 7 days of menstrual flow were heavy when not on treatment), prolonged nosebleeds in childhood, and hematuria with urinary tract infections. She did not have thrombocytopenia, and she had no exposure to major hemostatic challenges. Her father, uncle, and grandfather had a striking bleeding history, and two of them had thrombocytopenia. The bleeding in her relatives included joint bleeds with trauma and severe, delayed-onset bleeding after trauma and surgery (usually more than a day later), which continued for weeks despite platelet transfusions. One of these relatives reported no bleeding when he had a tooth extracted while receiving fibrinolytic inhibitor therapy. Although menorrhagia is not specific to any one type of bleeding disorder, the delayed bleeding in affected relatives suggests a possible autosomal dominant disorder and either a fibrinolytic defect or a factor defect or deficiency (e.g., dysfibrinogenemia; the latter had been excluded in previous tests of the affected relatives). Because of the family history of thrombocytopenia, joint bleeds, and delayed bleeding, which did not respond well to platelet transfusions, testing was done for the Quebec platelet disorder. Genetic testing for duplication mutation of the urokinase plasminogen activator gene confirmed this diagnosis in the patient and her relatives. This case illustrates the importance of evaluating both the personal and family bleeding history and highlights the fact that bleeding-symptom severity can vary among affected family members, in part because of their different exposures to challenges and treatments.

Case 3: Illustration of the Importance of Assessing Bleeding Problems Over Time

A 72-year-old man was referred for evaluation of a severe bleed after receiving a single dose of low-molecular-weight heparin for unconfirmed deep vein thrombosis. He had a history of a similar bleeding episode several years previously while on warfarin treatment for atrial fibrillation. There was no other bleeding history, and the patient subsequently developed a spontaneous iliopsoas bleed. He had undergone numerous surgeries earlier in life without any bleeding problems, and there was no family history of bleeding. The bleeding history suggested the possibility of an acquired bleeding problem, possibly acquired von Willebrand disease or an acquired factor deficiency. Diagnostic testing indicated that he had acquired factor XIII deficiency. This case illustrates the fact that there may be more than one risk factor for bleeding: in this case, several exposures to anticoagulants triggered bleeding in a patient with an acquired factor deficiency. On initial treatment of his iliopsoas bleed with factor XIII concentrate, there was partial neutralization of the infused factor followed by accelerated clearance, consistent with acquired factor XIII deficiency secondary to an autoantibody.

more suspicious, require treatment, and/or are highly predictive of a bleeding problem.¹⁻³ Some individuals have multiple risk factors for bleeding (e.g., low von Willebrand factor levels, exposure to drugs that inhibit platelet function after a surgical procedure associated with a high risk for bleeding).³ Although some symptoms, such as nosebleeds, easy bruising, and menorrhagia, are quite prevalent in the general population (10% or more report these symptoms),

these problems are more frequent and more severe in individuals with bleeding disorders.^{1–5,7,9,14–18} Menorrhagia requiring treatment is common among women, and it can sometimes be life-threatening in those with severe bleeding disorders.^{10,12,14,16,17} With moderate or severe disorders, there is less uncertainty about the disease prevalence than there is for milder disorders (e.g., type 1 von Willebrand disease) where there is ongoing debate about the diagnostic criteria that define a pathologic abnormality.⁹ There is less information on the prevalence of disorders that require complex tests for diagnosis and have many potential causes (e.g., platelet function disorders). Undefined disorders (definite bleeding problems despite normal or nondiagnostic test findings) have emerged as a common cause of mucocutaneous bleeding.^{18,19}

The process of referral for bleeding makes it likely that the person has had some bleeding symptoms that may or may not reflect an underlying congenital or acquired bleeding problem.^{1,3} Because of this referral bias, the prevalence of bleeding disorders in tertiary referral clinics is much higher than in the general population. The prevalence of inherited bleeding disorders in the general population is quite low (from 0.00023% to over 1% for von Willebrand disease, with much lower estimates based on studies of bleeding disorder-clinic cases compared with those derived from population screening studies that used higher cutoffs to define quantitative deficiencies; 0.005% to 0.01% for hemophilia; and much lower for other coagulation factor deficiencies). Consequently, unselected screening is not recommended.^{1,3,9,20} Founder effects in populations can alter the prevalence of both common and rare inherited bleeding disorders.

A person with a first-degree relative with an autosomal dominant bleeding problem (e.g., [Case 2](#)), or a sibling with a recessively inherited disorder, has a higher pretest probability of an inherited bleeding disorder.^{7,9} When assessing the relative of someone with a positive family history of a bleeding problem, it is important to realize that the person may have the same condition, with or without additional defects, or a different bleeding problem.⁷ Furthermore, it is common for affected family members to show some variability in the severity of their bleeding symptoms (e.g., [Case 2](#)).^{7,9} Index cases typically have more severe bleeding symptoms.^{1,4} Accordingly, laboratory investigations are often used to assess family members at high risk, even in the absence of a remarkable personal bleeding history.

Common bleeding disorders that are inherited as autosomal dominant traits include von Willebrand disease, many common platelet function disorders (including many secretion defects, MYH9-related disorders, gain-of-function disorders such as platelet-type von Willebrand disease and Quebec platelet disorder), and dysfibrinogenemia.^{1,3,9,15} Because the diagnostic criteria for mild von Willebrand disease have changed,⁹ a positive personal or family history often requires reevaluation over time.

X-linked bleeding disorders include hemophilia A, hemophilia B, and X-linked congenital platelet disorders (e.g., Wiskott-Aldrich syndrome or thrombocytopenia caused by GATA1 mutations).^{1,3,15} X-linked disorders typically affect males but can affect women with skewed X-chromosome inactivation or Turner syndrome. Recessively inherited bleeding disorders are the rarest, and their prevalence is highest in populations in which consanguinity is culturally accepted.²¹

Acquired bleeding problems are common, and the most frequent cause is a drug-induced defect.^{1,3} Drugs that alter hemostasis may cause bleeding on their own or they may unmask or worsen symptoms from a mild or moderate underlying bleeding disorder.^{1,3,9,22} Drug-induced problems to consider include the following: (1) use of prescription or nonprescription nonsteroidal antiinflammatory drugs (NSAIDs) that transiently inhibit platelet cyclooxygenase-1 (patients may not recall taking these drugs if they received them after a surgical procedure^{2,3,22}); (2) aspirin or P2Y₁₂ or $\alpha_{IIb}\beta_3$ inhibitors used for acute or chronic prevention or treatment of cardiovascular disorders; (3) anticoagulants prescribed for the prevention or treatment of venous thromboembolic disease, atrial fibrillation, or acute management of atherosclerotic disease; (4) antidepressant medications (e.g., serotonin reuptake inhibitors), which may cause bruising; and (5) glucocorticoid therapy.^{1,19,23,24} Some dietary practices affect

platelet function (e.g., use of fish oil supplements, ingestion of herbal supplements with aspirin-like properties), as can acute alcohol intoxication.^{3,15}

Among adults with von Willebrand disease, factor VIII deficiency, and factor XIII deficiency, about 10% of the cases result from an acquired, autoantibody-induced deficiency state. Autoimmune causes of other bleeding disorders include immune thrombocytopenia, immune-mediated platelet dysfunction (more commonly arising from antibodies against glycoprotein IbIXV or $\alpha_{IIb}\beta_3$), and acquired factor V deficiency.^{1,3} Bone marrow disorders are associated with an increased risk for autoimmune or nonimmune bleeding problems, including thrombocytopenia, secondary platelet function defects of diverse etiology (e.g., acquired forms of dense granule deficiency, Glanzmann thrombasthenia, or Bernard-Soulier syndrome), or acquired von Willebrand disease.¹⁵ They can also result from the evolution of an inherited bleeding disorder (e.g., the development of acute myelogenous leukemia or myelodysplastic syndrome in a person with a RUNX1 or ANKRD mutation). Acquired bleeding problems can also occur with renal impairment, liver disease, hypothyroidism, or Cushing syndrome.^{1,3} Some patients present with acquired skin bleeding that, on examination, is restricted to exposed parts of the body and reflects sun damage to the skin.

PATHOBIOLOGY

There are many different components of the hemostatic, fibrinolytic and vascular response to injury that are important for prevention and control of bleeding (see [Chapters 122, 123, 125–127, 130, 131, 135, 137 and 138](#)). Normal hemostasis requires platelet adhesion to collagen and platelet activation and aggregation at sites of tissue injury, processes that require von Willebrand factor and other adhesive proteins; the initiation of coagulation by tissue factor; followed by amplification and propagation of coagulation to generate thrombin and convert fibrinogen to fibrin. It also requires stabilization of fibrin through the cross-linking actions of activated factor XIII. The activation of fibrinolysis (which is important for wound healing) is part of the normal response to tissue injury and repair. Fibrinolysis is retarded by platelets (which release large quantities of stored plasminogen activator inhibitor 1 [PAI-1]) and accelerated by deficiencies or defects in PAI-1 or α_2 -antiplasmin, gain-of-function defects in plasminogen activators, and pathologic states that increase fibrinolysis. The interdependence of hemostatic mechanisms explains why a failure of platelet adhesive mechanisms (e.g., from defects in platelet number or function or von Willebrand disease) may cause persistent, delayed, and/or recurrent bleeding from a wound site, particularly if initial hemostasis was inadequately managed or controlled. That activation of fibrinolysis occurring during hemostasis explains why fibrinolytic inhibitors are often effective for treating diverse bleeding problems (e.g., menorrhagia and bleeding from oral/nasal surgical or dental procedures) in patients with conditions ranging from von Willebrand disease and platelet disorders to factor deficiencies and fibrinolytic defects. Some individuals with severe nosebleeds or gastrointestinal bleeds from platelet function disorders (e.g., Glanzmann thrombasthenia) that are refractory to platelet transfusions (because of development of antibodies) may respond to treatment with recombinant factor VIIa.

Hemostasis is also influenced by other factors, such as anemia. The red cell number in blood influences platelet margination, which facilitates platelet adhesion to the injured vessel wall. Accordingly, anemia can worsen bleeding and increase bleeding risk. Some disorders of hemostasis reflect defects in the vessel wall. For example, hereditary hemorrhagic telangiectasia (HHT), which is often (but not always) associated with telangiectasia on the nose, lips and oral cavity,²⁵ can cause troublesome bleeding from vascular malformations. HHT can cause epistaxis (present in about 95% of persons with this disorder), gastrointestinal bleeding, and less commonly, intracranial or pulmonary hemorrhage, typically without excessive bleeding with surgical procedures or menorrhagia.^{1,3,25}

CLINICAL MANIFESTATIONS

Age of Presentation and Extent of Symptoms

Inherited bleeding disorders can present at any age, but if severe, a bleeding disorder typically presents at a younger age.^{1,3,6,7,26} Milder disorders can present at any age and may require a significant hemostatic challenge to come to medical attention, often a major surgical procedure or a dental extraction.^{1,3,6,7,26} Women with mild, moderate, or severe inherited bleeding disorders may present with troublesome bleeding at the onset of menses or with childbirth-related bleeding.^{1,3,7,26} When the bleeding risk is only mildly increased (e.g., low von Willebrand factor levels without other defects, mild inherited platelet secretion defects), there may be a history of bleeding with some, but not all, hemostatic challenges.^{1,3,9}

The severity of the bleeding disorder affects the number, severity, and type of manifestations. Numerical scores, derived from standardized bleeding-history assessment tools, show considerable overlap among subjects with different disease severities.^{4,5} Although use of a standardized tool to quantify bleeding symptoms has been recommended by the International Society on Thrombosis and Haemostasis,⁶ the tool requires further prospective validation before it is used in routine clinical practice.

Family History and Syndromic Disorders

It is important to consider that the family history of an inherited bleeding disorder is influenced by the disorder severity, the mode of inheritance, and whether there is more than one bleeding disorder in the family. The family history is often negative in the case of an acquired problem, such as iatrogenic bleeding from anticoagulant therapy or a technical problem complicating a surgical or dental procedure.¹ The family history is typically positive when the disorder is autosomal dominant and has high penetrance.^{3,7,9} The family history is negative in individuals with novel mutations and in those with recessive disorders unless there are affected siblings or many affected relatives from consanguinity or founder effects. Individuals with mild disorders who have never had a hemostatic challenge may be referred after another family member is identified to have a bleeding problem or if the person has bleeding after a significant hemostatic challenge.^{1,3} Early identification of a bleeding disorder may alter the natural history, particularly if treatment is given before hemostatic challenges.⁷

Some patients have other clinical problems that suggest the possibility of a syndromic disorder (e.g., albinism or a history of delayed pigmentation, hearing loss, nephritis, absent radii) or an alternative diagnosis (e.g., hyperextensibility of the joints because of Ehlers-Danlos syndrome). An evaluation for symptoms and signs of joint hypermobility (affecting the spine, elbows, knees, and/or metacarpophalangeal joints) can help assess for collagen disorders amongst individuals referred for bleeding symptom assessment.²⁷

Bruising, Petechiae, and Other Skin Changes

Bruising (which reflects bleeding into the skin) is a commonly reported bleeding symptom.^{2-4,7,9,15} Bruising is reported more frequently by women than men.² Some bruising symptoms are more suggestive of a bleeding problem than others. For example, bruises from bleeding disorders often occur after minimal or no recalled trauma.^{3,4,7,9,15} Bruises that are unusually large (e.g., as big or bigger than an orange) or lumpy or that migrate (i.e., track downward to the feet over time) are consistent with more extensive bleeding into cutaneous or subcutaneous tissues and are more specific, but not highly sensitive, for bleeding disorders.^{4,7,9} When bruises are large or multiple, patients may hide them (by wearing pants and long-sleeved shirts) to avoid being questioned. Severe bruising symptoms may lead to lifestyle changes (e.g., avoidance of sports or other activities that increase the risk for bruising).⁷ When there is significant swelling with

a bruise, imaging (e.g., with ultrasound) may be necessary to exclude bleeding into deeper tissues.

Bruising symptoms (that are normal or abnormal) can fluctuate over time, depending on activity levels and exposure to drugs or trauma that increase the risk of bruising (e.g., increased bruising when moving house, traveling, or engaging in physical sports; bruising in a toddler who just started walking; worsened bruising after initiating antidepressant therapy). Like normal bruising, bruising from bleeding disorders usually occurs at sites that are commonly exposed to trauma (e.g., lower limbs, outer hips, arms). However, bruising with acquired hemophilia A may be extensive and involve other regions (e.g., the trunk). This type of bruising is most often autoantibody related because it does not occur in congenital hemophilia, even if there is an inhibitor.

Skin examination sometimes reveals bruising associated with skin pigmentation changes from iron deposition. This is typical of repeated bleeds in persons with severe platelet function disorders or moderate to severe forms of von Willebrand disease. These pigment changes are typically localized to sites of recurrent trauma (e.g., anterior shins), and the distribution (which can be spotty) helps to distinguish the finding from the pigmentation associated with venous stasis.

Petechiae and/or oral blood blisters are typical of severe thrombocytopenia and are less commonly seen in other conditions, including severe platelet function disorders. Scurvy can cause perifollicular hemorrhage (often on the shins), bruising, and gum bleeding, typically with associated swelling and redness. Schamberg disease is a pigmented purpuric dermatitis that does not represent a bleeding problem and can be mistaken for petechiae. Early lesions of purpura fulminans, from congenital deficiency of protein C or protein S, may be mistaken for bruises, but the age of the patient and the distribution of the lesions help to establish the diagnosis. Skin bleeding from minor lesions (e.g., skin cancers) can be unusually troublesome for patients with severe bleeding disorders.

Epistaxis

Epistaxis is a commonly reported bleeding symptom that does not always reflect a bleeding disorder, even when the bleeding is frequent and/or requires medical interventions.^{2-5,7} Although nosebleeds can be caused by mucocutaneous bleeding disorders (e.g., platelet or von Willebrand factor problems), they can also result from severe deficiencies of common pathway coagulation factors (e.g., congenital deficiency of factor V, factor X, or prothrombin), fibrinolytic defects (PAI-1 or α_2 -antiplasmin deficiency, increased platelet urokinase plasminogen activator from Quebec platelet disorder) or HHT.^{1,3,7,9,15,21} Nosebleeds from bleeding disorders or other causes are often worse in childhood.

When the volume of bleeding from the nose is large, the patient may experience passage of clots from the nose or may present with melena. Although nosebleeds are not specific to bleeding disorders, it is important to ask about them because severe nosebleeds can be disabling for some individuals with bleeding disorders, such as von Willebrand disease.^{3,9}

Gum Bleeding and Bleeding With Loss of Primary Teeth

Gum bleeding can be problematic with inherited or acquired bleeding disorders that affect platelets or von Willebrand factor, although it more frequently reflects gum disease.^{1,3,9,21} Severe bleeding with the loss of primary teeth is also suspicious of an underlying bleeding disorder.^{1,3,7,9}

Gastrointestinal Bleeding

Gastrointestinal bleeding can complicate a bleeding disorder, but it is rarely the presenting problem, and it requires investigation to

determine the source of the bleeding.^{1,3,4,9} Gastrointestinal bleeding can be severe with HHT.²⁵

Challenge-Related Bleeding

The assessment of challenge-related bleeding is an important part of taking a bleeding history. Bleeding related to accidental trauma may be more difficult to evaluate than bleeding associated with surgery or dental procedures because accidental trauma often causes bleeding, and it is difficult to determine whether the extent of bleeding was excessive.⁷ In addition, large wounds may continue to bleed until sutured.

A history of bleeding with surgical or dental procedures can include being told that there was excessive bleeding by a dentist, physician, or other health care worker and/or experiencing excessive oozing or drainage from an incision or extraction sites; wound hematomas; delayed wound healing; bleeding requiring repeated surgery, suturing of an extraction site, an admission to hospital, a longer hospital stay, and/or transfer to the intensive care unit; and receiving blood transfusions, drugs, and/or factor replacement for hemorrhage control.^{1,3,7} Patients may not spontaneously report some symptoms, such as extensive bruising around surgical incisions. Occasionally an operative report or other medical document provides important confirmation that there was abnormal bleeding with surgery (e.g., an operative note that documents generalized oozing during a procedure and greater-than-expected total blood loss).^{1,3} Iatrogenic reasons (e.g., oozing vessels that were not cauterized or ligated) should be considered when there is a history of an isolated bleeding episode.

Many individuals undergo dental extractions at some point in their life. Bleeding that persists beyond the first day, or that becomes problematic one or more days after a dental extraction, should be considered suggestive of a bleeding disorder.^{1,3} Severe bleeding with dental cleaning should be considered suggestive of a congenital or an acquired bleeding disorder (e.g., von Willebrand disease or a platelet function disorder).

In individuals with a moderate-to-severe bleeding problem, bleeding after surgery, dental procedures, or a severe throat infection can lead to airway compromise, whereas bleeding from a surgical or traumatic limb injury can lead to compartment syndrome.^{1,3,28}

Bleeding Symptoms Restricted to Women

Women with bleeding disorders experience more bleeding than men because of the hemostatic challenges associated with menses and childbirth.^{16,29} Such women are also at increased risk for developing endometriosis and hemorrhage from ovarian cysts.^{16,29} They may also report troublesome bruising or bleeding with sexual activity.

Menorrhagia is a fairly common manifestation of bleeding disorders, and the hemostatic cause can be von Willebrand disease, a platelet disorder, or a defect in coagulation or fibrinolysis.^{7,15,16,29} However, menorrhagia can arise from other causes, such as fibroids.^{3,17,29} Menorrhagia from inherited bleeding disorders is often long standing, but it can be influenced by treatments. Accordingly, it is important to ask about menses when on, and not on, treatment. Menorrhagia can develop as a manifestation of an acquired bleeding problem (e.g., from acquired von Willebrand disease or anticoagulant therapy for deep vein thrombosis).

In general, it is more helpful to ask women quantitative or categorical questions about menses, rather than qualitative questions (e.g., are/were your menstrual periods heavy?). Questions to consider include the following: How many days of bleeding do you have with your typical menstrual periods? How many days of this bleeding were heavy flow? On your heavy days of flow, did you soak through sanitary products in an hour or less? What treatments have you taken for heavy periods? When you were not on treatment, how many days of bleeding (and how many days of heavy flow) did you have with a typical menstrual period? Were your periods like this

when they first began, or did the heavy-flow problems start later in your life?

Menses up to 7 days in total duration, with 2–3 days of heavy flow, can be considered normal.^{4,5,7,16,29} Although influenced by the absorbency of the products used, soaking through sanitary products in less than an hour is suspicious of menorrhagia, as is doubling up on products because of heavy flow and gushing and flooding accidents. Dysmenorrhea is common among women with bleeding disorders, and the passage of large blood clots (which reflect increased flow), which is typically painful, suggests the possibility of a bleeding disorder.⁵ Pictorial bleeding-assessment tools (which are not applicable to an initial consultation visit) can be helpful to document menorrhagia and responses to treatment.^{11,29}

Postpartum hemorrhage is rarely caused by an underlying bleeding problem, and it can be complicated by a profound acquired coagulopathy, typically with severe fibrinogen depletion.^{11–13} On the other hand, excessive or prolonged bleeding after childbirth or pregnancy loss can be problematic for some women with bleeding problems.^{9,11} In addition, severe fibrinogen disorders and factor XIII deficiency compromise carrying a pregnancy to term and need to be excluded if the patient has unexplained pregnancy losses that are associated with hemorrhagic placental abruption³ (see box on [Case 4: Evaluation of an Isolated Symptom—Recurrent Pregnancy Loss With Bleeding](#)).

During the first week after childbirth, the bleeding (lochia) is typically characterized by brighter red flow than a normal period. Afterward, the flow usually lightens and continues for up to 6 weeks postpartum. Flow can be heavier, or persist longer, in women with bleeding disorders.^{9,11}

Anemia Related to Bleeding

A history of anemia and/or prior treatment with iron replacement is frequently reported by women with bleeding disorders.^{3,16} Pallor of the palms is often observed when the hemoglobin is below 10 g/dL. Anemia is uncommon in individuals with bleeding disorders unless there is acute bleeding or chronic persistent bleeding leading to iron deficiency that compromises red cell production. Many women with bleeding disorders and menorrhagia have low iron stores, but not anemia. Low iron stores may also reflect ongoing gastrointestinal bleeding (overt or occult), which if present, requires investigation even if there is a known congenital or acquired bleeding problem. Some bleeding disorders (e.g., platelet disorders from GATA1 mutations) are associated with anemia and thrombocytopenia.

Joint Bleeds and Muscle Bleeds

Joint bleeds and bleeding into muscles (e.g., iliopsoas bleeds), which are uncommon bleeding symptoms, suggest a severe coagulation

Case 4: Evaluation of an Isolated Symptom—Recurrent Pregnancy Loss With Bleeding

A 32-year-old woman was referred for evaluation of a low fibrinogen level in the setting of acute placental abruption, resulting in a third pregnancy loss (this time in the third trimester). She had no prior bleeding history apart from having suffered three placental abruptions associated with severe bleeding that required transfusion. The family history was negative for bleeding problems. She had previously been investigated for thrombophilia but had not been tested for a bleeding disorder. The low fibrinogen level persisted over many months (levels of approximately 90 mg/dL), suggesting that the defect was inherited. She received fibrinogen concentrate for two subsequent pregnancies, which she carried to term and delivered without bleeding problems. This case illustrates the need to consider inherited disorders when the bleeding symptoms are unusual and severe, even if there is only one bleeding symptom. It also illustrates that prognosis is dependent on diagnosis and treatment.

defect or a fibrinolytic disorder.^{1,3–7} However, bleeding into a joint after an injury or an orthopedic (e.g., arthroscopic) procedure can be experienced by persons with other types of bleeding disorders.^{1,3–7} In patients with severe factor deficiencies, the clinical assessment should evaluate for symptoms and signs of arthropathy and muscle wasting and if relevant, neurologic sequelae complicating compartment syndrome bleeds.

Subdural and Intracranial Hemorrhage

A newborn or child presenting with spontaneous intracranial hemorrhage or a large cephalohematoma should be investigated for severe underlying bleeding disorders, such as thrombocytopenia, hemophilia, factor XIII deficiency, other coagulation factor deficiencies, or a severe defect in platelets or von Willebrand factor.^{1,3–5} Trauma-related subdural or intracranial hemorrhages can also be manifestations of a severe bleeding disorder.^{1,3–5} In adults, ischemic strokes are more frequent than hemorrhagic strokes, although hemorrhagic strokes appear to predominate with some bleeding disorders (e.g., Quebec platelet disorder⁷), and they can be complications of anti-thrombotic drug treatment.

Hematuria

Urinary tract bleeding with an infection is a commonly reported symptom, whereas spontaneous (or unexplained) hematuria can complicate hemophilia and other bleeding disorders, such as Quebec platelet disorder.^{3,7,28}

Bleeding at Birth, Age-Related Changes in Bleeding, and Very Rare Bleeding Symptoms

Many individuals cannot answer questions about bleeding at the time that they were born. Nonetheless, bleeding from the umbilical stump or a cephalohematoma at birth can be symptoms of a bleeding disorder.^{4,5,7} Menarche can be associated with a marked increase in bleeding in women with inherited or acquired bleeding problems. Some individuals with inherited bleeding disorders report a reduction in their bleeding symptoms as they age, which could reflect lifestyle adaptation and age-related increases in hemostatic protein levels (e.g., von Willebrand factor or fibrinogen) and thrombin generation. Increases in bleeding with aging can suggest an acquired problem (see box on [Case 5: Illustration of Changes in Bleeding Problems Over Time](#)).

Some types of bleeds are quite rare among individuals with bleeding disorders, including spontaneous hemorrhage into the spleen, which can lead to rupture (see box on [Signs of Active or Recent Bleeding](#)).

LABORATORY MANIFESTATIONS

The general investigations that are appropriate for most assessments of bleeding problems include (1) a complete blood count (to establish if there is thrombocytopenia or anemia), (2) an assessment for a low ferritin level to evaluate for iron deficiency (less commonly associated with microcytosis or anemia; iron deficiency should be corrected if bleeding risks are increased), (3) a blood group and antibody screen, particularly for individuals with prior pregnancies or transfusions and upcoming surgery or major dental procedures, and (4) tests of renal function (creatinine) if antifibrinolytic therapy will be considered because the dosage is dependent on renal function or if an MYH9-related disorder is suspected (see box on [The Laboratory Manifestations of Bleeding Disorders](#)). The bleeding time test is no longer recommended, because of its technical limitations and poor sensitivity to common bleeding disorders.^{3,15,30} Electrolyte levels merit monitoring when repeated doses of desmopressin therapy are given

Case 5: Illustration of Changes in Bleeding Problems Over Time

A 65-year-old woman presents for urgent evaluation of a bleeding problem, requiring treatment for a symptomatic, expanding subdural hematoma. She had been previously diagnosed with type 1 von Willebrand disease but indicated that she had no bleeding problems (despite many challenges) until she reached 30 years of age, when she began to experience increasing problems with bruising, menorrhagia, and challenge-related bleeding, including severe gum bleeds with routine dental cleaning. An activated partial thromboplastin time (aPTT) had been performed and was elevated. Testing confirmed a low level of factor VIII (14%) and a low level of ristocetin cofactor activity (less than 10%). The patient was given emergency treatment with plasma-derived von Willebrand factor concentrate containing factor VIII. Intravenous γ -globulin was given because she had a very poor response to replacement, suggesting rapid clearance of von Willebrand factor and factor VIII. Within 24 hours of the intravenous γ -globulin administration, her von Willebrand factor and factor VIII levels increased above normal, consistent with acquired von Willebrand syndrome. Additional tests indicated that she had an immunoglobulin (Ig) G paraprotein without evidence of myeloma. Several features of her presentation suggested that her von Willebrand factor abnormalities were probably acquired and not because of type 1 von Willebrand disease (which is more common): her increasing bleeding symptoms over time and lack of bleeding problems during childhood or early adulthood, her very low level of factor VIII (because of its clearance with von Willebrand factor), the IgG paraprotein, her poor response to von Willebrand factor replacement, and her excellent response to intravenous γ -globulin. She has since been managed with intermittent intravenous γ -globulin treatment.

Signs of Active or Recent Bleeding and Conditions Associated With Bleeding

Although findings from the physical examination in bleeding disorders are often normal, it is important to look for signs of active or recent bleeding, including the following:

1. Petechiae, perifollicular hemorrhages (typical of scurvy)
2. Oral blood blisters, particularly if the patient has thrombocytopenia
3. Ecchymoses, hematomas, and skin pigmentation changes because of recurrent bleeds
4. Signs of active bleeding from a site of trauma or an incision, including excessive blood loss into drains
5. Sequelae of previous bleeds in individuals known or suspected to have a severe bleeding disorder, such as muscle wasting and arthropathy, neurologic abnormalities from prior intracranial or compartment syndrome bleeds
6. Pallor arising from anemia: the palms are usually notably pale when the hemoglobin is less than 10 g/dL
7. Signs of an underlying hematologic disorder, such as lymphadenopathy and/or splenomegaly
8. Signs of acute or chronic liver disease, such as jaundice, hepatomegaly, spider nevi, palmar erythema, or Dupuytren contractures
9. Signs of an endocrine disorder, such as hypothyroidism or Cushing syndrome
10. Vascular lesions such as telangiectasia on the face, lips, tongue, buccal mucosa, or fingers which can suggest hereditary hemorrhagic telangiectasia
11. Hyperextensibility if the bleeding history suggests a collagen disorder as a potential diagnosis
12. Signs suggestive of a syndromic bleeding disorder (albinism, hearing impairment, absent radii)

and/or if the fluid balance is difficult to assess. Tests of liver function are warranted if the person has risks for transfusion-acquired, chronic liver disease. Tests for liver and thyroid disease (particularly hypothyroidism) can be helpful if the history suggests an acquired bleeding problem of unknown etiology. Screening for Cushing syndrome (24-hour urine test for free cortisol) should be restricted

The Laboratory Manifestations of Bleeding Disorders

The laboratory manifestations of bleeding disorders can include abnormalities from the following:

1. The underlying hemostatic defect
2. Bleeding complications (e.g., anemia, iron deficiency, coagulopathy secondary to hemodilution after resuscitation for a massive bleed, development of red cell antibodies after transfusion)
3. False-positive abnormalities (e.g., prolonged aPTT caused by incidental mild factor XII deficiency, which is found in about 1 of 200 patients, or a lupus anticoagulant, which can be a transient finding in about 5% of hospitalized patients)
4. Extremes of normal variation (e.g., mildly low von Willebrand factor levels in an individual who is blood group O, absent secondary aggregation with epinephrine in adjusted platelet rich-plasma aggregation studies).

to patients with acquired bleeding problems that suggest this possibility (e.g., bleeding associated with obesity, the development of type 2 diabetes, hypertension, striae, and/or changes in physical appearance).

The investigations for a bleeding problem typically also include screening tests (prothrombin time, aPTT, thrombin clotting time, and fibrinogen level), which are inexpensive tests, that detect acquired coagulopathies much more commonly than they detect inherited bleeding disorders because of differences in prevalence. These investigations are useful as a baseline for individuals at risk for developing a dilutional coagulopathy from bleeding and as initial investigations of a possible inherited or acquired coagulation disorder. Abnormalities, if detected, require further evaluation to determine if the cause is a fibrinogen disorder or a deficiency of one or more coagulation factors. Screening tests for von Willebrand disease are warranted for individuals with a personal or familial history of mucocutaneous bleeding.⁹ Platelet function disorders should be evaluated by aggregation tests and tests for dense granule release, if available, because these tests are useful for assessing common bleeding disorders.^{15,19,30} Chapter 129 provides more detail on the specific diagnostic tests that are appropriate for a laboratory workup of bleeding problems.

DIFFERENTIAL DIAGNOSIS OF BRUISING AND BLEEDING

The initial differential diagnosis should focus on three major categories (Table 128.1): deciding whether there is (1) no bleeding disorder, (2) a possible bleeding disorder (equivocal bleeding history and nondiagnostic laboratory findings), or (3) a definite bleeding disorder.

There are many potential inherited and acquired causes of definite bleeding problems (summarized in Tables 128.2 and 128.3). The history should be evaluated to determine if the problems suggest a defect in the initial control of bleeding (e.g., defects in platelet adhesion from von Willebrand disease or a platelet problem) or if there are delayed bleeding problems that suggest a defect in a coagulation factor or a fibrinolytic protein. Laboratory findings are important for distinguishing undefined bleeding problems from von Willebrand disease and platelet function disorders, because their symptoms are quite similar.^{1,3,18,30}

Acquired bleeding problems arising from drugs are often diagnosed solely on the basis of the medical history (i.e., acquired bleeding problems that occurred while taking a medication that inhibits coagulation or platelet function), although laboratory testing can be useful to rule out other causes. The subject's medical history and laboratory findings are helpful for determining if there is a possibility of acquired bleeding problems from a bone marrow disorder, liver disease, renal failure, or an endocrine disorder (e.g., hypothyroidism or, less commonly, Cushing syndrome).

TABLE 128.1

Differential Diagnosis of Bleeding Problems

Major Categories	Comments
No bleeding disorder	Symptoms do not reflect a bleeding disorder and have another explanation (e.g., a surgical bleed, not caused by a bleeding disorder).
Possible bleeding disorder	The laboratory findings are nondiagnostic, and the bleeding history is considered equivocal (e.g., unexplained serious bleed with one surgical procedure; unexplained menorrhagia without other bleeding problems).
Definite bleeding disorder, undefined or indeterminate type	The bleeding history is consistent with a bleeding disorder; however, the laboratory findings are nondiagnostic. Commonly the bleeding history resembles mild to moderate defects in platelet function or von Willebrand factor. The diagnosis should only be made once an adequate evaluation for common bleeding disorders (e.g., for von Willebrand disease and platelet aggregation and release defects) is completed. If testing is not complete, the classification should indicate the types of conditions excluded or not excluded, for example: mild mucocutaneous bleeding problem, von Willebrand disease excluded, mild mucocutaneous bleeding problem, platelet release defects not yet excluded.
Definite bleeding disorder with a defined cause	The symptoms and laboratory findings are considered diagnostic of a bleeding disorder. Tables 128.2 and 128.3 summarize many of the potential inherited and acquired causes.

PROGNOSIS

The prognosis for bleeding problems depends on the severity and nature of the hemostatic defect, exacerbating factors, and whether these problems can be readily corrected (e.g., vitamin K to correct a deficiency, discontinuing aspirin) or if they require hemostatic therapies, such as factor concentrates and/or drugs (e.g., desmopressin, tranexamic acid, or aminocaproic acid). Life expectancy is generally normal unless there is a severe bleeding disorder (e.g., severe hemophilia) or a complication (e.g., transfusion-acquired chronic hepatitis or human immunodeficiency virus). The prognosis for some rare disorders significantly improves after puberty (e.g., factor IX Leyden). A few show progressive worsening over time (e.g., development of aplasia from congenital amegakaryocytic thrombocytopenia, transformation of thrombocytopenia from an inherited RUNX1 mutation into myelodysplasia or acute myeloid leukemia). Other disorders (e.g., acquired hemophilia) may go into complete remission after immunosuppressive treatment with risk for later relapses.

Mild platelet function disorders, mild type 1 von Willebrand disease, and many common undefined conditions that cause mucocutaneous bleeding usually respond well to prophylactic desmopressin therapy, which is given to prevent bleeding with major surgical and dental procedures or bleeding with childbirth. Nonetheless, it is important to have a specific diagnosis to manage situations in which desmopressin therapy alone is insufficient to control bleeding.

Women with bleeding disorders have a similar prognosis to men, although they often have a greater burden of symptoms because of menorrhagia and childbirth-related bleeding.^{1,3} Their outcomes with pregnancy and childbirth are often similar to individuals without bleeding disorders provided that they receive treatment to control bleeding with delivery.^{1,3} However, some disorders have sufficiently

TABLE 128.2 Differential Diagnosis of Congenital Bleeding Disorders

Disorder	Comments
Fibrinogen deficiency or dysfunction	Deficiencies can be mild-moderate hypofibrinogenemia or severe afibrinogenemia. Fibrinogen function is abnormal in dysfibrinogenemias, which can present with bleeding, thrombosis, or both. Fibrinogen levels can be reduced in some dysfibrinogenemias.
X-linked coagulation factor deficiencies—hemophilia	Presentation is influenced by the degree of deficiency. Factor VIII deficiency is more common than factor IX deficiency. If factor VIII is low, von Willebrand disease needs to be excluded as the cause.
Rarer, coagulation factor deficiencies	Deficiencies can affect factors XI, V, II, VII, or X, and the presentation is dependent on the severity of the deficiency. Hereditary deficiencies of multiple coagulation factors are rare (e.g., of factors V and VIII, or multiple vitamin K–dependent coagulation factors for congenital defects impairing γ -carboxylation) and can easily be excluded by measuring multiple factors.
Fibrinolytic defects	Causes include disorders caused by loss of function, such as α_2 -antiplasmin or PAI-1 deficiency, and by gain-of-function defects, such as Quebec platelet disorder (overexpression of urokinase plasminogen activator in megakaryocytes).
von Willebrand disease	Causes include quantitative (partial type 1 to severe type 3) and qualitative defects (loss of function in type 2M and 2A, gain of function in type 2B and platelet-type). Type 1 von Willebrand disease can be confused with low von Willebrand factor levels (e.g., because of blood group O).
Platelet disorders	These conditions can affect platelet number, function, or both. The most common type of platelet function disorder is a platelet secretion defect, which may or may not also impair aggregation responses. Disorders of platelet function are commonly subclassified by the nature of the defect, such as the following: 1. Defects of membrane receptors for adhesive proteins (e.g., Glanzmann thrombasthenia and Bernard-Soulier syndrome) or agonists (e.g., P2Y₁₂ deficiency) 2. Defects of signaling or secretion (the largest subcategory) 3. Cytoskeletal defects (e.g., MYH9-related disorders) 4. Storage pool disorders (e.g., gray platelet syndrome, dense granule deficiency, α-storage pool deficiency, Quebec platelet disorder) 5. Defects of procoagulant function (e.g., Scott syndrome)
Vascular disorders	Congenital vascular malformation, including hereditary hemorrhagic telangiectasia, Ehlers-Danlos syndrome

PAI-1, Plasminogen activator inhibitor 1.

good outcomes with childbirth that treatment for uncomplicated childbirth is not required (e.g., for Quebec platelet disorder).^{7,28} Childbirth plans for women with bleeding disorders requires consideration of the options for pain management and avoidance of procedures, such as spinal or epidural anesthesia, to limit bleeding risks unless the defect can be readily corrected.

THERAPY

An individual's bleeding history is an important consideration whenever formulating therapeutic plans to control and minimize bleeding risks. Some symptoms do not warrant therapy (e.g., bruising), whereas treatment is important for controlling menorrhagia and for preventing and limiting challenge-related bleeding (e.g., from major or minor surgery and dental procedures, and traumas). For severe disorders, prophylactic treatment is warranted to prevent spontaneous bleeding and to limit challenge-related bleeding, which can be severe. The focus of therapy for some acquired conditions (e.g., acquired hemophilia) is immunosuppressive therapy to achieve a remission while managing any acute bleeding that warrants therapy. For individuals with mild bleeding disorders, who have undergone multiple prior surgical procedures without bleeding, it may be appropriate to have treatment available (e.g., desmopressin on "standby") that is to be administered if and when abnormal bleeding occurs, provided that the procedural-related risks of bleeding are small and readily managed (e.g., biopsy under local anesthetic) while waiting for the medication to have an effect.

For women with bleeding disorders, there are general treatments that can be considered for symptomatic management regardless of the type of bleeding disorder. For example, options for menorrhagia management include oral contraceptives, antifibrinolytic drugs, and hormone-releasing intrauterine devices. When menorrhagia limits lifestyle and further pregnancies are not desired, surgical options

(endometrial ablation, hysterectomy) may be preferred options, particularly when menopause is not imminent.

General management of bleeding often includes supportive care, correction and prevention of anemia (e.g., iron replacement for iron deficiency), and immunization against viruses that may be acquired by blood transfusion (e.g., hepatitis A and B) (see box on [Case 6: Illustration of Changes in Bleeding Outcomes With Treatment](#)). If the patient is immobilized or is undergoing a procedure with significant risks for thrombosis, there should be plans for thromboprophylaxis if the defect can be corrected during this treatment (e.g., by factor replacement therapy for hemophilia or von Willebrand disease, fibrinolytic inhibitor therapy for Quebec platelet disorder) or for alternative thromboprophylaxis if this is not possible (e.g., use of venous compression devices without anticoagulant drugs if the treatment will provide only brief hemostatic correction [e.g., desmopressin, platelet transfusions]). Other measures to limit bleeding risks from bleeding disorders, with surgery, include the avoidance of intramuscular injections, spinal and epidural anesthesia, and NSAIDs for pain management. In older individuals with bleeding disorders and symptomatic atherosclerotic disease (e.g., angina), aspirin therapy may be appropriate, with increased vigilance for signs and symptoms of significant bleeding.

FUTURE DIRECTIONS

The development of a bleeding-assessment tool with sufficient utility to distinguish persons with bleeding disorders from those without significant bleeding problems could improve the clinical assessment of bleeding disorders. There is a need for more information on the genetic causes of common disorders (e.g., type 1 von Willebrand disease, common platelet function disorders such as secretion defects) to further understand bleeding disorder pathogenesis and bleeding risks.

TABLE
128.3

Differential Diagnosis of Acquired Bleeding Problems

Disorder	Comments
Drug induced	Aspirin, NSAIDs, other platelet function inhibitors (e.g., P2Y ₁₂ and $\alpha_{IIb}\beta_3$ inhibitors), anticoagulants, fibrinolytic drugs, and antidepressants are common causes
Acquired factor deficiencies	The causes can be immune (e.g., acquired factor VIII deficiency, acquired factor V deficiency) or nonimmune. Reductions in multiple factors can result from vitamin K deficiency, treatment with vitamin K antagonists, liver disease, hemodilution, and rarely snakebites. Severe acquired hypofibrinogenemia is commonly caused by a postpartum coagulopathy or severe liver disease. Prothrombin deficiency occurs with some lupus anticoagulants. Amyloidosis can cause an acquired factor X deficiency, which may be associated with reductions in other coagulation factors synthesized in the liver if the liver is involved.
Disseminated intravascular coagulation	The manifestations can include thrombocytopenia, consumption of coagulation factors, including fibrinogen, and impairment of hemostatic mechanisms from the fibrin/fibrinogen degradation products. Causes are wide ranging and include postpartum consumptive states, prostate and other cancers, and snakebites.
Acquired von Willebrand disease	The cause can be immune (often in association with an IgG paraprotein) or nonimmune (e.g., increased proteolysis of von Willebrand factor with stenotic aortic valvular disease).
Immune thrombocytopenia	Bleeding is usually influenced by the extent of the thrombocytopenia. Some autoantibodies interfere with platelet membrane receptor function, causing bleeding disproportionate to the thrombocytopenia.
Non-drug induced, acquired platelet function disorders	The cause can be immune (see earlier) or nonimmune, typically from bone marrow disorders, although secretion defects can be secondary to Cushing syndrome or hypothyroidism.
Liver disease	Liver disease can cause thrombocytopenia, deficiencies of coagulation factors, hypofibrinogenemia and dysfibrinogenemia, and increased fibrinolysis. In mild liver disease, factor VII and sometimes factors XI and XII are low. Fibrinogen is often increased in early liver disease, and if low, the finding suggests severe liver disease.
Renal disease	Anemia is an important predictor of uremic bleeding. Uremic bleeding is typically associated with severe renal impairment.
Hypothyroidism	Hypothyroidism can cause an acquired von Willebrand disease and acquired defects in platelet function.
Cushing syndrome	This syndrome should be suspected when there are symptoms and findings suggestive of Cushing syndrome or treatment with systemic or topical glucocorticoids.
Surgical bleeding	This is often a diagnosis of exclusion, although the procedural notes sometimes document that a technical problem was encountered that led to abnormal bleeding.
Vitamin K deficiency	Newborns are at risk, as are individuals with malabsorption and/or receiving broad-spectrum antibiotics that reduce vitamin K production by reducing gut bacteria. Older adults are also at greater risk for developing vitamin K deficiency, because of reduced stores from poorer intake of vitamin K. If the patient does not respond to parenteral vitamin K, other causes should be considered.
Vitamin C deficiency (scurvy)	This diagnosis should be considered when there is lethargy with skin and gum bleeding (perifollicular hemorrhages, gum bleeding with swelling). The condition is rare in developed countries. The cause is usually a very poor diet or malabsorption.

IgG, Immunoglobulin G; NSAID, nonsteroidal antiinflammatory drug.

Case 6: Illustration of Changes in Bleeding Outcomes With Treatment

A 38-year-old woman was evaluated for a bleeding disorder. Her family physician had already excluded the possibility of von Willebrand disease. The patient had a long-standing history of massive bruises, often without recollection of trauma, prolonged nosebleeds requiring medical attention since early childhood, prolonged bleeding from minor cuts, and severe bleeding requiring blood transfusions with many surgical procedures. She had a history of recurrent iron-deficiency anemia, menorrhagia requiring medical therapies, and immediate postpartum bleeding. Her father had a history of bleeding problems, but the cause of the bleeding problem in the family was unknown. The history suggested an inherited disorder, possibly a platelet function disorder or a form of von Willebrand disease. The testing indicated that she had a platelet secretion defect

with multiple aggregation abnormalities, with no evidence of von Willebrand disease. She underwent additional surgical procedures, using desmopressin treatment to reduce her bleeding risks, with no abnormal bleeding. Her menorrhagia was controlled with tranexamic treatment. She self-administered desmopressin treatment to control nosebleeds, with good effect. This case illustrates that treatment affects bleeding outcomes and the importance of evaluating for common defects in hemostasis.

For more information on therapies for specific disorders, see the chapters on hemophilia (Chapters 135 and 136), rare coagulation factor deficiencies (Chapter 137), von Willebrand factor (Chapter 138), and platelet disorders (Chapters 125 and 130–132).

LABORATORY EVALUATION OF HEMOSTATIC AND THROMBOTIC DISORDERS

Menaka Pai

This chapter provides a practical approach to the laboratory evaluation of hemostatic and thrombotic disorders. Any assessment of hemostatic or thrombotic disorders must start with a thorough history and physical exam. These can provide clues to guide subsequent laboratory testing, diagnosis and management.

Physiologic hemostasis is a complex interplay of cellular or plasma elements: the adhesion of platelets to damaged endothelium, the aggregation of platelets to form a temporary plug, the successive activation of coagulation factors to form a stabilizing fibrin clot, clot retraction to repair endothelial damage, and finally clot breakdown through fibrinolysis (Fig. 129.1). Commonly available laboratory tests focus on the individual components of hemostasis by testing coagulation proteins, platelets, and fibrinolytic proteins; this chapter is organized into similar components, to provide a structured laboratory approach to the patient with a hemostatic or thrombotic problem. Yet the clinician must be mindful that in the body, the components of hemostasis work together to form a product that is more than the sum of its parts.

LABORATORY EVALUATION OF COAGULATION PROTEINS

The Physiology Underlying Laboratory Evaluation of Coagulation Proteins

For over half a century, the process of fibrin clot formation has been conceptualized as a “coagulation cascade.” This is based on the waterfall hypothesis of Davie, Ratnoff, and MacFarlane, who almost simultaneously reported a sequence of proteolytic reactions starting with factor XII (Hageman factor) activation by surface contact and ending with thrombin’s proteolysis of fibrinogen to form fibrin.^{1,2} However, upon its introduction, this hypothesis of successive necessary proteolytic reactions already appeared to be too simplistic. Nearly a decade earlier, Ratnoff had identified that deficiencies of factor XII were not associated with bleeding; others soon established that deficiency of factor XII’s cofactors (prekallikrein and high-molecular-weight kininogen) did not result in a bleeding phenotype either. In 1977, Osterud and Rappaport recognized that the factor VIIa/tissue factor complex can activate factor IX to factor IXa.³ Broze later recognized that this complex cannot directly activate factor X, because of the presence of tissue factor pathway inhibitor (TFPI); factor IX activation is a prerequisite. Though deficiency of factor XII and its antecedents is not associated with bleeding, factor XI deficiency is. In 1991, Gailani and Broze explained this by proposing that factor XI can be activated independent of factor XII, as formed thrombin cycles back to activate factor XI and thus amplifies its own formation.⁴ Factor XII, long considered to have no role in coagulation in vivo, has been found to play a role in thrombus formation and angiogenesis.⁵ Our understanding of hemostasis has advanced still further in recent years, as blood coagulation research is increasingly performed under flow conditions with cellular elements in vitro, and in live animals in vivo.

The physiologic “coagulation cascade” now appears to be an intricate system with built-in shortcuts and feedback loops. It is triggered by factor VIIa and tissue factor, and results in the activation

of zymogens that become serine proteases. This system functions in concert with platelet activation and fibrinolysis (Fig. 129.2). However, clinical laboratory testing of coagulation proteins is not based on this current understanding—it follows the original Ratnoff-Davie-MacFarlane surface-activated coagulation cascade hypothesis.^{1,2} These tests attempt to mimic in vivo processes by carrying them out in vitro, and thus do not capture the true complexity of physiologic hemostasis. They are still useful in diagnosing coagulation protein deficiencies and important bleeding disorders. However, they can be misleading, as they can also detect abnormalities of questionable clinical significance. The clinician must therefore understand the distinction between the complexity of physiologic hemostasis and the simplistic picture presented by laboratory tests.

As we proceed in reviewing tests for coagulation proteins, we can place them into three technical categories:

1. **Immunologic tests**, which include enzyme-linked immunosorbent assays (ELISA), immunoelectrophoresis, and immunoturbidimetric (latex agglutination) tests. These tests are quantitative, and detect specific proteins with polyclonal or monoclonal antibodies. Their sensitivity and specificity depend on the antibody used (polyclonal versus monoclonal) and the presence of interfering substances (e.g., rheumatoid factor, other autoantibodies).
2. **Chromogenic or amidolytic assays**, which measure the activity of the serine proteases of the coagulation system as they react with synthetic peptides. The reaction (and thus the activity of serine protease) can be measured as the synthetic peptide releases a colored dye. Chromogenic assays are affected by the specificity of the peptide substrate. A disadvantage of these assays is that their fairly narrow measure of an enzyme’s activity may not correlate with its biologic activity in vivo or its activity in clot-based assays.
3. **Clot-based or coagulation assays** that are functional, and compare the clotting potential of a patient’s plasma with standard plasma that has a known clotting potential. These tests are more difficult and time-consuming to perform than the others, and are susceptible to interference from other factors. However, they most closely approximate in vivo hemostasis.

SCREENING FOR COAGULATION PROTEIN DEFECTS: ACTIVATED PARTIAL THROMBOPLASTIN TIME, PROTHROMBIN TIME AND THROMBIN CLOTTING TIME

The three assays most commonly used to screen for coagulation protein defects are: (1) the activated partial thromboplastin time (APTT), induced in vitro by surface-activation of factor XII; (2) the prothrombin time (PT), induced in vitro by the addition of excess tissue factor; and (3) the thrombin clotting time (TCT), a test of fibrinogen integrity and thrombin inhibition. The PT, APTT, and TCT are clot-based assays that measure the rate of clot formation, and are based on the waterfall hypothesis of coagulation. They trigger a sequence of proteolytic reactions in the intrinsic, extrinsic, and common pathways (Fig. 129.3). The reactions culminate in the proteolysis of fibrinogen to form a fibrin clot, which causes soluble

Fig. 129.1 SCHEMATIC DIAGRAM OF HEMOSTASIS. Two equally important arms of activity contribute to physiologic hemostasis. The platelet contribution to hemostasis is as follows. When a vessel is injured, exposing collagen, platelets adhere to the injury site via von Willebrand factor and, in high-shear areas, glycoprotein VI (not shown in figure). Upon adherence, the platelets are activated and release their granule contents. Released ADP and other granule contents recruit more platelets to the injury site. Simultaneously at the site of injury, subendothelial cell tissue factor is upregulated and with activated factor VII (VIIa) activates factor IX to activated factor IX (IXa) and, sequentially, factor X to activated factor X (Xa), and prothrombin (II) to thrombin. Exposed collagen also allows for factor XII autoactivation and generation of additional thrombin (not shown in figure). Thrombin stimulates more platelets, enhancing the platelet plug. Thrombin also proteolyzes fibrinogen to form fibrin monomer, which then polymerizes into a fibrin clot. These events occur on or about the activated platelet surface. *Epi*, Epinephrine; *Fb*, fibrinogen; *PAF*, platelet-activating factor; *PAR*, protease-activated receptor, *TF*, tissue factor; *vWF*, von Willebrand factor.

proteins to precipitate in the patient's plasma sample. These soluble proteins can be detected by either increased electric impedance or decreased optical clarity, based on the instrumentation used to measure the result.

Any defect in one of the coagulation proteins along the pathway to clot formation will give an abnormal result (i.e., a delayed time to clot formation), (see Fig. 129.3). For example, a factor XI deficiency will lead to a prolonged APTT. Furthermore, because clot formation depends on a series of reactions, any substance (e.g., inhibitory antibodies, anticoagulants) that interferes with the assay *downstream* from a specific coagulation protein will lead to an abnormal result. For example, a profound fibrinogen deficiency will lead to a prolonged APTT and PT, even when the levels and function of all the upstream coagulation proteins are normal.

In the APTT assay, activation of the blood coagulation system occurs when factor XII comes in contact with a negatively charged surface such as kaolin, celite, silica, or elagic acid (hence the intrinsic pathway's alias as the "contact pathway"). This causes the protein to change shape, allowing its autoactivation and subsequent initiation of the cascade of proteolytic reactions seen in the coagulation system. The APTT measures many proteins that are critical to physiologic hemostasis, including factor VIII and factor IX. However, it also

measures proteins like factor XII, prekallikrein, and high-molecular-weight kininogen that are not necessary for physiologic hemostasis. To perform the APTT assay, equal parts of a negatively charged surface and phospholipid mixture are incubated with patient plasma for a predetermined time. Calcium chloride is added to recalcify the citrated plasma, and the time to clot formation is measured. The APTT assay measures all the proteins of the intrinsic system (factor XII, prekallikrein, high-molecular-weight kininogen, factor XI, factor IX, and factor VIII) and the proteins of the common pathway (factors X, V, II, and fibrinogen). These proteins have different threshold levels to which they must fall before the APTT shows an abnormality. For example, most commercial APTT reagents detect a decrease in factor VIII when the protein level decreases to 35% to 45% of normal (i.e., 0.35–0.45 U/mL). Alternatively, factor XII and high-molecular-weight kininogen levels must fall to 10% to 15% of normal before the APTT becomes abnormal. The sensitivity of the screening tests for detection of specific abnormalities varies with the factor being tested, the commercial reagent used in the assay, and the equipment platform for measurement. Each clinical laboratory should know the level of decrease for each coagulation factor that produces an abnormal APTT with their current equipment and reagents.

Fig. 129.2 SCHEMATIC DIAGRAM OF PHYSIOLOGIC HEMOSTASIS. Formation of the tissue factor–activated factor VII complex (TF/VIIa) results in factor IX activation to activated factor IX (IXa). TF/VIIa does *not* normally activate factor X directly (*brown line*). Activated factor IX activates factor X to activated factor X (Xa) in the presence of activated factor VIII (VIIIa), which must have been formed from some prior thrombin activation of factor VIII (tenase). Activated factor X in the presence of activated factor V activates prothrombin to thrombin (IIa) (prothrombinase). Thrombin proteolyzes fibrinogen to form a fibrin clot. If more thrombin is needed, thrombin can activate factor XI to activated factor XI (XIa), which then activates more factor IX to factor IXa, which makes more activated factor X and thrombin. If more thrombin-induced clot formation is needed, thrombin also activates carboxypeptidase U to form a thrombin-activatable fibrinolysis inhibitor that inhibits fibrinolysis (pathway not shown). Factor XI also can be activated by activated factor XII, which is formed secondarily by the constitutive activation of prekallikrein in the presence of high-molecular-weight kininogen by contact activation in collagen-exposed injured vessels. These latter mechanisms are *not* constitutive for physiologic hemostasis. However, in nonphysiologic states, such as sepsis, clot formation in the intravascular compartment, or cardiopulmonary bypass, activated factor XII can activate factor XI to initiate hemostasis with thrombin formation. This latter mechanism is the basis of the activated partial thromboplastin time, a major screening test for hemostatic disorders. HK, High-molecular-weight kininogen; PK, prekallikrein; PL, Phospholipid; TF, tissue factor; Va, activated factor V. (Modified from Schmaier AH, Miller J: *Coagulation and fibrinolysis*. In McPherson RA, Pincus MR, editors: *Henry's clinical diagnosis and management by laboratory methods*, ed 22, Philadelphia, 2011, Elsevier, p 785).

In the PT assay, addition of excess tissue factor creates a nonphysiologic change in the normal stoichiometric relationship of coagulation factors, allowing factor VIIa to overcome the inhibitory effect of TFPI; the factor VIIa/tissue factor complex then activates factor X to factor Xa (this bypasses the usual physiologic requirement for this process to occur through factor IX activation). To perform the PT assay, one part patient plasma and two parts tissue thromboplastin (tissue-derived or recombinant human tissue factor) and phospholipid are incubated for a predetermined time. The plasma is then recalcified by the addition of calcium chloride, and the time required to clot formation is measured. The PT assay measures the extrinsic pathway of coagulation, which consists of factor VII and the proteins of the common pathway (factors X, V, II, and fibrinogen). Like the APTT, the PT becomes abnormal at different threshold levels for different factors, depending on the commercial reagent and the

equipment platform. For example, factor VII levels must generally fall below 35% to 40% before the PT becomes abnormal.

The PT can also be used to monitor warfarin therapy if the test reporting is modified so it can be interpreted universally. Because of the plethora of commercially available PT reagents and coagulation instruments, it is impossible to know the normal range for the PT from any given laboratory. The international normalized ratio (INR) was thus developed to standardize the reporting of the PT, and create a universal benchmark for monitoring warfarin therapy. $INR = (\text{patient PT}/\text{mean laboratory PT})^{ISI}$, where the ISI (international sensitivity index) for a given thromboplastin reagent is a measure of its responsiveness to reduction of the vitamin K–dependent coagulation factors, factors II, VII, IX, and X. The ISI (provided by each reagent's manufacturer, but ideally locally validated) is based on the degree of variation of the thromboplastin reagent from the World

Fig. 129.3 ORGANIZATION OF THE COAGULATION SYSTEM BASED ON CURRENT SCREENING ASSAYS. The intrinsic coagulation system consists of the protein factors XII, XI, IX, and VIII and prekallikrein and high-molecular-weight kininogen. The extrinsic coagulation system consists of tissue factor and factor VII. The common pathway of the coagulation system consists of factors X, V, and II and fibrinogen (I). The activated partial thromboplastin time requires the presence of every protein except tissue factor and factor VII. The prothrombin time requires factors VII, X, V, and II, and fibrinogen. The thrombin clotting time only tests the integrity of fibrinogen. (Modified from Schmaier AH: *Approach to the bleeding patient*. In Schmaier AH, Petruzzelli LM, editors: *Hematology for the medical student*, Philadelphia, 2003, Lippincott Williams & Wilkins, p 79).

Health Organization (WHO) reference thromboplastin. This reference has an arbitrarily assigned value of 1. INR derivation can be performed by developing a calibration line for any given thromboplastin, using orthogonal regression or linear regression and incorporating the PT determined with the WHO standard.⁶ Determination of the ISI requires samples from a minimum of 20 normal donors and 60 patients on stable warfarin therapy with INRs from 1.5 to 5.0.⁷ The higher the ISI, the less sensitive the thromboplastin. In practice, changes in the INR are considered interchangeable with changes in the PT. However, the INR is correctly used only to characterize the degree of PT prolongation of a plasma sample from a patient on warfarin.

In the TCT assay, exogenous thrombin is added to examine the integrity of its major substrate, fibrinogen. To perform this assay, purified thrombin is added to plasma, and the time to clot formation is measured. The TCT is thus a direct measure of the conversion of fibrinogen to fibrin (see Fig. 129.3). When performing this assay, it is essential to use the minimal amount of α -thrombin (3000 U/mg specific activity) that will reproducibly “clot” fibrinogen, usually 2–6 U/mL, aiming for approximately 20 seconds with pooled normal plasma to achieve maximal sensitivity for a clinically useful assay. This assay is distinguishable from the clottable fibrinogen assay (Claus assay) by the amount of thrombin used. The clottable fibrinogen assay uses far more thrombin (100 U/mL) and calculates the amount of functional fibrinogen in patient plasma compared with known levels of functional fibrinogen in calibration plasma.⁸ A prolonged

TCT, as indicated by values outside the 95% confidence interval for the time to clot of a population of 20 or more normal donors, suggests reduced fibrinogen levels (usually <100 mg/dL), abnormal fibrinogen function, or the presence of an inhibitor of the exogenous thrombin (e.g., heparin or a direct thrombin inhibitor). The TCT can also be elevated if there is interference with fibrin polymerization, which can be caused by elevated levels of fibrinogen degradation products or the presence of a paraprotein. Some drugs, such as valproic acid, also cause elevation of the TCT.⁹

EVALUATION OF SPECIFIC COAGULATION PROTEIN DEFECTS

When the APTT, PT, or TCT indicate a coagulation protein defect, the plasma concentration of the coagulation factors should be evaluated. Factor assays determine the nature and severity of coagulation protein defects, and can also be used to monitor factor replacement therapy. Coagulation protein defects can take three forms: a true protein deficiency; an abnormal protein that cannot participate in its physiologic function(s); or an inhibitor that targets the active site of the protein or enhances its clearance. Inherited protein deficiencies and abnormalities can be caused by deletions, insertions, and missense/nonsense mutations in individual genes. Inhibitors are generally immunoglobulins, although abnormally produced endogenous heparin, fibronectin, or cryoglobulins can also serve as acquired inhibitors to coagulation proteins.

If a coagulation protein defect is suspected, clinical laboratory testing can be done with immunologic, chromogenic or clot-based assays. Clot-based assays for coagulation proteins are functional: they will be abnormal with both true deficiencies and dysfunctional proteins. These take the form of one-stage assays that use the APTT (for factor XII, prekallikrein, high-molecular-weight kininogen, factors XI, IX, and VIII) or the PT (for factors VII, X, V, and II) as the platform. Specific factor-deficient plasma is the key to clot-based factor assays. These assays are based on the principle that when plasma (either from a reference standard or from a patient) containing the factor is added to plasma completely deficient in that factor, it can “correct” (i.e., shorten) the prolonged clotting time. For example, a factor VIII assay requires reference plasma, factor VIII-deficient plasma (which has <1 U/dL of factor VIII and normal levels of all other factors), and patient plasma. A number of different dilutions of the reference plasma are set up, creating a range of known concentrations of factor VIII. Factor VIII-deficient plasma is added to each dilution, and after incubation for a predetermined time, APTTs are performed according to laboratory protocol. A calibration curve can then be set up by plotting the known concentration of factor VIII present (x-axis) against the time to clot in seconds (y-axis). This process is repeated, substituting patient plasma for reference plasma. If the patient plasma has decreased levels of factor VIII, it cannot compensate for the absence of factor VIII in the factor VIII-deficient plasma; the time to clot formation is prolonged when compared to a similar dilution of reference plasma. By comparing the time to clot of the patient’s plasma to the calibration curve, the level of factor VIII in the patient’s plasma can be quantitated.

Immunologic assays can be used to establish the quantity (as opposed to the quality) of coagulation proteins. When used together with clot-based tests, these assays can detect a protein with reduced function, but normal production. For example, an abnormal fibrinogen (dysfibrinogenemia) can be detected by measuring clottable fibrinogen and fibrinogen antigen on the same sample. If fibrinogen clottability is less than 90% of the amount of fibrinogen antigen, the protein produced is likely functionally abnormal.

Evaluation of Specific Inhibitors of Coagulation Proteins

An inhibitor is generally suspected when a prolonged clot-based assay does not correct after mixing patient plasma in equal quantities with

normal plasma (i.e., in a 1:1 mix), or if an apparent factor deficiency is not consistent with the patient's clinical history. Screening for inhibitors is accomplished by using a 1:1 mix in a clot-based assay. If coagulation factor–deficient plasma is mixed with normal plasma, clotting will not be impaired, as the normal plasma will compensate for the deficient plasma and “correct” its prolonged clotting time. However, if inhibitor-containing plasma is mixed with normal plasma, clotting will be impaired, as the inhibitor will decrease the activity of coagulation factors in the normal plasma as well. Specific inhibitors of coagulation proteins are generally time-dependent, that is, clotting may not be impaired immediately after the 1:1 mix is performed. However, if it is incubated for 2 hours, the clotting time will be prolonged.

Inhibitors of specific coagulation proteins increase a patient's risk for bleeding. The most common acquired inhibitor is an antibody to factor VIII (see [Chapters 135](#) and [136](#)). It can occur as an alloantibody in persons with hemophilia, or as an autoantibody in those with previously normal hemostasis.¹⁰ Patients with an autoantibody-type acquired factor VIII inhibitor present with a prolonged APTT and hemophilia-like bleeding. Both males and females can develop this type of inhibitor. It is characteristically seen in older adult patients, patients with B-cell malignancies, patients with connective tissue disorders such as systemic lupus erythematosus, and in the postpartum period. Management decisions in these patients are influenced by the severity of bleeding and the titer of the inhibitor.^{10,11} Quantitative measurement of factor VIII inhibitors is performed using the Bethesda method. This method is based on the observation that if a coagulation factor is incubated with plasma containing its specific inhibitor, the factor will be progressively neutralized. If the amount of factor added and the duration of incubation are standardized, the inhibitor strength can be measured according to how much of the factor is inhibited. One Bethesda unit is defined as the amount of factor VIII inhibitor that will neutralize 50% of 1 unit of factor VIII in normal plasma after 2 hours of incubation at 37°C. Normal plasma pool is considered to represent 1 unit of factor VIII. The Bethesda assay is performed by incubating patient plasma with normal plasma for 2 hours at 37°C. At the end of the incubation period, the residual factor VIII is assayed and plotted against a standard graph of Bethesda units versus residual factor VIII activity. The factor VIII percentage nearest to 50% (between 30% and 60%) is chosen for calculating the strength of inhibitor. At 50% inhibition, the test plasma contains, by definition, 1 Bethesda inhibitor unit per mL. The Nijmegen modification allows for more accurate determination of inhibitor titers at low levels of factor VIII inhibition. Increases in pH and decreases in protein concentrations can lead to increased inactivation of factor VIII, potentially leading to false-positive results using the standard Bethesda assay. The Nijmegen modification buffers normal plasma with 0.1 M imidazole buffer, and uses immunodepleted factor VIII–deficient plasma in the control mixture.

Inhibitors directed against other coagulation factors are rare. Autoantibodies against von Willebrand disease (vWD) can develop in the context of a paraproteinemia, whereas autoantibodies against prothrombin are a rare complication of systemic lupus erythematosus. Inhibitors to other factors can be measured with modifications of the Bethesda method.

Evaluation of Acquired Inhibitors of Coagulation Proteins

The most commonly detected acquired inhibitors are the antiphospholipid antibodies (APLAs) (see [Chapter 141](#)). APLAs represent antibodies directed to epitopes of proteins that bind phospholipids. They include the lupus anticoagulant (LAC), anticardiolipin antibodies (aCL) and anti- β_2 glycoprotein I antibodies (a β_2 GPI). LAC variably interfere with the APTT and PT, depending on the nature of the commercial APTT or PT reagent. Despite their ability to inhibit coagulation factors, LAC (like other APLAs) do not increase bleeding risk. APLAs may have no clinical significance at all, or they may predispose to thrombosis. Laboratory assays of APLAs fall into

three categories: (1) clot-based assays that detect the LAC; (2) immunoassays that detect aCL; and (3) immunoassays that detect a β_2 GPI. There is currently a lack of standardization of these assays, and their findings do not always correlate with clinical symptoms. However, laboratory identification of APLAs is a key component of diagnosing antiphospholipid syndrome, an autoimmune syndrome that increases the risk of thrombotic and pregnancy complications.¹² Current laboratory principles of detecting APLAs are well described in [Chapters 140](#) and [141](#). Highlights are outlined here.

LAC screening comprises two tests based on different principles: the dilute Russell viper venom time, and a sensitive APTT, using an APTT reagent containing silica as the activator.¹² Both tests are phospholipid-dependent. If at least one of the two tests suggests the presence of a LAC, a 1:1 mixing test using pooled normal plasma should be performed. Confirmatory testing must also be done with an assay that is less sensitive but more specific to LAC, by increasing the phospholipid content. aCL and a β_2 GPI antibodies are detected using immunoassays. Traditionally, the enzyme-linked immunosorbent assay (ELISA) technique was used. However, newer automated assays have been introduced; these are expected to improve test reproducibility, specificity, and accuracy of detection. At this time, aCL and a β_2 GPI testing is not well standardized, and there is a lack of uniformity in reference material used for calibration. Reporting is also not standardized. aCL assays are expressed in GPL (units of aCL immunoglobulin [Ig] G antibodies, calculated against the original Harris standards) or MPL (units of aCL IgM antibodies, calculated against the original Harris standards). a β_2 GPI can be expressed in U/mL, ng/mL, and μ g/mL among others.

PRACTICAL APPROACH TO LABORATORY TESTING OF COAGULATION PROTEINS

The first step in interpreting laboratory tests of coagulation proteins is synthesizing the results of the PT, APTT, and TCT. When all three assays are performed simultaneously, they can give the clinician a high level snapshot of the patient's coagulation factors, and inform a practical differential diagnosis ([Table 129.1](#).) An abnormality in one test suggests an abnormality in one branch of the Ratnoff-Davie-Macfarlane coagulation cascade, whereas abnormalities in more than one test suggest a problem in the common pathway of coagulation.

Isolated prolongation of the APTT is caused by abnormalities in the intrinsic pathway, only some of which are associated with an increased bleeding risk. It is essential to consider the APTT in the context of a thorough clinical bleeding assessment. If the prolonged APTT is associated with bleeding, then the differential diagnosis is decreasing likelihood of frequency is: factor VIII deficiency; factor IX deficiency; or factor XI deficiency. Factor VIII and IX deficiencies are X-linked, and affect 1:5000–10,000 males and 1:25,000–30,000 males respectively.¹³ Factor XI deficiency is an autosomal disorder that affects both males and females, and has a variable prevalence.¹³ It causes a clinically significant bleeding disorder in 1:1 million in the general population, but has a rate of heterozygosity as high as 8% to 9% in Ashkenazi Jews (see [Chapters 135](#) and [137](#) for a full discussion of these factor deficiencies). If the isolated prolonged APTT is not associated with bleeding symptoms, the most common cause is an APLA, often found in otherwise healthy individuals. Coagulation protein deficiencies that prolong the APTT but do not cause bleeding include factor XII, prekallikrein, and high-molecular-weight kininogen deficiency (see [Table 129.1](#)). It is important to consider these three proteins in the evaluation of an isolated prolonged APTT, to preclude misguided attempts to “correct” the prolonged APTT by giving patients unnecessary blood products or factor concentrates.

An isolated PT prolongation associated with bleeding usually indicates factor VII deficiency (see [Chapter 137](#)); these deficiencies are partial, as complete factor VII deficiency appears to be incompatible with life.¹³ Sometimes, mild defects in common pathway proteins (e.g., factors II, V, and X) may initially appear as an isolated PT prolongation, though as they progress they eventually prolong the

TABLE 129.1 Synthesizing Results of PT, APTT, and TCT

Test			Possible Diagnoses
PT	APTT	TCT	
Normal	Normal	Normal	Normal hemostasis, disorder of platelet function, factor XIII deficiency, disorder of vascular hemostasis, mild coagulation protein deficiency, mild vWD, disorder of fibrinolysis (α_2 -antiplasmin deficiency/defect, plasminogen activator inhibitor-1 deficiency/defect)
Prolonged	Normal	Normal	Factor VII deficiency, early oral anticoagulation, lupus anticoagulant, mild factor II, V or X deficiency, specific factor inhibitor
Normal	Prolonged	Normal	Factor VIII, IX, XI, XII, prekallikrein or HMWK deficiency, lupus anticoagulant, amyloid-adsorbed factor IX, specific factor inhibitor
Prolonged	Prolonged	Normal	Multiple factor deficiency (e.g., liver failure, vitamin K deficiency, oral anticoagulants), factor V, X or II deficiency, amyloid-adsorbed factor X, specific factor inhibitor
Prolonged	Prolonged	Prolonged	Anticoagulants, DIC, dilutional coagulopathy, liver disease, fibrinogen deficiency/disorder, inhibition of fibrin polymerization, hyperfibrinolysis

APTT, Activated partial thromboplastin time; DIC, disseminated intravascular coagulation; HMWK, high-molecular-weight kininogen; PT, prothrombin time; TCT, thrombin clotting time; vWD, von Willebrand disease.

APTT as well. This asynchronous prolongation occurs because PT reagents with an ISI approaching 1 are more sensitive to factor deficiencies than the APTT. Conversely, the PT and APTT are relatively insensitive to mild defects in fibrinogen. With some reagents, APLAs may also prolong the PT.

When confronted with prolongation in both the PT and APTT, the hematologist should first consider clinical situations that broadly affect these tests: anticoagulant therapy, vitamin K deficiency, liver disease, or disseminated intravascular coagulation (DIC). These conditions are far more common than isolated factor deficiencies of the factors in the common pathway (factor II, V and X). Anticoagulants act by inhibiting one or many coagulation proteins in the common pathway, while vitamin K deficiency decreases functional factor II, VII, IX and X. Vitamin K deficiency is found in individuals receiving warfarin therapy, who are profoundly nutritionally deplete (caused by a poor diet, or the receipt of incomplete parenteral nutrition), who have altered gut microbiota as a result of intestinal surgery or antibiotic therapy, or, very rarely, who have defects in transport proteins or enzymes for vitamin K metabolism. The liver synthesizes all coagulation proteins, so liver disease can have a profound effect on laboratory tests of hemostasis by causing multiple factor deficiency. Prekallikrein, factor XI, factor VII, and factor V production drop in hepatic failure, and fibrinogen synthesis becomes abnormal. DIC, an important cause of APTT and PT prolongation, is discussed in detail toward the end of this chapter.

TCT prolongation can be caused by reduced fibrinogen levels (e.g., because of liver disease), abnormal fibrinogen function, or large amounts of thrombin inhibitors like heparin. The TCT also detects defects in fibrinopeptide A and B release, as well as polymerization defects. The reptilase time uses Batroxobin (Reptilase), a purified enzyme from the snake *Bothrops atrox*, to “clot” fibrinogen by liberating only fibrinopeptide A. An abnormal TCT with a normal reptilase time indicates a fibrinopeptide B–release defect, an abnormality that gives very long APTT and PT values but is not associated with bleeding. The reptilase time also will not be altered by the presence of heparin, and can thus be used to determine if a prolonged TCT is the result of heparin. Another practical way to determine if a prolonged TCT is a result of heparin is to use the protamine neutralization test. This test is based on the TCT, but varying amounts of protamine sulfate are added to patient plasma before the addition of thrombin. Protamine sulfate can neutralize heparin, and thus normalize the TCT. The concentration of heparin in the plasma can be calculated from the amount of protamine sulfate required to produce this effect.

When presented with a prolonged clot-based assay, the hematologist must also be able to differentiate between a coagulation

protein deficiency and an inhibitor to a specific coagulation protein. Two approaches can be used to obtain a specific diagnosis. The first approach uses the 1:1 mix, a test in which patient and normal plasma are mixed in equal proportions. Mixing studies based on the PT or APTT are interpreted based on the fact that 50% levels of any coagulation factor will yield normal PT and APTT values. Only when the level drops below 50% will clot formation become prolonged, though the sensitivity of the assay then depends on the factor and the test reagent. Practically, this means that if a patient has less than 1% of a factor, and their plasma is mixed 1:1 with normal plasma, the PT or APTT will be normal. However, if a patient has something in their plasma that interferes with protein function in normal plasma (e.g., an inhibitor, an anticoagulant), the PT or APTT will be prolonged. The 1:1 mix can thus be used to screen for the presence of factor deficiency and inhibitors. This approach is far from perfect. No studies provide standardized evidence-based laboratory procedures for these screening assays, so the ratio of patient plasma to normal plasma used, the time of incubation from mixing to assay, and the sensitivity and specificity for assessing factor deficiencies and circulating anticoagulants is variable. This makes it difficult to translate the results of mixing studies into meaningful diagnostic data. If a factor deficiency or inhibitor is suspected, it is essential to perform the appropriate specific testing, as outlined previously.

Other comorbid illnesses may also result in a bleeding diathesis. For example, systemic amyloidosis is associated with decreases in plasma factor X or IX as a result of adsorption of the coagulation proteins onto the amyloid protein. In the case of factor X adsorption, the PT and APTT may be affected, while in the case of factor IX adsorption, only the APTT is affected. Hypergammaglobulinemic states seen with multiple myeloma or Waldenström macroglobulinemia (IgM) can be associated with inhibitors to coagulation protein function. Dysfibrinogenemias are common in these patients because fibrinogen readily binds the immunoglobulin.

LABORATORY EVALUATION OF PLATELETS AND VON WILLEBRAND FACTOR

Screening for Disorders of Primary Hemostasis

Disorders of platelets and von Willebrand factor (vWF), the key components of primary hemostasis, are characterized by disproportionate bleeding after injury or surgery, petechiae, purpura, ecchymoses, mucosal bleeding (including epistaxis and gum bleeding), and heavy menstrual bleeding. Most patients have a family history of similar

mucocutaneous bleeding. In the past, the Ivy bleeding time—a test in which the forearm is cut, and the time until bleeding stops is measured—was used to screen for disorders of primary hemostasis, including platelet function disorders (PFDs) and vWD.¹⁴ This test is no longer considered to be useful in the investigation of bleeding disorders. It is invasive, operator dependent, can be affected by nonhematologic factors (e.g., Ehlers-Danlos syndrome, osteogenesis imperfecta, scurvy, skin quality, skin temperature, vascular function), and has low predictive value for surgical bleeding.¹⁵ It is also not useful in detecting platelet dysfunction in the setting of thrombocytopenia. Importantly, the bleeding time is neither sensitive nor specific enough to preclude further testing for vWF or platelet abnormalities.¹⁶ A normal bleeding time should not reassure the clinician that an important bleeding disorder is not present.

Several automated analyzers have been proposed as replacements for the bleeding time, and potentially useful screening tools for disorders of primary hemostasis. The platelet function analyzer PFA-100 (Siemens, Deerfield, IL), has been best evaluated. The PFA-100 attempts to recreate the high shear conditions under which primary hemostasis occurs in vivo. Using citrated whole blood, it measures the closure time required for platelets to adhere to agonist-coated membranes and aggregate under high shear stress (5000–6000/s). Two cartridges are available: one with collagen–adenosine diphosphate (ADP) membranes, and the other and collagen–epinephrine coated membranes. Platelet function is measured as a function of the time needed to occlude the aperture, termed *closure time*. Abnormalities can lead to lengthening of the closure time. The PFA-100 is more sensitive than the bleeding time in patients with previously diagnosed vWD, but less sensitive in those with mild platelet secretion disorders (which are the most frequent PFDs) and platelet storage pool deficiency. In a prospective study by Quiroga et al, the overall sensitivity of closure time in vWD and PFDs was 50% and 18%, respectively.¹⁶ This suggests that the PFA-100 is only marginally more useful than the bleeding time. It is still not sensitive or specific enough to preclude further testing for vWF or platelet abnormalities, and cannot definitively rule out important bleeding disorders.

At this time, laboratory screening tests for disorders of primary hemostasis have limited usefulness. Diagnosis of these disorders must be grounded in a thorough clinical history and physical exam, and ultimately relies on the performance of the specific and sensitive tests outlined in the following.

Evaluation of Platelets

The first step in the investigation of platelet disorders is determining the platelet count, as thrombocytopenia alone may increase bleeding risk (thrombocytopenia is discussed in detail in [Chapters 131 and 132](#)). Obtaining a detailed list of medications the patient is taking, allopathic and naturopathic, prescription and over-the-counter, is also essential, as many drugs impact platelet number and function. Platelet function can also be altered in the setting of systemic disorders, such as renal disease, liver disease, myeloproliferative and myelodysplastic disorders, and malignancy. Inherited platelet disorders are often syndromic, and are associated with manifestations like albinism, bone changes, sensorineural hearing loss, renal disease, and immunodeficiency.

Platelet function can be evaluated with platelet aggregation studies. These tests measure the ability of agonists to cause in vitro platelet activation and aggregation. Two forms of platelet aggregation studies are available: light transmission aggregometry (LTA) in platelet-rich plasma and impedance aggregometry in platelet-rich plasma or whole blood. LTA in platelet-rich plasma is considered the gold standard of platelet function testing, whereas impedance aggregometry is less well characterized. A number of recent guidelines have laid out standards on how to perform and interpret LTA.¹⁷ Briefly, when a platelet agonist is added to platelet-rich plasma, aggregation occurs and light transmission increases. When factors like temperature, platelet count, and mixing speed are controlled, the amount and rate of this increase depends on how reactive platelets

are to the added agonist. The increase in light transmission can be measured spectrophotometrically. Recommended agonists include ADP, epinephrine, arachidonic acid, collagen, and thromboxane analogue U46619 at predetermined concentrations.¹⁷ Ristocetin, an antibiotic that facilitates vWF binding to the glycoprotein Ib/IX/V complex, is also used in LTA to cause platelet agglutination. ADP and epinephrine result in a biphasic aggregation pattern; primary aggregation occurs in response to activation of the platelet glycoprotein IIb/IIIa receptor, then platelets degranulate and cause secondary aggregation. Conversely, arachidonic acid, thromboxane analogue, and collagen result in a monophasic aggregation pattern. Several defects of platelet function have well-characterized LTA patterns.¹⁸ Bernard-Soulier syndrome, a defect in glycoprotein Ib, results in normal aggregation to ADP and collagen, but absent agglutination to ristocetin (this pattern can also be seen in vWD.) Glanzmann thrombasthenia, a defect in glycoprotein IIb/IIIa, results in an absent primary response to ADP and collagen. Impaired aggregation to arachidonic acid suggests an aspirin effect, or cyclooxygenase deficiency. Platelet storage pool disorders can be diagnosed with LTA and studies that measure proteins within or released from platelet α -granules or dense granules. Tests of ATP secretion from platelets can also be valuable in assessing PFDs, as they complement and expand on LTA results.¹⁹ ATP secreted by dense granules is measured by a sensitive luminescent (firefly luciferin-luciferase) assay for extracellular ATP. Platelet electron microscopy is increasingly used to evaluate the ultrastructure of platelets, including the dense granules. Finally, with appropriate monoclonal antibodies, flow cytometry can examine the surface of the platelet. Flow cytometry has a variety of uses, including detection of platelet activation by using antibodies to proteins expressed on the platelet surface (e.g., P-selectin, thrombospondin), diagnosis of platelet surface glycoprotein deficiencies, and measurement of dense granules.

Evaluation of Von Willebrand Factor

vWD is discussed in detail in [Chapter 138](#). It is diagnosed when patients have a history of mucocutaneous bleeding (usually with a positive family history), and quantitative or qualitative abnormalities of vWF. Laboratory testing of vWD includes the factor VIII assay, vWF antigen (vWF:Ag), and vWF activity (most commonly measured with the ristocetin cofactor assay, vWF:Rco).²⁰ Many laboratories also test vWF further with the collagen binding assay (vWF:CB, abnormal when there is a loss of high-molecular-weight vWF multimers or impaired binding of vWF to vascular endothelium), the low-dose ristocetin-induced platelet aggregation assay (abnormal in loss-of-function and gain-of-function defects that characterize type 2B vWD and platelet-type pseudo-vWD), and vWF multimer analysis (which is useful in type 2A and 2M vWD).²⁰ Assays that measure factor VIII binding to vWF can identify patients with defects in factor VIII binding, such as type 2N vWD.²⁰ Highly specialized coagulation laboratories may also perform vWF gene sequence analysis and vWF propeptide analysis; the latter shows promise in detecting defects associated with accelerated vWF clearance.²⁰

The diagnosis of vWD—particularly type 1 vWD, which is defined as a partial, quantitative deficiency of vWF—can be challenging.¹⁴ Studies have shown a high prevalence of bleeding symptoms in normal, healthy individuals. By definition, 2.5% of the population will also have a level of vWF:Ag that falls below the lower limit of laboratories' normal reference range. Thus, there is a danger of coincidentally associating low vWF with bleeding symptoms, and overdiagnosing type 1 vWD in the general population.²¹ To further complicate the situation, the normal range of plasma vWF is quite broad. vWF is an acute phase reactant, and can go up in patients who are inflamed, infected, pregnant, under stress, or suffering from comorbid diseases like cancer. vWF goes up with age, and is lower in individuals with blood type O. It is recommended that the label of type 1 vWD be applied only when the clinical presentation is consistent, and when vWF levels are persistently low and <30 IU/dL.¹⁴

LABORATORY EVALUATION OF FIBRINOLYSIS

Disorders of fibrin cross-linking and fibrinolysis are not recognized by routine coagulation protein and platelet testing (see Table 129.1). Congenital factor XIII deficiency, a rare disease with a prevalence of 1:2 or 3 million people worldwide, is one example.²² Screening tests for factor XIII deficiency aim to dissolve fibrin clots in acetic acid, monochloroacetic acid, or urea.²² In the urea clot solubility test, patient plasma and a normal plasma control are induced to clot with or without added thrombin. Both samples are exposed to a 5 M urea solution and observed over time. The control clot should remain undissolved at 24 hours, as fibrin clots cross-linked in the presence of thrombin and factor XIII are stable. If the patient is factor XIII-deficient, the clot will dissolve rapidly. The urea clot solubility test, and related assays, are not standardized and have poor sensitivity; their detection limit is generally less than 5% of factor XIII activity. Suspected factor XIII deficiency must be confirmed by functional assays (which measure the release of ammonia during the transglutaminase reaction, or incorporation of radioactive amines into proteins), or immunologic factor XIII antigen assays.²²

Tests that give a global picture of fibrinolysis can also be performed; they measure the combined effect of plasminogen activators (e.g., urokinase, tissue plasminogen activator) and inhibitors (e.g., α_2 -antiplasmin defects, plasminogen activator inhibitor 1). Defects in the latter group of proteins can produce hyperfibrinolytic states and increased bleeding potential. In the euglobulin clot lysis assay, plasma is diluted and acidified. This causes precipitation of the acid insoluble or euglobulin fraction of plasma, which includes fibrinogen, plasminogen, plasminogen activators, and plasminogen activator inhibitor-1. The precipitate is redissolved, and the fibrinogen is clotted by adding calcium. The time to spontaneous lysis of the fibrin clot is then monitored. Shortened lysis times are observed in hyperfibrinolytic states such as DIC, or when there is a deficiency of plasminogen activator inhibitor-1; however, like the urea clot solubility test, the euglobulin clot lysis time is hampered by a lack of standardization and susceptibility to interference by other factors. Specialized coagulation laboratories may offer specific assays for plasminogen inhibitors as well.

OTHER ACTIVITIES FOR HEMOSTASIS LABORATORIES

Global Hemostasis Assays

Standard coagulation tests are capable of measuring the individual components of hemostasis. There is tremendous interest in evaluating hemostasis more globally, to accurately evaluate *in vivo* hemostatic function, sensitively and specifically diagnose hemostatic disorders, monitor treatment, and better predict clinical manifestations of disordered hemostasis. Global hemostasis assays aim not only to measure components of hemostasis, but also determine how they interact with each other. They do so by assessing the rate of thrombin generation, the quantity of thrombin generation, the formation of clots in whole blood, and/or the polymerization of fibrin.

Measurement of thrombin generation was first described in the early 1950s by MacFarlane and Biggs (who used whole blood), and Pitney and Dacie (who used plasma). Over the years, methods were refined; ultimately, continuous measurement of thrombin generation was accomplished by using a thrombin-chromogenic substrate in defibrinated plasma, or a fluorogenic substrate in whole plasma. In general, modern thrombin generation assays (TGAs) use recalcified platelet-rich or platelet-poor plasma, and then trigger clotting using tissue factor. TGAs can capture not only the rate and amount of thrombin generated, but also the role of platelets (which act as an amplifying surface for thrombin activity). TGAs have been widely used in research. Clinically, they may play a role in thrombophilic states (e.g., ATIII deficiency, protein C or S deficiency, activated protein C resistance, cancer-associated thrombosis) and in hemorrhagic tendencies (hemophilia, other factor deficiencies, cardiac surgery). In hemophilia, TGAs might more accurately predict

bleeding risk and efficacy of inhibitor bypassing than traditional tests.²³ TGAs are not yet used broadly in the clinical context; test procedures are not yet well standardized, and validated reference ranges for specific conditions have not been developed.

Viscoelastic assays like thromboelastography and thromboelastometry are increasingly used in the clinical context. Viscoelastic tests are based on the premise that the end result of normal hemostasis is to rapidly create a strong, stable clot; changes in the speed of clot creation, or its strength or stability, may indicate abnormal hemostatic function. Thromboelastography was first described in 1948 by Hartert, who presented a method in which clotting was triggered in fresh whole blood with the addition of celite (an activator of the intrinsic pathway). The blood was then put into a continuously rotating cup, and a torsion wire was introduced into the system. As the clot gradually became stronger, the movement of the torsion wire dampened and ultimately stopped. A tracing of the torsion wire's movement over time reflected the velocity of clot formation, its maximal stability, and its gradual dissolution. This tracing was recorded onto light-sensitive photographic paper by a mirror-galvanometer; the image developed over hours to days.

Currently, two semi-automated commercial viscoelastic devices on the market allow results to be obtained in 10–15 minutes: the ROTEM-analyzer (TEM International, Munich, Germany), which uses a fixed cup with a rotating pin and optical detector, and the TEG-analyzer (Haemonetics Corp., Braintree, MA, USA), which uses a torsion wire and a rotating cup. Both are kinetic tests, and their tracings measure clot formation over time. They also measure maximal clot strength, clot elasticity, and clot lysis. Both use citrated whole blood that is recalcified and added to a cuvette. An activator (e.g., tissue factor) is commonly used to standardize the test, and speed up the assay. These analyzers can perform additional tests (using different activators or additives) to provide information similar to that of the APTT or PT, to neutralize heparin, to inhibit fibrinolysis, and to qualitatively analyze the functional fibrinogen component.

Viscoelastic methods are increasingly used at the bedside. They have shown some promise in detecting coagulopathies and guiding the use of blood products and other prohemostatic therapy intraoperatively, in obstetric hemorrhage, in the trauma setting, and in the intensive care unit.^{24,25} They may also be helpful in screening for hypercoagulable states, as some individuals with a history of thromboembolism demonstrate accelerated clot propagation. Viscoelastic methods do have some drawbacks. They are insensitive to platelet and vWF dysfunction, as well as factor XIII problems. Assay standardization and variability of results continue to be a challenge.^{26,27}

Evaluation of Prothrombotic States

In addition to the diagnosis of bleeding disorders, the hemostasis laboratory can help evaluate acquired and inherited prothrombotic states (see Chapter 140). It is known that certain prothrombotic states (e.g., antithrombin, protein C, and protein S deficiencies; antiphospholipid antibody syndrome) may confer a higher risk for recurrent thrombosis. Patients with these abnormalities may benefit from long-term anticoagulation after their first episode of thrombosis. Less severe prothrombotic states (e.g., heterozygous factor V Leiden and prothrombin 20210 polymorphisms, functional defects in fibrinogen and plasminogen) do not appear to impact the risk of recurrence. Clinicians often consider testing for prothrombotic states in patients who develop thrombosis at a young age, who have a strong family history of thrombosis, who have thrombosis at an unusual site, or who experience recurrent or unexplained thrombosis. However the utility of this testing is limited, as the results usually do not affect patient management or result in improved patient outcomes.²⁸ Testing can also result in potential harm, including inappropriate use of anticoagulation and undue patient anxiety. For these reasons, testing for prothrombotic states is not routinely recommended in unselected patients with thrombosis. Testing should only be undertaken with patients whose clinical presentation strongly suggests an underlying prothrombotic condition. Before testing is done,

clinicians should consider how it will affect management, and if it is aligned with the patient's values and preferences.

Monitoring Anticoagulant Therapy

The coagulation laboratory plays an important role in the monitoring of patients on anticoagulant therapy. Historically, monitoring was limited to unfractionated heparin and warfarin, which are monitored using the clot-based APTT and INR assays, respectively. However, coagulation laboratories are increasingly developing assays to monitor low-molecular-weight heparin (LMWH), fondaparinux, parenteral direct thrombin inhibitors, and the target-specific oral anticoagulants (TSOACs), which include dabigatran, rivaroxaban, and apixaban. Therapeutic ranges for these agents are not clinically validated, and vary by laboratory and by indication. However, clinicians may consider measurement of on-therapy drug levels in patients who are obese, have renal or hepatic insufficiency, experience thrombosis or bleeding while on therapy, or require urgent surgery.

The ability to neutralize the enzymatic activity of factor Xa or thrombin is the most reliable way to assay for the plasma level of anticoagulants. Antifactor Xa chromogenic assays can be used to measure Xa inhibitors like LMWH, fondaparinux, rivaroxaban, and apixaban, while antithrombin chromogenic and clot-based assays can measure direct thrombin inhibitors like argatroban, bivalirudin, hirudin, and dabigatran. Standard curves for anticoagulants are constructed by combining known amounts of the anticoagulant and the factor it inhibits. Residual factor activity is inversely proportional to the concentration of drug in the sample. Antifactor Xa assays to monitor LMWHs can be developed against WHO's International Standard for LMWH, which serves as a calibrator of drug levels. Other anticoagulants require unique calibrated assays, established by the individual laboratory.

The TSOACs also affect more commonly used clot-based assays. The TCT and APTT are more sensitive to dabigatran than the PT, and the TCT can be used to exclude the presence of dabigatran and its anticoagulant effect.²⁹ The PT is sensitive to rivaroxaban (though sensitivity varies by laboratory reagent), while it is less sensitive to apixaban.³⁰ The PT should not be used to exclude clinically significant drug concentrations of either rivaroxaban or apixaban; appropriately calibrated antifactor Xa assays are more appropriate.

Evaluating Activated Coagulation States

Specialized coagulation laboratories can monitor activated coagulation states that result in acute hemostasis and thrombosis, such as antiphospholipid antibody syndrome (see [Chapter 141](#)), heparin-induced thrombocytopenia (see [Chapter 132](#)), and warfarin-skin necrosis. The classic activated coagulation state is DIC (see [Chapter 139](#)). DIC is a clinicopathologic state characterized by excessive and dysregulated activation of coagulation and fibrinolysis, with consequent consumption of prothrombotic and antithrombotic factors. DIC is triggered by an underlying cause, such as sepsis, malignancy, trauma, obstetric complications or intravascular hemolysis. There are two forms of DIC: an *acute* and a *chronic* form. The acute form is characterized by overwhelming defibrination and a tendency to hemorrhage. The APTT and PT are elevated, and the fibrinogen and platelet count are low. The more indolent chronic form is characterized by partially compensated coagulation and a tendency to thrombosis. The APTT, PT, and platelet count may be normal or slightly low, and the fibrinogen can be normal or even elevated.

The laboratory diagnosis of DIC requires evidence of simultaneous coagulation and fibrinolysis. Evaluation begins with a complete blood count, PT, APTT and fibrinogen. The D-dimer assay is a useful adjunct to confirm fibrinolysis. D-dimers are insoluble degradation products that arise when fibrin is cross-linked by thrombin-activated factor XIII, then cleaved with plasmin. Though D-dimer elevation is a sensitive test for DIC, it is not specific for this condition; D-dimer

elevation occurs in pregnancy, large vessel thrombosis, hepatic failure, and many other conditions. Isolated D-dimer elevation in the absence of another etiology can also suggest chronic DIC. Laboratory testing can be repeated serially to monitor the severity of DIC, and its response to treatment.

ACKNOWLEDGMENTS

The author wishes to recognize the invaluable assistance and expertise of Karen A. Moffat, who provided many thoughtful comments on versions of this chapter.

ACQUIRED DISORDERS OF PLATELET FUNCTION

Reyhan Diz-Küçükkaya and José A. López

Acquired disorders of platelet function are among the most common hematologic abnormalities, a reflection of the sensitivity of platelets to external and internal perturbations. The clinical challenge in evaluating acquired disorders of platelet function is to determine whether observed derangements in platelet function pose a threat to the patient. Although platelet function can be altered to predispose to either hemostatic or thrombotic disorders, this chapter deals primarily, but not exclusively, with platelet disorders that may compromise hemostasis. We attempt also to guide clinicians in trying to determine the clinical importance of these disorders, but the marked variation in bleeding risks associated with any particular disorder of platelet function make this a difficult task. Bleeding in patients with acquired platelet dysfunction is likely to occur less frequently and predictably than in those affected by severe inherited platelet disorders such as Bernard-Soulier syndrome or Glanzmann thrombasthenia, and may manifest only in the setting of trauma or surgery or in the presence of additional hemostatic defects. However, even some patients with inherited platelet disorders only bleed when stressed by surgery or trauma, making the distinction between inherited and acquired disorders less clear cut.

The laboratory evaluation of these patients may illuminate these disorders (see [Chapter 129](#)) but may offer little concrete guidance in management. Acquired platelet defects ([Table 130.1](#)) may produce abnormal laboratory test results, such as a prolonged closure time on a platelet function analyzer (PFA) or abnormal aggregation in response to added agonists. Historically, the bleeding time was used to evaluate bleeding risk in patients with jaundice or uremia, but it measures hemostasis only in one vascular bed (the skin) and bears inherent interoperator variability. These platelet assays are useful research tools; however, defects quantified by laboratory tests, including the bleeding time, are not predictive of bleeding in these patients. Additionally, some acquired platelet disorders increase the risk of thrombosis rather than bleeding, a risk for which there is currently no effective screening test. Lastly, tests that depend on assessing the functions of platelets *ex vivo* do not assess the contributions of labile substances from the endothelium (see [Chapter 123](#)) and occasionally (as in platelet aggregometry) do not account for flow, a key component of *in vivo* platelet function.

DRUGS, FOODS, AND ADDITIVES THAT AFFECT PLATELET FUNCTION

The most common causes of acquired platelet dysfunction are drugs. In a large prospective study, 5649 unselected adult patients were screened preoperatively for hemostatic defects with activated partial thromboplastin time (aPTT), prothrombin time (PT), platelet counts, platelet function analyzer (PFA)-100 testing, and a questionnaire regarding bleeding history.¹ Bleeding history was positive in 628 patients (11.1%), and impaired hemostasis was verified in 256 (40.8%) of these patients. Of these 256 patients, 162 (63.28%) were found to have acquired platelet dysfunction. Antiplatelet drugs or nonsteroidal antiinflammatory drugs (NSAIDs) were responsible for the acquired platelet dysfunction in 147 patients and antibiotics in 10 patients.

Numerous drugs affect platelet function ([Table 130.2](#)). For several, inhibition of platelet function is their intended effect ([Fig. 130.1](#)); for most, platelet dysfunction is an unintended and

undesired side effect. Drug-induced platelet function abnormalities do not usually cause a clinically significant problem in healthy individuals. However, these drugs may increase the bleeding risk with interventions (e.g., surgery, biopsy), trauma, or in the presence of other hemostatic defects, such as those associated with cirrhosis or uremia. Antiplatelet agents are discussed more fully in [Chapter 149](#). For all of these drugs, their effects on platelet function are defined by an abnormality of platelet aggregation, but their contribution to a risk of excessive bleeding is definitively established only for aspirin, clopidogrel, ticlopidine, and inhibitors of α IIB β 3 function.

ANTIPLATELET DRUGS

Aspirin

Aspirin has been in routine use worldwide for more than 100 years and is still by far the most common agent associated with platelet dysfunction.² The antipyretic and analgesic effect of willow bark was first recorded by Galen. In 1826 and 1828 Leroux and Buchner isolated a compound from willow bark that they called *salicin* (which means *willow* in Latin).³ In 1897 a German chemist, Felix Hoffman from the Bayer Company, inspired by his father's severe arthritis and the untoward side effects of salicylic acid, discovered a method to convert salicylic acid, the active compound in willow bark, to a compound with less gastrointestinal (GI) toxicity, acetyl salicylic acid (aspirin).⁴ However, with Hoffmann's subsequent synthesis of heroin from morphine, commercial development of aspirin was relegated to the back burner for a number of decades.⁵ Aspirin was widely used for rheumatic fever in the 1940s. In the 1950s, case reports and uncontrolled studies were published suggesting that aspirin could prevent myocardial infarction and stroke.^{3,6} The clinical importance of the antithrombotic effect of aspirin was clearly demonstrated in a study of 22,071 physicians who received either 325 mg of aspirin or placebo every other day over the course of 5 years.⁷ Those receiving aspirin had a 44% decreased incidence of myocardial infarction. In a large metaanalysis, it was shown that aspirin reduced death from vascular events by 15% and nonfatal vascular events by 30%.⁷ The primary mechanism by which aspirin impairs hemostasis is through irreversible acetylation of the enzyme cyclooxygenase-1 (COX-1), an early enzyme in the synthetic pathway that produces the potent platelet agonist, thromboxane A₂ (TXA₂). Because platelets have no nuclei and therefore retain only a limited capacity to synthesize new proteins, a single low dose of aspirin (30–100 mg)⁸ or as little as 10 mg taken daily for 1 week can completely inhibit TXA₂ production and therefore impair the function of a cohort of platelets for their circulating life span.⁹ Aspirin also acetylates the isoform of COX mostly present in endothelial cells, COX-2; COX-2 acetylation blocks synthesis of prostacyclin, a strong inhibitor of platelet function.¹⁰ However, COX-2 is markedly less sensitive than COX-1 to inhibition by aspirin,² and endothelial cells, unlike platelets, are able to synthesize new enzymes quite rapidly.¹¹

Platelets exposed to aspirin either *in vivo* or *in vitro* predictably demonstrate impaired aggregation in response to epinephrine, ADP, arachidonic acid, and low concentrations of collagen and thrombin,¹² a result of defective TXA₂ production. These agonists have therefore been defined as *weak* agonists, requiring that TXA₂ diffuse out of the

TABLE 130.2 Drug-Induced Platelet Dysfunction**Anti-Platelet Drugs**

COX inhibitors: aspirin

ADP receptor antagonists

Thienopyridines: clopidogrel, ticlopidine, prasugrel

Nonthienopyridines: ticagrelor, cangrelor

 $\alpha_{IIb}\beta_3$ inhibitors: abciximab, eptifibatide, tirofiban

PDE inhibitors

Nonselective PDE inhibitors: pentoxifylline, caffeine, theophylline

PDE3 inhibitors: cilostazol, milrinone, anagrelide

PDE5 inhibitors: dipyridamole, sildenafil

Adenyl cyclase stimulators: epoprostenol, iloprost, beraprost

Drugs that adversely affect platelet function

NSAIDs: ibuprofen, naproxen, indomethacin,

Cardiovascular agents

Calcium channel blockers: nifedipine, diltiazem, verapamil

 β -Blockers: propranolol

Vasodilators: nitrates, nitroprusside

Diuretics: furosemide

Angiotensin II receptor antagonist: losartan, valsartan, and olmesartan

Antibiotics: β -lactams, amphotericin, hydroxychloroquine, nitrofurantoin

Antifungal drugs: Miconazole, amphotericin B

Psychiatric drugs: TCAs, fluoxetine, chlorpromazine, promethazine, trifluoperazine

Oncologic drugs: mithramycin, daunorubicin, BCNU, asparaginase, vincristine, dasatinib, ibrutinib

Anesthetics: dibucaine, procaine, halothane, sevoflurane, propofol

Plasma expanders: dextran, hydroxyl ethyl starch

Heparins and thrombolytic agents

Miscellaneous: clofibrate, statins, cocaine, ketanserin, radiographic contrast agents, antihistamines, immunosuppressive drugs

ADP, Adenosine diphosphate; BCNU, carmustine; COX, cyclooxygenase; NSAID, nonsteroidal antiinflammatory drug; PDE, phosphodiesterase; TCA, tricyclic antidepressant.

platelet, bind to its receptor on the platelet membrane, and reinforce aggregation by promoting secretion from α and dense granules. Aspirin-treated platelets stimulated with these agonists demonstrate only a primary, reversible wave of aggregation without granule secretion. Stronger agonists (high concentrations of thrombin and collagen) do not require TXA₂ synthesis to cause platelet secretion and irreversible aggregation, and thus some hemostatic function is maintained in aspirin-treated patients.

Aspirin may also have COX-independent actions that may affect coagulation. At the site of microvascular injury, platelets bind to exposed collagen, and coagulation is initiated by tissue factor concurrently. It was reported that low-dose aspirin (30 mg/day for 7 days) decreased thrombin formation in healthy volunteers.¹³ Undas et al¹⁴ used the same microvascular injury model and showed that aspirin at 75 mg/day for 7 days decreased the velocity of prothrombin consumption by 29%, thrombin generation by 29%, and delayed both activation and maximum cleavage of factor XIII by thrombin. Interestingly, high cholesterol levels (>240 mg/dL) impaired the antithrombotic effect of low-dose aspirin in a microvascular injury model.¹⁵

In contrast to the antiplatelet effect of aspirin, which appears unrelated to the dose above small threshold doses, GI mucosal toxicity is dose related.¹⁶ The mechanism of mucosal injury appears to be distinct from the effect on hemostasis, involving ionic trapping of aspirin within gut mucosal cells¹⁷ and diminished synthesis of protective gut prostaglandins.^{18,19} The inhibitory effect of even a single dose of aspirin on gastric prostaglandin synthesis is prolonged, with one study showing that gastric COX activity was still 57% suppressed 72 hours after a single 325-mg dose of aspirin.²⁰ Bleeding may originate from discrete ulcers or diffuse mucosal damage and is more common to arise from the upper GI tract. The risk of bleeding is increased even with doses of aspirin as low as 10–30 mg/day;²¹ the protective effect of resistant coatings is unproven.²² The GI risk of aspirin is increased in elderly adults (older than 65 years of age) and in those with concomitant medical conditions, such as cardiovascular disease, as well as in those taking certain other medications, such as other NSAIDs.²² Aspirin appears to delay the healing of gastric ulcers, possibly because it interferes with the release of growth factors from platelets, such as endostatin and vascular endothelial growth factor.²³

Regular use of aspirin (≥ 75 mg) impairs primary hemostasis dose-dependently.⁸ Aspirin treatment was associated with a small but significant increase in mucocutaneous bleeding as evidenced by easy bruising, hematemesis, melena, epistaxis, and an increased frequency of blood transfusion surrounding surgeries. Because low doses have been shown to be effective in preventing thrombosis, it is likely that the risk of bleeding can be reduced while maintaining an antiplatelet effect.

Aspirin may unmask mild hereditary disorders of platelet function.²⁴ For example, patients with mild von Willebrand disease often have a normal bleeding time that becomes markedly increased with aspirin therapy.²⁴ The bleeding risk associated with aspirin is increased in the presence of other hemostatic defects, or if aspirin is given simultaneously with anticoagulant drugs.

Aspirin Resistance

The response to aspirin therapy varies among individuals. Every day, the human body can produce approximately 10×10^{11} platelets, and this production can increase 10-fold if needed. The life span of platelets is 8–10 days, and every day nearly 10%–12% of the platelets are replaced by new platelets. The capacity of the bone marrow to produce new platelets, the aspirin dosage, the aspirin exposure time (spot doses or regular use), and individual parameters will determine the antihemostatic effect of aspirin in any particular individual.

The issue of aspirin resistance is hotly debated, with reported incidence rates varying from 0% to 57%.^{25–28} The presence of aspirin resistance is associated with high rates of cardiovascular events.^{27,28}

The most important issue in determining whether laboratory aspirin resistance is real is compliance. Schwartz et al²⁹ evaluated 190

Fig. 130.1 MECHANISM OF INHIBITION OF PLATELET FUNCTION BY VARIOUS DRUGS. Some of the drugs shown, such as Ridogrel, VCL (rA1 domain of von Willebrand factor), and ATA (aurin tricarboxylic acid), are not now used clinically. 5-HT, serotonin (5-hydroxytryptamine); ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanylyl monophosphate; DAG, diacylglycerol; GP, glycoprotein; GTP, guanylyl triphosphate; IP3, inositol triphosphate; ITAM, immunoreceptor tyrosine-based activation motif; MLCK, myosin light chain kinase; NO, nitric oxide; PAF, platelet activating factor; PI3K, phosphatidylinositol 3-kinase; PLA₂, phospholipase A₂; PLC, phospholipase C; TXA₂, thromboxane A₂; vWF, von Willebrand factor.

patients with a history of coronary disease and receiving aspirin therapy. They investigated these patients on regular aspirin therapy, after withdrawal of aspirin for 7 days, and after an observed ingestion of 325 mg of aspirin. They found that 17 patients (9%) receiving regular aspirin therapy had aspirin resistance as defined by defective inhibition of arachidonic acid-stimulated platelet aggregation. After being observed to take the 325 mg aspirin, however, all patients but one displayed inhibition of aggregation. Similar results were observed in other studies.³⁰ These investigators concluded that noncompliance was the predominant cause of aspirin resistance, and higher doses of aspirin may eliminate the resistance. Although it has been shown that aspirin inhibits platelet functions in a dose-dependent manner,³¹ higher aspirin doses failed to reduce the risk of thrombosis in large trials.³²

Higher aspirin resistance rates are reported in elderly patients, probably owing to the fact that increased gastric pH affects aspirin absorption in patients taking enteric-coated forms of aspirin.^{8,33} Other causes of aspirin resistance may include increased platelet

turnover and increased COX-1 expression in new platelets³⁴ and overexpression of COX-2 in macrophages and endothelial cells.³⁵ It has also been reported that concomitant use of some NSAIDs such as ibuprofen and naproxen may prevent COX-1 inactivation in patients receiving low-dose aspirin.^{36,37} Interindividual variation of aspirin response can also be explained by genetic variations involved in the genes for COX-1 and COX-2, platelet integrin α_2 or β_3 , the ADP receptors P2Y₁ and P2Y₁₂, the TXA₂ receptor and some coagulation proteins.^{26,38–41} However, these studies showed conflicting results and have failed to confirm that aspirin therapy tailored to account for genetic variation improves clinical outcomes.

In patients treated with aspirin who experience recurrent arterial thrombosis, it is important to keep in mind that arterial thrombosis is a multifactorial process and that the inhibition of one pathway of platelet activation may be insufficient to prevent recurrent events.

Assessment of aspirin's inhibitory effects on platelets is important in two clinical situations: (1) in patients with arterial thrombosis, or

at high risk for arterial thrombosis, to insure that sufficient platelet inhibition is achieved by a given aspirin dose; (2) for estimating the bleeding risks in patients who need surgery or who have experienced trauma.

The antiplatelet effect of aspirin can be screened by different techniques, including light-transmission aggregometry, whole-blood aggregometry, platelet function analyzer (PFA)-100, VerifyNow Aspirin, measurement of serum/plasma or urinary TXB₂ metabolites, thromboelastography, flow cytometry, or other tests (see [Chapters 128 and 129](#)).

Adenosine Diphosphate Receptor Antagonists

The thienopyridines selectively and irreversibly inhibit ADP-mediated platelet activation and aggregation.⁴² ADP activates platelets by raising the concentration of cytoplasmic Ca²⁺ through influx from the extracellular fluid and mobilization from internal stores, and by decreasing the concentration of intracellular cyclic adenosine monophosphate (cAMP) coupled to inhibition of adenylyl cyclase. ADP receptors can be divided into two groups: the G protein-coupled receptors, termed P2Y, and the ionotropic receptors, P2X. Platelets contain two P2Y receptors, P2Y₁ and P2Y₁₂, complexed to the heterotrimeric G proteins G_q and G₁₂, respectively. ADP binding to P2Y₁ is necessary for platelet aggregation but is not sufficient. Rather, P2Y₁ is responsible for ADP-induced platelet shape change, and its engagement by ADP triggers a transient aggregatory response. P2Y₁₂, coupled to inhibition of adenylyl cyclase, mediates the amplification of the aggregation response.⁴³ The thienopyridine derivatives have no effects on arachidonic acid metabolism and hence act synergistically with aspirin to inhibit platelet function.

The thienopyridines are all prodrugs of similar structure that produce active metabolites that bind irreversibly to P2Y₁₂, inhibiting ADP-mediated aggregation for up to 10 days after withdrawal of the drug, paralleling the platelet life span.⁴⁴ Because most platelet agonists require ADP for their full activity, the thienopyridines inhibit platelet activation by all agonists except strong agonists at high concentrations.⁴⁵ They have a further hypothetical advantage over aspirin in that they inhibit shear-induced platelet aggregation.⁴⁶

There are three generations of thienopyridine drugs, represented by ticlopidine, clopidogrel, and prasugrel. The use of ticlopidine has been greatly curtailed because of serious side effects such as agranulocytosis, thrombocytopenia, and thrombotic thrombocytopenic purpura.⁴⁷

Platelet $\alpha_{IIb}\beta_3$ (Glycoprotein IIb/IIIa) Inhibitors

A myriad of pathways lead to platelet aggregation, the final common step being activation of the major platelet integrin $\alpha_{IIb}\beta_3$ to a ligand-competent form, which can bind multivalent ligands such as fibrinogen or von Willebrand factor (vWF) to cross-link the platelets into an aggregate. Conventional antiplatelet agents such as aspirin and clopidogrel each inhibit only one pathway leading to platelet aggregation, aspirin preventing thromboxane production, and clopidogrel blocking ADP receptors. Dual therapy with aspirin and clopidogrel improves the clinical benefit of antiplatelet therapy, but aggregation is still able to proceed through the action of other agonists such as thrombin. Because $\alpha_{IIb}\beta_3$ engagement is required for aggregation through all pathways, blocking this receptor inhibits platelet aggregation more effectively.

Inhibitors of $\alpha_{IIb}\beta_3$ work selectively and competitively to inhibit platelet aggregation.^{48,49} These agents are intended to produce a transient effect akin to the defect in Glanzmann thrombasthenia, but there are important differences between the drug effect and the disease.

Although these agents share many similarities in their antithrombotic properties, they also have a number of clinically important pharmacokinetic and off-target effect differences. Three drugs are available: eptifibatide, tirofiban, and abciximab.

Abciximab

The first $\alpha_{IIb}\beta_3$ inhibitor approved for clinical use, abciximab (ReoPro), is a human-murine chimeric Fab fragment of a monoclonal antibody that targets the β_3 subunit of $\alpha_{IIb}\beta_3$ and therefore also reacts with another integrin that shares the β_3 subunit, $\alpha_v\beta_3$. Although $\alpha_{IIb}\beta_3$ expression is restricted to megakaryocytes and platelets, $\alpha_v\beta_3$ is expressed on platelets; at low levels; and in cells of the vascular wall, including endothelial cells and fibroblasts.⁵⁰ In addition to its anti-thrombotic properties, abciximab may also reduce infarct size, prevent stent thrombosis, and modulate inflammatory responses by virtue of β_3 subunit inhibition in other tissues.⁴⁸

Abciximab administered intravenously as a standard 0.25 mg/kg bolus blocks approximately 80% of surface $\alpha_{IIb}\beta_3$ and inhibits platelet aggregation to a similar extent, although the extent of inhibition is variable.⁵¹ This level of blockade increases the bleeding time only mildly. The bleeding time only becomes markedly prolonged when receptor blockade exceeds 90%. After the bolus dose, abciximab is infused at 0.125 μ g/kg/min for 12 hours. Several trials have established this as a clinically effective regimen.⁵² Plasma levels of free abciximab drop rapidly after its administration, with an initial half-life of approximately 30 min. Most of the drug is bound to platelets. This explains why patients with thrombocytosis may require larger weight-adjusted doses of abciximab to attain a therapeutic antiplatelet effect⁵³ and why patients with lower platelet counts treated with the usual dose of abciximab display more profound platelet inhibition. Abciximab is not excreted in the urine and is probably metabolized by the reticuloendothelial system at the time platelets (with bound abciximab) are cleared from the circulation. The dose of abciximab does not have to be adjusted in patients with renal impairment. Although a daily platelet turnover rate of 10% would predict that no abciximab would be detected in blood after 10 days of its administration, platelet-bound abciximab has been observed up to 3 weeks after its initial administration, suggesting platelet-to-platelet redistribution of the drug or release of new platelets from megakaryocytes that had previously bound the drug. Several in vitro and in vivo studies confirm abciximab's ability to exchange between platelets.⁵¹ Because of the low plasma levels of unbound abciximab, the drug's inhibitory effect can be rapidly reversed by platelet transfusion, and hemostasis should be normal when the concentration of infused platelets exceeds 50,000/ μ L, as it is in normal individuals. However, because of abciximab's ability to redistribute to the newly transfused platelets, the platelet-bound abciximab may produce a gradual inhibitory effect on the infused platelets;⁵¹ in severe or refractory bleeding, it may be necessary to infuse a very large dose of platelets, sufficient to leave 50% of $\alpha_{IIb}\beta_3$ receptors free, a number shown to be sufficient for normal hemostasis in studies of Glanzmann thrombasthenia heterozygotes. Without platelet transfusions, platelet aggregation generally returns to baseline levels within 12–24 hours after discontinuing abciximab.

Eptifibatide

Eptifibatide (Integrilin) is a cyclic heptapeptide based on the Lys-Gly-Asp (KGD) sequence found in barbourin, a platelet-inhibitory disintegrin from the venom of the Southeastern Pigmy rattlesnake, *Sistrurus miliarius barbouri*.⁵⁴ Barbourin differs from other integrin-binding proteins with the Arg-Gly-Asp (RGD) canonical sequence in that the arginine is conservatively substituted by lysine, a change that renders the protein a specific inhibitor of $\alpha_{IIb}\beta_3$. Eptifibatide incorporates the KGD sequence within a cyclic seven-member peptide of high potency. Eptifibatide differs pharmacokinetically from abciximab in several important ways.⁵⁵ For example, unlike abciximab, intravenous eptifibatide infusion produces high levels of unbound drug because of its lower affinity for the receptor. Platelet transfusions therefore are not a good method for acutely reversing eptifibatide's antiplatelet effect because the newly transfused platelets are rapidly inhibited. However, its short plasma half-life ($\approx$ 2.5 hours) allows for rapid clearance of eptifibatide and the reversal of its antiplatelet effect when administration is discontinued. Platelet

aggregation returns to normal in approximately 4 hours, with the bleeding time normalizing within 1 hour.⁵⁵

Tirofiban

Tirofiban (Aggrastat) is a peptidomimetic agent based on the RGD sequence, with a pharmacokinetic profile similar to that of eptifibatide.⁵⁶ Tirofiban antagonizes $\alpha_{IIb}\beta_3$ and does not cross-react with $\alpha_v\beta_3$.⁵⁶ As with eptifibatide, the maximum antiplatelet effect is seen at concentrations that leave a high concentration of unbound drug in the plasma. Therefore platelet transfusions are not often effective in reversing tirofiban's antiplatelet effect. However, its half-life is even shorter than that of eptifibatide (≈ 2 hours), and its antiplatelet effect diminishes rapidly after discontinuation of infusion.

The major adverse effects of $\alpha_{IIb}\beta_3$ inhibitors are thrombocytopenia and bleeding complications. Up to 5% of patients receiving abciximab may experience mild thrombocytopenia ($<100,000/\mu\text{L}$), and 1% may develop profound thrombocytopenia (platelet count $<20,000/\mu\text{L}$).^{57,58} The incidence of severe thrombocytopenia is lower with tirofiban and eptifibatide, being approximately 0.2%.^{58,59} A decrease in the platelet count is appreciable within the first hours after administration. It is therefore essential that a platelet count be obtained 2–4 hours after initiating treatment. Most patients with severe thrombocytopenia respond well to platelet transfusions and their platelet counts usually recover within 5 days, although they may take more than 1 week to do so.

Bleeding complications with $\alpha_{IIb}\beta_3$ inhibitors are quite common, especially in the inguinal area when the femoral artery has been breached during procedures. Rates of major bleeding vary between 0.7% and 5.2% in different randomized controlled studies.^{59,60} Intracranial bleeding is very rare (0.09%).⁵⁹ Bleeding risk increases in patients older than 65 years of age; in patients weighing less than 50 kg; in patients taking anticoagulant, antiplatelet, or thrombolytic therapies; and in patients with inherited or acquired bleeding disorders such as hemophilia and uremia, respectively.^{59,60}

Phosphodiesterase Inhibitors

Elevation of cAMP or cyclic guanosine monophosphate (cGMP) inhibits many pathways involving platelet activation, including shape change, $\alpha_{IIb}\beta_3$ activation, and degranulation. Phosphodiesterases (PDEs) catalyze degradation of cAMP and cGMP, thus preventing platelet inhibition. Eleven PDE isoforms have been described, and three are expressed in platelets: PDE2, PDE3, and PDE5.⁶¹ Many PDE inhibitors have antiplatelet effects.

Nonselective Phosphodiesterase Inhibitors

These include the methylxanthines caffeine (1,3,7-trimethylxanthine), theophylline (1,3-dimethylxanthine), and pentoxifylline (3,7-dimethyl-1-(5-oxohexyl)xanthine). Caffeine, at a dosage of 250 mg orally three times a day for 1 week, was demonstrated to reduce platelet aggregation in healthy subjects.⁶²

PDE3 inhibitors are anagrelide, cilostazol, and milrinone. Although anagrelide inhibits platelet aggregation in vitro, it surprisingly also inhibits megakaryocyte maturation and proliferation, and causes thrombocytopenia in humans by a mechanism that is poorly understood.⁶³ Anagrelide is used to treat essential thrombocythemia.⁶⁴

Cilostazol is a cyclic nucleotide PDE inhibitor with both platelet inhibitory and vasodilatory effects; its current clinical use for peripheral artery disease in the United States was preceded by its use in Japan and other Asian countries. In addition to selectively inhibiting PDE, cilostazol also inhibits adenine nucleotide uptake, a property not shared with other PDE inhibitors that further enhances its antiplatelet activity.⁶⁵

Milrinone inhibits platelet aggregation and shape change. The drug is used for congestive heart failure.

PDE5 Inhibitors

Dipyridamole has several biologic effects, including PDE inhibition, targeting the PDE5 isoform that degrades cGMP.⁶⁶ It also enhances the release and prevents the breakdown of prostaglandin I_2 (prostaglandin).^{61,67} Primarily used for prevention of stroke, its usefulness was demonstrated by a metaanalysis of randomized trials showing that the combination of dipyridamole (particularly the modified release form) and low-dose aspirin was more effective than aspirin alone in secondary prevention of vascular events after transient ischemic attack or stroke.⁶⁸ Dipyridamole has been associated with a significantly increased risk of GI bleeding when used either as a single agent or in combination with aspirin.⁶⁹

Recently, inhibitors of PDE5 have become popular in the treatment of erectile dysfunction.⁷⁰ PDE5 is expressed in platelets, and its inhibition results in increases in the level of platelet cGMP, an effect similar to the effect of the well-known inhibitor of platelet function, nitric oxide. One study examined the activation response of platelets drawn from patients taking sildenafil (Viagra) when stimulated with either ADP or low-dose thrombin. The results showed significantly reduced activation in response to ADP in sildenafil-treated platelets, suggesting that the drug impairs selected pathways of platelet function in vivo. Several reports of sildenafil-associated bleeding have appeared, including epistaxis,^{71,72} hemorrhoidal bleeding,⁷³ spontaneous intracranial hemorrhage,⁷⁴ and acute variceal bleeding.⁷⁵

Adenyl Cyclase Stimulators or Prostacyclin Analogues

Epoprostenol (the synthetic salt of prostacyclin), prostacyclin (iloprost), and an orally active stable analogue (beraprost) are prostacyclin-like agents in clinical use. Despite the potent inhibition of platelet aggregation by prostacyclin in vitro, the effects on the bleeding time are minimal and inconsistent. These drugs are used for pulmonary arterial hypertension and peripheral artery disease.⁷⁶

Other Drugs That Adversely Affect Platelet Function

Nonsteroidal Antiinflammatory Drugs

In addition to aspirin, many other drugs used for their antiinflammatory and analgesic properties can impair platelet function.⁷⁷ As with aspirin, their mechanism of action appears to be the inhibition of COX-1; but in contrast to aspirin, these agents only temporarily affect COX-1 function, inhibiting the enzyme only as long as the active drug circulates. Among these agents, therefore, only drugs such as piroxicam, which has a plasma half-life of more than 2 days,⁷⁸ affect platelets for more than a few hours. Like with aspirin, the most sensitive indicator of impaired platelet function is the inhibition of in vitro platelet aggregation and secretion. These agents induce little or no prolongation of the bleeding time, consistent with the bleeding time being a less sensitive measure of the aspirin-induced defect.⁷⁷ PFA-100 may detect the defect, manifested as a prolonged closure time with the collagen/epinephrine cartridge.⁷⁹

Reports of bleeding correlate with the effects of these agents on platelet function, suggesting that they increase the risk for excessive bleeding less than aspirin. As with aspirin, they may increase the bleeding times in patients with severe hemophilia, but in two studies, therapeutic doses of ibuprofen had no effect on the bleeding time in 19 of 20 patients with hemophilia.⁸⁰ Therefore, the clinical approach to patients taking any drug that can inhibit COX-1 should be similar, but the reversibility of the effect of NSAIDs provides an added margin of safety when these agents are used. Because of the increased bleeding risk, these drugs should be stopped before surgery. The timing for cessation of NSAIDs is based on the half-lives of the individual drug. Indomethacin, ibuprofen, ketoprofen, and diclofenac all have short half-lives (2–6 hours), and discontinuing these

drugs 1 day before surgery is sufficient. Naproxen, sulindac, diflunisal, and celecoxib have intermediate half-lives (7–15 hours) and should be stopped 2 or 3 days before surgery. Nabumetone, meloxicam, and piroxicam have very long half-lives (>20 hours). The ACCP guidelines recommend discontinuing these drugs 10 days before surgery.⁵² Analgesics such as acetaminophen and sodium or choline salicylate do not inhibit platelet function and have no adverse effects on hemostasis.⁸⁰

Cardiovascular Drugs

Many cardiovascular drugs affect platelet functions through a variety of mechanisms.⁸¹ Administration of nitroglycerin, isosorbide dinitrate, or nitroprusside can decrease platelet aggregation and secretion in vitro, but their effects in vivo are minimal and inconsistently observed.⁷⁷ The mechanism of platelet inhibition appears to involve the production of nitric oxide from the drug, with concomitant increases in platelet cAMP and, more markedly, cGMP.⁸² β -Adrenergic receptor blockers such as propranolol, metoprolol, atenolol, and pindolol have also been shown to inhibit platelet aggregation, apparently through mechanisms independent of β -adrenergic receptor blockade.^{83,84} Several of these agents have been shown to blunt platelet aggregation to ADP and collagen,⁸⁵ and to decrease platelet TXA₂ production in response to agonists.⁸³ Blunting of serotonin uptake by platelets and inhibition of the response to serotonin have also been demonstrated. There are numerous reports of antiplatelet effects of calcium channel blockers, such as nifedipine, verapamil, and diltiazem. Most of these studies demonstrated inhibition of platelet aggregation in washed platelets at high concentrations (micromolar) of the drug. This effect is mainly with epinephrine as the agonist, and it does not appear to be related to inhibition of calcium ion influx. Proposed mechanisms include inhibition of epinephrine binding to α_2 -adrenergic receptors, inhibition of the platelet response to TXA₂, and inhibition of serotonin-induced aggregation. In therapeutic doses, the calcium channel blockers do not prolong the bleeding time. At high concentrations, quinidine can act as an antagonist of platelet α_2 -adrenergic receptors. In one report, a patient taking 800 mg of quinidine and 650 mg of aspirin daily developed melena and generalized petechiae with a normal platelet count and a bleeding time over 35 minutes.⁸⁶ In a subsequent study in two healthy volunteers, quinidine caused a mild prolongation of the bleeding time that was apparently potentiated by aspirin. Quinidine and its stereoisomer, quinine, can also impair hemostasis by inducing drug-dependent antibodies that cause thrombocytopenia.

The commonly used angiotensin receptor antagonists losartan, valsartan, and olmesartan interact with the TXA₂ receptor and inhibit thromboxane-dependent platelet adhesion and aggregation.⁸⁷ Valsartan also inhibits the expression of major platelet receptors including $\alpha_{IIb}\beta_3$ and glycoprotein (GP)Ib.⁸⁸

Antibiotics

Antibiotics can also affect platelet function. Those implicated most often are the penicillins and cephalosporins, which share a β -lactam ring structure. Some of these drugs produce predictable dose- and duration-related effects on the bleeding time.^{89–91} Because the effect on bleeding time is seen only in patients who are receiving large parenteral doses of antibiotics, this is a potential problem only for hospitalized patients. In a study of 74 hospitalized patients with a consistently prolonged bleeding time, the likely cause was penicillin in 39 patients (30 patients were receiving >15,000,000 U/day of penicillin G, and 9 were receiving 6–8 g/day of ampicillin) and aspirin or related drugs in 7 patients.⁹¹ Floxacillin (an isoxazolyl penicillin) has been shown to significantly impair platelet function and cause severe bleeding when used in high dose in a patient with infective endocarditis.⁹²

The structural properties that cause some, but not all, penicillins and cephalosporins to affect platelet function are unknown. The side

chain structure alters the antibacterial and pharmacologic properties of the penicillins and cephalosporins, and may also determine their effects on platelet function. It is postulated that the antibiotic associates with the platelet plasma membrane via a lipophilic mechanism where it perturbs receptor–agonist interactions or signal transduction.⁹³ The characteristic laboratory findings are a prolonged bleeding time and abnormal platelet aggregation studies that occur after several days of high-dose parenteral therapy.^{90,91,94} These abnormalities do not usually subside until several days after the antibiotic is discontinued.

The frequency of clinically important bleeding in patients taking β -lactam antibiotics is low and is not predicted by a prolonged bleeding time; consequently, the causal relation to antibiotic treatment is unproved.⁹⁵ For each report implicating an antibiotic as a cause of hemorrhage, many more patients receive the same antibiotics in large doses without bleeding complications.⁹⁵

Although antibiotic-induced platelet dysfunction usually is of little clinical importance, there are some exceptions to this rule. The frequency of clinically important hemorrhagic complications with moxalactam appears to be higher than with other antibiotics.⁹⁶ This drug has been demonstrated to inhibit ADP- and collagen-induced platelet aggregation in a dose-dependent fashion and to decrease TXA₂ generation,⁹⁷ which suggests that, like aspirin, it acts on the thromboxane synthesis pathway. Furthermore, in contrast to most other β -lactam antibiotics, moxalactam contains a methylthiotetrazole-leaving group that has been implicated in the inhibition of synthesis of the vitamin K-dependent coagulation factors.⁹⁸ Therefore, moxalactam-induced bleeding may be caused by the combination of deficiencies in vitamin K-dependent coagulation factors and impaired platelet function.

Nitrofurantoin, an antibiotic structurally unrelated to the β -lactam antibiotics, may mildly prolong the bleeding time and impair platelet aggregation at plasma concentrations in excess of 20 μ M.⁹⁹

Antifungal Drugs

Miconazole has been shown to inhibit platelet aggregation in rabbits,¹⁰⁰ but there is no evidence that the drug causes platelet dysfunction in humans. Concomitant use of miconazole and vitamin K antagonists may cause significant bleeding because miconazole is a strong inhibitor of CYP2C9.¹⁰¹

Amphotericin B inhibits thrombin-induced platelet aggregation, serotonin uptake, and thrombin-induced serotonin release in vitro studies.¹⁰² Studies have shown that platelet transfusion immediately after amphotericin B infusion caused poor platelet recovery and survival. An interval of at least 2 hours should separate platelet transfusion from amphotericin B therapy.¹⁰³

Psychiatric Drugs

Platelets from patients taking tricyclic antidepressant drugs (imipramine, amitriptyline, nortriptyline) or phenothiazines (chlorpromazine, promethazine, trifluoperazine) can exhibit impaired in vitro aggregation and secretion responses to ADP, epinephrine, and collagen, but this effect is not associated with an increased risk for bleeding.⁷⁷ However, there are numerous reports of antiplatelet effects of the widely used selective serotonin reuptake inhibitors (SSRIs; paroxetine, sertraline, fluoxetine, citalopram), which block the only means of platelet serotonin uptake for storage;^{104–108} the effect of these drugs in decreasing platelet serotonin levels has been documented.^{109,110} Prolonged bleeding times,¹¹¹ excessive bruising,¹¹² and defective platelet aggregation have all been noted in patients taking fluoxetine.¹¹³ SSRI use increases perioperative and postoperative bleeding,¹¹⁴ increases red cell transfusion rates during and after surgery,¹¹⁵ and increases the risk of postpartum hemorrhage in pregnant women.¹¹⁶ On the other hand, the cessation of the SSRI antidepressant drug may cause discontinuation syndrome or depression relapse. Thus the risk–benefit profile should be considered before cessation of an SSRI drug prior to elective surgery.

Additionally, the risk of GI bleeding is increased in patients taking SSRIs, particularly when they are combined with NSAIDs.¹¹⁷ A recent prospective population study showed that the use of antidepressants, especially SSRIs was associated with a low risk for myocardial infarction.¹¹⁸

Oncologic Drugs

Administration of mithramycin has been associated with decreased platelet aggregation, a prolonged bleeding time, and mucocutaneous bleeding.¹¹⁹ Daunorubicin and bis-chloroethyl-nitrosourea can both inhibit platelet aggregation and secretion when added to platelet-rich plasma, but these effects do not appear to be clinically important.⁷⁷ Vincristine inhibits platelet aggregation by interfering with the microtubule network.¹²⁰

Tyrosine kinase inhibitors, which are used for the treatment of chronic myeloid leukemia, can cause thrombocytopenia and/or platelet dysfunction. Dasatinib and imatinib both have been demonstrated to impair platelet aggregation.¹²¹ Dasatinib may cause clinically relevant bleeding because of platelet dysfunction.¹²²

Ibrutinib is an orally administered Bruton kinase inhibitor used for the treatment of B-cell malignancies. It also inhibits signaling downstream of platelet GPVI and affects platelet adhesion to vWF under arterial flow, increasing the risk for bleeding.¹²³

Anesthetics

Although some local and general anesthetic agents have been shown to inhibit platelet function in vitro, this effect is generally produced at high drug concentrations.^{124,125} Sevoflurane suppresses formation of TXA₂; propofol and nitrous oxide inhibit calcium mobilization.¹²⁴ Procaine inhibits calcium and P-selectin release from platelet storage pools.¹²⁶ Dibucaine is a calpain activator, induces platelet apoptosis, and inhibits platelet functions.¹²⁷ At usual doses, halothane reversibly inhibits platelet aggregation.¹²⁸

Plasma Expanders

Dextran is partially hydrolyzed branched polymers of glucose. Of the two preparations in clinical use, dextran 70 has an average molecular mass of 70–75 kDa and dextran 40 has an average molecular mass of 40 kDa. Both preparations are effective plasma expanders and can affect platelet function, but the high-molecular-weight molecules have a greater effect on hemostasis.¹²⁹ Dextran infusion also impairs platelet aggregation and platelet procoagulant activity, and can cause a modest reduction in plasma vWF concentration. However, dextran has no effect on platelet function when added directly to platelet-rich plasma in vitro.¹³⁰ Because of its effects on platelet function, dextran was explored as an antithrombotic agent, but it is no longer used for this purpose.

Hydroxyethyl starch, known as *hetastarch*, is a synthetic glucose polymer with an average molecular weight of 450,000 (range: 10,000–1,000,000) that is also used for plasma expansion. Hetastarch use has been associated with abnormal platelet function (albeit inconsistently), a problem more evident with the higher-molecular-weight forms.¹³¹ Like dextran, it can prolong the bleeding time, particularly if administered at doses higher than 20 mL/kg in a 6% solution, and predisposes to bleeding if administered simultaneously with heparin or in the presence of a preexisting hemostatic defect.¹³²

Heparins and Thrombolytic Agents

Although heparin is best known for its anticoagulant effect and its association with HIT and thrombosis (see [Chapters 133](#) and [149](#)), it also has the potential to affect platelet function. Heparin can bind to

the platelet surface,¹³³ induce platelet aggregation and secretion,¹³⁴ and impair vWF-dependent platelet function.¹³⁵ Heparin can also increase the bleeding time.¹³⁶ Whether these phenomena contribute to heparin-induced bleeding is unknown. The prolonged bleeding time is probably the result of inhibition of thrombin generation, analogous to the slight but significant increase in bleeding times seen in patients with hemophilia.¹³⁴

Paradoxically, heparin is also capable of inducing the association of vWF with the GPIb complex.¹³⁷ Whether this is restricted to certain individuals or occurs only at certain heparin concentrations is unclear, but it raises the possibility that this mechanism may contribute to heparin-induced thrombosis.

Bleeding during therapy with plasminogen activators is predominantly caused by fibrin degradation, hypofibrinogenemia, and increased levels of fibrin(ogen) degradation products, usually in the setting of structural lesions. At pharmacologic concentrations, streptokinase, urokinase, and tissue plasminogen activator (t-PA) may also impair platelet function through several potential mechanisms, all related to excessive production of plasmin.¹³⁸ First, high levels of fibrin(ogen) degradation products and low levels of fibrinogen can impair platelet aggregation. Second, the binding of plasminogen to the platelet surface may facilitate its conversion to plasmin.¹³⁹ Plasmin can degrade GPIIb/IIIa (thereby impairing the interaction of the platelet with vWF¹⁴⁰) and fibrinogen (thereby dispersing platelet aggregates).¹⁴¹ Third, plasmin can inhibit platelet aggregation by blocking the release of arachidonic acid from platelet membranes, thereby limiting TXA₂ production.¹⁴² The clinical importance of these observations is unknown.

In addition to decreasing platelet function, plasmin has been shown to directly activate platelets,^{143,144,145,146} an effect that may contribute to vessel reocclusion after t-PA treatment for myocardial infarction.¹⁴⁷ Platelet activation is the result of plasmin-mediated cleavage of protease-activated receptors (PAR), particularly PAR4.¹⁴⁸

Miscellaneous Drugs

The statins, which inhibit 3-hydroxy-3-methylglutaryl coenzyme A reductase, are widely used in patients with dyslipidemia.¹⁴⁹ These agents reduce the risk of cardiovascular events through a variety of mechanisms, including reducing the risk of atherothrombosis. Among its antithrombotic effects are decreases in platelet reactivity, brought about by its beneficial effects on endothelial cells, with increased production of nitric oxide and prostacyclin, and by direct effects on platelets.¹⁵⁰ Membrane cholesterol content, which is lowered by the statins, has been correlated with platelet reactivity,^{151,152} with studies demonstrating that the content of cholesterol in platelet membranes correlates with localization of important adhesive and agonist receptors within membrane microdomains known as *lipid rafts*.^{153,154} Statins, in addition to lowering plasma and membrane cholesterol levels, also reduce the activity of stimulatory signaling pathways involving the small guanyl triphosphate (GTP)-binding proteins Ras, Rho, and Rac, which require posttranslational prenylation to be targeted to cell membranes. Statins inhibit protein prenylation.¹⁵⁵ No bleeding complications have been associated with statin use, but a substudy of the Platelet Receptor in Ischemic Syndrome Management (PRISM) trial showed that their sudden withdrawal in the setting of acute coronary syndrome was associated with an increased cardiac risk compared with the risk in patients who continued to receive statins (relative risk: 2.93) or never received statins.¹⁵⁶ This increase in cardiac events was partially attributed to increased platelet reactivity. A recent meta-analysis found no correlation between statin therapy and increased intracranial hemorrhage.¹⁵⁷

Clofibrate, another lipid-lowering drug, diminishes platelet responsiveness to ADP, collagen, and epinephrine when given to patients with type II hyperbetalipoproteinemia, and can diminish the responsiveness of normal platelets to ADP and epinephrine in vitro.⁷⁷

Cocaine accounts for more drug-related visits to emergency departments in the United States than any other drug except alcohol. Its use is associated with a large increase in the incidence of myocardial

infarction in individuals who are otherwise at low risk, and it has been hypothesized that cocaine-induced platelet aggregation is a major contributor to this risk.¹⁵⁸ In vitro, however, cocaine inhibits platelet aggregation in response to several agonists and dissociates preformed aggregates.¹⁵⁹ Another important prothrombotic mechanism associated with cocaine use is the ability of cocaine and its long-acting metabolites to induce release of vWF from endothelial cells.¹⁶⁰

Ketanserin, which has been studied for its potential to prevent atherosclerotic complications, decreases platelet aggregation in response to serotonin. Antihistamines, some radiographic contrast agents, and immunosuppressive drugs can also impair platelet aggregation. The mechanisms responsible for these effects are unknown.

Foods and Food Additives

Certain foods and food additives can have important effects on platelet function, particularly when consumed in large quantities. In a classic study published in 1979, Dyerberg and Bang¹⁶¹ reported that Greenland Eskimos on traditional diets had markedly prolonged bleeding times compared with gender- and age-matched Danish control subjects (mean: 8.1 min vs. 4.8 min, respectively), and they correlated this finding with an impaired secondary wave of platelet aggregation to ADP and collagen, and high plasma levels of ω -3 fatty acids. The proposed mechanisms by which ω -3 fatty acids (eicosapentaenoic acid, C20:5 ω -3; and docosahexaenoic acid, C22:6 ω -3) interfere with platelet function is through competition with arachidonic acid for the 2-acyl position of membrane phospholipids or access to COX-1.^{162,163} ω -3 Fatty acids not only reduce TXA₂ synthesis in response to platelet agonist stimulation by competing with the substrate arachidonic acid, but also by producing inhibitory eicosanoids. The latter mechanism was substantiated in the original study of Eskimos by the demonstration that administration of aspirin decreased the bleeding time in all subjects tested but not to normal levels.¹⁶¹ Additionally, ω -3 fatty acids may increase the production of antiaggregatory prostaglandins by cells in the vessel wall.¹⁶¹

Ethanol, one of the most commonly and excessively ingested substances in the world, acts synergistically with aspirin to prolong the bleeding time.¹⁶⁴ In addition, ethanol acts cooperatively with agents that block binding of fibrinogen to $\alpha_{IIb}\beta_3$ to further reduce platelet aggregation in response to several agonists, an effect not solely the result of reduced TXA₂ generation.¹⁶⁵ Ethanol can also impair collagen-induced platelet aggregation, secretion, arachidonate mobilization, and TXA₂ formation, but it did not inhibit platelet adhesion to deendothelialized rabbit aortae.¹⁶⁶

Other food components or additives can also affect platelet function and increase the risk of minor bleeding. Easy bruising after eating Chinese food has been attributed to a platelet inhibitory effect of black tree fungus.¹⁶⁷ A component of onion extract can inhibit platelet arachidonic acid metabolism.¹⁶⁸ Ajoene, a component of garlic, is an inhibitor of fibrinogen binding to platelets and platelet aggregation.¹⁶⁹ Extracts from frequently consumed spices—cumin, turmeric, and clove—can decrease platelet thromboxane production and inhibit platelet aggregation.¹⁷⁰ Bromelain, an extract from pineapple, can inhibit ADP-induced platelet aggregation, and prolong both the PT and aPTT.¹⁷¹ Parsley (*Petroselinum crispum*) may inhibit ADP-induced platelet aggregation.¹⁷²

It can be concluded that platelets are sensitive to a variety of therapeutic and dietary compounds, the extent of inhibition primarily depending on the dose of the inhibitory agent.¹⁷³ However, an increased risk for clinically important bleeding has been demonstrated only for aspirin and agents specifically designed to inhibit platelet function. Reports of increased bleeding with all other agents must be viewed with caution. Despite this qualification, it is prudent for clinicians to have a thorough understanding of the antiplatelet effects of prescribed drugs and to always consider the potential impacts of drug- or diet-induced platelet dysfunction, particularly in patients with coexisting hemostatic defects.

CLONAL DISORDERS

Hematological Clonal Disorders

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs; see Chapters 67–72) are clonal disorders arising from hematopoietic stem cells affected by somatic mutations that cause abnormal production of mature myeloid cells. Philadelphia chromosome–negative MPNs, which include polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis, are the most common MPNs. These disorders are characterized by varying degrees of leukocytosis or thrombocytosis; patients with PV usually have a markedly elevated hematocrit. Particularly in PV and ET, thrombosis or bleeding account for a high percentage of the associated morbidity of the disorders, with thrombosis being the most common.

Bleeding in patients with MPN is primarily mucocutaneous. The bleeding time is prolonged in a small percentage of patients with MPNs, but bleeding complications can occur even in patients with normal bleeding times. Routine plasma coagulation tests, such as the PT and aPTT, may be falsely prolonged if the red blood cell mass is increased. Because the plasma volume in these patients is reduced, it is important to adjust the citrate concentration in the tubes used to collect the blood for coagulation testing.

The mechanisms of bleeding are multifactorial in patients with MPN. Some bleeding episodes can in part be attributed to thrombosis, such as variceal bleeding resulting from thrombosis-induced portal hypertension.¹⁷⁴ Acquired platelet abnormalities, acquired coagulation factor (especially factor V) and vWF deficiencies,¹⁷⁵ antiplatelet drug usage, and drugs used for the clonal disease (such as anagrelide) may cause bleeding problems.

The platelets of patients with MPNs can show various morphologic abnormalities, including variations in size and shape, as well as reduced numbers of secretory granules. Platelet survival can be decreased in ET. The most common platelet abnormality is decreased aggregation and secretion in response to agonists, particularly epinephrine, ADP, and collagen.¹⁷⁶ These abnormalities are not simply the result of the high platelet count because patients with reactive thrombocytosis have functionally normal platelets.¹⁷⁷ In what may appear to be a paradox, some patients demonstrate spontaneous in vitro platelet aggregation in platelet-rich plasma. Decreased platelet aggregation or secretion and decreased procoagulant activity may be caused by decreased (1) agonist-induced release of arachidonic acid from membrane phospholipids; (2) conversion of arachidonic acid to prostaglandin endoperoxides or lipoxygenase products; (3) platelet responsiveness to TXA₂; (4) dense-granule or α -granule contents; or (5) α_2 -adrenergic receptors. Some of the described abnormalities may also be a consequence of platelet activation in vivo or ex vivo during platelet preparation.

Specific platelet membrane abnormalities have also been reported, including deficiencies of GPIIb and GPIX, causing an acquired form of the Bernard-Soulier syndrome;¹⁷⁸ deficiencies of receptors for prostaglandin D₂;¹⁷⁹ c-MPL receptors;¹⁸⁰ and an increased number of Fc receptors.¹⁸¹ Because MPNs are clonal in origin, the abnormal platelets can arise from a clone of abnormal megakaryocytes.¹⁸² Alternatively, the findings may be the result of platelet hyperreactivity and previous activation.^{183,184} It is important to emphasize several features about the platelet function defects reported in MPNs. First, no defect has consistently predicted the risk for bleeding or thrombosis. Second, no defect is unique to, and therefore predictive of, a particular MPN. Third, the relative frequency of the different defects varies widely. Therefore the clinical importance of the abnormalities of platelet function in MPNs is unknown.

Acquired von Willebrand syndrome (Chapter 138) can cause mucocutaneous bleeding or complicate surgical interventions in nonbleeding patients. In acquired von Willebrand syndrome, the largest multimers of vWF are absent, possibly as a consequence of their adsorption to binding sites on the elevated numbers of platelets,^{185–189}

or because of enhanced a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13 (ADAMTS13) proteolysis of the large multimers.¹⁹⁰ In a prospective study of MPN patients, the incidence of acquired von Willebrand syndrome was 11%.¹⁹¹ Although increased adsorption of plasma vWF multimers by platelets is the cause of the syndrome and decreased vWF:RCO/Ag or vWF:collagen binding/Ag ratio was found in patients with extreme thrombocytosis,¹⁸⁹ acquired von Willebrand syndrome has also been described in patients with platelet counts between 120 and $135 \times 10^9/\mu\text{L}$.¹⁹¹

Several intrinsic platelet function defects result, at least in part, from an increased sensitivity of the platelets to activation, a potential consequence of the *JAK2* gain-of-function mutation. For example, a study demonstrated an increased risk of thrombosis in patients with chronic MPN when the mutant kinase was detected in platelets or in platelets and granulocytes.¹⁸² Likewise, the *JAK2* mutation in platelets correlated with increased platelet expression of tissue factor and P-selectin, decreased expression of CD41 and CD42b, and increased quantities of platelet–neutrophil aggregates, all indicators of a hyperreactive platelet phenotype.¹⁸³ Panova-Noeva et al¹⁸⁴ evaluated the platelets from 140 patients with MPN (80 ET, 60 PV) for global procoagulant potential by measuring thrombin generation and expression of tissue factor and P-selectin on the platelet surface. They found that patients with the *JAK2* V617F mutation had the highest values for thrombin generation and platelet tissue factor and P-selectin expression. These findings correlated with *JAK2* V617F allele burden.¹⁸⁴

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria (PNH; see Chapter 31) is another clonal disorder that involves all blood cells. The hematopoietic stems cells and their progeny are defective in the synthesis of the glycosylphosphatidylinositol attachments required for the plasma membrane expression of some membrane proteins, leading to a defect in all glycosylphosphatidylinositol-linked proteins on blood cells,¹⁹² including platelets.¹⁹³

Thrombosis is a leading cause of mortality in PNH, affecting at least half of these patients. The platelet function abnormalities described in PNH range from hypersensitivity to agonists to dysfunction.¹⁹⁴ One study showed platelets to be hypersensitive to epinephrine, ADP, and collagen, as judged by their abilities to aggregate and to release ¹⁴C serotonin.¹⁹⁵ The total release of nucleotides was also markedly increased over normal with all aggregating agents. By contrast, another study examining platelets from PNH patients showed them to be profoundly hyporeactive, as measured by defective clot formation, adhesion, and aggregation.¹⁹⁶ This finding was interpreted as being a consequence of chronic overstimulation of the platelets while they circulate.

Platelet activation and increased platelet microparticle formation have also been demonstrated in PNH patients.^{194,195,197}

Paraproteinemias

Although thrombotic complications can occur in patients with paraproteinemias because of hyperviscosity, bleeding complications also are seen. Platelet dysfunction is observed in approximately one-third of patients with immunoglobulin (Ig)A myeloma or Waldenström macroglobulinemia, in 15% of patients with IgG myeloma, and occasionally in patients with benign monoclonal gammopathy.^{198,199} Additional hemostatic problems in these patients can be caused by the hyperviscosity syndrome,^{200,201} a heparin-like coagulation inhibitor,²⁰² acquired von Willebrand syndrome,¹⁸⁹ or complications of amyloidosis (e.g., acquired factor X deficiency²⁰³ or enhanced fibrinolysis).²⁰⁴ Patients may have markedly abnormal results on laboratory tests (e.g., a prolonged thrombin time) with no evidence of clinical bleeding.¹⁹⁸

Abnormalities of platelet function correlate with the concentration of the plasma paraprotein. Myeloma proteins can inhibit all

platelet functions (aggregation, secretion, procoagulant activity, and clot retraction), and normal platelets can acquire these defects when incubated with the purified monoclonal immunoglobulin.^{205,206} In some cases, specific interactions of the monoclonal protein have been described. One IgA myeloma protein inhibited the ability of a suspension of aortic connective tissue to aggregate normal platelets.²⁰⁷ The bleeding time and bleeding symptoms of the patient from whom this paraprotein was isolated were corrected when the IgA myeloma protein was removed by plasmapheresis. One patient had a fatal hemorrhage from an IgG1κ paraprotein that bound GPIIIa (β₃ integrin) and inhibited platelet aggregation.²⁰⁸ A number of reports have described acquired von Willebrand disease in patients with myeloma, benign monoclonal gammopathy, or chronic lymphocytic leukemia.²⁰⁹ In some patients, the plasma concentration of vWF was decreased; in others, the larger multimers were deficient. The myeloma protein can either accelerate vWF clearance from plasma or interfere with its binding to platelet GPIb.

Easy bruising, epistaxis, periorbital purpura (in patients with amyloidosis), and GI hemorrhage are the most common bleeding symptoms associated with the paraproteinemias. Because bleeding appears to be related to high plasma paraprotein concentrations,²¹⁰ chemotherapy for the underlying plasma cell neoplasm should be given to effect a longer lasting reduction of the paraprotein. In emergency situations, plasmapheresis should be performed expeditiously; the effectiveness of this therapy can be evaluated by improvement of bleeding. Intravenous immunoglobulin (IVIG) infusions are effective in controlling bleeding in patients with plasma cell dyscrasias and acquired von Willebrand disease. IVIG can produce a clinical and laboratory response in 12–72 hours, and the effect usually persists for 1–3 weeks. In patients with severe bleeding, IVIG can be combined with plasmapheresis, DDVAP, and infusions of vWF concentrates or factor VIIa.^{189,191,199,209}

LEUKEMIAS AND MYELODYSPLASTIC SYNDROMES

Bleeding in patients with the leukemias and myelodysplastic syndromes (MDS) is almost always caused by thrombocytopenia, but abnormalities of platelet function have also been described. In acute myeloid leukemia and its variants, platelets may be larger than normal, abnormally shaped, and vary in their granule numbers. Abnormal platelet structure and function have been described, especially in association with acute megakaryoblastic leukemia (FAB M7),^{211–213} with one study describing three patients with decreased aggregation to collagen, ADP, epinephrine, and the thromboxane analogue U46619, along with a decreased platelet serotonin content.²¹¹ Platelet abnormalities can also be found in the MDS, with defective aggregation and glass bead retention most often associated with hypolobulated megakaryocytes and the 5q[−] syndrome.^{213,214} Abnormal platelet function has also been described in association with B-cell malignancies, such as hairy cell leukemia, which can persist after splenectomy,²¹⁵ and with chronic lymphocytic leukemia,²¹⁶ in which the platelets exhibit reduced responses to GPVI agonists such as collagen and convulxin.

Also, acquired platelet GP defects have been reported in hematological malignancies, including acquired Glanzmann thrombasthenia in a patient with Hodgkin lymphoma²¹⁷ and acquired Bernard-Soulier syndrome in a child with MDS.²¹⁸

SOLID TUMORS

Bleeding complications in patients with cancer are related to decreased platelet production caused by bone marrow infiltration, the myelosuppressive effects of chemotherapy and radiotherapy, sepsis, disseminated intravascular coagulation, microangiopathic hemolytic anemia, drug-induced thrombocytopenia, immune thrombocytopenia, or hypersplenism. Although several defects of platelet functions have been described in cancer patients, none are specific.²¹⁹

SYSTEMIC METABOLIC DISORDERS

End-Stage Renal Disease

The pathogenesis of the hemorrhagic diathesis in patients with end-stage renal disease (ESRD) is complex (Chapter 154). Factors such as platelet function abnormalities caused by uremic toxins, anemia, hemodialysis procedures (both the artificial circulation and the use of anticoagulation), and decreased drug clearance may impair hemostasis.

In ESRD patients both platelet hypofunction and platelet hyperactivity can occur.²²⁰

Deficiencies in the number of GPIb complexes in uremic platelets have been reported, the number inversely correlating with the creatinine level.²²¹ Consistent with this finding, another study demonstrated that defective ristocetin-induced platelet aggregation of uremic platelet-rich plasma was not corrected by resuspending the platelets in normal platelet-poor plasma. Likewise, uremic platelets suspended in normal plasma were defective in their adhesion to deendothelialized rabbit vessels at high shear, a test of the competency of the interaction between GPIb and vWF.²²² Conversely, the same study demonstrated that plasma factors also influence platelet function by showing that normal platelets suspended in uremic plasma acquired an adhesion defect possibly related to an abnormal interaction of vWF with the subendothelium. This led to the suggestion that vWF may be abnormal in uremia. Two studies have demonstrated normal-to-elevated vWF antigen and activity (measured as ristocetin cofactor activity) in uremic patients but decreased levels of the largest, most hemostatically active multimers,^{223,224} reflected in one study as a decreased ratio of activity to antigen level compared with the vWF from normal subjects.²²³ Taken together, the various studies consistently indicate that the first step of platelet adhesion at sites of vessel wall injury is abnormal, a defect that could be clinically significant if coupled with other defects of platelet function.²²⁰

The platelets of uremic patients frequently exhibit reduced fibrinogen binding, aggregation, and secretion in response to a wide variety of agonists. This abnormality may persist when the platelets are removed from uremic plasma, and in some studies, uremic plasma has induced these defects in normal platelets. One potential mechanism is provided by the demonstration that fibrinogen fragment levels are elevated in patients with ESRD and bind to platelet $\alpha_{IIb}\beta_3$, inhibiting platelet aggregation.²²⁵

Uremic platelets can also exhibit a reduction in several of the biochemical responses necessary for aggregation and secretion, including the rise in cytoplasmic calcium ion concentration, release of arachidonic acid from membrane phospholipids, conversion of arachidonic acid to TXA₂, and dense-granule and α -granule secretion. Abnormal cytoskeletal assembly and deficient tyrosine phosphorylation have also been noted in uremic platelets, abnormalities only partially corrected by dialysis.^{220,226}

The accumulation of dialyzable platelet-inhibitory substances in the plasma of uremic patients has long been recognized. The ability of uremic plasma to inhibit platelet function was demonstrated in the late 1960s by Horowitz and colleagues,²²⁷ who showed reduced ADP-induced platelet aggregation and a prolonged Stypven clotting time, a measure of platelet procoagulant activity. This activity, previously called *platelet factor 3*, is vital for the support of coagulation factor complex assembly on the platelet surface and requires externalization of the anionic phospholipid phosphatidylserine. One uremic substance with platelet inhibitory properties described by Horowitz and coworkers²²⁸ was guanidinosuccinic acid, which accumulates in uremic plasma as an alternative byproduct of L-arginine metabolism,²²⁹ a consequence of the inhibitory effect of high urea levels on enzymes of the urea cycle. Similar to L-arginine, guanidinosuccinic acid is a precursor of nitric oxide, which is produced in increased quantities in the endothelial cells and platelets of uremic patients and experimental animals.²²⁹ Consistent with an important role for nitric oxide in uremia, infusion of the nitric oxide synthesis inhibitor monomethyl L-arginine reduced the bleeding time in uremic rats.²³⁰ Furthermore, suppression of nitric oxide production

appears to correlate with the benefit of conjugated estrogens in improving the bleeding time in uremia.²³¹ Increased expression of vascular prostacyclin has also been described in uremic rats, a factor that would further depress in vivo platelet function.²³²

Dialysis itself may be associated with alterations in platelet function. For example, hemodialysis can reduce the responsiveness of platelets to agonists in vitro,²³³ and chronic hemodialysis and peritoneal dialysis are associated with an increase in reticulated platelets, suggesting accelerated platelet turnover.²³⁴ Of the two forms of dialysis, hemodialysis appears to have the greatest effect on platelet function, with one study noting abnormal cytoskeletal assembly and defective tyrosine phosphorylation to thrombin stimulation in the platelets of patients on hemodialysis, parameters that returned almost to normal with the institution of ambulatory peritoneal dialysis.²²⁶ The cause of the defect associated with hemodialysis is likely to be the chronic low-level platelet activation associated with the procedure. In particular, polymerization and depolymerization of actin, release of granule proteins and their binding to the platelet surface, and shedding of membrane proteins may render the platelets relatively refractory to activation.

Uremia and artificial surfaces during hemodialysis also affect platelet mRNA and microRNA profiles, and alter protein expression.²³⁵

As would be expected, platelets from uremic patients may be unusually sensitive to medicines that decrease platelet function. Aspirin has been reported to produce a greater prolongation of the bleeding time in uremic patients than in controls, an effect that may be attributable to more than the irreversible inhibition of COX-1.²³⁶ Similarly, β -lactam antibiotics that prolong the bleeding time can also have a greater effect in uremic patients and may increase the risk of bleeding, particularly those antibiotics cleared by the kidney.^{173,237}

Anemia, which does correlate with the severity of renal failure, is an independent cause of a prolonged bleeding time,^{237–240} and the defect correlates with the severity of the anemia. The relationship of the bleeding time to hematocrit in uremic patients has been confirmed by its correction with the transfusion of red blood cells and by treatment with erythropoietin.^{220,240,241}

In contrast to the studies of platelet function performed to understand the possible increased risk for bleeding in patients with chronic renal failure, the coagulation and fibrinolytic systems have been interrogated to understand the increased risk for thrombotic complications, a major cause of mortality.²⁴²

Uremia-related contributions to a thrombotic tendency include endothelial dysfunction, increased TF expression, increased microparticle generation, increased coagulation factors (fibrinogen, FXIIa, FVIIa) and proinflammatory markers, decreased natural anticoagulant levels, and changes related to renal replacement therapy as extracorporeal thrombin generation, decreased fibrinolysis, and membrane-induced platelet activation.^{220,243}

Liver Disease

The bleeding diathesis observed with fulminant or end-stage liver disease (Chapter 153) is multifactorial, with contributing causes including thrombocytopenia, anemia, deficiencies in liver-synthesized coagulation factors, and excessive fibrinolysis.^{244,245} Patients with chronic liver disease and hepatic cirrhosis of various causes have been reported to have prolonged bleeding times, and these disorders are associated with other platelet function abnormalities possibly related to a decrease in GPIb.²⁴⁶ Although an association between prolonged bleeding time and GI hemorrhage has been demonstrated in some studies of cirrhotic patients,²⁴⁷ other studies showed that the bleeding time and platelet aggregation abnormalities correlated best with the degree of thrombocytopenia,²⁴⁸ suggesting that no specific platelet function defect exists in liver disease. An aspirin-like defect has been reported in patients with severe liver disease, with defective aggregation and TXA₂ production.²⁴⁹ Interestingly, one study showed that platelets obtained from the portal circulation of patients with hepatocellular cancer on a background of cirrhosis showed decreased and delayed aggregation in response to collagen compared with

circulating platelets.²⁵⁰ In addition to portal hypertension and esophageal varices, this finding raises the possibility that localized vascular bed factors (including increased prostacyclin) may contribute to variceal bleeding.

Because patients with cirrhosis often have a complicated hemostatic picture that includes thrombocytopenia, decreased fibrinogen levels, and prolonged prothrombin and aPTTs, one might expect this to uniformly produce a severe bleeding diathesis. However, recent studies have shown that the hemostatic defects in these patients are at least partially compensated through several mechanisms. The potential to bleed because of thrombocytopenia is reduced because vWF levels are often elevated and ADAMTS13 activity is decreased,^{251–253} perhaps as a consequence of decreased synthesis by hepatic stellate cells. The decreased concentrations of procoagulant factors are balanced by the decreased concentrations of anticoagulant proteins.²⁵⁴ Dysfibrinogenemia produces a less severe hemostatic defect because of decreased plasminogen levels.^{255,256} This balance may easily be tipped in either direction, favoring either bleeding or thrombosis.

Although patients with cirrhosis may have platelet dysfunction, it is usually not associated with serious bleeding. Bleeding in these patients cannot be predicted with routine diagnostic tests, such as the platelet count and bleeding time.^{257,258}

PLATELET DYSFUNCTION RELATED WITH EXTRACORPOREAL CIRCUITS

Extracorporeal circuits such as cardiopulmonary bypass (CPB), extracorporeal membrane oxygenation (ECMO), continuous flow left ventricular assist devices (LVADs), and total artificial heart generate high shear stress and affect blood cells, endothelial cells, and plasma proteins.

Bleeding complications can be seen in 10%–20% of the patients undergoing CPB, and hemostatic disturbances are responsible from bleeding in nearly half of those patients.^{259,260} CPB activates both coagulation and fibrinolytic systems, and causes consumption coagulopathy. Besides the surgery itself, high shear stress and exposure of the blood to artificial surfaces activates FXII and FXI directly, and induces blood cells to express TF.^{259,261}

Typical findings after bypass surgery include a prolonged bleeding time (longer than expected for the degree of thrombocytopenia), decreased platelet aggregation, decreased platelet agglutination in response to ristocetin, and depletion of platelet α -granule and dense granule contents.²⁶²

As with hemodialysis, the platelet defect caused by CPB is most likely a consequence of platelet activation and fragmentation within the extracorporeal circuit. The severity of the platelet abnormalities correlates with the duration of the bypass procedure.²⁶⁰ With uncomplicated surgery, platelet function returns to normal within 24 hours; however, a much longer time may be required in some patients, and the platelet count typically does not return to normal for several days.²⁶³

Thrombocytopenia is caused by hemodilution and deposition of platelets on the bypass circuit and, to a lesser extent, sequestration of damaged platelets in the liver. Platelet dysfunction during bypass may be caused by reversible adhesion and aggregation of platelets on fibrinogen adsorbed from plasma onto the bypass circuit material, mechanical trauma and shear stress, cardiotomy suction, trace concentrations of circulating thrombin and ADP, complement activation, hypothermia, blood conservation devices; bypass priming solutions; and, with bubble oxygenators, exposure of platelets to the blood–air interface.^{173,259} CPB consistently induces the formation of platelet fragments, or membrane “microparticles,” evidence that the platelet surface membrane is subjected to severe mechanical stress and activation during the procedure.²⁶⁴ Thus considerable platelet activation and aggregation occur during CPB, which leads to deleterious effects from substances released from the platelets and the new adhesive molecules exposed on their surfaces, and renders the platelets relatively refractory to activation by agonists.

Another surgical cause of platelet dysfunction relates to the use of deep hypothermic circulatory arrest in some surgeries. This procedure involves cooling the vital organs to temperatures between 15°C and 22°C (59°F and 71.6°F) for reducing oxygen requirements of major organs such as the heart, brain, and kidney.²⁶⁵

In patients with mechanical circulatory support such as LVADs or ECMO, continuous exposure of blood to nonbiological surfaces creates additional hemostatic problems.^{266,267} Continuously elevated shear stress both elongates and breaks down vWF multimers mechanically and facilitates the cleavage of high-molecular-weight vWF multimers by ADAMTS13, causing acquired von Willebrand disease.²⁶⁷ Increased shear stress created by these devices also causes platelet receptor shedding. In a study evaluating patients with ECMO and continuous flow LVADs, platelet surface receptor shedding was demonstrated by elevated soluble GPVI levels in plasma, and significantly reduced expression of GPVI and GP Ib α on the platelet surface.²⁶⁸

MISCELLANEOUS

Hypothermia

Hypothermia is defined as core body temperature below 35°C or 95°F and is classified as mild (32–35°C or 90–95°F), moderate (28–32°C or 82–90°F), severe (20–28°C or 68–82°F), and profound (below 20°C or 68°F). Major causes of hypothermia are exposure to cold weather or immersion in cold water, but hypothermia can also be caused by dehydration, severe trauma, massive transfusion, head injury, burns, sepsis, and drugs (e.g., alcohol, sedatives, and hypnotics). Age is an important risk factor because elderly adults and newborns are particularly prone to hypothermia. Hypothermia is also intentionally induced in some cardiac operations.²⁶⁵

Mild hypothermia is usually well tolerated, but mortality increases when the core body temperature falls below 20°C. In animals, hypothermia causes thrombocytopenia because of platelet sequestration in the spleen and liver. Hypothermia inhibits platelet aggregation in response to thrombin and thromboxane, increases platelet expression of P-selectin, and decreases expression of the GPIb-IX-V complex.²⁶⁹ Both the thrombocytopenia and the functional defects are reversible, returning to normal when the body temperature normalizes.²⁶⁵

ANTIPLATELET ANTIBODIES

Immunoglobulins can bind to platelets in a specific or nonspecific fashion and can disrupt platelet function. In conditions such as immune thrombocytopenic purpura (ITP), systemic lupus erythematosus (SLE), and platelet alloimmunization, the antibodies can trigger accelerated platelet destruction and subsequent thrombocytopenia. Surviving platelets, known as *stress platelets*, display enhanced function.²⁷⁰ Indeed, bleeding times in ITP may be shorter than expected for the degree of thrombocytopenia. Sometimes, however, the hemorrhagic tendency is out of proportion to the degree of thrombocytopenia or persists after the platelet count returns to normal, suggesting that the bound antibody is perturbing platelet function.²⁷¹

In some patients with ITP or SLE, platelet dysfunction may be suspected because mucocutaneous bleeding symptoms occur despite platelet counts that are usually sufficient for normal hemostasis (>50,000/ μ L), and the bleeding time may be longer than expected for the degree of thrombocytopenia. Patients with antiplatelet antibodies can exhibit defective platelet function in vitro even if they do not have prolonged bleeding times or clinical symptoms of excessive bleeding, a situation similar to what occurs with aspirin ingestion or renal disease. For example, in two studies, 13 of 19 patients with ITP demonstrated impaired platelet aggregation to ADP, epinephrine, or collagen.^{272,273} In two other studies, 22 of 35 patients with SLE were found to have decreased platelet aggregation in response to these agonists.^{274,275} The platelet function abnormalities appear to be

antibody mediated because IgG purified from the plasma or eluted from the platelets of these patients inhibited the aggregation of normal platelets.

Platelet antibodies may affect several aspects of platelet function. The most frequently observed abnormality is absence of platelet aggregation in response to low concentrations of collagen and absence of the second wave of aggregation in response to ADP or epinephrine. This pattern is identical to the abnormalities caused by aspirin, described earlier. In ITP and SLE, the abnormal aggregation may be related to a reduction in the contents of dense and α -granules, or to an activation defect manifested by diminished synthesis of TXA₂.

Autoantibodies or alloantibodies usually impair the function of the antigen against which they are targeted. For example, alloantibodies (e.g., anti-PI^{A1}) and autoantibodies that bind to $\alpha_{IIb}\beta_3$ produce a syndrome similar to Glanzmann thrombasthenia.^{276–280} These antibody-associated thrombopathies can be severe.²⁸¹

It is not surprising that many of the antiplatelet antibodies target $\alpha_{IIb}\beta_3$ because this is the most abundant receptor on the platelet surface and required for all aggregation responses.²⁸² Antibodies that target GPIb have also been described, in one case producing a syndrome of severe refractory thrombocytopenia and a functional defect resembling that observed in Bernard-Soulier syndrome.²⁸³ An interesting aspect of antibodies against GPIb is their association with more severe thrombocytopenia than that observed with antibodies directed against other antigens.²⁸⁴ This finding is consistent with the observations that anti-GPIb antibodies inhibit megakaryopoiesis²⁸⁵ and proplatelet formation in vitro.²⁸⁶ Autoantibodies have been described that target GPIa (integrin α_2),^{287,288} GPIV,²⁸⁸ and GPVI.^{289–291}

Platelet-activating antibodies have been described. Of particular interest is the report of a patient who presented with immune thrombocytopenia and an antibody against CD9 (a member of the tetraspanin protein family) that was capable of activating normal platelets.²⁹² After recovery of the platelet count, the patient relapsed, this time with an antibody described against the platelet Fc receptor, Fc γ RIIA. The latter antibody blocked the capacity of the first antibody to activate platelets, confirming that activation involved stimulation of the Fc receptor.

Platelets that have been activated and induced to secrete but have not been incorporated into aggregates are likely to be refractory to platelet agonists and deficient in secretory granule contents, essentially leading to an acquired storage pool deficiency, which has also been described in association with autoantibodies.²⁹³

SCURVY

Vitamin C deficiency results in defective collagen synthesis and abnormal bleeding from fragile capillaries. However, significant platelet aggregation defects can be seen in patients with scurvy, which normalize after vitamin C supplementation.²⁹⁴

ACQUIRED PLATELET DYSFUNCTION WITH EOSINOPHILIA

Acquired platelet dysfunction with eosinophilia is a self-limited disorder characterized by mucocutaneous bleeding and hyper-eosinophilia.^{295,296} The platelet count is usually normal; however, the platelets are pale by light microscopy (as in gray platelet syndrome), and aggregation studies show an acquired storage pool defect. All reported cases have been from South-East Asia. In some cases

eosinophilia and platelet dysfunction returned to normal after anti-helminthic therapy, which suggests a parasitic infection.

DISEASES OF PLATELET NUMBER: IMMUNE THROMBOCYTOPENIA, NEONATAL ALLOIMMUNE THROMBOCYTOPENIA, AND POSTTRANSFUSION PURPURA

Donald M. Arnold, Michelle P. Zeller, James W. Smith, and Ishac Nazy

Platelets are anucleate cells that are required for primary hemostasis. Platelets have a life span of 7–10 days in the circulation, after which time they are cleared by the cells of the reticuloendothelial system (RES), including the spleen. Platelet production is stimulated by thrombopoietin (TPO), a hormone that is constitutively secreted by the liver. TPO binds to c-Mpl, its receptor on platelets, hematopoietic progenitor cells, and bone marrow (BM) megakaryocytes. When bound to c-Mpl, TPO is internalized, degraded, and removed from the circulation; thus when the platelet count is low, free TPO levels are high, and more platelets are produced. In contrast, when platelet counts are high, circulating TPO levels are low, and platelet production declines. This primitive feedback system is very effective at maintaining the platelet count at a stable level. Recent evidence in mice has shown that the Ashwell-Morell receptor on murine hepatocytes binds platelets that have lost sialic acid residues on their surface. Binding activates a JAK-STAT signaling pathway, resulting in increased hepatic TPO mRNA expression and TPO production. The role of this pathway in normal human thrombopoiesis is not yet known.

Immune-mediated platelet disorders disrupt normal regulation of platelet number because of antibody-mediated or cell-mediated platelet destruction or platelet underproduction. Antibodies that target self (autoimmune) or nonself (alloimmune) antigens on platelets can cause severe thrombocytopenia. Immune thrombocytopenia (ITP) is an autoimmune disorder characterized by antibodies directed against platelet glycoproteins (GPs). Neonatal alloimmune thrombocytopenia (NAIT) is a thrombocytopenic syndrome caused by platelet alloantibodies. Posttransfusion purpura (PTP) has features of both alloantibody- and autoantibody-mediated processes. These platelet disorders have related immunologic features with distinct clinical characteristics (Table 131.1). The pathophysiology, clinical manifestations, and management of these disorders are discussed in this chapter.

IMMUNE THROMBOCYTOPENIA

ITP is a common autoimmune disease characterized by a low platelet count that can be associated with an increased risk of bleeding. Increased platelet destruction resulting from platelet autoantibodies is a hallmark of ITP. Recently, however, it has become evident that relative platelet underproduction is also an important mechanism for the thrombocytopenia in ITP. Conventional treatments, including corticosteroids, intravenous immunoglobulin (IVIg), immunosuppressant drugs, and splenectomy are aimed at preventing platelet destruction. TPO receptor agonists are medications that work by increasing platelet production. They represent the most significant advance in ITP management since the first description of IVIg as a treatment for ITP in the early 1980s. TPO receptor agonists have been shown to be effective in clinical trials^{1,2} and were the catalyst for several key initiatives in ITP including the standardization of terminology (2009)³ and the development of the American Society of Hematology (ASH) Guidelines on diagnosis and management of ITP (2011).⁴

Epidemiology

The natural history of ITP is different in children and adults. For the majority of children, ITP presents acutely and resolves within several weeks, often in the absence of intervention. Seasonal variability suggests that viral infections may trigger the disease in many children. Conversely, adult-onset ITP tends to be insidious in onset and is characterized by a chronic or remitting and relapsing course.

Incidence and Prevalence of Immune Thrombocytopenia in Children

The incidence of acute ITP in children is estimated at 1.9–6.4 per 100,000 per year. Nearly 70% of childhood ITP occurs between the ages of 1 and 10 years with the peak prevalence between 4 and 6 years. Most studies in children report an overall male predominance in early childhood and equalization or reversal to female predominance in older children. Reported prevalence estimates are 12.6 per 100,000 for girls and 9.3 per 100,000 for boys in the older age groups.

Incidence and Prevalence of Immune Thrombocytopenia in Adults

Incidence estimates for adult-onset ITP are reported to be between 1.6 and 3.9 per 100,000 per year. A retrospective analysis from the United Kingdom described a bimodal distribution for men, with peak incidences before the age of 18 years and between 75 and 84 years of age. Relatively stable incidence rates were found in women up to the age of 60 years with a steady increase thereafter. The incidence of ITP has been reported to double in patients over 60 years of age.

The overall prevalence of ITP in adults has been estimated at 9.5 per 100,000, and ranges from 4.1 per 100,000 in younger ages (19–24 years) to 16 per 100,000 in older age groups (55–64 years). Male and female prevalence rates are 16.6 and 27.2 per 100,000 adults, respectively, for those 18–64 years of age, with prevalence rates increasing significantly after the age of 65 years. The female predominance is attenuated in older age groups and may revert to a male predominance after the age of 65 years. Indeed, the prevalence of ITP in older men is reported to be as high as 38.3 per 100,000. Increasing incidence and prevalence rates may reflect a true rise in disease frequency with age or ascertainment bias because of the higher likelihood of discovering incidental thrombocytopenia with more frequent medical visits in older individuals.

Pathophysiology

ITP is caused by increased platelet destruction and impaired platelet production. Until recently, the pathogenesis of immune-mediated thrombocytopenia was mainly attributed to platelet-reactive autoantibodies; however, it is now evident that the pathophysiology of ITP

TABLE 131.1 Antibody-Mediated Thrombocytopenic Disorders Caused by Autoantibodies (Immune Thrombocytopenia), Alloantibodies (Neonatal Alloimmune Thrombocytopenia) or Potentially Both (Posttransfusion Purpura)

	Immune Thrombocytopenia	Neonatal Alloimmune Thrombocytopenia	Posttransfusion Purpura
Immune reaction	Autoimmune	Alloimmune	Features of both allo- and autoimmunity
Incidence	5 per 100,000 population	40 per 100,000 births (or 1 per 2500)	1 per 100,000 blood transfusions
Principal antigenic target	GPIIb/IIIa	HPA-1a	HPA-1a plus autoantigens
Nature of the antibody	Intermittent	Persistent (past 1 year)	Persistent often at high titers
Mode of sensitization	Autoantibody	Alloantibody	Features of allo- and autoantibodies
Sensitizing event	Mostly unknown; some viral illnesses, chronic infection	Exposure to fetal platelet antigens early in first pregnancy	Blood transfusion (RBCs or platelets) 5–10 days earlier
Bleeding frequency	Uncommon	Common	Very common
Epidemiology	Higher incidence in children and elderly adults; female predominance in early adulthood	Majority affects fetus or newborn carrying the HPA-1a antigen	Almost all are HPA-1bb women sensitized by previous transfusion or pregnancy

GP, Glycoprotein; HPA, human platelet antigen; RBC, red blood cell.

is more complex and involves alterations in cellular immunity and immune-mediated megakaryocyte injury.

The antibody hypothesis began with the observation that blood from patients with ITP was able to cause a reduction in platelet count levels in other individuals. In one of the first experiments, William Harrington infused blood from ITP patients into normal volunteers and observed a decrease in the platelet counts in most recipients.⁵ The circulating factor in blood responsible for this effect was later identified as an immunoglobulin (Ig) that bound to the surface of platelets. In further studies, investigators were able to quantify platelet-associated IgG (PAIgG) on or inside platelets. PAIgG was not able to discriminate between immune and non-ITP and eventually assays were developed to detect antibodies directed against specific platelet GPs, specifically GPIIb/IIIa or GPIb/IX. GP-specific assays exhibited improved specificity but had limited sensitivity (50%–66%) since many patients with ITP had no detectable antibody. Autoantibodies against platelet GPs target those cells for rapid opsonization and clearance in the RES, particularly the spleen. Peptides from phagocytosed platelets may be processed and presented to specific T cells, which in turn stimulate B cells to produce additional platelet autoantibodies. This process, known as *epitope spreading*, may explain why patients have circulating autoantibodies targeting a variety of platelet antigens. Other proposed mechanisms of antibody-induced platelet destruction are complement activation and platelet apoptosis.

In ITP, platelet production does not compensate for the increased platelet destruction, suggesting that BM megakaryocyte growth and/or ability to produce platelets are impaired. Evidence supporting reduced platelet production in ITP derives from radiolabeled autologous platelet studies demonstrating normal or reduced platelet turnover; and from clinical studies that have consistently demonstrated the capacity of TPO receptor agonists to increase platelet counts in patients with severe thrombocytopenia. Megakaryocytes also express GP receptors, which may render them targets of ITP autoantibodies. Indeed, in vitro studies demonstrated suppression of megakaryocyte growth and maturation when the cells were incubated with IgG from ITP patients.

In addition to the effect of autoantibodies, cytotoxic T cells from ITP patients may have direct cytolytic effects on platelets. Some patients with active ITP but without detectable platelet autoantibodies had CD8⁺ T cells that induced platelet lysis in vitro. In contrast, CD8⁺ T cells from patients in remission did not show significant platelet reactivity. Furthermore, compared with cells from controls, CD3⁺ cells from ITP patients exhibited increased expression of genes involved in cell-mediated cytotoxicity including tumor necrosis factor- α (TNF- α), perforin, and granzyme A and B, and CD8⁺ T cells exhibited increased expression of FasL (Fas–Fas ligand) and TNF- α .

In the broadest sense, autoimmunity develops because of a breakdown in regulatory checkpoints that occurs during development or maturation of the immune system. Although the precise events that trigger the loss of self-tolerance to platelet GPs are largely unknown, patients with ITP have been shown to exhibit several immune alterations to platelet antigens including dysfunctional cellular immunity because of T-helper (Th)0/Th1 polarization, decreased regulatory T-cell function, and autoreactive platelet-specific cytotoxic T cells. In addition, ITP patients may have increased circulating levels of cytokines and soluble factors that promote the survival of self-reactive T and B cells, including B-cell activating factor, a proliferation-inducing ligand, and B-cell lymphoma-2 interacting mediator of cell death. Reduced levels of proapoptotic cytokines that regulate self-reactive T-cells, including Fas, interferon- γ , interleukin-2 receptor β (IL2RB), Bax, and caspases 8 and A20, have also been demonstrated.

Primary and Secondary Immune Thrombocytopenia

Primary ITP, which was previously known as *idiopathic* but is now referred to as *immune thrombocytopenia* (Table 131.2) occurs for unknown reasons. Secondary ITP is important to recognize because treatment of the underlying cause is often necessary to increase the platelet count. Examples are ITP occurring in the setting of infection, pregnancy, drugs, or lymphoproliferative disease.

Infection may stimulate the formation of platelet reactive autoantibodies. Cross-reactive antibodies (molecular mimicry) have been described in *Helicobacter pylori*, human immunodeficiency virus (HIV), and hepatitis C virus (HCV) infections. Molecular mimicry between the highly antigenic *H. pylori* CagA protein and platelet antigens is the suspected mechanism of *H. pylori*-associated ITP. In most patients, *H. pylori* can be successfully eradicated with a 1–2 week course of clarithromycin (500 mg twice daily), amoxicillin (1000 mg twice daily), and a proton pump inhibitor (e.g., pantoprazole 40 mg twice daily); however, the effect of *H. pylori* eradication on the platelet count is variable. In a metaanalysis that included 788 patients, *H. pylori* eradication resulted in platelet counts that were $34 \times 10^9/L$ higher than those in untreated control participants and $52 \times 10^9/L$ higher than those in treated patients whose *H. pylori* was not eradicated. Another systematic review evaluating 696 patients reported that 42.7% of treated patients achieved platelet counts above $100 \times 10^9/L$; however, the effect was highly dependent on geographic location with the beneficial effect mainly observed in patients from Japan. Evidence-based guidelines for the investigation and management of ITP recommend against routine screening for *H. pylori* in patients presenting with ITP because of the low yield of testing and the low likelihood of a platelet count increase with *H. pylori*

TABLE 131.2**Standardized Terminology and Definitions for Immune Thrombocytopenia Proposed by the International Working Group (Vicenza Consensus Conference) in 2009**

Terminology	Definition
ITP	Immune thrombocytopenia (rather than idiopathic or immune thrombocytopenic purpura)
Platelet threshold for ITP diagnosis	$<100 \times 10^9/L$
Primary ITP	ITP with no associated cause (diagnosis of exclusion)
Secondary ITP	ITP in the setting of an underlying cause such as drugs, HIV, or SLE
Newly diagnosed ITP	Designation for patients at diagnosis (rather than “acute” ITP).
Persistent ITP	Sustained or recurrent thrombocytopenia lasting 3–12 months
Chronic ITP	Thrombocytopenia lasting >12 months
Complete response	Achievement of a platelet count of $\geq 100 \times 10^9/L$ in the absence of bleeding
Response	Achievement of a platelet count of $\geq 30 \times 10^9/L$ and at least a twofold increase from baseline in the absence of bleeding
Refractory ITP	Failure to achieve a response or relapse after splenectomy ^a and requirement for treatment(s) to minimize the risk of clinically significant bleeding

^aSplenectomy failure may not be applicable in children.

HIV, Human immunodeficiency virus; ITP, immune thrombocytopenia; SLE, systemic lupus erythematosus.

eradication. Testing may be warranted in countries where *H. pylori* infection is endemic, particularly those where the response rates to eradication therapy are high.

ITP also may present for the first time or relapse in pregnancy. Although mild ITP may be difficult to differentiate from incidental thrombocytopenia of pregnancy, pregnancy-related vascular disorders must be excluded.⁶ Incidental thrombocytopenia of pregnancy (also called *gestational thrombocytopenia*) represents a physiologic change in platelet count. Pregnancy-related vascular disorders include preeclampsia, microangiopathy caused by HELLP syndrome (characterized by hemolysis, elevated liver enzymes, and a low platelet count), and acute fatty liver. Platelet counts tend to be mildly reduced and hypertension is common.

Pregnancy-associated ITP may present early in pregnancy and thrombocytopenia can be severe. Typically, platelet counts increase after ITP-specific therapies such as IVIg or corticosteroids. In contrast, incidental thrombocytopenia of pregnancy, which occurs late in pregnancy, is associated with a mild reduction in platelet count and does not respond to immune-modulating therapy. Platelet count thresholds for instituting treatment are the same as those for women with ITP who are not pregnant. In the absence of bleeding, treatment should be considered when the platelet count decreases to less than $20 \times 10^9/L$. Vaginal deliveries are thought to be safe for mothers with ITP, even if the platelet count is very low, and most clinicians try to maintain the count above $20\text{--}30 \times 10^9/L$. Epidural anesthesia is not recommended with platelet counts below $70\text{--}80 \times 10^9/L$; however, this practice is operator driven and based on little evidence. IVIg and corticosteroids are generally safe in pregnancy, but corticosteroids can be associated with hypertension, gestational diabetes, intrauterine growth restriction, and other pregnancy-associated morbidities. Splenectomy is rarely performed during pregnancy because most

women can successfully be managed with less aggressive treatments. Immunosuppressant medications, such as azathioprine, have been used in pregnancy but should be reserved for refractory pregnancy-associated ITP with bleeding. There is a risk of severe thrombocytopenia in the newborn because of passive transfer of maternal antiplatelet autoantibodies. This can occur in 10% of newborns.

Clinical and Laboratory Features

Thrombocytopenia

Thrombocytopenia is the defining feature of ITP. The international working group on standardization of terminology in ITP established a platelet count below $100 \times 10^9/L$ as the cutoff for the diagnosis (see Table 131.2).³ The rationale behind this threshold was that patients with mild thrombocytopenia ($100\text{--}150 \times 10^9/L$) have a low risk (approximately 7%) of developing persistent thrombocytopenia (platelets less than $100 \times 10^9/L$); platelet counts slightly below $150 \times 10^9/L$ may be normal for certain ethnic groups; and mild thrombocytopenia may be caused by physiologic processes, such as pregnancy. Nonetheless, primary ITP remains a diagnosis of exclusion, and as such, investigations are directed towards ruling out nonimmune causes, including pseudothrombocytopenia, myelodysplastic syndromes, thrombotic microangiopathies, splenomegaly, or hereditary thrombocytopenia; and secondary immune causes such as infection, concomitant autoimmune disease, or lymphoproliferative disorders.

Clinical Outcomes: Mortality, Bleeding and Quality of Life

Patients with ITP most commonly present with asymptomatic thrombocytopenia. Although some patients bleed with platelet counts less than $30 \times 10^9/L$, many do not. Bleeding symptoms characteristic of ITP (“platelet-type bleeding”) include skin bleeding (i.e., bruises, nonpalpable purpura, or petechiae), oral hemorrhagic blood blisters or oral petechiae, epistaxis, menorrhagia, or gastrointestinal bleeding. The most severe complication is intracerebral hemorrhage (ICH).

In a systematic review of prospective studies, the incidence of ICH was 1.4% for adults (95% confidence interval [CI], 0.9–2.1) and 0.4% for children (95% CI, 0.2–0.7).⁷ The proportion of patients with severe (non-ICH) bleeding was 9.6% for adults (95% CI, 4.1–17.1) and 20.2% for children (95% CI, 10.0–32.9). Risk factors for severe bleeding include severe thrombocytopenia, previous bleeding, and older age.

Chronic ITP has been associated with a risk of death that is up to four times higher than that in the general population. ITP patients are more likely to die of bleeding, infection, and hematologic malignancies. Some deaths are attributable to adverse effects of treatment rather than the disease. Quality of life is affected, at least in part, because of the prevalence of fatigue that appears to be independent of platelet count levels.

Investigations of Patients With Suspected Immune Thrombocytopenia

Patients presenting with newly identified thrombocytopenia require a careful history and physical examination to uncover the underlying cause of the thrombocytopenia and to assess the risk of bleeding. A complete blood count and review of the blood film is required (Fig. 131.1). HIV and HCV testing should be performed in any patient suspected of having ITP. There are insufficient data to support routine screening for antinuclear antibodies or antiphospholipid antibodies unless other signs and symptoms of systemic lupus erythematosus or antiphospholipid syndrome are present. BM aspiration and biopsy should be reserved for patients with abnormalities affecting other cell

Fig. 131.1 BLOOD FILM EXAMINATIONS FROM PATIENTS WITH THROMBOCYTOPENIA. (A) Pseudothrombocytopenia showing marked platelet clumping. (B) Schistocytes (fragmented red blood cells) and reticulocytosis in a patient with thrombotic thrombocytopenic purpura. (C) Macrothrombocyte (*left panel*) and neutrophil-containing cytoplasmic inclusions (Döhle bodies, *right panel*) in a patient with May-Hegglin anomaly. (D) A patient with immune thrombocytopenia with low platelets and postsplenectomy Howell-Jolly bodies (*arrows*).

lines such as anemia, leukopenia, or macrocytosis. Most patients with typical ITP do not require BM examination. Quantitative Ig levels may be useful in children to exclude common variable immune deficiency and thyroid testing can uncover subclinical hypothyroidism if surgery is planned.

First-Line Therapy

Corticosteroids with or without IVIg are first-line treatments for patients with newly diagnosed ITP. Second-line therapies include rituximab, splenectomy, TPO receptor agonists, or immunosuppressant medications. ASH guidelines for the management of ITP were developed using GRADE methodology to assess the level of evidence associated with each recommendation.⁴ Aligned with these guidelines, the authors recommend a treatment approach starting with those that are least toxic (Fig. 131.2).

Observation

One of the ASH 2014 Choosing Wisely recommendations is that patients with ITP should not be treated unless they are bleeding or have very low platelet counts.⁸ Most patients with platelet counts above $30 \times 10^9/L$ and no bleeding can be managed safely with observation alone. This is especially true for children with ITP who are at low risk of serious bleeding. Furthermore, in up to 80% of cases, childhood ITP resolves within 6 months with no treatment. If

Fig. 131.2 STAIRCASE MODEL OF IMMUNE THROMBOCYTOPENIA TREATMENT. Therapies build on each other, often cumulatively, in a stepwise fashion starting from the least toxic. After a period of observation, corticosteroid-based treatment is the accepted first-line therapy. Splenectomy, rituximab, and thrombopoietin receptor agonists may be reasonable second-line therapies. Rituximab is not currently licensed for immune thrombocytopenia. Thrombopoietin (TPO) receptor agonists are indicated for immune thrombocytopenia (IVIg) patients who have failed to respond to other therapies, including splenectomy. (Modified with permission from Arnold DM, Kelton JG: Current options for the treatment of idiopathic thrombocytopenic purpura. *Semin Hematol* 44:S12, 2007.)

First-Line Therapy

An 8-year-old girl is brought to the emergency department because her mother noticed bruising on her legs. She has had a sore throat and fever for the past 7 days but is otherwise well and not taking any medications. On physical examination, there are a few small bruises on her legs but no petechiae on her skin or purpura in her mouth. Neurologic examination findings are normal, and the spleen is not palpable. The platelet count is $23 \times 10^9/L$. The presumed diagnosis is ITP without significant bleeding; thus the decision is made to observe the child in the hospital with no specific treatment. The next day, the platelet count is $33 \times 10^9/L$. On day 2, it is $37 \times 10^9/L$, and the child is discharged home. One week later, the platelet count is $66 \times 10^9/L$, and 1 month later, it is up to $155 \times 10^9/L$.

patients present with bleeding, such as epistaxis or mucosal hemorrhage, treatment is required. For adults, a period of observation may be reasonable if there is no evidence of bleeding and the platelet count is above $20 \times 10^9/L$; however, most adults will require treatment because spontaneous remissions are rare. To reflect current practice, the ASH 2011 guidelines recommend using a platelet count below $30 \times 10^9/L$ as the threshold for starting treatment.

Corticosteroids

The conventional starting dose of prednisone is 1–2 mg per kg for 2–4 weeks followed by tapering over a several week period once the platelet count improves. In general, 60% to 70% of adults with acute ITP achieve an initial response with corticosteroids. Sustained platelet count responses (platelet count $>100 \times 10^9/L$ at 6 months) with corticosteroids are infrequent in practice, but have been reported to be as high as 47% in some studies. The risk of relapse increases with longer duration of follow up. Low-dose prednisone (0.5 mg/kg per day followed by a taper) may be as effective as the conventional dose for initial ITP treatment, but long-term remissions are rare. The optimal duration of prednisone treatment and the optimal tapering schedule have yet to be established.

High-dose dexamethasone, typically administered at a dose of 40 mg/day for 4 consecutive days, is also effective. In one study that included 125 adults with ITP, approximately 40% of patients had a sustained response that lasted 2–5 years.⁹ Repeated cycles of high-dose dexamethasone (once per month for 6 months) may result in even higher rates of durable remissions, although this effect may simply reflect the total corticosteroid exposure. High-dose dexamethasone is associated with side effects that may limit the use of this treatment including hypertension, muscle weakness, insomnia, and impaired cognition. In a systematic review of randomized trials comparing high dose dexamethasone and prednisone in adults with previously untreated ITP ($n = 533$), treatment with dexamethasone resulted in improved overall (79% vs. 59%; $P = .048$) and complete platelet count response (64% vs. 36%; $P = .040$) without excess toxicity.^{9a} Sustained responses at 6 months were not different between groups, but platelet count responses occurred more rapidly with high dose dexamethasone.

Intravenous Immunoglobulin and Anti-D

The predominant mechanism of action of high-dose IVIg and anti-D is thought to be via RES blockade. Individuals with low plasma IgG levels exhibit more rapid clearance of sensitized red blood cells (RBCs) (indicating enhanced RES capacity) than those with high levels of plasma IgG, such as those achieved with high-dose IVIg. A competitive model of RES clearance would also explain why anti-D administration to Rhesus (Rh)-positive individuals is effective in improving platelet counts in patients with ITP. Thus IgG-sensitized RBCs compete for Fc receptor occupancy. Other potential mechanisms of action of IVIg or anti-D include antiidiotypic antibodies, stimulation of

proinflammatory and antiinflammatory cytokines, upregulation or downregulation of various Fc receptors, and the induction of soluble immune complexes. In a mouse model of ITP, transfer of IVIg-primed dendritic cells recapitulated the effect of IVIg.

Based on the results of a metaanalysis of randomized controlled trials that included 410 children, the probability of achieving a platelet count above $20 \times 10^9/L$ at 48 hours was higher with IVIg than corticosteroids (relative risk for corticosteroids, 0.74; 95% CI, 0.65–0.85).¹⁰ Similar results have been observed in adults. Common side effects of IVIg include headache, hypertension, and chills. Hemolysis, thrombosis, renal impairment, and neutropenia are rare complications.

Anti-D (50–75 IU/kg) and IVIg have similar efficacy in children. Hemolysis is expected with anti-D administration, and rarely, intravascular hemolysis can be severe or even fatal. Consequently, the United States Food and Drug Administration has issued a black box warning about the use of anti-D for the treatment of ITP, and the drug has been removed from certain European markets. In general, the use of anti-D is restricted to nonsplenectomized patients who are Rh-positive and have a negative direct antiglobulin test.

Second-Line Therapy

Splenectomy

Splenectomy was first proposed as a treatment for ITP in 1913 and was subsequently shown to be an effective means of rapidly increasing the platelet count in most ITP patients. In a systematic review, approximately two-thirds of patients achieved a platelet count response after splenectomy, usually within days.¹¹ Despite the high success rate with splenectomy, patients (and physicians) are often reluctant to undertake an invasive procedure such as splenectomy, when pharmacologic alternatives are available. Only younger age has been identified as a predictor of splenectomy success, although some investigators have found a correlation between prior response to IVIg and a splenic pattern on radiolabeled platelet sequestration studies.

With currently available minimally invasive surgical techniques, complications after splenectomy are uncommon. The overall mortality rate is approximately 1% with open surgery and about 0.2% after laparoscopic splenectomy. The most frequent perioperative complications include pneumonia, subphrenic abscess or pleural effusion (4%), major bleeding (1.5%), and thromboembolism (1%). With laparoscopic techniques, patients have less postoperative pain, shorter hospital stays, and fewer wound complications.

Because the spleen is involved in clearance of encapsulated bacteria, asplenic individuals are at risk for infection with *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b. Therefore all patients undergoing splenectomy should receive vaccinations against these bacteria at least 2 weeks before surgery. Poor compliance and vaccine failures contribute to the ongoing risk of serious postsplenectomy infections. The lifetime risk of overwhelming postsplenectomy infection is estimated to be 1% to 3% with the risk being higher in children younger than 15 years of age and in patients with hematologic malignancies. Although the risk of an infection requiring hospitalization was highest in the first 90 days after splenectomy in a cohort of 3812 splenectomized patients in Denmark, this risk remained 2.5 times higher than that in the general population even after 90 days.

The ITP International Working Group and the revised ASH guidelines consider splenectomy an acceptable second-line therapy for ITP. However, the former group considers splenectomy equal to other medical options, whereas the ASH guidelines favor splenectomy (grade 1B evidence) over rituximab or TPO receptor agonists (grade 2C evidence). Splenectomy leads to a high rate of durable remission. In a systematic review, 1731 (66%) of 2623 adults with ITP achieved a complete response following splenectomy at a median follow up of 28 months (range 1–153 months) and this response rate was maintained for 10 years or more after splenectomy.

Disadvantages of splenectomy include a lack of validated predictors of response, surgical risk with 30-day mortality, and complication rates of 0.2% and 9.6% for laparoscopic splenectomy, respectively, and 1.0% and 12.9% for open splenectomy, respectively, and an increased risk of postsplenectomy infection, and vascular thrombosis.

Rituximab

Rituximab has been widely used in patients with various autoimmune diseases, including ITP. Rituximab is an anti-CD20 monoclonal antibody that targets and destroys CD20⁺ B lymphocytes, some of which are likely involved in autoantibody production. Data correlating cellular profiles with clinical outcomes suggest that the efficacy of rituximab reflects improvement in T-cell function and reversion of T-cell abnormalities; processes downstream to its direct effect on B-cell depletion. The effects of rituximab on platelets and autoantibodies require further investigations.

In a systematic review of 19 observational studies that enrolled 313 ITP patients of whom 46.2% were not splenectomized, rates of complete response (platelet count $>150 \times 10^9/L$) and overall response (platelet count $>50 \times 10^9/L$) with rituximab after a median follow up of 9.5 months were 43.6% (95% CI, 29.5–57.7) and 62.5% (95% CI, 52.6–72.5), respectively.¹² The typical rituximab regimen was 375 mg/m² administered by intravenous infusion once weekly for 4 consecutive weeks. The median time to response was 5.5 weeks, and responses lasted a median of 10.5 months. Other observational studies have reported lower rates of durable remission, ranging from 24% at 12 months to 35% at 57 months. A metaanalysis of five randomized trials demonstrated that complete platelet count response was more frequent with rituximab plus standard of care than with standard of care alone (relative risk 1.4, 95% CI, 1.1–1.8); however, there was limited evidence for sustained platelet count responses beyond 6–12 months.¹³

In a prospective observational study that included 60 nonsplenectomized adult patients with ITP who had a median of two prior therapies, 24 (40%) achieved a platelet count above $50 \times 10^9/L$ and at least twice their baseline value at 1 year, and 20 (33%) maintained their platelet count response at 2 years with rituximab treatment. In a follow-up study of 72 adults and 66 children with chronic ITP who achieved an initial response to rituximab, 21% to 26% maintained a treatment-free response for at least 5 years.¹⁴ Low-dose rituximab (100 mg per week for 4 weeks) has been shown to be effective in ITP, but the frequency of durable responses is uncertain.

Minor infusion-related side effects of rituximab occur in approximately 30% of patients with ITP and include hypotension, rash, sore throat, fever, and rigors. Severe or fatal infusion reactions are rare in patients treated for autoimmune diseases. Serum sickness, which is characterized by arthropathy, fever, and low serum complement levels, may be more common in children than in adults and often necessitates treatment interruption. Progressive multifocal leukoencephalopathy (PML) is a rapidly fatal neurologic syndrome caused by reactivation of latent JC virus in the brain. Rare reports have linked PML with rituximab treatment.

Rituximab also interferes with the response to polysaccharide vaccines. This is of potential concern in patients who may subsequently undergo splenectomy and supports the practice of administering immunizations before initiating rituximab therapy.

The 2011 ASH treatment guidelines gave rituximab a weak (grade 2C) recommendation for patients who have failed corticosteroids, IVIg, or splenectomy.

Thrombopoietin Receptor Agonists

Drugs aimed at increasing platelet production by stimulating the c-Mpl receptor have been investigated for the treatment of thrombocytopenia. Initial studies with pegylated recombinant human megakaryocyte growth and development factor were halted because of the

development of cross-reactive antibodies against endogenous TPO, which led to severe and sustained thrombocytopenia in some healthy volunteers. These findings prompted the development of second-generation TPO receptor agonists that have no homology to endogenous TPO. Two such drugs are now approved for the treatment of patients with chronic ITP, romiplostim (Nplate, Amgen) and eltrombopag (Promacta/Revolade, GlaxoSmithKline). These agents increase the platelet count in most ITP patients including those with refractory disease. The effect on platelet count is generally sustained as long as the TPO receptor agonists are administered; when they are stopped, platelet counts tend to fall rapidly to baseline levels.

Romiplostim (administered as a once-weekly subcutaneous injection) is a synthetic peptibody consisting of four peptides linked to an IgG Fc fragment. The molecule binds the c-Mpl receptor at the same location as endogenous TPO and stimulates megakaryocyte proliferation and platelet production through intracellular JAK/STAT and mitogen-activated protein kinase signaling. In a phase III trial, a durable platelet count response (defined as the achievement of a platelet count of $50 \times 10^9/L$ or higher for 6 or more of the last 8 weeks of treatment) was achieved in 41 of 83 patients (49.4%) receiving romiplostim compared with 1 of 42 (2.4%) patients receiving a placebo.¹⁵ In a subsequent randomized trial that compared romiplostim plus standard of care with standard of care alone, romiplostim was associated with more platelet count responses, fewer treatment failures, fewer splenectomies, less bleeding, and better quality of life.² Weekly doses of romiplostim ranged between 1 and 10 µg/kg; however, most patients achieved a suitable response with a dose of 3 µg/kg. Weekly doses were titrated up or down to maintain the platelet count in the appropriate range ($30\text{--}100 \times 10^9/L$).

Eltrombopag (administered as an oral daily tablet, 50–75 mg daily) is a small molecule, nonpeptide TPO receptor agonist. Eltrombopag also activates the c-Mpl receptor, but unlike romiplostim, eltrombopag binds to the transmembrane domain of the receptor and does not compete with circulating TPO for binding. In a phase III trial, eltrombopag was associated with an eightfold increase in platelet count response compared with placebo throughout the 6-month treatment period.¹⁶ The time to response was 1–2 weeks (similar to romiplostim) and there was minimal need for dose titration. Durable responses were achieved in 57 of 95 patients (60%) receiving maintenance eltrombopag and in only 4 of 39 patients (10%) receiving placebo.

In a recent systematic review that summarized the data from randomized trials comparing TPO receptor agonists with standard of care in ITP patients, the authors concluded that although romiplostim and eltrombopag increased the platelet count response, neither agent significantly lowered the rate of severe, life-threatening, or fatal bleeding. These findings highlight the need for studies that evaluate patient focused outcomes.

TPO receptor agonists are generally well tolerated but have been associated with headache, fatigue, and insomnia. The development of BM reticulins in patients with ITP was an early concern; however, this problem was rarely encountered in prospective studies and the changes improved with discontinuation of the medication. TPO receptor agonists have also been associated with thromboembolic events (independent of platelet count), although the strength of this association remains uncertain. One study of eltrombopag in patients with advanced liver disease was ended early because of an increase in portal vein thrombosis. Eltrombopag has been associated with serum liver function test abnormalities in approximately 10% of patients. Treatment-related serious adverse events were infrequent even after prolonged exposure to romiplostim ($n = 292$) or eltrombopag ($n = 299$). Thromboembolic events occurred in 6.5% of patients on romiplostim and 4% of patients on eltrombopag.

Long-Term Follow-Up

The best treatment for patients with ITP who fail to respond to first-line therapy remains controversial and depends on the severity of symptoms, side effect profile, and patient preference. Splenectomy has been used for many years and is the treatment option most likely to be associated with durable remissions. Rituximab may achieve a

platelet count response in up to 60% of patients, but responses are rarely sustained past 6–12 months. TPO receptor agonists (romiplostim or eltrombopag) are associated with a platelet count response in up to 60% of patients as long as treatment is maintained. These drugs are generally well tolerated; however, long-term safety data beyond 5 years are not yet available and long-term maintenance therapy is expensive since either agent costs approximately \$3,000 per month.

Treatment of Refractory Immune Thrombocytopenia

As suggested by the International Working Group on standardization of terminology in ITP, the term *refractory ITP* is used to define patients who have failed splenectomy or relapsed thereafter and either exhibit severe thrombocytopenia or have a risk of bleeding that necessitates therapy (see Table 131.2).³

Evidence to help guide management of patients with chronic refractory ITP after splenectomy is limited, and treatment has been mainly unsatisfactory. However, TPO receptor agonists provide a new and effective option for this challenging group of patients. The overarching principle of therapy for this population is to prevent bleeding with the achievement of a stable, although not necessarily normal, platelet count, and that combination therapy may be more effective than single agent treatment for achievement of this goal.

In randomized trials, nonsplenectomized patients with ITP tended to show better platelet count responses to TPO receptor agonists than splenectomized patients; however, the difference was small, and response rates in splenectomized patients approached 50%. Although some patients included in the trials had failed up to five prior therapies, the results may not be applicable to all patients with refractory ITP seen in clinical practice.

Before the availability of TPO receptor agonists, a systematic review identified rituximab, azathioprine, and cyclophosphamide as the agents most often associated with complete responses in patients with refractory ITP. Good response rates have also been reported with a combination of cyclosporine, azathioprine, and mycophenolate (CellCept). Similarly, a combination of IVIg, intravenous methylprednisolone, vincristine, or intravenous anti-D followed by maintenance therapy with danazol and azathioprine have shown good response rates. Other treatment options include low-dose or alternate-day corticosteroids, repeated doses of IVIg, high-dose chemotherapy, or dapsone. High-dose chemotherapy followed by stem cell transplantation has also been used successfully in this population, but with the advent of TPO receptor agonists, transplantation is no longer used.

NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

NAIT is an uncommon but serious thrombocytopenic disorder that can cause fetal or neonatal bleeding resulting in death or disability. It is important to recognize this disorder because treatment may prevent recurrence in subsequent pregnancies. With NAIT, intracranial bleeding can occur during the neonatal period or in utero, in which case the diagnosis is first suspected after abnormal fetal ultrasonography. The incidence of NAIT has been estimated to range from 1:1000–1:5000 births; however, it is often underdiagnosed.

Clinical Presentation

Thrombocytopenia may be severe in infants affected by NAIT and often the platelet count is less than $10\text{--}20 \times 10^9/\text{L}$ shortly after birth. The differential diagnosis is broad and includes septicemia, hypoxia, and birth trauma, among other factors (Table 131.3). Typically, NAIT presents as severe thrombocytopenia, possibly with associated bleeding, in an otherwise healthy neonate with no other explanation for the low platelet count. The thrombocytopenia often worsens hours or days after delivery, likely reflecting increased RES function in the newborn, particularly within the lungs. Without treatment,

Hemangioma with Thrombocytopenia
Kasabach-Merritt syndrome
Bone marrow Infiltration
Congenital leukemia

thrombocytopenia may last for days, but occasionally, it can be severe and can persist for many weeks. Bleeding symptoms range from petechiae and bruising to gastrointestinal or intracranial hemorrhage. Bleeding occurs in up to 20% of neonates with NAIT and can occur early in pregnancy. For infants with severe thrombocytopenia, mortality estimates of 10% have been reported and infants with intracranial bleeding may be left with developmental delays and permanent neurologic deficits.

Pathophysiology

Fetal and neonatal thrombocytopenia in NAIT reflects the clearance of IgG-sensitized fetal platelets by maternal alloantibodies directed against fetal/paternal platelet-specific antigens. The syndrome can be considered analogous to the destruction of fetal RBCs in hemolytic disease of the newborn (HDN) but with several differences. Perhaps most importantly, NAIT often presents in a first pregnancy, possibly because of early maternal sensitization to paternally derived antigens expressed on fetal platelets. In contrast, it is uncommon for HDN to occur in a first pregnancy without previous sensitization to the Rh antigen. This difference suggests that unlike RBCs, transplacental passage of fetal platelets or platelet antigens into the maternal circulation occurs early in pregnancy. Another difference is that pregnant women at risk for HDN (e.g., those who are Rh negative) can be identified early by screening and treatment with anti-Rh immune globulin reduces the risk of sensitization. To date, screening programs for NAIT have not been widely implemented because women at risk are not readily identifiable before sensitization has occurred, and therapies to prevent maternal alloimmunization are not currently available. Screening programs for NAIT continue to be an active area of research (see box on [Neonatal Alloimmune Thrombocytopenia Versus Hemolytic Disease of the Newborn](#)).

Laboratory Investigation of Suspected Neonatal Alloimmune Thrombocytopenia

The diagnosis of NAIT is established by documenting the presence of platelet-specific antigen incompatibility between mother and infant (or mother and father) and the presence of maternal antiplatelet alloantibodies directed against the incompatible antigen (Fig. 131.3).¹⁷

Diagnosis of Neonatal Alloimmune Thrombocytopenia (NAIT) Testing for Human Platelet Antigens (HPA) and Antibodies

As currently practised at the McMaster University Platelet Immunology Reference Laboratory 2017

Fig. 131.3 DIAGNOSTIC TESTING ALGORITHM FOR INVESTIGATION OF NEONATAL ALLOIMMUNE THROMBOCYTOPENIA AND MANAGEMENT RECOMMENDATIONS BASED ON RESULTS OF TESTING. This algorithm is currently used by the McMaster University Platelet Immunology Reference Laboratory, 2017. Maternal blood samples are tested for platelet antigens (phenotyping and polymerase chain reaction genotyping) and platelet alloantibodies. Amniocentesis and fetal genotyping are recommended when the father is known to be heterozygous for the incompatible antigen. *HPA*, Human platelet antigen; *NAIT*, neonatal alloimmune thrombocytopenia. (Modified from Arnold DM, Smith JW, Kelton JG: *Diagnosis and management of neonatal alloimmune thrombocytopenia*. Transfus Med Rev 22:255, 2008, with permission.)

Neonatal Alloimmune Thrombocytopenia Versus Hemolytic Disease of the Newborn

NAIT can be viewed as the platelet equivalent of HDN with some important differences: (1) maternal sensitization by fetal platelet antigens can occur early in the first trimester, (2) NAIT can affect first pregnancies, (3) women at risk for NAIT are not easily identifiable before sensitization and thus are not amenable to universal screening programs, and (4) a specific therapy that targets prevention of platelet antigen sensitization is lacking (e.g., Rh-immune globulin that target RBC antigen exposure).

Consequently, diagnosis requires allele-specific genotyping using polymerase chain reaction technology to identify a maternal–fetal (or maternal–paternal) antigenic mismatch. Serologic confirmation for the complete array of maternal alloantibodies is more difficult for two reasons. First, the technology is complex and relatively few laboratories perform these tests. In general, most commercial assays detect platelet alloantibodies directed against only a limited number of antigens. This limitation necessitates the use of more specific assays, such as monoclonal antibody immobilization of platelet

antigen assays or antigen capture assays.¹⁸ Even these tests are limited by the lack of monoclonal antibodies required to capture the different target proteins that express the alloantigens (e.g., human platelet antigen (HPA)-15 on CD109). An alternative method uses radioimmunoprecipitation, which can detect all of the known alloantibodies described to date. Second, for unknown reasons, up to 25% of HPA-1a–negative women with NAIT have no detectable antibodies using currently available laboratory methods. Recent studies have used surface plasmon resonance to identify alloantibodies in women suspected of having NAIT, but who tested negative in conventional immunoassays. Low affinity anti-HPA-1a antibodies were detected in some, suggesting that standard immunoassays may be limited in their capacity to detect such antibodies.¹⁹ Low-incidence platelet-specific alloantigens expressed on platelets only from the paternal lineage may account for fetomaternal incompatibility. Detection of alloantibodies in these cases requires that maternal serum be tested against paternal platelets whenever possible.

Alloantibodies recognize epitopes on platelet GPs that are defined by genetic polymorphisms. To date, all of these antigens are the result of single nucleotide polymorphisms or in-frame deletions of the codon. Consequently, platelet typing using genetic analysis is

relatively straightforward. The majority of platelet alloantigens occur on GPIIIa, which is the most abundant platelet GP (50,000–75,000 copies per platelet). GPIIIa, also known as β_3 , forms a heterodimer with platelet GPIIb to form the integrin $\alpha_2\beta_3$, which serves as the binding site for fibrinogen and enables platelet aggregation.

The most common platelet alloantigen implicated in NAIT is HPA-1a. This important alloantigen is defined by a leucine (HPA-1a) to proline (HPA-1b) substitution at amino acid 33 on GPIIIa. Maternal incompatibility to HPA-1a is implicated in more than 80% of women with NAIT. These women lack the common HPA-1a antigen (i.e., their genotype is HPA-1bb) and during pregnancy they are immunized with fetal HPA-1a antigen inherited from the father.

The next most commonly implicated antigens in NAIT are HPA-5a5b on GPIa/IIa and HPA-15a15b on the glycosylphosphatidylinositol-anchored protein, CD109. Only 6 of the 28 platelet antigen systems have been defined by maternal alloantibodies against both alleles; these include the HPA 1, 2, 3, 4, 5, and 15 systems. There are a number of other low-frequency alleles, the majority of which are expressed on platelet GPIIb/IIIa and are usually found within a single family. Although maternal immunization to low-frequency antigens is implicated in some cases of NAIT, these antigens account for a minority of the NAIT cases that remain unresolved after investigation for common HPA antigens.²⁰ Frequently, discrepancies in human leukocyte antigen (HLA) and ABO, which are also expressed on platelets, are found during the course of investigations for NAIT; however, their significance is uncertain. A database of genetically confirmed alloantigens is maintained by the European Bioinformatics Institute (<http://www.ebi.ac.uk>).

Management

Management of Infants After Delivery

When NAIT is suspected and depending on the platelet count, treatment should be initiated even before confirmatory test results are available. It is important to appreciate that moderate or severe thrombocytopenia at birth ($20\text{--}50 \times 10^9/\text{L}$) can worsen over the next few days. Treatment should be initiated immediately if thrombocytopenia is severe (platelets $<50 \times 10^9/\text{L}$); if there are petechiae or purpura; or if there is evidence of serious bleeding, such as intracranial bleeding on cranial ultrasonography. The initial treatment is platelet transfusion along with high-dose IVIg (1–2 g/kg).²¹ Ideally, platelet products for transfusions should be alloantigen compatible; however, if these are unavailable, random donor platelets can be used because they often produce adequate increases in the platelet count.²²

Antenatal Management of the Mother

Women with a previously affected infant with NAIT are at high risk of having another affected infant. Consequently, careful management in subsequent pregnancies is required. Similar to HDN, the disorder is often more severe in subsequent pregnancies than it is in the first. The exception is if the father is heterozygous for the implicated platelet antigen, in which case antigenic testing can be performed by amniocentesis to determine if the fetus is at risk and whether treatment is required.

Antenatal treatment options for at-risk mothers during subsequent pregnancies range from careful observation, to IVIg with or without corticosteroids, to fetal blood sampling (FBS) and intrauterine platelet transfusion. Invasive strategies that include FBS are associated with a high rate of complications, including fetal death and premature labor; thus a noninvasive approach is often recommended.

The mainstay of antenatal therapy for women with a previously affected infant is high-dose IVIg (1–2 g/kg) administered weekly throughout pregnancy starting at 18–22 weeks of gestation. A systematic review summarizing the results of four randomized trials that included 206 women compared weekly IVIg with a variety of other therapies, including alternate dosing of IVIg or IVIg plus corticosteroids.²³ Although no definitive conclusions could be drawn, most

clinicians use IVIg for antenatal treatment. Corticosteroids (prednisone or dexamethasone) given in combination with IVIg should be considered for mothers at high risk, such as those with a previously affected infant with intracranial hemorrhage or severe thrombocytopenia or if the response to IVIg is suboptimal.

Fetal Monitoring During Pregnancy

Serial ultrasonography is indicated for fetal surveillance. This provides a simple, noninvasive method for identifying fetal bleeds at an early stage. FBS by percutaneous cannulation of the umbilical or intrahepatic vein may be a way of capturing high-risk fetuses, identifying those who require treatment, and monitoring response to therapy. However, FBS is technically challenging and is associated with significant morbidity and mortality. In one study, 6% of FBS procedures were associated with complications, including fetal death from exsanguination and premature induction of labor.²⁴ Furthermore, a platelet transfusion protocol based on the detection of fetal thrombocytopenia would necessitate frequent FBS procedures because of the short (7-day) life span of transfused platelets. Because the risks associated with FBS exceed the benefits, routine FBS is not recommended.

Mode of Delivery

There is no evidence that planned cesarean section is safer than uncomplicated vaginal delivery for infants with NAIT. Nonetheless, planned cesarean section delivery can ensure that personnel and resources, including antigen-compatible platelet transfusions, are readily available.

Population Screening for Neonatal Alloimmune Thrombocytopenia

Universal NAIT screening programs for all pregnant women are not currently available because of the difficulty in early identification of at-risk women and the lack of specific and proven treatments. Screening algorithms also have to account for the large difference in numbers of women lacking an antigen and those who will later develop NAIT. About 2% of women will be identified as HPA-1bb, whereas only 1 in 20 of these will have an affected child because of HPA-1a immunization. One study screened 100,448 pregnant women and offered those with HPA-1a antibodies early cesarean section together with compatible platelet transfusions.²⁵ This approach identified 161 affected infants, of whom three (6%) died or had an intracranial bleed, compared with 10 of 51 infants (20%) born to mothers who were not screened. These results are encouraging, and additional studies of NAIT screening programs are ongoing.

POSTTRANSFUSION PURPURA

PTP is a rare thrombocytopenic syndrome that is provoked by an immune-mediated reaction against HPAs, most frequently HPA-1a. PTP presents 5–10 days following exposure to platelets or platelet antigenic material in blood transfusions with profound thrombocytopenia and clinically significant bleeding.

Epidemiology

PTP is rare with an estimated incidence of 1–2 per 100,000 transfusions. Data from the Serious Hazards of Transfusion surveillance program from the United Kingdom have shown that the incidence of PTP has decreased in the last decade (Fig. 131.4).²⁶ Reasons for this trend may be related to universal leukoreduction, which was implemented in the United Kingdom in 1999. The average annual incidences of PTP in the years preceding 1996–99 and following the implementation of universal leukoreduction between 2000 and 2005

Fig. 131.4 CONFIRMED CASES OF POSTTRANSFUSION PURPURA REPORTED BY THE UK SERIOUS HAZARDS OF TRANSFUSION (SHOT) SURVEILLANCE PROGRAM. Universal leukoreduction began in the United Kingdom in late 1999 and coincided with a decrease in new cases of posttransfusion purpura. (From www.shotuk.org.)

Clinical Presentation of Posttransfusion Purpura

On postoperative day 8 after spinal surgery, a 43-year-old woman has a platelet count of $3 \times 10^9/L$. During the operation, she received 3 units of non-leuko-reduced packed RBCs because of intraoperative bleeding. She is receiving intravenous ampicillin and prophylactic doses of the low-molecular-weight heparin dalteparin. On physical examination, she has extensive oral mucosal purpura and petechiae on both lower extremities. HIT testing results (anti-PF4/heparin enzyme-linked immunosorbent assay and serotonin release assay) are negative. The ampicillin is stopped, and she is treated with IVIG (2 g/kg) and platelet transfusions. Three days later, the platelet count is $4 \times 10^9/L$, and the patient develops melena. The presumed diagnosis is posttransfusion purpura; therefore, HPA-1a-negative platelets and high-dose parenteral corticosteroids are administered, and daily plasma exchange is initiated. One week later, the thrombocytopenia and bleeding symptoms resolve. Platelet antibody testing reveals the presence of anti-HPA-1a antibodies.

were 10.3 and 2.3 cases per year, respectively. Since the implementation of universal leukoreduction, there has also been a shift from red cell concentrates to platelet concentrates as the inciting transfusion event, which may be attributable to the reduction in platelet contamination of red cell products with leukoreduction methods. A recent study estimated that the frequency of PTP corresponds to 1.8 per 100,000 transfusions.²⁷ In this study, platelet containing transfusions posed a significantly higher risk than RBC transfusions.

Approximately 85% of PTP episodes occur in women, the majority of whom had a history of pregnancy. In a report of 61 patients, the sensitizing event among women was pregnancy alone in 58%, pregnancy and/or transfusion in 34%, and transfusion alone in 7.5%. Males had associated transfusion histories in 55%, with some having no known exposure. PTP has not been reported in children.

Clinical Presentation

PTP presents with severe thrombocytopenia (platelets $<10 \times 10^9/L$) and bleeding, which may include petechiae, purpura, mucosal hemorrhage, hematuria, and rarely ICH. The thrombocytopenia is often refractory to platelet transfusions even with antigen-negative platelets. Mortality because of severe thrombocytopenia and bleeding has been estimated to be 5% to 20%. The thrombocytopenia occurs 5–10 days after blood transfusion and typically resolves within weeks, but occasionally can be prolonged and severe and can persist for months. Other causes of

thrombocytopenia with similar clinical presentation include primary ITP, drug-induced ITP, sepsis, disseminated intravascular coagulation, and thrombotic thrombocytopenic purpura; however, association with transfusion and bleeding severity suggest a diagnosis of PTP. Patients with PTP may present with features that overlap with heparin-induced thrombocytopenia (HIT), and positive HIT testing in the context of anti-HPA antibodies has been reported; however, thrombocytopenia is typically less severe with HIT and bleeding is rare.

Diagnosis

Most patients with PTP lack the common HPA-1a platelet antigen and are homozygous for HPA-1b. These patients develop anti-HPA 1a antibodies from sensitizing events such as previous pregnancies or transfusions. Anti-HPA 1a antibodies may persist for many years in these patients. In addition, platelet antibodies with specificities other than HPA-1a may also be found.²⁸

Pathophysiology

Platelets contain abundant amounts of GPIIb/IIIa; thus even small numbers of platelets or platelet microparticles contained within RBC concentrates can be immunogenic and can lead to the development of PTP. Genotypic analyses have shown that HLA-II alleles DR β 3*0101 and DQ β 1*0201 are commonly associated with this disorder. This is similar to NAIT: the frequency of immunization depends on platelet alloantigen discrepancy plus the presence of certain immune response genes.

The most intriguing feature of PTP is that the patient's own antigen-compatible platelets are destroyed. Furthermore, platelet reactive antibodies can be eluted from both antigen-positive and antigen-negative platelets. Although the mechanism is still poorly understood, theories to explain this "innocent bystander" phenomenon include immune complex formation, passive antigen adsorption, and autoantibody formation. As discussed later, some of these mechanisms may be overlapping.

Immune complexes can form if the anti-HPA-1a antibodies bind soluble antigen. Alternatively, platelet alloantigens contained within the transfused blood product may be passively adsorbed onto autologous platelets, converting them from antigen negative to antigen positive and rendering them targets for immune destruction. Immune complexes may then bind to platelets through Fc-receptors causing platelet destruction. Anti-HPA-1a antibodies have been shown to

induce platelet activation through release of platelet-derived RANTES (regulated on activation, normal, T-cell expressed and secreted), a proinflammatory and immunomodulatory chemokine involved in multiple immunologic processes, including Ig synthesis and regulation of Th1/Th2 cytokine homeostasis. In some patients with PTP, the alloantibodies have been shown to interfere with cell-fibrinogen interaction, thereby increasing the risk of bleeding.

The stimulation of specific anti-HPA alloantibodies could in turn initiate the formation of platelet-reactive *autoantibodies*. Production of pan-reactive antibodies has been shown to correspond with the period of greatest thrombocytopenia and serologic analyses of PTP cases demonstrated the presence of reactive IgG and IgM antibodies against GPIIb/IIIa, GPIX, and GPIa/IIa; however, only HPA-specific IgG antibodies persisted.²⁹ The presence of autoantibodies can help to explain the destruction of both donor and recipient platelets.

Management

Treatment of PTP should be initiated even before serologic test results for anti-HPA-antigens are available. The primary goal of treatment is to abbreviate the period of severe thrombocytopenia and minimize the risk of bleeding. Multiple treatments are often administered simultaneously or in rapid succession because of the desperate nature of the disorder when it is severe.

Patients with PTP require admission to hospital for close observation, supportive treatments, and rapid management of bleeding symptoms should they occur. Nonessential transfusions should be discontinued. The mainstay of therapy is high dose IVIg, which is followed by a platelet count increase after 3–4 days.³⁰ High-dose corticosteroids have also been tried as a means of inhibiting RES phagocytosis and reducing IgG synthesis. Patients with bleeding should be transfused with HPA-compatible platelets. While awaiting the results of antigen typing, HPA-1a-negative platelet transfusions can be administered to reduce further antibody production. Patients with PTP may be at increased risk of transfusion reactions such as fever, dyspnea, and allergic reactions. Plasma exchange should be considered in patients who do not respond to IVIg and corticosteroids.

THROMBOCYTOPENIA CAUSED BY PLATELET DESTRUCTION, HYPERSPLENISM, OR HEMODILUTION

Theodore E. Warkentin

Thrombocytopenia is defined as a platelet count below the lower limit of the normal range ($\approx 150 \times 10^9/L$). Sometimes an expanded definition of thrombocytopenia is appropriate. For example, an abrupt drop in the platelet count can signify the onset of a platelet-destructive process such as heparin-induced thrombocytopenia (HIT) or bacteremia even if the platelet count remains above $150 \times 10^9/L$. This is especially relevant in the second or third week after surgery because patients usually have platelet counts that peak at levels 2–3 times greater than their usual preoperative value (postoperative thrombocytosis).

In the clinical evaluation of a patient with thrombocytopenia, three questions must be asked. First, could the patient have pseudothrombocytopenia? Second, what is the most likely explanation for the thrombocytopenia? And third, what are the risks posed by the causative disorder and the severity of the thrombocytopenia? For example, severe thrombocytopenia caused by drug-dependent antibodies or platelet-reactive autoantibodies is often associated with bleeding. By contrast, thrombocytopenia caused by HIT antibodies or attributable to disseminated intravascular coagulation (DIC) secondary to adenocarcinoma is associated with thrombosis. Often, the underlying cause of the thrombocytopenia (e.g., bacteremia, cancer, cirrhosis), rather than the thrombocytopenia itself, poses the greater risk.

Thrombocytopenia can be caused by any of four general mechanisms: (1) platelet underproduction, (2) increased platelet destruction or consumption, (3) platelet sequestration, and (4) hemodilution. Platelet underproduction usually occurs in association with underproduction of other blood cell lines, which results in bicytopenia or pancytopenia. Thrombocytopenia caused by increased platelet destruction develops when the rate of platelet loss surpasses the ability of the bone marrow (BM) to produce platelets and may be caused by immune or nonimmune mechanisms (Table 132.1). Thrombocytopenia from platelet sequestration is caused by redistribution of platelets from the circulation into an enlarged splenic vascular bed. Hemodilution is characterized by a decrease in the number of platelets, as well as red blood cells (RBCs) and white blood cells (WBCs) as a result of the administration of colloid, crystalloid, or platelet-poor blood products.

In the postoperative period, platelet count changes reflect several processes, including initial hemodilution (immediate platelet count decrease) and increased platelet consumption (first 2–4 days), at which point the platelet count begins to rise because of increased platelet production; when the platelet count reaches its postoperative peak—usually about 14 days after surgery—platelet production decreases somewhat, and the platelet count returns to baseline (Fig. 132.1).¹ In addition to usual mechanisms, the differential diagnosis of thrombocytopenia in pregnancy includes some unique causes (Table 132.2).

APPROACH TO PATIENTS WITH THROMBOCYTOPENIA

History and Physical Examination

Certain information should be ascertained, including (1) the location and severity of bleeding (if any); (2) the temporal profile of the hemostatic defect (acute, chronic, or relapsing), particularly the temporal relationship with potential proximate triggers (e.g., new

drug, recent infection); (3) the presence of symptoms of a secondary illness, such as a neoplasm, infection, or an autoimmune disorder such as systemic lupus erythematosus (SLE); (4) history of recent medication use, alcohol ingestion, or transfusion; (5) presence of risk factors for certain infections, particularly human immunodeficiency virus (HIV) infection or viral hepatitis; and (6) family history of thrombocytopenia.

As part of the physical examination, evidence of hemostatic impairment should be sought, as well as secondary causes of thrombocytopenia. The signs of platelet-related bleeding include petechiae and purpura. Petechiae typically occur in the dependent regions of the body or on traumatized areas. Spontaneous mucous membrane bleeding (wet purpura), epistaxis, and gastrointestinal bleeding indicate a more serious hemostatic defect. Although petechiae are common in patients whose platelet counts are less than $10\text{--}20 \times 10^9/L$, most patients with platelet counts over $50 \times 10^9/L$ have no signs of hemostatic impairment. The physical examination may provide an explanation for the thrombocytopenia. For example, enlarged lymph nodes may indicate a viral infection, such as infectious mononucleosis or HIV infection, or a neoplastic process. An enlarged spleen raises the possibility of hypersplenism.

Timing of Onset and Severity of Thrombocytopenia

Many thrombocytopenic disorders, particularly those involving an immune pathogenesis, exhibit characteristic temporal features that can aid in the diagnosis. For example, if the platelet count begins to fall 5–10 days (median, 6–7 days) after starting a new drug or after a blood transfusion and reaches a nadir of less than $20 \times 10^9/L$ a few days later, the diagnosis of drug-induced immune thrombocytopenia (D-ITP) or posttransfusion purpura (PTP), respectively, should be considered (Fig. 132.2).² Patients with these disorders typically have mucocutaneous bleeding and are at risk for fatal intracranial hemorrhage.

A similar temporal profile is also characteristic of typical-onset HIT, although there the platelet count only falls below $20 \times 10^9/L$ in only 10% of affected patients (see Fig. 132.2); in approximately 80% of patients, the platelet count nadir ranges from $20\text{--}150 \times 10^9/L$, and in the remainder, the platelet count nadir never falls below $150 \times 10^9/L$ despite a large reduction in the platelet count. When the platelet count falls abruptly after drug administration, the possibility of rapid-onset thrombocytopenia caused by preexisting drug-dependent antibodies should be considered, as is well described with HIT. Indeed, so-called rapid-onset HIT is the presenting feature of this adverse drug reaction in 25% to 30% of cases.³ Rapid-onset thrombocytopenia is also a feature of glycoprotein (GP) IIb/IIIa antagonist-induced ITP.

Occasionally, thrombocytopenia worsens in the first few days after surgery; this can occur with multiorgan system failure (e.g., cardiogenic or septic shock) (see Fig. 132.2). If the patient develops concomitant DIC and hypotension, there is high risk for ischemic limb injury secondary to microvascular thrombosis (“symmetric peripheral gangrene”), especially if the patient has “shock liver” (ischemic hepatitis), which is a risk factor for severe depletion of protein C, an important endogenous anticoagulant.^{4,5} If the platelet count falls to very low levels and is accompanied by microangiopathic hemolysis,

TABLE 132.1 Mechanisms of Platelet Destruction or Consumption

Type of Thrombocytopenia	Specific Example(s)
Immune Mediated	
Autoantibody-mediated platelet destruction by RES	Primary and secondary idiopathic (immune) ITP ^a
Alloantibody-mediated platelet destruction by RES	NAIT, ^a PTP, ^a PAT; alloimmune platelet transfusion refractoriness ^a
Drug-dependent, antibody-mediated platelet destruction by RES	Drug-induced immune ITP (e.g., vancomycin) (see Fig. 132.5)
Platelet activation by binding of IgG Fc of drug-dependent IgG to platelet FcγIIa receptors	HIT
Non-Immune Mediated	
Platelet activation by thrombin or proinflammatory cytokines	DIC ^a ; septicemia or systemic inflammatory response syndromes
Platelet destruction via ingestion by macrophages (hemophagocytosis)	Infections, certain malignant lymphoproliferative disorders
Platelet destruction through platelet interactions with altered vWF ^b	TTP, ^a HUS ^a
Platelet losses on artificial surfaces	CPB, ^a use of intravascular catheters
Decreased platelet survival associated with cardiovascular diseases	Congenital and acquired heart disease, cardiomyopathy, PE

^aSee Chapter 131 for a discussion of thrombocytopenia in these disorders.

^bAlthough platelet destruction is not directly caused by antibodies, immune mechanisms can explain altered vWF (e.g., autoimmune clearance of vWF-cleaving metalloprotease).

CPB, Cardiopulmonary bypass surgery; DIC, disseminated intravascular coagulation; HIT, heparin-induced thrombocytopenia; HUS, hemolytic uremic syndrome; IgG, immunoglobulin G; ITP, idiopathic (immune) thrombocytopenic purpura; NAIT, neonatal alloimmune thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PE, pulmonary embolism; PTP, posttransfusion purpura; RES, reticuloendothelial system; TTP, thrombotic thrombocytopenic purpura; vWF, von Willebrand factor.

Fig. 132.1 POSTSURGERY PLATELET COUNT CHANGES. Initial platelet count declines result from hemodilution and increased platelet consumption, with the platelet count nadir occurring between days 1 to 4 (median, day 2). There is constitutive production of thrombopoietin (TPO) by the liver. TPO binds to platelets and megakaryocytes via a specific receptor (c-Mpl, not shown), and receptor-bound TPO is removed from circulation and degraded. The level of circulating TPO is thus inversely related to the mass of platelets and megakaryocytes. In early postsurgery thrombocytopenia, fewer TPO binding sites are available, resulting in high free TPO levels, which stimulates megakaryocyte proliferation and differentiation and leads to increased platelet production. With subsequent thrombocytosis, the high platelet mass acts as a “sink” for removing TPO, with decreased stimulus for platelet production. Thus after acute postsurgery thrombocytopenia, TPO levels rise about twofold, leading to increased platelet production that begins on days 2–4, with resulting thrombocytosis that generally peaks at approximately day 14 (postoperative thrombocytosis) and returns to baseline by about day 21. (Reprinted, with modifications, with permission, from Arnold DM, Warkentin TE: *Thrombocytopenia and thrombocytosis*. In Wilson WC, Grande CM, Hoyt DB, editors: *Trauma: Critical care, vol 2*, New York, 2007, Informa Healthcare, p 983).

the possibility of postoperative thrombotic thrombocytopenic purpura (TTP) should be considered.⁶

Mild to moderate platelet count decreases that occur soon after transfusion of blood products are common and can be explained by hemodilution; however, a marked platelet count fall after transfusion may be the result of passive alloimmune thrombocytopenia (PAT) or sepsis because of contaminated blood products (see Fig. 132.2).

Other characteristic temporal features of thrombocytopenia include postterohemorrhagic *Escherichia coli*-associated hemolytic

uremic syndrome (HUS); thrombocytopenia and microangiopathic hemolysis that begin approximately 1 week after a prodromal diarrheal illness; and fungemia-associated thrombocytopenia (onset, 1–3 weeks after complex illness involving indwelling catheters and broad-spectrum antibiotic usage). In contrast, thrombocytopenia of insidious onset that progresses over several years suggests chronic liver disease, with evolution to portal hypertension and associated splenomegaly (e.g., cirrhosis secondary to alcohol or hepatitis C) or a slowly progressive BM disorder (e.g., myelodysplasia).

TABLE 132.2 Differential Diagnosis of Thrombocytopenia in Pregnancy

Incidental thrombocytopenia of pregnancy (gestational thrombocytopenia)
Preeclampsia or eclampsia ^a
DIC secondary to:
Abruptio placentae
Endometritis
Amniotic fluid embolism
Retained fetus
Preeclampsia or eclampsia ^a
Peripartum or postpartum thrombotic microangiopathy
TTP
HUS

^aPreeclampsia or eclampsia usually is not associated with overt DIC. DIC, Disseminated intravascular coagulation; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

Laboratory Evaluation

Laboratory evaluation of patients with thrombocytopenia is summarized in Table 132.3 (also see Chapter 129). The blood film is examined to exclude pseudothrombocytopenia, which is characterized by in vitro platelet clumping. This phenomenon, which is evident in approximately one in 1000 blood samples, is most often caused by naturally occurring GPIIb/IIIa ($\alpha_{IIb}\beta_3$)-reactive autoantibodies that induce aggregation of platelets in the presence of the calcium-chelating anticoagulant ethylenediamine tetraacetic acid (EDTA). Because the platelet aggregates are not counted by the electronic particle counter, the automated platelet count appears falsely low. The correct platelet count usually can be determined by collecting the blood into sodium citrate or heparin or by performing the count on nonanticoagulated finger prick samples; maintaining the blood sample at 37°C often attenuates platelet clumping. EDTA-dependent pseudothrombocytopenia has no pathologic significance other than potentially placing a patient in jeopardy for inappropriate

Fig. 132.2 TIMING OF ONSET AND SEVERITY OF THROMBOCYTOPENIA: IMPLICATIONS FOR DIFFERENTIAL DIAGNOSIS. The usual postoperative platelet count nadir is seen between postoperative days 1 to 3 (inclusive). Early and progressive platelet count declines often reflect severe postoperative complications such as sepsis and multiorgan failure; severe thrombocytopenia can (rarely) indicate postsurgery thrombotic thrombocytopenic purpura. Thrombocytopenic disorders that begin approximately 1 week after surgery are often immune mediated: moderate thrombocytopenia can indicate heparin-induced thrombocytopenia (HIT), both “typical onset” or (if heparin is not being given) “delayed onset”; very severe thrombocytopenia can indicate drug-induced immune thrombocytopenia (D-ITP) or (rarely) posttransfusion purpura. An abrupt decline in platelet count after receiving a heparin bolus in a patient who has received heparin within the past 7–100 days can indicate “rapid-onset” HIT; thrombocytopenia that begins abruptly after transfusion of a blood product can indicate sepsis from bacterial contamination or (rarely) passive alloimmune thrombocytopenia caused by transfusion of platelet-reactive alloantibodies. D-ITP, Drug-induced immune thrombocytopenia; HIT, heparin-induced thrombocytopenia; PAT, passive alloimmune thrombocytopenia; PTP, posttransfusion purpura; TTP, thrombotic thrombocytopenic purpura. (Reprinted, with permission, from Greinacher A, Warkentin TE: *Acquired non-immune thrombocytopenia*. TABLE 132.3 Laboratory Tests Used to Investigate a Patient With Thrombocytopenia

Test	Rationale
Common Tests	
CBC	Isolated thrombocytopenia usually is caused by platelet destruction, but involvement of all cell lines suggests underproduction or sequestration
Examination of the blood film	Pseudothrombocytopenia (platelet clumps) Toxic changes and granulocyte “left shift” suggest septicemia Atypical lymphocytes suggest viral infection RBC fragments suggest TTP or HUS Parasites (e.g., in malaria) White cell inclusions suggest hereditary macrothrombocytopenia
Blood cultures	Bacteremia, fungemia
ANA test	Systemic lupus erythematosus
Direct antiglobulin test	Exclude immune hemolysis accompanying ITP (Evans syndrome)
Coagulation Assays	
aPTT, PT (INR), thrombin time, fibrinogen, D-dimer assay	DIC
LA assay (nonspecific inhibitor), anticardiolipin and anti- β_2 -glycoprotein I assays	aPL antibody syndrome
Serum protein electrophoresis; IgG, IgM, IgA levels	ITP associated with lymphoproliferative disorder (monoclonal); hypersplenism associated with chronic hepatitis (polyclonal)
HIV serologic studies	HIV-associated thrombocytopenia
BM aspiration, biopsy	Assess megakaryocyte numbers and morphology; exclude primary BM disorder
Specialized Tests	
GP-specific platelet antibody assays (e.g., MAIPA)	Relatively specific assay for primary and secondary ITP
Drug-dependent increase in platelet-associated IgG	Specific assay for D-ITP
Drug-dependent platelet activation test (e.g., platelet serotonin release assay) or PF4–heparin (or PF4–polyanion) ELISA	HIT
Radionuclide platelet life span study with imaging (e.g., ^{111}In platelet survival study)	Define the mechanism of thrombocytopenia; identify an “accessory” spleen postsplenectomy

ANA, Antinuclear antibody; aPL, antiphospholipid; aPTT, activated partial thromboplastin time; BM, bone marrow; CBC, complete blood count; DIC, disseminated intravascular coagulation; D-ITP, drug-induced immune thrombocytopenia; ELISA, enzyme-linked immunosorbent assay; GP, glycoprotein; HIT, heparin-induced thrombocytopenia; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; IgG, immunoglobulin G; INR, international normalized ratio; ITP, idiopathic (immune) thrombocytopenic purpura; LA, lupus anticoagulant; MAIPA, monoclonal antibody immobilization of platelet antigens; PF4, platelet factor 4; PT, prothrombin time; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

treatment for thrombocytopenia that does not exist. A much less common (one in 10,000 blood samples) antibody-mediated pseudo-thrombocytopenic disorder is platelet satellitism, in which rosette-like clusters of platelets surround neutrophils. This entity is produced by immunoglobulin G (IgG) antibodies that recognize EDTA-induced cryptic epitopes on both platelet GPIIb/IIIa and neutrophil Fc γ III receptors.

BM examination can be helpful for assessment of platelet production, particularly if megakaryocytes are reduced in number or abnormal in appearance. Examination of the BM can be diagnostic in some disorders (e.g., leukemia, metastatic tumor, Gaucher disease, megaloblastic anemia).

Elevated platelet-associated IgG (PAIgG) can be detected in patients with either immune or non-ITP; therefore, this assay is not useful diagnostically. In contrast, GP-specific platelet antibody assays, such as the monoclonal antibody immobilization of platelet antigens (MAIPA) assay or antigen capture enzyme immunoassay, are relatively specific for detection of autoimmune thrombocytopenic disorders. These assays can also be adapted for detection of drug-dependent GP-reactive antibodies.

When the mechanism of chronic thrombocytopenia is unclear, an autologous platelet survival study using ^{111}In -labeled platelets may be informative. Three patterns can be seen: (1) normal platelet survival and recovery (underproduction), (2) marked reduction in the platelet life span (increased destruction), and (3) reduced recovery but a normal or near-normal life span (sequestration). However, platelet survival studies are rarely performed.

Therapy

The risk of bleeding in patients with thrombocytopenia can be reduced by avoiding drugs that impair hemostasis (e.g., alcohol, antiplatelet agents, anticoagulants) and invasive procedures (e.g., intramuscular injections). If drug-induced thrombocytopenia is suspected, as many medications as possible, especially those started within the preceding 5–14 days, should be stopped. Life-threatening bleeding episodes should be treated with platelet transfusion regardless of the mechanism of the thrombocytopenia.

The underlying cause and anticipated natural history of the thrombocytopenic disorder influence the decision about prophylactic platelet transfusion. As a general rule, patients with chronic thrombocytopenic disorders characterized by increased platelet destruction (e.g., chronic ITP) or chronic underproduction (e.g., aplastic anemia or myelodysplasia) can tolerate long periods of severe thrombocytopenia without major bleeding. In addition, prophylactic platelet transfusions can trigger alloimmunization against human leukocyte antigen (HLA) or platelet antigens, thereby jeopardizing future therapeutic platelet transfusions. Consequently, prophylactic platelet transfusions are seldom indicated for such patients except when they are at risk of bleeding because of trauma or major surgery. When platelets are given, the platelet count should be maintained above $50 \times 10^9/\text{L}$. Invasive procedures such as thoracentesis, paracentesis, and liver biopsy are not usually associated with excess bleeding if the platelet count is greater than $50 \times 10^9/\text{L}$.

Prophylactic platelet transfusions should not be given to patients with strongly suspected or confirmed HIT, TTP, or HUS because they may exacerbate platelet-mediated thrombotic complications, and, particularly with HIT, mucocutaneous bleeding is uncommon. However, bleeding in the setting of severe thrombocytopenia may justify platelet transfusion even in these disorders.

ANATOMY AND PHYSIOLOGY

The Spleen: Anatomy and Function

The spleen is a small, well-perfused organ that receives about 5% of the total cardiac output. In adults, the spleen weighs between 150 and 200 g and measures approximately 11 cm in length.

The anatomy of the spleen is uniquely suited for its function; progressive branching of the splenic artery into trabecular and central arteries helps separate the plasma from the cellular elements (see Chapter 160). The central arteries arise perpendicularly from the trabecular arteries and skim the plasma layer from the cells. Soluble antigens in the plasma are delivered to the white pulp, where phagocytic cells process them and antibody production is initiated.

A cell-rich, hemoconcentrated fraction of the blood is delivered to the red pulp. Some of this blood flows directly to the splenic veins (the closed system), but most moves into the splenic cords (the open system). Here, the cellular elements percolate through a meshwork of reticulum fibers, reticuloendothelial cells, and supporting cells to reach the splenic sinuses. The cells enter the sinuses by passing through narrow fenestrations in the basement membrane of the endothelial cells lining the sinuses. The blood exits through the splenic vein into the portal system. Because the veins in the portal system lack valves, any increase in portal pressure is transmitted to the splenic microcirculation.

The spleen plays a number of important roles. It is the largest lymphoid organ in the body and contributes to host defense by clearing microorganisms and antibody-coated cells. The spleen is also important for antibody synthesis, especially antibodies directed against soluble antigens. The filtering function of the spleen includes (1) culling (removal of damaged or senescent cells and bacteria), (2) pitting (removal of RBC inclusion bodies or parasites), and (3) remodeling (reticulocyte sequestration and maturation). The spleen also serves as a reservoir of platelets (accommodating about one-third of the platelet mass in normal individuals). By contrast, the human spleen contains less than 2% of the total RBC mass, although in some animals (dogs and cats), the spleen is a much more important RBC reservoir.

Physiologic Platelet Sequestration

Radiolabeled platelet studies have shown that approximately 30% of the total platelet mass exists as a freely exchangeable pool in the spleen. Because the normal platelet life span is 9–10 days, platelets spend approximately one-third of their lives, or 3 days, within the spleen. In patients with hypersplenism, up to 90% of the platelets can be found in the spleen.

After labeled platelets are injected, there is accumulation in both the liver and the spleen. An initial, irreversible phase of hepatic uptake occurs. This equilibrates during the first 5 minutes and may reflect hepatic clearance of platelets damaged during the labeling procedure. Simultaneously, there is a slow increase in activity over the spleen that peaks in about 20 minutes. Splenic platelet uptake is thus dependent on input (spleen blood flow) and output (clearance).

The splenic platelet pool size can be decreased and the platelet count increased with intravenous infusions of epinephrine in normal persons and in patients with splenomegaly. By contrast, isoprenaline increases the splenic pool size. Splenic blood flow increases with increasing spleen size, although perfusion (flow per unit of tissue volume) falls. Blood flow can be increased in some inflammatory disorders (e.g., SLE) without an increase in spleen size. A marked increase or decrease in splenic perfusion alters the proportion of platelets within the spleen.

Fig. 132.3 shows why approximately 30% of the platelets are normally present in the spleen.¹ Because about 5% of cardiac output goes to the spleen and because the average splenic transit time (i.e., the time for the platelet to pass through the spleen) is approximately 10 minutes—compared with the usual average time of 1 minute for a platelet to make a complete circulatory pass—approximately one-third of the platelets are within the spleen
