Normal Gross Anatomy and Embryology

The parathyroid glands, the last major organ to be recognized in humans, were discovered in 1880 by Ivar Sandstrom, a Swedish medical student, as recounted by Aidan Carney in his delightful essay on the subject.[1]

Normally, there are four oval, pliable parathyroid glands, each averaging $4 \times 3 \times 1.5$ mm. In rare cases, more than four glands are present. In their classic study of 527 autopsy cases, Gilmour and Martin[2] reported two instances in which there were six glands (0.2%) and 31 in which there were five (5.2%). Variations in the weights of the normal glands were studied by the same authors,[2] who found that the mean weight of all four glands was 117.6 ± 4 mg in men and 131.3 ± 5.8 mg in women. The color varies from reddish brown to light tan to yellow, depending on fat content, which in turn depends on age, nutrition, and activity of the individual.

Parathyroid glands are arranged in two pairs. The upper pair arises from the fourth branchial cleft and descends into the neck with the thyroid gland during embryonic life. The lower pair arises from the third branchial cleft and descends into the neck with the thymus. Normally, the upper pair is located on the middle third of the posterolateral border of the thyroid gland, and the lower pair is close to the lower pole of the thyroid gland, near the inferior thyroid artery. The parathyroid glands usually have a symmetric distribution—when one superior parathyroid gland is located in one place, the opposite parathyroid gland will usually be in the contralateral mirror image of that place.[3]

The vascular supply of the lower parathyroid glands comes from branches of the inferior thyroid arteries. This supply is usually independent; a circumstance that may be helpful in locating abnormally placed glands. If one of these arteries is ligated, infarction of the parathyroid gland may result.

Faulty migration of the glands during embryonic life may result in anomalous positions. The upper glands may be found inside the carotid sheath or behind the cervical or thoracic esophagus. The lower glands may continue their descent with the thymus into the anterior portion of the mediastinum.[4] They may also be located inside the thyroid gland (0.2%),[5] in the pharynx,[6] or within the vagus nerve.[7] Interestingly, they can also be found within autonomic ganglia in the neck.[8] Wang[9] has pointed out that despite the wide distribution patterns that parathyroid glands may exhibit, these fall into an orderly scheme and can be uncovered by the experienced surgeon in the great majority of cases, although some patients have required multiple surgeries to identify anomalously located diseased glands.

Normal Histology

In the past a rigid division of cell types has been applied to the normal parathyroid gland; however, evidence suggests that this organ is made up of but one basic cell type, the **chief cell**, and that all the other cells that have been described represent morphologic variations of the former that reflect differences in physiologic activity.[10,11]

The chief cell measures 6–8 μm in diameter and has a centrally located nucleus and a moderate amount of pale granular cytoplasm. Ultrastructurally, there are variable amounts of glycogen particles and secretory droplets, an inverse relationship existing in the amount of these two components.[11] Parathormone (PTH) and PTH-related

protein secretion can be demonstrated immunohistochemically.[12,13] There is also cytoplasmic reactivity for various types of keratin, and for chromogranin A, but not for vimentin, glial fibrillary acidic protein, neurofilament, or chromogranin B.[14,15]

The **oxyphil cell** has a more abundant cytoplasm, which is deeply granular and acidophilic. A rich content of oxidative enzymes can be demonstrated histochemically, although the ratio of enzyme content per mitochondrion seems to be decreased.[16] These oxyphilic cells are often present in the form of nodular collections. **Transitional oxyphil cells** have an appearance that is intermediate between chief cells and oxyphil cells. The **water-clear cell** (rarely if ever seen in the normal gland) is characterized by abundant optically clear cytoplasm and sharply defined cell membranes. **Transitional water-clear cells** have an appearance that is intermediate between chief cells and water-clear cells. Both types of transitional cell are more common in hyperfunctioning than in normal glands.

The frequency distribution of the different cells varies with the age of the patient. Until puberty, the gland is composed wholly of chief cells that contain cytoplasmic glycogen but not fat. The latter appears in these cells as very fine droplets soon after puberty at about the same time that the oxyphil cells appear. They appear first singly, then in pairs, and, after 40 years of age, in the form of sharply outlined but not encapsulated islands, which may be large.

After puberty, mature adipose tissue appears in the stroma and increases in amount until about 40 years of age, remaining relatively constant thereafter. Whereas the average percentage of stromal fat cell in the adult parathyroid is about 40%, the variations in the amount of fat present (while the parenchymal cell content remains relatively constant) make it very difficult to distinguish a normal from an abnormal parathyroid solely on the basis of stromal fat content.[17,18] In a classic study, Gilmour[19] demonstrated in 1947 that small parathyroid glands in adult individuals are the result of a decreased amount of stromal fat rather than parenchymal cell mass.

A few follicles and cysts of varying sizes are observed in about half of parathyroid glands after puberty. They may be filled with granular and cellular debris or with a dark blue–staining, finely granular material that is morphologically indistinguishable from thyroid colloid.[20] This material, which sometimes is positive with amyloid stains, is thought to result from a conformational change in the stored PTH polypeptide.[21] When these follicles are present, the distinction between thyroid and parathyroid tissue may become difficult, especially on frozen section. The presence of sizable amounts of cytoplasmic glycogen favors a parathyroid nature. Conversely, the presence of birefringent crystals of calcium oxalate (easily detectable with polarized light) favors thyroid, a feature to remember at the time of frozen section.[22] If doubts persist, immunohistochemical stains (e.g. for thyroglobulin, TTF-1, PTH, and/or chromogranin) should dispel them.

Normal Physiology

The parathyroid glands mediate their endocrine function through the production of PTH, an 84-amino acid polypeptide that results from serial cleavage of preproparathyroid hormone and proparathyroid hormone.[23] There are several forms of circulating PTH. The relationship among them is not clear, but it is known that the structural requirements for the biologic activity reside in the first 34 amino acid residues.[24,25] The chief cells are most critically sensitive to calcium concentrations in vivo and in vitro.[26]

PTH and vitamin D are the primary regulators of mineral metabolism.[27] The primary target organs for PTH activity are the kidneys, intestines, and bones. The most important physiologic actions of PTH are increased renal excretion of phosphate, increased renal tubular reabsorption of calcium, increased intestinal absorption of calcium, and direct effects in bone. The latter are mainly manifested by an increase in the number of osteoclasts and an apparent increase in their phagocytic activity, resulting in resorption of bone tissue.

Adenoma

Generalities and Gross Features

Parathyroid adenomas occur in women and men in a ratio of 3 : 1. They can develop at almost any age, but most occur in patients in the fourth decade. A few cases have been reported in children,[28] and some after radiation therapy to the head and neck region.[29,30] The vast majority are solitary masses. Cases of double or triple adenomas exist,[31-34] but the distinction between multiple adenomas and asymmetrical hyperplasia can be difficult and arbitrary. Accordingly, some of the reported cases of multiple adenomas would be reinterpreted today as examples of chief cell hyperplasia. Their size and weight vary greatly, with the majority being too small to allow detection on palpation of the neck. Some may be recognizable only microscopically ("microadenomas").[35] Adenomas are usually oval, may show slight lobulation, and are surrounded by a thin connective tissue capsule. On section, they are often grayish brown (Fig. 9.1). Foci of hemorrhage, calcification, and cystic change may occur. In terms of location, about 75% involve one of the lower glands (Fig. 9.2), 15% involve one of the upper glands, and 10% occur in anomalous positions. Of the latter, 70% are in the mediastinum,[36,37] 20% are intrathyroidal,[38,39] and the remainder in the soft tissues behind the esophagus or—in rare cases—the esophageal wall itself.[40,41]

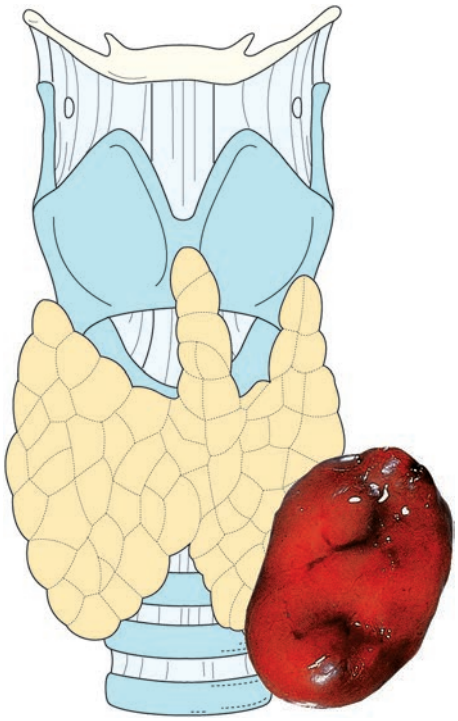

Figure 9.2 Parathyroid adenoma arising from the left lower parathyroid gland.

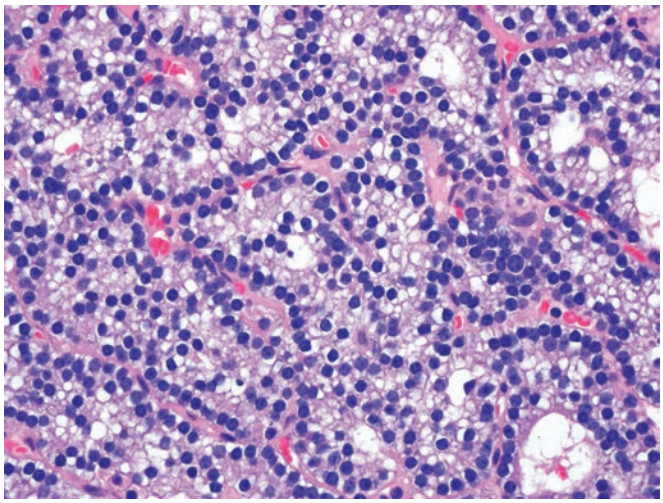

Figure 9.3 Parathyroid adenoma. The tumor is hypercellular, homogeneous, and well vascularized.

Microscopic Features

Microscopically, adenomas are encapsulated and highly cellular (Fig. 9.3). An adjacent rim of compressed non-neoplastic parathyroid tissue can be identified in about 60% of cases. The adenoma itself may be composed of any of the various cell types that make up the normal parathyroid gland (see Fig. 9.3), but chief cells usually predominate.[42] Combinations of chief cells, oxyphil cells, water-clear cells, and transitional elements are common. Variation in nuclear size may be conspicuous, with the presence of tumor cells with isolated or clustered huge hyperchromatic nuclei (Fig. 9.4). Mitotic figures are usually absent, but occasional ones may be found. The pattern of growth is generally diffuse, but it may be nesting, follicular,

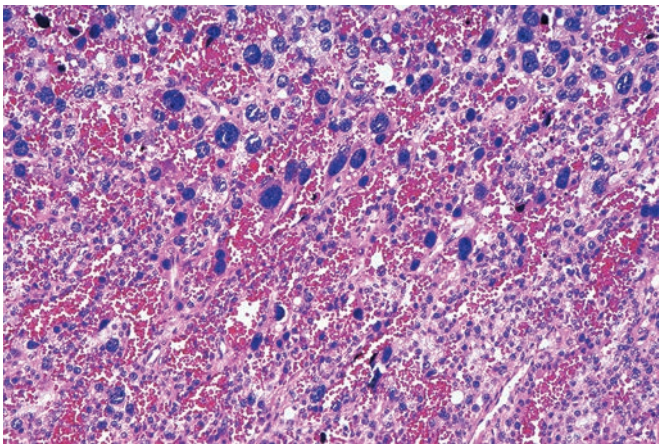

Figure 9.4 Parathyroid adenoma with clusters of bizarre nuclei. This feature is not an indication of malignancy.

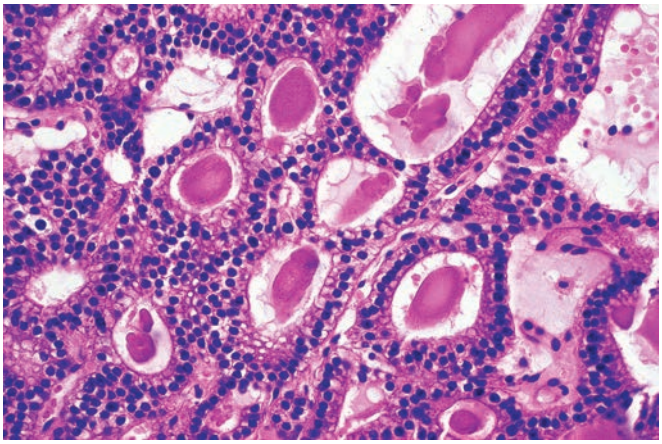

Figure 9.5 Parathyroid adenoma with follicular structures containing a colloid-like material simulating thyroid.

or pseudopapillary (Fig. 9.5).[43] The follicles may contain a colloid-like material. This material sometimes stains for amyloid, as in the normal gland.[44] The presence of follicular structures may closely simulate the appearance of thyroid. Presence of birefringent crystals is a good clue for the identification of the latter. Occasionally, prominent clusters of mature lymphocytes of B and T cell type (sometimes admixed with plasma cells) are seen scattered throughout the tumor (Fig. 9.6).[45] This may be accompanied by degenerative changes in the tumor cells. It is important not to overdiagnose this inconsequential microscopic finding, which may or may not have an autoimmune pathogenesis, as a lymphomatous infiltrate.[46,47]

In the typical case of parathyroid adenoma, the other parathyroid glands have a normal or even atrophic appearance. Indeed, the presence of a *microscopically normal* second gland is thought to represent the best evidence that a given parathyroid lesion is an adenoma rather than chief cell hyperplasia, although the surgical practice of biopsying a second gland to demonstrate its normalcy in order to establish a diagnosis of adenoma has fallen out of favor and has been replaced in part with visualization of the other glands and intraoperative PTH monitoring.[48]

Immunohistochemical Features

Immunohistochemically, there is reactivity for PTH, various types of keratin, and neuroendocrine markers (e.g. chromogranin A and

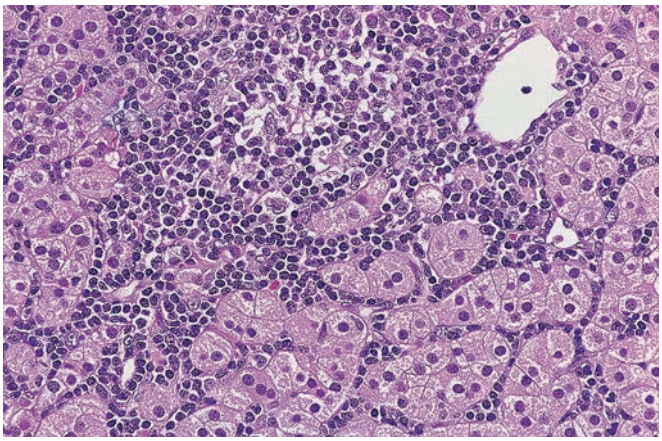

Figure 9.6 Heavy lymphocytic infiltrate within a parathyroid adenoma.

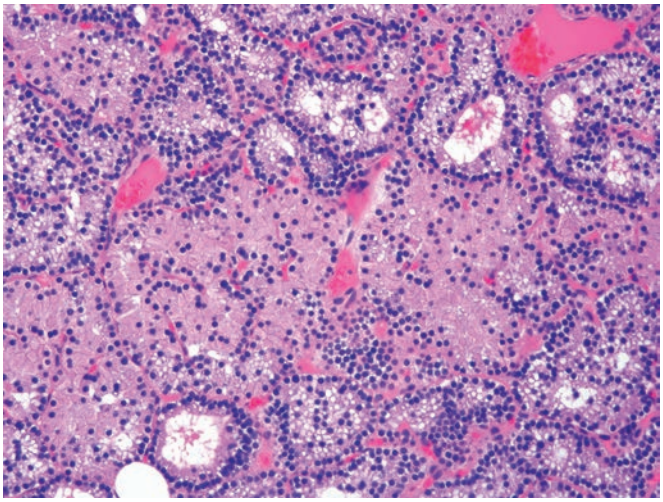

Figure 9.7 Parathyroid adenoma composed of an admixture of chief cells and oncocytic cells.

synaptophysin).[14] The intensity of the PTH staining tends to be weaker in the adenoma than in the peripheral rim of residual normal gland.[49] The adenoma cells express neurofilament, an intermediate filament not found in normal parathyroid cells.[14] Cyclin D1 and bcl-2 expression can be observed in a subset of adenomas,[50-54] whereas immunoreactivity for p53 is rare.[55] Expression of Ki-67 is observed, but the frequency of positive cells is lower compared to carcinoma.[56] The large majority of adenomas express parafibromin, the gene product of *CDC73*, which is lost in the majority of parathyroid carcinomas.[57-60]

Molecular Genetic Features

There has been a steady and substantial increase in the knowledge of the genetics of parathyroid tumors. Several genetic abnormalities have been detected in parathyroid adenomas, most of which are sporadic but can also occur as part of several hereditary syndromes. The primary genetics drivers known to date include somatic alteration of *MEN1*[61-65] and *CCND1/PRAD*.[66-68] Loss of function of the *MEN1* tumor suppressor gene is thought to be an early event in the pathogenesis of parathyroid adenomas, similar to other endocrine tumors.[69] Biallelic inactivation of *MEN1* occurs in about 25%–35% of tumors. Activating mutations of *CCND1/PRAD*, resulting in overexpression of cyclin D1, have been reported in 20%–40% of parathyroid adenomas[70,71] In addition, next-generation sequencing studies have identified low frequency mutation in known cancer genes, including *ZFX* (5%), *CTNNB1* (2%–5%), *EZH2* (1%), and *POT1* (<1%).[67,68]

In addition to genetic alterations, epigenetic alterations such as DNA methylation have emerged as playing a highly significant role in the pathogenesis of sporadic parathyroid adenomas.[72-75] Many of the methylated genes are related to calcium homeostasis, Wnt/β-catenin signaling pathway, cell cycle progression, and transcriptional regulation.[74,76] Reflecting the biologic complexity of gene regulation in cancer, microRNA expression has also been proposed to play a role in parathyroid tumor development.[77,78] Gene expression studies of parathyroid adenomas have identified two main classes of parathyroid adenoma, which may reflect the underlying genotype, specifically loss of 11q13.[79,80]

Adenoma Variants

Oxyphil adenoma is a term that should be restricted to parathyroid adenomas composed entirely or almost entirely of oxyphil cells, inasmuch as a component of oxyphil cells can be found in many adenomas (Fig. 9.7).[81] When thus defined, most oxyphil adenomas are nonfunctioning; however, cases associated with hyperparathyroidism (HPT) have been reported, with secretion of PTH and proparathormone being documented ultrastructurally, immunohistochemically, and biochemically.[82-85]

Lipoadenoma is an unusual morphologic variant of parathyroid adenoma in which the glandular elements are associated with abundant mature adipose tissue, the latter sometimes exhibiting myxoid changes.[86-88] Closely related if not identical lesions have been reported as *parathyroid lipohyperplasia*, *parathyroid hamartoma*, *parathyroid adenoma with myxoid stroma*, and *parathyroid myxoadenoma*. Most lipoadenomas are functioning.[89,90]

Chief Cell Hyperplasia

Chief cell hyperplasia, a condition accompanied by increased production of PTH, can be primary or secondary to impairment of renal function or chronic malabsorption.

Primary chief cell hyperplasia can be observed in several hereditary cancer predisposition syndromes, including multiple endocrine neoplasia types 1, 2A, and 4 (MEN 1, MEN 2A, MEN 4) and hereditary hyperparathyroidism–jaw tumor (HPT-JT).[91,92] In contrast, patients with MEN 2B exhibit normal parathyroid histology during childhood and only a minimal degree of chief cell hyperplasia (consistent with absence of normal involution) during adulthood.[93] MEN 1 is autosomal dominant and caused by inactivating mutations of the *MENIN* tumor suppressor gene at 11q13. Its pathologic phenotype is characterized by multiglandular parathyroid disease, either hyperplasia or multiple adenomas in greater than 90% of cases, along with gastroenteric neuroendocrine tumors in 60% of cases and pituitary adenomas in 30% of cases[94] The histologic distinction between parathyroid hyperplasia and multiple adenomas can be difficult and arbitrary. MEN 2A is caused by activating germline mutations of *RET* at 10q11.2 and its pathologic phenotype is characterized by parathyroid hyperplasia in 30% of cases, as well as medullary thyroid carcinoma in the setting of C cell hyperplasia and pheochromocytomas in the setting of medullary hyperplasia.[95] MEN 4 is a MEN 1–like syndrome, yet without germline *MEN1* mutations. These patients contain inactivating germline mutations of a different tumor suppressor gene located at 12p13.1, *CDKN1B*, which plays a role in cyclin D1 signaling.[94,96,97] HPT-JT syndrome is yet another autosomal dominant syndrome that is phenotypically characterized by multiglandular parathyroid disease,

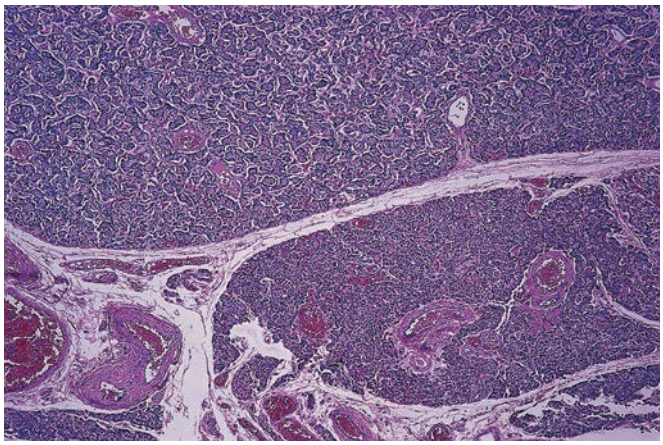

Figure 9.8 Chief cell hyperplasia with multinodular pattern of growth.

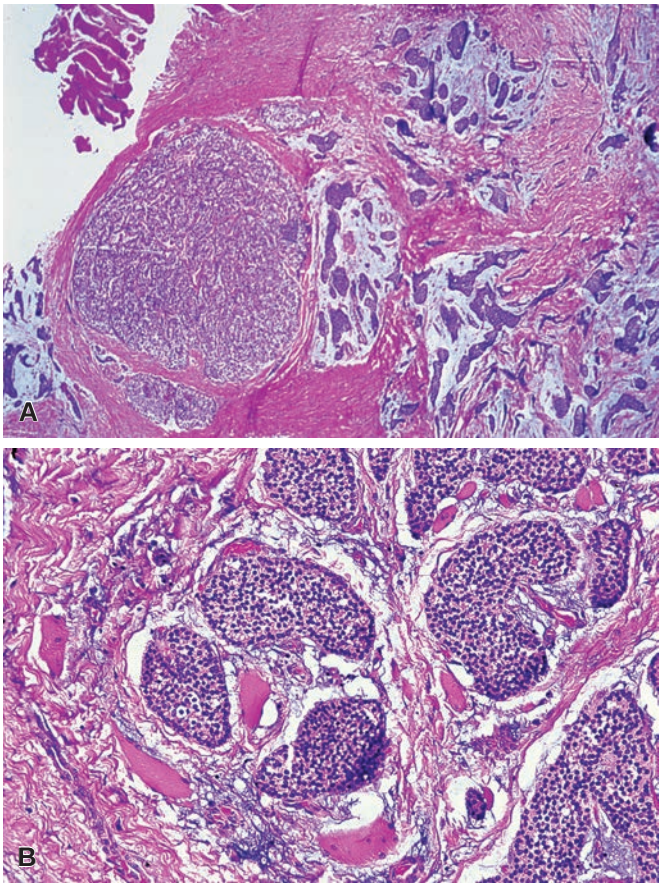

Figure 9.9 **A** and **B,** Parathyroid gland with chief cell hyperplasia that has been surgically transplanted into the forearm. The clusters of hyperplastic chief cells infiltrate the skeletal muscle, thus simulating carcinoma.

often associated with cystic change. These parathyroid lesions are at high risk of progressing to parathyroid carcinoma (up to 20%). These patients may also develop fibro-osseous lesions of the mandible and maxilla, as well as other rare tumors such as Wilms tumor. Molecularly, HPT-JT is related to inactivating germline mutations of *CDC73* (formerly known as *HRPT2*) at 1q31.2,[98] which encodes the parafibromin protein, a vital tumor suppressor in the parathyroid gland.[99]

In a *classic* case of primary chief cell hyperplasia, all glands are enlarged (sometimes weighing 10 g or more) and have a tan to reddish color.[100,101] The upper glands tend to be larger than the lower ones, but the difference is not as striking as in water-clear cell hyperplasia. In other instances, only one gland is visibly enlarged and nodular, whereas the others are nearly normal in size. This latter variant can be confused grossly with an adenoma and is therefore referred to as *pseudoadenomatous*. In still other cases (designated as *occult*) all four glands appear normal in size to the surgeon but are hyperplastic on histologic examination.[102]

Microscopically, the predominant element is the chief cell, but other cell types are also present in most instances. The pattern of growth may be diffuse or nodular, the former being more common among young patients and the latter in the elderly (Fig. 9.8). Glands with nodular chief cell hyperplasia tend to be asymmetric, with a variable cellular arrangement and a high proportion of oxyphil cells.[103] Fibrous septa, acinar formations, and cells with giant hyperchromatic nuclei may be present.[100]

Exceptionally, innumerable microscopic foci of hyperplastic parathyroid tissue are found in the neck in association with primary chief cell hyperplasia of the four glands, in the absence of previous surgery. This phenomenon, called *parathyromatosis*, may be responsible for some cases of recurrent HPT after technically successful surgical therapy.[104] Another rare entity is that of chief cell hyperplasia associated with *chronic parathyroiditis*, interpreted by some as a possible parathyroid equivalent of Hashimoto thyroiditis.[105]

Hyperplastic parathyroid glands surgically transplanted in the forearm as part of the surgical treatment of HPT and which need to be excised because of recurrence of the HPT can exhibit morphologic features, which if present in the orthotopic situation, would have strongly suggested malignancy, such as significant mitotic activity, fibrous strands, and infiltration of the skeletal muscle (Fig. 9.9).

In **secondary chief cell hyperplasia**, all gradations are seen. At one end is the normal-sized gland that is recognized as hyperplastic only because of its tan to reddish color and the microscopic hypercellularity; at the other, there is the gland measuring up to 2 cm and weighing up to 6 g. In general, there is an inverse correlation between the size of the gland and the mean serum calcium level.[106] Microscopically, chief cells predominate, but there may also be increased numbers of oxyphil and transitional oxyphil cells that form nodular collections.

The distinction between primary and secondary chief cell hyperplasia cannot be made on morphologic grounds with any certainty.[107] As a rule, nodularity, fibrous septation, acinar formation, and giant nuclei are more prominent in the primary form, whereas the number of oxyphil cells is higher in the secondary form. However, in the final analysis, the differential diagnosis is made on the basis of the clinical and laboratory findings.[100] Another difficult and more pressing problem is the morphologic distinction between chief cell hyperplasia and adenoma. Size, shape, color, consistency, the cell types present, and their relative frequency are of no help in this regard. The presence of a marked degree of nuclear pleomorphism is said to favor adenoma, but the overlap with hyperplasia is too pronounced for this to represent an absolute criterion.[108] The degree of proliferative activity (as measured by Ki-67 immunostain) is also similar in adenoma and chief cell hyperplasia, the most intense foci in both instances being present in the form of nodular collections.[109] The presence of a rim of normal parenchyma around the mass, visualization of other normal glands, and the normalization of PTH as measured by intraoperative PTH are the only definite criteria by which a diagnosis of adenoma can be made over that of chief cell hyperplasia, but these criteria may be difficult to evaluate.

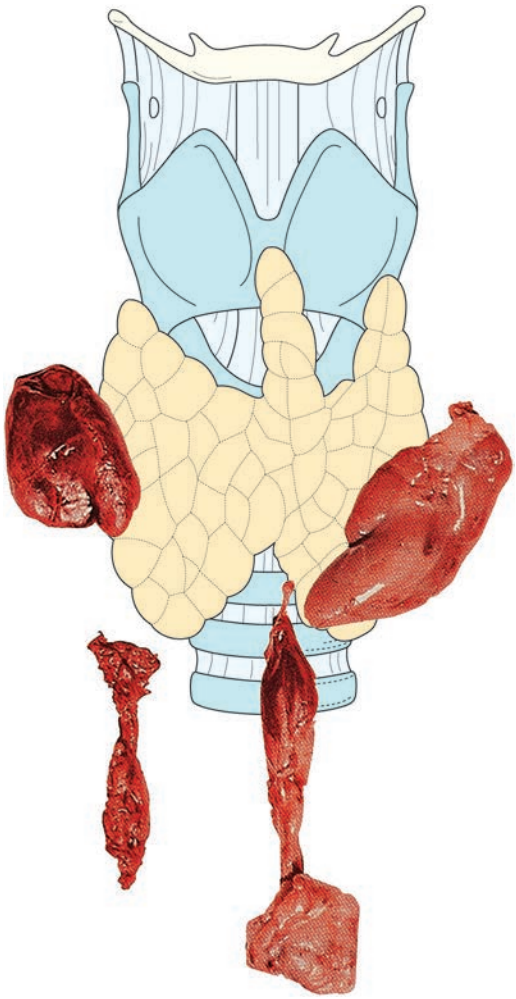

Figure 9.10 Water-clear cell hyperplasia. Note the chocolate brown color, the pseudopods, and the greater involvement of the upper glands. (Redrawn from Castleman B. *Tumors of the Parathyroid Glands. Atlas of Tumor Pathology*, series 1, fascicle 15. Washington, DC: Armed Forces Institute of Pathology; 1952.)

Water-Clear Cell Hyperplasia

In contrast to chief cell hyperplasia, water-clear cell hyperplasia shows no familial incidence and is not associated with multiple endocrine neoplasia or other hereditary syndromes. Interestingly, water-clear cell hyperplasia is strongly associated with blood group O, which may be a prerequisite for development.[110] It is characterized by extreme enlargement of all parathyroid tissue so that the total weight of the glands may exceed 100 g. Strangely, this disorder (which made up a significant proportion of cases of primary HPT in older series) has all but disappeared in recent times, for reasons unknown.[101,103]

Grossly, the superior glands are distinctly larger than the inferior. Moreover, glands may coalesce so that two glands appear as one. They are soft and have a typical chocolate brown color (Fig. 9.10). Cysts and hemorrhages have been observed. Another common gross feature is the formation of pseudopods that may extend a considerable distance from the main mass of the gland. A close correlation exists between the weight of the parathyroid tissue and the severity of the symptoms.

Microscopically, the most characteristic feature is the presence of cells with optically clear cytoplasm throughout the lesion. These

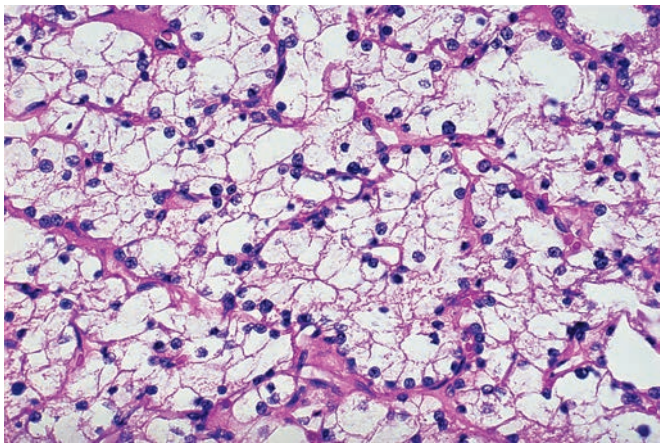

Figure 9.11 Water-clear cell hyperplasia. The cells are very large, optically clear, and have sharply outlined cell membranes.

cells vary markedly in size, from some no larger than normal parathyroid cells to others that measure up to 40 µm (Fig. 9.11). Thus there is a combination of hyperplasia and hypertrophy. In most regions, the cytoplasm of the cell is water-clear, but in some cells small eosinophilic granules are present. High-power examination of thin sections reveals that the clarity of the cytoplasm is the result of a conglomerate of spherical clear vacuoles surrounded by thin portions of eosinophilic cytoplasmic material. The nuclei average 6–7 µm and are basally oriented, a very distinctive feature. Although their size may vary, giant forms are not seen. The pattern of growth may be alveolar (pseudoglandular) or compact. The connective tissue is delicate and sparse for the most part, but in some areas it may be dense. A chief cell component is occasionally present.

Carcinoma

Parathyroid carcinoma typically presents with HPT; in an old series, skeletal disease was present in 73% of the patients and renal disease in 26%.[111] A few convincing nonfunctioning cases are on record, and these are said to be more aggressive.[112] The absence of function may be caused by the lack of conversion of the preparathormone to the biologically active compound.[113] Parathyroid carcinoma may coexist with chief cell hyperplasia[114,115] and with adenoma,[116] the former sometimes seen in a familial setting.[117] They have also been seen in the setting of MEN 1.[118]

Clinical features suggestive of parathyroid carcinoma in a hyperparathyroid patient include very high values of serum calcium or PTH, a palpable cervical mass, vocal cord paralysis, and recurrence of HPT a short time after surgery.[54,119,120,121] Some patients present with parathyroid crises.[122] At operation, a parathyroid tumor should be suspected of being carcinoma if it is hard, surrounded by a dense fibrous reaction, and adherent to or infiltrating adjacent structures.[123]

Microscopically, carcinomas differ from adenomas mainly because of their trabecular arrangement, dense fibrous bands (present in 90% of the cases), spindle shape of the tumor cells, presence of mitotic figures (in 81%), capsular invasion (in 67%), and blood vessel invasion (in 12%) (Figs. 9.12 and 9.13).[124,125] Rare parathyroid carcinomas show high-grade histology with numerous mitoses (Fig. 9.14). Some caveats are in order. A certain degree of fibrous banding can also occur in adenoma and in chief cell hyperplasia, particularly the primary form of the latter. Nests of tumor cells may be present within the capsule of a benign tumor as a result of the combined effect of proliferative and regressive changes.[126] Intrathyroidal

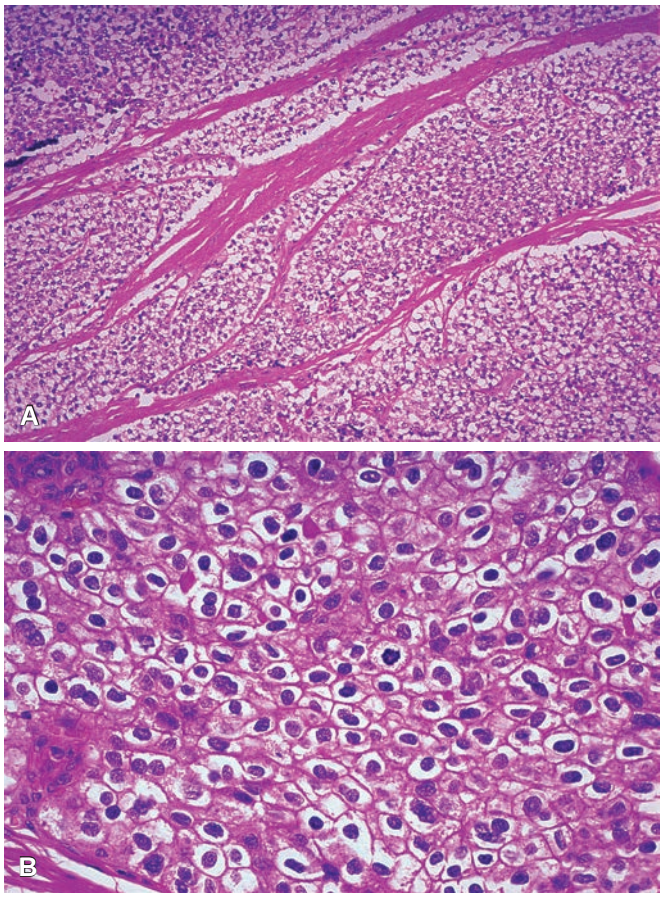

Figure 9.12 Parathyroid carcinoma. **A,** Sharply outlined fibrous bands incompletely dividing the tumor into lobules. **B,** Mitotic features.

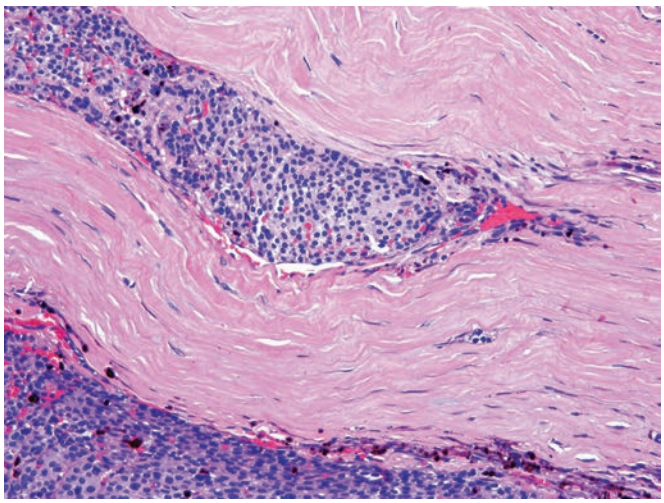

Figure 9.13 Parathyroid carcinoma with lymphovascular invasion.

parathyroid adenomas tend to be associated with fibrosis, sometimes extensive. The residual rim of normal (or hyperplastic) parathyroid tissue of generally semilunar shape often found on the outside of the capsule of a parathyroid neoplasm should not be overinterpreted as evidence of extracapsular invasion. The presence of an occasional mitotic figure in a parathyroid lesion does not necessarily indicate that the lesion in question is a carcinoma. Snover and Foucar[127]

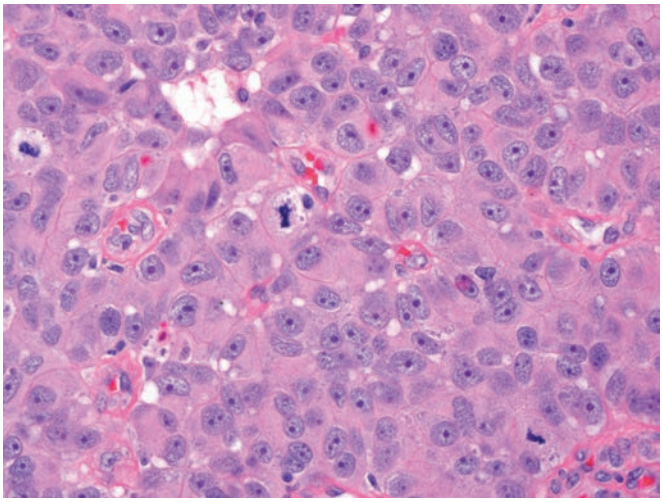

Figure 9.14 High-grade parathyroid carcinoma with abundant mitotic figures.

found rare mitoses by exhaustive search in 71% of adenomas and 80% of the chief cell hyperplasias that they examined. It is also important to be certain that the mitoses are in the tumor cells rather than in the endothelial cells of the prominent hyperplastic blood vessels that so commonly accompany these tumors. Taking everything into account, vascular invasion, obvious extension into the soft tissues, and abundant mitotic figures are the most important indicators of malignancy. As in the thyroid, the diagnosis of vascular invasion can be made only if the tumor tissue is attached to the vessel wall and if the vessel in question is in the capsule or beyond. If doubts persist, a conservative approach is to be recommended. DeLellis[128] has suggested the use of the term *atypical adenoma* for tumors exhibiting some of the features associated with carcinoma but lacking clear-cut evidence of invasion, although this terminology is potentially confusing to clinicians.

In rare cases, parathyroid carcinoma is composed of oxyphil cells.[129,130] In contrast to parathyroid chief cell adenomas, these tumors are usually negative for CK14. They also tend to express a higher Ki-67 labeling index and a lower p27 index than their benign counterparts.[129] If the parathyroid origin of the tumor is questionable—particularly in the absence of function—immunochemical demonstration of PTH should be carried out.[131]

Genetically, somatic inactivating mutations of *CDC73* are found in up to 70% of parathyroid carcinomas.[132,133] The mutations cause absent or decreased expression of parafibromin, which can be demonstrated by immunohistochemistry.[59,133-135] Unexpectedly, rare patients with sporadic parathyroid carcinoma exhibit germline mutation of *CDC73*, suggesting a new proband of HPT-JT syndrome or a phenotypic variant.[132] The allelic losses commonly found in parathyroid adenomas (such as *MEN1* at 11q13) are uncommon in parathyroid carcinomas, suggesting that most parathyroid carcinomas do not arise from preexisting adenomas.[136] Other allelic imbalance studies also support a de novo origin for parathyroid carcinoma.[137]

Special techniques can be of some help in the differential diagnosis between parathyroid adenomas and carcinomas. Most of them are direct or indirect indicators of the rate of cellular proliferation. Thus, a significantly increased mean AgNOR (argyrophilic nucleolar organizer region) number has been found in carcinomatous glands when compared with benign (normal, hyperplastic, or adenomatous) glands.[138-140] Also, Ki-67 expression is significantly higher in carcinomas than in adenomas and hyperplasias.[54,141,142] Overexpression

of cyclin D1 occurs in over 90% of the carcinomas but in less than 40% of the adenomas.[51] An immunohistochemical marker usually expressed by parathyroid carcinomas but not adenomas is galectin-3.[141] Unfortunately, cases of primary and secondary parathyroid hyperplasia are also commonly positive, severely limiting its utility.[143] DNA ploidy studies have shown significant statistical differences between carcinomas and adenomas, and that among the former the presence of aneuploidy is associated with a more aggressive clinical course in carcinomas.[144-148] Kytola et al.[136] found "highly significant differences" by comparative genomic hybridization (CGH) between parathyroid carcinomas and adenomas, but there were no alterations that were specific for one or the other. Allelic loss of the *RB* gene (detected genetically or through absence of the Rb product immunohistochemically) occurs in a variable proportion of carcinomas or otherwise "aggressive" parathyroid tumors but only exceptionally in adenomas.[54,149,150] Finally, mutations of the *CDC73* gene (which can be inferred by a loss or decreased immunostaining for the parafibromin protein[151]) are found in a high percentage of parathyroid carcinoma cases but are rare in parathyroid adenomas.[132]

A few parathyroid carcinomas have been studied at the genomic level. Kasaian et al.[152] determined the genome sequence of a sporadic and recurrent parathyroid carcinoma and identified several novel mutations, such as *MTOR*, *MLL2*, *CDKN2C*, and *PIK3CA*, along with several structural alterations. Additional studies of larger cohorts will expand our understanding of the somatic genetic landscape of parathyroid carcinoma and shine additional light on its pathogenesis.

Prognosis

In a follow-up of 43 patients with parathyroid carcinoma reported by Holmes et al.,[111] it was found that 30 (65%) of the patients were dead, 5 were living with persistent tumor, and 8 were living without evidence of recurrent disease. Of 39 patients studied by Schantz and Castleman,[125] 41% were alive and well, 13% were alive with disease, and 46% were dead of carcinoma. Local recurrence within the first 2 years after surgery was found to be an ominous prognostic sign. Among 286 cases of parathyroid carcinoma collected in the U.S. National Cancer Database, neither tumor size nor lymph node status was found to be a significant prognostic factor. Overall relative survival at 5 years and 10 years was 85.5% and 49.1%, respectively.[153] In a series from M.D. Anderson, the 5-year survival was remarkably similar (85%) but the 10-year survival rate was higher (77%). Adjuvant radiation appeared to improve prognosis independent of the type of surgery and disease stage.[154]

Kameyama et al.[155] have proposed classifying parathyroid carcinomas into *low grade* when local infiltration is minimal and *high grade* when infiltration is widespread, a seemingly sensible approach that should to be tested by other groups.

Other Lesions

Parathyroid cysts usually arise from the lower glands but can be located in the upper region of the neck or in the mediastinum.[156,157] In most cases they cause no symptoms other than those related to pressure. Their mean diameter is 4 cm.[156] They are lined by cuboidal or low columnar epithelial cells and contain parathyroid tissue in their wall. Heterotopic salivary gland tissue can be found around the cyst.[158]

The cyst fluid contains assayable PTH.[159] The few reported cases of parathyroid cysts associated with HPT most likely represent adenomas with cystic degeneration.[160]

Amyloidosis often involves the parathyroid gland, in both primary and "reactive" forms of the disease.[161]

Langerhans cell histiocytosis involving simultaneously the parathyroid and thyroid glands has been reported.[162]

Hemangioma of the parathyroid gland has been described in two patients with HPT, but it is likely that the vascular tumor was simply an incidental finding.[163]

Metastatic carcinoma to the parathyroid glands is very rare, but papillary thyroid carcinoma can invade them in continuity with the main tumor.[164]

Hyperparathyroidism

The term **hyperparathyroidism** (HPT) is applied to any condition associated with the persistent production of parathyroid hormone. It is divided according to the presumed mechanism of production into primary (autonomous), secondary (due to a chronic condition that stimulates the producing of PTH), and tertiary (due to the formation of an autonomous clone in secondary HPT).

Primary Hyperparathyroidism

In primary HPT, there is no evidence of previous parathyroid stimulation by chronic renal or intestinal disease.[165] The pathologic changes in the gland may be those of adenoma, chief cell hyperplasia, carcinoma, or water-clear cell hyperplasia. Multigland disease is responsible for about 15% of cases of primary HPT.[48] Carcinoma constitutes about 1% of cases, and water-clear cell hyperplasia has essentially disappeared; therefore the large majority of cases are caused by either adenoma or chief cell hyperplasia.[166] Adenoma is responsible for over 80% of the cases.

Primary HPT is said to be present in 2.5 per 1000 individuals. It is usually seen in adults but can also be found in children.[167] When seen in a familial setting, the abnormality is usually chief cell hyperplasia, although exceptions occur.[168] It may also be seen, again in a familial form, as a component of MEN or HPT-JT.[169,170] In these syndrome, the parathyroid change is practically always chief cell hyperplasia, perhaps humorally induced.[171] An association between primary HPT and sarcoidosis has been encountered,[172] and a definite increase in the incidence of HPT after irradiation to the neck has been documented.[173,174]

The typical case of primary HPT is biochemically characterized by hypercalcemia, hypophosphatemia, lowering of the renal phosphate threshold, hypercalciuria, elevated levels of immunoreactive PTH, elevated concentrations of 1,25-dihydroxyvitamin D, and enhanced excretion of nephrogenous cyclic AMP. Another associated, albeit inconstant, chemical finding is elevation of the serum alkaline phosphatase level. Although hypercalcemia has traditionally been one of the most constant biochemical markers of parathyroid hyperfunction, well-documented instances of normocalcemic primary HPT do exist.[175] In a series of 84 patients with this variant, parathyroid adenomas were found in 19, chief cell hyperplasia in 39, and normal parathyroid glands in 26; no morphologic differences were detected between patients in this group and patients with conventional primary HPT associated with hypercalcemia.[176] However, at a functional level the glands have a profile closer to normal glands than those associated with conventional hypercalcemic HPT.[177]

According to the clinical presentation, patients with primary HPT have been traditionally classified into: (1) those with osseous manifestations; (2) those with renal manifestations; and (3) those with neither of the foregoing. There is a predominance of the latter group, referred to as "occult" or "asymptomatic."[175,178]

The **skeletal changes** of HPT are always generalized, although they may appear localized clinically or radiographically. The initial lesions show merely a decrease in bone density. In time, they may become very extensive and lead to deformities and fractures. The

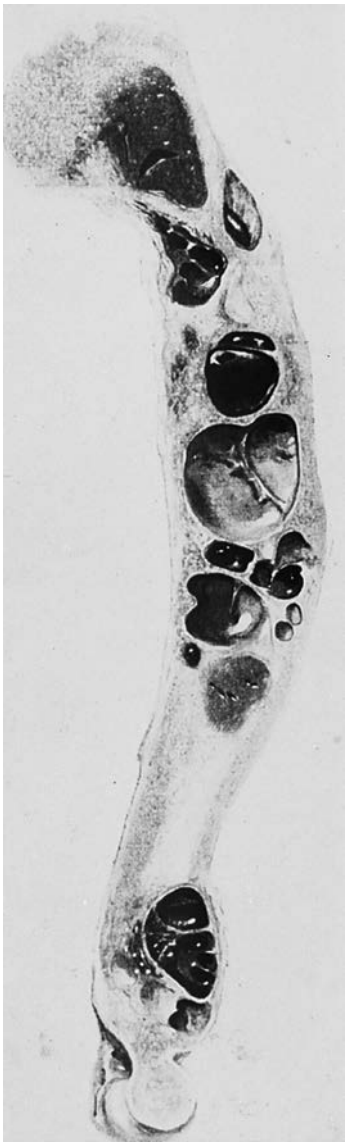

Figure 9.15 Historical example of extreme osteitis fibrosa cystica. Note deformity of bone with numerous cysts and brown tumors. (From Hunter D, Turnbull HN. Hyperparathyroidism. Generalized osteitis fibrosa, with observations upon bones, parathyroid tumors, and normal parathyroid glands. *Br J Surg*. 1931;19:203–284.)

full-blown osseous manifestations of HPT have been traditionally known as osteitis fibrosa cystica or Recklinghausen disease (not to be confused with neurofibromatosis, which also carries this eponym) (Figs. 9.15–9.17). The seemingly localized lesions are those more likely to be misinterpreted. They present radiographically as expansile, multilocular masses. The jaw is the preferred location, and this may be the first clinical manifestation of the disease. Grossly, there is an alternation of solid and cystic areas; the latter often have a brown color because of the accumulation of abundant hemosiderin, hence the term *brown tumor* sometimes used for them. Microscopically, there is a combination of osteoblastic and osteoclastic activity, often associated with cyst formation and clusters of hemosiderin-laden macrophages. It is this combination of findings that should suggest the diagnosis (Fig. 9.18).

The differential diagnosis with central giant cell reparative granuloma may be impossible on morphologic grounds because both lesions have a predilection for the jaw and their microscopic appearances are essentially the same; therefore the distinction is based on laboratory findings. The other differential diagnosis is with giant cell tumor, with which brown tumor has often been confused in the past. In giant cell tumor, the osteoclasts are more evenly spaced, the stromal cells are plumper, and osteoblastic activity is less conspicuous.

Removal of the hyperfunctioning gland is usually followed by a spectacular reversal of the bone changes, sometimes in a remarkably short time; however, some of the cystic lesions may persist indefinitely (see Figs. 9.16 and 9.17).

The **renal changes** of primary HPT include renal stones, nephrocalcinosis, polyuria, polydipsia, and impairment of renal function. Renal stones are the most common clinical manifestation of HPT.[165] These renal lesions are frequently associated with hypertension. In contrast to the skeletal changes, the renal abnormalities may still progress after the removal of the parathyroid lesion.

Other manifestations of HPT include hypertension, peptic ulcer, acute and chronic pancreatitis, and mental disturbances. The peptic ulcer is usually in the duodenum and is more common in males[179]; it often heals after removal of the hyperfunctioning gland.

Rarely, acute gastrointestinal, cardiovascular, or central nervous system symptoms develop because of very high serum calcium levels. This condition, designated as **parathyroid crisis**, is fatal unless the offending gland or glands are rapidly excised.[180]

Secondary Hyperparathyroidism

Secondary HPT occurs as a consequence of chronic renal disease or intestinal malabsorption, usually the former. The renal insufficiency leads to elevation of the serum phosphorus level and reciprocal decrease of serum calcium concentrations, with the resulting stimulation of the parathyroid glands.[181] Vitamin D resistance is a characteristic feature of advanced renal disease and also may play a role by contributing to reduced serum calcium concentrations.[182] Determinations of circulating PTH levels have shown these to be roughly proportional to the severity of renal failure. These levels are higher in renal failure than in any form of primary HPT.

The bone changes are qualitatively similar to those seen in primary HPT. They are usually milder, but sometimes extensive changes with cyst formation occur. *Cutaneous calciphylaxis* is an uncommon and potentially lethal disorder characterized by progressive cutaneous vascular calcification. It is mainly seen in the setting of renal failure–associated HPT. Microscopically, the mural vascular calcification is often associated with skin ulceration and calcifying septal panniculitis.[183]

The parathyroid abnormality in secondary HPT is **chief cell hyperplasia** of a generally diffuse but sometimes nodular pattern of growth.

"Tertiary" Hyperparathyroidism

The term **"tertiary" hyperparathyroidism** is applied to cases of HPT secondary to chronic renal disease or intestinal malabsorption, in which one or more of the stimulated parathyroid glands seem to become autonomous.[184] This phenomenon, which is also referred to as **nonsuppressible**, **autonomous**, or **refractory** HPT, is usually detected after correction of the renal disease by hemodialysis or homotransplantation.[185] Follow-up studies seem to indicate that if enough time is given, the parathyroid glands will revert to a normal state in the large majority of cases.[186,187]

Morphologically, the changes in the parathyroid gland are those of chief cell hyperplasia, the main difference with the ordinary case of **suppressible** secondary HPT being a greater tendency to nodularity

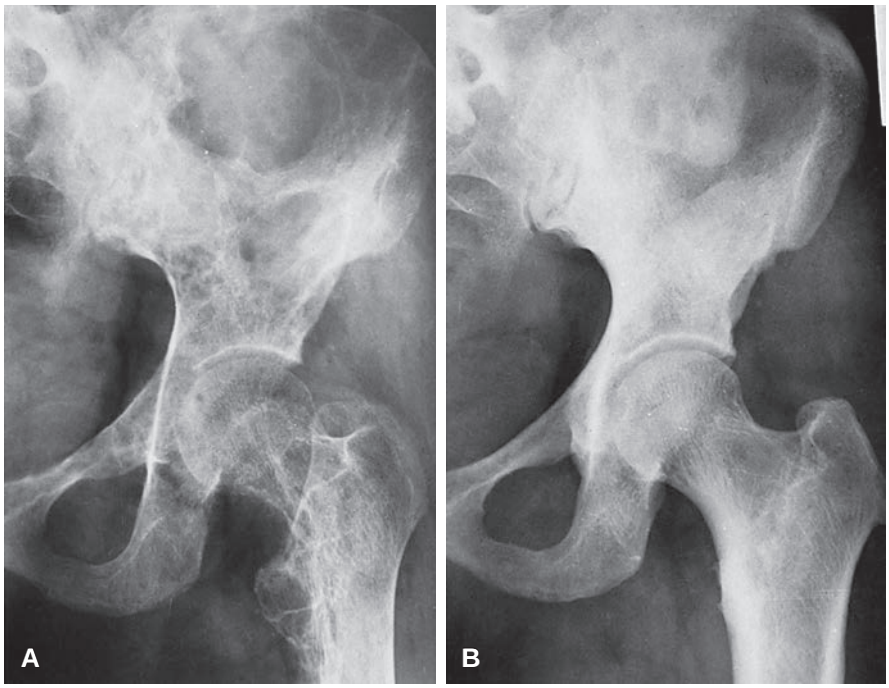

Figure 9.16 **A,** Extensive changes in bones of pelvis and femur caused by functioning parathyroid adenoma. **B,** Same pelvis and femur 8 years after removal of adenoma. Note complete reversion to normal. (From Black BK, Ackerman LV. Tumors of the parathyroid. A review of twenty-three cases. *Cancer*. 1950;3:415–444.)

Figure 9.17 **A,** Cystic changes and cortical alterations in bones of hands of patient with functioning parathyroid adenoma. **B,** Dramatic reparative change evident 9 months after removal of adenoma.

and heterogeneity, in the sense of the nodular components having a higher percentage of oxyphilic cells and acinar cell arrangements, and showing a marked variability of PTH immunoreactivity.[188-190] Sometimes an entire nodule is made up of oxyphilic cells.[190] Even when the hyperplastic changes remain diffuse, the nuclear size has been shown by morphometry to be larger than that of secondary hyperplasia and approaching that of adenoma.[191] It has been demonstrated that the presence of a nodular pattern of growth (especially if coupled with a high Ki-67 fraction) is associated with a higher risk of recurrence of the HPT.[192] These nodules have a high prevalence of *TP53* expression immunohistochemically.[189] In extreme cases, one of these nodules will acquire an appearance that is indistinguishable from that of a true adenoma. However, the finding of allelic losses at chromosomes 7p, 18q, and 2 suggests that its molecular pathways are different from those of the ordinary adenoma.[193]

Differential Diagnosis

Primary HPT must be distinguished clinically from a relatively large number of conditions associated with hypercalcemia. These include sarcoidosis, hyperthyroidism, multiple myeloma, milk–alkali syndrome, vitamin D and vitamin A intoxication, familial hypercalcemic hypocalciuria, and humoral hypercalcemia of malignancy.

Familial hypocalciuric hypercalcemia should be suspected in young patients with a presumptive diagnosis of HPT, especially if there is a family history.[194,195] Determination of the calcium:creatinine

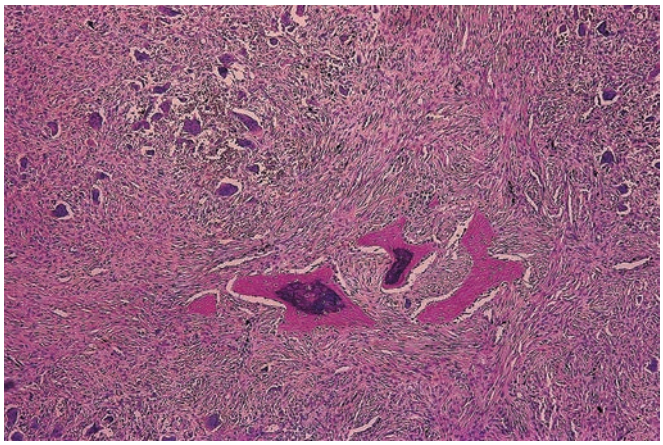

Figure 9.18 Bone changes in hyperparathyroidism. There is marked resorption of bone trabeculae and clustering of osteoclasts.

clearance ratio is the traditional test to identify this disorder. Heterozygous inactivating mutations of calcium-sensing receptor are found in about two-thirds of the patients.[196] Microscopically, the parathyroid glands may appear normal or exhibit a mild degree of chief cell hyperplasia, sometimes with a prominent clear cell component.[197] In other instances they show features of lipohyperplasia.[196]

Humoral hypercalcemia of malignancy. Nonparathyroid tumors may induce hypercalcemia by producing widespread metastases in the skeletal system. In addition, symptoms and signs suggestive of HPT may be seen in malignant tumors of nonparathyroid origin in the absence of significant osseous metastases.[198,199] This condition is sometimes referred to as pseudohyperparathyroidism. Renal cell carcinoma and squamous cell carcinoma of the lung account for 60% of cases.[200] The parathyroid glands appear morphologically normal or only minimally hyperplastic,[201,202] but the serum biochemical parameters clearly indicate a state of suppressed parathyroid function. The mechanism for the hypercalcemia has been found to be the secretion by the tumor cells of a peptide with a partial homology to PTH, known as PTH-related peptide or PTH-related protein.[203-205]

Treatment

According to the most recent guidelines from the American Association of Endocrine Surgeons,[48] parathyroidectomy is the preferred treatment for HPT and is indicated for all symptomatic patients. Surgery is also indicated for asymptomatic patients whose serum calcium level is greater than 1 mg/dL above normal. Parathyroidectomy is also indicated for patients with evidence of renal involvement, osteoporosis, and/or compression fractures, in patients under age 50 regardless of symptoms and clinical findings, and in patients suspected of having parathyroid carcinoma. Patients who elect not to undergo surgery should be evaluated annually. Parathyroidectomy is not indicated when the surgical risks are greater than the expected benefits.

Experienced surgeons, that is, those who perform more than 10 parathyroidectomies per year, have better outcomes. The surgeon embarking on therapy for HPT should have a thorough knowledge of parathyroid physiology and of the variations in the appearance and anatomic locations of the parathyroid glands[206,207] as well as the tumors arising from them.

Several techniques have been used to localize the abnormal gland preoperatively and should be used after deciding to proceed with surgery, as it can guide operative planning. Cervical ultrasonography is the mainstay of localization and can be combined with computed tomography scan and sestamibi radioactive scan. Magnetic resonance imaging and selective venous catheterization can be used in difficult cases. Fine needle biopsy is not recommended for localization.

Adenomas are adequately treated by excision of the tumor.[208] Surgical identification of *all four* parathyroid glands via bilateral exploration remains a widely used approach,[209,210] although minimally invasive parathyroidectomy, that is, a limited neck dissection, has become increasingly used for primary HPT patients with a single adenoma. Advances in the preoperative localization of abnormal parathyroid glands have reduced the number of glands submitted for histologic examination.[211] The use of intraoperative PTH measurement has reduced the surgical failure rate and the need for frozen section. While excision or biopsy at least one other parathyroid gland was once performed to rule out the alternative possibility of chief cell hyperplasia, this approach has been replaced with bilateral exploration with visualization of the glands and intraoperative PTH monitoring.

Primary chief cell hyperplasia and the exceptionally rare water-clear cell hyperplasia are conventionally treated by subtotal parathyroidectomy, as defined by total excision of three glands and partial excision of the fourth, leaving 30–50 mg of viable tissue.[212]

An alternative approach to the treatment of primary or secondary chief cell hyperplasia has been the performance of total parathyroidectomy with autotransplantation of parathyroid tissue into the forearm muscle or chest wall fat pad.[213,214] The transplanted tissue may regrow briskly and lead to recurrence of the HPT.[215,216] The hyperplastic gland may infiltrate the skeletal muscle, simulating a malignant process. The danger of overdiagnosis under these circumstances is made greater by the fact that mitoses can be easily found in this tissue even if absent in the original lesion.

Parathyroid carcinoma is best treated by excision of the tumor and surrounding soft tissues and removal of the ipsilateral lateral thyroid lobe; the indication for ipsilateral node dissection remains controversial,[111,119,217,218] as well as the need for extensive surgery.[219] Surgical resection of isolated metastases is justified because of its marked palliative effect.[220]

The large majority of patients with secondary and "tertiary" HPT respond well to medical treatment[182,221]; however, if bone lesions are severe and if the hypercalcemia is excessive, subtotal parathyroidectomy may become necessary.

Frozen Section

Unless dealing with an exceptionally experienced and gifted surgeon,[222] the pathologist's main role at the time of surgery is to determine by frozen section whether a given nodule removed from the neck is actually parathyroid tissue, since nodules of thyroid gland, small lymph nodes, aberrant thymic tissue, and even fat may be mistaken grossly for parathyroid tissue.[223-225] This determination has an accuracy rate of over 99%.[226,227] With experience, this determination can also be made in imprints stained with polychrome methylene blue, a technique that saves considerable surgical time.[228-230]

As far as the pathologist providing a specific diagnosis is concerned, most cases of water-clear cell hyperplasia and some carcinomas should be identifiable by frozen section, particularly if the carcinoma has invaded local tissues; however, this comprises a very small proportion of cases. The two most common—and unfortunately most difficult—situations faced by the pathologist are to decide whether a gland is normal or abnormal and, if abnormal, whether it is involved by chief cell hyperplasia or adenoma. Fortunately, with the advent of intraoperative PTH measurement, the surgical approach is often guided by visualization of normal glands and normalization of PTH after removal of an enlarged gland, rather than frozen section. Therefore, pathologists are much less often faced with this differential diagnosis and parathyroid frozen section practice has been reduced to confirming the presence of parathyroid tissue.

Normal Anatomy

Grossly the lungs are subdivided into lobes, three on the right (upper, middle, and lower) and two on the left (upper and lower). Each lobe is supplied by a dedicated lobar bronchus with a companion artery and vein that subdivides into bronchopulmonary segments. Bronchopulmonary segments are of special importance to thoracic surgeons because they are amenable to surgical excision in those patients for whom less than lobectomy is preferred. The cut surface of normal lung is characterized by connective tissue septa that subdivide the parenchyma into polygonal pulmonary lobules (Fig. 10.1).

The two main components of the lung interstitium are the alveolar walls and the extra-alveolar connective tissue affiliated with bronchopulmonary bundles, interlobular septa, and visceral pleura.[1] The alveoli are normally covered primarily by type I pneumocytes with small attenuated nuclei and large cytoplasmic processes and cuboidal type II (granular) pneumocytes with a hobnail appearance; the latter produce surfactant and comprise the minority of alveolar lining cells in normal lungs but are the main proliferating component after alveolar injury.[2] The alveolar walls contain capillaries whose basement membrane fuses with that of the alveolar epithelium to constitute a single alveolar capillary membrane.[2]

The main types of bronchial and bronchiolar epithelial cells are basal cells, neuroendocrine cells, ciliated cells, serous cells, Clara cells, and goblet cells.[1,2] Goblet and ciliated cells decrease in number as one approaches the terminal bronchioles, whereas the number

Abstract

This chapter provides an overview of non-neoplastic and neoplastic disorders of the lung following a brief overview of normal gross and microscopic anatomy. Non-neoplastic diseases include common and uncommon infections, other non-infectious granulomatous diseases, and diffuse diseases that are common sources of diagnostic difficulty in surgical and transbronchial lung biopsies. Neoplastic diseases include mainly malignant epithelial tumors with special emphasis on current diagnostic criteria and the role of immunohistochemical and molecular tools for both classification and management. The chapter concludes with a review of less common tumors that may frequently complicate differential diagnosis in both small and large specimens.

of Clara cells increases proportionally. Clara cells have a secretory function and represent the main progenitor cells after bronchiolar injury. They are recognized—whether in normal, reactive, or neoplastic conditions—by the presence of apical secretory granules that are periodic acid–Schiff (PAS) positive and diastase resistant and have a dense appearance ultrastructurally. Airway-associated neuroendocrine cells are part of the diffuse neuroendocrine system and are numerous in the fetus and neonate but very scanty and difficult to demonstrate in the adult.[3]

Small clusters of neuroendocrine cells located within the epithelium of bronchi and bronchioles (and sometimes also at the level of alveoli) are referred to as *neuroepithelial bodies*; their function is unknown.[2]

Submucosal glands are associated with the larger bronchi; they are composed of both serous and mucous cells and are invested by a myoepithelial cell layer. In older individuals, these glands may exhibit oncocytic changes.

Structures sometimes seen in alveolar spaces that are of no diagnostic significance include fresh red blood cells (usually the result of surgical trauma), alveolar macrophages that are frequently pigmented in smokers, corpora amylacea (common in elderly people), and blue bodies (composed primarily of calcium carbonate).[4] The lungs of adult city dwellers often contain black anthracotic pigment (carbon); scattered birefringent silica crystals may also be found, a feature which, by itself, is not diagnostic of silicosis.

Megakaryocytes are a common incidental finding in the alveolar walls; the large, hyperchromatic, and distorted nuclei of these cells should not be misinterpreted as evidence of malignancy or viral infection.

Metaplastic bone is an age-related change sometimes seen in the bronchial cartilage; it may be accompanied by calcification and by bone marrow elements.

Lymph vessels follow the bronchovascular structures and are found mainly beneath the pleura and in septa, but not in alveolar walls. They drain to intrapulmonary peribronchial and hilar lymph nodes. The drainage is mainly cephalad, primarily through mediastinal lymph node groups, but also to abdominal lymph nodes.

Intrapulmonary lymph nodes may be found in the peribronchial region and occasionally as individual intraparenchymal nodules in the peripheral, subpleural lung.[5] The vasculature of the lung derives from the pulmonary vessels and bronchial vessels, the latter belonging to the systemic circulation. Pulmonary arteries have both an internal and external elastic membrane, whereas pulmonary veins have a single (outer) elastic layer.

Ectopic tissues sometimes occur in otherwise normal lung or form localized abnormalities and comprise skeletal muscle[6] (sometimes present extensively in the newborn lung, a condition known as rhabdomyomatosis[7]), neuroglial elements,[8] pancreas,[9] and adrenal cortex.[10] Histologically normal thyroid tissue occurs only rarely in the lung; whether all such cases represent metastases from well-differentiated carcinomas remains controversial.[11,12]

Non-Neoplastic Lesions

Biopsy

Lung biopsies performed to evaluate patients suspected of having non-neoplastic lung diseases come in many different shapes and sizes. Small closed biopsies are often done to minimize procedural risk and morbidity. The relative value of different procedures depends on the clinical and radiological setting. It is helpful, especially when interpreting smaller specimens, for the pathologist to know the clinical history and radiological findings before drawing a firm conclusion regarding the diagnosis. Basic facts such as patient age, whether or not the patient is immunocompromised, onset and tempo of disease progression (i.e. acute or chronic), localized versus diffuse radiological distribution of abnormalities, presence and degree of functional impairment, and occupational or travel history can be especially helpful in this regard.

The type of lung biopsy obtained is also important. Wedge biopsies have the highest sensitivity, specificity, and accuracy for nearly all non-neoplastic lung diseases, but smaller biopsies obtained through a bronchoscope using either a biopsy forceps (*transbronchial* biopsy) or a cryoprobe *(cryobiopsy)* are especially helpful in certain diseases like infections, sarcoidosis, diffuse alveolar damage (DAD), pulmonary alveolar proteinosis, eosinophilic pneumonia, and hypersensitivity pneumonia.[13] Histologic findings that complicate interpretation of transbronchial biopsies include a 'holes' or 'bubbles' artifact that mimics the appearance of exogenous lipid pneumonia,[14] procedure-related hemorrhage which is common, and mesothelial cells when the biopsy unintentionally captures pleural tissue.[15] Multiple-step sections are extremely helpful in maximizing the diagnostic yield of transbronchial lung biopsies, especially in patients suspected of having sarcoidosis.[16,17]

Surgical lung biopsies are especially useful in patients suspected of having idiopathic interstitial pneumonias, such as usual or nonspecific interstitial pneumonia (NSIP).[18] The lingula and right middle lobes may be appropriate biopsy targets depending on the

radiological distribution of abnormalities.[19] Areas of extreme scarring and honeycombing are likely to show only end-stage disease and therefore are not very informative. Ideally, samples should be obtained from two or three different areas.[18] A formalin-filled syringe attached to a small (25-gauge) needle may be used to gently infuse fixative into wedge biopsies until fully expanded. A simpler approach is to remove the staple line before teasing apart the lung parenchyma and using a fresh scalpel blade to breadloaf the sample from the nonpleural surface.[4] Routine submission of tissue for microbiologic studies has little value and is a procedure best reserved for patients in whom the clinical suspicion of infection is high.[20]

Cystic Diseases

Cystic lung diseases may be congenital or acquired, and each of these categories can be further subdivided into localized and diffuse diseases. Some of the diffuse diseases in which cysts are a prominent radiological finding (e.g. lymphangioleiomyomatosis, Langerhans cell histiocytosis [LCH]) are reviewed elsewhere.

Congenital Cystic Diseases

Congenital cystic disease is a generic term for any cystic process of the lung thought to be already present at birth.[21] Congenital cystic diseases are generally viewed as diseases of childhood, but they occasionally go undetected until adulthood.[22] The most common types of congenital cystic disease encountered in surgical pathology include congenital lobar overinflation (i.e. congenital lobar *emphysema*), congenital cystic adenomatoid malformation (CCAM) also referred to as congenital pulmonary airway malformation (CPAM), bronchogenic cyst, and pulmonary sequestration.[23] A significant overlap exists between these entities, suggesting a common pathogenesis.[24] Some patients also have extrapulmonary anomalies. Congenital cystic diseases of the lung are frequently diagnosed *in utero* and are associated with excellent postnatal outcomes in the absence of fetal hydrops or other severe congenital abnormalities.[25,26]

Congenital lobar overinflation (congenital lobar emphysema) occurs in young children. It affects only one of the upper lobes or the right middle lobe of the lung. Theories for its occurrence include mucosal folds, mucous plugs, and deficiencies in the bronchial cartilages. The pathologic change consists of massive overdistention of the alveolar spaces, not accompanied by tissue destruction. It is therefore not truly a cystic or an emphysematous process. Severe compression of the other pulmonary lobes may result from this lesion.

CCAM (CPAM) is characterized by the presence of variously sized intercommunicating cysts lined by cuboidal-to-ciliated pseudostratified columnar ('adenomatoid') epithelium (Figs. 10.2 to 10.4).[23,25–27] Those that are not detected prenatally usually present with respiratory distress in early infancy due to compression of lung tissue and mediastinal shift. They are usually solitary and involve a single lobe. Some go undetected until later in life when they may be complicated by mucinous adenocarcinoma with lepidic-predominant *(bronchioloalveolar)* growth patterns.[12,28] Three morphologic variants have been described based on size and number of cysts (Stocker types 1, 2, and 3).[27] These subcategories show significant histologic overlap limiting their value. They can be more simply divided into large (>2 cm) and small (<2 cm) cyst types, roughly corresponding to Stocker types 1 and 2, respectively.[23] Large cyst CCAMs can be unilocular or multilocular and show cystic spaces lined by ciliated respiratory epithelium. Mucinous columnar epithelium resembling gastric mucosa may be present in both the cyst wall lining and adjacent lung tissue. Small cyst CCAMs show a compact

Figure 10.2 Gross appearance of congenital cystic adenomatoid malformation of lung.

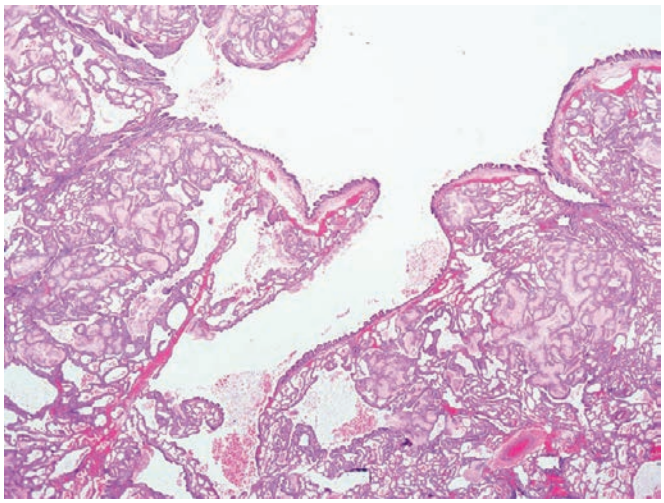

Figure 10.3 Microscopic appearance of large cyst (Stocker type 1) congenital cystic adenomatoid transformation. A large cystic air spaces is lined by ciliated respiratory epithelium and mucinous gastric-like epithelium is scattered throughout the adjacent lung parenchyma.

arrangement of irregularly shaped microcystic spaces and variable numbers of tubular bronchiole-like structures that lack companion arteries. Mucinous epithelium is less common than in large cystic variants.

Acquired cystic diseases of the lung are a heterogeneous group of unrelated lesions that have in common the presence of cysts on computed tomography (CT) scans of the chest. **Emphysema** is the most common form of acquired cystic disease and is defined as an increase in the size of airspaces distal to the terminal bronchiole associated with destruction of their walls.[29] Emphysema is the most important morphologic substrate of chronic obstructive pulmonary disease, which in turn is a leading case of disability and death. Emphysema is most commonly encountered as an incidental finding in surgical specimens excised for other reasons, in wedge resections following pneumothorax, as part of volume reduction surgery in patients with severe disease, or in explanted lungs from patients undergoing transplantation.[30–32] Emphysematous *bullae* are large (1 cm or greater) cystic spaces covered by a thin, stretched pleura. Giant bullae can result in an appearance vaguely reminiscent of chorionic villi, a change that has been designated as *placental transmogrification* (Fig. 10.5).[33] Symptoms may result from hemorrhage, infection, compression of adjacent lung, or pneumothorax. *Blebs* are formed by the rupture of an alveolus directly beneath the pleura and the escape of air into the areolar layer of the pleura, which results in interstitial emphysema. They are less than 1 cm in diameter. A bleb may rupture into the free pleural space, causing pneumothorax and *reactive eosinophilic pleuritic*, which is a common finding after pneumothorax of any cause.

Swyer–James (McLeod) syndrome, thought to be the result of repeated episodes of pulmonary infection, is characterized by the development of severe emphysema (occasionally accompanied by placental transmogrification), bronchiectasis, and/or bronchiolitis obliterans.[34]

Pleuropulmonary blebs and cysts (usually basilar) can represent the pulmonary component of the **Birt–Hogg–Dubé syndrome**, a rare genodermatosis associated with an increased risk of renal and colonic neoplasia.[35,36]

Chondroid cystic malformation associated with trisomy 8 mosaicism is a rare form of localized cystic lung malformation in which connective tissue septa contain cartilaginous islands.[37]

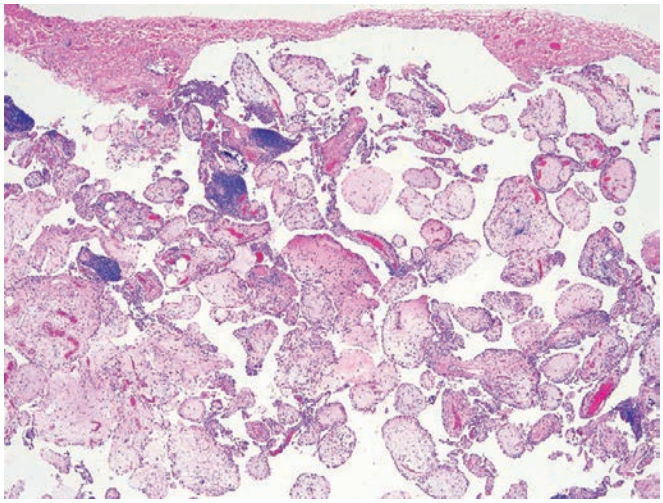

Figure 10.5 Microscopic appearance of placental transmogrification in which connective tissue papillae persist in a giant bulla resulting in an unusual histology that is reminiscent of chorionic villi.

Bronchopulmonary Sequestration

Bronchopulmonary sequestration is characterized by partial or complete separation of a portion of a lobe of the lung with a systemic arterial supply often affiliated with no connection to the functional components of the tracheobronchial tree *(bronchial atresia)*.[23] The pathogenesis of sequestration remains controversial, but most authorities argue persuasively that they are developmental abnormalities rather than acquired lesions.[23]

The **extralobar** variety develops from aberrantly located pulmonary mesenchyme as an extrapulmonary island of lung tissue enveloped by its own pleural covering. Extralobar sequestrations can be located at any level from the thoracic inlet to the diaphragm, or even within the abdominal cavity (Fig. 10.6).[23] About 90% of cases occur in the left side. Other congenital malformations, especially diaphragmatic hernias, occur in approximately 20% of patients. On occasion, the sequestered lung communicates with the foregut. An association with polyhydramnios and edema has been observed. The arterial supply is usually by one or several small arteries from the aorta or one of its branches. The venous drainage is into the azygos system.

The **intralobar** variety is a more heterogeneous group for which the alternative term *bronchial atresia with systemic vascular connection* has been proposed.[23] Intralobar sequestrations are much more likely to be symptomatic. They are characteristically located within the lower lobe, especially in the posterior basal segment, and are also more commonly located in the left lung (Fig. 10.7). Grossly, the sequestered portion may present as a single cyst, as a multicystic area, or as a solid mass. The segment is supplied by a *large* artery arising from the aorta or one of its branches; this artery arises above the diaphragm in 75% of the patients and below the diaphragm in the remainder. Despite its origin, the artery is always of the elastic pulmonary type. Microscopically the findings are relatively nonspecific, reflecting the consequences of proximal bronchial atresia and comprise a combination of chronic inflammation and fibrosis. Key to diagnosis is the surgeon's identification of a large elastic artery representing the systemic vascular connection.

Figure 10.6 Extralobar type of pulmonary sequestration. The lung has a spongy appearance and is covered by normal pleura.

Figure 10.7 Intralobar type of pulmonary sequestration. As is often the case with this variety, there are extensive secondary inflammatory changes. (Courtesy of Dr. J Costa, New Haven, CT.)

Figure 10.8 Localized bronchiectasis involving the lower lobe in a lung resected from a patient with a centrally obstructing endobronchial neoplasm.

Bronchiectasis

Bronchiectasis refers to the permanent dilation of bronchi usually associated with destruction of some elements of the bronchial wall and inflammatory changes that extend into the surrounding or distal lung parenchyma. It represents the end stage of a variety of unrelated disorders and can be divided into localized and diffuse forms.[38]

Localized bronchiectasis often results from partial or total obliteration of the bronchial lumen by a neoplasm, foreign body, localized inflammatory process, inspissated mucus, or external compression (e.g. broncholithiasis due to a calcified lymph node) (Fig. 10.8). It can occur in any area of the lung and follows the branching pattern of the obstructed bronchus. If the source of obstruction is relieved at an early stage, the bronchiectatic changes will regress; otherwise, the secondary inflammatory and fibrotic changes will render the condition irreversible. Localized bronchiectasis is a common finding in patients with middle lobe syndrome, a condition characterized by fixed radiological abnormalities limited to the right middle lobe and/or lingula.[39]

Diffuse bronchiectasis is a consequence of inflammation and postinflammatory destruction of airway walls that is usually the result of repeated episodes of infection. This is the form of bronchiectasis often seen in patients with cystic fibrosis (Fig. 10.9). Two other disorders associated with chronic sinonasal infection and frequent bronchiectasis are *Kartagener* or *immotile cilia syndrome (primary ciliary dyskinesia)*, associated with complete situs inversus and infertility, and *Young syndrome*, associated with infertility caused by azoospermia but lacking ultrastructural ciliary abnormalities.[40] The distribution of diffuse bronchiectasis depends on the underlying condition. For example, bronchiectasis patients with cystic fibrosis and allergic bronchopulmonary aspergillosis usually presents with upper lobe predominant disease.

Inflammation of the bronchial wall is a constant finding in bronchiectasis of any cause and usually includes a mixed infiltrate of both acute and chronic inflammatory cells. Lymphocytes often predominate and typically include lymphoid aggregates with secondary germinal centers (i.e. lymphoid hyperplasia). Areas of ulceration are common, but the residual epithelium is usually ciliated and otherwise normal; squamous metaplasia can occur, but it is unusual. In a more advanced stage, granulation tissue develops in the lamina propria, the cartilage is fragmented or destroyed, and the muscle is erased or undergoes focal hyperplastic changes. The mucous glands persist longer than other structures. The bronchial arteries often become greatly enlarged, tortuous, and thick walled. Distal lung parenchyma, including smaller airways, usually shows a range of nonspecific postobstructive changes that may include organizing pneumonia. Multiple carcinoid tumorlets may occur in distal lung parenchyma and should not be confused with metastatic disease.[41]

Complications of bronchiectasis such as bronchopleural fistula with empyema, brain abscess, and amyloidosis are no longer frequent. Conservative medical treatment focused on prevention or suppression of infection and early treatment for acute exacerbations is sufficient to control the disease in most patients.[38] Surgical resection is limited primarily to patients with localized disease in whom hemorrhage and/or repeated pulmonary infections cannot be controlled with more conservative measures.[42] Cystic fibrosis with respiratory failure is also an indication for double-lung transplants in highly selected patients.[43]

Abscess

In the pre-antibiotic era, solitary lung abscesses often followed tonsillectomies and other ear, nose, and throat operations. Presently,

Figure 10.9 Diffuse bronchiectasis in lung resected from a patient with cystic fibrosis.

Figure 10.10 Bronchopneumonia with abscess formation in a 2-year-old boy secondary to aspiration of a foreign body (timothy grass inflorescence). The first recorded case of this condition seems to be that recorded in a book entitled *Some account of Lord Boringdon's accident on July 21st, 1817, and its consequences* as follows: 'In 1662, Armand de Boutree, son of the Compte de Nogent, was seized with a violent fever, accompanied by a great difficulty in breathing, a dry cough, afterwards spotting of blood, sleeplessness, and great pain in the right side. A tumor at length appeared on that side, and a surgeon extracted from it an ear of barley almost entire which was quite green and had undergone no change.' (From Kissane JIM. *Pathology of Infancy and Childhood*. 2nd ed. St Louis, MO: Mosby; 1975.)

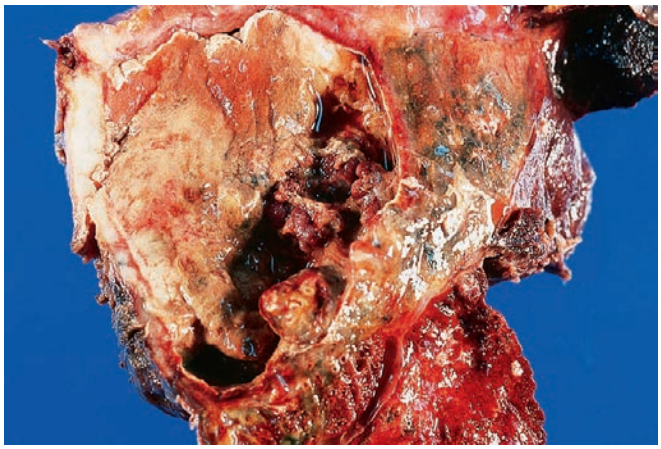

Figure 10.11 Large lung abscess.

most lung abscesses follow the aspiration of foreign material or are a complication of necrotizing pneumonia (Fig. 10.10).[44]

The most common locations of lung abscesses in surgical series are the right lower lobe, the right upper lobe (particularly the subapical segment), and the left lower lobe, in that order of frequency (Fig. 10.11).[44] The apical segment of the lower lobes is particularly vulnerable in patients who must assume a supine position. Anaerobic organisms are the agents that are most commonly responsible. Chronic abscesses have thick fibrotic walls and are surrounded by areas of organizing pneumonia.

Lung abscesses in children are most commonly due to *Streptococcus* species, *Staphylococcus aureus*, and *Klebsiella pneumoniae*.[45]

Complications of untreated lung abscesses include overgrowth of fungi (particularly *Mucor* and *Aspergillus*) in the cavity, spread of the process to other portions of the lung, massive hemorrhage, bronchopleural fistula with empyema, and brain abscess.

Intravenous antibiotics have been used successfully for the treatment of lung abscesses, particularly in children. For small unilocular abscesses, aspiration and drainage or partial resection of the lobe may be curative.[41] For larger lesions, lobectomy is preferable because it is associated with a much lower probability of postoperative complications such as bronchopleural fistula and empyema.

Granulomatous Inflammation

A large number of diseases in which granulomatous inflammation is a dominant feature involve the lung; some of them simulate radiological and gross features of neoplastic processes.[46,47] Microscopic examination is insufficient to establish a specific diagnosis in some patients; therefore it is important to submit a sample for culture and to perform stains for mycobacteria (Ziehl–Neelsen) and fungi (Gomori methenamine silver, GMS) in every case.[48]

Tuberculosis

Tuberculosis is second only to HIV as a cause for fatal infection in the developing world and remains a major global public health challenge.[49] The prevalence of tuberculosis in the United States has fallen dramatically since the early 1990s and is now more commonly

diagnosed in foreign-born rather than native-born persons.[50] Tuberculosis in foreign-born persons is most commonly the result of reactivation of infection with multidrug-resistant organisms acquired before entry into the United States; secondary transmission accounts for fewer newly diagnosed cases.[51] Most patients are diagnosed using a combination of skin testing, cultures, and other emerging techniques applied to sputum or blood.

Specimens harboring tuberculosis that are received in the pathology laboratory are usually from patients in whom some other diagnosis was suspected and may be a biopsy obtained with the fiberoptic bronchoscope, material procured via fine-needle aspiration, a surgical lung biopsy, or a resected lobe. There are still patients with pulmonary tuberculosis who fail medical therapy and therefore become candidates for therapeutic surgical intervention, but this is increasingly rare.[52] Historical indications for pulmonary resection were summarized by Strieder et al. as follows[53]:

1. Open cavity (with or without positive sputum) after a suitable period (4–6 months) on a satisfactory drug regimen
2. Residual caseous or fibrocaseous disease, with or without positive sputum
3. Irreversible destructive lesion, such as bronchostenosis or bronchiectasis
4. Recurrent or persistent hemorrhage, usually arising in a cavity or bronchiectasis
5. Thoracoplasty failure
6. Unexpandable lobe or lung, with associated chronic encapsulated tuberculous empyema
7. Suspected neoplasm.

The gross features of tuberculosis in tissue obtained for diagnosis differ from surgical specimens obtained from patients who have failed medical management in whom most of the resected tissue typically consists of inflamed, fibrotic, and otherwise nonfunctioning lung parenchyma (Fig. 10.12). Peribronchial tuberculous lymph nodes may infect the bronchial mucous glands by direct extension or penetrate the bronchial wall and erode into the lumen, especially when these nodes are calcified (i.e. broncholithiasis).

Tuberculous cavities removed in patients after prolonged antimicrobial therapy may show resolution into a stellate scar. In other patients the lesion stabilizes as a chronic open cavity that may harbor viable organisms in inspissated caseous material. Treated tuberculosis rarely resolves into a sterile cavity with a thin fibrous wall and a smooth surface that has no lining except for a short squamous segment at the point where the bronchus enters the cavity. Examination of these healed cavities for acid-fast organisms is invariably negative.

Tuberculomas, a term referring to localized conglomerates of necrotizing granulomatous infection due to *Mycobacterium tuberculosis* presenting as solitary lung nodules, are usually seen in adults and are a form of tuberculous reinfection. This is the form of tuberculosis most likely to be encountered by the surgical pathologist. Grossly, tuberculomas present as round, discrete, firm nodules (Fig. 10.13); they are usually solitary and located immediately beneath a white or slightly yellowish pleura. On section the lesions show central necrosis that may be complicated by calcification or cavitation. Microscopically, there is often central caseous necrosis characterized by paucicellular, granular, eosinophilic debris surrounded by a mixed inflammatory infiltrate that includes epithelioid and multinucleated giant cells with associated fibrosis (Fig. 10.14). Non-necrotizing granulomas are often present in the adjacent lung tissue. Specific pathogens cannot be reliably predicted on the basis of routine histologic finding in necrotizing granulomatous inflammation and frequently require special stains, cultures, or molecular studies for identification.[48] Organisms are usually present within the central zone of necrosis and can be demonstrated using Ziehl–Neelsen or other comparable stains for acid-fast bacilli (Fig. 10.15).[54] Highly sensitive molecular genetic techniques are available in a limited number of centers and may be helpful in highly selected cases.[55,56]

Atypical Mycobacteriosis

A significant number of granulomatous infections of the lung are caused by 'atypical' or 'unclassified' mycobacteria, such as *M. avium* complex (MAC), *M. kansasii*, *M. xenopi*, and *M. abscessus*.[56] Many of these cases are seen in immunocompromised hosts and/or in patients with preexisting lung disease, including chronic obstructive lung disease, previous tuberculosis, pneumoconiosis, bronchiectasis, and lung carcinoma. Infection due to *MAC* in elderly women may resemble the middle lobe syndrome (Lady Windermere syndrome). *Hot tub*

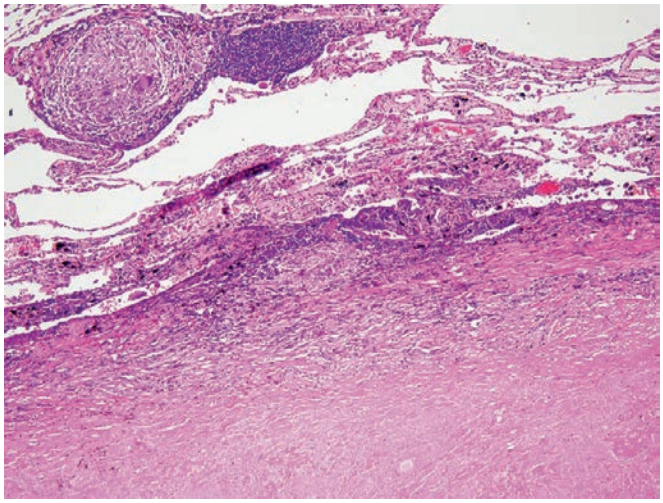

Figure 10.14 Tuberculosis. An area of caseous necrosis is bounded by a mixed inflammatory infiltrate that includes epithelioid and multinucleated histiocytes. A sarcoidal non-necrotizing granuloma accompanied the necrotizing granuloma.

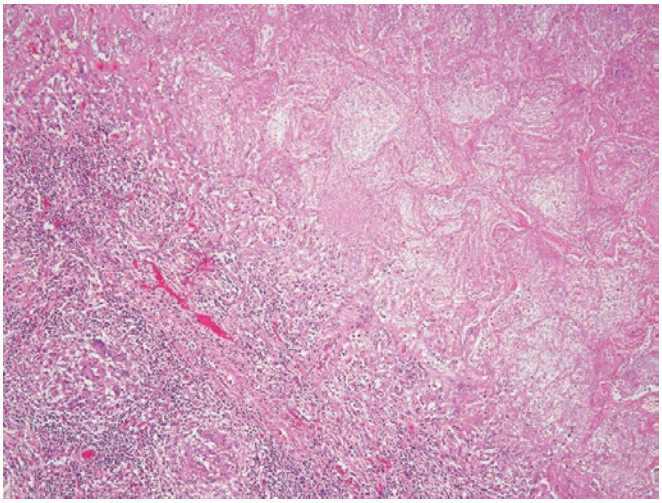

Figure 10.16 Atypical mycobacteriosis due to MAC. An area of necrosis showing 'infarct-like' features is surrounded by an inflammatory infiltrate that includes epithelioid and multinucleated histiocytes. Loose clusters of epithelioid and multinucleated giant cells also form non-necrotizing granulomas at the periphery. These histologic features are indistinguishable from those seen with other infectious granulomatous diseases including tuberculosis. Cultures from this case grew *M. avium* complex.

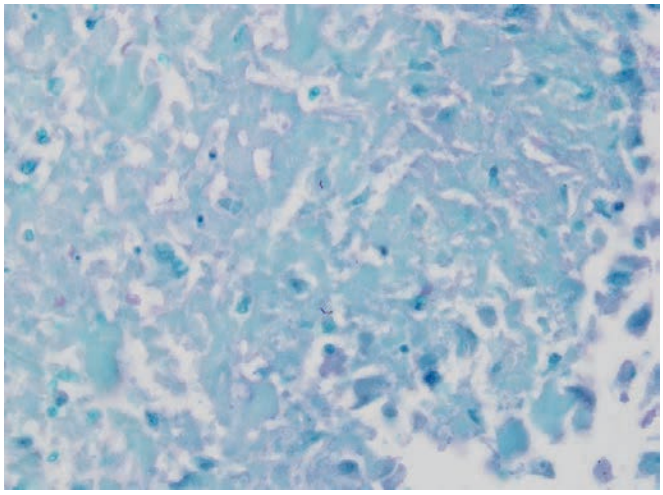

Figure 10.15 Tuberculosis. Ziehl–Neelsen stain demonstrating two acid-fast bacilli.

Figure 10.17 Coccidioidomycotic granuloma. The necrotic center is surrounded by fibrous tissue showing concentric lamination.

lung refers to a syndrome resembling hypersensitivity pneumonia resulting from exposure to hot tubs contaminated with nontuberculous mycobacteria.[46]

Infections by atypical mycobacteria cannot be distinguished from tuberculosis on the basis of their gross or microscopic appearance (Fig. 10.16).[48] The diagnosis may be suspected from the appearance of the organisms in acid-fast preparations, since they tend to be longer (about 20 µm), thicker, more coarsely beaded, and much more bent than tubercle bacilli. However, positive identification of the organism by culture and/or polymerase chain reaction (PCR) techniques is necessary for precise speciation.[56]

Other Granulomatous Infections

Granulomatous infections due to organisms other than tuberculous and nontuberculous mycobacteria likely to be encountered by surgical pathologists comprise mainly fungal infections that target immunocompetent as well as immunocompromised patients. Rates of disease for individual pathogens are linked to geographic variation in prevalence of the organisms. In North America those most likely to present as necrotizing granulomatous inflammation in surgical specimens include histoplasmosis, blastomycosis, cryptococcosis, and coccidioidomycosis.[46] These same organisms have a worldwide distribution, causing disease in Central and South America, parts of Asia, Africa, and Europe.

Granulomatous fungal infections have highly variable clinical manifestations, often presenting as asymptomatic solitary pulmonary nodules (Fig. 10.17). The inflammation in each of these conditions frequently includes a combination of necrotizing and non-necrotizing granulomas with overlapping histologic features making it difficult to predict a specific pathogen on the basis of the histologic findings alone. Diagnosis is dependent on identifying the organisms for which special stains (e.g. GMS) are extremely helpful (Fig. 10.18). *Blastomyces dermatitidis* (Fig. 10.19), *Cryptococcus neoformans* (Figs. 10.20 and 10.21), and *Coccidioides immitis* (Fig. 10.22) are visible on routinely stained sections in which their distinctive morphologic features are sometimes seen to better advantage. *Histoplasma capsulatum* is usually not visible on routinely stained sections except in

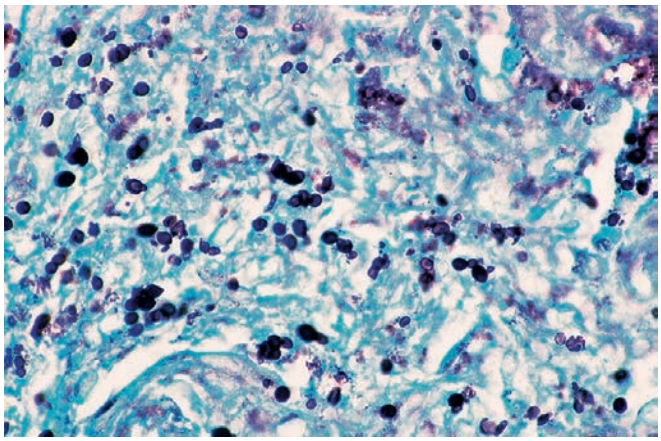

Figure 10.18 Pulmonary histoplasmosis. The organisms are demonstrated with the Grocott stain and are relatively small (1–5 μm) with a characteristic oval or teardrop shape.

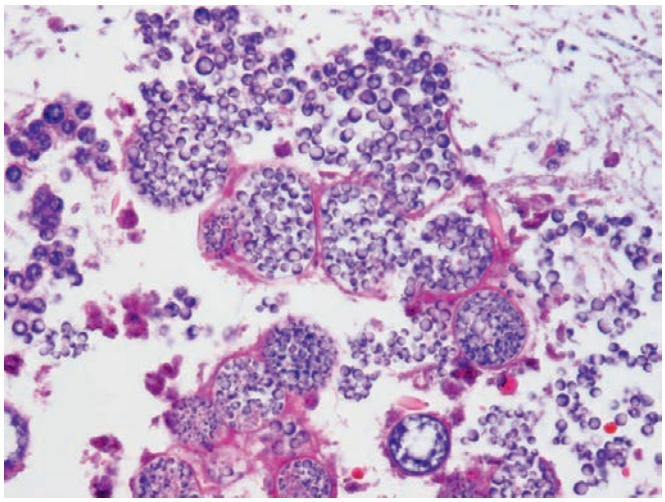

Figure 10.22 Microscopic appearance of *C. immitis* in a hematoxylin and eosin stain. Large (30–60 μm) intact and ruptured spherules contain much smaller (2–5 μm) endospores. In this example there are also mycelia *(upper right)* which is an uncommon finding.

disseminated histoplasmosis in which numerous organisms parasitize dense infiltrates of histiocytes without well-formed granulomas (Fig. 10.23).

Dirofilariasis of the lung usually presents as an incidental asymptomatic solitary nodule on chest radiographs or CT scans performed for other reasons, but it can also be multiple and/or symptomatic (Fig. 10.24). Microscopically, there is a histiocyte-rimmed necrotic nodule with marked eosinophilia containing fragments of *Dirofilaria immitis* (Fig. 10.25).[57]

Sarcoidosis

Sarcoidosis can present in the thoracic cavity in various ways: moderate to marked perihilar lymph node involvement without pulmonary disease, diffuse pulmonary disease without radiographic evidence of node involvement, a combination of lymph node enlargement and diffuse pulmonary disease, pulmonary interstitial fibrosis, and

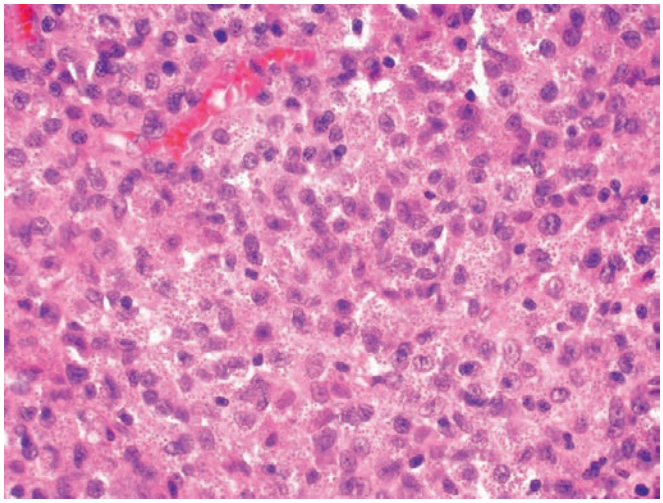

Figure 10.23 Disseminated histoplasmosis. Sheets of histiocytes demonstrate numerous organisms within their cytoplasm.

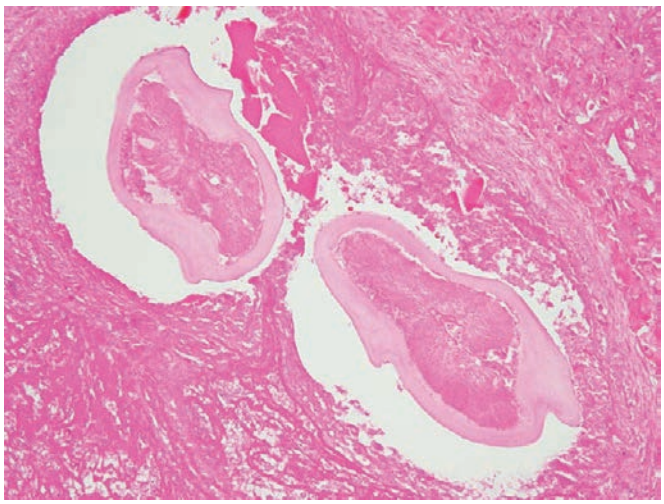

Figure 10.25 Microscopic appearance of *D. immitis* within the necrotic center of a dirofilarial nodule.

localized bronchostenosis with distal bronchiectasis and atelectasis.[58–60] The great majority of cases fall into the first and third categories. The etiology of sarcoidosis remains controversial.

Microscopically, the hallmark of the disease is a compact non-caseating granuloma composed of epithelioid cells, Langhans giant cells, and lymphocytes (Fig. 10.26). These compact, well-formed granulomas are confined to the interstitium, where they tend to be distributed along lymphatic pathways and may coalesce to form macroscopic nodules *(nodular sarcoidosis)* (Fig. 10.27).

There are many variations in this morphologic theme. Circumferential fibrosis, central hyalinization, and diffuse interstitial fibrosis in late stage disease may render the diagnosis difficult.[61] Small foci of necrosis having a bright eosinophilic ('fibrinoid') appearance may be found in the center of some granulomas. Intracellular and extracellular inclusions of several kinds may be seen, including birefringent calcium salts, but none is specific.[62] The granulomas often surround bronchioles (but not large bronchi); because of this, transbronchial lung biopsy is positive in more than 80% of the cases.[63] Granulomas are also frequently present around and within

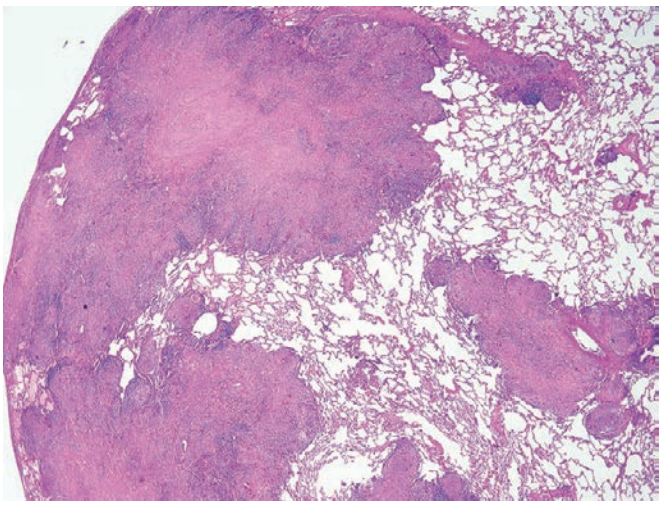

Figure 10.27 Sarcoidosis. Numerous granulomas with associated fibrosis form conglomerate nodules that expand visceral pleura, interlobular septa, and bronchovascular bundles in a characteristic 'lymphangitic' pattern.

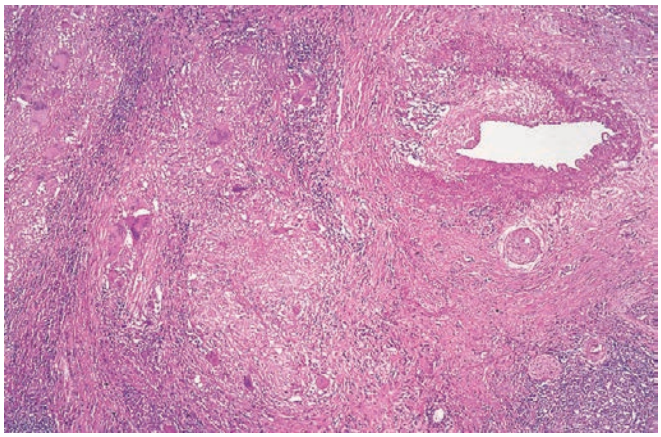

Figure 10.28 Necrotizing sarcoid granulomatosis. There is extensive involvement of large vessels by the inflammatory infiltrate, which has a necrotizing quality. Most authorities consider this a variant of nodular sarcoidosis.

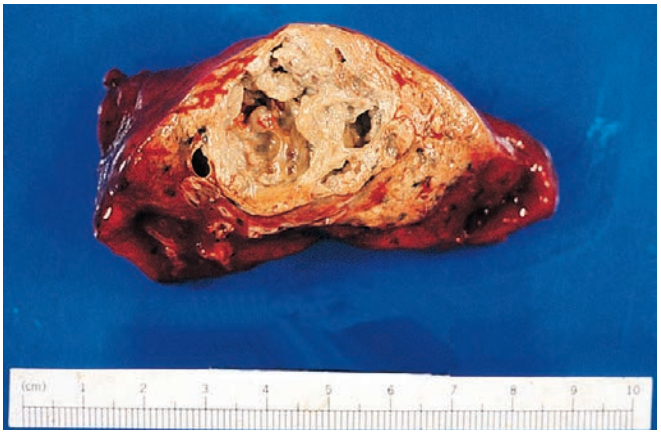

Figure 10.29 Granulomatosis with polyangiitis (Wegener's). The lesion is well circumscribed, with a granulomatous and partially necrotic appearance.

blood vessel walls including predominantly pulmonary veins, and may contribute to pulmonary hypertension.[64] Vascular necrosis, however, is not a feature.

Necrotizing sarcoid granulomatosis is the name given by Liebow to a pulmonary disease characterized by extensive vascular granulomas that infiltrate and occlude pulmonary arteries and veins and are accompanied by widespread necrosis of lung tissue (Fig. 10.28). The preponderance of evidence strongly suggests that this is a variant of nodular sarcoidosis.[65] Response to steroid and immunosuppressive drugs is good, and excision of localized lesions is usually curative.[66]

Granulomatosis With Polyangiitis (Wegener's)

Granulomatosis with polyangiitis (Wegener's), abbreviated *GPA*, is the term endorsed by a number of authoritative medical societies for the syndrome referred to historically as Wegener granulomatosis.[67] GPA is the best known member of the group of heterogeneous diseases designated by Liebow as *pulmonary angiitis and granulomatosis*. It is increasingly clear that this group comprises a number of totally unrelated entities, and it is therefore a term of historical interest but one that should not be retained for current disease classification. It is perhaps more useful to categorize GPA with the other antineutrophil cytoplasmic autoantibody (ANCA)-associated small vessel vasculitides: *microscopic polyangiitis* and *eosinophilic granulomatosis with polyangiitis (EGPA) (Churg–Strauss)*, an asthma-associated vasculitis referred to historically as Churg–Strauss syndrome.[68] ANCA characterized by a *cytoplasmic* (C-ANCA) staining pattern with immunofluorescence and/or corresponding antiproteinase three antibodies with the ELISA test are found in over 90% of classic cases of GPA and in about 60% of patients with limited disease and can be a useful adjunct in diagnostically challenging cases.[67]

GPA is defined by a combination of necrotizing granulomatous inflammation and necrotizing vasculitis targeting small to medium size vessels.[68] **Classic GPA** is characterized by the triad of necrotizing angiitis, aseptic necrosis (involving both the upper respiratory tract and the lungs), and focal glomerulitis.[66] Other vessels may be involved, such as the temporal artery and cutaneous small vessels, resulting in tumefactive lesions at extrapulmonary sites.[69] If untreated, the disease runs an accelerated clinical course; however, it has proved quite responsive to cytotoxic drugs (particularly cyclophosphamide) as first line induction therapy.[69] Current treatment strategies for refractory disease and maintenance therapy include a growing list

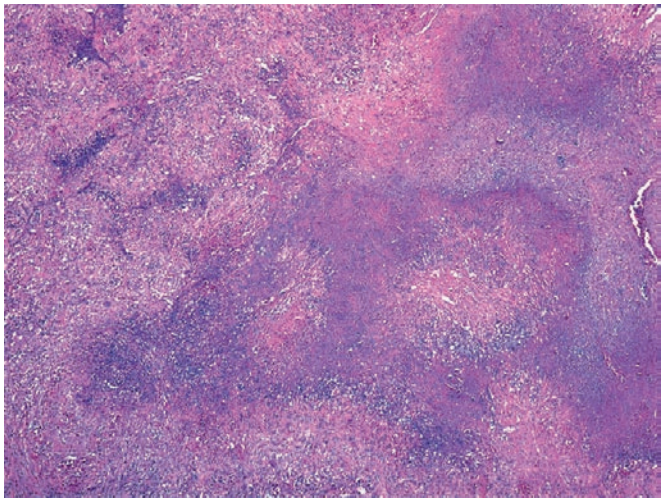

Figure 10.30 Granulomatosis with polyangiitis (Wegener's) demonstrating characteristic 'geographic' pattern of necrosis.

of novel agents such as rituximab which may selectively target vasculitis-associated changes while being relatively ineffective for granulomatous inflammation.[70]

The lungs are commonly involved at the time of diagnosis in patients with GPA. The main morphologic change in the lungs is necrotizing granulomatous inflammation grossly resembling other localized necrotizing processes (Fig. 10.29). The necrotic zones have an irregularly shaped *(geographic)* configuration at low magnification and are occasionally centered on airway lumens, a phenomenon that when dominant is referred to as the *bronchocentric variant* (Figs. 10.30 and 10.31).[71] The necrosis often has a characteristic 'dirty' basophilic appearance due to prominent karyorrhexis of neutrophils. Smaller granulomatous microabscesses with centrally necrotic zones containing nuclear dust surrounded by palisaded histiocytes and multinucleated giant cells are another distinctive form of granulomatous inflammation characteristic of GPA (Fig. 10.32). Well-formed non-necrotizing granulomas like those seen more commonly in granulomatous infections and sarcoidosis are generally not present in GPA.[72] In addition to neutrophils and modified histiocytes, the mixed inflammatory infiltrate invariably includes eosinophils, lymphocytes, and plasma cells in various proportions. Eosinophils are common and when conspicuous account for descriptions of the

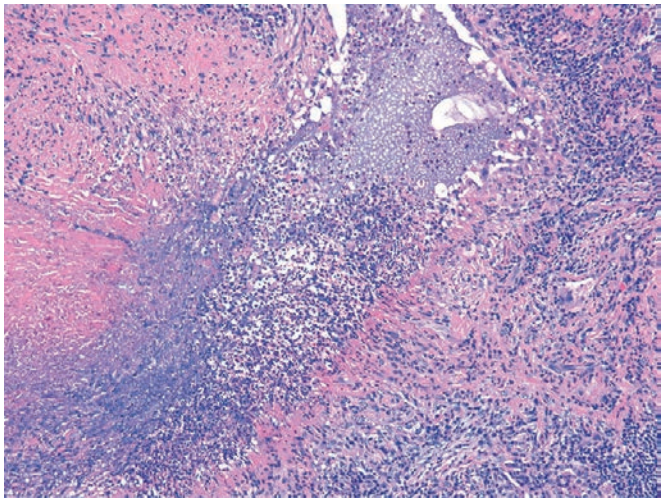

Figure 10.31 Bronchocentric variant of granulomatosis with polyangiitis (Wegener's) in which the necrosis is centered an airway lumen and the airway wall partially replaced by a granulomatous infiltrate comprising palisaded histiocytes.

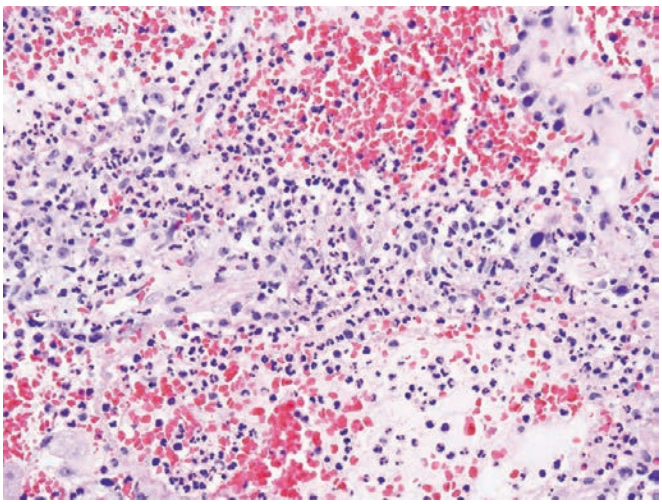

Figure 10.34 Capillaritis and alveolar hemorrhage in a patient with granulomatosis with polyangiitis (Wegener's).

eosinophilic variant.[73] Establishing the diagnosis with confidence requires a destructive leukocytolytic angiitis involving arteries and veins (Fig. 10.33).[73] The vasculitis is patchy in distribution characterized by abrupt transmural neutrophil-rich inflammatory infiltrates with associated karyorrhexis and vessel wall necrosis. Occasionally the necrotizing vasculitis includes granulomatous features in the form of multinucleated giant cells. In rare cases diffuse pulmonary hemorrhage with associated necrotizing capillaritis is a dominant feature, a combination of findings also seen in other vasculitic syndromes, including microscopic polyangiitis and systemic lupus erythematosus (Fig. 10.34).[74,75] The diagnosis of GPA can be made or suggested in transbronchial biopsy specimens.[76]

Limited (localized) GPA is confined to the lungs, more specifically with no renal involvement, and has a more protracted clinical course.[73] Steroids and cytotoxic drugs are highly effective. Grossly, there are multiple bilateral nodules, some round and others infarctlike, frequently located in the lower lobes. Microscopically, the disease is indistinguishable from the classic variety. Necrotizing vasculitis is a requisite for the diagnosis. However, it should be recognized that vessels located within ordinary infectious granulomas can exhibit secondary inflammatory changes that mimic vasculitis.[54] Therefore the presence of angiitis *away* from the areas of necrosis and massive inflammation should be searched for to document the diagnosis. The diagnosis of GPA should be made with caution in granulomas that appear solitary by radiographic examination.[77]

Eosinophilic Granulomatosis With Polyangiitis (Churg–Strauss)

EGPA (Churg–Strauss) is the current term for the disease referred to historically as Churg–Strauss syndrome.[66] EGPA is defined by a combination of necrotizing granulomatous inflammation, eosinophilia, and necrotizing vasculitis involving small and medium-size vessels. It presents a clinical picture of systemic vasculitis resembling polyarteritis nodosa but is associated with asthma, peripheral eosinophilia (up to 80%), and a higher incidence of pulmonary involvement.[78–80] In some patients this asthma-associated vasculitis syndrome may be unmasked or exacerbated when

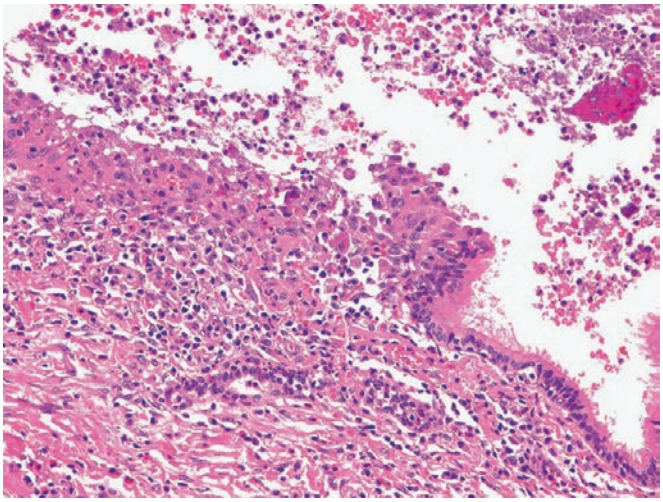

Figure 10.35 Bronchocentric granulomatosis in a patient with allergic bronchopulmonary aspergillosis. The bronchial wall is partially replaced by epithelioid histiocytes with associated eosinophilia.

Figure 10.36 Mucoid impaction of bronchi in a patient with allergic bronchopulmonary aspergillosis. Thick, tenacious secretions expand ectatic bronchi and in this patient formed a hilar mass for which clinical concerns included carcinoma.

transitioning from corticosteroids to steroid-sparing leukotriene receptor antagonists, such as montelukast, although the precise role that these agents have in the pathogenesis of vasculitis remains controversial.[81]

Microscopically, both the pulmonary and the extrapulmonary lesions are characterized by a prominent eosinophilic infiltrate, foci of necrosis (some associated with eosinophils and some unrelated to them), a granulomatous reaction around some of these necrotic foci, and necrotizing vasculitis. Finding all of these features in a single biopsy is uncommon, and therefore establishing the diagnosis on the basis of lung biopsy often requires careful correlation with other clinical and laboratory data. In lung biopsies, for example, the eosinophilic infiltrates often take the form of eosinophilic pneumonia, which is a relatively nonspecific finding in the absence of necrotizing granulomatous inflammation and/or necrotizing vasculitis. About 70% of patients will have a positive P-ANCA corresponding to an anti-myeloperoxidase (MPO) autoantibody by ELISA.[78]

Bronchocentric Granulomatosis, Mucoid Impaction of Bronchi, and Allergic Bronchopulmonary Mycosis

Bronchocentric granulomatosis is a form of necrotizing granulomatous inflammation in which all or nearly all the granulomas are centered on bronchi and bronchioles, leading to their destruction. Broncho- or bronchiolocentric necrotizing granulomatous inflammation is not specific to any one disease and can be seen in GPA as well as granulomatous infections. For that reason the term *bronchocentric granulomatosis* is generally limited to patients with **allergic bronchopulmonary aspergillosis**, a disease occurring almost exclusively in asthmatics and patients with cystic fibrosis in whom the bronchocentric granulomatosis (Fig. 10.35) is usually accompanied by eosinophilic pneumonia and mucoid impaction of bronchi.[82] Globally allergic bronchopulmonary mycosis can be due to other fungi, such as *Candida albicans*, *Bipolaris*, and *Curvularia* organisms.[83]

Mucoid impaction of bronchi is a process in which proximal ectatic bronchi become filled with thick inspissated mucus (Fig. 10.36). This change may cause localized radiological abnormalities for which diagnostic considerations include neoplasms. Occasionally patients expectorate these histologically distinctive plugs that comprise a combination of inspissated mucus, necrotic eosinophils, and Charcot–Leyden crystals distributed in a layered fashion resembling the rings of a tree (Fig. 10.37).

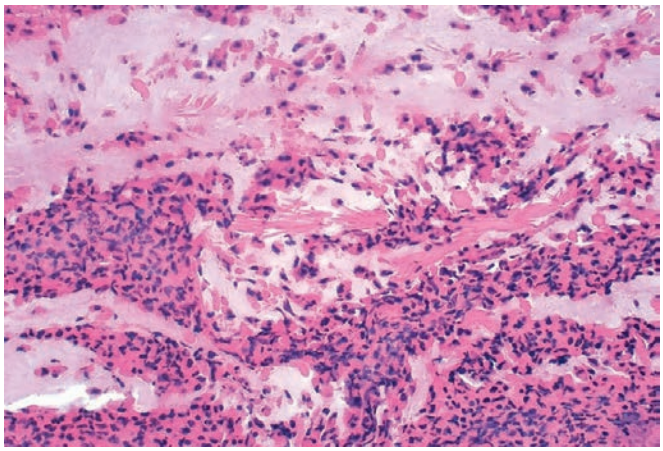

Figure 10.37 Mucoid impaction of bronchi showing the 'allergic mucin' typical of allergic bronchopulmonary aspergillosis including numerous Charcot–Leyden crystals.

Other Granulomatous Inflammations

Granulomas are occasionally seen in other noninfectious conditions, including aspiration of particulates and drug abuse in which inorganic fillers common in the oral medications used instead for intravenous injection elicit a perivascular granulomatous response (Fig. 10.38). Occasionally granulomas are present in diffuse lung diseases other than sarcoidosis, including most commonly hypersensitivity pneumonia, lymphoid interstitial pneumonia, and related forms of lymphoid hyperplasia, and eosinophilic pneumonia.

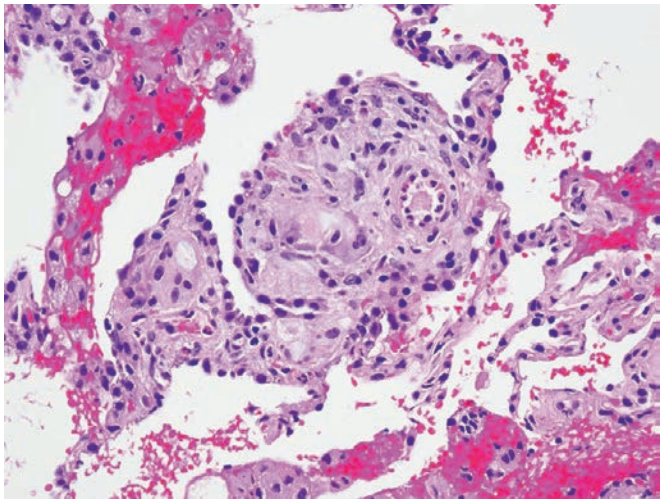

Figure 10.38 Drug abuser's lung in which perivascular granulomas include foreign body giant cells containing birefringent particulates, in this case a combination of talc and cellulose.

Table 10.1 Classification of idiopathic interstitial pneumonias[18]

Chronic fibrosing interstitial pneumonias	UIP NSIP
Smoking-related interstitial pneumonias	RBILD SRIF
Acute/subacute interstitial pneumonias	Diffuse alveolar damage Organizing pneumonia
Rare interstitial pneumonias	LIP Pleuroparenchymal fibroelastosis Unclassifiable interstitial pneumonia

LIP, Lymphoid interstitial pneumonia; *NSIP*, nonspecific interstitial pneumonia; *RBILD*, respiratory bronchiolitis-interstitial lung disease; *SRIF*, smoking-related interstitial fibrosis; *UIP*, usual interstitial pneumonia.

Diffuse Interstitial Lung Disease

This is a complex group of non-neoplastic pulmonary diseases that often require correlation of morphologic, clinical, and radiological findings. High-resolution computed tomography (HRCT) represents a major advance in this area, and a multidisciplinary approach provides at present the highest levels of diagnostic reproducibility.[84]

Idiopathic interstitial pneumonias account for a substantial subset of the diffuse lung diseases that a surgical pathologist is likely to encounter and can be divided into *chronic fibrosing* interstitial pneumonias, *smoking-related* interstitial pneumonias, and the *acute or subacute* interstitial pneumonias (Table 10.1).[18] The chronic fibrosing interstitial pneumonias comprise the largest category and account for over 80% of patients with idiopathic interstitial pneumonia who undergo surgical lung biopsy.[85–88] The same range of histologic abnormalities also occur in patients with underlying connective tissue diseases, a distinction that hinges in large part on clinical and laboratory studies.

Usual interstitial pneumonia (UIP) is the most common of the idiopathic interstitial pneumonias, accounting for nearly two-thirds of patients who undergo biopsy for diffuse lung disease of unknown cause.[85–88] Most patients with UIP fall into the clinical category of idiopathic pulmonary fibrosis (IPF), a syndrome that classically has

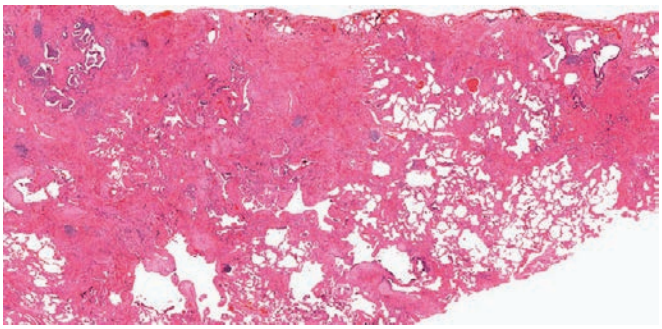

Figure 10.39 Usual interstitial pneumonia. Patchwork pattern of fibrosis with scarring and honeycomb change is characteristic.

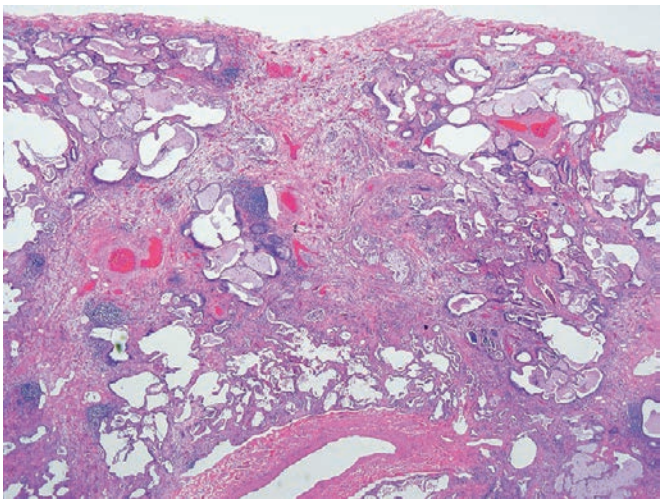

Figure 10.40 Usual interstitial pneumonia. Characteristic appearance of honeycomb change.

an insidious onset characterized by a combination of breathlessness and cough with a relentlessly progressive evolution, many of the patients dying of respiratory failure after 3–4 years.[4] Acute exacerbation is increasingly recognized as a common final pathway in patients with underlying UIP and is characterized by sudden worsening of symptoms and more rapid progression of respiratory failure.[89] Some instances of UIP show a familial pattern indicating a heritable predisposition.[90] Others have underlying systemic connective tissue diseases, most commonly rheumatoid arthritis, scleroderma, and systemic lupus erythematosus.

Microscopically, UIP is a primarily interstitial fibrosing process. According to Katzenstein et al., the single most important feature that distinguishes UIP from the other interstitial pneumonias (including so-called NSIP) is the marked regional variation in the nature and degree of the fibrosis, with a distinct patchwork distribution and evidence of architectural derangement (Fig. 10.39).[91–93] The architectural derangement takes the form of scarring and *honeycomb change*, the latter referring to cystic spaces situated within distally collapsed, fibrotic lung (Fig. 10.40). Areas of fibrosis in UIP are often most advanced in peripheral, subpleural lung where it is frequently associated with smooth muscle hyperplasia. Small *fibroblast foci* are often sandwiched between surface epithelium and fibrotic scar and are composed of spindled fibroblasts and myofibroblasts organized in a vaguely linear fashion within a pale-staining stroma (Fig. 10.41).[91] These findings are complicated by a superimposed pattern of acute lung injury that usually takes the form of organizing DAD in patients with acute exacerbation.[94] Less commonly patients

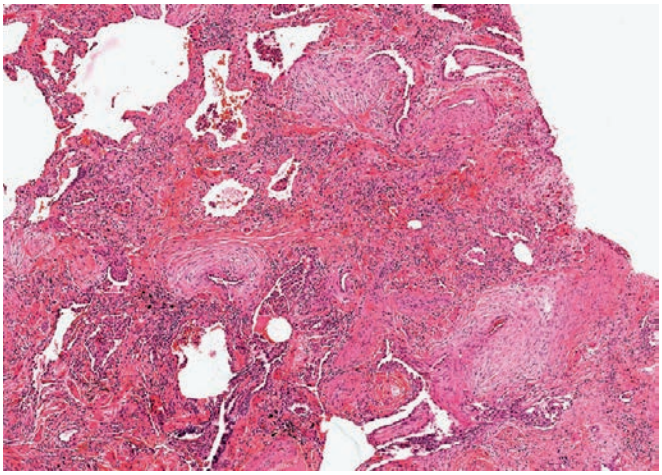

Figure 10.41 Usual interstitial pneumonia with prominent fibroblast foci. Fibroblast foci resemble organizing pneumonia except for their interstitial location.

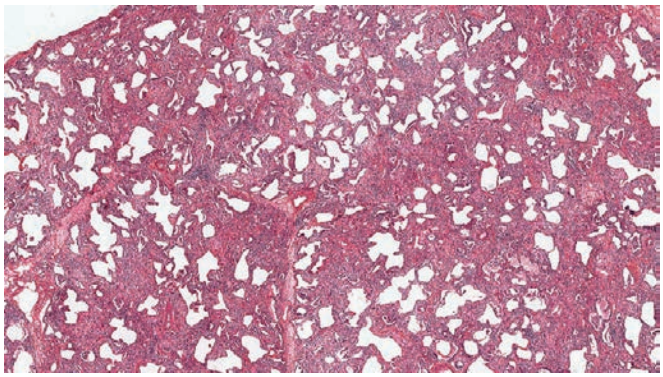

Figure 10.42 Nonspecific interstitial pneumonia demonstrating the diffuse uniform interstitial widening without the patchwork fibrosis or honeycomb change typical of UIP.

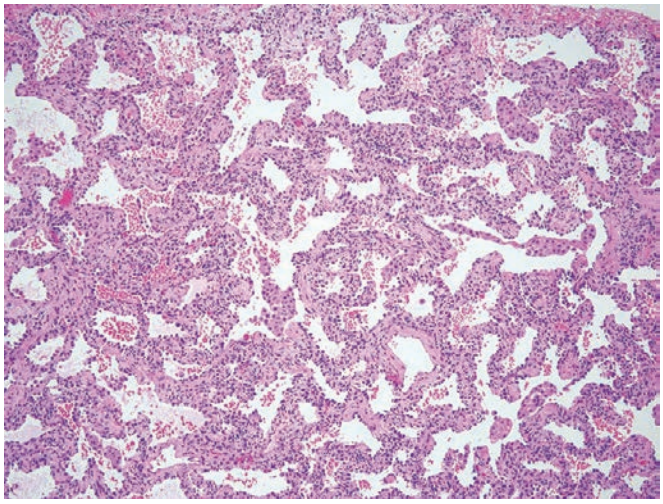

Figure 10.43 Cellular NSIP. Alveolar septa are uniformly expanded by cellular infiltrate with minimal fibrosis.

with acute exacerbation show a combination of UIP and organizing pneumonia. Patchy changes resembling eosinophilic pneumonia have also been described in UIP and appear to have limited clinical significance.[95]

Ultrastructural studies suggest that fibroblast foci are foci of abnormal wound healing in which activated mesenchymal cells migrate from the interstitial into the intraluminal compartment through defects in the basement membrane following epithelial necrosis, resolving through a disordered process of alveolar collapse, reepithelialization, and remodeling.[96,97] Fibroblast foci are characteristic of UIP but are not specific and can be seen in other diffuse lung diseases. They are the consequence of aberrant activation of epithelial cells and fibroblasts in lungs with an aging phenotype leading to accumulation of extracellular matrix and architectural distortion.[98]

NSIP/fibrosis is a term that was originally used for cases that could not be classified into any of the major categories of interstitial pneumonia, but which has now acquired an identity of its own.[18,99,100] Patients with NSIP fall into several different categories, including a subset with underlying systemic connective tissue disorders in which NSIP is the most common form of diffuse fibrotic lung disease.[101] NSIP is the second most common finding in patients with interstitial pneumonias of unknown cause ('idiopathic NSIP').[100] In either circumstance patients with NSIP generally have a better prognosis than patients with UIP.[102]

The main morphologic difference with UIP is that NSIP lacks the heterogeneous pattern of lung involvement characteristic of the former (Fig. 10.42).[18,85,91,99,102–104] The changes in NSIP may be patchy or diffuse but retain a degree of qualitative uniformity in areas of abnormality that set it apart from UIP. Interstitial structure including alveolar septa are expanded by an inflammatory infiltrate with ('fibrotic NSIP') or without ('cellular NSIP') collagen fibrosis (Fig. 10.43). Even with fibrosis, NSIP lacks the architectural derangement typical of UIP and instead is characterized by relative preservation of lung structure. Focal areas resembling NSIP can occur in otherwise classical UIP, which is why deciding that NSIP is a representative finding even in surgical lung biopsies requires careful correlation with clinical and radiological information.[91,92,104]

Respiratory bronchiolitis is a common incidental finding in heavy smokers but in some instances accounts for a form of symptomatic diffuse lung disease referred to as **respiratory bronchiolitis-interstitial lung disease** (RBILD).[105,106] Histologically, respiratory bronchiolitis is characterized by an accumulation of lightly pigmented alveolar macrophages within respiratory bronchioles spilling into neighboring alveoli (Fig. 10.44). The changes differ from the lesion referred to historically as desquamative interstitial pneumonia (DIP) in that the histiocytic accumulation is centriacinar instead of diffuse and lacks an associated interstitial pneumonia. Occasionally, RBILD is accompanied by mild, paucicellular fibrosis in the form of lamellar eosinophilic collagenous thickening of alveolar septa in a patchy, mainly subpleural distribution, a condition referred to as **smoking-related interstitial fibrosis** (SRIF) (Fig. 10.45) that is not to be confused with chronic fibrosing interstitial pneumonias such as UIP and NSIP.[107] The presence or absence of SRIF is not helpful in distinguishing patients with incidental respiratory bronchiolitis from those with RBILD, a distinction that is primarily dependent on clinical and radiological data. It is likely that SRIF in patients with symptomatic lung disease not attributable to COPD includes what would have been referred to historically as DIP.

DIP was defined historically by a filling of the alveolar spaces by large mononuclear cells, associated with relatively minor interstitial changes (Fig. 10.46).[108] Ultrastructurally, the cells that were originally thought to be desquamated pneumocytes have features of macrophages instead, making the term *DIP* a misnomer. Katzenstein and others have proposed that patients previously diagnosed as DIP are more properly categorized today as RBILD, SRIF, or NSIP, and therefore

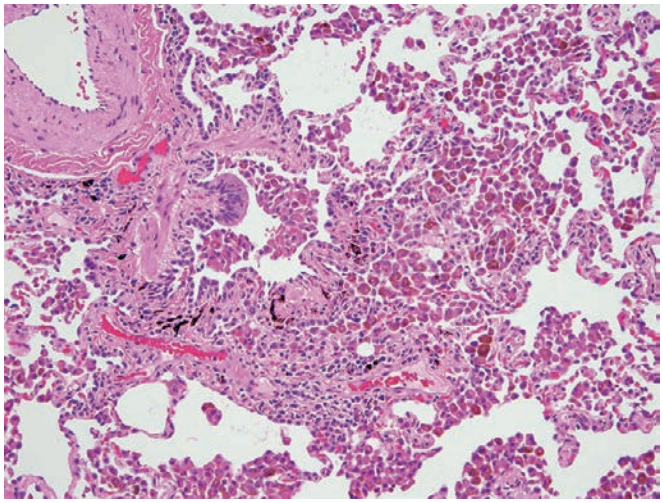

Figure 10.44 Respiratory bronchiolitis. Pigmented (smoker's) macrophages are clustered in the lumens of distal airways and peribronchiolar air spaces. The smoking-associated pigment is positive with Prussian-blue iron stains and should not be confused with hemosiderin.

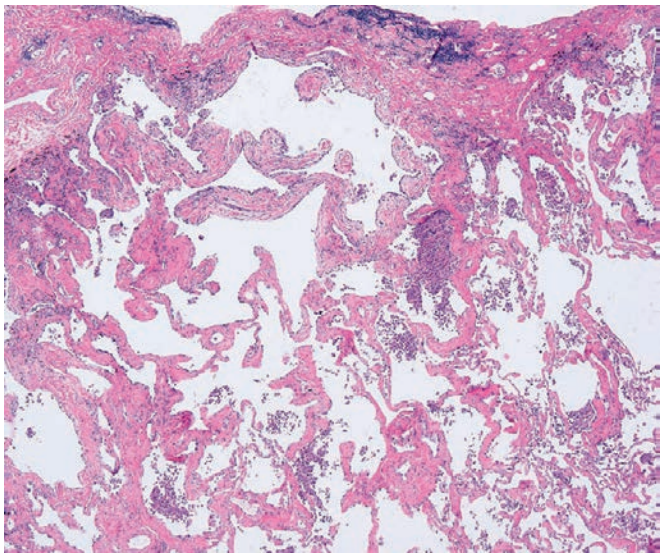

Figure 10.45 Smoking-related interstitial fibrosis. Subpleural septa are expanded by deeply eosinophilic collagen but without the patchwork distribution or honeycomb change characteristic of UIP. There is associated emphysema and respiratory bronchiolitis.

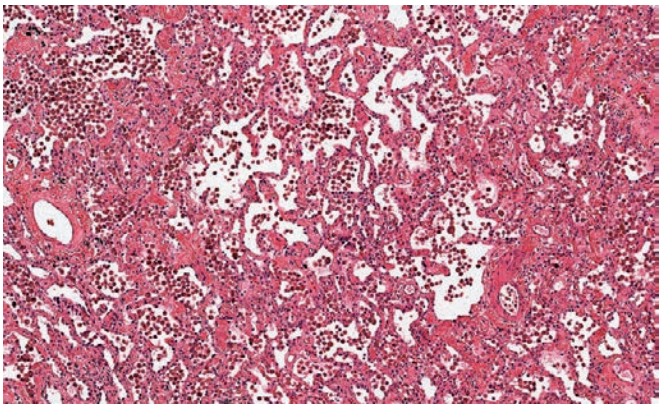

Figure 10.46 Desquamative interstitial pneumonia, an increasingly anachronistic term that should be abandoned in favor of the more modern alternatives NSIP, RBILD, or SRIF with considerable overlap between the latter two. Pigmented ('smoker's') macrophages identical to those illustrated in RBILD are more extensively distributed within alveolar spaces.

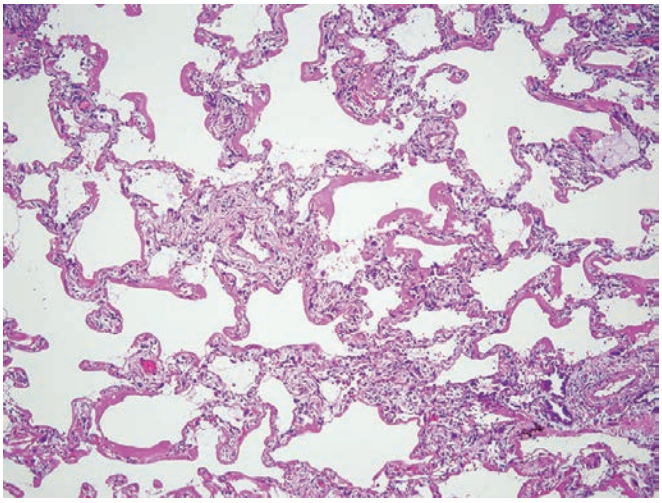

Figure 10.47 Diffuse alveolar damage in the acute phase with well-formed hyaline membranes.

the term DIP should be abandoned (personal communication). Others have argued for continued use of the term, citing potentially important prognostic differences.[109] Whatever terminology one prefers for this uncommon group of overlapping conditions the important point is to avoid confusing them with UIP given that all of them have a better prognosis and frequently benefit from some combination of smoking cessation and steroids.[110]

DAD is usually diffuse and bilateral in patients with the acute respiratory distress syndrome (ARDS).[111] It may be caused by infectious agents (particularly viruses), inhalants (such as oxygen), drugs (especially chemotherapeutic agents), ingestants (such as kerosene or paraquat), shock, sepsis, radiation, and acute exacerbation of UIP.[111,112] With the exception of pathogens detectable on routine histology or with special stains, the cause of DAD cannot be determined from the microscopic picture alone. The earliest stages consist of edema, intra-alveolar hemorrhage, and fibrin deposition. This is followed by hyaline membrane formation (most prominent 3–7 days after the injury), a sparse interstitial inflammatory infiltrate, fibrin thrombi (inconstant), and hyperplasia of the alveolar lining cells (Fig. 10.47). These cells, which are mainly reparative type II (granular) pneumocytes, may exhibit atypia, mitotic activity, and cytoplasmic hyaline bodies. A distinctive form of squamous metaplasia in bronchiolar epithelium combined with cytologic atypia can be pronounced enough to mimic a squamous cell carcinoma.[113] Foamy alveolar macrophages may also be present and may be more common in cases resulting from amiodarone.[114] In a later (organizing) stage, there is interstitial and intraluminal proliferation of organizing fibroblasts and myofibroblasts associated with persistence of the hyperplastic lining cells and collapse of alveolar structures resulting in marked architectural remodeling (Fig. 10.48).[97]

Acute interstitial pneumonia (AIP) is a rapidly progressive form of idiopathic interstitial pneumonia and is synonymous with the *Hamman–Rich syndrome*.[115,116] By definition, there is no identifiable initiating event. The typical patient is a young adult who presents with dyspnea following an influenza-like illness. The prognosis is very poor, with most patients dying within 2 months of onset.

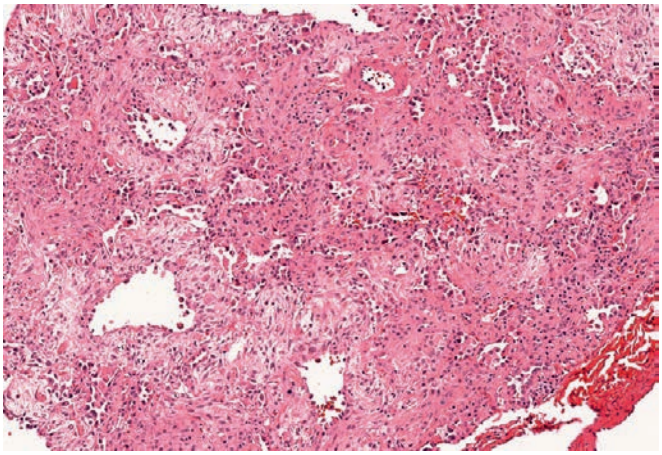

Figure 10.48 Diffuse alveolar damage in the organizing phase accompanied by alveolar collapse.

Microscopically, the appearance is equivalent to that of the organizing phase of DAD, the most striking feature being the interstitial expansion and distortion by organizing fibroblasts and myofibroblasts.

Organizing pneumonia, also termed bronchiolitis obliterans–organizing pneumonia (BOOP), is a nonspecific form of organizing acute or subacute lung injury that is associated with several conditions, including infections, inhalants (including silo-filler's lung), drugs, and collagen-vascular diseases. Organizing pneumonia occasionally occurs as a form of diffuse lung disease of unknown ('idiopathic') cause termed *cryptogenic organizing pneumonia (COP)*, a syndrome referred to historically as idiopathic BOOP.[18,117,118] COP is frequently grouped with the idiopathic interstitial pneumonias, but the clinical and radiological findings at presentation more closely mimic the features of infectious pneumonia. The onset is usually acute and characterized by cough, dyspnea, fever, and malaise. Less commonly COP presents as a solitary radiological opacity that may be asymptomatic and mimic the appearance of a neoplasm, a variant to which some have applied the term *focal organizing pneumonia* (Fig. 10.49).[119] The prognosis is generally excellent; patients requiring treatment often improve with sustained corticosteroids but may relapse when their steroid dose is tapered.[120] Morphologically, the hallmark of organizing pneumonia in any clinical context is represented by fibroblastic plugs ('Masson bodies') filling air spaces (Fig. 10.50). These plugs have a typical elongated to serpiginous, bifurcating shape reflecting the configuration of distal bronchioles and alveolar ducts and are formed by spindle to stellate fibroblasts embedded in a pale-staining matrix. Other changes include clusters of foamy macrophages, a few scattered neutrophils, and thickening of alveolar septa in the areas of intraluminal fibrosis. It is characteristic for the process to have a patchy appearance on low-power examination, a feature of importance in the differential diagnosis with UIP (see earlier). The rare cases of COP with unfavorable outcome (steroid unresponsive) have shown scarring and remodeling of the lung parenchyma on microscopic examination, suggesting an underlying chronic fibrosing lung disease.[121]

Lymphoid (lymphocytic) interstitial pneumonia (LIP) is characterized by a lymphocytic infiltrate with associated lymphoid follicles, often admixed with histiocytes and plasma cells, that expands alveolar septa and peribronchiolar interstitium.[122,123] Although included by some as a rare form of idiopathic interstitial pneumonia, LIP is a lymphoproliferative disorder analogous to reactive lymphoid hyperplasia that overlaps clinically, radiologically, and histologically with follicular bronchiolitis.[122] A third of the cases have been

Figure 10.49 Hilar mass that was considered radiographically to be carcinoma but proved pathologically to be organized pneumonia.

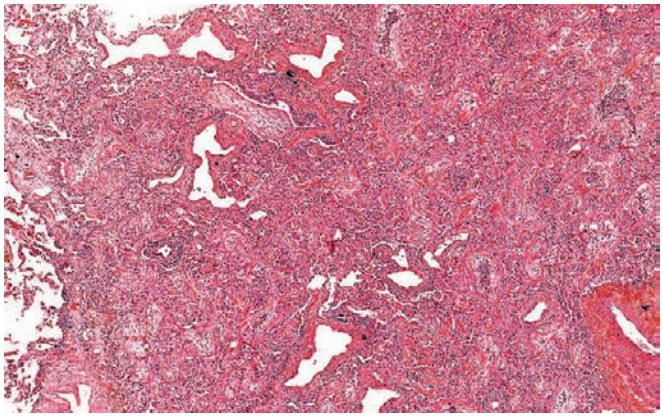

Figure 10.50 Cryptogenic organizing pneumonia showing characteristic intraluminal plugs of organizing fibroblasts and myofibroblasts. The central portion of some of the plugs show an infiltrate of chronic inflammatory cells, a nonspecific finding of no special significance.

associated with Sjögren syndrome, a circumstance in which distinction from marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT) may be challenging. Another large subset of cases are associated with underlying immunodeficiencies, including HIV infection and common variable immunodeficiency. Some of the cases have been incorporated into the ever-enlarging spectrum of IgG4 disease.[124] The radiological appearance is that of interlobular septal lines often accompanied by ground-glass opacities and cysts. Cysts occur especially in patients with underlying Sjögren's syndrome, including some with diffuse variants of MALT lymphoma, often with associated amyloid or non-amyloid light chain deposition.[125] Histologically alveolar septa are expanded by a cellular infiltrate

composed of a combination of lymphocytes and plasma cells with prominent peribronchiolar lymphoid follicles, many of them with secondary germinal centers (Fig. 10.51).[123,126] Non-necrotizing granulomas accompany the infiltrates in some cases. Granulomas are especially common in patients with common variable immunodeficiency for which the term *granulomatous and lymphocytic interstitial lung disease* is sometimes used.[127]

LIP overlaps with **follicular bronchitis and bronchiolitis**, a nonspecific inflammatory reaction in which reactive germinal centers are seen adjacent to airways in the absence of chronic obstructive pulmonary disease. Follicular bronchitis/bronchiolitis is a common secondary finding in bronchiectasis but also occurs as a primary lymphoproliferative disorder in the same clinical circumstances described for LIP.[123,128]

Pleuroparenchymal fibroelastosis (PPFE) is a rare pattern of diffuse lung fibrosis with histologic features that overlap with the much more common *apical cap*, a localized form of fibroelastosis unique to the lung apices and superior segments of the lower lobes.[129] PPFE tends to preferentially affect the upper lobes and is exquisitely localized to peripheral subpleural parenchyma and bronchovascular bundles (Fig. 10.52).[130] PPFE is not a specific disease in that this pattern of fibrosis occurs in a number of clinical scenarios, including lung and stem cell transplants, drug-induced lung disease, and connective tissue disease.[131,132] Importantly this form of peripheral fibroelastosis can also coexist with other forms of diffuse fibrotic lung disease, most importantly UIP.

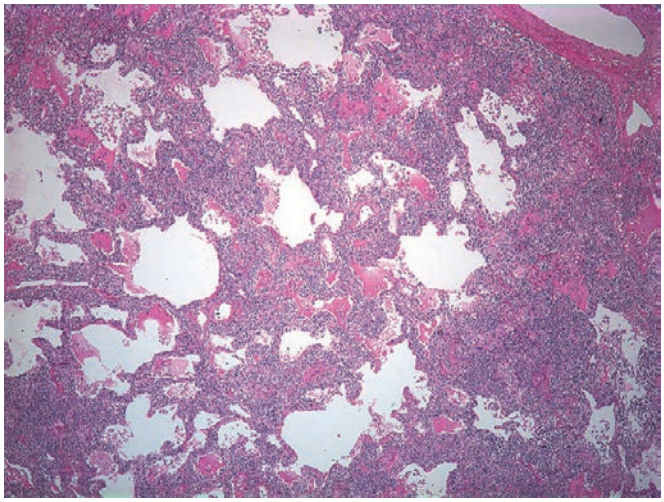

Figure 10.51 Lymphoid interstitial pneumonia in a patient with Sjögren syndrome.

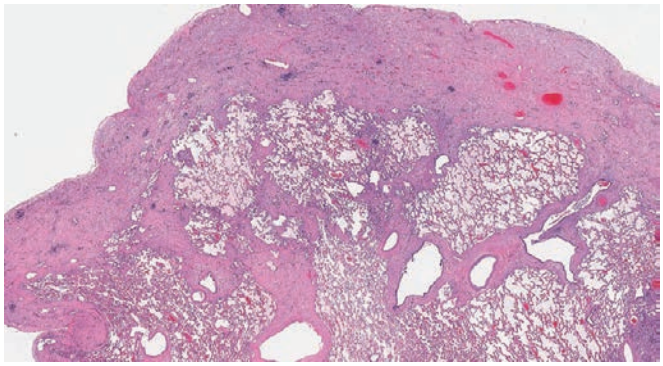

Figure 10.52 Pleuroparenchymal fibroelastosis.

Hypersensitivity Pneumonia (Extrinsic Allergic Alveolitis)

Hypersensitivity pneumonia (extrinsic allergic alveolitis) is the generic term given to an acute, subacute, or chronic inflammatory process representing a tissue reaction to an inhaled allergen.[133] Patients suffering from this condition have both cellular and humoral immune processes directed against the organic allergen. The most common offending antigens include thermophilic bacteria (e.g. farmer's lung, humidifier lung), molds (e.g. Japanese summer type hypersensitivity), and avian proteins (e.g. pigeon breeder's lung). In acute hypersensitivity pneumonia, fever and dyspnea develop a few hours after exposure to relatively high doses of the offending antigen. With repeated exposures, often to relatively low doses of an environmental antigen that may be unknown to the patient, a chronic fibrosing lung disease develops than can mimic many of the features of IPF.

Microscopically, classical hypersensitivity pneumonia is characterized by a combination of a cellular interstitial pneumonia that tends to be accentuated around airways *(bronchiolocentric)*, equally cellular chronic bronchiolitis, and a distinctive pattern of granulomatous inflammation (Figs. 10.53 and 10.54). This combination of findings predicts for the diagnosis of hypersensitivity pneumonia even in patients for whom no exposure was known prior to lung biopsy.[134,135] Fibrosis occurs in some patients and when advanced can closely mimic UIP or the fibrotic stage of NSIP; the presence of isolated giant cells, poorly formed granulomas, and/or Schaumann bodies in a peribronchiolar location should suggest the right diagnosis.[136] Fibrosis is associated with a generally poor prognosis.[137]

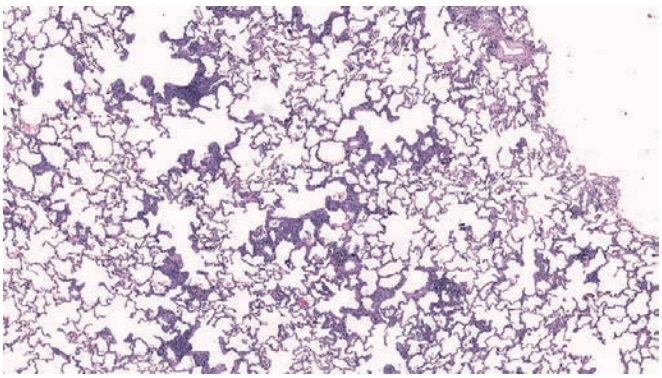

Figure 10.53 Hypersensitivity pneumonia showing patchy interstitial infiltrate of lymphocytes distributed in an exquisitely bronchiolocentric fashion.

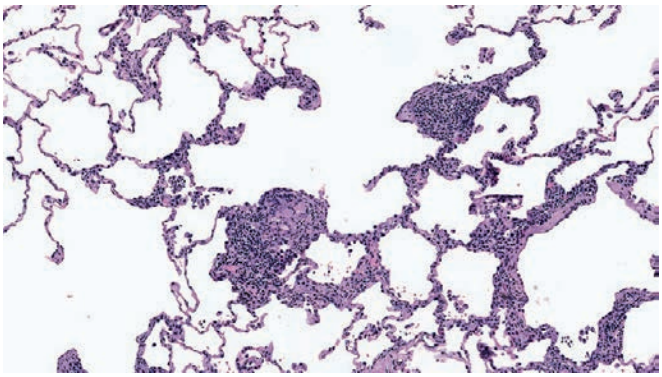

Figure 10.54 Hypersensitivity pneumonia with characteristic loose cluster of multinucleated giant cells in peribronchiolar interstitium.

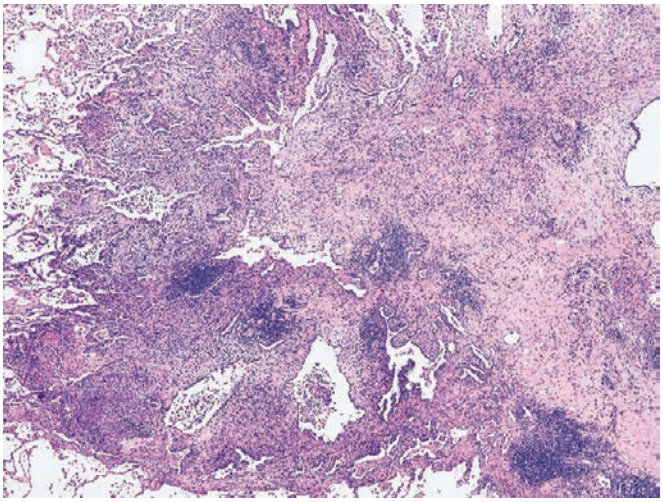

Figure 10.55 Langerhans cell histiocytosis.

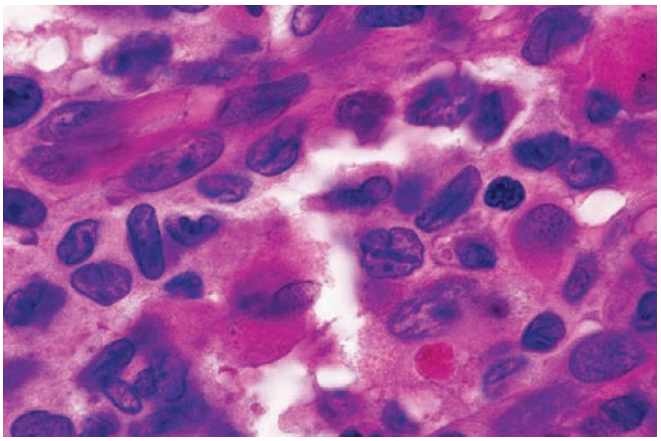

Figure 10.56 Prominent longitudinal grooves in the nuclei of Langerhans cells in a case of pulmonary Langerhans cell histiocytosis.

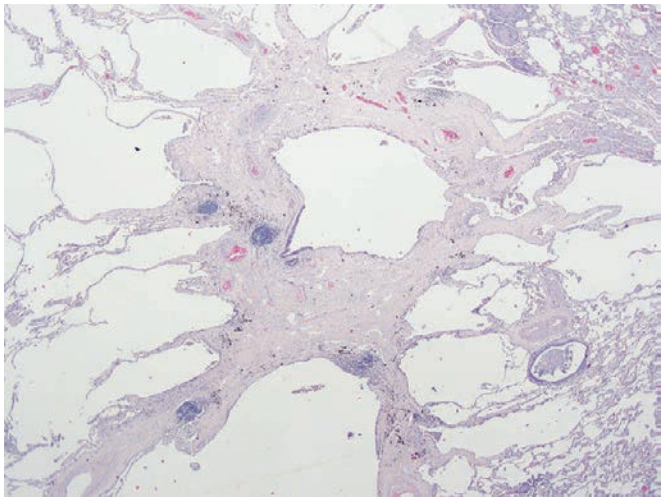

Figure 10.57 Fibrotic Langerhans cell histiocytosis showing characteristic stellate configuration and associated peripheral 'scar emphysema' (paracicatricial air space enlargement).

Silo-filler's disease should be clearly separated from the aforementioned group, since it is a form of acute lung injury secondary to nitrogen dioxide inhalation and is characterized by the presence of DAD without granulomatous inflammation.[138]

Langerhans Cell Histiocytosis and Other Histiocytic Disorders

Pulmonary LCH, referred to historically as Langerhans cell granulomatosis, histiocytosis X, and eosinophilic granuloma of the lung, is most commonly seen in the third and fourth decades of life.[139–141] LCH occurs almost exclusively in cigarette smokers in whom it typically presents as a diffuse process and rarely as a solitary nodule.[142] It predominates in the upper lobes and produces a combination of nodules and cavitary lesions or cysts. In approximately 20% of the patients, there is associated extrapulmonary involvement, usually as isolated lesions in bones or the pituitary region. Spontaneous pneumothorax is a common complication. In most patients with LCH of the lung, the disease resolves or stabilizes. A few patients develop progressive pulmonary disease that is ultimately fatal.

Microscopically, there is a compact interstitial infiltrate that expands peribronchiolar interstitium and is, composed of Langerhans cells, variable numbers of eosinophils, and other mononuclear inflammatory cells (Fig. 10.55). Langerhans cells are the essential element for the diagnosis; they have an abundant acidophilic cytoplasm and a vesicular nucleus, with typical grooves and indentations (caveat: similar grooves also can be seen in reactive mesothelial cells and alveolar macrophages) (Fig. 10.56). Immunohistochemical staining for S-100 protein, CD1a, or langerin can be very helpful in highlighting Langerhans cells and can also be applied to cells in bronchoalveolar lavage fluid.[143] The bronchiolocentric nodules heal through a process of fibrosis that begins in the center eventually extending into peribronchiolar alveolar septa where it is accompanied by a characteristic patter of scar emphysema (paracicatricial air space enlargement). At this late fibrotic stage it may be very difficult to establish a microscopic diagnosis of LCH since the characteristic Langerhans cells may be absent (Fig. 10.57). Correlation with CT scans can be helpful in showing a pattern and distribution of cystic lung disease characteristic of LCH. In the healing stage, the disease may no longer be diagnosable microscopically.

Molecular studies using a variety of techniques suggest that there is a clonal proliferation of Langerhans cells in at least a subset of patients.[144–147] Evidence of clonal evolution in pulmonary LCH includes $BRAF^{V600E}$ mutations in 20%–50% of patients.[145,147,148] Some of these patients may benefit from targeted therapy with vemurafenib.[149]

Reactive eosinophilic pleuritis is a nonspecific response to pleural injury that may closely simulate LCH because of the mixture of eosinophils, mesothelial cells, and histiocytes (which can look very similar to Langerhans cells); in contrast to true eosinophilic granuloma, this lesion by itself does not show interstitial lung disease.[150] However, in some instances it may be accompanied by eosinophilic infiltration of the pulmonary vessels.[151]

Erdheim–Chester disease is another histiocytic disorder which can affect the lung, in conjunction with bones (the latter often in the form of symmetric osteosclerosis), soft tissues, and the central nervous system.[139,152] Pulmonary involvement is typically septal (lymphatic) in distribution and characterized by an infiltrate of foamy histiocytes, lymphocytes, and Touton giant cells (Figs. 10.58 and 10.59). The histiocytes are consistently positive for CD68, sometimes reactive for S-100 protein, and negative for CD1a. Recent studies demonstrate $BRAF^{V600E}$ mutations in more than half as well as recurrent mutations in *RAS* and *PIK3CA*, indicating that this is a myeloid neoplasm for which targeted therapy with vemurafenib is proving effective in a large number of patients.[153–155]

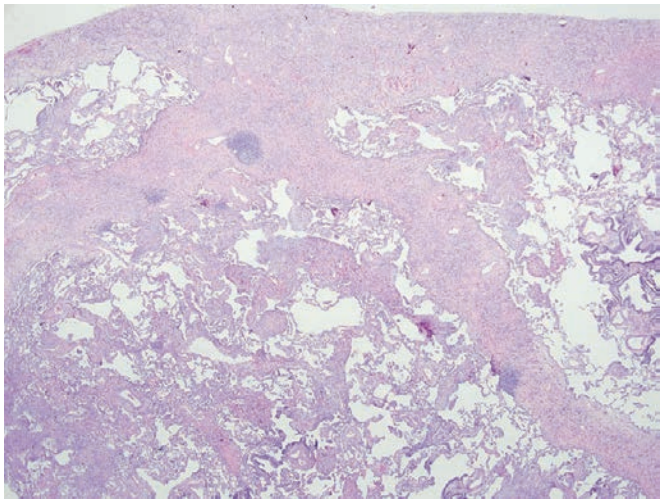

Figure 10.58 Erdheim–Chester disease.

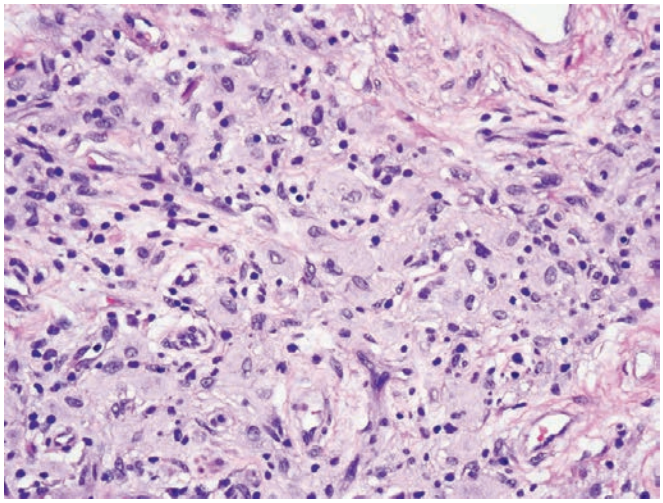

Figure 10.59 Erdheim–Chester disease involving the lung showing histiocyte-rich infiltrate.

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) is seen in the lung parenchyma only exceptionally, in contrast to its relatively frequent involvement of the upper respiratory tract.[156–158] The histologic findings overlap with IgG4-related disease, which is a diagnostic pitfall requiring careful correlation with the clinical and radiological findings.[159,160]

Pneumoconiosis

Pneumoconiosis is defined as the non-neoplastic reaction of the lungs to inhaled mineral or organic dust, exclusive of asthma, bronchitis, and emphysema.

Anthracosis is often applied as a general and relatively nonspecific term to black pigment with minimal associated fibrosis in the lungs of heavy smokers and residents of heavily polluted urban environments. Pigmented dust macules also occur in coal workers, however, in whom the term *anthracosis* has a specific and more narrow interpretation, and therefore the term is probably best avoided. *Coal worker's pneumoconiosis* may present either as 'coal nodules' (of little functional significance) or as progressive massive fibrosis (which results in pulmonary function abnormalities).[161–163]

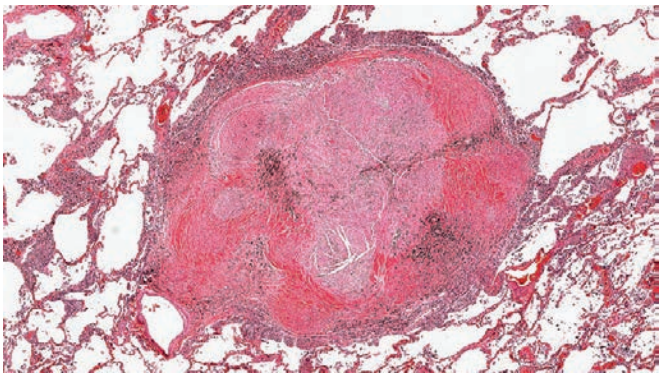

Figure 10.60 Simple silicosis showing classic, uncomplicated silicotic nodule.

Silicosis results from the deposition in the lung of particles of free crystalline silica (quartz, silicon dioxide). The lesions are characterized by micronodular scars with a characteristic pattern of central lamellar fibrosis distributed in a bronchiolocentric pattern with a cellular periphery in which dust-laden macrophages predominate (Fig. 10.60). Complicated silicosis and progressive massive fibrosis result from fusion of nodules to form larger (≥1 cm) macroscopic nodules and masses. Larger nodules may undergo necrosis and cavitate as a result of ischemia, or more commonly superimposed mycobacterial infection; acid-fast stains should be performed when necrosis is identified. Silicotic nodules in patients with rheumatoid arthritis *(Caplan syndrome)* assume some of the morphologic changes characteristic of rheumatoid nodules, including central necrosis with palisaded histiocytes at the periphery.[164]

Silica particles are best demonstrated under polarized light. They appear as weakly birefringent spicules with pointed ends, 5 µm or less in length, and are usually accompanied by more brightly birefringent contaminants. They may be found intracellularly or extracellularly. It should be emphasized that the mere presence of silica particles in a lung specimen does not establish the diagnosis of silicosis. Such a diagnosis should be reserved for cases showing silica in association with characteristic silicotic nodules.[165]

Mixed dust fibrosis is the term used for pneumoconioses resulting from mixed dust exposure, including silica and quartz. It affects foundry workers, arc welders, hematite miners, and boiler scalers. Most cases show a combination of dust macules and fibrotic nodules that may or may not include a minor component of silicotic nodules.[166]

Asbestosis refers to diffuse lung fibrosis attributable to asbestos exposure. Aside from an incriminating occupational history, the clinical and radiological findings may be indistinguishable from other forms of diffuse fibrotic lung disease save for the presence of calcified pleural plaques on imaging studies. Histologic diagnosis requires a combination of diffuse interstitial fibrosis and asbestos bodies in ordinary 5-µm sections.[167–169] The histologic features closely mimic UIP, although there tends to be less inflammation, fewer fibroblast foci, and more visceral pleural fibrosis (Fig. 10.61).[169] The diagnosis of asbestosis in lung biopsy samples requires the identification of asbestos bodies, usually by conventional microscopy although special techniques can be helpful in a limited number of contexts.[170] The typical asbestos body is a long, thin, symmetric, beaded structure with bulbous ends (Fig. 10.62). It is usually straight, but it may be bent or branched. Its core is translucent, a key feature in separating asbestos bodies from other types of non-asbestos ferruginous bodies.[171]

Other pneumoconioses include siderosis (seen in iron workers, hematite miners, and welders), berylliosis, and disorders resulting

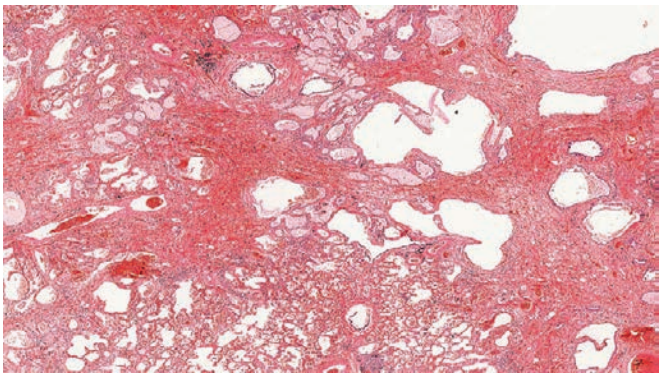

Figure 10.61 Asbestosis showing a pattern of fibrosis resembling UIP.

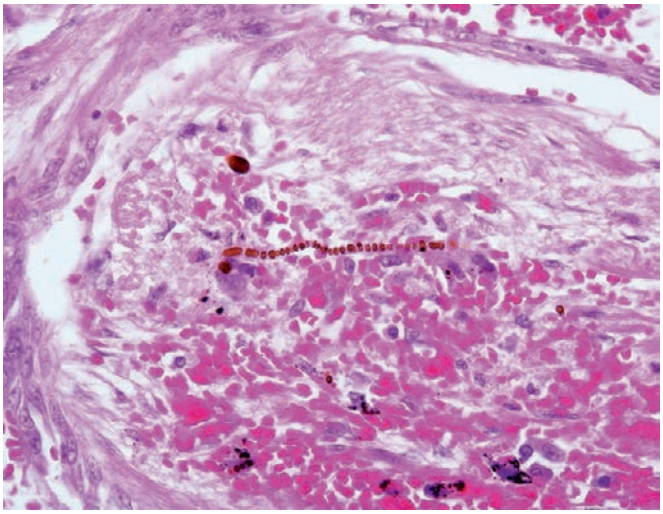

Figure 10.62 Asbestos body in a patient with asbestosis showing characteristic beaded appearance with central translucent core.

from talc and other silicates, aluminum, hard metals, and silicon carbide.

Lipoid Pneumonia

Lipoid pneumonia is often a complication of debilitating disease found as an incidental post mortem finding. However, the local expression of this process may be confused with a malignant neoplasm and consequently may become a surgical problem.

Lipoid pneumonia can be divided into two types: exogenous and endogenous. In the *exogenous* type, now seen only rarely, mineral oil from nasal sprays, laxatives, or other sources reaches the lung through the tracheobronchial tree (Fig. 10.63).[172] Grossly, exogenous lipoid is well circumscribed and firm. Microscopically, coarse lipid vacuoles that vary markedly in size are present within the air spaces and the interstitial compartment where they are accompanied by a combination of inflammation and variable degrees of fibrosis. The inflammatory infiltrate includes multinucleated giant cells that surround and engulf the lipid vacuoles. Identifying the giant cell reaction is extremely helpful in separating exogenous lipoid pneumonia from the 'holes' *(pseudolipoid)* artifact common in both surgical and transbronchial lung biopsies.[14] The much more common *endogenous* type is the consequence of bronchial obstruction by carcinoma or some other process resulting in accumulation of finely vacuolated lipid-laden macrophages in distal air spaces with infrequent involvement of the peribronchiolar interstitium. The gross distribution

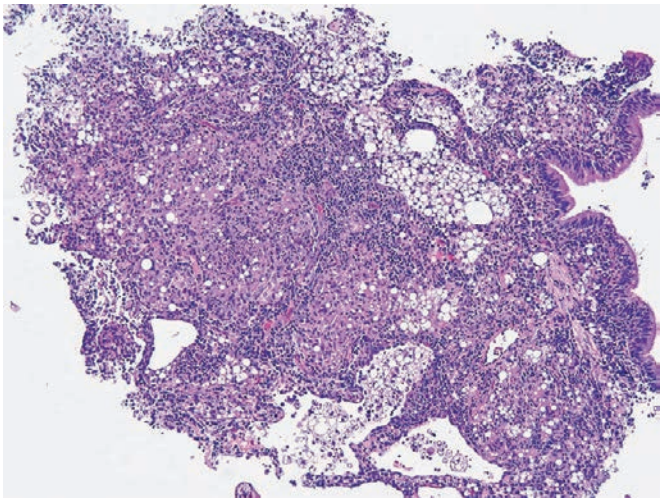

Figure 10.63 Exogenous lipoid pneumonia in a transbronchial biopsy from a patient suspected of having a malignancy.

of the abnormality depends on the level of the obstruction, frequently reflecting the lobar or segmental anatomy of the lung.

Aspiration Pneumonia

Aspiration pneumonia (other than the previously listed exogenous form of lipoid pneumonia) is often due to the aspiration of food and is a well-recognized complication in debilitated patients. Aspiration pneumonia is increasingly recognized as a cause for symptomatic or asymptomatic lung disease that can be multifocal or localized and bilateral or unilateral on radiographs or CT scans of the chest.[173–175] When solitary, aspiration pneumonia can simulate a neoplastic process. Microscopically, the changes are mainly represented by BOOP, usually in combination with multinucleated giant cells, acute bronchopneumonia and/or bronchiolitis, and suppurative granulomas. The key finding is the presence of foreign material, most often food remnants or inorganic fillers (e.g. microcrystalline cellulose, crospovidone) commonly used in oral medications (Figs. 10.64 and 10.65).[174]

Eosinophilic Pneumonia

Eosinophilic pneumonia is a histologically distinct pattern of tissue eosinophilia that may or may not be associated with peripheral eosinophilia (Fig. 10.66). Eosinophilic pneumonia is a common manifestation of drug-induced lung disease and can also occur as a component of a more complex combination of histologic findings in patients with EGPA (Churg–Strauss) and allergic bronchopulmonary aspergillosis. Changes overlapping with eosinophilic pneumonia have also been described in coccidioidomycosis, an important diagnostic consideration in endemic areas.[175] Patients in whom eosinophilic pneumonia is an unexplained primary pathologic abnormality fall into several different clinical categories.[176,177] An acute self-limited form of *simple eosinophilic pneumonia*, characterized by fleeting pulmonary infiltrates accompanied by eosinophilia and lasting no more than a month, is commonly referred to as *Löeffler syndrome*. *Tropical eosinophilic pneumonia*, as the term implies, is limited to patients living in the tropics where it is a well-recognized syndrome of pulmonary infiltrates with eosinophilia thought to be related to filarial infestations. Neither patients with simple or tropical eosinophilic pneumonia are likely to be biopsied.

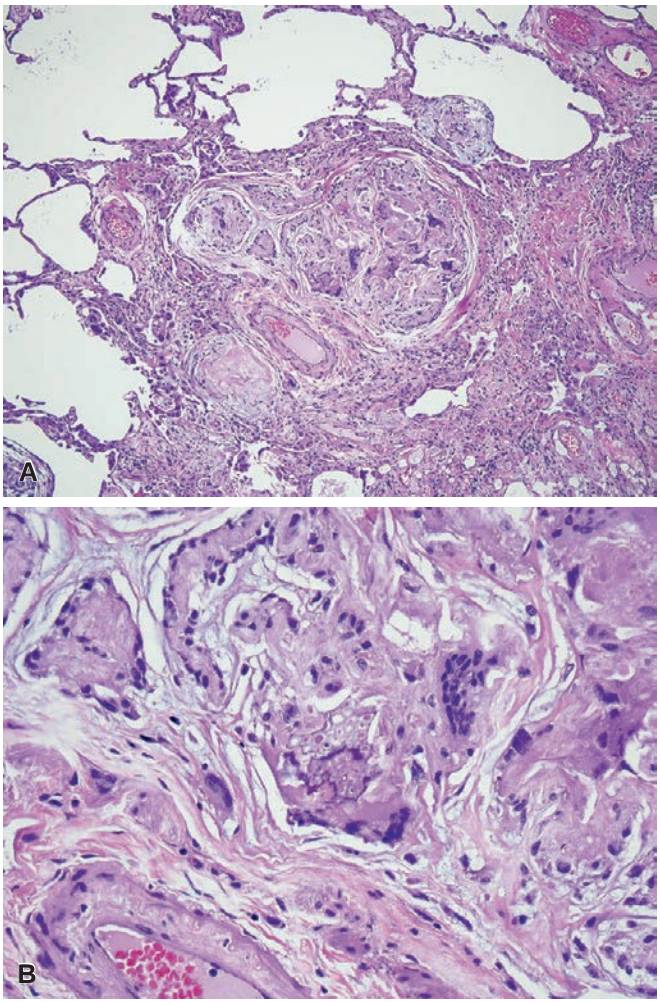

Figure 10.64 Aspiration pneumonia showing a combination of organizing pneumonia with granulomatous inflammation **(A)** and degenerated organic particulates typical of food **(B)**.

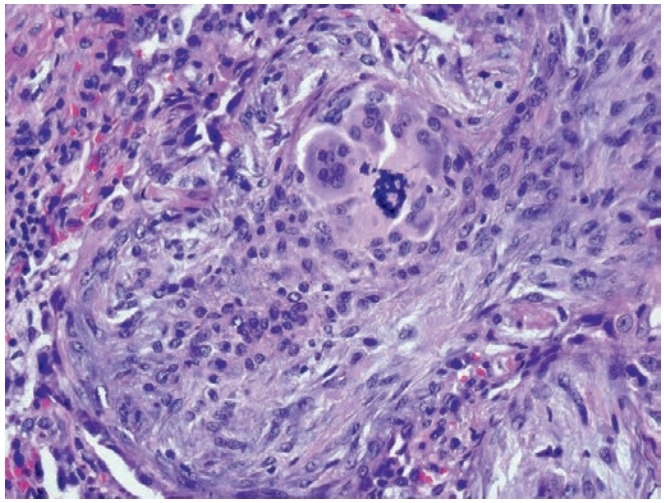

Figure 10.65 Aspiration pneumonia with organizing pneumonia and granulomatous inflammation in which a multinucleated giant cell contains crospovidone, an inorganic filler used in oral medications.

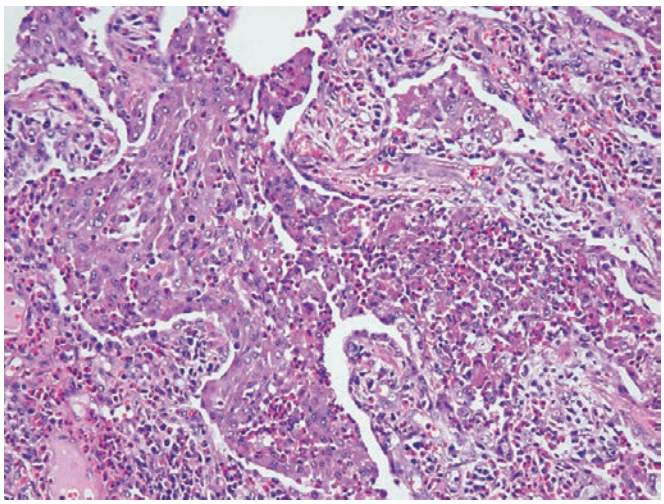

Figure 10.66 Eosinophilic pneumonia. Numerous mature eosinophils are admixed with histiocytes and granular pneumocytes.

Most patients with eosinophilic pneumonia discovered in a diagnostic lung biopsy have a respiratory syndrome characterized by a subacute or chronic onset referred to as *chronic eosinophilic pneumonia*.[178,179] This is a disease that affects women more often than men, usually between the ages of 30 and 50 years. About half of patients have a history of asthma, and most have peripheral eosinophilia. Clinically, the onset is characterized by fever, weight loss, cough, and dyspnea. Chest roentgenograms and CT scans show a characteristic peripheral distribution of infiltrates in about half of patients. As in all other forms of eosinophilic pneumonia the most notable microscopic change is alveolar and interstitial infiltration by eosinophils and histiocytes often with an associated fibrinous exudate (see Fig. 10.66). Charcot–Leyden crystals may be found. Additional features may include mild angiitis, giant cells, and occasionally non-necrotizing granulomas, organizing fibroblasts, and myofibroblasts resembling organizing pneumonia, focal necrosis, mucous plugging, and bronchiolitis.

Acute eosinophilic pneumonia presents as acute respiratory failure, often with profound hypoxemia requiring intubation and mechanical ventilation.[180] As with other forms of eosinophilic pneumonia, however, patients respond quickly and dramatically to corticosteroid therapy. Histologically acute eosinophilic pneumonia shows histologic features that overlap eosinophilic pneumonia and DAD.

Pulmonary alveolar proteinosis (alveolar lipoproteinosis) is a rare disorder characterized by a paucicellular granular air space exudate composed of a combination of surfactant lipids and proteins.[181–183] It affects men more commonly than women, usually in the fourth to fifth decades of life. Pulmonary alveolar proteinosis is rare in neonates in whom it is affiliated with mutations in surfactant protein or granulocyte macrophage-colony stimulating factor (GM-CSF) receptor genes. Conventional chest radiographs show bilateral perihilar infiltrates resembling pulmonary edema. CT scans show a characteristic but nonspecific combination of opacities and septal lines described as *crazy paving*. A large majority (90%) of adult patients with alveolar proteinosis have an autoimmune disorder characterized by high concentrations of neutralizing anti-GM-CSF autoantibodies. In a small subset of patients, pulmonary alveolar proteinosis is secondary to inhalational injuries *(acute silicoproteinosis)* or underlying hematological neoplasms. Whole-lung lavage is the mainstay of therapy. Inhaled or systemically administered GM-CSF and strategies aimed at reducing the levels of circulating anti-GM-CSF autoantibodies may also have value in patients with autoimmune pulmonary alveolar proteinosis.[182,183]

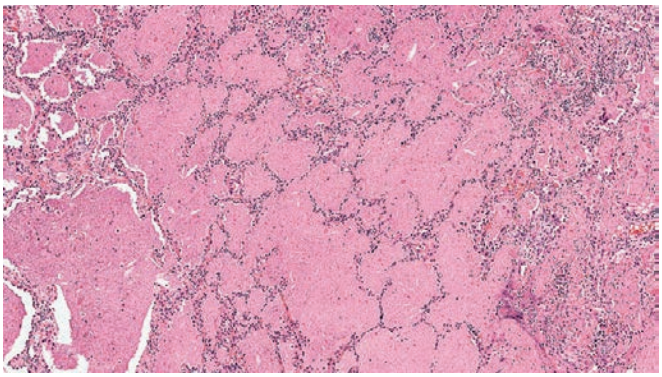

Figure 10.67 Filling of alveolar spaces by amorphous grumous material in alveolar proteinosis.

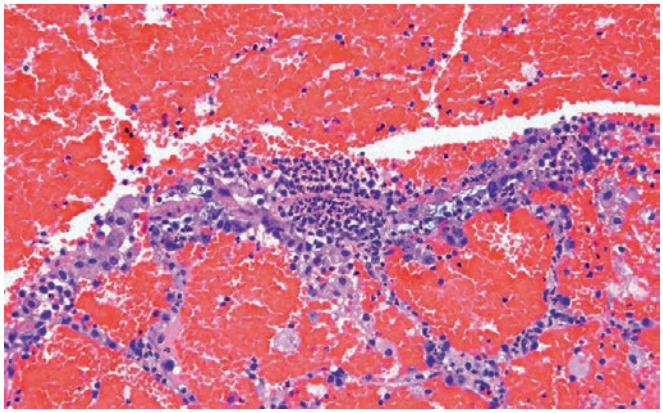

Figure 10.68 Diffuse alveolar hemorrhage with capillaritis in a patient with granulomatosis with polyangiitis (Wegener's).

Microscopically, the hallmark of the process is the accumulation of an amorphous eosinophilic (but sometimes basophilic) PAS-positive material of predominantly phospholipid nature in the alveolar lumina, associated with a minimal infiltrate of lymphocytes, macrophages, and desquamated pneumocytes. The air space exudate is usually affiliated with only mild interstitial abnormalities including a lymphocytic infiltrate with minimal associated fibrosis (Fig. 10.67). In patients who have underlying hematological disorders or are otherwise immunocompromised, alveolar proteinosis may be associated with infections such as nocardiosis, pneumocystis, histoplasmosis, cryptococcosis, aspergillosis, tuberculosis, or cytomegalovirus, making appropriate use of special stains and other microbiologic assays mandatory in this context.

Pulmonary Hemorrhage

Diffuse pulmonary (alveolar) hemorrhage is uncommon. Most patients are symptomatic and complain of a combination of dyspnea, cough, fever, chest pain, and/or hemoptysis. Vasculitic syndromes, anti-glomerular basement membrane disease (**Goodpasture syndrome**) and systemic connective tissue diseases are among the most common causes; affected patients often have concomitant glomerulonephritis (pulmonary-renal syndrome).[184] Patients with underlying vasculitides frequently have circulating ANCA (*ANCA-associated vasculitides*). In Goodpasture syndrome there is an associated glomerulonephritis, circulating antiglomerular basement membrane antibodies, and linear deposits of IgG along glomerular and alveolar basement membranes. Other less common causes of diffuse alveolar hemorrhage include congestive heart failure, occupational exposure to trimellitic anhydride, drug-induced hemorrhage, inhalational lung injury (e.g. crack cocaine), and various clotting diorders.[185] In some patients no underlying cause or immune-mediated disease is identified. Chest roentgenograms and CT scans usually show relatively nonspecific diffuse opacities. Surgical lung biopsies show alveolar hemorrhage, often associated with hemosiderin pigment and organizing pneumonia, with associated small vessel vasculitis *(necrotizing capillaritis)* in those with vasculitis syndromes (most commonly GPA [Wegener's], microscopic polyangiitis, or systemic lupus erythematosus) (Fig. 10.68).

Idiopathic pulmonary hemosiderosis is a rare condition that classically presents in children and young adults with dyspnea, cough, hemoptysis, and refractory anemia.[186] Children who present with diffuse pulmonary hemorrhage show the same range of underlying systemic diseases, including ANCA-associated vasculitides, as adults making idiopathic pulmonary hemosiderosis a diagnosis of exclusion. Down syndrome and celiac disease are common underlying conditions in children with idiopathic pulmonary hemosiderosis. Microscopically, large accumulations of hemosiderin-laden macrophages in the alveolar lumens are accompanied by hyperplastic alveolar pneumocytes lining thickened alveolar septa. Necrosis, vasculitis, granulomas, and lymphoid follicles do not occur, and there are no deposits of IgG on the alveolar basement membranes, an important distinction from Goodpasture syndrome.

Localized pulmonary hemorrhage is usually secondary to some underlying condition, such as a necrotizing primary or metastatic neoplasm, necrotizing infection, or bronchiectasis.[187] **Hematoma** of the lung can present as a distinct round mass that radiographically resembles a neoplasm; it usually develops as a result of nonpenetrating blunt trauma to the thorax.[188]

Miscellaneous Infections

Improved microbiologic assays applied to various noninvasively acquired samples have diminished the role of tissue biopsies in establishing non-granulomatous infectious diagnoses in the lung. Despite these trends there remain a subset of pulmonary infections for which lung biopsy is occasionally required.

Pneumocystis jirovecii Pneumonia

Pneumocystis jirovecii pneumonia is an opportunistic fungal infection.[189,190] Most cases are seen in individuals who are chronically debilitated and immunosuppressed, such as those receiving therapy for neoplastic disease or affected with AIDS. Pneumocystis remains the most prevalent opportunistic infection in AIDS patients. In severely immunocompromised patients, the infection may spread to extrapulmonary sites and become disseminated.

Bronchoalveolar lavage is the most commonly used method for diagnosing pneumocystis pneumonia. Lung biopsy is reserved for those patients in whom bronchoalveolar lavage is unsuccessful or in whom the diagnosis was not anticipated. Microscopically, the typical case is characterized by a foamy or honeycombed intra-alveolar exudate accompanied by a lymphoplasmacytic interstitial infiltrate (Fig. 10.69). However, these features may be inconspicuous or absent in some cases, which may exhibit instead epithelioid granulomas, focal multinucleated giant cells, marked interstitial fibrosis, vasculitis, a marked infiltrate of alveolar macrophages, calcifications, or DAD.[191,192] Given the variability in the histologic findings associated with *P. jirovecii* pneumonia one should have a low threshold for performing special stains in potentially immunocompromised patients.

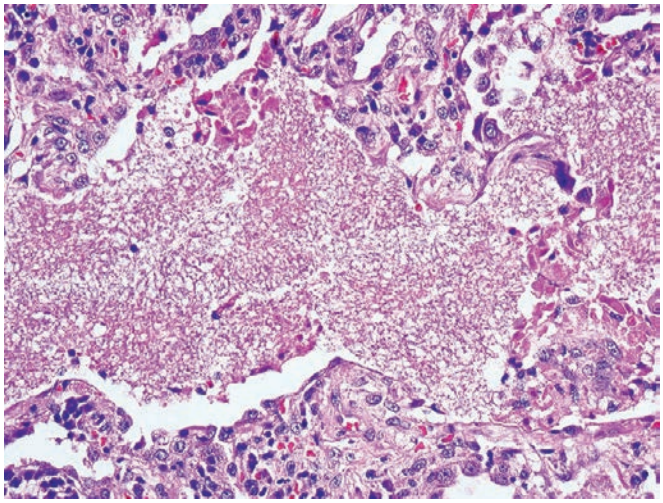

Figure 10.69 Frothy alveolar exudate in *P. jirovecii* pneumonia.

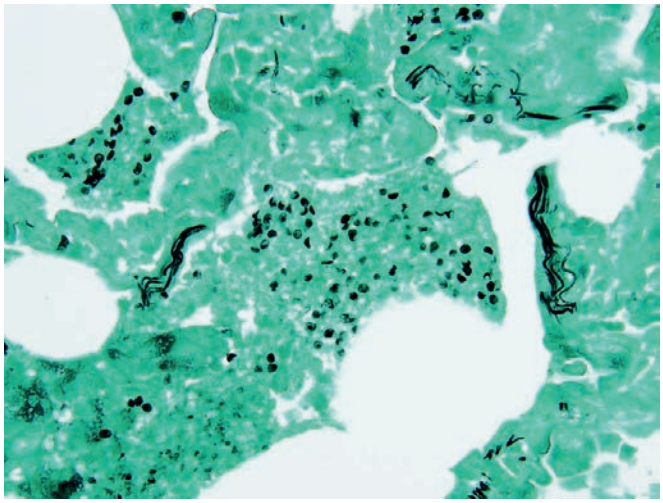

Figure 10.70 GMS stain showing *P. jirovecii* in frothy alveolar exudate.

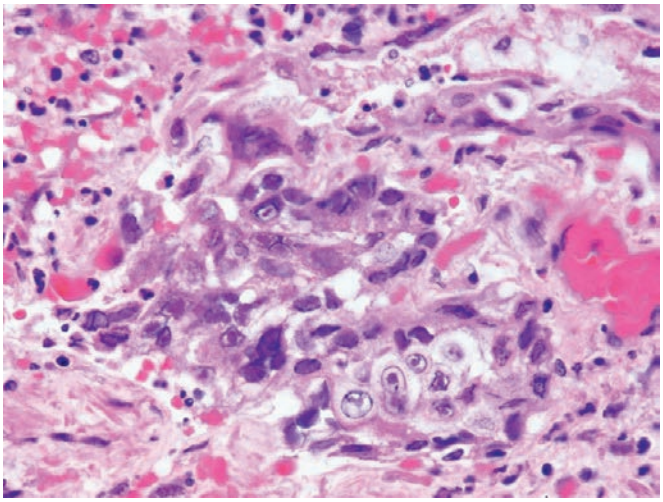

Figure 10.72 Intranuclear inclusions in herpes simplex pneumonia.

The diagnosis of pneumocystic pneumonia depends on identification of the organism.[189] Cytology and biopsy specimens should be cultured (to rule out the possibility of other infectious processes), imprints should be taken, and the rest of the sample processed routinely or subjected to frozen section examination. If *P. jirovecii* is present, the imprints are almost invariably positive. The most reliable stain for detecting the organism is GMS (Fig. 10.70). The cystic forms of the organism appear with the silver stain as round structures, up to 5 µm in diameter, containing single or paired discrete 'intracystic bodies' measuring 1–2 µm. Some of the cysts are crumpled and others are collapsed, with a crescentic shape. False-negative staining with GMS does occur, making careful interpretation of routinely stained sections and use of appropriate positive controls all the more important.[193] Immunoperoxidase techniques using monoclonal antibodies and PCR methods are also available.

Cytomegalovirus pneumonia is usually seen in immunocompromised patients, such as those with AIDS or lymphoid malignancies, transplant recipients, and those receiving cytotoxic drugs.[194] Radiographically, it may present in the form of small (2–4 cm) peripherally located nodules or consolidated opacities, as an acute miliary pattern, or as a diffuse interstitial process. Microscopically, a patchy mixed inflammatory infiltrate is seen in conjunction with an air space exudate and hyperplasia of the alveolar epithelium. In the diffuse pattern, these changes may be associated with focal areas of hemorrhagic necrosis and DAD. Viral inclusion bodies are found in the nucleus and cytoplasm of alveolar macrophages, epithelial cells, and endothelial cells and can be detected in most but not all of the cases (Fig. 10.71). Cytoplasmic inclusions are stained with both PAS and GMS, a fact that may lead to a mistaken diagnosis of *P. jirovecii* pneumonia.[195]

Herpes simplex pneumonia occurs in immunocompromised patients and immunocompetent patients requiring prolonged mechanical ventilation.[196] Microscopically herpes simplex pneumonia usually results in a necrotizing tracheobronchitis and bronchopneumonia that is frequently accompanied by DAD. Intranuclear viral inclusions can be found in airway epithelial cells at the edge of the necrotic areas (Fig. 10.72).

Adenovirus pneumonia also causes a necrotizing bronchiolitis and bronchopneumonia frequently accompanied by DAD, but differs from herpes simplex virus in that adenovirus pneumonia affects previously health immunocompetent as well as immunocompromised patients. The characteristic cytopathic changes include a combination of smudged nuclei and bricklike intranuclear inclusions in epithelial cells (Fig. 10.73).

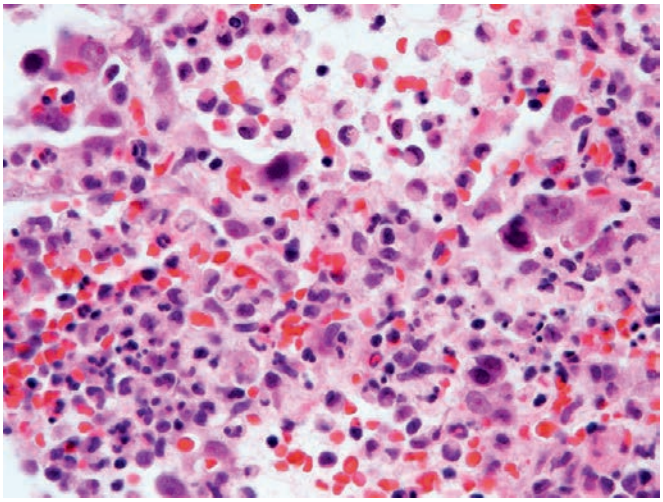

Figure 10.73 Adenovirus showing characteristic smudge cells.

Figure 10.74 Gross appearance of hydatidosis of lung. (Courtesy of Dr. RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

Influenza pneumonia can result in a wide range of morphologic changes, most commonly a combination of necrotizing pneumonia and DAD.[197] Mild acute and organizing pneumonia can also occur. Unlike the previously described viral pneumonias there are no characteristic viral cytopathic changes, and diagnosis requires confirmatory cultures or serological studies. Similar changes occur in H1N1 influenza A and are often accompanied by pulmonary hemorrhage, vascular thrombosis, and hemophagocytosis in lung and extrapulmonary sites.[198]

Severe acute respiratory syndrome (SARS) is an infectious condition caused by a coronavirus. It emerged from Guangdong Province in China in November 2002 and resulted in widely publicized outbreaks in Hong Kong, Vietnam, and Singapore. Microscopically, the predominant pattern is that of DAD, often associated with a fibrinous air space exudate resembling that described in acute fibrinous and organizing pneumonia.[199]

Hantavirus pulmonary syndrome is a severe pulmonary disease caused by a previously unrecognized hantavirus.[200] An outbreak has occurred in the southwestern United States. The usual morphologic finding is pulmonary edema and/or DAD with focal hyaline membranes.[201]

Legionnaires' disease became an instant media sensation in 1976, when it occurred in a small epidemic form among persons attending a convention in a hotel in downtown Philadelphia.[202] It turns out that it is anything but a new disease; apparently, sporadic cases have been seen by the thousands over previous decades. Involvement of the hilar lymph nodes occurs in nearly half of autopsied patients, and in about one-fourth of the cases there is hematogenous spread to other organs. Occasionally, an open or transbronchial lung biopsy is performed in these patients. Microscopically, the process is characterized by intra-alveolar accumulation of neutrophils, macrophages, and fibrin as in other bacterial pneumonias.[203] However, many cases also show a leukocytoclastic neutrophilic inflammatory infiltrate, small vessel vasculitis, and necrosis. The Dieterle silver impregnation stain has proved to be the most reliable for identifying the short gram-negative bacillus that is the etiologic agent. Immunostains are also available but carry a risk of falsely negative staining.

Nocardiosis is another opportunistic lung infection sometimes seen in transbronchial or surgical lung biopsies.[204,205] Approximately half of the reported cases have occurred in patients who have a history of organ transplantation, immunosuppression, steroid usage, or chemotherapy. Microscopically, the picture is that of a focal necrotizing bronchopneumonia with microabscesses and a peripheral inflammatory infiltrate that frequently includes palisaded histiocytes resulting in a vaguely granulomatous appearance. Gram and GMS stains show slender, slightly beaded, branching filamentous bacilli.

***Mycoplasma pneumoniae* pneumonia**, formerly known as *atypical pneumonia*, is dominated by upper respiratory tract symptoms and bronchiolitis with shifting pulmonary infiltrates. Disease is usually mild and self-limited, but in some patients *M. pneumoniae* causes pneumonia that may be severe and potentially life-threatening, especially in patients with underlying lung disease.[206] Microscopically, the main change is a severe acute and chronic bronchiolitis with an acute inflammatory exudate in the lumens of small airways.[207] The bronchiolitis may be accompanied by other changes including organizing pneumonia and, in severely ill patients, DAD.

Hydatidosis (echinococcosis) results from infestation by *Echinococcus granulosus* (which is usually cystic) and only rarely by *Echinococcus multilocularis* (which causes alveolar echinococcosis) (Figs. 10.74 and 10.75).[121]

Lung in AIDS

Pulmonary disease occurs frequently during the course of AIDS and may necessitate bronchoalveolar lavage, transbronchial biopsy, or less commonly surgical lung biopsy for appropriate management.[208,209] Surgical lung biopsies are uncommon in AIDS patients but still have value in a highly selected subset of patients, especially those with noninfectious lung diseases.[210,211] Opportunistic infections remain the most common abnormalities, including *Pneumocystis*

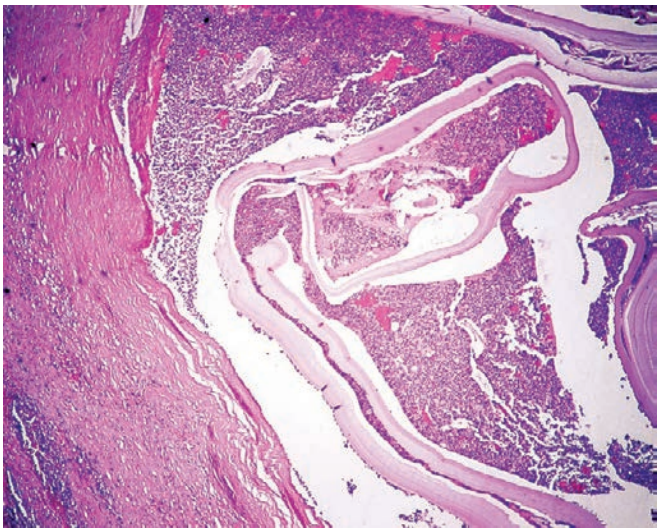

Figure 10.75 Microscopic appearance of pulmonary hydatidosis.

pneumonia, cytomegalovirus pneumonia, atypical mycobacteriosis and tuberculosis, candidiasis, invasive aspergillosis, toxoplasmosis, cryptococcosis, histoplasmosis, blastomycosis, *Rhodococcus equi*, and microsporidiosis.[212] The histologic findings are generally similar to those affiliated with these pathogens in non-AIDS patients. *R. equi* causes a histologically distinct histiocyte-rich inflammatory response indistinguishable from malakoplakia.[213] Noninfectious pulmonary complications include neoplasms, most notably Kaposi sarcoma and lymphomas including lymphomatoid granulomatosis.[214,215] Kaposi sarcoma can be an especially challenging diagnosis in transbronchial biopsies.[216] AIDS patients may get other nonlymphomatous lymphoproliferative lesions that are frequently lumped under the designation of lymphoid interstitial pneumonia.[217] Sometimes the morphologic changes are nonspecific and overlap with the idiopathic interstitial pneumonias.[218]

Lung and Transplantation

Most late nonleukemic deaths after **bone marrow transplantation** are caused by infectious and noninfectious pulmonary diseases, including cytomegalovirus pneumonia, DAD, constrictive (obliterative) bronchiolitis, venoocclusive disease, and various forms of chronic interstitial pneumonia including PPFE.[219–222] Regardless of the histologic findings, late-onset noninfectious pulmonary complications are highly related to, and likely a manifestation of, graft-versus-host disease.

Lung biopsies in patients who are status post **lung transplantation** are most commonly performed to evaluate allograft rejection for which the differential diagnosis is usually infection.[223] Grading of acute and chronic rejection has been standardized by the International Society for Heart and Lung Transplantation, but rates of interobserver agreement remain low.[224,225] Acute cellular rejection is recognized by the accumulation of perivascular and interstitial mononuclear inflammatory cells, often with associated eosinophils. Acute rejection is graded based on the intensity and extent of the inflammatory infiltrate, from A0 (negative) to A4 (severe).[224] Perivascular and interstitial inflammation is often accompanied by a lymphocytic bronchiolitis that is also graded based on the intensity of the inflammatory infiltrate. Perivascular inflammation and bronchiolitis occur commonly in opportunistic infections, most importantly pneumocystis and cytomegalovirus, and therefore infection should be carefully excluded before ascribing these changes to acute rejection.[223] The pathology of acute antibody-mediated rejection has not yet been well defined.[226] Chronic rejection is manifested by fibrosis narrowing the lumen of bronchioles *(obliterative bronchiolitis)*, arteries, and veins and is graded on the basis of the airway changes as either absent (C0) or present (C1).

Vascular Diseases

The term pulmonary hypertension includes a variety of diseases that have different etiologies, but which may have similar clinical presentations, overlapping histologic findings, and variable responses to medical treatment.[227,228] Histopathology plays a less important role in current classification schemes which define phenotypes based on a combination of clinical and physiological findings as well as an expanding list of biomarkers.[227]

Surgical lung biopsies are rarely performed to evaluate otherwise unexplained pulmonary hypertension. Various forms of primary pulmonary hypertension are more likely to be seen in explanted lungs from patients who undergo transplantation. The histologic features unique to pulmonary hypertension were extensively studied in historical studies of patients with congenital heart disease for whom histologic grading of pulmonary hypertension played an important role in determining the potential effectiveness of corrective surgery.[229,230] Elastic tissue stains are very helpful in evaluating the status of arteries, veins, and smaller vessels. In patients with congenital heart disease vascular disease is considered reversible when the arterial lesions are restricted to medial hypertrophy, thickening of longitudinal intimal smooth muscle, post-thrombotic intimal fibrosis, or cellular intimal hyperplasia.[229] Concentric-laminar intimal fibrosis of moderate or severe degree probably does not regress. Fibrinoid necrosis and/or plexiform (plexogenic) lesions are regarded as contraindications to surgery unless the nature of the defect is such that one lung is spared. An increase in the number of neuroendocrine cells has been detected in hypertensive pulmonary vascular diseases.[231] Many of the principles that link histopathologic findings to the severity of pulmonary hypertension in patients with congenital heart disease also apply to patients with primary pulmonary hypertension.[232,233]

Pulmonary veno-occlusive disease (PVOD) accounts for about 10% of patients with idiopathic pulmonary arterial hypertension and affects men and women equally across a wide age range.[234] Radiological findings are distinct compared with other forms of primary pulmonary hypertension and may overlap with the diffuse interstitial diseases.[235] Pulmonary hypertension develops because of widespread occlusion of medium and small-sized branches of the pulmonary veins, accompanied by recanalization and pseudoangiomatous changes. Redundant alveolar septal capillary loops *(capillary hemangiomatosis-like change)* are common and overlap with **capillary hemangiomatosis**, a condition that some have advocated may be indistinguishable from PVOD.[236] Arterial thickening and prominent hemosiderosis are also present. The etiology of idiopathic PVOD is unknown; identical changes are sometimes seen in patients with chronic venous hypertension resulting from primary cardiac disease which should always be excluded. PVOD has also been described as a consequence of drug toxicity and in bone marrow transplant patients with chronic graft-versus-host disease.

Arteriovenous malformations (aneurysms) are radiographically discernible, frequently multiple lesions that occur most often in the lower lobes (Figs. 10.76 and 10.77). Most are congenital, occurring most commonly in patients with hereditary hemorrhagic telangiectasia (Rendu–Osler–Weber syndrome). Because of the shunt, there may be bruits and cyanosis on physical examination accompanied by polycythemia and hypoxemia. Excision is curative. Others can be successfully managed using radiologically guided embolization. They

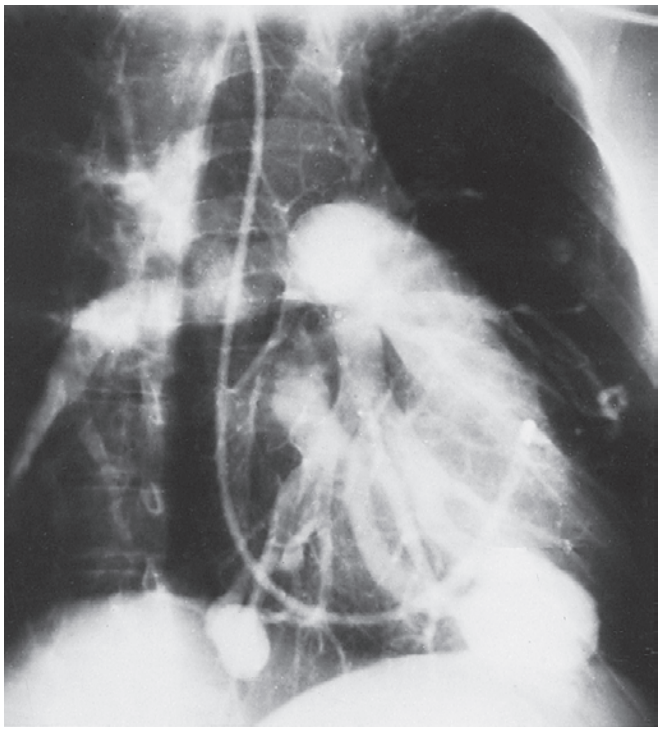

Figure 10.76 Angiogram of a 28-year-old man with multiple arteriovenous malformations. The patient had Rendu–Osler–Weber syndrome (hereditary hemorrhagic telangiectasia). After left lower lobectomy, oxygen saturation rose from 86% to 95%.

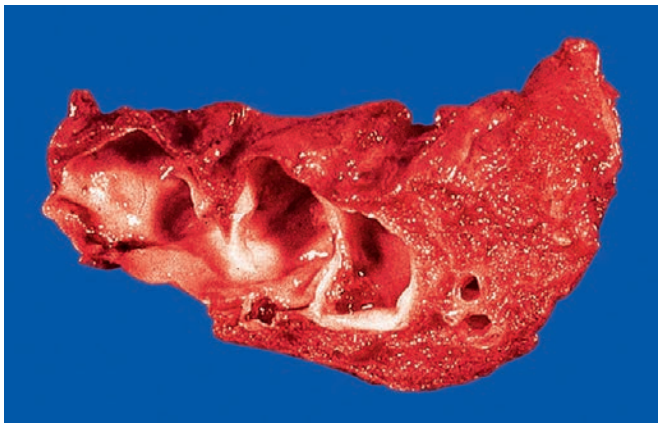

Figure 10.77 Gross appearance of pulmonary arteriovenous malformation.

are made up of large vascular channels with arteriovenous communications. Microscopically, the vessels are abnormal, often showing deficiencies and excesses of muscle, which make it impossible to distinguish artery from vein.

Infarcts resulting from pulmonary thromboembolic disease are usually identified as such on the basis of radiological studies demonstrating a combination of thromboemboli and pleural-based triangular opacities. However, occasionally they simulate a malignant tumor and are either biopsied or resected (Fig. 10.78).[237] Those that come to the attention of a surgical pathologist are less likely to demonstrate the characteristic wedge-shaped configuration on chest imaging studies and instead present as solitary or multiple nodules.[237]

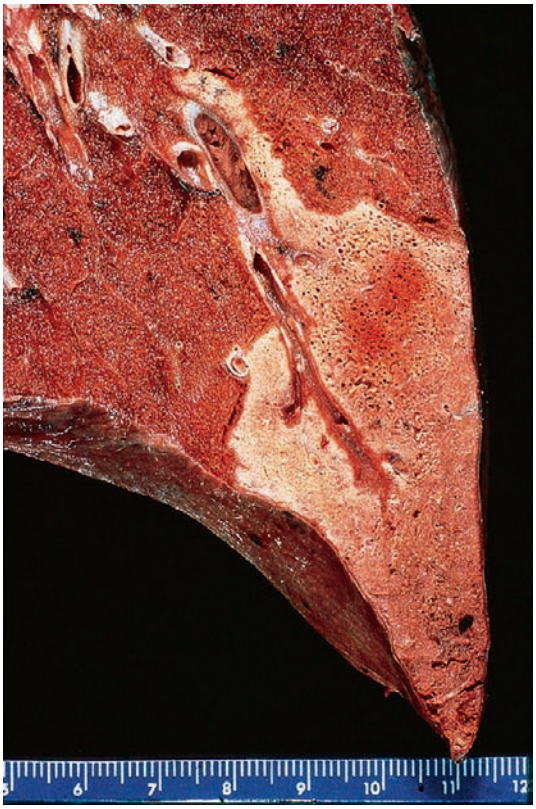

Figure 10.78 Typical wedge-shaped appearance of pleural-based pulmonary infarct. A large occluding thrombus is evident in the vessel leading to the area of the infarct.

Other Non-Neoplastic Diseases

Broncholithiasis is defined as the presence of calcified material within the lumen of a cartilaginous airway and is most commonly a complication of infectious granulomatous diseases (particularly tuberculosis and histoplasmosis) in which a calcified granuloma erodes into a bronchus.[238] Less common causes include calcification of aspirated food or inspissated secretions in bronchiectasis.

Pulmonary hyalinizing granuloma usually presents in minimally symptomatic or asymptomatic adults with multiple, bilateral nodules or infiltrates that may mimic metastatic disease.[239,240] Microscopically, the central portion is made up of hyalinized, keloid-like collagen. This is surrounded by a mixed inflammatory infiltrate comprising mainly lymphocytes, plasma cells, and a minor component of macrophages including rare multinucleated giant cells, the overall appearance simulating nodular amyloidosis (Fig. 10.79). However, special stains for amyloid are negative. Necrotic areas and non-necrotizing epithelioid granulomas are distinctly unusual in this condition, which is of importance in the differential diagnosis. Some patients have evidence of antecedent or concomitant granulomatous infection, but in most the pathogenesis is unknown. Pulmonary hyalinizing granuloma may be associated with sclerosing mediastinitis and/or retroperitoneal fibrosis, with recent evidence suggesting a link to the spectrum of IgG4-related sclerosing diseases.[241]

Endometriosis of the lung may present with recurrent catamenial hemoptysis, or as asymptomatic nodules discovered on routine chest x-ray film.[242] Most of the reported cases have been located on the right side. The disease often extends to the pleural surface.[243]

Pulmonary alveolar microlithiasis is a rare disease characterized by the presence of microliths or calcospherites within the alveoli of an otherwise normal lung.[244] The process is diffuse and bilateral,

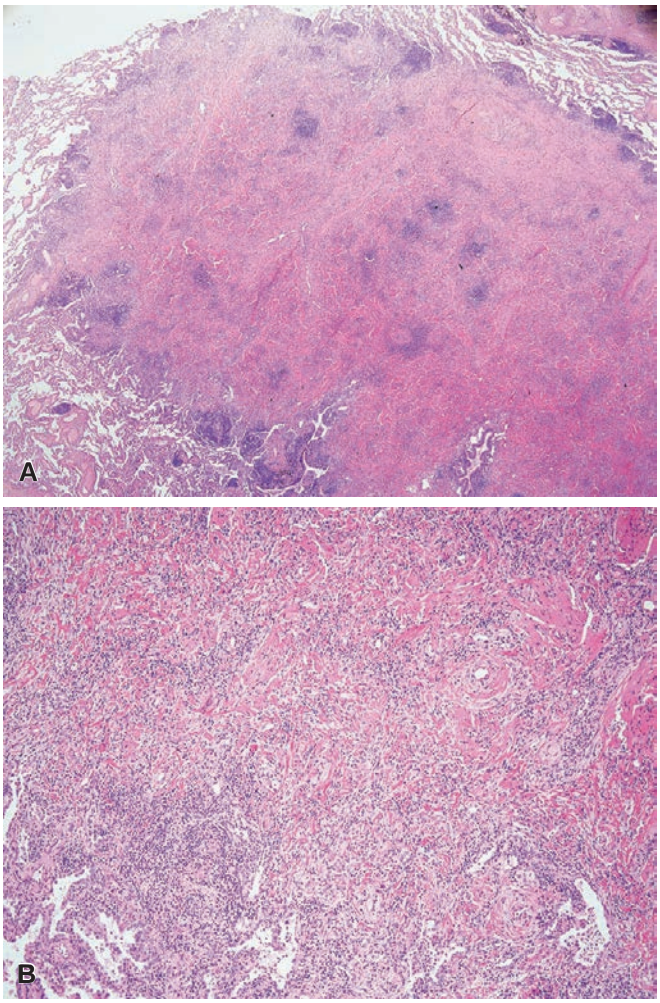

Figure 10.79 Pulmonary hyalinizing granuloma showing circumscribed nodule **(A)** with characteristic pattern of collagen fibrosis and inflammation **(B)**.

and the clinical course is extremely long. The chest radiographic appearance is virtually diagnostic.[245]

Carcinoma

General and Clinical Features

Carcinoma of the lung has become very frequent since the 1930s. The American Cancer Society reported that in 2015 there were 221,200 new cases and 158,040 deaths from lung cancer in the United States. The only hopeful trend in this dreadful situation is the fact that the incidence rates overall are declining in the United States, having peaked in men in the mid-1980s and stabilized in women in the first two decades of the 21st century after steadily increasing through the 1980s and 1990s.[245] The declining trend in men and steady increases in women have converged to a place of near parity across sexes, with a male to female ratio of 1 : 1. These trends are not unique to the United States and have been documented on multiple continents.[246] More than 98% of the patients diagnosed in 2015 are projected to be 45 years of age or older, but cases have also been reported in young adults and adolescents.

Much has been written about the epidemic nature of lung carcinoma, the leading cause of cancer-related deaths. Many factors thought in the past to be of pathogenetic importance—such as tuberculosis, tarring of roads, the 1918 influenza epidemic, anthracosis, and anthracosilicosis—are now considered to be totally unrelated to cancer or to account for only a minimal fraction of cases. Exposure to asbestos; polycyclic aromatic hydrocarbons; arsenic, nickel, and chromium compounds; bis(chloromethyl) ether (BCME); chloromethyl methyl ether (CMME); vinyl chloride; radiation (as seen in uranium workers and in people with high radon concentration in their houses); and other occupational agents undoubtedly account for some of the cases.[247] This is particularly true for asbestos (thought to be responsible for about 5% of all lung carcinoma deaths) and for radon.[248] However, the significance of all these factors pales by comparison with the role played by cigarette smoking, both in males and in females.[245] This is true for all major histologic types of lung carcinoma. The fact that smokers living in urban areas and/or exposed to asbestos are at a higher risk for lung carcinoma than others suggests the potentiating effect of air pollution and asbestos on the carcinogenic effect of tobacco, a possibility that is supported by some experimental models.[249] Significantly, in animals there is a nearly total absence of spontaneously occurring lung tumors that are histologically similar to smoking-related human lung cancers.[250]

The relationship of cigarette smoking with malignant, dysplastic, and metaplastic alterations of the tracheobronchial tree has also been thoroughly documented by the meticulous histologic observations of Auerbach et al.[251] and confirmed by others[252]; at autopsy, Auerbach et al. found an almost linear correlation between the severity of the changes and the amount of cigarette consumption. A similar relationship between smoking and lung cancer precursors has been suggested for marijuana and may be additive with tobacco use.[253]

Approximately 10%–15% of cases of lung carcinoma occur in never-smokers. Among them, three-fourths are women, and a high proportion of cases show an adenocarcinoma histology.[254] Adenocarcinoma occurring in never-smoker women appears to be more prevalent in Asian populations.

Another factor thought to be related to the development of carcinoma is pulmonary fibrosis, through a preceding stage of atypical proliferation of the terminal bronchiolar epithelium. Malignant tumors arising at the site of scars resulting from bullets, other foreign bodies, and old granulomas have been well documented, although in most the cause-and-effect relationship between scar and cancer is uncertain at best.[255] The relationship between lung carcinoma and diffuse fibrosis is more complicated. In a classic study of 153 consecutively resected lung tumors,[256] 21% were associated with—and presumably preceded by—honeycombing and atypical epithelial proliferation. Most of these tumors were in the upper lobe, and one-third of them were adenocarcinomas. Others have documented a clear relationship between UIP and increased lung cancer risk, although the effect of fibrosis *per se* is confounded by the high prevalence of cigarette smoking in these patients.[257] Carcinomas arising in UIP show disproportionate involvement of the lower lobes which mirrors the distribution of the fibrotic changes. Peripheral squamous cell carcinomas are over-represented in UIP patients and are especially common in older male smokers.[258,259]

Atypical adenomatous hyperplasia of type 2 alveolar cells has emerged as an important potential precursor of adenocarcinoma in a subset of patients.[260,261]

Rare examples of squamous cell carcinomas of the lung resulting from human papilloma virus (HPV)-driven malignant transformation of respiratory papillomatosis have been reported.[262,263] On the whole, however, HPV does not seem to play an important role in the genesis of lung cancer.[264]

Lung carcinoma is multiple (either synchronous or metachronous) in about 2%–6% of patients[265,266] and is associated with independent smoking-related cancer of the head and neck region in about 5%–15%

of patients.[267] Molecular genetic studies have shown that a majority of multicentric lung tumors (whether synchronous or metachronous) show evidence of a common clonal origin.[268,269] Despite the molecular evidence, patients thought to have multifocal synchronous or metachronous primary lung carcinomas on the basis of established histologic criteria have a substantially better prognosis than those with intrapulmonary metastases.[270]

Most lung cancers are in a relatively advanced stage by the time of diagnosis; about 60% are inoperable as a result of extensive locoregional spread and/or distant metastases. Symptoms and signs develop relatively late in the course of the disease, are often related to partial or complete bronchial obstruction, and may lead to confusion with a primary inflammatory process. Overall survivals remain low, with about 17% surviving 5 years in a large cohort (2005–2011) from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) Program.[271]

The most common symptoms, in decreasing order of frequency, are cough, weight loss, pain, increased sputum production, hemoptysis, malaise, fever, and those resulting from paraneoplastic manifestations. Peripherally located lesions are clinically silent until they reach a sufficient size to ulcerate into a bronchus or to involve the pleural space. Carcinomas located in the superior pulmonary sulcus result in a clinical picture peculiar to their location, known as *Pancoast syndrome*.[272] This is characterized by pain in the distribution of the ulnar nerve and is often accompanied by Horner syndrome secondary to involvement of the sympathetic chain.

Sometimes lung carcinoma presents as a solitary pulmonary nodule ('coin lesion') on the chest x-ray film or CT scan of an asymptomatic individual. About 35%–50% of solitary pulmonary nodules in adults evaluated using modern imaging techniques represent lung carcinoma.[273] The percentage is higher for patients older than 60 years and for noncalcified lesions. The incidence of malignancy in coin lesions exhibiting obvious calcification is less than 1%.

Lung neoplasms are sometimes associated with extrapulmonary manifestations *(paraneoplastic syndromes)* remote from the sites of primary or metastatic tumor.[274] Although exceptions occur, there is a fairly good correlation between some morphologic parameters of the tumor and the systemic effect produced. These are summarized in Table 10.2. These manifestations are caused by the tumor's secretion of biologically active compounds. In the case of the *Lambert–Eaton syndrome* associated with small cell carcinoma, voltage-gated calcium channel autoantibodies have a pathophysiologic role. Additional substances that have been detected in some cases of lung carcinoma include amylase, calcitonin, CEA, alpha-fetoprotein (AFP), β-pregnancy-specific glycoprotein, and epidermal growth factor receptors (EGFRs). A preponderance of small cell carcinomas exists in this group; however, the correlation between the presence of a tumor marker and the histologic tumor type is generally poor.

Because of the generally late stage of clinically diagnosed lung carcinomas, screening efforts have been mounted over the years at a considerable cost to detect early and potentially curable cases in high-risk individuals.[275] Until now, those efforts have been generally disappointing. At present, extensively publicized multi-institutional studies and a randomized controlled National Lung Screening Trial have indicated an opportunity to reduce lung cancer mortality through thoughtfully implemented screening programs applied to carefully selected high-risk populations. How to implement current screening recommendations in a cost-effective manner remains controversial.[276–278] Parenthetically, the large majority of screening-detected carcinomas—whether solitary or multiple—were adenocarcinomas, including some with doubling times much longer than those historically associated with incident lung carcinomas reflecting the risk of overdiagnosis in this population.[279,280]

Table 10.2 Systemic effects of lung carcinoma and their most commonly related tumor type[275]

SYSTEMIC EFFECT AND HORMONE RESPONSIBLE	TUMOR TYPE
Cushing syndrome (ACTH)	Small cell carcinoma Carcinoid tumor
Carcinoid syndrome	Carcinoid tumor Small cell carcinoma
Hyponatremia (ADH)	Small cell carcinoma
Hypercalcemia (parathyroid hormone-related protein)	Squamous cell carcinoma
Gynecomastia (hCG)	All tumor types
Clubbing of fingers and hypertrophic pulmonary osteoarthropathy	Unrelated to tumor type; mainly dependent on proximity to pleural surface
Mental syndromes (i.e. toxic confusional psychosis)	Small cell carcinoma
Cortical cerebellar degeneration	All tumor types
Encephalomyelitis	Small cell carcinoma
Sensory neuropathy	Small cell carcinoma
Myopathic–myasthenia syndrome (Lambert–Eaton syndrome)	Small cell carcinoma

Pathologic and Immunohistochemical Features

Several microscopic classifications of lung carcinoma exist. The one most widely used derives from the World Health Organization (WHO) Classification of Tumors developed in collaboration with the International Association for the Study of Lung Cancer (IASLC).[281] It includes the following major categories:

1. Adenocarcinoma
2. Squamous cell carcinoma
3. Neuroendocrine tumors (including small cell carcinoma, large cell neuroendocrine carcinoma, typical and atypical carcinoid tumors, and diffuse neuroendocrine cell hyperplasia)
4. Large cell carcinoma
5. Adenosquamous carcinoma
6. Sarcomatoid carcinoma (including pleomorphic, spindle cell and giant cell carcinoma, carcinosarcoma, and pulmonary blastoma).

Several studies have shown the reproducibility of this classification and the close correlation between biopsies and surgical specimens.[283] The current WHO classification of lung tumors differs from its predecessors in including not only criteria based on routine light microscopy but also immunophenotypic criteria based on a limited number of commonly available immunostains.[281]

Larger lung carcinomas often show a combination of histologic patterns which complicates classification. In a study of 100 consecutive cases of lung carcinomas in which either the entire tumor or 10 blocks were examined, just over half were composed of a single histologic type.[284] The immunophenotypes of the main histologic tumor types are relatively stable and highly reproducible, although rare exceptions to the anticipated immunostaining patterns are well documented.[283,285,286]

The relative frequencies of the various microscopic types of lung carcinoma have changed over the years. Adenocarcinomas are now the most common incident lung carcinoma while incidence rates for both squamous cell and small cell carcinoma have declined.[246] The relative frequencies are also influenced by the utilization of immunostains for histologic classification which has sharply reduced those cases assigned to the category of large cell carcinoma.[287]

The histochemical, immunohistochemical, ultrastructural, and molecular genetic features of lung carcinoma are discussed with the respective histologic categories. Suffice it to say here that the most important generic immunomarkers of lung carcinomas are the following:

- *Keratins*. They are present in all types of lung carcinoma, but the expression of individual keratins is dependent upon the tumor subtype.[288]
- *TTF-1*. Thyroid transcription factor 1, which is consistently expressed in normal type 2 pneumocytes and Clara cells, has emerged as one of the most useful markers of epithelial lung tumors.[289,290] It is expressed in over 80% of the adenocarcinomas, a similar proportion of small cell carcinomas, and in a much smaller percentage of the other lung carcinoma types.[285] Given relatively high sensitivity and specificity, the current WHO classification scheme proposes positive staining for TTF-1 (or napsin A) as a criterion for classifying otherwise poorly differentiated non-small cell carcinomas as adenocarcinomas. 'False-positive' results sometimes occur when staining in non-neoplastic respiratory epithelial cells is mistakenly attributed to neoplastic squamous cells, a diagnostic trap especially important to remember when interpreting small biopsies.[291] Detection of TTF-1 in metastases in brain or other extrapulmonary sites is also very helpful in identifying lung as a likely primary site. There is only one major caveat: as its name indicates, the other tissue in which TTF-1 is consistently expressed is the thyroid epithelium. TTF-1 staining has also been described at low frequencies, and usually with a very focal distribution, in small cell carcinomas originating in nonpulmonary sites such as the prostate and bladder and in adenocarcinomas of the breast, colon, ovaries, and endometrium.[289]
- *Napsin A*. Napsin A is an aspartic proteinase involved in the maturation of surfactant protein B. It is detected in the cytoplasm of type II pneumocytes and alveolar macrophages. It is a highly sensitive marker for pulmonary adenocarcinomas (positive in about 80% of cases) and thus is a useful adjunct in TTF-1 negative tumors.[292] Napsin staining is also seen in a subset of renal cell carcinomas and tall cell variants of papillary thyroid carcinomas.[293] Like TTF-1, napsin stains non-neoplastic respiratory epithelial cells that may be intimately admixed with neoplastic squamous cells, a potential diagnostic trap that complicates interpretation.[294]
- *p63 & p40 (ΔNp63)*. *p63* comprises a family of variants (isoforms) including transcriptionally active tumor suppressor genes and transcriptionally inactive oncogenes. The p63 antibody most commonly used for tissue diagnosis is a 'pan-p63' marker while p40 is a nontransactivated isoform (ΔNp63) with greater specificity for squamous/basal-type epithelium.[295] Both are diffusely positive in nearly all squamous cell carcinomas from any site, including the lung, but p63 is less specific in that focal staining is also seen in a third or more of lung adenocarcinomas.[296] The current WHO classification of lung tumors suggests that diffuse staining for p63 or p40 should be used as a criterion for classifying TTF-1 negative poorly differentiated non-small cell lung carcinomas as squamous cell carcinomas.

A selected immunohistochemical profile of the major types of lung carcinoma, extracted from the literature by Pandit et al.,[297] is shown in Table 10.3. A practical approach for classifying poorly differentiated non-small cell carcinomas that are difficult to classify on the basis of routine histology alone that also preserves tissue for molecular testing in small biopsies or cytologies is a combination of TTF-1 and either p63 or p40. Adding immunostains for high-molecular-weight keratins (CK5/6 rather than 34βE12 given greater specificity) and napsin A may have value in cases for which TTF-1 and p63/p40 are insufficient.[290,298] Low rates of discordance with final classification of resected tumors are explained primarily by the impact of sampling rather than fidelity of immunostaining profiles.

Table 10.3 Immunohistochemical profile of the major types of lung carcinoma

	TTF-1 (%)	CD56 (%)	CK5/6 (%)	34βE12 (%)
Adenocarcinoma	77	3	0	46
Squamous carcinoma	7[a]	6	100	97
Small cell carcinoma	88	95	0	12

[a]Ordonez and others hypothesize that TTF-1 (and napsin A) staining in squamous cell carcinomas is limited to non-neoplastic respiratory epithelium.[292,295]
TTF-1, Thyroid transcription factor 1.

Blood vessel and/or lymphatic invasion is seen in about half of resected non-small cell carcinomas and is more frequent in larger tumors.[299] The prognostic significance of vascular and/or lymphatic invasion remains somewhat controversial but both tend to predict a greater likelihood of recurrence and shorter survival and should be included in pathology reports for resected lung carcinomas.[300,301] Visceral pleural invasion occurs in about 20% of resected non-small cell carcinomas and also predicts for shorter overall survival in otherwise early stage node-negative lung carcinomas.[302] Aside from being a prognostic factor, visceral pleural invasion is also important in upstaging (stage IB) small (≤3.0 cm) node-negative tumors that might otherwise be considered earlier stage (stage IA) carcinomas.[303]

Adenocarcinoma

Adenocarcinomas comprise over half of all lung carcinomas in females and nearly 45% of those in males.[304] Incidence rates for adenocarcinoma are higher than for other microscopic type of lung cancer, to the extent that it is now the most common form.[246] In data collected from two large national databases in the United States for the period 2004–2009, adenocarcinomas were 1.7 times more common than squamous cell carcinomas and 2.5 times more common than small cell carcinomas.[305]

Grossly, invasive adenocarcinomas usually present as poorly circumscribed gray–yellow peripheral lesions (Fig. 10.80). They may be single or multiple. If they secrete abundant mucin, they have a gelatinous, glairy appearance. Cavitation is unusual. About 65% of the cases are located peripherally, and often about the visceral pleura at the time of excision, resulting in pleural fibrosis or 'puckering' (Fig. 10.81). Occasionally, a small peripheral adenocarcinoma spreads massively into the pleural space and coats both pleural layers so as to closely simulate the appearance of diffuse mesothelioma *(pseudomesotheliomatous carcinoma)* (Fig. 10.82).[305] Adenocarcinomas only rarely present as endobronchial polypoid masses (Fig. 10.83).[306]

Adenocarcinomas occasionally arise in association with a peripheral scar, including apical caps.[307] In a classic series of 82 'scar cancers' reviewed by Auerbach et al.,[308] 72% were adenocarcinomas and 18%

were squamous cell carcinomas, the rest being assigned to the category of large cell undifferentiated carcinomas at a time that immunostains were not used to subclassify poorly differentiated non-small cell lung carcinomas. There were no small cell carcinomas. A number of studies have proposed that many (most?) of these peripheral cancers do not arise from preexisting scars but instead reflect scar formation by the tumor through various combinations of desmoplasia, infarcts, alveolar collapse, and fibroelastosis.[309–311]

Microscopically, adenocarcinomas exhibit a wide range of differentiation, from well-differentiated *in situ* adenocarcinomas formerly termed *bronchioloalveolar carcinoma* to poorly differentiated solid adenocarcinomas that would have been previously classified as large cell carcinoma. The two morphologic signs of glandular differentiation that define adenocarcinoma, often found together, are formation of tubules or papillae and/or secretion of mucin. On occasion, lung adenocarcinoma cells exhibit prominent eosinophilic intracytoplasmic globules that are distinct from mucin globules.[312] Immunoreactivity for pneumocyte markers, most commonly TTF-1 and/or napsin A, is also sufficient to establish the diagnosis of adenocarcinoma in poorly differentiated carcinomas that lack glandular histology or mucin secretion, assuming no compelling histologic features (e.g. keratinization) to suggest an alternative.[261,313]

Adenocarcinomas are histologically heterogeneous with many of them showing a combination of growth patterns. Identifying the predominant growth pattern may have prognostic value in predicting the likelihood of disease-free survival depending on the stage of disease. In patients with small (≤3.0 cm) node-negative tumors, noninvasive *(in situ)*, minimally invasive (≤0.5 cm of invasive carcinoma), and *lepidic* predominant adenocarcinomas (a group of well-differentiated adenocarcinomas referred to in previous iterations of lung tumor classifications as *bronchioloalveolar carcinoma*) (Fig. 10.84) are affiliated with an excellent prognosis.[314] Most early-stage lesions that lack evidence of invasion are composed of nonmucinous columnar cells, although there are rare examples of in situ and minimally invasive adenocarcinomas in which bland, mucinous columnar cells comprise the neoplastic population. Frankly invasive stage 1 adenocarcinomas in which a lepidic *(bronchioloalveolar)* growth pattern comprises at least 50% of the tumor without other adverse histologic findings (i.e. angiolymphatic and/or visceral pleural invasion, a focal micropapillary growth pattern) are affiliated with the same excellent prognosis described for in situ and minimally invasive adenocarcinomas.[315] Indeed some have shown that the presence of even a minor lepidic (bronchioloalveolar) component is associated with better survival compared with adenocarcinomas that lack this distinctive well-differentiated growth pattern.[316] Micropapillary (Fig. 10.85) and solid (Fig. 10.86) adenocarcinomas are more likely to be affiliated with higher-stage disease and portend a poor prognosis.[314,316] The presence of even a minor micropapillary component is worth noting in pathology reports as it implies a more aggressive tumor with greater potential for recurrence and distant relapse.[317] Conventional acinar (Fig. 10.87), papillary (Fig. 10.88), and invasive mucinous (Fig. 10.89) adenocarcinomas are affiliated with an intermediate prognosis.[314] Rare variants of adenocarcinoma

include *signet ring cell adenocarcinoma* (Fig. 10.90),[318] invasive *mucinous carcinoma* (see Fig. 10.89) which includes cases formerly classified as mucinous bronchioloalveolar carcinomas and overlaps with descriptions of colloid carcinoma and cystadenocarcinomas,[319] *adenocarcinoma with enteric (goblet cell)*[320] and *hepatoid*[321] *differentiation*, *adenocarcinoma with rhabdoid features*,[322] *microcystic adenocarcinoma*[323] (a pattern that overlaps with cribriform carcinomas[324]), and *adenocarcinoma with massive lymphocytic infiltration*.[325]

It should be remembered that a lepidic growth pattern (lining of tumor cells along alveolar walls) is not unique to primary adenocarcinomas of the lung and also occurs in metastatic tumor types, including those arising from breast and thyroid which may also be TTF-1 positive.[326] The frequency of TTF-1 staining in adenocarcinomas arising from sites other than lung and thyroid (e.g. breast, colon, pancreaticobiliary tract, ovary, endometrium) is heavily dependent on the antibody clone that is used; of the most commonly used commercially available antibodies 8G7G3/1 (Dako) is less sensitive but more specific than SPT24 (Leica/Novocastra) which is more

likely to show unanticipated TTF-1 staining in tumors from other sites.[327]

Pagetoid spread within the mucosa of large bronchi has been reported only rarely in primary adenocarcinomas of the lung.[327]

Immunohistochemically, adenocarcinomas of the lung are usually positive for low-molecular-weight keratins (sometimes with coexpression of vimentin[328]), EMA, CEA, secretory components, MOC-31, Ber-EP4, TAG-72, BG-8, and various members of the MUC family.[329] Expression of keratin 7 has been taken as evidence of glandular differentiation in lung carcinoma but is not specific and occurs in a substantial number of squamous cell carcinomas.[286] TTF-1 and napsin A are positive in most cases, as previously summarized. The usual negativity for CDX2 is helpful in the differential diagnosis with metastatic colorectal adenocarcinoma, but this does not apply to a subset of lung adenocarcinomas with enteric differentiation, including some mucinous carcinomas.[319,330] Similarly, their usual negativity for estrogen receptors (ERs) is helpful in the differential diagnosis with metastatic breast carcinoma but is not an absolute criterion given that focal ER positivity occurs in fewer than 10% to nearly 30% of lung adenocarcinomas, depending on the antibody used.[331] In about half of cases there is positivity for surfactant

apoprotein (PE-10), a feature of potential utility in the differential diagnosis with other types of primary lung carcinoma and with metastatic adenocarcinoma, although its value as a diagnostic tool has been largely supplanted by TTF-1 which is more sensitive and specific.[332] Lung adenocarcinomas also show consistent expression of Lewis X and Y blood group antigens, a feature that may be of some differential diagnostic value in separating benign from malignant epithelial proliferations.[333] Adenocarcinomas with Clara cell differentiation are immunoreactive for DC-LAMP, a molecule normally expressed in mature dendritic cells that is also expressed in endometrial adenocarcinomas.[334]

Pulmonary adenocarcinomas, like other histologic types of non-small cell carcinomas, harbor multiple genetic and epigenetic alterations.[335,336] *TP53* mutations, most commonly in the form of point mutation and sometimes homozygous deletion, are found in about 50% of cases.[337] Mutations in *KRAS* were second in frequency to *TP53* in the large comprehensive molecular profiling of lung adenocarcinomas performed by The Cancer Genome Atlas (TCGA) Research Network and were associated with cigarette smoking, as were high fractions of C greater than A nucleotide transversions *(transversion-high)* in individual genes and genome wide.[336] The detection of *KRAS* oncogene activation in lung adenocarcinomas from former and current smokers suggests that *KRAS* mutations constitute an early and irreversible event in the development of smoking-related adenocarcinomas. Other driver mutations demonstrated in TCGA analysis of lung adenocarcinomas included *EGFR (14%)*, *BRAF (10%)*, *PIK3CA* (7%), *MET* (7%), *RIT1* (2%); tumor-suppressor genes *STK11* (17%), *KEAP1* (17%), *NF1* (11%), *RB1* (4%), and *CDKN2A* (4%); chromatin-modifying genes *SETD2* (9%), *ARIDIA* (7%), and *SMARCA4* (6%); RNA-splicing genes *RBM10* (8%) and *U2AF1 (3%)*; and *MGA* (8%), a gene encoding a protein important in the MYC pathway.[336] *KRAS* and *EGFR* mutations are also present in *atypical adenomatous hyperplasia*, a putative adenocarcinoma precursor defined as a small (≤0.5 cm) localized proliferation of mildly to moderately atypical nonmucinous columnar cells without significant associated inflammation and/or fibrosis.[337] *EGFR* mutations are mutually exclusive of *KRAS* mutations and occur at a significantly higher frequency in adenocarcinomas from East Asians than from non-Asians, from women than from men, and from never-smokers than from ever-smokers.[338,339] The importance and details of *molecular* testing for specific abnormalities is discussed in a subsequent section on treatment.

There is a rapidly growing list of molecular abnormalities other than single gene mutations that play important roles in the pathogenesis of lung adenocarcinomas. Specific translocations of the *ALK* (anaplastic lymphoma kinase) gene, with the usual fusion partner *(EML4)* also from the 2p chromosome (i.e. inversion), occur in fewer than 10% of lung adenocarcinomas, depending on the population studied.[340] *ALK*-translocated pulmonary adenocarcinomas show the following characteristics: occurrence in never-smokers or light smokers, younger patient age, and lack of mutations in the *EGFR*, *KRAS*, and *TP53* genes.[341–343] These tumors tend to show a solid growth pattern, often with signet ring cell morphology.[342–344] There has been great interest and enthusiasm in this minor subset of adenocarcinomas because inhibitors that target ALK tyrosine kinase yield objective responses in nearly three-fourths of patients and longer progression-free survival on average compared with standard chemotherapy.[345] Given the potential impact of these sorts of targeted approaches to therapy, molecular testing for *EGFR* mutations and *ALK* rearrangements (a list that has expanded to include other potentially targetable genetic and epigenetic abnormalities in many laboratories) are now endorsed by multiple pathology organizations and the American Society of Clinical Oncology as the standard of care for selected patients with adenocarcinoma of the lung.[346,347]

Squamous Cell Carcinoma

Squamous cell carcinomas are the second most common form of lung carcinoma, accounting for a third of incident lung cancers in males and 20%–25% of lung cancers in females.[304] Most cases are centered in segmental bronchi (Fig. 10.91) and therefore present as hilar or perihilar masses in chest radiographs and CT scans. The bronchial mucosa adjacent to the tumor usually shows squamous metaplasia and sometimes carcinoma in situ, occasionally extending several centimeters from the main mass. Rarely, squamous cell carcinoma presents as an endobronchial polypoid mass with only minimal spread beyond the bronchial wall.[348] As a consequence of their tendency to involve central airways, exfoliated malignant cells are more commonly identified in sputum or brushing cytology specimens than for other types of lung carcinoma. Signs of bronchial obstruction, such as obstructive pneumonia or atelectasis, are found in approximately half of the patients presenting with centrally located tumors. The tumors have a special tendency to undergo central necrosis with cavitation (Fig. 10.92). Calcification is unusual. Squamous cell carcinomas can also be found peripherally and even subpleurally.[349,350] When they do, they may fill the alveolar lumens

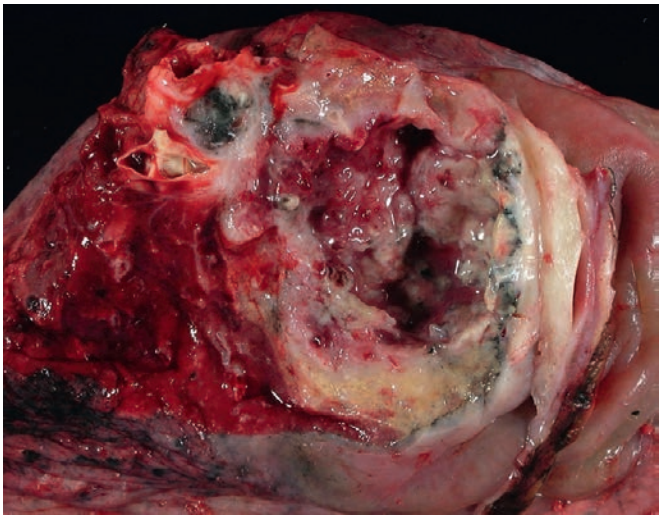

Figure 10.92 Large squamous cell carcinoma associated with central cavitation.

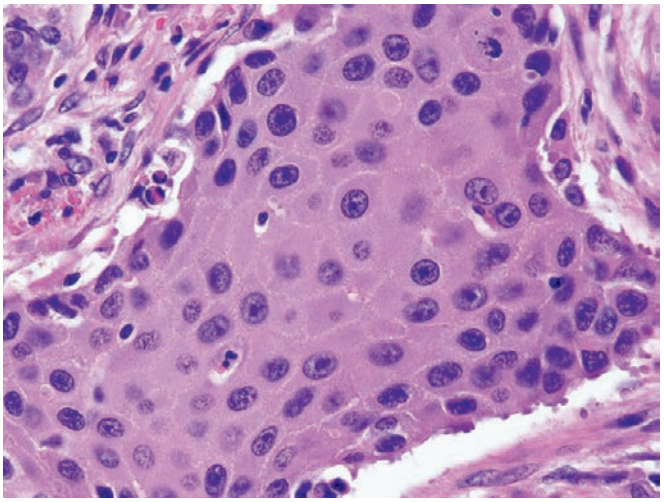

Figure 10.94 Microscopic appearance of squamous cell carcinoma with intercellular bridges.

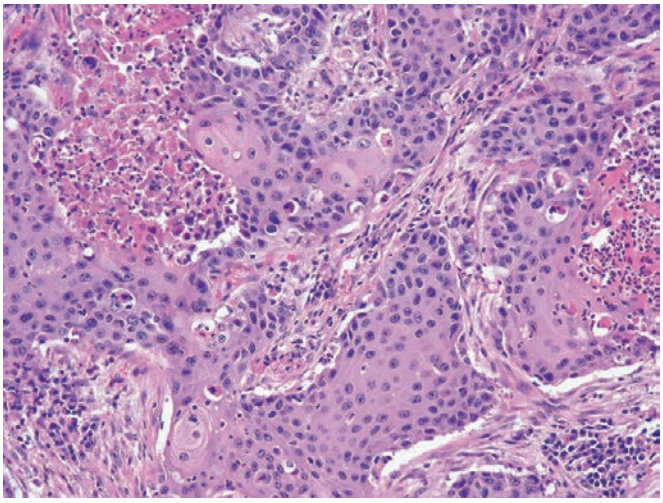

Figure 10.93 Microscopic appearance of squamous cell carcinoma with keratinization and necrosis.

in a lepidic-like fashion, mimicking a growth pattern more typically associated with adenocarcinomas.[351] A predominant alveolar space–filling growth pattern in small, early stage, peripheral tumors may predict a more favorable outcome in squamous cell carcinomas much as a lepidic growth pattern does in adenocarcinomas.[352]

Microscopically, the diagnosis of malignancy is based on cell atypia and invasion, and the diagnosis of squamous cell type on the detection in hematoxylin and eosin sections of keratinization and/or intercellular bridges (Figs. 10.93 and 10.94).[353] Keratin formation may be seen in isolated cells or, more commonly, in the form of 'keratin pearls.' Isolated necrotic cells should not be confused with keratinized cells. Strong, diffuse staining for markers of squamous differentiation such as CK5/6 (high-molecular-weight cytokeratins) and/or p63 or p40 is also sufficient to classify an otherwise nonclassifiable poorly differentiated non-small cell carcinoma as a squamous cell carcinoma.[353]

The finding of an occasional intracytoplasmic mucin droplet in an otherwise typical squamous cell carcinoma should not lead to a reclassification of the tumor. Only when at least 10% of the sampled tumor comprises a histologically distinct matous component is the designation of *adenosquamous carcinoma* justified.[354]

Other morphologic features that can be encountered in squamous cell carcinoma include oncocytoid appearance of the tumor cells (due to increased mitochondrial density); giant cell foreign body reaction to keratin; palisaded granulomas; and extensive infiltration by neutrophils and other inflammatory cells. Further subclassification into *small cell, clear cell, and papillary variants* is of limited value beyond describing the range of histologic features that may complicate differential diagnosis.

The exception is *basaloid squamous cell carcinoma*, a poorly differentiated carcinoma analogous to the homonymous tumor arising in the upper aerodigestive tract (see Chapter 4) with a characteristically lobulated growth pattern and peripheral palisading of neoplastic cells (Fig. 10.95A).[355] A subset of these tumors show focal and abrupt keratinization; more commonly they are nonkeratinizing carcinomas with a pattern of diffuse immunoreactivity for p63 and/or p40 characteristic of squamous differentiation (see Fig. 10.95B). Immunostains are also positive for antibodies directed against high-molecular keratins such as CK5 or CK5/6 but are negative for TTF-1. Focal staining for neuroendocrine markers is seen in a minority of basaloid squamous cell carcinomas. This is an important subgroup of centrally occurring carcinomas characterized by an aggressive clinical course similar to that seen with other same stage poorly differentiated squamous cell carcinomas.[356,357]

Squamous cell carcinomas are graded into well, moderately, and poorly differentiated on the basis of the amount of keratinization present. Electron microscopic examination shows abundant tonofilaments, complex desmosomes, and basal lamina formation (Fig. 10.96).

Immunohistochemically, there is consistent staining for low- and high-molecular-weight keratins as well as p63 and p40, as previously outlined. Of the most commonly available antibodies directed against high-molecular-weight keratins, CK5/6 shows greater specificity than 34βE12 and is the antibody of choice for distinguishing squamous cell carcinomas from adenocarcinomas in the lung.[284] GATA3 is positive in only about 10% of squamous cell carcinomas of the lung, which may be helpful in distinguishing lung primaries from cutaneous and urothelial metastases.[358] Desmocollin-3 and glypican-3 are additional proteins more commonly expressed in squamous cell carcinomas than adenocarcinomas for which there are commercially available antibodies.[359,360]

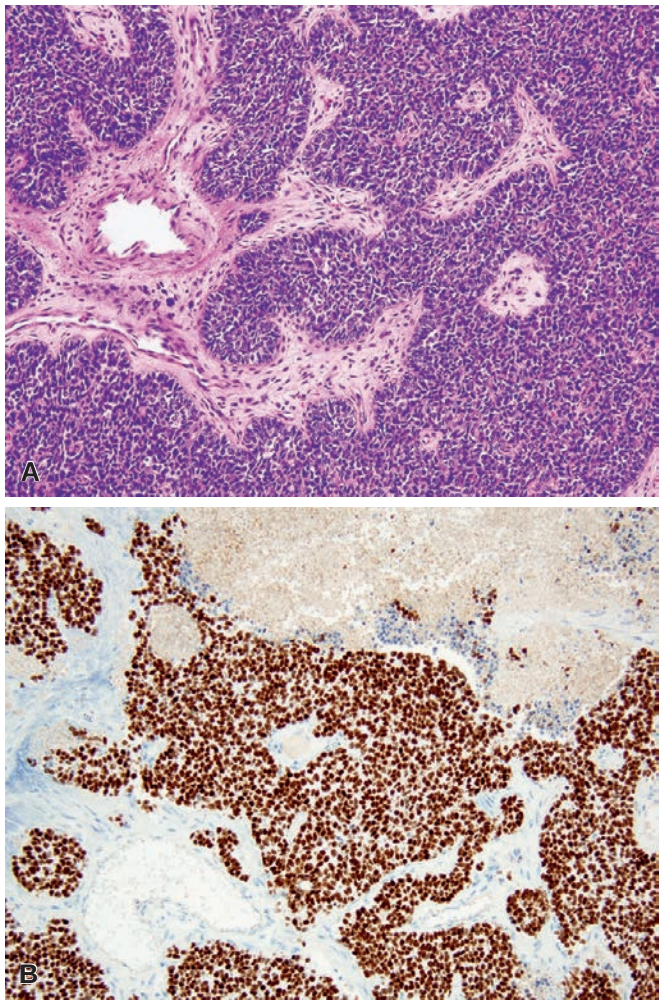

Figure 10.95 Basaloid squamous cell carcinoma with characteristic lobulated growth pattern **(A)** and diffusely positive staining for p63 **(B)**.

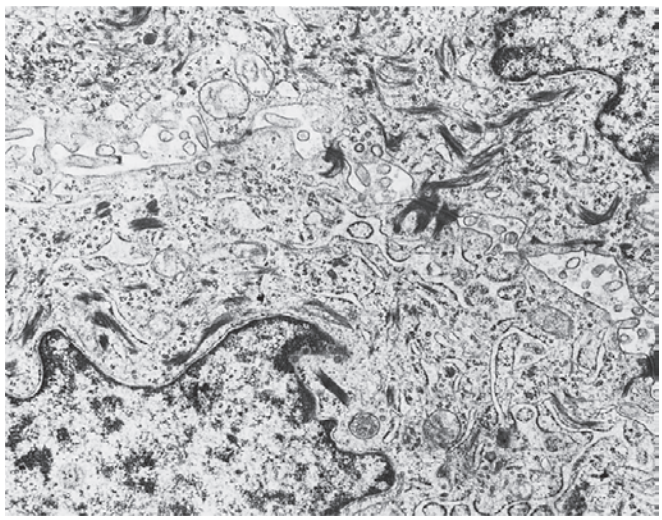

Figure 10.96 Squamous cell carcinoma of lung. Neoplastic cells with numerous tonofilaments, some of them attached to desmosomes. This is characteristic of squamous differentiation (×16,850).

HPV has been documented in a minority of squamous cell carcinomas and in some adenocarcinomas, with a prevalence that is highly variable depending in large part on geographic origin.[361] HPV 16 and 18 are the most commonly detected high-risk genotypes, but their role in carcinogenesis remains uncertain.[264,362]

At the genetic level, the most common alterations are somatic mutations in *TP53* and inactivation of *CDKN2A* through epigenetic silencing, inactivating mutations, and homozygous deletion.[363] Other frequently altered genes include a subset involved in squamous differentiation *(SOX2, TP63, NOTCH1, NOTCH2, ASCL4, FOXP1)* and another group that regulate the oxidative stress response (*KEAP1*, *CUL3*, and *NFE2L2*).[363]

Neuroendocrine Tumors

Neuroendocrine lung tumors include two high-grade variants, *small cell carcinoma* and *large cell neuroendocrine carcinoma*, an intermediate-grade category termed *atypical carcinoid tumors*, and low-grade *typical carcinoid tumors*. *Tumorlets* and *diffuse neuroendocrine cell hyperplasia* are two overlapping lesions more likely to present as diffuse multifocal disease in contrast to the other neoplasms included in this category. Small cell carcinoma and large cell neuroendocrine carcinoma are high-grade neuroendocrine carcinomas for which there are low rates of interobserver agreement even among experts in consistently separating one from the other.[364] This may be of limited significance given overlapping natural histories in clinical studies, overlapping immunophenotypes, and emerging molecular profiling studies showing that they tend to cluster together but are separate and distinct from atypical and typical carcinoid tumors.[365,366]

Small cell carcinoma comprises 10%–20% of incident lung cancers in the United States.[304] Incidence rates in men and women have been converging toward parity since the 1980s and early 1990s.[246] Small cell carcinoma, like squamous cell carcinoma, shows a very strong dose-dependent association with cigarette smoking; nearly all affected patients are current or former smokers.[367] Small cell carcinoma is disseminated (stage III or IV) at the time of diagnosis in around 90% of patients; 10% have limited stage disease for which therapeutic options may include surgical excision.[368,369]

Small cell carcinoma is typically a lesion of the central portions of the lung, but occasionally it is found in a peripheral location. Grossly, the tumor is white-tan, soft, friable, and extensively necrotic. When centered in a large bronchus (the usual situation), it may involve it in a circumferential fashion and/or spread widely beneath the normal mucosa (Fig. 10.97). The bronchus may be totally occluded in the late stages, but pure or predominant endobronchial involvement is unusual.

Microscopically, small cell carcinoma should be viewed as a distinctive tumor type rather than as an undifferentiated form of lung cancer. The histologic pattern is generally solid or sheetlike, combined with other growth patterns commonly affiliated with neuroendocrine differentiation including a nested or organoid architecture, often with peripheral palisading of neoplastic cells, ribbons trabeculae, and rosettes or pseudorosettes.[370] Necrosis is common and is usually extensive.

The *'pure'* form of small cell carcinoma is characterized by small round or oval cells resembling lymphocytes (Fig. 10.98).[371] The nuclei are finely granular and hyperchromatic, nucleoli are inconspicuous, mitoses are frequent, and the cytoplasm is so scanty as to be almost unrecognizable in routine preparations. In some instances the cells have a spindle shape. Nuclear 'molding,' a change first described in cytologic smears, can also be appreciated in microscopic preparations and is a consequence of scant cytoplasm relatively free of intermediate filaments. In rare cases, small cell carcinomas that are otherwise typical may contain scattered giant tumor cells.[372] A very common

Figure 10.97 Small cell carcinoma of the lung. The tumor is growing diffusely along the wall of a lobar bronchus and its branches.

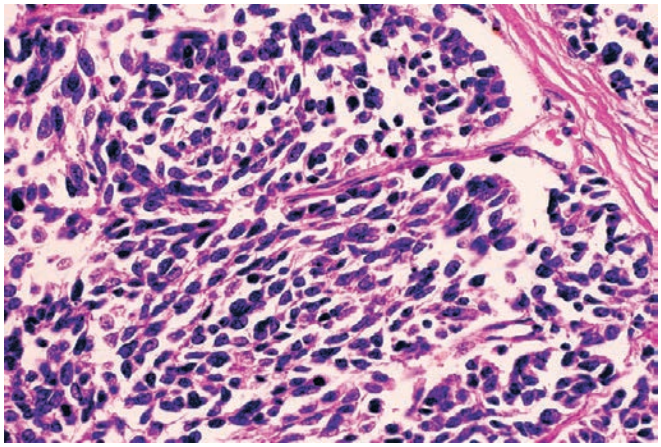

Figure 10.98 Small cell carcinoma showing cells with darkly staining oval to spindle nuclei and extremely scanty cytoplasm.

artifact, particularly prominent in small biopsy specimens, is elongation of the nuclei, with deformation, clumping, and diffusion of the chromatin (Fig. 10.99). If present throughout the specimen, it may make the diagnosis impossible on a biopsy specimen, although correlation with corresponding cytology specimens is often very

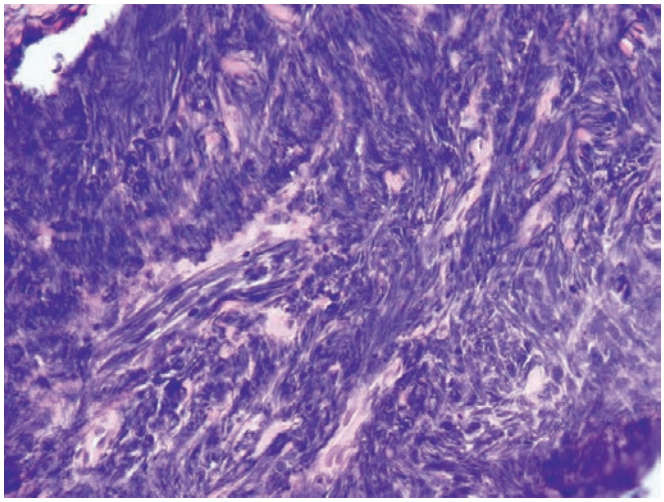

Figure 10.99 Small cell carcinoma in bronchial biopsy with extensive crush artifact making diagnosis all but impossible in this field.

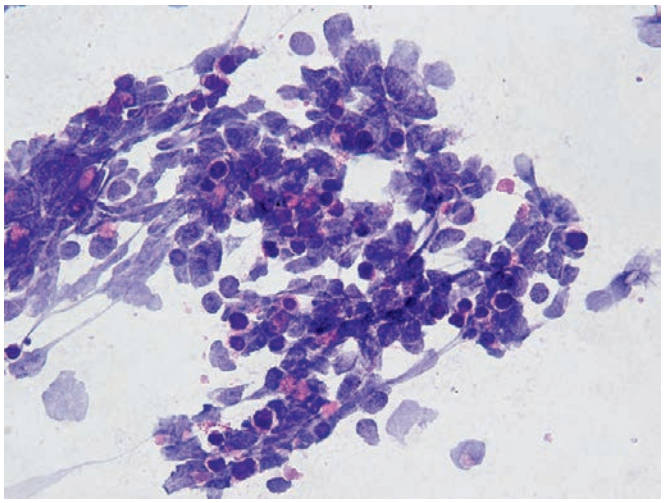

Figure 10.100 Small cell carcinoma smear from endobronchial ultrasound-guided fine-needle aspiration of subcarinal lymph node.

helpful (Fig. 10.100).[373] Another artifact, often referred to as the *Azzopardi effect*, that is sometimes seen in small cell carcinomas is chromatin diffusion and encrustation of blood vessel walls, which appear strongly hematoxyphilic (Fig. 10.101).

Interestingly, the classic appearance of small cell carcinoma is seen almost exclusively in small biopsies. In specimens obtained from lymph node or distant metastases or from the rare resection specimens of the primary tumor, the tumor cells are usually larger and with more abundant cytoplasm.[370] This suggests that some degree of artifactual shrinkage is at least partially responsible for the 'small cell' phenotype which may contribute to the challenge in separating from large cell neuroendocrine carcinoma.

Historical subclassifications of small cell carcinoma were primarily based on cytologic criteria, subdividing small cell carcinomas into *oat cell*, *intermediate cell*, and *mixed small and large cell* categories. These subclassification schemes lacked reproducibility and had no consistent clinical or biologic significance, instead reflecting a range of cytologic heterogeneity in these high-grade neuroendocrine carcinomas heretofore too narrowly defined.[374,375] Both the 2004 and 2015 WHO tumor classification schemes regard small cell carcinoma as a single entity that, like all other forms of lung

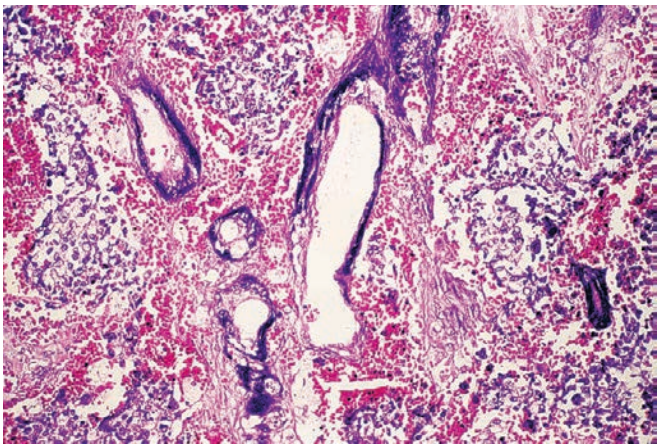

Figure 10.101 Small cell carcinoma with extensive necrosis associated with hematoxyphilic staining of the vessel walls (so-called 'Azzopardi effect').

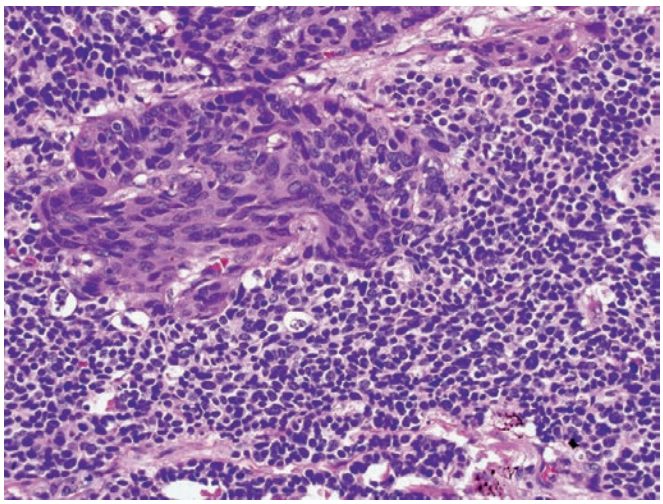

Figure 10.102 Combined small cell–squamous cell carcinoma.

carcinoma, can present in a 'pure' form or admixed ('combined') with other cell types.[371] *Combined small cell carcinoma* is uncommon and is defined as a small cell carcinoma combined with a second component comprising squamous cell carcinoma, adenocarcinoma, or rarely variants of sarcomatoid carcinoma (Fig. 10.102).

The key factor in determining whether a lung tumor belongs to the small cell category or not, in either a pure or a combined form, is not the detection of neuroendocrine differentiation (as discussed in the following paragraph) or the nuclear size, but rather the chromatin and nucleolar patterns as determined by light microscopic examination of routinely stained material.[373] The chromatin should be finely dispersed, without prominent clumps; more importantly, nucleoli should be inconspicuous or absent altogether.

Immunostains are of limited value in establishing a diagnosis of small cell carcinoma but are frequently useful to narrow the differential diagnosis, especially in small biopsies.[373] Nearly all small cell carcinomas are positive for keratins, especially low-molecular-weight keratins.[373,376,377] This is useful in distinguishing small cell carcinoma from lymphoma, a tumor that can mimic the clinical, radiological, histologic, and cytologic features of small cell carcinoma. Immunostains can be especially helpful in separating small cell carcinoma from basaloid variants of squamous cell carcinoma given that small cell carcinomas are usually negative or show only focal staining of isolated tumor cells for high-molecular-weight cytokeratins

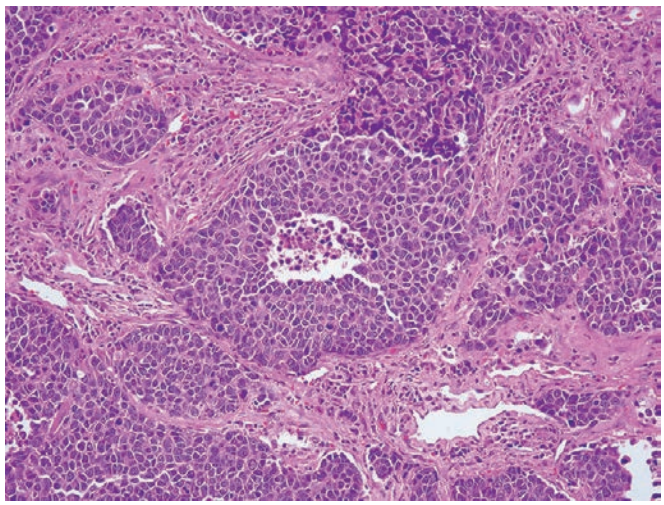

Figure 10.103 Large cell neuroendocrine carcinoma with a nested ('organoid') growth pattern, characteristic pattern of necrosis and numerous mitoses.

(e.g. 34βE12 and CK5/6), p63, and p40.[377] TTF-1 is positive in about 80%–90% of small cell carcinomas, another feature that distinguishes small cell carcinomas from basaloid squamous cell carcinoma.[378] The proliferation rate, as measured with Ki-67 (MIB-1), is almost 100%, a key finding in the differential diagnosis with carcinoid and atypical carcinoid tumor on small biopsies.[379] Stains for neuroendocrine markers are of limited value because as many as 40% of small cell carcinomas may be negative for synaptophysin and chromogranin. CD56 is more sensitive but less specific. At the same time nearly a third or more of conventional non-small cell carcinomas show evidence of neuroendocrine differentiation using a three-antibody panel (chromogranin, synaptophysin, and CD56 or CD57).[380]

At the molecular genetic level, small cell carcinoma is characterized by a deletion in chromosome 3 (p14–p23) in almost 100% of cases, mutation of *TP53* in over 80%, inactivating mutations of the *RB* gene in over half, and amplification of *MYC*, *SOX2*, and *FGFR1* in a minority.[381,382] Mutations in *KRAS* and *EGFR* are rarely found.[382]

Large cell neuroendocrine carcinoma is another form of high-grade neuroendocrine carcinoma with substantial histologic, immunophenotypic, molecular, and clinical overlap with small cell carcinoma. Like small cell carcinoma it is strongly associated with a history of heavy cigarette smoking. Large cell carcinoma is defined by a neuroendocrine architecture under the microscope (i.e. organoid, trabecular, peripheral palisading, and rosette-like structures), relatively large cells with prominent nucleoli and variably abundant cytoplasm, a high (>10 mitoses per 2 mm^2) mitotic rate, necrosis, and immunohistochemical evidence of neuroendocrine differentiation (Fig. 10.103). The neuroendocrine architecture distinguishes large cell neuroendocrine carcinoma from other high-grade non-small cell carcinomas that happen to have neuroendocrine differentiation, the mitotic rate separates it from atypical carcinoid tumors, and the combination of prominent nucleoli and more abundant cytoplasm is what separates large cell neuroendocrine carcinoma from small cell carcinoma. Cell size by itself is of limited value given considerable overlap with small cell carcinoma.[383]

Carcinoid Tumor

Carcinoid tumors comprise less than 1% of primary lung cancers.[384] Pulmonary carcinoid tumors are separated into *typical* and *atypical* categories based on a combination of necrosis and mitotic rate.

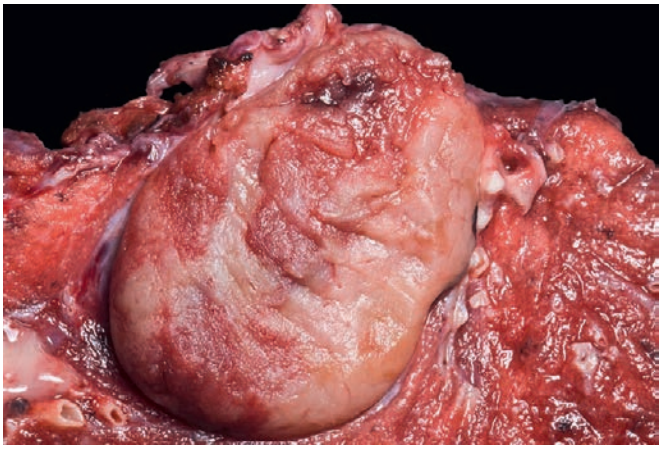

Figure 10.104 Central carcinoid tumor showing well-circumscribed quality situated within a large bronchus. (Courtesy of Dr. J. Carvalho, Minneapolis, MN.)

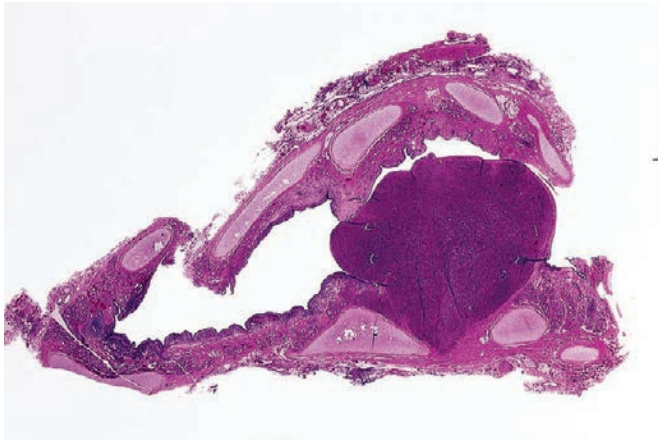

Figure 10.105 Whole mount of central carcinoid tumor showing polypoid endobronchial growth.

Typical carcinoid tumor is the most common of the neuroendocrine lung tumors, known in the distant past as bronchial adenoma.[385] It usually presents as a slow-growing, solitary polypoid mass within a major bronchus (Figs. 10.104 and 10.105); because of its location and highly vascular stroma, hemoptysis and postobstructive pulmonary infection are common. About one-fourth of typical carcinoid tumors occur peripherally and are more likely to be detected as asymptomatic solitary lung nodules. Most cases occur in adults, but they can also develop in children, in whom they are the most common primary malignant lung neoplasm.[386] The gender incidence is almost equal in adults and children. Most cases are endocrinologically silent at the clinical level. However, patients with carcinoid syndrome and elevated urine 5-HIAA have been documented. ACTH-secreting typical and atypical carcinoid tumors are also a rare but important potential cause of Cushing syndrome.[387]

Grossly, typical carcinoid tumors are predominantly endobronchial neoplasms with an intact, nonulcerated mucosal surface and limited infiltration through the bronchial wall to the surrounding parenchyma. Marked invasion of adjacent lung parenchyma is uncommon, however, and more commonly signifies an atypical carcinoid tumor.[388] Peripheral tumors are grossly nonencapsulated but well circumscribed, variegated gray to tan-brown, and focally hemorrhagic nodules with no anatomic relationship to a bronchus (Fig. 10.106).

Figure 10.106 Peripheral carcinoid tumor showing characteristic subpleural location and well-circumscribed configuration.

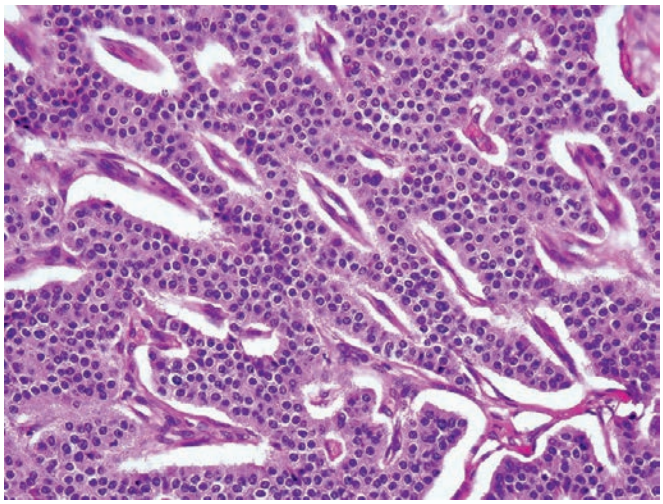

Figure 10.107 Carcinoid tumor showing characteristic architecture and cytology.

Microscopically, carcinoid tumors are well circumscribed with limited invasion of adjacent lung tissues.[388] They are composed of intermediate-size uniform cells having central nuclei, small nucleoli, and a moderate amount of finely granular cytoplasm (Fig. 10.107). Occasionally, prominent nuclear *(endocrine-type)* pleomorphism comprising a combination of hyperchromasia and anisonucleosis is seen in the absence of necrosis or mitoses; this feature by itself is not sufficient to place the tumor in the atypical carcinoid category. Neoplastic cells form compact nests, ribbons, and festoons[385]; pseudopapillary or a true papillary growth pattern is rare.[389] Small glands with a rosette-like appearance are only rarely present. Vascularity is pronounced and is the reason that bronchoscopists may choose not to biopsy endobronchial lesions with the gross appearance of a carcinoid. Tumor cells may be seen within lymph vessels in or around the tumor, a finding of no prognostic significance.

Microscopic variants of carcinoid tumor are relatively uncommon but may complicate differential diagnosis. Spindle cell carcinoid tumors are composed predominantly of spindle cells that may closely simulate the appearance of nonepithelial tumors, including smooth muscle neoplasms and monophasic synovial sarcoma (Fig. 10.108).

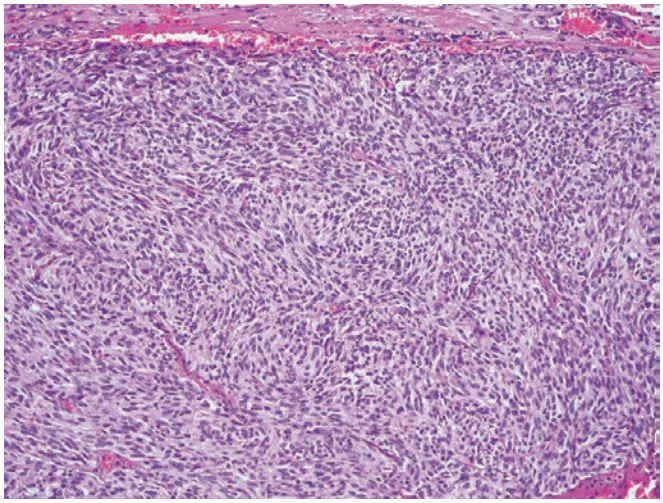

Figure 10.108 Spindle cell appearance of peripheral carcinoid tumor, which may simulate a mesenchymal neoplasm.

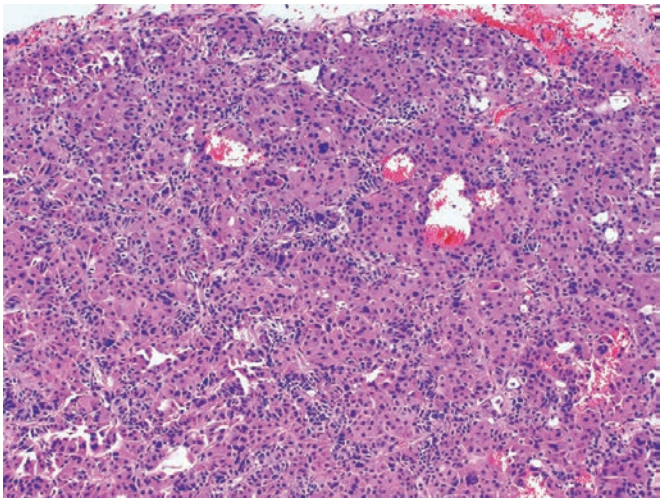

Figure 10.110 Oncocytic variant of carcinoid tumor.

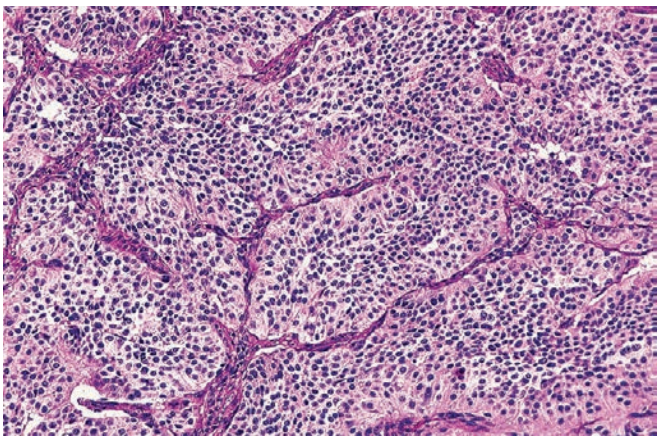

Figure 10.109 Central carcinoid tumor with paraganglioma-like pattern of growth.

The arrangement of the cells is less orderly and the nuclei smaller and more hyperchromatic with finely divided chromatin and higher N:C ratios sometimes mimicking small cell carcinoma.[390] Spindle cell carcinoids are more commonly peripheral in location, frequently presenting as asymptomatic solitary nodules, but can also occur centrally. As in the case of more classical appearing carcinoid tumors, spindle cell carcinoids may acquire paraganglioma-like features, including the presence of S-100 protein–positive sustentacular cells (Fig. 10.109).[391] Oncocytic variants are less common but may be confused with higher-grade lesions, given the tendency toward nuclear pleomorphism and prominent nucleoli (Fig. 10.110).[392] In exceptional cases, carcinoid tumors contain melanin granules in the tumor cells ('melanotic carcinoid tumor').[393] The stroma in carcinoids can be heavily sclerotic or hyalinized and may exhibit focal calcification or ossification.[394]

Immunohistochemically, there is variable but usually positive reactivity for keratin and a broad array of neuroendocrine markers, including neuron-specific enolase, chromogranin A and B, synaptophysin, CD56, and neurofilaments.[384] In addition, many peptide hormones have been detected in individual tumors, sometimes in combination. In addition to many neuroendocrine-type markers, carcinoid tumors display immunoreactivity for the transcription factor TTF-1 in over half of the cases (higher in the peripheral type),[378,395–397] whereas they are consistently negative for CDX2 and PAX8, thus rendering these three markers important tools for the differential diagnosis between primary and metastatic carcinoid tumors in the lung from the gastrointestinal tract and pancreas, respectively.[398,399] Carcinoid tumors with a prominent nesting pattern of growth may acquire a 'paraganglioid' appearance, which is accentuated by the presence of S-100 protein–positive sustentacular cells at the periphery of the nests (see Fig. 10.109).

Carcinoid tumors demonstrate a low mutation burden compared with other higher-grade primary lung neoplasms and usually lack the *TP53* and *RB1* mutations more common in high-grade neuroendocrine lung tumors. Comprehensive molecular profiling has demonstrated mutually exclusive driver mutations in genes affecting histone methylation *(MEN1/PSIP1)* and ATP-dependent chromatin-remodeling (*ARID2*, *SETD1B* and *STAG1*).[400]

From a diagnostic viewpoint, central carcinoid tumors are easily identifiable with the bronchoscope in the majority of cases. Bronchoscopic biopsy is usually positive, although severe hemorrhage may result because of the marked vascularity of the tumors. The microscopic diagnosis is generally easy, although small samples with crush artifact can be confused with small cell carcinoma, as we have seen on several occasions. A Ki-67 (MIB-1) immunostain can be very useful in this circumstance, since it will be positive in nearly all cells of a small cell carcinoma but usually in less than 10% of the cells of a typical carcinoid.[379,401]

The treatment is surgical.[402] Removal through the bronchoscope is not sufficient because of the potentially infiltrative nature of the tumor. Depending on the location of the tumor along the bronchial tree and the status of the distal lung, the operation may be a segmental bronchial resection, a lobectomy (the usual procedure), or a pneumonectomy. Metastases to regional lymph nodes occur in about 5% of the cases and are usually limited to N1 nodes, a finding that has no impact on the generally excellent prognosis affiliated with typical carcinoid tumors.[403]

Atypical carcinoid tumor not only exhibits the overall architectural, ultrastructural, and immunohistochemical features of carcinoid tumor, but also exhibits atypical features in the form of increased mitotic activity (2–10 mitoses per 2 mm^2) and/or foci of necrosis (Fig. 10.111).[404] These have been referred to as *atypical carcinoid tumors*. Like their typical counterparts, they express various neuroendocrine and neural markers with the same relative frequencies[405] and may be occasionally accompanied by amyloid deposition in the stroma.[406] Historically, atypical carcinoid tumors were thought to represent a

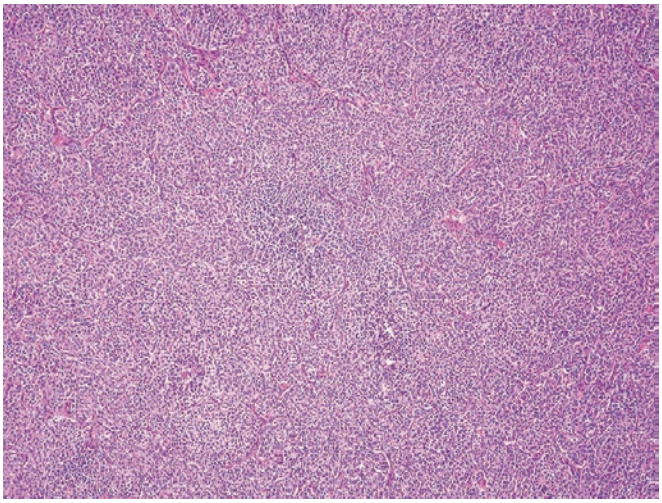

Figure 10.111 Atypical carcinoid tumor.

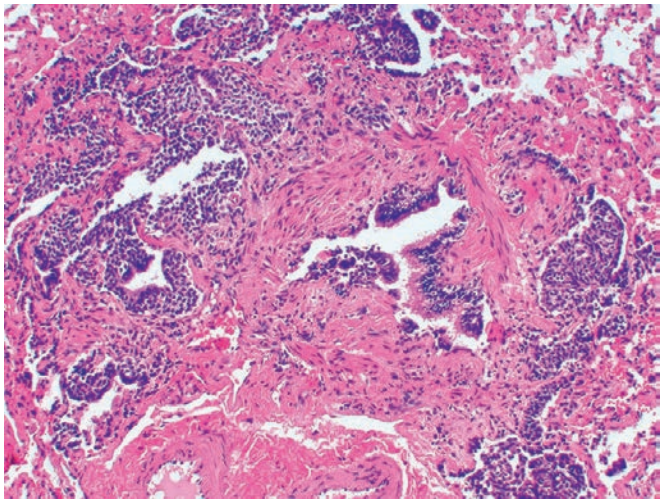

Figure 10.112 So-called pulmonary tumorlet.

link between typical carcinoid tumor and small cell carcinoma. There is now strong molecular evidence against it,[365,366,400] but there is no question that, for prognostic and therapeutic purposes, typical carcinoid tumors should be sharply separated from the atypical variety given marked differences in natural history and survival.[388,404,407] In one surgical series the incidence of lymph node metastases for atypical carcinoid was just over 35%, as opposed to an incidence of about 9% for the typical carcinoid.[408] The authors concluded that the treatment for surgical candidates should be more aggressive and not substantially different from that for ordinary lung carcinoma of non-small cell type, including conventional resection and radical mediastinal lymphadenectomy.[408,409] In this large series, the 5-year survival of atypical carcinoid was 78% and dropped to 60% in those with nodal involvement. Features of adverse prognostic significance are female gender, large tumor size, nodal involvement, higher mitotic rates, marked invasion into adjacent lung parenchyma, and lymph vessel invasion.[388,407,408]

The role of Ki-67 staining in routinely separating carcinoid tumors of the lung into meaningful groups is unresolved. In several studies subclassification using current WHO mitotic rate cutoffs outperformed Ki-67 labeling index in predicting disease progression and survival.[410,411] Others have argued that Ki-67 staining is more reproducible than current histologic criteria for grading neuroendocrine lung tumors and separating them into prognostically useful categories.[412–414]

Tumorlet *(carcinoid tumorlet)* is the term given to a nodular proliferation of small spindle cells seen in relation to bronchioles, often in association with bronchiectasis and other conditions associated with scarring including intralobular sequestration (Fig. 10.112). Tumorlets are frequently multiple and in rare cases are affiliated with a *diffuse* proliferation of airway-associated neuroendocrine cells in a condition referred to as *diffuse idiopathic pulmonary neuroendocrine hyperplasia* (DIPNECH) (Fig. 10.113).[415] Cases with multiple tumorlets may also be affiliated with one or more carcinoid tumors, thus mimicking the radiological appearance of metastatic disease in patients being followed for other malignancies.[416] Exceptionally, one may find tumorlet-like nests of neuroendocrine cells in intrathoracic lymph nodes, a finding that should not be misconstrued as evidence of metastatic disease.[417]

Pulmonary tumorlets closely resemble spindle cell carcinoid tumors, differing mainly in size, distribution, and histologic context. An arbitrary size criterion of 0.5 cm has been used to distinguish between tumorlet and carcinoid tumor given their overlapping histologic and cytologic features. The fact that at the cytogenetic level tumorlets generally lack the 11q13 allelic imbalance that is characteristic of carcinoid tumors suggests a different molecular pathogenesis for the two lesions and provides a potential tool for their distinction.[418]

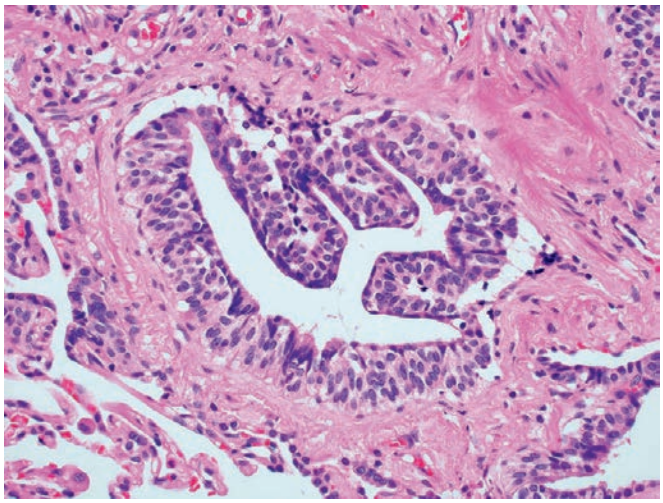

Figure 10.113 Diffuse idiopathic pulmonary neuroendocrine cell hyperplasia in a patient with multiple carcinoid tumorlets.

The behavior of tumorlet is generally benign, although isolated instances of metastatic behavior have been reported. The main practical importance is that they can be misdiagnosed radiographically and microscopically for lung metastases, especially in patients with a history of breast carcinoma.[416,419]

Large Cell Carcinoma

Large cell carcinomas are pleomorphic malignant epithelial tumors without cytologic, histologic, or immunophenotypic features of adenocarcinoma, squamous cell carcinoma, small cell carcinoma, or large cell neuroendocrine carcinoma.[420] The tumor cells are large, at least in comparison with those of small cell carcinoma, and demonstrate marked nuclear pleomorphism and variably abundant cytoplasm mimicking other pleomorphic poorly differentiated tumors, such as melanoma and lymphoma (Fig. 10.114). Many high-grade

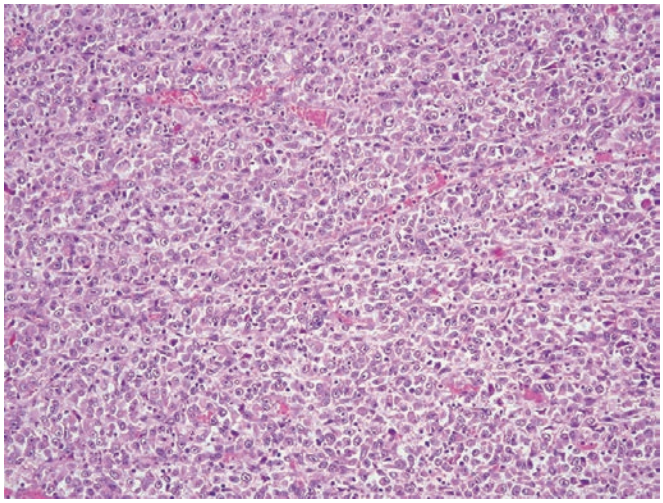

Figure 10.114 Large cell carcinoma.

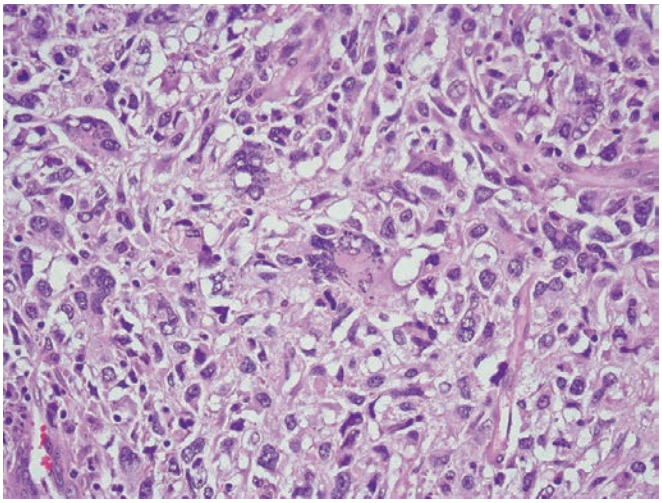

Figure 10.116 Prominent neoplastic giant cells in a sarcomatoid ('giant cell') carcinoma.

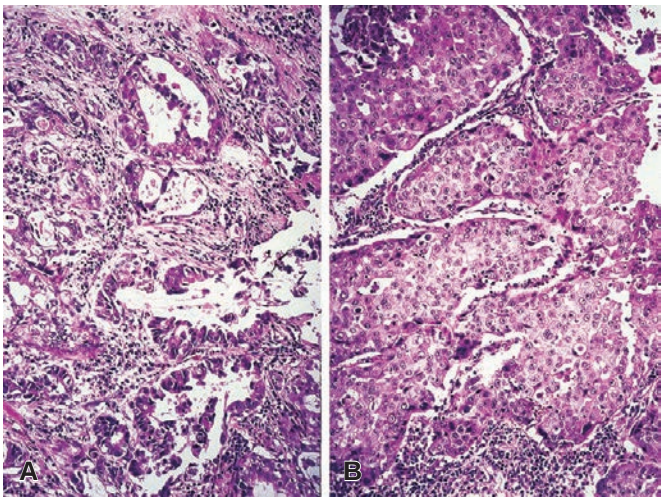

Figure 10.115 Adenosquamous carcinoma of lung showing an admixture of glandular (**A**) and squamous (**B**) components in the same tumor.

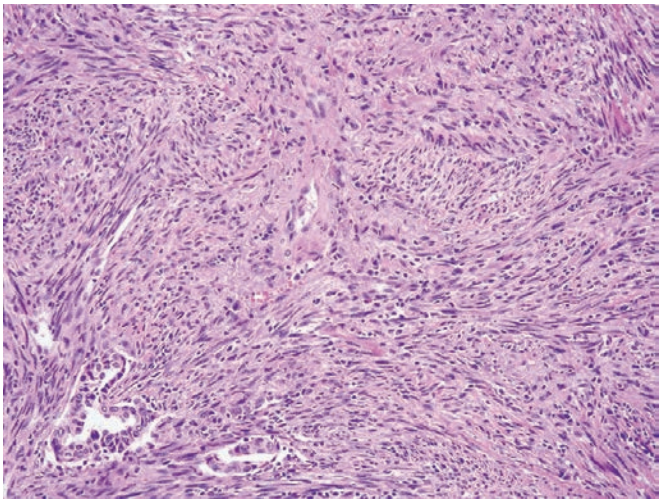

Figure 10.117 Prominent spindle cells in a sarcomatoid ('spindle cell') carcinoma.

non-small cell carcinomas historically assigned to this category are now considered poorly differentiated adenocarcinomas and squamous cell carcinomas based on the results of immunohistochemical and molecular studies. This applies to previously included variants like basaloid carcinomas, lymphoepithelioma-like carcinomas, clear cell carcinomas, and large cell carcinomas with rhabdoid phenotype.[421,422] Large cell neuroendocrine carcinoma has been recategorized with other neuroendocrine lung tumors. As a consequence large cell carcinomas represent a smaller and smaller subset of lung carcinoma types. Large cell carcinomas accounted for only 4% of lung carcinomas in a review of two large national databases accruing incident cases from 2004 to 2009, and declined from a rate of six cases per 100,000 person-years in the 1990s to about 1 case per 100,000 person-years in 2010 in another study.[246]

Adenosquamous Carcinoma

The term adenosquamous carcinoma is used for lung tumors in which distinct areas of squamous and glandular differentiation are found in the same neoplasm, each accounting for at least 10% of the sampled tumor (Fig. 10.115).[354] Squamous cell carcinomas having occasional mucin-producing cells or adenocarcinomas with minute foci of squamous differentiation are named according to their predominant component. Thus defined, adenosquamous carcinomas account for less than 5% of lung cancers. Most of the cases are located peripherally and often are associated with a scar, suggesting a closer relationship with adenocarcinoma than with squamous cell carcinoma.

Sarcomatoid Carcinoma and Carcinosarcoma

As in other organs, there exists in the lung a family of carcinomas having sarcoma-like features referred to generically as *sarcomatoid carcinomas*.[423–425] Further subtyping of these tumors is of limited biologic or clinical significance and is dependent upon minor variations in their microscopic appearance and the histogenetic biases of the observer. When composed predominantly of tumor giant cells, they have been designated as *giant cell carcinomas* (Fig. 10.116). When predominantly composed of spindle cells but still identifiable as epithelial on morphologic, ultrastructural, or immunohistochemical

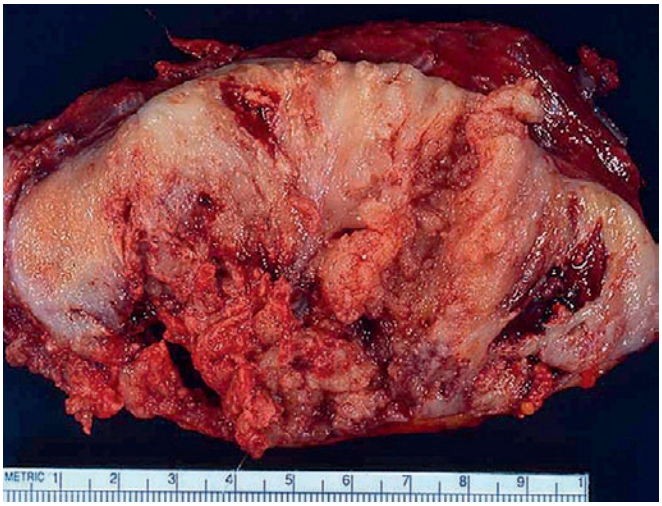

Figure 10.118 Sarcomatoid carcinoma with extensive necrosis.

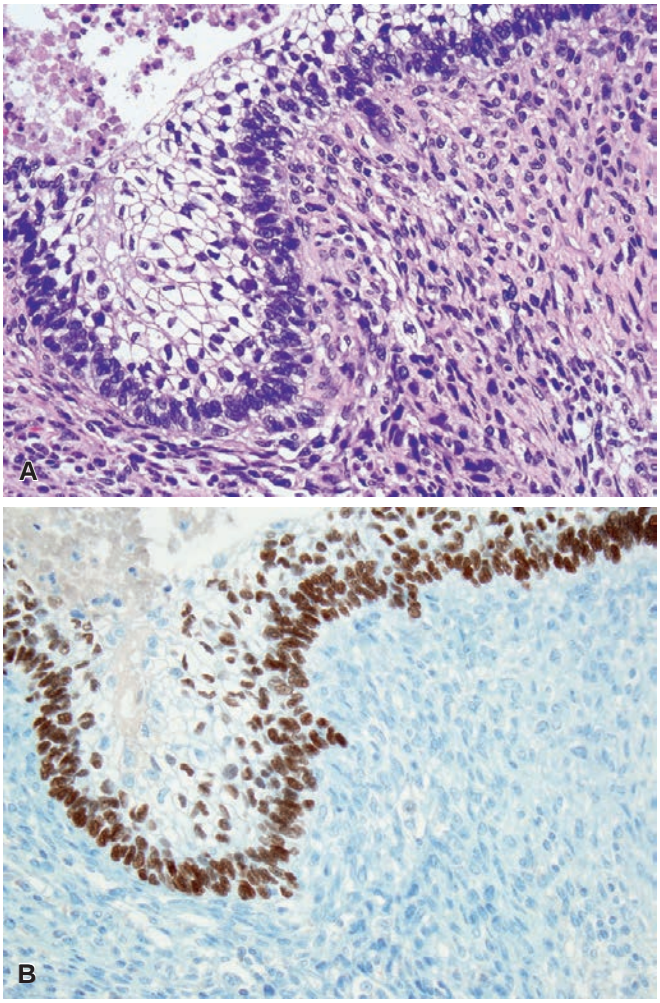

Figure 10.119 Sarcomatoid ('pleomorphic') squamous cell carcinoma showing a spindle cell component and an epithelial component with squamous differentiation demonstrating clear cell change **(A)**; staining for p63 was limited to the squamous component **(B)**.

grounds, they have been called *spindle cell carcinomas* (Fig. 10.117). Some authors have applied the term *pleomorphic carcinoma* to tumors in which there are both giant cell and spindle cell components, often in combination with a more histologically classic component of adenocarcinoma, squamous cell carcinoma, or undifferentiated non-small cell ('large cell') carcinoma. When the carcinomatous and sarcoma-like components are segregated and the latter demonstrates heterologous elements (e.g. chondrosarcoma, osteosarcoma, rhabdomyosarcoma), the term *carcinosarcoma* has been used. Studies of large series of cases with morphologic, immunohistochemical, and molecular techniques have rendered apparent the fact that these represent various manifestations of the same biologic phenomenon, by which neoplastic cells derived from pluripotent stem cells lose in part or completely their epithelial phenotype and acquire characteristics of mesenchymal cells, a phenomenon sometimes referred to as epithelial–mesenchymal transition.[426,427]

Grossly, these tumors can appear either as intraparenchymal or endobronchial polypoid masses that are frequently large and partially necrotic (Fig. 10.118).[425] Microscopically, the identifiable epithelial elements, when present, may show squamous differentiation, glandular differentiation, or be undifferentiated, thus resembling large cell carcinoma (Fig. 10.119). The sarcoma-like component may be nondescript, or resemble chondrosarcoma, osteosarcoma, rhabdomyosarcoma, or angiosarcoma. Osteoclast-like giant cells can be present, resulting in histologic features resembling those seen in giant cell tumor of bone. As indicated, the interface between the carcinomatous and the sarcoma-like components can be indistinct or sharp. Bronchoscopic or needle biopsy may show one or both elements.

The immunostains traditionally used to support the presence of epithelial differentiation in sarcomatoid carcinomas, albeit in a less than specific fashion, are pankeratin, EMA, and p63.[428] Immunostains for TTF-1 are also useful in a surprising number of cases of sarcomatoid lung carcinomas.[423] There remain a minority of cases in which immunostains may fail to show convincing evidence of epithelial differentiation in sarcomatoid components. In this circumstance, knowledge of the radiological distribution of disease is helpful given that sarcomatoid carcinomas often present as large, bulky solitary lung masses with or without intrathoracic adenopathy.

The prognosis of this tumor is poor, overlapping with same-stage poorly differentiated non-small cell carcinomas of other histologic subtypes.[429]

Pulmonary Blastoma

Pulmonary blastoma typically presents in adults, in contrast to blastomas of other organs. Pulmonary blastoma should not be confused with *pleuropulmonary blastoma (PPB)*, a pediatric malignancy with a totally different presentation and morphologic appearance (see p. 428). Pulmonary blastoma usually presents as a peripherally located, solitary, well-circumscribed, large mass grossly resembling other sarcomatoid carcinomas (Fig. 10.120).[430] Microscopically, it is characterized by the presence of a well-differentiated adenocarcinomatous component in a cellular stroma composed of undifferentiated small ('blastematous') spindle cells (Fig. 10.121).[431] The overall appearance resembles fetal lung between 10 and 16 weeks' gestation and is also reminiscent of Wilms tumor.[432] The glandular cells often show subnuclear and supranuclear cytoplasmic vacuoles and variably abundant cytoplasmic glycogen. Solid balls of cells with abundant acidophilic cytoplasm ('morules') are common, mimicking the appearance of endometrioid adenocarcinomas; curiously, the nuclei in these formations often have a ground-glass (optically clear) appearance, said to be due to the accumulation of biotin.[433] Taken on its own the epithelial component is indistinguishable from *fetal adenocarcinoma* (referred to historically as *pulmonary endodermal tumor resembling fetal lung*) (Fig. 10.122), the only difference being the

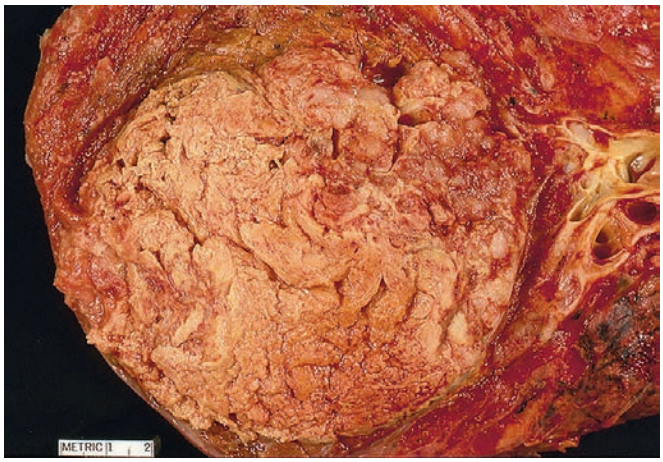

Figure 10.120 Pulmonary blastoma forming a large well-circumscribed necrotic mass.

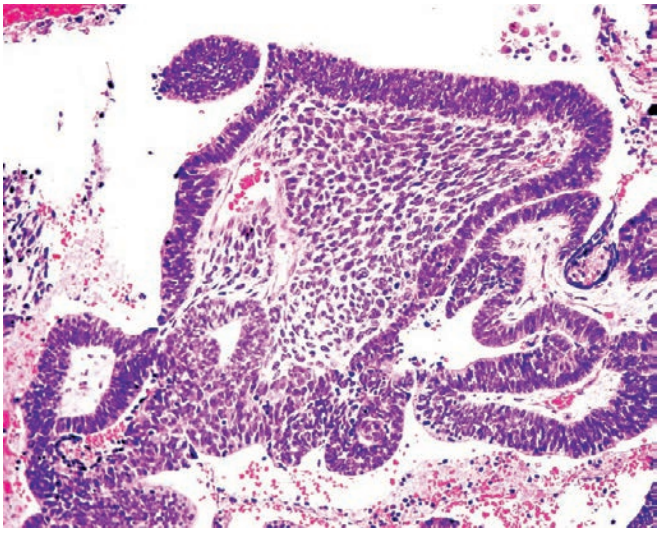

Figure 10.121 Pulmonary blastoma showing typical biphasic pattern of growth and 'fetal' appearance of the epithelial component.

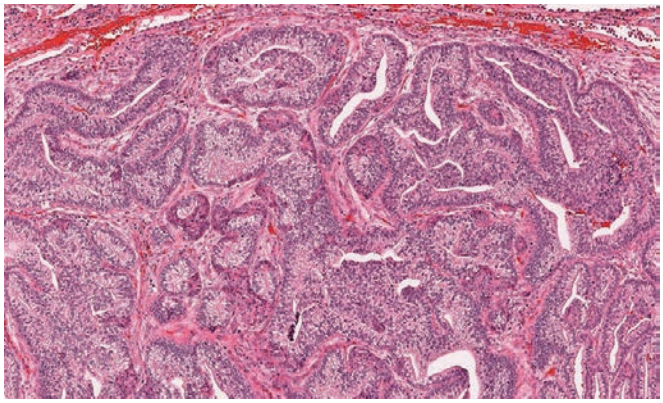

Figure 10.122 Fetal adenocarcinoma (pulmonary endodermal tumor resembling fetal lung). In contrast to pulmonary blastoma, a mesenchymal component is absent.

associated primitive appearing stroma in pulmonary blastoma.[434] Both the stromal component and the epithelial component may show divergent or heterologous differentiation, including skeletal muscle, cartilage, or bone in the former and intestinal, yolk sac, and malignant melanoma in the latter. Like other forms of sarcomatoid carcinoma, classical pulmonary blastoma is an aggressive tumor with greater than 50% mortality at 2 years and median survivals of less than 6 months in a small retrospective cohort.[430]

The occasional presence of combined or transitional forms between pulmonary blastoma and sarcomatoid carcinoma/carcinosarcoma (particularly the latter form) and their similar immunohistochemical and ultrastructural features suggest that they are histogenetically overlapping entities and that in a given case the distinction may not be possible.[435] More recently mutations in the *β-catenin* gene have been identified in fetal adenocarcinoma as well as the epithelial and stromal components of pulmonary blastoma, suggesting that activation of the Wnt signaling pathway may be a distinguishing feature.[436] β-Catenin mutations are associated with aberrant nuclear and cytoplasmic localization of β-catenin by immunohistochemistry, a potentially useful diagnostic tool for separating pulmonary blastoma from other forms of sarcomatoid carcinoma.

Carcinoma Precursors

Dysplasia and carcinoma in situ are the precursors of invasive squamous cell carcinoma. It has been known for a long time that squamous cell carcinomas of the lung have a long preclinical stage in which the lesion progresses from various degrees of dysplasia (mild, moderate, and severe) to carcinoma in situ, microinvasive carcinoma, and frank invasive carcinoma.[437] This progression is neither obligatory nor linear, making it difficult to assess the risk for developing an invasive carcinoma based solely on histologic grading of preinvasive lesions.[438] Detailed morphologic studies of very early cases have demonstrated that most potentially significant squamous cell carcinomas arise unifocally in a segmental bronchus (Fig. 10.123).[439] Grossly, the bronchial mucosa may show slight irregularities in the form of granularity, papillation, and loss of rugae, or it may appear unremarkable. Microscopically, the diagnostic criteria are similar to those applied for this diagnosis elsewhere, including a full-thickness change with an intact basement membrane. There is often extension into the ducts of the submucosal glands, a change that may be difficult to distinguish from broad-based early submucosal invasion. The presence of stromal desmoplasia favors the latter. The proliferative index, as measured with Ki-67 (MIB-1), parallels the morphologic changes.[440] Genetically, early events include loss of heterozygosity at 3p and 9p in squamous metaplasia and dysplasia, followed by *TP53* mutations in carcinoma in situ, and aberrant coexpression of p53 and EGFR.[441,443]

The terms 'early invasive' and 'intramucosal' carcinoma have been used somewhat interchangeably (and somewhat inaccurately) to designate tumors exhibiting superficial invasion of the stroma that does not extend to the level of the bronchial cartilage; most of these are well-differentiated to moderately differentiated tumors (Fig. 10.124).[444] The majority of screening-detected early squamous cell carcinomas show extensive surface involvement with little invasion ('creeping' type); a minority show more deep invasion through the bronchial wall without longitudinal extension along the mucosal surface ('penetrating' type).[445] The observation that penetrating growth patterns are underrepresented in occult squamous cell carcinomas suggests that they may be more rapidly growing and therefore more likely to present as clinically and radiologically significant tumors.

Atypical adenomatous hyperplasia is thought to be the preinvasive precursor of nonmucinous BAC and of some peripheral

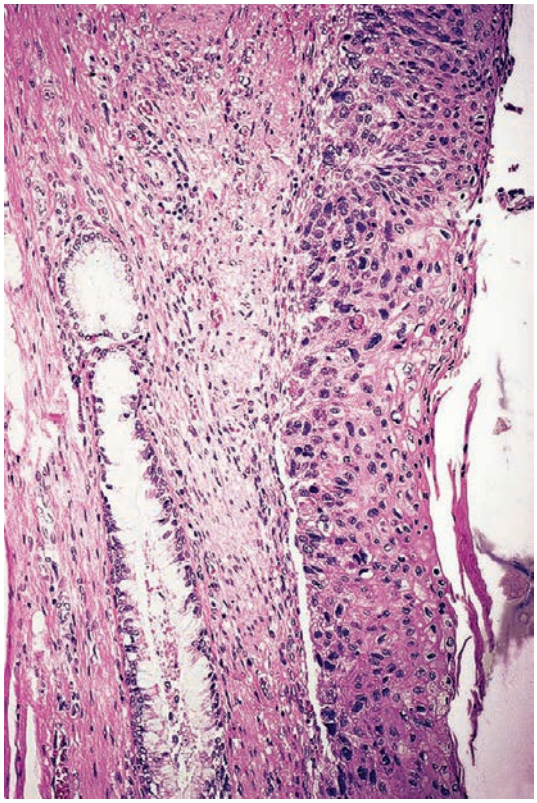

Figure 10.123 Carcinoma in situ of bronchial mucosa.

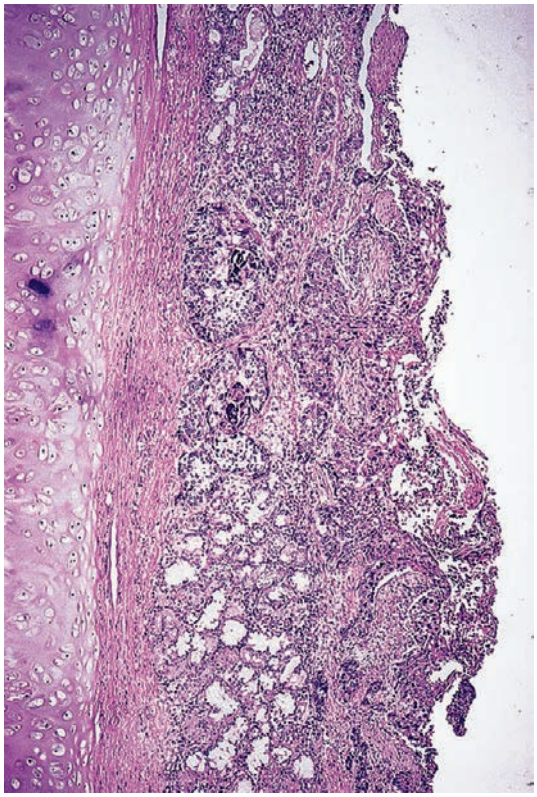

Figure 10.124 Early invasive squamous cell carcinoma of bronchial mucosa.

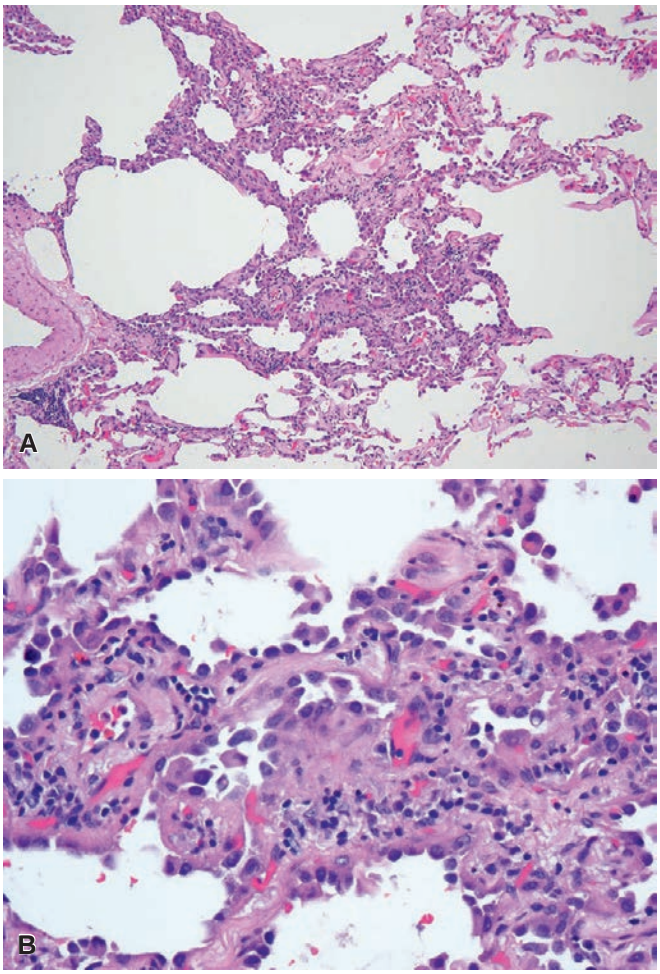

Figure 10.125 Low **(A)** and high **(B)** magnification view of atypical adenomatous hyperplasia.

adenocarcinomas.[262] Atypical adenomatous hyperplasia represents localized proliferations of mildly atypical nonmucinous columnar cells forming small (generally no larger than 5 mm) peripheral nodules in the absence of underlying inflammation or fibrosis (Fig. 10.125). The nodules of atypical adenomatous hyperplasia can be solitary or multiple and are seen more commonly in resected adenocarcinomas (around 15%–20%) than in resected squamous cell carcinomas (fewer than 5%) and occur more commonly in women than in men.[446–450] Importantly, the finding of atypical adenomatous hyperplasia in resected lung carcinomas has no impact on outcomes.[447,451]

Genetically, atypical adenomatous hyperplasia resembles adenocarcinoma in demonstrating mutually exclusive *KRAS* and *EGFR* mutations but differs in that the frequency of the two is markedly different, at least in Asian populations, with *KRAS* mutations more common in atypical adenomatous hyperplasia and *EGFR* mutations more common in adenocarcinoma.[452] This difference is aligned with experiments in genetically engineered mice in whom *KRAS* mutations affecting respiratory epithelial cells is commonly affiliated with atypical adenomatous hyperplasia rather than adenocarcinoma, while the reverse is true for *EGFR* mutations.[453,454]

Frozen Section

Frozen section is an important procedure in debatable lesions of the lung and has its greatest value in peripherally located lesions.

In patients with resectable lung carcinoma, bronchoscopic and/or cytologic examination combined with percutaneous image-guided needle biopsy will yield a diagnosis in the majority of the cases. There remain a number of patients who will undergo surgery for suspected cancer without a definite preoperative diagnosis. For peripheral lesions, it is better to excise them entirely with a margin of normal lung. This is usually in the form of a wedge excision. Frozen section is then done. Sometimes, the lesion proves to be a benign process such as a hamartoma, organizing pneumonia, or granulomatous inflammation, in which case no additional surgery is necessary. If it is carcinoma, the surgeon will decide whether to proceed to completion lobectomy, an especially important decision as less-than lobectomy becomes an increasingly viable option for managing patients with early stage screening-detected lung cancers.[455]

Frozen sections are an accurate method for diagnosing small pulmonary nodules, the chief potential pitfalls being the distinction of carcinoid tumors from other lesions and of early noninvasive or minimally invasive adenocarcinomas from atypical adenomatous hyperplasia and non-neoplastic reactive atypia.[456] Stromal hyalinization, an organoid growth pattern, and spindle cell cytology can be helpful in supporting a diagnosis of carcinoid tumor at the time of frozen section, while a desmoplastic stroma, nuclear pleomorphism, irregular nuclear contours and a mitotic rate above 5 per 10 high powered fields should suggest alternatives.[457] Accurate diagnosis of small in situ or minimally invasive adenocarcinomas at the time of frozen section is especially challenging in smaller (less than 1 cm) lesions and may benefit from more extensive sampling, correlation with findings on CT scans of the chest, and inflation of lung specimens with diluted embedding medium.[458,459] Observation of multiple growth patterns, variation in cell size, extensive atypia involving at least three-fourths of the area of interest, macronucleoli, and atypical mitoses are features that favor well differentiated adenocarcinomas over reactive atypia.[460] It is important that pathologists exercise caution in making a diagnosis of well-differentiated adenocarcinoma in the face of significant inflammation and fibrosis. Uncommon tumors, like sclerosing pneumocytoma, can be accurately diagnosed in most cases, especially when frozen section includes careful examination of the gross specimen.[461]

Two important contributions of frozen section to the surgical handling of lung carcinoma are the mapping of hilar and mediastinal lymph nodes and the evaluation of the bronchial margin. The latter is particularly valuable for central tumors, particularly those of salivary gland–type, and is less valuable in more peripheral tumors.[462,463]

Spread and Metastases

Centrally located lung cancer spreads by direct extension proximally and distally along the bronchus of origin and may reach the trachea at the level of the carina. It also grows into the lung parenchyma, from where it may reach the mediastinum or pleura. The latter event may result in seeding in both pleural layers and extension into the chest wall and diaphragm. Pleural effusion is very common under these circumstances. Occasionally, the entire pleural space is seeded in a fashion mimicking mesothelioma (see Fig. 10.82). Invasion of blood vessels is very common (over 80% of the cases); sometimes, this may lead to extensive tumor emboli and cor pulmonale, an uncommon phenomenon reported with not only primary lung adenocarcinomas but also metastatic adenocarcinomas, for which breast and stomach are the most commonly reported sites.[464] It has been postulated that tumor cells also spread through air spaces, with seeding through the air passages and development of secondary deposits at some distance from the main mass.[465] Indeed observation of spread through air spaces in otherwise low-stage adenocarcinomas may predict for a greater likelihood of locoregional and distant relapse.

Lymph node metastases occur first in the interlobar and hilar region, then in the mediastinal and lower cervical (supraclavicular) groups, and less commonly in axillary and subdiaphragmatic sites. Skip metastases occur in as many as 25% of patients and may reflect the frequency with which micrometastases are clinically and radiologically occult.[466] The site of resection, mediastinal lymph nodes, and supraclavicular fossa remain common sites of locoregional relapse after surgical resection independent of nodal status at the time of diagnosis.

Distant metastases are more common in liver, other areas of lung, adrenal, bone and bone marrow, kidney, and central nervous system.[467] Less common sites include the gastrointestinal tract, pancreas, thyroid, spleen, ovary, pituitary gland, skin, and skeletal muscle. Brain metastases seem to be more common in adenocarcinoma and may be the first manifestation of the disease.[468] The presence of distant metastases at the time of initial diagnosis is particularly high in small cell carcinoma, although the small subset of patients who present without clinical evidence of locoregional or distant spread may benefit from stage-appropriate surgery.[368,469]

Treatment

The standard therapy for operable non-small cell carcinoma of the lung is complete surgical excision through video-assisted thoracoscopic surgery or thoracotomy. The excision can be in the form of pneumonectomy, lobectomy, bilobectomy, or less than lobectomy in highly selected patients, depending on the location and type of the tumor. The first successful lung resection for squamous cell carcinoma was performed by Dr. Evarts A. Graham at Barnes Hospital in St. Louis, Missouri, in 1933. The patient, a physician, died 30 years later of an unrelated disease (Fig. 10.126). Ironically, he survived Dr. Graham, who died as a result of lung carcinoma. As illustrated by this historical patient, surgical therapy is regarded as sufficient in cases of early stage disease, whereas a combined modality therapy is usually applied to patients who present with higher tumor stage.

Radiation therapy can effectively control the local growth of lung cancer and sometimes results in long-term survival[470]; however, like surgery, it fails to cure most patients, mainly because as many as 50% of them have distant metastases when diagnosed or shortly following the initial diagnosis. It also has a limited impact on rates of recurrence in the cases showing microscopic evidence of involvement of the bronchial margin. The role of radiation therapy seems to be greater, whether given alone or as a preoperative measure, for tumors of the superior pulmonary sulcus (Pancoast tumor), as an adjunctive measure in the treatment of small cell carcinoma, and when administrated as adjuvant therapy in combination with chemotherapy.

A significant advance in the treatment of lung cancer is exemplified by the success story of tyrosine kinase inhibitors (such as gefitinib, erlotinib, afatinib), which is a showcase of the new paradigm in targeted therapy for cancer. Analysis of several phase III clinical trials has demonstrated that tyrosine kinase inhibitors outperform standard combination chemotherapy in patient with advanced stage non-small cell lung carcinomas harboring *EGFR*-activating mutations.[471] The same effect has been demonstrated using crizotinib, a small molecule inhibitor of ALK, MET, and ROS1 kinases, as first line therapy in patients with advanced stage non-small cell carcinomas positive for *ALK* translocations.[345] Promising results have also been demonstrated in a phase I trial of crizotinib in patients with *ROS1* rearrangements who have failed conventional therapy.[472] These results are the exemplars for the rapidly evolving field of precision ('personalized') medicine and serve as the underpinnings for current recommendations

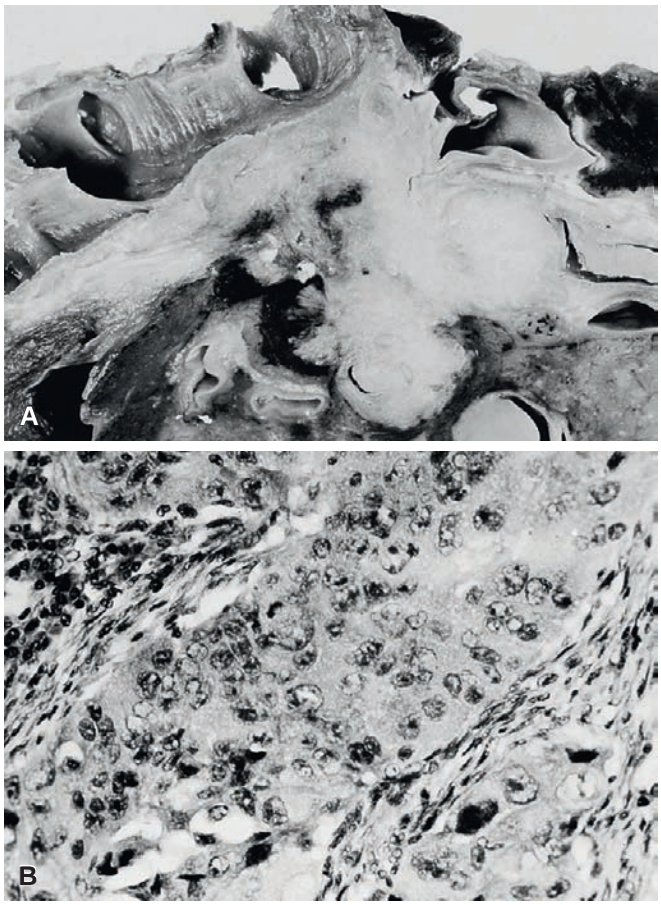

Figure 10.126 **A,** Squamous cell carcinoma of lung resected by Dr. Evarts A. Graham in 1933. Note extension into surrounding lung and involvement of two regional lymph nodes. The patient died in 1962 without evidence of cancer. **B,** Poorly differentiated squamous cell carcinoma shown in **A**.

regarding routine application of molecular testing in patients with advanced or recurrent non-small cell carcinomas.[346] Given that small biopsies with insufficient tissue remain a key impediment to molecular testing in these patients it is increasingly important that surgical pathologists remain stewards of these precious patient assets, minimizing utilization of immunostains unlikely to add substantial value and focusing instead on preservation of tissue for the sorts of testing likely to impact important decisions regarding treatment.[339] This is an important paradigm shift in the role of surgical pathologists in not only diagnosing but also managing patients with lung cancer. This shift will apply to a larger and larger pool of patients as new molecular targets are identified in not only adenocarcinomas but also squamous cell carcinomas for which immunotherapy (nivolumab) has already been approved as a potential therapy, although the role of companion diagnostics relevant to surgical pathology is less clear.[473]

Prognosis

The long-term prognosis of lung carcinoma remains disappointingly poor, with limited improvement having been made in recent years in long-term survival rates. In a recent review of data from the United States collected in the SEER program, 1-year survival rates had increased from 34.4% in 1975–1977 to 44.7% in 2006–2009. But overall 5-year survival rates remained low, at 18.2% for non-small cell lung carcinomas and 6.3% for small cell carcinoma.[474]

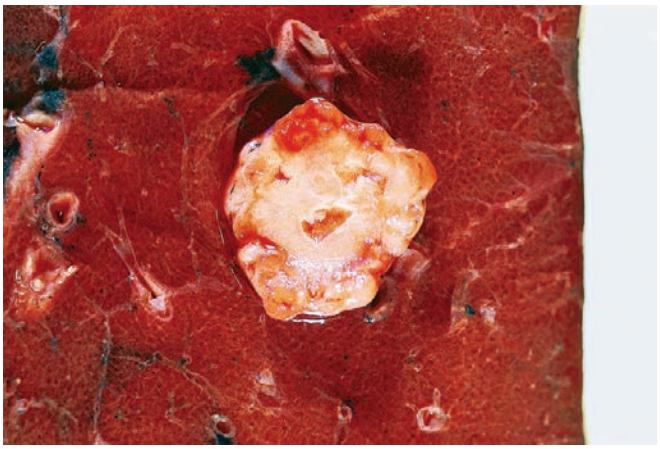

Figure 10.127 Lobulated shape and shiny cut surface of pulmonary hamartoma. (Courtesy of Dr. RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

The prognosis of lung carcinomas has been related to a large number of factors, tumor stage chief among them including tumor size and presence or absence of visceral pleural and lymphatic space invasion in those with apparently localized node-negative disease who undergo resection with curative intent.[475,476] Older age, male gender, and low performance status at the time of diagnosis also influence natural history and prognosis.[477] Subtyping or grading of non-small cell carcinomas may have value, particularly in cases of early-stage adenocarcinoma in which solid and micropapillary growth patterns predict for lower rates of disease-specific survival.[478]

A burgeoning list of biomarkers suggests a complex interplay of factors that may affect outcome, including selected genetic markers. For example, *KRAS* mutations have been associated with lower overall survival rates in patients with earlier stage (stage I–IIIa) adenocarcinomas.[479] Survival of patients with activating *EGFR* mutations who are treated with tyrosine kinase inhibitors is influenced by the specific type of mutation, with cases characterized by deletions in exon 19 surviving longer than cases with L858R point mutations.[480] *ALK*-rearranged cases are overrepresented in patients who present with advanced-stage disease, suggesting that it may predict for a subset of more aggressive adenocarcinomas that tend to affect younger nonsmokers.[342]

Other Primary Tumors

Hamartoma

Hamartoma is the most common benign neoplasm encountered in surgical pathology and generally occurs in adults and is more common in males.[481] It is usually solitary but can be multiple. Its most common location is the peripheral lung parenchyma just beneath the pleura, and it presents in most instances as an asymptomatic solitary pulmonary nodule. Endobronchial hamartomas account for only about 10% of cases and are more likely to present with cough or symptoms related to obstruction.[482] Hamartomas are usually small, measuring less than 2.0 cm on average. Radiographically, a characteristic popcorn pattern of calcification is seen in two-thirds of the cases.[483] Grossly, it is sharply delineated and lobulated (Fig. 10.127). The cut surface is characterized by glistening nodules of cartilage separated by ill-defined clefts. A less common presentation is as a polypoid mass inside a large bronchus (Fig. 10.128).[483]

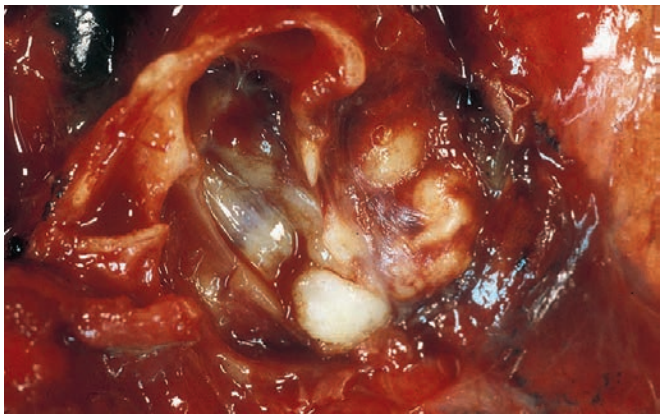

Figure 10.128 Endobronchial hamartoma.

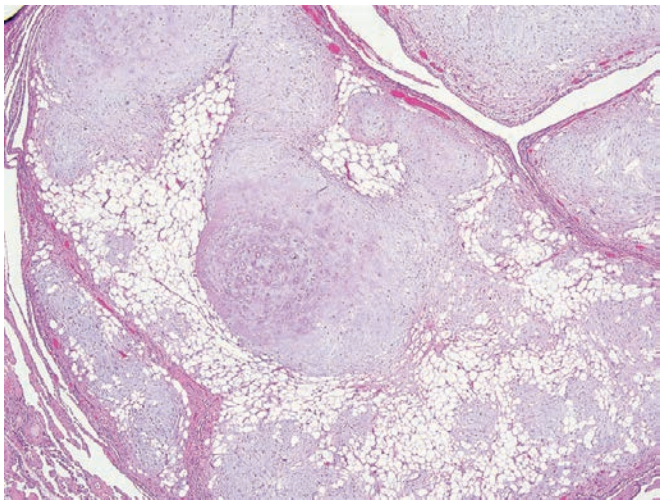

Figure 10.129 Pulmonary hamartoma showing intermingling of hyaline cartilage, fat, myxoid stroma, and non-neoplastic respiratory epithelium.

Microscopically, hamartoma is made up of normal cartilage arranged in islands, fat, smooth muscle, a characteristic myxoid stroma, and clefts lined by ciliated or nonciliated respiratory epithelium (Fig. 10.129). Any one of these components can predominate in any individual tumor, resulting in a range of histologies that include leiomyomas and lipoma. Sometimes exaggerated invagination of non-neoplastic epithelium results in a pattern resembling so-called *placental transmogrification*, characterized by the formation of placental villus-like papillations.[484]

Immunohistochemically, some of the spindle cells of this lesion have features of myoepithelial cells, such as positivity for actin and S-100 protein. The spindle cells in myxoid areas are unique in expressing glial fibrillary acidic protein (GFAP), a finding they have in common with fetal cartilage.[485] There is also common expression of ER, progesterone receptor (PR), and androgen receptor (the latter only in males), most of it in the myoepithelial-like cells.[486] We have seen two salivary gland–type tumors with a myoepithelial cell component and a well-differentiated liposarcoma arising from pulmonary hamartoma.[487,488]

Hamartomas are acquired nonepithelial neoplasms characterized by clonal rearrangements of chromosome 6p21 (implicating the *HMGA1* gene) or chromosome 12q14–15 (implicating the *HMGA2* gene).[489,490]

The treatment of hamartoma is in the form of conservative surgery usually performed as a diagnostic procedure: wedge resection or enucleation of peripheral lesions and sleeve resection of endobronchial lesions.

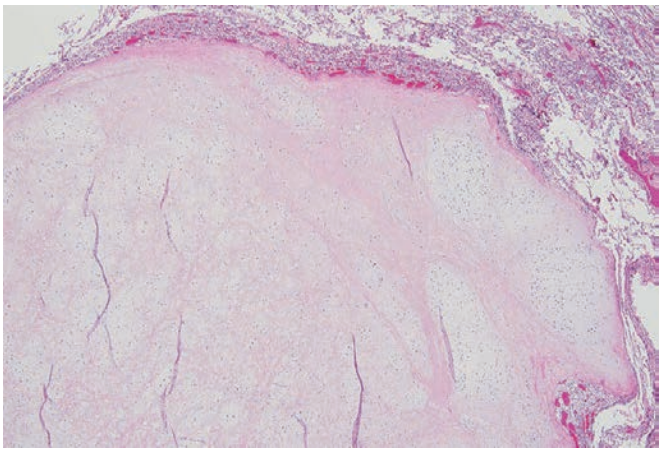

Figure 10.130 Pulmonary chondroma.

Carney has identified a nonfamilial syndrome ('Carney triad') in which pulmonary chondromas (usually multiple) are associated with gastric epithelioid leiomyosarcomas (most of which would be currently categorized as gastrointestinal stromal tumors, [GISTs]), and functioning extra-adrenal paragangliomas.[491] Pulmonary chondromas differ from the usual hamartomas in being purely cartilaginous with a more sharply circumscribed fibrous pseudocapsule without entrapped, invaginated epithelium (Fig. 10.130).[492] Pulmonary chondromas also show a broader range of cellularity and cytologic atypia in the neoplastic cartilage.

Paraganglioma and Other Neural Neoplasms

Paragangliomas have been exceptionally described in the lung, presenting as solitary (usually peripheral but sometimes endobronchial) masses.[493] Their histologic appearance is identical to that of paragangliomas in other sites. The differential diagnosis with carcinoid tumor may be extremely difficult, even after applying electron microscopic and immunohistochemical techniques, and this had led some authors to doubt the very existence of pulmonary paragangliomas. The presence of ribbons, festoons, rosettes, and positivity for mucin, CEA, and especially keratin, favor carcinoid, whereas a prominent 'Zellballen' pattern throughout the tumor and the presence of a population of S-100 protein–positive sustentacular cells at the periphery of the nests favor paraganglioma.[494] Excision is usually curative, but metastasizing cases have also been reported.

Other neural tumors that have been described in the lung include *ganglioneuroblastoma*[495] (one combined with carcinoid tumor[496]) and *gangliocytic paraganglioma*[497,498] (one associated with Cushing syndrome[499]). It is difficult to escape from the suspicion that these are histogenetically closely related tumors that have been interpreted and named just a little differently. A single example of a purported primary pulmonary ependymoma has been reported.[500]

Minute Meningothelioid Nodules and Meningioma

Meningothelial-like nodule (MLN) is the term currently preferred for a curious, usually clinically inconsequential pulmonary lesion originally misinterpreted as pulmonary paraganglioma (chemodectoma).[501,502] It is generally seen as an incidental finding in surgically

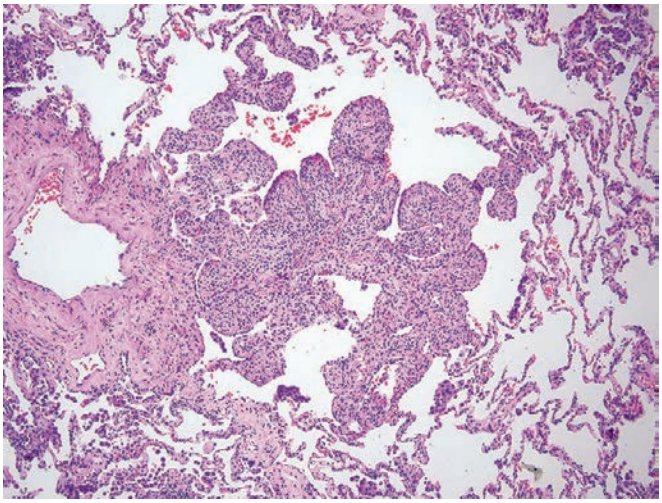

Figure 10.131 Incidentally discovered meningothelial-like nodule.

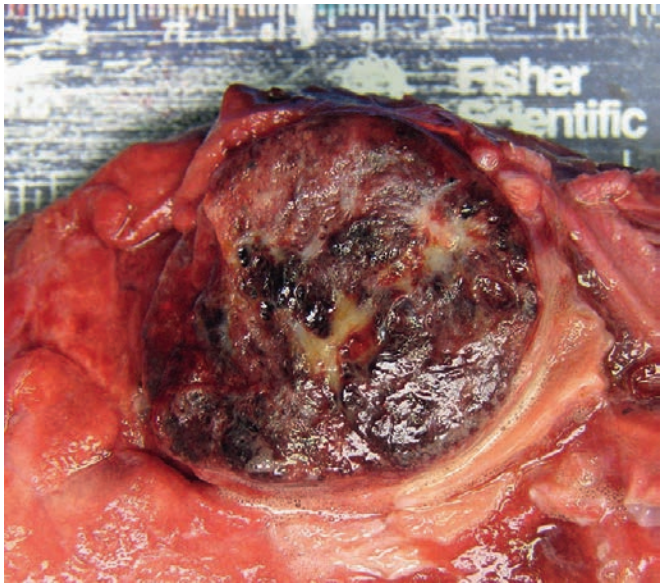

Figure 10.132 Sclerosing pneumocytoma. Yellow solid areas alternate with foci of fresh hemorrhage and fibrosis. (Courtesy of Dr. J. Carvalho, Minneapolis, MN.)

excised lungs, the lesions presenting as one or more 1–3 mm tan-yellow nodules randomly distributed within the interstitium (Fig. 10.131).[502] Occasionally, the lesions are disseminated and bilateral, associated with symptoms of restrictive pulmonary disease.[503] Ultrastructural studies have shown a total lack of neurosecretory granules or other features suggestive of neuroendocrine differentiation. The cells have instead an appearance similar to that of normal arachnoidal cells and the cells of meningioma.[504] Immunohistochemically, they are negative for keratin and positive for vimentin, EMA, CEA, CD56, and PR, a profile again similar to that of meningothelial cells.[502] Their genotypic features, however, are different from those of CNS meningiomas[505] and more in keeping with a reactive than a neoplastic process.

True *meningioma* of lung presenting as a primary solitary nodule has also been described,[506] including a chordoid[507] and a malignant variety.[508] These should be distinguished from 'benign metastasizing meningioma,' a rare but well-documented occurrence.[509,510]

Sclerosing Pneumocytoma

Sclerosing pneumocytoma, referred to historically as *sclerosing hemangioma*, is a distinctive lesion that occurs mostly in younger adult females, usually detected as an asymptomatic small, solitary nodule on a chest radiograph or CT scan.[511–516] On serial films, the lesion is found to be stable or, at the most, very slow growing. Grossly, it is a well circumscribed but not encapsulated, solid peripheral, subpleural mass with a variegated tan, yellow, and frequently hemorrhagic cut surface (Fig. 10.132). Microscopically, sclerosing pneumocytoma is characterized by a combination of architectural and cytological heterogeneity, with growth patterns that may be solid, papillary, sclerosing, and hemorrhagic, resulting in a variegated appearance at low magnification (Fig. 10.133). At higher magnification the cytologic heterogeneity results from a combination of bland interstitial round cells that represent the neoplastic population and incorporated non-neoplastic respiratory epithelial cells that line papillary surfaces in a manner analogous to that seen with other slowly growing lesions such as hamartoma (Fig. 10.134).

The histogenesis of this lesion has been highly controversial since its description as an entity, which has been variously proposed to be of endothelial, histiocytic, mesothelial, and epithelial nature.[514] Immunohistochemically, there are two distinct components. One

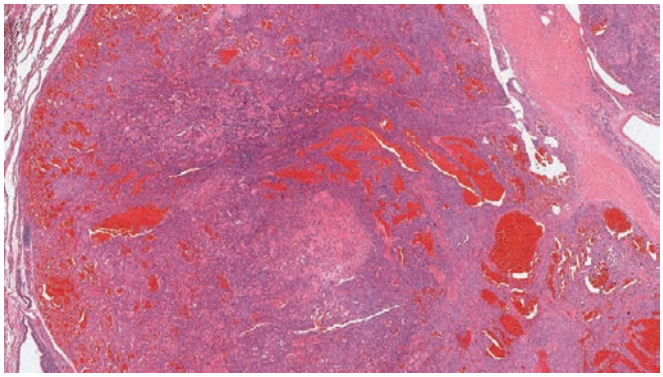

Figure 10.133 Sclerosing pneumocytoma. A variety of growth patterns is appreciated on low-power examination resulting in a characteristic variegated appearance.

(referred to as *surface cells*) is of clearly epithelial nature and reactive for EMA, keratin, CD15, Ber-EP4, apocrine epithelial antigen, surfactant apoprotein, TTF-1, napsin A, and ER beta.[511–513,516–521] Some of these reactivities correspond to those of type 2 pneumocytes, as supported by the ultrastructural finding of a microvillous-like folding of the cell membrane and lamellar inclusions. The second—and numerically more prominent—component (referred to as *round* or *stromal cells*) is negative for many of these markers except EMA, ER beta, and TTF-1, features that suggest an origin from primitive respiratory epithelium. The similar pattern of allelic loss that has been found between sclerosing hemangioma and bronchioloalveolar carcinoma also suggests an origin from the terminal lobular unit.[522] These observations served as the drivers for adoption of the term *sclerosing pneumocytoma* in the most recent WHO classification scheme.[523]

From a clinical standpoint, sclerosing hemangioma is a benign lesion cured by conservative surgery. There are rare reports of local lymph node deposits, but these patients have done well without evidence of distant metastases or tumor-related death.[512,524]

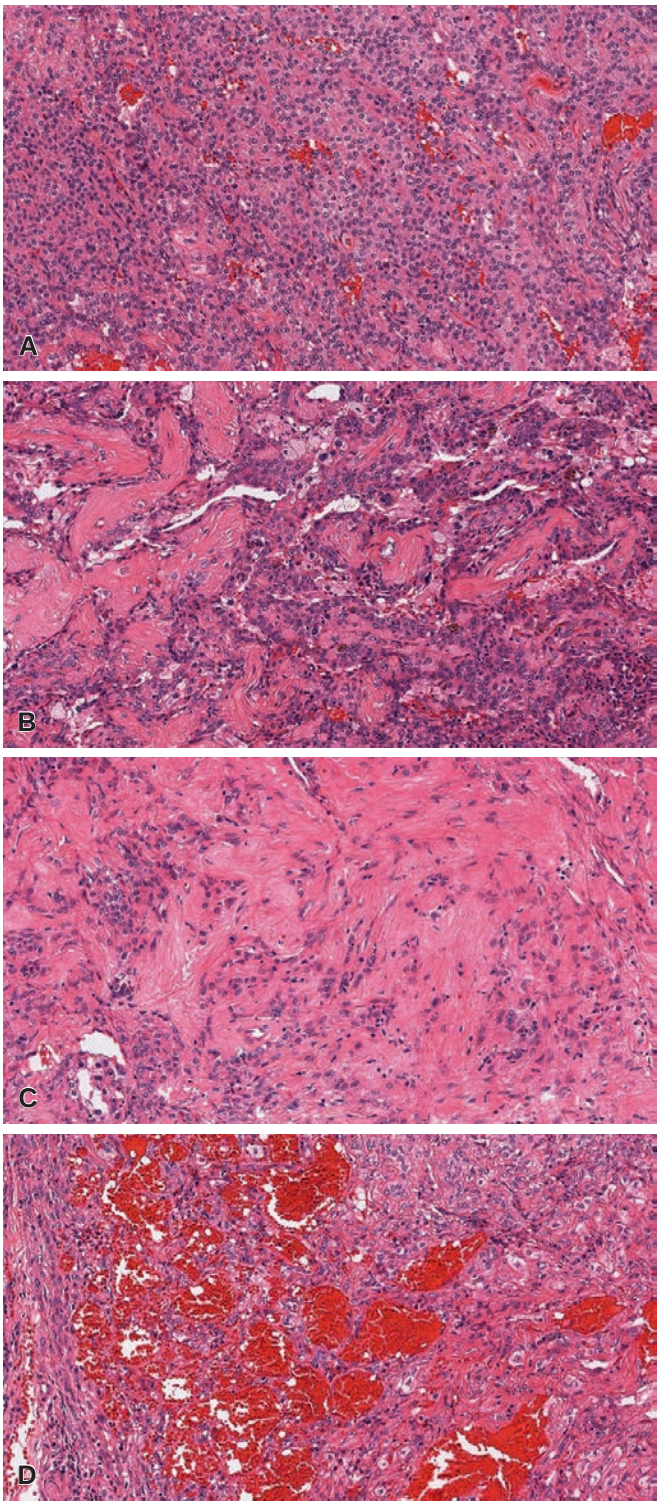

Figure 10.134 Sclerosing pneumocytoma. Higher-magnification views of tumor illustrated in Fig. 10.133 show solid **(A)**, papillary **(B)**, sclerotic **(C)**, and hemorrhagic **(D)** areas. Areas of solid growth **(A)** show neoplastic round cells while papillary areas **(B)** show non-neoplastic bronchiolar epithelium lining papillary surfaces.

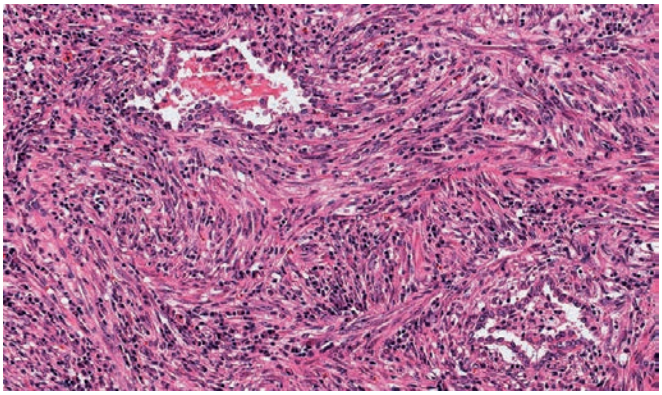

Figure 10.135 Inflammatory myofibroblastic tumor. Elongated myoid cells are heavily infiltrated by plasma cells. Incorporated non-neoplastic respiratory epithelium results in a 'pseudobiphasic' appearance.

Inflammatory Pseudotumor and Inflammatory Myofibroblastic Tumor

There is a group of pulmonary lesions presenting as more or less circumscribed nodules, having as a common denominator the presence of large numbers of mononuclear inflammatory cells. Wide variations on this basic theme occur from case to case or even within the same case and are responsible for the many names and histogenetic interpretations that this group of lesions has received. In addition to inflammatory cells, these variations include vascular proliferation, fibrosis that may take the form of organizing pneumonia, hyalinization, myxoid change, fat accumulation with the formation of xanthoma cells, hemosiderin deposition and proliferation of non-neoplastic respiratory epithelial cells.

It seems likely that within the heterogeneous group of lesions diagnosed as inflammatory pseudotumor is a subset with a reasonably distinct morphologic appearance for which the term *inflammatory myofibroblastic tumor* has been proposed.[525] In this condition, the predominant element is a spindle cell with immunohistochemical and ultrastructural features (actin reactivity, cytoplasmic filaments) consistent with those of myofibroblastic cells, or—alternatively—the cells of the accessory immune system known as fibroblastic (myoid) reticulum (dendritic) cells.[526,527] These are accompanied by a heavy mononuclear infiltrate in which plasma cells often predominate and are intimately admixed with the spindle cells in a fashion reminiscent of that seen in other reticulum (dendritic) cell tumors (Fig. 10.135). The consistent finding of chromosomal rearrangements involving 2p23 (harboring the *ALK* gene), including *EML4-ALK* inversions analogous to those described in adenocarcinomas, in about half of these lesions supports the neoplastic nature of this subset.[528] Other kinase fusions involving *ROS1* and *RET* occur in a smaller number of cases, bringing to two-thirds the total number of inflammatory myofibroblastic tumors that may be amenable to treatment with appropriately targeted kinase inhibitors.[529] Interestingly this applies mainly to inflammatory myofibroblastic tumors in children in whom sensitizing kinase fusions are more common and less so to those diagnosed in adults in whom kinase fusions are rare. HHV8 has been detected in only rare cases.[526,530]

Most cases diagnosed as inflammatory pseudotumors of the lung occur in adults, but a good number of those rich in plasma cells ('plasma cell granulomas') are seen in children. Actually, they constitute the most common isolated primary lesion of the lung in patients under 16 years of age. The majority present as asymptomatic solitary, small peripheral nodules, yellow and firm, covered by an intact pleura. In rare instances there is extension to the pleura or

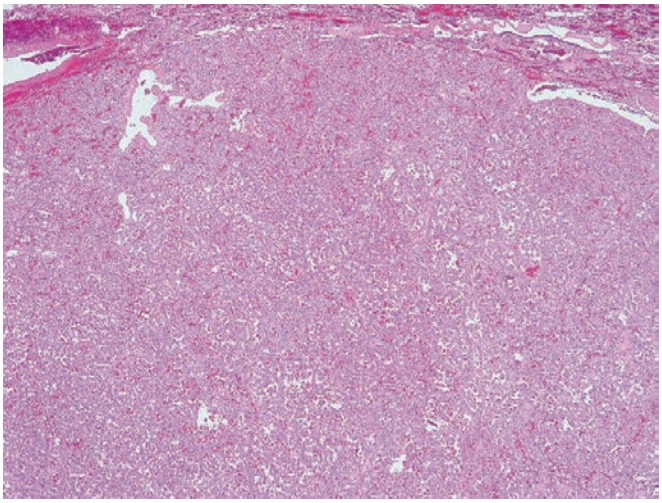

Figure 10.136 Capillary hemangioma presenting as solitary mass in a child.

Figure 10.137 Endobronchial glomus tumor.

mediastinum. Other cases present as polypoid endobronchial masses and may lead to distal inflammatory changes. Interestingly, some cases show many IgG4-positive plasma cells, suggesting an immune-mediated pathogenesis or at least overlap with IgG4-related sclerosing disease. There is emerging evidence that the presence of significantly increased IgG4-positive plasma cells is a feature that distinguishes inflammatory pseudotumor, a non-neoplastic proliferation, from inflammatory myofibroblastic tumor.[531–533]

Surgical excision is usually curative, but some aggressive examples have been described, especially when the appearance corresponds to that of an inflammatory myofibroblastic tumor.

Vascular Tumors

Vascular tumors of the lung are extremely rare. Bona fide **hemangioma** is seen more commonly in children; it can be either endobronchial or parenchymal and should not be equated with the lesion formerly referred to as sclerosing hemangioma (now termed sclerosing pneumocytoma), a nonvascular lesion. Microscopically, most are of the capillary type (Fig. 10.136).[534]

Hemangiomatosis, which is by definition multifocal or diffuse, presents with symptoms and signs of pulmonary hypertension *(pulmonary capillary hemangiomatosis)* accompanied by radiological findings more typical of diffuse interstitial lung disease.[535] The histologic findings include not only the 'capillary hemangiomatosis-like change' previously described in PVOD, but also nodular proliferation of capillary size vessels that infiltrate the interstitium and vessel walls in a manner more characteristic of a neoplastic process.[236]

Hemangiopericytoma (including its *lipomatous variant*) has been described as a primary lung tumor, but most such cases would be placed in other categories at present, particularly cellular solitary fibrous tumor. A particularly notorious trap is the misdiagnosis of a solitary lung metastasis of endometrial stromal sarcoma as a hemangiopericytoma.[536]

Glomus tumor can exceptionally involve the lung, its appearance being similar to that of its more common cutaneous and soft tissue counterparts.[537,538] Most of the few reported cases presented as asymptomatic peripheral nodules with a median diameter of 2.0 cm but with a broad size range (1.1–6.5 cm). Symptomatic endobronchial tumors are even more rare but mimic the appearance of carcinoid tumor at bronchoscopy (Fig. 10.137). It can also be confused with carcinoid tumor histologically; immunostains are helpful with negative staining for cytokeratins and neuroendocrine markers in glomus tumors that are instead positive for smooth muscle actin and desmin. Three reports of malignant glomus tumors *(glomangiosarcoma)* included follow-up in two; one died a year and a half after surgery and the other was alive with disease 5 years after resection.[537]

Kaposi sarcoma primary in the lung is usually a manifestation of AIDS but can also occur in immunocompetent individuals.[217] The distribution of the disease typically follows lymphatic channels.

Angiosarcoma can present as a single mass or as diffuse pulmonary infiltrates as an expression of a primary lung malignancy but in most patients represents metastatic disease of nonpulmonary origin for which potential primary sites include the heart and great vessels.[539] A subset of patients with metastatic angiosarcoma may have a clinical presentation that mimics diffuse alveolar hemorrhage syndromes.[540]

Lymphangioma and **diffuse lymphangiomatosis** are extremely rare; both of these conditions are more common in children but occasionally present in adulthood.[541,542]

Epithelioid hemangioendothelioma is the term for the neoplastic process originally described in the lung as *intravascular bronchioloalveolar tumor* (IV-BAT) that typically presents as multiple nodules.[543] Many of the patients are young adults, and females outnumber males by 3–4 : 1.[543–545] Microscopically, the most common growth pattern is multiple centrally hyalinized and/or necrotic nodules in which there are variably conspicuous acidophilic endothelial cells that may resemble epithelium, histiocytes, or decidualized stromal cells. The surprisingly bland neoplastic cells are distributed individually, in small solid cords, and in a vaguely lobulated pattern often as a thin rim surrounding an eosinophilic or basophilic ('chondroid') mass of hyalinized stroma, which is sometimes calcified (Figs. 10.138 and 10.139). These polypoid formations fill alveoli and occasionally bronchioles. The walls and lumen of both arteries and veins may also be occupied by tumor, even at a distance from the main mass, as the tumor spreads in a lymphangitic pattern. Grading into low and intermediate grades based on mitotic rate, necrosis, and nuclear pleomorphism can separate them into subsets that differ in prognosis, but that together are better than high-grade epithelioid angiosarcoma.[546] Unusual growth patterns include rare reports of solitary nodules and diffuse pleural disease mimicking mesothelioma.[547] Although originally interpreted as a variant of bronchioloalveolar carcinoma, ultrastructural and immunohistochemical studies have shown that the tumor is composed of endothelial cells and that it represents the pulmonary version of epithelioid hemangioendothelioma. Neoplastic cells are positive for vascular markers such as

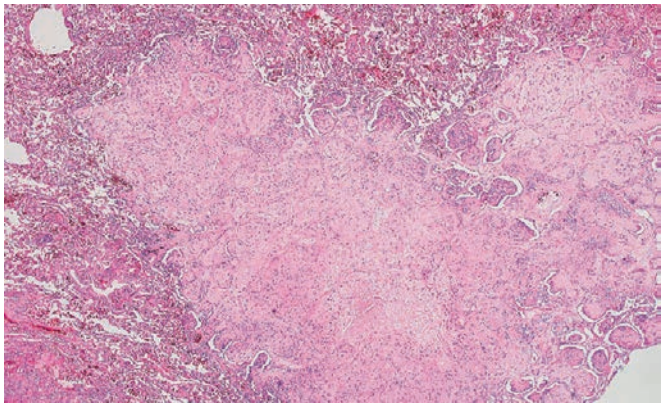

Figure 10.138 Epithelioid hemangioendothelioma. Nodular intra-alveolar aggregates of tumor cells are seen enclosing an amorphous eosinophilic material.

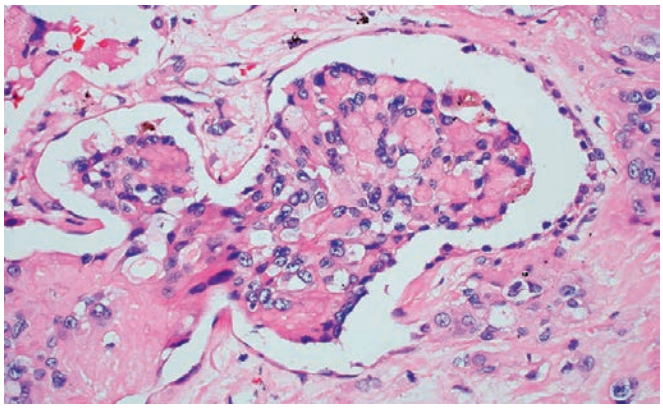

Figure 10.139 Prominent intracytoplasmic lumen formation and cytoplasmic intranuclear pseudoinclusions in epithelioid hemangioendothelioma.

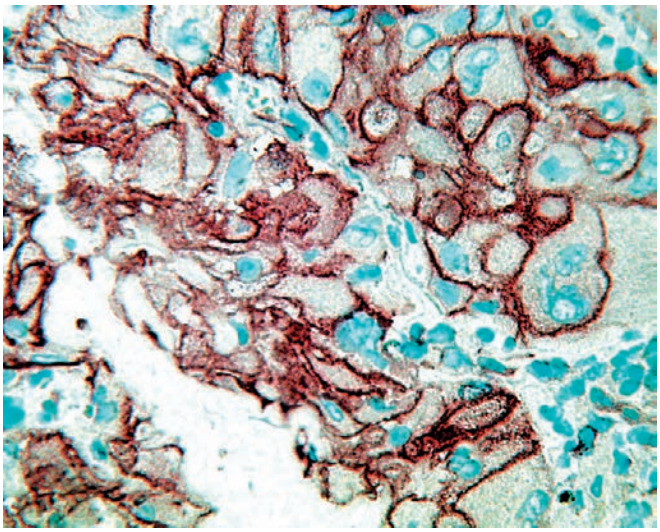

Figure 10.140 Strong immunoreactivity for CD31 in epithelioid hemangioendothelioma.

CD31, ERG, and CD34 but can also be positive for keratins, a potential diagnostic trap (Fig. 10.140).[546,548] Thoracic epithelioid hemangioendotheliomas, like their soft tissue counterparts, show recurrent translocations corresponding to *WWTR1-CAMTA1* and *YAP1-TFE3* gene fusions. Nuclear expression of CAMTA1 in tumors with *WWTR1-CAMTA1* fusions (85%–90%) and strong nuclear staining for TFE3 in the minority with *YAP1-TFE3* fusions is relatively specific and offers another diagnostically useful immunostain.[549]

The tumor grows in a very slow but progressive fashion, with a tendency to remain restricted to the thoracic cavity. Some patients die as a result of pulmonary insufficiency. Poor prognostic factors at the time of diagnosis include respiratory symptoms and/or pleural effusion, and intermediate histologic grade.[544–546] Most of these tumors are primary in the lung, but others with an identical appearance have been interpreted as metastases from epithelioid hemangioendotheliomas located elsewhere, particularly liver.

Epithelioid hemangioma (angiolymphoid hyperplasia with eosinophilia) has been reported in the lung.[550] As in other sites in which it is more frequent, its neoplastic versus inflammatory nature remains controversial.

Lymphoid Tumors and Tumorlike Conditions

The lung can be involved by various types of lymphoproliferative processes, either secondarily or as the only manifestation of the disease.[551,552] Secondary lung involvement can be peribronchial/perivascular, nodular alveolar, interstitial, pleural, or (more commonly) a combination of them. **Leukemic involvement** of the lung is found at autopsy in 30%–40% of the chronic lymphocytic forms, in about 15%–20% of the chronic myelogenous types, and in over 60% of the adult acute forms, but most of them do not result in clinical manifestations.[553–556] Occasionally, however, significant pulmonary impairment results from the infiltrate of chronic lymphocytic leukemia acquiring a selective bronchiolocentric distribution.[555] In rare cases, acute myeloid leukemia presents with widespread pulmonary nodules or infiltrates *(myeloid sarcoma)*.[557,558]

For purposes of discussion, lymphoproliferative disorders presenting in the lung can be divided into four main categories: extranodal marginal zone lymphomas of MALT lymphoma, lymphomas of conventional type spanning the spectrum of phenotypes and histologies including intravascular large B-cell lymphoma, lymphomatoid granulomatosis, and Hodgkin lymphoma.

Small lymphocytic proliferations forming pulmonary nodules are often difficult to interpret. This broad and historically nebulous category comprises predominantly MALT lymphomas, the most common form of primary pulmonary lymphoma.[559] Most patients are in the sixth and seventh decades of life and asymptomatic at the time of diagnosis, the lesion presenting as a solitary nodule or infiltrate on a chest x-ray film or CT scan without associated lymphadenopathy. Underlying autoimmune diseases (especially Sjögren syndrome) and monoclonal gammopathies are common.[559] MALT lymphomas may also complicate pulmonary lymphoid hyperplasia in patients with common variable immunodeficiency.[560]

Grossly, they appear as a relatively well-defined but unencapsulated mass, which on cut surface has a homogeneous white to gray appearance (Fig. 10.141). Microscopic features are similar to those described in other extranodal marginal zone lymphomas and include a tumefactive infiltrate of small lymphocytes, monocytoid B cells, and plasma cells with associated germinal centers scattered throughout and variably well-developed lymphoepithelial complexes (Fig. 10.142). Occasional cases have associated amyloid; in fact, most cases of nodular amyloidosis in the lung are MALT lymphomas in which amyloid deposits overrun the clonal lymphoplasmacytic infiltrate.[561] Histologically indistinguishable nodules composed of non-amyloid light chain may also complicate MALT lymphoma.[562] Nodular hyperplasia is extremely uncommon but the main differential diagnosis for MALT lymphoma.[552,563] Features in favor of malignancy are the monomorphic nature of the infiltrate; the presence of plasmacytoid features with associated intranuclear Dutcher bodies;

Figure 10.141 Gross appearance of a MALT lymphoma in a surgical lung biopsy.

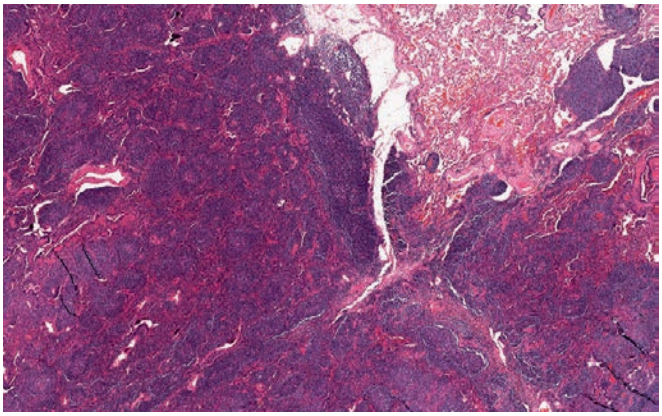

Figure 10.142 MALT lymphoma of lung showing a tumefactive and vaguely nodular configuration on the left with extension along lymphatic pathways on the right.

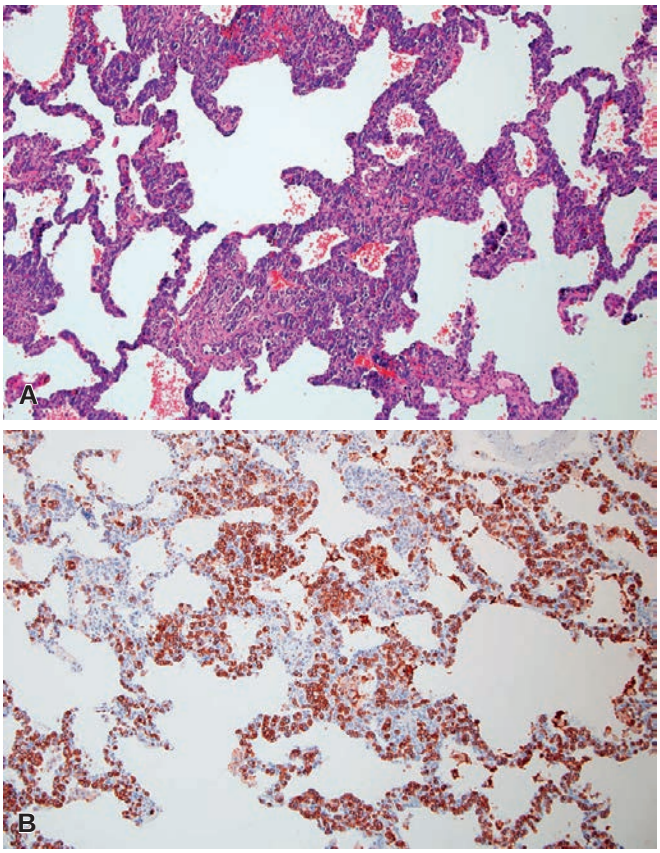

Figure 10.143 **A,** Intravascular lymphoma in a patient with unexplained breathlessness. **B,** An immunostain for CD20 shows neoplastic large B cell exquisitely localized to alveolar septal capillaries.

the presence of amyloid in the stroma; the invasion of bronchial cartilage, wall of large vessels, or visceral pleura; a lymphangitic pattern of infiltration at the periphery; and light chain restriction and/or clonal rearrangements of the immunoglobulin heavy chain gene.[552,559]

Amyloidosis of the lung can be divided into four categories on the basis of distribution: nodular (for which previous comments regarding overlap with MALT lymphoma are relevant), tracheobronchial, diffuse alveolar septal (usually in patients with systemic disease), and vascular (never a serious clinical problem when it occurs in isolation).[564] Radiographically, lesions in the first and second categories can be solitary or multiple and can simulate granulomatous infection or a metastatic neoplasm. Diffuse alveolar septal amyloidosis may lead to a severe impairment of lung function, a diffuse infiltrate on radiographic examination, and a poor prognosis. The amyloid material is mostly made up of AL protein. There are rare reports of localized deposits of non-amyloid light chain forming nodules that are indistinguishable from amyloidosis in routinely stained sections.[562] *Crystal storing histiocytosis* is a related condition resulting from massive accumulation of crystallized immunoglobulin in the cytoplasm of non-neoplastic histiocytes. The disease, which is usually a manifestation of a MALT lymphoma or plasma cell neoplasm, can be localized to the lung or other sites, or systemic.[565]

Plasmacytoma should be used as a diagnostic term only for neoplastic lesions composed entirely of neoplastic, light chain restricted plasma cells. Plasmacytic tumors with a lymphoid component should be classified with the MALT lymphomas; it is likely that some of the tumors previously regarded as primary pulmonary plasmacytomas were instead MALT lymphomas.[566] CD56 can be a helpful immunostain in distinguishing MALT lymphomas from plasmacytomas, as it tends to be positive in the latter and negative in the former.[566] Plasmacytomas of lung may be intraparenchymal or endobronchial, may be associated with nodal or bone involvement, and may exhibit production of light chain protein,[567] which may appear in the tissue in the form of diffuse or nodular deposits that resemble amyloid but are not congophilic.[568]

Large cell lymphoma of conventional type presents as a large mass, sometimes occupying most of a lobe, and is often accompanied by foci of necrosis.[569] Occasionally the pattern of growth is predominantly endobronchial. Microscopically, a monomorphic infiltrate of large lymphoid cells is present. Most cases are diffuse large B-cell lymphomas, with rare examples resembling primary mediastinal large B-cell lymphoma.[570] Intravascular lymphoma is a form of extranodal large B-cell lymphoma that sometimes presents with lung involvement, often in symptomatic patients with minimally abnormal imaging studies (Fig. 10.143)[571,572]; central nervous system, skin, and bone marrow are other commonly affected sites. Anaplastic large cell lymphomas can also occur in the lung.[573]

Lymphomatoid granulomatosis, originally included by Liebow in his *pulmonary angiitis and granulomatosis* group,[574] is now placed among the B-cell lymphoproliferative disorders.[575] It usually presents

in middle age with bilateral rounded mass densities, which radiographically may resemble metastases.[576,577] Cases of lymphomatoid granulomatosis and similar atypical lymphoproliferative processes have been reported in immunosuppressed transplant recipients in whom it represents a form of post-transplant lymphoproliferative disorder, and in HIV-infected patients.[216] The key microscopic picture is the presence of a polymorphic infiltrate comprising a combination of plasma cells, small lymphocytes in which T-cells predominate, immunoblasts, and atypical large lymphoid cells, with a tendency to form centrally necrotic nodules and to involve the walls of pulmonary vessels as transmural, circumferential infiltrates (Fig. 10.144). The multinucleated giant cells and necrotizing vasculitis of GPA (Wegener) are not present. Lymphomatoid granulomatosis can be graded according to the relative proportion of atypical large cells (grades 1–3), although the criteria proposed and the relationship to prognosis are inconsistent.[576,578,579]

Extrapulmonary involvement occurs in over a third of the cases.[577] The most common sites are the skin (particularly in the lower extremities) and central nervous system. Other less commonly involved sites include kidneys, liver, spleen, adrenal glands, heart, and gastrointestinal tract. The histologic appearance is similar in all of these sites. In rare cases the microscopic changes of lymphomatoid granulomatosis are seen in an extrapulmonary site in the absence of pulmonary involvement.

It has become increasingly evident that both the morphologic features of lymphomatoid granulomatosis and its clinical course are more in keeping with a malignant than a reactive process and that it is common for large cell lymphomas of the lung to exhibit vascular infiltration. Accordingly, lymphomatoid granulomatosis is currently viewed as a primary EBV-related lymphoproliferative disease that either is or has a great tendency to become malignant lymphoma.[575,577] On the basis of combined immunohistochemical and in situ hybridization studies, most cases of lymphomatoid granulomatosis represent a proliferation of EBV-infected B cells associated with a prominent T-cell reaction with prominent vascular involvement.[580–583]

Response to steroids is poor, but multidrug chemotherapy induces complete remission in about half of cases.[584] Novel treatments including a combination of immunotherapy and chemotherapy have been effective in some cases.[585] Despite treatment advances, lymphomatoid granulomatosis remains an aggressive disease with relatively high disease-related mortality.[577]

Hodgkin lymphoma involving the lung parenchyma is usually associated with nodal involvement, direct extension from the mediastinum (thymus) being frequent in the nodular sclerosis form. However, rare cases of primary pulmonary Hodgkin lymphoma have been well documented.[586–588] They are reported with slightly greater frequency in women over a broad age ranges and usually appear as solitary or multiple nodular lesions on chest x-rays and/or CT scans.[586–588] Endobronchial involvement can also occur, either in the form of a plaquelike infiltrate or as a polypoid mass.

Salivary Gland–Type Tumors

Several types of epithelial tumor with patterns analogous to those of salivary gland neoplasms occur in the lung, probably arising from submucous bronchial glands. Most of them are located within the trachea or the main cartilaginous bronchi.[589]

Adenoid cystic carcinoma is the most common type. It is usually centered in the major bronchi (Fig. 10.145) and often involves the trachea, although peripheral examples are also on record.[590] Metastases to regional lymph nodes occur in a minority of cases.[589,591] The histologic, immunohistochemical, and cytogenetic findings are indistinguishable from those described for adenoid cystic carcinomas arising in extrathoracic salivary glands (see Chapter 6), including a characteristic t(6:9)(q22–23;p23–24) translocation resulting in fusion of the *MYB* oncogene and *NFIB* transcription factor in about half of cases.[591] TTF-1 and napsin A staining have been reported in lung metastases from extrapulmonary primaries but is rare in primary pulmonary adenoid cystic carcinomas, making these stains of little value in separating primary from metastatic tumors.[592] The primary treatment is surgical excision. Irradiation therapy may induce marked regression, but it is not curative. The total duration of the disease is long, but the ultimate prognosis is poor.[589]

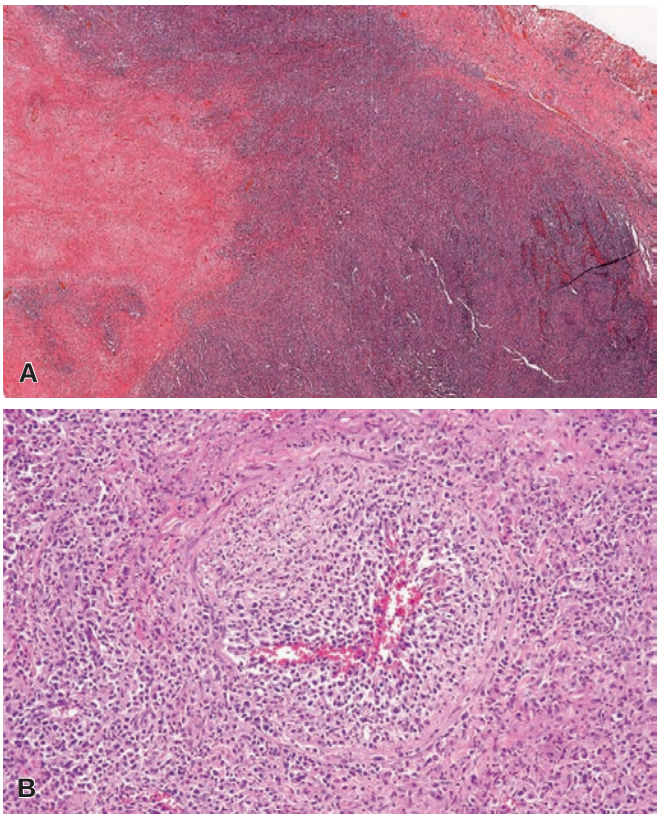

Figure 10.144 Lymphomatoid granulomatosis showing polymorphic infiltrate forming centrally necrotic nodule **(A)** and characteristic angioinvasive growth pattern **(B)**.

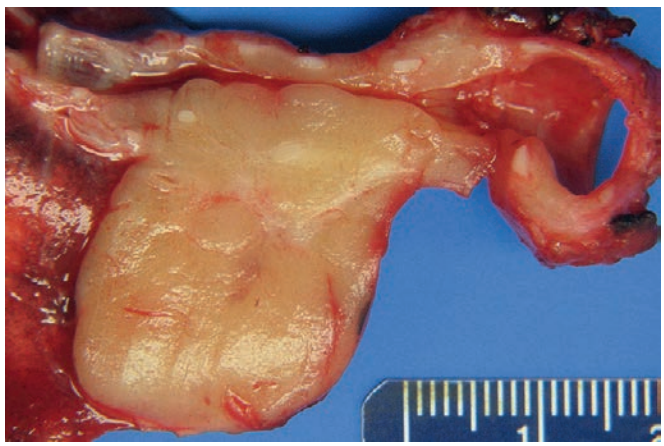

Figure 10.145 Adenoid cystic carcinoma presenting as an endobronchial mass invading adjacent lung parenchyma.

Figure 10.146 Endobronchial growth of mucoepidermoid carcinoma.

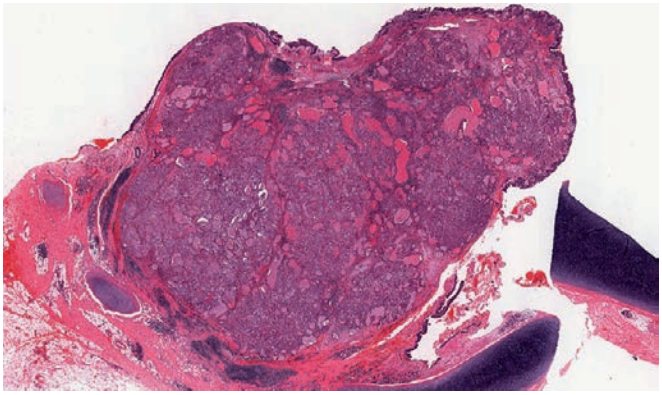

Figure 10.147 Endobronchial mucoepidermoid carcinoma showing characteristic low-grade histology.

Mucoepidermoid carcinomas of the lung affect males and females equally across a broad age range, including children, and usually present as an exophytic endobronchial mass (Fig. 10.146).[589,593,594] They can be divided into low-grade and high-grade varieties, like their salivary gland counterparts.[594] High-grade variants are rare and not easily separated from adenosquamous carcinoma. As in their more common extrathoracic salivary gland location, they are composed of a combination of mucus-secreting cells, squamous cells, and cells of intermediate type (Fig. 10.147). Rarely, they are accompanied by a heavy lymphoplasmacytic infiltrate.[595] Immunohistochemical stains show a profile identical to that described in mucoepidermoid carcinomas arising in other sites (see Chapter 6), including negative staining for TTF-1 and napsin A.[593] Pulmonary mucoepidermoid carcinomas demonstrate the same t(11;19)(q21;p13) translocation of the *mucoepidermoid carcinoma translocated 1 (MECT1)* and *mammalian mastermind-like 2 (MAML2)* genes resulting in the MECT1–MAML2 fusion oncoprotein unique to all mucoepidermoid carcinomas of salivary gland origin.[596]

Low-grade mucoepidermoid carcinoma has a low malignant potential, characterized mainly by local invasion and a relatively good prognosis[589,593,594,597] The rare cases of high-grade mucoepidermoid carcinoma have a stage-dependent prognosis resembling that seen with other forms of high-grade non-small cell carcinoma.[594] These tumors, like adenoid cystic carcinomas, lack the sensitizing *EGFR* mutations that occur in a subset of conventional lung adenocarcinomas.[598]

Cases of lung carcinoma with adenosquamous features, a suggestion of myoepithelial cell differentiation (such as positivity for S-100 protein), and amyloid-like stroma made up of basement membrane material have been reported and may represent a unique subset of lung carcinomas with features resembling salivary gland neoplasms.[599]

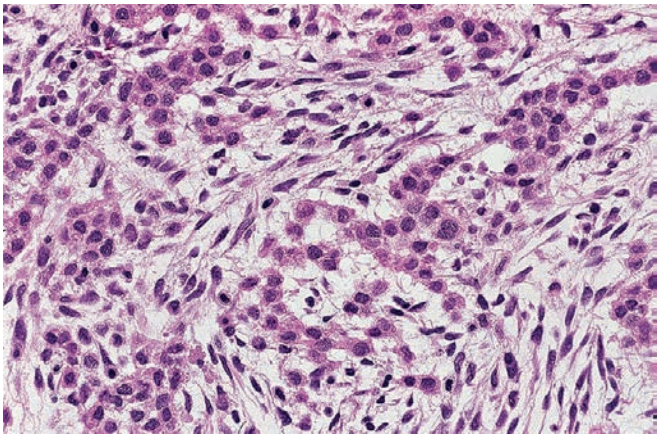

Figure 10.148 Myoepithelioma of lung. This particular tumor had arisen from a typical hamartoma.

Other less common tumors belonging to this rather generic category of salivary gland or salivary gland–like neoplasms include:

- **Pleomorphic adenoma** (benign mixed tumor)[600]
- **Malignant mixed tumor**[600,601]
- **Myoepithelial tumors**
  Epithelial–myoepithelial carcinoma[602]
  Pneumocytic adenomyoepithelioma[603]
  Myoepithelioma arising in hamartoma (Fig. 10.148)[487]
- Acinic cell carcinoma[604]
  Combined with typical carcinoid tumor[605]
- **Oncocytoma**.[606] This tumor, which can be malignant, is analogous to oncocytomas of salivary gland origin and should be distinguished from oncocytic neuroendocrine tumors and adenocarcinomas, a task that may require immunohistochemical evaluation[392,607]

PEComatous Tumors

Clear cell tumor ('sugar tumor') is analogous to PEComas arising in other nonpulmonary sites. In the lung, these rare tumors present as a round or ovoid solitary peripheral lung nodule usually measuring no more than 2 cm in greatest dimension.[608] It usually occurs in adults, but it has also been reported in children.[609] Microscopically, it is made up of large cells with clear to eosinophilic granular cytoplasm crowded with glycogen granules (Fig. 10.149). Some cells have a 'spidery' appearance. Fat is absent. Mitoses are not seen. There is scanty intervening stroma, but thin-walled vessels may be prominent, as well as extracellular amorphous eosinophilic material (sometimes calcified).

Immunohistochemically, clear cell tumors of the lung show the same expression of melanogenesis-associated markers affiliated with PEComas elsewhere, including staining for HMB-45, S-100 protein, and cathepsin B accompanied by focal and inconstant positivity for actin, neuron-specific enolase, and synaptophysin.[608,610] By electron microscopy, most of the glycogen is membrane bound in lysosome-like organelles.[608] Intracytoplasmic filaments may be present. Dense-core granules compatible with premelanosomes have been found in a few of the cells; in rare cases, well-developed melanosomes occur.[608] Basal lamina often surrounds the tumor cells.

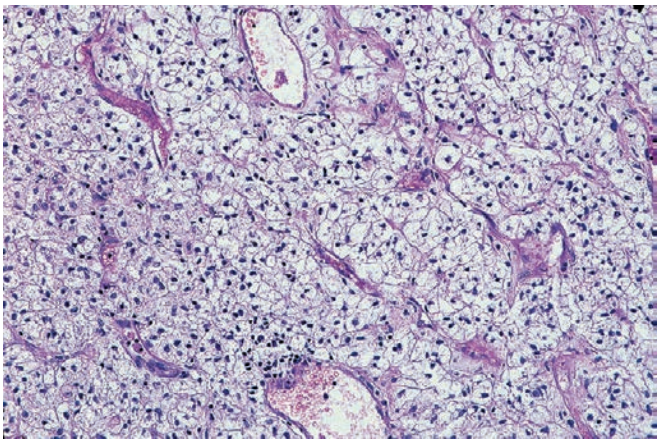

Figure 10.149 Clear cell tumor (PEComa) of lung. Medium-sized clear cells grow in a solid pattern, separated by a prominent vasculature.

The histogenesis of this tumor has been a source of great controversy. Pericytes, smooth muscle cells, neuroendocrine cells, Clara cells, and epithelial cells have all been proposed at one time or another. The HMB-45 immunoreactivity, occasional detection of melanosomes, and other similarities with renal angiomyolipoma suggest that it belongs to a family of tumors thought to be derived from perivascular epithelioid cells (so-called PEComas), a family of tumors that includes lymphangioleiomyomatosis.[611–613]

Lymphangioleiomyomatosis involves both lungs, usually presenting as diffuse cystic lung disease in young women who present with spontaneous pneumothorax and/or pulmonary symptoms, most commonly dyspnea on exertion.[614,615] It occurs only very rarely in men.[616,617] Some patients are affected by tuberous sclerosis (including nearly all of the rare cases reported in men), renal angiomyolipomas, and PEComas of uterus and other sites.[614,618] Grossly, early cases may simply suggest emphysematous changes, whereas more advanced cases show widespread cystic spaces separated by thick, whitish-gray septa (Fig. 10.150). The microscopic features include a combination of cystic spaces associated with interstitial spindled and epithelioid cells with cytologic characteristics typical of other PEComatous lesions (Fig. 10.151). These findings are often accompanied by hemosiderosis, an especially conspicuous feature in more advanced disease.[619] The proliferating ('LAM') cells are immunoreactive for HMB-45 and other melanocytic markers such as melan-A and microphthalmia transcription factor (MiTF) in a patchy distribution with more widespread staining for smooth muscle markers (e.g. smooth muscle actin, desmin) as well as ER and PR. LAM cells are also immunoreactive for β-catenin, which may be a more sensitive marker than HMB-45.[620] LAM cells demonstrate the same complement of mutations in tumor suppressor genes *tuberous sclerosis complex (TSC) 1* or *TSC2* as other PEComatous lesions with clonal identity across sites in cases with multiorgan involvement, including some who develop recurrent pulmonary disease after lung transplant.[621] These observations suggest that lymphangioleiomyomatosis is a low-grade metastasizing neoplasm. Transplantation and, more recently, sirolimus are the mainstays of therapy for cases of lymphangioleiomyomatosis.[622] The prognosis of lymphangiomyomatosis is variable, but survivals measured in decades are the rule rather than the exception.[623] Respiratory symptoms and/or pleural disease (i.e. pneumothorax or chylous effusion) at presentation predict shorter transplant-free survivals.

Muscle Tumors

Leiomyoma presenting as a primary solitary pulmonary mass is rare.[624] Peripheral lesions are more common and typically present as asymptomatic nodules; endobronchial lesions are more likely to be affiliated with findings related to postobstructive bronchiectasis and pneumonia. Multiple EBV-associated leiomyomas and leiomyosarcomas involving the lungs and gastrointestinal tract have been described in HIV-infected children and in MEN 1 patients.[625,626]

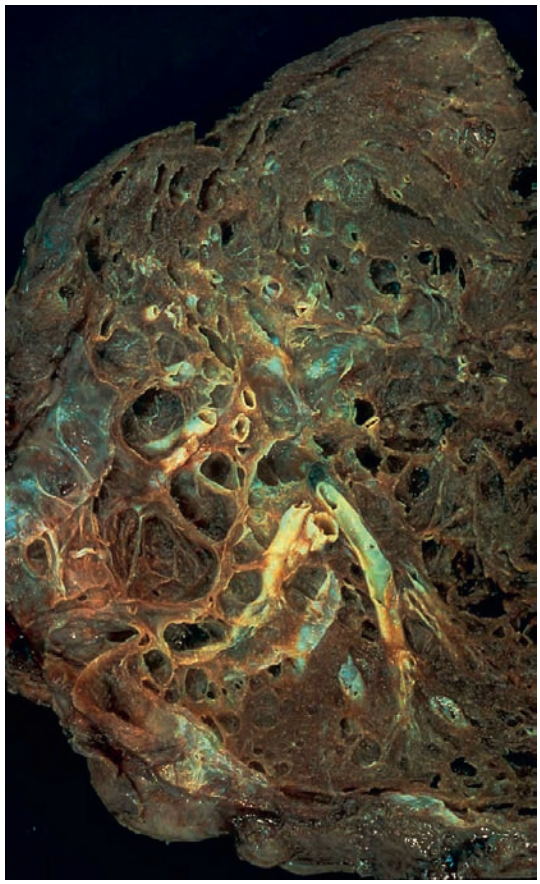

Figure 10.150 Explanted lung showing lymphangioleiomyomatosis in a woman whose pretransplant diagnosis was emphysema.

Occasionally, a middle-aged asymptomatic or minimally symptomatic female is seen with multiple small pulmonary nodules composed of well-differentiated smooth muscle, sometimes enclosing epithelial-lined clefts in a condition referred to most commonly as *benign metastasizing leiomyoma* (Fig. 10.152).[627] Concomitant or preexistent uterine smooth muscle tumors are invariably present. In most cases the pulmonary nodules likely represent clonally related metastases from well-differentiated uterine smooth muscle neoplasms.

Leiomyosarcoma primary in the lung does occur both in adults and children,[628] but in the presence of a malignant smooth muscle tumor in the lung—even if solitary—the chances are overwhelming that the lesion is metastatic. Most are intraparenchymal masses, some associated with an endobronchial component. Leiomyosarcomas arising from the pulmonary veins can invade secondarily the lung parenchyma.[629]

Some cases originally reported as congenital leiomyosarcomas have been reinterpreted as *myofibroblastic tumors* and have been found to be characterized by an indolent clinical course.[630]

Rhabdomyosarcoma can present in its *pleomorphic* form in the lungs of adults (exceptionally rare)[631] or as an expression of the *embryonal* variety in the lungs of children. In children, it tends to occur against a background of cystic changes and blends with the PPBs having a prominent rhabdomyoblastic component (see later).[632]

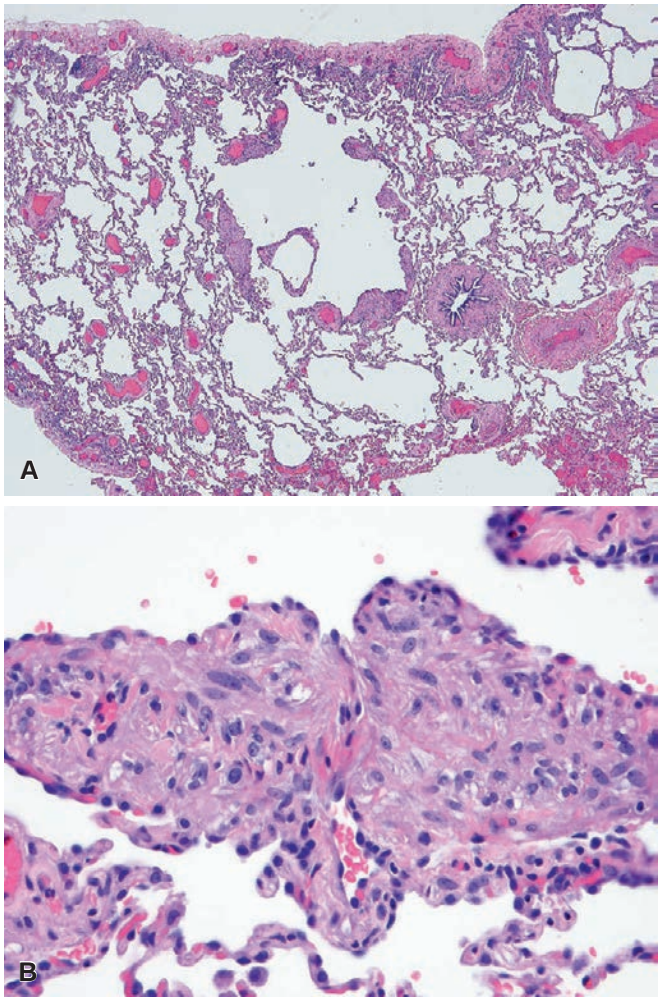

Figure 10.151 Lymphangioleiomyomatosis in which cystic space **(A)** is associated with loose interstitial aggregates of lesional smooth muscle-like (LAM) cells **(B)**.

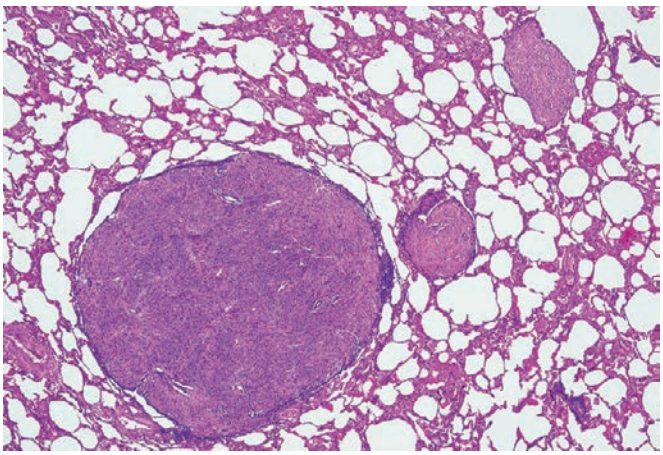

Figure 10.152 Benign metastasizing leiomyoma.

Pleuropulmonary Blastoma

PPB is a dysontogenetic (embryonal, blastomatous) malignant pediatric neoplasm that is pulmonary and/or pleural based.[633] It is unrelated to pulmonary blastoma, which is described elsewhere in this chapter as a histologically distinct form of high-grade sarcomatoid carcinoma in adults. PPB is characterized histologically by an admixture of primitive blastomatous and sarcomatous elements.[634,635] The latter may exhibit evidence of skeletal muscle and cartilaginous differentiation. An epithelial component is either lacking or present only in the form of benign-looking, presumably entrapped epithelium. A three-type system has been proposed for this entity, type I tumors being predominantly cystic and type III tumors almost entirely solid. Care should be exercised to avoid underdiagnosing type I tumors as a developmental cystic malformation.[636] Mutations of the *DICER1* gene have been detected in about two-thirds of cases.[634] The behavior of this tumor is potentially aggressive, particularly for the more solid forms (i.e. types II and III).[634,637]

The recently described **fetal lung interstitial tumor** may or may not be related to the cystic form of (type I) PPB.[638]

Miscellaneous Primary Tumors

Squamous papillomas account for about 70% of solitary lung papillomas, the others showing glandular or mixed types of epithelial lining cells.[639] Squamous papillomas are more common in men and more likely to be associated with cigarette smoking and HPV infection. The prognosis for solitary papillomas is excellent independent of the epithelial type.[639] Multiple squamous papillomas may involve the lower respiratory tract in patients with recurrent respiratory papillomatosis and are more likely to be associated with an aggressive course including progression to squamous cell carcinoma.[640]

Granular cell tumor can present either as a polypoid endobronchial mass with signs of bronchial obstruction or as an asymptomatic peripheral lung nodule.[641] Most are solitary, but multicentric lesions have been described.

Benign lung tumors other than those already mentioned are rare and include intrapulmonary *thymoma*,[642] *schwannoma*,[643] *ganglioneuroblastoma*,[644] *endobronchial blue nevus*,[645] *microcystic fibromyxoma*,[646] *ciliated muconodular papillary tumor* (a benign or low-grade tumors frequently associated with *BRAF-V600E* or *EGFR* mutations)[647,648] and *lipoma* (*endobronchial*, *peripheral*, and *atypical*),[649–651] a lesion probably related to the more conventional hamartoma described elsewhere in this chapter. We have seen a case of *multifocal microcysts and papillary cystadenoma* of the lung associated with striking vascular proliferation in a patient with von Hippel–Lindau disease, and a similar case has been reported.[652]

Solitary fibrous tumor, although usually pleural based (see Chapter 11), can be entirely intrapulmonary and should therefore be considered in the differential diagnosis of spindle cell tumors of this organ.[653]

Synovial sarcoma is now recognized as one of the most common types of primary pulmonary sarcoma. The large majority are of the monophasic spindle type, a relatively high percentage (higher than in the soft tissue) are poorly differentiated, and extremely few are biphasic (Fig. 10.153).[654] Sometimes they are cystic and present with recurrent pneumothorax.[655]

Primary sarcomas of lung other than those already mentioned are rare. *Fibrosarcoma* affecting pediatric age patients,[656] so-called *undifferentiated pleomorphic sarcoma* (previously termed *malignant fibrous histiocytoma*),[657] *low-grade fibromyxoid sarcoma* (including the related *hyalinizing spindle cell tumor with giant rosettes*),[658] *chondrosarcoma*[659] (including the *mesenchymal* variety[660]), *osteosarcoma*,[661] *malignant peripheral nerve sheath tumor* (including *malignant triton tumor*),[662] *Ewing sarcoma/PNET*,[663] *desmoplastic small cell tumor*,[664] and *follicular dendritic cell tumor/sarcoma*[665] have been described in the lung. *Primary pulmonary myxoid sarcoma* is a more recently described form of lung sarcoma that tends to target younger adults and has a characteristic *EWSR1-CREB1* fusion (Fig. 10.154).[666] Primary pulmonary myxoid sarcoma shares morphologic and molecular

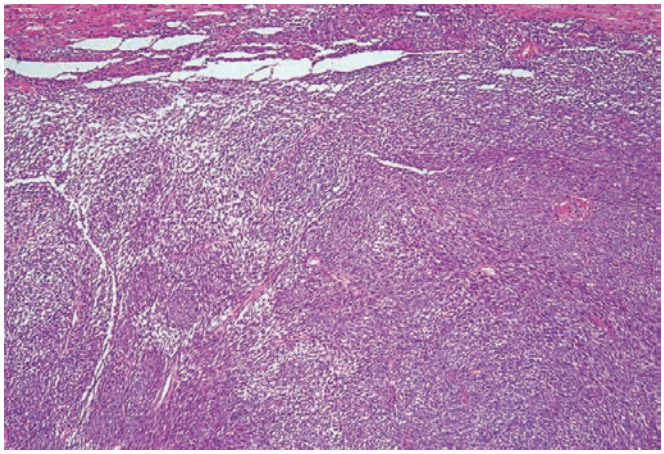

Figure 10.153 Primary monophasic synovial sarcoma of lung. Some areas have a fibroblastic appearance, whereas in others the cells are slightly plumper, although still lacking an identifiable epithelial organization. There was focal immunoreactivity for keratin.

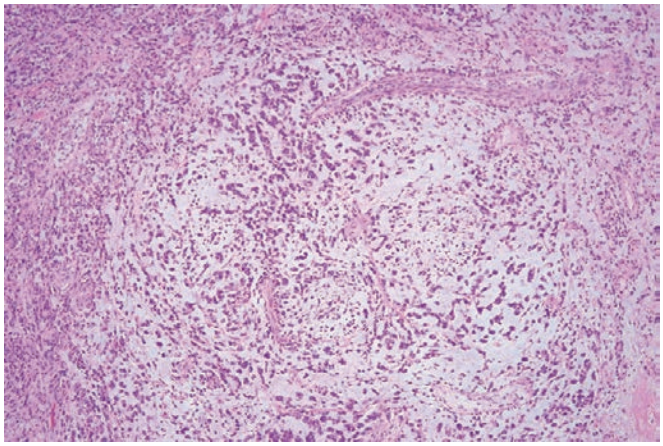

Figure 10.154 Primary pulmonary myxoid sarcoma with a *EWSR1-CREB1* fusion.

features with *angiomatoid fibrous histiocytoma,* leading some to conclude that they may be overlapping entities.[667] In the presence of any of these tumors, all efforts should be made to rule out the possibility of a primary tumor elsewhere and/or of a primary lung carcinoma with a sarcoma-like appearance. This applies particularly to the cases reported as *rhabdoid tumor* or *rhabdoid sarcoma* of lung, most of which are dedifferentiated forms of lung carcinoma.[323]

Malignant melanoma primary in the lung is yet another tumor type that should be diagnosed with great caution. Although reasonably convincing examples exist (supported by the presence of a 'junctional' bronchial component),[668] the large majority represent metastatic deposits from known or occult primaries.

Germ cell tumors of choriocarcinomatous, yolk sac, and other (nonseminomatous) types allegedly primary in the lung have been described.[669–671] They need to be distinguished from pulmonary metastases of gonadal germ cell tumors[672] and from primary lung carcinomas with germ cell–like features, both of which are much more common. Lung carcinomas have the capacity to secrete a number of proteins more commonly associated with germ cell tumors including the alpha subunit of hCG[673] and AFP,[674,675] the latter particularly in association with rare cases of adenocarcinoma resembling hepatocellular carcinoma *(hepatoid adenocarcinoma*[676]*)*.

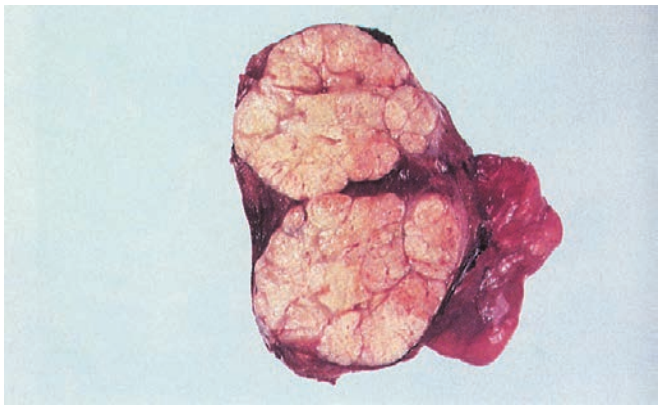

Figure 10.155 Metastatic renal cell carcinoma to lung. The lesion is well circumscribed, multinodular, and golden yellow.

Metastatic Tumors

The lung is a very common site of metastatic disease, sometimes as the only expression of distant tumor spread. Most metastases are multiple, bilateral, sharply outlined, and rapidly growing; this is particularly true for metastases from some types of carcinoma (breast, gastrointestinal tract, and kidney), sarcomas, and melanomas. They range from miliary nodules to 'cannonball' lesions and are more common in the lower lobes. Other metastases (particularly from carcinomas of stomach, breast, pancreas, and prostate) tend to present as widespread neoplastic involvement of the pulmonary perivascular and peribronchial lymphatics (so-called *lymphangitic carcinomatosis*), which may result in severe dyspnea and pulmonary hypertension *(tumor-related thrombotic pulmonary microangiopathy)*, sometimes in the absence of chest x-ray abnormalities.[677]

In other instances the metastases present as isolated nodules and may simulate the appearance of primary tumors (Figs. 10.155 to 10.159). Central cavitation can occur in them; this is particularly common in squamous cell carcinomas of the upper aerodigestive tract and adenocarcinomas of colorectal origin.

Another type of lung metastasis that can be confused with a primary tumor results from the penetration of intraparenchymal or nodal deposits into the wall of a major bronchus and their presentation as polypoid endobronchial masses mimicking primary lung carcinomas.[678] The most common primary sites of origin for endobronchial metastases are breast, large bowel, kidney, stomach, prostate, and melanoma and in some cases is the first manifestation of malignancy.

The differential diagnosis between primary and metastatic lung carcinoma can be difficult and sometimes impossible. Multiplicity of lesions and extensive lymphatic permeation favor a metastasis. The presence of atypical or in situ changes in the bronchial mucosa adjacent to a squamous cell carcinoma, and of honeycombing and atypical hyperplasia of bronchiolar epithelium in the parenchyma surrounding an adenocarcinoma, favor a primary tumor. However, it should be remembered that many metastatic cancers to the lung (particularly from large bowel and pancreas) can line the alveolar walls in a 'lepidic' fashion, simulating well differentiated adenocarcinomas of the lung.[679] One of least common forms of metastatic lung involvement by adenocarcinomas from the gastrointestinal tract is the form associated with pseudomyxoma peritonei which accounts for rare reports of parenchymal deposits resembling primary colloid carcinomas.[680]

Immunohistochemical staining may provide great assistance in some situations as summarized earlier in this chapter. Depending on suspected extrapulmonary primary sites, TTF-1 and napsin A can

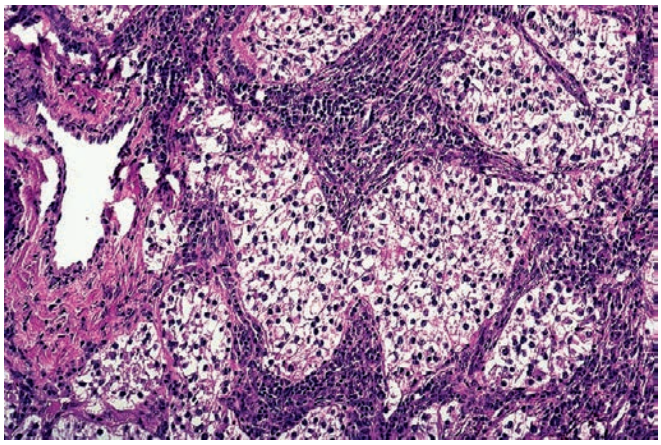

Figure 10.156 Renal cell carcinoma of clear cell type metastatic to lung.

be especially helpful in supporting pulmonary origin, while staining for PAX8, GATA3, and other selected markers often signify origin from elsewhere.

Among the sarcomas, there are some that are notorious for their ability to simulate primary lung processes. Some metastatic spindle cell sarcomas grow extensively along bronchi and vessels, a pattern that Liebow referred to as *pulmonary sarcomatosis*. Some metastatic angiosarcomas masquerade either as primary vascular tumors or as diffuse pulmonary hemorrhage.[540,681] Among uterine tumors, well-differentiated leiomyosarcomas are well known for their ability to simulate leiomyomatous hamartomas, and endometrial stromal sarcomas have often been confused with primary hemangiopericytomas, spindle carcinoid tumors, and other lung primary neoplasms. The fact that the interval between the removal of the original tumors and the appearance of the (often single) lung metastasis can be measured in years or decades contributes to the potential diagnostic pitfall.[536] Another potential diagnostic pitfall pertains to cystic metastases from low-grade nonepithelial tumors (Fig. 10.160), such as cutaneous fibrous histiocytomas *(cystic fibrohistiocytic tumors*[682]*)*, dermatofibrosarcoma protuberans, and low-grade smooth muscle tumors, that may mimic other forms of cystic lung disease such as lymphangioleiomyomatosis or LCH.

When the pulmonary metastatic foci are few *(oligometastases)* and sharply circumscribed, they may be amenable to surgical excision (metastasectomy).[683–685] Poor prognostic signs are multiplicity and size of metastases and presence of extrapulmonary disease. A particularly aggressive approach has been taken toward lung metastases in children, often including some combination of metastasectomy, radiation, and chemotherapy. Five-year survival rates of 25%–40% have been obtained, which is a remarkable achievement.[686]

Normal Anatomy of the Pleura

Both the visceral and parietal pleural layers have a lining of mesothelial cells endowed with a continuous basement membrane and resting on a layer of well-vascularized fibroelastic connective tissue matrix.[1,2] The submesothelial connective tissue is divided by superficial and deep elastic lamina.[3] All of these elements are mesodermally derived. The normal mesothelial cell is flat or low cuboidal. Ultrastructurally, it features apical tight junctions, desmosomes, long and slender surface microvilli, and bundles of cytoplasmic tonofilaments. Immunohistochemically, it shows reactivity for both low- and high-molecular-weight keratins[4] and for many other markers, which are discussed in the section on mesothelioma.

The normal subserosal cells have ultrastructural features of fibroblasts and express the intermediate filament vimentin but not keratin; however, when these "multipotential subserosal cells" or "submesothelial fibroblasts" proliferate in reactive conditions, they coexpress keratin and vimentin and develop surface differentiation, consistent with the notion that they are progenitors of mesothelial cells.[4]

The pleural space is drained by three adjacent lymphatic pathways that connect separately into hilar, retroperitoneal, and lower mediastinal lymph node groups. In normal physiological conditions, fluid is drained primarily through lymphatic stomata in the parietal pleural surface.[1]

Pleuritis and Other Non-Neoplastic Lesions

Infectious and noninfectious inflammatory diseases of the lung may also involve the pleura.[2] The vast majority of pleural space infections, including those resulting in a potentially life-threatening suppurative acute inflammatory exudate (i.e. empyema), are caused by infectious lung disease. The pulmonary lesion may completely resolve but leave a pleural *symphysis* (fusion between the two pleural layers) secondary to prominent pleural fibrosis, which can be several centimeters thick. The underlying lung parenchyma may be perfectly normal after recovery from infection, but its expansion is prevented by the surrounding rigid and contracted thickened pleura. If this dense fibrous layer is peeled off, pulmonary function improves markedly. It is likely that the process designated *shrinking pleuritis with atelectasis*, *folded lung syndrome*, or *rounded atelectasis* represents a variation on this theme.[5,6]

Tuberculosis can involve the pleura in various ways: as a complication of a subpleural primary lung infection, by direct extension from reinfection pulmonary disease, and as a result of hematogenous spread.[2]

Systemic connective tissue diseases, especially rheumatoid arthritis and systemic lupus erythematosus, are a common cause of noninfectious pleuritis. The microscopic appearance of the inflammatory infiltrate is often nonspecific, usually comprising a combination of lymphocytes and plasma cells. In some instances, however, the presence of palisaded spindle histiocytes underlying a layer of fibrin and arranged perpendicularly to the pleural surface should make the pathologist suspect a rheumatoid arthritis.[7] Rheumatoid nodules may also involve the pleura, usually as subpleural lung nodules that erode into and sometimes through the visceral pleura (Fig. 11.1).[3]

Endometriosis of the pleura and diaphragm has been reported, accounting for rare reports of catamenial pneumothorax and, less commonly, hemoptysis.[8,9] Most of the cases have occurred in the right hemithorax and are often associated with pelvic endometriosis. Histologic evidence of endometriosis is not always documented in pleural tissue from patients with catamenial pneumothorax.[10]

Amyloidosis can involve the pleura; the diagnosis is possible with needle biopsy.

Abstract

This chapter reviews pathology of the visceral and parietal pleura. It begins with a brief review of normal anatomy followed by inflammatory, non-neoplastic diseases. The relationship between asbestos and both benign and malignant pleural diseases is summarized. The bulk of this chapter is devoted to pleural tumors with a focus on mesothelioma. Other, less common primary pleural neoplasms are discussed, followed by an overview of metastatic tumors.

Keywords

Mesothelioma,
immunohistochemistry,
solitary fibrous tumor,
calcifying fibrous pseudotumor,
epithelioid hemangioendothelioma,
pyothorax-associated lymphoma,
primary effusion lymphoma,
pleural effusion

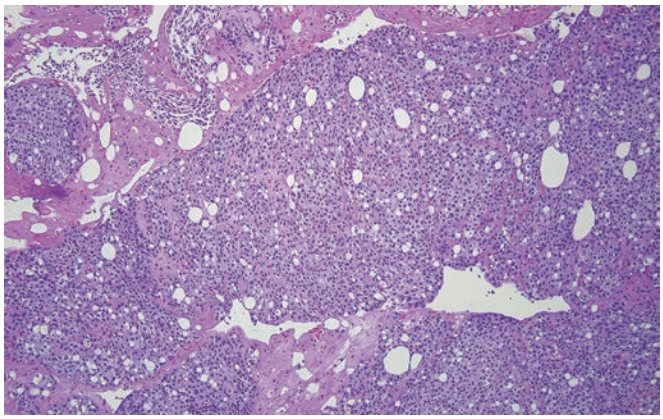

Figure 11.2 Nodular histiocytic/mesothelial hyperplasia forming a cellular aggregate loosely attached to visceral pleura in a patient with lymphangioleiomyomatosis who suffered pneumothorax.

Reactive eosinophilic pleuritis is secondary to pneumothorax of any cause and is discussed in greater detail in Chapter 10.

Nodular histiocytic/mesothelial hyperplasia is a reactive process composed of histiocytes/monocytes and mesothelial cells. It is more common in hernia sacs and heart (where it is known acronymically as MICE for mesothelial/monocytic incidental cardiac excrescence) but can also occur in the lung and pleura, where it may be confused with a neoplastic proliferation (Fig. 11.2).[11]

Asbestos and the Pleura

Asbestos is a family of fibrous hydrated silicates that are divided into two groups: the serpentines and amphiboles.[12] Those of commercial importance are chrysolite in the first group and amosite and crocidolite in the second. These minerals were a component of a large variety of manufactured products, particularly in the construction industry, until their use from insulation products was banned in 1972.[13] Proof of the widespread use of this material until that time is the finding of asbestos bodies in lung smears (particularly in the lower lobes) in approximately 40% of persons autopsied in the United States.[14] Inhalation of these fibers can result in various pathologic processes, which depend on the type of mineral, the dimensions and concentration of the fibers, and the duration of the exposure. The main pleural manifestations of asbestos exposure are pleural plaques, pleural fibrosis, and mesothelioma.

Pleural plaques are made up of hyalinized fibrous tissue. They are usually but not always associated with asbestos (mainly amosite and crocidolite) exposure.[15] The occurrence of these plaques correlates well with the duration and intensity of exposure. They are not topographically related to so-called *pleural black spots* (i.e. foci of accumulation of inhaled particles), suggesting that there is no pathogenetic connection between the two processes.[16]

Pleural plaques are characteristically located on the parietal side, mainly in the intercostal spaces on the anterior and posterolateral aspects of the chest wall and on the dome of the diaphragm, at sites where the visceral and parietal pleura approximate during respiratory excursions. Over time, they become calcified and therefore detectable on chest x-ray films and computed tomography (CT) scans.

The relationship between asbestos and **mesothelioma**, first identified by Wagner et al.[17] in South Africa, has now been documented all over the world. The average prevalence of mesothelioma in people with prolonged heavy exposure to asbestos is 2%–3% but has reached up to 10% in some series. The latency period is usually 20 years or longer, the incidence in the United States having apparently peaked in the 1990s as a result of the banning of asbestos use in 1972.[18] It should be pointed out, however, that a substantial minority of pleural mesotheliomas are not associated with a history of asbestos exposure, and for that reason the presence or absence of a history of exposure should play no part in the histopathologic diagnosis of mesothelioma.[19] Furthermore, the risk of asbestos exposure leading to mesothelioma may vary depending on the genetic makeup of the individual or because of exposure to other carcinogens, such as SV40.[20]

Amosite and crocidolite are the fiber types found in most cases of asbestos-related mesothelioma.[13] There can be superimposed deposition of oxalate salts.[21] Asbestos bodies are more commonly found in the underlying lung parenchyma than within the mesothelioma. They can also be found in pulmonary hilar nodes.[22] Microscopic examination using asbestos bodies as surrogates for uncoated asbestos fibers is a very insensitive and nonspecific method for detection and identification of asbestos fiber burden. Extraction methods to increase the yield combined with biophysical techniques (such as electron microprobe analysis) are necessary to properly study their true incidence and composition.

Tumors

Benign Mesothelioma

Benign (papillary) mesothelioma is a term applied historically to solitary lesions of the peritoneum and tunica vaginalis with histologic features that overlap with well-differentiated papillary mesothelioma, which is discussed elsewhere in this chapter.[23] Analogous localized lesions occur rarely if at all in the pleura.

Two types of benign mesothelial proliferation that are common in the peritoneal cavity and genital region, respectively, but very uncommon in the pleura, are so-called **benign multicystic mesothelioma** and **adenomatoid tumor**. However, a few convincing cases of both conditions in this location are on record.[24,25]

Malignant Mesothelioma

Generalities

Malignant mesothelioma is usually seen in older adults, although well-documented cases in young individuals are on record.[26] In some instances familial clustering has been demonstrated.[27] Cases have been reported following radiation therapy for Hodgkin lymphoma.[28] Typically, the tumor presents with chest pain and pleural effusion which may be hemorrhagic. In most instances the initial involvement is in

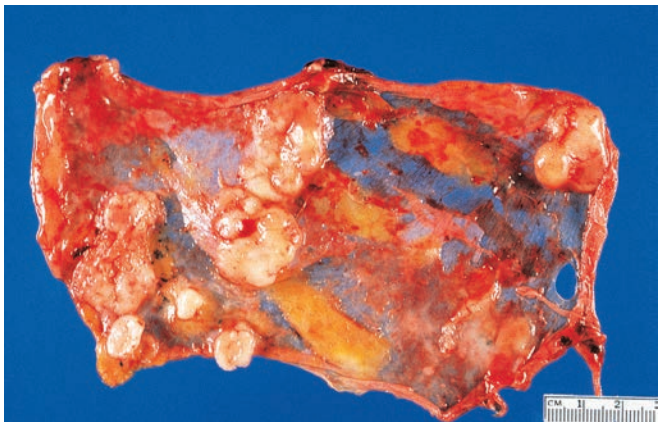

Figure 11.3 Malignant mesothelioma growing as multiple nodules on the parietal pleura.

the lower half of a hemithorax, but spread to the rest of the pleural cavity is the rule. Circumferential pleural thickening with involvement of mediastinal pleura combined with pleural nodules on CT scans tend to favor malignant over benign mesothelial proliferations.[29] Serum levels of osteopontin and mesothelin are potentially useful diagnostic biomarkers, but they are not yet widely available.[30]

Morphologic Features

Grossly, the classic presentation is that of multiple gray or white ill-defined nodules in a diffusely thickened pleura (Figs. 11.3 and 11.4). It is much rarer for it to present as a localized pleural mass.[31,32] Microscopically, diffuse pleural mesothelioma can be divided into purely epithelioid tumors, purely sarcomatoid tumors, and biphasic or mixed tumors. Epithelioid mesotheliomas comprise the majority and in their most classic form are characterized by neoplastic formations with a tubulopapillary architecture, accompanied by solid nests in some cases (Fig. 11.5).[33] The cytoplasm is abundant and acidophilic, sometimes resulting in a histiocytoid appearance. Variations on this classical histology account for myriad histologic variants, as summarized elsewhere in this chapter.

Sarcomatoid mesotheliomas are much less common than epithelioid tumors, accounting for 10%–20% of cases, and are composed of neoplastic spindle cells without an identifiable epithelial element.[34] Pleural effusion is less common, and distant metastases are more frequent at diagnosis in sarcomatoid mesothelioma cases. Grossly they show the same diffuse growth pattern characteristic of epithelioid mesotheliomas with a tendency to encase the lung.[34] Microscopically, the tumor is highly cellular, formed by interwoven bundles of spindle cells (Fig. 11.6). Nuclear atypia is present, and mitotic figures are common. Rarely they are associated with heterologous elements (i.e. rhabdo-, osteo-, and/or chondrosarcomatous differentiation), a finding that is more common in, but not unique to, sarcomatoid variants.[35] Biphasic mesotheliomas occur more frequently than purely sarcomatoid tumors and are characterized by a combination of epithelioid and spindle cell components (Fig. 11.7), resulting in a histologic appearance that may mimic synovial sarcoma. The World Health Organization (WHO) tumor classification proposes that an epithelioid and sarcomatoid component should comprise at least 10% of a mesothelioma to merit the designation of *biphasic*.[36]

Mesothelioma Variants

Well-differentiated papillary mesotheliomas that are multicentric, extensive, and/or associated with pleural effusion should be regarded with great caution, given that these features can be seen focally in otherwise typical epithelioid mesotheliomas. In rare cases, however, the histologic features throughout are identical to those described in patients with the much more common well-differentiated papillary mesotheliomas of the peritoneum: prominent formation of papillae lined by bland mesothelial cells with minimal or no invasion (Fig. 11.8). They are generally associated with an indolent clinical course and long survival but have the capacity to spread widely and behave more aggressively than their peritoneal counterparts.[37]

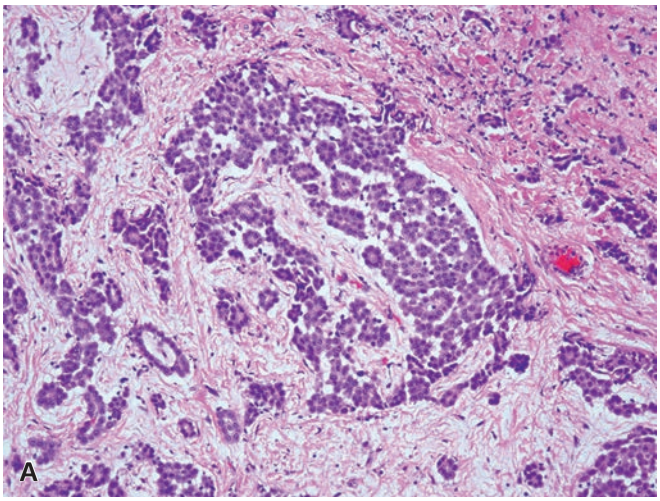

Figure 11.4 Classic pattern of spread of advanced pleural mesothelioma. (Courtesy of Dr. R.A. Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

Deciduoid mesothelioma is characterized by the presence of large tumor cells with an abundant ground-glass cytoplasm that simulates the appearance of decidual cells.[38,39] Originally described in the abdominal cavity of young women, it has now also been seen in the pleural cavity, in an older age group, and in patients of both sexes. In a small retrospective cohort study of 21 cases including 17 pleural tumors, high-grade cytology predicted shorter survivals.[38]

Mesothelioma with clear cell features can be confused with lung carcinoma and metastatic carcinoma, particularly from the kidney.[40] The cytoplasmic clearing is most often due to the accumulation of glycogen, in which case the alternative term *glycogen-rich mesothelioma* has been used.

Mesothelioma with rhabdoid features combines areas of typical mesothelioma (usually of the epithelioid type) with areas rich in

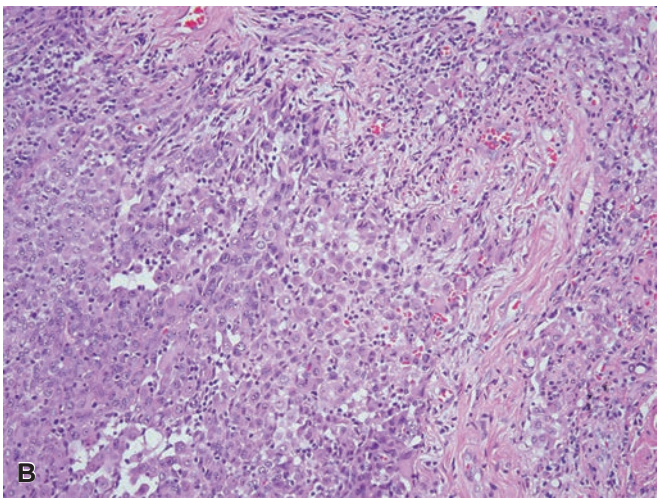

Figure 11.5 Histologically classic malignant pleural mesothelioma with a predominantly tubulopapillary **(A)** and focally solid **(B)** growth pattern.

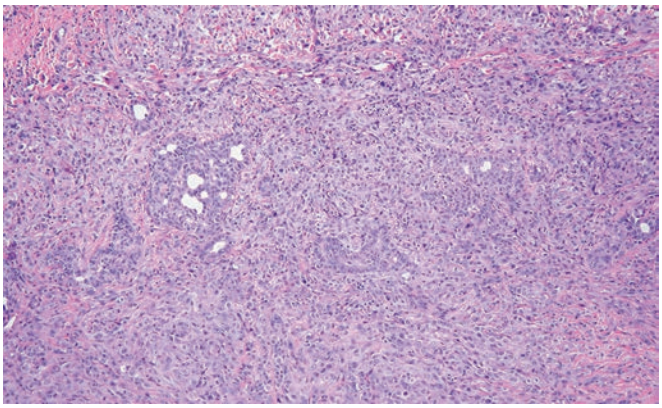

Figure 11.7 Biphasic mesothelioma with both epithelioid and spindle cell components.

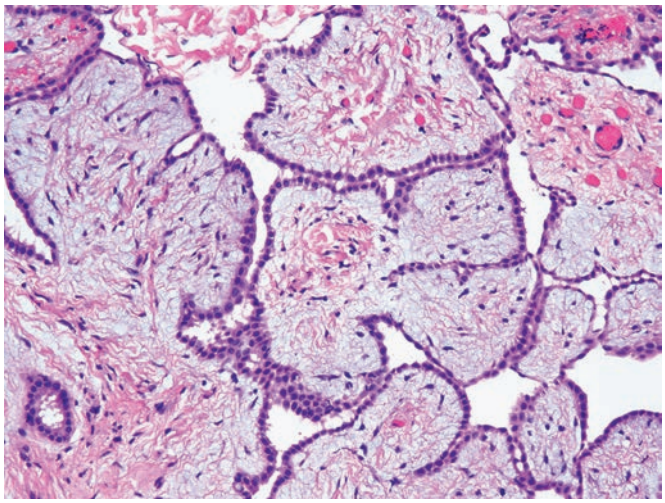

Figure 11.8 **Well-Differentiated Papillary Mesothelioma.**

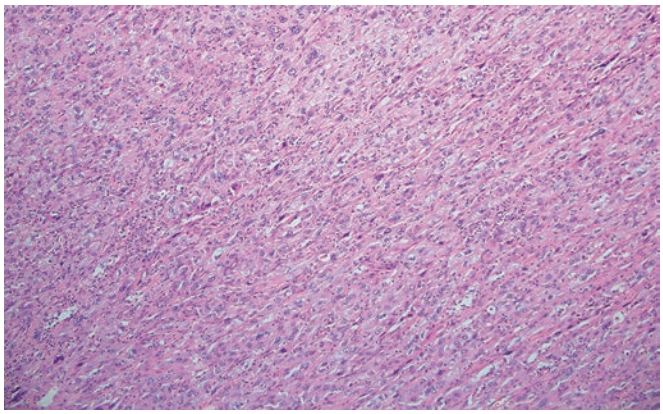

Figure 11.6 Sarcomatoid mesothelioma composed of neoplastic spindle cells.

rhabdoid cells. As it is true for rhabdoid cell-containing tumors in most other sites, this mesothelioma variant runs a markedly aggressive course.[41]

A small cell variant of malignant mesothelioma has been described.[42,43] The small cell component may predominate in small biopsies but is invariably overshadowed by histologically classical features in more thoroughly sampled surgical specimens. Most of the reported cases have been immunoreactive for keratin and mesothelial markers, including calretinin, CK5/6, WT1, and podoplanin; some cases also stained for neuron-specific enolase and occasionally Leu7 (CD57).[42,43]

Lymphohistiocytoid mesothelioma is characterized microscopically by a diffuse proliferation of atypical histiocyte-like malignant mesothelial cells admixed with numerous lymphocytes (almost exclusively of T-cell type) and a lesser number of plasma cells.[44] The phenotype of the histiocyte-like elements reflects their mesothelial nature. The behavior of this tumor is aggressive, as is true for nearly all diffuse mesotheliomas of the pleura, but more closely matches that of conventional epithelioid tumors, suggesting to some that this be considered a variant of epithelioid, rather than sarcomatoid, mesothelioma.[44,45]

Pleomorphic mesothelioma is currently considered a variant of epithelioid mesothelioma in the WHO classification scheme that is characterized by highly pleomorphic large cells with abundant eosinophilic cytoplasm and single or multiple nuclei with marked variation in size and shape and large nucleoli.[46,47] They are consistently positive for pankeratin and cytokeratin 7, but staining for traditional mesothelioma markers like calretinin, CK5/6, and WT1 is variable.[47] A number of authors have advocated that this be considered a variant of sarcomatoid or biphasic, rather than epithelioid, mesothelioma

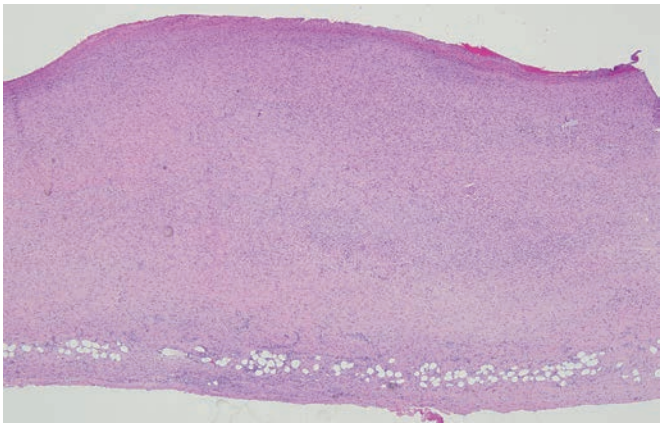

Figure 11.9 Desmoplastic mesothelioma showing characteristic random variation in cellularity, "patternless pattern of Stout," and invasion of chest wall fat.

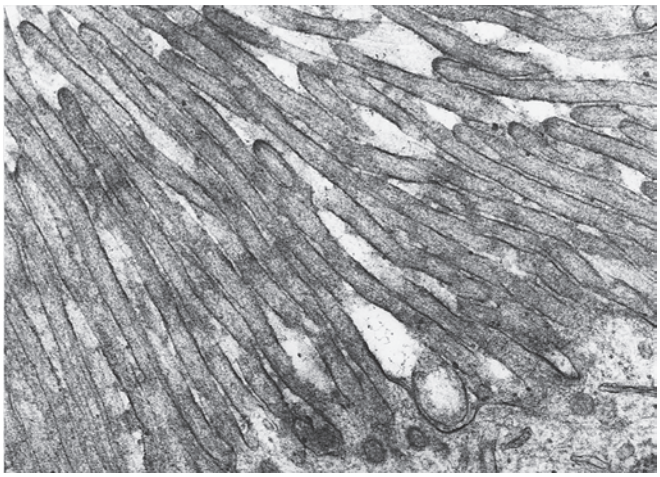

Figure 11.10 Electron Micrograph of a Malignant Mesothelioma of the Pleura. Detail of profuse, long, thin, nonintestinal-type microvilli devoid of a glycocalyx and actin rootlets. (×37,800). (Courtesy of Dr. Robert E. Erlandson, Memorial Sloan-Kettering Cancer Center.)

based on a characteristically aggressive course more typical of sarcomatoid tumors.[46,48]

Desmoplastic mesothelioma is a subtype of sarcomatoid mesothelioma accompanied by abundant deposition of fibrous tissue demonstrating a storiform or "patternless pattern of Stout" arrangement of neoplastic spindle cells (Fig. 11.9). The main differential diagnosis is with benign fibrous lesions of the pleura and more cellular types of solitary fibrous tumors, some of which may be malignant themselves. Immunohistochemical positivity for keratin, calretinin, and WT1 is the best evidence in favor of mesothelioma over solitary fibrous tumor but does not establish a diagnosis of malignancy, given that reactive submesothelial fibroblasts frequently acquire a mesothelial immunophenotype.[49] Histologic features helpful in separating desmoplastic mesothelioma from benign fibrous proliferations include invasion of chest wall soft tissue or lung parenchyma, bland necrosis, frankly sarcomatoid areas with cytologic atypia, and the characteristic storiform growth pattern in the context of random variation in cellularity.[50]

Differential Diagnosis and the Role of Histochemistry, Immunohistochemistry, Electron Microscopy, and Molecular Testing

Early cases of epithelioid mesothelioma must be distinguished from reactive mesothelial hyperplasia, as seen in association with inflammatory or neoplastic diseases of the underlying lung, or sometimes with no apparent cause. Features in favor of malignancy include stromal invasion, full-thickness involvement, expansile nodules, random variation in cellularity, architectural complexity, and irregular distribution of vessels.[29] Of these, invasion is regarded as the most reliable criterion of malignancy. The diagnosis of malignant mesothelioma in the absence of detectable invasion ("mesothelioma in situ") is problematic in the absence of invasive disease elsewhere and should be made with great caution if at all. Homozygous deletion of *p16^{INK4a} (CDKN2A)* detected using a fluorescent in situ hybridization (FISH) assay and loss of BAP1 expression by immunohistochemistry may be helpful in separating benign from malignant mesothelial proliferations, including desmoplastic mesothelioma.[51,52] Other immunostains, such as epithelial membrane antigen (EMA), p53, GLUT1, and IMP3, proposed for separating benign from malignant mesothelial proliferations, are of considerably less value with sensitivities and specificities that make them difficult to apply in any individual case.[53,54] When in doubt, a conservative approach is indicated, reflected by a terminology such as *atypical mesothelial proliferation*.[55] If the lesion is a mesothelioma, usually this will become apparent in a few months.

Obviously malignant epithelioid mesotheliomas need to be distinguished from metastatic carcinoma, particularly pulmonary adenocarcinomas with a pseudomesotheliomatous growth pattern.[56,57] This may be a very difficult or even impossible task at the hematoxylin and eosin–level in a biopsy specimen and sometimes even in a surgical specimen. In general, the cells of mesothelioma are more uniform and regular than those of adenocarcinoma, with a more constant nuclear to cytoplasmic ratio. Their shape is usually cuboidal; presence of a substantial number of columnar-shaped cells favors a diagnosis of adenocarcinoma. Cellular crowding and nuclear molding also favor adenocarcinoma. Given the limitations of routine histology, immunohistochemistry can be very useful in making this distinction and has supplanted a role for histochemistry and electron microscopy in most but not all cases. The role of immunohistochemistry is considerably more limited in separating sarcomatoid mesotheliomas from sarcomatoid carcinomas and soft tissue sarcomas, a distinction that relies in large part on knowing the distribution of disease given that sarcomatoid carcinomas and soft tissue sarcomas rarely if ever grow as diffuse pleural lesions.

Mesotheliomas usually produce large amounts of hyaluronic acid, which can be demonstrated with the alcian blue or colloidal iron stains.[58] This material is nearly always mucicarmine negative, and the alcian blue positivity can be removed almost entirely by pretreatment with hyaluronidase. The presence of obvious droplets of mucicarmine-positive or periodic acid–Schiff (PAS)-positive material *in the cytoplasm of the tumor cells* makes the diagnosis of mesothelioma very unlikely, although it does not rule it out completely inasmuch as the existence of rare mucin-positive mesotheliomas has been documented.[59]

At one time electron microscopy played a pivotal role in the differential diagnosis between mesothelioma and metastatic carcinoma, to the point of being considered the gold standard.[60,61] This was primarily based on the appearance of the microvilli in the apical surface of the tumor cells, which in mesothelioma are longer and more slender than those in adenocarcinoma (Fig. 11.10). The validity of this observation stands, but its practical utility has decreased markedly as a result of the development of immunohistochemical stains that achieve the distinction in the large majority of the cases.[62]

Immunostains are most useful for distinguishing epithelioid mesotheliomas from metastatic carcinomas, particularly in small

biopsies. The staining strategy depends to some extent on the differential diagnosis, given variability in the sensitivity and specificity of commonly used carcinoma markers and the potential role for organ-specific stains. Lung adenocarcinomas account for the majority of cases presenting with a pseudomesotheliomatous growth pattern and is therefore the most likely primary site in the absence of a history of prior or concomitant extrathoracic malignancy. Other metastatic carcinomas that can cause a pseudomesotheliomatous pattern include breast, urothelial, renal cell, pancreatic ductal, prostate, and squamous cell carcinomas from a variety of sites.[56] The following is an incomplete summary of available immunostains, focusing on those that are most commonly available and utilized.

1. *Epithelial markers that are usually present in both tumors:* pankeratins, EMA, basement membrane components (also demonstrable ultrastructurally),[63] and S-100 protein (variable). Many metastatic adenocarcinomas likely to be confused with mesothelioma are positive for cytokeratin 7, as are epithelioid mesotheliomas, making cytokeratin 7 and 20 of limited value except in the very specific context of metastases from the gastrointestinal tract.[64]
2. *Markers that are usually expressed in carcinoma but not in mesothelioma:* MOC-31, Ber-EP4, carcinoembryonic antigen (CEA), B72.3, BG8, CD15, MUC4, and claudin-4.[65,66] Sensitivity and specificity of these markers are dependent on origin and histology of the carcinoma.
3. *Organ-associated and lineage-specific markers that are often expressed in metastatic carcinoma (most common sites highlighted in parentheses) but not mesothelioma:* TTF-1 (lung and thyroid), napsin A (lung and kidney), PAX8 (kidney, müllerian, thymus), CDX2 (gastrointestinal, pancreaticobiliary), GCDFP (breast), mammaglobin (breast), estrogen receptor (ER) (breast, müllerian), p63/p40 (squamous cell, urothelial), and GATA3 (breast, urothelial, squamous cell),[65,67,68] It is important that the TTF-1 antibody used for this differential diagnosis is the 8G7G3/1 rather than the SP141 clone given the greater specificity of the former. A recent report described staining for TTF-1 using the SP141 monoclonal antibody in a subset of sarcomatoid mesotheliomas.[69]
4. *Markers that are usually expressed in mesothelioma but not in carcinoma (with important exceptions highlighted in parentheses)*: calretinin (breast, müllerian serous), WT1 (breast, müllerian serous), keratin 5/6 (squamous cell, urothelial), D2-40/podoplanin (müllerian serous, squamous cell), and thrombomodulin (squamous cell) (Fig. 11.11).[65,67]

As useful as these markers are in this difficult diagnosis, it should be realized that few, if any, of them are 100% sensitive or specific. It should also be remembered as a practical rule that a negative immunoreaction never rules out a diagnosis.

Taking into account the plethora of available markers and variations in their performance characteristics, a selection needs to be made. Several authors have suggested that a limited panel of immunostains should suffice in most cases, depending on the differential diagnosis predicated on the history, distribution of disease, and histologic features. Ordonez has suggested, for example, that a panel of four markers—calretinin, cytokeratin 5/6 (or WT1), CEA, and MOC-31 (or B72.3)—enables a correct diagnosis in nearly every instance if the issue is mesothelioma versus pulmonary adenocarcinoma.[70] Mohammad et al. similarly showed that a combination of calretinin, cytokeratin 5/6, CEA, and CD15 was highly effective in separating mesothelioma from adenocarcinoma of the lung.[71] Yaziji et al. prefer instead a panel composed of calretinin, MOC-31, and BG8 (Lewis Y blood group), which demonstrated 96% sensitivity and specificity for distinguishing epithelioid mesothelioma and adenocarcinoma.[72]

It should be restated that immunostains are useful primarily for cases in which the diagnostic issue is epithelioid mesothelioma versus metastatic carcinoma. Immunostains are much less useful in differentiating sarcomatoid mesothelioma from other sarcomatoid or frankly sarcomatous tumors. Keratin stains are usually positive, at least focally, in sarcomatoid mesotheliomas using pancytokeratin antibodies or antibody cocktails, but as many as 5%–10% may be negative, including those with heterologous elements.[36] Antibodies directed against

podoplanin (i.e. D2-40, antipodoplanin) are more sensitive than calretinin for sarcomatoid mesothelioma.[73] Other mesothelioma markers, such as WT1 and CK5/6, are relatively insensitive.

Molecular Genetic Features

The most common recurrent somatic mutations in malignant mesothelioma target three genes functioning as tumor suppressors: cyclin-dependent kinase inhibitor 2A (*CDKN2A)*, BRCA1-associated protein 1 *(BAP1)*, and neurofibromin 2 (merlin) *(NF2)*.[74,75] Mutations in the *TP53* gene are uncommon. Homozygous deletion of $p16^{INK4a}$ *(CDKN2A)* occurs in 60%–80% of mesotheliomas and, as previously referenced, is a useful diagnostic tool for separating benign from malignant mesothelial proliferations; it is less useful in differentiating mesothelioma from carcinoma.[52–54,76–79] *CDKN2A* deletion is also a potential biomarker that has been linked to a more aggressive course in some studies.[80,81] Loss of BAP1 expression by immunohistochemistry is less sensitive, occurring in around 70% of epithelioid mesotheliomas but in fewer (20%–30%) sarcomatoid and biphasic mesotheliomas.

Spread and Metastases

The typical pattern of spread of malignant mesothelioma is by contiguity and perhaps implantation. Through either mechanism it may spread to the entire pleural space, both pleurae, interlobular septa, pericardium, chest wall, diaphragm, and even the peritoneum.[82] Extension into the subpleural portions of the lung is also common, and intraparenchymal spread can occur,[83] but the presence of nodular masses within the lung parenchyma favors a primary lung cancer with prominent pleural spread. Exceptionally, mesothelioma grows in an intrapulmonary lepidic fashion that can simulate minimally invasive ("bronchioloalveolar") adenocarcinoma.[84,85] Distant extrathoracic metastases in mesothelioma generally occur only in the late stages of the disease, if at all.[86] Therefore, presence of prominent hilar and supraclavicular lymphadenopathy at the time of initial presentation favors carcinoma over mesothelioma. However, we and others have seen pleural mesotheliomas that have presented initially with lymph node involvement in the cervical or axillary region.[87] We have also seen cases of mesothelioma presenting with distant metastases in unusual places, such as the tongue.[88]

Treatment and Prognosis

There is no universally effective treatment for malignant mesothelioma at present. Surgical excision is often attempted, sometimes of heroic proportions (pneumonectomy, parietal and mediastinal pleurectomy, diaphragmectomy), but on the whole the results have been disappointing. On the other hand, bulk resection of the tumor combined with radiation and systemic chemotherapy ("trimodality therapy") has sometimes resulted in long-term remissions in a very small subset of highly selected patients with epithelioid histology, early stage disease, gross total removal of tumor by either extrapleural pneumonectomy or pleurectomy/decortication, and a measurable response to radiation therapy.[89–95] Patterns of relapse after aggressive trimodality therapy are variable and may include miliary involvement of the contralateral lung.[96] Radiation therapy can induce the appearance of bizarre multinucleated tumor cells and intense polymorphic inflammation, whereas the use of chemical (talc) pleurodesis can result in a marked pseudosarcomatous fibroblastic proliferation.[97]

Prognostic factors that need to be mentioned in relation to malignant mesothelioma are the following:

1. *Stage:* There is a definite relationship between tumor stage, including N2 disease at presentation, and prognosis, acknowledging that the prognosis is generally poor in all patients.
2. *Gender:* The prognosis seems to be poorer in males than in females.
3. *Tumor subtype:* Sarcomatoid mesotheliomas, including desmoplastic variants, are associated with a shorter survival than the conventional epithelioid type,[98] whereas the reverse is true for low-grade deciduoid,[38] well-differentiated,[37] and localized variants.[31]

Solitary Fibrous Tumor

Solitary fibrous tumor of pleura (formerly called solitary fibrous mesothelioma) is symptomatic in about half of patients, including most commonly cough, chest pain, dyspnea, and pulmonary osteoarthropathy.[99,100] Hypoglycemia is an uncommon manifestation of solitary fibrous tumor *(Doege-Potter syndrome)* resulting from secretion of insulin-like growth factor II by neoplastic cells and is resolved with complete excision.[101] Solitary fibrous tumor is not associated with asbestos exposure. On rare occasions, it is found together with a microscopically similar tumor in the peritoneum or retroperitoneum.[102]

Grossly, the lesion is well circumscribed, firm, lobulated, gray–white to yellow–white, with frequent whorling and fasciculation. The mean diameter is 6 cm, but some are very large, completely opacifying a hemithorax. The gross appearance is reminiscent of uterine leiomyoma (Fig. 11.12). Cystic degeneration is very unusual, but solitary fibrous tumor can present as a mural nodule within a large pleural-lined cyst. The majority are attached to the visceral (80%) or parietal pleura,[99] within an interlobar fissure, or sometimes within the lung parenchyma without a pleural connection (intrapulmonary solitary fibrous tumor).[103] Lesions with an identical microscopic appearance are now known to occur in a large number of sites, including peritoneum, retroperitoneum (including kidney), mediastinum, nasopharynx, oral cavity, orbit, soft tissues, pancreas, prostate, and breast (see respective chapters).[104]

Microscopically, both benign and malignant forms occur, the former greatly predominating.[99,100,105] The distinction between them can be difficult given the absence of clearly articulated criteria for predicting behavior; malignant tumors are characterized by various combinations of increased cellularity, cytologic atypia that includes nuclear hyperchromasia and pleomorphism, mitoses, and necrosis.[99,100,105] In the typical benign case, there is a tangled network of fibroblast-like cells, squeezed in between abundant collagen fibers, many of which have a keloid-like quality, resulting in what some have referred to as the *patternless pattern of Stout* (Fig. 11.13). The degree of cellularity varies a great deal from area to area.

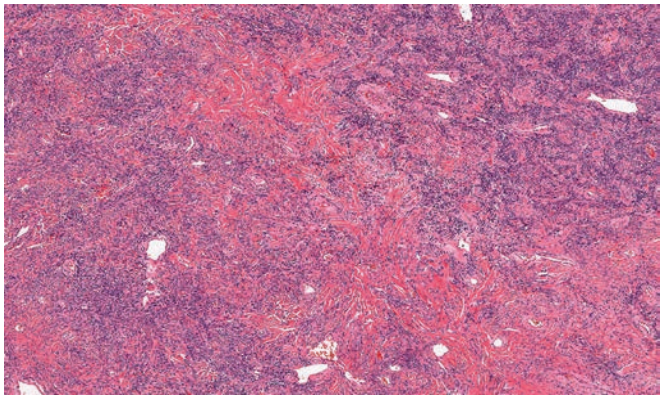

Figure 11.13 Solitary Fibrous Tumor of Pleura. The proliferation of mesenchymal spindle cells separated by thick bands of keloid-type collagen is characteristic of this entity.

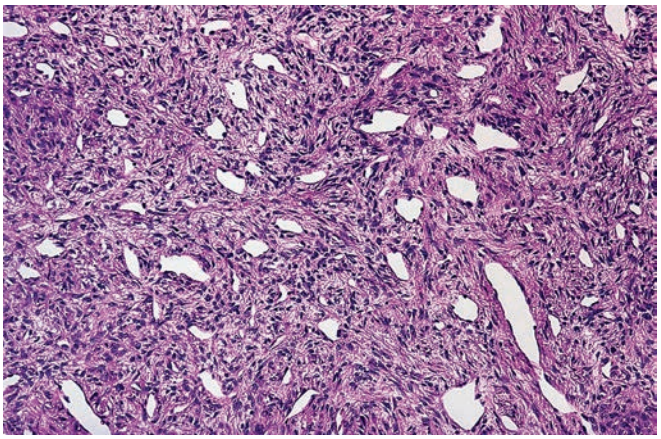

Figure 11.14 Prominent hemangiopericytoma-like pattern in solitary fibrous tumor.

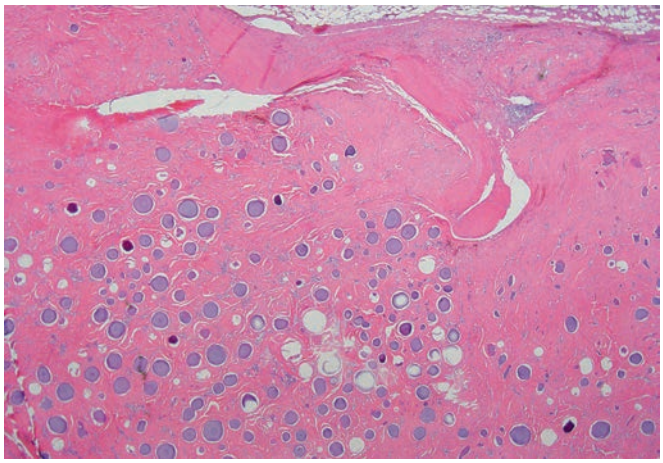

Figure 11.15 Calcifying Fibrous Pseudotumor of Pleura.

Hemangiopericytoma-like changes are frequent in the more cellular zones (Fig. 11.14), and some tumors have prominent myxoid features.[106]

The differential diagnosis of the more sclerotic types of solitary fibrous tumor include fibrous plaque, fibromatosis (desmoid tumor),[107] and calcifying fibrous pseudotumor (Fig. 11.15).[108] Myxoid

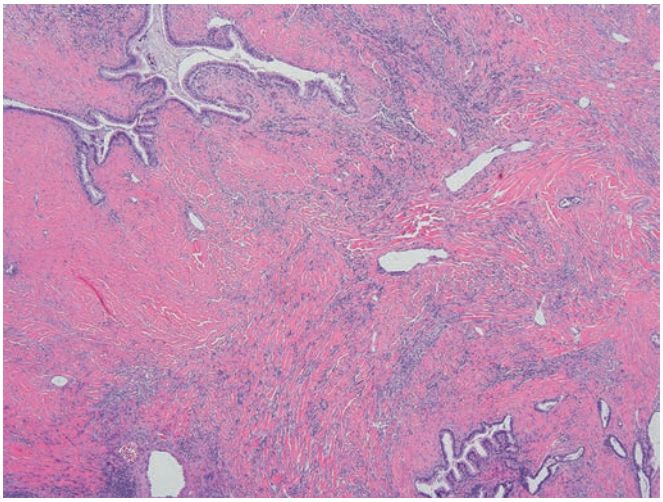

Figure 11.16 Intrapulmonary solitary fibrous tumor with entrapped non-neoplastic respiratory epithelium resulting in a biphasic appearance.

tumors need to be distinguished from low-grade myxofibrosarcoma and low-grade fibromyxoid tumor. The most cellular types may be misdiagnosed as fibrosarcoma or malignant peripheral nerve sheath tumor. If proper attention is paid to the lack of nuclear aberrations and the rarity or absence of mitoses, confusion is unlikely to occur. In some instances, entrapped non-neoplastic epithelial cells are found at the periphery of predominantly fibrous tumors (Fig. 11.16); these represent entrapped mesothelium or respiratory epithelium and should not be misconstrued as evidence of a truly biphasic neoplasm. Malignant solitary fibrous tumors are characterized by increased cellularity, atypia, mitotic activity, and necrosis.

This neoplasm was regarded historically as a form of mesothelioma, largely on the basis of the pattern of growth that the tumor cells exhibit in tissue culture[109]; however, on ultrastructural examination these cells show fibroblast-like rather than mesothelial-like features, and by immunohistochemistry their filament profile includes vimentin and sometimes desmin but not keratin.[110,111] The most likely interpretation of this tumor, therefore, is that it arises from noncommitted mesenchymal cells present in the areolar tissue subjacent to the mesothelial lining. This has led to the proposal of alternative terms, such as submesothelioma or submesothelial fibroma, which, however, are hard to apply to tumors located well away from any mesothelial-lined surfaces.

The tumor cells of this lesion stain strongly and consistently for CD34 and BCL2, a useful finding in the differential diagnosis with some of the entities described previously.

Recurrent intrachromosomal rearrangements resulting in fusion of *NAB2* and *STAT6* on chromosome 12q have been identified as a unique driver mutation in solitary fibrous tumors.[112] The fusion product is overexpressed in nearly all cases and can be detected using a commercially available antibody directed against STAT6 characterized by diffuse nuclear staining (Fig. 11.17). STAT6 staining is a very useful addition to CD34 as a relatively sensitive marker in diagnostically challenging cases, but STAT6 staining can also be seen in other potential mimics, including synovial sarcoma, and therefore should be interpreted with caution.[104]

The vast majority of solitary fibrous tumors of the pleura are cured with complete surgical excision and tumor-free margins.[113] Relapse can present as recurrent intrathoracic (Fig. 11.18) or widely metastatic disease, the latter restricted in large part to cases with

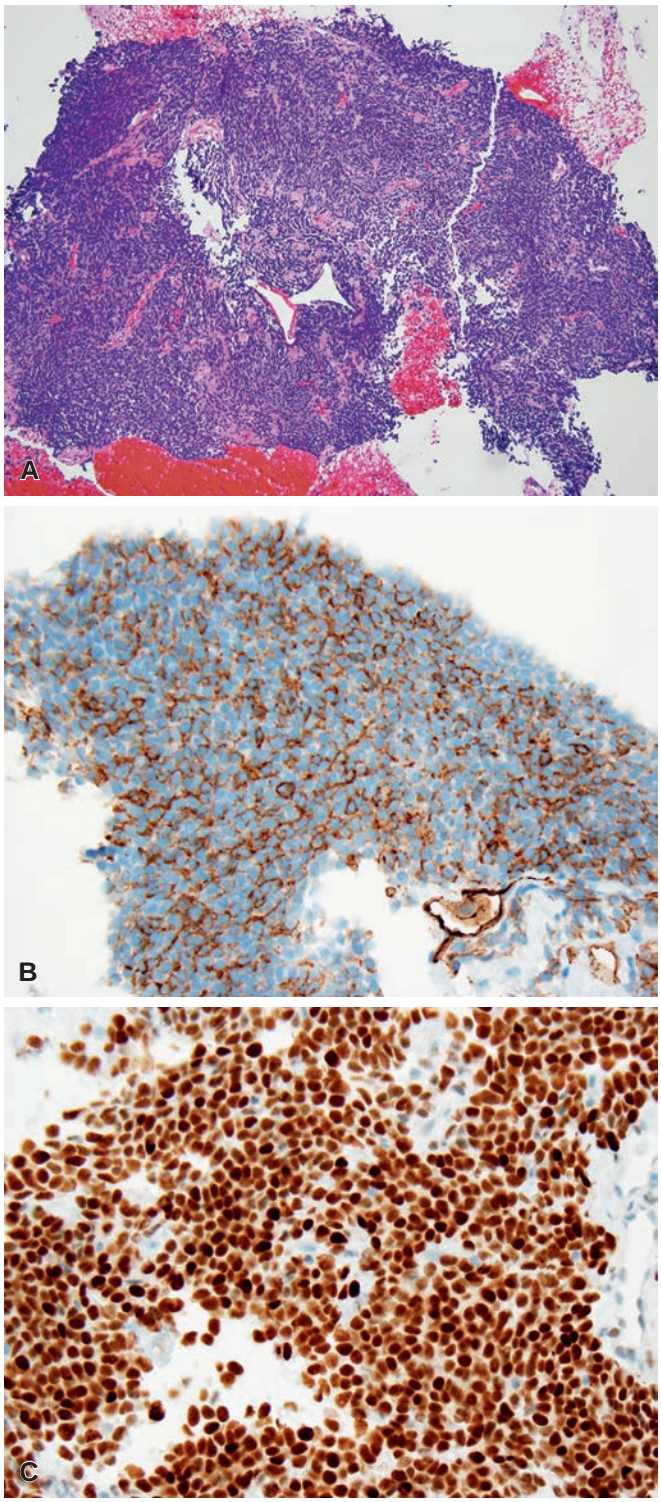

Figure 11.17 Intrathoracic solitary fibrous tumor on core needle biopsy **(A)** showing positive staining for CD34 **(B)** and STAT6 **(C)**. Stains for keratins and TLE-1 were negative, which were helpful in excluding monophasic synovial sarcoma.

malignant histologic features.[100,113] In a scoring system intended to predict risk of recurrence, Tapias et al. proposed parietal (vs. visceral) origin, sessile (vs. pedunculated) gross morphology, size (≥10 cm), hypercellularity (i.e. crowded tumor cells with back-to-back and/or overlapping nuclei and minimal/absent matrix), necrosis or

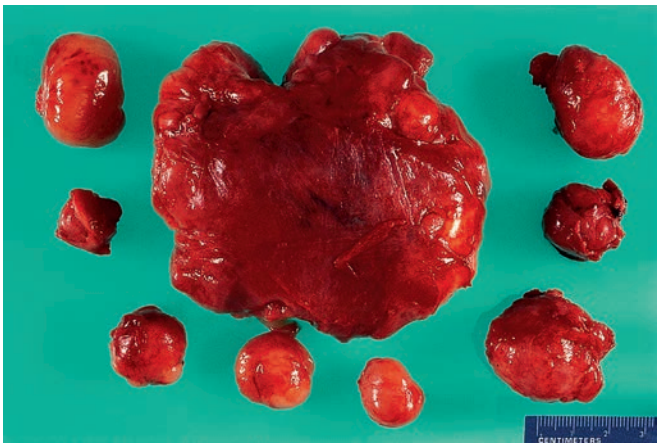

Figure 11.18 Malignant solitary fibrous tumor of pleura resulting in numerous serosal implants.

hemorrhage, and a high (≥4/10 hpf) mitotic rate as adverse prognostic factors (≥3 = "high risk"); however, high mitotic rate was the only factor significantly associated with recurrence in multivariate analysis.[114]

Other Primary Tumors

Two cases of primary **mucoepidermoid carcinoma** have been reported, each presenting as a localized pleural-based mass.[115]

Soft tissue–type tumors of various types can occur in the pleura.[116] These need to be distinguished from the more common sarcomatoid mesothelioma and the malignant form of solitary fibrous tumor, as described elsewhere in this chapter.

Synovial sarcoma has now been recognized as sometimes arising in the pleura and is the most common of those soft tissue sarcomas that may present as primary intrathoracic neoplasms.[116,117] In the past, most of these cases were diagnosed as malignant mesotheliomas or malignant solitary fibrous tumors. Both biphasic and monophasic forms occur.[118,119] Molecular testing for the *SYT–SSX* gene fusion that characterizes this tumor may be helpful to confirm the diagnosis in some cases. Other soft tissue tumors and tumorlike conditions that have been reported in the pleura are *fibromatosis* (desmoid tumor), *calcifying fibrous pseudotumor*, *liposarcoma*, *chondrosarcoma*, so-called *pleomorphic undifferentiated sarcoma* (formerly termed malignant fibrous histiocytoma), *gastrointestinal stromal tumor (GIST)*, *desmoplastic small round cell tumor*, *primitive neuroectodermal tumor* (Askin tumor), and *liposarcoma*.[116]

Epithelioid hemangioendothelioma and *angiosarcoma* may diffusely infiltrate the pleura in a fashion simulating mesothelioma (Fig. 11.19).[120] Rarely angiosarcomas have occurred against a background of chronic pyothorax.[121]

Malignant lymphoma involving the pleura is usually associated with systemic disease. The most frequent type is diffuse large B-cell lymphoma, followed by follicular lymphoma.[122] Lymphoma centered in the pleural cavity can complicate longstanding pyothorax, a variant referred to as *pyothorax-associated lymphoma*. This is an Epstein–Barr virus (EBV)-related diffuse large B-cell lymphoma distinguished not only by its peculiar presentation but also frequent plasmacytoid features and aberrant expression of T-cell markers.[123,124] Pyothorax-associated lymphoma is unrelated to human herpesvirus 8 (HHV8), a feature that sets it apart from primary effusion lymphoma. *Primary effusion lymphoma* occurs most often in the setting of immunodeficiency and does not result in tumor mass formation as in

Figure 11.19 Epithelioid Hemangioendothelioma of Pleura. The tumor involves the pleural surface in a fashion indistinguishable from diffuse malignant mesothelioma.

pyothorax-associated lymphoma.[125,126] It is composed of a population of large pleomorphic lymphoid cells that frequently demonstrates a null or ambiguous immunophenotype that may include expression of T-cell associated antigens; despite an ambiguous immunophenotype, molecular studies show rearrangements of immunoglobulin heavy chain genes consistent with a B-cell lineage lymphoma in nearly all cases.[125–127] Primary effusion lymphoma, like pyothorax-associated lymphoma, is EBV related but differs in also being invariably associated with HHV8 virus, an extremely helpful diagnostic feature.[127]

Thymoma can also present as a primary pleural mass, resulting in possible diagnostic confusion with mesothelioma.[128]

Metastatic Tumors

Most malignant tumors involving the pleura are of metastatic nature; of these, about 75% are metastatic carcinomas. They are second only to congestive heart failure as the cause of pleural effusions in patients over 50 years of age.[129] Dyspnea, cough, and chest pain are the most common presenting symptoms. Most malignant pleural effusions are greater than 500 mL. The fluid is most often serous to serosanguineous, but it may be frankly hemorrhagic. The most common sites for the primary lesion are lung (33%), breast (20.9%), and stomach (7.3%).[130] Approximately 90% of the lung, breast, and ovarian malignant effusions are ipsilateral to the primary lesion. A malignant pleural effusion may be the first evidence of the existence of cancer.

Biopsy and Cytology

Needle biopsy of the parietal pleura is very useful for the differential diagnosis between inflammatory and neoplastic processes.[131] Histopathologic examination and culture of pleural biopsies has played an important part in the diagnosis of pleural tuberculosis,[132] but the advent of modern techniques, including polymerase chain reaction (PCR)-based assays, may improve diagnostic sensitivity.[133,134]

If pleural effusion is present, cytologic examination of the fluid has been found to be more effective in detecting malignancy than pleural biopsy.[134–136] The sensitivity and specificity is improved with use of ancillary techniques, including flow cytometry, immunohistochemistry, and molecular techniques, including FISH assays for p16 deletion in the case of mesotheliomas.[51,81,137] In the huge series by Johnston, a cytopathologic diagnosis conclusive for cancer was obtained in the first specimen of fluid in 90.5% of the cases; there were no false-positive diagnoses.[138] Therefore, when the possibility of malignancy is considered in the presence of pleural effusion, a cytologic examination of the pleural fluid should always be performed, regardless of the gross appearance of the fluid.

There is probably no area in diagnostic cytology that is more difficult to interpret than that of effusions in serous cavities. This is mainly because proliferating reactive mesothelial cells can acquire features dangerously similar to those of cells of mesothelioma and even metastatic carcinoma. The cells of mesothelioma can occur singly or in clusters with scalloped borders. The cytoplasm is dense and often has small, regular, centrally located vacuoles.[139] Nuclei are atypical, the nuclear to cytoplasmic ratio is altered, and multinucleated forms may be present. The cytologic features of potential value in separating mesothelioma, benign mesothelial proliferations, and adenocarcinoma are preserved in liquid-based monolayers preparations, such as ThinPrep.[140] Cytologic preparations can also be used for histochemistry, immunohistochemistry, electron microscopy, and molecular testing using the previously described diagnostic tools.

Generalities

The mediastinum is the portion of the thoracic cavity located between the pleural cavities, extending anteroposteriorly from the sternum to the spine and from the thoracic inlet superiorly to the diaphragm inferiorly. The numerous organs and structures it contains make it a veritable Pandora's box, within which congenital cysts, benign tumors, and primary and metastatic neoplasms may develop.

An arbitrary division of the mediastinum into *superior*, *anterior*, *middle*, and *posterior* compartments has proven useful, since most cysts and neoplasms have a predilection for one compartment over the others. The most common mediastinal lesions are noted in Fig. 12.1 according to their frequency and most common site of occurrence in adults.[1] As expected, the relative frequencies of these lesions are considerably different in the pediatric population.[2]

About half of the patients with mediastinal cysts and tumors are asymptomatic, the lesions being discovered incidentally on chest x-rays or CT scans done for other reasons. When symptoms develop, they usually result from compression and/or invasion of adjacent structures, and include chest pain, cough, and dyspnea. Development of the superior vena cava syndrome is usually indicative of malignancy, the two most common causes in adults being metastatic lung carcinoma and malignant lymphoma,[3] and in children malignant lymphoma and acute leukemia.[4] However, it can also occur with benign conditions such as fibrosing mediastinitis.[5] Pulmonary stenosis can also occur with mediastinal tumors as a result of compression of the pulmonary artery or the right ventricular outflow tract.

The location of lesions in the mediastinum, together with their configuration, provides important diagnostic information, but many lesions (both benign and malignant) result in similar radiographic and CT scan appearances. Biopsy and/or exploration are therefore mandatory in most instances. Preoperative irradiation should be avoided when possible because the resulting changes may render the pathologic interpretation difficult or even impossible. Core needle and fine-needle aspiration of mediastinal masses are important diagnostic strategies, particularly in lesions of the anterosuperior compartment.

Inflammatory Diseases

Acute mediastinitis is usually the result of traumatic perforation of the esophagus, or descent of infection from within the neck through the "danger space" anterior to the prevertebral fascia; in both cases, it involves predominantly the posterior portion of the mediastinum. The initial lesion may be a neck abscess resulting from dental infection, Ludwig angina, necrotizing fasciitis, or a pyriform sinus fistula.[6] Abscess formation usually takes place and generally requires surgical drainage. Superior vena cava syndrome is an uncommon complication

Abstract

This chapter reviews diseases of the mediastinum after a brief overview of mediastinal compartments and the importance of gross features and distribution of disease in differential diagnosis. Inflammatory diseases, mediastinal cysts, and lesions arising in thyroid and parathyroid tissue is followed by a more detailed review of the anatomy of the thymus and thymic pathology in various primary immunodeficiencies. Thymic cysts and other non-neoplastic conditions precede a more exhaustive summary of primary thymic epithelial and non-epithelial neoplasms. The chapter concludes with a brief summary of metastases that may involve the mediastinum.

Keywords

Pericardial cysts,
foregut cysts,

synovial sarcoma

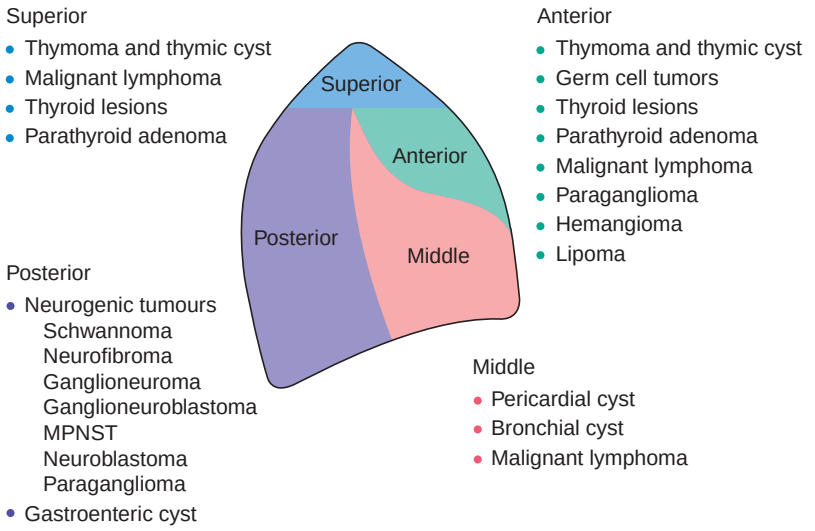

Figure 12.1 Location of most common lesions of mediastinum. *MPNST*, Malignant peripheral nerve sheath tumor.

Figure 12.2 Fibrosing mediastinitis constricting the superior vena cava resulting in superior vena cava syndrome.

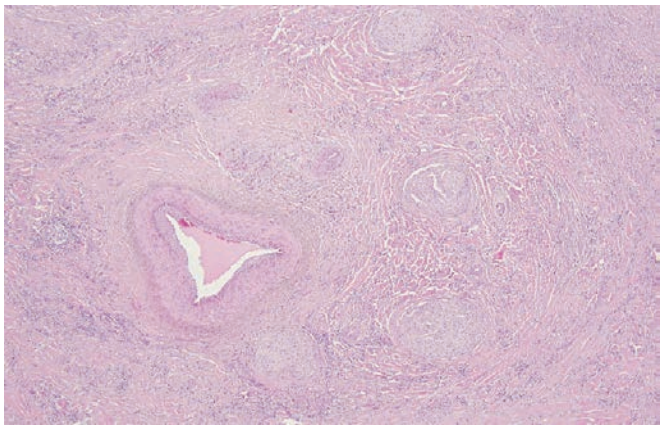

Figure 12.3 Fibrosing Mediastinitis. Dense ropey collagen bundles surround nerves and vessels.

of acute mediastinitis but has been described in cases of *Nocardia* spp. and other types of bacterial lung infections with secondary mediastinal involvement.[7–9]

Other types of mediastinitis are those resulting from spread of infection from the chest wall and those developing after heart surgery.[10]

Chronic mediastinitis can produce compression of mediastinal structures and simulate a malignant process.[11,12] The typical location is the anterior mediastinum, in front of the tracheal bifurcation. Microscopically, one may find necrotizing granulomatous infection *(granulomatous mediastinitis)*, fibrosis *(fibrosing mediastinitis)*, or a combination of both.[13] *Histoplasma capsulatum* (histoplasmosis) is the organism most commonly identified in those cases of fibrosing mediastinitis for which a specific etiology can be determined.[14]

Fibrosing mediastinitis is characterized by coarse, keloid-like, collagen deposition that can invade the superior vena cava, resulting in superior vena cava syndrome, and can also invade the pulmonary hilum, resulting in complete occlusion of hilar vessels (Figs. 12.2 and 12.3). The latter may result in complete obstruction of venous outflow, resulting in a peculiar pattern of microscopic subpleural and paraseptal infarction *("venous infarcts")*.[15] The fibrosis is accompanied by a variable but generally mild, patchy infiltrate of lymphocytes and plasma cells. In selected cases a lymphoplasmacytic infiltrate is accompanied by other changes characteristic of IgG4-related disease (i.e. storiform fibrosis, obliterative phlebitis/arteritis, and an increase in IgG4-positive plasma cells above proposed diagnostic thresholds), a finding that is not yet fully understood.[16] Cases in which there is an associated granulomatous infection show necrotizing granulomas in which there may be relatively few epithelioid or multinucleated histiocytes. Special stains may be helpful in identifying pathogens within the necrotic zones. The differential diagnosis for fibrosing mediastinitis includes primarily neoplastic disorders that may contain extensive areas in which only fibrosis and chronic inflammation predominate; this is particularly true for Hodgkin lymphoma.

In many instances of fibrosing mediastinitis, a specific infectious etiology cannot be demonstrated (*idiopathic* fibrosing mediastinitis). Some of these cases belong to a group of fibrosing (sclerosing) inflammatory conditions, which includes pulmonary hyalinizing granuloma, retroperitoneal fibrosis, sclerosing cholangitis, Riedel struma, and inflammatory pseudotumor of the orbit. As previously mentioned, fibrosing mediastinitis has in common with the other members of this list a link to IgG4-related disease.

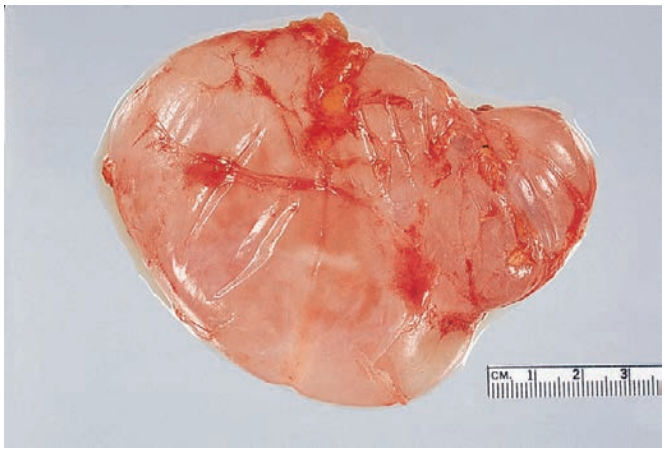

Figure 12.4 Gross Appearance of Pericardial Cyst. Note the thin translucent quality of the wall, which is partially covered by adipose tissue.

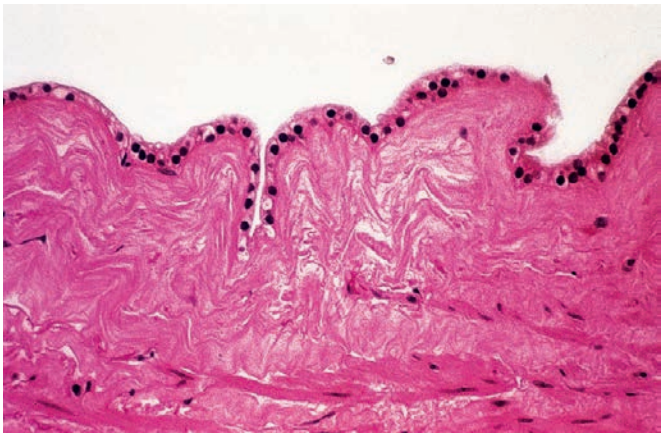

Figure 12.5 Microscopic Appearance of Pericardial Cyst. The lining is composed of a single layer of mesothelial cells.

The tendency for fibrosing mediastinitis to grow in an invasive fashion accounts for the historically high rates of morbidity and mortality attributed to this condition; a more recent report suggests that overall survival may be equivalent to age-matched controls.[14] The treatment of fibrosing mediastinitis includes surgical excision and nonsurgical interventions in those with compression of vital mediastinal structures.[14] Anti-inflammatory and anti-fungal strategies are generally ineffective. A few cases have benefitted from rituximab, a strategy targeting the predominance of B lymphocytes in some examples.[17]

Cysts (Other Than Thymic)

Pericardial (Coelomic) Cysts

The pericardial sac is formed by the fusion of multiple disconnected lacunae. Failure of one of the lacunar cavities to merge with the others results in the development of a pericardial (coelomic) cyst. Such cysts are usually located at the right cardiophrenic angle.[18] They are soft and unilocular, usually loosely adherent to the pericardium and attached to the diaphragm; sometimes they communicate with the pericardial cavity (Fig. 12.4). Less commonly, they are seen in a suprapericardial position. At times, multiple cysts may be present. They contain clear fluid unless infected. The blood supply comes from the pericardium. The inner surface of the cyst wall is covered by a single layer of flat or cuboidal mesothelium, which is strongly immunoreactive for keratin and mesothelial markers (Fig. 12.5).

Foregut Cysts

During embryonic development, fusion of the lateral walls that form the tracheoesophageal septum begins caudally. If a small bud or diverticulum of the foregut is pinched off during this process, it will be carried into the mediastinum by the downward growth of the lungs. This structure contains the endoderm and mesoderm that were destined to become part of the trachea, bronchi, esophagus, stomach, or intestine.

Bronchial cysts occur along the tracheobronchial tree, their most common location being posterior to the carina.[19] Rarely, they are located just above the diaphragm. They can be missed on plain films but are easily detectable on CT scans. These cysts contain clear or gelatinous fluid; they are usually unilocular, thin-walled, and spherical

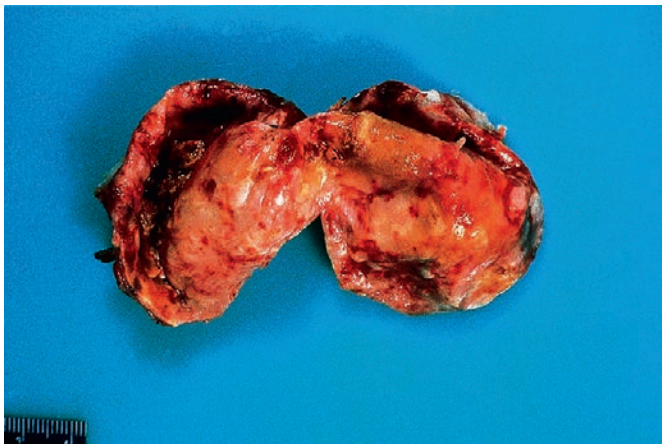

Figure 12.6 Gross Appearance of Bronchial Mediastinal Cyst. The inner lining has a granular quality.

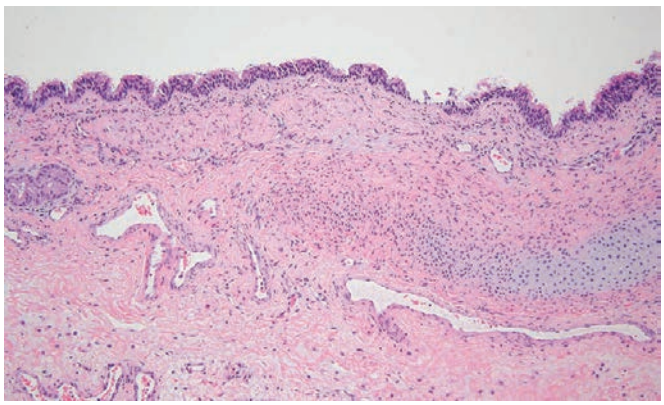

Figure 12.7 Microscopic Appearance of Bronchial Mediastinal Cyst. The lining is composed of pseudostratified ciliated respiratory epithelium; the wall contains hyaline cartilage and submucosal glands.

with an average diameter of 3–4 cm (Fig. 12.6). Microscopically, they usually are lined by ciliated columnar epithelium, but focal or extensive squamous metaplasia and/or extreme attenuation of this lining can occur (Fig. 12.7). The wall may contain hyaline cartilage, smooth muscle, bronchial glands, and nerve trunks.

Esophageal cysts probably arise from a persistence, in the wall of the foregut, of vacuoles that form during the solid tube stage of

development. Most are found embedded in the wall of the lower half of the esophagus. The lining may be squamous, ciliated, columnar, or a mixture of these. Distinction from bronchial cyst may be difficult or even impossible, especially because the latter can be found entirely within the wall of the esophagus. The best evidence that a cyst in this location is of esophageal type is the presence of a definite double layer of smooth muscle in the wall.

Gastric and **enteric cysts** usually are located in the posterior mediastinum in a paravertebral location, attached to the wall of the esophagus or even embedded within the muscle layer of this organ. Nearly all cases are associated with vertebral malformations. The gastric variety is made up of the same coats as the stomach, whereas the enteric type simulates the wall of normal intestine. Combined forms occur and are designated as **gastroenteric cysts**. Nerve fibers and ganglia are often present in them.[18]

Pancreatic cysts and pseudocysts may have a primarily mediastinal presentation.[20] Knowing the tendency of mediastinal germ cell tumors to contain pancreatic tissue (see elsewhere in this chapter), it is logical to assume that some of these pseudocysts have a teratomatous origin.

These congenital cysts only exceptionally communicate with the tracheobronchial tree or the esophagus. Malignant change within them is very unusual, but when it occurs takes the form of adenocarcinoma.[21] Symptoms from these cysts depend on their size and location; they are related to pressure phenomena and consist of cough, dysphagia, recurrent pulmonary infection, dyspnea, pain, and rarely hemoptysis. Most bronchial, esophageal, and enteric cysts are asymptomatic and are found incidentally. In contrast, gastric and gastroenteric cysts are often symptomatic and even life-threatening because of the occurrence of gastric secretion and the hemorrhage, peptic ulcer, or perforation that may supervene as a result.

Other Cysts

Thymic cysts are discussed elsewhere in this chapter and **parathyroid cysts** in the next section.

Cases of mediastinal cysts arising from the **thoracic duct** (the largest lymph vessel in humans) have been reported.[22] Some of these may represent examples of cystic lymphangiomas.

A type of posterior mediastinal cyst occurring in adult women and lined by ER+ PR+ epithelium resembling fallopian tube mucosa and a smooth muscle–containing thin wall are of probable **müllerian origin**.[23]

Another bizarre occurrence is that of an **adenomatoid tumor** presenting as a cystic mass in the anterior mediastinum.[24]

Thyroid and Parathyroid Lesions

Thyroid tumors and tumorlike conditions of several types can present as superior mediastinal masses. The most common pathologic change in mediastinal thyroid glands is nodular hyperplasia, which can reach huge proportions and cause compression symptoms.[25,26] Thyroid nodular hyperplasia in the mediastinum may occur in the form of seemingly independent nodules (so-called parasitic or accessory nodules), a fact that may lead the unwary to regard the lesion as malignant. Actually, malignant change in mediastinal thyroid (except for the clinically inconsequential papillary microcarcinomas) is too unusual to justify excision because of fear of this complication; the main rationale for surgery is the relief of compression symptoms.

From a pathogenetic standpoint, the nodular hyperplasia in most instances probably does not arise from ectopic thyroid tissue but rather from cervical thyroid that has been pulled down either into the anterior prevascular compartment or the retrotracheal compartment (so-called posterior descending goiter) by the nodular enlargement. Support for this interpretation comes from the fact that these masses retain their cervical blood supply through a narrow pedicle. Radioactive iodine scanning yields a positive result in over half of the cases.

Parathyroid tumors and tumorlike conditions can also occur in the mediastinum, a not surprising event in view of the embryologic origin of the parathyroid glands and their intimate relationship with the thymus. About 7% of parathyroid adenomas are found in the superior mediastinum, and most of them can be excised through a suprasternal incision. Most of the others are located in the anterior mediastinum where they can sometimes be excised using a combination of preoperative targeting and either mediastinoscopy or video-assisted thoracoscopy.[27,28] Because of their location, these adenomas can grow to a much larger size than their equivalents in the neck. Like their cervical counterparts, mediastinal parathyroid adenomas can be accompanied by a heavy lymphocytic infiltrate.

Mediastinal parathyroid carcinomas have also been reported, some of them being nonfunctioning.[29]

Parathyroid cysts of the mediastinum are usually located in the anterosuperior compartment, and are often functioning.[30]

Thymus

Normal Anatomy

The thymus is a lobulated organ covered by a capsule and divided into cortical and medullary portions, the cortex being further subdivided into a subcapsular (outer) and a deep region. The cortex stains more deeply basophilic at low magnification in routinely stained sections due to a higher proportion of lymphocytes compared to cortical epithelial cells, while the medullary portions are more pale as a result of fewer lymphocytes compared to medullary epithelial cells including Hassall corpuscles. The two major cell types are endodermally derived epithelial cells (with a possible minor ectodermal contribution) and bone marrow–derived lymphocytes. The epithelial cells have been further divided on the basis of their location, appearance, and phenotypic properties into cortical (dendritic), subcapsular, medullary, and Hassall corpuscle related.[31] These epithelial cells are keratin positive and express HLA-DR antigens, the keratin profile showing differences related to the anatomic compartment and the functional status (growth phase or involution) of the gland.[32] One or more subsets of these cells are responsible for the differentiation of T lymphocytes. It has been assumed for a long time that this process is modulated in the thymic microenvironment through the secretion of thymic hormones; however, the specificity, mechanism of action, and exact role of these substances remain elusive despite decades of work on the subject by several groups.[33] Thymic lymphocytes (traditionally known as thymocytes) have a T-cell phenotype; a whole range of differentiation exists among them, the better defined stages being those of subcapsular thymocyte, cortical thymocyte, medullary thymocyte, and mature (peripheral type) T lymphocyte.[34] Other cells normally present in the thymus include B cells (present both in the thymic medulla and in the perivascular compartment),[35] interdigitating reticulum cells, Langerhans cells,[36] mast cells, eosinophils (particularly in neonates), and the usual nonspecific types of stromal cell. Aggregates of benign nevus cells have also been described within the substance of the thymus.[37] A notable subtype of stromal-type cell found in the thymic medulla and possibly playing a role in the pathogenesis of myasthenia gravis is a skeletal muscle cell known as *myoid cell*, from which a human cell line has been established.[38] The embryologic origin and functional significance of these enigmatic cells remain controversial.

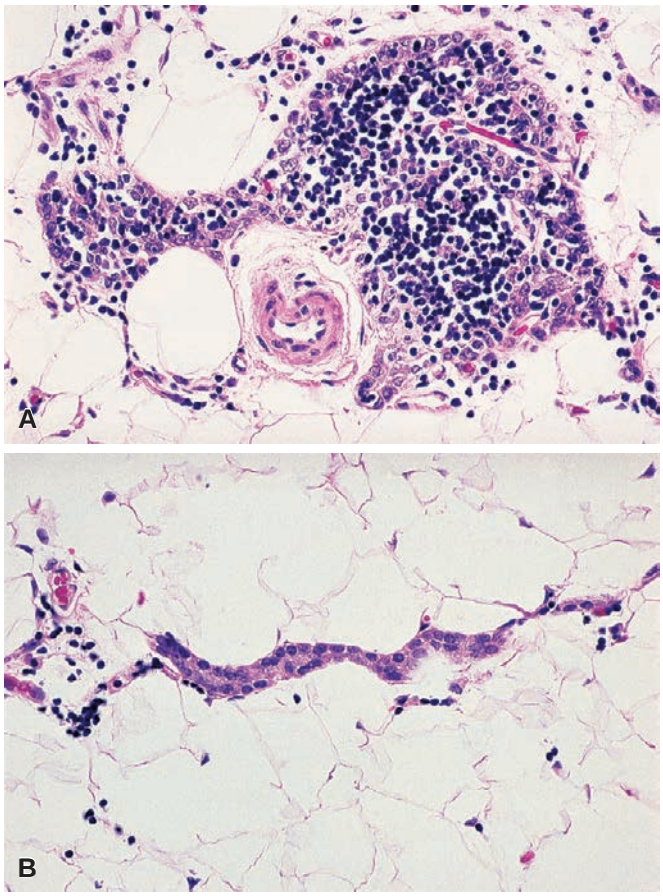

Figure 12.8 Residual Thymic Tissue. A, This island is predominantly composed of small lymphocytes, but a row of epithelial cells is visible at the periphery. **B**, This thin elongated strand is predominantly composed of oval to spindle epithelial cells.

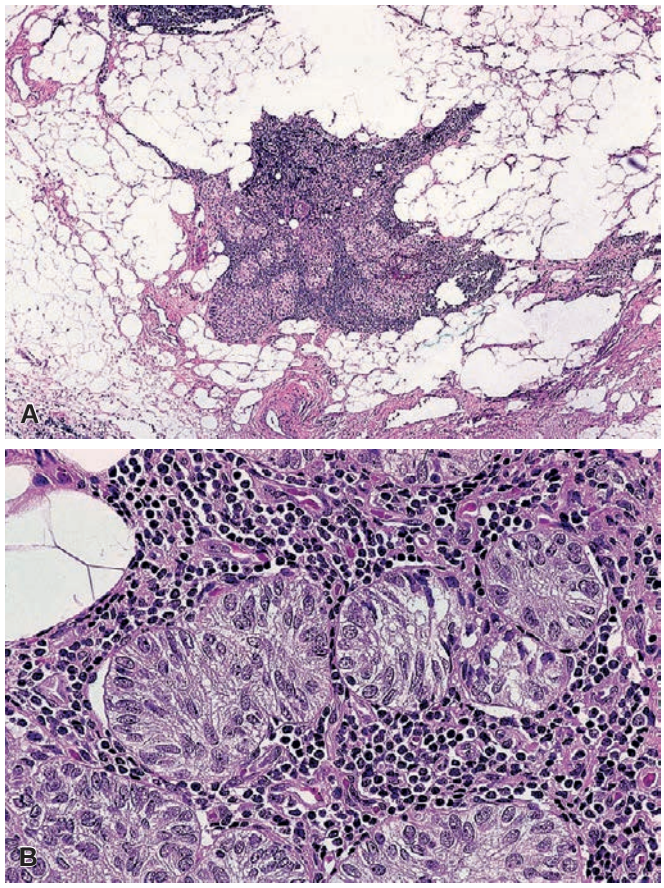

Figure 12.9 A and **B**, Low-power and higher appearance of nodular hyperplasia of thymic epithelium.

The thymus undergoes normal involution after puberty, although it never disappears completely.[39,40] Islands of thymic tissue are consistently found on microscopic examination of the prepericardial fat and sometimes also in the retrocarinal fat.[41] The islands predominantly composed of lymphocytes may be confused with lymph nodes, whereas those mainly made up of epithelial cells show trabecular or rosette-like formations and may be misinterpreted as carcinomatous or neuroendocrine (Fig. 12.8).[42] Occasionally the epithelial component acquires a nodular character. This inconsequential change, which can also be seen in ectopic thymus, probably represents nodular hyperplasia (or a *thymic tumorlet*, so to speak) and should therefore be distinguished from a bona fide small thymoma ("microthymoma") (Fig. 12.9).[43]

Primary Immunodeficiencies

Thymic dysplasia is the generic term that has been proposed for a congenital thymic alteration thought to be the expression of a failure and/or arrest in the development of the organ.[44] The most salient features are very small size (less than 5 g), primitive-appearing epithelium without segregation into cortical and medullary regions, presence of tubules and rosettes, absence of Hassall corpuscles, and almost total absence of lymphocytes. Nezelof[44] has described four morphologic variations on the theme, which probably are more a reflection of the degree of severity of the process than an indicator of the specific type of immunodeficiency. Diseases accompanied by thymic dysplasia include the usual X-linked or autosomal recessive form of *severe combined immunodeficiency*, *ataxia–telangiectasia*, and related *chromosomal instability syndromes*, *Nezelof syndrome*, and the *incomplete form of DiGeorge syndrome*; in the last condition, the thymus is not only dysplastic but is also often located ectopically. In the complete form of DiGeorge syndrome the thymus is by definition absent (i.e. there is *thymic aplasia*).

In most other types of immunodeficiency there is no primary thymic abnormality. These include *congenital agammaglobulinemia* and *adenosine deaminase* (*ADA*) *deficiency* (also known as the ADA-negative form of severe combined immunodeficiency).[45]

The main differential diagnosis of thymic dysplasia is with the *acute thymic involution* resulting from "stress" and superimposed infections, which of course are often present in immunosuppressed populations, particularly at autopsy.[46] Acute thymic involution is characterized by marked lymphocytic depletion accompanied by preservation of the lobular architecture and of Hassall corpuscles. The identification of well-formed Hassall corpuscles in a thymus biopsy is the best evidence against the diagnosis of primary thymic dysplasia. In some instances, these structures become prominent by virtue of their cystic dilation, the cysts containing an admixture of keratin, calcium, and mucinous material.

In acute thymic involution, the size of the vessels is large for the size of the lobules, this being another important feature in the differential diagnosis with thymic dysplasia. A scattering of inflammatory cells is present in the interlobular and perilobular tissue, sometimes with a marked predominance of plasma cells. This acute involution process can proceed at a rapid rate, leading to almost complete lymphocytic depletion of the cortex within 1 week.[45]

Figure 12.10 Multilocular Thymic Cyst. The fibrous septa separating the individual cysts are rather thick. The content of the cysts varied from cloudy to blood tinged.

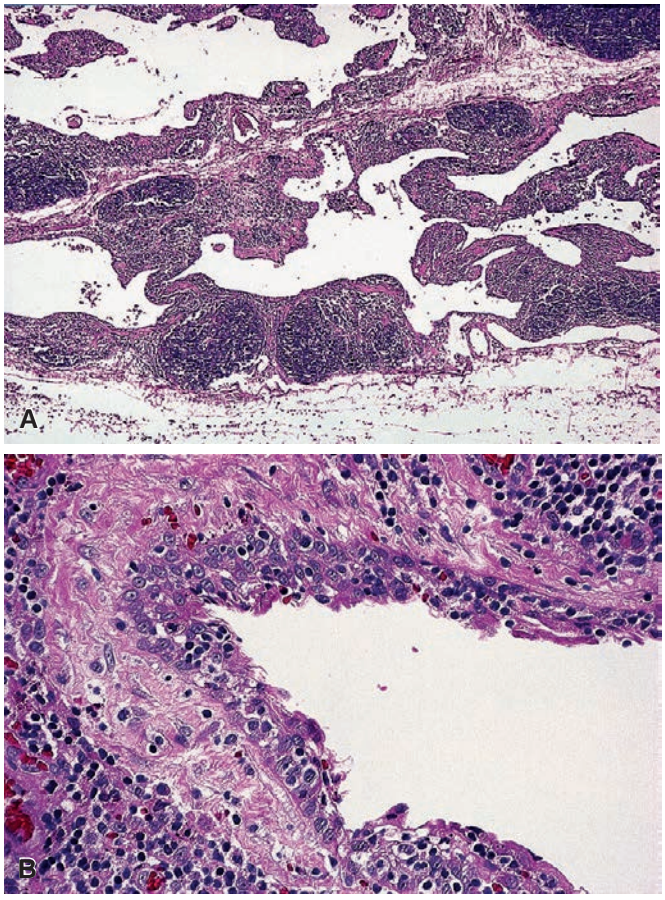

Figure 12.11 A and **B**, Microscopic appearance of multilocular thymic cyst. This case was associated with thymic Hodgkin lymphoma, not shown in the photographs. The high-power view shows the stratified squamous lining of the cyst, which is infiltrated by lymphocytes.

Cysts

Thymic cysts can be divided into two distinct types. **Unilocular thymic cysts** are of developmental origin, thought to arise from remnants of the third branchial pouch–derived thymopharyngeal duct. They are generally small and located in the neck more often than in the mediastinum.[47] The cervical cysts tend to be elongated and can be found anywhere along a line extending from the angle of the mandible to the manubrium sternum. The wall is thin and translucent, and inflammation is usually lacking. The epithelial lining is flattened, cuboidal, columnar, or (rarely) squamous. Thymic tissue is present in the wall, some of it connecting with the lining epithelium.

Multilocular thymic cyst is in all likelihood an acquired process of a reactive nature.[48] It is by definition multilocular and always accompanied by inflammation and fibrosis (Fig. 12.10). It can be an incidental microscopic finding or result in a large tumorlike mass adherent to other mediastinal structures, simulating a malignant process at thoracotomy. The lining of the individual cysts may be flat, cuboidal, ciliated columnar, or (often) squamous, either single or stratified (Fig. 12.11). In some areas it may be absent, whereas in others it may have a highly reactive appearance, occasionally acquiring the features of pseudoepitheliomatous hyperplasia.[49] Cholesterol granulomas are common. In some instances the inflammatory infiltrate is very prominent, with formation of numerous lymphoid follicles.[50]

We believe that multilocular thymic cyst is the result of an acquired cystic dilation of medullary duct epithelium–derived structures, induced by an inflammatory reaction of the thymic parenchyma.[48] This inflammation is usually idiopathic, although in some cases a specific etiology (such as HIV infection or an autoimmune disorder) can be documented.[51] The so-called *Dubois abscesses* described in the thymuses of neonates with congenital syphilis probably also belong to this category.[48]

Most importantly, a morphologically similar change can be seen in about half of the thymuses harboring nodular sclerosis Hodgkin lymphoma[52] or seminoma (germinoma).[53] It can also be seen, although with much lesser frequency, in association with other tumors such as thymoma,[54] large cell lymphoma, yolk sac tumor,[55] and mature teratoma.[56] Therefore, in the presence of these cystic changes it is important to determine whether the changes are purely inflammatory or whether an underlying neoplastic process is present. In regard to the pathogenesis of the lesion, it is of interest that the two malignant tumors most commonly associated with it (Hodgkin lymphoma and seminoma) are those in which a non-neoplastic lymphocytic component is particularly prominent.

We have made the proposal that the process of lymphocyte-induced cystic ductular dilation resulting in multilocular thymic cyst is also responsible for the development of the following head and neck lesions: branchial cleft cyst, multiple branchial cleft-like cysts in Hashimoto thyroiditis,[57,58] benign lymphoepithelial cysts, lymphoepithelial cysts in the parotid glands with HIV infection, and possibly even Warthin tumor of parotid.[48]

Multilocular thymic cysts must be distinguished from thymomas undergoing cystic degeneration[59] and from cystic lymphangioma. Exceptionally, squamous cell carcinomas,[60] basaloid carcinomas,[61] and well-differentiated neuroendocrine carcinomas (carcinoid tumors)[62] have been seen in intimate connection with these cysts and possibly arose from them.

Other Non-Neoplastic Diseases

Ectopic thymus with an entirely normal microscopic appearance can present as a mass in the neck or pleural surface.[63] The maldescended thymic tissue in the neck can be unilateral or bilateral. It is often located adjacent to the thyroid gland and usually associated with a parathyroid gland. Ectopic thymic tissue in the skin of the neck can be a clue to the *branchio-oculo-facial syndrome*.[64]

Ectopic tissues sometimes found in a normally located thymus include *parathyroid gland* (not surprising in view of their common embryogenesis) and *sebaceous glands*.[65]

Acute thymic involution is a constant feature of chronic, debilitating diseases. As already stated, these changes are of a secondary nature and should not be misinterpreted as evidence of a primary immune defect. In patients with HIV infection, thymic involution is particularly pronounced and is accompanied by effacement of the corticomedullary junction, marked lymphocytic depletion, variable degrees of plasma cell infiltration and fibrosis, and inconspicuous Hassall corpuscles.[66] Apparently, these late changes are preceded by thymic follicular hyperplasia.

Diffuse thymic fibrosis is occasionally seen in the absence of another primary thymic lesion or features of IgG4-related disease.[67] It is not clear whether it represents a nonspecific pattern of injury or a distinct entity, but the former seems more likely.

True thymic hyperplasia is defined as thymic enlargement beyond the upper limits of normal for the age (as determined by weight using the Hammar table or by volumetric measurement) but accompanied by a microscopically normal gland. It has been most often described in infants and children but has also been found in adults, sometimes after successful chemotherapy for malignant disease.[68,69] In some cases it may simply represent a failure of involution, but in others it is clearly an acquired phenomenon secondary to some therapeutic manipulation.

Thymic follicular hyperplasia (often called simply "thymic hyperplasia", a misleading term) is defined as the presence of more than an occasional lymphoid follicle in the thymus independent of the size of the gland. Actually, the weight of most of the thymuses with lymphoid hyperplasia is within normal limits.[70] These follicles are of secondary type, with germinal center formation (Fig. 12.12), and are largely composed of B lymphocytes. According to some authors, their presence is accompanied by a disorderly arrangement and hypertrophy of medullary epithelial cells.[71]

Follicular hyperplasia is seen in about 65% of patients with myasthenia gravis (see next section). It is also commonly present in patients with hyperthyroidism, Addison disease, lupus erythematosus, and other immune-mediated diseases. It has also been described in the early stage of HIV infection, sometimes associated with multilocular cystic formation.[51,72]

A few germinal centers also may be found in the apparently normal thymus, especially during infancy and childhood; therefore only their presence in a substantial number in adult patients can be viewed as a distinctly abnormal finding.

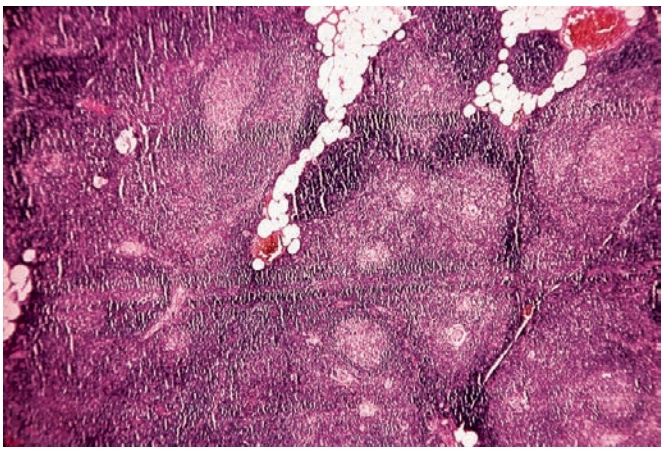

Figure 12.12 Prominent follicular hyperplasia of thymus in a patient with myasthenia gravis. Florid germinal centers are present throughout the organ.

Langerhans cell histiocytosis can present as a thymic mass, either alone or with involvement of other sites.[73,74] The microscopic appearance is characteristic, and the overall prognosis is excellent. Exceptionally, it is seen in association with myasthenia gravis.[75] It may also coexist with multilocular thymic cyst.[76] Granulomas containing numerous eosinophils and simulating Langerhans cell histiocytosis can develop in the thymic capsule as a result of diagnostic pneumomediastinum, a procedure that has been largely abandoned, and is likely equivalent to the reactive eosinophilic pleuritis seen in patients with pneumothorax.[77]

Other inflammatory diseases that can occasionally involve the thymus are **eosinophilic granulomatosis with polyangiitis** (Churg–Strauss disease)[78] and **Castleman disease** (giant lymph node hyperplasia).[79,80]

Thymoma and Thymic Carcinoma

General Features

Thymoma is a term that should be restricted to neoplasms of thymic epithelial cells, independently of the presence or number of lymphocytes.[81] Seminoma, carcinoid tumor, Hodgkin lymphoma, and non-Hodgkin lymphoma can all involve the thymus primarily; thus they can be viewed as thymic tumors but should not be regarded as variants of thymoma.

Nearly all thymomas present in adult life. Thymomas in children are exceptional; most of the cases so diagnosed in the past actually represent lymphoblastic lymphomas of the thymus. However, some well-documented cases exist, most of them occurring near the age of puberty with an appearance and behavior equivalent to that of their adult counterpart, including an occasional association with myasthenia gravis.[82] Some younger children are found to have highly malignant thymic neoplasms with unusual morphologic features, the nature of which has not yet been thoroughly elucidated[83]; it is possible that some cases may represent so-called NUT midline carcinoma (see Chapter 4).[84,85] Familial incidence of thymoma has been recorded only exceptionally.

The usual location of thymoma is the anterosuperior mediastinum; however, this tumor can also occur in other mediastinal compartments (although a posterior location is very rare), in the neck, within the thyroid (see later section), within the pericardial cavity, within a cardiac myxoma, in the pulmonary hilum, within the lung parenchyma, or in the pleura itself, sometimes coating it in a mesothelioma-like fashion.[86]

Radiographically, thymoma usually presents as a lobulated opacity that may be calcified (Fig. 12.13). CT scan and MRI are the methods of choice for preoperative diagnosis and evaluation of extent. Fine-needle aspiration has been used with success, the diagnosis of thymoma being based on the finding of a dual population of epithelial cells and lymphocytes with the appropriate cytologic features.[87]

Myasthenia Gravis

In patients with myasthenia gravis, the thymus shows follicular hyperplasia as the only abnormality in about 65% of cases, a thymoma (with or without follicular hyperplasia in the non-neoplastic portion of the gland) in 10%, and no gross or overt microscopic abnormalities in 25% (see later text).[70] Viewed from another angle, about 30%–45% of patients with thymoma develop myasthenia.[88] The tumor may be diagnosed during the investigation of a myasthenic patient, or—less commonly—the myasthenia may develop months or years after the tumor has been excised. A patient with myasthenia is more likely to have a thymoma if male and/or developing symptoms after the age of 50.[89] The incidence of aggressive behavior in these tumors

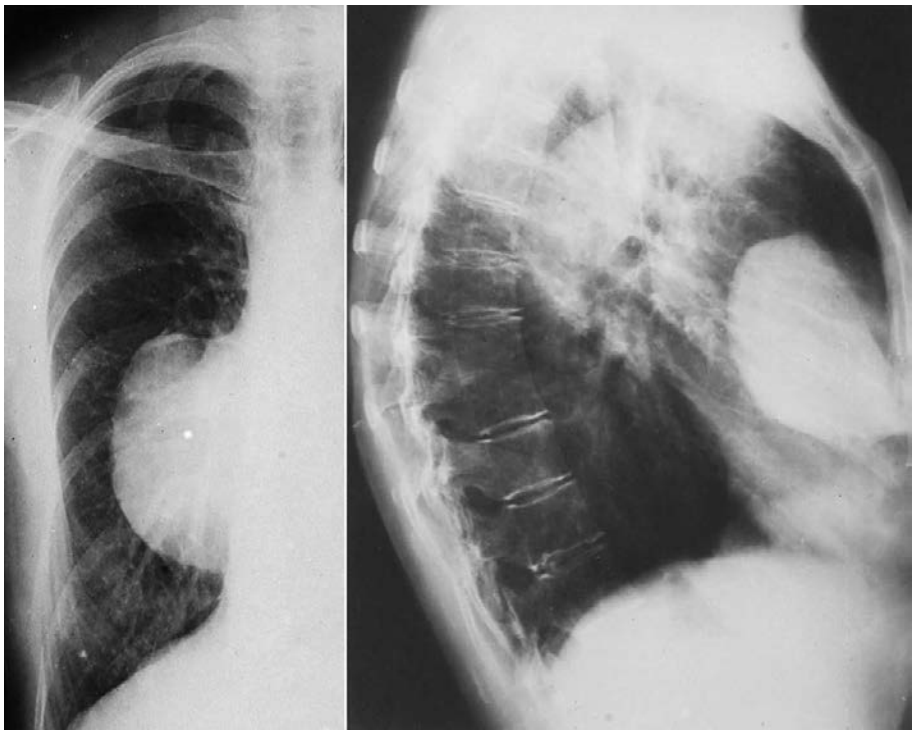

Figure 12.13 Lobulated large benign thymoma located in anterior portion of mediastinum.

seems to be similar to that seen in patients without myasthenia gravis. Thymomas associated with myasthenia almost always have epithelial cells of stellate or cuboidal rather than spindle shape, but only a percentage of the tumors with these morphologic features will be associated with myasthenia.

The relative proportion of epithelial cells and lymphocytes does not seem to correlate with the presence of myasthenia. No consistent ultrastructural or immunohistochemical differences have been found between myasthenic and nonmyasthenic thymomas.[90] Actually, the most accurate way to predict the likelihood of myasthenia in a patient with thymoma is to find lymphoid follicles in the adjacent non-neoplastic thymic tissue or, exceptionally, even in the thymoma itself.[91]

In the past, the presence of myasthenia in a patient with thymoma had a profound influence on survival. In a large series reported by Wilkins et al. in the 1960s, the 10-year cumulative survival rate for patients with thymoma with and without myasthenia was 32% and 67%, respectively.[92] Most of the deaths in the former group resulted from myasthenic crisis. As a consequence of marked improvements in the medical treatment of myasthenia, the picture has changed dramatically.[93] As a matter of fact, subsequently published series of patients with thymomas show that this association is no longer of prognostic significance.[88,94] Similarly, the presence of a thymoma is no longer viewed as a negative prognostic indicator in patients with myasthenia gravis.[95,96]

Myasthenia gravis has been found to be related in nearly all cases to a defect in the nicotinic acetylcholine receptor (AChR) located in the subsynaptic membrane of the neuromuscular junction (motor end plate), as a result of circulating autoantibodies that bind to this molecule.[97–99]

AChR or a related protein has been detected in the normal thymus. Although it has been suggested that this compound might be expressed by thymic epithelial cells, it seems clear that it is mainly localized to a subset of intrathymic cells that exhibit phenotypic features of skeletal muscle cells (such as cross striations and immunoreactivity for myoglobin and desmin) and that are generally designated as *myoid cells*.[97] It has also been found that non-neoplastic thymuses in myasthenic patients (whether exhibiting obvious follicular hyperplasia or appearing microscopically normal) often contain cell clusters composed of myoid cells, infiltrating antigen presenting cells, and CD3+/CD4+ T lymphocytes, that some of these T lymphocytes are AChR specific, that activated AChR-reactive B cells may also be demonstrated, and that there is increased production of interleukins.[99] The theory has thus evolved that the autosensitization process leading to myasthenia is initiated in the thymus through an aberrant interaction between myoid cells with AChR-specific T lymphocytes, followed by emigration of these activated thymic T cells to the peripheral immune system and induction of complementary B lymphocytes to produce myasthenogenic autoantibodies.

The role that thymoma, when present, plays in this pathogenetic scheme remains unclear. Some have suggested that the two events are not directly related and that the mechanism for the myasthenia is independent of the presence or absence of a thymic epithelial neoplasm. Others have postulated that the thymoma is directly responsible for myasthenia in a subset of patients, through the presence of one or more proteins unique to the tumor that share an antigenic determinant with the nicotinic AChR or other structures of the neuromuscular junction and that trigger an autoimmune response.[100]

Myasthenia gravis should be distinguished from the Lambert–Eaton syndrome, a similar condition that is frequently associated with pulmonary small cell carcinoma and that is also autoimmune related[101] (see Chapter 10).

The treatment of myasthenia includes thymectomy, regardless of the presence or absence of thymoma.[93,102] Symptomatic improvement is more likely if the thymus is the site of follicular hyperplasia than if it is normal or involved by thymoma. The long-term results of

the operation may be related to the duration and severity of the myasthenic symptoms and the age of the patient; however, substantial differences in this regard exist among the various published series.[103–105] Persistence of symptoms has been attributed to residual thymic tissue with lymphoid hyperplasia.

Other Associated Diseases

In addition to myasthenia gravis, thymoma has been found to be associated with a large number of systemic disorders, nearly all of which are immune mediated. These include hypogammaglobulinemia (12% of the cases), erythroid hypoplasia/pure red cell aplasia (5%) and, more rarely, white blood cell aplasia, myositis, myocarditis, dermatomyositis, systemic lupus erythematosus, rheumatoid arthritis, scleroderma, Sjögren disease, multiple myeloma, Kaposi sarcoma, subacute motor neuronopathy, inappropriate antidiuretic hormone secretion, bullous dermatoses, hyperglobulinemic purpura, mucocutaneous candidiasis, graft-versus-host-like colitis, autoimmune enteropathy, peripheral T-cell lymphocytosis, T-cell chronic lymphocytic leukemia, and T-cell lymphoblastic lymphoma/leukemia. Most of the thymomas associated with erythroid hypoplasia have been said to be largely composed of spindle cells (type A thymomas), but a critical review of the literature did not show a strong correlation with a particular histologic type.[106]

Pathologic Features; Electron Microscopic, Histochemical, Immunohistochemical, and Molecular Genetic Features

Grossly, the typical thymoma is largely or entirely solid, yellowish gray, and separated into lobules by connective tissue septa (Figs. 12.14 and 12.15).[88,107] In approximately 80% of cases, the tumor is well encapsulated and can be removed with ease. In the remainder, infiltration of surrounding structures is noted at surgery. Most clinically evident tumors are large, but very small thymomas ("microthymomas") may be discovered incidentally in the course of cardiac surgeries or in thymectomy specimens from cases of myasthenia gravis or red cell aplasia.[43] Foci of necrosis and cystic degeneration are common, particularly among larger tumors. Sometimes the entire tumor undergoes prominent cystic, necrotic, and hemorrhagic changes, many sections being needed to identify residual diagnostic areas (Fig. 12.16).[108] This sort of infarct-like necrosis and hemorrhagic degeneration does not by itself convey a poor prognosis in an otherwise well encapsulated thymoma. Predominantly cystic thymomas should be distinguished from multilocular thymic cysts which can coexist with thymoma and other thymic neoplasms prone to undergo cystic changes.

Microscopically, the majority of thymomas are composed of a mixture of neoplastic epithelial cells and non-neoplastic lymphocytes, the proportion among them varying widely from case to case and in different lobules of the same tumor (Figs. 12.17–12.23).[109,110] The epithelial cells may have a round–polygonal ("plump"), stellate, or spindle/oval shape (see Figs. 12.17 and 12.20). The nuclei are vesicular and of smooth contour; the nucleolus may be conspicuous, particularly when the nuclei are round or polygonal. The lymphocytes may appear mature (inactive) or show varying degrees of "activation," manifested by a larger nuclear size, open chromatin pattern, visible nucleolus, identifiable cytoplasmic rim, and mitotic activity; however, they should not appear convoluted or cleaved. Thymomas with a sizable component of epithelial cells often show one or more features suggestive of organoid differentiation, which correlate with the various subtypes. These include *perivascular spaces* containing lymphocytes, proteinaceous fluid, red blood cells, foamy macrophages, or fibrous tissue (see Fig. 12.21); *rosettes without central lumens* (see Fig. 12.18); *glandlike formations* within the tumor or, more often, in the tumor

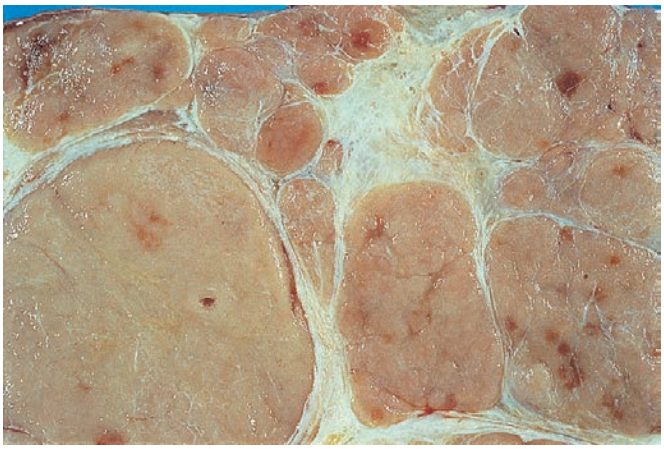

Figure 12.15 Close-up of the Cut Surface of Thymoma. Note the sharp lobulation induced by the fibrous bands. The pointed ends of some of the nodules are particularly typical of this entity.

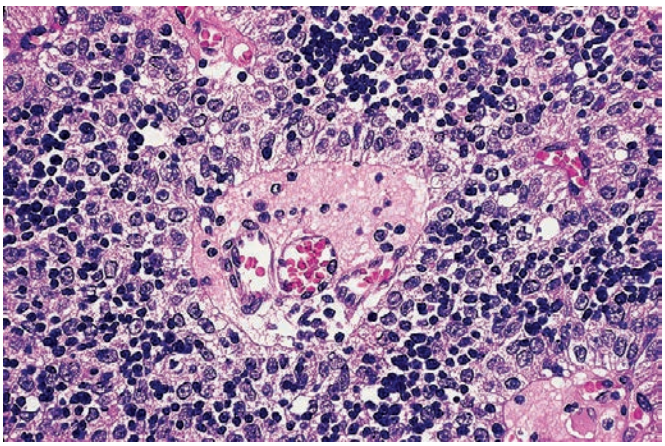

Figure 12.21 Perivascular Space in Type B2 Thymoma. The space is occupied by a proteinaceous fluid and lymphocytes.

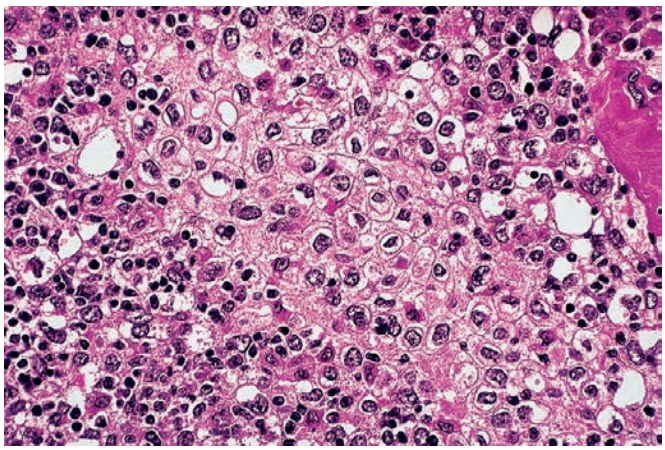

Figure 12.22 Type B3 Thymoma. This tumor, which is predominantly composed of slightly atypical neoplastic thymic epithelial cells, is also known as squamoid thymoma, atypical thymoma, and well-differentiated (organotypic) thymic carcinoma.

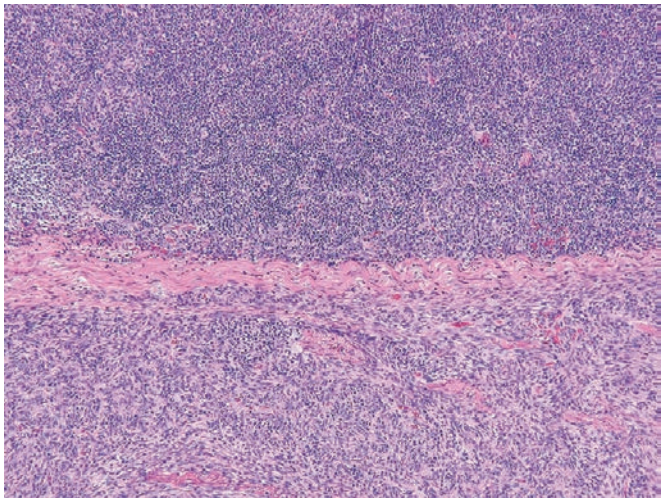

Figure 12.23 Type AB Thymoma. This is one of the most common thymoma subtypes.

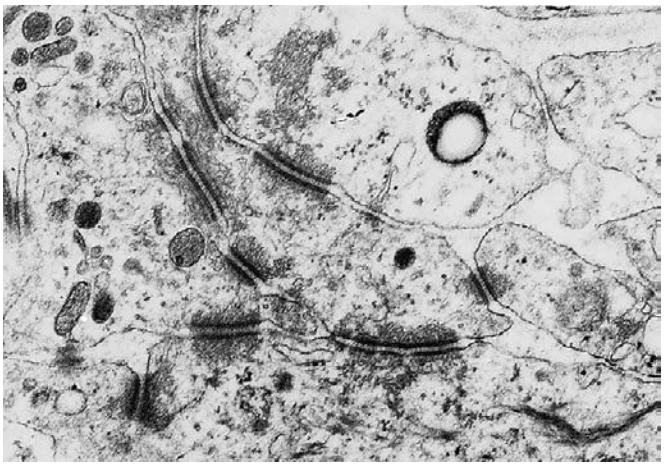

Figure 12.24 Numerous desmosomes and tonofibrils in tumor cells as seen ultrastructurally indicate epithelial origin of a thymoma composed of spindle cells. (Uranyl acetate–lead citrate; ×54,500). (From Levine GD, Bensch KG. Epithelial nature of spindle cell thymoma. An ultrastructural study. *Cancer*. 1972;30:500–511.)

capsule; *true glandular structures* (an exceptional event); and *whorls suggestive of abortive Hassall corpuscle formation*. Well-formed Hassall corpuscles are occasionally found within thymomas, but their presence in large numbers is usually an indication of preexisting structures surrounded by a tumor and is actually more common in other neoplasms (such as malignant lymphoma of the thymus) than in thymoma. Presence of rosette-like structures with *well-defined lumens* should suggest a diagnosis of thymic carcinoid rather than thymoma. In lymphocyte-rich (type B1, see later section) thymomas, it is common to find round, lighter foci of medullary differentiation, an important clue to the diagnosis (see Fig. 12.19). Other helpful diagnostic features of thymoma are the thick, often calcified fibrous capsule, the lobular arrangement induced by these fibrous bands, the sharp interphase between tumor lobules and fibrous tracts, and the angular shape of some of the lobules, resembling arrowheads. Vascularization may be prominent and result in a mistaken diagnosis of hemangiopericytoma. Microcystic and pseudopapillary formations may be focally present. Sclerosis may be very extensive, possibly as a manifestation of tumor regression, and may obscure the neoplastic component.[111] Exceptionally, there is a massive plasma cell infiltrate.[112]

By electron microscopy, the neoplastic epithelial cells exhibit branching tonofilaments, complex desmosomes, elongated cell processes, and basal lamina (Fig. 12.24).[113] These characteristics have proven historically useful in the segregation of thymoma from other anterior mediastinal tumors, such as thymic carcinoid, malignant lymphoma, seminoma, and solitary fibrous tumor but have been largely supplanted in daily practice by immunohistochemical stains (Table 12.1).

The epithelial cells of thymoma are immunoreactive for keratins, including cytokeratin 7, high-molecular cytokeratins (e.g. CK5/6, 34βE12), p63 and p40 (ΔN-p63α), and PAX8 (Fig. 12.25).[114–117] Staining for epithelial membrane antigen (EMA) is usually restricted either to the glandlike formations of spindle thymomas or to the tumors predominantly composed of round or polygonal cells.[118] Thymomas have also been found to express the tissue blood group O (H) and peanut agglutinin receptor antigens,[119] major histocompatibility complex (MHC) class II molecules,[120] epidermal and nerve growth factor receptors,[121] growth hormone,[122] and metallothionein.[123] Two novel thymic epithelial markers—CD205 and Foxn1—are positive in nearly all thymomas and a subset of thymic carcinomas; unfortunately, they are also sometimes expressed in carcinomas of other sites.[124] Stains for basement membrane material, such as laminin or type IV collagen, show abundant deposition around individual tumor cells in spindle-shaped tumors and paucity of this material in those made up of stellate or round or polygonal cells.[125]

Markers that are preferentially expressed in thymic carcinomas (referred to historically as type C thymomas) as opposed to conventional (types A, AB, and B) thymomas are discussed elsewhere.

The lymphocytes of thymoma are of T-cell derivation, except for those located in lymphoid follicles (whether the patients have myasthenia gravis or not).[126] Most of these T lymphocytes are immature thymocytes rather than mature (peripheral) T cells. As such, they are reactive for terminal deoxynucleotidyl transferase (TdT), CD99, and CD1a.[127,128] A close correlation has been found between the morphologic features of the more organoid thymomas and the phenotype of the lymphocytes. In the more lymphocyte-rich areas, the lymphocytes have the features of cortical (very immature) thymocytes; in areas of medullary differentiation they acquire features of medullary (less immature) thymocytes. It should be pointed out that *both* the lymphocytes of thymoma and those of lymphoblastic lymphoma usually exhibit an immature T phenotype, and therefore cell marker studies cannot be used to separate these two disorders. Instead, it has been shown that the lymphocytes of thymoma do not show evidence of clonality at the molecular level, even if this can be simulated by the presence of a polyclonal incomplete rearrangement of the T-cell receptor gene.[129,130] This finding not only provides another criterion for distinguishing the two entities but also offers corroborating evidence for the non-neoplastic nature of the lymphocytes of thymoma. Incidentally, the number of these non-neoplastic lymphocytes will be greatly decreased in patients who have been treated preoperatively with corticosteroids.[131]

In addition to epithelial cells and lymphocytes, thymomas often contain an important population of S-100 protein– and CD1a-positive cells, presumably non-neoplastic *interdigitating reticulum cells*.[132] Kondo et al.[132] found that their number and distribution correlated with the microscopic type of thymoma but not with invasiveness. Interestingly, there is also a population of interdigitating cells (designated as "asteroid cells") located in the medullary portion of the more organoid thymomas that react immunohistochemically for the B-cell marker CD20.[133] Even more peculiar (and potentially misleading

Table 12.1 Differential features of tumors of the anterior mediastinum[a]

FEATURES	THYMOMA[a]	LARGE CELL LYMPHOMA	LYMPHOBLASTIC LYMPHOMA	THYMIC HODGKIN LYMPHOMA	THYMIC SEMINOMA	THYMIC CARCINOID
Patterns (low-power observation)	Sharply defined, angular lobules Fibrous bands and capsule Mottling and trabeculation (caused by epithelial–lymphocyte admixture)	Diffuse growth Variable fibrosis with occasional compartmentalizing sclerotic pattern Residual cystic thymus	Diffuse growth or pseudonodular pattern (both in lymph nodes and in thymus)	Extensive fibrosis with rounded lobules of tumor Prominent cysts seen at low power	Subdivided by fine fibrous trabeculae into variable-sized compartments	Ribbons, festoons, punctate calcified necrosis producing discrete and rounded masses of tumor
Nuclei	Often fine chromatin contrasting with well-defined nuclear membrane Usually inconspicuous nucleoli; great variation, including spindle shape Epithelial mitoses usually rare	Vesicular with prominent nucleoli Marked folding of nuclei ("cloverleaf") Variable chromatin pattern Mitotic figures variable (usually readily found)	Even chromatin ("dusky" at low power) Scant inconspicuous nucleoli Numerous mitotic figures	Cytologic features—those of nodular sclerosing Hodgkin lymphoma complicated by admixture with thymic epithelium and cysts	Coarse chromatin, marked prominence of nucleoli, variable numbers of mitotic figures	Rounded nuclei with sharp stippling chromatin Variable number of mitotic figures (note spindle cell variant)
Cytoplasm	Great variation from scant to squamoid to squamous Intracytoplasmic cysts (emperipolesis) Glandlike spaces	Variable, occasionally abundant and rich in RNA (methyl green–pyronine positive)	Scant	Lacunar cells often prominent	Marked retraction of cytoplasm; often glycogen rich	Polyhedral cells with finely granular eosinophilic cytoplasm True gland formation
Associated features	Germinal centers in surrounding thymus (in cases of myasthenia gravis) Incorporation of non-neoplastic thymus (13%)	Residual lymphocytes often form tight perivascular cuffs Necrosis frequent Markedly invasive	Residual Hassall corpuscles	—	Germinal centers, epithelioid and giant cells	—
Electron microscopy	Well-formed desmosomes	Nuclear blebs Absence of epithelial features	Nuclear blebs Fine chromatin Absence of epithelial features	Absence of epithelial characteristics in Reed–Sternberg cells	Even chromatin Prominent nucleoli Glycogen rich Scant desmosomes Only rare tonofilaments	Dense-core granules Desmosomes inconspicuous or poorly formed Tonofilaments only rarely prominent
Immunohistochemistry	Keratin	B-lymphocyte markers	T-lymphocyte markers	CD15, CD30	PLAP, CD117	Chromogranin, synaptophysin

[a]Nuclear and cytoplasmic features refer only to epithelium.
Modified from Levine GD, Rosai J. Thymic hyperplasia and neoplasia. A review of current concepts. *Hum Pathol*. 1978;9:495–515.

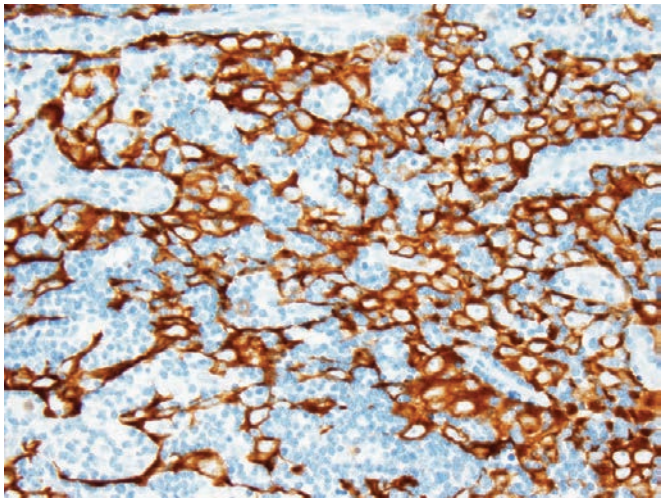

Figure 12.25 Type B1 (lymphocyte-rich) thymoma stained for keratins (AE1/AE3 and CAM5.2 cocktail). The cytoplasm and cell processes of the neoplastic epithelial cells are strongly immunoreactive for this marker.

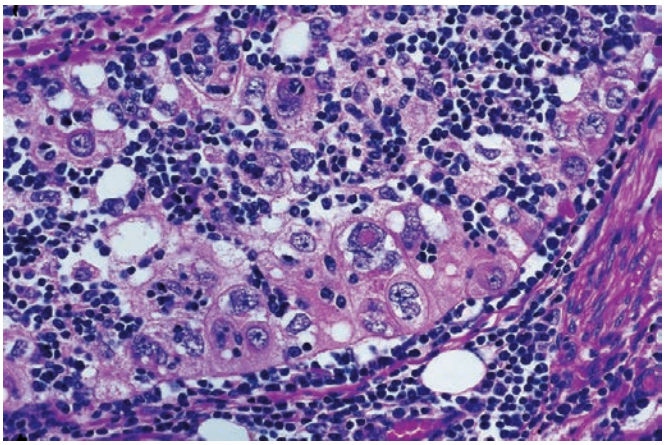

Figure 12.27 Thymic tumor bridging the gap between thymoma and thymic carcinoma. The degree of atypia in the neoplastic cell is such as to justify a diagnosis of thymic carcinoma, but the overall configuration of the tumor and the phenotype of the lymphocytes were those of conventional thymoma.

Figure 12.26 Gross Appearance of Thymic Carcinoma. The tumor is invasive and shows foci of necrosis.

from a diagnostic standpoint) is the fact that CD20 sometimes also reacts with some of the neoplastic epithelial cells of the thymoma, as evidenced by the coexpression of keratin by these cells.[134]

Coexpression of bcl-2 and p53 is seen in a subset of thymomas and seems to be stronger in the clinically aggressive and histologically higher-grade tumors.[135] There is also common expression of Fas antigen, another apoptosis-related marker.[136]

Cytogenetically, the most frequent aberrations found in thymoma are located on chromosome 6, half of them occurring in region 6q25.2.[137] The type and frequency of these aberrations vary among the thymoma subtypes, suggesting that these tumors may develop along different pathways.[138] Type A thymoma shows few genetic alterations except chromosome 6p deletion.[139] Type B3 thymoma commonly shows gain of 1q and loss of 6 and 13q.[139]

Thymic carcinoma is defined as a thymic epithelial tumor exhibiting clear-cut cytologic features of malignancy (Fig. 12.26).[140–143] Despite its rarity, it displays a relatively large variety of microscopic patterns, described in the following text. As a group, they differ from other conventional types of thymoma in the following respects[1]: they are very rarely associated with myasthenia gravis or any of the other previously listed immune-mediated systemic diseases[2]; they generally lack all of the ancillary features of thymoma seen with one or another of the other types, such as perivascular spaces, foci of medullary differentiation, abortive Hassall corpuscles, rosettes, or glandlike spaces; and[3] they lack immature T lymphocytes. Lymphocytes may be present and even numerous, but they exhibit the phenotype of mature T or (rarely) B cells. In other words, thymic carcinomas lack all of the morphologic and functional attributes of the other thymoma types, allowing for the rare occurrence of intermediate or hybrid forms (Fig. 12.27). Their appearance is instead similar to and sometimes indistinguishable from that of corresponding carcinoma types in other organs, and their specific identification as thymic neoplasms can therefore be difficult or impossible. The diagnosis is often one of exclusion, in the presence of a malignant epithelial tumor located in the thymic region in the absence of disease in the lung or any other organ.

There are some immunostains that can be of great assistance in the identification of the two major subtypes of thymic carcinoma[1]: CD5 (a receptor molecule that signals cell growth in T cells), which is present in the majority of thymic carcinomas but absent in other types of thymoma and in carcinomas of nonthymic origin[2,144]; CD117 (c-kit), positive in 80% or more of thymic carcinomas, almost always negative in thymomas, and occasionally positive in nonthymic carcinomas[3,145,146]; CD70, a member of the tumor necrosis factor (TNF) family that mediates the interaction between B and T lymphocytes which is present in most thymic carcinomas but not in conventional thymomas[4,147]; CEA, MUC-1, and GLUT-1 (glucose transporter 1) are usually positive in thymic carcinoma and are less commonly positive in B3 thymomas, with MUC-1 and GLUT-1 showing the highest sensitivity for carcinoma and CEA showing greater specificity in separating carcinoma from thymoma[5,148]; TTF-1, which stains a high percentage of lung carcinomas but not thymic carcinomas.[127] Furthermore, thymic carcinomas show higher expression of p53, stronger immunoreactivity for bcl-2, and higher rates of nuclear staining for p16 than thymomas.[135,149] It should also be noted that about half of thymic carcinomas—in striking contrast with the other thymoma types—exhibit immunohistochemical evidence of focal (and sometimes extensive) neuroendocrine differentiation (Fig. 12.28).[150]

On comparative genomic hybridization, common findings in thymic squamous cell carcinoma include loss of 16q, 6, 3p, and 17p and gain of 1q, 17q, and 18.[139] Of note, loss of chromosome

6 and gain of 1q are common in type B3 thymoma, suggesting possible evolution to squamous cell carcinoma or a close histogenetic relationship between the two tumor types. Comprehensive sequencing demonstrates a low mutation burden in thymic carcinomas.[151] *TP53* mutations are the most common recurrent mutations, occurring in about 30% of cases, and correlate imperfectly with p53 overexpression by immunohistochemistry.[151,152] *KIT* mutations are rare and do not correlate with the CD117 staining seen in the majority of cases.[151,153]

The following microscopic types of thymic carcinoma are recognized by the World Health Organization (WHO) Committee for the Histologic Typing of Tumors of the Thymus, and other exceptionally rare types that have been described.[141,154] In terms of relative frequency, the first category accounts for over 70% of the cases.[143,155]

Squamous Cell Carcinoma

Like squamous cell carcinomas in other sites, this form is composed of atypical polygonal epithelial cells arranged in characteristic epidermoid growth patterns often with associated intercellular bridges (Fig. 12.29).[155] The range of appearances is similar to squamous cell carcinomas arising in other locations, including well, moderately and poorly differentiated forms that may or may not demonstrate keratinization.[155] However, a lobular pattern of growth is generally maintained, and the tumor lobules are even more widely separated from each other by fibrous bands than in more conventional thymoma types (Fig. 12.30).[156] Before a diagnosis of primary squamous cell carcinoma of the thymus is made, the alternative possibility of metastatic carcinoma (particularly from the lung) should always be considered.

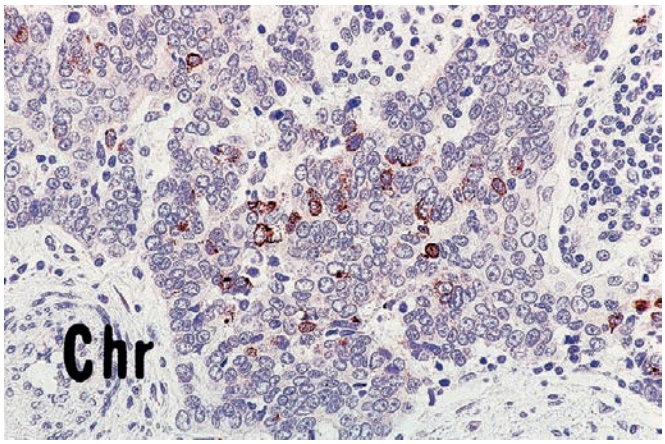

Figure 12.28 Chromogranin Reactivity in Some Tumor Cells of Thymic Carcinoma. This is a common finding in thymic carcinoma, as opposed to conventional thymomas.

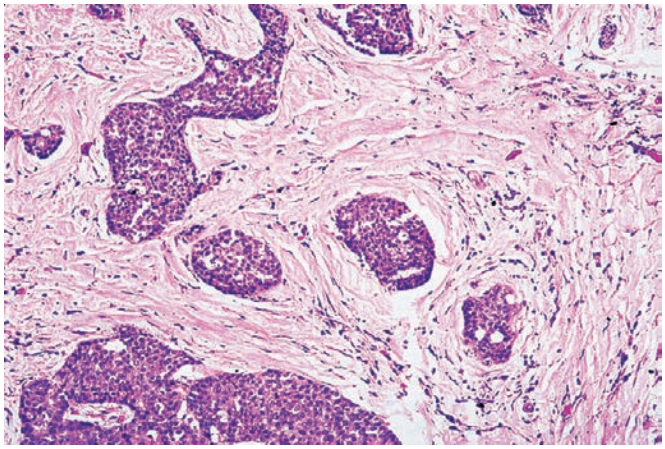

Figure 12.30 Low-Power View of Thymic Carcinoma. The tumor lobules are more widely separated by fibrous tissue that more closely resembles a desmoplastic stromal response than the better organized and smaller fibrous septa characteristic of conventional thymoma.

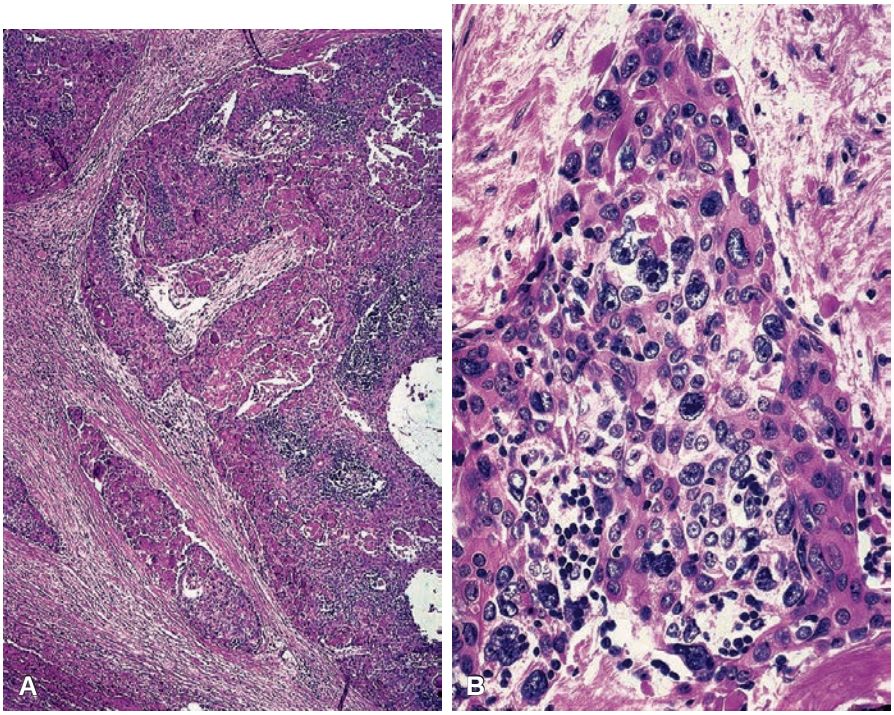

Figure 12.29 A and **B**, Low-power and high-power appearances of thymic squamous cell carcinoma. Note the distinct lobulation in this example.

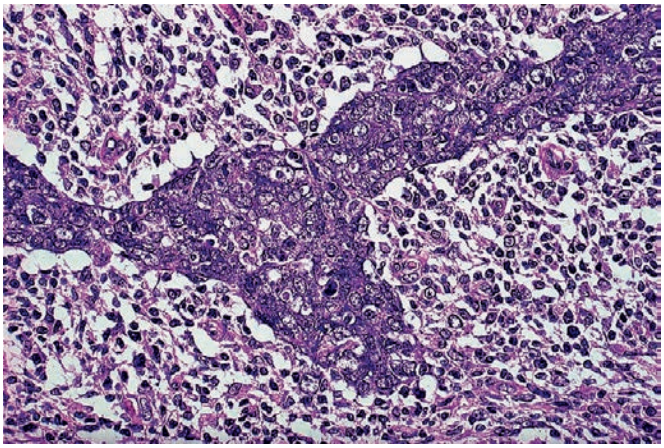

Figure 12.33 Lymphoepithelioma-like variant of thymic carcinoma.

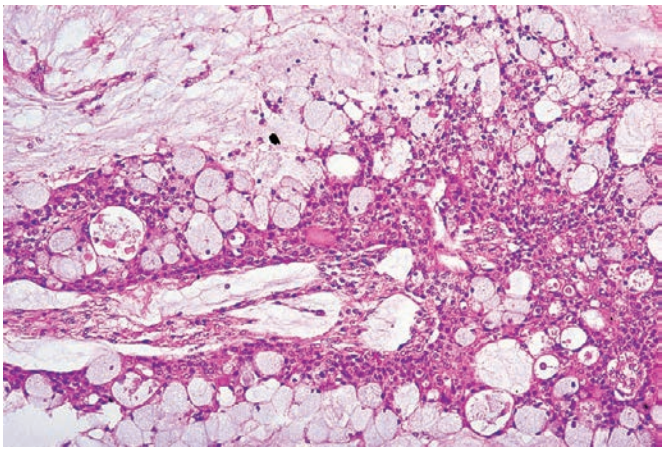

Figure 12.32 Thymic Carcinoma of Mucoepidermoid Type.

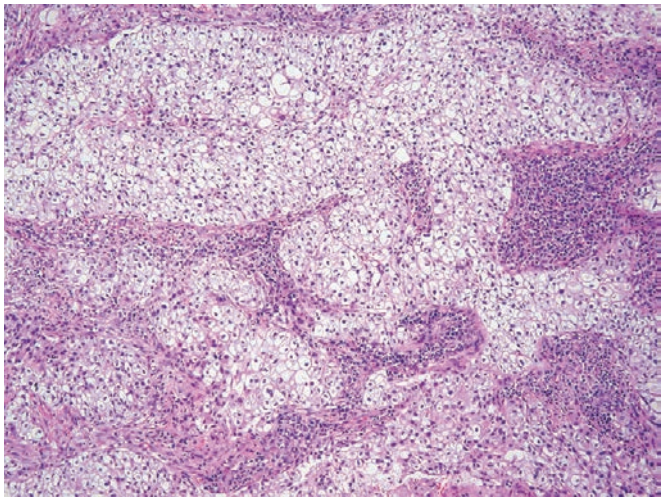

Figure 12.34 Thymic Carcinoma of Clear Cell Type. This tumor needs to be distinguished from metastatic carcinoma, particularly from the kidney.

Basaloid Carcinoma

This tumor is formed by well-defined epithelial islands with prominent peripheral palisading, a combination of features typical of basaloid carcinomas arising in other sites including the lung. Focal squamous differentiation is seen in a minority of cases.[157] It may present as a mural nodule in what otherwise looks like a squamous-lined thymic cyst (Fig. 12.31).[158] The main differential diagnosis is with thymic carcinomas with adenoid cystic carcinoma-like features.

Mucoepidermoid Carcinoma

Areas of squamous and mucin-producing glandular differentiation alternate in this neoplasm. The histologic features are identical to mucoepidermoid carcinomas arising in major salivary glands and lung. Rearrangements of the *MAML2* gene characteristic of these tumors in other sites also occur in primary thymic mucoepidermoid carcinomas.[159] Most examples are low-grade tumors and associated with a good prognosis (Fig. 12.32).[160] High-grade and high-stage cases are uncommon and portend a more aggressive and usually fatal course.

Lymphoepithelioma-Like Carcinoma

The appearance of the tumor approaches, and sometimes becomes indistinguishable from, that of lymphoepithelial carcinoma (so-called lymphoepithelioma) of the tonsil and nasopharynx. Large, deeply acidophilic nucleoli that are sharply outlined and perfectly round are one of the hallmarks of this neoplasm, which is also characterized by a "syncytial" appearance (Fig. 12.33). Keratinization and intercellular bridges are absent; however, the tumor cells are consistently immunoreactive for keratin, including high-molecular-weight cytokeratins such as CK5/6, as well as p63 and p40. The lymphocytes of this tumor, which can be very numerous, have the phenotype of mature peripheral T cells rather than the immature thymocytes seen in ordinary thymoma. The finding of the Epstein–Barr virus (EBV) genome in some cases of this entity suggests that the similarity with nasopharyngeal carcinoma may sometimes extend beyond the morphologic parameters.[161,162] EBV is consistently absent from other thymic epithelial tumors, despite initial reports to the contrary.

Clear cell carcinoma is a rare variant characterized by large amounts of glycogen-rich, clear cytoplasm in the tumor cells, which results in a striking resemblance to renal cell carcinoma (Fig. 12.34).[141,143,158,163]

Sarcomatoid Carcinoma (Carcinosarcoma)

This cytologically malignant tumor simulates a mesenchymal neoplasm by virtue of its diffuse pattern of growth and the prominent spindling of tumor cells.[164,165] The diagnosis is made by finding, somewhere in the tumor, foci with an epithelial appearance or

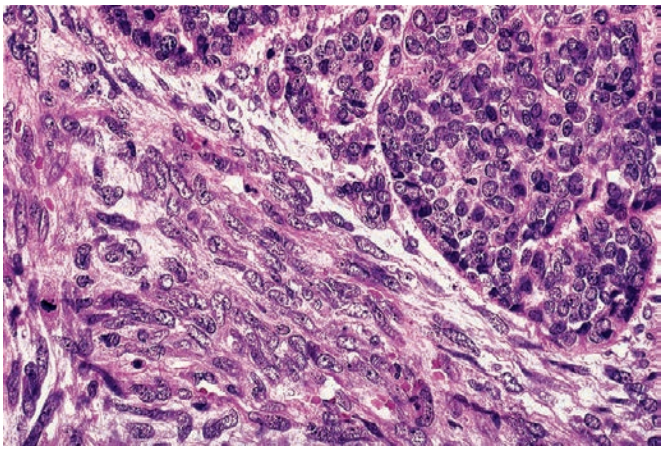

Figure 12.35 Sarcomatoid Carcinoma of Thymus. Because of the sharp segregation of the carcinomatous and the sarcoma-like components, tumors with this appearance are often called *carcinosarcomas*.

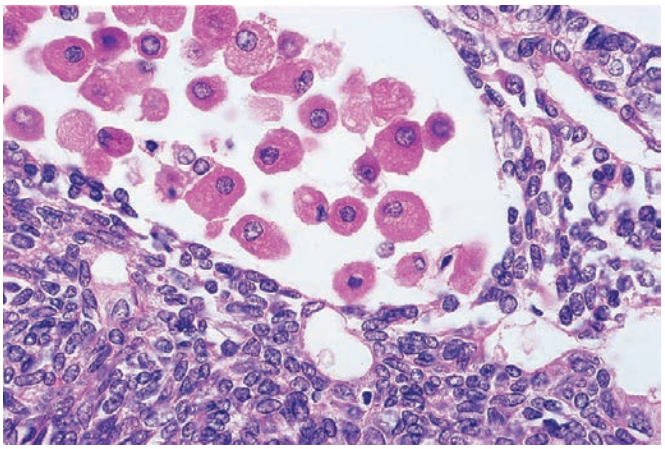

Figure 12.36 Thymoma with clusters of myoid cells showing abundant eosinophilic cytoplasm. These cells were strongly immunoreactive for myoglobin.

evidence of an epithelial phenotype in neoplastic spindle cells (Fig. 12.35). Some authors draw a distinction between sarcomatoid or spindle cell carcinoma on one side and carcinosarcoma on the other, but we regard the exercise just as futile as in other organs, in the sense that both types represent carcinomas in which a component of the tumor has undergone a "phenotypic switch." The sarcoma-like areas may include foci of cartilaginous and skeletal muscle differentiation, the latter having been described as *rhabdomyosarcomatous thymic carcinoma*. Parenthetically, skeletal muscle differentiation in cytologically bland myoid cells has also been described in thymomas and is not by itself diagnostic of carcinoma (Fig. 12.36).

The differential diagnosis of sarcomatoid carcinoma includes germ cell tumors and malignant schwannoma ("triton tumor"). It also includes a low-grade thymic tumor designated as *metaplastic thymoma* in the current WHO classification scheme[166] and previously reported as *thymoma with pseudosarcomatous stroma*[167] and *low-grade metaplastic thymic carcinoma*.[168] It is characterized by a biphasic epithelial and spindle cell morphology, with absence of significant atypia and low proliferation rates in both components.[169] Nearly all of the reported patients have been cured by surgical excision. We agree with the WHO terminology that places these tumors among the thymomas ("metaplastic thymoma") rather than thymic carcinomas while also acknowledging the probable epithelial nature of the spindle cell component. The appearance and interplay of the two components is very reminiscent of that seen in ectopic hamartomatous thymoma, suggesting that this lesion may represent its "orthotopic" counterpart. Further support for this interpretation derives from reports of sarcomatoid carcinomas arising in metaplastic thymomas.[170,171]

Adenocarcinomas are a histologically heterogeneous group, as is true in most other organ sites, and are extremely uncommon. **Papillary adenocarcinoma** resembles papillary thyroid carcinoma by virtue of the complex arborizing structure and the presence of psammoma bodies. However, it lacks optically clear nuclei, it is positive for CD5, and it shows no reactivity for thyroglobulin or TTF-1.[172] Most of the reported cases have arisen from type A (spindle cell, medullary) thymomas. **Mucinous and tubular adenocarcinomas** are a rare variant that includes mucinous adenocarcinoma with enteric differentiation characterized by expression of cytokeratin 20 and CDX2.[173]

NUT (midline) carcinoma is a form of high-grade carcinoma frequently demonstrating squamous differentiation that tends to affect midline structures, most commonly the mediastinum[174,175] (see Chapter 4). This highly aggressive and frequently lethal form of carcinoma tends to affect younger individuals and accounts for fewer than 5% of poorly differentiated thymic carcinomas and undifferentiated thymic neoplasms.[84] Although not pathognomonic, the most common histologic appearance is a highly undifferentiated carcinoma with variably conspicuous foci of abrupt squamous differentiation.[175] Diagnosis hinges on identifying the characteristic rearrangement of the *NUT* gene on chromosome 15q14 which results in fusion with a member of the bromodomain (BRD)-containing protein family, most commonly *BRD4* on chromosome 19.[84,175] The disease-defining genotype can be identified using an immunohistochemical assay for the fusion product, fluorescence in situ hybridization (FISH), or a reverse transcriptase-polymerase chain reaction technique.[176,177]

Undifferentiated (Anaplastic) Carcinoma

This tumor shows no detectable differentiation in any specific direction and tends to exhibit considerable pleomorphism. The more undifferentiated the neoplasm, the more seriously one should consider alternative possibilities, especially large cell or anaplastic lymphoma and germ cell tumors. With regard to the latter, we have seen several cases of upper mediastinal tumors in young adults that we have interpreted as *undifferentiated thymic carcinoma with germ cell–like features*, analogous to those that have been reported in the lung and other organs. We have also observed cases *of undifferentiated large cell carcinomas of the thymus accompanied by a Castleman disease–like reaction* which featured an unexpectedly indolent behavior.[178]

Rare variants of thymic carcinomas include **carcinomas with adenoid cystic carcinoma–like features** resembling its homonymous tumor in the salivary glands. These are among the rarest of thymic carcinomas; the few reported cases tend to present as multicystic lesions.[179] The single example of **hepatoid carcinoma** on record so far presented as a large solid mass that closely resembled hepatocellular carcinoma in nearly all respects except that it was positive for cytokeratin 7 with coexpression of Hep Par-1 and negative staining for alpha-fetoprotein.[180]

Classification

A rich and sometimes contentious history has evolved over the years concerning the classification of thymic epithelial tumors. Historically, two attempts that were perhaps most influential included a descriptive scheme originally proposed by Lattes et al.[181,182] and adopted by Bernatz et al.[183] that divided thymomas into spindle cell, lymphocytic, epithelial, and mixed categories. A second scheme based on

assumptions regarding histogenesis was developed by Marino and Müller-Hermelink and separated thymomas into medullary, mixed, predominantly cortical (organoid), cortical, and well-differentiated thymic carcinoma.[184]

It should be noted that neither of these schemes includes any of the types of thymic carcinoma listed in the preceding section, the potentially misleading terminology used for the fifth tumor type (i.e. well-differentiated thymic carcinoma) in the Müller-Hermelink scheme notwithstanding.[185]

The WHO Committee for the Histologic Typing of Thymic Tumors[186] opted for a new nomenclature, revised in the most current WHO scheme,[110] that acknowledges the malignant potential of all thymic epithelial neoplasms, incorporates the salient points of preexisting classifications, and takes into account two important factors. The first is that the thymus is unique in that it can be viewed as two different organs: the active, functional gland of the fetus and infant, and the inactive, "postmature" structure of adult life. The other is the presence, as an expression of differentiation, of a non-neoplastic lymphocytic component in the tumors composed of functional thymic tissue. For these, the general rules of tumor pathology apply. The better differentiated tumors (lymphocyte-rich or predominantly cortical types) recapitulate the structure of the normal organ almost to perfection, in terms of both cortical *and* medullary regions. Progression in these tumors composed of functional thymic tissue is manifested by an increase in the number of neoplastic epithelial cells, an increasing degree of atypia in these epithelial cells, and a corresponding decrease in the non-neoplastic lymphocytic component.

The WHO scheme consists of a combination of letters and numbers, assigned according to the following general criteria:

1. The thymomas are divided into two major types based on the cytological characteristics of neoplastic epithelial cells and the relative contribution of non-neoplastic immature T lymphocytes typical of normal thymic cortex. Type A thymomas are those in which neoplastic epithelial cells and their nuclei have a spindle/oval shape with few, if any, non-neoplastic T cells. Type B thymomas are those in which neoplastic epithelial cells have a dendritic or plump ("epithelioid") appearance and a variably conspicuous component of non-neoplastic immature T cells. Tumors combining these two morphologies are designated as *type AB*.
2. Type B thymomas are further subdivided on the basis of the proportional increase (in relation to the lymphocytes) and emergence of atypia of the neoplastic epithelial cells into three subtypes, respectively designated as *B1*, *B2*, and *B3*.

Thymic carcinomas are named as such, although they could be viewed as yet another subtype of thymoma (referred to historically as *type C thymoma*), an interpretation supported by the existence of hybrid and combined forms.[187]

Combinations of thymomas other than AB occur. For these cases, a term such as "combined thymoma" can be used, followed by a listing of the various components and their relative amounts, although the clinical value of this exercise is untested.[141] The reader may associate the various letters in the WHO scheme with the various tumor patterns by mnemonically assuming that "A" stands for atrophic (i.e. the effete spindle thymic cell of adult life), and "B" for bioactive (i.e. the biologically active organ of the fetus and infant).

The subtypes of thymomas included in the WHO classification, the corresponding terms in the two preceding schemes, their definition, and a few comments follow.

Type A Thymoma (Spindle Cell; Medullary)

A tumor composed of a population of neoplastic thymic epithelial cells having a spindle/oval shape, lacking nuclear atypia, and accompanied by few or no non-neoplastic lymphocytes (see Figs. 12.17 and 12.18).

The appearance of this tumor can simulate that of a mesenchymal neoplasm, but the immunohistochemical and ultrastructural features are clearly those of an epithelial tissue. A peculiar feature of the neoplastic epithelial cells in type A thymomas is expression of CD20 in about half of them.[134,188] Rosette-like formations (without a central lumen), foci with a storiform pattern of growth, and glandlike formations may be present, the latter often located within or immediately beneath the tumor capsule. Many of the features of the cells of this tumor are reminiscent of the cells seen in the atrophic thymus of adult life, some of which happen to be located in the subcapsular (rather than medullary) region.

There are rare thymomas composed of spindle cells but exhibiting some combination of hypercellularity, nuclear hyperchromasia, pleomorphism, mitotic activity, and/or necrosis. Mitotic activity (≥4/10 high-power fields) and necrosis have been proposed as the most reproducible features for identifying this extremely rare variant for which the term *atypical type A thymoma* has been proposed.[142] Necrosis was the only feature that predicted for higher tumor stage in a large retrospective cohort of type A and AB thymomas.[189] Distinguishing atypical type A thymomas from spindle cell type B3 thymomas may be challenging given the potential presence of nuclear atypia in both. Positive staining for CD20 in type A thymomas is inconsistent but may be helpful; in the absence of CD20 staining separating atypical type A from spindle type B3 thymomas hinges on other histologic findings including rosette-like, glandular, and storiform growth in type A thymoma and perivascular spaces in type B thymomas.[142]

Type AB Thymoma (Mixed)

A tumor in which foci having the features of type A thymoma are admixed with foci rich in lymphocytes including a significant proportion of immature T cells (see Fig. 12.23).[190]

This is a particularly common type of thymoma. The segregation of the two patterns can be sharp or indistinct, and there is a wide range in the relative amount of the two components. In particular, type A areas can be extremely scant, and therefore thorough sampling may be necessary to separate from type B1 thymomas. The presence of Hassall corpuscles strongly favors B1 thymomas; spindled or oval morphology and/or immunoreactivity for CD20 in epithelial tumor cells within lymphocyte-rich areas strongly favor a diagnosis of AB thymoma over a type B thymoma.[142]

Type B1 Thymoma (Lymphocyte-Rich; Lymphocytic; Predominantly Cortical; Organoid)

A tumor that resembles the normal functional thymus in that it combines large expanses having an appearance practically indistinguishable from normal thymic cortex in which cytologically bland thymic epithelial cells are evenly dispersed within a background of immature T cells and accompanied by areas resembling thymic medulla (see Fig. 12.19).[191]

The resemblance between this tumor type and the normal active thymus is such that the distinction between the two may be impossible on high-power examination. Absence of epithelial cell clusters and presence of medullary islands are especially helpful in separating B1 from B2 thymoma (see next).[141]

Type B2 Thymoma (Cortical)

A tumor in which the neoplastic epithelial component appears as scattered plump cell, often including small (≥3 contiguous epithelial cells) clusters, with vesicular nuclei and distinct nucleoli among a heavy population of immature T cells.[192] *Perivascular spaces are common and sometimes very prominent (see Fig. 12.21). A perivascular arrangement of tumor cells resulting in a palisading effect may be seen.* Medullary differentiation and rare Hassall corpuscles may be present but when present are less conspicuous than in B1 thymoma.

The cytoplasm of the tumor cells tends to be abundant and the shape of the cells round or polygonal, this feature having led to the alternative designation (large) polygonal cell thymoma. Like B1 thymoma, type B2 thymoma is lymphocyte rich (albeit to less degree), resulting in a mixed lymphocyte–epithelial pattern (see Fig. 12.20).

Type B3 Thymoma (Epithelial; Atypical; Squamoid; Well-Differentiated Thymic Carcinoma)

A type of thymoma predominantly composed of mildly atypical epithelial cells having a round or polygonal shape admixed with a minor component of immature T cells, resulting in a sheetlike growth of the neoplastic epithelial cells (see Fig. 12.22).[193]

This thymoma type has been traditionally known as epithelial, a term that is accurate but somewhat misleading since it implies that the other types of thymoma are not. Another term that has been suggested for it is atypical, but this is also somewhat inaccurate in view of the fact that the degree of atypia present in it may not be greater than that seen in type B2 thymoma, from which it is distinguished primarily on the basis of the proportionally larger number of epithelial cells compared to non-neoplastic lymphocytes. Another previously proposed term that has been largely discarded is *well-differentiated thymic carcinoma*, which is potentially confusing because of the fact that in most articles on the subject and in most classification schemes this tumor is included with the thymomas rather than with the thymic carcinomas. Yet another proposal is that of squamoid thymoma because of the common presence of squamoid or squamous features in the tumor cells. However, this is neither a constant nor an exclusive feature of this tumor type.

Rare subtypes of thymoma that do not easily fit into the A-B nomenclature include *micronodular thymoma* characterized by a micronodular growth pattern in which epithelial islands are separated by lymphoid stroma that may include florid follicular hyperplasia (Fig. 12.37).[194] The lymphocytes are composed mainly of B cells and mature T cells, and the epithelial cells are generally negative for CD20, two findings that may be helpful in distinguishing micronodular thymoma from type AB thymoma.[188] *Metaplastic thymoma* is another rare subtype that, as previously referenced (see previous section on sarcomatoid carcinomas), is a biphasic tumor in which solid areas of epithelial cells are variably well demarcated from cytologically bland, fibroblast-like spindle cells (Fig. 12.38). *Microscopic thymoma* refers to thymomas measuring less than 0.1 cm in greatest dimension and are usually discovered as multifocal incidental findings in thymectomies from patients with myasthenia gravis.[195] This lesion has also been referred to as *nodular hyperplasia* of thymic epithelium, which may be a more accurate and appealing term.[43] Microscopic thymomas (nodular hyperplasia) are found as frequently in unselected autopsies as they are in patients with myasthenia gravis, leaving the clinical significance of this finding in doubt.[196]

Thymic Carcinoma

A thymic tumor exhibiting clear-cut cytologic atypia and a set of cytoarchitectural features no longer specific to the thymus (as for types A, AB, and B thymomas) but rather analogous to those seen in carcinomas of other organs (see Figs. 12.29–12.35) as discussed in a preceding section.

Cytology

The most important criterion for the cytologic recognition of a thymoma is the identification of a distinct population of epithelial cells admixed with lymphocytes, preferably confirmed by a positive immunostain for keratin. Limitations of the procedure include the difficulty in separating the various subtypes of type B thymoma (not very important clinically) and the inability to detect invasion (a critical prognostic factor).[197]

Staging

Historically, thymomas of any type (other than thymic carcinomas) that appear totally encapsulated have been regarded as benign, whereas those of similar microscopic types but exhibiting evidence of aggressiveness in the form of local invasion, pleural or pericardial implants, or distant metastases have been designated as malignant (Fig. 12.39). The current classification scheme acknowledges that all thymomas have malignant potential that is heavily dependent on disease stage.[142] Because predicting behavior relies so heavily on the presence and, to some extent, on the degree of invasion, the staging system for thymomas first proposed by Masaoka et al.[198] in 1981, modified by Koga et al.[199] in 1994, and refined by Detterbeck et al.[200] in 2011 (Table 12.2) has repeatedly proven superior to histologic classification as an independent prognostic factor.[201] The tenets fundamental to this staging system have been preserved with a few key modifications in the more recently published staging system offered by the American Joint Committee on Cancer (AJCC) for all primary thymic epithelial neoplasms (i.e. thymoma, thymic carcinoma and thymic neuroendocrine neoplasms) in the 8th Edition of their Cancer Staging Manual (Table 12.3).[202] Tumor-related

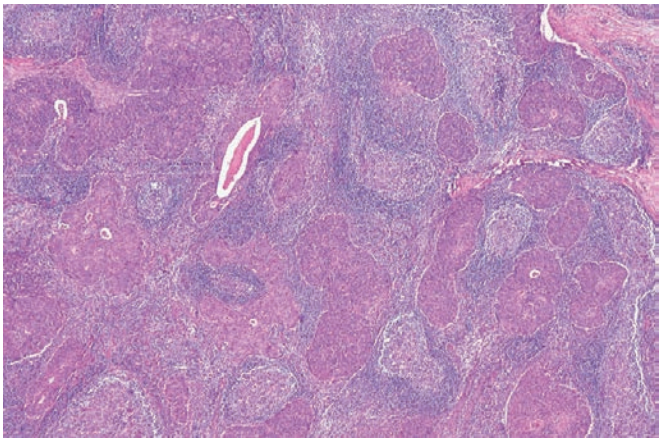

Figure 12.37 Micronodular thymoma with lymphoid stroma in which epithelial islands are separated by an epithelium-free lymphoid stroma.

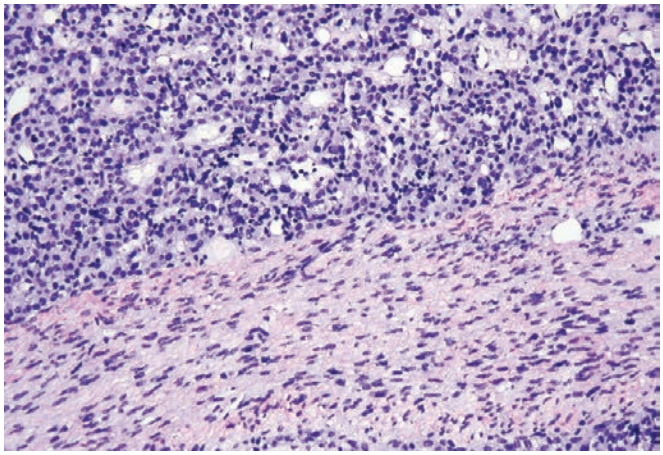

Figure 12.38 Metaplastic thymoma, previously referred to as low-grade metaplastic carcinoma given bland epithelial component juxtaposed with fibroblast-like spindle cells.

Table 12.2 Modified Masaoka–Koga staging system for thymic epithelial neoplasms

STAGE	DEFINITION
I	Grossly and microscopically encapsulated tumor
II	Capsular invasion
a	Limited (≤3 mm) microscopic transcapsular invasion
b	Macroscopic (microscopically confirmed) invasion into thymic or surrounding adipose tissue without pleural or pericardial involvement
III	Macroscopic (microscopically confirmed) invasion into neighboring organs (i.e. mediastinal pleura, pericardium, visceral pleura ± lung parenchyma, phrenic or vagus nerves, major vessels); adherence (i.e. fibrous attachment) to lung or other adjacent organs if (and only if) there is concomitant microscopic invasion of mediastinal pleura and/or pericardium
IV	Metastases
a	Pleural or pericardial metastases (i.e. nodules separate from main mass involving visceral or parietal pleura, or pericardial or epicardial surfaces)
b	Lymphogenous (intrathoracic or extrathoracic lymph nodes) or hematogenous (pulmonary parenchymal or extrathoracic) metastases

Modified from Detterbeck FC, Nicholson AG, Kondo K, et al. The Masaoka-Koga stage classification for thymic malignancies: clarification and definition of terms. *J Thorac Oncol*. 2011;6(7 suppl 3):S1710–S1716.

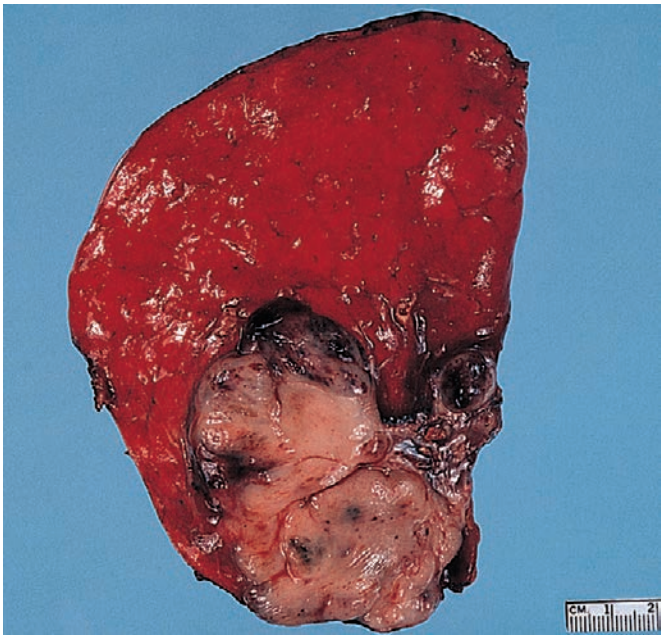

Figure 12.39 Gross appearance of malignant thymoma invading lung.

Table 12.3 American Joint Committee on Cancer staging of primary thymic epithelial neoplasms

Primary Tumor (T)[a,b]	
T CATEGORY	**T CRITERIA**
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor encapsulated or extending into the mediastinal fat; may involve the mediastinal pleura
T1a	Tumor with no mediastinal pleura involvement
T1b	Tumor with direct invasion of mediastinal pleura
T2	Tumor with direct invasion of the pericardium (either partial or full thickness)
T3	Tumor with direct invasion into any of the following: lung, brachiocephalic vein, superior vena cava, phrenic nerve, chest wall, or extrapericardial pulmonary artery or veins
T4	Tumor with invasion into any of the following: aorta (ascending, arch, or descending), arch vessels, intrapericardial pulmonary artery, myocardium, trachea, esophagus
Regional Lymph Node (N)[c]	
N CATEGORY	**N CRITERIA**
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in anterior (perithymic) lymph nodes
N2	Metastasis in deep intrathoracic or cervical lymph nodes
Distant Metastasis (M)	
M CATEGORY	**M CRITERIA**
M0	No pleural, pericardial, or distant metastasis
M1	Pleural, pericardial, or distant metastasis
M1a	Separate pleural or pericardial nodule(s)
M1b	Pulmonary intraparenchymal nodule or distant organ metastasis

[a]Involvement must be microscopically confirmed in pathological staging, if possible.
[b]T categories are defined by "levels" of invasion; they reflect the highest degree of invasion regardless of how many other (lower-level) structures are invaded. T1, level 1 structures: thymus, anterior mediastinal fat, mediastinal pleura; T2, level 2 structures: pericardium; T3, level 3 structures: lung, brachiocephalic vein, superior vena cava, phrenic nerve, chest wall, hilar pulmonary vessels; T4, level 4 structures: aorta (ascending, arch, or descending), arch vessels, intrapericardial pulmonary artery, myocardium, trachea, esophagus.
[c]Involvement must be microscopically confirmed in pathological staging, if possible.
From Detterbeck FC, Marom EM. Thymus. In: Amin MB, Edge SB, Greene FL, et al., eds. *AJCC Cancer Staging Manual*. 8th ed. New York: Springer; 2017:423–429.

categories in this recently proposed staging system disregard the distinction between encapsulated tumors and those that show limited extracapsular invasion into non-neoplastic thymus and thymic fat since this finding alone has little if any prognostic significance.[203] The AJCC staging system instead focuses on contiguous invasion of adjacent structures:

- T1 tumors may (T1b) or may not (T1a) directly invade mediastinal pleura,
- T2 tumors invade the pericardium,
- T3 tumors invade lung, chest wall, phrenic nerve, and/or selected vessels, and
- T4 tumors invade aorta, arch vessels, intrapericardial pulmonary artery, myocardium, trachea or esophagus.

In the absence of metastases the T categories dictate stage groupings (i.e. T1a, T1b = stage I, T2 = stage II, T3 = stage IIIA, T4 = stage IIIB) while stage IV disease is predicated on the presence of nodal metastases (N1 and N2) and/or extranodal metastases (M1a and M1b). The extent to which this model allows for greater precision in predicting prognosis compared to the refined Masaoka–Koga staging system is uncertain[204,205]; regardless, it is likely to become the preferred method for reporting resected thymic epithelial neoplasms.[206]

Overall, about 70%–80% of thymomas are encapsulated or, at most, minimally invasive at the time of diagnosis. Direct local invasion into adjacent structures such as lung or implants into the pleural or pericardial surfaces are considerably more common than extrathoracic metastases. When local invasion is extensive, it is already apparent to the surgeon at the time of thoracotomy. It is therefore important for the pathologist to know the surgical findings while remembering that fibrous adhesions resulting from secondary inflammatory, necrotic, and multilocular cystic changes can give the false impression that the tumor is invasive. The presence of large nerves surrounded by tumor also represents indirect evidence of invasion (sometimes the only such evidence present on the case). Distant metastases, which are exceptional, have been documented in mediastinal and cervical lymph nodes, lung, liver, bone (particularly spine), ovary (we have seen three examples), and other sites. Usually, these distant metastases develop months or years after an invasive thymoma has been detected and treated but sometimes are noted at presentation and exceptionally represent the first clinical manifestation of the disease.

There is a close relationship between the microscopic subtype of thymoma and the likelihood of invasion, and therefore outcome, as follows[205,207]:

A < AB < B1 < B2 < B3

It is, however, important to point out that *any* thymoma type can be associated with the presence of direct extension, pleural or pericardial implants, or distant metastases (Fig. 12.40).

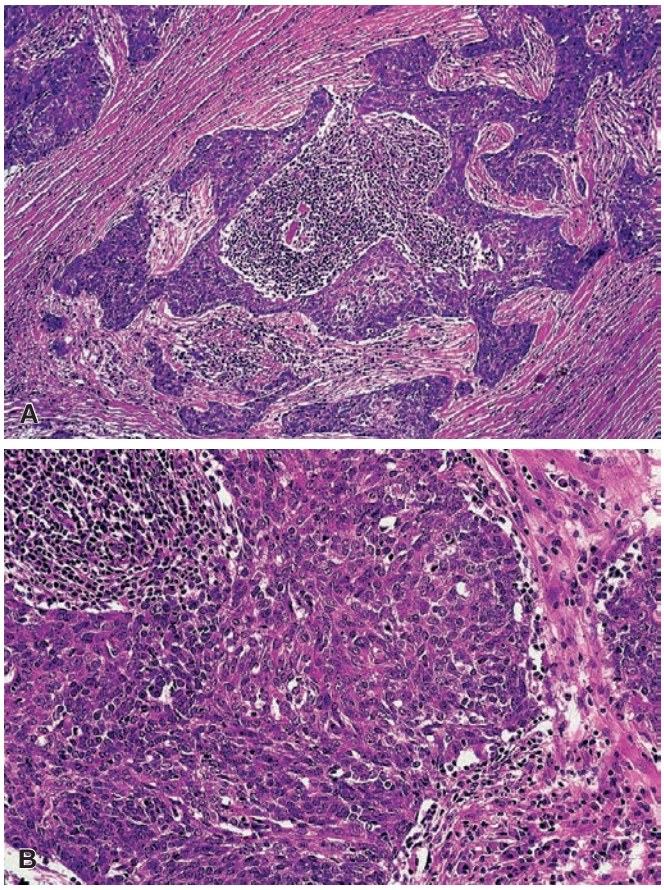

Figure 12.40 **A** and **B**, This tumor had the morphologic features of a type A thymoma, yet it was widely invasive.

Treatment

The primary treatment of thymoma is en-bloc surgical excision and complete thymectomy.[208] For the entirely encapsulated (Masaoka stage I) and minimally invasive (Masaoka stage II) thymomas that have been removed in toto with tumor-free margins, no additional therapy is necessary regardless of their microscopic type. If there is any question about the possibility of residual tumor, postoperative radiation therapy should be considered for tumors other than types A or AB (unless they are extensively invasive, which is very rarely the case).

For thymomas associated with preoperative radiological evidence of gross or suspected invasion and/or intrathoracic implants, multimodality therapy including neoadjuvant chemotherapy followed by adjuvant radiation in selected patients yields improved survivals.[208,209]

Thymic carcinomas are treated with surgery and radiation therapy, with chemotherapy added in selected cases.[210]

Prognosis

Stage remains the single most important prognostic determinant, regardless of the system used, and applies equally to thymomas and thymic carcinomas.[205] The prognosis of fully encapsulated and minimally invasive thymoma after complete surgical excision is excellent. Recurrence has been found in 2%–10% of cases, depending on the series. These local recurrences are still amenable to surgical removal.[211]

In the case of invasive thymomas, the prognosis correlates with the degree of invasion as measured by either the modified Masaoka–Koga or the more recently proposed AJCC staging system. As previously mentioned the prognosis of minimally invasive (modified Masaoka–Koga stage II) thymomas is not significantly different from that of encapsulated (modified Masaoka–Koga stage I) tumors,[203] but it drops markedly for the tumors showing gross invasion or implants and even more for the few cases associated with distant metastases.[204]

There is a definite relationship between the subtype of thymoma (whatever the classification system used) and prognosis. This fact was already very evident in the large series from the Mayo Clinic reported by Lewis et al. in 1987.[88] The reason the usefulness of

Table 12.4 Salient features of tumors in the neck showing thymic or related branchial pouch differentiation

TUMOR	GENDER	MEAN AGE (YEARS)	ANATOMIC LOCATION	MAJOR HISTOLOGIC FEATURES	BEHAVIOR
Ectopic hamartomatous thymoma	M > F	49.9	Supraclavicular or suprasternal soft tissue	Circumscribed; haphazard admixture of bland-looking spindle (epithelial) cells, solid and cystic epithelial islands (commonly squamous and glandular), and mature fat cells	Benign: *No recurrence or metastasis* after excision
Ectopic cervical thymoma	M < F	42.7	Soft tissue of neck, often in a juxtathyroid location, or sometimes inside thyroid	Similar to mediastinal thymomas; encapsulated or invasive; jig-saw puzzle-like lobules; mixture of pale epithelial cells (plump or spindled) and lymphocytes	Most pursue a benign course with *no recurrence*; exceptionally, metastasis can occur
SETTLE	M = F (about the same)	15	Thyroid gland	Encapsulated or infiltrative; highly cellular tumor; merging of compact or reticulated spindle (epithelial) cells with glandular elements; mucous glands often present; component of lymphocytes lacking	Protracted clinical course, with a propensity to develop *delayed distant metastasis*
CASTLE	M < F	48.5	Thyroid gland (usually lower pole) and surrounding soft tissue, or soft tissues of the neck	Lymphoepithelioma-like carcinoma that may show foci of squamous differentiation; lobulation; pushing margins; lymphocytic infiltration often present	Generally indolent tumor that can *recur after long intervals; regional lymph node metastasis* occurs in about half of the cases; occasional cases pursue a more aggressive course

From Chan JK, Rosai J. Tumors of the neck showing thymic or related branchial pouch differentiation. A unifying concept. *Hum Pathol.* 1991;22:349–367.

the microscopic subdivision of thymoma along these lines was minimized by Lewis et al. and other authors is that it is largely superseded by the staging system, which is a more important independent prognostic factor. Three independent studies carried out by Rosai and associates comprise three different series of thymoma patients. One deals with patients treated at the Memorial Sloan Kettering Cancer Center,[212] one with personal consultation cases,[213] and the third with patients seen at the National Cancer Institute of Milan, Italy.[214] The results of these three series, which were notably similar, confirmed the previously referenced relationship between the microscopic type of thymoma and prognosis. When the tumor stage is taken into account, however, the prognostic value of the microscopic type drops considerably. **Completeness of excision** is also an important prognostic parameter, which is directly related to the tumor stage.[212]

Proliferation index (i.e. Ki-67 labeling index) and DNA ploidy correlate with stage and microscopic type but neither has demonstrated consistent value as an independent prognostic biomarker.[215,216]

Cervical Tumors of Thymic or Related Branchial Pouch Derivation

As mentioned previously, *ectopic thymic tissue* and *unilocular thymic cysts* can be found in the lateral aspects of the neck as a result of a malformation related to the third or possibly fourth branchial pouch. In addition, the following neoplasms can develop in a similar location and on a presumably similar histogenetic basis (Table 12.4).

1. **Ectopic (cervical) thymoma.** The microscopic appearance of this tumor is not noticeably different from that of its orthotopic mediastinal counterpart.[86,217] A striking and unexplained predilection for the female gender is present. All of the reported cases have behaved in a benign fashion.[218]
2. **Ectopic hamartomatous thymoma.** The location of this lesion, which shares features of a hamartomatous and a neoplastic process, is the supraclavicular–suprasternal area.[219] Nearly all patients are males, in striking contrast with the previous entity. The bulk of the mass is composed of epithelial cells that are extremely spindle shaped and mesenchymal-like[220]; this finding often results in a misdiagnosis of a Schwannian or fibroblastic neoplasm. However, ultrastructural examination or keratin immunostaining reveals their epithelial nature. Atypia, necrosis, and mitotic figures are absent. The other component (which can be very focal) is represented by solid squamous nests, thin anastomosing cords (sometimes composed of clear cells), and epithelial-lined cysts (Fig. 12.41). Islands of mature fat and clusters of small lymphocytes may also be present. This tumor, which may reach a huge size, does not seem to have a mediastinal counterpart. The behavior is benign,[220] with occasional instances of local recurrence,[221] but exceptional cases with a superimposed carcinoma are on record.[222] Although originally hypothesized to be derived from third branchial arch derivatives,[219] others have suggested origin from

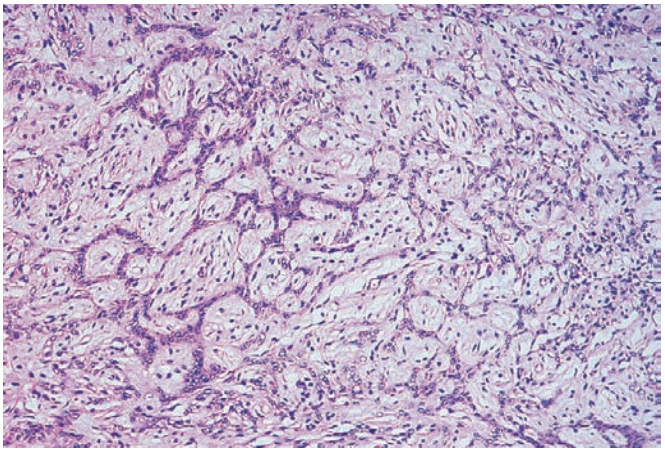

Figure 12.41 Ectopic Hamartomatous Thymoma. Thin anastomosing strands of epithelial cells merge with spindle foci having a mesenchyme-like appearance.

alternative branchial cleft remnants that lack an embryological link to the thymus.[221] Whatever its derivation, ectopic hamartomatous thymoma is a rare clinically and histopathologically distinct entity that should not be confused with other potentially more aggressive lesions.[220]

3. **Spindle epithelial tumor with thymus-like elements (SETTLE).** Most cases of this rare neoplasm have been found in adolescents or young adults and have been located in or around the thyroid.[218] Microscopically, a biphasic pattern resulting from a predominant spindle cell component (more cellular than in the previous type and mitotically active) and a mucin-secreting, occasionally cystic glandular component is present (Fig. 12.42).[223] Immunohistochemically and ultrastructurally, both tumor components have an epithelial phenotype. Prominent mitotic activity and focal necrosis have been reported in a subset of cases.[224] At the molecular level, *KRAS* gene mutation has been detected in a single example of this entity; SETTLE lacks the fusion genes characteristic of synovial sarcoma, a finding of potential value in diagnostically challenging cases.[225,226] The natural history is characterized by a tendency for late (measured in years or decades) distant metastases.[227] The main differential diagnosis for SETTLE is synovial sarcoma, particularly when the spindle cell component predominates ("predominantly monophasic") to the near exclusion of the glandular element (Fig. 12.43).[228] SETTLE should be favored in the presence of stromal hyalinization, lower overall grade, presence of glomeruloid glandular structures, absence of intraglandular necrotic debris, and diffuse expression of high-molecular-weight keratin. If doubts persist, molecular studies for the synovial sarcoma fusion genes can be helpful, as referenced previously.
4. **Carcinoma with thymus-like elements (CASTLE).** This tumor also tends to be located within or around the thyroid,[218] to the point that most of the earliest reported cases were thought to represent squamous cell or undifferentiated carcinomas of this organ.[229] Their microscopic appearance is indistinguishable from that of thymic carcinoma (Fig. 12.44), of which it can be regarded as its ectopic (cervical) equivalent. Support for the thymic rather than thyroidal origin of CASTLE is provided by its immunoreactivity for CD5, CD117, high-molecular-weight keratin, BCL2, p63, and mcl-1 (all of these markers being usually positive in thymic carcinoma) and negativity for thyroglobulin and TTF-1.[230] The tumor has a tendency for late local recurrences, but its behavior is rather indolent, certainly more so than that of undifferentiated thyroid carcinoma.[218]

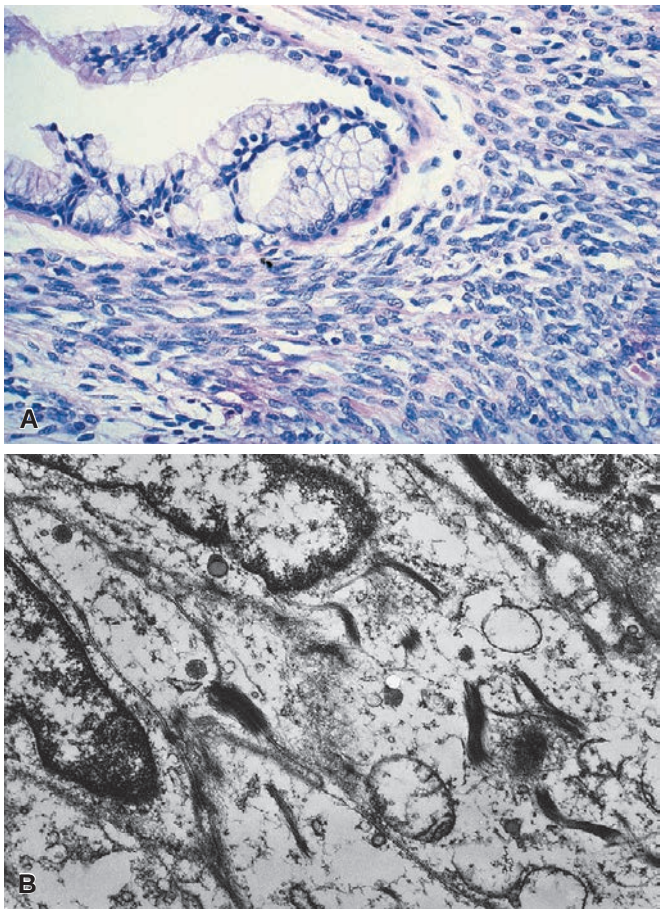

Figure 12.42 A, SETTLE. Spindle epithelial cells of mesenchyme-like appearance surround a well-differentiated gland lined by mucin-producing epithelium. **B**, Electron micrograph of SETTLE. Neuroendocrine Tumors

The thymus is the site of several types of neuroendocrine neoplasm, many of which were previously misinterpreted as variants of thymoma.[231] The gamut of neuroendocrine tumors that can develop in the thymus is basically the same as for the lung, the main difference being the relative frequencies of the various types using the same or similar histologic criteria (see Chapter 10).[232,233] Thus, whereas most neuroendocrine tumors of the lung fall into the two extremes (typical carcinoid and small cell carcinoma), those of the thymus tend to fall into an intermediate category (atypical carcinoid), although many publications have lumped typical and atypical carcinoid tumors together.[234] Symptoms and signs of local compression are common at diagnosis. As many as half of cases will have associated endocrinopathies, most commonly Cushing (and only rarely carcinoid) syndrome[235]; it seems apparent that all of the cases of thymomas reported historically to be associated with Cushing syndrome are examples of thymic carcinoids.[236] Thymic neuroendocrine tumors can also occur as a component of multiple endocrine neoplasia (MEN) type 1 or 2a or as *formes frustes* of these syndromes.[235,237] In these patients and in those with Cushing syndrome, the tumor tends to run a more aggressive clinical course. It has also been described in patients with neurofibromatosis type 1.

Typical and atypical carcinoid tumors of the thymus are malignant neoplasms histologically equivalent to their primary pulmonary counterparts that often invade locally and metastasizes distantly.[232,235,238] Histologic grading of thymic neuroendocrine tumors using criteria similar to those applied in the lung has prognostic value,[232] but stage, resectability, and presence of paraneoplastic endocrinopathies at presentation are more significant predictors of outcome.[233,238] Unlike their lung counterparts, thymic neuroendocrine tumors in all categories are more likely to present with more advanced disease and therefore more likely to be affiliated with an aggressive course even if low grade (i.e. typical carcinoid tumors).

Grossly, thymic carcinoid is solid, usually well circumscribed but not encapsulated, and lacks the distinct lobulations of thymoma (Fig. 12.45). Like carcinoid tumors elsewhere it tends to be highly vascularized and may be frankly hemorrhagic, including ectatic blood-filled spaces.[239]

Microscopically, thymic carcinoid tumor exhibits ribbon and festoon formation, rosette-like glands with central lumina, "balls" or nests of cells, and a delicate highly vascular stroma (Figs. 12.46). Lymphocytes, perivascular spaces, and other features of thymoma

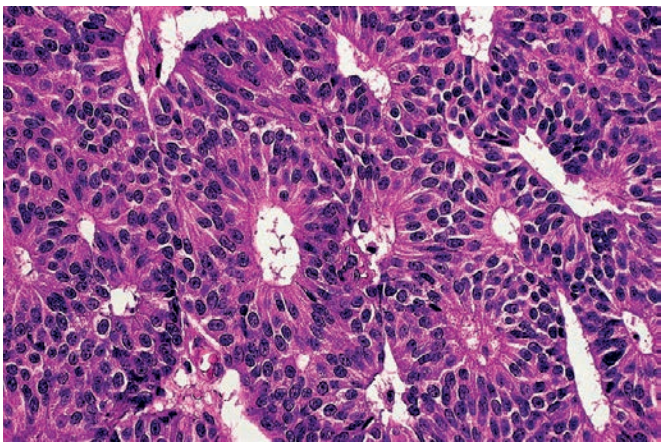

Figure 12.46 Well-differentiated architectural and cytologic appearance of thymic typical carcinoid. Ribbons and rosettes are evident.

are absent. The tumor cells have a more granular cytoplasm than those of thymoma, the nuclear chromatin is slightly coarser, and mitotic activity is frequent. As previously referenced, applying to thymic carcinoids, the criteria currently used for the homonymous bronchial lesion as proposed in the current WHO classification scheme relegates[234] most of them to the category of *atypical* carcinoid tumor (Fig. 12.47).[232,233,238,240] In many tumors the histologic findings are heterogeneous, including areas of low-, intermediate-, and high-grade histology.[241] This probably explains the fact that, as a group, thymic carcinoid is a more aggressive neoplasm than bronchial carcinoid, in which the atypical form represents a minority.[232,235,240]

Special techniques are very useful for confirmation of a diagnosis of thymic carcinoid. Electron microscopy, a technique of historical interest only, shows short interdigitating cell processes, focal basal lamina, scanty junctional processes, and practically no complex desmosomes or tonofilaments. The cytoplasm contains many dense-core granules and sometimes perinuclear whorls of microfilaments[242,243] (Fig. 12.48). Immunohistochemically, there is reactivity for keratin, chromogranin, synaptophysin, neuron-specific enolase, and other general endocrine markers. About a third stain for PAX8, while staining for TTF-1 is rare, a finding sometimes helpful in separating primary thymic neuroendocrine tumors from metastatic pulmonary lesions.[244] In addition, the tumors associated with Cushing

syndrome show positivity for adrenocorticotropic hormone (ACTH).[245,246] Other substances detected in this tumor include serotonin, somatostatin, cholecystokinin, neurotensin, metenkephalin, and growth hormone-releasing hormone (GHRH).[234,245]

Morphologic variants of thymic carcinoid tumor include lesions with a spindle cell pattern[247,248] (Fig. 12.49), a prominent oncocytic component,[249] and melanin pigment.[246] There are also tumors containing amyloid and calcitonin and therefore analogous to medullary thyroid carcinoma.[250] Finally, there are carcinoid tumors accompanied by a high-grade sarcomatoid component.[251]

Small cell neuroendocrine carcinoma of the thymus has an appearance indistinguishable from that of its considerably more common pulmonary counterpart[241,250] (Fig. 12.50). For that reason, a diagnosis of primary small cell carcinoma of the thymus can only be entertained when a mediastinal metastasis from a pulmonary neoplasm has been ruled out. As in the lung, thymic tumors have been described having an admixture of small cell and squamous cell carcinoma[158] and may also be combined with carcinoid tumor.[241]

Large cell neuroendocrine carcinoma, defined according to the criteria applied to pulmonary neoplasms, has been seen in the thymus, albeit only exceptionally.[252]

It is important to point out the difference that exists between all of the previous tumors, generically embraced into the neuroendocrine category, and otherwise conventional thymic carcinomas that show immunohistochemical evidence of neuroendocrine differentiation,[150] a circumstance analogous to use of these terms in the lung (see Chapter 10).

It should also be mentioned that not all thymic tumors showing neural differentiation (e.g. neuroblastoma) are neuroendocrine

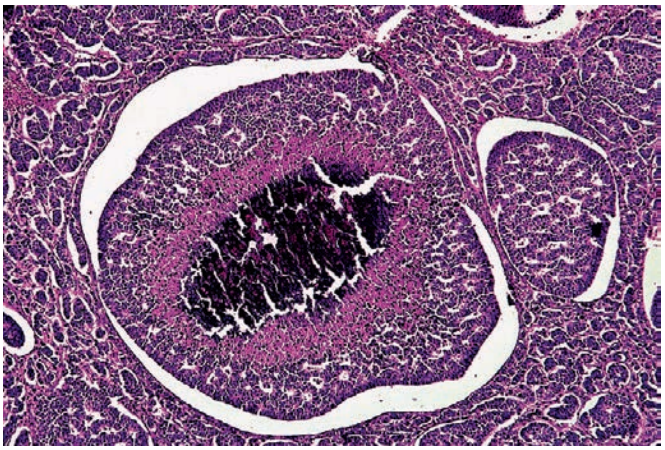

Figure 12.47 Thymic Atypical Carcinoid. The tumor nests show characteristic central necrosis with calcification.

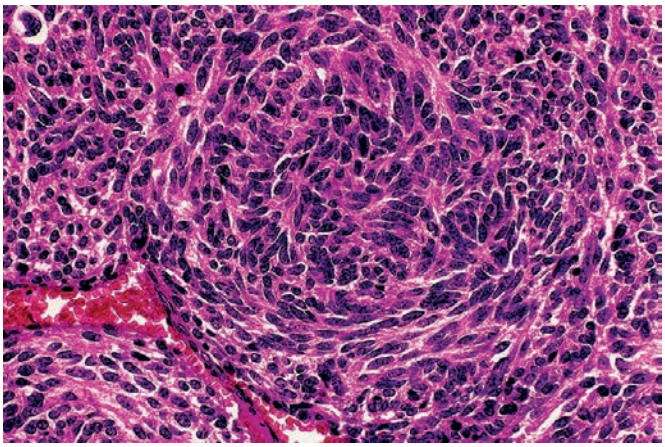

Figure 12.49 Thymic Carcinoid of Spindle Cell Type. This tumor is easily confused with a type A (spindle cell) thymoma.

carcinomas and that rarely posterior mediastinal neuroendocrine carcinomas may arise from structures other than the thymus.[253]

Stromal and Other Tumors

Thymolipoma is an encapsulated benign thymic lesion that can attain a huge size and can simulate radiographically cardiomegaly or pulmonary sequestration.[254] It is questionable whether it represents a true neoplastic process, but the finding in one case of the chromosomal aberration typical of lipoma suggests that it is a neoplasm of thymic fat.[255] The majority of the cases are asymptomatic, but isolated instances of association with myasthenia gravis, aplastic anemia, and Graves disease are on record.[256] Their appearance on CT scan and MRI is characteristic. Grossly, the lesion has the appearance of a lipoma except for the focal presence of whitish solid areas. Microscopically, there is an admixture in various proportions of mature adipose tissue and unremarkable thymic tissue (Fig. 12.51). The amount of the latter is well in excess of that normally expected for the patient's age. Isolated case reports have described associated myoid cells,[257] fibroconnective tissue ("thymofibrolipomas")[258] or vessels ("thymohemangiolipoma"),[259] sebaceous differentiation,[260] and even thymoma and thymic carcinoma.[261]

We and others have seen cases of low-grade malignant mesenchymal tumors seemingly arising from the thymic stroma that we interpreted as **thymic stromal sarcomas**. Their microscopic appearance is variable, but well-differentiated liposarcoma/atypical lipomatous tumor is the predominant component ("thymoliposarcoma") (Fig. 12.52).[262]

Other stromal tumors arising in the thymus are rare, including a single reported case of *kaposiform hemangioendothelioma* in an infant.[263]

Malignant melanoma has been seen presenting as an apparently primary thymic mass.[264] Parenthetically, metastatic tumors to the thymus are exceptional.

Germ Cell Tumors

Germ cell tumors account for approximately 20% of the mediastinal tumors and cysts. Their histogenesis is controversial, but a primary origin from extragonadal germ cells is favored.[265] In this context, it should be pointed out that the mediastinal location of germ cell tumors is specifically related to the thymus gland, even if normal germ cells in this organ have yet to be conclusively demonstrated and their possible function—if indeed they are present—remains

an enigma. The thymic connection of germ cell tumors is also evident by the fact that, when small, they are found totally encased within this organ. However, they seem to have no histogenetic relationship with true thymoma and should not be labeled as such. The possibility of any mediastinal germ cell tumor representing a metastasis from a testicular or ovarian primary lesion should always be investigated, although in the presence of a single upper mediastinal tumor with no evidence of retroperitoneal involvement the chances of this being the case are remote.

Some cases of mediastinal germ cell tumors have occurred in association with Klinefelter syndrome; it has been estimated that the incidence of this syndrome among patients with mediastinal germ cell neoplasms is up to 50 times that seen in the general population.[266]

A definite relationship exists between the patient's sex and the incidence of the various mediastinal germ cell tumors. Seminoma (germinoma), for all practical purposes, affects only males[267]; we have yet to see a convincing case in a female. Embryonal carcinoma, endodermal sinus tumor, teratocarcinoma, and choriocarcinoma show a great male predilection, but unquestionable cases in females have been reported.[268,269]

Seminoma (germinoma) of the mediastinum arises almost always within the thymus but—as already stated—should be regarded as a germ cell tumor rather than a true thymoma (Fig. 12.53). The morphologic appearance is identical to that of its testicular counterpart at the light microscopic, immunohistochemical, and ultrastructural level (Figs. 12.54 and 12.55).[267,270,271] Histologic features common to both is the characteristic cytology of neoplastic cells including prominent nucleoli and clear cytoplasm with distinct cytoplasmic borders, fibrous septa, and a dense inflammatory infiltrate comprising a combination of lymphocytes and granulomatous inflammation that may obscure the underlying neoplasm (Fig. 12.56). Like their testicular counterparts, mediastinal seminomas are frequently positive for various cytokeratins but are more frequently positive for low-molecular-weight cytokeratins (e.g. CAM5.2).[272] Combined with staining for CD117 (c-kit), this is a dangerous diagnostic trap given

Figure 12.53 Seminoma of Thymus. The tumor is solid and homogeneous, with focal necrosis. Residual thymic tissue is seen at the periphery.

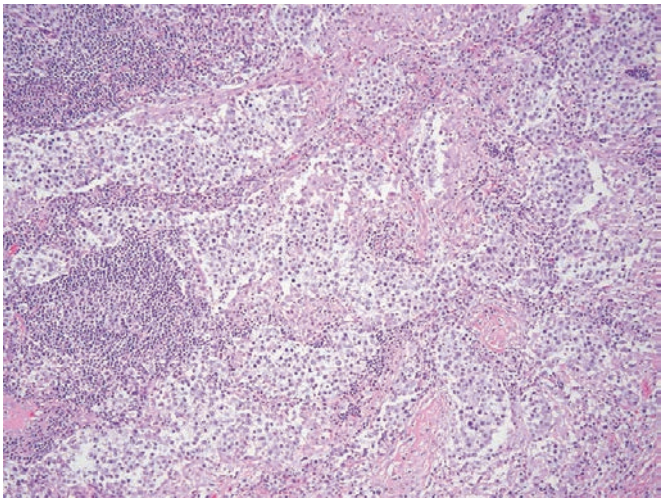

Figure 12.54 Seminoma of thymus showing compact nests of large tumor cells surrounded by lymphocyte-rich fibrous septa.

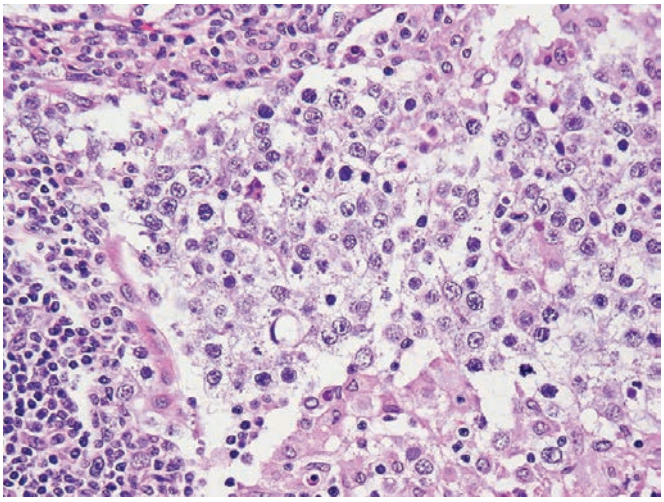

Figure 12.55 This high magnification view shows the multiple prominent and often irregularly shaped nucleoli that are typical of seminoma.

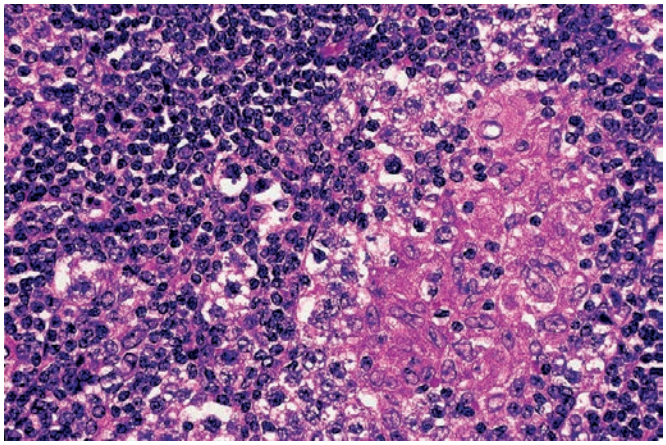

Figure 12.56 Seminoma of Thymus. The associated granulomatous response can obscure the true nature of the lesion.

the immunohistochemical overlap with thymic carcinoma. Staining for OCT3/4 and SALL4 is nearly universal and can be especially helpful in resolving this diagnostic problem.[271,272] Mediastinal seminomas are somewhat different from homologous gonadal tumors in their p53 immunostain profile and specific sites and types of *KRAS* and *KIT* mutations.[273,274]

The differential diagnosis of mediastinal seminoma includes thymoma, thymic carcinoma, and large cell lymphoma. The presence of fibrous septa infiltrated by lymphocytes and plasma cells, epithelioid granulomas, numerous germinal centers, large amounts of cytoplasmic glycogen, and an irregular, skein-like nucleolus favors a diagnosis of seminoma. As summarized previously, immunostains can be especially helpful in this circumstance given the specificity of staining for OCT3/4 and SALL4 in seminoma compared to thymic epithelial tumors and lymphomas. Chromosome 12p abnormalities, most commonly 12p amplification, as detected with a FISH technique are almost always present and offers another potentially useful diagnostic tool.[271] The primary treatment is a combination of chemotherapy and radiation, combined modality therapy resulting in disease-free survivals of nearly 90%.[275,276]

Mature cystic teratoma competes with seminoma as one of the most common types of mediastinal germ cell neoplasms in adults[269] and accounts for the majority of mediastinal germ cell tumors in children.[277] It usually becomes clinically apparent in early adult life. It may grow to a large size and has a distinct, sharply delineated wall that often becomes calcified.[278] The cut surface is predominantly cystic (Fig. 12.57). Adherence to surrounding structures is common. If the sebaceous material within it escapes, a prominent xanthogranulomatous inflammatory reaction follows. Perforation into the tracheobronchial tree may occur, and the patient coughs up sebaceous oily material and hair.

The microscopic appearance resembles that of the more common mature cystic teratoma of ovary. The cysts are lined by stratified squamous epithelium and contain sebaceous glands and hair follicles. Other common components are neural tissue, gastrointestinal tract, cartilage, and respiratory structures. Pancreatic tissue is particularly frequent in this location[279]; it may be accompanied by islet cell elements and result in hypoglycemia. The prognosis for mature teratoma is excellent following complete surgical excision.[280]

Figure 12.57 Mature Cystic Teratoma With Prominent Cystic Component. This tumor contained abundant pancreatic tissue, some of which was heavily inflamed.

Immature teratoma is defined, as in other sites, as a germ cell tumor similar to mature teratoma but also containing immature epithelial, mesenchymal, or neural elements without a component of embryonal carcinoma; the number of cases reported in the mediastinum is too small to know what to expect in terms of behavior, although anecdotal reports suggest more aggressive behavior in older children and young adults.[281] This condition should be distinguished both from teratocarcinoma (see later section) and from malignant ("somatic") transformation of mature cystic teratoma, the latter being a very rare event as summarized elsewhere.

Embryonal carcinoma is an invasive, highly necrotic neoplasm. Its microscopic appearance is, by definition, poorly differentiated. Immunohistochemically, there is reactivity for keratin, PLAP, OCT4, SALL4, CD30, and CD57 (Leu7). It is very important for the pathologist to consider the possibility of germ cell tumor in the presence of a poorly differentiated malignant neoplasm of the mediastinum, especially if the patient is a young male, instead of automatically relegating it to the category of "undifferentiated malignant tumor"; otherwise one might be denying the patient the opportunity of remission or cure with current chemotherapeutic regimens combined with surgery in selected patients.[282,283]

Yolk sac tumor (endodermal sinus tumor) may occur admixed with other germ cell elements or (more rarely) as a pure neoplasm (Fig. 12.58).[268,284] Yolk sac tumor is the second most common mediastinal germ cell tumor in children less than 15 years of age; yolk sac elements are more common in mediastinal than in testicular neoplasms.[285] Mediastinal yolk sac tumors may have prominent spindle cell features,[286] contain a hepatoid component,[287] or be accompanied by secondary multilocular cystic changes in the adjacent non-neoplastic thymus.[55] An OCT4–, SALL4+ immunophenotype is of great help in confirming the diagnosis, especially when combined with staining for alpha-fetoprotein and glypican-3.[288,289] The prognosis of pure yolk sac tumor has improved with combination chemotherapy and surgery.[283]

Teratocarcinoma is an older term used to describe mixed germ cell tumors characterized by a combination of embryonal carcinoma and teratoma (mature and/or immature), and comprises about 5% of all mediastinal germ cell tumors. Grossly, areas of hemorrhage and necrosis are present (Fig. 12.59). Microscopically, areas of embryonal carcinoma alternate with foci of predominantly mature teratoma.

Choriocarcinoma of the mediastinum occurs, for the most part, in the third decade of life.[290] It is often associated with gynecomastia

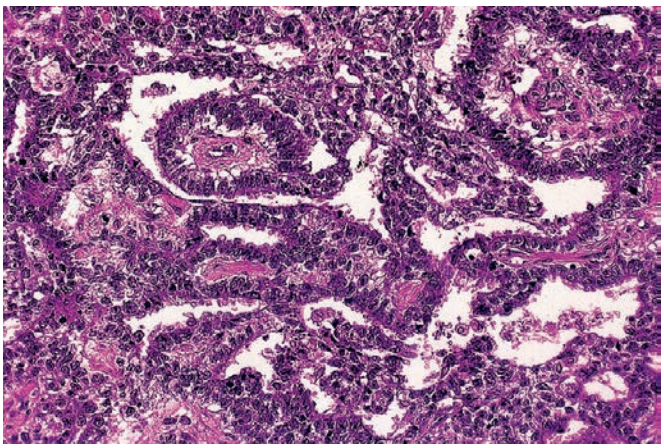

Figure 12.58 Yolk sac tumor of mediastinum, with well-developed Schiller–Duval bodies.

Figure 12.59 Mixed germ cell tumor of the mediastinum comprising a combination of embryonal carcinoma and teratoma *(teratocarcinoma)* that has undergone massive necrosis.

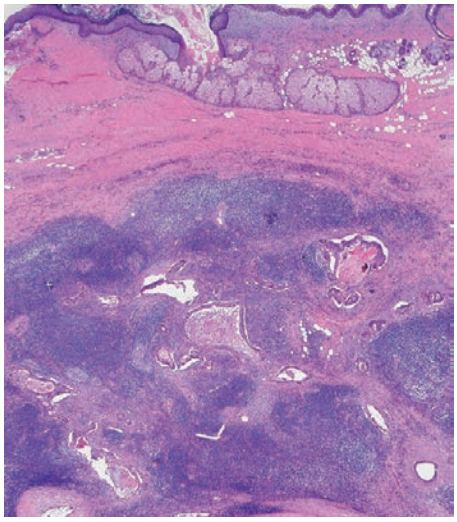

Figure 12.60 Somatic adenocarcinoma arising in a mediastinal teratoma from a 25-year-old man with chest and shoulder pain.

and invariably accompanied by elevated serum levels of human chorionic gonadotropin (hCG). The prognosis is extremely poor. The occurrence of choriocarcinoma as a primary lesion in the mediastinum has been accepted after several classical autopsy studies described cases in which serial sections of both testes showed no abnormalities. It should be emphasized, however, that it is in choriocarcinoma, more than any other germ cell tumor, that the possibility of an occult testicular primary lesion exists because of the tendency for this tumor type to be very small and even regressed ("burnt out") at the time that the metastases develop. The distinction, however, is mainly of academic interest inasmuch as the treatment (systemic chemotherapy) and the prognosis are similar regardless of whether an occult testicular tumor is identified or not. Placental site trophoblastic tumor is the only other type of mediastinal germ cell tumor showing trophoblastic differentiation reported in a 14-year-old boy 2 years after resection of a teratoma.[291]

As in other extragonadal locations and in the gonads, admixtures of various types of germ cell tumor are common.[269] These tumors are collectively referred to as *mixed germ cell tumors*; it is important to accurately report the components present.[292]

A cytogenetic aberration of germ cell tumors that is seen in over 80% of the cases, regardless of microscopic type or whether the tumor is primary or metastatic, is the presence of i(12p), that is, a gain of 12p, usually in the form of an isochromosome.[293] This determination can be of great diagnostic utility in this context and can be performed on formalin-fixed, paraffin-embedded material using a FISH technique.[294]

As a group, nonseminomatous germ cell tumors of the mediastinum respond reasonably well to a combination of chemotherapy and surgery with long-term survivals of around 50%.[282,283] Tumor stage, treatment response, and elevation of serum tumor markers following surgery are important prognostic indicators.[283]

A particularly ominous complication of nonseminomatous germ cell tumors of the mediastinum is the occasional development of a **somatic-type malignant tumor**, such as adenocarcinoma (Fig. 12.60), neuroendocrine tumors, angiosarcoma, malignant peripheral nerve sheath tumor (MPNST) or rhabdomyosarcoma.[295,296] Mediastinal germ cell tumors seem to be more prone to this event than gonadal neoplasms, occurring in adult males usually in association with tumor relapse following chemotherapy.[297] The prognostically unfavorable aspect of this development is that these somatic-type malignancies do not respond to germ cell–type chemotherapeutic protocols the way that conventional germ cell tumors do.[298]

The rare but well-documented development of clonally related hematologic neoplasms in this context can be viewed pathogenetically as another manifestation of this phenomenon.[299,300] It may take the form of acute leukemia or systemic mast cell disease diagnosed concurrently or within a year of the germ cell tumor and is particularly common in tumors with a yolk sac component.[301] The detection in these hematopoietic elements of i(12p) indicates that these cells are clonally related to the germ cell tumor and are not therapy-induced malignancies arising from the host bone marrow.

Malignant Lymphoma

Malignant lymphoma can present as an anterior, superior, or middle mediastinal mass, in this order of frequency. It represents the most common primary neoplasm of the middle portion of the mediastinum. It may appear in this area as a manifestation of a disseminated process, or it may present as a primary mediastinal disease. The diagnosis can be suspected on the basis of clinical and radiological features and can sometimes be confirmed with fine-needle aspiration and or core needle biopsy, including those obtained using an endobronchial ultrasound-guided transbronchial (EBUS) approach.[302] However, in a substantial subset of cases incisional biopsy using a surgical approach is required for diagnosis and classification.[303] The majority of malignant lymphomas presenting as primary mediastinal neoplasms fall into one of the four categories discussed in the following sections. The general features of these lymphomas are discussed in Chapter 37; only comments pertaining specifically to their mediastinal location will be mentioned here.

Classical Hodgkin Lymphoma

Mediastinal Hodgkin lymphoma can involve primarily the thymus, mediastinal lymph nodes, or both.[304] Most patients are young adults, and there is a predilection for females. The disease may present with local pressure symptoms (dyspnea, cough, chest pain) or be found incidentally in a chest x-ray or CT scan examination. Exceptional

cases of thymic Hodgkin lymphoma have been seen in association with myasthenia gravis[305] and with erythroid hypoplasia.[306] Primary Hodgkin lymphoma of the mediastinum is nearly always of the nodular sclerosis subtype. When affecting the nodes, its gross and microscopic appearance is similar to that seen elsewhere. When involving the thymus, it is usually sharply outlined and sometimes surrounded by a thick capsule not too dissimilar from that of a thymoma. The nodules may be multiple (a very rare event in true thymoma), and residual thymic tissue is usually identified. The consistency is hard, and the cut surface is vaguely or distinctly nodular (Fig. 12.61). It is not uncommon to find within the mass variously sized cysts containing clear or grumous fluid. Occasionally, the entire lesion has a gross appearance indistinguishable from that of a benign thymic cyst[307] resulting from the previously described cystic and proliferative reaction of thymic epithelium to form multilocular thymic cysts.[48]

The low-power appearance may resemble that of true thymoma by virtue of the presence of cellular nodules encircled by fibrous bands. In thymoma, however, the interphase between the fibrous strands and the neoplastic nodules is usually sharper, and the contour of the nodules tends to be angular rather than round (Fig. 12.62).

The infiltrate of Hodgkin lymphoma tends to be polymorphic, with lymphocytes, plasma cells, eosinophils, histiocytes, and the elements that provide the diagnosis, that is, Reed–Sternberg cells, their mononuclear variants, and lacunar cells (Fig. 12.63). These are often seen in intimate association with epithelial-lined cysts, Hassall corpuscles, and isolated thymic epithelial cells (Fig. 12.64). This feature has led in the distant past to a misinterpretation of the lesion as a "granulomatous" thymoma.[308] The fact that the thymus is the only extranodal site in which Hodgkin lymphoma occurs frequently and the intimate relationship that the Reed–Sternberg cells and other lymphoid elements have with the thymic epithelium suggest a pathogenetic mechanism that ought to be explored. Immunohistochemical stains for CD15 or CD30 and keratin sharply delineate the lymphoid neoplastic and epithelial reactive components, respectively. Another confusing pattern results from the arrangement of these cells in compact and rather monomorphic clusters, often surrounding foci of necrosis ("syncytial type" of Hodgkin lymphoma, see Chapter 37). These foci may simulate non-Hodgkin lymphoma, germ cell tumor, and carcinoma. Conversely, some foci—especially at the periphery—may show only a nonspecific chronic inflammatory infiltrate and fibrosis and be misdiagnosed as sclerosing mediastinitis. In some instances, the disease is accompanied by the formation of lymphoid follicles with prominent germinal centers, leading to a

mistaken diagnosis of Castleman disease. In cases of this sort, if there is a strong radiographic suspicion of malignancy, a new biopsy from a more centrally located area should be requested. An important differential diagnostic point about the fibrosis is that, in addition to wide bands, it also manifests itself as a fine network that entraps small groups of cells or even individual cells, this resulting in a blurring of the boundaries of the nodules. This is not a feature of thymoma, although it can also be seen in large cell lymphoma.

The prognosis of mediastinal Hodgkin lymphoma is similar whether the neoplasm involves the thymus, the mediastinal lymph nodes, or both. The disease seldom spreads subdiaphragmatically in the absence of supraclavicular lymph node involvement.

The primary treatment is usually combination chemotherapy and radiotherapy, although irradiation alone or chemotherapy alone is adopted for occasional cases.[309] Sometimes, the aforementioned multilocular thymic cystic formations develop after the therapy and may simulate tumor relapse.[310] Thymic hyperplasia is another complication of treatment that may simulate recurrent disease.[311]

Lymphoblastic Lymphoma

Lymphoblastic lymphoma occurs primarily in children and young adults in whom it has a particular predilection for the thymic region.[312] It is usually of immature (precursor) T-cell type, but a certain degree of phenotypic heterogeneity occurs including cases of precursor B-cell and natural killer cell lineage.[313,314] Its typical presentation includes symptoms resulting from compression of mediastinal structures in an adolescent, sometimes requiring emergency radiation therapy. Males are more commonly affected than females. The disease is usually restricted to the supradiaphragmatic region, with frequent involvement of cervical, supraclavicular, and axillary nodes but sparing of peripheral blood or bone marrow (but see later). Grossly, the tumor is generally solid, soft, and nonencapsulated. Some preservation of the thymic shape can be appreciated in early cases. Microscopically, the infiltrate involves the thymic parenchyma and can be confused with a lymphocyte-rich (type B1) thymoma. However, the lymphocytes are atypical, with a very fine chromatin pattern, frequent nuclear convolutions (hence the older term *convoluted cell lymphoma*), numerous mitotic figures, and equally numerous necrotic cells (Fig. 12.65). Their "blastic" appearance is indistinguishable from that seen in the cells of acute lymphoblastic leukemia, to the point that a distinction between the two processes is arbitrary and mainly based on the sites of involvement. There is usually extension into the perithymic fat, and invasion of blood vessel walls is frequent (Fig. 12.66). Residual thymic lobules and Hassall corpuscles that have been expanded and infiltrated by the lymphoma cells should not be misinterpreted as evidence of thymoma (Fig. 12.67). It also should be remembered that true thymomas in children are exceptional. Fibrosis and formation of multilocular thymic cysts can be seen in thymic lymphoblastic lymphoma, but both phenomena are distinctly less common than in Hodgkin lymphoma. Occasionally, there is a scattering of eosinophils, and we have seen a case accompanied by focal granulomatous reaction. Necrosis can be very extensive, whether spontaneous or induced by radiation or steroid therapy, to the extent that the entire biopsy may show only necrotic lymphoma tissue. Under these circumstances, if the clinical and radiological features are compatible, the possibility of lymphoblastic lymphoma should be suspected, and a new biopsy requested.

A few cases of lymphoblastic lymphoma apparently developing from the lymphocytic component of lymphocyte-rich (type B1) thymomas have been reported.[315]

Primary Mediastinal (Thymic) Large B-Cell Lymphoma

Primary mediastinal (thymic) large B-cell lymphoma is a clinically and biologically distinct form of diffuse large B-cell lymphoma

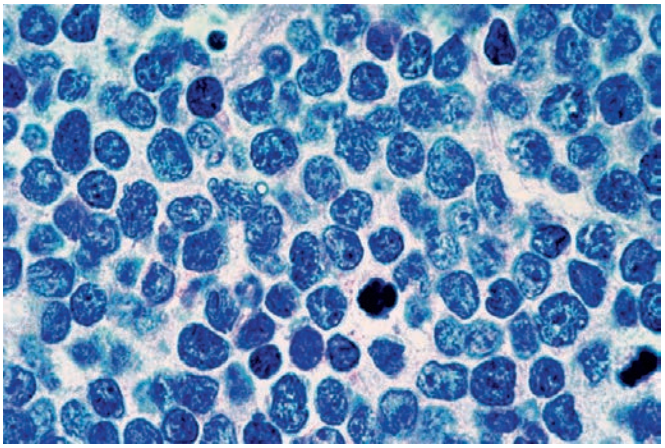

Figure 12.65 High-power view of lymphoblastic lymphoma of thymus, showing delicate convolutions of the nuclear membrane of the tumor cells.

of thymic origin that presents as bulky locally invasive anterior mediastinal disease without bone marrow involvement and nodal disease limited to contiguous cervical and intrathoracic sites. Most patients are young adult females, and presentation with superior vena cava syndrome is frequent.[316] The tumor has grossly invasive features: extension into pericardium, pleura, lung, sternum, and chest wall is common.[317] The consistency is generally firm, and there are frequent foci of necrosis (Fig. 12.68). Microscopically, a sometimes striking feature is the presence of wide bands of fibrosis, which results in compartmentalization of the tumor cells (Fig. 12.69)

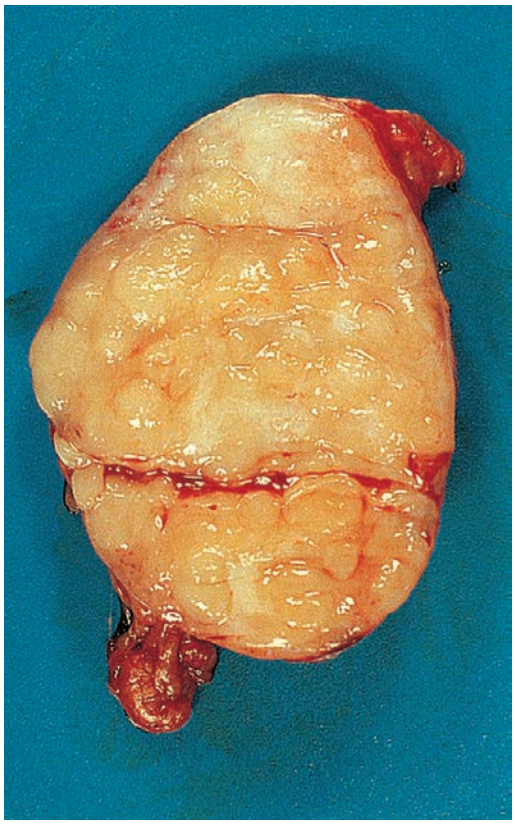

Figure 12.68 Gross Appearance of Large Cell Lymphoma With Sclerosis of the Thymus. There is distinct nodularity induced by the fibrous strands. This appearance is not too dissimilar from that of nodular sclerosis Hodgkin lymphoma.

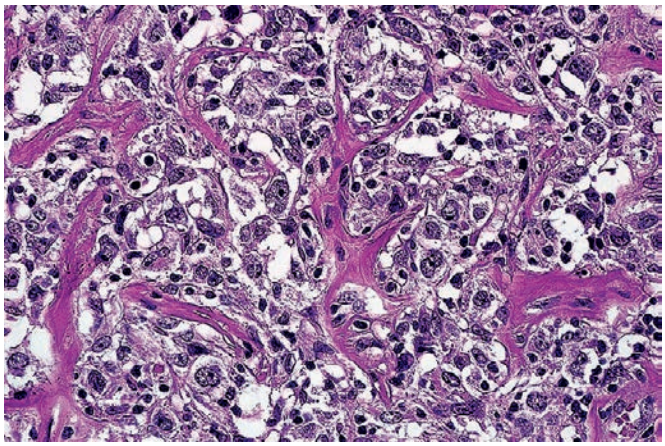

Figure 12.69 Primary mediastinal (thymic) large B-cell lymphoma with extensive fibrosis and nodularity.

and a microscopic appearance that simulates an epithelial, germ cell, or neuroendocrine neoplasm. Other reasons for the frequent misdiagnosis of this tumor include the following: perivascular collections of lymphocytes (which may be misinterpreted as the perivascular spaces of thymoma) (Fig. 12.70); artifactual clearing of the cytoplasm induced by formalin fixation (not present in B5 or Zenker's fixed material) simulating seminoma (Fig. 12.71); presence of a large number of reactive T cells; rosette-like formations mimicking thymoma and thymic carcinoma[318]; and entrapment of thymic epithelium.[319]

A diagnosis of large cell lymphoma should be favored in the presence of tumor cells with large, vesicular, irregularly shaped nuclei (indented, kidney-shaped, polylobated); entrapment of intrathymic and perithymic fat; invasion of blood vessel wall, pleura, or lung; and the fact that the fibrosis is manifested not only in the form of wide hyaline bands but also as a fine network that entraps individual cells.[317,320] In some cases, the cellular pleomorphism is extreme.[321] Exceptionally, the tumor cells show tropism for germinal centers. The diagnosis may also be suspected on the basis of fine-needle aspiration material. Immunohistochemical reactivity for CD45 and B-cell antigens such as CD20 is invariably found reflecting the B-cell nature of this tumor. Close to 70% of the cases also express CD30, which is often variable in its intensity and distribution.[322] A

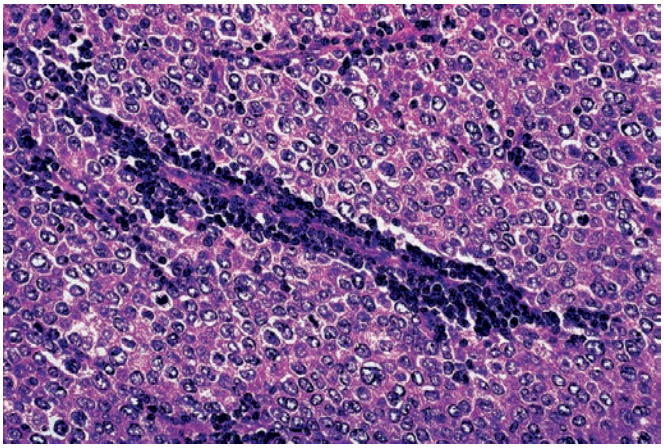

Figure 12.70 Perivascular cuffing by small non-neoplastic lymphocytes in primary mediastinal (thymic) large B-cell lymphoma. These formations should not be confused with the perivascular spaces of thymoma.

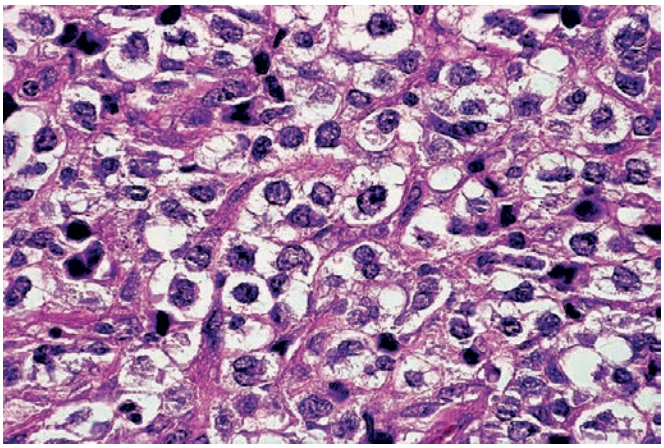

Figure 12.71 Artifactual cytoplasmic clearing in a case of primary mediastinal (thymic) large B-cell lymphoma which has been formalin fixed.

diagnostically helpful marker is CD23, which is expressed in 70% of cases of mediastinal large B-cell lymphoma, but in less than 15% of large B-cell lymphomas of other sites.[323] They also variably express BCL6 and CD10, indicating phenotypic overlap with large B-cell lymphomas derived from germinal center cells.[324] The peculiar morphologic, immunohistochemical, and molecular attributes of primary mediastinal (thymic) large B-cell lymphoma are significantly different from those of large B-cell lymphoma at other sites.[325] It has been postulated that it represents a distinct type of lymphoma, possibly arising from a subset of intrathymic lymphoid cells ("asteroid B-cells"), and that MAL (an integral membrane protein located in glycolipid-enriched membrane microdomains, called lipid rafts) is a distinct molecular marker for this tumor.[326] In contrast to other diffuse large B-cell lymphomas, primary mediastinal (thymic) large B-cell lymphoma rarely exhibits *BCL2* or *BCL6* gene rearrangement.[327] Common genetic changes are gains at 9p24 (including *JAK2*, *PDL1*, and *PDL2* loci) and 2p15 (including *REL* and *BCL11A* loci).[328–330] Inactivating mutations in *SOCS1*, an inhibitor of JAK/STAT signaling, occur in about half of the cases and contribute to activation of STAT.[331] In addition, the nuclear factor kappa B (NFκB) pathway is constitutively activated, but the pathogenetic mechanism remains unclear.[332]

It should be kept in mind that in young females with a clinically and microscopically malignant mediastinal tumor in which the differential diagnosis is among malignant thymoma, seminoma (germinoma), and primary mediastinal (thymic) large B-cell lymphoma, the correct diagnosis will be the latter entity in the large majority of cases.

Primary mediastinal (thymic) large B-cell lymphoma is usually restricted to the intrathoracic region at the time of initial presentation. An excellent response to radiation therapy and combination chemotherapy including rituximab is the rule,[316] but in some instances the tumor recurs within the chest and spreads to other sites, including peripheral lymph nodes and central nervous system.[333] We have been impressed by the high frequency with which the kidneys have been found to be involved in recurrent disease,[317] raising the possibility that some "homing" mechanism analogous to that hypothesized for mucosa-associated lymphoid tissue (MALT) lymphoma is involved.

Marginal Zone B-Cell Lymphoma

In recent years there have been increasingly frequent reports of cases of marginal zone B-cell lymphomas involving the thymus, particularly from Asian countries.[334] A marked predilection for females has been noted, and many of the patients had a history of Sjögren disease[335] or rheumatoid arthritis.[336] Some of the cases have been associated with lymph node[337] or gastric involvement.[338]

Microscopically, the tumors are predominantly composed of small lymphocytes with a variable admixture of monocytoid cells and plasma cells (Fig. 12.72). Prominent lymphoepithelial lesions are present, and there may be cystic formations.[334] Indeed, the presence in otherwise typical thymic lymphoid hyperplasia (of the type seen in association with collagen–vascular diseases) of sheets of centrocyte-like B cells disrupting the cytokeratin-positive medullary epithelial network should suggest the possibility of lymphoma, even if molecular analysis may be necessary to confirm the diagnosis.[339]

Notably, most cases of MALT-type thymic lymphoma express an IgA phenotype (in striking contrast with the IgM phenotype observed with this tumor type at other sites) and lack the *API2–MALT1* gene fusion and IgH-associated abnormalities described in MALT-type lymphomas elsewhere.[334] Instead they frequently demonstrate a pattern of chromosomal abnormalities, including trisomy 3, that is characteristic of autoimmune-associated MALT lymphomas arising in salivary gland and thyroid.[340] The clinical course is usually indolent; however, as with marginal zone B-cell lymphomas at other sites, there may be transformation to a large cell lymphoma.[341]

Other Hematolymphoid Conditions

Composite lymphomas of various types have been observed in this location. A type that we have seen with inordinately high frequency is that comprised by large B-cell lymphoma with sclerosis and nodular sclerosis Hodgkin lymphoma, each component exhibiting its distinctive phenotype. The relationship between these two lymphoma types may manifest itself synchronously—either as two distinct zones within the same mass or as a mass having transitional features throughout (so-called mediastinal gray zone lymphoma, now termed *B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma*)—or sequentially, that is, as a tumor type appearing as a recurrence of the other.[342,343] The frequency of the association, the blending of the two components one sometimes observes, and the several clinicopathologic features they share (predilection for young females, tendency to induce sclerosis) suggest that these two processes are histogenetically and pathogenetically related. Support for this hypothesis comes from a molecular study carried out in one such composite case, in which the results suggested an origin of the tumor from a common precursor in which a secondary molecular event gave rise to two different clonally related lymphomas.[344] Furthermore, the gene expression profile of mediastinal large B-cell lymphoma shows greater similarities with that of classical Hodgkin lymphoma than conventional large B-cell lymphoma, including downregulation of the B-cell receptor signaling pathway and high expression of cytokine pathway components, TNF family members, and extracellular matrix elements.[325,345] These findings can help to explain the development of this form of composite lymphoma.

Anaplastic large cell lymphoma can present as a primary mediastinal mass.[346,347] The main differential diagnostic criteria are the same as for lymph nodes and other sites (see Chapter 37).

Myeloid sarcoma (chloroma, granulocytic sarcoma, extramedullary myeloid tumor) can also present as a mediastinal mass and be mistaken for malignant lymphoma on microscopic grounds.[348,349] As with myeloid sarcomas in other sites (see Chapter 39), it may present as an isolated finding or with associated leukemia.[350]

Plasmacytoma has been reported as a mediastinal mass, preceding the onset of multiple myeloma.[351]

Castleman disease (giant lymph node hyperplasia) has a special predilection for the mediastinum and is discussed in greater detail in Chapter 37. Before its recognition as an entity, it was often confused with thymoma, in part because the hyalinized germinal centers that constitute the hallmark of the hyaline vascular form of this disease were misinterpreted as Hassall corpuscles.[352] It usually involves mediastinal nodes, but exceptionally it may be located within the thymus.[79] Surgical removal of a solitary mass of the hyaline vascular type of this disease (which is by far the most common) is curative.[353]

Extramedullary hematopoiesis may present as a large, solitary mediastinal mass, usually located along the paravertebral column. The primary disease in most patients is hereditary spherocytosis or thalassemia; sickle cell disease has also been reported.[354,355] *Myelolipoma* is a microscopically similar process but it usually lacks evidence of a background hematologic disorder.[356]

Follicular dendritic cell tumor can present as a primary mediastinal mass arising from either lymph nodes or thymus, and may arise in a background of Castleman disease[357] (Fig. 12.73). It is listed in this section because of the functional relationship of the cells of this tumor with the lymphoid system, but its behavior and response to therapy are more in keeping with a sarcoma. Remarkably, a case has been reported associated with myasthenia gravis.[358] The main differential diagnosis because of the location is with type B thymoma. This can be very difficult at the H&E level, but their immunohistochemical profiles are very different.[357]

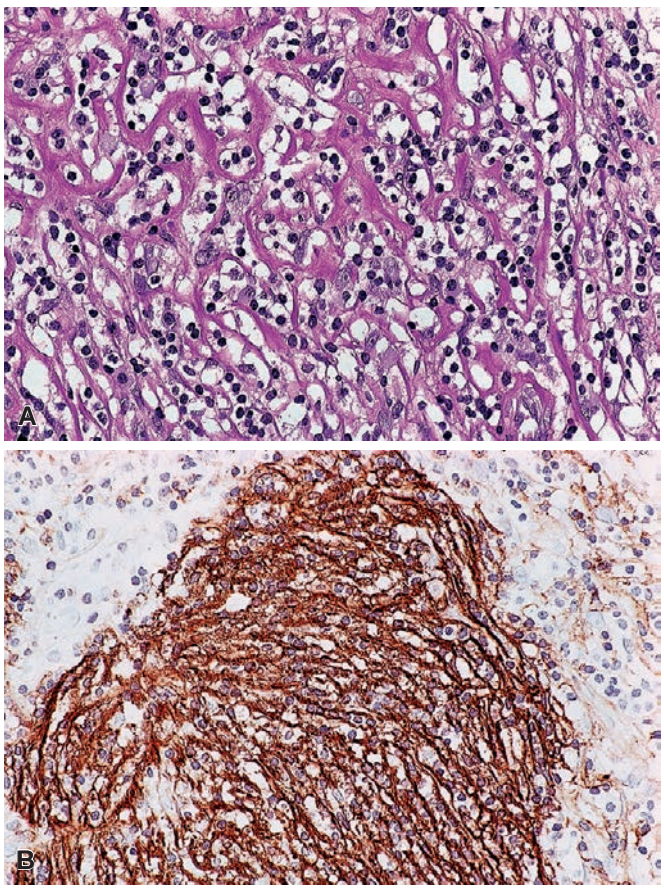

Figure 12.73 **A** and **B**, H&E appearance and CD21 immunoreactivity of dendritic follicular cell tumor of mediastinum. The biphasic pattern resulting from the presence of numerous non-neoplastic lymphocytes can elicit a mistaken diagnosis of thymoma.

Neurogenic Tumors

Neurogenic tumors make up a high proportion of the posterior mediastinal neoplasms, in both adults and children, but they can also occur in other mediastinal compartments. The two major categories are tumors of the *sympathetic nervous system* and tumors of *peripheral nerve sheath*. A definite relationship between age and the relative incidence of these tumors exists.[359] In a series of 160 cases, the majority of the tumors occurring in patients younger than the age of 10 years belonged to the sympathetic nervous system category, and all of those in patients younger than 1 year of age were neuroblastomas or ganglioneuroblastomas.[360] Most ganglioneuromas, paragangliomas, and tumors of nerve sheath origin were seen after the age of 20 years. Radiographically, most tumors of the sympathetic nervous system have an elongated tapered appearance, whereas benign tumors of nerve sheath origin are round and well circumscribed.

Tumors of Sympathetic Nervous System

The general features of these tumors are discussed elsewhere in this text. The main difference between the mediastinal and retroperitoneal (particularly adrenal) tumors is the greater degree of differentiation seen in the former. Thus **neuroblastoma** is rather unusual in this location, appearing as an infiltrative mass with areas of necrosis and calcification, usually high in the posterior mediastinum and seen almost exclusively in children, although notable exceptions occur.[361] Most of the mediastinal tumors of this group in children are examples of **ganglioneuroblastoma**, a tumor that has an intermediate degree of differentiation and that is related to differentiating neuroblastoma and immature ganglioneuroma.[362] Grossly, it tends to be better circumscribed than neuroblastoma and is sometimes surrounded by a well-formed capsule. It should be mentioned that some neuroblastomas and ganglioneuroblastomas are located in the anterosuperior mediastinum (in close relationship with the thymus) rather than in the usual posterior location.[363] Curiously, some of these cases have been associated with inappropriate secretion of antidiuretic hormone (Fig. 12.74).[364] Others have arisen from a mediastinal germ cell tumor[365]; ganglioneuroblastomatous differentiation has also been reported in a thymoma.[366]

Ganglioneuroma occurs in older children and in adults and is the most common of the three tumors.[359] Grossly, it forms a smooth, well-encapsulated mass, usually in the posterior portion of the

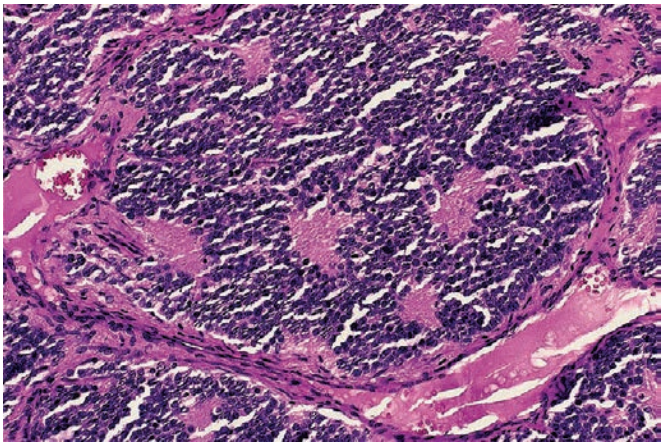

Figure 12.74 Neuroblastoma of mediastinum with prominent rosettes in an adult patient. These tumors can be associated with inadequate secretion of ADH.

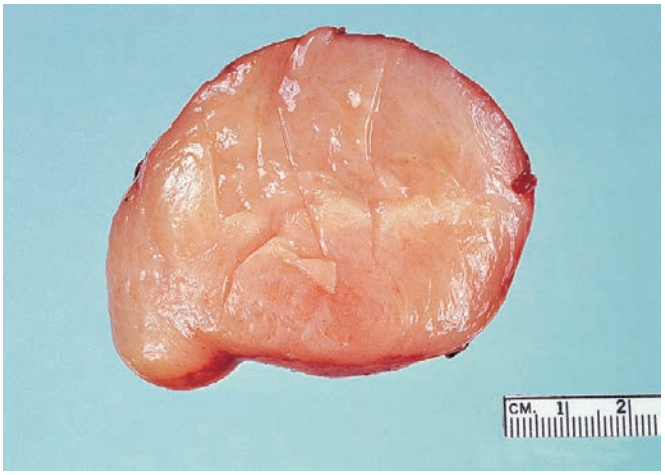

Figure 12.75 Mediastinal Ganglioneuroma. The tumor is solid, yellowish, and homogeneous.

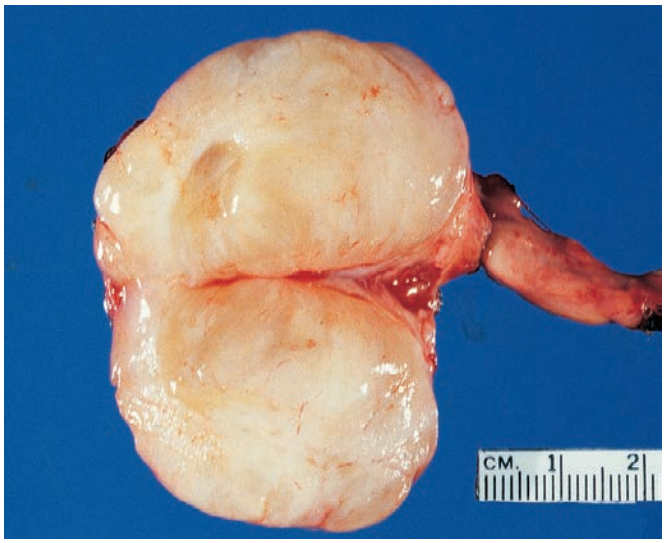

Figure 12.76 Mediastinal Neurofibroma. The tumor is attached to a large nerve trunk.

mediastinum. The consistency is soft, and the cut surface is yellowish gray; it may contain cystic areas and fatty degeneration, but fresh necrosis is generally absent (Fig. 12.75). Microscopically, an admixture of mature ganglion cells and spindle cells, which could be viewed either as Schwann cells or as satellite cells, is present. The ganglion cells may have several nuclei and are often arranged in clusters. Focal collections of lymphocytes are often present; they should not be confused with the immature cells of ganglioneuroblastoma. These tumors can be multiple and can occur in different locations, with various degrees of differentiation.

The survival rate in patients with tumors of the sympathetic nervous system is directly related to the degree of differentiation of the tumor. As already stated, thoracic neoplasms tend to be better differentiated than their retroperitoneal (particularly adrenal) counterparts; this probably explains why as a group they are associated with a better prognosis.[367,368] Relapses in the central nervous system have occurred in some cases of intrathoracic neuroblastoma.[369] Adequate excision effects cure in all patients with ganglioneuromas but may be less impactful in intrathoracic cases.[368] The prognosis in patients with ganglioneuroblastomas that contain both elements is somewhat unpredictable, but cure is achieved in most instances.[362] As expected, the prognosis in neuroblastoma is the least favorable for the entire group.

Tumors of Peripheral Nerves

The three major tumors in this category are schwannoma, neurofibroma, and MPNST (Fig. 12.76).[360,370] The general features of these tumors are discussed in Chapter 41. It is interesting to note that whereas neurofibroma in most other locations is a nonencapsulated tumor, in the mediastinum it is often surrounded by a complete fibrous capsule, perhaps because of the large size that it can reach at this site. Therefore the presence of encapsulation cannot be used as a distinguishing feature between the two types of benign peripheral nerve tumor. Another feature common to these neoplasms, perhaps again the result of their sometimes unduly large size, is the high frequency of regressive change, such as fatty degeneration, hemorrhage, and cystic formation. Some can become completely cystic, and their recognition may be difficult. Schwannomas exhibiting prominent cystic and other regressive changes have been described as "ancient," under the assumption that they have been present for a very long time. Indeed, most benign peripheral nerve sheath tumors are asymptomatic and are discovered incidentally on radiological examinations. Some schwannomas can be very cellular, somewhat pleomorphic, and mitotically active and thus be confused with sarcoma.[371,372] The prognosis for both schwannoma (including its cellular variant) and neurofibroma is excellent, excision being curative in nearly every instance.

MPNST of mediastinum may arise de novo or, more commonly, in the setting of neurofibromatosis type 1.[373] In the initial stages of the malignant transformation of a neurofibroma, the change may be barely perceptible microscopically, the only suggestion being some slight increase in cellularity. With outspoken malignant change, the tumor cells become bizarre, and it may then be impossible to recognize the malignant tumor as originating from a preexisting neurofibroma. In these instances, the presence of neurofibromatosis in a previous biopsy, or the presence of other neurofibromas may suggest the diagnosis.

Some mediastinal MPNSTs have areas of glandular differentiation or rhabdomyoblastic features (so-called "triton tumor"). The prognosis, which is generally poor, seems to be related to resection status, tumor size, and tumor grade.

Other Neurogenic Tumors

Two types of central nervous system-related neoplasm that can exceptionally present as primary (usually posterior) mediastinal neoplasms are **ependymoma**[374] and **meningioma**[375]; the latter, which may have its origin in the stellate ganglion, is closely related to and sometimes indistinguishable from perineurioma.

Tumors of Paraganglia

Most mediastinal paragangliomas occur in association with the aorticopulmonary paraganglia and therefore occur in the anterosuperior mediastinum, close to the base of the heart (Fig. 12.77). Others arise from mediastinal aorticosympathetic paraganglia and occur posteriorly, along the costovertebral sulcus. Their morphologic appearance is identical to paragangliomas in other locations, such as the carotid body (see Chapter 29). A few have been pigmented (melanotic).[376] The majority of these tumors are nonfunctioning. Some, however (particularly when related to the sympathetic system), can result in hypertension and are sometimes referred to as extra-adrenal pheochromocytomas. However, it is now agreed to reserve

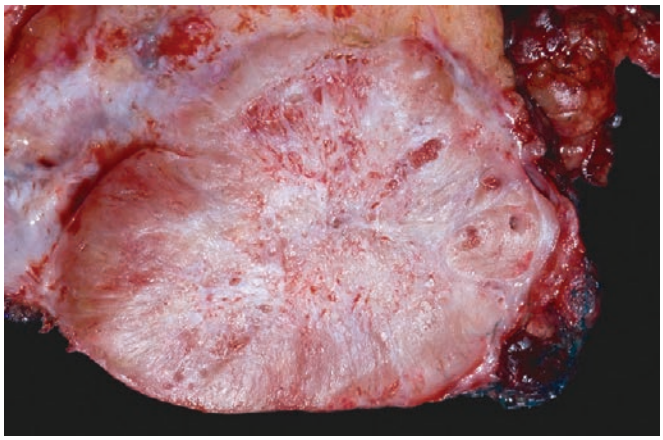

Figure 12.77 Mediastinal Paraganglioma. The well-circumscribed tumor has a characteristic solid, yellow tan cut surface with a vaguely lobular architecture but without the connective tissue septa typical of thymoma. (Courtesy of Dr. J. Carvalho, Minneapolis, MN)

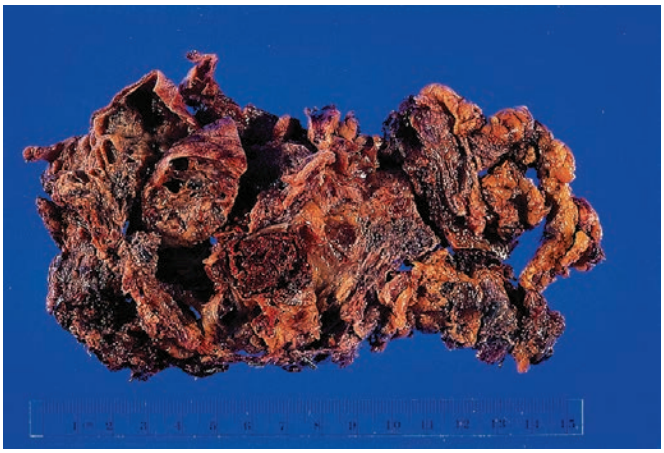

Figure 12.78 Hemangioma of Mediastinum. The tumor is formed of large tortuous vessels.

the designation of pheochromocytomas for paragangliomas located in the adrenal medulla, whether they are functioning or not.

Some mediastinal paragangliomas have occurred as a component of the Carney triad, together with pulmonary hamartomas and malignant gastrointestinal stromal tumors (GISTs).[377]

Traditionally, mediastinal paragangliomas have been regarded as generally benign in nature. However, a critical long-term follow-up study of 35 reported cases revealed that the tumor had behaved in an aggressive fashion in 16 (46%), resulting in significant morbidity and sometimes in death.[378] Subsequent experience with this tumor has confirmed these findings.[379]

Mesenchymal Tumors

The list of microscopic types of neoplasms arising in mediastinal soft tissues outside of the thymus is long despite their rarity.[380]

Lipoma is one of the most common benign mesenchymal neoplasms of the mediastinum. It is often very large and located just above the diaphragm. Occasionally, it extends into both pleural cavities, making complete removal difficult. The absence of thymic tissue separates mediastinal lipoma from thymolipoma. The differential diagnosis also includes *lipomatosis*, a diffuse accumulation of mature adipose tissue that may occur in association with obesity, Cushing disease, or steroid therapy,[381] and which can lead to a "sabre sheath" tracheal deformity radiographically.

Other benign adipose tissue tumors of the mediastinum include *lipoblastoma* and *lipoblastomatosis* of infancy,[382] *hibernoma*,[383] *angiolipoma*,[384] and *angiomyolipoma*.[385]

Lymphangioma is another common mediastinal neoplasm. Most cases are seen in the anterosuperior mediastinum of children, often in continuity with a cervical component.[386] *Lymphangiomyoma* and *lymphangiomyomatosis* occur exclusively in females, the distinction among the two depending on their circumscribed versus infiltrative pattern of growth, respectively; they are included in the family of PEComas and are discussed elsewhere (see Chapters 10 and 41).

Hemangioma in adults is usually of the cavernous variety (Fig. 12.78).[387] Microscopically, it is composed of dilated vessels lined by attenuated endothelium, separated by fine septa. Foci of thrombosis, calcification, and cholesterol granulomas may be present. Excision is usually curative. In children, the hemangiomas may have a very cellular appearance (benign hemangioendotheliomas).[388] **Glomus tumors** have been described in the mediastinum, some of them having atypical features.[389] **Hemangiopericytomas** have been described in this location, but most anterosuperior mediastinal tumors with a hemangiopericytoma-like pattern are either well-vascularized thymomas or cellular solitary fibrous tumors (see following section). Another vascular tumor that can occur in the mediastinum is **epithelioid hemangioendothelioma**[390]; curiously, some of these tumors have been accompanied by osteoclast-like multinucleated giant cells, a feature almost never seen in epithelioid hemangioendotheliomas at other sites. **Angiosarcoma** also occurs[391]; in such cases, the possibility of the lesion having arisen against a background of a germ cell tumor should be investigated by thorough sampling.

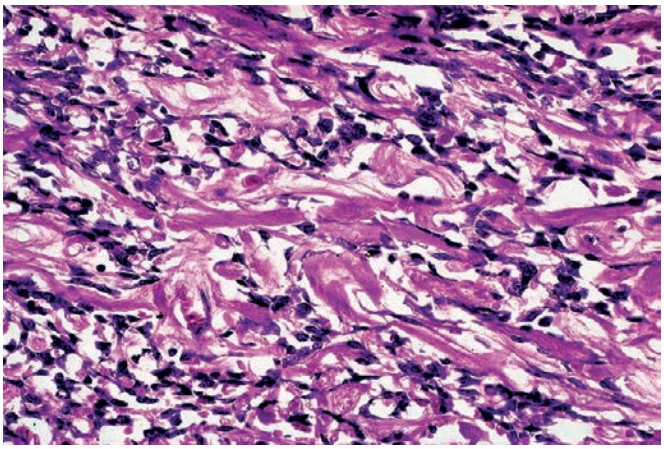

Figure 12.79 Solitary Fibrous Tumor of Mediastinum. The alternation of hypercellular and hypocellular areas is typical of this entity.

Leiomyoma, sometimes arising from vascular trunks, has been sporadically reported.[392]

Rhabdomyoma has been seen not only within the thymus but also independently arising in mediastinal soft tissues.[393]

Solitary fibrous tumor of the mediastinum is the mediastinal equivalent of solitary fibrous tumor of the pleura.[394] It is possible that some of these tumors grow into the mediastinum from the medial pleura, but we think that most originate from the mediastinal (including thymic) stroma. Their microscopic appearance and immunohistochemical profile are similar to those of their pleural counterpart (Fig. 12.79), but a higher proportion of the reported cases have run an aggressive clinical course.

Figure 12.80 Gross appearance of an atypical lipomatous tumor (well-differentiated liposarcoma) of mediastinum.

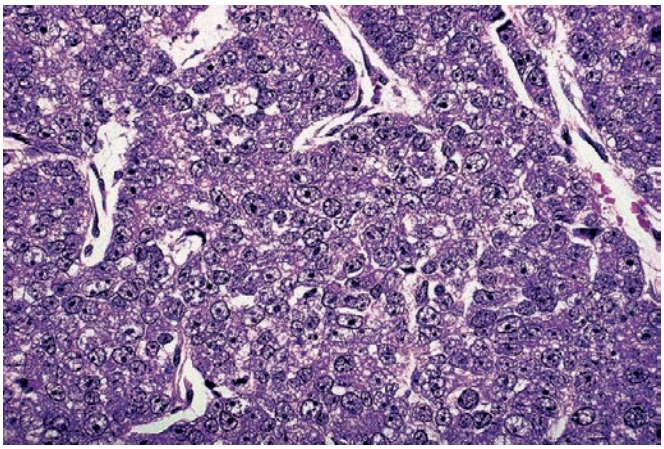

Figure 12.82 **Mediastinal Metastasis of Prostatic Adenocarcinoma.** This tumor was initially misdiagnosed as a thymic carcinoma.

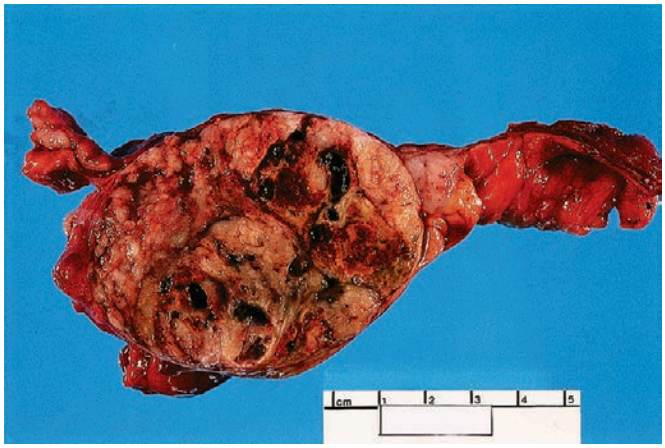

Figure 12.81 Gross appearance of a primary synovial sarcoma of mediastinum.

Liposarcoma predominates among the malignant mesenchymal neoplasms (Fig. 12.80).[262] Sometimes it is seen in conjunction with liposarcoma of thigh or retroperitoneum as a manifestation of multicentric disease. As referenced previously in this chapter, some mediastinal liposarcomas containing thymic tissue can be viewed as thymic stromal sarcomas with a liposarcomatous component and as possible counterparts of thymolipomas (i.e. as thymoliposarcomas). Most mediastinal liposarcomas are well-differentiated tumors, sometimes accompanied by areas of dedifferentiation.

Synovial sarcoma can present as a primary mediastinal neoplasm, its morphologic appearance being the same as that of tumors occurring in the extremities (Fig. 12.81).[395] Biphasic, monophasic, and poorly differentiated types occur. The most important differential diagnosis is with SETTLE (see previous section in this chapter).[227]

Other malignant mesenchymal tumors that have been observed in the mediastinum include **low-grade fibromyxoid sarcoma**,[396] **leiomyosarcoma**,[397] **rhabdomyosarcoma** (unassociated with germ cell, thymic, or peripheral nerve elements),[398] **chondrosarcoma**[399] (including the mesenchymal variety[400]), **alveolar soft part sarcoma**,[401] **giant cell tumor of soft parts**,[402] **malignant mesenchymoma**, and so-called **malignant fibrous histiocytoma** (undifferentiated pleomorphic sarcoma).[403]

Metastatic Tumors

Some tumors metastatic to the mediastinum can mimic clinically and radiographically a primary mediastinal neoplasm. Small cell undifferentiated carcinoma of the lung is the most notorious example, often appearing as a huge mediastinal mass in the presence of a small, radiographically undetectable bronchial lesion. Other types of lung carcinoma may produce a similar picture, by either direct extension or nodal metastases.

Direct mediastinal extension can also occur with tumors of the esophagus, pleura, chest wall, vertebra, or trachea. Other tumors that can metastasize to the mediastinum and be confused with primary neoplasms—sometimes even at the microscopic level—are carcinomas of the breast, thyroid, nasopharynx, larynx, kidney, prostate, and ovary (which may simulate multilocular thymic cyst[404]); testicular germ cell tumors; and malignant melanoma.[405,406] Two such tumor types that we have seen initially misinterpreted as thymic carcinomas were metastatic prostatic carcinoma and metastatic malignant melanoma (Fig. 12.82). Since most of these tumors are located, at least initially, in mediastinal lymph nodes, they are usually centered in the middle mediastinum (where most mediastinal lymph nodes are situated), and they may exhibit a residual nodal component at their periphery.

Normal Anatomy of the Esophagus

The esophagus is a muscular tubular structure that measures approximately 25 cm in adult individuals and extends from the cricopharyngeal muscle, which forms the upper esophageal sphincter (at the level of the sixth cervical vertebra, about 15–18 cm from the incisors), to the lower esophageal sphincter, which forms the gastroesophageal junction (GEJ; several centimeters below the diaphragm). The lower esophageal sphincter is usually described as being 40 cm from the incisors, but this is subject to considerable individual variations.[1]

The esophagus is lined by stratified nonkeratinized squamous mucosa. The basal layer is one to four cells thick and does not exceed 15% of the total epithelial thickness except in the most distal esophagus.[2] Melanocytes and neuroendocrine cells may be found in this layer. The lamina propria is composed of loose connective tissue that, in the distal portion of the organ, contains mucous glands, referred to as (esophageal) cardiac glands. The esophageal muscularis mucosae is rather thick compared with other portions of the gastrointestinal tract, especially in the distal portion.

The submucosa contains mucous glands distributed throughout the esophagus; their ducts, which open into the esophageal lumen, sometimes are found to be cystically dilated and surrounded by lymphoid collections. The esophageal muscularis propria consists of an admixture of striated and smooth muscle in the upper quarter and exclusively smooth muscle in the rest of the organ.[3] The esophagus lacks a serosal layer, except for its most distal portion. The autonomic nervous plexuses are represented by the Meissner plexus in the submucosa (very sparse) and the Auerbach (myenteric) plexus between the two layers of muscularis propria.

A perennial area of contention is the site and definition of the *GEJ*. The GEJ is the point at which the tubular esophagus flares to the saccular stomach and is recognized endoscopically by the proximal margin of the gastric folds.[4,5] Thus defined, the GEJ does not necessarily correspond to the squamocolumnar junction (SCJ) or "Z line," which is the irregular meeting point of the squamous and glandular epithelia. On the contrary, in many individuals the SCJ will be found *proximally displaced* above the GEJ.

The upper third of the esophagus drains into the cervical nodes, the middle third into the paraesophageal and paratracheal mediastinal nodes, and the lower third into the nodes around the aorta and celiac axis.[6]

Atresia and Related Anomalies

The esophagus of a 3-week-old embryo is an annular constriction between the pharynx and stomach. With growth of the lung beds and elongation of the neck, it becomes tubular. At first, the cephalad portions of the esophagus and trachea form a single channel. Later, a septum grows in and separates them.

Five major types of tracheoesophageal anomalies have been described as a result of failures in this process (Fig. 13.1). The most common, referred to as *type C*, is esophageal atresia with a fistula

Abstract

The esophagus is one of the most common sites of endoscopic mucosal biopsy in the gastrointestinal tract. Most of these biopsies are performed to exclude esophagitis (usually secondary to gastroesophageal reflux disease) or to document the presence or absence of Barrett esophagus, with or without dysplasia. Other forms of infectious esophagitis include esophagitis secondary to *Candida* spp., cytomegalovirus, or herpes simplex virus. The esophagus is also the site of glandular and squamous dysplastic processes that predispose to adenocarcinoma and squamous cell carcinoma, respectively.

squamous cell carcinoma

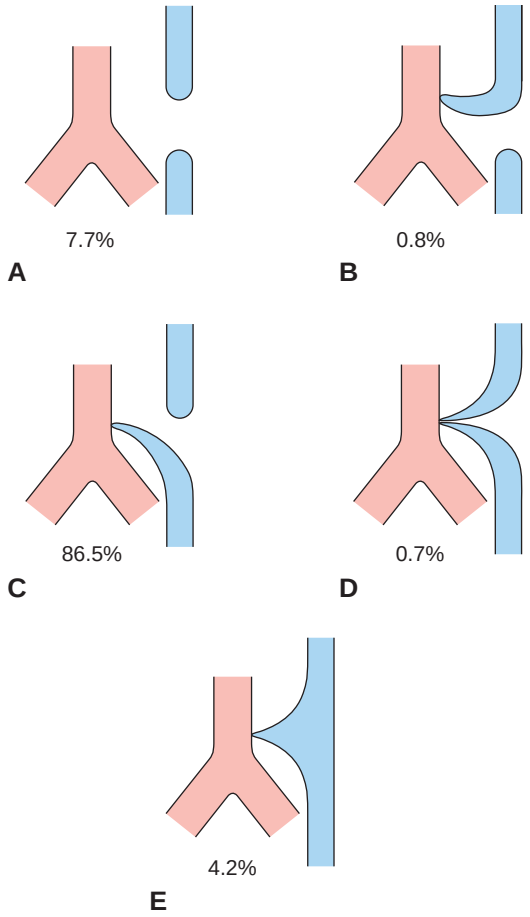

Figure 13.1 Types of tracheoesophageal anomalies and their relative frequencies. (Adapted from Holder TM, Ashcraft KW. Esophageal atresia and tracheoesophageal fistula. *Ann Thorac Surg*. 1970;9:445–467.)

between the lower portion of the esophagus and the respiratory tree.[7] In this type, the hypertrophied and dilated upper portion of the esophagus ends blindly at a variable distance below the larynx, whereas the lower portion communicates with the trachea (usually about 0.5 cm above the bifurcation) or the right mainstem bronchus. Striated muscle is present in the upper portion of the esophagus but not in the lower, which instead may contain cartilaginous rings near its fistulous end. Tracheomalacia, abnormalities of the Auerbach plexus, and cardiovascular anomalies can be seen in association with tracheoesophageal fistula.[8] There also can be defects of the esophagus alone, such as congenital narrowing, stenosis, or an occluding diaphragm of mucous membrane. Successful surgical repair can be accomplished for most of these abnormalities.[9] Survival rates of over 90% can be expected in esophageal atresia with tracheo/esophageal fistula.[10] The treatment of esophageal atresia without fistula remains particularly challenging.[11]

Heterotopia

Heterotopic gastric mucosa can occur at any point in the esophagus but is most common in the postcricoid region, within the first few centimeters of the esophagus.[12] It has been detected in 1%–4% of patients who undergo esophagoscopic examination as a circular, flat, orange to red area, often referred to as the "(*cervical*) *inlet patch*."[13] It is usually asymptomatic but may produce dysphagia and simulate a malignant neoplasm clinically and radiographically.[14]

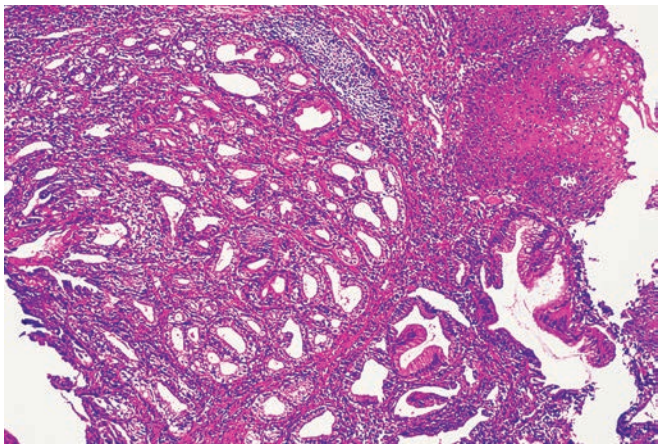

Figure 13.2 Heterotopic gastric mucosa in the esophagus (cervical inlet patch).

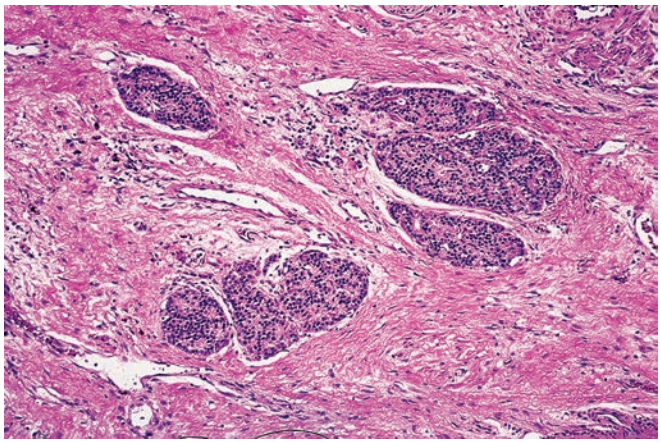

Figure 13.3 Heterotopic pancreas at the gastroesophageal junction, mainly represented by islets of Langerhans.

Grossly, the surface has an appearance similar to that of normal gastric mucosa. It is sharply delineated, and the border with the normal stratified epithelium is apparent. Microscopically, the heterotopic gastric mucosa is usually made up of gastric glands of cardiofundic type, with mucous glands admixed with fundic gland elements (Fig. 13.2). Goblet cells may be present, and it has been reported that up to 20% of patients also have Barrett esophagus.[13] There is often an extensive inflammatory reaction in the heterotopic mucosa that may induce a reactive proliferation and complex glandular architecture, leading to a mistaken diagnosis of malignancy. True instances of adenocarcinoma of the upper esophagus in heterotopic gastric mucosa have been described, in which normal lining squamous epithelium was present both proximal and distal to the lesion.[15]

Heterotopic pancreatic tissue (pancreatic acinar metaplasia) in the form of acinar structures and/or Langerhans islands is commonly seen in the vicinity of the GEJ (Fig. 13.3). Recent studies suggest that this is a congenital rather than an acquired condition.[16] However, other studies have found an association with advancing age, *Helicobacter pylori* infection, female gender, and gastroesophageal reflux disease (GERD).[17]

Heterotopic sebaceous glands may rarely be seen in the midportion or distal portion of the esophagus.[18]

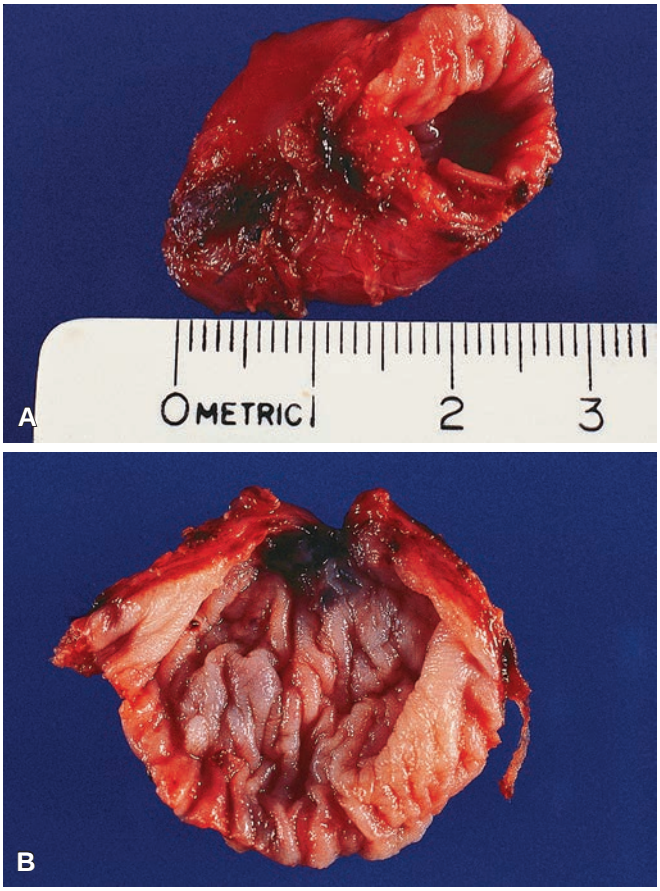

Figure 13.4 **A** and **B,** Outer aspect and inner surface of Zenker diverticulum.

Diverticula

Diverticula located in the upper portion of the esophagus **(Zenker diverticula)** are the most common type of diverticulum in the upper aerodigestive tract.[19] They are the result of outpouching of esophageal mucosa in the wall of the esophagus at the junction with the pharynx (Fig. 13.4). They are therefore more properly designated as pharyngoesophageal and are classified pathogenetically as **pulsion diverticula**. They occur at this point because of the weakness resulting from the relationship between the inferior constrictor muscle and the obliquely passing fibers of the cricopharyngeal muscles as they descend on the posterior wall of the esophagus to become longitudinal.

In the lower third of the esophagus and in the region of the hilum of the lung, inflammatory lymph nodes (usually tuberculous) can become firmly attached to the esophagus and produce **traction diverticula**.[20]

Just above the diaphragm, so-called **epiphrenic diverticula** of the pulsion variety may occur. These outpouchings contain mucosa and submucosa and are lined by inflamed squamous epithelium. Many are associated with achalasia.[21] Complications include obstruction, aspiration pneumonia and lung abscess, infection with perforation and mediastinitis, hemorrhage, and even malignancy (carcinomas). The indications for surgical removal of esophageal diverticula (particularly of the epiphrenic type) remain controversial,[22] but many can be removed by minimally invasive surgery.[23]

An altogether different type of esophageal diverticular process has been designated **diffuse intramural esophageal (pseudo) diverticulosis**.[24] Dysphagia may be the presenting symptom. Endoscopic examination reveals innumerable 1–3 mm flask-shaped diverticula, with a pinpoint mouth, more numerous in the upper third of the organ. The lining is predominantly squamous. A short stricture is usually present in the region. It has been suggested that these formations represent cystically dilated ducts of submucosal glands and, therefore, are not a true diverticular process.[25] The pathogenesis is not completely clear, but underlying esophageal motor abnormalities have been implicated.[26]

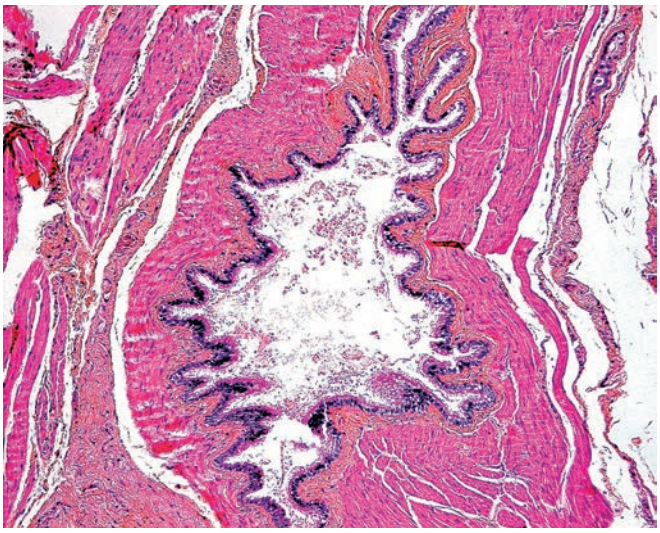

Figure 13.5 Esophageal cyst lined by ciliated columnar epithelium.

Cysts

Esophageal cysts are classified into *inclusion cysts* (lined by squamous or columnar epithelium, sometimes ciliated), *retention cysts* or mucoceles (arising from cystic dilation of submucosal glands), and *developmental cysts* (of esophageal, bronchial, or gastric origin) (Fig. 13.5).[27,28] Their microscopic distinction may be very difficult. Cases of squamous cell carcinoma and adenocarcinoma arising in these cysts have been reported.[29,30]

Rings and Webs

Esophageal shadows with a configuration resembling rings and webs are often described by radiologists in patients complaining of dysphagia. Those located in the upper esophagus of women and associated with iron-deficiency anemia are a component of the Plummer–Vinson or Paterson–Kelly syndrome, in which an increased incidence of carcinoma has been described.[31] Those located in the lower esophagus are commonly referred to as Schatzki, esophagogastric, or lower esophageal rings. Some rings are caused by a transverse circumferential fold of the mucosa, typically located at the SCJ. Others are formed by localized annular thickening of the muscle.[32]

Cervical esophageal (pharyngoesophageal) webs also represent transverse folds of normal mucosa and submucosa.[33] The treatment of esophageal webs includes endoscopic dilation and surgical myomectomy.[34]

Achalasia and Related Motor Disorders

Achalasia (cardiospasm, megaesophagus) is due to a failure of relaxation of the lower esophageal sphincter while peristaltic waves

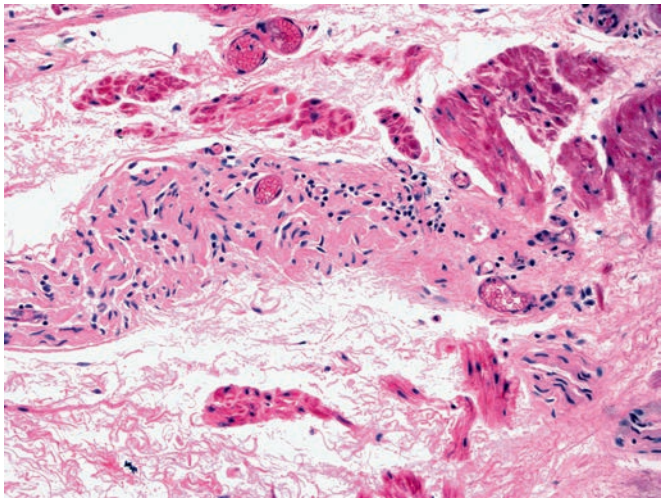

Figure 13.6 Myenteric plexus in achalasia with scattered lymphocytes and no residual ganglion cells.

conveying food through the esophagus reach it. It is usually seen in adults but can also occur in children.[35] Some of the patients are affected by the Allgrove (triple A) syndrome, in which the achalasia is combined with adrenal deficiency or addisonianism and alacrima.[36] A nearly complete loss of myenteric ganglion cells is present in the lower third of the esophagus in almost all cases; this loss extends to the middle third of the esophagus in about 20% of cases.[37] Secondary changes include marked hypertrophy of the muscularis propria and prominent mucosal and submucosal inflammation. The primary abnormality is inflammatory destruction of myenteric ganglion cells, predominantly by CD3+ T cells.[38] Eventually, there is loss of ganglion cells and widespread fibrosis of the myenteric nerves (Fig. 13.6). In longstanding cases, the mucosa shows marked squamous hyperplasia and an increased incidence of P53 immunoreactivity, possibly indicating the preneoplastic nature of this mucosa.[39]

The pathogenesis of achalasia remains unknown. At present, the hypothesis that achalasia is an inflammatory, immune-mediated disease is favored, but the responsible antigen remains unknown.[40,41]

In the early stages, achalasia is reversible. With time, however, chronic inflammation and ulceration supervene, and fibrotic stricture results. Esophagomyotomy and pneumatic dilation remain the major treatment modalities.[42,43] Rarely, carcinoma develops in association with longstanding achalasia,[44] with an estimated 16–33-fold increased risk.[45] Almost all are squamous cell carcinomas, most commonly arising in the middle esophagus.

Cricopharyngeal dysphagia (cricopharyngeal achalasia, cricopharyngeal spasm) is a well-recognized entity with prominent clinical symptoms but only meager microscopic findings, represented by degeneration and regeneration of the fibers of the cricopharyngeal muscle, accompanied by interstitial fibrosis.[46]

Chagas disease, an endemic parasitosis of South America, can be associated with alterations of Auerbach plexus and megaesophagus.[47]

Pseudoachalasia is an esophageal motor disorder usually associated with malignancy; the clinical, radiographic, and manometric features are very similar to those of achalasia.[48,49] The most common microscopic finding, which is in keeping with its presumed pathogenesis, is neoplastic infiltration of the myenteric plexus,[48] although some cases are paraneoplastic.

Giant muscular hypertrophy (diffuse spasm, corkscrew esophagus, diffuse leiomyomatosis) is a motor disorder of the esophagus characterized clinically by dysphagia and pathologically by focal or diffuse hypertrophy of the muscular layer.[50] Some cases have been reported in association with Alport syndrome, a hereditary glomerular nephropathy.[51] Mutations of the *COL4A5* gene have been implicated in this process.[52]

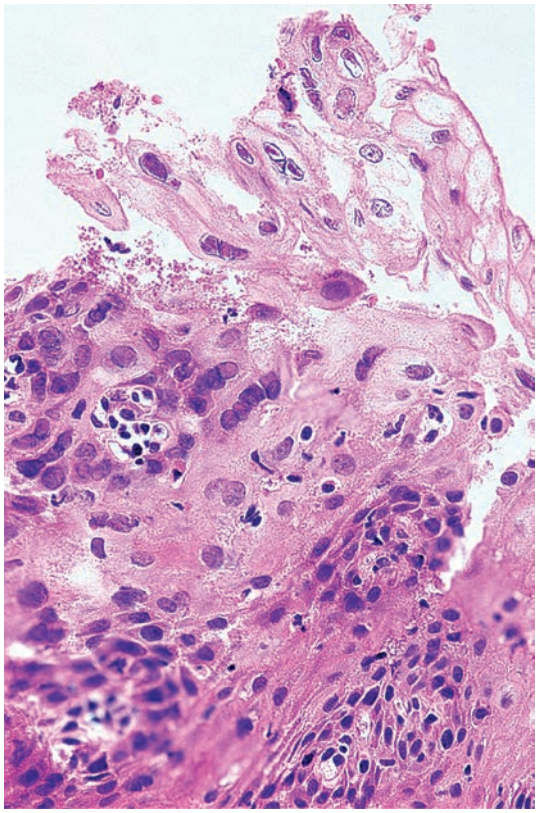

Figure 13.7 Herpes Simplex Esophagitis. Several intranuclear eosinophilic inclusions are seen in the squamous mucosa.

Lye Strictures

Lye strictures of the esophagus are most common at the level of bifurcation of the trachea. The mean age of the patients at the time of lye ingestion is about 6 years. Once the lesion is well established, most patients require surgical resection, although, more recently, endoscopic therapies have been attempted.[53] Carcinoma of the esophagus may develop at the site,[54] most often at the level of the tracheal bifurcation. The mean latent time is about 40 years; the later in life the lye is ingested, the shorter the interval.

Esophagitis (Nonreflux Related)

Herpes simplex esophagitis can arise in both immunosuppressed and immunocompetent individuals.[55] It may be asymptomatic or result in odynophagia, retrosternal chest pain, and fever.[56] The diagnosis should be suspected in the presence of "volcano ulcers" at endoscopy and discrete, diffusely scattered, shallow ulcers on double-contrast esophagogram.[57] Microscopically, inflammation, ulcerations, and Cowdry type A inclusions are the hallmarks of the disease, but the latter are not always identifiable (Fig. 13.7).[58] Multinucleated epithelial cells constitute another classic morphologic feature of herpes esophagitis; however, it should be noted that similar multinucleated cells can be seen in esophagitis of other etiologies as a nonspecific regenerative response to injury.[59] Aggregates of large

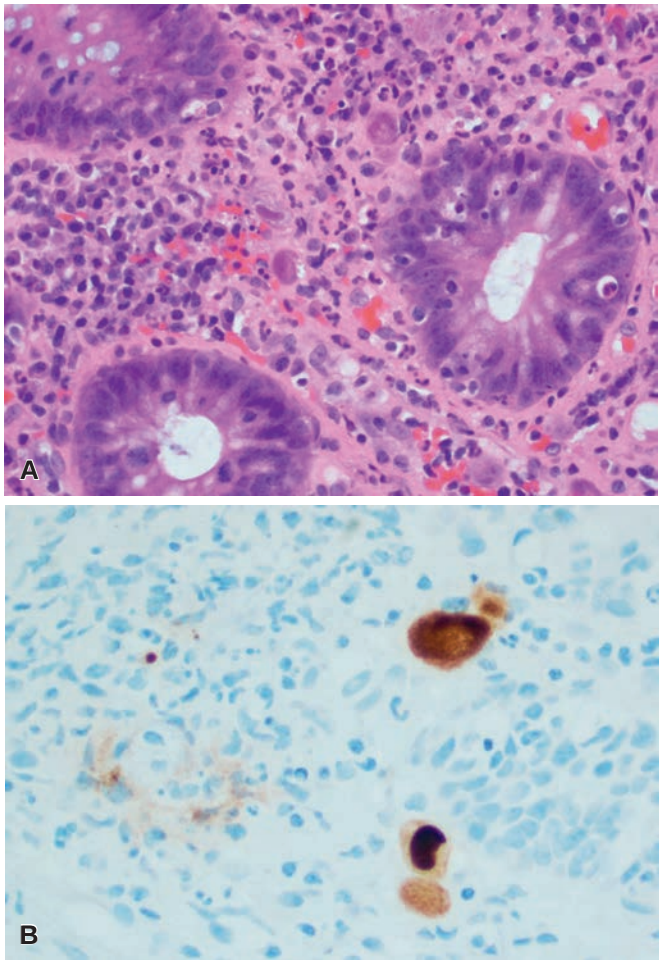

Figure 13.8 A, CMV inclusions in a patient with Barrett esophagus. **B,** CMV immunostain showing rare immunopositive cells.

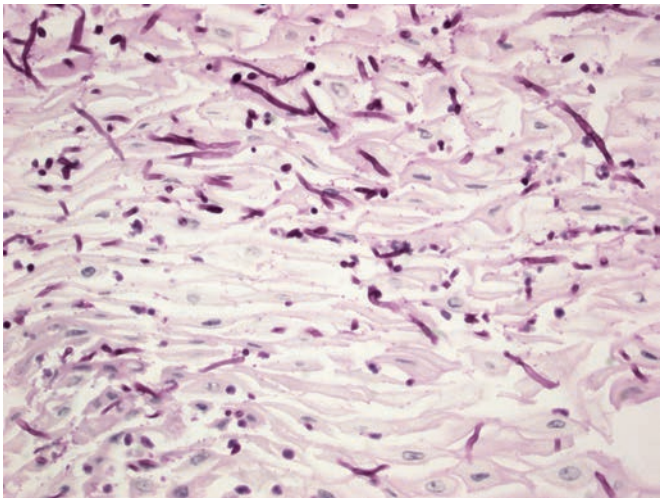

Figure 13.9 Esophageal Candidiasis. Pseudohyphae are seen within the squamous mucosa.

mononuclear cells with convoluted nuclei (CD68+) adjacent to the inflamed epithelium constitute an important diagnostic clue.[60]

Cytomegalovirus (CMV) esophagitis is also on the rise because of its predilection for immunocompromised patients.[61] Its endoscopic appearance is similar to that of herpes esophagitis. Microscopically, the diagnosis is made by finding the typical large cells with basophilic cytoplasm and large oval, eosinophilic intranuclear inclusions,[62] usually at the base of the ulcer (Fig. 13.8).

Candida esophagitis can complicate the ulcers of herpes or CMV esophagitis or appear in the absence of viral infection, usually in immunosuppressed individuals,[63] but it may be seen in immunocompetent individuals as well. At endoscopy, it typically appears as white plaques that are often easily scraped away. Pseudohyphae can be seen in a background of active esophagitis (Fig. 13.9); in some cases, special stains (periodic acid–Schiff [PAS], silver stain) may be of use.

AIDS-related chronic idiopathic esophageal ulceration is characterized by the presence of large, undermined ulcers with severe acute inflammation.[64–66] No evidence of herpes simplex, CMV, fungi, or tumors has been found, and the startling suggestion has been made that the ulcers are the direct result of the HIV itself.[67]

Crohn disease can involve the esophagus, usually in association with gastric and/or intestinal disease.[68] Some cases clearly show an esophageal mucosal infiltration of lymphocytes (lymphocytic esophagitis), but some have found that patients with Crohn disease were not more likely than controls to show this morphologic finding.[69]

Eosinophilic (allergic) esophagitis is an allergic eosinophilic disorder that seems to be increasing in frequency.[70] The favored interpretation is that it is the result of local hypersensitivity to food- or blood-borne allergens, and that antigen-presenting cells play an important role in its pathogenesis.[71] This condition should be distinguished from the much more common eosinophilic infiltration of esophageal mucosa seen in patients with gastroesophageal reflux, discussed later. Although eosinophilic microabscesses and lamina propria fibrosis favors the diagnosis of eosinophilic esophagitis (Fig. 13.10), no histologic feature is specific for this condition, as diagnosis requires clinical, endoscopic, and pathologic data.[70] Although this condition may result in many endoscopic appearances, the most characteristic is the ringed esophagus.

Esophagitis dissecans superficialis ("sloughing esophagitis") is an endoscopically defined disease characterized by detachment of large fragments of squamous esophageal mucosa. It affects mainly adults, with a female predominance.[72] The etiology is unknown, and the usual evolution is towards total resolution. Microscopically, there is "sloughing" and "flaking" of the superficial squamous epithelium, with occasional bullous separation of the layers, parakeratosis, and nonspecific inflammation (Fig. 13.11).[72,73] Some cases may be medication induced, and psychoactive agents, clindamycin, and acid-suppressive agents have been implicated.[72,74]

Other types of esophagitis include those caused by *tuberculosis*,[75] *blastomycosis*,[76] *Behçet disease*,[77] *drugs* (including iron medication[78]), *irradiation*,[79] and *ingestion of corrosive chemicals*.[80] Dermatologic diseases that can involve the esophagus include *scleroderma*,[81] *pemphigus vulgaris*,[82] *lichen planus*,[83] and *epidermolysis bullosa*.[84] Inflammation and sometimes perforation of the esophagus may result from *instrumentation*, *intubation*, or the *ingestion of foreign bodies*.[85] Recently, Salaria et al. described a form of esophagitis resembling lichen planus (lichenoid esophagitis) characterized by intraepithelial and lamina propria lymphocytosis and apoptosis of squamous cells (so-called Civatte bodies) but showing an association with viral hepatitis and HIV infection.[86]

Reflux Esophagitis

As the name indicates, this form of esophagitis (also known as GERD) is the result of reflux of gastroduodenal contents into the esophagus (Fig. 13.12). It is often associated with a sliding hiatal hernia. Esophageal reflux is accompanied by regurgitation, heartburn,

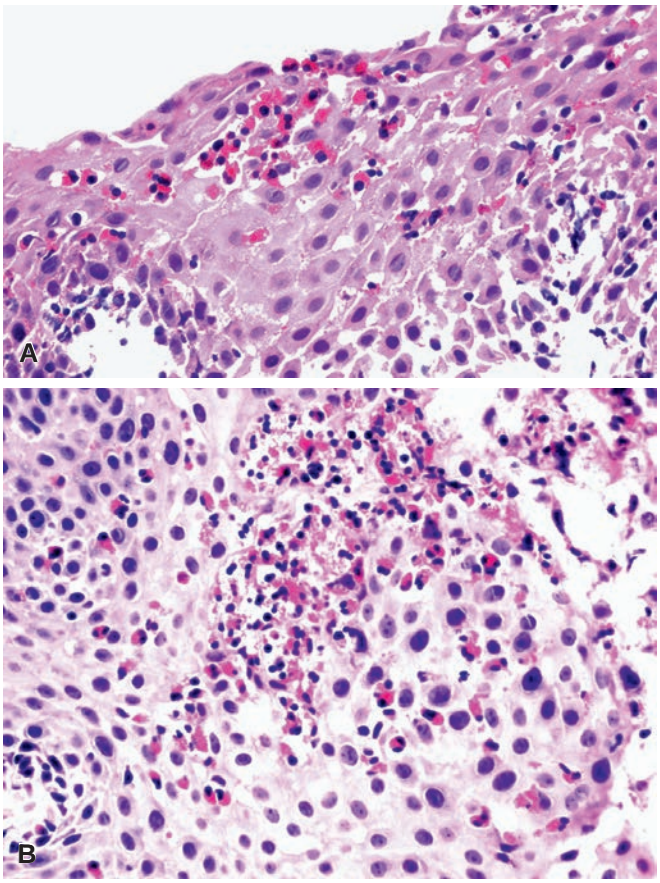

Figure 13.10 Eosinophilic Esophagitis. A, There is a marked increase in the number of intraepithelial eosinophils with a surface-heavy infiltrate. **B,** Eosinophilic microabscesses are characteristic.

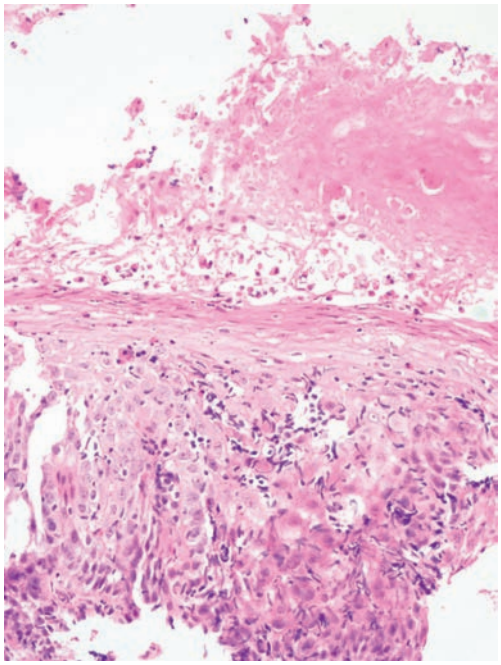

Figure 13.11 Characteristic histologic appearance of so-called sloughing esophagitis.

Figure 13.12 Gross Appearance of a Severe Case of Reflux Esophagitis. Marked hyperemia with focal hemorrhage is present in the area of reflux.

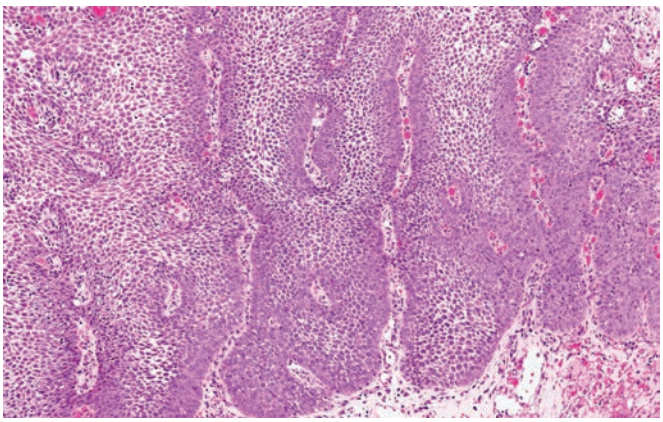

Figure 13.13 Gastroesophageal reflux disease with marked squamous hyperplasia and basal cell hyperplasia. Scattered intraepithelial inflammatory cells are seen.

pain, and dysphagia. The early microscopic lesions consist of epithelial hyperplasia and infiltration by neutrophils and eosinophils, sometimes accompanied by focal epithelial necrosis (Fig. 13.13).[87–89] The papillary height of the lamina propria and the degree of basal cell proliferation are substantially higher than in control subjects, as estimated subjectively and corroborated with morphometric techniques.[90,91] Dilated and congested venules are seen high up in the top of the lengthened papillae between the epithelial layers.[92,93] Intraepithelial eosinophils are among the most common features seen in reflux, but this feature lacks sensitivity (since it is not found in many patients with reflux)

and specificity (as it is found in many other conditions). Cells with irregular nuclear contours can be seen amid the epithelial elements in reflux esophagitis; they represent reactive T-lymphocytes and are a component of the inflammatory response.[94,95] Although this constellation of histologic features is characteristic, no single feature or combination of features is diagnostic of GERD; this is a clinicopathologic and endoscopic diagnosis that cannot be made by the pathologist in isolation.

Reflux esophagitis may progress to superficial ulceration and circumferential fibrosis with stricture formation and fixation to the surrounding structures. Occasionally, the inflammatory reaction associated with the esophagitis may be of such a degree as to result in a pseudolymphomatous appearance.[96]

Depending on the severity of the symptoms, reflux esophagitis can be treated medically (with motility-promoting drugs, H_2-receptor antagonists, or proton pump inhibitors) or surgically.[97] All of the various operations that have been devised for this disorder (such as fundoplication) involve the reduction of the hiatal hernia (often present) coupled with the construction of a valve mechanism to reestablish gastroesophageal competence.

Barrett Esophagus

This condition is defined as replacement of esophageal squamous mucosa by metaplastic columnar epithelium with goblet cells (Fig. 13.14). According to guidelines provided by the American College of Gastroenterology, this condition requires an endoscopic abnormality (columnar-lined esophagus) and the identification of unequivocal goblet cells in a biopsy from the area of the endoscopic abnormality.[98] A large majority of patients are adult white males. However, it has also been reported in children, sometimes in association with cystic fibrosis (a condition known to induce gastroesophageal reflux) and following chemotherapy.[99] A genetic predisposition to develop Barrett esophagus has been detected.[100] Lack of a precise definition on the nature and location of the GEJ and the microscopic variations at this junction have clouded the issue as to whether this condition is congenital or acquired, but most clinical and experimental evidence indicates that this change is acquired and the result of acid-induced ulceration with subsequent reepithelialization by columnar cells.[101] The origin of the columnar cells remains uncertain; theoretically, they could arise from migration of gastric mucosa as a result of a phenotypic switch of undifferentiated elements in the stem cell population or as a repopulation from underlying submucosal glands.[102–104]

Some have suggested that the so-called multilayered epithelium having morphologic and ultrastructural features of both squamous and columnar epithelium could be the precursor epithelium that gives rise to Barrett mucosa.[105]

This columnar epithelial extension may be circumferential or in the form of finger-like projections or islands. At present, only intestinal metaplasia is diagnostic of this condition, although there typically is an admixture of other types of columnar mucosa of cardiac or fundic type.[103] Most cases show incomplete intestinal metaplasia, but many show an admixture of incomplete and complete intestinal metaplasia. Interesting, the non-goblet columnar cells have immunophenotypic[106] and DNA flow cytometric abnormalities similar to those found in intestinal metaplasia.[107] Some have suggested that perhaps the definition of Barrett esophagus is too restrictive and should include this "preintestinalized" non-goblet columnar mucosa.[108]

The topic of intestinal metaplasia at the GEJ is controversial. While some believe that all intestinal metaplasia in this location is indicative of Barrett esophagus,[109,110] others believe this is a multifactorial condition,[111] and, as such, these cases should be diagnosed as intestinal metaplasia of the GEJ, as opposed to Barrett esophagus. Although a number of immunohistochemical markers have been reported to be useful in distinguishing intestinal metaplasia of distal esophagus versus proximal gastric origin (CDX2, Das1, CK7/20), none has been found to be of sufficient sensitivity and specificity to be used clinically.[111] On the other hand, subtle clues may be present in the biopsy to suggest an esophageal origin of intestinal metaplasia, including squamous epithelium overlying intestinalized glands, hybrid glands (a mixture of goblet cells and non-goblet columnar cells) and the identification of esophageal glands/ducts.[112]

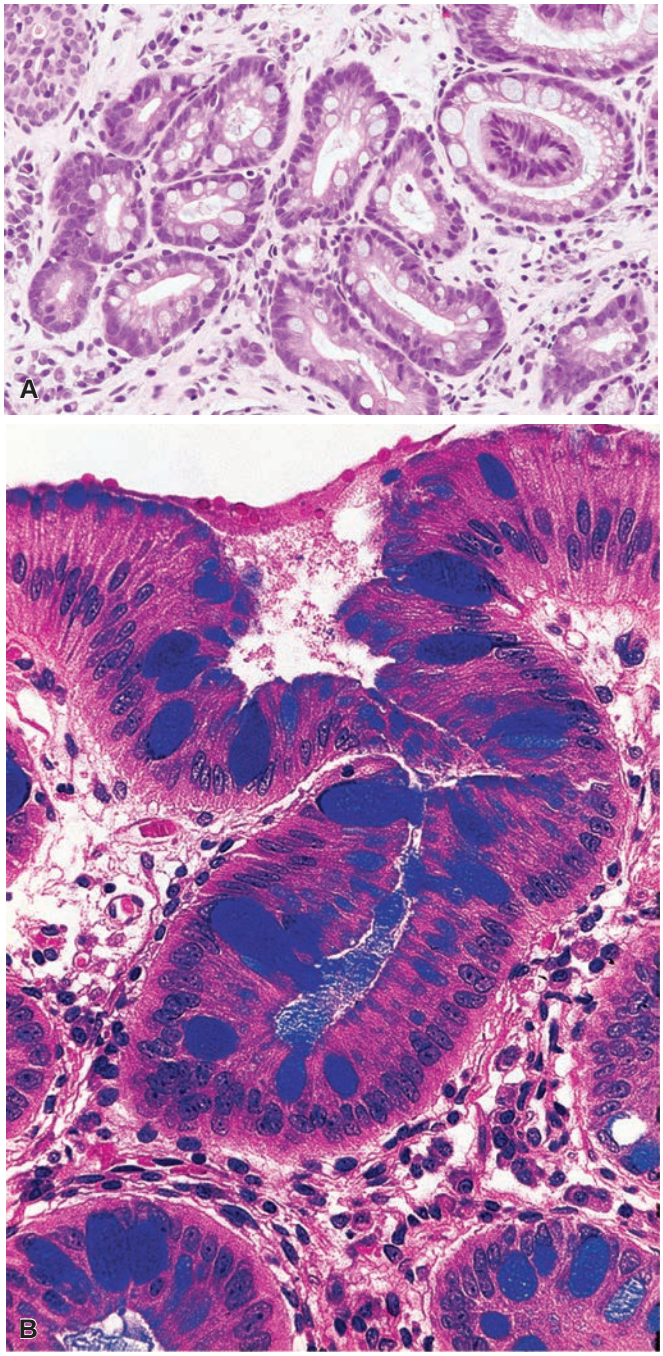

Figure 13.14 **A,** Barrett esophagus with scattered goblet cells. **B,** Alcian blue stain at pH 2.5 highlighting the acid mucin-containing goblet cells.

An interesting feature often seen in Barrett esophagus is the formation of a new, superficially located muscularis mucosae (reduplication), which results in the division of the lamina propria into a superficial and deep compartment.[113,114] This has clinical importance, as it is easy to overstage tumors invading into the native (deeper) muscularis mucosal layer, since this can be misinterpreted as evidence of muscularis propria invasion.

Barrett esophagus has been further subdivided into *long segment* (the classic form, in which the changes involve 3 cm or more of the esophagus) and *short segment* (less than 3 cm). For practical purposes, these two artificially defined types are managed similarly. At the histochemical level, most of the mucin present in specialized columnar epithelium is of neutral type, but in over 70% of the cases there are also sialomucins and sulfomucins.[115] The intestinal type of differentiation is also evidenced by the common presence of the intestinal-type mucin MUC2, in addition to gastric-type mucins (MUC5AC, MUC6), TFF peptides (TFF1 and TFF2)[116,117] and by the presence of the CDX2 protein, as detected immunohistochemically.[118]

The main complications of Barrett esophagus are the same as for reflux esophagitis (i.e. peptic ulcer, stricture, bleeding), plus the development of dysplasia and adenocarcinoma[119]; the latter is discussed in detail in the next section. Once a diagnosis of Barrett esophagus is established, most patients undergo endoscopic surveillance at regular intervals. If biopsies show changes indefinite for dysplasia (IND) or low-grade dysplasia (LGD), anti-reflux medical therapy is maximized, and the patient returns for repeat endoscopy with biopsy in a shorter period of time.[101] If a diagnosis of high-grade dysplasia (HGD) is rendered, patients are now often referred for endoscopic ablative therapy (radiofrequency ablation and cryoablation, among others).[120] In the past, many of these patients would have undergone an esophagectomy, a major operation with not insignificant morbidity and mortality.[121] Endoscopic mucosal resection is commonly used in patients with an endoscopic lesion, which is determined to be either an intramucosal or superficial submucosal adenocarcinoma.[122]

Diagnostic Categories in Barrett Esophagus

The vast majority of biopsies for Barrett esophagus are negative for dysplasia, and most patients never develop dysplasia or adenocarcinoma. The diagnostic categories listed later are those agreed upon at the 1988 consensus conference for grading dysplasia in Barrett esophagus (Fig. 13.15).[123] These criteria were further refined by Montgomery and colleagues in 2001.[124] Unfortunately, a high degree of interobserver variability remains.[125,126]

- **Negative for dysplasia**: The architecture is within normal limits. The nuclei do not vary greatly in size or shape and are located basally. The nucleocytoplasmic ratio is not increased, and the nuclear envelope is generally smooth. Nucleoli are not markedly enlarged. Focal nuclear stratification is acceptable, as are small numbers of "dystrophic" goblet cells, the apical aspect of which does not communicate with the luminal surface. Greater nuclear alterations are acceptable when associated with evidence of inflammation, erosion, or ulceration. Apical cytoplasmic mucus is usually present but may be reduced or absent in inflammation.
- **IND:** The architecture may be moderately distorted. Nuclear abnormalities are less marked than those seen in dysplasia. Other features that may lead to a diagnosis of IND include more numerous dystrophic goblet cells, more extensive nuclear stratification, diminished or absent mucus production, increased cytoplasmic basophilia, and increased mitoses. The diagnosis of IND should be limited to cases in which the changes are too marked for negative but not sufficient for the diagnosis of dysplasia.
- **Positive for LGD or HGD:** The diagnosis of LGD or HGD is based on the severity of both architectural and cytologic alterations. Although either architectural or cytologic abnormalities may predominate, HGD is diagnosed if either one is sufficiently prominent. Architectural abnormalities may include budded, branched, crowded, or irregularly shaped glands; papillary extensions into gland lumina; and villiform configuration of the mucosal surface. Nuclear features may include marked variation in size and shape, nuclear and/or nucleolar enlargement, increased nucleocytoplasmic ratio, hyperchromasia, and increased numbers of abnormal mitoses. Nuclear alterations are especially noteworthy if they involve the mucosal surface. Diagnostic features easily recognizable at low power are cytoplasmic basophilia with loss of mucus, nuclear hyperchromasia, and excessive nuclear stratification, often extending from the epithelial basement membrane to the luminal surface. The significance of crypt dysplasia *with surface maturation* (also known as basal crypt dysplasia) is yet to be defined, but the view has been advanced that it represents dysplasia that has not yet involved the surface.[127]
- **Intramucosal adenocarcinoma:** Intramucosal adenocarcinoma is defined as carcinoma that has penetrated through the basement membrane of the glands into the lamina propria or muscularis mucosae, but not below. Most biopsy specimens are not deep enough to rule out submucosal invasion. Useful features include back-to-back glands with little to no intervening stroma, identification of individual cells, small cell groups, or irregularly shaped glands in the lamina propria and dilated deep glands with intraluminal necrosis.[128]

In some cases of dysplasia, the polypoid architecture of the lesion and the crowding and stratification of the hyperchromatic nuclei are similar to those seen in adenomas of the large bowel.[129]

The risk for the development of invasive carcinoma in patients with Barrett-related dysplasia is certainly increased, but the exact magnitude of this risk remains to be determined.[101,130] Certainly, the risk for progression from HGD to carcinoma is significant; up to 50% progress to carcinoma in 5 years.[131] The risk of progression from LGD is less well established, mostly due to the notorious lack of reproducibility of this diagnosis.[132,133]

A large number of biomarkers have been evaluated in the Barrett–dysplasia–carcinoma sequence, which are too numerous to mention in detail.[134–136] At this point, no biomarker has been found to be superior to the morphologic identification of dysplasia in predicting progression to carcinoma. Since the vast majority of patients with this disease do not progress to carcinoma, the identification of a biomarker in nondysplastic Barrett mucosa that is predictive of progression would be extremely helpful. Studies from the University of Washington have suggested that somatic mutations in *CDKN2A* and *TP53* may be predictive of progression from nondysplastic Barrett mucosa.[137]

Adenocarcinoma Arising in Barrett Esophagus

The large majority of invasive carcinomas developing in Barrett esophagus are adenocarcinomas, although rare cases can show squamous[138,139] or even neuroendocrine differentiation.[140] The majority of patients are elderly white males, but not all patients fit into this demographic group. Some of the reported cases have been in children.[141] The main features used to suggest an origin for an esophageal adenocarcinoma from Barrett mucosa are the identification of goblet cells adjacent to the neoplasm and the epicenter of the tumor being located on the esophageal side of the GEJ. Adenocarcinomas of the GEJ have essentially similar morphologic, immunohistochemical, and epidemiologic features whether an associated Barrett metaplasia can be detected in the specimen or not.[142,143] The tumor may be multicentric and is often far advanced at the time of diagnosis, with extension into the wall and nodal metastases.[144] Microscopically, a wide range of glandular differentiation exists, sometimes in the same tumor.

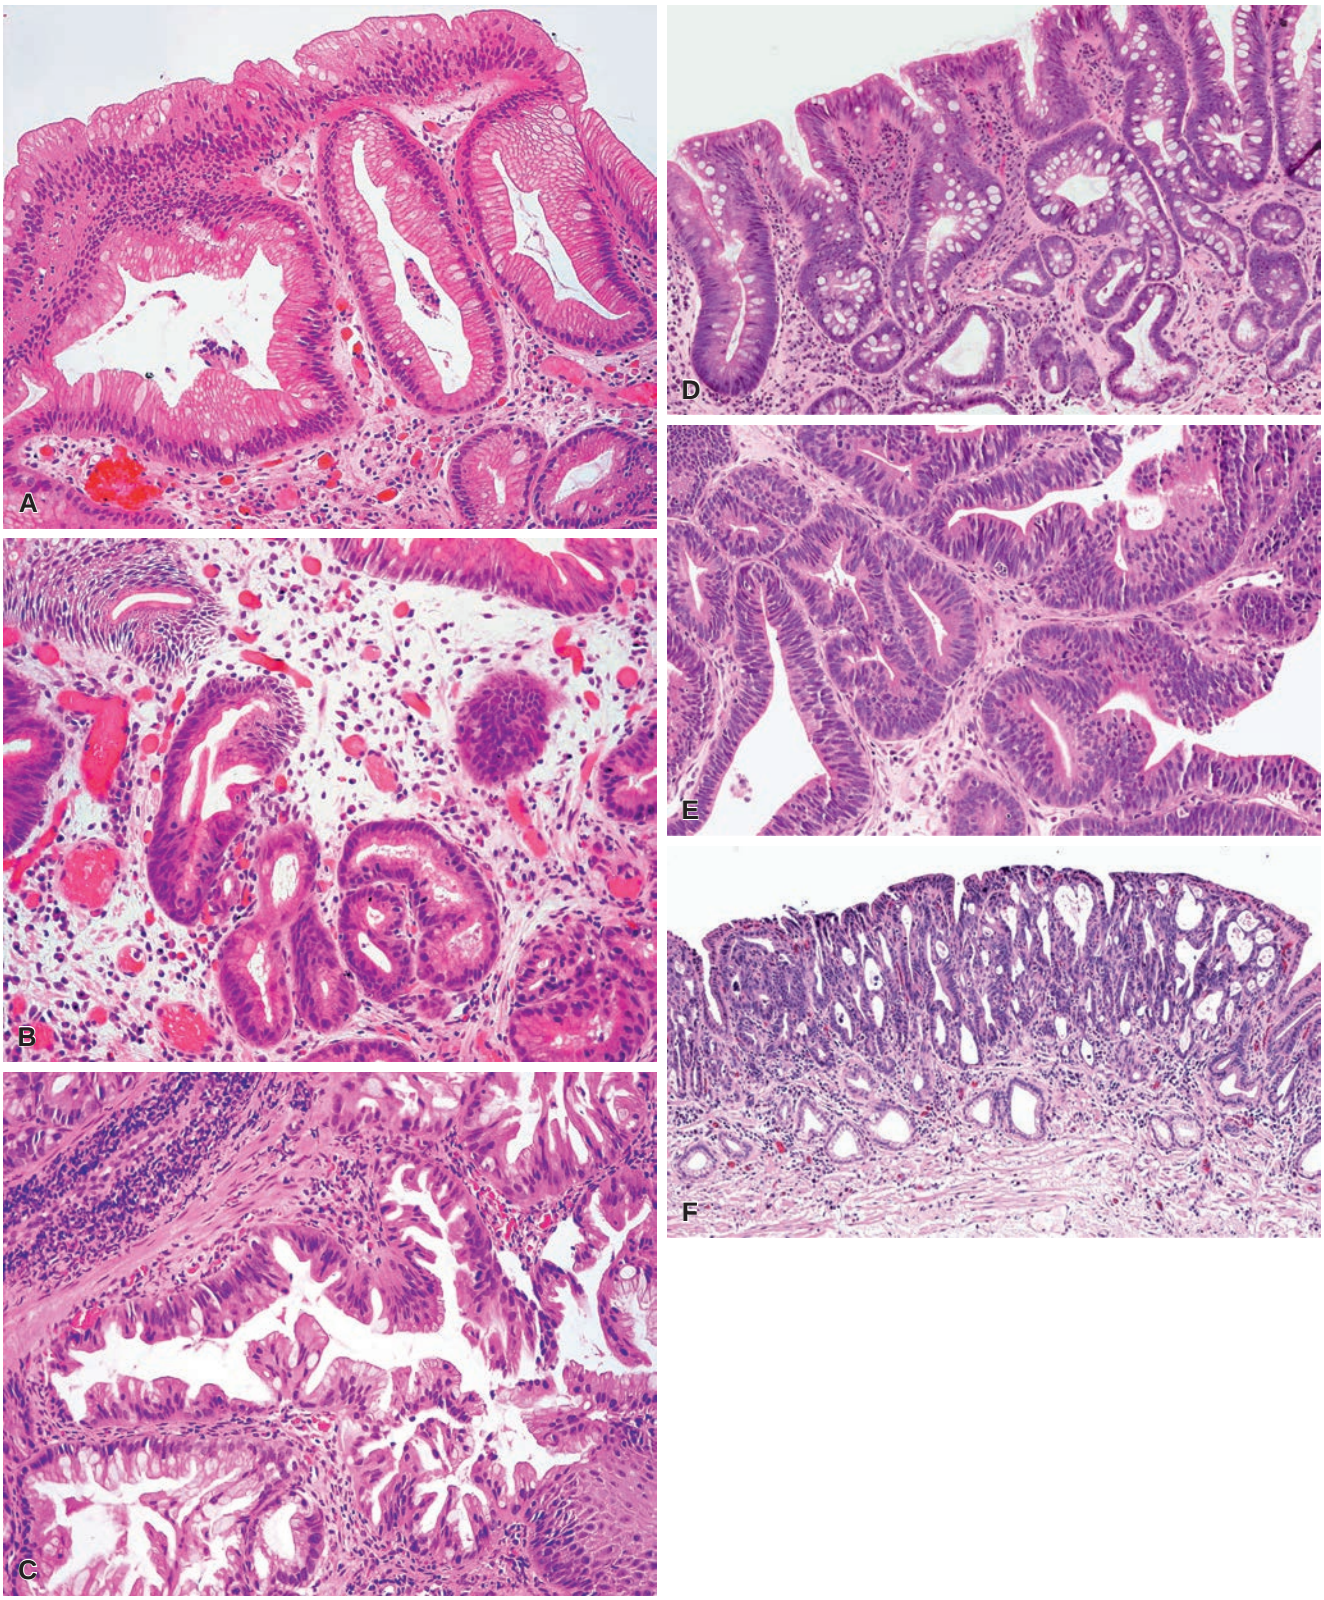

Figure 13.15 **A,** Barrett esophagus negative for dysplasia. **B,** Barrett esophagus with mild chronic inflammation and reactive glandular atypia, negative for dysplasia. **C,** Barrett esophagus with epithelial alterations indefinite for dysplasia. **D,** Barrett esophagus with low-grade dysplasia, intestinal type. **E,** Barrett esophagus with high-grade dysplasia, intestinal type. **F,** Intramucosal adenocarcinoma with infiltration of glands into the lamina propria.

Architecturally and immunohistochemically, most of these tumors resemble their gastric counterparts, while others exhibit an intestinal phenotype. Signet ring carcinomas are much less common than in the stomach but show aggressive clinical behavior.[145] Rare cases of Barrett-related adenocarcinoma become sarcomatoid.[146]

Many molecular alterations have been identified in specimens of Barrett esophagus containing lesions within the dysplasia–adenocarcinoma sequence.[147,148] These include *TP53* mutation and overexpression, altered expression of various apoptosis-related proteins, *MYC* amplification,[149,150] mutations of β-catenin and other alterations of the cadherin/catenin membrane complex,[151] hypermethylation of multiple tumor suppressor genes (such as *APC*, *TERT*, *RUNX3*, *TIMP3*),[152] loss of heterozygosity (including *CDKN2A* at 9p21)[137] and microsatellite instability,[147] alterations of MUC expression,[153] and *HER2* amplification,[154] among many others. It appears that the earliest molecular changes are loss of *CDKN2A* (by deletion or hypermethylation) and *TP53* (by mutation and deletion).[155]

Surgical resection is the primary treatment, sometimes combined with preoperative neoadjuvant chemoradiotherapy.[156,157] In some cases, prominent pools of mucin can be found in the wall of the esophagus after neoadjuvant therapy and should not be misinterpreted as evidence of residual adenocarcinoma unless viable tumor cells are identified.[158]

The prognosis of adenocarcinoma in Barrett esophagus is poor, with a 5-year survival rate of less than 20%.[159] The most important prognostic factors, as in many other sites, is tumor stage (Tables 13.1 and 13.2), particularly in relation to the depth of invasion and the lymph node status.[159–162] Histologic evidence of tumor regression following neoadjuvant chemotherapy seems also to be a strong prognostic indicator.[163] Other potential prognostic factors include lymphatic vessel density,[160] extracapsular lymph node involvement,[164] *HER2* amplification,[165] and β-catenin abnormal expression.[166]

Squamous Cell Carcinoma

General and Clinical Features

Squamous cell carcinoma of the esophagus occurs more frequently in men over 50 years of age. It is relatively common in China and other Asian countries[167] and is the most common tumor of the gastrointestinal tract in the African Bantus.[168] In the United States over the past decades, it has become distinctly less common than

Table 13.1 Definitions of AJCC TNM for squamous cell carcinoma and adenocarcinoma

Primary Tumor (T)	
T CATEGORY	**T CRITERIA**
Tx	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined to the epithelium by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades the lamina propria or muscularis mucosae
T1b	Tumor invades the submucosa
T2	Tumor invades the muscularis propria
T3	Tumor invades adventitia
T4	Tumor invades adjacent structures
T4a	Tumor invades the pleura, pericardium, azygos vein, diaphragm, or peritoneum
T4b	Tumor invades other adjacent structures, such as the aorta, vertebral body, or airway

Regional Lymph Nodes (N)	
N CATEGORY	**N CRITERIA**
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes

Distant Metastasis (M)	
M CATEGORY	**M CRITERIA**
M0	No distant metastasis
M1	Distant metastasis

Histologic Grade (G)	
G CATEGORY	**G CRITERIA**
Gx	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated, undifferentiated

Location (L)*	
L CATEGORY	**L CRITERIA**
X	Location unknown
Upper	Cervical esophagus to lower border of azygos vein
Middle	Lower border of azygos vein to lower border of inferior pulmonary vein
Lower	Lower border of inferior pulmonary vein to stomach, including gastroesophageal junction

*Location plays a role in stage grouping of esophageal squamous cancers and is defined by the position of the epicenter of the tumor in the esophagus.

Barrett-related adenocarcinoma.[169] Smoking and alcohol are two important and well-known risk factors.[170] The tumor has also been reported in association with lye strictures,[54] achalasia,[171] Plummer–Vinson syndrome,[172] diverticula,[173] tylosis (an autosomal dominant disorder characterized by hyperkeratosis of palms and soles),[174] and history of previous irradiation.[175]

Another known association is with squamous cell carcinoma in other sites, particularly the oropharynx and larynx,[176] some of whom show clear-cut evidence of high-risk human papillomavirus (HPV) infection.[177] Studies searching for DNA sequences of HPV in esophageal squamous cell carcinomas have given widely divergent results, with a tendency for low prevalence in North American cases.[178–180] Tumor multicentricity in the esophagus is a rare event, but it may occur, either synchronously or metachronously.[181] Most patients present with dysphagia related to the local spread of the tumor and this is usually the expression of advanced disease.

Morphologic Features and Local Spread

Squamous cell carcinoma can occur in any portion of the esophagus but is most common in the middle and lower thirds.[182] Grossly, the tumor usually is circumferential, often ulcerated, with sharply demarcated margins; rare cases have a polypoid appearance (Fig. 13.16).[183] On cut section, a grayish white tumor is seen to invade part or all of the muscular wall, from which it may extend into the surrounding soft tissues and trachea. Intraluminal growth also occurs and may eventually lead to total obstruction. Distally located tumors often invade the stomach. Submucosal spread, not always appreciable grossly, is also common, sometimes up to 5 cm or more beyond the gross margins of the tumor.[184] Intraepithelial spread along the submucosal gland/ducts may also be seen.[185] Vascular invasion is present in the majority of cases. Separate tumor nodules may be seen in the wall of the esophagus or stomach (so-called intramural metastases).[186]

Microscopically, the degree of squamous differentiation is variable, but most tumors are well or moderately differentiated (Fig. 13.17). The main differential diagnosis in a biopsy specimen is with atypical regenerative hyperplasia.[187] Occasionally, lack of cohesiveness of tumor cells results in an acanthotic appearance. True glandular and/or mucus-secreting components are found focally in up to 20% of cases, and, when extensive, the tumors are designated *adenosquamous carcinomas*.[188] The occasional presence of an intraepithelial component with the appearance of *Paget disease* has also been described,[189] although most cases with esophageal Paget cells are associated with an underlying adenocarcinoma.[190]

Immunohistochemical and Molecular Genetic Features

Esophageal squamous cell carcinomas are invariably immunoreactive for cytokeratins, particularly high-molecular-weight cytokeratins (CK5/6).[191] p63 is also a highly sensitive marker of this tumor, and both of these markers are useful in distinguishing squamous cell carcinoma from adenocarcinoma.[191,192] Some poorly differentiated carcinomas react for human chorionic gonadotrophin (hCG), even in the absence of morphologically demonstrable trophoblastic differentiation.[193] Production of basement membrane components, such as laminin and type IV collagen, correlates with the degree of differentiation of the tumor.[194]

DNA studies have shown that two-thirds to three-fourths of the cases have an aneuploid pattern, which correlates with a higher grade and a higher incidence of nodal metastases.[195] Heterogeneity in DNA ploidy, whether comparing the primary tumor with its metastasis or comparing different areas of the primary tumor, is common.[196]

Squamous cell carcinoma of the esophagus develops through accumulation of somatic mutations and epigenetic changes in oncogenes, tumor suppressor genes, and cell adhesion molecules.[197] Mutations and/or overexpression of *TP53* have been found in a high proportion of squamous dysplasia and esophageal squamous cell carcinomas, suggesting an early genetic alteration in this sequence.[198]

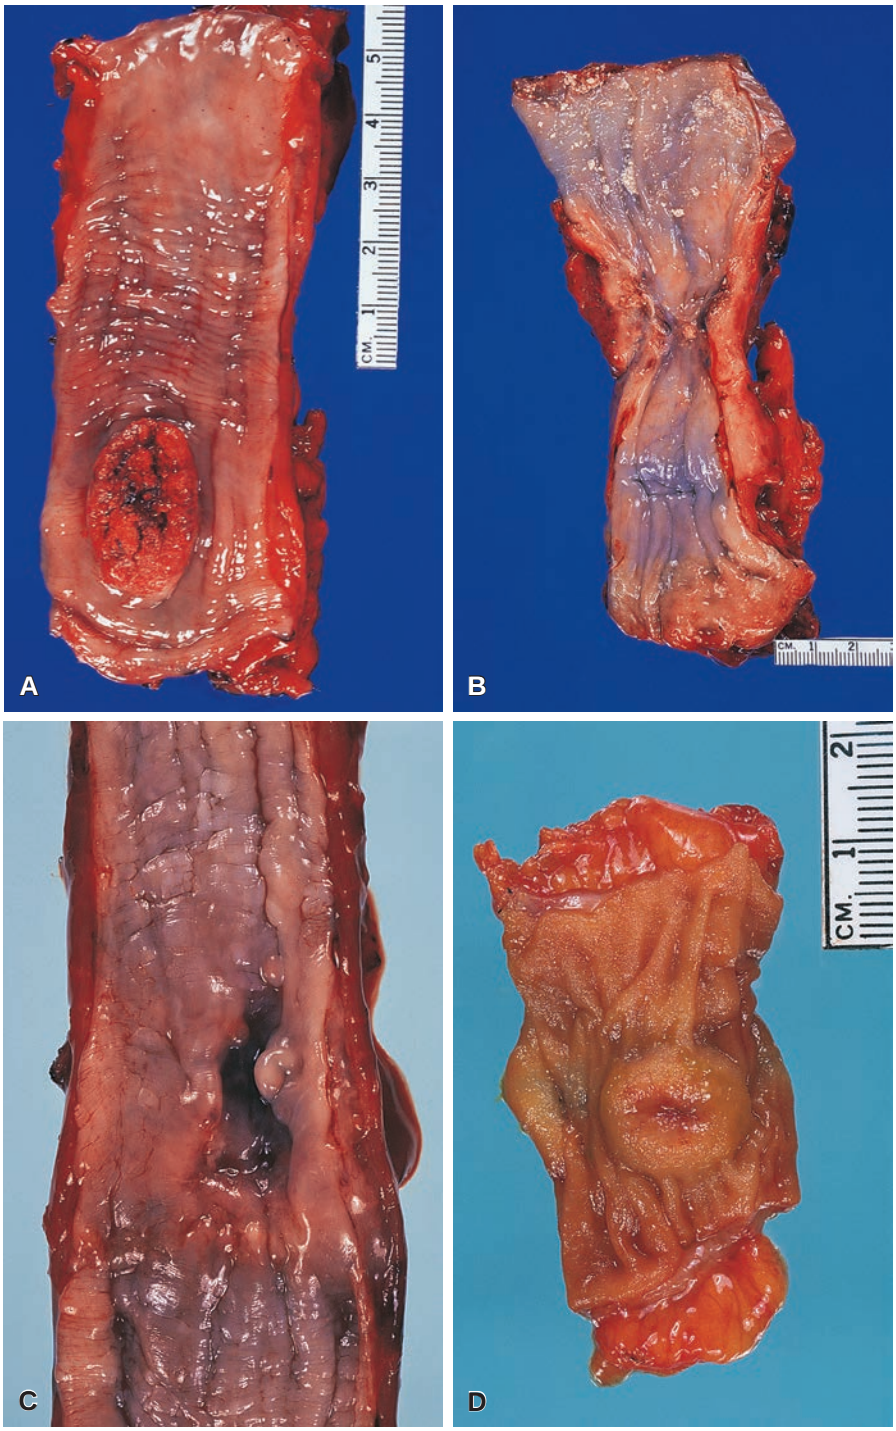

Figure 13.16 Various Gross Appearances of Esophageal Squamous Cell Carcinoma. A, Cakelike exophytic mass. **B,** Circumferential constricting lesion. **C,** Elevated round nodule with central ulceration. **D,** Widely invasive lesion with deep ulceration.

Esophageal Squamous Dysplasia

Squamous dysplasia of the esophagus is being recognized with increasing frequency, particularly in regions of the world with a high incidence of invasive esophageal squamous cell carcinoma.[199,200] Risk factors for esophageal dysplasia are the same as for the invasive tumors.[201] As in other sites, squamous dysplasia may be the only lesion present, or it could represent the peripheral component of an invasive carcinoma, the latter being more common. Squamous dysplasia/carcinoma in situ has been found at the periphery of an invasive tumor in approximately 30% of cases, the incidence being much higher when no preoperative irradiation has been given and when the main lesion is superficial[202]; sometimes the dysplastic lesion is found anatomically separate from the main tumor supporting the concept of a field effect.[203] The dysplastic change can extend into the ducts of the submucosal glands in a fashion analogous to

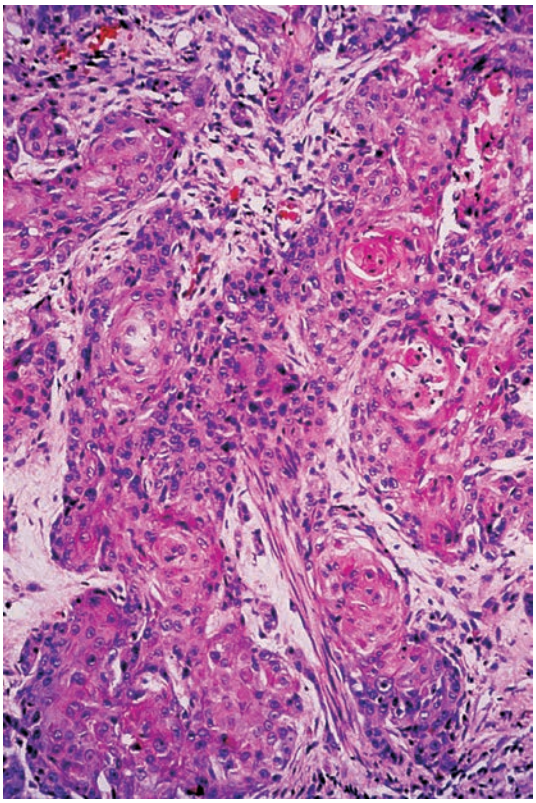

Figure 13.17 Low-power view of an invasive moderately differentiated squamous cell carcinoma of the esophagus.

endocervical gland involvement by cervical carcinoma in situ.[204] Occasionally, the dysplastic or malignant cells exhibit a pagetoid pattern of growth, which can be extensive.[189]

Intramucosal carcinoma is the term used for the carcinomas that do not invade beyond the muscularis mucosae, *superficial* (*or microinvasive*) *carcinoma* for those that do not invade beyond the submucosa, and *superficial*(*ly*) *spreading carcinoma* for those tumors having a lateral intramucosal spread of at least 2 cm beyond the invasive lesion.[205–207] Grossly, superficial carcinomas have been arbitrarily divided into flat, coarse, verrucous, polypoid, and ulcerating infiltrating patterns.[208] The more polypoid the lesion, the more likely that it will be found to invade the submucosa and that it will be associated with lymph node metastases.[209,210] The incidence of nodal metastases is virtually zero for intramucosal carcinomas; it ranges from over 20% to almost 50% in cases with submucosal invasion, depending on the series.[211–213] Depth of tumor invasion and any lymphatic invasion are independent predictors of nodal metastases.[212] Some have found the depth of invasion into the submucosa (divided into inner, middle, and outer thirds) is predictive of nodal metatatic risk.[213]

Metastases

The abundant lymphatic supply of the esophagus is responsible for the high frequency of lymph node metastases in the periesophageal area, below the diaphragm, and upward into the cervical nodes.[214] These nodal metastases occur early in the course of the disease and are the main reason for treatment failure. It should be pointed out that in small carcinomas confined to the esophageal wall, the lymph node metastasis is solitary in almost half of the cases.[215] Metastases to distant organs are also frequent, particularly to liver, lung, and adrenal glands. The tumor may also metastasize to the submucosa of the stomach, probably through the submucosal lymphatic plexus.[216]

Cytology

Exfoliative cytology in experienced hands is an extremely accurate technique for the evaluation of esophageal lesions, particularly those of the lower third.[217] However, since the introduction of the flexible fiberoptic endoscope, the diagnostic accuracy of direct-vision biopsy has surpassed that of cytology.[218] It is clear these are complementary methods which, when used together, provide diagnostic accuracy higher than either technique alone. Diagnostic cytology is particularly rewarding in countries with a high incidence of esophageal carcinoma, such as China or South Africa.[219,220]

Treatment

Traditionally, radiation therapy has been the most common form of treatment for carcinoma of the upper two-thirds of the esophagus, and surgery (in the form of esophagogastrectomy) the usual approach for carcinoma of the lower third. The current approach favors combined modalities consisting of preoperative radiation therapy (intracavitary or external beam) followed by surgery or the combination of chemotherapy and radiation therapy, with or without surgery.[221,222] Unfortunately, the overall results with any of these combination therapies remain disappointingly poor.[223]

Prognosis

The overall prognosis for esophageal squamous cell carcinoma is very poor (Tables 13.1 and 13.3). A recent study reported 3- and 5-year survival rates of 29.8% and 15%, respectively.[224] Factors thought to influence survival include gender (females > males),[225] tumor grade,[226] status of surgical margins,[227] and angiolymphatic invasion.[212] A number of yet to be substantiated biomarkers have also been reported to be of prognostic significance.[228] Histopathologic response following neoadjuvant chemoradiotherapy, as estimated by the percentage of residual tumor cells, is an independent prognostic factor.[229]

Other Types of Carcinoma

Sarcomatoid carcinoma (carcinosarcoma, spindle cell carcinoma, polypoid carcinoma) accounts for approximately 2% of all esophageal carcinomas and usually presents as a large polypoid neoplasm (Fig. 13.18).[230,231] The epithelial-appearing component can be quite inconspicuous and is usually limited to a few areas of in situ or superficially invasive carcinoma. Its appearance is usually that of a squamous cell carcinoma of either conventional or basaloid type. The bulk of the tumor has a pleomorphic sarcoma-like appearance (Figs. 13.19 and 13.20), sometimes exhibiting focal "divergent" differentiation toward cartilage, bone, or skeletal muscle.[232,233] Evidence suggests this component is also of epithelial derivation, and that all of the morphologically diverse tumor components have the same clonal origin.[234] Ultrastructurally, *some* of these sarcoma-like cells in *some* of the tumors retain epithelial markers, such as desmosomes and tonofibrils, but most have the appearance of myofibroblasts or other mesenchymal cells.[235] Immunohistochemically, cytokeratin can be consistently demonstrated in the epithelial-appearing component and, in a variable proportion of cases, also in some of the sarcoma-like cells. For sarcomatoid squamous cell carcinomas, markers such as CK5/6, p63, and p40 can be extremely helpful. The epithelial component may exhibit focal neuroendocrine features as an additional sign of multidirectional differentiation.[236] The sarcoma-like component has a higher proliferative index and higher aneuploidy than

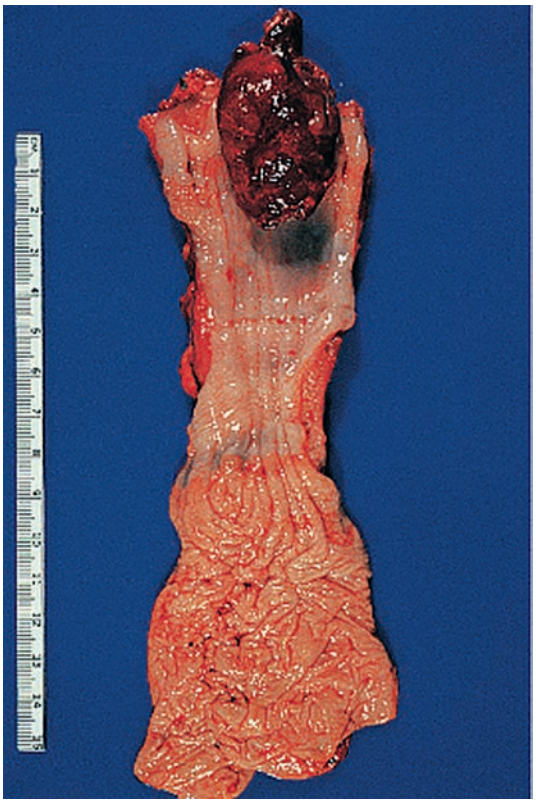

Figure 13.18 Gross appearance of sarcomatoid carcinoma of the esophagus. The tumor has a characteristic large size and polypoid shape.

the morphologically identifiable carcinomatous component, thereby giving it a growth advantage and probably explaining its dominance in most cases.[237] Metastases or recurrences supervene in about 20% of the patients undergoing surgery, and the overall survival rate is in the neighborhood of 50%.[238] The nodal metastases usually contain epithelial elements alone or a mixture of epithelial and spindle elements; occasionally, the entire metastatic focus is made up of the spindle cell element, giving further credence to the interpretation that this component is indeed neoplastic and not a stromal reaction to the tumor.[239]

Verrucous carcinoma, morphologically identical to its more common counterpart in the oral cavity, has been described in the esophagus.[240,241] It is grossly polypoid and well differentiated throughout microscopically, which makes it extremely difficult to diagnose on superficial endoscopic biopsies.[242] Despite these features and its inability to metastasize, the mortality associated with this tumor in this particular location is high.[243]

Basaloid squamous cell carcinoma is the preferred term for a variant of squamous cell carcinoma with prominent peripheral palisading (Fig. 13.21), accounting for approximately 3% of esophageal squamous cell carcinomas.[244] Stage for stage, this variant seems to be more clinically aggressive than conventional squamous cell carcinoma, and, as such, an attempt should be made to distinguish these tumors.[244,245] Immunohistochemically, the cells express CK5/6 as well as keratins 14 and 19 at the periphery of the basaloid nests.[246] Recent studies have not found this variant to be associated with high-risk HPV.[247] The tumor can be difficult to distinguish from **adenoid cystic carcinoma**, an even more rare esophageal neoplasm.[248,249] This tumor presumably arises from the submucosal glands and is morphologically identical to the tumor of the same name which arises in salivary glands.

Adenocarcinoma of the esophagus can arise from Barrett metaplastic mucosa (previously discussed), from a focus of heterotopic gastric mucosa (also mentioned earlier in this chapter) or from esophageal glands.[250] A very small proportion of primary esophageal adenocarcinomas have *signet ring cell* features, which generally portends a poor prognosis and poor response to preoperative chemoradiation.[251,252] In these cases, esophageal extension of a gastric carcinoma should be excluded.

Adenosquamous carcinoma shows evidence of both squamous and glandular differentiation.[188] This tumor generally behaves in an aggressive manner and should be distinguished from both the low-grade **mucoepidermoid carcinoma,** possibly arising in salivary-type submucosal esophageal glands,[253] and the equally rare **collision**

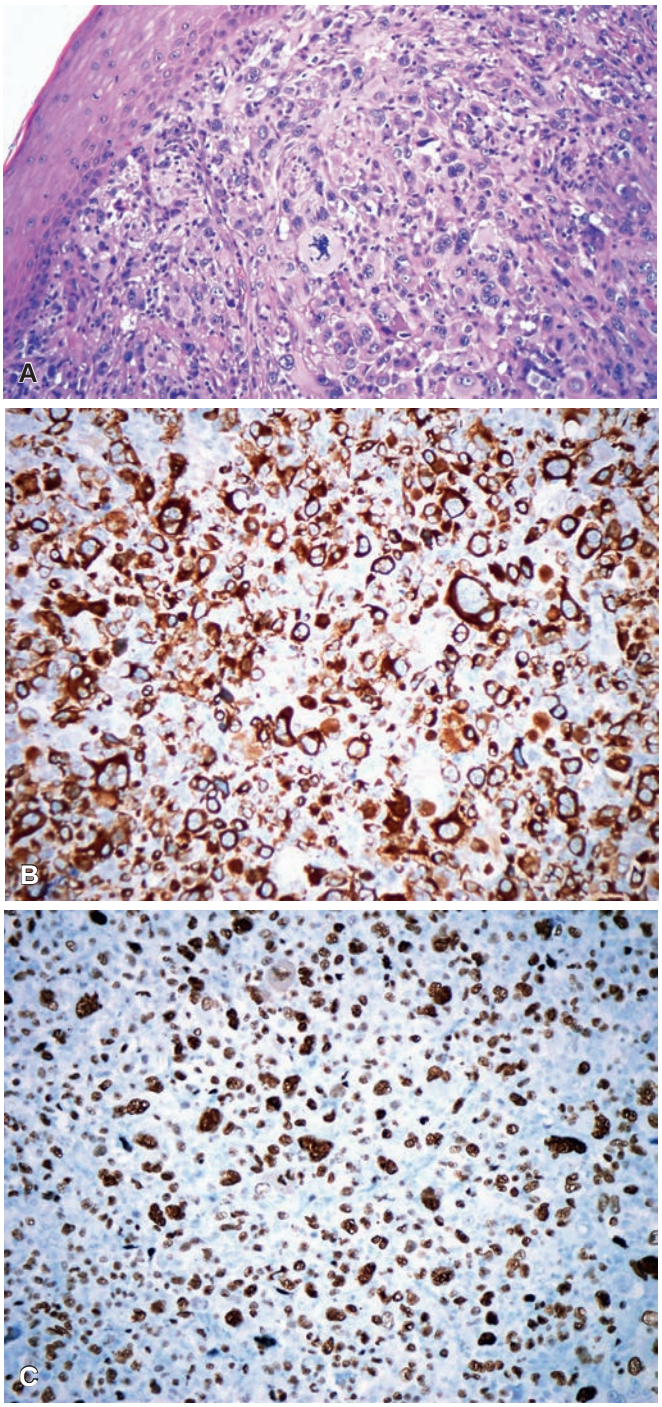

Figure 13.19 **A,** Pleomorphic (sarcomatoid) carcinoma of the esophagus. **B,** Strong cytokeratin 5/6 immunoreactivity is characteristic. **C,** There is also strong nuclear expression of p63.

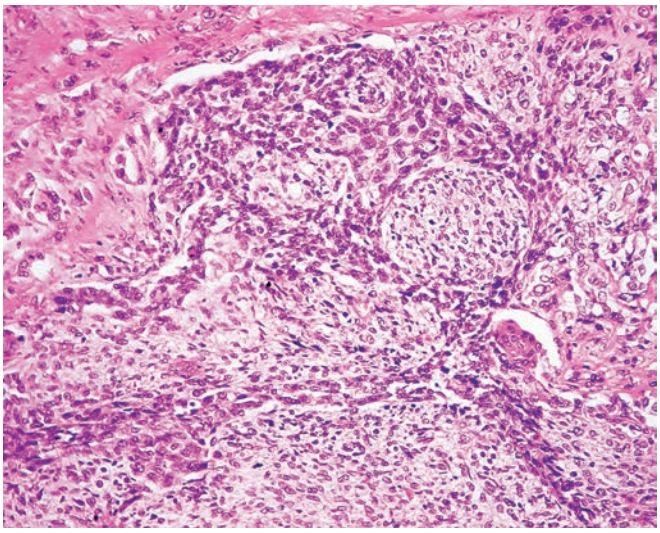

Figure 13.20 Sarcomatoid carcinoma of the esophagus. In this case, the carcinomatous component has a basaloid appearance.

tumor, represented by a merging of two originally separate neoplasms (i.e. squamous cell carcinoma and adenocarcinoma).[254] Molecular studies suggest that most of these tumors are actually derived from a single clone.[255]

Lymphoepithelioma-like carcinoma has been reported in the esophagus; as in other sites, it has been found to contain Epstein–Barr virus DNA.[256]

Small cell (neuroendocrine) carcinoma is a highly malignant esophageal tumor having morphologic features similar to those of its pulmonary counterpart.[257,258] Microscopically, small cells with dark nuclei of round or oval shape and scanty cytoplasm are seen growing in a predominantly diffuse fashion and accompanied by a rich vasculature. As in small cell carcinoma of the lung, there may be rosette formation and focal mucin secretion. Neuroendocrine markers, such as chromogranin and synaptophysin, are usually detectable immunohistochemically. The prognosis is very poor; most patients die within 1 year with generalized metastases.[258,259] This tumor probably arises from the same multipotent epithelial basal cells that give rise to conventional squamous cell carcinoma; interestingly, some cases are associated with squamous dysplasia or invasive squamous cell carcinoma.

Small cell carcinoma should be clearly separated from the much better differentiated **carcinoid tumor (well-differentiated neuroendocrine tumor)**.[260] The latter neoplasm, which is vanishingly rare in this location, probably arises from the endocrine cells ordinarily present in the normal esophageal mucosa. Its gross appearance tends to be polypoid. Some of the cases have been seen as an incidental finding in association with adenocarcinoma arising in the background of Barrett esophagus.[261] **Large cell neuroendocrine carcinoma** of the esophagus has also been described, the diagnostic criteria being the same as for its pulmonary counterpart.[262,263]

Smooth Muscle Tumors and Gastrointestinal Stromal Tumors

Leiomyomas are the most common benign tumors of the esophagus.[264] In a meticulous study by Abraham et al., an astounding 47% of resection specimens for tumors of the esophagogastric junction were found to harbor such lesions, almost always as an incidental microscopic finding.[265] Half of the patients with surgically excised lesions are asymptomatic; dysphagia and vague thoracic pain are the main complaints in the others.[264] The majority arise from the inner circular muscle and two-thirds arise in the middle or distal thirds of the esophagus. Multiple leiomyomas may occur and need to be distinguished from both gastrointestinal stromal tumors (GISTs; see later) and giant muscular hypertrophy. Grossly, leiomyomas form well-defined masses in the esophageal wall and have a solid, grayish white appearance on cross section (Fig. 13.22). When they grow intraluminally, they encroach on the mucosa and appear as sessile or pedunculated polyps. Ulceration of the overlying mucosa is uncommon.

Microscopically, leiomyomas have the usual characteristics of a benign smooth muscle tumor and stain for muscle markers such as desmin and smooth muscle actin (Fig. 13.23). Local resection or enucleation is usually successful.

Leiomyosarcomas are quite uncommon in the esophagus. In a study from the Armed Forces Institute of Pathology, only 3 esophageal leiomyosarcomas were identified out of 68 esophageal mesenchymal neoplasms.[266] Grossly, they may be indistinguishable from leiomyoma, although they tend to be larger and softer and often are associated with areas of hemorrhage and necrosis. The presence of cytologic atypia, mitotic figures, and necrosis are the main microscopic criteria by which they are separated from their more common benign counterpart (Fig. 13.24).

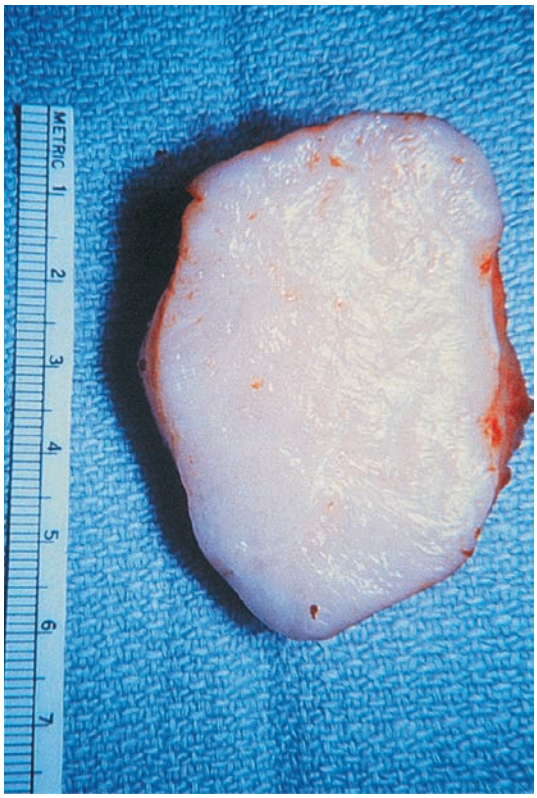

Figure 13.22 Gross Appearance of an Esophageal Leiomyoma. The tumor is sharply circumscribed and has a white color and elastic consistency.

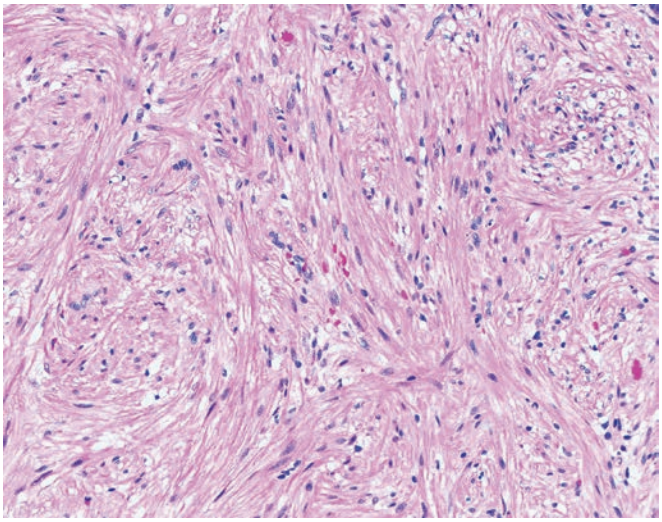

Figure 13.23 Esophageal leiomyoma with bland-appearing, densely eosinophilic spindle cells.

GISTs also occur in the esophagus, although the relative frequency of the clinically significant cases is considerably lower than in the stomach or bowel.[266] As in other locations, they are characteristically positive for DOG1, CD117, and CD34, with occasional immunoreactivity for smooth muscle actin. At the genetic level, they usually show mutations in exon 11 of *KIT*, similar to their counterparts in other parts of the gastrointestinal tract. Microscopically, most have a spindled morphology (Fig. 13.25), but some have epithelioid features. As a group, the behavior of clinically detectable esophageal

stromal tumors is aggressive, particularly for those which are large and/or mitotically active.[266]

Other Tumors and Tumorlike Conditions

Glycogenic acanthosis appears grossly as multiple, uniformly sized, oval or round white elevations usually measuring less than 1 cm.[267] They represent areas of focal thickening of the epithelium resulting from a marked increase in cytoplasmic glycogen.[268]

Amyloidosis in its localized form (so-called amyloid tumor) can present as an intramural esophageal mass; exceptionally, it may result in perforation and hematemesis.[269]

Squamous papillomas may be found in the esophagus,[270] and there is some evidence that human papillomavirus plays a pathogenetic role,[271] at least in some cases (Fig. 13.26).

Benign fibrovascular polyps of the esophagus usually are pedunculated and solitary and may attain huge dimensions ("giant").[272] Patients present with dysphagia and sometimes with intermittent regurgitation of a fleshy mass in the mouth. Most of the 53 cases reviewed by Jang et al. occurred in adults, and approximately 85% were located in the upper third of the esophagus.[273] Microscopically, they are composed of fibrous tissue and numerous blood vessels, with stromal edema and mild lymphocytic infiltration.[274] If hyperchromatic cells are seen, consideration should be given to a diagnosis of atypical lipomatous tumor (and confirmed using molecular techniques).[275] These polyps most likely represent a non-neoplastic condition and local excision is curative.[276]

Hyperplastic polyps of the esophagus and GEJ are characterized by hyperplastic epithelium of foveolar and/or squamous type accompanied by stromal inflammation. They are usually associated with (and probably the result of) recent esophageal ulcers and erosive esophagitis.[277] Some patients also show evidence of Barrett esophagus, further suggesting a role for reflux.[278]

Granular cell tumors may be found in the esophagus, as either solitary or multiple nodules; sometimes they are associated with similar lesions in other parts of the gastrointestinal tract (Fig. 13.27).[279] As in other sites, they can induce pseudoepitheliomatous hyperplasia of the overlying epithelium, resulting in a mimic of squamous cell carcinoma. Almost all of these act in a clinically benign fashion.

Other benign tumors that have been exceptionally reported in the esophagus include *lobular capillary hemangioma (pyogenic*

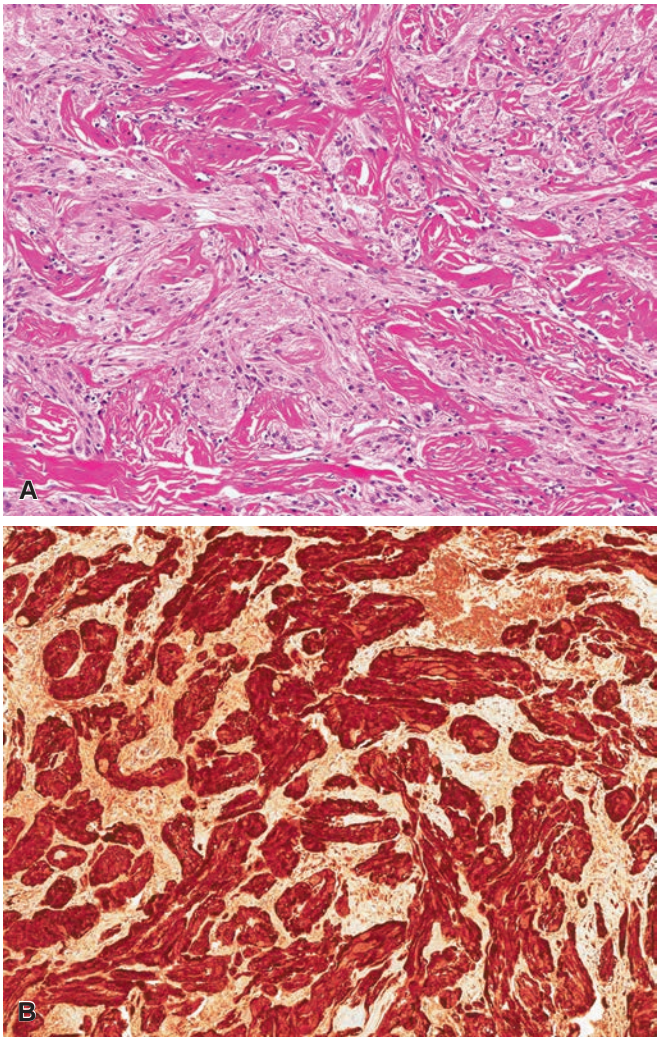

Figure 13.27 **A,** Esophageal granular cell tumor with nests of ovoid cells with granular cytoplasm. **B,** Strong S-100 protein staining in esophageal granular cell tumor.

Figure 13.28 **Malignant Melanoma of Esophagus.** The tumor has a characteristic polypoid appearance and is partially ulcerated. The dark color is the combined result of melanin deposition and hemorrhage within the tumor.

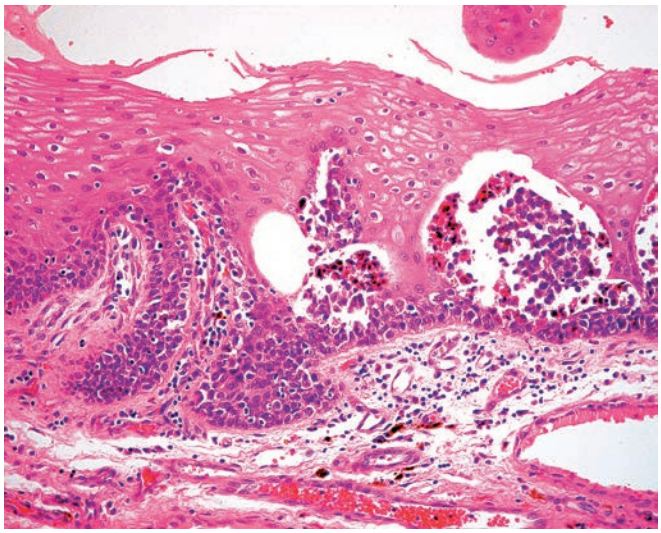

Figure 13.29 **Primary Malignant Melanoma of the Esophagus.** There is a prominent intraepithelial component with the formation of large tumor nests.

granuloma),[280] *neurofibroma,*[281] *schwannoma,*[282] *perineurioma,*[283] and *solitary fibrous tumor.*[284]

Malignant melanoma is an uncommon esophageal neoplasm that can be located at any level in the esophagus but has a predilection for the lower third.[285,286] Grossly, the tumor is usually large and has a prominent polypoid appearance (Fig. 13.28). Microscopically, epithelioid, spindled, and pleomorphic areas may be seen singly or in combination, with variable melanin production (Fig. 13.29). Immunohistochemically, S-100 protein and HMB-45 positivity are the rule. The search for a lateral intraepidermal component ("junctional activity") should be made in order to confirm the primary nature of the tumor.[285] At the molecular level, esophageal melanoma shows differences with other mucosal melanomas with frequent *NRAS* mutations.[286] The prognosis is exceedingly poor.

Non-Hodgkin malignant lymphoma[287] and **plasmacytoma**[288] occasionally present with dysphagia because of diffuse esophageal involvement. Some esophageal lymphomas have occurred in HIV-infected patients.[289] The esophageal wall can also be the site of leukemic infiltration[290] or Hodgkin lymphoma.[291]

Malignant mesenchymal neoplasms other than smooth muscle/stromal tumors are rare, including *osteosarcoma,*[292] *rhabdomyosarcoma,*[293] *synovial sarcoma,*[294] *epithelioid sarcoma,*[295] *Ewing sarcoma/primitive neuroectodermal tumor,*[296] and *malignant peripheral nerve sheath tumor.*[297]

Metastatic carcinoma in the esophagus usually represents extension from pulmonary, laryngeal, gastric, or thyroid tumors, either directly or via periesophageal nodes. Rarely, blood-borne metastases occur from carcinomas of distant sites, such as prostate, endometrium, or breast.

Normal Anatomy

The stomach is divided into the following regions: *cardia*, *fundus*, *corpus* or *body*, *antrum*, and *pylorus*. The superomedial margin is termed the *lesser curvature*, and the inferolateral margin is termed the *greater curvature*. The junction between the corpus and the antrum is marked on the serosal side by a notch in the lesser curvature known as the *incisura*. Internally, the mucosa is thrown into coarse folds called *rugae*.

These anatomic regions show some correspondence to (but should not be equated with) the three traditionally recognized microscopic types of gastric mucosa: *cardiac*, *fundic*, and *pyloric (antral)*, with transitional forms in the boundary areas. The mucosa is composed of two major compartments—the foveolar and glandular compartments. The differences among the various types of gastric mucosa depend on the relative proportions between foveolae and secretory portions and the microscopic composition of the latter. Cardiac and pyloric glands are similar: foveolae occupy the upper half, and branching mucus-secreting glands occupy the lower half. Looser packing of the glands and the presence of occasional cysts in cardiac glands are the only two minor microscopic differences that exist with the pyloric glands. The cytoplasm of the pyloric cells can be bubbly, vacuolated, granular, or glassy.[1] Subnuclear vacuolization of mucous cells sometimes occurs and should not be misinterpreted as an expression of metaplasia.[2] Similarly, pyloric cells with glassy cytoplasm occurring in cohesive clusters should not be confused with signet ring adenocarcinoma.[3] Ciliated cells are sometimes found in the pyloric area; they are more common in the Japanese and are regarded by some as an expression of metaplasia.[4]

The fundic (oxyntic) glands are characterized by foveolae, which occupy only one-fourth of the mucosal thickness, and straight glands of composite cell distribution, which includes chief (zymogenic) cells, parietal (acid-secreting) cells, endocrine cells, and mucous neck cells. Immunohistochemical and in situ hybridization studies have shown production of pepsinogen I in both chief and mucous

Abstract

The stomach is the site of common inflammatory processes including *Helicobacter pylori*–related gastritis and alterations of the mucosa secondary to mucosal injury, generally referred to as reactive gastropathy. Other forms of gastritis including lymphocytic gastritis and other types of infectious gastritis are relatively uncommon. As is true in other organs, the most common neoplastic process is adenocarcinoma, commonly occurring in patients with *H. pylori* infection. Other neoplastic processes include lymphoma (most commonly of MALT type) and mesenchymal neoplasm (most commonly gastrointestinal stromal tumors).

neck cells (but not in the pyloric region, which features instead production of pepsinogen II).[5]

The provocative suggestion has been made that the only normally occurring epithelia in the gastroesophageal junction are esophageal squamous mucosa and gastric fundic mucosa. According to this concept, the mucosa that has been traditionally regarded as cardiac is actually metaplastic rather than native.[6] However, autopsy studies have suggested a small native and microscopically identifiable gastric cardiac mucosa exists, which of course does not preclude that this can coexist with more proximally located metaplastic cardiac-type mucosa.[7]

The mucin secreted by the gastric mucosa is almost entirely of neutral type and therefore is positive for periodic acid–Schiff (PAS) but negative for alcian blue. At the immunohistochemical level, the foveolar epithelium expresses MUC1 and MUC5AC, and the glands express MUC6[8]; these mucins have also been detected in carcinomas derived from this mucosa.[9]

Many types of endocrine–paracrine cells have been identified in the gastrointestinal mucosa, and many of them occur in the stomach.[10] In the pyloric mucosa, approximately 50% of the endocrine cells are G cells (gastrin producing), 30% are enterochromaffin (EC) cells (5-hydroxytryptamine (serotonin) producing), and 15% are D cells (somatostatin producing). In the fundic mucosa, the predominant endocrine cell is the enterochromaffin-like (ECL) cell (histamine storing); ECL cells are thought to play a key role in the mechanism of gastric acid secretion as controlled by gastrin stimulation.[11]

The other two components of the mucosa are the lamina propria and the muscularis mucosae. The latter is composed of an inner circular and an outer longitudinal layer; it is continuous with thin fascicles of smooth muscle that go up inside the lamina propria to reach beneath the surface epithelium. Under normal conditions the lamina propria contains few or no lymphoid follicles.[12]

The other layers of the stomach are the same as for the rest of the gastrointestinal tract, that is, submucosa, muscularis propria, and serosa. The submucosa consists of loose connective tissue with numerous elastic fibers; it contains plexuses of arteries, veins, lymphatics, and the Meissner nerve plexus. The muscularis propria is composed of three layers: outer longitudinal, inner circular, and innermost oblique. The inner circular layer forms the pyloric sphincter at the gastroduodenal junction. The Auerbach (myenteric) plexus is located between the circular and longitudinal layers of the muscularis propria. The interstitial cells of Cajal are also intimately associated with the nerves of the myenteric plexus and seem to play an important role in the development of gastrointestinal stromal tumors (GISTs; discussed later).

The blood supply of the stomach originates from the celiac axis, hepatic artery, and splenic artery. The lymphatic channels drain into four major areas, according to the following scheme:

1. Cardia and most of lesser curvature: left gastric nodes
2. Pylorus and distal lesser curvature: right gastric and hepatic nodes
3. Proximal portion of the greater curvature: pancreaticosplenic nodes in the splenic hilum
4. Distal portion of greater curvature: right gastroepiploic nodes in greater omentum and pyloric nodes at the head of the pancreas.

Heterotopic Tissues

Heterotopic pancreas can present clinically as a gastric mass or be discovered incidentally at autopsy or at laparotomy.[13] Grossly, it may form a hemispheric mass, a symmetric cone, or a short cylindric nipple-like projection. In the last instance, one or more ducts are usually seen emptying on the gastric lumen; this feature constitutes an important diagnostic sign radiographically (Fig. 14.1).

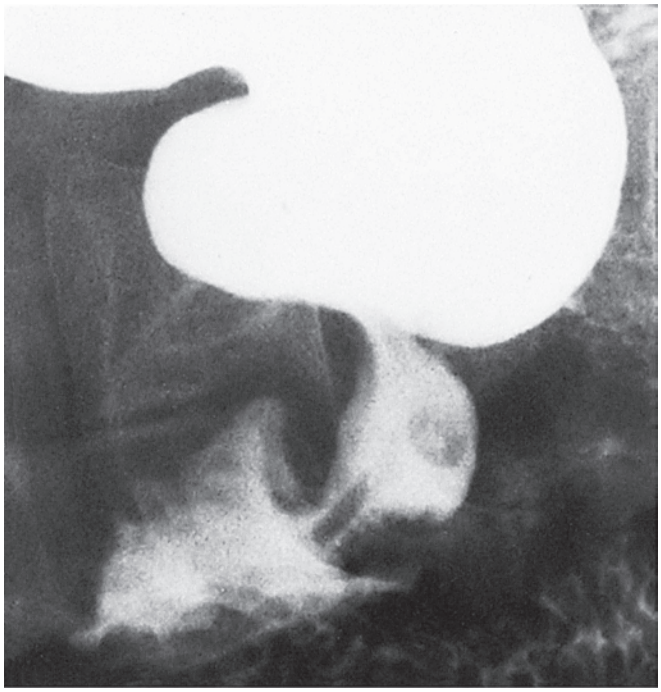

Figure 14.1 Heterotopic pancreatic tissue presenting radiographically as a small, round nodule with central umbilication in the antrum.

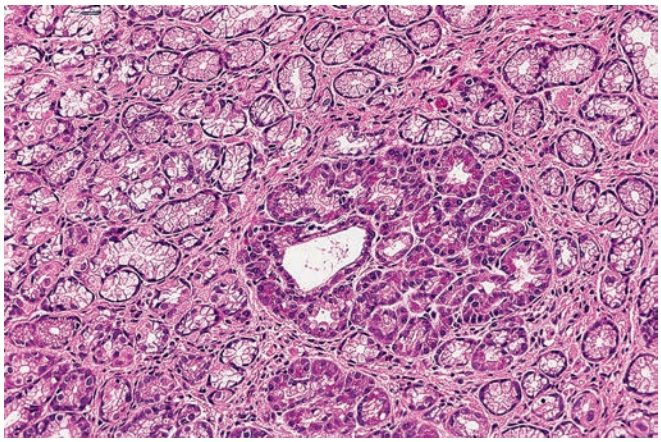

Figure 14.2 Island of exocrine pancreatic tissue composed of acini within the gastric mucosa.

Approximately 85% of these lesions occur in the submucosa and most of the remainder are in the muscular layer. It arises predominantly in the antrum (61%) followed by the pylorus (24%). Grossly, the cut surface looks like normal pancreas except for the occasional occurrence of cystic structures. Microscopically, pancreatic acini and ducts are always present, whereas islets are seen in only one-third of the cases. Mucocele-like changes and calcifications may be present.[14] Rare cases of adenocarcinoma have been reported to arise in these heterotopic tissues.[15]

An altogether different phenomenon is represented by the **pancreatic acinar metaplasia** of gastric mucosa, frequently seen in patients with chronic gastritis (Fig. 14.2).[16] These cells, which can be found in both adults and children, are immunohistochemically reactive for pancreatic lipase and trypsinogen[17]; they also contain amylase but not as frequently or abundantly as the heterotopic glands.

The lesion described as gastric **adenomyoma** is closely related to heterotopic pancreas. It is probably a hamartoma rather than a true neoplasm, the usual components being large ducts, Brunner glands, and prominent smooth muscle bundles.[18] Like conventional heterotopic pancreas, it has occasionally been found to undergo malignant transformation.[19]

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis is one of the most common congenital anomalies, but its incidence is decreasing, suggesting that environmental factors are of importance in this disorder, although its identification in twins also suggests a genetic component.[20] Most patients are males, and the most common age of onset is between 3 and 12 weeks. The gross appearance is that of a greatly thickened pyloric muscle, which occludes the pyloric channel and partially obstructs the gastric outflow. The etiology and pathogenesis remain obscure, although there is increasing evidence that the smooth muscle cells of the gastric wall are not properly innervated, and that the phasic and tonic contractile activity in the gastroduodenal junction of these patients is not coordinated with the antral contractions.[21,22] The operation of choice for decades has been the Fredet–Ramstedt pyloromyotomy, which basically consists of a linear incision through the hypertrophic muscle, leaving the mucosa intact, a procedure that is usually performed endoscopically.[23] Usually no tissue is resected in this procedure. The few microscopic studies that have been done on this condition have shown no pathologic alterations of note.[24]

The main differential diagnosis of congenital hypertrophic pyloric stenosis is with *pyloric atresia*, a genetically determined disease associated with epidermolysis bullosa.[25] The treatment consists of the surgical removal of the atretic segment (Heineke–Mikulicz technique).

Hypertrophy of the pylorus in the adult is a rare condition, usually arising in males. Clinically and radiographically, a tumor is often suspected and the stomach resected. Grossly and microscopically, all that is found is hypertrophy of the pyloric circular muscle fibers that ends abruptly at the duodenum, sometimes accompanied by a mild degree of fibrosis.[26,27]

Pyloric hypertrophy in an adult in the absence of another gastric abnormality occurs only exceptionally. Although it is possible that some of the cases represent a persistence of the infantile form into adult life, in most instances the process is probably secondary to antral gastritis or peptic ulcer of the pyloric channel, which may have healed by the time of surgery. It is also good to remember that the gross appearance of pyloric hypertrophy can be simulated by the diffuse form of gastric adenocarcinoma (traditionally known as linitis plastica).

Chronic Gastritis

The incidence and natural history of chronic gastritis has been greatly clarified by the systematic use of endoscopic gastric biopsy. The two main features of this disease are infiltration of the lamina propria by inflammatory cells and eventually atrophy of the glandular epithelium. Plasma cells and lymphocytes (with occasional formation of lymphoid follicles) predominate among the inflammatory cells, but eosinophils and neutrophils may also be present. If the inflammatory infiltrate is limited to the foveolar region and unaccompanied by glandular atrophy, the condition is designated as **chronic superficial gastritis** (Fig. 14.3). Subtle epithelial abnormalities seen in this form include a reduced amount of cytoplasmic mucin, nuclear and nucleolar enlargement, and some increase in foveolar mitoses. When the inflammation is more extensive and accompanied by glandular atrophy, the condition is termed **chronic atrophic gastritis**. Glandular atrophy is also manifested by an increase in the distance between the individual

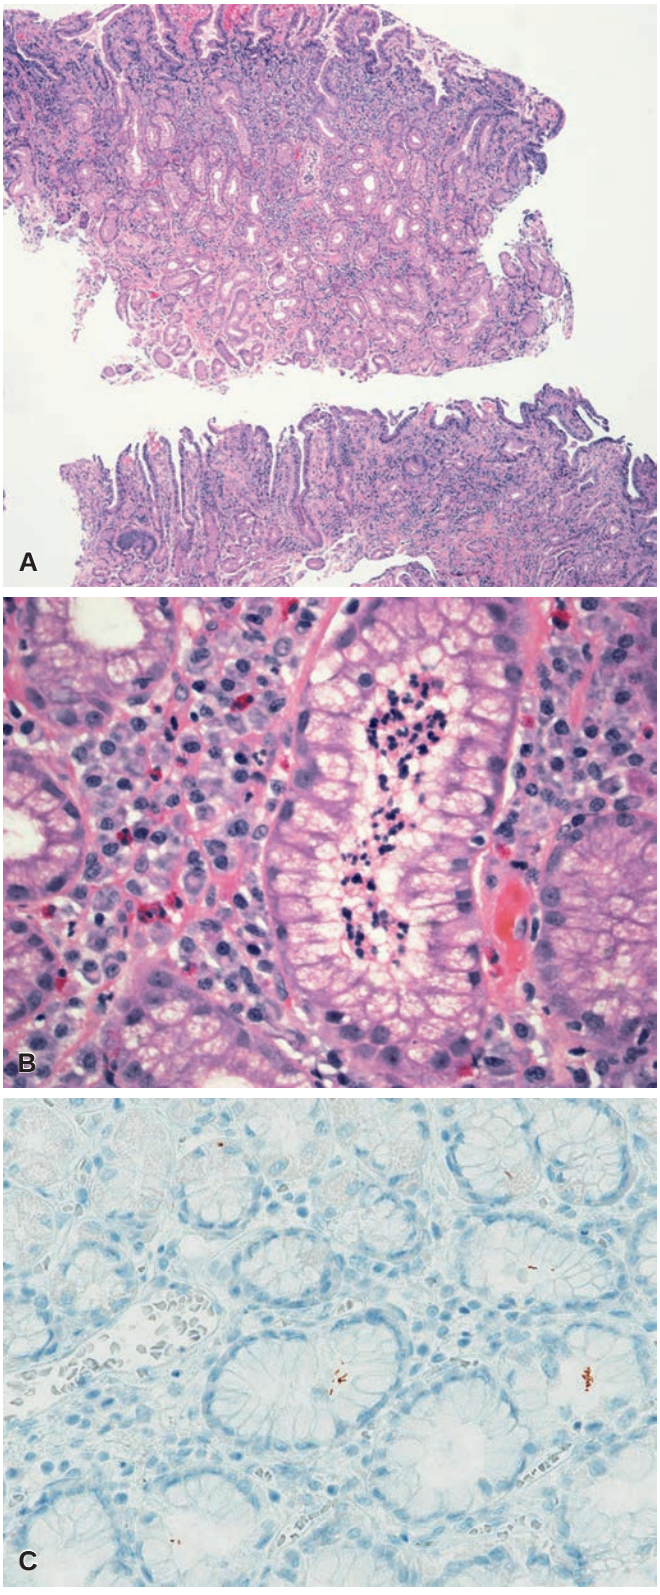

Figure 14.3 Low-Power View of a Gastric Biopsy With *Helicobacter pylori*–Related Gastritis. glands and is virtually always accompanied by intestinal metaplasia. In rare cases of (auto)immune gastritis (see later), the atrophy may have a patchy quality, resulting in a pseudopolypoid appearance of the oxyntic mucosa (Fig. 14.4).[28] Cases of gastritis in which small collections of lymphocytes and histiocytes (sometimes admixed with neutrophils) are seen surrounding a small group of glands have been referred to as *focally enhanced gastritis*; some believe this to be a marker of inflammatory bowel disease, particularly Crohn disease, but this has not been confirmed in other studies.[29]

Two types of **metaplastic change** can occur in chronic gastritis, often in combination: pyloric metaplasia of the fundic mucosa and intestinal metaplasia. In *pyloric metaplasia*, there is a replacement of the fundic-type glands by mucus-secreting glands. This is a gradual process that proceeds as an advancing front along the fundic–pyloric junction and moves proximally toward the cardia. *Intestinal metaplasia* refers to the progressive replacement of the gastric mucosa by epithelium having the light and electron microscopic features of intestinal epithelium of either small or large bowel type, including goblet cells, absorptive (brush border) cells, Paneth cells, and a variety of endocrine cells.[30] Intestinal metaplasia has been further divided into *complete (type I)* and *incomplete (type II)* types. In complete metaplasia, the gastric mucosa changes to a pattern nearly identical to that of small bowel epithelium, with the development of villi and crypts in the most advanced cases. In incomplete metaplasia, absorptive cells are absent, whereas columnar cells with the appearance of gastric foveolar cells are retained. Histochemically, the predominant mucin present in complete intestinal metaplasia is sialomucin, with small amounts of sulfomucins and/or neutral mucins; in the incomplete form, there may be predominance of either neutral mucins (type IIA) or sulfomucins (type IIB).[31] Immunohistochemically, type I intestinal metaplasia is characterized by MUC2 intestinal-type mucin and a correspondingly decreased or absent expression of MUC1, MUC5AC, and MUC6. In type II metaplasia there is, as expected, a coexpression of MUC2 and the mucins normally expressed in the stomach.[8,32]

The relationship between intestinal metaplasia of the stomach and *Helicobacter pylori* is of interest. *H. pylori* is usually absent in foci of type I intestinal metaplasia but may be present in type II foci, that is, those in which some gastric features are retained.[33] Type IIB intestinal metaplasia is said to show a closer association with intestinal-type gastric carcinoma than the other types,[34] but the results in the literature have been conflicting.[35]

Chronic gastritis is a very common disease. Its prevalence in the US population is unknown, but it clearly increases in incidence with advancing age. Most patients with mild forms of chronic gastritis are asymptomatic. Endoscopically, well-developed atrophic gastritis and gastric atrophy produce a thin, smooth mucosa with undue prominence of submucosal vessels. There is an excellent correlation between the degree of gastric atrophy as estimated by endoscopic biopsy and the results of acid secretory tests. Conversely, the correlation of histology with symptomatology, radiology, and gastroscopy is poor.[36]

Chronic gastritis has been divided into two types having similar histologic features (as already described) but a presumed different pathogenesis. The first type, which is less common, is designated as *type A* or *immune*.[37] It usually affects the fundus in a diffuse manner, spares the antrum, shows characteristic neuroendocrine hyperplasia, and is associated with antibodies to parietal cells, hypochlorhydria or achlorhydria, and high serum gastrin levels (Fig. 14.5). The alpha and beta subunits of the gastric proton pump have been identified as the major molecular target of this presumed autoimmune disease, which may evolve into pernicious anemia.[38,39] A variation on the theme is atrophic autoimmune pangastritis, in which there is both antral and fundic involvement but absence of neuroendocrine hyperplasia.[40]

The other type, by far the more frequent and referred to as *type B* or *nonimmune gastritis*, begins in the antrum and progresses proximally.[36] In some classification schemes, this has been further subdivided into a form restricted to the antrum and associated with hyperchlorhydria and often duodenal peptic ulceration *(hypersecretory gastritis)* and a form that involves both antrum and fundus in an initially patchy and eventually diffuse distribution *(environmental gastritis)*.[41,42]

Chronic atrophic gastritis is usually present in cases of gastric carcinoma, and in general its severity is proportional to the extent of the tumor. Most cases of gastric peptic ulcer are associated with antral and fundic gastritis, whereas in duodenal ulcer the gastritis, if present at all, is restricted to the antrum. The incidence and extent of intestinal metaplasia are greatest in stomachs removed for carcinoma, least in those with duodenal ulcer, and intermediate in cases of gastric ulcer.[43]

The pathogenesis of type B chronic gastritis was elucidated by the discovery of the central role of *H. pylori*, formerly known as

Campylobacter pylori. This is a curved spirochete-like bacterium that colonizes the gastric mucosa (particularly the antrum and cardia) in a variety of ways: free in mucus, surface adhesion, and intercellularly.[44] Cases with intracellular colonization show the greatest degree of epithelial damage, which includes loss of apical mucus with formation of epithelial pits and, less frequently, erosions and ulcerations.[45] *H. pylori* can be recognized in routine hematoxylin and eosin stains, especially in cases with neutrophil-mediated epithelial injury (activity). However, if the density of the organism is low, its detection can be greatly facilitated by the performance of special stains, which include Giemsa, Warthin–Starry, Steiner silver stains, the alcian yellow–toluidine blue method, Genta stain, or immunohistochemistry.[46] With the use of these techniques, *H. pylori* has been found in up to 90% of patients with chronic gastritis, 95% with duodenal ulcer disease, 70% with gastric ulcer, and 50% with gastric carcinoma.[47]

In 1991, a system was proposed for the comprehensive microscopic reporting of gastritis, referred to as "the Sydney system"[48] and later modified at Baylor.[49]

Recommendations include:

1. For antral and corpus biopsies to be assessed separately
2. For gastritis to be classified into

   Acute
   Chronic
   Special (e.g. lymphocytic, granulomatous)

3. For the following variables to be graded

   H. pylori
   Chronic inflammation
   Neutrophils (as a sign of activity)
   Atrophy
   Intestinal metaplasia

4. A concluding summary is to be provided, indicating the etiology (if known), topography (antrum, corpus, or pangastritis), and morphology (including all variables).

Other Types of Gastritis

Acute gastritis may result from the ingestion of alcohol, salicylates, and other anti-inflammatory drugs, or by the reflux of bile salts. It is more often referred to as *reactive* or *chemical gastropathy*, as there is typically little inflammation, and as such, there is little gastritis (Fig. 14.6).[50] Endoscopic biopsies often show foveolar hyperplasia, reactive epithelial alterations, subepithelial capillary ectasia, increased lamina propria smooth muscle, and sometimes an erosion. Neutrophilic infiltration of the foveolar and glandular lumina may also be present, but in general the inflammatory component is not significant.

Hemorrhagic gastritis is an acute life-threatening condition usually engrafted on a background of chronic gastritis.[51] Alcoholism, anti-inflammatory drugs, and stress have been implicated as precipitating factors.[52] Some cases have been attributed to cytomegalovirus (CMV) infection.[53] The appearance of the stomach at surgery is characterized by multiple areas of hemorrhage throughout the entire mucosa (Fig. 14.7). The microscopic appearance is not as dramatic as the surgical findings would suggest. In some cases, multiple superficial erosions are found (and the term *erosive gastritis* is therefore used), but in many others the only abnormality seen in the biopsy is a chronic atrophic gastritis, with perhaps some extravasation of blood in the lamina propria. The diffuse gastric condition, often seen as a complication of portal hypertension and sometimes leading to severe hemorrhage, is often reported as a form of hemorrhagic gastritis, but the microscopic changes are more consistent with reactive gastropathy and referred to as *portal hypertensive gastropathy*.[54]

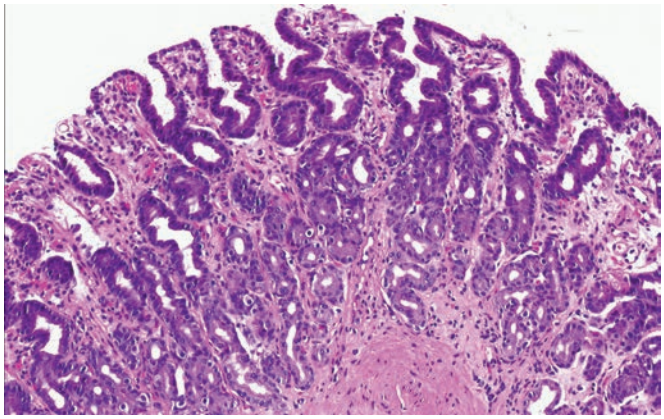

Figure 14.6 Reactive gastropathy with loss of mucin within the epithelium and regenerative nuclear changes.

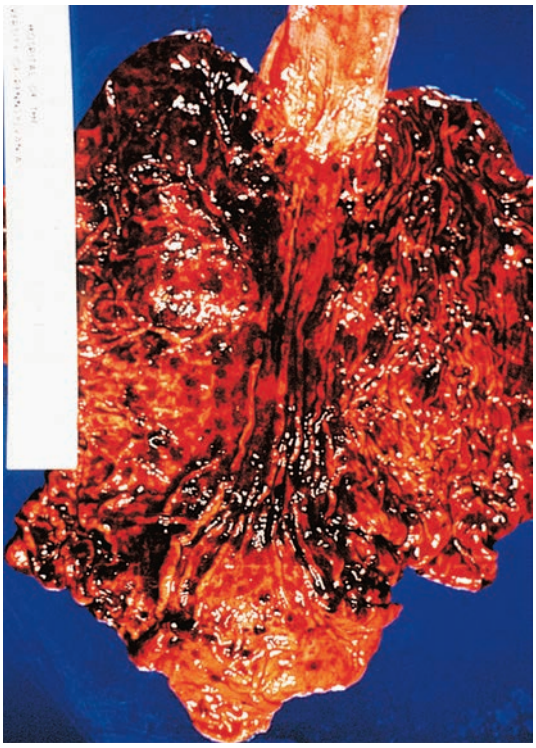

Figure 14.7 Gross appearance of hemorrhagic gastritis as seen at autopsy. The entire gastric mucosa is involved by fresh hemorrhage.

Collagenous gastritis is an exceptionally rare condition which—like its more common colonic counterpart—is characterized by a thick subepithelial collagen band associated with a mucosal inflammatory infiltrate often rich in eosinophils (Fig. 14.8).[55,56] Most pediatric cases have presented with anemia and abdominal pain and have been limited to the stomach, whereas those in adults have been usually associated with involvement of the ileum and colon (but not of the duodenum).[57]

Lymphocytic gastritis is a fairly uncommon form of chronic gastritis that shows some resemblance to celiac disease and lymphocytic colitis.[58] Indeed, most cases are associated with celiac disease, although others may be related to *H. pylori* infection.[59] Microscopically,

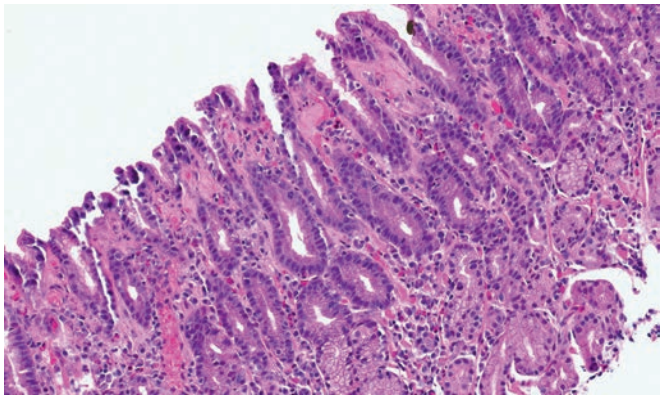

Figure 14.8 Collagenous gastritis with thickening of the subepithelial collagen table.

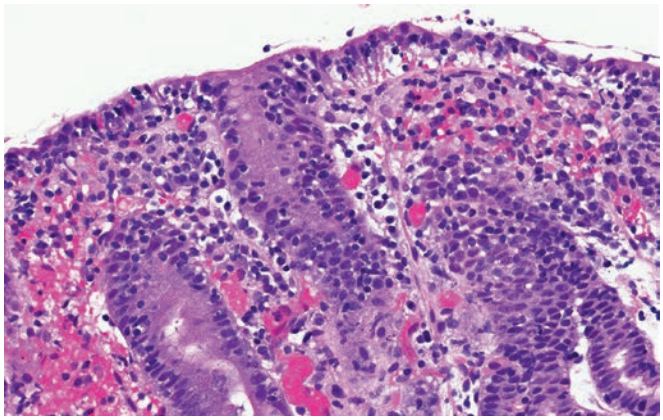

Figure 14.9 Lymphocytic gastritis showing significant surface epithelial lymphocytosis.

the condition is characterized by lymphocytosis of foveolar and surface epithelium (intraepithelial lymphocytosis) with expansion of the lamina propria by plasma cells (Fig. 14.9).[60]

Allergic/eosinophilic gastroenteritis presents in a gastric biopsy as infiltration of the lamina propria by eosinophils, which in severe cases is diffuse and accompanied by degenerative and regenerative changes of the surface and foveolar epithelium.[61] This occurs most commonly in young male patients, often in patients with food allergies. This mucosal disease can result in malabsorptive diarrhea, iron deficiency anemia, protein-losing enteropathy, or failure to thrive. Most patients have a peripheral eosinophilia. This is essentially a diagnosis of exclusion.[62]

There are mural and serosal forms of eosinophilic gastroenteritis which appear to be unrelated to the mucosal form. The mural form predominates in the antrum, resulting in mural thickening and occasionally obstructive symptoms.[62] Some patients respond to *H. pylori* eradication therapy. The rare serosal form typically results in acute abdominal pain and eosinophilic ascites fluid. Patients do not have a history of hypersensitivity, and the exact cause is unknown. Parasitic infection can closely mimic this condition.[63]

Granulomatous gastritis can be caused by tuberculosis,[64] mycosis,[39] sarcoidosis,[65] or Crohn disease[58] or may be part of a diffuse vasculitis syndrome.[66] When the cause of the inflammation remains unknown, the term *idiopathic granulomatous gastritis* is used but with the understanding that this is not a specific entity.[67] Although the relationship is not clear, some patients with this finding also have *H. pylori* infection.

Syphilis of the stomach, now extremely rare but still encountered, begins as an erosive or ulcerative lesion in the pylorus.[68] In later stages, the stomach becomes shrunken and fibrotic, with a leather bottle appearance that simulates radiographically and grossly the "linitis plastica" appearance of diffuse carcinoma.[69] Microscopically, there is ulceration, chronic inflammation rich in plasma cells, and lamina propria fibrosis; endarteritis obliterans may also be present. Other cases may show a heavy lymphoid infiltrate. Treponemal DNA has been isolated from some of these cases by polymerase chain reaction.[70] The organism can also be identified immunohistochemically.[71]

Malakoplakia can present as a focal gastric lesion.[72] As in other sites, the disease is characterized microscopically by a predominantly histiocytic inflammatory infiltrate containing Michaelis–Gutmann bodies.

CMV infection may be identified in gastric biopsies of bone marrow transplant recipients and other immunocompromised patients; the finding is indicative of generalized disease.[73] It may rarely be complicated by perforation and fistula formation.[74] Its diagnosis may require immunohistochemistry, in situ hybridization, or even PCR.[75]

Cryptococcosis is another infectious disease that has been observed in the stomach and other portions of the digestive tract in susceptible individuals, including patients with HIV infection.[76] Similarly, **bacillary angiomatosis** can involve the stomach of HIV-infected individuals and result in severe hematemesis.[77]

Graft-versus-host disease following allogeneic bone marrow transplantation manifests in the stomach with subtle microscopic findings, including apoptosis and gland destruction, sparse inflammatory infiltrate, and granular eosinophilic debris in dilated glands.[78] The latter is a very specific but relatively insensitive marker. In its absence, the distinction from CMV infection may not be possible.[79]

Peptic and Other Benign Ulcers

Peptic ulcer can occur wherever mucosa is bathed by gastric secretion. This includes the stomach, duodenum, lower third of esophagus, margin of a gastrojejunostomy, and Meckel diverticulum with ectopic gastric mucosa. Acid peptic digestion is the ultimate cause for ulceration, but the mechanism(s) that render the mucosa susceptible to this digestion are just as important for the pathogenesis.

Duodenal ulcers (which are more common than gastric ulcers, although their relative incidence seems to be decreasing) are classically associated with acid hypersecretion, whereas most patients with gastric ulcer secrete either low normal or below normal amounts of acid. Thus it would seem that the initial event in gastric ulcer is mucosal injury, which renders it more susceptible to acid peptic damage. This injury may be mediated in some instances by reflux of bile and pancreatic juice and is manifested anatomically by the presence of gastritis, an almost invariable finding in patients with peptic ulcer disease. Considerable evidence has accumulated indicating that *H. pylori* plays a crucial role in the pathogenesis of this disease.[80,81] The risk for the development of a peptic ulcer is approximately 10-fold higher in patients with nonatrophic *H. pylori*–positive gastritis than in those with a normal stomach, and the risk is increased further (twofold to threefold) when there is antral atrophy. Instead, the presence of corpus atrophy decreases the incidence of ulcer (to practically negligible levels when the atrophy is complete).[82]

Acute gastric ulcer is a common finding at autopsy and is usually a terminal event (Fig. 14.10). It may also be seen during life in any debilitating illness, in sepsis, following surgery or trauma *(stress ulcer)*, in patients with central nervous system injury or disease *(Cushing ulcer)*, as a complication of long-term steroid therapy *(steroid ulcer)*, in association with aspirin ingestion, in patients with extensive

Figure 14.10 Multiple acute ulcers of the stomach occurring in a chronically debilitated patient. Microscopically, there was little fibrous reaction in the ulcer bed.

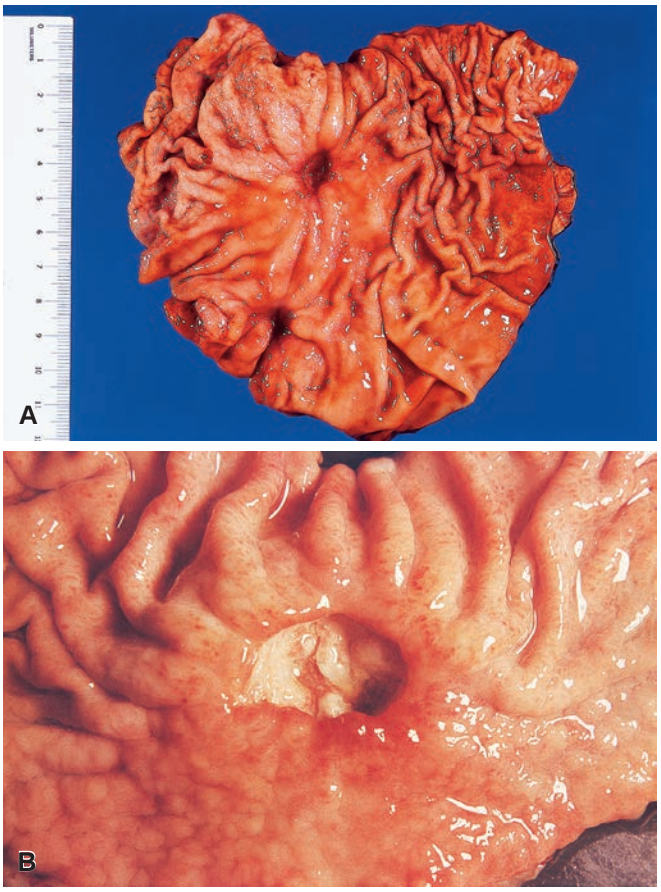

Figure 14.11 **A,** Typical gross appearance of chronic peptic ulcer of the stomach. Sharply delimited chronic peptic ulcer with converging folds of mucosa in the upper half. **B,** The ulcer bed is covered by fibrinopurulent exudate.

burns *(Curling ulcer)*, as a complication of radiation therapy or hepatic arterial chemotherapy, and following the introduction of tubes into the stomach.[83] Marked epithelial atypia may be present in the gastric lesions resulting from hepatic arterial infusion chemotherapy, which can be easily confused with carcinoma.[84,85] If the ulcer involves only the mucosa (erosion), it can heal completely; if part of the muscle is destroyed, it is replaced by fibrotic tissue, leaving a depressed pit. Any of these ulcers, if deep enough, may perforate; this complication is particularly common in ulcers induced by radiation therapy.[86]

Chronic peptic ulcer always occurs in an achlorhydric zone of mucosa (i.e. an area of stomach lined by pyloric-type mucosa). Up to 95% of the ulcers are located on the lesser curvature near the incisura angularis; however, since chronic gastritis is accompanied by antral metaplasia of the fundal mucosa that advances proximally from the pylorus, peptic ulcer can be found anywhere in the stomach, although it is always surrounded by pyloric-type mucosa.

The average age at the time of diagnosis is 50 years, but the disease can occur in any age group, including children. A male predilection exists but seems to be decreasing. Approximately 5% of ulcers are multiple. Although some controversy persists, most authors believe that ulcers larger than 3 cm, or those located in the greater curvature, do not indicate a high likelihood of malignancy as formerly believed. The diagnosis of peptic ulcer has been greatly facilitated by the use of fiberoptic gastroscopy, which allows the endoscopist to have a direct view of the ulcer, to photograph it, and to obtain biopsies from the edges.

Grossly, an active lesion is sharply delineated, usually oval or round but sometimes linear, with converging mucosal folds extending to its margin (Fig. 14.11). The proximal margin tends to have overhanging edges, whereas the distal margin usually has sloping borders. On section, there is undermining of the edges (especially on the proximal side) and complete replacement of the muscle wall by white fibrous tissue. On the serosal side, there may be subserosal fibrosis and inflammatory enlargement of regional lymph nodes. Prominent marginal nodularity about the ulcer suggests the presence of carcinoma; however, it should be remembered that it may be impossible to grossly distinguish a peptic ulcer from an ulcerated carcinoma, as 10%–15% of gastric carcinomas appear, grossly, to be benign ulcers.

Microscopically, chronic peptic ulcer will show four more or less distinct layers: (1) a surface coat of purulent exudate, bacteria, and necrotic debris; (2) fibrinoid necrosis; (3) granulation tissue; and (4) fibrosis, which can replace the muscle wall and even extend into the subserosa (Fig. 14.12). At the edges, the muscularis mucosae is seen to fuse with the muscularis externa. Other common features in the ulcer bed include thickening of vessels (caused by subendothelial fibrous proliferation) and hypertrophy of nerve bundles. The necrotic surface may show superimposed infection by *Candida albicans*. As already stated, the mucosa surrounding the ulcer is of pyloric type. In cases infected with *H. pylori*, a typical constellation of morphologic changes (loss of the apical portion and dropout of epithelial cells, epithelial pits, erosions, and cellular tufts) is seen at the ulcer edge.[87]

In the healing process of a peptic ulcer, regenerating epithelium grows over the surface. This epithelium often exhibits intestinal metaplasia and may contain chief and parietal cells when the ulcer is located in the fundic area. As already stated, the danger of overdiagnosis is particularly great in ulcers caused by arterial infusion chemotherapy because of the marked epithelial atypia that may be present.

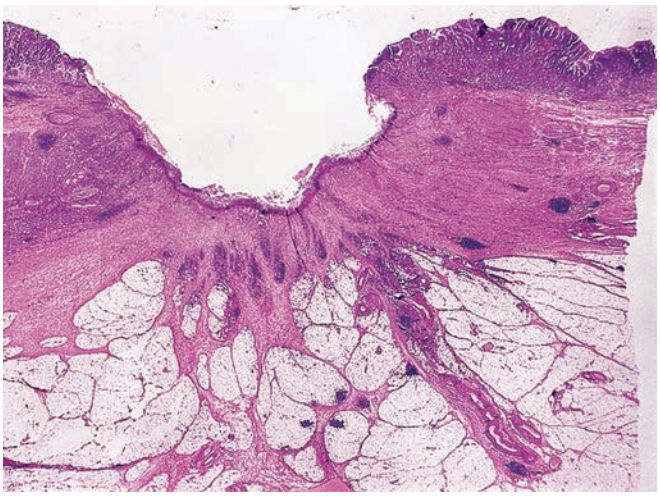

Figure 14.12 Whole-Mount View of Chronic Peptic Ulcer. The external muscle layer has been totally destroyed. Note the overhanging mucosa on one edge and the sloping mucosa on the other.

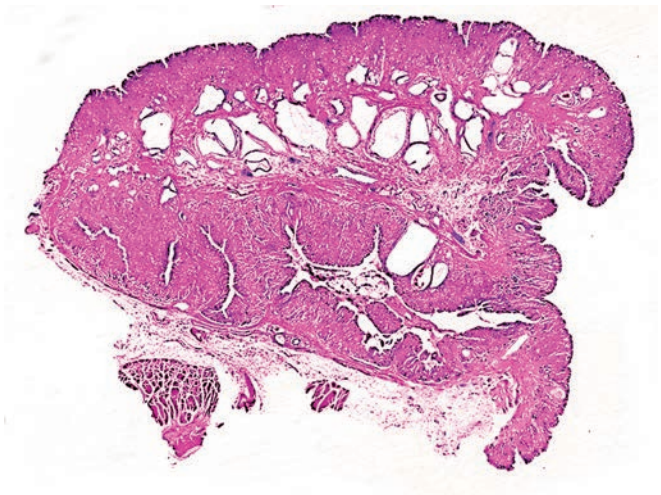

Figure 14.13 Whole-mount view of gastritis cystica profunda.

Figure 14.14 Huge Trichobezoar Removed From the Stomach. The tangled mass of hair looks like a mold of the gastric cavity.

The medical treatment of gastric ulcer consists of neutralizers of gastric acid (antacids, proton pump inhibitors, and/or H_2-blockers), and antibiotic eradication of *H. pylori* when present.[88] The development of complications (hemorrhage, perforation, obstruction), and recurrence of the ulcer are indications for surgery, including subtotal gastric resection without vagotomy, truncal vagotomy and drainage (either gastroenterostomy or pyloroplasty), and truncal vagotomy plus antrectomy. When a portion of stomach is removed, continuity is reestablished through a gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II). The long-term results of surgery are good to excellent in over 80% of the patients.[89]

Other Non-Neoplastic Lesions

Duplication of the stomach, a very rare anomaly, presents as a unilocular or multilocular cyst lined by gastric mucosa.[90] It may communicate with the lumen of the normal stomach; usually it does not, the result being distention with fluid causing obstruction and a palpable mass. **Diverticula** most often occur in a juxtacardiac position and likely are the result of anatomically weak areas.[91]

Cysts may be found in a mucosal or submucosal location. Intramucosal cysts are the most common and are often associated with intestinal metaplasia.[92] Submucosal cysts have also been designated as *gastritis cystica profunda* (Fig. 14.13).[93] Although some may be an expression of heterotopia, most seem to be acquired.[94]

Bezoars are foreign bodies in the stomach and are occasionally seen as surgical specimens (Fig. 14.14).[95] The great majority fall into two categories: *trichobezoar*, composed of hair, and *phytobezoar*, composed of vegetable matter.[96] More than 85% of the latter are caused by ingestion of unripened persimmons.[97] Factors favoring the development of bezoars include lack of teeth, vagotomy or previous gastric surgery, and obstructing lesions of the gastric outlet.[98]

Aneurysms of gastric vessels (Dieulafoy disease; caliber-persistent artery) are thought to be malformative rather than degenerative in origin.[99,100] They are usually single, located in the submucosa, usually high on the lesser curvature, and characterized by a large tortuous vessel surmounted by a small defect in the overlying mucosa.[101] When the lesion perforates, massive and sometimes fatal hemorrhage may result.

Gastric antral vascular ectasia (GAVE or "watermelon stomach") is an acquired vascular disease of the stomach that may result in blood loss and iron deficiency anemia.[102] Endoscopically, one sees parallel red stripes at the crest of the mucosal folds in the antrum, resembling the stripes of a watermelon. Cases involving the cardia have also been described.[103] The microscopic changes on gastric biopsy are minimal and consist of an increase in the number and caliber of vessels, fibrin thrombi, and fibromuscular hyperplasia.[104,105] The changes resemble those of reactive gastropathy but include the characteristic fibrin thrombi, and correlation with the endoscopic findings is required to render a diagnosis.

Xanthoma (xanthelasma) of the stomach appears as a small yellow intramucosal lesion characterized by the accumulation of neutral fat in foamy histiocytes in the lamina propria. This clinically insignificant lesion should not be confused microscopically with early carcinoma or signet ring carcinoma.[106]

Other rare non-neoplastic gastric disorders, many of them clinically inconsequential, associated with ulcers or inflammatory processes, and possibly beginning as perivascular fibrotic lesions, include **pseudoxanthoma elasticum** (which can result in severe hemorrhage),[107] **elastofibroma**,[108] **mucosal calcinosis** (secondary to the administration of aluminum-containing antacids or sucralfate therapy in organ transplant patients),[109] **siderosis** (diffuse iron deposition in antral and fundic epithelium),[110] **amyloidosis** (diffuse or localized, sometimes complicated by bleeding),[111] **barium granuloma**

(developing in the gastric wall following radiographic examination),[112] isolated **Langerhans cell histiocytosis**,[113] **parasitic infections** (such as strongyloidosis in immunocompromised patients)[114] and Rosai–Dorfman disease.[115]

Polyps

The nomenclature of gastric polyps has been confusing, in part because they have often been regarded as analogous to colorectal polyps in microscopic appearance and natural history, whereas in fact most types of gastric polyp do not have an exact counterpart in the large bowel.[116]

Hyperplastic polyps are a fairly common type of gastric polyp. Use of the term *hamartomatous polyp* for these lesions should be discouraged because it elicits confusion with the different type of polyp seen as a component of the Peutz–Jeghers syndrome. The term hyperplastic polyp is preferable, but it should be emphasized that this lesion is morphologically very different from the lesion so named in the large bowel. Gastric hyperplastic polyps tend to arise in a background of hypochlorhydria, low levels of pepsinogen I, hypergastrinemia, chronic gastritis, and gastric atrophy.[117] Interestingly, they have also been found to be more common in post-transplant patients.[118]

Hyperplastic polyps are randomly distributed in the stomach and are generally small, sessile, and multiple, with a smooth or slightly lobulated contour (Fig. 14.15). Microscopically, they show elongation, tortuosity, and dilation (often cystic) of the gastric foveolae, with a component of pyloric or—less commonly—fundic type of glands in the deeper portion. The stroma, usually prominent, is characterized by edema, patchy fibrosis, inflammatory cells, and scattered smooth muscle bundles from the muscularis mucosae. Exceptionally, collections of foamy macrophages (not to be confused with signet ring cells) are present. Epithelial atypia may be present but is regenerative in nature and limited to the tips of the foveolae. Some authors separate hyperplastic from inflammatory polyps on the basis of relative amounts of glandular and stromal changes, but the presence of a continuous spectrum suggests that these are different stages of the same process.[119] The polypoid lesion sometimes developing on the gastric side of gastroenterostomy stomas may also have a microscopic appearance similar to that of a hyperplastic polyp, except for its more diffuse nature; dysplastic changes can also occur at this site.[120]

Hyperplastic polyps have been found to coexist frequently with carcinoma elsewhere in the stomach,[121] but these figures are biased, since most of the specimens studied had been removed because of carcinoma. The incidence of gastric carcinoma developing after endoscopic removal of hyperplastic polyps is quite low and probably more related to the atrophic gastritis that often accompanies the polyp than to the polyp itself[122]; in a study by Orlowska et al., only 2 of 131 patients with hyperplastic polyps (1.6%) developed carcinoma in follow-up.[123]

As the name indicates, hyperplastic polyps have traditionally been regarded as non-neoplastic; however, they share some molecular alterations with the adenomatous lesions described next. Furthermore, they may undergo progression to dysplasia or carcinoma, although the likelihood of this occurring remains much lower than for their adenomatous counterparts.[124] Malignant transformation is accompanied by increased proliferative activity and overexpression of p53.[125]

Adenomas are usually antral in location, generally single and large, and either sessile or pedunculated (Fig. 14.16). Microscopically, they are composed of dysplastic glands with pseudostratified epithelium showing nuclear abnormalities and prominent mitotic figures.[116] They have been further subdivided into *foveolar-type* and *intestinal-type,* depending on the nature of the glandular epithelium.[126,127] The intestinal-type adenomas, which are the most common, are analogous in appearance and natural history to those in the colorectum and are thought to arise in a background of mucosal atrophy and intestinal metaplasia (Fig. 14.17).[127] Adenomatous polyps appear grossly as elevated lesions with a flat surface. A few of these polyps appear as shallow mucosal depressions rather than elevations; these are referred to as *depressed adenomas*.[128] Many of

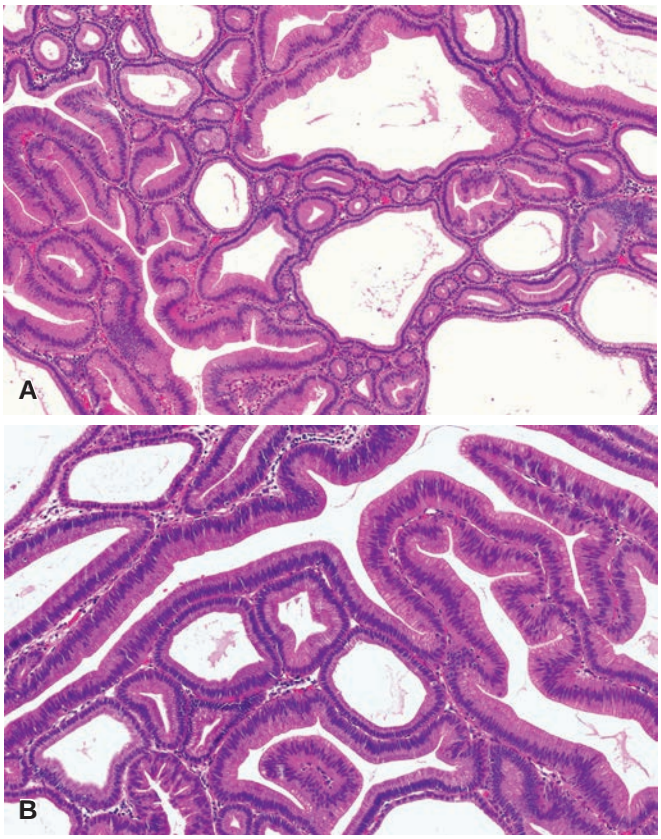

Figure 14.19 Low-power **(A)** and higher-power **(B)** views of a gastric pyloric gland adenoma.

these polyps have been described in stomachs that have been removed because of an independent carcinoma, but a selection bias is obviously operating; however, there is no question that the two processes are related and that the polyps themselves can undergo malignant transformation, similar to their colorectal counterparts (Fig. 14.18).[129] The exact incidence of progression is not known but appears to be relatively low. The tendency for malignant transformation is higher for the intestinal-type than for the foveolar-type adenomas[127] despite the fact that the molecular alterations that have been detected in these two polyp types are similar.[126]

Pyloric gland adenoma is a well-described type of gastric polyp, although they are relatively uncommon. They also frequently develop in the setting of chronic gastritis with intestinal metaplasia and/or atrophy,[130,131] and they are most common in elderly patients, with a slight female predilection.[130,131] They most often arise in the fundus/body and are usually less than 2 cm. Histologically, it is composed of tightly packed tubules comprised of cuboidal or columnar cells with pale to eosinophilic cytoplasm (Fig. 14.19). They lack an apical cap of mucin. These lesions stain with antibodies to MUC5AC and MUC6, the latter marker being typically absent in intestinal and foveolar-type adenomas.[132] Between 10% and 40% show conventional dysplasia, and invasive carcinomas may also arise from these lesions.[130,131] As such, they are ideally treated by complete removal.[133]

Oxyntic gland adenoma may arise in the setting of chronic gastritis or familial adenomatous polyposis (FAP) and is composed of oxyntic glands with parietal and chief cells.[134] It typically arises in the fundus/body, and, although cytologic atypia is often present, they typically behave in a benign fashion. Prior to more recent studies, such lesions were often referred to as "gastric adenocarcinoma with chief cell differentiation."[135]

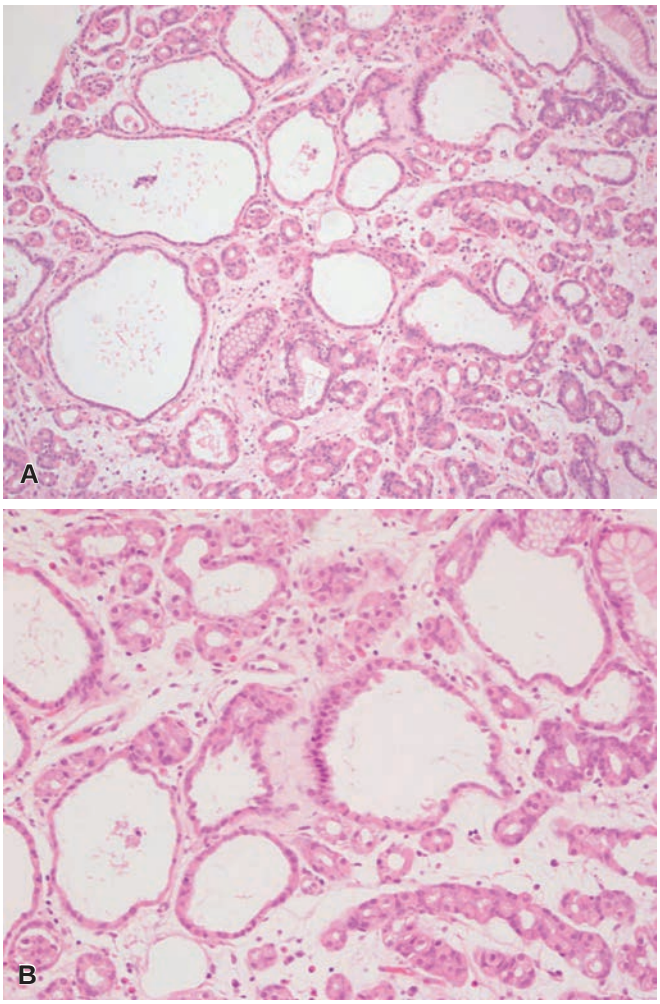

Figure 14.20 Low-power **(A)** and high-power **(B)** views of a fundic gland polyp with cystic dilation of fundic glands.

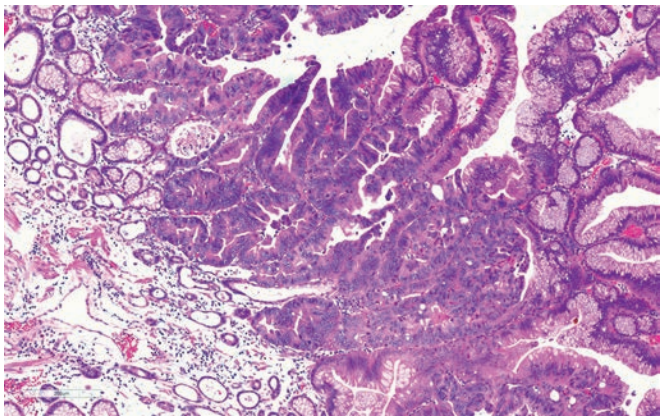

Figure 14.21 Fundic gland polyp with a focus of high-grade dysplasia.

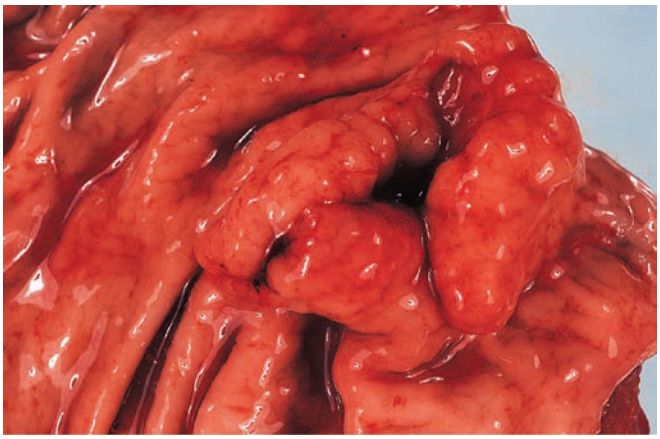

Figure 14.22 Gross appearance of inflammatory fibroid polyp of stomach. The surface has a knobby appearance.

Fundic gland polyps are incredibly common and present as multiple small (average size 2.3 mm) polypoid projections in the gastric fundus or body.[136,137] Their distinguishing microscopic feature is the presence of microcysts lined by fundic epithelium (Fig. 14.20); the overlying foveolae are usually shortened.[138] These polyps can occur in a sporadic form or present in patients with the Zollinger–Ellison syndrome,[139] those on long-term treatment with proton pump inhibitors,[140] and those affected by FAP. In the latter instance, they are more likely to show focal dysplastic changes than otherwise (Fig. 14.21).[141,142] It has been proposed that the key molecular alteration in sporadic fundic gland polyps is an activating mutation of the β-catenin gene,[143] whereas those associated with FAP harbor somatic, second hit alterations in the *APC* gene.[144]

Other types of gastric epithelial polypoid lesions that have been described include *foveolar hyperplasia* (which arises against a background of atrophic gastritis and represents an early stage of hyperplastic polyp)[145] and the *hamartomatous polyps* associated with Peutz–Jeghers syndrome and juvenile polyposis.

It should be stated that polyps of different types can coexist in the same stomach and that occasional lesions cannot be easily placed in a specific category, especially in small biopsy specimens.

Polyposis syndromes of the gastrointestinal tract often involve the stomach. In FAP and the related Gardner syndrome, gastric involvement occurs in over 50% of the cases; the gastric polyps can be adenomatous (including pyloric gland adenomas), hyperplastic, or of the fundic gland type.[141,142,146] As stated above, fundic gland polyps in these patients often show dysplastic features. In Peutz–Jeghers syndrome, hamartomatous gastric polyps have been found in approximately 20% of the cases (sometimes accompanied by an adenomatous component) and occasionally gastric adenocarcinomas.[147–149] In generalized juvenile polyposis and Cronkhite–Canada syndrome, the incidence of gastric retention (juvenile) polyps is very high,[150,151] and there have been occasional cases of associated gastric adenocarcinoma.[152] Cowden syndrome (multiple hamartoma syndrome) can also be accompanied by small sessile gastric polyps, most of which seem to be of the hyperplastic type.[153]

Inflammatory fibroid polyp of the stomach is not uncommon, may be associated with hypochlorhydria or achlorhydria, and is usually located in the antrum.[154] Radiographically, endoscopically and grossly, it presents as a sessile or pedunculated mass (Fig. 14.22). Microscopically, this lesion is centered in the submucosa and is characterized by a vascular and fibroblastic proliferation (often in a whorl-like arrangement around blood vessels) and a polymorphic inflammatory response, usually dominated by eosinophils (Fig. 14.23).[155] Many also show focal staining for $CD34_{156}$, raising the possibility of dendritic cell origin.[156] Local excision (preferably in the form of endoscopic removal) is the treatment of choice, and the evolution is benign. Interestingly, it has been shown that gastric inflammatory fibroid polyps consistently express platelet-derived growth factor receptor alpha *(PDGFRA)*, and activating mutations

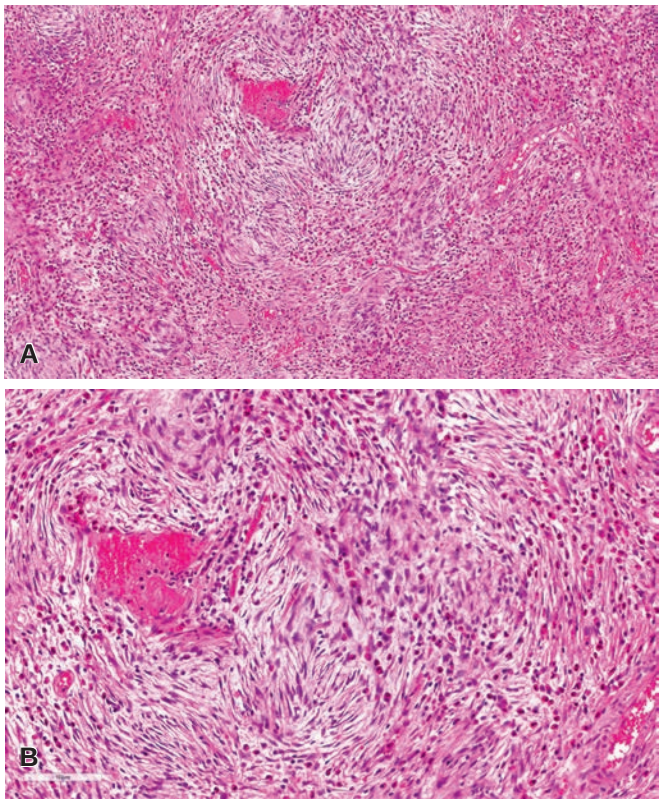

Figure 14.23 Low-grade **(A)** and higher-power **(B)** views of a gastric inflammatory fibroid polyp. Concentric cellularity and fibrosis around blood vessels is a prominent feature, as is a scattering of eosinophils.

Figure 14.24 Gross Appearance of Ménétrier Disease. The entire fundic mucosa is involved by an exuberant proliferative change. Note the sharp edge of the lesion at the junction of the fundus and antrum.

of the encoding gene are found in 70% of cases,[157,158] raising the possibility of a neoplastic process.

Ménétrier Disease and Zollinger–Ellison Syndrome

Ménétrier disease, also known as hypertrophic or hyperplastic gastropathy, giant hypertrophic gastritis, and giant hypertrophy of gastric rugae, is accompanied by hypochlorhydria or achlorhydria and often by impressive hypoproteinemia.[159] Chronicity and severity are the rule in adults, but it is often self-limited in the few reported pediatric cases.[160] Radiographically, endoscopically, and grossly, the condition can be confused with malignant lymphoma and carcinoma. It is often centered along the greater curvature of the stomach and is characterized grossly by markedly hypertrophic rugae resembling cerebral convolutions (Fig. 14.24). The transition between normal and diseased mucosa is always abrupt. In the typical form of the disease, there is diffuse involvement of the fundic portion, with sparing of the antrum. In the localized form, there is a well-circumscribed cerebroid mass either in the fundus or the antrum.[161] Microscopically, there is a striking *foveolar hyperplasia*, accompanied by hypermucinous change, tortuosity, some degree of cystic dilation, and extension into the base of the glands and sometimes even beyond the muscularis mucosae (Fig. 14.25). The glandular component is diminished, and the stroma is edematous and inflamed, with a component of eosinophils.[162] Many cases diagnosed by radiologists and endoscopists as hypertrophic gastritis do not show the diagnostic morphologic features of Ménétrier disease, but rather a chronic gastritis with prominent lymphocytic infiltration and varying degrees of glandular atrophy ("hypertrophic lymphocytic gastritis").[163] The relationship between the latter disorder (sometimes designated as "varioliform gastritis" by endoscopists) and the fully developed Ménétrier disease is not clear.[164] The differential diagnosis also often includes gastric involvement by juvenile polyps. Carcinoma may develop in a stomach affected by Ménétrier disease, but the incidence does not seem higher than that seen in ordinary atrophic gastritis.[165]

Zollinger–Ellison syndrome may be accompanied by gastric changes radiographically and grossly similar to those of Ménétrier disease; however, microscopic examination will reveal hyperplasia primarily affecting the *secretory* rather than the foveolar portion of the fundic gland, even if the latter may also participate (Fig. 14.26). This hyperplasia mainly involves the parietal cells, but there may also be an increase in the number of ECL cells, both resulting from gastrin stimulation.[166] In some of these patients, the Zollinger–Ellison syndrome is part of a multiple endocrine neoplasia syndrome. We have seen several cases of this syndrome associated with multicentric carcinoid tumors, mainly located in the fundus and composed of ECL cells. Other abnormalities of the gastric mucosa that can be seen in patients with Zollinger–Ellison syndrome include fundic gland polyps and intramucosal cysts.[167]

The occurrence of gastric lesions with morphologic features similar to those seen in the Zollinger–Ellison syndrome but without hypergastrinemia (some of them associated with protein loss and others with gastric adenocarcinoma) suggests the existence of clinicopathologic variations among these poorly understood disorders.[161,162]

Regenerative Changes and Dysplasia

Regenerative changes occur most often in areas of mucosal injury, resulting in epithelial cells which are immature, with basophilic cytoplasm, slightly hyperchromatic nuclei, and reduced or absent mucus secretion. These cells are uniform in size and shape, with basally or centrally located nuclei arranged in a row; pseudostratification is slight or absent. Maturation and differentiation toward the surface are present. There is usually an accompanying

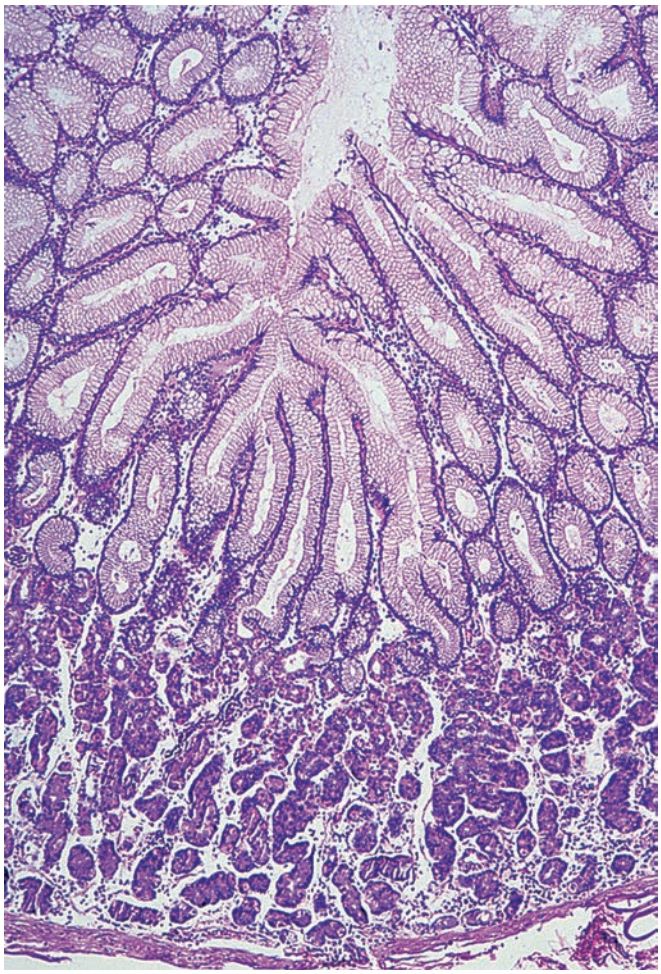

Figure 14.25 Microscopic Appearance of Ménétrier Disease. There is marked hyperplasia of the foveolar epithelium accompanied by atrophy of the underlying secretory mucosa.

inflammatory reaction, sometimes intense, and focal erosive changes are common. A particularly atypical form of reactive change occurs following chemoradiotherapy for esophageal carcinoma.[168]

Dysplasia should be clearly distinguished from regenerative changes, which are far more common. Most carcinomas of the stomach are accompanied and often preceded by dysplasia; therefore, the recognition of this condition in biopsy specimens is of great importance in giving warning of the possibility of a coexisting carcinoma and in indicating that the patient may be at a higher risk for the subsequent development of gastric cancer. Interestingly, this risk seems to be much higher in Asian and European countries than in the United States. In **dysplasia**, there is increased cell proliferation accompanied by abnormalities in cell size, configuration, and orientation (Fig. 14.27). Mucus secretion is reduced or absent, and there is an increase in the nucleocytoplasmic ratio, loss of nuclear polarity, and pseudostratification. Mitoses are numerous, including atypical forms. These cellular abnormalities are accompanied by architectural derangement of the glands, resulting in cellular crowding, intraluminal folding, and glandular budding and branching. There are two forms

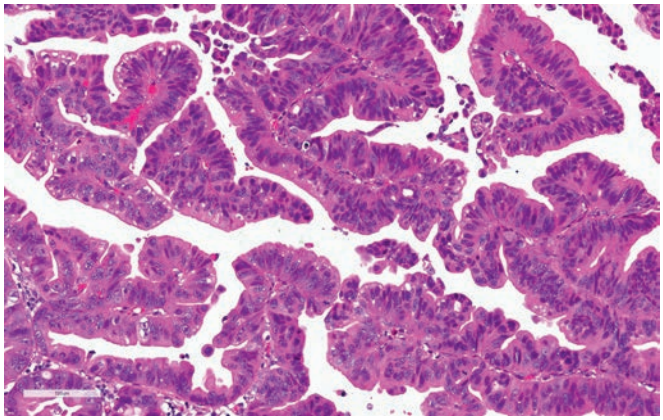

Figure 14.27 High-grade dysplasia of the gastric mucosa showing a prominent villiform architecture.

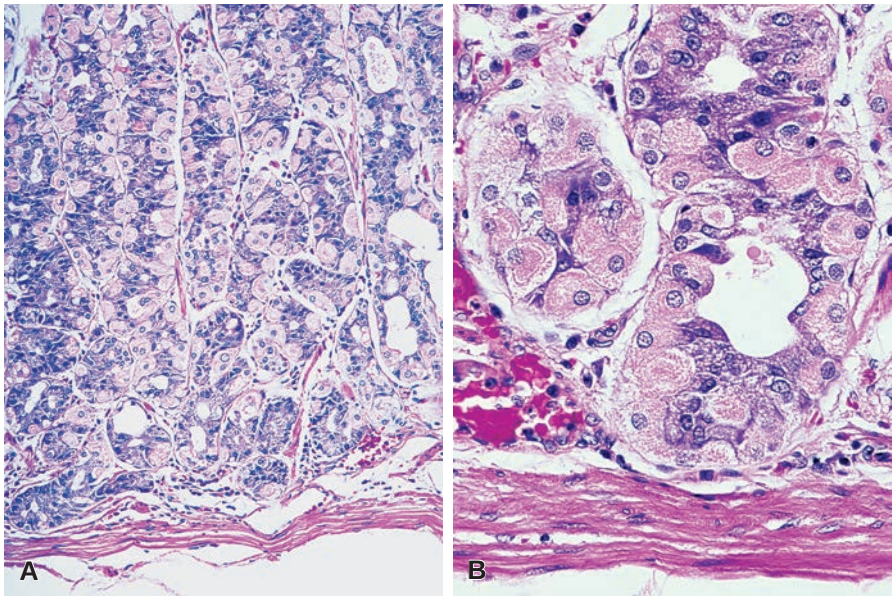

Figure 14.26 Low-power **(A)** and high-power **(B)** views of gastric mucosa in a patient with Zollinger–Ellison syndrome. Note the large increase in the number of parietal cells.

of gastric dysplasia—intestinal type (adenomatous, type 1) and gastric type (foveolar, type 2), as well as combined (hybrid) forms—each having different patterns of mucin expression.[169,170] Gastric dysplasia can be divided into two categories: *low grade* and *high grade*. High-grade dysplasia is regarded as synonymous with carcinoma in situ (CIS) and must be distinguished from intramucosal carcinoma, in which the process has penetrated the basement membrane. As such, gastric biopsies can be grouped for reporting purposes into the following categories:

1. Negative for dysplasia
2. Indefinite for dysplasia
3. Low-grade dysplasia
4. High-grade dysplasia (which incorporates so-called CIS)
5. Intramucosal carcinoma
6. Invasive carcinoma.

The risk for invasive carcinoma is small for low-grade dysplasia and considerable for high-grade dysplasia; surgical excision (including a gastrectomy) should be considered whenever the latter change is found.[171]

Carcinoma

General Features

The pathogenesis of gastric carcinoma is closely related to environmental factors. Its incidence has markedly decreased in some countries, such as the United States and England,[172,173] but it remains inordinately high in others, such as Japan, Chile, and Italy.[174] However, there is increasing evidence that a genetic predisposition plays an important role in at least a subset of patients, as already suggested by the fact that familial aggregation of the disease is seen in about 10% of the cases.[175,176] Although most patients are over 50 years of age, rare cases arise in younger individuals and even children.[177]

Practically all gastric carcinomas arise from the generative (stem/basal) cells of the foveolae, in most instances on a background of chronic atrophic gastritis with intestinal metaplasia and preceded by various stages of dysplasia.[178]

Gastric carcinoma is accompanied by hypochlorhydria in 85%–90% of cases; hypochlorhydria may precede gastric cancer by several years. It has been postulated that high intragastric pH promotes the growth of bacteria that reduce dietary nitrate to nitrite and then convert dietary amines, in the presence of this nitrite, into carcinogenic *N*-nitroso compounds.[179] The coexistence of chronic atrophic gastritis and carcinoma is common, but the etiopathogenic link between the two and the relative risk for malignancy in the former condition remain controversial.[180] The same could be said for pernicious anemia; the rate of carcinoma development, although statistically increased, is not high enough to justify surveillance in asymptomatic patients.[181]

The most important development in the field has been the identification of *H. pylori* as an important etiologic factor in gastric carcinoma through its role in the development of chronic gastritis.[182,183] This is particularly true for the most common subtype, referred to as *intestinal-type adenocarcinoma* by Lauren.[184] The other, designated as the *diffuse type*, does not show as close an association to these environmental factors.

Other factors thought to be involved in the pathogenesis of gastric cancer (albeit in a minor fashion) are gastric polyps, Ménétrier disease, gastric peptic ulcer, and gastric stump (see respective sections in this chapter). Cases of gastric carcinoma in young patients following irradiation and chemotherapy for other malignancies have been reported.[185] Some cases of gastric adenocarcinomas are Epstein–Barr virus (EBV) related, the incidence varying from 6% to 7% in Japan and Europe to 16% in the United States.[186,187] Such tumors often show a lymphoepithelioma-like appearance.[187,188]

From Bosman FT, Carniero F, Hruban RH, Theise ND (eds). World Health Organization Classification of Tumours of the Digestive System. Lyon: IARC; 2010.

Morphologic Features and Classification

There is wide variation in the gross appearance of gastric carcinoma (Table 14.1). Many intermediate stages exist between the two extremes, represented by the intraluminal fungating tumor and the flat, ulcerated, and deeply invasive tumor growing through the wall of the stomach (Figs. 14.28 and 14.29). Carcinomas located in the fundic area are more likely to have invaded the submucosa and beyond at the time of surgery than those located in the pyloric area.[189] Depending on the relative amounts of mucin secreted and desmoplastic reaction elicited, the tumors may have a fleshy, fibrous, or gelatinous gross appearance. Any area of the stomach can be affected: anterior and posterior walls, lesser curvature, and greater curvature (in that order of frequency).[190] Multiple tumors are found in approximately 6% of the cases.[191]

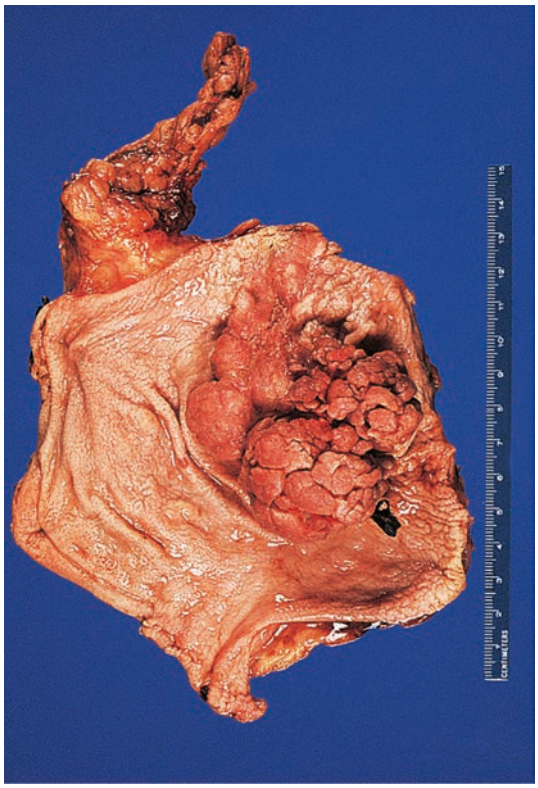

Figure 14.28 Gross appearance of polypoid gastric adenocarcinoma.

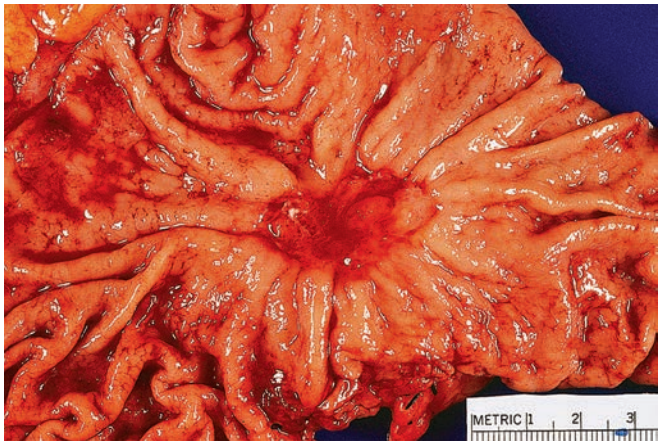

Figure 14.29 Gross appearance of gastric adenocarcinoma of ulcerative type showing marked resemblance to chronic peptic ulcer.

The non-neoplastic mucosa adjacent to the carcinoma is often thickened, a feature that may result in false-negative endoscopic biopsies and that has been attributed to production of epidermal growth factor by the tumor.[192] Microscopically, nearly all gastric carcinomas are adenocarcinomas. As already indicated, two major categories exist, which have been designated *intestinal* (53%) and *diffuse* (33%) by Lauren[184]; the remainder are either *mixed* or *unclassifiable*.[193]

Intestinal-type adenocarcinomas show a wide range in the degree of differentiation, which correlates inversely with tumor size.[194] In the better differentiated tumors, most of the cells are columnar and mucin secreting (Fig. 14.30). On occasion, the tumor is so well differentiated as to simulate a complete-type intestinal metaplasia.[195] Poorly differentiated variants have a predominantly solid pattern. Exceptionally, the better differentiated tumor cells are ciliated.[196]

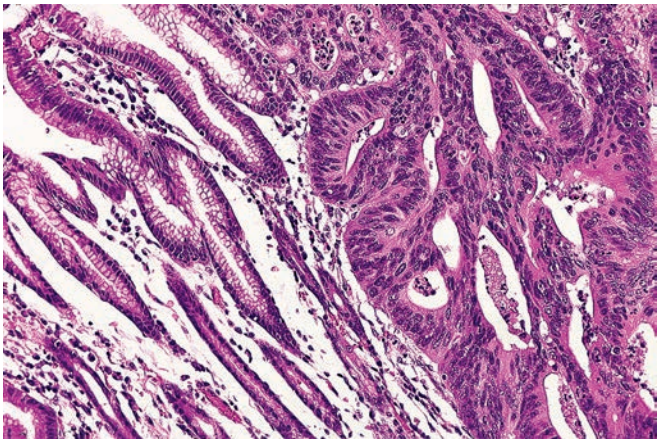

Figure 14.30 Gastric adenocarcinoma of intestinal type.

The amount of mucin production is highly variable; when abundant, it is often accompanied by calcification. Sometimes, metaplastic ossification is present either in the primary tumor or the metastasis. Scattered endocrine cells may be demonstrated with immunohistochemical stains.[197] The occurrence of easily identifiable Paneth cells is less common. On occasion the stroma of the tumor is heavily infiltrated by neutrophils or histiocytes.[198]

Diffuse-type adenocarcinomas are best represented by the tumor type classically known as *linitis plastica* and currently designated as *signet ring (adeno)carcinoma*. It represents a disproportionately high percentage of gastric cancers occurring in the young,[199] and its *relative* incidence seems to be on the rise in the United States.[200] The gross alterations usually begin in the prepyloric area. Pyloric obstruction often develops as the wall of the stomach becomes thickened and rigid (Fig. 14.31). The muscle is hypertrophic and segmented by the presence of thin, parallel, grayish white, longitudinal lines that give it a comblike appearance. These lines are continuous with foci of subserosal thickening.

Microscopically, a diffuse growth of malignant cells is seen, associated with extensive fibrosis and inflammation. Often the entire wall is involved. Although an *intramucosal* type of signet ring carcinoma occurs, in many cases the mucosa is less affected than the deeper layers. Glandular formations are rare, and most tumor cells grow individually or in linear arrays (Fig. 14.32). Most of the mucin produced is intracytoplasmic, resulting in the typical signet ring appearance (Fig. 14.33). Pools of extracellular mucin may also be present, but as long as signet ring cells are evident, this tumor should be categorized as signet ring adenocarcinoma rather than mucinous adenocarcinoma.

There are few malignant tumors in the human body that are more likely to be missed on microscopic examination than this type of gastric cancer. Over the years, we have seen specimens from stomach wall, lymph nodes, omentum, mesentery, pelvic peritoneum, and ovary that were initially misinterpreted as a benign process because of the inconspicuousness of the tumor cells and the marked degree of inflammatory and desmoplastic reaction. The tumor may also closely simulate malignant lymphoma because of its diffuse pattern of growth and the round shape of the cells and their nuclei.

The differential diagnosis of gastric carcinoma in a biopsy specimen includes severe dysplasia and a variety of reactive or otherwise non-neoplastic conditions that may simulate malignancy, including bizarre epithelial atypia associated with chemotherapy or radiochemotherapy,[168] radiation-induced atypia due to extrahepatic localization of yttrium microspheres used for selective internal radiation therapy,[201] degenerative changes associated with erosion and regeneration, plump

Figure 14.31 Typical gross appearance of diffuse carcinoma of the stomach (so-called linitis plastica). Virtually the entire gastric wall is involved by tumor. Note the prominence of rugal folds.

reactive mesenchymal cells related to granulation tissue, and gastric xanthoma, just to name a few.

Histochemical and Immunohistochemical Features

The secretory product of most gastric adenocarcinomas (especially those of intestinal type) is an acid mucosubstance, easily detected with Mayer mucicarmine, alcian blue, or colloidal iron stains and

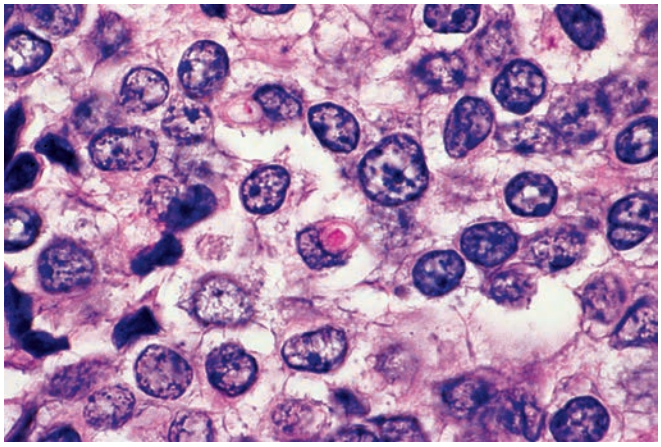

Figure 14.33 Intracytoplasmic mucin droplet in the cell in the very center is seen on this Mayer mucicarmine stain.

having features analogous to those of intestinal-type mucins.[202] The mucin secreted by the diffuse-type carcinoma and present within the cytoplasm of the signet ring cell is of either acidic or neutral type, the latter predominating in some cases.[203]

At the immunohistochemical level, the main mucin types expressed (with many variations and overlaps) are MUC1 for the intestinal type, MUC5AC for the diffuse type, MUC2 for the mucinous type, and MUC5B for the unclassified type (see later).[9,204,205] There is also an interesting relationship between mucin type and tumor location, in the sense that MUC5AC is prevalent in antral tumors whereas MUC2 is preferentially expressed in cardia tumors. CDX2 is present in about 90% of the cases and HepPar-1 in approximately 80%.[206] The former appears very early in tumor development, indicating a switch from a gastric to an intestinal phenotype.[207] The keratins present are usually of the simple epithelial type (low molecular weight), but sometimes those seen in normal squamous epithelia (such as CK13 and 16) are also detected.[208] The CK7/CK20 expression patterns of gastric carcinoma vary considerably; on the whole, approximately 70% of the cases are CK7+ and 20% are CK20+.[209] Immunohistochemical positivity for α1-antitrypsin, α1-antichymotrypsin, and α2-macroglobulin is also common, particularly in advanced tumors.[210] Reactivity to human chorionic gonadotropin (hCG) is found in scattered tumor cells in approximately 10%–50% of the cases[211]; the microscopic appearance of these tumors is usually not different from others, and therefore this phenomenon should not be equated with the rare entity of gastric choriocarcinoma, whether pure or associated with adenocarcinoma.

Molecular Genetic Features

Intestinal-type and diffuse-type gastric carcinoma appear to evolve through different molecular pathways, involving different oncogenes and tumor suppressor genes. Development of the former follows a multistep progression, from chronic gastritis to intestinal metaplasia, dysplasia, and carcinoma. Some have proposed the presence of an in situ component that gives rise to signet ring carcinomas.[178] Gene expression profiling studies show that diffuse-type carcinoma exhibits altered expression of genes related to cell-matrix interaction and extracellular-matrix components, whereas intestinal-type carcinoma exhibits enhancement of cell growth.[212]

Germline truncating mutations of the E-cadherin *(CDH1)* gene have been found in families with hereditary diffuse gastric cancer. The penetrant susceptibility is so high that prophylactic gastrectomy for these individuals is advised.[213,214] In the gastrectomy specimens,

occult intramucosal signet ring adenocarcinoma is commonly found.[213] Female carriers of the *CDH1* mutation also have an increased risk for lobular carcinoma of the breast.[215] Inactivating somatic mutation of *CDH1* or hypermethylation of its promoter is found in up to 50% of sporadic diffuse-type carcinomas but rarely in intestinal-type tumors.[216,217] This molecular alteration, which results in decreased or loss of expression of E-cadherin, a component of the adherens junctions, provides a neat explanation for the observed discohesive growth of diffuse-type gastric carcinoma.

Intestinal-type carcinomas show microsatellite instability in 15%–50% of cases,[218] commonly associated with frameshift mutations in *TGFβRII*, *IGFIIR*, *BAX*, *MSH6*, *MSH3*, and *E2F4*.[219,220] They also commonly exhibit *TP53* mutations and a higher *hTERT* expression level.[125,221] A subset of cases show strong membrane immunostaining for HER2 due to amplification of the *HER2* gene (5%–15% of all gastric carcinomas, almost always of intestinal type).[222] The presence of the latter feature is a predictor of the response to targeted therapy using trastuzumab.[223]

The tumor suppressor gene *RUNX3*, a member of the Runt domain family of transcription factors that are master regulators of gene expression in major developmental pathways, is implicated in gastric carcinogenesis.[224] Hypermethylation of the *RUNX3* promoter occurs in more than 60% of gastric carcinomas, more frequently in intestinal-type than diffuse-type tumors.[225,226]

Somatic mutations of the *APC* gene are present in 4%–21% of gastric adenocarcinomas, in contrast to an incidence of 76% in adenomas or flat dysplasia,[129] suggesting that *APC* mutations do not play a significant role in the progression from adenoma to carcinoma.

Other Microscopic Tumor Types

Neuroendocrine differentiation can be seen in a wide range of gastric neoplasms, which differ greatly in both morphologic and clinical features.[227] Although admixtures and overlaps occur, most gastric tumors with neuroendocrine differentiation can be placed into one of the following categories:

1. Well-differentiated and slow-growing **well-differentiated neuroendocrine tumors** (WDNETs; traditionally known as carcinoid tumors), composed of any of the neuroendocrine cells of the gastric mucosa.
2. Tumors with obvious morphologic features of neuroendocrine differentiation (trabeculae, rosettes, insulae; dense-core secretory granules ultrastructurally; immunoreactivity for neuroendocrine markers) but equally obvious atypical morphologic features (marked invasiveness, necrosis, and mitotic activity). Like their counterparts in the lung, these tumors have been variously called *atypical carcinoid tumors* and *large cell neuroendocrine carcinomas*.[228] This is a heterogeneous group (as it is in the lung), a fact which probably explains the differences in prognosis among different series. When the tumor has features analogous to those of large cell neuroendocrine carcinoma of the lung, the prognosis is poor.[228]
3. **Small cell carcinomas** that are morphologically analogous to their more common pulmonary counterpart and characterized by a very aggressive clinical course.[229,230]
4. Otherwise typical **adenocarcinomas** of either diffuse or intestinal type (particularly the former), having cells that show evidence of neuroendocrine differentiation. Rarely, the neuroendocrine cells can be recognized at the hematoxylin and eosin level because of the fact that their granules are brightly eosinophilic, resembling those of Paneth cells. These tumors do not behave differently from ordinary adenocarcinomas.
5. **Adenosquamous** and **squamous cell carcinomas** comprise less than 1% of all gastric carcinomas.[231,232] Only cases surrounded on all sides by gastric mucosa can be accepted, particularly for the pure squamous cell carcinomas. Those also involving the lower end of the esophagus should be interpreted as primary esophageal carcinomas with gastric extension. The behavior of gastric adenosquamous carcinomas is largely determined by the degree of differentiation of the glandular component, which varies widely.[233] Careful sectioning of tumors originally thought to be squamous cell carcinomas often show a minute glandular component.

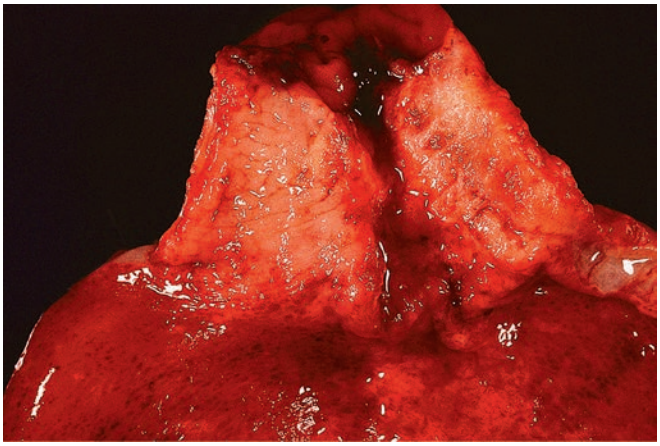

Figure 14.34 Gross appearance of mucinous adenocarcinoma of the stomach. The cut surface has a homogeneous gelatinous appearance.

Mucinous adenocarcinoma is characterized by prominent glandular formations and abundant mucin deposition, nearly all of which is extracellular (Figs. 14.34 and 14.35). The mucin secreted by this tumor is a distinct *O*-acylated form of sialomucin which is immunoreactive for MUC2.[8,234] The prognosis is better than that of signet ring carcinoma but not significantly different from that of ordinary adenocarcinoma.

Hepatoid adenocarcinoma is a type of gastric carcinoma having both glandular and hepatocellular differentiation, with frequent admixtures between the two components.[235] There is also a tubulopapillary pattern with clear cells, which has been interpreted as representing enteroblastic differentiation.[236] As a group, these tumors are characterized by a nodular pattern of growth, presence of abundant cytoplasmic glycogen and hyaline globules, extensive venous invasion, and poor prognosis. Sometimes this venous permeation extends to the omental and mesenteric vessels in a fashion resembling that of hepatocellular carcinoma. Similar to hepatocellular carcinoma, a "canalicular" pattern of staining is seen with polyclonal CEA, and there is often immunoreactivity for HepPar1[237] with alpha-fetoprotein (AFP) expression in about half of the cases.[238] Furthermore, positivity for PLUNC protein (palate, lung, and nasal epithelium carcinoma-associated protein) and the germ cell marker SALL4 have been identified immunohistochemically in hepatoid adenocarcinomas of the stomach but not in hepatocellular carcinomas of the liver.[239,240] Gastric hepatoid carcinomas should be distinguished from otherwise typical gastric adenocarcinomas (without morphologically recognizable hepatoid features) which are immunoreactive for AFP.[238] Glypican 3 (GPC3) is generally present in AFP-producing gastric carcinomas, whether they have hepatoid features or not.[241]

Lymphoepithelioma-like carcinoma (undifferentiated carcinoma with intense lymphoid infiltration) resembles morphologically the homonymous tumor of the upper respiratory tract; the presence of

Figure 14.35 Microscopic appearance of mucinous adenocarcinoma of the stomach. In contrast to diffuse carcinoma, most of the mucin is located extracellularly.

EBV has been documented in most of the cases.[186–188] This tumor is probably identical to gastric medullary carcinoma with lymphocytic infiltration, which also shows a similarly strong relationship with EBV.[242] It should be noted that EBV is also found in a certain percentage of gastric adenocarcinomas of conventional microscopic types.[243] Lymphocyte-rich gastric carcinoma has also been found to be associated with microsatellite instability.[244]

Sarcomatoid carcinoma (carcinosarcoma) is a tumor of dual composition, with epithelial elements (usually glandular) intermingling with a sarcoma-like spindle cell component.[245,246] The sarcomatoid component may contain heterologous elements, such as skeletal muscle and bone,[247] and the epithelial component may contain neuroendocrine cells.[248] This tumor type is much less common in the stomach than in the esophagus. An even rarer occurrence are tumors in which the epithelial component appears benign (so-called adenosarcoma), analogous to the tumors seen in the female genital tract.[249]

(Adeno)carcinoma with rhabdoid features is a very rare form of gastric carcinoma that grows in a solid fashion and is characterized by the presence of rhabdoid cells with paranuclear inclusions filled with intermediate filaments.[250] These neoplasms coexpress cytokeratin and vimentin and show loss of SMARCB1 (INI1). As is true of other tumors with rhabdoid differentiation, they are clinically highly aggressive neoplasms.[251]

Gastric carcinoma with osteoclast-like giant cells has a solid or cribriform pattern of growth and a scattering of multinucleated cells that exhibit histiocytic markers.[252]

Acinar cell carcinoma of pancreatic type has been reported beneath a focus of pancreatic metaplasia of the gastric mucosa, presumably arising from it.[253]

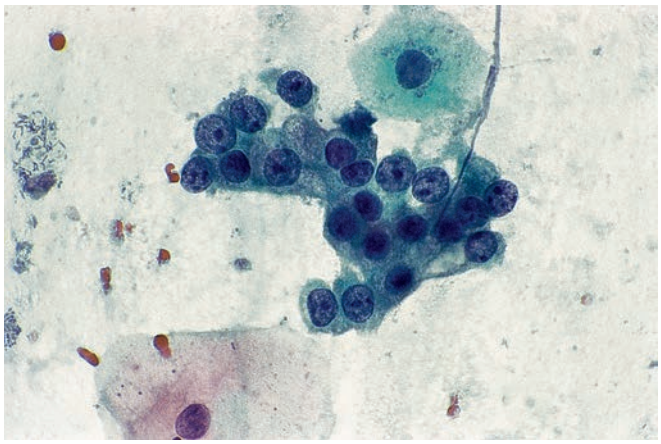

Figure 14.36 Cytologic appearance of reactive (reparative) atypia.

Clear cell (glycogen-rich) adenocarcinoma is vanishingly rare. Most of the few reported cases presented as high-stage disease.[254] Renal metastasis to the stomach should be excluded.

Micropapillary carcinoma morphologically similar to its homonym in breast, bladder, and other sites can exceptionally occur in the stomach.[105] It is associated with prominent lymphovascular invasion, frequent lymph node metastases, and a poor prognosis,[255,256] although one study did not find a significant difference in outcome when compared with conventional adenocarcinoma.[257]

Diagnosis—Biopsy and Cytology

Symptoms from gastric carcinoma usually indicate advanced disease. If the tumor is located in the cardiac or pyloric areas, it may produce obstruction relatively early; otherwise the symptoms are vague and nonspecific, usually consisting of dyspepsia, weight loss, and anemia. Sometimes, the first sign of gastric carcinoma is the detection of a nodal, hepatic, or pulmonary metastasis. Isolated nodal metastasis in the left supraclavicular region is sometimes referred to as *Trousseau sign* or *Virchow node.*

Radiographic examination of the stomach demonstrates the lesion in most cases, but in approximately 10% it will be impossible to determine whether the lesion is benign or malignant.

In countries with a high incidence of gastric carcinoma, particularly Japan, the increased use of mass screening, endoscopy, cytology, and biopsy has resulted in the identification of a large percentage (up to a third) of early cases, with a corresponding increase in survival rates.[258,259]

With the introduction of the flexible fiberoptic gastroscope, the results of direct-vision gastric biopsy and brush cytology have improved dramatically (Figs. 14.36–14.38).[260] False-negative diagnoses with biopsy specimens are most often seen with the ulcerating types and are inversely related to the number of specimens obtained.[261] There is also a greater rate of false-negative results with diffuse compared with intestinal-type carcinomas, a finding not surprising in view of the predominantly submucosal distribution of this tumor.

So-Called Early Carcinoma

"Early" gastric carcinoma is defined by the Japanese authors as a carcinoma confined to the mucosa or to the mucosa and submucosa (not extending into the muscularis externa), regardless of the status of the regional lymph nodes (Fig. 14.39).[262] The name is inaccurate because the concept is not related to the presumed duration of the lesion but exclusively to its depth of penetration. Other terms that

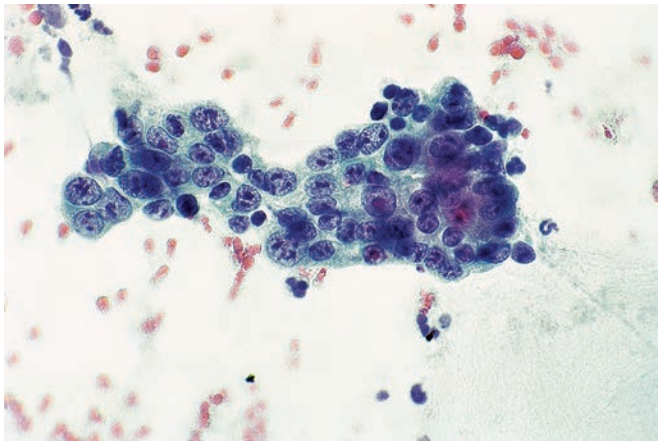

Figure 14.37 Cytologic appearance of intestinal-type gastric adenocarcinoma.

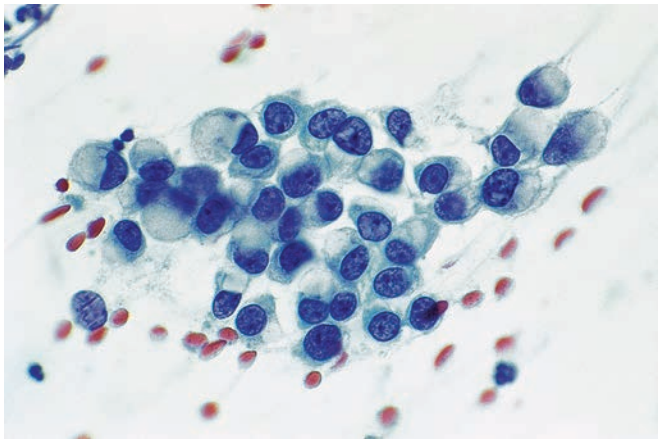

Figure 14.38 Cytologic appearance of diffuse-type gastric adenocarcinoma.

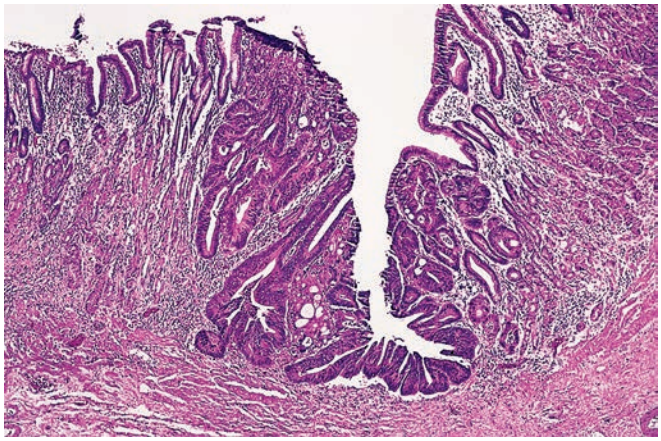

Figure 14.39 Early gastric adenocarcinoma limited to the mucosa.

have been used for the various subsets of this entity include *surface*, *superficial*, *superficial spreading*, and *microinvasive cancer*. The form limited to the mucosa, known as *intramucosal carcinoma*, needs to be separated from high-grade dysplasia, as the former shows evidence of invasion through the glandular basement membrane into the lamina propria or muscularis mucosae, a determination that is admittedly not always easy to make.

Most cases of early carcinoma are of Lauren's intestinal type, but early forms of diffuse carcinoma (composed almost entirely of signet ring cells) and of mucinous carcinoma also exist.[263] The degree of microscopic differentiation varies widely. The better differentiated types show closer association with *H. pylori* than the poorly differentiated tumors. The deep mucosal component underlying the carcinoma often shows cystic dilation of the glands.[264]

The relative incidence of early carcinoma is clearly related to the magnitude of the diagnostic efforts. In Japan, the proportion of early carcinoma cases has risen from 5.7% in the early 1920s to 45% in the late 1990s.[265] Variations in gross appearance of early carcinoma at endoscopy mirror those of its larger counterpart—protruding or type I (polypoid, nodular, or villous), superficial or type II (elevated, flat, or depressed), and excavated or type III. Combinations of the gross appearances are common.[266] Most cases are located in the distal third of the stomach, but they also occur at the gastric cardia; multicentricity is seen in approximately 10%–20% of the cases.[267] Genetic studies suggest that these lesions are truly multicentric, supporting the theory of field cancerization.[268]

On average, lymph node metastases are seen in approximately 6% of intramucosal tumors and in 25%–30% of those invading the submucosa.[269] In intramucosal carcinomas, lymph node metastatic disease correlates with diffuse histology and deep invasion into the muscularis mucosae.[270] For those tumors invading the submucosa, the incidence of nodal metastases is higher in those with angiolymphatic invasion, those invading over half of the submucosa, and those in which the submucosal invasion is expansile, with complete destruction of the muscularis mucosae.[271,272] Most "early" carcinomas are treated at present by minimal surgical procedures, such as endoscopic mucosal or submucosal resection or laparoscopic partial resection.[273,274] The 5-year survival rate following resection is between 80% and 95% and remains remarkably high even when nodal metastases are present.[275] As expected, the prognosis of early gastric carcinomas with focal invasion of the muscle layer is intermediate between that of the truly superficial tumors and the obviously invasive ones.[276]

Spread and Metastases

Distal carcinomas of the stomach invade the duodenum in a high percentage of cases. Similarly, carcinomas of the proximal stomach often involve the esophagus (to the point that a distinction between them and the tumors arising from Barrett esophagus is not always possible) and induce reactive changes in the adjacent esophageal epithelium. Serosal spread is common, its extent being greater in tumors with an infiltrative pattern of growth than in the expanding types.[277] Local extension also occurs to the omentum, colon, pancreas, and spleen. The rich mucosal and submucosal (Borrman) lymphatic plexus of the stomach is often invaded; from here, the tumor can spread to perigastric, periaortic, and celiac axis-related lymph nodes.[278] Tumors of the distal third of the stomach show a high incidence of involvement of hepatoduodenal nodes.[279] The presence of mucosal lymphangiectasia has been found to be statistically associated with the presence of regional lymph node metastases.[280] Invasion of the blood vessel walls by the tumor *("vasculitis carcinomatosa")* can also occur.[281]

The incidence of detectable lymph node metastases is influenced by the method used to search for them; it is significantly higher when a comprehensive fat-clearing method is employed[282,283] or if the microscopic sections are evaluated immunohistochemically for cytokeratin.[284] Tumor cells can also diffusely permeate the lymphatic plexus of the bowel, more often at the level of the upper duodenum

but sometimes down into the distal ileum and even the large bowel; the latter feature is seen almost exclusively in carcinomas of the diffuse type.[285] The most frequent sites of distant metastases are liver (often found unexpectedly at operation), peritoneum, lung, adrenal gland, and ovary. Bilateral ovarian metastases from the diffuse type of gastric carcinoma constitute the majority of cases referred to as *Krukenberg tumor*, but ovarian metastases of intestinal-type tumors can also supervene and be confused with primary ovarian endometrioid or mucinous neoplasms.[286] The diffuse type of gastric carcinoma shows a wider pattern of dissemination than the intestinal type, with more frequent involvement of peritoneum, lungs, and ovary.[287] On the other hand, liver metastases are more common with intestinal-type tumors; occasionally, the liver metastases grow in a diffuse intrasinusoidal pattern and lead to hepatic failure.[288]

Treatment

The standard treatment for gastric carcinoma (excluding "early" carcinoma) is gastrectomy, the extent of surgery being largely dependent on the extent of tumor and status of the rest of the mucosa.[289] In the United States, the resectability rate remains much lower than in Japan.[290] The operations most commonly performed are subtotal gastrectomy, radical subtotal gastrectomy, and total gastrectomy. These are often accompanied by splenectomy, but there is no evidence that this increases survival.[199] There is also no convincing evidence that extended lymph node dissection, as advocated by some Japanese surgeons, significantly increases survival.[291] The operative mortality following total gastrectomy is low, but the morbidity remains high. This operation is most often performed for carcinomas located at the cardia or high on the lesser curvature. For most of the others, subtotal resections are often performed because of the lower morbidity, despite occasional tumor recurrence in the gastric stump.[292] There seems to be relatively little benefit to chemoradiotherapy,[293] but as previously mentioned, *HER2* has been validated as a molecular target for this disease.[294]

Prognosis

The prognosis for gastric carcinoma in the United States remains disappointingly poor. The overall survival rate for all patients is between 4% and 13%. In a series of 10,000 consecutive cases from Fukuoka, Japan, the 5-year survival rates were 46% for advanced carcinoma and 89% for "early" carcinoma.[295] Possible explanations for these strikingly better survival rates when compared with the West include a greater frequency of superficial carcinomas, a more meticulous pathologic examination of the specimens, the performance of extended nodal dissection, and intrinsic differences in the growth patterns of the tumors. Different criteria in the differential diagnosis between high-grade dysplasia and carcinoma between Japanese and Western authors may also account for some of the differences.[296]

Anatomic stage remains the strongest prognostic indicator, and, as such, careful examination of the gastrectomy specimen with procurement of (ideally) at least 15 lymph nodes is critical in this evaluation (Tables 14.2 and 14.3).[297] In fact, lymph node status is the single best predictive indicator of prognosis.[174,298] There are several types of lymphadenectomy which can be performed during gastrectomy, but the more extensive the procedure, the more accurate the pathologic staging can be.[299]

Other prognostic parameters have been reported as well. Japanese ethnicity and female gender has been reported to be favorable prognostic indicators.[300] Some have found tumors in the distal stomach to be associated with a better outcome than those in the proximal stomach.[301] Younger patient age at diagnosis seems to be an adverse prognostic indicator,[302] but this may be related to the

Table 14.2 Definitions of AJCC TNM for squamous cell carcinoma and adenocarcinoma

Primary Tumor (T)	
T CATEGORY	**T CRITERIA**
Tx	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia, defined as malignant cells confined to the epithelium by the basement membrane
T1	Tumor invades the lamina propria, muscularis mucosae, or submucosa
T1a	Tumor invades the lamina propria or muscularis mucosae
T1b	Tumor invades the submucosa
T2	Tumor invades the muscularis propria[a]
T3	Tumor penetrates the subserosal connective tissue without invasion of the visceral peritoneum or adjacent structures[b,c]
T4	Tumor invades the serosa (visceral peritoneum) or adjacent structures[b,c]
T4a	Tumor invades the serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures/organs
Regional Lymph Nodes (N)	
N CATEGORY	**N CRITERIA**
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in one or two regional lymph nodes
N2	Metastasis in three to six regional lymph nodes
N3	Metastasis in seven or more regional lymph nodes
N3a	7–15
N3b	16 or more
Distant Metastasis (M)	
M CATEGORY	**M CRITERIA**
M0	No distant metastasis
M1	Distant metastasis

[a]A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified as T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified as T4.

[b]The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

[c]Intramural extension to the duodenum or esophagus is not considered invasion of an adjacent structure, but is classified using depth of greatest invasion in any of these sites.

higher percentage of diffuse-type cancers in this age group. Small tumor size is a favorable indicator, but this in turn may be linked to depth of invasion.[295] The presence of a pushing margin is more favorable than those with infiltrating margins.[295]

At the molecular level, it is clear that intestinal and diffuse-type cancers result from different genetic pathways involving a number of tumor suppressor genes, DNA mismatch repair genes, and oncogenes.[303] None of these alterations has been proven to have prognostic significance above that which has been mentioned previously.[304]

Well-Differentiated Neuroendocrine Tumors ("Carcinoid Tumors")

Discussed in this section are all the well-differentiated neoplasms composed of any of the cells of the diffuse (neuro)endocrine system, of which many types are known to occur in the normal stomach of humans. In the past, these WDNETs had been known as *carcinoid tumors*, but the latter term is now discouraged (Fig. 14.40).

Grossly, gastric WDNETs tend to be small, sharply outlined, and covered by a flattened mucosa, although they can cause a polyp.

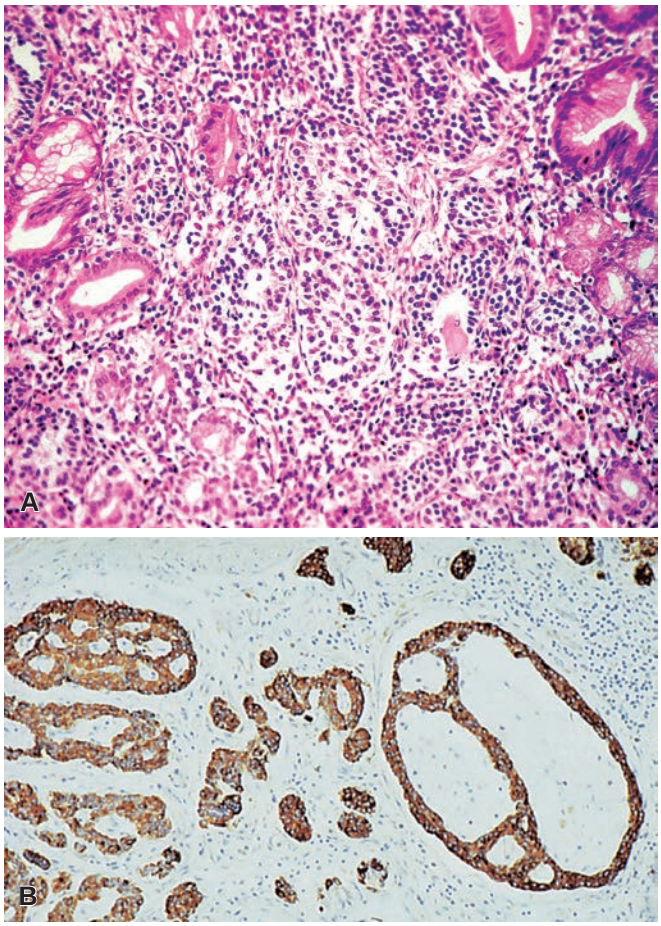

Figure 14.40 **A,** Well-differentiated neuroendocrine tumor of the stomach composed of enterochromaffin-like cells. **B,** Immunohistochemical stain for chromogranin.

Microscopically, the predominant pattern of growth may be microglandular, trabecular, or—rarely—insular. The nuclei are regular and normochromatic, mitoses are scanty, necrosis is usually absent, and vascularization is florid. Exceptionally, the cytoplasm of the tumor cells has a clear appearance.[305] Focal mucin positivity may be present. Immunohistochemically, there is consistent positivity for neuron-specific enolase, chromogranin, synaptophysin, and cytokeratin. Ultrastructurally, dense-core secretory granules are found in the cytoplasm, usually in abundance. The rate of growth of these tumors is very slow.

The histogenetic diversity of WDNETs of the stomach is already indicated by the wide variety of products that these tumors have been found to secrete, such as 5-hydroxytryptophan (serotonin), epinephrine, norepinephrine, somatostatin, VIP, PP, YY peptide, secretogranin, ACTH, β-MSH, and α1-antitrypsin.[306]

A combined morphologic, ultrastructural, and immunohistochemical approach has allowed the identification of at least two definite subtypes of gastric WDNETs.[307] The first is a tumor composed of **G cells** (gastrinoma), analogous to its most common pancreatic or duodenal counterpart; this is usually solitary, located in the antrum, non-argentaffin and non-argyrophilic, immunoreactive for gastrin, and sometimes associated with peptic ulcer. Parenthetically, gastric G-cell tumor should be clearly separated from the disputed entity of *primary G-cell hyperplasia*, in which an increased number of G cells in the antrum is accompanied by hypergastrinemia and an ulcerogenic syndrome resembling the Zollinger–Ellison syndrome.[308]

The second form, which constitutes by far the most common type of gastric WDNET, is composed of **ECL cells**.[309] These lesions are usually multiple, often polypoid, and distributed throughout the fundus. They are non-argentaffin but strongly argyrophilic, nonreactive for any of the standard gastroduodenopancreatic hormones, and accompanied by diffuse hyperplasia of similar cells in the surrounding mucosa. These tumors and associated hyperplasias usually occur on a background of atrophic gastritis with intestinal metaplasia, with or without pernicious anemia.[11,310] The gastritis is usually of type A (immune) with a low incidence of *H. pylori* colonization. The tumors have also been seen in association with the Zollinger–Ellison syndrome, either alone or as a component of multiple endocrine neoplasia type 1 (MEN 1).[311–313] Since the common denominator for these disorders is hypergastrinemia, and since gastrin is known to have a trophic influence on ECL cells, it has been postulated that these tumors are the direct result of the combined continuous stimulation by gastrin and a predisposing genetic background.[314] On the basis of these observations, it has been proposed that ECL cell tumors of the stomach be divided into three types: type I, associated with chronic atrophic gastritis; type II, associated with MEN 1; and type III, sporadic. Loss of heterozygosity of 11q13 (where the *MEN1* gene is located) has been detected in nearly all cases of type II ECL cell tumors; interestingly, a high frequency of this genetic alteration has also been found in type I but not in type III tumors.[315]

Regression of type I and type II lesions has been documented following the performance of antrectomy and normalization of serum gastrin levels,[316,317] suggesting that some of them may represent nodular hyperplasias of ECL cells rather than true neoplasms. Indeed, a spectrum exists between the clearly hyperplastic and the clearly neoplastic proliferations, making the dividing line between the two processes a rather arbitrary one. The figure of 0.5 mm has been suggested as the criterion by which to distinguish WDNETs from their precursors.[318]

In terms of natural history, most WDNETs of the stomach grow very slowly. Metastases, if they occur, are usually restricted to regional lymph nodes and liver, and their presence does not preclude long-term survival.[319] This favorable outcome applies particularly to types I and II ECL cell tumors. Conversely, the rare type III (sporadic) ECL cell tumors tend to run a more aggressive clinical course.[320] In terms of morphologic criteria, the main features that relate to prognosis are direct invasion, metastases, angioinvasion, tumor size, and mitotic activity and/or Ki-67 index.[320,321]

Composite tumors are made up of WDNETs admixed with a glandular (exocrine) component. Composite endocrine–exocrine tumors should be distinguished from the phenomenon of colonization of normal gastric glands by a pure WDNET.[322]

High-grade neuroendocrine tumors and adenocarcinomas with focal endocrine features are discussed in the section on gastric carcinoma.

Stromal Tumors (Gastrointestinal Stromal Tumors and Related Lesions)

Histogenetic Considerations: Microscopic, Immunohistochemical, and Molecular Genetic Features

Stromal tumors constitute the majority of primary nonepithelial neoplasms of the stomach.[323] They are members of a larger family that can also involve any portion of the gastrointestinal tract, omentum, mesentery, retroperitoneum, and other sites, collectively designated as *GISTs*.[324] The general features of this complex group and their peculiarities as they pertain to their gastric location are

discussed here, whereas the features connected with the other sites are dealt with in the respective sections.

For many years, these tumors were regarded as being of smooth muscle nature and designated as leiomyomas and leiomyosarcomas when composed of spindle cells, and as benign or malignant leiomyoblastomas (or epithelioid leiomyomas and leiomyosarcomas, respectively) when composed of epithelioid cells.[325] More recently, it has been suggested that these tumors are derived from (or differentiate towards) interstitial cells of Cajal, given that these "pacemaker cells" are positive for KIT and (as discussed later) almost all GISTs also stain for this antigen. However, this argument is flawed for the reason that KIT (CD117) expression by GIST is due (as indicated later) to an altogether different mechanism, i.e. a gain-of-function mutation of the *KIT* gene. The link between GIST and the interstitial cell of Cajal on the basis of their alleged shared reactivity for CD34 has not fared better following the realization that the normal CD34 positive cells in the gastric wall are not the interstitial cells of Cajal but rather fibroblasts adjacent to them.[326] It is our impression that all attempts to rigidly subdivide GISTs along histogenetic lines (i.e. muscular, neural, Cajal cell, schwannian, fibrous, etc.) are ill conceived, whether based on ultrastructural, immunohistochemical, or combined grounds. Rather, we believe there is a wide range of differentiation among these tumors along several lines.

The most important advance that has occurred in the field has been the discovery that about 90% of GISTs in adults are accompanied by a somatic mutation of *KIT*, and that many of the remainder have mutations of *PDGFRA*, these mutations being mutually exclusive. KIT is a tyrosine kinase receptor normally expressed by the interstitial cells of Cajal, mast cells, and germ cells.[327–329] This mutation (which is usually absent in GISTs in children and in some syndromic conditions, see later) is usually at exon 11, rarely at exons 9 and 13, and occasionally at other sites.[330,331] It results in a ligand-independent activation of the receptor, which in turn leads to its detection at the immunohistochemical level.[332] This has provided a very useful tool for the confirmation of the diagnosis of GIST, although it is clear that KIT-negative GISTs do occur, as discussed later.[333] The most convincing pattern of CD117 (KIT) positivity is one featuring a cell membrane component in addition to a cytoplasmic one. Mesenchymal tumors others that GIST that may stain for CD117 tend to show only cytoplasmic staining with a coarse granular pattern.

DOG1 is a more recently described immunohistochemical marker for GIST which has both high sensitivity and specificity for this tumor.[334–339] In effect, virtually all GISTs are positive for one or both of these markers, although KIT-negative tumors are more likely to have an epithelioid morphology, arise in the omentum, harbor *PDGFRA* mutations, have myxoid stroma and numerous mast cells.[333,340–342] It must be remembered that CD117 staining in a GIST does not necessary indicate that *KIT* mutation is present and, conversely, that a *KIT* mutation may exist in the absence of CD117 staining.

General, Clinical, and Gross Features of Gastrointestinal Stromal Tumor

Clinically, most GISTs occur in adults, but they have also been described in children and even neonates.[343,344] About 60% of GISTs occur in the stomach, the most common symptoms being abdominal pain and melena. Approximately 60% are submucosal and grow toward the lumen, where they make a smooth projection. In time, central ulceration may occur (more commonly with the clinically malignant tumors) and may penetrate deeply into the tumor mass and result in hematemesis. The smooth outline of the tumor and the central niche result in a highly characteristic radiographic appearance. Approximately 30% of the tumors are subserosal, and the other 10% are intramural. Grossly, they tend to be well circumscribed and have a smooth, lobulated, or whorled-silk appearance on cut section. An hourglass defect may occur at the cardia or pylorus if the tumor encircles the stomach.

About 5% of cases of GIST occur in patients with von Recklinghausen disease, most of them being located in the small bowel.[345] They tend to be multiple, their microscopic appearance not being necessarily more neural-like than others, except for the more common presence of skeinoid fibers (collagen globules).[346,347] They consistently lack *KIT* or *PDGFRA* mutations.[345,348] Other cases of GIST develop in the context of the Carney triad, in conjunction with pulmonary chondroma and extra-adrenal paragangliomas.[349] Still others arise in the Carney–Stratakis syndrome (associated with familial paraganglioma).[350] These GISTs tend to arise in the stomach of young patients, especially females, and show a multinodular growth pattern, epithelioid morphology, and often lymph node metastases. Despite the latter, these tumors usually show indolent clinical behavior, as well as mutations in the succinate-dehydrogenase complex of genes (SDH deficient).[351,352] Similar to pediatric GISTs, all of these tumors show loss of staining of SDHB.[352,353] Overall, 8%–10% of "wild-type GISTs" show SDH mutations. A smaller number show mutation of the *BRAF* gene.[351,354,355] Exceptionally, germline mutations of the *KIT* gene are seen in patients with familial GIST.[356,357]

Microscopic Features and Differential Diagnosis of Gastrointestinal Stromal Tumor

Gastric GISTs may be predominantly spindled or epithelioid, although some show an admixture of both cell types. Spindle cell tumors range from those which are characteristically low risk, showing bland spindle cells arranged in packets or whorls with normochromatic nuclei, perinuclear vacuoles, little mitotic activity (fewer than 5 mitotic figures/5 mm^2), sometimes nuclear palisading resembling that seen in schwannoma and collagenous stroma, occasionally with dystrophic calcification (Fig. 14.41), to high-risk lesion composed of atypical spindle cells arranged into fascicles with easily identifiable mitotic figures, necrosis, and mucosal invasion (Fig. 14.42). Similarly, epithelioid tumors range from low-risk lesions composed of epithelioid cells with abundant eosinophilic or clear cytoplasm, multinucleation, rare mitotic figures, abundant stroma, and no necrosis or mucosal invasion (Fig. 14.43), to those which are highly cellular tumors with high-grade nuclei, less cytoplasm, numerous mitotic figures and show evidence of necrosis and/or mucosal invasion (Figs. 14.44 and 14.45).

Knowing the wide morphologic spectrum of gastric GISTs, one is not surprised that the differential diagnosis of this entity is vast.[358] Depending on the tumor location and the microscopic features, it includes solitary fibrous tumor, fibromatosis, inflammatory fibroid polyp, glomus tumor, schwannoma, leiomyoma/leiomyosarcoma, and even malignant lymphoma and carcinoma. Fibromatosis (desmoid tumor) is particularly likely to be misdiagnosed as GIST because it can extensively involve the gastrointestinal wall and, at least in some labs, exhibit CD117 immunoreactivity (although the latter tends to be exclusively cytoplasmic and not on the cell membrane).[359] Solitary fibrous tumor shares CD34 positivity with GIST but is negative for CD117 and DOG1 and consistently expresses STAT6. The differential diagnosis of GIST with leiomyoma/leiomyosarcoma and schwannoma becomes cloudy because of the smooth muscle and/or neural-like features that GIST can exhibit. True smooth muscle tumors exhibit more densely eosinophilic cytoplasm and stain strongly for smooth muscle markers (smooth muscle actin, desmin, h-caldesmon) and do not stain for CD117 or DOG1. Gastric schwannomas show a characteristic peripheral lymphoid infiltrate, stain strongly for S-100 protein, and lack CD117 and DOG1 positivity.

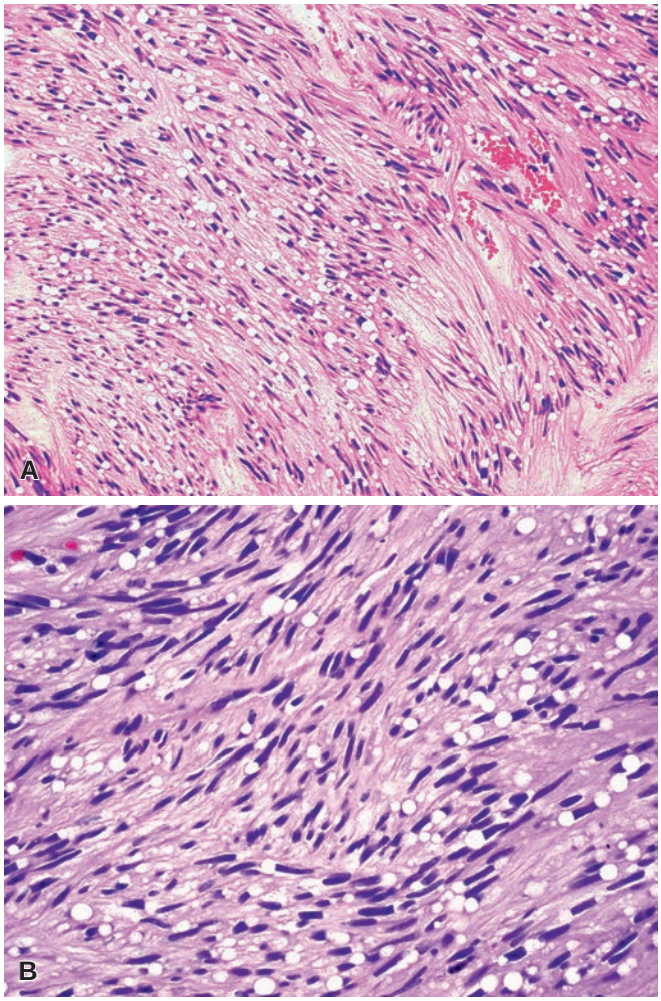

Figure 14.41 Low-power **(A)** and high-power **(B)** views of a low-risk gastrointestinal stromal tumor of the stomach of spindled type. Note the prominent perinuclear vacuoles. The cells are cytologically bland, and mitotic activity is not seen.

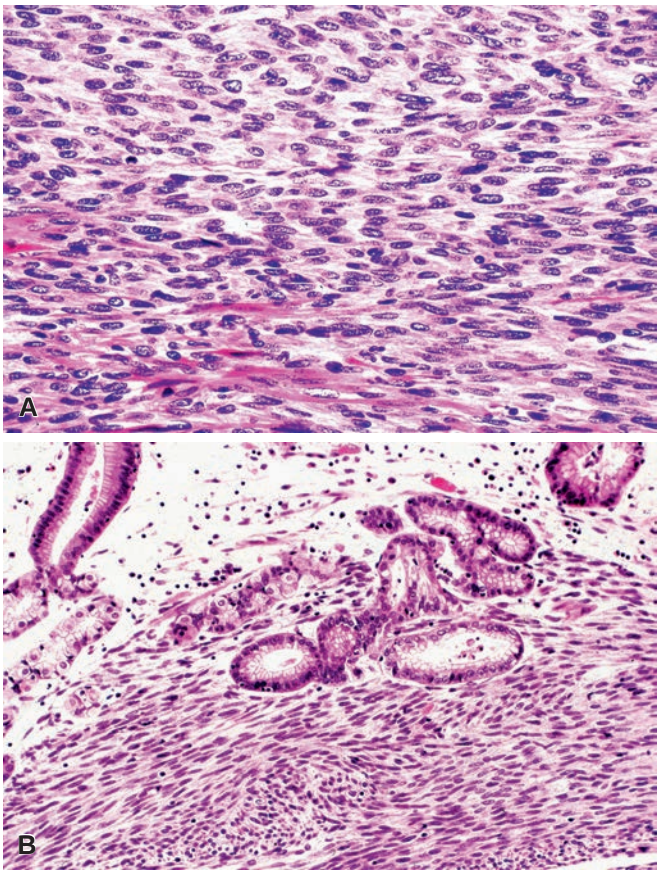

Figure 14.42 High-Risk Spindled Type of Gastrointestinal Stromal Tumor of the Stomach. A, The cells are tightly packed and arranged in sweeping fascicles. Perinuclear vacuoles are not apparent. **B,** Mucosal invasion is often associated with aggressive behavior in these tumors.

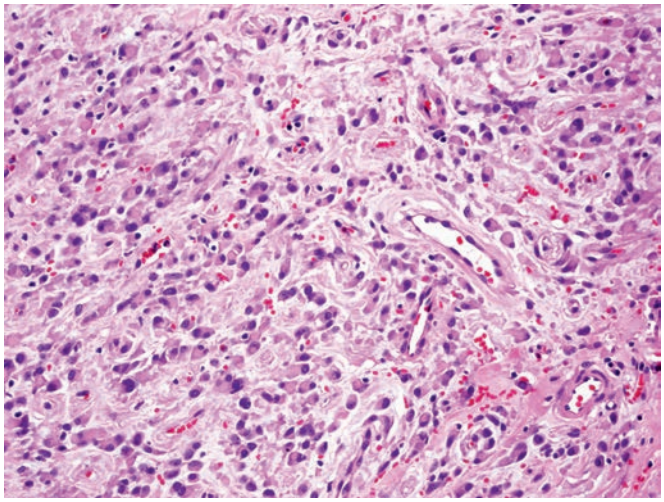

Figure 14.43 Epithelioid type of gastrointestinal stromal tumor of the stomach, low-risk type. The cells have abundant cytoplasm and a somewhat plasmacytoid appearance.

Tumor Multiplicity

As previously indicated, GISTs may present in the form of multiple tumors in the following situations[360]:

1. Neurofibromatosis type 1 (von Recklinghausen disease)
2. Carney triad
3. Associated with paraganglioma but different from Carney triad (Carney–Stratakis syndrome)
4. As a familial syndrome, associated with germline mutations of *KIT* and with small intestinal neuronal dysplasia.

They can also appear as multiple tumors in the absence of any of these conditions. Those of a microscopic size (sometimes called GIST tumorlets, mGISTs, or "seedling" GISTs) are very common and predilect the upper stomach.[361,362] The fact that they have different clonal molecular aberrations is in keeping with an independent origin.[363,364]

Spread and Metastases

The most common sites of metastases of malignant GISTs are the liver (Fig. 14.46), peritoneum, and lungs. Metastases to other sites, such as ovary, can also occur.[365] These metastases can develop as long as 30 years after the removal of the primary tumor.

Treatment

The primary treatment of GIST consists of surgical excision of the tumor with a good margin of normal tissue. Depending on the site and size of the tumor, this may involve a partial, subtotal, or total gastrectomy. Simple enucleation of the tumor should be discouraged.

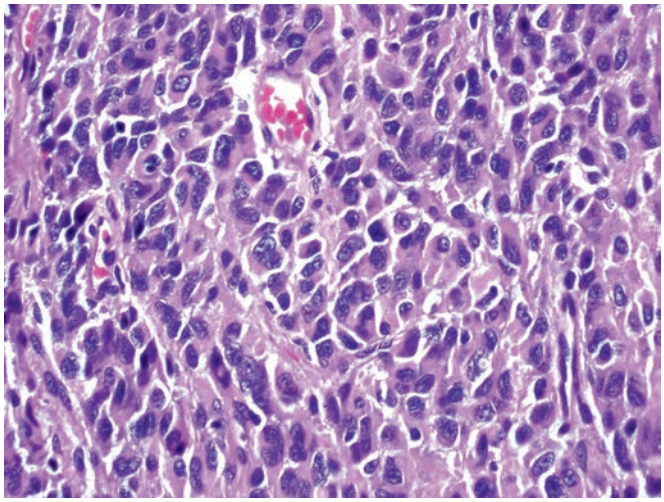

Figure 14.44 Highly cellular high-risk epithelioid gastrointestinal stromal tumor of the stomach.

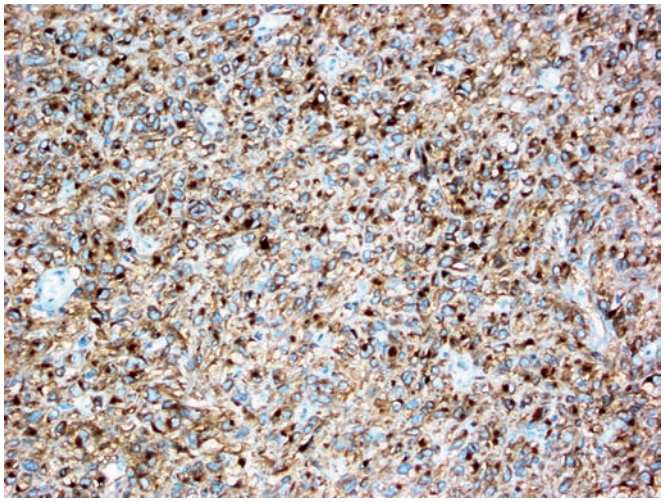

Figure 14.45 Diffuse CD117 (KIT) immunoreactivity in a high-risk epithelioid gastrointestinal stromal tumor of the stomach. Perinuclear globular immunoreactivity can also be seen.

Wide resection of lymph node areas is not indicated because of the extreme rarity of lymph node metastases. The type and extent of the operation are more dependent on the tumor size and location.

A remarkable development in the treatment of GISTs has been the discovery that most of these tumors are exquisitely sensitive to the action of the tyrosine kinase inhibitor imatinib mesylate (STI571; Gleevac; Glivec),[366,367] a response that is dependent upon the presence and type of *KIT* mutation (highest with exon 11 mutations and lowest with a wild-type phenotype).[334] This has led to some of the most spectacular results ever obtained with the medical therapy of solid tumors, even if the initial total regression is often followed by a recurrence in the form of a tumor that has acquired resistance to the drug through an additional mutation.[368]

Response to imatinib therapy is manifested by the loss of tumor cells, resulting in a practically acellular myxohyaline background.[369] Recurrent tumors may show a phenotypic change, such as loss of CD117 immunoreactivity[370] and divergent rhabdomyoblastic differentiation.[371]

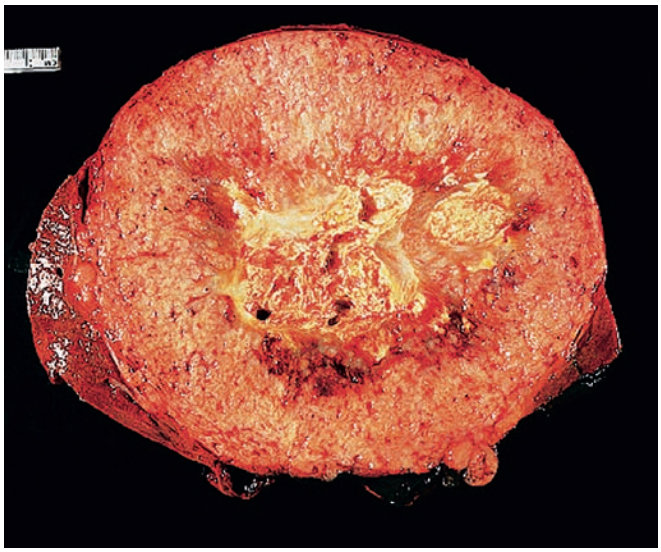

Figure 14.46 Gross appearance of a liver metastasis from a gastric GIST.

Prognosis

Although there are innumerable studies published in the older literature assessing histologic prognostic indicators, current recommendations for assessing prognosis are restricted to three parameters—tumor site, tumor size, and mitotic index (mitoses/5 mm^2).[334] Although the initial risk stratification scheme did not account for tumor site,[372] several large clinicopathologic studies from the Armed Forces Institute of Pathology resulted in separation of these categories by location.[344,345,373] For example, as seen in Table 14.4 gastric GISTs that are less than or equal to 2 cm and have a mitotic index of less than or equal to 5/5 mm^2 have essentially no risk of recurrence or metastasis. In addition to these parameters, tumor rupture (either before or during surgery) has also been found to be an adverse prognostic indicator.[374] As one might expect, incomplete tumor resection is associated with a higher risk of recurrence.[375] Although tumors with *PDGFRA* mutations tend not to respond to imatinib therapy as well as those with *KIT* mutations,[376–378] patients with *PDGFRA* mutations seem to have an overall less aggressive clinical course.[379]

Lymphoid Tumors and Tumorlike Conditions

Primary malignant lymphoma of the stomach makes up only a small percentage (about 10%) of all malignant tumors of this organ, but there is evidence that its incidence is increasing. They are regarded as primary gastric tumors if the bulk of the disease is present in the stomach, with or without regional lymph node involvement. Nearly all of the cases are of non-Hodgkin type and the large majority are of B-cell derivation.[380–382] As such, they show monotypic expression of immunoglobulin and rearrangements of the immunoglobulin genes.[383] For practical purposes, they can be divided into two large categories: (1) low-grade lymphomas, composed of small lymphoid cells; and (2) high-grade lymphomas, composed of large cells. Mixed small cell–large cell lymphomas also occur, but they constitute a distinct minority of the cases.

Occasionally, gastric lymphoma of one type or another is seen adjacent to an adenocarcinoma, as an expression of collision tumor.[384] In other instances, the lymphoma precedes a carcinoma by several years.

Table 14.4 Rates of metastases or tumor-related death in GISTs grouped by tumor location, tumor size, and mitotic rate

TUMOR PARAMETERS			PERCENT OF PATIENTS WITH PROGRESSIVE DISEASE DURING LONG-TERM FOLLOW-UP AND CHARACTERIZATION OF RISK (IN PARENTHESES) FOR METASTASES			
GROUP	TUMOR SIZE	MITOTIC RATE	GASTRIC GISTS	JEJUNAL AND ILEAL GISTS	DUODENAL GISTS	RECTAL GISTS
1	≤2cm	≤5/50-HPFs	0% (none)	0% (none)	0% (none)	0% (none)
2	>2cm to ≤5cm	≤5/50-HPFs	1.9% (very low)	4.3% (low)	8.3% (low)	8.5% (low)
3a 3b	>5cm to ≤10cm >10cm	≤5/50-HPFs ≤5/50-HPFs	3.6% (low) 12% (moderate)	24% (moderate) 52% (high)	34% (high)[b]	57% (high)[b]

Adapted from Miettinen M, Lasota J. Semin Diagn Pathol 2006; 23:70-83.
[a]Tumor categories with very few cases.
[b]Groups 3a and 3b, 6a and 6b are combined in duodenal and rectal GISTs because of the small number of cases.
[c]No tumors in this category were included in the study.
Note: Small intestinal and other intestinal GISTs show a markedly worse prognosis in many mitosis and size categories than gastric GISTs.

The Mucosa-Associated Lymphoid Tissue Concept

Mucosa-associated lymphoid tissue (MALT) is the term originally proposed by Isaacson et al. for the component of the immune system that has evolved to protect the freely permeable surface of the gastrointestinal tract and other mucosal membranes directly exposed to the external environment.[385,386] This comprises lymphoid nodules (which in the ileum form the Peyer patches), lymphocytes and plasma cells in the lamina propria, and intraepithelial lymphocytes. The corollary of this concept is that this immune compartment has distinctive morphofunctional features, and that this is also true of the lymphomas arising from it ("MALTomas" or "MALT-type lymphomas").[387] One such feature is their propensity to involve other mucosal sites when they spread, which has been explained by the normal homing pattern of MALT lymphocytes[388]; as part of this scheme, a particular tendency of lymphoma of Waldeyer ring to develop following gastrointestinal lymphoma has been detected.[389]

Originally the concept was applied primarily to small lymphocytic low-grade lesions, but a significant proportion of cases of intermediate/high-grade (large cell) lymphomas appear to have evolved from MALT lymphomas, on the basis of their occasional coexistence, immunohistochemical and molecular similarities, and clonal link.[390] Another interesting corollary of this concept relates to the pathogenesis of gastric lymphoma, as *H. pylori* infection provides the necessary background in which this tumor develops[391,392]; there is idiotype identity between MALT-type lymphoma and the inflammatory component,[393] the lymphoma cells may be antigen responsive,[387] and the lymphoma may regress following eradication of *H. pylori* infection with antibiotics.[394]

A fascinating point of discussion is whether a well-differentiated lymphocytic population in an *H. pylori*-infected stomach, which has a remarkably indolent clinical course and which may even disappear following eradication of the microorganism, deserves to be regarded as a lymphoma, that is, a malignant tumor, because of the fact that it is clonal, bearing in mind that monoclonality is a common finding in the lymphoid follicles of gastritis.[395,396] Lo et al. showed that these lesions may fluctuate between polyclonality, oligoclonality, and monoclonality, and pointed out that *none of them defines an irreversible stage for progression to MALT lymphoma*.[397] Genta expressed a similar feeling very sharply in his witty and thoughtful editorial entitled *"Le lymphome imaginaire."*[398]

Low-Grade Lymphomas

Low-grade lymphomas comprise about half of all gastric lymphomas. They usually occur in individuals over the age of 50 years. Some arise in immunosuppressed patients.[399] The clinical symptoms often simulate those of gastritis or benign peptic ulcer. Grossly, advanced cases may present as giant convolutions mimicking hypertrophic gastritis or gastric polyps.[400] Microscopically, there may be mucosal–submucosal or transmural involvement. Most cases are located in the distal half of the stomach, but the pylorus is involved only rarely. Multicentricity is common, as supported by molecular studies; with progression, dominant clones appear which disseminate throughout the organ.[401]

Microscopically, the large majority of these low-grade tumors are of the so-called "MALT type" (extranodal marginal zone lymphoma) (Figs. 14.47 and 14.48). There is a dense infiltrate of small lymphoid cells, often accompanied by scattered reactive lymphoid follicles. The lymphoid cells include a variable admixture of small lymphocytes, centrocyte-like cells, and monocytoid cells. It is common for them to exhibit focal or extensive plasmacytoid differentiation. Dutcher bodies (true intranuclear eosinophilic inclusions made up of immunoglobulin), when present, are of great diagnostic significance. Despite the high frequency of plasmacytoid features, it is extremely rare for these tumors to be associated with the presence of an M protein in the serum. An important diagnostic sign is the infiltration of the glandular epithelium by the neoplastic lymphocytes, resulting in so-called lymphoepithelial lesions. Reactive lymphoid follicles may be infiltrated or even replaced by neoplastic cells (follicular colonization). Scattered larger neoplastic cells may also be seen. *H. pylori* may be seen in biopsies of the adjacent non-neoplastic mucosa;

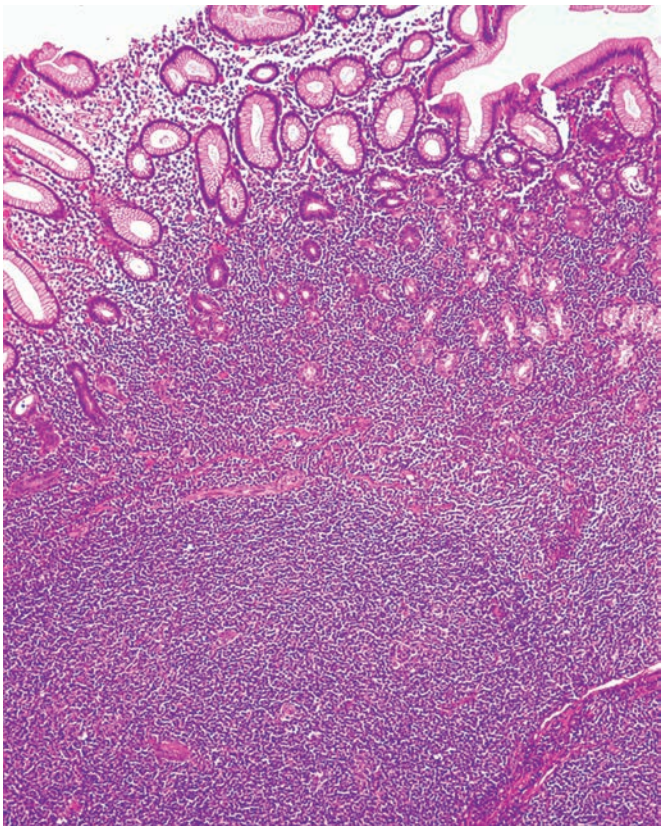

Figure 14.47 MALT-type lymphoma of the stomach involving mucosa and submucosa.

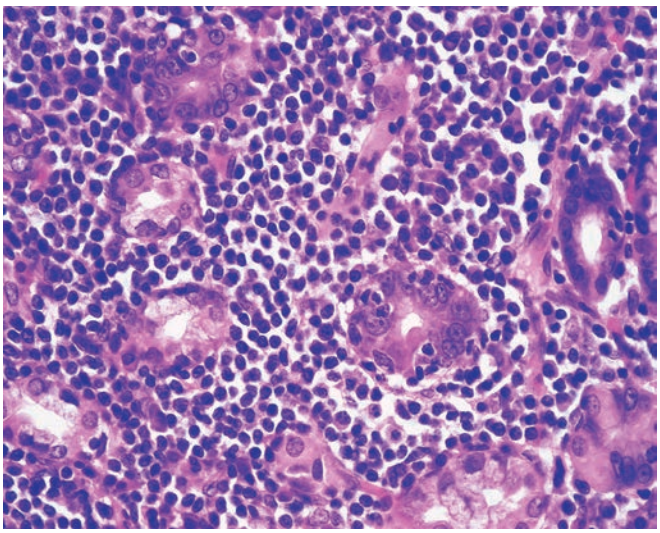

Figure 14.48 High-power view of mucosal involvement by MALT-type lymphoma. A few of the neoplastic lymphocytes are seen within the glandular epithelium (lymphoepithelial lesion).

the ability to find organisms is greatest in superficial lesions and those which are entirely low grade.

By immunohistochemistry, the neoplastic cells stain for CD20 but are negative for CD5, CD10, BCL6, and cyclin D1. They also stain for BCL2. Cytokeratin stains are useful for highlighting the lymphoepithelial lesions. Molecular studies reveal clonal rearrangements of immunoglobulin heavy and light chain genes.

At the molecular level, low-grade MALT-type lymphoma often shows microsatellite instability, allelic imbalance, and trisomies, particularly of chromosome 3; the latter can be detected by fluorescence in situ hybridization (FISH) in paraffin-embedded material.[402] Approximately one-third of the cases have the *API2 (also known as BIRC3)–MALT1* fusion, the result of the t(11;18) translocation, an abnormality that is absent in all other types of gastric lymphoma.[403–405] Gastric MALT lymphomas harboring *API2–MALT1* fusion often comprise a more monotonous cell population than the MALT lymphomas lacking this genetic alteration.[406] This genetic abnormality predicts a lack of response to anti-*Helicobacter* therapy[407] but can apparently protect against transformation to a large B-cell lymphoma.[386] It is also associated with higher-stage disease. Less commonly, these tumors harbor a t(1;14)(t22;q32) involving *BCL10* and *IGH*.[408]

The major diagnostic considerations are distinguishing marginal zone lymphoma from chronic gastritis and other low-grade lymphomas. The presence of cytologic atypia, Dutcher bodies and lymphoepithelial lesions are the most helpful diagnostic clues favoring a lymphoma which can be confirmed by demonstrating monotypic light chain expression as well as a diffuse infiltrate of B cells which coexpress CD43. *Mantle cell lymphoma* is far less common and is composed of a monotonous population of small- to medium-sized B cells that express CD5 and cyclin D1. *Follicular lymphoma* has a more distinct follicular architecture and is composed of more irregular nuclei which express CD10 and BCL6.

Large cell transformation may occur in the background of a marginal zone lymphoma and requires sheets or confluent clusters of large atypical cells (diffuse large B-cell lymphoma).[409] BCL6 highlights the areas of large cell transformation, which portends a worse prognosis.[410]

PCR has been used to demonstrate clonality in paraffin-embedded endoscopic biopsy specimens, but great caution should be exercised in its interpretation, in the sense that the presence of a clonal lymphocytic population does not always imply the existence of a malignant tumor, as indicated previously. It needs to be recognized that, in many instances, it will not be possible to determine with certainty in a gastric biopsy whether one is dealing with a chronic gastritis or a lymphoma.

Low-grade lymphoma is characterized by a very slow clinical evolution, a tendency to remain localized for a long time, and a propensity to involve other mucosal sites when spreading.[411] Regional lymph node involvement is much less frequent than in large cell lymphoma.[412] The treatment is dependent on the stage: antibiotic therapy or extended field radiation therapy for stage I and a combination of radiation therapy and chemotherapy for stages II and III. Approximately 70% of patients with stage I disease are cured.

Large Cell Lymphomas

Large cell lymphomas are usually seen in patients over the age of 50 years, but the age range is wider than for low-grade tumors. Patients may have a large palpable mass and still be in excellent physical condition. Grossly, the tumor usually appears as a large lobulated (sometimes polypoid) mass. Superficial or deep ulceration is common (Fig. 14.49). The gross or radiographic distinction from carcinoma may be very difficult. Like the low-grade form, it has a predilection for the distal half of the stomach, with a tendency to spare the pylorus. Full-thickness invasion of the gastric wall, direct extension to adjacent organs, and involvement of regional and retroperitoneal nodes develop late in the course of the disease. At times, free perforation into the abdominal cavity occurs.

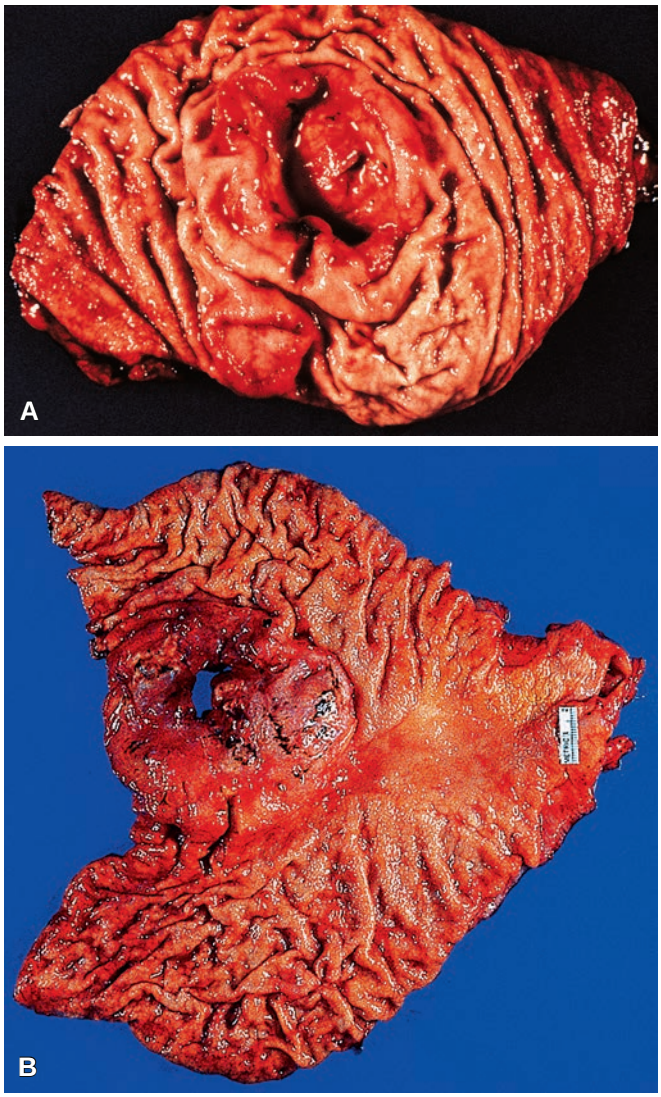

Figure 14.49 **A,** Large cell lymphoma of the stomach presenting as a large ulcerated mass. **B,** Large cell lymphoma of the stomach presenting grossly as a large polypoid mass with central ulceration.

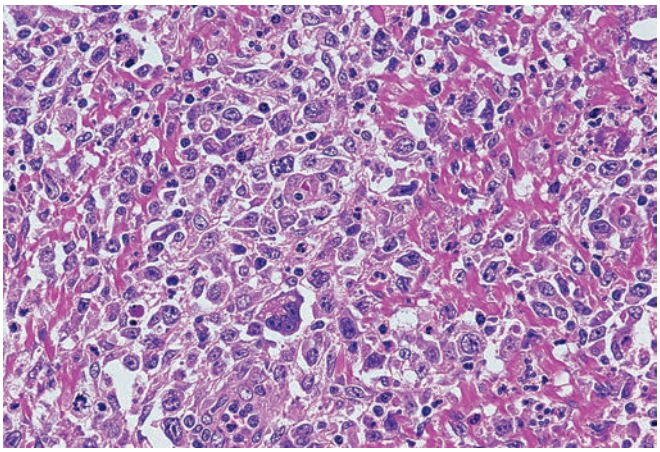

Figure 14.50 High-power view of a large cell lymphoma of the stomach with transmural involvement. The pleomorphism and the presence of multinucleated giant cells may cause confusion with Hodgkin lymphoma.

Large B-cell lymphoma of the stomach constitutes a heterogeneous category.[413] As mentioned previously, many cases represent transformed MALT lymphoma, but the remainder are de novo lymphomas belonging to several different categories.[414–416] A high proportion of large cell lymphomas of the stomach express BCL6 (in contrast to low-grade lymphomas), whether they are thought to be related to MALT lymphoma or not.[417]

Some cases of large B-cell lymphoma of the stomach seen in a setting of immunosuppression (i.e. transplant recipients) and inflammatory bowel disease have been shown to be EBV positive.[418] These tumors seem distinct from conventional gastric large B-cell lymphomas.

Microscopically, most cases of gastric large B-cell lymphoma are composed of cells resembling large noncleaved cells (centroblasts) but with a slightly more abundant cytoplasm, sometimes resulting in a plasmablastic or immunoblastic appearance (Fig. 14.50). Multinucleated cell forms resembling Reed–Sternberg cells may be present. The phenotypic features are those of B cells.

The main microscopic differential diagnosis of large B-cell lymphoma is with undifferentiated carcinoma. Features favoring a diagnosis of lymphoma are the lack of continuity between epithelium and tumor cells, lack of suggestion of an acinar pattern, and preservation of muscularis mucosae fibers. If uncertainties remain, they can be eliminated in nearly every instance with immunohistochemical evaluation using lymphoid and epithelial markers. Another diagnostic consideration is Burkitt lymphoma, which can uncommonly present as a gastric primary.[419]

Following a biopsy diagnosis of large cell lymphoma, exploratory laparotomy with gastric resection and surgical staging is usually indicated.[420] Controversy still exists as to whether postoperative radiation therapy and/or chemotherapy should be given in cases of apparently limited disease, but most authors recommend a combination of radiation therapy and chemotherapy for all stages.[421] The tumor may also be treated with radiation therapy following a biopsy diagnosis, but danger of gastric perforation exists if the tumor involvement is transmural. Distant disease is the most common form of treatment failure.[422]

The prognosis for gastric large B-cell lymphoma is substantially better than for gastric carcinoma. The overall 5-year disease-free survival rate is approximately 65%[423] and is directly related to the stage of the tumor.[424] Favorable prognostic features are small tumor size, superficial mural invasion, presence of low-grade MALT-type areas, and absence of regional lymph node involvement.[424] Some large cell lymphomas run an unusually aggressive course.[425]

Other Types of Lymphoma and Related Conditions

Anaplastic large cell (Ki-1) lymphomas can rarely present as primary gastric neoplasms.[426]

True histiocytic sarcoma is similarly very uncommon.[427]

Plasmacytoma and **multiple myeloma** can involve the stomach,[428] but before making this diagnosis one should rule out the more likely possibility of a malignant lymphoma with plasmacytoid features.

Peripheral T-cell lymphoma has been described, mainly by Japanese authors, sometimes in association with HTLV-1.[429]

Extranodal NK/T-cell lymphoma can involve the stomach as primary disease or part of systemic disease.[430]

Hodgkin lymphoma of the stomach also occurs but is extremely rare[431]; most cases so designated in the past are actually examples of various types of non-Hodgkin lymphoma.

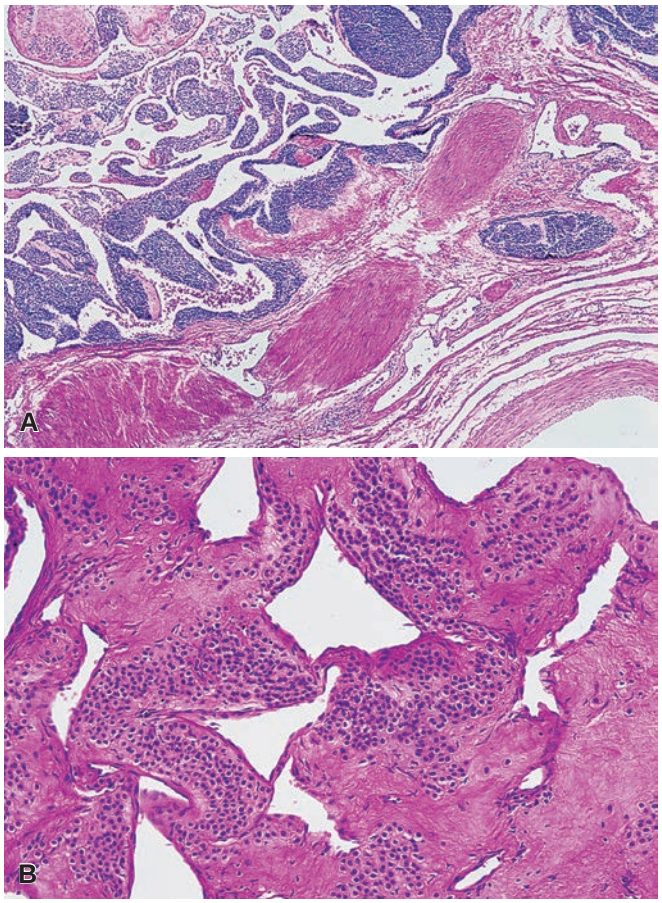

Figure 14.51 **A** and **B,** Two cases of glomus tumor of the stomach. The small size of the round epithelioid cells and the intimate relationship with blood vessels with dilated lumina are characteristic.

Granulocytic sarcoma can occasionally present as a gastric tumor in the absence of bone marrow involvement and be confused with malignant lymphoma or carcinoma.[432]

Langerhans cell histiocytosis may be encountered in the stomach, either as an isolated lesion or in association with disease elsewhere.[113,433] Exceptionally, this infiltrate (which is characteristically immunoreactive for S-100 protein, CD1a, and langerin) has atypical cytologic features.[434]

Other Tumors

Glomus and related tumors (such as **glomangiomyomas**) may arise in the stomach.[435,436] In fact, for some peculiar reason, the stomach is one of the most common extracutaneous sites for this tumor and shows a strong female predominance.[437] Microscopically, the tumors are composed of clear epithelioid cells arranged around dilated vessels (Fig. 14.51). Immunohistochemically, glomus tumors are reactive for actin and calponin and are surrounded by abundant basement membrane material, as demonstrated by type IV collagen and laminin stains. They are negative for desmin, S-100 protein, and CD117.[437] The behavior of this tumor is almost always benign, but one reported case showed multicentricity and extensive intravascular spread,[438] and another resulted in the patient's death from liver metastases.[437]

Lipomas arise within the gastric wall and may protrude into the lumen, resulting in a typical filling defect on radiographic examination.[439] Sometimes they mimic peptic ulcer in their clinical presentation.

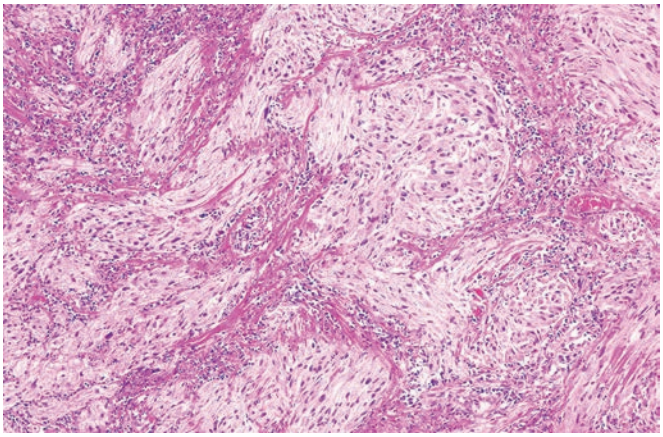

Figure 14.52 Granular cell tumor of the stomach with nests of granular cells.

Granular cell tumors can occur beneath the gastric mucosa (Fig. 14.52): they can be either solitary or multiple and can be associated with similar tumors in other portions of the gastrointestinal tract.[440,441]

Peripheral nerve sheath tumors can occur in the stomach and need to be distinguished from GISTs and other mesenchymal neoplasms. They include *schwannoma*, *neurofibroma*, and *perineurioma*.[439] Some of these tumors have developed in patients with von Recklinghausen disease. As mentioned previously, almost all gastric schwannomas are surrounded by a prominent cuff of lymphocytes, a curious feature rarely if ever seen in their usual soft tissue locations (Fig. 14.53).[442] At the molecular level, gastric schwannomas appear to be different not only from GISTs but also from conventional schwannomas of soft tissues.

Other mesenchymal tumors of the stomach are extremely rare. *Fibromas* and *myxofibromas* have been reported,[443] but most cases so designated are probably examples of other types of mesenchymal neoplasms with secondary regressive changes. Both *inflammatory myofibroblastic tumor*[444] and *calcifying fibrous tumor*[445] can involve the stomach and need to be distinguished from inflammatory fibroid polyp, which is more common.[446] Virtually every other type of sarcoma (e.g. synovial sarcoma, Ewing family of tumors) has been reported in the stomach, but these are described in greater detail elsewhere (see Chapter 41).

Gastroblastoma is the term that has been suggested for a peculiar biphasic epitheliomesenchymal gastric tumor which resembles synovial sarcoma but lacks the classic chromosomal translocation of the latter.[447–450]

Plexiform fibromyxoma is another recently described tumor which is usually located in the antrum and characterized microscopically by a plexiform intramural growth with multiple micronodules containing paucicellular to moderately cellular myxoid, collagenous, and fibromyxoid areas.[451] In contrast with GIST, this tumor is negative for CD117, DOG1, and CD34, showing instead immunoreactivity for smooth muscle actin.[451] This neoplasm had also been described under the designation *plexiform angiomyxoid myofibroblastic tumor.*[452]

Germ cell tumors can arise in the stomach, the two most common forms being *choriocarcinoma* and *yolk sac tumor*. Either can present in a pure form, admixed with each other, or associated with conventional adenocarcinoma (Figs. 14.54 and 14.55).[452,453] The choriocarcinomas show immunohistochemical evidence of hCG production and can be associated with elevated serum levels of this marker.[454] The tumors combined with adenocarcinoma (some of which have arisen in a gastric stump) have been shown to belong to the same clone.[455] Molecular genetic studies in

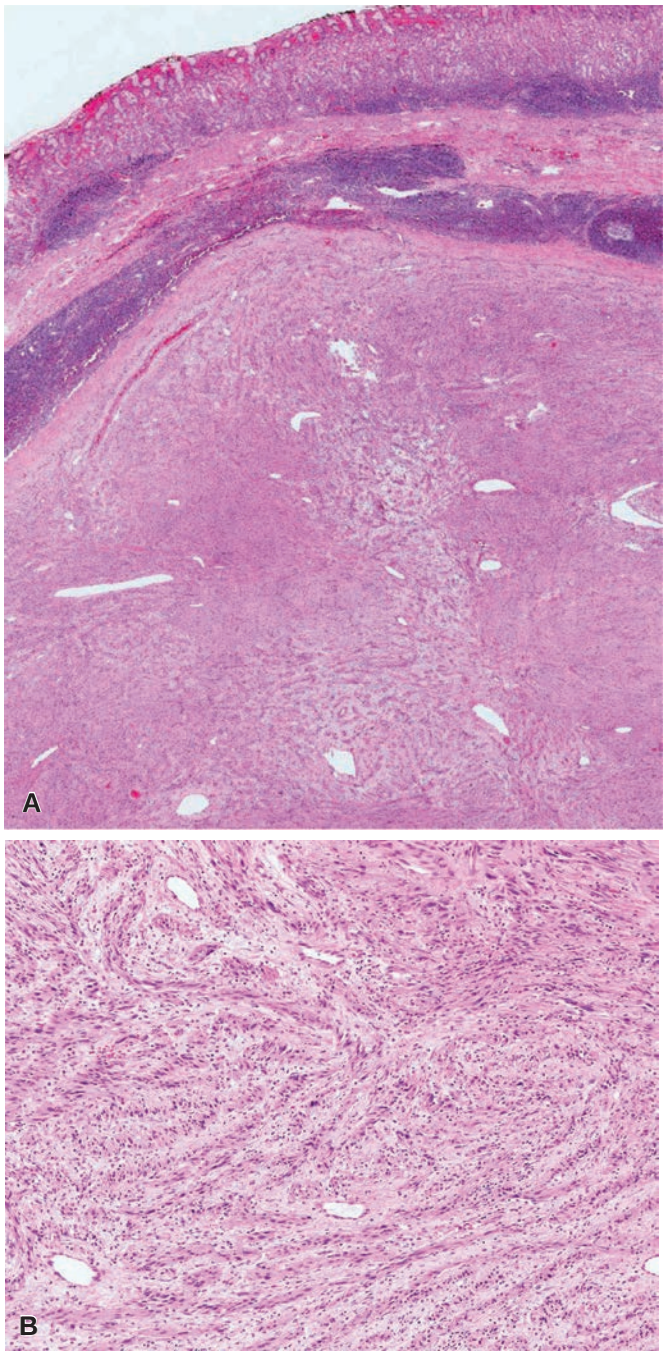

Figure 14.53 **A,** Characteristic low-power view of a gastric schwannoma with a prominent peripheral lymphoid infiltrate. **B,** High-power view showing a trabecular pattern in this gastric schwannoma.

primary gastric choriocarcinoma have shown aberrations usually associated with gastric adenocarcinomas combined with others commonly seen with gestational choriocarcinoma, suggesting that this tumor represents an alternative differentiation pathway of adenocarcinoma.[456]

Metastatic carcinoma may develop in the stomach from any widely disseminated neoplasm, particularly from the breast and lung.[457,458] Endoscopically, some of these lesions have been described as having a characteristic volcano-like ulcerative appearance.[457] Metastases to the stomach from lobular carcinoma of the breast can

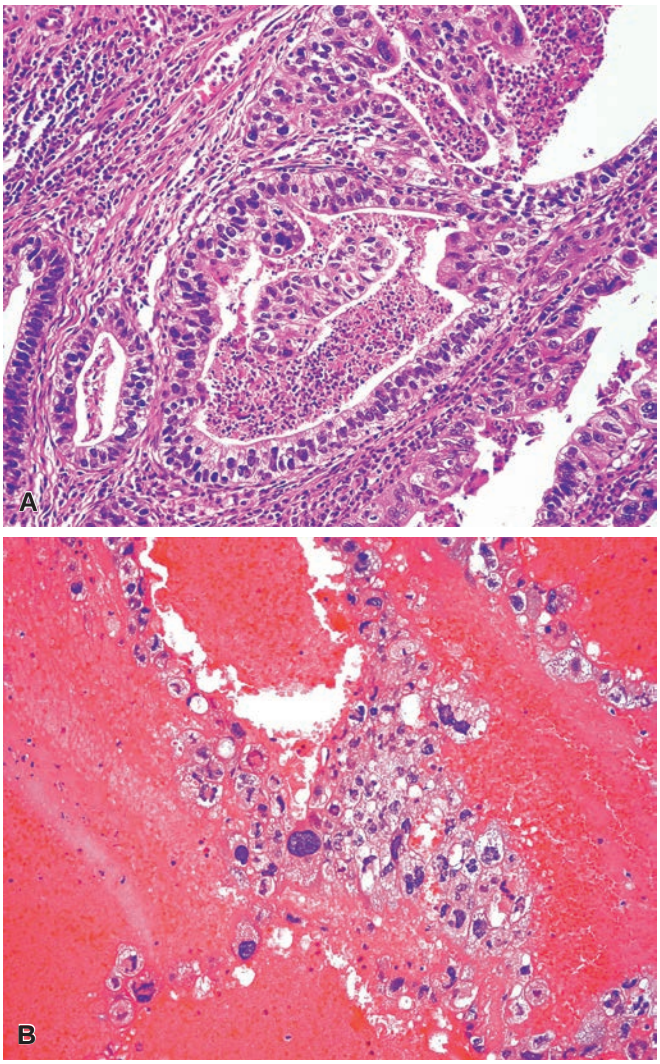

Figure 14.54 **A,** Mixed adenocarcinoma and choriocarcinoma of the stomach, adenocarcinomatous portion. **B,** Choriocarcinomatous portion surrounded by massive hemorrhage.

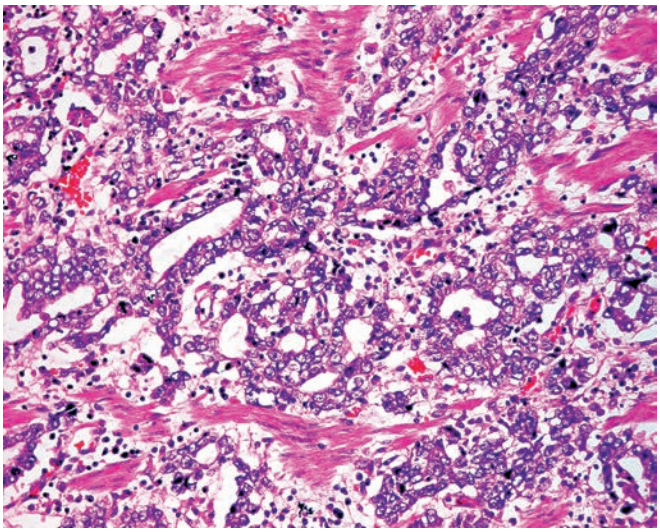

Figure 14.55 Yolk sac tumor of the stomach associated with a high elevation of serum AFP levels.

look indistinguishable from primary diffuse carcinoma of this organ ("linitis plastica") (Fig. 14.56). It has been said that, in the United States (considering the high frequency of breast carcinoma and the low frequency of gastric carcinoma), the occurrence of a linitis plastica-type appearance in the stomach is more likely to be due to metastatic mammary lobular carcinoma than to a primary tumor of this organ. The presence of tumor cells with a bull's-eye appearance (indicative of intracellular lumina), immunoreactivity for hormone receptors, GCDFP-15, and GATA3, and loss of E-cadherin favor metastatic breast carcinoma, whereas positivity for cytokeratin 20, DAS-1, MUC2, MUC5AC, MUC6, and CDX2 favors a gastric primary.[459–461]

Another malignant tumor that may metastasize to the stomach as part of its systemic spread is malignant melanoma.[462] As is always the case, it may simulate microscopically a variety of other lesions, including carcinoma, lymphoma and sarcomas.

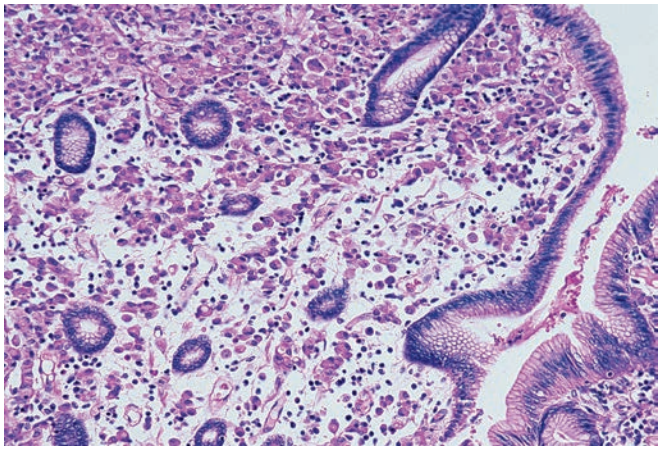

Figure 14.56 Lobular Carcinoma of the Breast Metastatic to Stomach. The tumor cells grow in a diffuse fashion within the lamina propria mimicking the pattern of growth of a primary diffuse-type adenocarcinoma of the stomach. Some of the cells even have a signet ring appearance.

Normal Anatomy

The small bowel extends from the pylorus to the ileocecal valve and measures approximately 6–7 m in length in adults. It is divided into three portions: *duodenum*, *jejunum*, and *ileum*. The *ligament of Treitz* is the anatomic landmark for the duodenojejunal junction, at which site the bowel becomes unfixed and wrapped in mesentery.[1,2]

The inner side of the small bowel is characterized by the presence of transverse mucosal folds known as *valvulae conniventes* (a double misnomer) or *Kerckring folds*. They are prominent in the proximal jejunum and flat or absent in the terminal ileum. Another characteristic feature of this region is represented by the *Peyer patches* (Fig. 15.1), which are located in the antimesenteric side of the terminal ileum. Their shape is oval, with the long axis parallel to that of the bowel. They represent lymphoid follicles and are more prominent in young individuals.

The small bowel ends at the *ileocecal valve*, a two-lip structure in which lymphoid tissue—and often adipose tissue (Fig. 15.2)—tends to accumulate.

Microscopically, the small bowel is composed of four layers: mucosa, submucosa, muscularis propria, and serosa. The mucosa is lined by villi, which are short and stubby (sometimes leaf-like) in the duodenum, tall and club-like in the jejunum, and of intermediate height in the ileum. The mucosa is made up of epithelium, lamina propria, and muscularis mucosae. The villous epithelium is composed of an admixture of tall columnar absorptive cells (enterocytes) and goblet cells (more numerous in the ileum).[1,2] Immunohistochemically, normal small bowel enterocytes are typically CK20 positive and CK7 negative.[3]

The *crypts of Lieberkuhn* comprise the lower 20% of the epithelium and represent its proliferative zone. They are surrounded by a pericrypt fibroblast sheath and are composed of multipotential stem cells (often exhibiting mitoses, about 1 or 2 per crypt), Paneth cells (with large cytoplasmic acidophilic granules containing a variety of digestive enzymes and lysozyme), scattered goblet cells, and neuroendocrine cells, of which the *Kulchitsky (argentaffin, basigranular)* cell is the better known representative (Fig. 15.3). The stem cells are the progenitors of all the cell types located in the intestinal mucosa, including those just mentioned. The sum total of the neuroendocrine or enteroendocrine cells (also known at one point as APUD cells) constitutes the so-called diffuse endocrine system, a concept brilliantly developed by Feyrter many decades ago. Functionally speaking, most of these cells are actually paracrine rather than endocrine, in that their action is exerted at a local level. They were thought to be of neural crest origin, but many independent studies (particularly those carried out by LeDouarin with her elegant quail–chick chimera model) have shown that they are endodermally derived,[4] at least in mammals.[5] The qualifier "neuroendocrine" can, however, be retained for them on functional/phenotypic grounds, in addition to the historical considerations.[6]

Abstract

This chapter covers the major congenital, inflammatory, and neoplastic entities that the surgical pathologist will encounter in the small bowel.

Keywords

Duodenum,
ileum,
jejunum,
celiac disease,
malabsorption,
lymphoma,
Crohn disease,
congenital,
inflammatory,
enteropathy,
infection,
adenocarcinoma,
melanoma

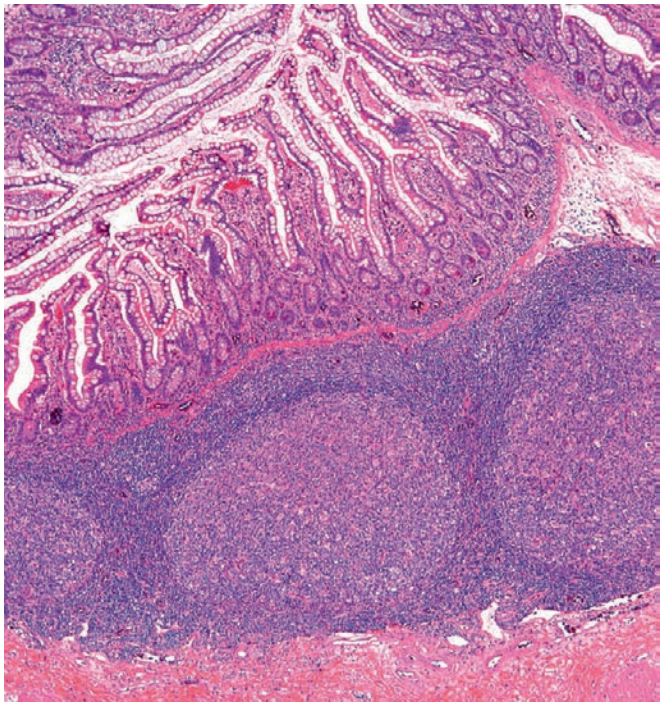

Figure 15.1 Peyer patches are a characteristic feature of the ileum. When large, they may resemble polyps macroscopically and can distort the overlying mucosa.

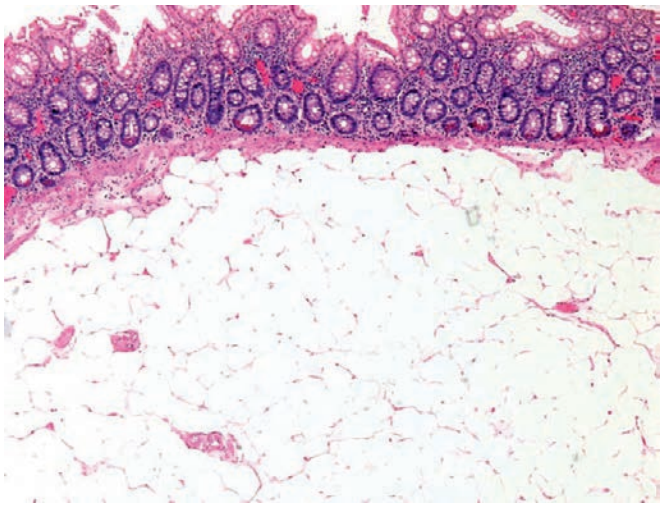

Figure 15.2 The ileocecal valve often contains abundant adipose tissue.

The lamina propria is composed of a loose connective tissue matrix. It contains lymphocytes, plasma cells, and occasionally eosinophils, macrophages, mast cells, and neutrophils. It also has blood vessels, lymph (lacteal) vessels, and numerous nerves. Interestingly, CD38 (a type of transmembrane glycoprotein involved in signaling and adhesion) has been found to stain the human lymph (lacteal) vessels of the bowel but not the lymph vessels of other organs.[7]

The submucosa consists of connective tissue, blood vessels, lymph vessels, and the *submucosal (Meissner) neural plexus*. In the duodenum (particularly the first two portions), it also contains numerous mucus-secreting glands known as *Brunner glands* (Fig. 15.4).

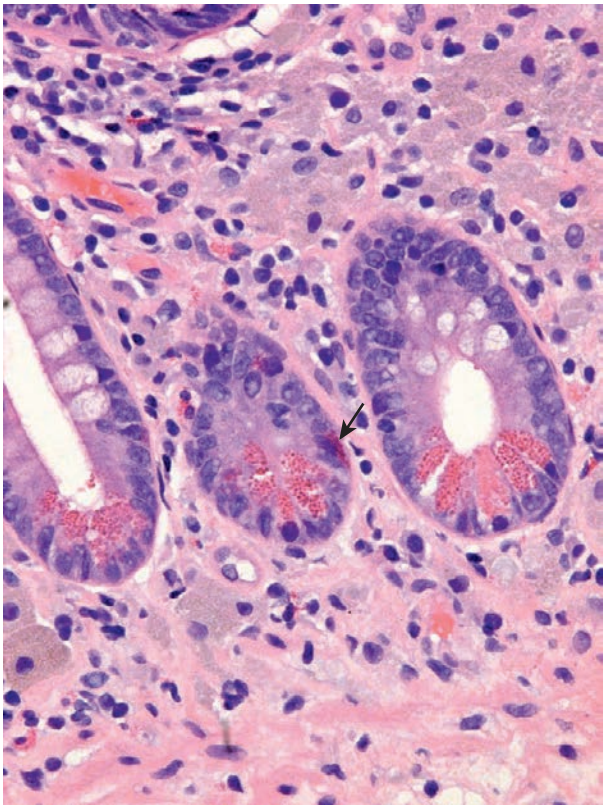

Figure 15.3 Paneth cells have large, red, supranuclear granules. In contrast, neuroendocrine cells in the crypts have smaller granules that are subnuclear and darker red to magenta *(arrow)*. This biopsy also contains pigmented macrophages indicating melanosis duodeni.

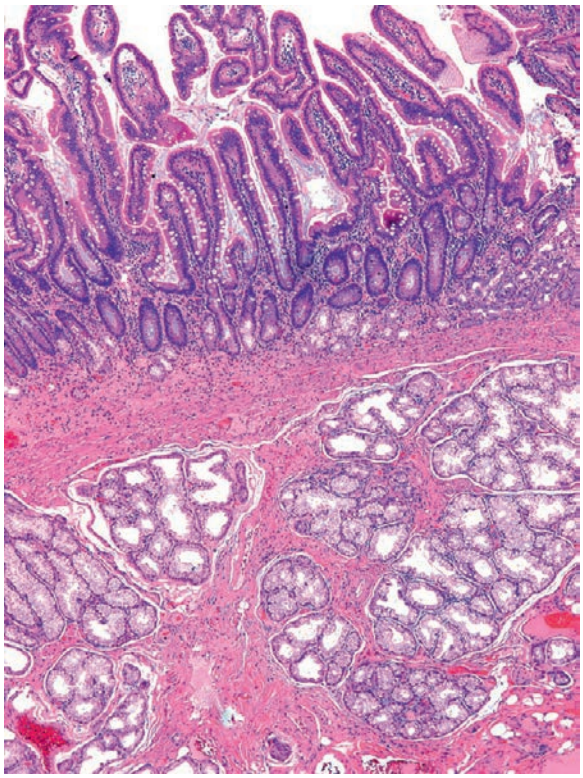

Figure 15.4 This biopsy shows nodular submucosal Brunner glands. When prominent, they may distort the overlying villous architecture.

The muscularis propria is made up of an inner circular and an outer longitudinal layer, with the *myenteric (Auerbach) plexus* located between. This plexus is composed of ganglion cells, satellite cells (similar but not identical to Schwann cells), and perineurial fibroblasts.[2,8,9] In addition, there is the "interstitial cell," described by Cajal in 1893, and interpreted by him as a primitive neural cell featuring several long anastomosing processes. These cells are intercalated between the ganglion cells and the effector smooth muscle cells, and function as the gastroenteric "pacemaker" system.[10,11] Their physiologic development depends upon signaling via the KIT receptor pathway.[12] They are normally immunoreactive for this molecule, as demonstrated with CD117, a fact that has implicated them (perhaps unjustly) in the histogenesis of gastrointestinal stromal tumor (GIST). They are negative for CD34, despite early claims to the contrary.[13] Their ultrastructural appearance is varied, ranging from smooth muscle–like to fibroblast-like; significantly, they lack neural features at this level.[14,15] The interstitial cells of Cajal originate from the same mesodermal precursors that give rise to smooth muscle cells, and not from the neural crest.[16,17] Therefore, these cells should not be regarded as neurally derived, a widespread misconception.

The serosa is covered by a single layer of attenuated mesothelium, separated from the muscularis by a normally thin layer of loose connective tissue. It contains vessels, lymphatics, and nerves.

The duodenum drains its lymph vessels into the portal and pyloric lymph nodes, the jejunum and proximal ileum into the nodes located in the mesentery and around the superior mesenteric artery, and the terminal ileum into the ileocolic nodes.

Congenital Defects

Heterotopias

Heterotopic pancreas consists mainly of ducts and acini, usually without islet tissue. The duodenum is the most common location (particularly in the region of the ampulla of Vater),[18] but it can also occur in the jejunum and (very rarely) in the ileum. Two lesions that are probably pathogenetically related to heterotopic pancreas are the tumorlike processes that have been described as *adenomyoma*[19] and *myoepithelial hamartoma*.[20] They are composed of exocrine-type ducts and bundles of smooth muscle, with or without an acinar cell component (Fig. 15.5). Blockage of the duct can occur where it empties into the intestinal tract, and this blockage can cause cystic dilation, infection, and fat necrosis.[21] Heterotopic pancreas is subject to any of the pathologic changes seen in the orthotopic organ, including acute pancreatitis, neuroendocrine tumors, and adenocarcinoma.[22] It has also been suggested that the rare *duodenal wall cysts* may be derived from the ductal component of ectopic pancreas.[23]

Foci of *heterotopic gastric mucosa* generally present as polyps in the duodenum, or rarely in the jejunum.[24–26] Endoscopically they appear as discrete small nodules or sessile polyps, although occasionally they form large polypoid lesions.[27] Microscopically, the mucosa is of fundic type, composed of chief and parietal cells (Fig. 15.6). Heterotopic gastric mucosa has been rarely associated with pyloric gland adenomas (see later).[28]

Duplication, Atresia, Stenoses, and Related Defects

Duplication and atresia of the gastrointestinal (GI) tract occur much more often in the small bowel (particularly ileum) than in the stomach or colon. Duodenal duplication (very rare) needs to be distinguished from the more common choledochocele, which it can mimic radiographically.

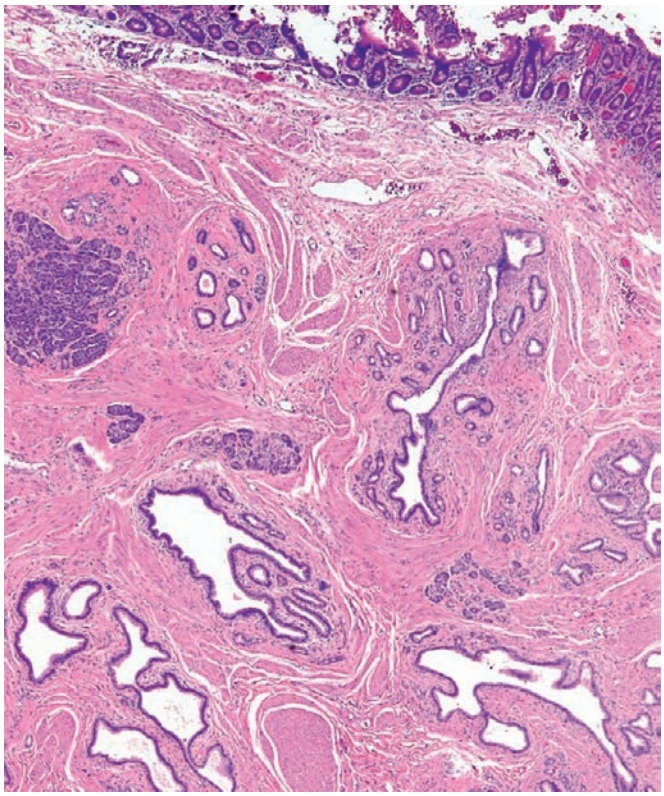

Figure 15.5 Heterotopic pancreas containing a focus of acinar parenchyma. The abundant ductal epithelium invested by smooth muscle creates a lobular appearance.

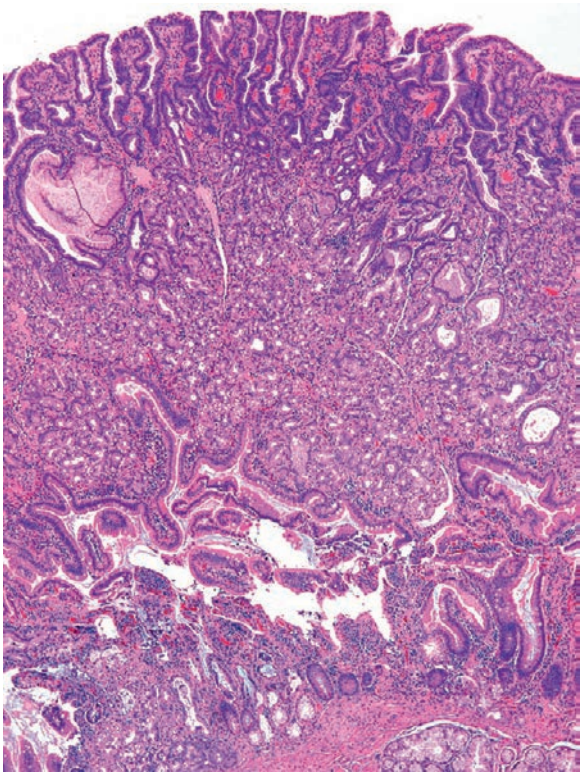

Figure 15.6 Polypoid gastric heterotopia occurring in the first portion of the duodenum. Parietal and chief cells are easily seen.

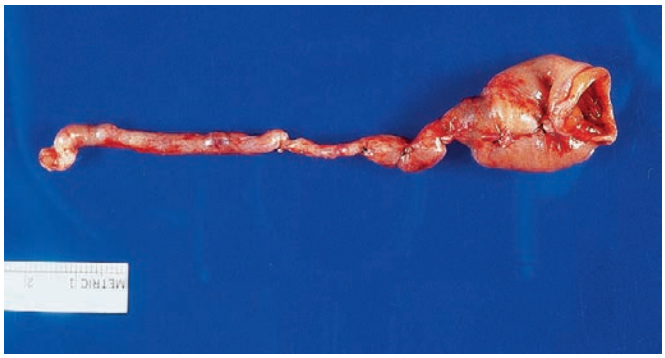

Figure 15.7 Long congenitally atretic segment of small bowel.

Intestinal duplication may be *spherical* (more common) or *tubular* and is usually incomplete, with a common muscular wall between the normal and the duplicate segments. The lumen of the duplicated segment sometimes communicates with the lumen of the bowel, and occasionally with the main pancreatic duct.[29,30] In other instances, the duplicated segment is totally independent and hangs free on its own mesentery. Exceptionally, it may be found within the substance of the liver.[31] Secondary inflammatory changes may supervene, and heterotopic mucosa is common. The treatment is surgical[32]; because the duplication cannot be separated in most cases from the adjacent normal bowel, the treatment usually involves resection of the entire duplication and the segment of normal bowel attached to it, or resection of the wall of the duplication that is not part of the wall of the normal bowel. Rare cases of malignant tumors (both squamous cell carcinoma and adenocarcinoma) developing within the duplicated bowel have been reported.[33,34]

Intestinal atresia can involve any portion of the small bowel and is associated with a wide variety of other congenital anomalies.[35–37] It is characterized by an obliteration of the bowel lumen and its replacement by a fibrous cord that connects the proximal and distal segments (Fig. 15.7). Traditionally, intestinal atresia has been regarded as an embryologic defect. Many believe that the disease is the result of in utero mechanical injury to the vascular system of the bowel, resulting from intussusception, volvulus, or incarceration.[37] A causal relationship between the use of dyes (e.g. methylene blue) during second-trimester amniocentesis and the occurrence of jejunal atresia has been suggested.[38] Complications of intestinal atresia include perforation, meconium peritonitis, and—as a rare late occurrence—brown bowel syndrome (see also Chapter 17).[39]

Infantile hypertrophic pyloric stenosis is an abnormal thickening of the pylorus that causes small bowel obstruction in the neonatal population. The etiology remains unknown. Surgical pyloromyotomy is the treatment of choice.[40] **Congenital absence of intestinal smooth muscle** has also been described, which may lead to obstruction, necrotizing enterocolitis, or spontaneous intestinal perforation.[41,42]

Congenital Diverticula and Related Vitelline Duct Abnormalities

Early in fetal life, the intestine communicates with the yolk sac. By the fourth week, the opening has gradually narrowed to form a tubular structure known as the *vitelline* or *omphalomesenteric duct*. At the 7-mm stage, the vitelline duct normally atrophies and forms a fibrous cord connecting the umbilicus and bowel. This band is subsequently absorbed as well. Failure of all or part of the vitelline duct to become obliterated accounts for the various types of vitelline duct abnormalities.[43] **Persistent fibrous cord** presents as a solid round cord of fibrous appearance, one end of which is attached to the umbilicus. The other end may be attached to the bowel wall, to the tip of a Meckel diverticulum, or to the mesentery. **Enteroumbilical fistula** is the consequence of a persistent patency of the entire vitelline duct.

Meckel diverticulum is the result of persistence of the proximal portion of the vitelline duct. It is found in 2% of the population and is more common in males.[44,45] Approximately 30% of patients have other congenital abnormalities, including tracheoesophageal fistula.[46] The usual location in the adult is approximately 80 cm proximal to the ileocecal valve. It is virtually always located on the outer antimesenteric border—an important diagnostic sign—and it varies in length from less than 1.0 to 8.0 cm. The lining is predominantly of small intestinal type, identical to that of the adjacent bowel; however, gastric, duodenal, or colonic mucosa may also be found, usually near the tip (Fig. 15.8).[47] Pancreatic tissue may also be present.

The complications of Meckel diverticulum include perforation, vesicodiverticular fistula,[48] ulceration, hemorrhage, intussusception, intestinal obstruction from attached bands, and tumors.[44] The ulceration is of peptic type, caused by acid secretion from the ectopic gastric mucosa, and is usually in the adjacent ileum rather than in the Meckel diverticulum itself. It may result in massive hemorrhage, particularly in children. *Helicobacter pylori* does not seem to be involved in the pathogenesis.[49] Among the neoplasms, well-differentiated neuroendocrine (WNET) (carcinoid) tumor predominates (Fig. 15.9),[50] either alone or—rarely—associated with carcinoid tumors of similar histologic appearance in the small bowel.[51] Other tumors include adenocarcinoma, GIST, and malignant melanoma.[52–54] Because of all these potential complications, Meckel diverticula should be removed whenever encountered incidentally at surgery.

Other Small Intestinal Diverticula

Duodenal diverticula occur in 1%–2% of all individuals. Most are solitary and located in the second portion; they can attain a large size and produce obstructive jaundice, pancreatitis, duodenal obstruction, fistulas, hemorrhage, and perforation.[55] Some of them project into the lumen like a polyp,[56] and some penetrate the pancreas along the embryologic fusion line of the ventral and dorsal components of this organ.[57] Microscopically, up to half of them show aggregates of foamy macrophages in the submucosa.[57]

Jejunal diverticula are found in 0.3%–1.4% of postmortem examinations. Most of them affect the upper portion of the jejunum and are characteristically located along the mesenteric border (Fig. 15.10).[58,59] They are often multiple, with thin walls and a decreased number of smooth muscle fibers. They tend to be associated with diverticula elsewhere in the GI tract. Some jejunal diverticula are congenital and may contain ectopic pancreatic tissue at their base; most are thought to be acquired, perhaps resulting from a defect in the muscle wall or myenteric plexus.[60] The majority are asymptomatic, but some may lead to hemorrhage, perforation, abscess formation, intramural gas cyst formation, obstruction caused by enterolith formation, or metabolic disturbances, such as vitamin B12 deficiency and malabsorption.[59,61] Many of these symptoms, which are typically intermittent, are thought to be caused by bacterial overgrowth within the diverticula.

Other Congenital Defects

Malrotation is a congenital anomaly resulting from an error in intestinal development such that (most commonly) the cecum is on the left, the duodenal-jejunal flexure is on the right, and the

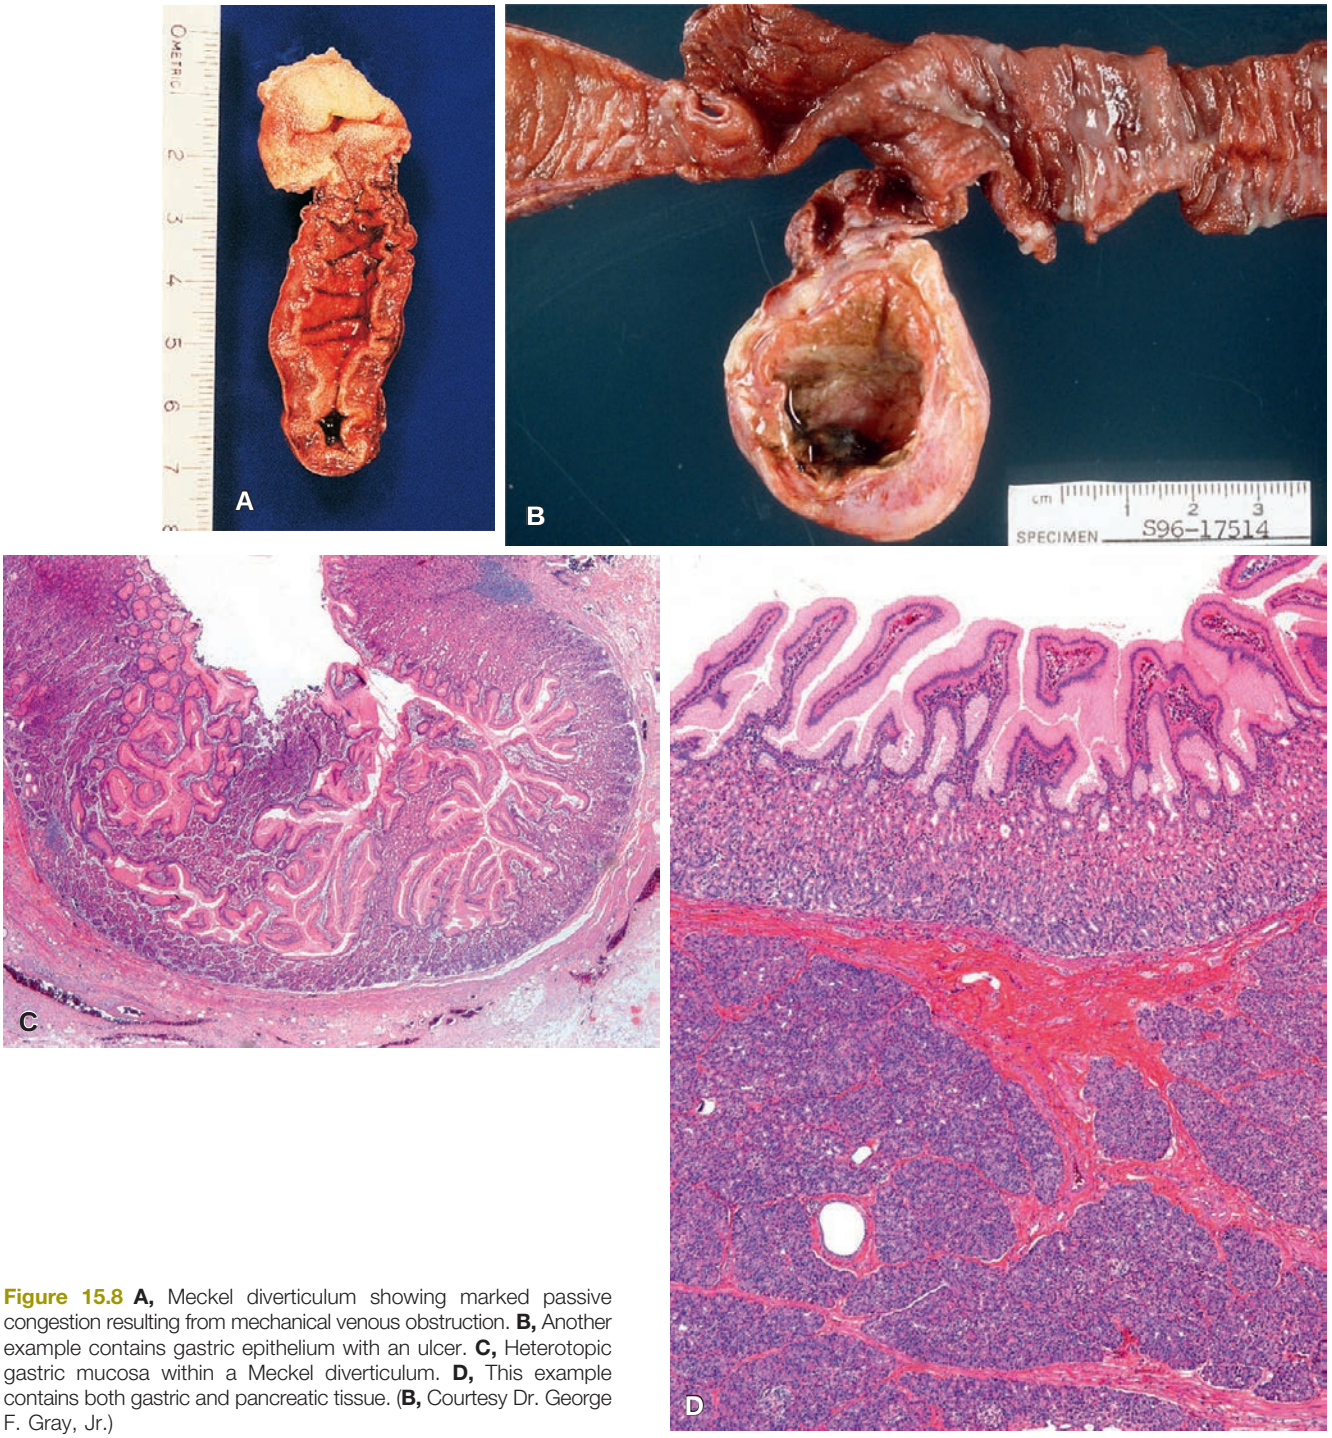

Figure 15.8 **A,** Meckel diverticulum showing marked passive congestion resulting from mechanical venous obstruction. **B,** Another example contains gastric epithelium with an ulcer. **C,** Heterotopic gastric mucosa within a Meckel diverticulum. **D,** This example contains both gastric and pancreatic tissue. (**B,** Courtesy Dr. George F. Gray, Jr.)

mesentery is narrow and unstable in position.[35] This may lead to volvulus with obstruction and ischemia, and affected infants often present with bilious vomiting. *Hirschsprung disease*, when involving the whole colon, may rarely extend to the small intestine, known as *total intestinal aganglionosis* (see also Chapter 17). The form is associated with a high mortality, the most common complication being enterocolitis.[62] *Ehlers–Danlos syndrome*, a congenital defect affecting collagen fibers throughout the body, may result in serious intestinal complications such as spontaneous perforation and massive bleeding.[63]

Inflammatory Disorders

Diseases of Malabsorption

The development of flexible endoscopes has made it possible to biopsy the mucosa of the small intestine with a minimum of discomfort or risk of serious complications, such as bleeding or perforation.[64] Small bowel biopsy is of the utmost importance in the evaluation of malabsorption, a constellation of signs and symptoms that can result from a large variety of disorders, of which

Figure 15.9 Meckel diverticulum complicated by the development of a carcinoid tumor, the cut surface of which has a characteristic yellow color after formalin fixation.

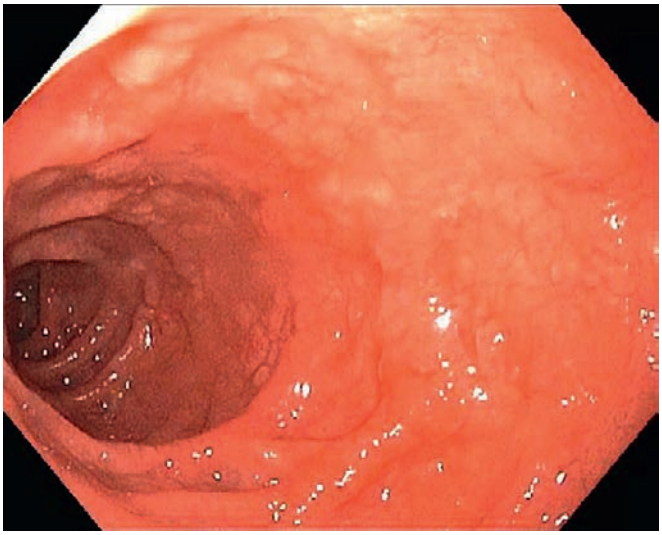

Figure 15.11 This endoscopic photo of the duodenum in celiac disease shows mucosal "mosaicism" and loss of normal folds. (Courtesy Dr. Rhonda Yantiss.)

Figure 15.10 Multiple Jejunal Diverticula. They are typically located along the mesenteric border. (Courtesy of Dr RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

celiac disease (CD) is the most commonly encountered. Since the morphology of the mucosa shows normal regional variations, it is important that biopsies be taken from approximately the same area in all patients. Separate biopsies should be obtained from the proximal duodenum/duodenal bulb and from the second and/or third portions of the duodenum.[65] Ideally, once biopsies are obtained, they should be placed quickly on a flat surface, mucosal side up, preferably with the aid of a dissecting microscope; filter paper and Gelfoam are commonly used for this purpose.[64] The tissue can be fixed in formalin with the filter paper or Gelfoam attached to it to prevent curling. The filter paper should be removed during any one of the subsequent steps, whereas Gelfoam can be embedded in the paraffin block attached to the tissue. It is imperative that sections be cut at right angles to the mucosal surface.[64,66] Unfortunately, although optimal for orienting the small bowel villi for histologic evaluation, this historical method of orienting, processing, and sectioning small bowel biopsies is no longer widely used in routine practice.

Celiac disease (celiac sprue, nontropical sprue, gluten-sensitive enteropathy) is an immune-mediated disease due to an abnormal response to gluten and related proteins in genetically susceptible people.[65] It is characterized in its fully developed state by totally flat mucosa, a dramatic clinical and morphologic response to the removal of gluten from the diet, and relapse when gluten is reintroduced.[65,67–68] The clinical manifestations can be extremely varied.[69]

Macroscopic findings in CD include scalloping or denting of the duodenal folds, an absence or reduction in the number of folds, a submucosal vascular pattern, and "mosaicism," in which the mucosa has a somewhat nodular appearance (Fig. 15.11). Grooves and fissures have also been described.[70] However, these findings are not specific to CD. Involvement may be patchy and is most prominent in the proximal small bowel with decreasing involvement distally.[67] Microscopically, in fully developed CD, the villi are markedly atrophic or absent, but the overall thickness of the mucosa is essentially normal due to presence of crypt hyperplasia (Fig. 15.12A). There is an increase in lymphocytes and immunoglobulin-containing plasma cells in the lamina propria, and accumulation of fat globules representing partially absorbed lipid in the surface epithelium.[71] Increased intraepithelial T lymphocytes, although far from being pathognomonic, are also a characteristic finding (see Fig. 15.12B).[72–74] It is important to note that in some cases the villous architecture is only mildly atrophic or entirely normal, and increased intraepithelial lymphocytes (IELs) may be the only evidence of disease. Interestingly, IELs have also been detected in the gastric and esophageal mucosa in patients with CD,[75–77] and there is an association with lymphocytic

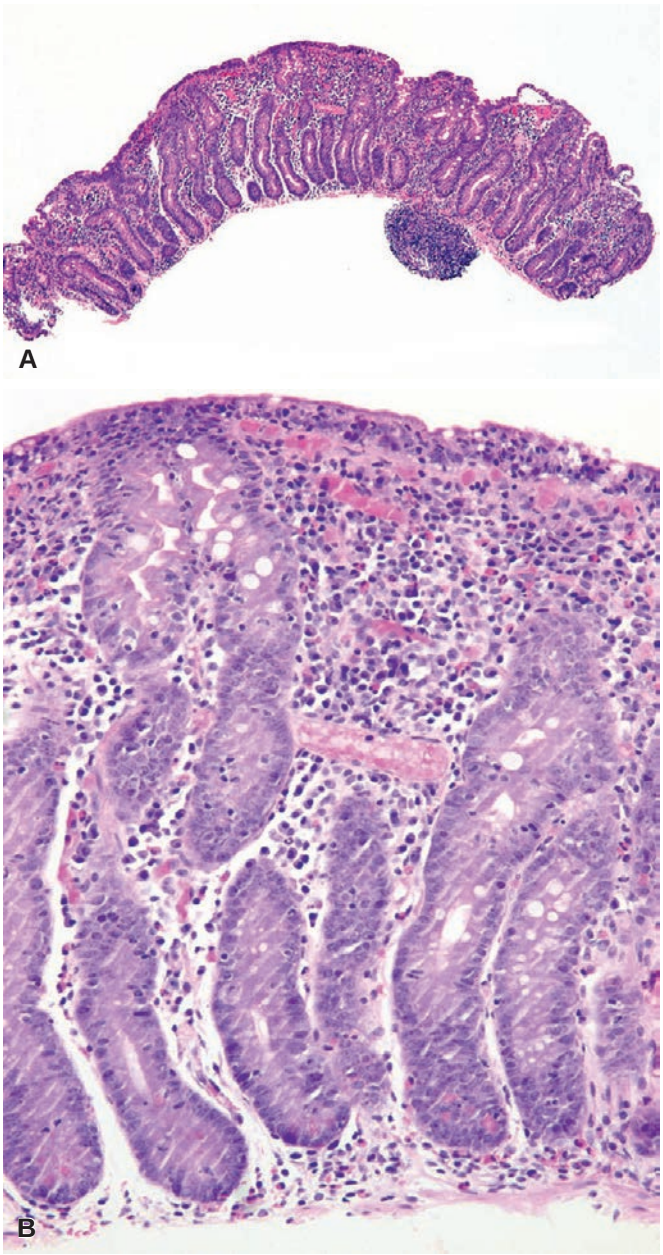

Figure 15.12 **A,** This biopsy from a patient with untreated celiac disease shows total villous atrophy, but concomitant crypt hyperplasia maintains the thickness of the mucosa. There is also a lymphoplasmacytic infiltrate in the lamina propria and a decrease in goblet cells at low power. **B,** Intraepithelial lymphocytes are prominent in both surface and crypt epithelium.

colitis in both children and adults.[78,79] An increase in the number of mitoses (including upwardly displaced mitoses) in the epithelium is a common feature,[80] as is a decrease in goblet cells[67] and hyperplasia of serotonin-containing neuroendocrine cells.[81] The epithelial cells have been shown to have a shortened life span.[82]

The most commonly used grading system for CD in small bowel biopsies is a modification of the Marsh (Marsh–Oberhuber) criteria adopted by the National Institutes of Health[67,74,83]:

Grade 0 = normal
Grade 1 = IELs only

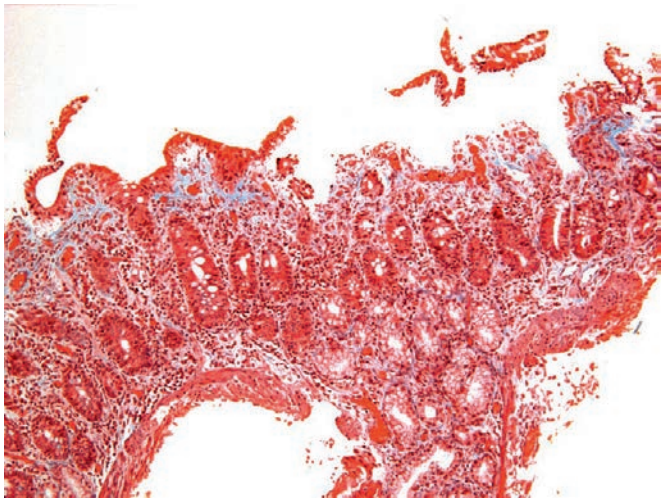

Figure 15.13 Subepithelial collagen deposition, villous atrophy, and increased intraepithelial lymphocytes are seen in this biopsy from a patient with collagenous sprue (Masson trichrome stain).

Grade 2 = IELs plus crypt proliferation
Grades 3 a, b, c = mild, moderate, and severe shortening of villi, respectively.

It is important to note, however, that the Marsh criteria are intended for use in patients with established CD, and it cannot be overemphasized that villous atrophy is not pathognomonic of CD. Therefore, a Marsh 1 lesion in a patient without a known diagnosis of CD could represent a number of conditions, including dermatitis herpetiformis, kwashiorkor, tropical sprue, autoimmune diseases, nonsteroidal anti-inflammatory drug (NSAID) use, and *H. pylori* infection, among others.[67,74,84]

The pathogenesis of CD is related to inappropriate intestinal T-cell activation in HLA-DQ2- or HLA-DQ8-positive individuals, which is triggered by antigenic peptides from wheat gluten or prolamins from barley and rye.[83,85,86] In addition to duodenal biopsy and clinical history, serologic studies are also helpful in diagnosis.[87] In patients above 2 years old, the anti–tissue transglutaminase (TTG) IgA antibody is the preferred serologic test. Anti-endomysial antibodies are more specific, but much more expensive and technically difficult to perform. Deamidated gliadin peptide (DGP) IgA and IgG or an anti-TTG IgG assay may be useful in children who are less than 2 years of age or in adults who are IgA deficient.[87,88]

Weinstein et al.[89] described the entity known as *collagenous sprue* (Fig. 15.13), characterized by increased deposition of eosinophilic hyaline material within the lamina propria, in addition to villous blunting and inflammatory changes. Whether this is a specific entity or merely a morphologic variant of CD is still argued, but the former seems more likely, particularly as many patients lack characteristic serologic findings and do not respond to a gluten-free diet.[90]

Refractory celiac disease (RCD) is a somewhat confusing term with differing definitions depending on the context.[91] Clinically, RCD is defined as persistent or recurrent symptoms and an abnormal biopsy, despite adherence to a gluten-free diet and the exclusion of other entities that could cause malabsorption. From an immunophenotypic standpoint, RCD can be further subdivided into type I, in which the lymphocytes maintain a normal immunophenotype, and type II, in which there is clonal expansion of an aberrant population of T cells that many believe represents an early form of enteropathy-associated lymphoma and have thus designated as "*cryptic intraepithelial lymphoma*."[92]

The development of lymphoma must be suspected in patients with a history of CD who, as discussed earlier, become unresponsive to a gluten-free diet and/or present with fever, weight loss, abdominal pain, rash, or lymphadenopathy.[93] Although CD and *enteropathy-associated T-cell lymphoma* (EATL) may be diagnosed concurrently, lymphoma typically arises within 5–10 years of a prior diagnosis of CD, although the time between initial diagnosis of CD and the development of lymphoma may be decades. The clinical course is aggressive and the prognosis is poor, in part due to the often delayed diagnosis and the poor nutritional status of patients in this situation.[94] Two types of EATL are recognized[95,96]: *type I* or *classical*, which is usually associated with CD and accounts for the majority of cases, and *type II* or *monomorphic epitheliotropic*, which is not typically associated with CD or the CD-associated HLA haplotypes (which has led some to question whether or not it should be regarded as an enteropathy-associated lymphoma at all).

Grossly, cases with full-blown lymphoma tend to involve the small bowel (particularly the jejunum) in a multifocal fashion, causing ulceration, stricture formation, and perforation.[96,97] Microscopically, type I EATLs are very variable,[95] consisting of a mixture of pleomorphic variably sized cells with conspicuous nucleoli and variably present necrosis (Fig. 15.14). Atypical binucleated or multinucleated cells may be present and lead to a mistaken diagnosis of Hodgkin lymphoma. Admixed eosinophils and histiocytes are also common. Morphologic features of CD, ranging from focally increased intra-epithelial lymphocytes to marked villous atrophy, may be present either adjacent to the lymphoma or elsewhere in the small bowel. Type I EATLs typically express CD3, CD7, TIA-1, and the αβ T-cell receptor but lose expression of CD4, CD5, and CD56. CD8 is variably expressed.[95,98,99] These tumors may also express CD30, leading to diagnostic confusion.[98] Type II EATLs, in contrast, are composed of monotonous small to intermediate sized cells with inconspicuous nucleoli. Most are CD8 and CD56 positive, along with CD3 and CD7; CD5 is typically negative, and either the αβ or γδ receptor can be expressed.[95,98,100,101] Increased IELs may be found adjacent to or away from the area of the lymphoma, and villous blunting is variably present.[96,100,101]

Clonal rearrangements of T-cell receptor genes are demonstrable in most cases of EATL.[102,103] Characteristic genetic changes are +9q31–q33 (70% of cases) and –16q12 (23% of cases).[104,105] Furthermore, type I is characterized by +1q32–q41, +5q34–q35, and the CD-associated HLA phenotype HLA-DQB1*02, while type II is characterized by +8q24, which includes the *MYC* gene locus.[104] Epstein–Barr virus (EBV) is usually absent.[106,107]

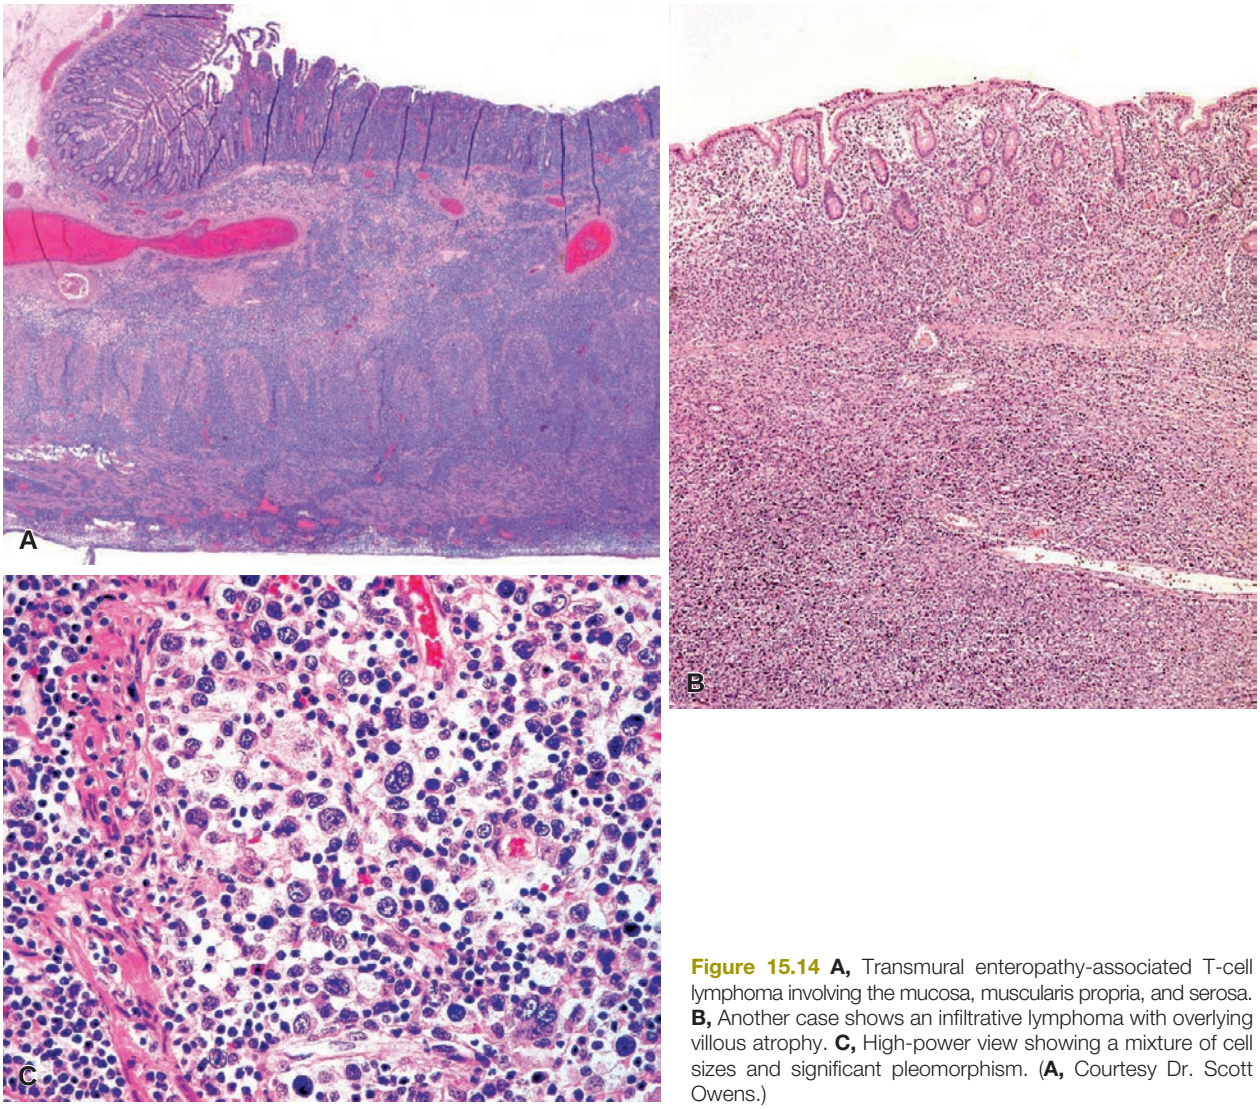

Figure 15.14 **A,** Transmural enteropathy-associated T-cell lymphoma involving the mucosa, muscularis propria, and serosa. **B,** Another case shows an infiltrative lymphoma with overlying villous atrophy. **C,** High-power view showing a mixture of cell sizes and significant pleomorphism. (**A,** Courtesy Dr. Scott Owens.)

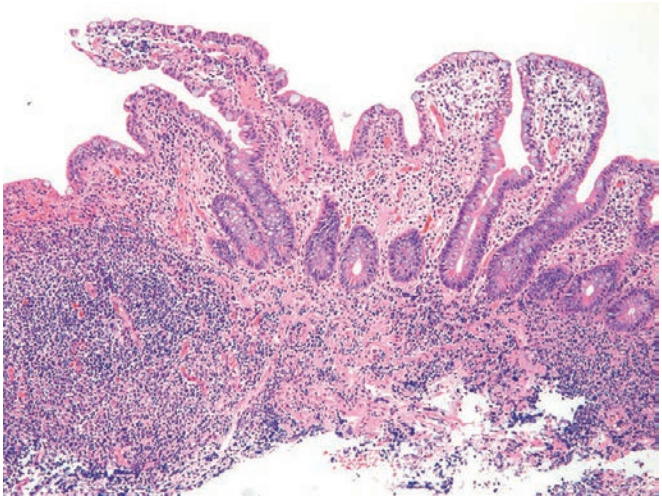

Figure 15.15 A biopsy from a patient with tropical sprue featuring mild villous blunting, a lymphoplasmacytic infiltrate in the lamina propria, and increased intraepithelial lymphocytes.

A complication of CD is *ulcerative duodenojejunoileitis*,[102,108] which is characterized by abdominal pain, fever, and intestinal perforation or obstruction superimposed on a background of a malabsorption syndrome. Most of these cases probably represent the initial stages of EATL, as supported by the fact that the lymphocytic population is clonal and that many patients go on to develop overt lymphoma.[102]

Yet another rare complication of adult CD is the development of *carcinoma*, usually in the small bowel but also in the esophagus.[109,110] Small bowel carcinomas arising in the context of CD are typically solitary adenocarcinomas.

Tropical sprue is an altogether different chronic malabsorptive condition that is unaffected by gluten ingestion.[111,112] It has a definite geographic distribution, affecting both residents and visitors to India, parts of Southeast Asia, Venezuela, Colombia, and parts of Mexico and the Caribbean islands. It is associated with both folate and vitamin B12 deficiencies and responds to vitamin supplementation and tetracycline.[113] The morphologic changes are nonspecific (Fig. 15.15). The large majority of cases show *partial* villous atrophy, with increased lamina propria inflammation and increased IELs. Unlike CD, both the distal and the proximal small bowel are involved.[112] The favored (although unproven) etiology at present is that of persistent bacterial infection or colonization.[111–113] Features in favor of this interpretation are the isolation of enterotoxigenic coliform bacilli, the endemic nature of the disease (and the fact that it may affect visitors to areas where it is endemic), and the well-known response to antibiotics.

Whipple disease (intestinal lipodystrophy) is a systemic disorder with protean manifestations, including arthritis; diarrhea, weight loss, and malabsorption; and neurologic symptoms.[114] Endoscopically, patients may have white plaques representing lipid deposition in the mucosa (Fig. 15.16A and B), although this finding is not always present. The microscopic findings are characteristic, consisting of an infiltrate of histiocytes that fills the lamina propria and distorts the villi (see Fig. 15.16C).[115] Varying numbers of neutrophils may be present, although a mononuclear inflammatory infiltrate is typically absent, and the lamina propria often contains small foci of fat. Epithelioid granulomas are present in a minority of cases.[116] Occasionally, the disease is restricted to the submucosa and can, therefore, be missed in a mucosal biopsy.[117] The cytoplasm of the histiocytes is strongly periodic acid–Schiff (PAS) positive (Fig 15.16D), due to the presence of bacilliform bodies. This organism, which has been named *Tropheryma whipplei*, was identified by sequencing the largest part of a bacterial 16S ribosomal DNA, followed by polymerase chain reaction (PCR) amplification.[118,119] The Whipple bacillus has also been demonstrated by electron microscopy and immunohistochemistry,[120,121] and there have been some allegedly successful attempts at culturing.[122] The response to antibiotic therapy is good, although relapses are common.[123] Of note, PAS-positive macrophages may persist in biopsies for years, even in patients who have been treated with long-term antibiotic therapy.

Macrophages of identical appearance have been identified in the rest of the alimentary tract, as well as in regional and peripheral lymph nodes (see Fig. 15.16E), heart, lung, liver, spleen, adrenal glands, nervous system, and several other sites.[124,125] Mesenteric adenopathy is common, and lymph node biopsy may be useful in diagnosis.[126] Involved lymph nodes may show aggregates of PAS-positive macrophages, as well as small foci of fat, and noncaseating granulomas may be seen there as well. It should be remembered that a similar change (although not accompanied by PAS-positive macrophages) is often seen in intra-abdominal lymph nodes of normal individuals, probably secondary to the ingestion of mineral oil.[127]

Whether Whipple disease represents a specific disease caused by a unique bacterium capable of intracellular survival and replication, or a common organism in a host with impaired immunity, remains to be determined.[123] Macrophages in patients with Whipple disease show several abnormalities, and T-cell abnormalities have also been reported.[123] A few cases of extraintestinal malignant lymphoma have also been reported in patients with Whipple disease.[128]

Important entities in the differential diagnosis include infection with *Mycobacterium avium-intracellulare (MAI)*[129] (see later) and *Rhodococcus equi*.[130] It should also be noted that the evaluation of rectal biopsies for Whipple disease is hampered by the fact that mucin-containing macrophages ("muciphages") present in the lamina propria of many normal individuals have a strong resemblance to the histiocytes of Whipple disease, at least on routine H&E evaluation.[131]

Other diseases associated with malabsorption that may feature increased IELs as well as villous abnormalities, and in which small bowel biopsy may be of value, include *bacterial overgrowth*; *nutritional deficiencies* (such as zinc or B12 deficiency); *allergies to proteins other than gluten*, such as cow's milk, eggs, or soy[67]; *common variable immunodeficiency* (CVID; see later); *autoimmune enteritis* (AIE; see later); *abetalipoproteinemia*, in which the apical villous cytoplasm shows striking vacuolation as a result of inability to synthesize β-lipoprotein[132] (Fig. 15.17); *intestinal lymphangiectasia*, in which a protein-losing enteropathy develops probably as a result of the entrance of protein-rich fluid into the extracellular space of the lamina propria from the dilated lymphatic channels, and subsequent drainage into the gut lumen[133]; *amyloidosis; scleroderma*[134]; and *parasitic infections*, such as giardiasis,[135,136] hookworm infection,[137] strongyloidiasis,[138] and capillariasis.[139]

Peptic Duodenitis/Duodenal Ulcer

Duodenal peptic ulcer remains a very common disease, although its incidence seems to be decreasing. *H. pylori* has been shown to be an important factor in its pathogenesis, but gastric acid hypersecretion (which is the rule in these patients) and reduced duodenal mucosal resistance are also believed to play an important role.[140,141] Thus, a preserved fundic mucosa in the stomach is a prerequisite for the formation of duodenal peptic ulcer.

Grossly, duodenal peptic ulcers are usually single and within 2 cm of the pylorus (Fig. 15.18), although they may also occur

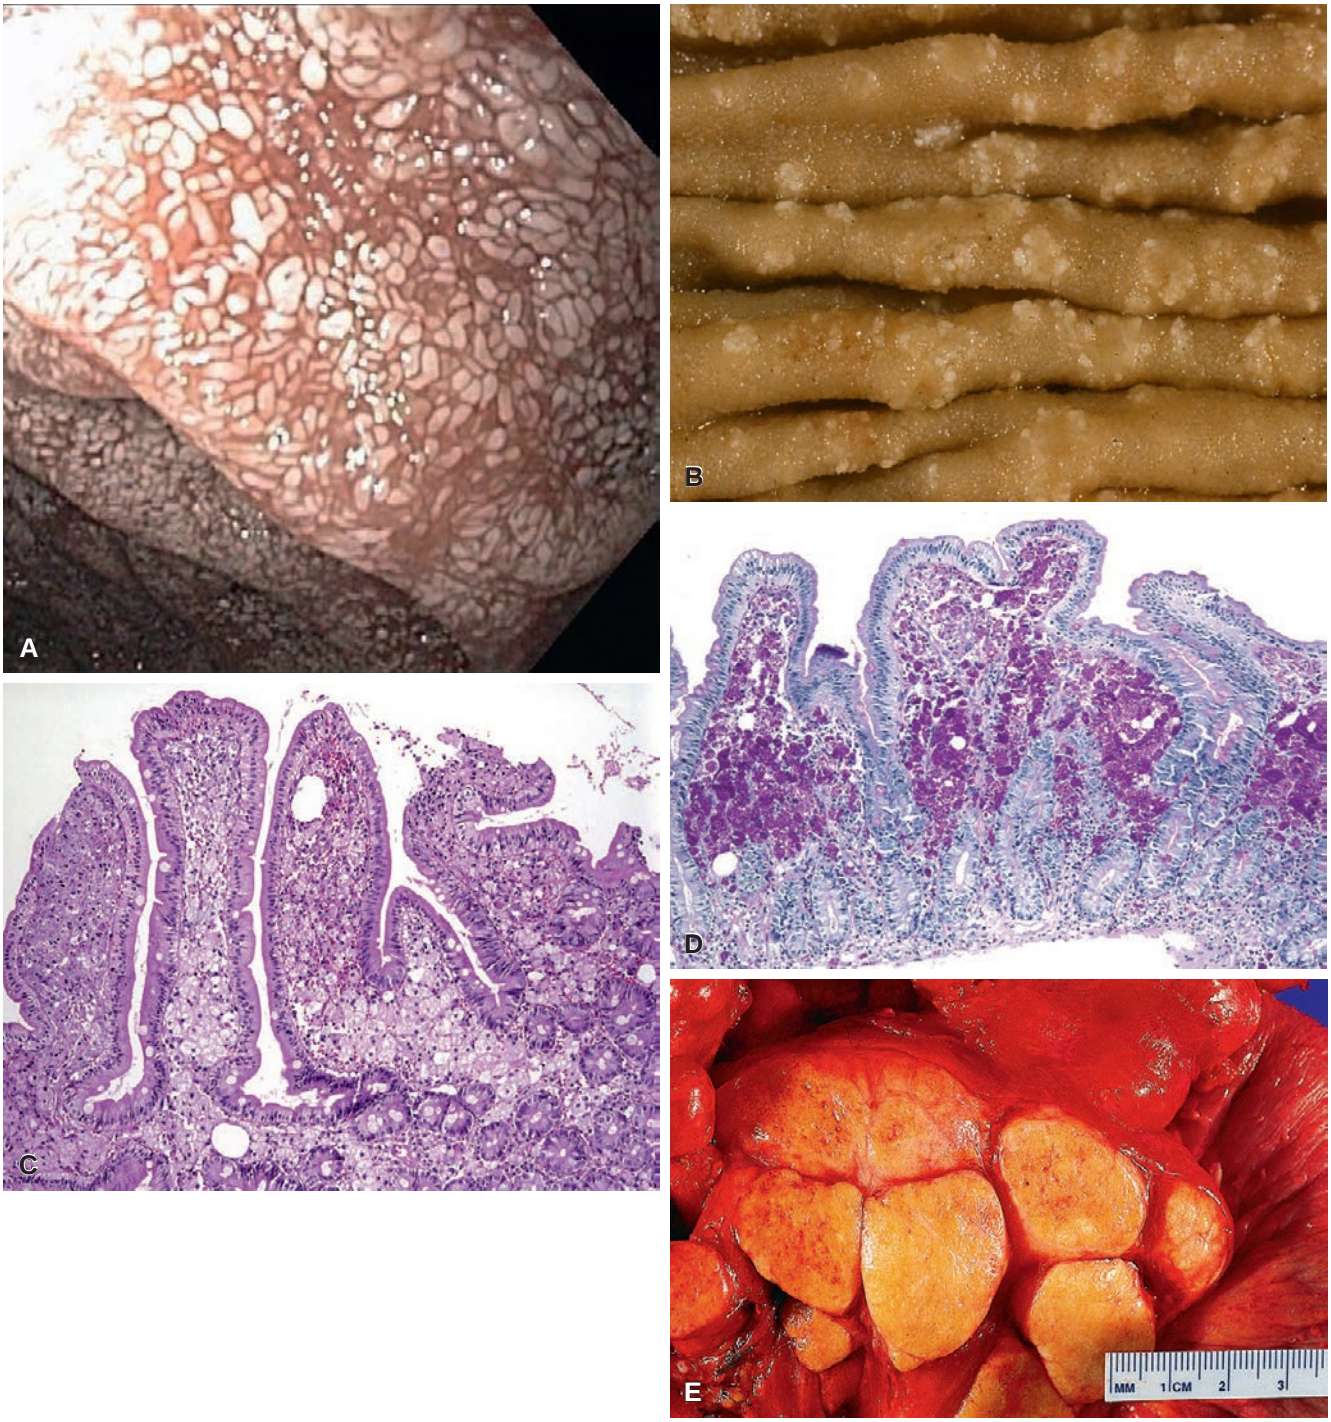

Figure 15.16 **Whipple Disease. A,** Endoscopic view of the small bowel showing white lipid-filled plaques in the mucosa. **B,** Similar changes are seen in a resection specimen. **C,** On biopsy, the lamina propria is packed with histiocytes and empty round spaces; the latter contained lipid material that has been extracted during tissue processing. **D,** PAS stain highlights the macrophages. **E,** Cut surface of mesenteric lymph nodes massively involved by Whipple disease.

in the second portion of the duodenum. When the ulcer is in the latter position, it may be the source of upper abdominal pain and bleeding, yet not be discernible radiographically. The margins are well defined and sharply demarcated from the surrounding mucosa. At times, a large vessel with an open lumen may be seen at the base of the ulcer. Fibrosis of a healed ulcer may produce secondary diverticula and considerable shortening of the duodenum. When duodenal ulcers are multiple and randomly distributed in the proximal and distal portions of the duodenum, the possibility of Zollinger–Ellison syndrome should be ruled out.

(Courtesy Dr. Wendy Frankel.)

Another important cause of non-*H. pylori*–related duodenal ulcer is NSAID usage.[142]

The microscopic features are analogous to those of its gastric counterpart (see Chapter 14). Gastric metaplasia is common, as is inflammation, loss of goblet cells, variably present villous blunting, and fibrosis in chronic cases.[143] The incidence of malignant change is negligible.

With the widespread use of H_2-receptor antagonists, proton pump inhibitors, and *H. pylori* eradication, the number of cases of duodenal ulcers requiring surgical intervention has markedly decreased. Refractory ulcers tend to occur in younger patients, to be larger, and to be associated with severe duodenitis.[144] Indications for surgery are complications, such as hemorrhage, perforation, and obstruction, and lack of response to medical therapy.[145] Historically, the two standard surgical techniques have been vagotomy with antrectomy and gastroenterostomy, and vagotomy with pyloroplasty. Simple closure is becoming increasingly common, however, as is surgical management via laparoscopy as opposed to laparotomy.[146]

Marginal ulcer is a type of peptic ulcer that appears at the site of a gastrojejunostomy opening. Although the ulcer may be at the stoma itself, in most instances it is located in the jejunum at some distance from the opening. It was a common complication at the time when gastroenterostomy for duodenal peptic ulcer was being done without a concomitant gastric resection. It is still seen, although rarely, following gastroenteroanastomosis with gastric resection (Billroth II operation) for duodenal ulcer, especially if the entire antrum is not removed or if the afferent jejunal loop is of excessive length. Occasionally, marginal ulcer develops following gastric resection for peptic ulcer or carcinoma of the stomach.

Small bowel ulcers that are not related to *H. pylori* infection or NSAID use[147] are uncommon. Many of the cases seen in the early 1960s were due to the ingestion of enteric-coated tablets of potassium chloride.[148] With that medication off the market, most of the "idiopathic" ulcers seen today are secondary to ischemia,[149] radiation, other medications (e.g. iron, colchicine), occult tumors, other infections, or Zollinger–Ellison syndrome.[150] A rare autosomal recessive inherited enteropathy secondary to SLCO2A1 prostaglandin transporter gene mutations has been reported to cause chronic small bowel ulceration,[151] and rare cases have been attributed to extensive gastric metaplasia.[152]

Peptic duodenitis is a common finding in patients with dyspepsia secondary to *H. pylori* infection and NSAID use,[153,154] and the microscopic appearance correlates well with endoscopic findings of duodenitis and/or abnormal mucosa.[155] Cases show increased numbers of plasma cells in the lamina propria, upward expansion of Brunner glands into the mucosa, gastric metaplasia, and a variable degree of neutrophilic infiltration (Fig. 15.19)[153]; more severe cases are accompanied by a more pronounced neutrophilic response. IELs and villous atrophy may also be encountered.[156,157]

Vascular Diseases

The consequences of mesenteric vascular occlusion are discussed elsewhere, but a few points regarding small bowel changes will be made here. Gross pathologic findings range from complete gangrene to foci of mucosal ulceration, accompanied by extensive submucosal edema.[158–160] Perforation may develop, and healing may lead to severe stenosis. Intramucosal signet ring cells may be seen due to mucosal injury, not to be misinterpreted as malignant.[161]

The vascular alterations in the bowel that lead to these complications are usually the result of atherosclerosis, but they can also be secondary to postoperative adhesions from radiation therapy; vasculitis, including rheumatoid arthritis,[162] periarteritis nodosa,[163] giant cell arteritis,[164] thromboangiitis obliterans,[165] and other forms of systemic vasculitis[166]; oral contraceptives[167]; cocaine ingestion[168]; amyloidosis[169]; and infection, typically by viruses[170] or vasotropic fungi.[171] Phlebitis may be seen in the absence of arteritis, in which case systemic involvement is typically absent.[172] Depending on the predominance of a given morphologic alteration, terms such as (*enteric* or *enterocolic*) *lymphocytic*, *granulomatous*, and *necrotizing phlebitis* have been used (Fig. 15.20), but all of these conditions are probably pathogenetically related.[173,174] Cases reported as *myointimal venous hyperplasia* and *veno-occlusive disease of small bowel* may also represent late stages of the same processes.[175] All of these conditions can closely mimic Crohn disease, both histologically, clinically, and radiographically, and can also produce an inflammatory mass that may mimic malignancy. A recently described noninflammatory, nonatherosclerotic entity termed *mesenteric arteriovenous dysplasia/vasculopathy* can also mimic Crohn disease or a mass lesion.[176] Although not an example of vasculitis, anticoagulant therapy can be complicated by the development of massive hemorrhage in the wall of both the small and large bowel.[177,178]

Other vascular diseases that may affect the small bowel include *portal hypertensive enteropathy,* a spectrum of changes in the mucosal microvasculature in patients with portal hypertension that may lead to lower GI bleeding (Fig. 15.21),[179,180] and, rarely, *Dieulafoy lesion* (Fig. 15.22).[181]

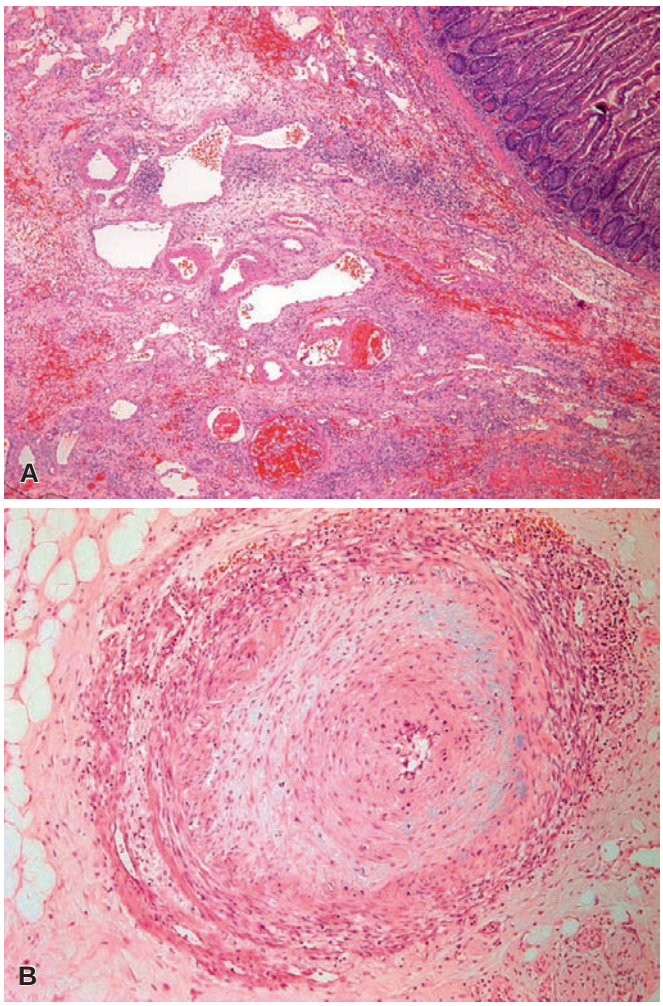

Figure 15.20 **A,** Necrotizing and lymphocytic phlebitis with associated thromboses in the small bowel. **B,** Another case shows a mesenteric vein with marked mural scarring, luminal narrowing, and lymphocytic inflammation.

Inflammatory Bowel Disease

Crohn disease occurs with equal frequency in both sexes.[182] Most patients are in their 20s or 30s,[183] but the disease can first manifest at any age, including childhood and old age. White individuals of Anglo-Saxon extraction are more susceptible to the disease, the incidence of which seems to be increasing.[183] The etiology remains unknown but appears to involve a complex interaction between genetic susceptibility, enteric microflora, and immune-mediated injury.[184] A tendency for familial clustering in Crohn disease has long been noted,[184,185] and a number of different genetic susceptibility loci have been identified.[184,186] Familial concordance studies, however, provide evidence that more than genetic susceptibility is needed for the development of Crohn disease, and the role of the enteric microbiome is now accepted as a major etiologic factor.[186] A number of organisms have been implicated, including several types of mycobacteria (particularly *Mycobacterium paratuberculosis*), *Escherichia*

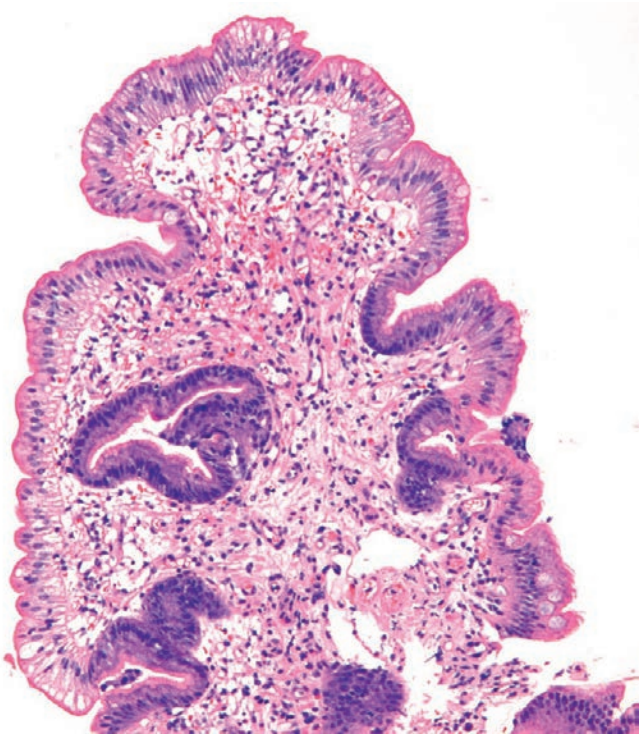

Figure 15.21 A polypoid lesion composed of small, proliferating, granulation tissue–like capillaries in portal enteropathy.

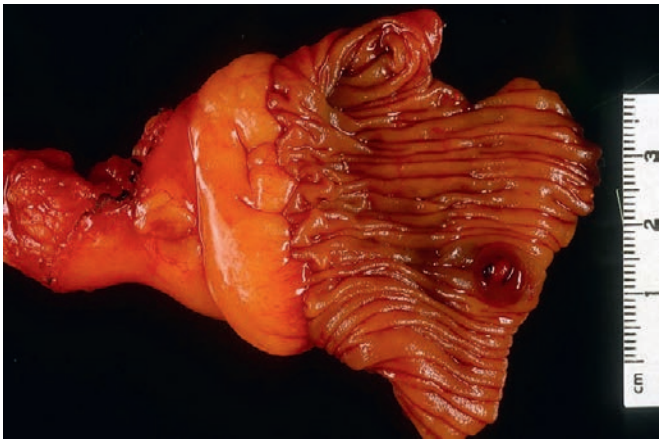

Figure 15.22 Dieulafoy lesion, defined as a solitary ulcer that erodes into a large submucosal artery, is most often found in the stomach but is rarely seen in the small bowel.

Figure 15.23 So-called aphthoid ulcers, an early feature of Crohn disease.

coli, *Yersinia*, *Streptococcus*, and viruses (including measles), but no specific causative agent has been identified.[187–192] The current hypothesis is that Crohn disease results from the interaction between host genetic polymorphisms and the gut microbiome (rather than conventional enteric pathogens), leading to an immune response and chronic inflammatory injury.[193–195]

Grossly, the ileum is the usual site of the disease, although any portion of the small bowel can be involved, and Crohn disease can affect any segment of the digestive tract including the oral cavity, minor salivary glands, esophagus, stomach, duodenum, large bowel, and anus (see also Chapters 14 and 17).[196–201] In a classic series of 297 cases of Crohn disease studied by Morson,[197] 66% of the cases were restricted to the small bowel, 17% were restricted to the large bowel, and 17% had involvement of both segments. In more recent series, lesions were limited to the small bowel in only one third of cases.[202]

Crohn disease can also involve sites outside the alimentary system, such as the skin (particularly around ileostomy or colostomy stomas),[203] vulva,[204] bones and joints,[205] skeletal muscle,[206] larynx, and spleen. The overall incidence of extraintestinal involvement is about 25%.[207] Nonspecific complications of the disease include arthritis, hydronephrosis, osteoporosis, amyloidosis, hidradenitis suppurativa, pyoderma gangrenosum, and various ocular disorders.[208–210]

Grossly, in the early stages of the disease the involved small bowel has a soggy feeling. The mucosa is reddish purple and may show pinpoint erosions known as "aphthoid ulcers" (Fig. 15.23).[211] One of the most distinctive gross features of Crohn disease is the often segmental nature of the process, with sharply outlined foci separated by seemingly normal bowel ("skip areas") (Fig. 15.24A). In later stages, ulceration becomes prominent; these ulcers are linear or serpiginous and often have a longitudinal disposition, arranged in parallel and connected by short transverse ulcerations.[211] As linear ulcerations cross the transverse folds of the bowel, the combination of ulceration and mucosal remnants results in the typical "cobblestone" appearance (see Fig. 15.24B and C). Rarely, the mucosa has a polypoid configuration because of granulation tissue formation or nodular lymphangiectasia (so-called inflammatory pseudopolyps).[212–213] The gross changes in the wall itself evolve from edema to fibrosis, with marked narrowing of the lumen accompanied by dilation and hypertrophy of the proximal segment (Fig. 15.24D and E). At this stage, the impression on palpation has been imaginatively likened to an eel in rigor mortis. The serosa may be focally or diffusely thickened; rarely, it is found to have multiple ("miliary") white nodules composed of either lymphoid aggregates or granulomas.[214] The mesentery becomes fibrotic and shortened, resulting in a corrugated bowel contour and piling up of mesenteric fat. Regional lymph nodes may be moderately enlarged.

Local complications of Crohn disease include the development of intramural abscesses and the formation of fistulas connecting the small bowel with other loops of small bowel or with large bowel, abdominal wall, or bladder.[215] At times, perforation occurs.[216]

The early lesion of Crohn disease is probably a very nonspecific focus of active mucosal inflammation.[211] This may be accompanied by lymphoid hyperplasia in the lamina propria and submucosa and a scattering of chronic inflammatory cells, including plasma cells, lymphocytes, eosinophils, histiocytes (some containing prominent lysosomal inclusions),[217] and mast cells.[218] Small foci of ulceration are often seen to begin at the very top of the lymphoid follicles (the microscopic correlate of the aforementioned aphthoid ulcer) (Fig. 15.25A).

The most typical ulcers in Crohn disease are referred to as *fissures*. These are seen in approximately 30% of the cases and are defined as slitlike formations with sharp edges and narrow lumina, arranged perpendicular to the mucosa, and extending deeply into the submucosa and even the muscularis propria. The nonulcerated mucosa may show cryptitis and crypt abscesses, abnormally shaped villi, architectural distortion, basal plasmacytosis, and regenerative changes. Foci of pyloric metaplasia may also be present (Fig. 15.25B).[211,219] In well-developed Crohn disease, there is nearly always microscopic evidence of transmural involvement (Fig. 15.25C), although the changes may be much more severe in the submucosa and subserosa than in the muscularis propria. Features of transmural involvement include transmural inflammation, often with prominent lymphoid follicles in a linear or "string of beads" array; edema; lymph vessel dilation; thickening of the muscularis mucosae; neural hyperplasia; and fibrosis.[211,220,221] The inflammatory changes can involve the walls of veins and arteries.[222] There is an increase in the number of smooth muscle fibers in the submucosa ("obliterative muscularization") as well, a change that may contribute to the development of obstruction.[223] Along these lines, it has been found that tenascin (an extracellular matrix protein involved in the morphogenesis of muscle tissue and wound healing) is strongly expressed, especially in areas of stricture.[224] Occasionally, following ulceration and reepithelialization, cystically dilated glands are seen in the wall of the bowel, an abnormality known as *enteritis cystica profunda*, which may be confused with invasive adenocarcinoma.[225]

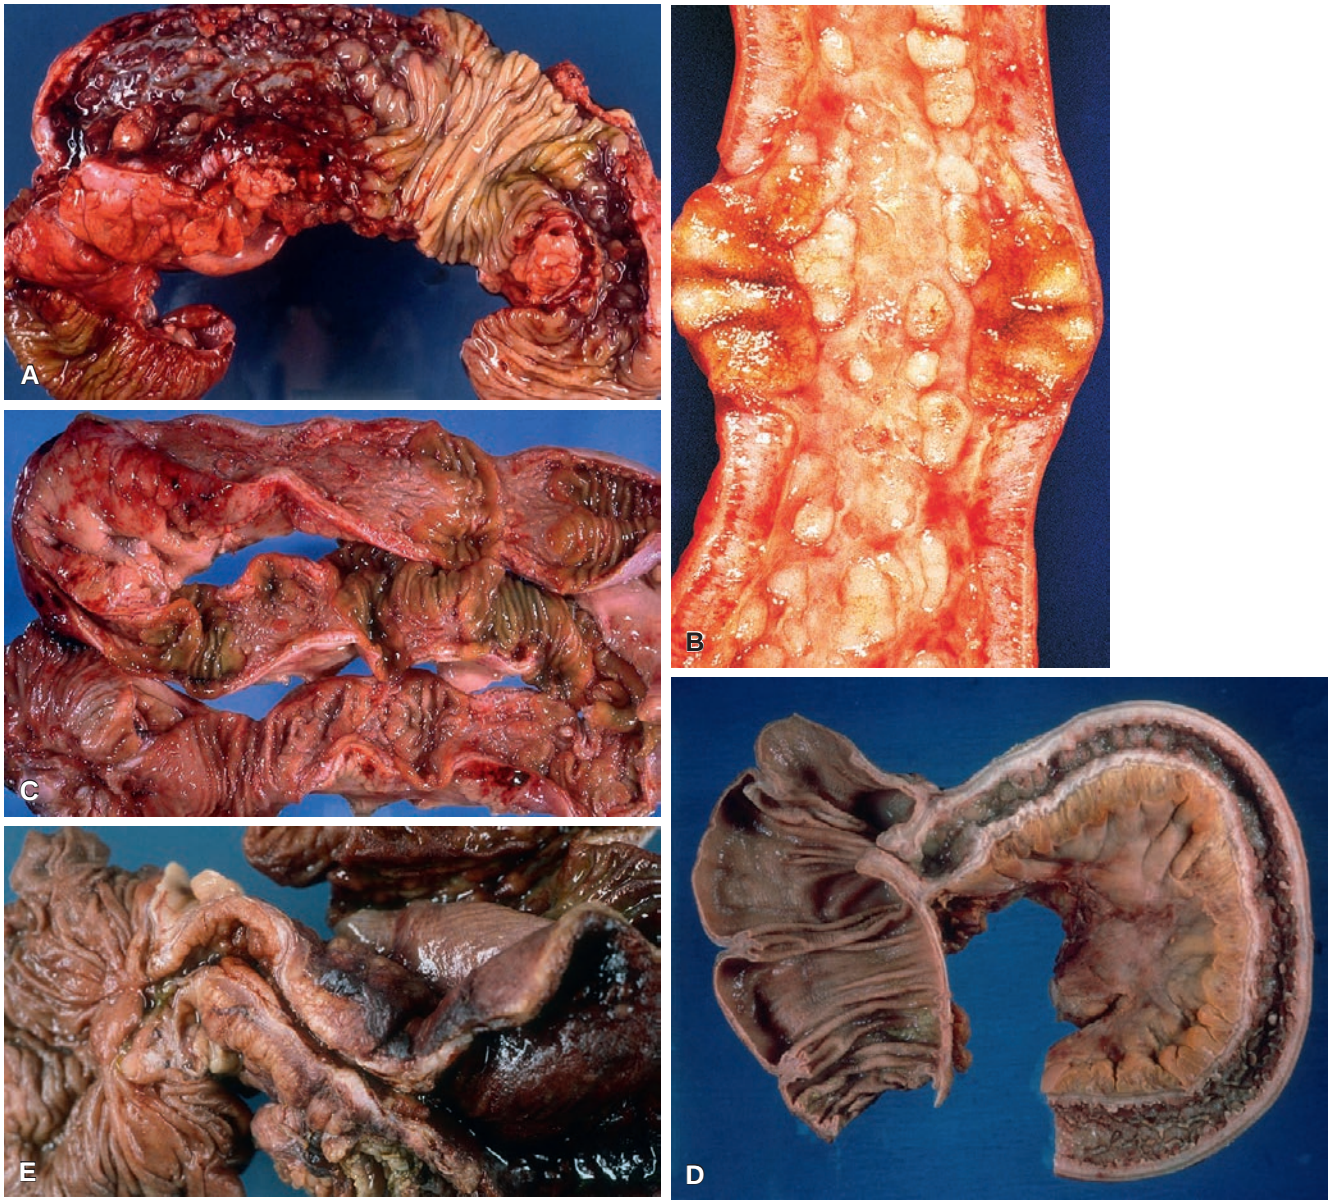

Figure 15.24 Gross Appearance of Crohn Disease. A, Note the segmental nature of the inflammation and the sharp demarcation between involved and uninvolved areas. **B,** The combination of ulceration and elevated remnants of mucosa results in a typical cobblestone appearance. **C,** The rigidity of the wall and the flattening of the mucosa are characteristic; note the linear fissuring ulcers. **D–E,** Fibrotic strictures and stenoses are common. (**A, C–E,** Courtesy Dr. George F. Gray, Jr.)

Another important microscopic change of Crohn disease is the presence of *granulomas* (see Fig. 15.25D), although in the small bowel they are seen only in approximately 50% of cases.[226] They are typically epithelioid and are often seen to arise from within the centers of the lymphoid follicles. Crohn granulomas are largely composed of epithelioid cells and multinucleated giant cells, with necrosis typically absent or limited to a small central area.[226] If necrosis is extensive, the alternative possibility of tuberculosis and other infectious processes should be excluded. The granulomas of Crohn disease may be found anywhere in the wall of the bowel (including serosa), in the regional lymph nodes (which may also show sinusoidal dilation and lymphoid hyperplasia), or at any other site of involvement. Granulomas indistinguishable from those of Crohn disease can be seen in many other conditions, however, particularly tuberculosis, yersiniosis, and (in the large bowel) complicated diverticular disease.[226] A minority of these granulomas are related to vessel walls, a feature that has been regarded by some as evidence of granulomatous vasculitis.[227]

Of all the microscopic features just described, those with greater diagnostic significance are transmural involvement, fissures, and granulomas. However, the first two may not be appreciable on mucosal biopsy. It should also be noted that a superficial variant of the disease exists in which the inflammation is limited to the mucosa and submucosa.[211]

Crohn disease has an undulating, yet progressive course, and complete regression is rare. Occasionally it is complicated by the

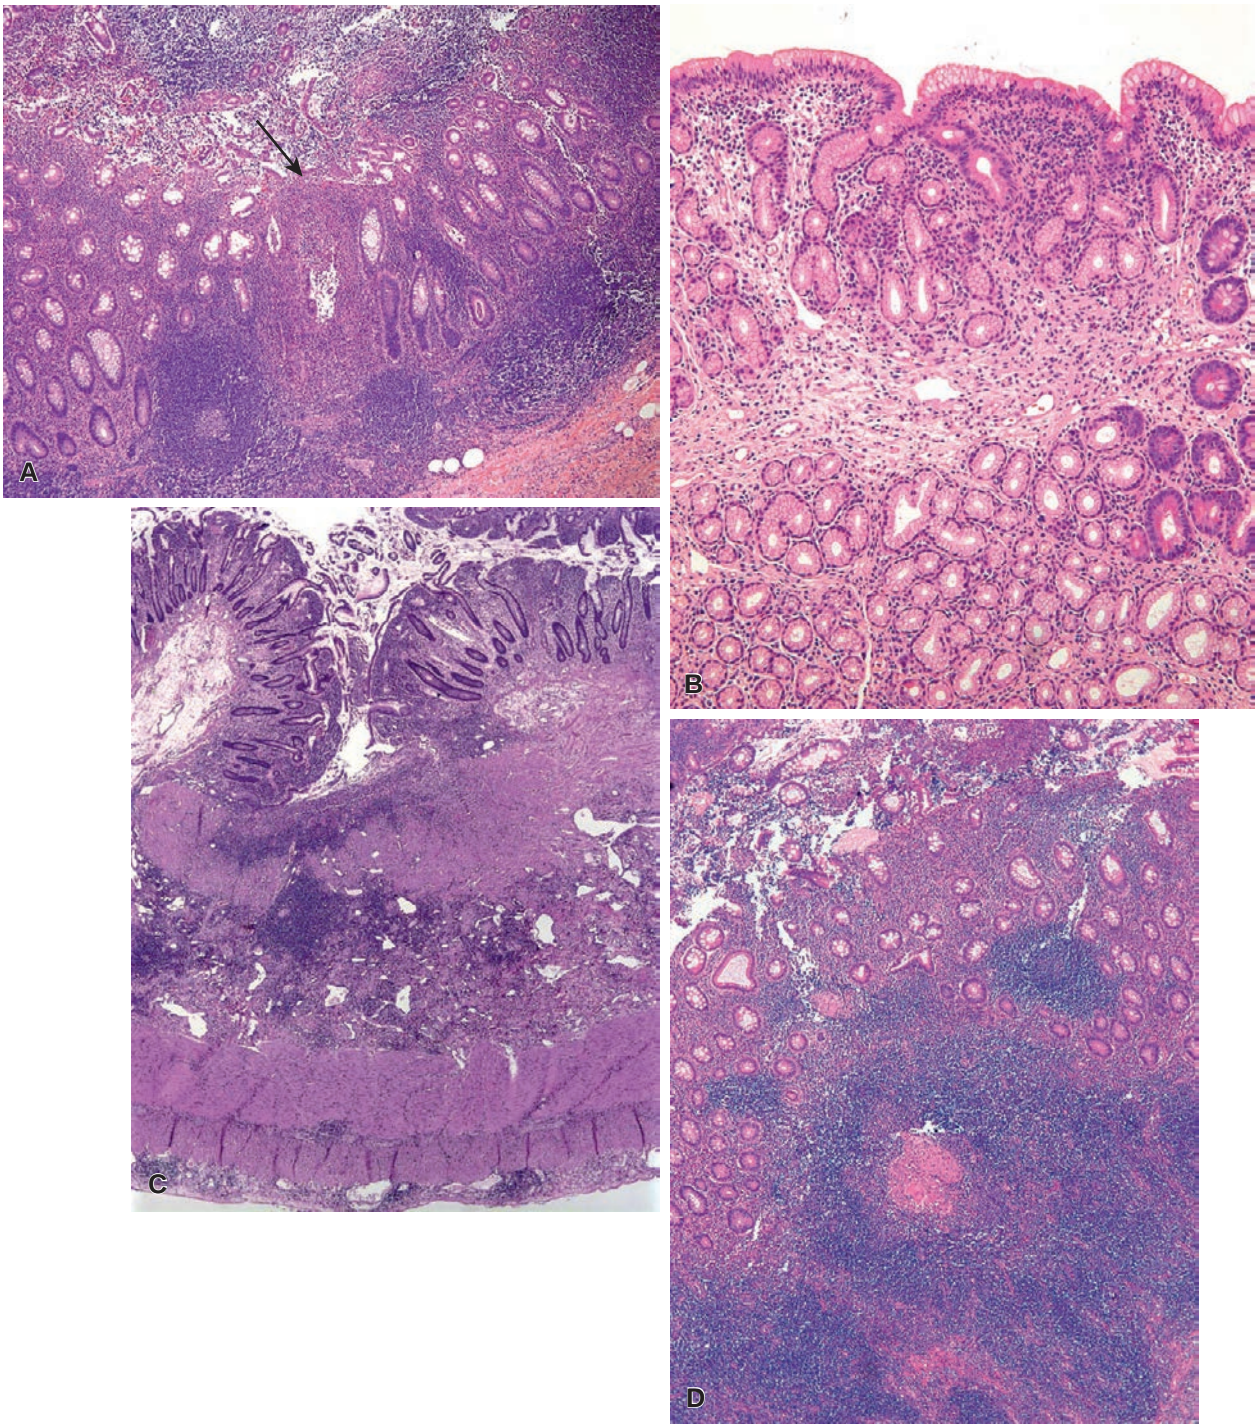

Figure 15.25 Microscopic Appearance of Crohn Disease. A, Superficial mucosal erosion *(arrow)* and active inflammation associated with lymphoid follicles constitutes an early lesion. **B,** Extensive pyloric metaplasia in a case of duodenal Crohn disease. **C,** Ileocecal Crohn disease showing transmural inflammation and fibrosis, along with a fissuring ulcer and markedly thickened muscularis mucosae. **D,** Small epithelioid granulomas in Crohn disease, associated with prominent lymphoid aggregates.

development of small bowel adenocarcinoma, typically located in the ileum.[228,229] Sometimes the tumors are very small and detected only at the time of pathologic examination.[230] The majority are associated with adjacent dysplasia, and some with dysplasia distant from the invasive adenocarcinoma.[231] The carcinomas virtually always develop in inflamed portions of bowel and may arise in a surgically bypassed segment.[232] Mixed adenocarcinoma/neuroendocrine tumors and WNETs (carcinoid tumors) have also been reported in the context of Crohn disease.[233,234] These patients are also at risk for the development of lymphoma, particularly with prolonged immunosuppressive therapy.[235]

The current medical management of Crohn disease includes medications (steroids, antibiotics, immunomodulators, or the newer

biologic agents) and nutritional therapy.[236–238] Despite advances in medical therapy, the vast majority of patients (~80%) require surgical intervention within a decade of diagnosis,[239] particularly in those with partial or complete intestinal obstruction due to strictures, fistulas, perforation, abscess, intractability despite medical management, and noncompliance with medical therapy. The surgical procedures most commonly used in current surgical management include resection and strictureplasty, and both open and laparoscopic approaches are used.[239] Recurrence following surgical remission is common, however, and the risk of recurrence is higher in ileocolonic disease than in pure ileal or colonic disease.[240,241] Other factors associated with recurrence include smoking, perforating disease prior to surgery, and short duration of disease before surgery.[242]

In general, the type and extent of the pathologic features appear to have little relationship with prognosis,[243] and claims have been made that the presence of granulomas portends both a better[244] and a worse[245] prognosis, depending on the study. Furthermore, no statistical relationship has been found between involvement of the surgical margins and recurrence.[246]

Ulcerative colitis usually spares the small bowel entirely, but some patients have ileitis, jejunitis, and even diffuse duodenitis.[247] The ileitis typically associated with ulcerative colitis (seen in about 17% of the cases) is referred to as *"backwash" ileitis* and is further discussed in Chapter 17. The main changes are villous atrophy with crypt regeneration, superficial erosions, neutrophilic and mononuclear inflammation in the lamina propria, and patchy cryptitis and crypt abscesses, although pyloric metaplasia may be present. Although it is usually associated with cecal involvement by ulcerative colitis (hence the term "backwash"), rarely ileitis may be present without involvement of the right colon.[248]

Patients with ulcerative colitis who undergo total proctocolectomy with ileal pouch–anal anastomosis may develop inflammation of the ileal mucosa, comprising the pouch, known as *pouchitis* (Fig. 15.26), the cause of which remains poorly elucidated.[249] Features include neutrophilic cryptitis/crypt abscesses, mucosal ulceration, lymphoplasmacytic inflammation in the lamina propria, and villous blunting in chronic cases.[250] Pyloric metaplasia may also be present.[251] It can be very difficult to distinguish pouchitis from ulcerative colitis involving the rectal cuff mucosa or from Crohn disease.[252] Patients with pouchitis have a small but definite risk of developing dysplasia and adenocarcinoma.[250]

Ileal involvement may also be seen associated with lymphocytic and collagenous colitis.[253,254]

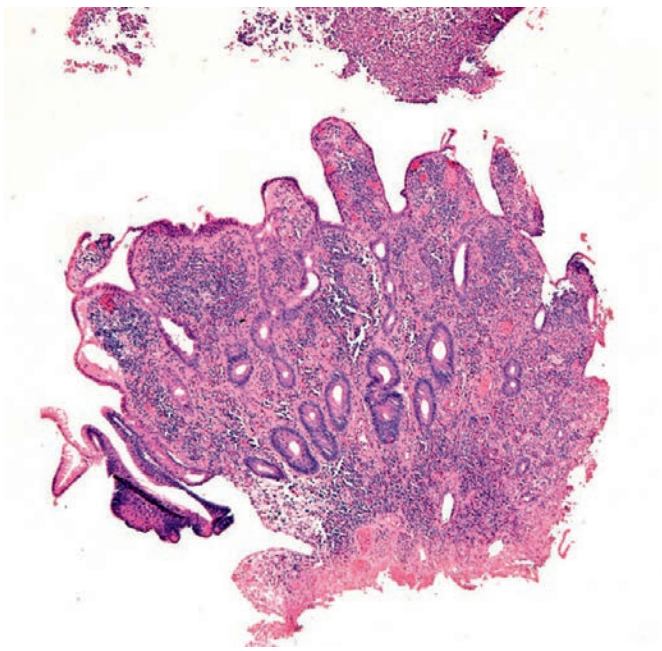

Figure 15.26 A biopsy from an ileal pouch in a patient with ulcerative colitis showing villous blunting, expansion of the lamina propria by a mixed inflammatory infiltrate, and overlying ulcer debris.

Infections

The small bowel may harbor a wide variety of pathogens, some of which are specific to the GI tract and some of which are a manifestation of disseminated disease. Many of the infections discussed here are seen in the context of immune compromise, including patients with AIDS and those who have undergone transplants[255–257]; small bowel biopsy may be very helpful in the diagnostic evaluation.[258] It should be noted, however, that occasionally some of these infections are seen in individuals without evidence of immunodeficiency.

Cytomegalovirus (CMV) infection most commonly presents in immunocompromised patients but occasionally presents in immunocompetent patients. Patients can present with ulcer-type symptoms and bleeding, or diarrhea, fever, and weight loss.[259,260] CMV infection may also cause a vasculitis with associated ischemia, particularly in renal transplant patients (Fig. 15.27).[261]

The term **AIDS enteropathy** has been used by some to describe the nonspecific histologic findings of villous blunting, crypt hyperplasia, and increased apoptotic epithelial cells in AIDS patients with diarrhea in whom no other pathogen can be found. Others believe that "AIDS enteropathy" is not a specific disease entity, and thus the term should not be used.[262–264]

Tuberculosis of the small bowel, still frequent in some parts of the world,[265,266] can be confused with Crohn disease on both clinical, gross, and microscopic grounds.[267,268] In contrast with Crohn disease, tuberculous ulcers are multiple and circumferential rather than linear and serpiginous.[268,269] Destruction of the muscularis externa is common in Crohn disease, and cobblestoning of the mucosa, aphthous ulcers, and skip lesions are not generally seen in tuberculosis. Tuberculosis is also more likely to form mass lesions. Microscopically, the tuberculous granulomas tend to be confluent and often have a caseous center and a peripheral lymphocytic ring. Obviously, special stains for acid-fast bacilli and molecular testing for *Mycobacterium tuberculosis* are in order whenever this differential diagnosis is entertained.

MAI is the most common mycobacterium isolated from the GI tract, and it is frequently found in the small bowel. Patients are typically immunocompromised, and the appearance on biopsy may be similar to Whipple disease (see also earlier). The lamina propria of the bowel and the regional lymph nodes are infiltrated by plump, foamy, macrophages containing a myriad of acid-fast organisms (Fig. 15.28).[270,271]

Yersiniosis results from infection by the gram-negative bacilli *Yersinia enterocolitica* and *Yersinia pseudotuberculosis*. It commonly involves the ileum and may manifest as ulcerative enteritis or enterocolitis (as well as appendicitis) with variably present mesenteric lymphadenitis.[272,273] The ileal changes may closely mimic Crohn disease both grossly and microscopically (Fig. 15.29), and molecular testing, cultures, and serologies may be useful in diagnosis.[274,275] ***Salmonella*** (both typhoid and nontyphoid) also affects the small bowel, particularly the ileum, and can also mimic chronic idiopathic inflammatory bowel disease.[276] Enteroadherent *E. coli* may also affect the ileum in immunocompromised patients in the form of *diarrheogenic bacterial enteritis,* a cause of diarrhea in this patient population.[277,278]

A number of parasites also affect the small bowel. **Cryptosporidiosis** is the result of infection by an intracellular protozoan,

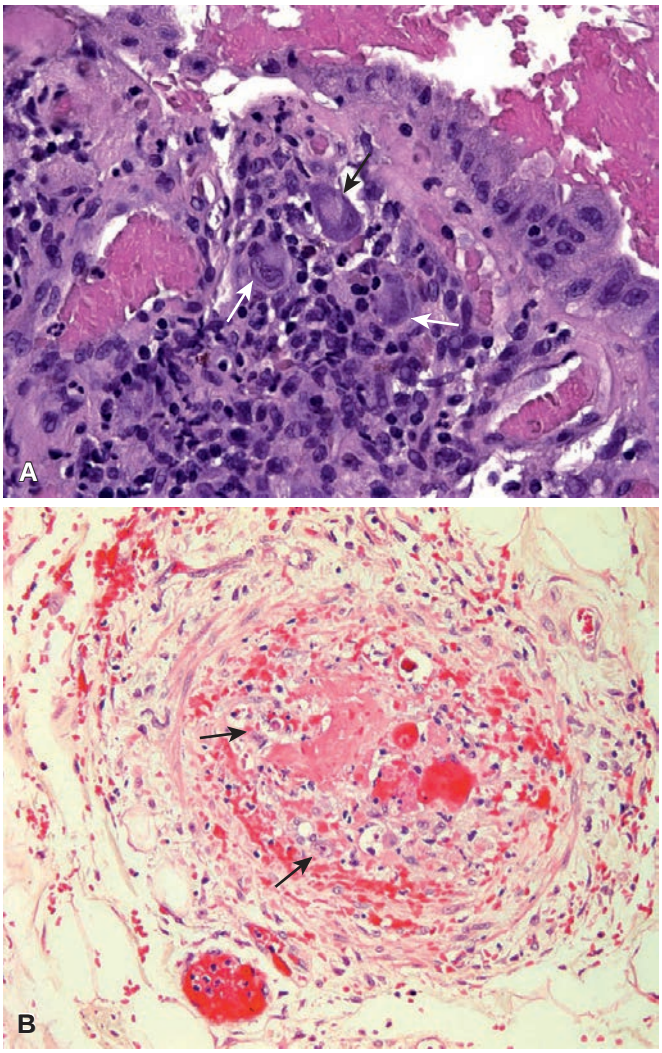

Figure 15.27 **A,** Multiple CMV inclusions *(arrows)* in a small bowel biopsy from a liver transplant patient with diarrhea. **B,** CMV inclusions *(arrows)* within endothelial cells with associated thrombosis and luminal occlusion in a case of CMV vasculitis.

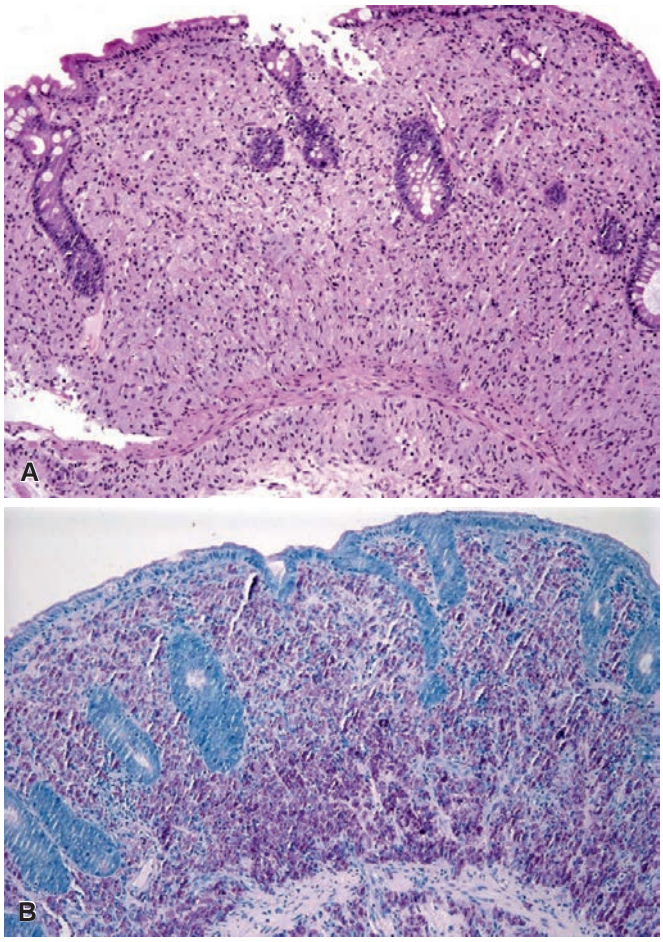

Figure 15.28 **A,** Duodenal biopsy in an AIDS patient with MAI, showing villous distension and blunting by an infiltrate of foamy macrophages. **B,** Ziehl–Neelsen stain highlights numerous organisms within macrophages.

Cryptosporidium parvum. In sections, the organisms appear as 2–5 µm basophilic spherical structures beneath the luminal surface of the epithelium (Fig. 15.30). Their appearance can be simulated by cellular debris or mucin. The organisms stain well with Giemsa, methenamine silver, and PAS but are not acid-fast. They typically do not result in significant light microscopic changes, although increased IELs and surface nuclear disarray may be present[279–281]; changes may be more prominent in cases of massive infection.[282] **Microsporidiosis** is another cause of diarrhea primarily seen in immunocompromised patients; it was originally classified as an obligate intracellular protozoan but is now believed to be closely related to fungi.[283] These organisms are difficult to appreciate by routine light microscopy, but can be detected with tissue Gram and other special stains (Fig. 15.31).[284–286] Exceptionally, systemic dissemination occurs.[287] The coccidians ***Cyclospora cayetanensis***[288,289] and ***Cystoisospora*** (formerly *Isospora*) ***belli***[289] also infect the small bowel, typically (but not always) in immunocompromised patients.

Giardiasis may result in malabsorption and chronic diarrhea[290] and may be associated with CVID (see later). The mucosa is usually intact and inflammatory changes are typically minimal, but there may be blunting of villi and an increased number of inflammatory cells. The organisms have a teardrop or pear shape, with paired nuclei and a central longitudinal axostyle (Fig. 15.32).[291] ***Strongyloides stercoralis***, a nematode with a worldwide distribution, also involves the small bowel (Fig. 15.33). Many patients are asymptomatic, but administration of corticosteroids may result in a life-threatening hyperinfection.[292,293]

A number of fungi affect the small bowel, including *Candida* species, *Aspergillus*, *Mucormycosis*, *Cryptococcus*, and *Histoplasma*[294]; small bowel involvement is usually part of a disseminated disease process in immunocompromised patients. Signs and symptoms of GI fungal infections are in general similar, regardless of fungus, and include diarrhea, vomiting, melena, frank GI bleeding, abdominal pain, and fever. Fungi may be identifiable on H&E sections in heavy infection, but special stains (GMS and PAS) are invaluable diagnostic aids. Fungi can often be correctly classified in tissue sections based on morphology, but culture and molecular testing should be relied upon for definite diagnosis.

Drugs, Chemotherapy, and Irradiation-Associated Enteritis

Mycophenolate mofetil (MMF) is a drug used for maintenance immunosuppression, primarily in solid organ transplant recipients but

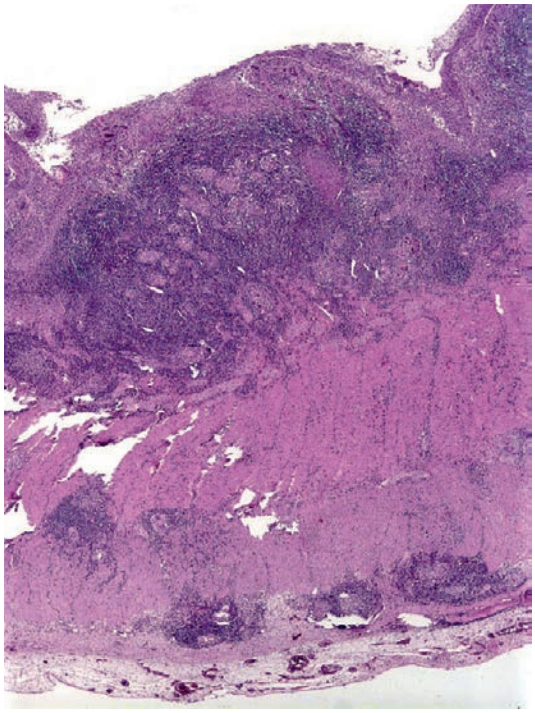

Figure 15.29 *Yersinia enterocolitica* infection featuring ulcerated mucosa, a markedly thickened wall, and numerous small, epithelioid granulomas associated with abundant transmural lymphoid tissue.

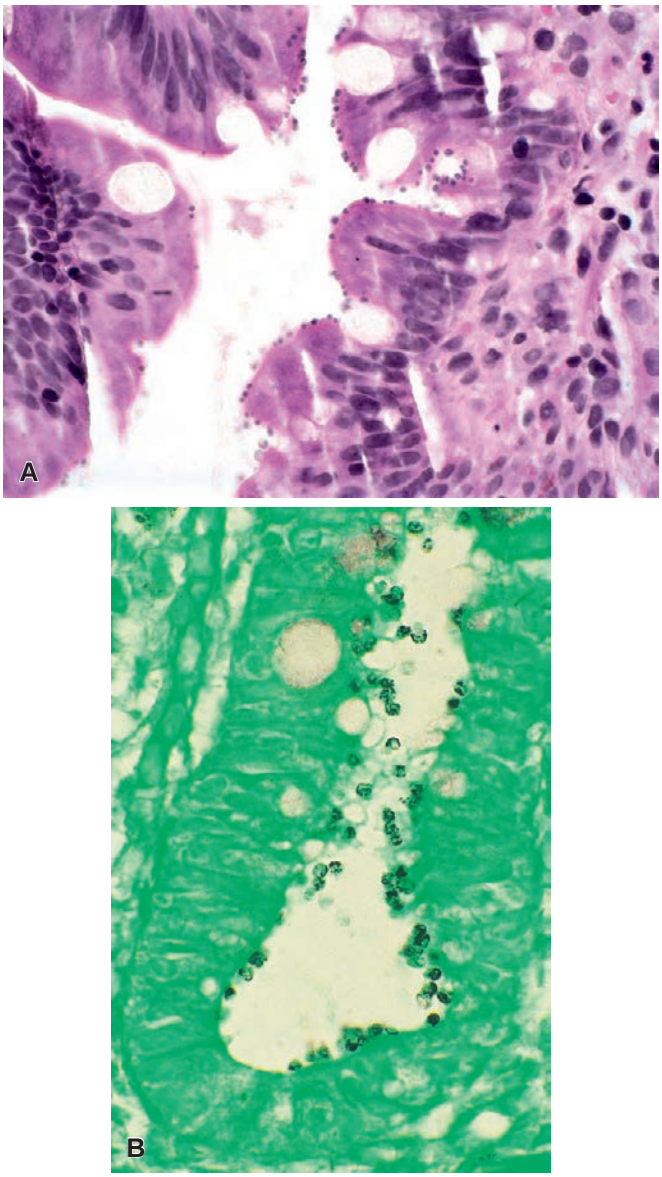

Figure 15.30 **A,** Cryptosporidiosis featuring small basophilic spheres beneath the luminal epithelium in a small bowel biopsy. **B,** The organisms will stain with methenamine silver as well.

also in bone marrow transplant recipients. Its most common side effect is GI toxicity, specifically diarrhea.[295] The colon is most commonly affected, but the small bowel may be affected as well. Histologic features can include increased apoptotic epithelial cells, increased IELs, villous atrophy, active and chronic inflammation, and architectural derangement (Fig. 15.34),[296–298] which can mimic several other entities including graft-versus-host disease (GVHD), chronic idiopathic inflammatory bowel disease, and viral infection. MMF toxicity should be suspected in transplant patients with diarrhea. Infection should be rigorously excluded, although it may certainly coexist with MMF toxicity in this patient population.

Chemotherapy is also well known to cause injury to the small bowel.[299,300] The changes are transient and should resolve within weeks of cessation of treatment; however, injury secondary to chemotherapy can be a significant problem in patients undergoing repeated cycles of treatment over many months. Biopsies often show crypt disorder and atrophy, with more severe mucosal denudation as the injury progresses. If patients are neutropenic, neutrophils will be conspicuously absent. Apoptotic epithelial cells are common, as are marked nuclear atypia and regenerative changes (Fig. 15.35).[301,302] The changes can mimic viral infection (which can coexist with chemotherapy-related injury), GVHD (which may also coexist with chemotherapy-related injury), and, rarely, ischemia.

NSAIDs cause a wide variety of findings in the small bowel, including focal active enteritis, erosions/ulcers, and the peculiar formation of multiple concentric fibrotic membranes known as *diaphragm disease*. NSAIDs are also one of the many drugs that cause increased apoptotic epithelial cells.[303,304]

Other drugs that significantly affect the small bowel include the angiotensin II receptor blocker *olmesartan*, which causes sprue-like changes with variably present subepithelial collagen (Fig. 15.36)[305]; and *ipilimumab*, a monoclonal antibody against the cytotoxic T-lymphocyte antigen-4 (CTLA-4) that is used to treat melanoma, which may cause a severe autoimmune-like enteritis (Fig. 15.37) and colitis.[306,307] *Stevens–Johnson syndrome*, or drug-associated toxic epidermal necrolysis involving skin and mucous membranes, may rarely involve the small bowel.[308]

Radiation therapy of malignant tumors within the peritoneal cavity may cause damage to the intestinal tract, the extent of which depends on many factors.[309] Damage occurs most frequently in patients treated for carcinoma of the cervix, but numerous cases have also been reported in children treated for Wilms tumor, malignant lymphoma, and other malignancies.[310] Symptoms usually appear years after radiation. Grossly, the small bowel appears thickened, and the wall may be partially replaced by fibrous tissue, particularly in the submucosa. This is often accompanied by mucosal ulceration.[311] There is a close correlation between the elapsed time interval between irradiation and the morphologic changes present.[309] Early irradiation effect is manifested by an increased production of mucus and by nuclear

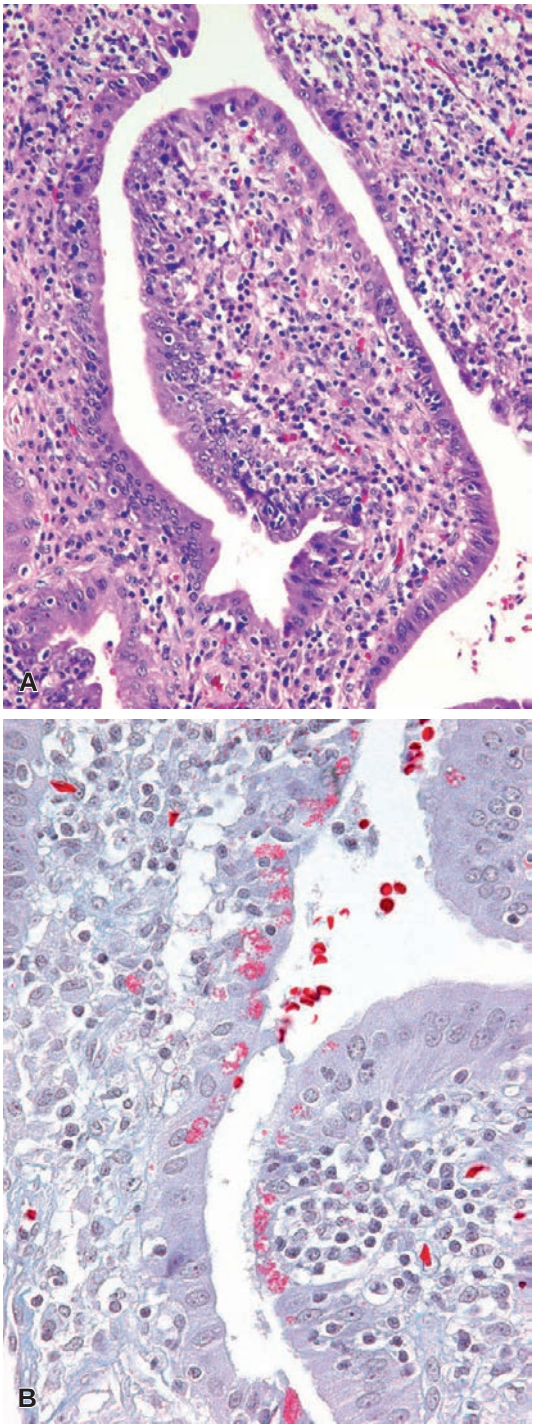

Figure 15.31 **A,** A duodenal biopsy from an AIDS patient with microsporidiosis shows increased intraepithelial lymphocytes and surface epithelial disarray. A subtle vacuolization of the surface epithelium is a clue to the presence of the organisms. **B,** A modified trichrome stain stains the spores a bright red, aiding in identification.

changes in the lining epithelium. Later, submucosal edema that may be completely reversible occurs. If the damage is severe, fibrosis of the muscular wall and ulceration develop (Fig. 15.38). Vascular changes are prominent; they are characterized by subendothelial accumulation of lipid-laden macrophages, calcification, and thrombosis.[312,313] Treatment is multifactorial, including nutritional support, anti-diarrheals, and anti-inflammatory therapy, but approximately a third of cases require surgery for intestinal obstruction, fistula formation, or perforation.[314]

Other Inflammatory Diseases

Acute phlegmonous enteritis is an obscure entity of unknown etiology, although it has been associated with *Bacillus thuringiensis* and *Streptococcus viridans*.[315,316] Grossly, the involved loop of bowel is sharply demarcated. The inflammation is mainly in the mucosa, but there may be pus on the serosal surface. The bowel wall is edematous and slightly distended. Microscopically, there is frequently a widespread lymphangitis and regional lymphadenitis, accompanied by lymph node enlargement. The mesentery has a somewhat glassy appearance. Abscesses between folds of the mesentery have been observed.

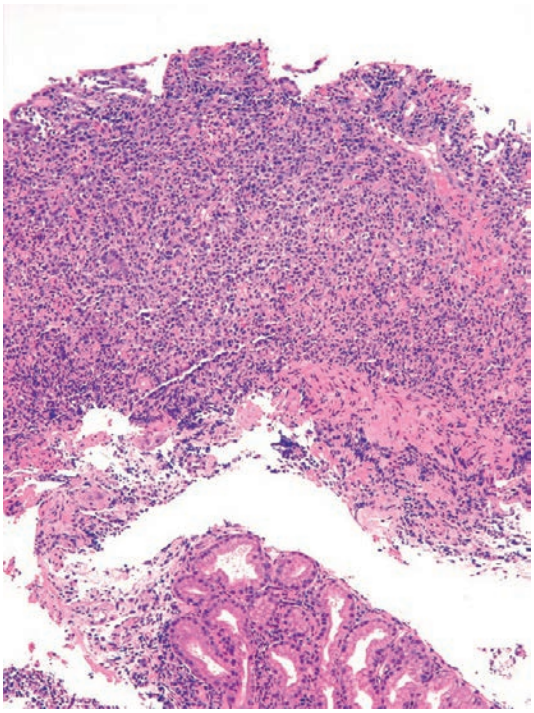

Figure 15.37 Ipilimumab-induced enteritis showing near total destruction of the mucosa secondary to a lymphoplasmacytic infiltrate.

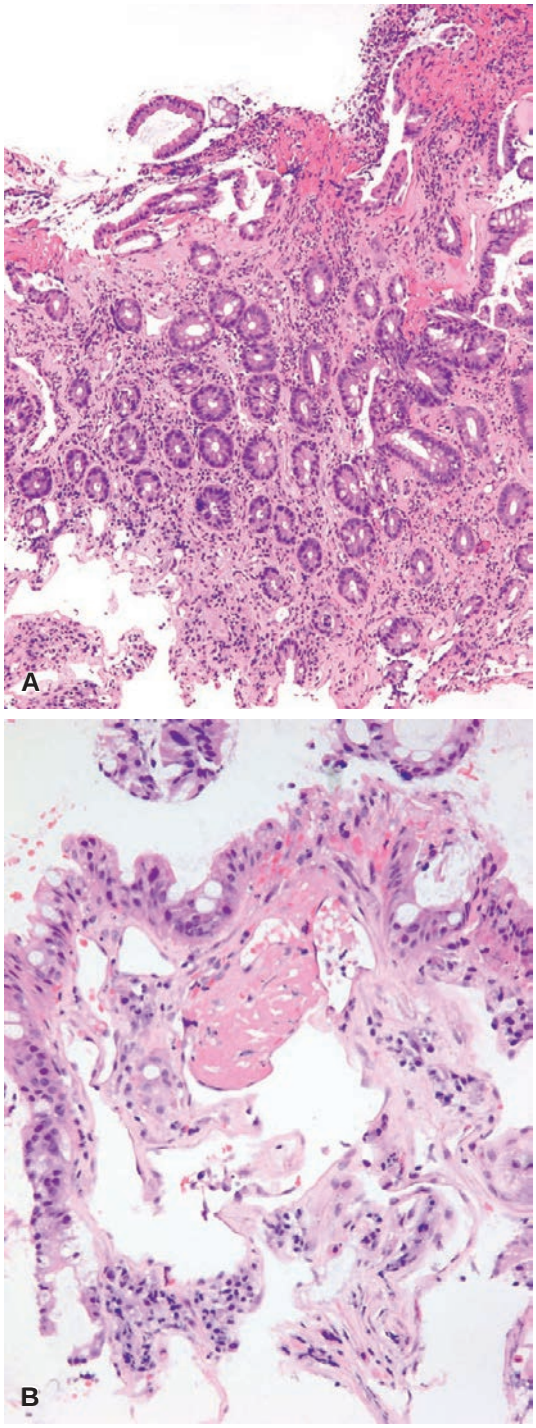

Figure 15.38 **A,** Radiation enteritis with mucosal ulceration, active inflammation, and fibrosis of the lamina propria. **B,** Vessels are ectatic and may contain fibrin thrombi.

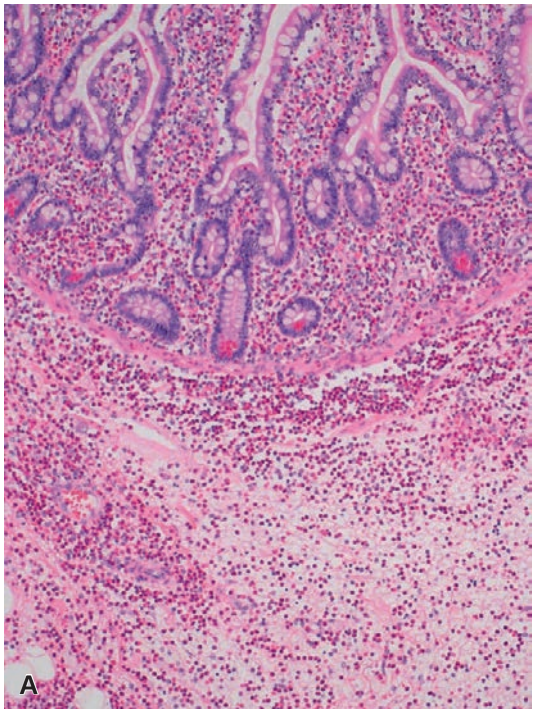
Sarcoidosis may involve the small bowel as part of disseminated disease, but it is the least commonly involved organ in the GI tract.[317] There may be associated folate and/or B12 deficiency.



Necrotizing enterocolitis, a disease predominantly affecting premature infants, is discussed in Chapter 17.

Idiopathic eosinophilic enteritis and **gastroenteritis** (EG) connotes a spectrum of diseases characterized by eosinophilic infiltration of one or more segments of the GI tract.[318] Although the pathogenesis remains unclear, many patients have peripheral eosinophilia and/or a history of allergic diseases or asthma. EG most commonly presents in children and adults younger than 50 years. Involvement may be predominantly mucosal, mural, or serosal, or a combination of all three.[319] In the case of serosal involvement, it is often associated with eosinophilic peritonitis and ascites.

The GI manifestations include nausea, vomiting, diarrhea, pain, steatorrhea, and protein-losing enteropathy. Morphologically, the main change is a patchy or diffuse dense eosinophilic infiltration of any layer of the intestinal wall (Fig. 15.39), variably accompanied by other inflammatory cells, eosinophil degranulation, eosinophilic microabscesses, mucosal ulceration, and submucosal edema. Other causes of eosinophilia must be excluded in order to render this diagnosis, including adverse drug reaction, food allergy, parasitic infection, Crohn disease, idiopathic hypereosinophilic syndrome, and vasculitis.[320]

AIE has been best characterized in infants and young children and is likely underdiagnosed in adults, in whom it is frequently mistaken for CD, Crohn disease, or ulcerative colitis.[321,322] Patients typically present with severe diarrhea and weight loss. Unlike CD, both the small and large bowel may be involved. Serum antienterocyte and/or anti-goblet cell antibodies are seen in many (but not all) patients, and many have other autoimmune diseases. Association with thymoma has also been reported.[323,324] Small bowel biopsies show variably severe villous blunting, as well as a striking increase in lamina propria plasma cells, increased apoptotic epithelial cells, and active inflammation (Fig. 15.40). IELs are typically not significantly increased, but a mild increase may be encountered. Patients with anti-goblet cell antibodies may show a dramatic absence of goblet cells.[321]

CVID is the second most common symptomatic primary immunodeficiency after IgA deficiency. It presents at any age, usually with recurrent bacterial upper respiratory tract infections, autoimmune manifestations, and often chronic GI symptoms. Immunologic defects include hypogammaglobulinemia and T-cell abnormalities.

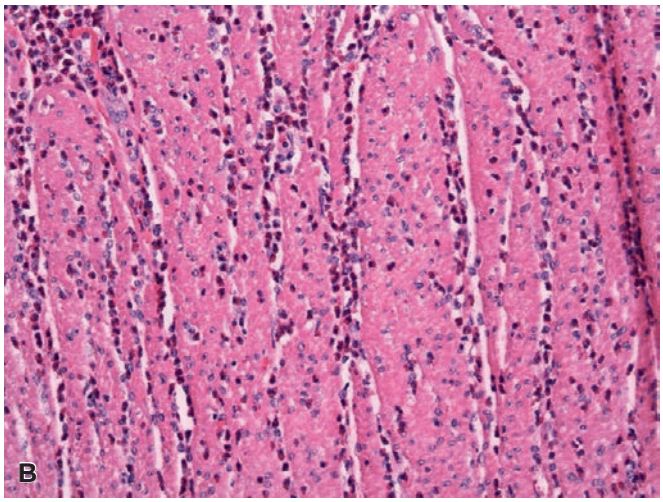


Figure 15.39 **A,** Dense infiltration of the mucosa and submucosa of the jejunum by a virtually pure eosinophilic population. **B,** In this case, the muscle wall was heavily involved.

Any segment of the GI tract can be affected. Increased apoptotic epithelial cells are a common feature as well as, usually but not always, significantly decreased or absent plasma cells (Fig. 15.41). In the small bowel, features may include villous blunting that resemble CD; granulomas; or architectural distortion mimicking chronic idiopathic inflammatory bowel disease. Lymphoid hyperplasia is common, and patients have an increased incidence of both lymphoma and infection, particularly giardiasis.[325]

GVHD following bone marrow transplantation affects primarily the skin, GI tract, and liver. Involvement of the small bowel is manifested clinically by diarrhea and microscopically by a variety of changes, of which single epithelial cell necrosis is the most consistent.[326,327]

Cryptogenic multifocal ulcerating stenosing enteritis is a rare disease resulting in recurrent small bowel ulcerations and stenosis, mimicking those seen with "diaphragm disease" resulting from chronic NSAID use. The etiology is unknown, but some cases have been associated with homozygous deletion mutations in cytosolic phospholipase A2-α.[328]

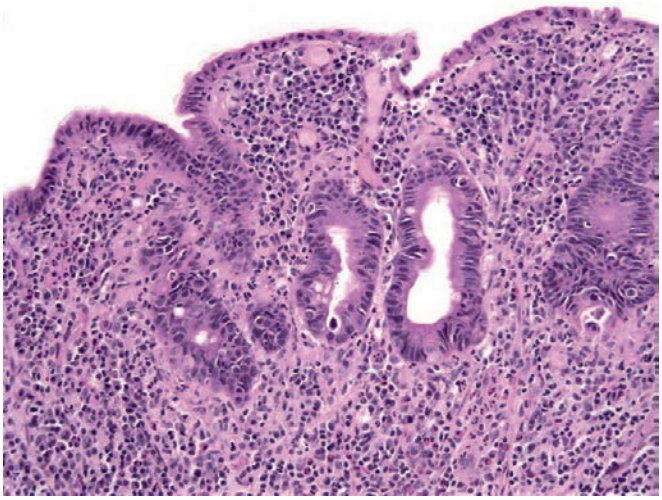

Figure 15.40 Duodenal biopsy in autoimmune enteritis featuring villous blunting, a dense plasmacytic infiltrate, loss of goblet cells, and scattered apoptotic epithelial cells.

Other Non-Neoplastic Diseases

Intussusception

In intussusception, a length of intestine (the *intussuscipiens*) literally swallows part of the bowel just proximal to it. This swallowed portion (the *intussusceptum*) is drawn down within the intussuscipiens until it can go no further because of traction of the mesentery (Fig. 15.42A). The specimen has a curved, sausage-like form, with concavity toward the root of the mesentery. Increasing traction and compression shuts off circulation to the intussusceptum so that it becomes necrotic, with associated mucosal sloughing. The upper ends of the intussuscipiens and the intussusceptum may become firmly united. In exceptional instances, the result has been spontaneous cure in the form of a naturally occurring equivalent of a surgical end-to-end anastomosis.

Most cases of intussusception are seen during the first 5 years of life, with over half occurring during the first year. This is probably related to the fact that the amount of lymphoid tissue in the ileocecal region and the degree of projection of the valve into the cecum are at their maximum during this period but decrease substantially after the second year of life.[329] There is now general agreement that the lymphoid hyperplasia precedes and is often the cause of the intussusception rather than the result, although secondary inflammatory changes certainly occur. The lymphoid hyperplasia is associated with viral infection (particularly adenovirus) in many cases, as indicated by the finding of intranuclear inclusion bodies[330] and the fact that viruses have often been isolated from these children.[331–333] Several cases of intussusception caused by lymphoid hyperplasia in AIDS patients have also been reported.[334]

In early uncomplicated cases, a barium enema may be used to reduce the intussusception, or manual reduction may be performed. Surgery is otherwise needed. Mortality is directly related to the time that elapses between onset and surgery. In children, there is a rapid rise in mortality after the second day. In older children and in adults, intussusception is frequently the result of a pedunculated intraluminal tumor such as lipoma, carcinoma, smooth muscle

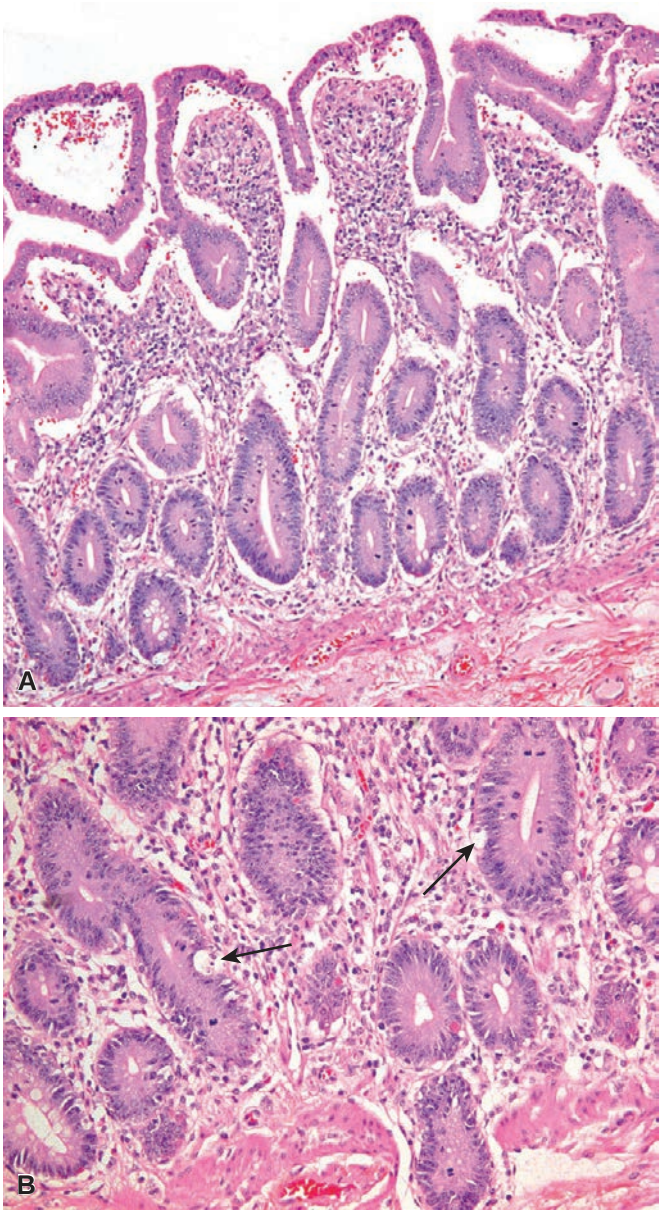

Figure 15.41 A, Sections of the small bowel in a case of common variable immunodeficiency show villous blunting with a mild increase in intraepithelial lymphocytes; apoptotic epithelial cells are visible even at low power. **B,** Higher-power view shows increased apoptotic epithelial cells *(arrows)* and an absence of plasma cells.

tumor/GIST, inflammatory fibroid polyp (IFP) or malignant lymphoma (see Fig. 15.42B).[335]

Brown bowel syndrome is characterized by a prominent brown discoloration of the bowel wall, grossly evident from both the serosal side and on cut section, and often associated with chronic malabsorption. Microscopically, large amounts of lipofuscin granules are seen in the cytoplasm of smooth muscle cells. The pathogenesis is unknown, but the suggestion that it may be caused by vitamin E deficiency has been advanced.[336]

The small bowel is the most frequently involved site in GI **amyloidosis,** which may involve the vessels, stroma, or lamina propria as part of generalized disease or—rarely—as a localized finding (Fig. 15.43).[337] In the latter instance, it may lead to intestinal obstruction.[338]

Scleroderma may involve the small bowel as well, presenting as obstruction or malabsorption.[339]

Microvillous inclusion disease (familial microvillous atrophy) is a disorder of the intestinal brush border that results in intractable secretory diarrhea in infants. The diagnosis has been based on the presence of microvillous inclusions at the ultrastructural level. Immunohistochemical staining for CD10 (a membrane-associated neutral peptidase) can aid in the diagnosis by showing a cytoplasmic staining pattern as opposed to the normal linear brush border pattern.[340]

Another congenital cause of intractable diarrhea and failure to thrive is **tufting enteropathy**, which has been associated with mutations in the EpCAM gene on chromosome 2p21 and features epithelial tufts in the intestinal mucosa along with villus alterations, but a normal brush border.[341]

Pneumatosis cystoides intestinalis is characterized by the presence of gas-filled cysts in the intestinal wall; it is associated with a variety of conditions including surgery, colonoscopy, and chronic pulmonary disease.[342] The cysts are macroscopically visible and may be mistaken for polyps or tumors. Histologically, the spaces are often surrounded by foreign body giant cells.

Polyps and Tumors

Benign Epithelial Tumors

Brunner gland nodules (which have also been referred to as Brunner gland hamartoma, Brunner gland adenoma, nodular hyperplasia of

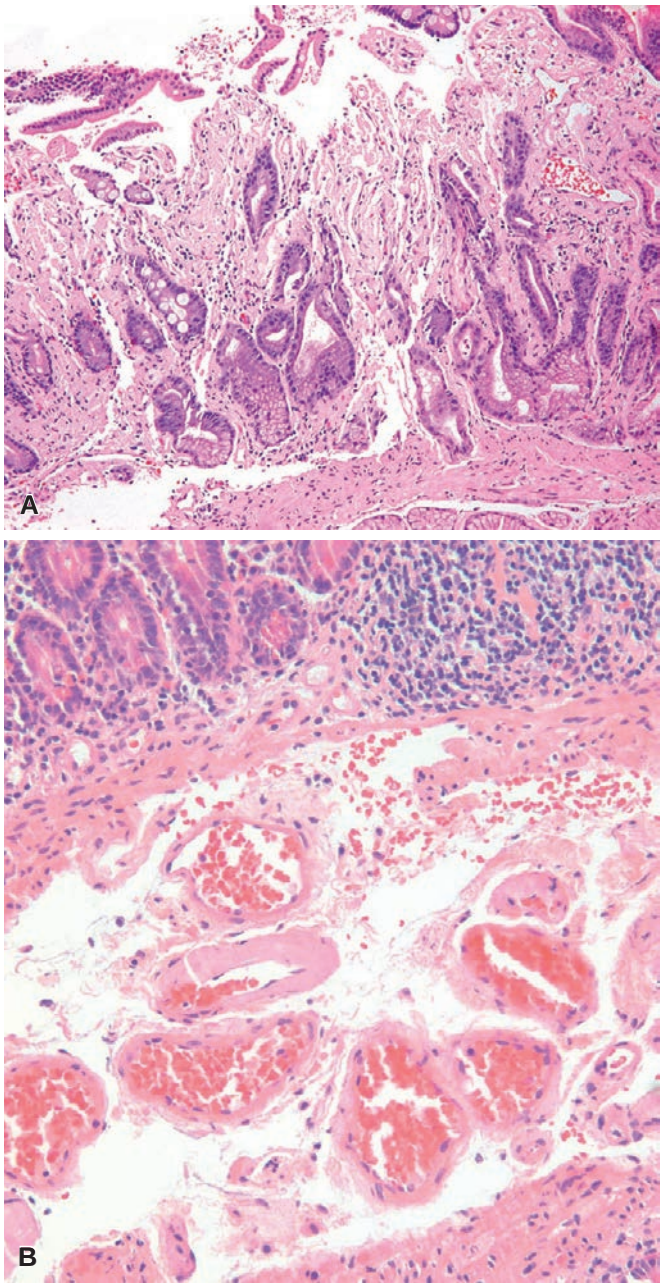

Figure 15.43 Amyloid involving the lamina propria **(A)** and small vessels **(B)** in the duodenum.

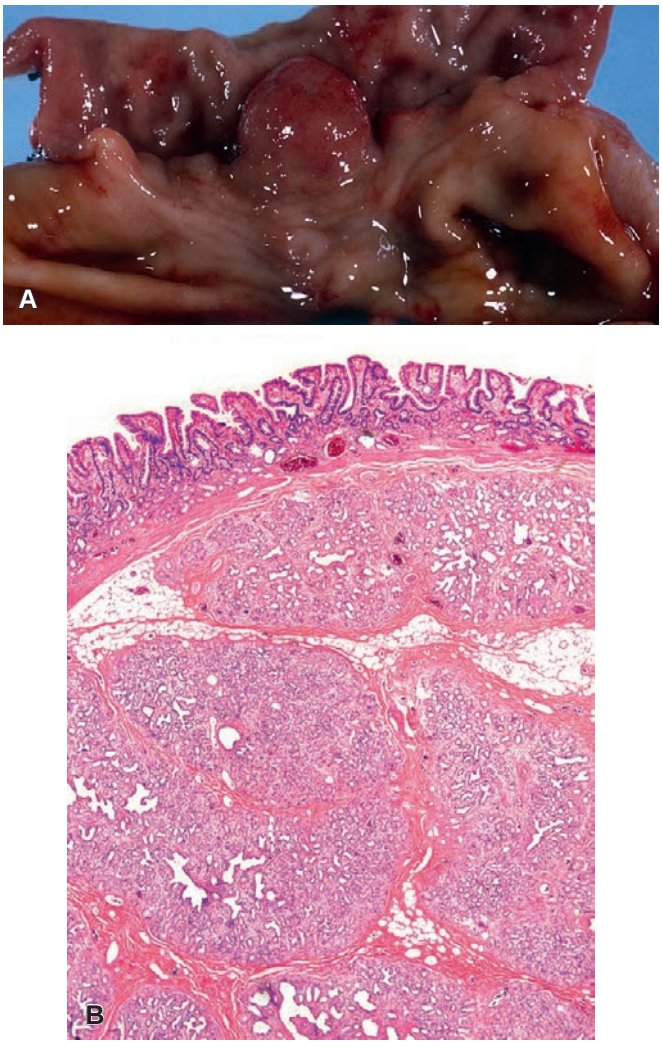

Figure 15.44 **A,** Pedunculated Brunner gland nodule. **B,** Lobules of benign, normal-appearing Brunner glands are separated by fibrous stroma. (**A,** Courtesy Dr. George F. Gray, Jr.)

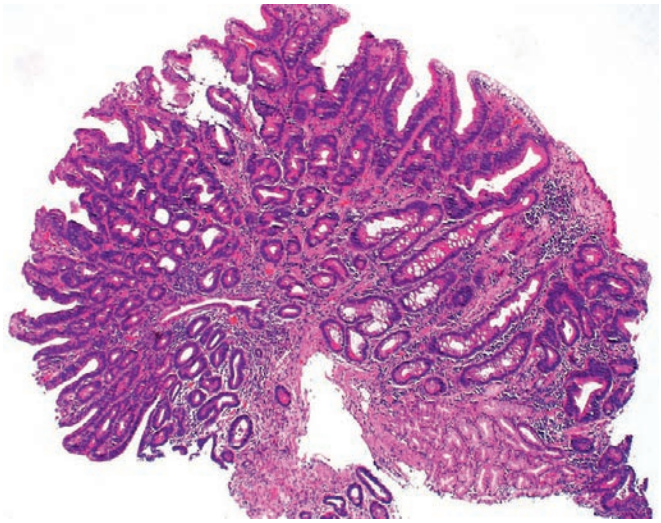
Brunner glands, or brunneroma) are characterized by a nodular proliferation of Brunner glands, accompanied by ducts and scattered stromal elements, and sometimes associated with ciliated cysts and adipose tissue (Fig. 15.44).[343,344] The process can be focal, multifocal, or diffuse. Microscopically, the Brunner glands are arranged in lobules separated by fibrous bands and have, for the most part, a normal appearance. This entity is probably not a true neoplasm but rather an expression of nodular hyperplasia or a hamartoma; therefore, many avoid the term "Brunner gland adenoma." However, it may exhibit foveolar metaplasia and dysplastic changes have been described.[345] The most common location is the posterior wall of the duodenum at the junction between the first and second portions. It can be seen associated with peptic duodenitis and erosions and may present with GI bleeding or duodenal obstruction.[343,346]

Adenomas similar to those of the large bowel can develop in the small bowel, but their frequency is minuscule.[347] The duodenum and jejunum are involved more often than the ileum. Duodenal adenomas have been reported with increasing frequency in recent years, undoubtedly as a result of the widespread use of endoscopy. Adenomas can be single or multiple, pedunculated, or sessile, and they can have the microscopic appearance of a tubular, tubulovillous, or villous adenoma (Fig. 15.45).[348,349] As with their colorectal counterparts, the incidence of malignancy is greater if the lesions are villous, large, and/or multiple. Villous lesions are often large and sessile, with a tendency to recur and a high incidence of malignant transformation.[349] Thorough sampling at endoscopy is of importance for detection of the latter.[350] Many duodenal adenomas are located at the ampulla of Vater or the periampullary region; these are further discussed in Chapter 22. Small bowel adenomas may also frequently develop in patients with familial adenomatous polyposis, particularly in the duodenum.[351,352] Small bowel adenomas have also been reported in the ileal patch following ileocystoplasty.[353,354]

Pyloric gland adenomas are also found in the small bowel, particularly in the duodenum (Fig. 15.46). These rare lesions are composed of tubular or cystically dilated pyloric-type glands, which



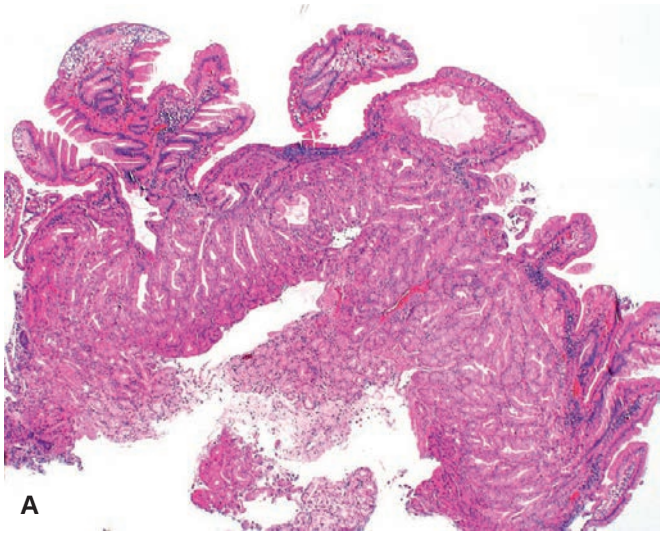


Figure 15.45 Duodenal adenoma, resembling colonic tubular adenoma.

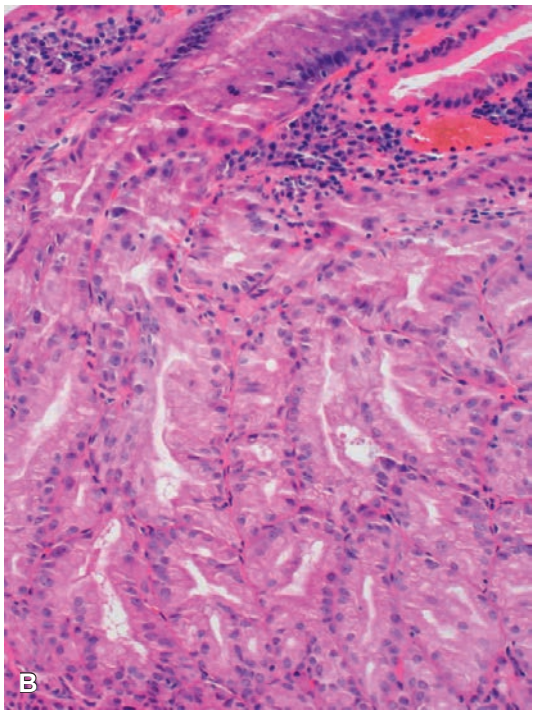

Figure 15.46 **A,** A duodenal pyloric adenoma composed of tightly packed tubules resembling pyloric glands. There is minimal inflammation. **B,** The nuclei are basally located, with small nucleoli.

typically express MUC6 and MUC5AC. These are also found with increased frequency in patients with familial adenomatous polyposis, and they may harbor *APC* mutations.[355] Both sporadic and syndromic pyloric gland adenomas may have *GNAS* and *KRAS* mutations as well.

A number of **hamartomatous polyps** may be encountered in the small bowel. *Peutz–Jeghers syndrome* is an autosomal dominant disorder with variable degrees of penetrance, caused by a germline mutation in the *LKB1* gene located on chromosome 19p13.3, which encodes a serine/threonine kinase.[356] Polyps can be present in the stomach, small bowel, and large bowel, and the patients have a typical pigmentation of the lips, oral mucosa, digits, palms, and soles. The polyps consist of lobules of nondysplastic epithelium and lamina propria, in which glands are supported by broad bands of smooth muscle fibers that are thick in the center of the lesion and thinner on the periphery (Fig. 15.47).[357,358] The architecture is similar for polyps occurring elsewhere in the GI tract, but the cytologic composition depends on the location.[359] Dysplasia may develop but is more common in colorectal Peutz–Jeghers polyps.[360] The intimate intermingling of glands and smooth muscle fibers may simulate the appearance of invasion and lead to a mistaken diagnosis of carcinoma.[361] Although solitary Peutz-Jeghers polyps have been described in the literature,[362] many believe that these patients harbor undetected *STK11* mutations or other features suggestive of the syndrome.[363]

Patients with Peutz–Jeghers syndrome are at significantly increased risk of both GI and extra-intestinal malignancy, including adenocarcinoma of the stomach, small bowel, and colon.[364] Patients with Peutz–Jeghers syndrome may also develop the distinctive ovarian neoplasm known as sex-cord tumor with annular tubules, so-called adenoma malignum of uterine cervix, ovarian mucinous tumors, breast carcinoma (often bilateral), and other types of malignancy.[365–367]

Other hamartomatous polyps encountered in the small bowel include *juvenile polyps* (Fig. 15.48), which in the small bowel are usually part of juvenile polyposis syndrome; and polyps that result from the *PTEN hamartoma tumor syndrome* (which includes *Cowden syndrome*).

Adenocarcinoma

Adenocarcinoma of the small bowel is 40–60 times less common than its counterpart in the large bowel. Most patients are elderly, and there is no sex predilection.[368–370] It can develop in any segment, but approximately half of cases occur in the duodenum.[370] Adenocarcinomas arising from the ampulla and periampullary region are discussed in Chapter 22. Small bowel adenocarcinomas are associated with sporadic small bowel adenomas,[370] familial adenomatous polyposis,[371,372] hereditary nonpolyposis colorectal carcinoma (Lynch) syndrome,[373] Peutz–Jeghers syndrome (see earlier), von Recklinghausen disease,[374] Crohn disease (see earlier), ileostomy sites,[375,376] surgically bypassed duodenum,[377] Roux-en-Y esophagojejunostomy,[378] and ileocystoplasty.[379]

Grossly, tumors may be nodular, polypoid, or infiltrative, with the latter being the most common growth pattern; patients with associated sporadic adenomas were more likely to have polypoid adenocarcinomas (Fig. 15.49).[370] Occasionally these carcinomas

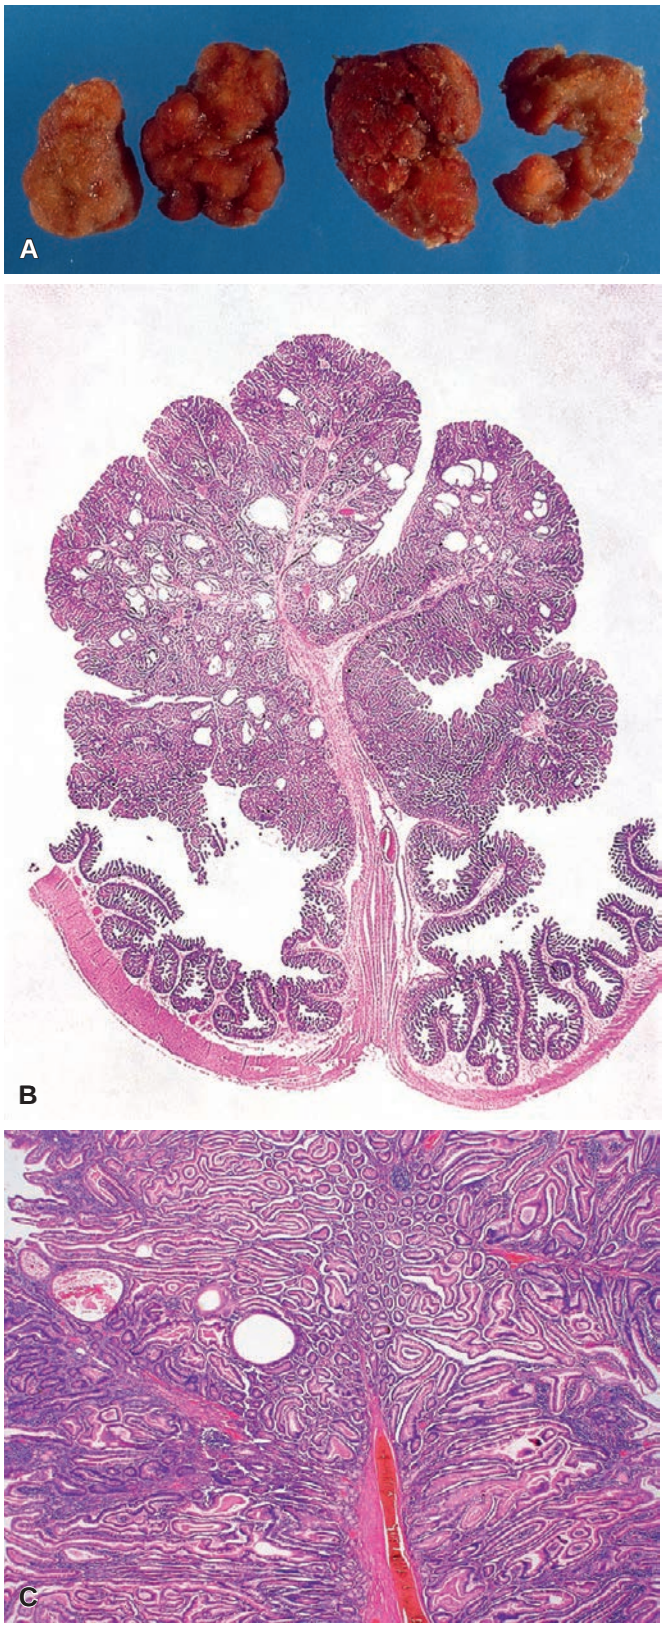

Figure 15.47 **A,** Large lobulated Peutz–Jeghers polyp. **B,** Whole mount view shows lobules of benign epithelium supported by arborizing bands of smooth muscle. **C,** Higher-power view shows benign, focally dilated glands devoid of atypia, separated by bundles of smooth muscle. (**A,** Courtesy Dr. George F. Gray, Jr.)

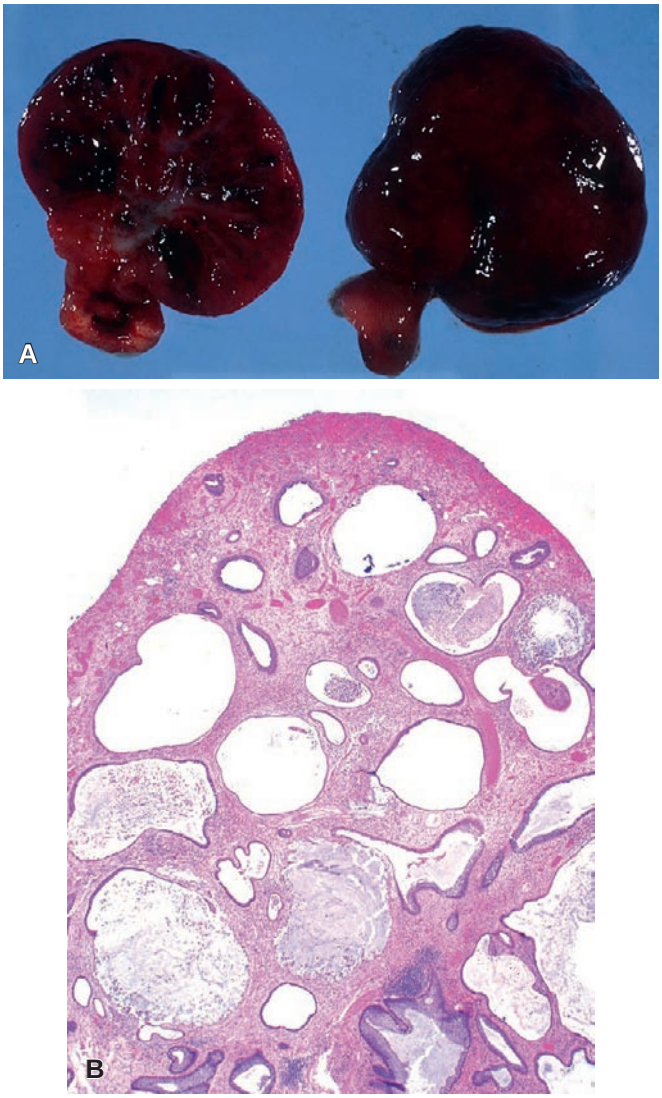

Figure 15.48 **A,** Juvenile polyp in which cystically dilated spaces are grossly apparent. **B,** Histologically the polyp features cystically dilated glands filled with inspissated mucus and inflammatory debris, along with supporting stroma that also contains inflammation. (**A,** Courtesy Dr. George F. Gray, Jr.)

present as multiple tumors[380] or in association with primary malignant neoplasms in other sites.[381,382]

Microscopically, these tumors are usually moderately differentiated adenocarcinomas (Fig. 15.50). CK7 and CK20 expression are variable, whereas immunohistochemical expression of CDX-2 is common.[383] HepPar-1 is also frequently positive in small bowel adenocarcinomas.[384]

At the time of diagnosis, the majority of the tumors have extended deeply into the wall and may have already metastasized to regional lymph nodes or seeded the retroperitoneum.[370] Significant adverse prognostic factors include lymph node involvement, retroperitoneal seeding, lymphovascular invasion and extent of tumor invasion.[370]

Other histologic tumor types include *mucinous* and *signet ring cell* adenocarcinomas.[370] *Adenosquamous* carcinoma has been reported on a few occasions, with either the glandular or the squamous component predominating.[385,386] *Anaplastic (sarcomatoid)* carcinoma is composed of highly bizarre tumor cells, some of them multinucleated, with

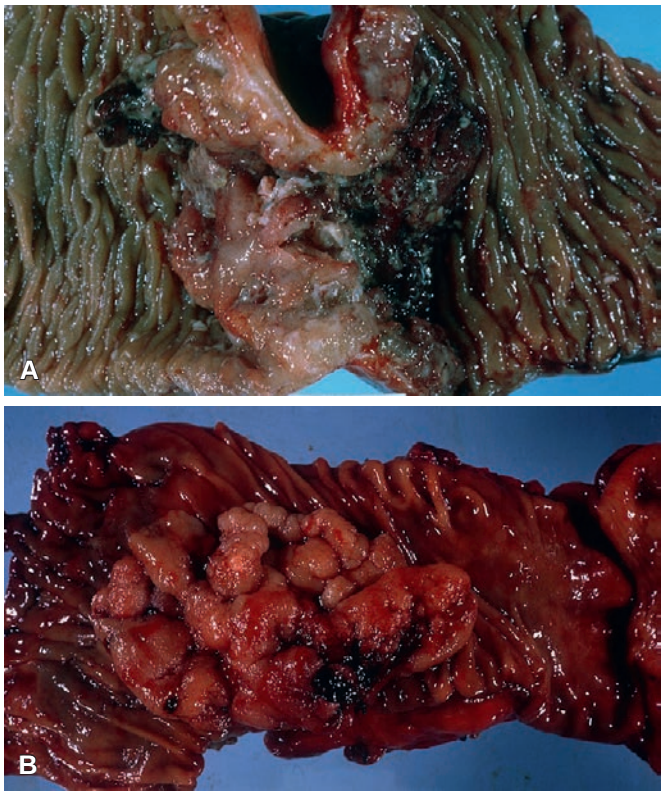

Figure 15.49 Small bowel adenocarcinomas with an infiltrative growth pattern, producing a "napkin-ring"-like lesion **(A)** and a nodular, polypoid growth pattern **(B)**. (Courtesy Dr. George F. Gray, Jr.)

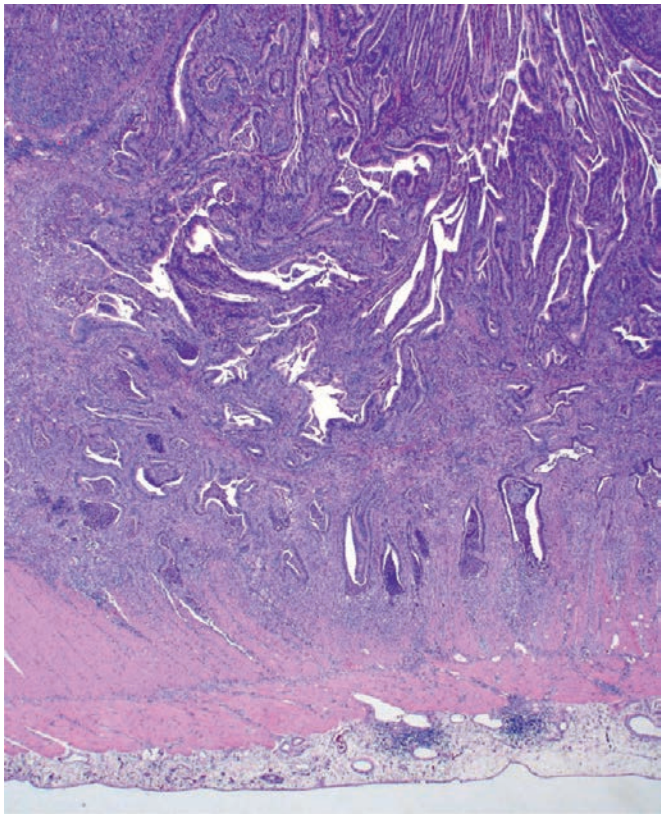

Figure 15.50 Small bowel adenocarcinoma, intestinal type, underlying a large villous adenoma.

abundant cytoplasm and no signs of glandular differentiation. The behavior is extremely aggressive.[387–389] Primary choriocarcinoma of the small bowel has also been reported rarely.[390]

Neuroendocrine Tumors

General and Clinical Features

WNET has replaced *carcinoid tumor* when referring to low-grade malignant neoplasms of the GI tract originating from the diffuse endocrine system.[391,392] The majority of WNET of small bowel occur in adults, but they have also been documented in children.[393] Most are located in the ileum (including Meckel diverticulum), followed in frequency by the jejunum and distal duodenum.[394,395] They have been described in small bowels affected by CD[396] and Crohn disease,[397] in bowel duplication,[398] in association with von Recklinghausen disease[399,400] and with inflammatory polyps.[401] WNETs tumors of the small bowel are multiple in 15%–35% of the cases (Fig. 15.51),[402] and molecular analysis indicates that when multiple, WNETs of the small intestine are derived from the same clone.[403]

Figure 15.51 Multiple carcinoid tumors of small bowel presenting as small sessile polyps. (Courtesy of Dr RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. Colour atlas of anatomical pathology. Edinburgh, 2004, Churchill Livingstone.)

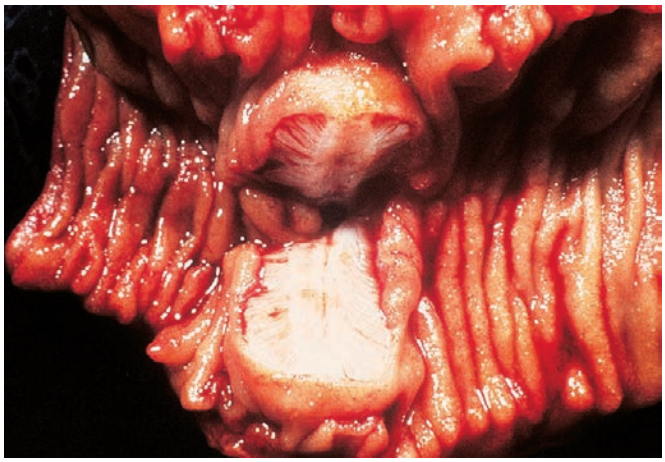

Figure 15.52 Cut surface of carcinoid tumor of the ileum. The tumor is solid, yellow, and accompanied by marked thickening of the muscularis propria.

Pathologic Features

The mucosa is often intact over the tumor. Infiltration of the submucosa is the rule, and extension into the muscularis propria is common (Fig. 15.52). The tumor invasion and the accompanying fibrosis may "buckle" the bowel wall. Following formalin fixation, the tumor acquires a bright yellow color that is not evident in the fresh state.

Microscopically, the most common pattern is that of solid nests of monotonous-appearing cells with small, round nuclei; a moderate amount of finely granular cytoplasm; and indistinct nucleoli (Fig. 15.53A and B). Peripheral palisading is common. Other histologic variations include trabecular and glandular patterns; the latter may contain intraluminal mucin. Multiple patterns are often present within the same tumor. The nesting pattern is often accentuated by artifactual retraction from the stroma. As noted previously, extensive fibrosis is common (see Fig. 15.53C). Lymphovascular invasion is often seen (see Fig. 15.53D), and it is also common to find tumor cells within submucosal nerves. WNETs are graded based on mitotic rate and/or proliferation (Ki-67) index. G1 tumors are characterized by <2 mitotic figures/10 HPF and/or a Ki-67 index of ≤2%. G2 tumors contain 2–20 mitotic figures/10 HPF and/or a proliferation index between 3% and 20%.[391]

In some cases, the mucosa surrounding WNETs may contain highly vascular polypoid formations that can simulate Crohn disease[404]; the change has been attributed by some authors to the secretion of a transforming growth factor by the tumor cells[405] and interpreted by others as a nonspecific reaction secondary to mucosal prolapse.[406] The non-neoplastic mucosa of a small bowel bearing one or more carcinoid tumors may show hyperplasia of endocrine cells, although this is not nearly as common or as prominent as with some types of carcinoid tumors of the stomach.

Histochemical, Immunohistochemical, and Ultrastructural Features

The distinctive phenotypic profile of WNETs can be demonstrated by a variety of special techniques. At the histochemical level, the tumor is argentaffin (and therefore also argyrophilic), positive for the diazo reaction, and generally negative for mucin stains (Fig. 15.54). Ultrastructurally, there are numerous dense-core pleomorphic secretory granules scattered throughout the cytoplasm.[407] Immunohistochemically, there is reactivity indicative of epithelial, intestinal, and neuroendocrine differentiation. Broad-spectrum keratins are usually positive, and—particularly in tumors with a trabecular component—apical or luminal CEA positivity may be seen.[408,409] Among the keratins, CK7 is expressed in almost 10% of the cases and CK20 in approximately 25%.[410] The intestinal lineage is made evident by the consistently strong immunoreactivity for CDX-2, a homeobox gene product necessary for intestinal development and differentiation.[411,412] They are almost universally negative for TTF-1, as opposed to its weak expression in gastric carcinoid tumors and its frequent positivity in pulmonary carcinoid tumors.[412] PAX6 and islet-1 are negative, which is helpful in distinguishing WNET arising in the small bowel from their pancreatic counterparts.[413] The neuroendocrine features are highlighted by chromogranin, synaptophysin, and protein gene product (PGP 9.5).[414–416]

A wide variety of peptide hormones have been found to be expressed in these tumors, but this is of limited clinical usefulness as hormone expression by immunohistochemistry does not correlate with functionality. These include serotonin,[417] substance P (by far the most common), gastrin, somatostatin (and somatostatin receptors[418]), glucagon, glycentin, pancreatic polypeptide (PP), bombesin, secretagogin,[419] gastrin-releasing peptide (GRP), and growth hormone–releasing factor (GRF).[420–427] Peptide YY is found only rarely, in contrast to its consistent presence in rectal carcinoids.[428,429] Neurofilaments are usually absent.[430] Other substances that have been detected in GI carcinoid tumors include calbindin-D28k (a calcium-binding protein expressed by some neural and neuroendocrine cells),[431] villin,[432] and myosin XVA (a member of the myosin superfamily).[433] Staining for S-100 protein is negative, in contrast to the positivity that may be encountered in WNETs of the appendix; this may be related to the alleged difference in the origin of these tumors: endocrine cells from Lieberkuhn crypts for WNETs of small bowel and subepithelial endocrine cells related to nerves for those in the appendix.[434–436] Curiously, prostatic acid phosphatase may also show immunoreactivity in small bowel WNET, although less commonly than rectal WNET.[437,438] Several growth factors and their receptors have been detected in carcinoid tumors of small bowel, and the suggestion has been made that they participate in the autocrine modulation of the tumor growth.[439–441]

Molecular Genetic Features

Loss of all or most of chromosome 18 is the commonest genetic alteration in small bowel WNET, followed by loss of heterozygosity of 9p and 16q.[442] There is also commonly gain on 14q mapped to the locus of the gene encoding the antiapoptotic protein DAD1.[442] Aneuploidy is present in over half of the ileal WNETs.[443] Loss of heterozygosity at the *MEN1* gene locus site on 11q is usually absent in jejunoileal WNETs, suggesting that the gene is not involved in their pathogenesis.[444] Immunoreactivity for P53 is rare[445] but is said to be more frequent in metastasizing lesions.[446]

Spread and Metastases

Many WNETs are low-grade neoplasms that have a slow growth rate, but they may also be highly invasive and have metastasizing properties.[447,448] Metastases occur most commonly in the regional lymph nodes and liver but are also seen in other sites, such as bone, skin, thyroid, and breast.[449,450] The liver metastases are usually multiple and solid but occasionally have a prominent cystic component.[451]

Treatment and Prognosis

Endoscopic resection may be used for tumors less than 1.0 cm that are confined to the submucosa.[452] The primary treatment of intestinal

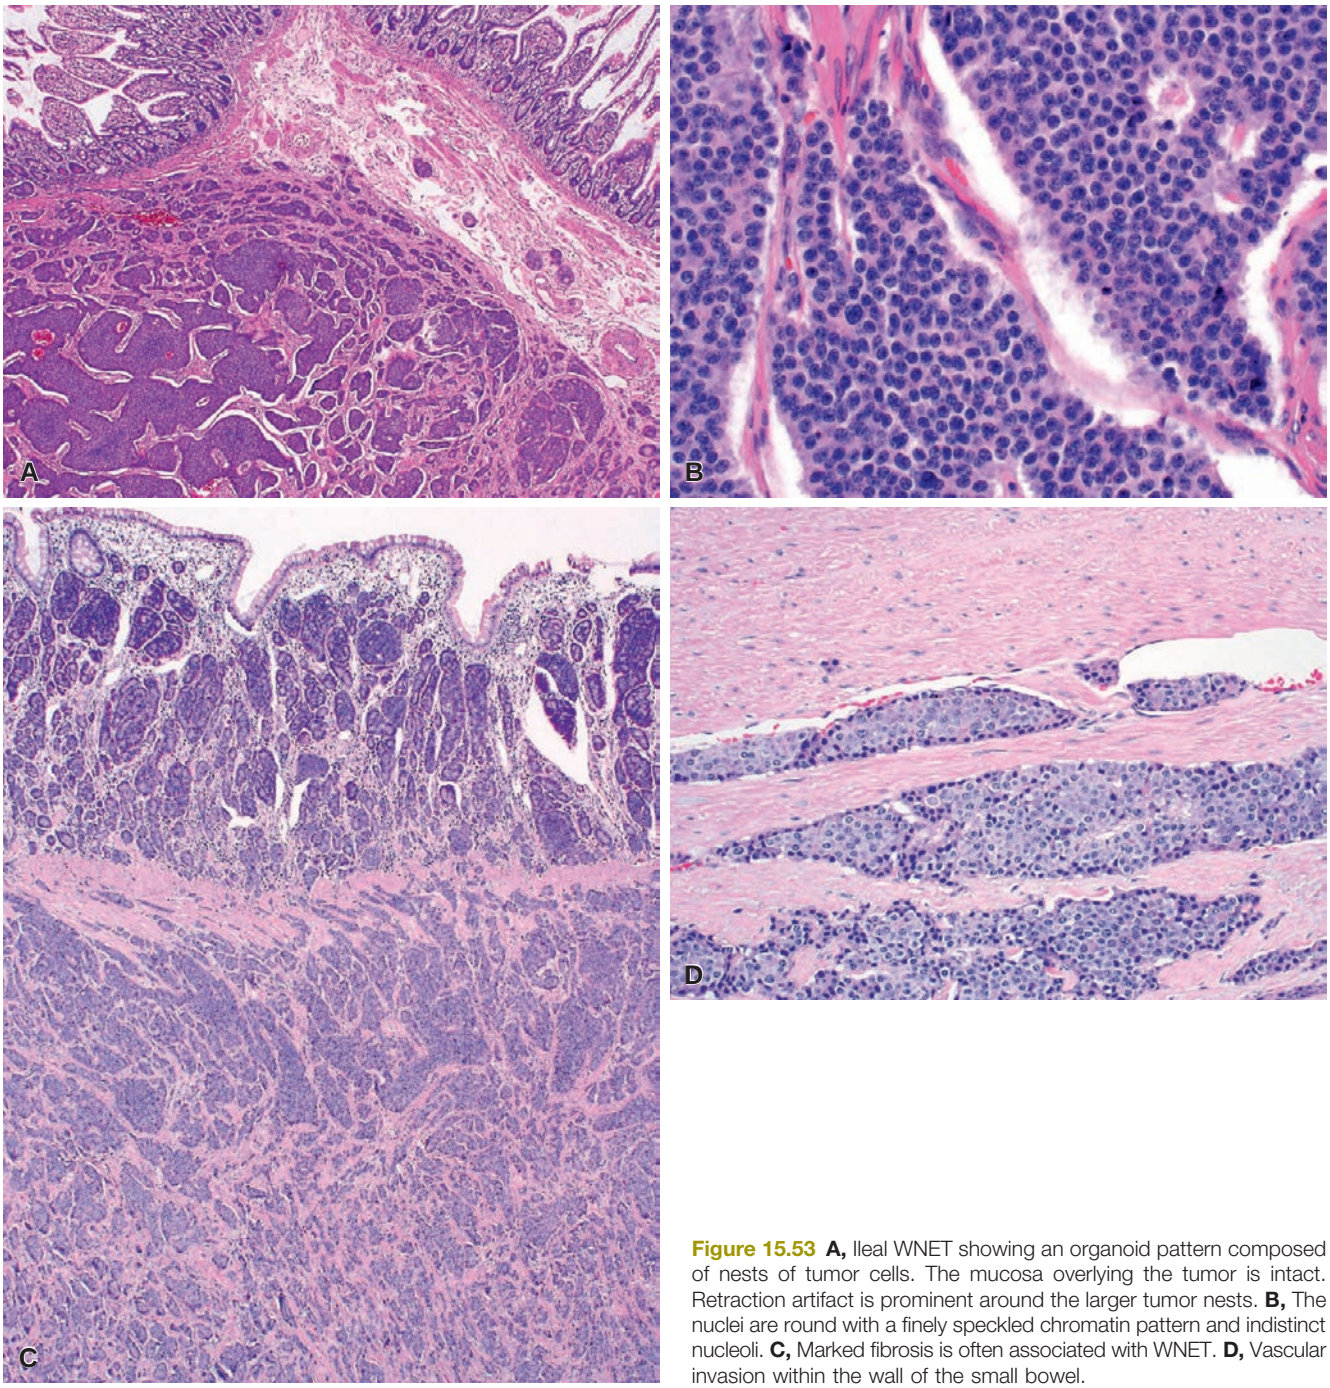

Figure 15.53 **A,** Ileal WNET showing an organoid pattern composed of nests of tumor cells. The mucosa overlying the tumor is intact. Retraction artifact is prominent around the larger tumor nests. **B,** The nuclei are round with a finely speckled chromatin pattern and indistinct nucleoli. **C,** Marked fibrosis is often associated with WNET. **D,** Vascular invasion within the wall of the small bowel.

WNET is wide surgical removal of the primary tumor and lymphadenectomy.[453] Solitary liver metastases are also amenable to surgical excision, and patients with multiple liver metastases may benefit from surgical debulking and have prolonged survival even under these circumstances.[454] Because of the propensity for multiplicity and association with other GI tumors, a thorough exploration of the abdominal cavity is indicated. Somatostatin analogues and similar drugs may be helpful for managing symptoms in patients who are not amenable to surgical therapy.[455] The overall 5-year relative survival rate of small bowel carcinoid is approximately 76%.[456] Prognosis appears to correlate with tumor size, depth of invasion, and node status.[457] TNM staging appears to correlate with prognosis.[458]

Carcinoid Syndrome

WNET tumor may be associated with the *carcinoid syndrome*.[459,460] Nearly all of the reported cases of this syndrome have occurred in tumors that have metastasized to the liver, presumably because of the liver's capacity to inactivate biologically active substances released by the primary tumor into the portal circulation; however, exceptions occur.[461] The syndrome is characterized by cyanosis of the face and anterior part of the chest, intermittent hypertension, palpitation, and frequent watery stools. Traditionally, it has been assumed that the syndrome was due to serotonin, an indolamine regularly secreted by the tumor cells and easily detectable in the urine in the form of

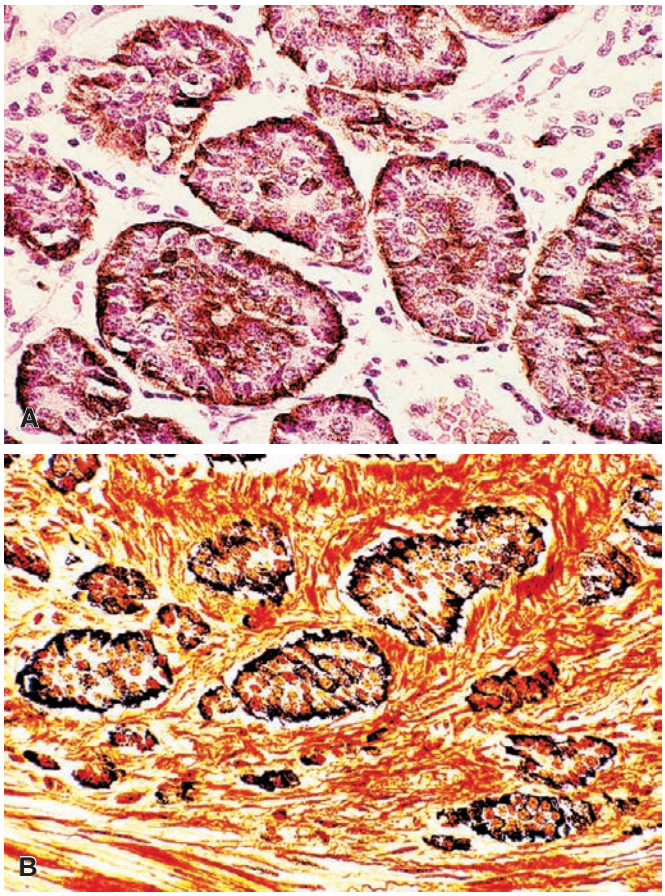

Figure 15.54 **A,** WNET of small bowel. Argentaffin reaction (Fontana–Masson). **B,** Argyrophil reaction (Sevier–Munger).

its catabolite 5-hydroxyindoleacetic acid; however, there is little relation between the serum levels of this marker and the occurrence of the syndrome, especially in regard to its vasodilation component. Other substances known to be secreted by WNETs—such as tachykinins, prostaglandins, and histamine—have been postulated to be responsible as well.[462–464] It is also apparent that the cells of carcinoid tumor must secrete some substance that elicits the deposition of extracellular connective tissue around the tumor and sometimes at a distance. Manifestations of this phenomenon include extensive fibrosclerosis, often seen in the tumor itself (see earlier); fibrosclerosis of the right-sided cardiac valves that results in so-called carcinoid heart disease;[465] obliterative elastic sclerosis of mesenteric blood vessels that may lead to small bowel gangrene[466,467]; and dermal sclerosis that results in scleroderma-like lesions.[468] Furthermore, a few WNETs have resulted in spontaneous hypoglycemia,[469] apparently because of insulin production by the tumor cells.[470]

Duodenal WNET

Endoscopically, duodenal endocrine tumors appear as smooth, round elevations, usually measuring between 5 and 20 mm in diameter but occasionally larger.[471] Gastrin-producing tumors (gastrinomas) may be associated with Zollinger–Ellison syndrome as well as multiple endocrine neoplasia (MEN) type 1.[472–474] They have also been found associated with *H. pylori* gastritis and long-term use of proton pump inhibitors, often against a background of G-cell hyperplasia in the non-neoplastic duodenal mucosa.[475] Somatostatinomas are usually hormonally silent at the clinical level.[476] A high percentage of duodenal somatostatinomas have occurred in patients with von Recklinghausen disease, many of them African-Americans.[477–479] Immunohistochemistry is needed to identify conclusively the specific cell types; however, the nature of these tumors can already be suspected in routinely stained sections by the fact that both of them tend to have a well-developed tubular component and that somatostatinomas have, in addition, numerous psammoma bodies, usually located within glandular lumina.[480–482] It should be noted, however, that psammoma bodies are not specific for somatostatin-secreting tumors; they can also be seen in WNETs of other types in both the bowel and the pancreas.[483] In contrast to their ileal counterparts, duodenal endocrine tumors are positive for PDX-1 and negative for CDX-2.[484]

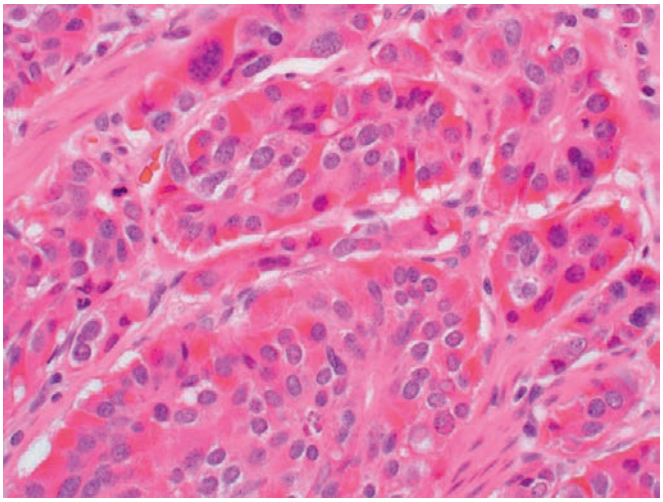

Figure 15.55 Jejunal WNETs often feature prominent eosinophilic cytoplasmic granules that contain serotonin.

Jejunal WNET

Jejunal WNETs are much more rare than ileal tumors but are among the most aggressive. Approximately one quarter are multiple.[394] Morphologically, jejunal WNETs often contain prominent eosinophilic cytoplasmic granules that contain serotonin (Fig. 15.55).

Neuroendocrine Carcinoma

Neuroendocrine carcinoma (NEC) includes tumors previously referred to as small cell carcinoma, large cell NEC, and poorly differentiated neuroendocrine neoplasm.[391] This rare type of small bowel malignancy composed of small, round, or oval cells with scant cytoplasm and hyperchromatic nuclei, very similar to that of pulmonary small cell carcinoma. They are typically immunoreactive with neuroendocrine markers as well as keratins. As high-grade (G3) neoplasms, NEC are characterized by >20 mitotic figures/10/HPF and/or a proliferation index of >20%.[391] They are deeply invasive, highly prone to metastasize, and associated with a very poor prognosis.

Mixed adenoneuroendocrine carcinomas (MANECs), by definition, contain at least 30% of a neuroendocrine component, usually NEC, although sometimes WNET is seen in association with an adenocarcinomatous pattern, whether in the primary tumor or in the metastases.[391,485]

Gangliocytic Paraganglioma

Gangliocytic paraganglioma (nonchromaffin paraganglioma, paraganglioneuroma) is a morphologically distinct tumor occurring almost exclusively in the second portion of the duodenum, usually

in proximity to the ampulla of Vater.[486,487] A few morphologically similar cases have been reported at a more distal location, including the jejunoileum[488] and appendix.[489] Occasionally they are multiple[490] or seen in association with von Recklinghausen disease and WNET.[491,492] Most lesions are small, pedunculated, and submucosal, with frequent ulceration of the overlying mucosa and bleeding. The microscopic appearance is distinctive, with few if any exact counterparts elsewhere in the body. Three cell components are present: (1) endocrine cells with a carcinoid-like appearance arranged in compact nests and trabeculae containing dense-core granules ultrastructurally and exhibiting immunoreactivity for a variety of markers, particularly PP; (2) isolated ganglion cells, immunoreactive for neuron-specific enolase and other neural markers; and (3) spindle-shaped Schwann cells and/or sustentacular cells, immunoreactive for S-100 protein (Fig. 15.56).[493–498] Somatostatin may be present in both ganglion cells and endocrine cells, and amyloid may also be present.[499] The peculiar location of this tumor, its highly organoid arrangement, and the striking predominance of PP cells have led to the suggestion that this lesion may represent a hamartomatous process derived from the ventral primordium of the pancreas.[497] Nearly all cases published so far have followed a benign clinical course, but isolated instances associated with lymph node metastases are on record.[500–502]

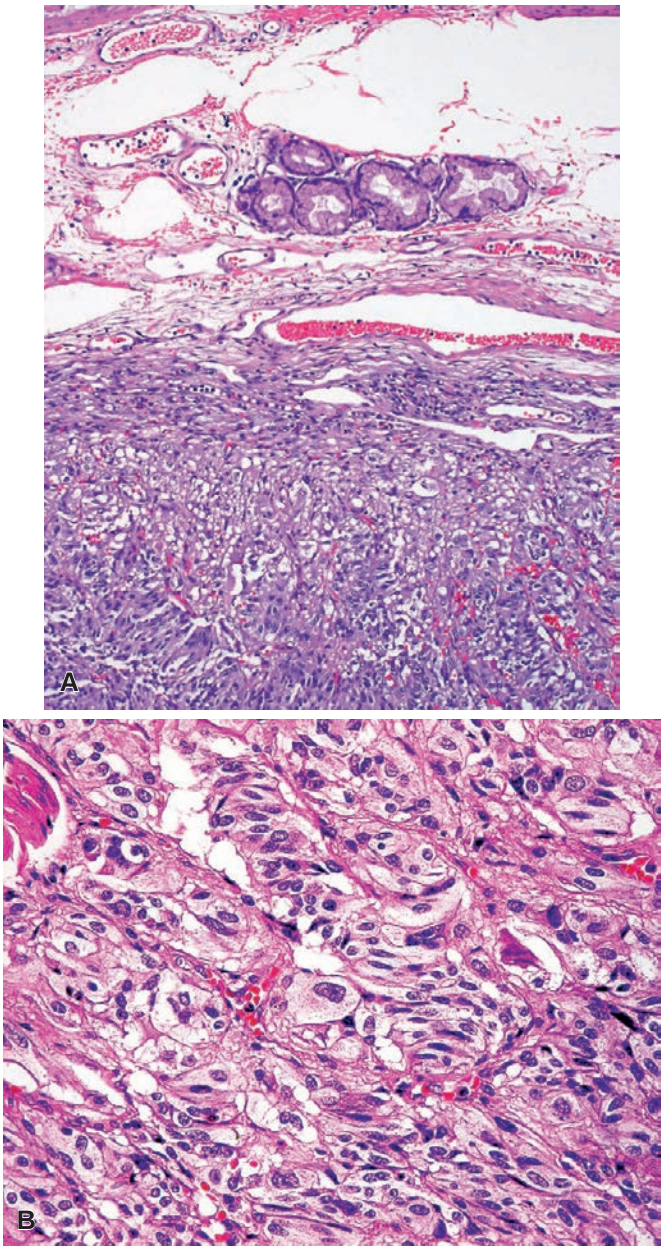

Figure 15.56 **A** and **B,** Gangliocytic paraganglioma of duodenum showing areas of spindle cells, nested epithelioid-appearing cells, and scattered ganglion-like cells (**B,** high power).

Gastrointestinal Stromal Tumors and Other Mesenchymal Tumors

The general considerations concerning GISTs are discussed in Chapter 14. Only features specific to small bowel GISTs will be addressed here.

Approximately 35% of GISTs occur in the small bowel (30% in the jejunum and ileum and 5% in the duodenum), and of these, 40%–50% are clinically malignant.[503] Most small bowel GISTs are spindled lesions, and in particular, GISTs containing so-called skeinoid fibers are characteristically found in this location (Fig. 15.57). Other patterns found in the small bowel include "neuropil"-like areas and epithelioid areas; the latter pattern is less common in the small

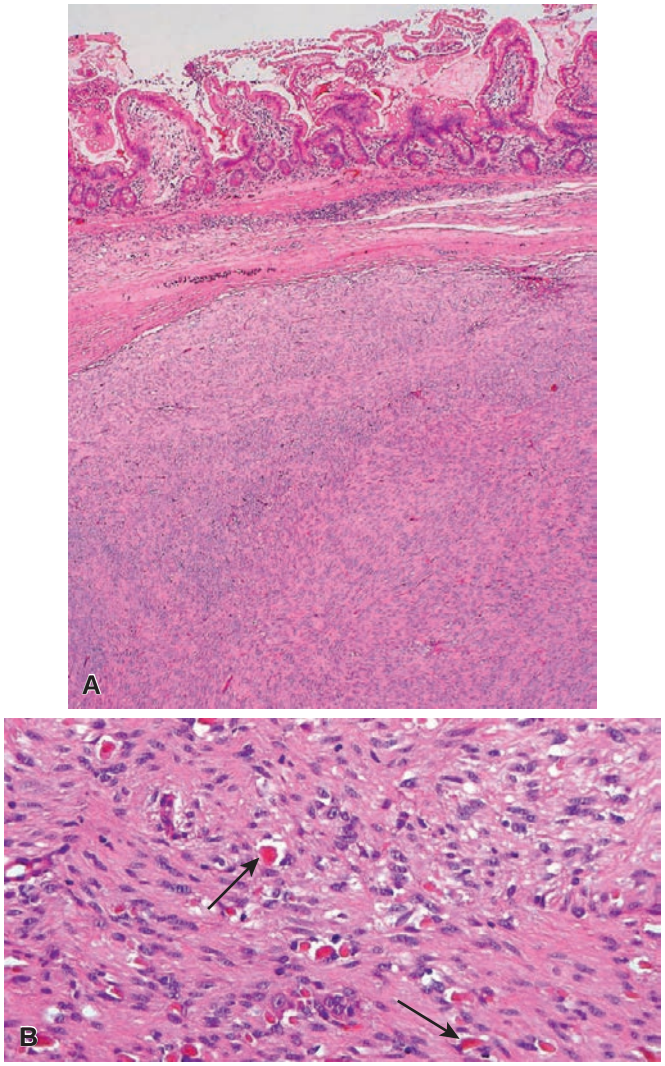

Figure 15.57 **A,** Spindled GIST arising in the wall of the ileum. **B,** Skeinoid fibers are commonly found in small bowel GISTs *(arrows)*.

bowel than in the stomach and is linked with malignant behavior.[503,504] The presence of skeinoid fibers is a sign of good prognosis.[505]

As in other sites in the GI tract, risk stratification of small bowel GISTs is based on site, mitotic count, and size of tumor (Table 15.1). In general, small bowel tumors less than 5 cm with 5 or fewer mitoses/HPF have a low risk of aggressive behavior.[506,507] Lymph node metastases are rarely seen with conventional GISTs, whereas metastases to liver or within the abdomen are much more common.[508] Cases of multiple GISTs of small bowel have been reported in association with von Recklinghausen disease and neuronal intestinal dysplasia.[509–511]

Table 15.1 Risk stratification of primary small bowel GIST

TUMOR CHARACTERISTICS		RISK OF METASTASIS AND/OR DEATH FROM DISEASE	
MITOTIC INDEX	SIZE	DUODENUM	JEJUNUM/ ILEUM
≤5/HPF	≤2 cm	Extremely low	Extremely low
	>2–≤5 cm	Low (8.3%)	Low (4.3%)
	>5–≤10 cm	Not enough data to evaluate	Intermediate (24%)
	>10 cm	High (34%)	High (52%)
>5/HPF	≤2 cm	Not enough data to evaluate	High but few reported cases
	>2–≤5 cm	High (50%)	High (73%)
	>5–≤10 cm	Not enough data to evaluate	High (85%)
	>10 cm	High (86%)	High (90%)

Data from Downs-Kelly E, Rubin BP, Goldblum JR. Mesenchymal tumors of the gastrointestinal tract. Gastrointestinal stromal tumors: pathology and prognosis at different sites. *Sem Diag Pathol* 2006;23:70–83; Joensuu H. Risk stratification of patients diagnosed with gastrointestinal stromal tumor. *Hum Pathol*. 2008;39:1411-1419.

Leiomyomas and **leiomyosarcomas** of the small bowel have become a rarity following the description of GISTs, but they do exist (in a proportion of 1 for 36). By definition they exhibit smooth muscle markers, are typically negative for CD117 and DOG1, and show no mutations of *KIT* or *PDGFR*.[512,513] Most of the stromal tumors occurring in the AIDS-affected population belong to the smooth muscle category and are associated with EBV infection.[514] *Leiomyomatosis peritonealis disseminata* is an unusual condition featuring multiple smooth muscle tumors arising beneath the peritoneum throughout the abdomen; it may rarely affect the small bowel.[515]

IFP appears grossly as a localized submucosal sessile polypoid mass, most often occurring in the ileum (and the gastric antrum, see also Chapter 14) (Fig. 15.58).[516,517] The process occasionally extends to involve the entire thickness of the bowel wall, and the overlying mucosa is often ulcerated. The lesion consists of a bland proliferation of spindled myofibroblasts cells with ill-defined borders. There are admixed inflammatory cells, especially eosinophils; stromal hyalinization may be prominent. Vessels are prominent and often (but not always) have surrounding "onion-skin" fibrosis. Ileal IFPs are similar to those found in the stomach, except that the neural-like features commonly seen in the latter are less prominent (Fig. 15.59). Immunohistochemically, there is consistent positivity for CD34, and variable immunoreactivity with smooth muscle actin.[517,518] CD117 is typically negative, as are desmin and S-100.[519] Recently, gain-of-function *PDGFRA* mutations similar to those often encountered in GISTs have been described in over half of the cases of IFPs.[520] The entirely benign IFP should be distinguished from inflammatory myofibroblastic tumor (IMFT) and from inflammatory pseudotumors.[521,522] Multiple and recurrent cases in a familial setting have been described.[523] Obstruction and intussusception are two well-known complications of this entity.[524]

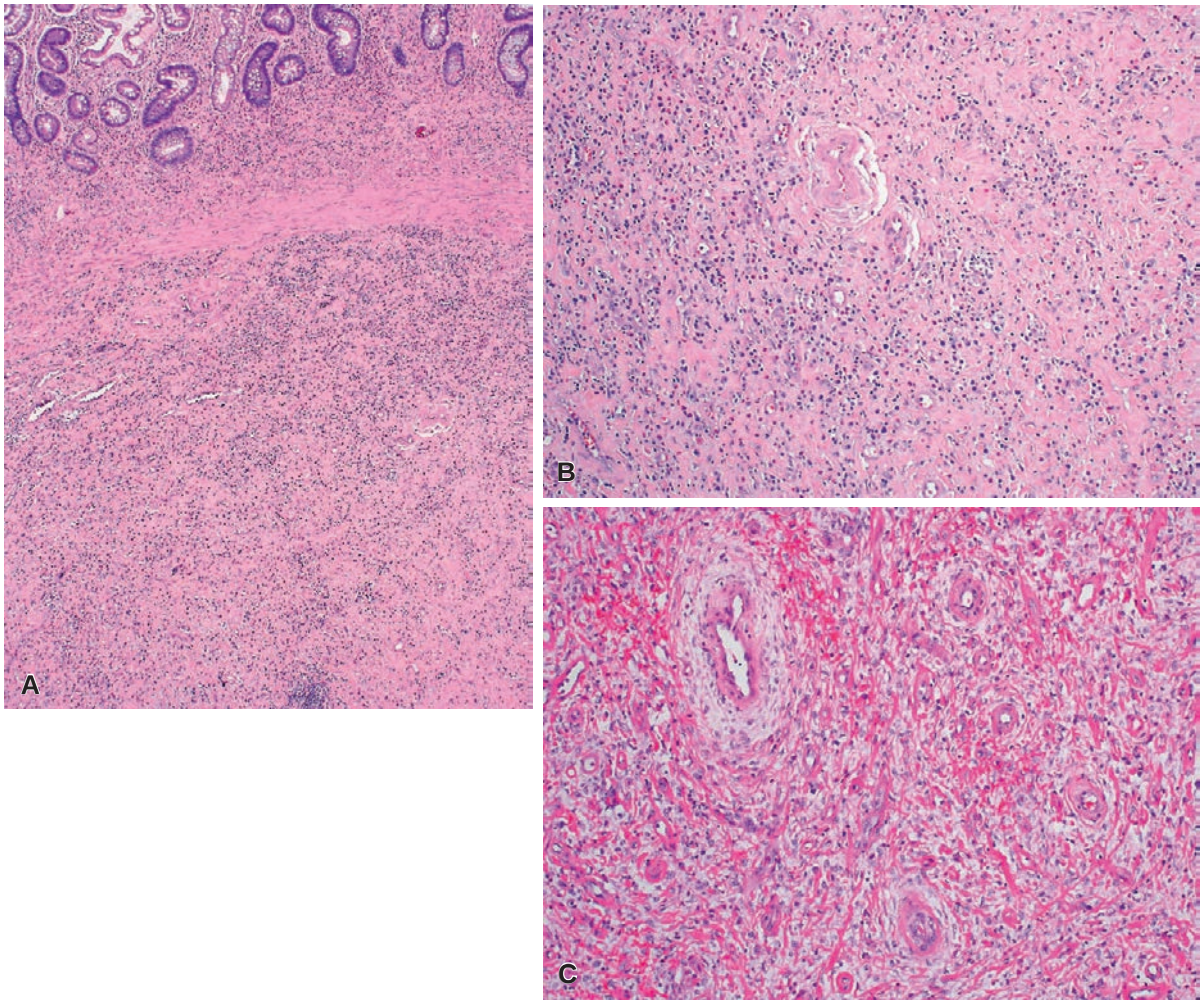

Figure 15.59 **A,** Submucosal-based inflammatory fibroid polyp with spindled stroma, prominent vessels, and a mixed inflammatory infiltrate. **B,** Eosinophils are typically prominent. **C,** Vessels are often surrounded by "onion-skin" fibrosis; this example also has prominent stromal hyalinization.

Lipoma of the small bowel is characteristically centered in the submucosa.[525,526] Grossly, it is a bright yellow, round, encapsulated tumor that bulges upward into the mucosal surface (Fig. 15.60). It has a very characteristic radiographic appearance.[527] The large majority are solitary. Approximately 5% are multiple; these should be distinguished from the rare condition known as *lipomatosis*, in which a segment of bowel (on occasions the entire organ) is infiltrated by mature fat, sometimes in association with diverticulosis or intussusception.[528] Complications of lipoma include ulceration and intussusception.

Benign vascular tumors and tumorlike conditions of various types occur in the small bowel. *Hemangiomas* may be single or multiple and may be associated with similar lesions in other organs.[529,530] They may bleed or perforate. Grossly, the lesions are soft, elevated, reddish, and not well defined. The mid jejunum is the most common location, but they can also occur in other sites. Microscopically, cavernous hemangioma is the most common variety. *Lymphangiomas* often occur in association with similar tumors in other sites, particularly in children (Fig. 15.61).[531] They should be distinguished from the *lymphatic cysts (lacteal cysts)* commonly seen as an incidental finding in the elderly.[532]

In *hereditary telangiectasia* there are vascular lesions of the mucous membrane and skin. These lesions are multiple, and severe GI hemorrhage can occur from them. Smith et al.[533] reported 159 patients, 21 of whom had significant hemorrhage. Demonstration of these lesions at surgery is difficult, and surgical resection is usually not successful.

There are isolated case reports of *intravascular papillary endothelial hyperplasia (Masson hemangioma)*,[534] *glomus tumor*,[535,536] and rare reports of *solitary fibrous tumor*.[537]

Schwannoma, neurofibroma, and **ganglioneuroma** may occur as isolated neoplasms or as components of von Recklinghausen disease or multiple endocrine neoplasia.[538–540] It should be mentioned here that GI involvement in von Recklinghausen disease may manifest in a variety of ways: hyperplasia of the submucosal and myenteric nerve plexuses, mucosal ganglioneuromatosis, GISTs showing varying degrees of neural or smooth muscle differentiation, somatostatin-rich endocrine tumor of the duodenum, adenocarcinoma with (and perhaps without) neuroendocrine features, and gangliocytic paraganglioma.[540]

IMFTs may arise in the mesentery of the small bowel, most often in children and young adults. Historically, these have also been known as *inflammatory pseudotumors of the GI tract* or *plasma cell granulomas*.[522,541,542] They are considered lesions of borderline malignancy, as they have a tendency to recur but metastasize only rarely. They may be spindled, myxoid, or sclerotic; approximately half

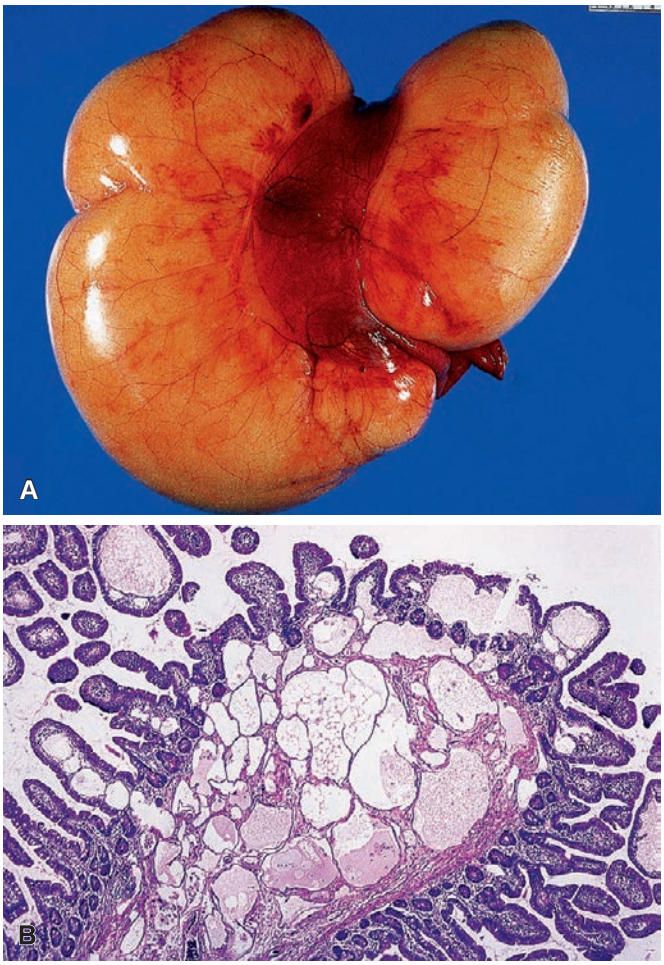

Figure 15.61 **A,** Lymphangioma involving small bowel and adjacent mesentery. **B,** Low-power appearance of lymphangioma showing predominantly submucosal involvement.

contain ganglion-like cells, and a there is often a prominent lymphoplasmacytic inflammatory infiltrate. Some tumors have striking cytologic atypia. IMFT are positive for SMA and variably positive for desmin, and approximately 30% are immunopositive with keratin. Unlike GIST, they are negative for KIT and DOG-1. Approximately half of tumors have an *ALK* gene rearrangement, although there is imperfect correlation between the gene rearrangement and ALK immunohistochemical positivity.[543] It is important to note that ALK staining is not specific to IMFT.[544]

Congenital fibromatosis may result in a solitary intestinal mass, leading to intestinal obstruction in the neonate,[545] whereas **mesenteric fibromatosis** (desmoid tumor) in the adult may involve the bowel wall and be misinterpreted as a GIST.[546] Nuclear β-catenin immunoreactivity is very helpful in diagnosing desmoid tumors.[547]

Malignant GI neurectodermal tumor[548] is a recently coined name that encompasses the exceedingly rare tumors previously described as osteoclast-rich tumors of the GI tract[549,550] or clear cell sarcoma-like tumor of the GI tract.[551] The ultrastructural features and absence of melanocytic differentiation separate these tumors from soft tissue clear cell sarcomas that involve the GI tract. These tumors typically express S-100 and SOX2 but are negative for melanocytic markers and CD117. The majority of cases contain *EWSR1-CREB1* or *EWSR1-ATF1* fusions.

Other mesenchymal and vascular tumors that rarely involve the small bowel include *Kaposi sarcoma* (characteristically multiple lesions)[552]; *angiosarcoma* (also with a tendency for multiplicity and sometimes showing epithelioid features)[553,554]; *synovial sarcoma*[555,556]; *liposarcoma*[557]; *pleomorphic sarcoma*[558]; *Ewing sarcoma/PNET*[559]; *rhabdomyosarcoma*[560,561]; and *PEComa*.[562]

Malignant Lymphoma and Related Disorders

Important concepts to consider when evaluating malignant lymphomas involving the small bowel include: (1) whether or not they are truly primary, versus part of a systemic disease; (2) their cell lineage (B, T or NK cell); and (3) the presence and type of an associated or predisposing condition.[563,564] Although the GI tract is the most common site of primary extranodal lymphoma,[564–566] the possibility of disease being present elsewhere should always be investigated, inasmuch as 10% of patients with non-Hodgkin lymphomas have involvement of some part of the GI tract at the time of initial evaluation.[567,568] The following discussion focuses on

lymphomas that are likely to occur as primary tumors of the small bowel.

T-cell malignant lymphomas represent, in most instances, a complication of longstanding celiac sprue or related malabsorption syndrome and are discussed previously.[95,96] The rare entity known as *extranodal NK/T cell lymphoma (ENKTL), nasal type* is in the differential diagnosis for EATLs, and the most frequent extranasal site of involvement is, in fact, the GI tract. These tumors are positive for CD56, TIA-1, and granzyme B but typically negative for CD4, CD8, and surface CD3. Angiocentric and/or angiodestructive features are characteristic, and these lesions are almost always associated with EBV.[569–572]

B-cell lymphomas are the most common type found in the small bowel. The large majority are thought to arise from mucosa-associated lymphoid tissue, that is, the component of the immune system that is believed to function as a protective mechanism for the freely permeable surface of the GI tract.[573–576]

Low-grade extranodal marginal zone B-cell lymphoma of "MALT type" (other than immunoproliferative small intestinal disease [IPSID], see later) is much less common in the small bowel than in the stomach. Its gross, microscopic, and immunohistochemical features are similar to those of its gastric counterpart, however (see Chapter 14).[563,577] The key features are the predominance of small lymphoid cells (centrocyte-like or monocytoid B cells), the formation of lymphoepithelial lesions, and the presence of reactive follicles (Fig. 15.62). The clinical course is generally very indolent.[578] Low-grade MALT lymphoma may transform to a **large B-cell lymphoma,** however (see next).

IPSID is a distinct type of B-cell lymphoma of small bowel thought to be a special form of MALT lymphoma; it is also known as Mediterranean lymphoma[579,580] and Middle Eastern lymphoma.[570] It is relatively common among non-European Jews, Arabs in the Middle East, and the black population of South Africa.[581] Patients often have a short history of diarrhea and malabsorption, but the mucosa is not completely flat in most cases. Biopsies of the bowel and regional lymph nodes in the low-grade form of this disease (by far the most common) show a heavy lymphoplasmacytic infiltration by cells that appear mature or only slightly immature at both the light and electron microscopic levels.[582,583] This is associated with the presence of monoclonal alpha heavy chains of immunoglobulins in their cytoplasm,[584–586] as well as in the serum and urine—hence the alternative designation "alpha chain disease." Light chains may also be detected.[587] It has been speculated that this lymphoplasmacytic infiltration is originally reactive in nature and that it represents a response to a continuous antigenic stimulus of possible infectious nature. The initially polyclonal nature of the proliferation and the fact that some cases have responded to tetracycline support this contention, and more recent data have demonstrated a connection between IPSID and *Campylobacter jejuni* infection.[588,589]

In the high-grade form of the disease, which is usually preceded and accompanied by the low-grade form, the microscopic appearance of the tumor is that of a highly pleomorphic large cell lymphoma with immunoblastic and plasmacytoid features.[589] Pangalis and Rappaport[590] have shown that the large tumor cells exhibit an immunocytochemical staining for alpha chains similar to that of the small cell lymphoplasmacytic component, suggesting that they represent a clone of highly malignant elements that originate from it. A prominent "starry sky" pattern may be present, as well as intense follicular lymphoid hyperplasia.[591]

The diagnosis of immunoproliferative small intestinal disease can usually be made by endoscopic biopsy, especially if areas with an infiltrating pattern are sampled.[592] The involvement centers in the distal portions of the duodenum and the upper jejunum. Grossly, the presence of diffusely thickened folds with small nodules or discrete tumor growths heralds the emergence of a high-grade malignancy, which proves rapidly fatal in most instances.

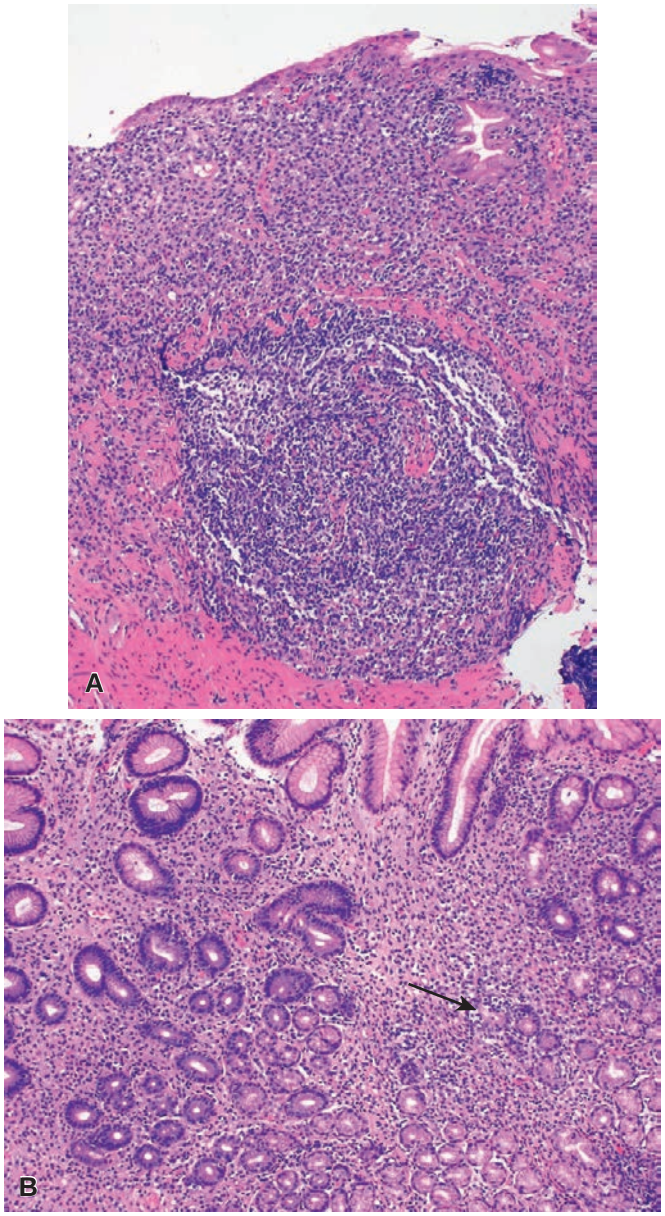

Figure 15.62 Extranodal marginal zone lymphoma of duodenum with plasmacytoid features, showing destruction of the normal mucosal architecture **(A)** and lymphoepithelial lesions (*arrow*, **B**).

Follicular lymphoma can occur anywhere in the GI tract as a primary tumor or secondary to systemic involvement. There is an unusual primary form, however, occurring most often in the duodenum of females, that has a good prognosis despite its morphologic similarity to other follicular lymphomas (Fig. 15.63).[593–595] Some of these cases present grossly as innumerable small polypoid masses throughout the bowel, a condition historically known as *lymphomatoid polyposis;* the lesions may localize around the ampulla of Vater.[596] The 14;18 translocation that is typical of this lymphoma type has been detected in these cases.[593] Curiously, primary follicular lymphoma of the duodenum is usually an unexpected finding on endoscopy performed for various reasons, such as nonspecific abdominal pain.[593,597] Histologically it is usually confined to the

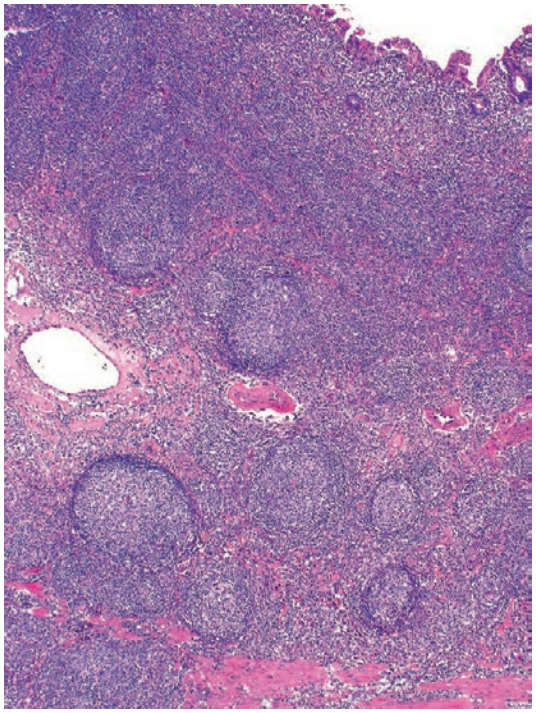

Figure 15.63 Primary follicular lymphoma of the small bowel featuring transmural extension of neoplastic follicles.

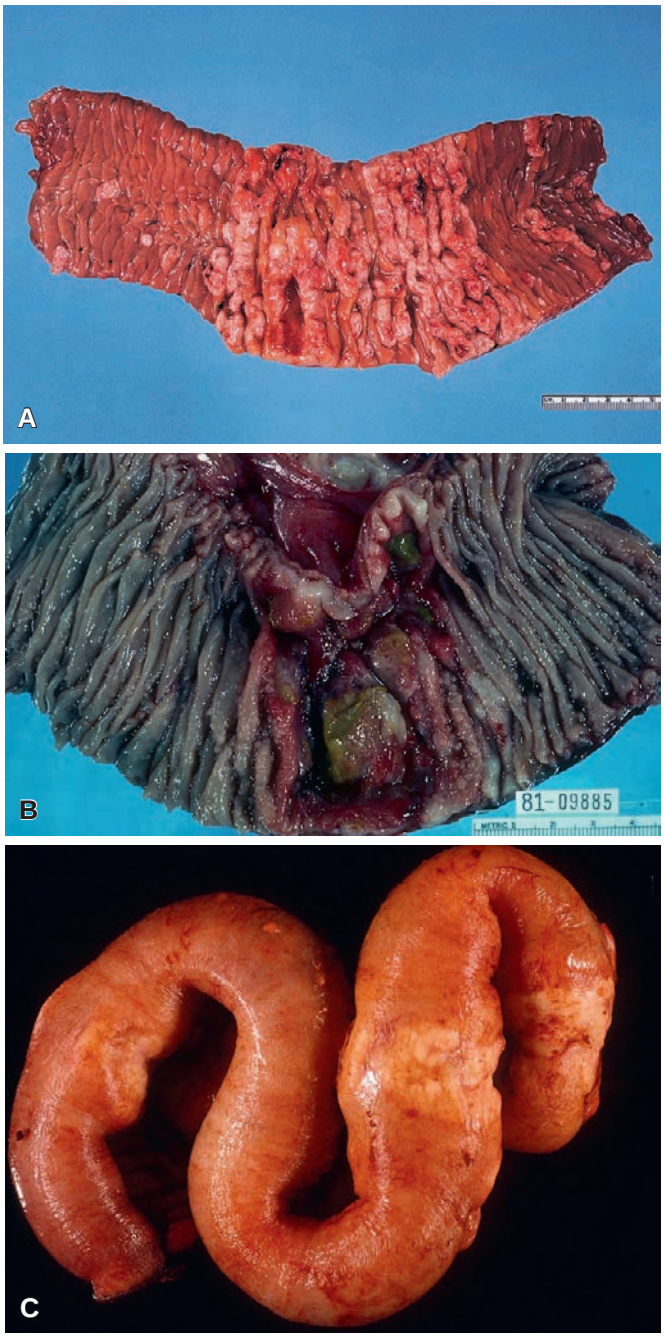

Figure 15.64 **A,** Gross appearance of malignant lymphoma involving the ileum in a diffuse fashion and resulting in polypoid prominence of the transverse mucosal folds. **B,** Malignant lymphoma of small bowel presenting as a circumferential ulcerated lesion that resulted in stenosis. **C,** This diffuse growth pattern in a segment of small bowel resembles a garden hose. (**B** and **C,** Courtesy Dr. George F. Gray, Jr.)

mucosa and/or submucosa, and of low histologic grade (grade 1 or 2), with CD10, BCL6, BCL2 expression. These primary small bowel follicular lymphomas are typically detected at an early stage and are associated with an excellent outcome even with conservative management.

Burkitt lymphoma is usually seen in children; the ileum and ileocecal valve are most often involved.[563,598] The endemic form of this tumor is relatively common in the Middle East and Algeria; the other two clinical settings include sporadic and immunodeficiency related. Many patients are in the pediatric age group, and a significant proportion are associated with EBV infection.

Diffuse large B-cell lymphoma of the small bowel is usually solitary. The ileum is more commonly affected, followed by the jejunum and duodenum.[599] Grossly, they can have a diffusely infiltrating mass with a garden hose appearance, a bulky tumor mass with extensive ulceration, or a predominantly polypoid growth pattern (Fig. 15.64). The regional lymph nodes are involved in approximately half of the patients. Most cases have a germinal center phenotype, suggesting an origin from germinal center B cells.[600] A recently described subset of B-cell lymphomas that harbor abnormalities in MYC as well as BCL2 or BCL6 are known as *double-hit lymphomas*. These neoplasms have features intermediate between Burkitt lymphoma and diffuse large B cell lymphoma.[601]

Mantle cell lymphoma uncommonly occurs as a primary tumor of the small intestine, but the intestine is commonly infiltrated as part of systemic involvement. Its morphologic distinction from the other low-grade B-cell lymphomas previously described can be very difficult, and immunophenotyping is crucial (CD20+, CD5+, nuclear cyclin D1+). Its gross presentation may be in the form of multiple lymphoid polyps similar to those seen with follicular lymphoma *(lymphomatous polyposis)*.[602–603]

Hodgkin lymphoma is extremely rare in the small bowel. Only two cases were found by Lewin et al.[568] in a review of 117 lymphomas of the GI tract.

Anaplastic large cell lymphoma can present as a primary lesion of the small bowel; most of the reported cases have been of T-cell lineage.[604]

Multiple myeloma can involve the bowel as a manifestation of systemic extramedullary disease,[605,606] as can Waldenström's macroglobulinemia.[607]

The small bowel is a frequent site of involvement by **post-transplant lymphoproliferative disorders**.[608,609] As in other sites,

the appearance of the neoplastic cells ranges from polymorphic to monomorphic, and the population may be polyclonal or monoclonal.[610,611] The majority of cases are associated with EBV.

True **histiocytic sarcomas** rarely occur in the small bowel, typically showing immunoreactivity for histiocyte markers and lysozyme.[612–615] Curiously, their appearance can be somewhat reminiscent of Rosai–Dorfman disease. *Follicular dendritic cell tumor* (another member of this family) can also rarely present as a primary mass in the small bowel.[613,616] It should be emphasized, however, that most of the large cell tumors that have been regarded in the past as histiocytic on morphologic grounds, and on the basis of their alleged immunohistochemical positivity for lysozyme and α1-antitrypsin, have been shown to be lymphoid neoplasms instead.[617]

Granulocytic sarcoma can present initially as a small bowel mass, preceding the development of acute myelogenous leukemia.[618]

Systemic mastocytosis may also involve the small bowel and present with diarrhea, abdominal pain, nausea, vomiting, and weight loss.[619] The mast cell infiltrates typically expand the lamina propria and are often accompanied by eosinophils (Fig. 15.65).

Lymphoid hyperplasia is a focal reactive process and has historically been known as *pseudolymphoma* (a term that is probably better avoided).[620,621] The ileocecal region is the most common location.[622] Lymphoid hyperplasia associated with viral infection, and leading to intussusception in young children is discussed previously. In other cases (sometimes termed *nodular lymphoid hyperplasia*) the entire small bowel is studded with well-circumscribed nodules of lymphoid tissue, which may be mistaken for other types of polyps. Lymphoid hyperplasia is associated with CVID as well as IgA deficiency.[325,623] In children, it may also be associated with viral infection.[624] The presence of highly reactive germinal centers, numerous cell types, prominent vascularity, and polyclonality (as determined immunohistochemically) are the most important features in the differential diagnosis with malignant lymphoma.[625] It has also become apparent in more recent years that many lesions designated as lymphoid hyperplasia in the past, on purely morphologic grounds, represent instead low-grade lymphomas.[626]

Other Tumors and Tumorlike Conditions

Endometriosis may result in a mass lesion causing intestinal obstruction[627] or mimicking Crohn disease[628] or malignancy (Fig. 15.66). Microscopically, endometrial glands and stroma, foci of fresh and old hemorrhage, and bundles of hypertrophic smooth muscle (which

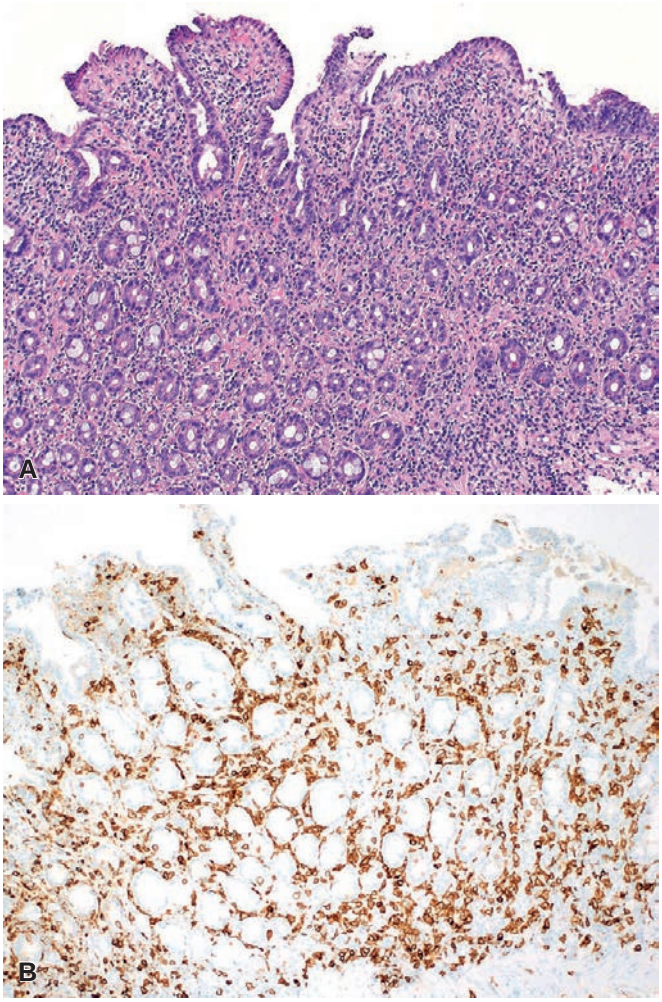

Figure 15.65 **A,** An infiltrate of mast cells expands the lamina propria of the duodenum in this patient with systemic mastocytosis. The mast cells have a "fried egg" appearance and there are scattered admixed eosinophils. **B,** CD117 stain highlights the mast cells.

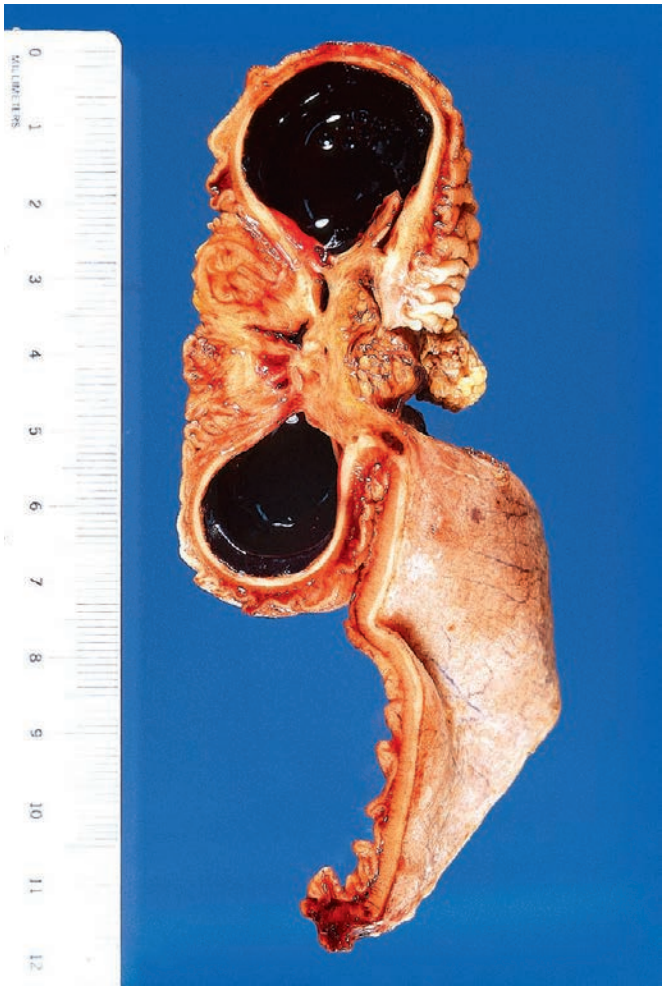

Figure 15.66 Large blood-filled cystic lesion in the wall of the small bowel due to endometriosis. There is also hyperplasia of smooth muscle, a very common finding. (Courtesy of Dr RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

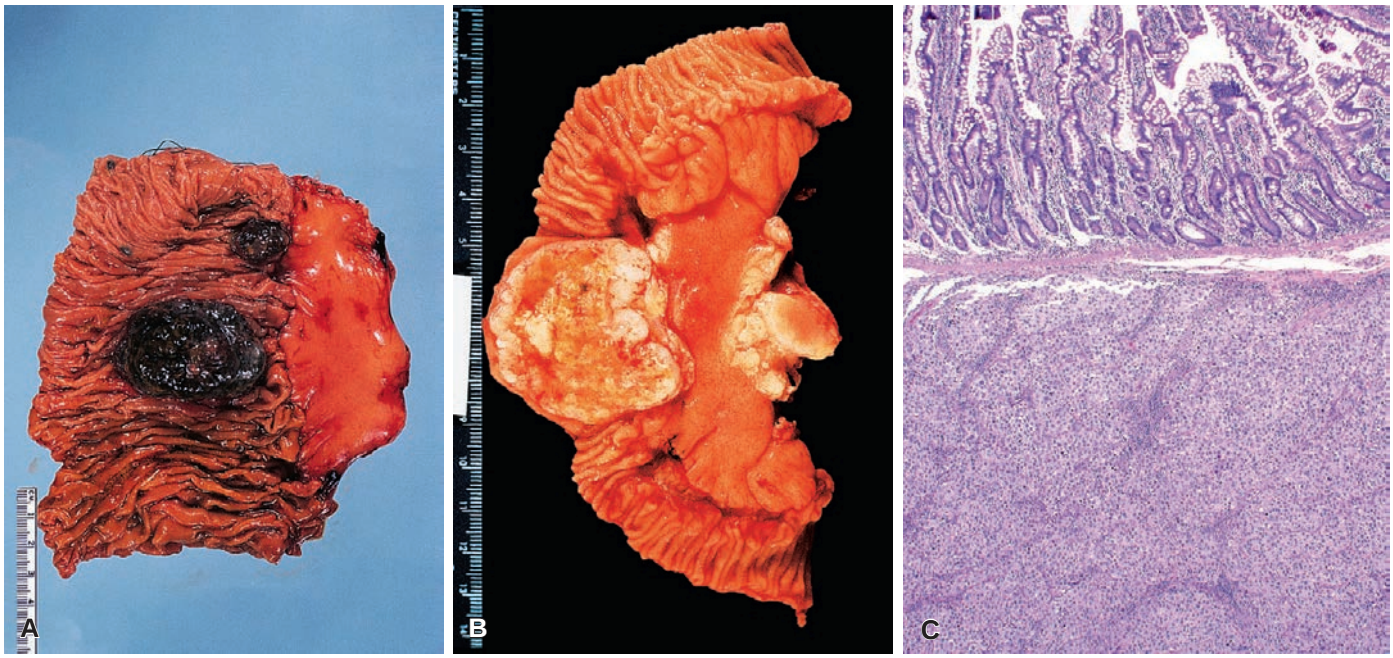

Figure 15.67 Malignant melanoma metastatic to small bowel, which can be deeply pigmented grossly **(A)** or amelanotic **(B)**. **C,** Metastatic melanoma undermining the duodenal mucosa.

may constitute the bulk of the process) are seen. These endometriotic foci may exceptionally undergo malignant transformation in the form of endometrioid carcinoma, müllerian adenosarcoma, or endometrial (endometrioid) stromal sarcoma.[627] *Endocervicosis* is a related müllerian-type process in which the metaplastic mucosa has the appearance of endocervix rather than endometrium.[629]

Neuromuscular and vascular hamartoma of the small bowel is a submucosally based proliferation of mature vessels, nerves, and smooth muscle fibers that can cause obstruction.[630] It has been suggested that this process may be related to so-called *diaphragm disease* and caused by the intake of nonsteroidal anti-inflammatory drugs (see also earlier).[631]

Amyloidosis can exceptionally form globular masses in the bowel wall and grossly evident polypoid lesions.[632]

Metastatic Tumors

Metastases frequently involve the small bowel, often in the form of multiple polypoid masses.[633] The lesions may result in obstruction or perforation, necessitating palliative resection.[634–636] The most common types of tumor metastasizing to the small bowel are malignant melanoma (Fig. 15.67), which must be distinguished from the rare primary melanoma of small bowel,[637] and carcinomas from lung, breast, and ovary, and choriocarcinoma.[634–639] Melanoma can present radiographically as intraluminal masses, ulcerated lesions, diffuse infiltration of the wall, or implants.[637] Patients with multiple metastases from melanoma usually die within 1 year following palliative surgery, but an occasional long-term survivor will be found among those with isolated metastases.[640]

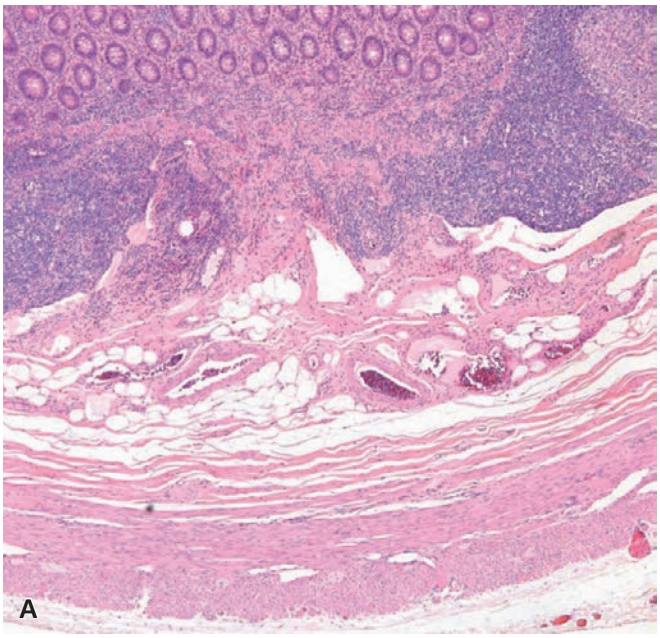
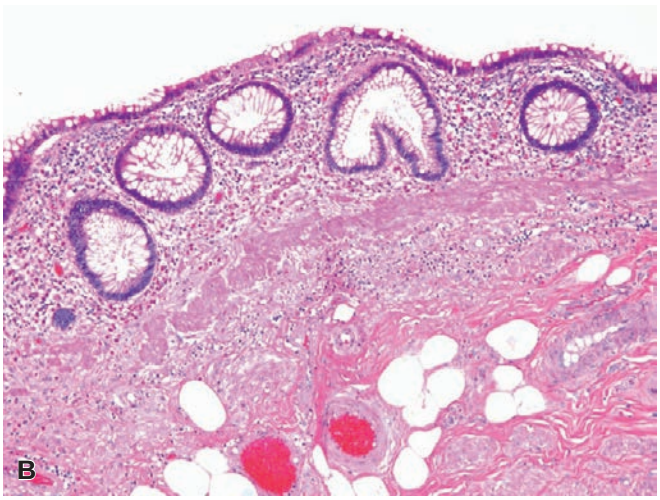
Normal Anatomy of the Appendix

The vermiform appendix is a tubular structure arising from the medial wall of the cecum; it averages 9 cm in length and 0.7 cm in greatest diameter, although the luminal dimensions may vary along the length of the organ. Despite ongoing speculation and debate, vermiform appendix has no known function in humans and is typically regarded as a vestigial organ. The appendix reaches its maximum diameter by 4 years of age and becomes narrower (particularly after age 40) as lymphoid tissue decreases and fibrosis increases.[1] The position of the appendix varies considerably, due to variation in the position and shape of the cecum that occur during its development and rotation. The appendix most often lies posterior to the cecum or ascending colon, below the ileocecal valve.[2] Other appendiceal locations include retroileal, preileal, pelvic, and in the hepatorenal recess.[1–3] The significance of this variation in anatomic location is that unusual locations may lead to atypical clinical presentations of acute appendicitis.[4]



The layers of the wall of the appendix are similar to that of the large bowel (Fig. 16.1A), except for a greater representation of lymphoid tissue (which is particularly prominent during childhood and adolescence). Irregular distribution of the crypts in the appendix can raise the possibility of chronic idiopathic inflammatory bowel disease, but this is normal physiological variation (Fig. 16.1B).[1,5] Large lymphoid aggregates may have prominent germinal centers and can disrupt the muscularis mucosae (Fig. 16.1C); the epithelium overlying them may be attenuated as well.[5,6] Of note, lymphoid hyperplasia in children (Fig. 16.2), which may be associated with a variety of viral infections, has been associated with intussusception and symptoms mimicking acute nonspecific appendicitis.[7] Microscopically, the epithelium is columnar, similar to the colon, and contains absorptive cells, goblet cells, neuroendocrine cells (mainly of Kulchitsky type and located at the base) and occasional Paneth cells (Fig. 16.3).[6,8] Neuroendocrine cells have also been detected (both ultrastructurally and with chromogranin or related stains) within the lamina propria, unconnected with the crypts but in close association with nerve fibers.[1,9] These complexes, first identified by Masson, have been referred to as *subepithelial neuroendocrine complexes* or *endocrine cell-nerve fiber complexes*, and some have postulated that they are the origin of appendiceal neuroendocrine tumors (NETs). The submucosal, muscular, and serosal layers are qualitatively similar to their counterparts in the rest of the lower intestinal tract. Nerves and ganglion cells are often easily identifiable within the inner and outer layers of the muscularis propria. Grossly, the serosa is smooth, glistening, and transparent, and a thin layer of peritoneum covers the entire appendix. The mesoappendix, which is largely made up of adipose tissue and is contiguous with the mesentery of the bowel, contains the appendiceal vessels. Very infrequently, one or more small lymph nodes are found within it; these drain to the pericolic and superior mesenteric nodes.



Abstract

This chapter covers the major congenital, inflammatory, and neoplastic entities that the surgical pathologist will encounter in the appendix.

Keywords

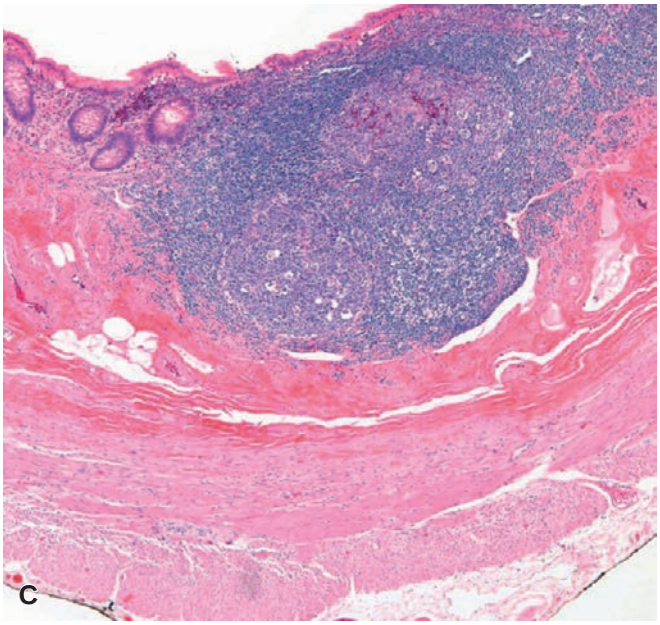

Figure 16.1 **A,** The layers of the walll of the appendix are similar to that of the large bowel. **B,** Irregular distribution of the crypts is a normal physiological variant and should not be misinterpreted as chronic idiopathic inflammatory bowel disease. **C,** Large lymphoid aggregates may disrupt the muscularis mucosae, and the overlying epithelium may be attenuated.

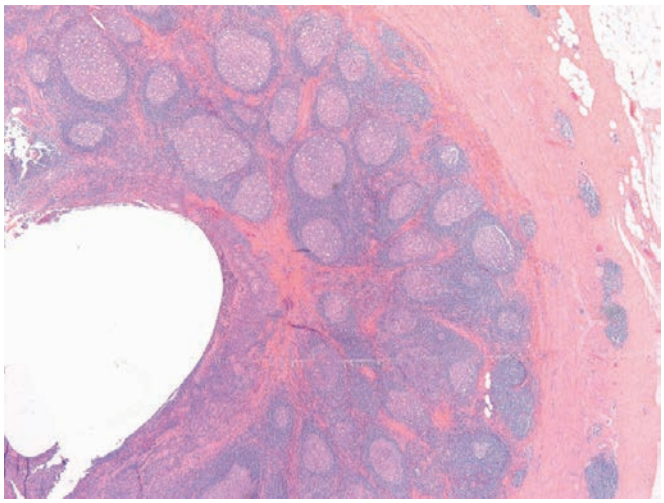

Figure 16.2 Lymphoid hyperplasia in children may be striking and is associated with viral infections as well as intussusception.

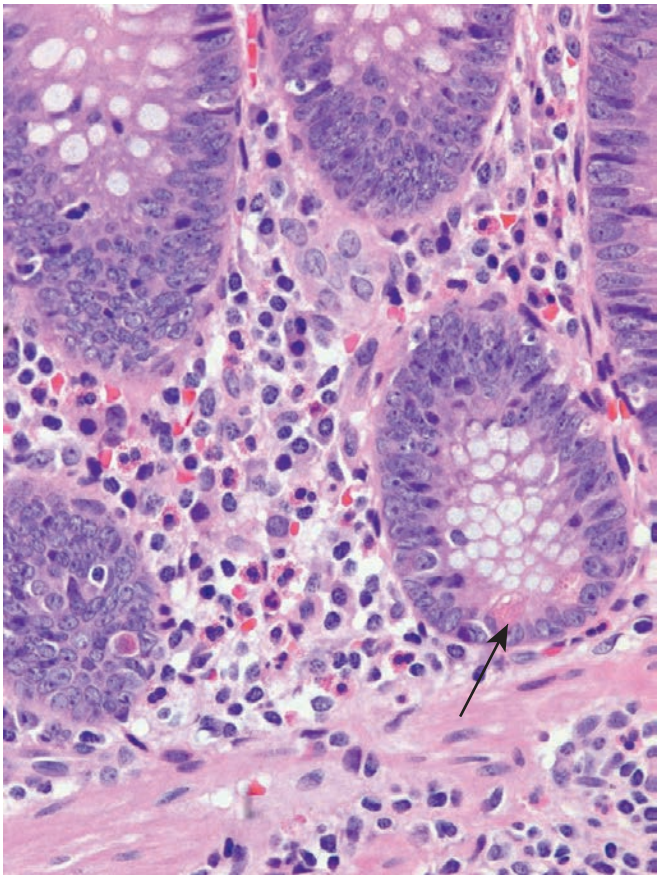

Figure 16.3 Paneth cells may be seen in the appendiceal mucosa *(arrow)*, along with neuroendocrine cells.

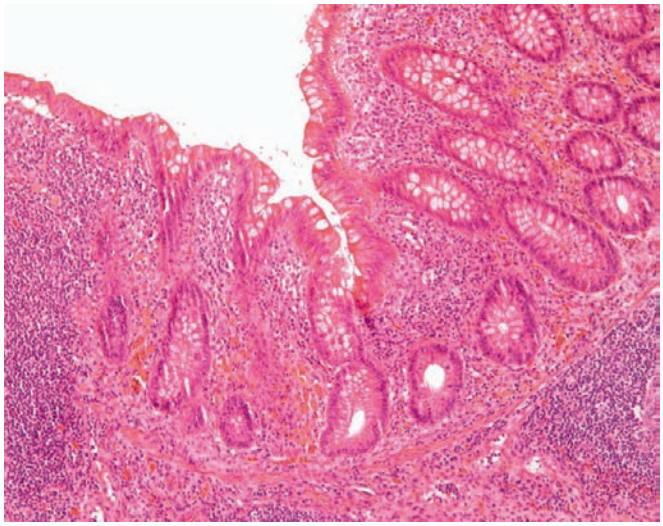

Figure 16.4 Melanosis is common in both adults and children and is analogous to melanosis coli.

Heterotopic gastric and **esophageal** tissue have been rarely described in the appendix.[10] **Melanosis** of the appendix, analogous to the homonymous large bowel condition, refers to the presence of melanin-like pigment in lamina propria macrophages (Fig. 16.4). It is relatively common at the microscopic level in both the pediatric and adult populations.[11,12]

Obliteration of the tip of the appendix is a frequent finding, the nature, significance, and mechanism of which remain controversial. The lesions in question consist of a variable mixture of nerve fibers, Schwann cells, neuroendocrine cells, fibrous tissue, and muscle, hence the variety of names for them including fibrous obliteration, neuroma, neuroappendicopathy, and neurogenic appendicitis (Fig. 16.5).[13–16] Some view this type of lesion as part of the normal aging process, and others as a sequela of a resolved acute appendicitis.[13,16] Regardless, many are incidental findings in patients whose appendices are removed for other reasons, and the incidence does increase with age. Appendiceal neural proliferations are rarely described in the context of neurofibromatosis type 1.[17] Importantly, appendiceal neural proliferations should not be mistaken for true appendiceal gastrointestinal stromal tumors (GISTs). The opposite phenomenon is characterized by a mild to moderate dilation of the lumen, an inconsequential process that may be distal to obstructive lesions such as fibrous obliteration or fecalith; in children, this finding has also been associated with an increase in goblet cells.[18] These lesions are sometimes dignified with the term *appendiceal ectasia*. Appendiceal ectasias should not be referred to as mucoceles or—worse—regarded as mucinous neoplasms (see later for further discussion).

Congenital Abnormalities of the Appendix

Congenital abnormalities of the appendix are fairly rare and include appendiceal agenesis, duplication, and congenital diverticula.[14] Congenital absence of the appendix is very rare and may be accompanied by developmental abnormalities of the cecum.[19,20] Appendiceal agenesis can be mimicked by several conditions, including unknown prior appendectomy, atrophy, autoamputation, and intussception.[19,21] Appendiceal duplication is more common, with an incidence of around 0.004%–0.009%.[22] Appendiceal duplication has been subdivided into multiple types, several of which are associated with multiple severe gastrointestinal and genitourinary anomalies.[14,23]

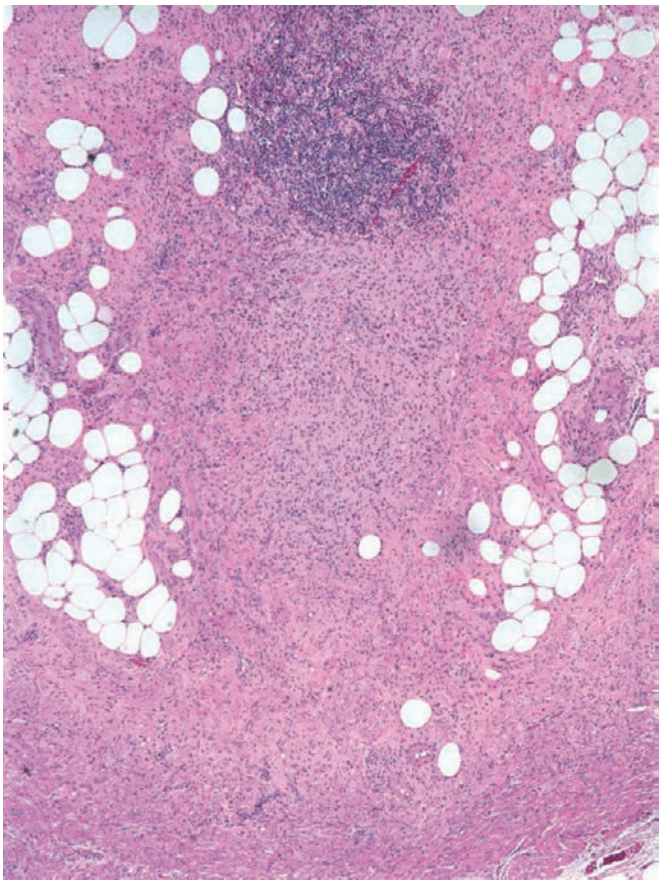

Figure 16.5 Fibrous obliteration of the appendiceal tip consists of a variable mixture of nerve fibers, fibrous tissue, Schwann cells, neuroendocrine cells, and muscle.

Appendiceal diverticula (see section later) can mimic duplications; the presence of a muscular wall virtually excludes acquired diverticulum. Appendiceal septa have also been described, typically in children and young adults, and in association with acute appendicitis.[24]

Acute Appendicitis

Epidemiology and Pathogenesis

Acute appendicitis is the most common abdominal surgical emergency, and it is predominantly a disease of the Western world. It is particularly common in the United States and Great Britain, and less common in Asia and Africa. In the United States, it is more common among whites than among African-Americans or Asians, and there is a male predominance.[25] Peak incidence is during the second and third decades, but acute appendicitis can occur at any time from early infancy to old age.

Historically, the most popular theory regarding the pathogenesis of acute "nonspecific" appendicitis has been that of obstruction of the appendiceal lumen. Advocates of this theory argue that obstruction (by fecalith, adhesions, tumor, lymphoid hyperplasia, etc.) leads to increased intraluminal pressure and that the resulting secretions under pressure impair the resistance of the mucosa to invasion by microorganisms.[26] Controversy persists, however, and detractors from the obstruction theory point out that evidence of obstruction is found in only a minority of appendices resected for acute appendicitis.[27,28] Other theories include compromise of the extramural

vascular supply, mucosal ulceration (possibly secondary to viral infection) with superimposed bacterial infection, and low-fiber diets resulting in retention of stool and resultant susceptibility to infection.[28–30] Rarely, acute appendicitis is caused by foreign bodies, including pins, bones, shotgun pellets, and other foreign objects.[29] It is fair to say that no single theory explains all cases of acute nonspecific appendicitis and that multiple factors may lead to mucosal ulceration and invasion of the wall by enteric bacteria.[28,31]

Clinical Features

The usual presentation of acute appendicitis is colicky periumbilical pain that eventually migrates to the right lower quadrant, accompanied by tenderness to palpation, nausea and vomiting, fever, leukocytosis, and elevated erythrocyte sedimentation rate and C-reactive protein.[32] Fewer than 50% of patients have all of these findings, however. The use of diagnostic imaging, especially the CT scan, is helpful in confirming or excluding a diagnosis of acute appendicitis.[32] If perforation of the appendix occurs, there may be temporary relief of pain followed by signs of acute peritonitis. Acute appendicitis in young children[33] and in the elderly[34,35] is more likely to be mishandled because of failure to consider the diagnosis and because the clinical findings are often atypical. The conditions most likely to mimic appendicitis clinically include gynecologic and urologic disease (e.g. adnexal mass and urinary tract infection), mesenteric lymphadenitis, Meckel diverticulitis, infarction or torsion of the greater omentum, and chemotherapy-induced typhlitis, particularly in children with leukemia and other malignancies.[36–39] False-positive diagnoses are twice as common in females as in males.[36] Of note, cases of acute appendicitis in AIDS patients does not differ significantly from that seen in immunocompetent individuals, except for a lower tendency to have an elevation of the white blood cell count.[40,41]

Pathologic Features

The macroscopic pathology of acute appendicitis is very variable, and the external appearance may not correlate with the extent of inflammation microscopically.[28,31] In addition, the correlation between the gross findings by the surgeon and the microscopic findings by the pathologist is only fair; in one series, one-third of appendices perceived to be normal by the surgeon at appendectomy showed inflammation at the microscopic level.[42] The earliest gross findings often consist of the usually glistening serosal surface becoming dull, with injection of the serosal vessels (Fig. 16.6A). As the inflammatory process progresses, there is increased edema and hyperemia, with variably present fibrinous or purulent exudates covering the serosa (Fig. 16.6B). The mucosal surface is often hyperemic as well, with associated intraluminal pus and narrowing of the lumen. Ultimately, the gangrenous appendix shows green, black, or purple discoloration of the wall, reflecting transmural inflammation and necrosis (Fig. 16.6C). The inflammatory process may involve the entire appendix, or only a part; if only one area is involved, it is most often the tip.[28]

The histologic findings in acute appendicitis are also very variable, ranging from minimal focal inflammation to total necrosis of the appendiceal wall. The degree of abnormality is at least partially dependent on the interval between the onset of symptoms and operation. In early lesions, neutrophils appear at the base of the crypts, often adjacent to a small defect in the epithelium (Fig. 16.7A). After this inflammatory process reaches the submucosa, it spreads quickly to the remaining appendix. Historically, neutrophilic infiltration of the appendiceal wall, often with associated mucosal ulceration, neutrophilic inflammation, and crypt abscesses, has been termed

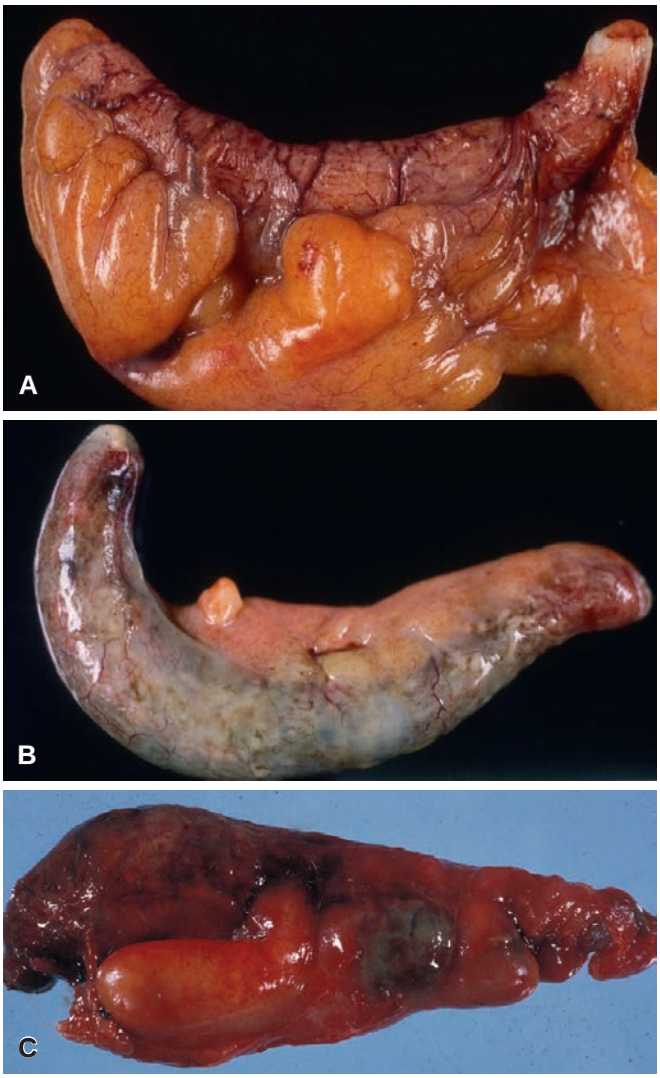

Figure 16.6 **A,** The earliest gross findings in acute appendicitis consist of dullness of the serosal surface, with injection of the serosal vessels. **B,** As the inflammatory process progresses, there is variably present fibrinous or purulent exudates along with hyperemia or hemorrhage. **C,** *Green*, *black*, or *purple* discoloration of the appendiceal wall indicates gangrene. (Photographs courtesy of Dr. George F. Gray, Jr.)

"acute suppurative appendicitis" (Fig. 16.7B and C).[28,31,43,44] Eosinophils may also be present within the exudate, the significance of which is unclear.[28] Thrombosed vessels are seen in approximately one-fourth of cases.[45] Gangrenous appendicitis features transmural inflammation and necrosis (Fig. 16.7D), often involving the mesoappendix as well, and perforation will occur without treatment. Fecaliths are frequently seen in cases of acute appendicitis but are also common in incidentally removed appendices.[46] Serosal vessels may be packed with lymphocytes, a change that may mimic chronic lymphocytic leukemia (Fig. 16.8).[47]

Controversy remains regarding the so-called "minimal diagnostic criteria" for acute nonspecific appendicitis. Some authorities maintain that inflammation limited to the mucosa and submucosa of the appendix alone are not adequate to explain the patient's symptoms and that the diagnosis of acute appendicitis requires the finding of neutrophils within the wall.[28] Others believe that early acute appendicitis does consist of mucosal neutrophilic inflammation and mucosal ulceration and that more impressive inflammation is often found

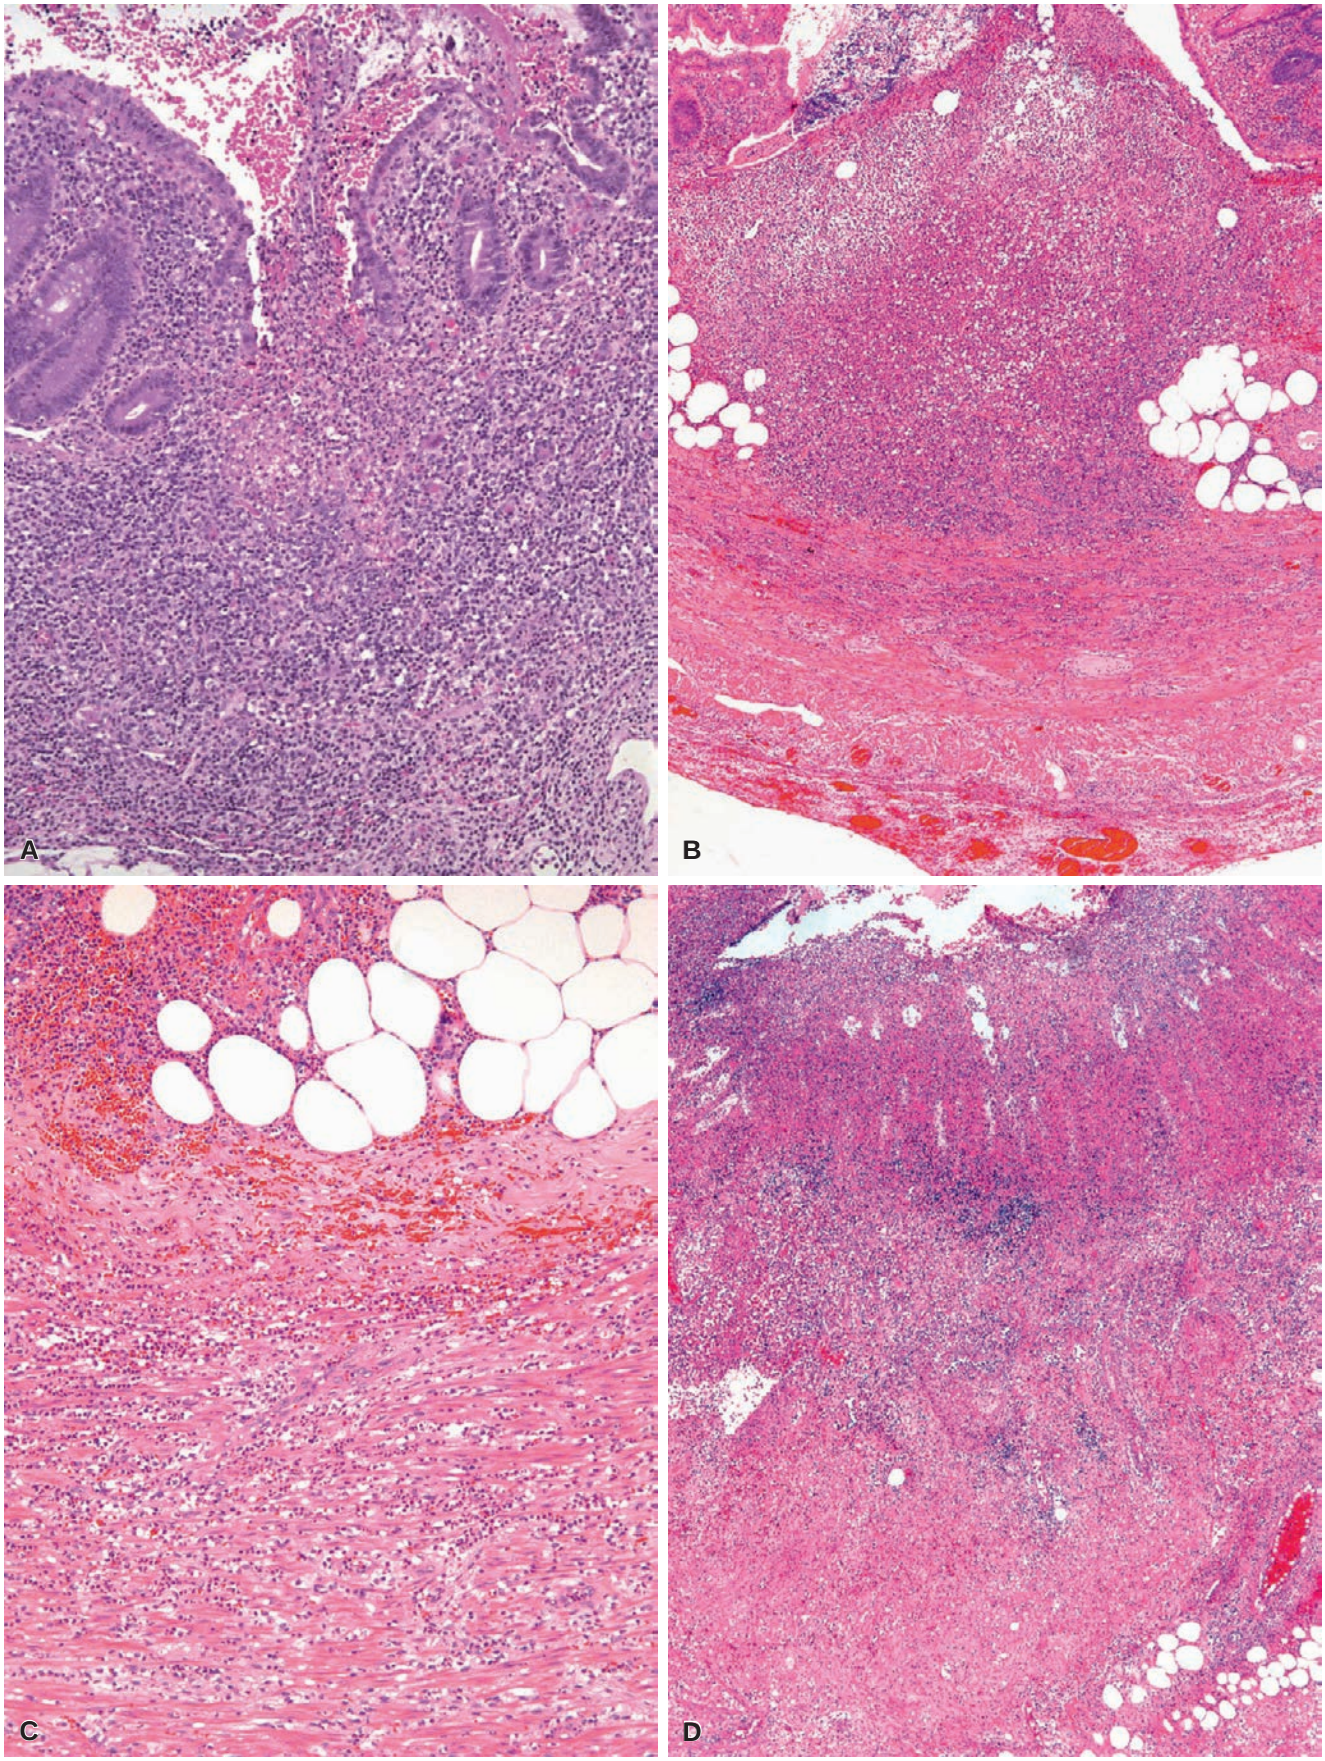

Figure 16.7 **A,** Early acute appendicitis with acute inflammation arising from a small mucosal defect. **B** and **C,** A more advanced case with massive acute inflammation extending into the muscular wall of the appendix, with extensive ulceration; residual mucosa is seen at the edges in **B**. **D,** Transmural inflammation and necrosis in gangrenous appendicitis.

if the specimen is extensively sampled. Although patients with symptoms of acute appendicitis may show only mucosal or submucosal inflammation even after extensive sampling, fecaliths and some enteric infections can also produce such changes. Clusters of neutrophils in the lumen should stimulate a search for evidence of mucosal or mural inflammation, but they are not diagnostic of acute appendicitis by themselves.

Some cases of appendicitis feature a prominent histiocytic component with clusters of xanthoma-like cells, which may be referred to as *xanthogranulomatous appendicitis*.[48] This pattern is regarded as an unusual healing pattern of appendicitis, often in protracted cases. It is associated with delayed or interval appendectomy (Fig. 16.9A), many of which may show granulomatous as well as xanthogranulomatous inflammation, in addition to transmural lymphoid aggregates and fibrosis that may mimic Crohn disease (Fig. 16.9B).[49]

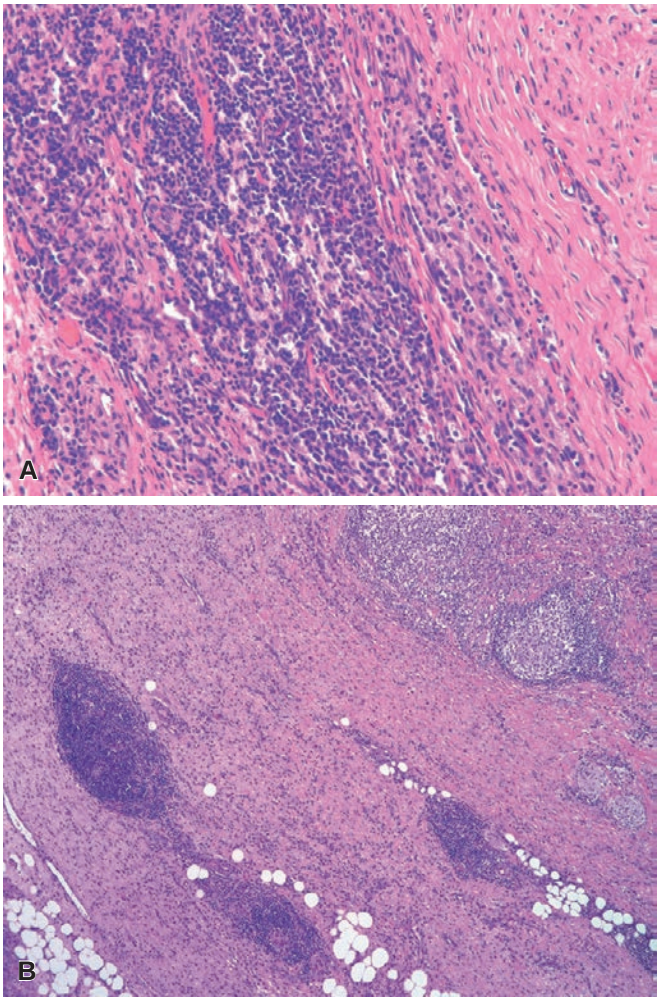

Figure 16.9 **A,** Interval appendectomy specimens often show lymphohistiocytic inflammation and transmural lymphoid aggregates that may mimic Crohn disease **(B)**. (Courtesy of Dr. Joel K. Greenson.)

Complications

The most common complication of acute appendicitis is perforation, which may lead to diffuse peritonitis or to the formation of a periappendiceal abscess or fibrous induration ("ligneous peri-typhlitis").[50,51] This latter condition, which may simulate a neoplasm clinically, is usually located in the right iliac fossa lateral to the cecum, but can occur in other sites depending on the original location of the appendix. Abscesses may perforate into the cecum, ileum, or rectum or even open onto the skin surface and form a fistulous tract. Another serious complication is the spread of the inflammation via the ileocolic, upper mesenteric, and portal veins to the liver, with formation of hepatic abscesses and occasionally complicated by septic thrombophlebitis.[52] Historically, appendicitis with perforation was also believed to be a risk factor for infertility in women because of obstruction of the fallopian tubes[53]; however, more recent studies have not provided substantial evidence that this is the case.[54]

The potential role of enteric bacteria in the development and the complications of acute appendicitis has been extensively debated.[31,55,56] Bacteriologic studies, most often performed using microbiologic cultures, have revealed a wide variety of aerobic and anaerobic bacteria, most commonly *Bacteroides* species,[55,57] but no causative role has ever been proven. It is, however, important to be aware of the variety of bacteria that can be present within an inflamed appendix and to select appropriately broad antibiotics if wound infection or other sequelae occur.[43,55]

Treatment

In 1886, Reginald H. Fitz (arguably the first American surgical pathologist) demonstrated that the appendix was the origin of the mysterious and often fatal inflammation of the right iliac fossa known at the time as *perityphlitis*.[58] Three years later, McBurney emphasized the importance of accurate early diagnosis of acute appendicitis and prompt surgical intervention. By 1900, the mortality rate had already fallen to 35%.[59,60] During the next three decades, it was further reduced to 5% as a result of better awareness on the part of the patient and the physician concerning the symptoms and signs of acute appendicitis, the need for early surgical intervention, and the dangers of catharsis and morphine for undiagnosed abdominal pain.

In the ensuing years, a combination of improved surgical technique, better preoperative and postoperative care, advances in anesthesiology, and the development of effective antibacterial agents have led to further declines in mortality to a fraction of 1%. Laparoscopic appendectomy is now considered the treatment of choice for acute appendicitis, even in complicated cases.[61]

Periappendicitis

Periappendicitis refers to acute or chronic inflammation of the appendiceal serosa.[28,31,43,44,62] It is almost always present in the

advanced stages of appendicitis with transmural inflammation, but it also occurs in the absence of primary appendiceal inflammation, secondary to spread of inflammation from another site (such as the female adnexa). Periappendicitis may be accompanied by a fibrinous exudate and/or adhesions. In the presence of periappendicitis, evidence of acute inflammation elsewhere within the appendix itself or an appendiceal diverticulum should be thoroughly sought, usually by submitting the entire appendix; if none is found, the diagnosis given should be that of periappendicitis rather than appendicitis, suggesting an extra-appendicular inflammatory process. In order not to overdiagnose this condition, however, it should be remembered that surgical manipulation may induce a neutrophilic infiltrate in the serosa.

The Negative Appendectomy

A certain percentage of appendices removed for signs and symptoms of acute appendicitis will be histologically normal. The rate of negative appendectomy specimens has declined significantly in recent years, most likely due to better diagnostic modalities, and is currently approximated at 8%–9%.[63] When initial sections are unremarkable, submission of the remainder of the appendix is recommended so that focal lesions are not overlooked. In many patients with grossly and histologically normal appendices, symptoms still resolve following appendectomy.[43] Some have suggested that these cases can be explained by expression of inflammatory mediators (such as cyclooxygenase 1 and 2, and prostaglandin E)[64] at the molecular level, but this remains a controversial proposition.

Stump Appendicitis

Stump appendicitis is defined as residual or progressive acute inflammation in the postresection appendiceal stump; contributing factors remain poorly elucidated.[65] It is an uncommon complication of appendectomy, and diagnosis is often delayed due to its rarity.[65,66] Patients typically present with nonspecific findings, including abdominal pain, nausea and vomiting, and fever, and imaging studies may reveal a distended appendiceal stump. Complications include stump necrosis and perforation. The histologic findings have not been well studied but appear to be similar to those of acute appendicitis. Stump appendicitis is likely under-reported and should be considered in patients with postappendectomy abdominal pain.

Chronic Appendicitis

The existence of primary chronic appendicitis as a pathologic or clinical entity has been greatly disputed, with putative symptoms and signs that are as vague and shadowy as the pathology. Normally, there may be collections of lymphocytes in the muscular wall of the appendix, as well as rare plasma cells or eosinophils in the mucosa, and these findings should not be diagnosed as chronic appendicitis. Fibrous obliteration of the appendiceal tip, whatever its pathogenesis, should not be regarded as chronic appendicitis either. Some patients may suffer recurrent bouts of acute appendicitis prior to resection, leading to chronic symptoms, and occasionally pathologists are confronted with an appendix containing a destructive mononuclear or plasmacytic infiltrate with associated fibrosis. These changes most likely represent resolving or ongoing acute appendicitis and are also seen in the context of delayed or interval appendectomy (see earlier). Most authorities agree that, although there are numerous chronic inflammatory disorders of the appendix (e.g. infection, involvement by chronic inflammatory bowel disease), "primary chronic appendicitis" is not an entity that should be clinically or pathologically recognized.[28,43]

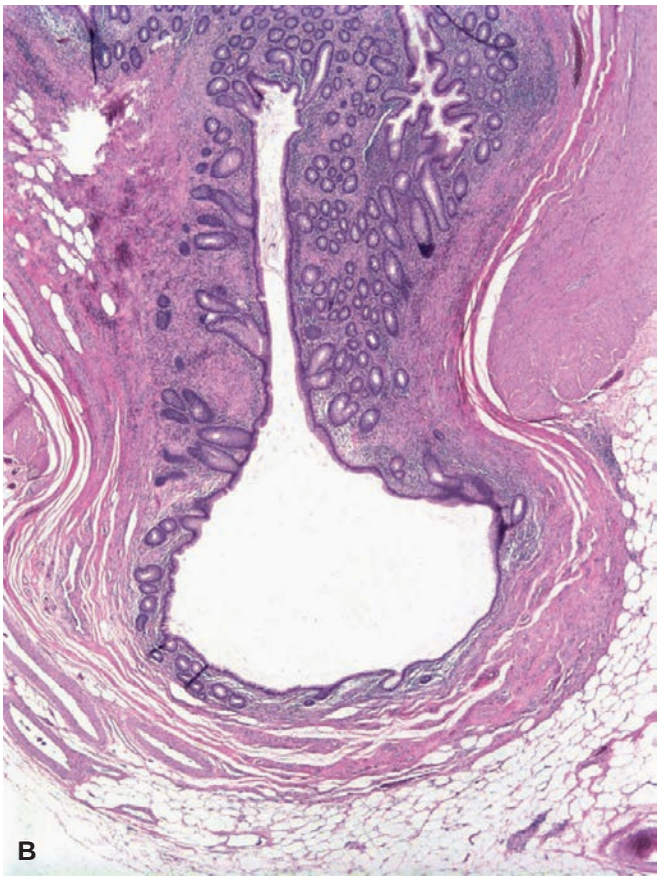
Other Inflammatory Processes

Diverticular Disease

Diverticula of the appendix may be congenital or acquired. Congenital diverticula are rare, with a reported incidence of 0.014%.[14,67] They are typically solitary and located on the antimesenteric border of the appendix.[14] They can be recognized by the presence of the muscularis propria.

Acquired appendiceal diverticula are more common, with an incidence varying between 0.2% and 1.7%.[14] They are usually multiple (Fig. 16.10A) and arise in a weak area of the appendiceal wall likely as a result of increased intraluminal pressure (similar to their colonic counterparts). Diverticulitis may occur, resulting in a clinical picture indistinguishable from that of acute appendicitis, although patients are often older at presentation.[68] The pathogenesis is likely related to obstruction and increased intraluminal pressure, a theory that is supported by the association of appendiceal diverticula with both neoplasms and cystic fibrosis.[69–72] For this reason, some authorities recommend submission of the entire appendix in specimens with diverticula, so that small neoplasms are not overlooked.

Appendiceal diverticula can occur on the mesenteric or antimesenteric aspect of the appendix and are frequently found at the tip.[14,73] Histologically, they consist of mucosa and submucosa herniating through the muscularis propria (Fig. 16.10B), with associated acute inflammation in cases of diverticulitis. When perforated, the extrusion of mucus can mimic low-grade appendiceal mucinous neoplasms (LAMNs; see Fig. 16.10C), although neoplastic epithelium should be absent in cases of appendiceal diverticula with extruded mucin.[74] Appendiceal diverticula are probably markedly underreported due to their small size and the fact that they are often obliterated by inflammation at the time of resection.[68]



Chronic Idiopathic Inflammatory Bowel Disease

Ulcerative colitis involves the appendix in many cases, often in the context of contiguous cecal involvement (Fig. 16.11).[75] The concept of the appendiceal "skip lesion" in ulcerative colitis is now well established, however, defined as patchy involvement of the appendix and peri-appendiceal orifice in patients with distal disease that spares the intervening segment of colon.[48,76,77] Clinically, these patients behave similarly to those without appendiceal skip lesions, and thus the presence of skip lesions without contiguous cecal involvement should not be regarded as evidence of Crohn disease (see Chapter 17).

The appendix is involved in approximately 40% of patients who undergo ileocecal resection for *Crohn disease*.[78] Histologic features are similar to Crohn disease elsewhere in the bowel and include transmural inflammation with lymphoid aggregates, crypt architectural distortion, mural fibrosis, neural hyperplasia, and granulomas (Fig. 16.12). However, only a minority of patients with isolated granulomatous appendicitis go on to develop Crohn disease elsewhere; these cases are usually attributable to infection (e.g. *Yersinia*, *Mycobacteria* spp.), interval appendectomy (see earlier), or sarcoidosis.[48,49,79–81] It is often impossible to distinguish between Crohn disease and other causes of granulomatous appendicitis, particularly *Yersinia* and mycobacterial infection, on histologic grounds alone, and correlation with cultures, molecular assays, imaging studies, and ultimately close clinical follow-up for additional manifestations of Crohn disease may be necessary.[48,80,81]

Sarcoidosis can involve virtually any organ of the body but is responsible for only a very small minority of the reported cases of granulomatous inflammation of the appendix. As in other organs,

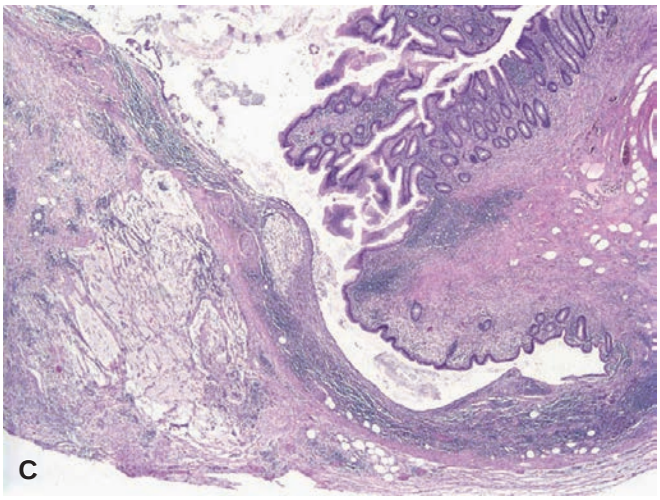


Figure 16.10 **A,** Appendiceal diverticula, at the tip and along the side of an appendectomy specimen. **B,** The mucosa and submucosa herniate through the muscularis propria, similar to colonic diverticula. **C,** Ruptured appendiceal diverticula can mimic low-grade mucinous neoplasms; note the lack of neoplastic epithelium.

(Photographs courtesy of Dr. Henry Appelman.)

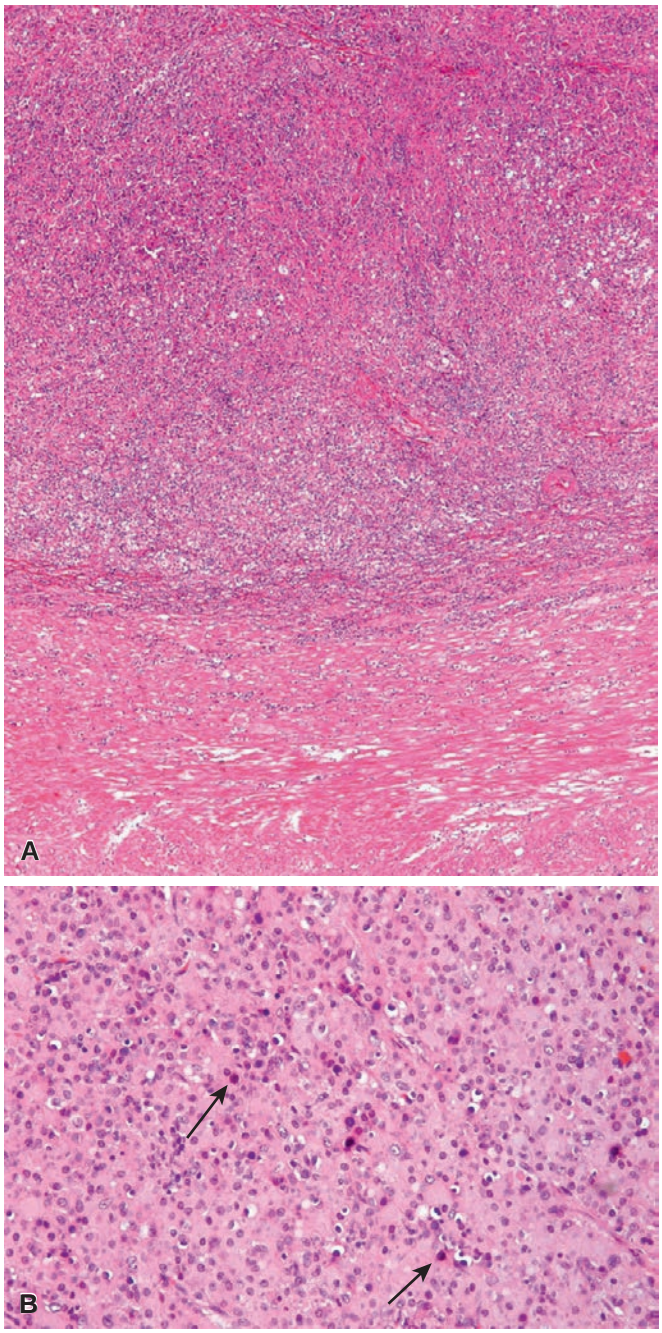

Figure 16.13 A, Malakoplakia is composed of an infiltrate of macrophages that in this case destroys the normal appendiceal architecture. **B,** Michaelis–Gutmann bodies are characteristic *(arrows)*.

sarcoidosis is a diagnosis of exclusion and should be diagnosed only after other causes of granulomatous appendicitis have been excluded. Extra-appendiceal disease is most helpful in confirming the diagnosis.[48,82,83]

Several types of **vasculitis** have been reported in the appendix; although some cases are organ-limited, many are associated with systemic diseases such as rheumatoid arthritis, polyarteritis nodosa, lupus, and Henoch–Schönlein purpura.[84–86] Enterocolic lymphocytic phlebitis has also been reported to involve the appendix.[87]

Although the appendix is a rare site for **malakoplakia**, occurrence there is well documented.[88,89] Malakoplakia in the GI tract is often associated with underlying malignancy or some other form of immunocompromise. As in other sites, this lesion consists of soft yellow-white plaques composed of an infiltrate of macrophages with granular cytoplasm and associated Michaelis–Gutmann bodies, which are virtually diagnostic (Fig. 16.13). These bodies stain positively with iron and calcium stains. There is usually an attendant mixed inflammatory infiltrate, and special stains for microorganisms are

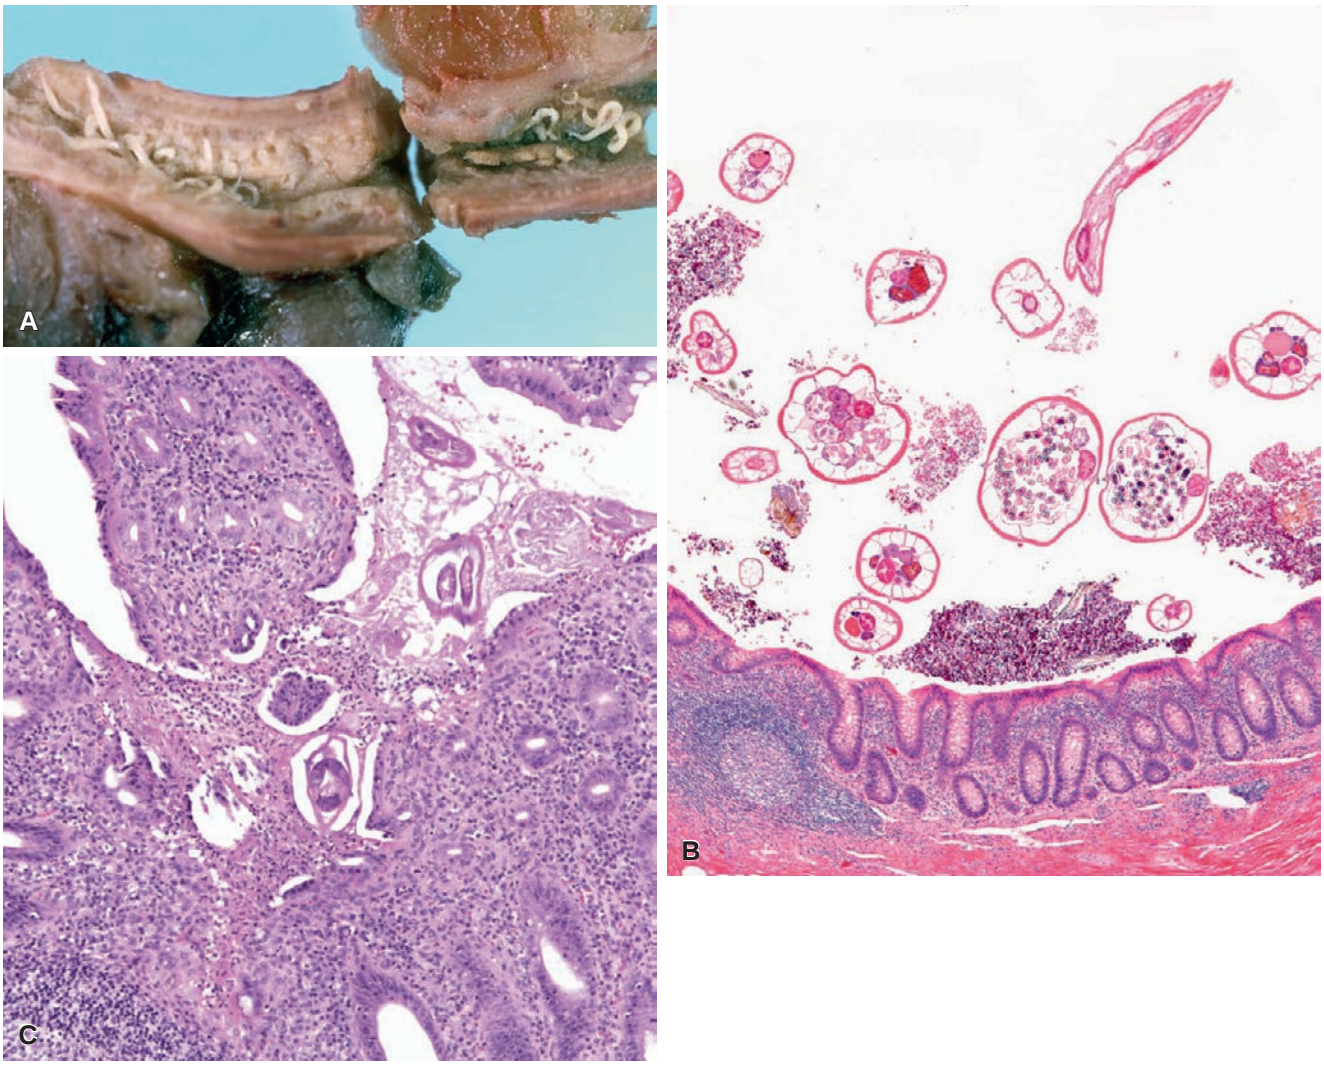

Figure 16.14 **A,** A resected appendix containing numerous pinworms. **B,** Typical appearance of pinworms within the appendiceal lumen, with eosinophilic cuticle and prominent lateral ala. **C,** Rarely, pinworms may invade the appendiceal mucosa. (**A,** Courtesy Dr. George F. Gray, Jr.)

typically negative. Many authorities believe that this unusual lesion represents some type of occult bacterial infection, and it has been postulated that Michaelis–Gutmann bodies represent mineralized portions of bacterial capsule. Several bacterial species have been detected within the lesions of malakoplakia using electron microscopy, microbiologic techniques, and PCR, including *Escherichia coli*, *Yersinia*, *Klebsiella*, *Aeromonas*, and *Rhodococcus* species.

Rosai–Dorfman disease can exceptionally involve the appendix as an isolated event, or in association with involvement of other portions of the gastrointestinal tract.[90]

Intussusception (invagination) of the appendix into the cecal lumen may develop spontaneously; the *intussusceptum* may be composed of the entire appendix or, more commonly, of only the base.[91] The underlying cause is often lymphoid hyperplasia, but intussusception has also been associated with tumors, polyps, infections, and endometriosis of the appendix.[91,92]

Parasitic Infections

Enterobius vermicularis (also known as pinworms or oxyuriasis) is found in 0.6%–13% of resected appendices (Fig. 16.14A and B).[43,93] Children and adolescents have the highest prevalence of infection.[93,94] Pinworms are more commonly seen in otherwise normal appendices, and although invasion of the mucosa has been rarely documented (Fig. 16.14C), the ability of the parasite to cause mucosal damage and appendiceal inflammation remains controversial.[93,95] Both worms and eggs can also fill and obstruct the lumen, causing inflammation similar to that caused by fecaliths.[43,93,94] *Strongyloidiasis stercoralis* in the appendix is often characterized by a diffuse eosinophilic and/or mixed eosinophilic and neutrophilic infiltrate or by the presence of granulomas with necrotic centers and an associated eosinophilic infiltrate.[31,96] The parasites are found only exceptionally within the granulomas, but characteristic larvae and worms with sharply pointed tails may be found within the appendiceal crypts (Fig. 16.15), similar to the remainder of the GI tract. *Schistosomiasis* can involve the appendix, but this is rare even in countries where infection is endemic. Arguments similar to those regarding pinworms and their ability to cause appendicitis have occurred pertaining to schistosomiasis, but it does appear that schistosomiasis causes appendicitis in rare cases, either by a granulomatous response to ova or by marked fibrosis leading to luminal obstruction.[31,97,98] Findings include calcified eggs in the appendix, with associated fibrosis

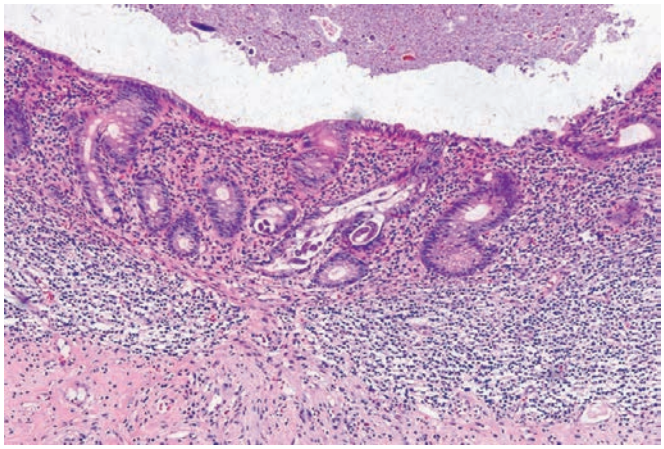

Figure 16.15 Larvae of *Strongyloides stercoralis* within the crypt epithelial cells of the appendix. (Courtesy Dr. Dennis Baroni-Cruz.)

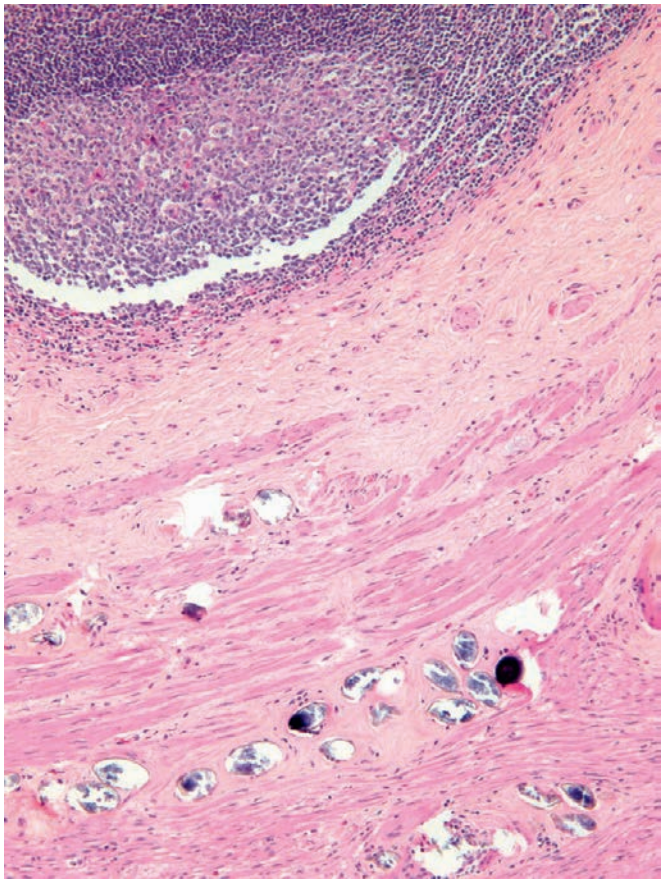

Figure 16.16 Appendiceal schistosomiasis featuring numerous calcified eggs with associated fibrosis within the wall of the appendix. (Courtesy Dr. Joseph Misdraji.)

(Fig. 16.16). Occasionally, appendices contain transmural inflammation that is rich in eosinophils, with granulomatous inflammation in response to the ova. Other parasitic infections that rarely affect that appendix include *Entamoeba histolytica*, which often represents extension from an infection of the right colon and must be distinguished from nonpathogenic amoeba[43,99]; *Cryptosporidium*, most often seen in immunocompromised patients[100]; and nematodes such as *Ascaris lumbricoides* (roundworms)[43,101] and *Trichuris* species (whipworms).[102]

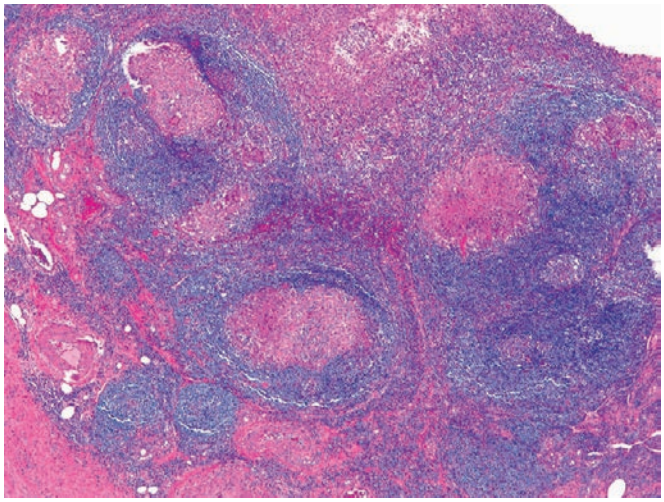

Figure 16.17 *Yersinia* infection of the appendix characteristically features epithelioid granulomas with prominent associated lymphoid tissue.

Bacterial Infections

Yersinia infection (caused by *Y. enterocolitica* or *Y. pseudotuberculosis*) is a well-known cause of granulomatous appendicitis. Characteristic histologic features, including epithelioid granulomas with associated prominent lymphoid tissue (Fig. 16.17), mural fibrosis, and transmural lymphoid aggregates, may be close mimics of Crohn disease. Microbiologic cultures or molecular testing may be necessary to confirm the diagnosis.[81,103,104] *Actinomycosis (Actinomyces israelii)* may involve the appendix and can produce a mixed suppurative and granulomatous inflammatory process (Fig. 16.18) with marked associated fibrosis that may simulate a tumor.[105,106] Because *Actinomyces* are gut commensals that are commonly found in the lumen of the appendix incidentally, it is necessary to identify organisms in the wall of the appendix with an appropriate associated inflammatory response to make the diagnosis, so that long-term antibiotic therapy is not given inappropriately.[43] Although the ileocecum is involved in almost half of cases of intra-abdominal *tuberculosis*, the appendix is affected in only about 1%.[107] Characteristic findings include caseating granulomas with mucosal ulceration.[108] Appendiceal tuberculosis must be differentiated from other granulomatous infections as well as Crohn disease. Atypical mycobacteria rarely cause appendicitis and occurs almost exclusively in immunocompromised patients.[31] Other bacterial infections that rarely involve the appendix include enteric organisms such as *Salmonella*, *Shigella*, and *Campylobacter* species.[31] Appendiceal involvement by *Clostridium difficile* is rare, but the macroscopic and histologic features are identical to those seen in *C. difficile*-associated colitis (Fig. 16.19).[109]

Viral Infections

Adenovirus is one of the more common viruses found in the appendix, causing lymphoid hyperplasia and subsequent intussusception (Fig. 16.20; see also Fig. 16.2).[110,111] *Measles* can be accompanied by appendicitis during its prodromal stage. Microscopic examination typically shows marked lymphoid hyperplasia with the presence of multinucleated giant cells of the Warthin–Finkeldey type, similar to those seen in the tonsil (Fig. 16.21)[112]; as infection progresses, a suppurative component may develop. An astute pathologist could thus tell the patient's physician that the child is about to break out into the characteristic rash of measles. *Infectious mononucleosis* (Epstein–Barr virus) can also be accompanied by changes similar to those seen in lymph nodes, including marked lymphoid hyperplasia and marked expansion of the lamina propria by a mixed proliferation

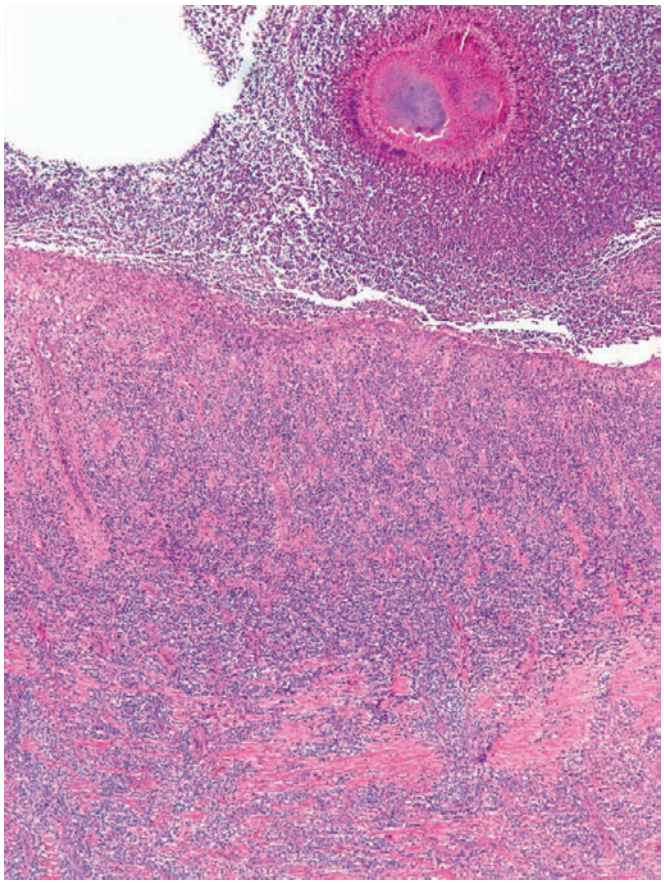

Figure 16.18 Actinomycosis of the appendix, featuring mucosal ulceration and mural fibrosis, with overlying clusters of bacteria with associated acute inflammation and Splendore–Hoeppli protein.

of small lymphoid cells and immunoblasts, some of the latter resembling Reed–Sternberg cells.[113] *Cytomegalovirus (CMV)* appendicitis (Fig. 16.22) has been reported in immunocompromised patients, including HIV-infected and organ transplant patients.[114,115]

Fungal Infections

Appendiceal fungal infections are very rare and are typically a manifestation of disseminated disease in immunocompromised patients. *Candida* spp., *Aspergillus* spp., *Mucor* spp., and *Histoplasma capsulatum* have been reported (Fig. 16.23).[116–118]

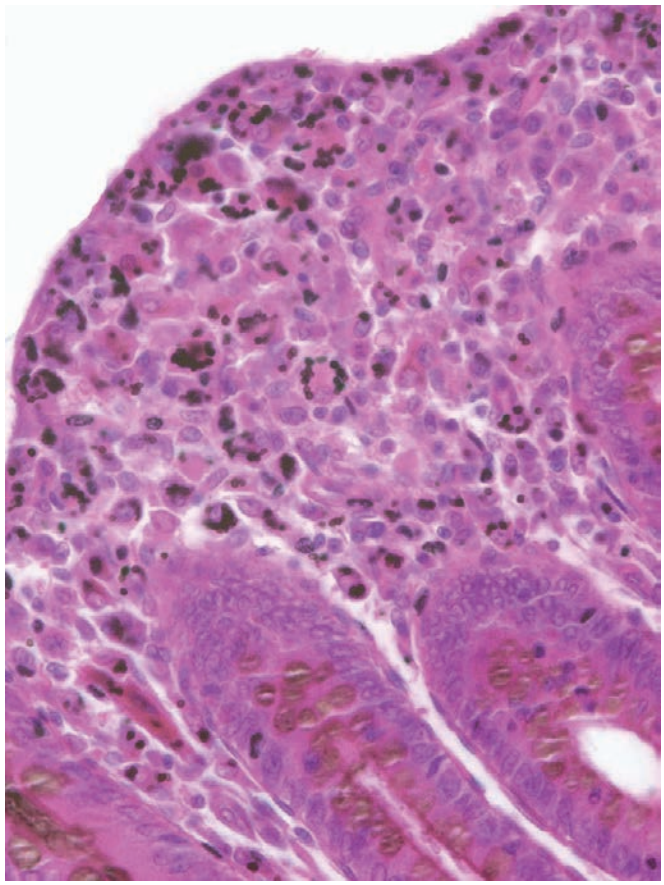

Figure 16.23 H&E/methenamine silver stain highlights *Histoplasma* within macrophages in the appendiceal mucosa. The patient was immunocompromised and died of disseminated histoplasmosis.

Tumors

Nonmucinous Tumors

Serrated Lesions

A variety of serrated lesions occur in the appendix, similar to those seen in the colon. In the appendix, they are often found incidentally in patients who undergo appendectomy for other reasons.

Hyperplastic polyps in the appendix are relatively rare. They are typically localized sessile nodules that do not involve the entire luminal circumference. The glands are elongated and serrated, most notably towards the surface, and are composed of a mixture of goblet cells and non-goblet columnar cells with microvesicles of cytoplasmic mucin, reminiscent of microvesicular hyperplastic polyps in the colorectum (Fig. 16.24).[119–121] A diffuse, nonpolypoid *mucosal hyperplasia* of the appendix has also been described, sometimes in association with inflamed appendices, which can involve a large portion of the surface area of the mucosa. The histologic features are similar to hyperplastic polyps, but the lesion is diffuse rather than localized.[119,121] Because diffuse mucosal hyperplasia was described long before the lesion now known as sessile serrated polyp/adenoma (SSP/A), some authorities do not recognize diffuse mucosal hyperplasia as an entity, and regard these lesions as sessile serrated adenomas/polyps.[120] Proponents of the entity, however, note that the architectural features that distinguish SSP/A (see later) are absent in diffuse mucosal hyperplasia, and thus regard it as an entirely benign lesion that is distinct from SSP/A and analogous to a diffuse form of hyperplastic polyp.[119]

SSPs/As of the appendix are larger than hyperplastic polyps and may appear as sessile polyps but often circumferentially involve the mucosa (Fig. 16.25A). Similar to the colon, they contain elongated

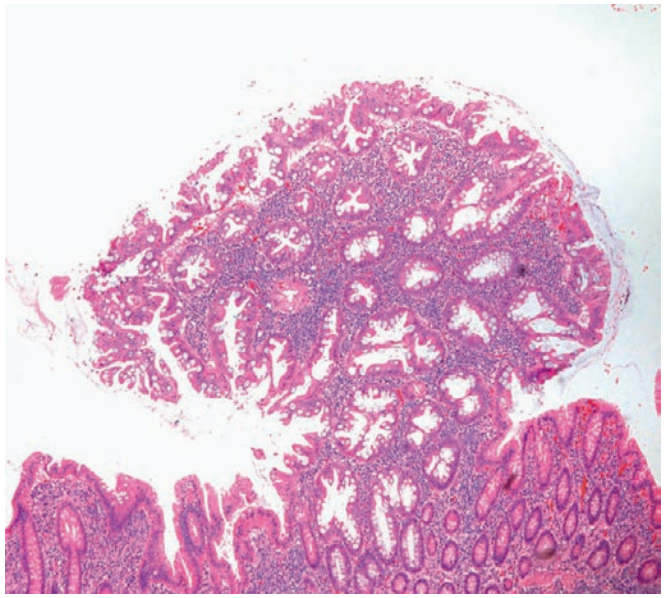

Figure 16.24 Hyperplastic polyp of the appendix, similar to hyperplastic polyps of the colon and rectum.

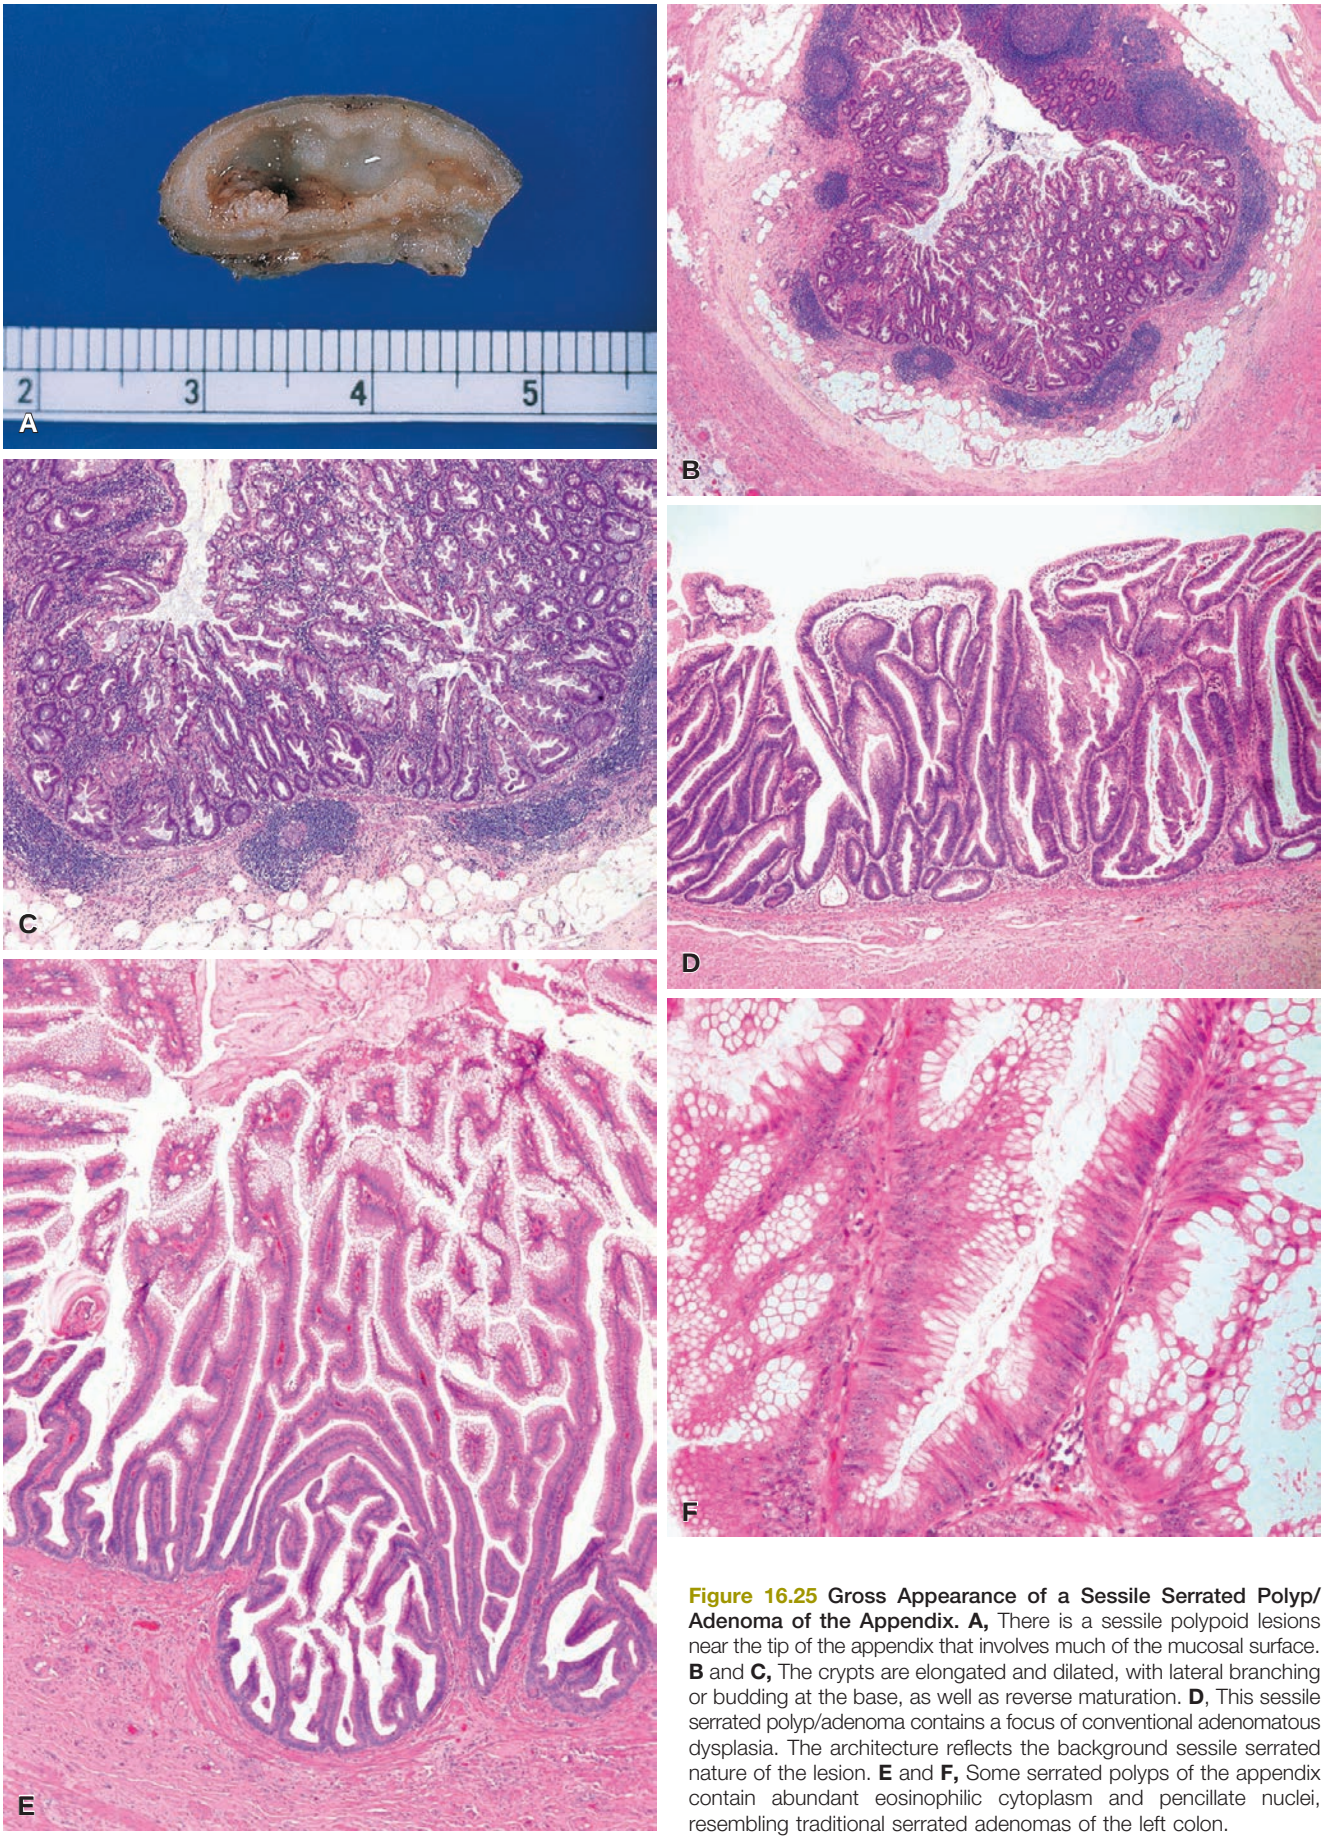

Figure 16.25 Gross Appearance of a Sessile Serrated Polyp/Adenoma of the Appendix. A, There is a sessile polypoid lesions near the tip of the appendix that involves much of the mucosal surface. **B** and **C,** The crypts are elongated and dilated, with lateral branching or budding at the base, as well as reverse maturation. **D**, This sessile serrated polyp/adenoma contains a focus of conventional adenomatous dysplasia. The architecture reflects the background sessile serrated nature of the lesion. **E** and **F,** Some serrated polyps of the appendix contain abundant eosinophilic cytoplasm and pencillate nuclei, resembling traditional serrated adenomas of the left colon.

and/or dilated crypts with a serrated appearance, lateral branching or budding of the glands at the base of the lesion, and goblet or foveolar-type cells at the base ("reverse maturation"; Figs. 16.25B and C).[120,122] Sessile serrated polyps frequently contain conventional-type (adenomatous or intestinal; Fig. 16.25D) or serrated dysplasia (see Chapter 17)[120,122,123]; historically, those that contain adenomatous dysplasia have also been referred to as "mixed hyperplastic/adenomatous" polyps, but the term "SSP/A with dysplasia" is now preferred by many, similar to the terminology used in the colon. Some serrated polyps of the appendix are composed of crypts lined by cells with abundant eosinophilic cytoplasm and pencillate nuclei, resembling traditional serrated adenomas of the left colon (Figs. 16.25E and F)[122,123]; these have also been referred to simply as "serrated adenomas" of the appendix.[122]

MUC 6 is positive in virtually all SSP/A, and Ki-67 immunostaining shows irregular, asymmetrical labeling of crypt epithelial cells, similar to their counterparts in the colon.[120,122] They also display partial loss of DNA repair protein expression, typically in the superficial epithelium, but this reflects the nonproliferative nature of the epithelium and is not associated with microsatellite instability.[122] Staining is preserved at the crypt bases, and the lesions are mismatch proficient by PCR. Mutually exclusive *BRAF* and *KRAS* mutations have been detected in a significant number of appendiceal serrated lesions, although the percentages vary between studies. As *BRAF* mutations are far more common and *KRAS* mutations are less frequent among similar-appearing colonic polyps, this is evidence that the molecular alterations underlying appendiceal serrated lesions are different from their colonic counterparts.[122,123]

Sessile serrated polyps/adenomas are distinguished from hyperplastic polyps by the presence of the previously mentioned features, including dilated crypts, serrations that extend the full length of the gland, lateral branching/budding of glands at the base, and "reverse maturation." However, there may be significant morphologic overlap. For this reason, as well as the challenges in terminology that plague any discussion of serrated neoplasia, and the fact that even nondysplastic serrated appendiceal lesions may harbor *BRAF* or *KRAS* mutations, some authors have suggested simply classifying appendiceal serrated lesions as either nondysplastic serrated polyps or dysplastic serrated polyps.[122,123]

The relationship between serrated lesions of the appendix and colorectal carcinoma remains unclear. Although earlier literature suggested a relationship between serrated appendiceal lesions and colorectal carcinoma, more recent data (also noted previously) show that serrated appendiceal lesions may in fact be unrelated to the "serrated pathway" of neoplasia in the colon.[122,123] Invasive adenocarcinomas of the appendix occasionally arise in association with serrated lesions, and these are discussed further below in the section on nonmucinous adenocarcinoma.

Intestinal-Type Adenoma

Intestinal-type adenomas, although common in the colon, are rare in the appendix, and are usually found after appendectomy is performed for other reasons. They may occur more frequently in patients with familial adenomatous polyposis.[119,121,124] Intestinal-type adenomas form polypoid projections that are sharply demarcated from adjacent normal-appearing mucosa, and in contrast to SSP/A and low-grade mucinous neoplasms, do not show circumferential involvement of the mucosa. They contain crowded, tubular crypts lined by dysplastic epithelial cells with elongated, hyperchromatic nuclei, similar to their colonic counterparts (Fig. 16.26A). Intestinal-type adenomas of the appendix have an apparently low risk of developing adenocarcinoma.[125] Adenomas involving the proximal appendix often represent extension of adenomas of the right colon into the appendiceal orifice (Fig. 16.26B).

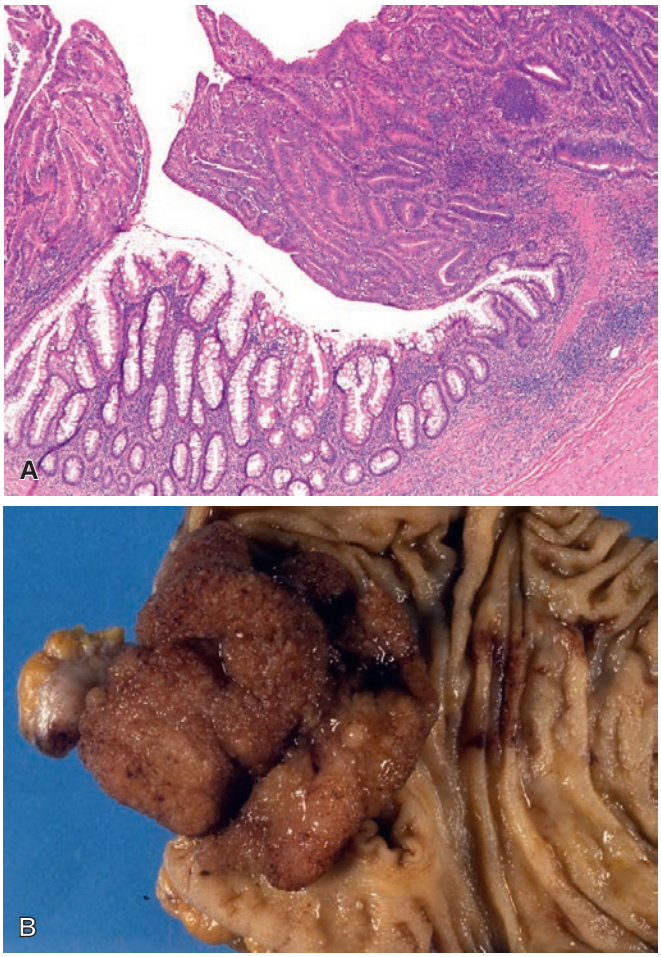

Figure 16.26 **A,** This tubular adenoma of the appendix is sharply demarcated from the surrounding mucosa and resembles a tubular adenoma of the colorectum. **B,** This large adenomatous polyp from the cecum extends to involve the appendiceal orifice and proximal appendix.

Nonmucinous Adenocarcinoma

Primary nonmucinous adenocarcinoma of the appendix is rare,[119,126] and most arise from either serrated lesions or goblet cell carcinoid (see later). The symptoms often resemble acute appendicitis, and inflammation is frequently found in addition to the carcinoma.[119,127] Most nonmucinous adenocarcinomas are asymptomatic until they penetrate the visceral peritoneum and cause abdominal pain, so they tend to be locally advanced at the time of diagnosis.[125]

These tumors can be located in any part of the appendix, although the proximal third is more commonly involved than the distal appendix.[119,128] Adenocarcinomas at the base of the appendix should be distinguished from cecal adenocarcinomas that extend into the proximal appendix.[119] The microscopic appearance is essentially the same as that of colorectal adenocarcinoma and is indeed referred to as colonic type (Fig. 16.27).[128,129] Adenocarcinomas associated with serrated appendiceal lesions show a destructive growth pattern with infiltrative glands that may have a tubular or serrated appearance.[125] Some tumors contain abundant extracellular mucin, but they are typically more cellular and show high-grade cytologic features with desmoplasia, beyond the spectrum of changes seen in appendiceal mucinous neoplasms with associated pseudomyxoma peritonei. Right hemicolectomy is the treatment of choice for nonmucinous adenocarcinomas. These tumors have a relatively poor prognosis,

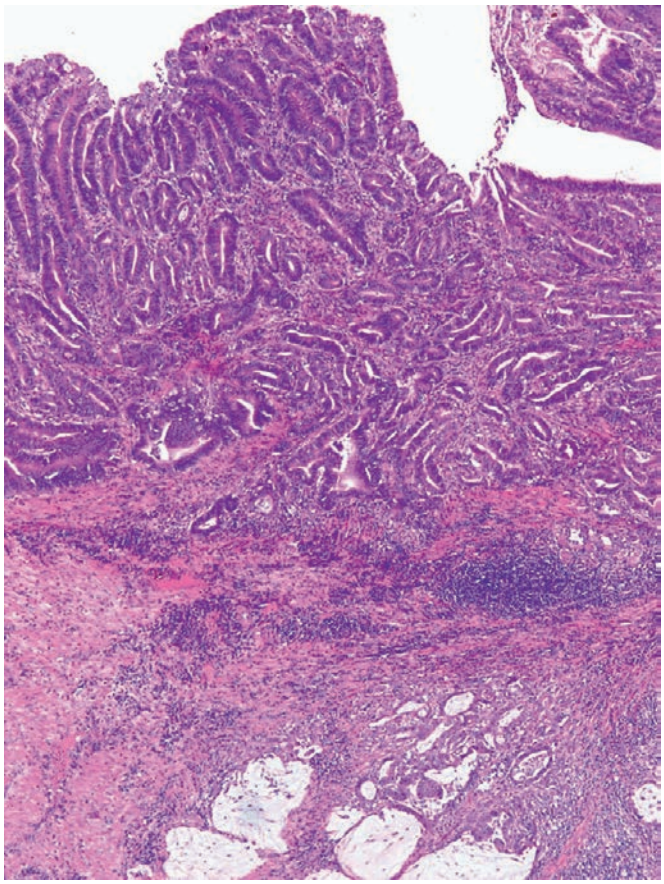

Figure 16.27 Nonmucinous adenocarcinoma of the appendix is histologically similar to intestinal-type colorectal adenocarcinoma. This lesion arises in a background of adenomatous polyp and extends into the wall.

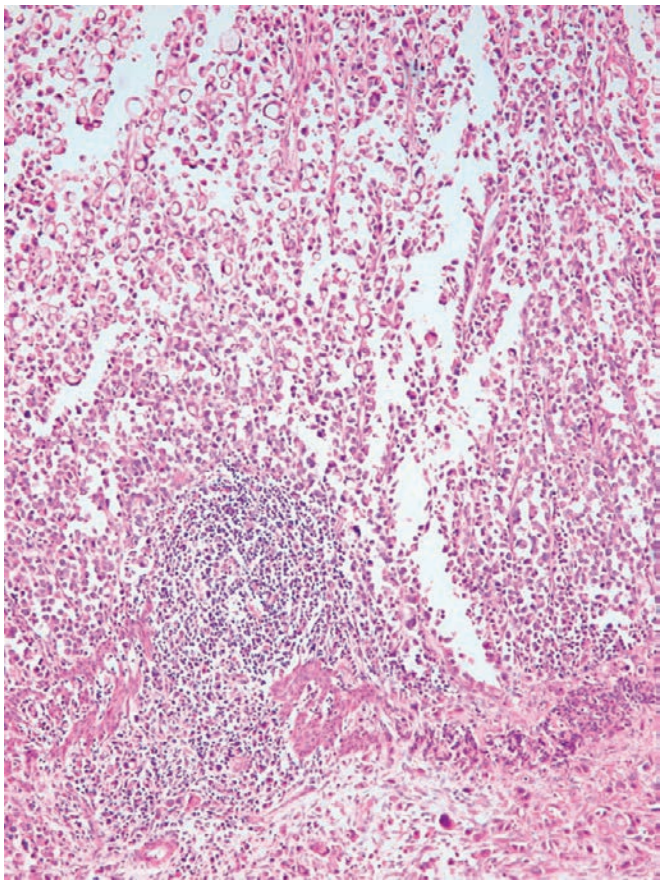

Figure 16.28 Primary signet ring cell carcinoma of the appendix.

with a 5-year survival of approximately 55%.[130] Distinction from mucinous adenocarcinomas of the appendix is important, as nonmucinous carcinomas are unlikely to respond to therapeutic regimens used for mucinous adenocarcinomas, and patients with mucinous adenocarcinoma typically have a better prognosis.[131]

An exceptionally rare type of primary appendiceal tumor is *signet ring cell carcinoma* (Fig. 16.28).[119,129] These tumors are morphologically similar to signet ring cell carcinomas at other sites and must be distinguished from metastases from the stomach or breast, and from goblet cell carcinoid tumors (see the following discussion), although signet ring cell carcinomas may arise from goblet cell carcinoids.[132] Signet ring cell carcinoma has a poor prognosis, due to dissemination within the peritoneal cavity; lymph node metastases and metastases to the ovaries are also common.[129,133]

Goblet cell carcinoid tumors are virtually unique to the appendix and have historically also been called *goblet cell–type adenocarcinoid*,[134] *mucinous carcinoid tumor*,[135] and *crypt cell carcinoma*.[136] Although traditionally classified as neuroendocrine, many have questioned the wisdom of placing into a carcinoid category a tumor in which the neuroendocrine component is only one of several and not necessarily the more conspicuous one. Goblet cell carcinoid tumors are now recognized as a distinct clinicopathologic entity with behavior that is more aggressive than classical appendiceal carcinoid tumors[125,137] and more akin to adenocarcinoma. In addition, they frequently give rise to poorly differentiated adenocarcinomas that behave in a stage-dependent fashion.[132] For this reason, appendices in which goblet cell carcinoid tumors are initially identified should be completely submitted to exclude the possibility of associated carcinoma.

Many goblet cell carcinoid tumors are found in patients with symptoms suggestive of acute appendicitis,[138] and acute appendicitis often coexists with these lesions. The diagnosis is rarely suspected at the time of surgery. Grossly, goblet cell carcinoids may be found in any portion of the appendix[125,139]; unlike classic carcinoid tumors, goblet cell carcinoid are more common in the midportion. They appear as an area of whitish, sometimes mucoid induration without dilation of the lumen, with poorly defined mural thickening that may be difficult to appreciate at the time of gross examination.

Microscopically, goblet cell carcinoids predominantly show deep mucosal and submucosal growth in a circumferential pattern around the lumen of the appendix (Fig. 16.29A) but unassociated with surface epithelial dysplasia. Extension into the muscle and serosa is common. The tumor is composed of small nests, clusters, and cords of goblet cells embedded in dense collagenous stroma (Fig. 16.29B), often arranged in a microglandular fashion and sometimes accompanied by extracellular mucus. Tumor cells are distended by large cytoplasmic mucin vacuoles that compress the nuclei towards the base of the cell. Mitotic activity is generally inconspicuous, and Ki-67 immunolabeling indices are low (<2%).[140] Paneth cells may be present, as well as neuroendocrine cells (Fig. 16.29C).[141] Mucicarmine and carcinoembryonic antigen (CEA) stains are consistently positive, but goblet cell carcinoid tumors show only patchy immunopositivity for neuroendocrine markers.[125,141] They typically express CK20 and occasionally express CK7, usually in a focal fashion.[125,141–143] There is also frequent expression of CK19 and CD99.[144]

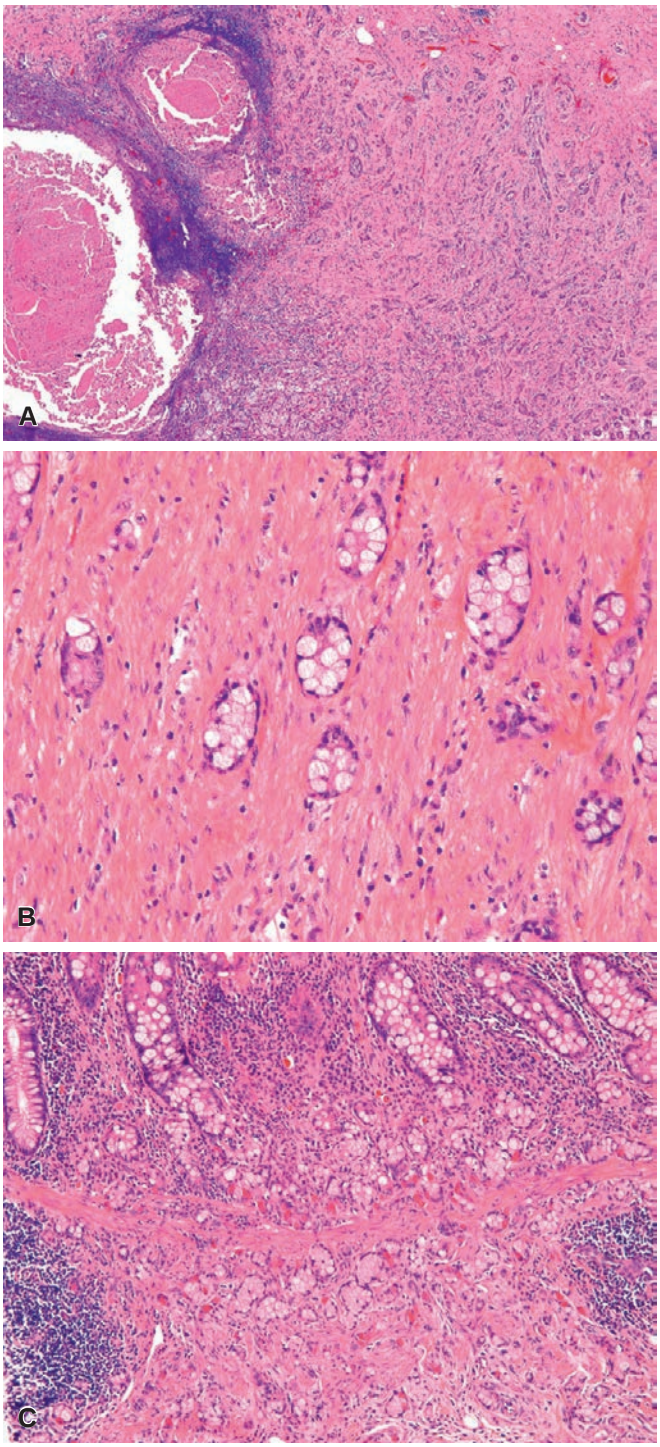

Figure 16.29 **A,** Goblet cell carcinoids have a circumferential growth pattern and typically extend deeply into the muscle and mesoappendix. **B,** The small nests, clusters, and cords of neoplastic cells have large mucin vacuoles and small basally located nuclei. **C,** Paneth cells may be very prominent.

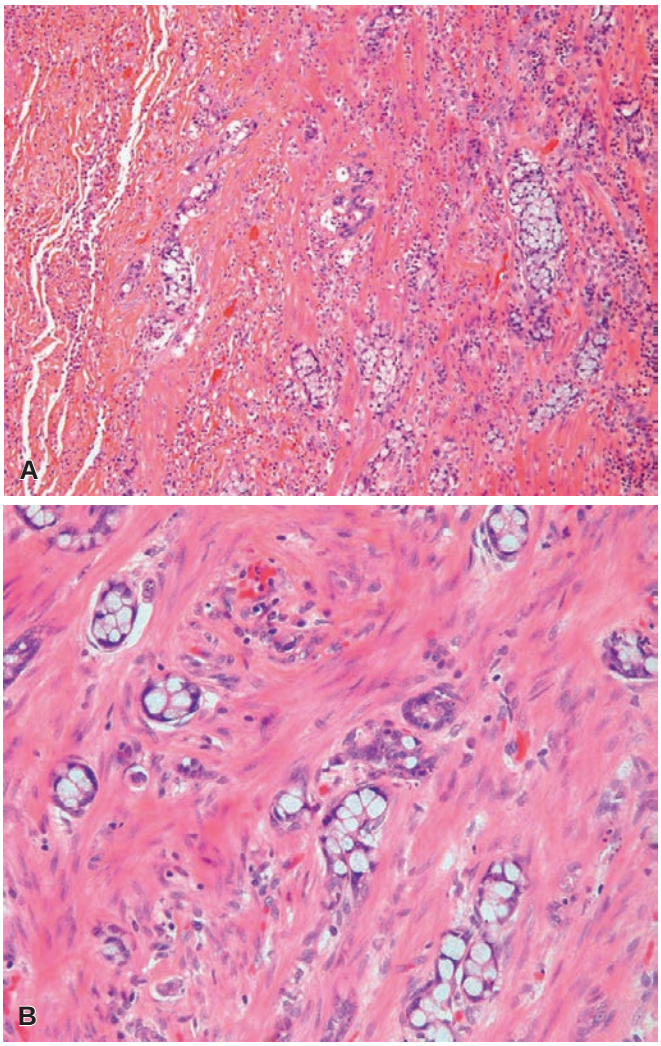

Figure 16.30 **A** and **B,** Poorly differentiated adenocarcinoma ex goblet cell carcinoid; note the nuclear atypia and infiltrating poorly differentiated glands admixed with elements of goblet cell carcinoid.

The matter gets even more complicated by the fact that at least half of goblet cell carcinoid tumors give rise to areas of adenocarcinoma, often signet ring cell type or poorly differentiated (Fig. 16.30), which has been termed "adenocarcinoma ex goblet cell carcinoid."[132] As one might imagine, the development of an overt malignancy in the context of goblet cell carcinoid represents an unfavorable prognostic turn of events. Features indicative of carcinoma include significant nuclear atypia, single infiltrating cells, loss of mucin production, and increased Ki-67 immunolabeling. Unlike other malignancies of the lower gastrointestinal tract, carcinomas derived from goblet cell carcinoid tumors do not show alterations affecting β-catenin, *KRAS*, *DPC4*, or *TP53*.[142]

Most goblet cell carcinoid tumors invade deeply into the appendiceal wall and penetrate the serosa, with frequent involvement of regional lymph nodes, peritoneum, and ovaries.[139,145] Metastases to the ovary are particularly common, where they can acquire the features of a Krukenberg tumor (Fig. 16.31).[146] Both the World Health Organization and American Joint Commission on Cancer classify and stage goblet cell carcinoid tumors as adenocarcinomas.[125] Management of goblet cell carcinoid tumors is not standardized, although appendectomy alone is unlikely to be adequate therapy owing to their high metastatic potential, and thus surgical management generally consists of right colectomy with lymph node dissection.

Classic and goblet cell carcinoid tumors can exceptionally occur together, and this combined form appears to behave more like goblet cell carcinoid tumors than classical carcinoids.[147]

Mucinous Neoplasms

The significance of mucinous appendiceal neoplasms lies in the fact that even low-grade, extremely bland-appearing neoplasms can involve the peritoneal cavity in the form of pseudomyxoma peritonei. Because these tumors with very low-grade features can, in fact, lead to significant morbidity and even death, they have been the subject of much (and ongoing) debate regarding terminology and classification, which continues to evolve.[119,121,148–150] Furthermore, the criteria for invasion in the appendix are not well defined, and the multiple classification schemes that exist reflect the difficulty with neatly labeling them as benign or malignant.

Figure 16.31 Ovarian metastasis of appendiceal adenocarcinoid tumor of goblet cell type. Sometimes this constitutes the initial presentation of this tumor type.

Adenoma/Cystadenoma

By definition, mucinous adenomas are confined to the appendiceal mucosa, and they should not have associated mucin on the serosal surface or in the mesoappendix.[121,148,149] Some are grossly unremarkable, whereas others cause focal or generalized dilatation of the appendix with accumulation of mucin (hence the term cystadenoma; Fig. 16.32A). Many authorities require the presence of an intact muscularis mucosae to make a diagnosis of adenoma.[126,150,151] The mucinous epithelium may be flat or undulating, but villous projections are present in many cases (Fig. 16.32B).[126,148,151] The deeper crypts typically have straight luminal edges similar to those of the non-neoplastic appendix, but some lesions contain crypts with a serrated appearance near the lumen.[151] Overall, adenomas generally lack significant architectural complexity.Most adenomas display low-grade cytologic atypia characterized by nuclear hyperchromasia and pseudostratification with rare mitotic figures (Fig. 16.32C).[148,151] High-grade dysplasia is uncommon and is characterized by architectural abnormalities, including cribriform and micropapillary growth, as well as nuclear pleomorphism with loss of cell polarity and readily identifiable mitotic figures (Fig. 16.33A and B).[150,151] In the past, lesions currently classified as adenomas with high-grade dysplasia have been classified in a number of ways, including noninvasive adenocarcinoma.[119,150] However, regardless of the degree of cytologic dysplasia, appendiceal mucinous adenomas are cured

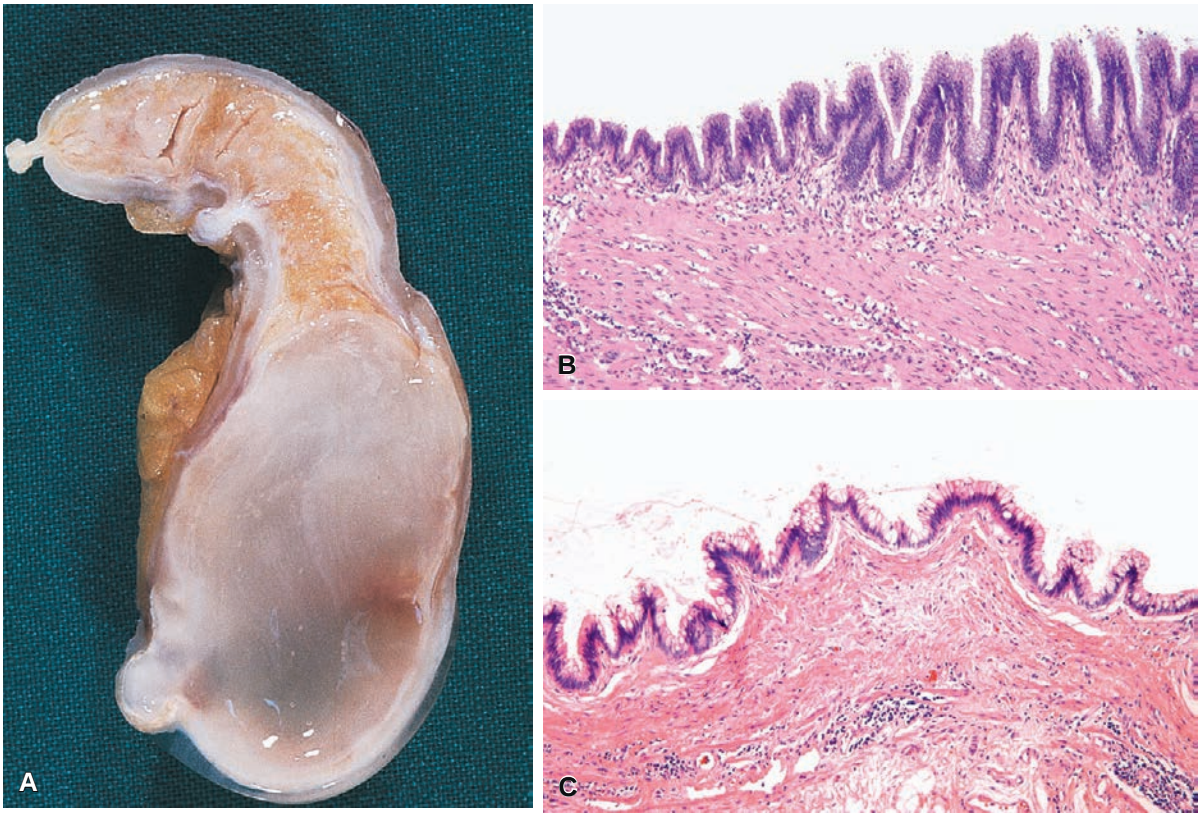

Figure 16.32 **A,** Mucinous cystadenoma involving the proximal half of the appendix and associated with formation of diverticula. Note the lack of mucin on the outside of the appendix. **B,** The epithelium is undulating with an intact muscularis mucosae and lacks architectural complexity. **C,** The cytologic atypia is low grade.

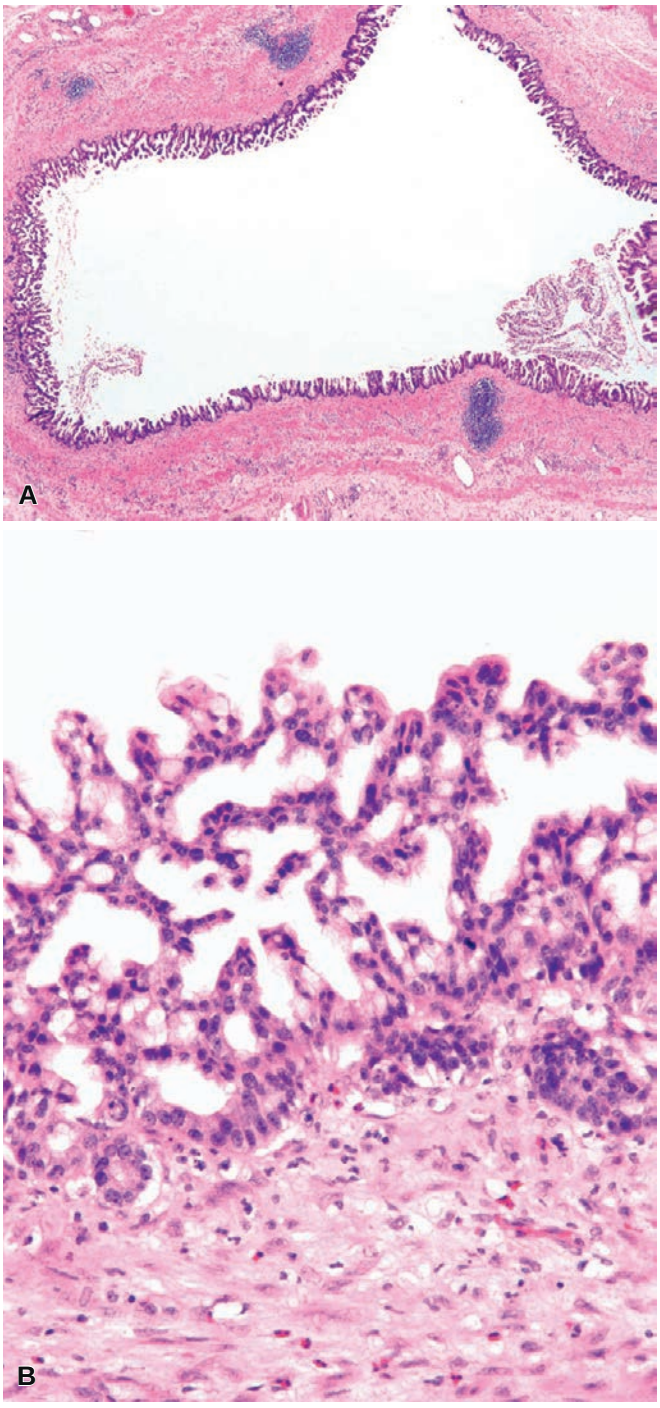

Figure 16.33 Adenoma confined to the appendix **(A)** but containing high-grade dysplasia **(B)**, characterized by architectural complexity, nuclear atypia, and mitoses.

by appendectomy with negative margin.[148,151] However, some authors have proposed that adenoma at the surgical resection margin warrants concern for recurrent disease or metastasis and consider such tumors to have uncertain malignant potential or low risk for recurrence.[148,149,151] For these reasons, the term "high-grade appendiceal mucinous neoplasm" (HAMN) has been proposed for these types of tumors. Submission of the entire appendix is essential in cases of mucinous adenoma, in order to exclude the possibility of extra-appendiceal epithelium and/or mucin, as described later. Low-grade mucinous

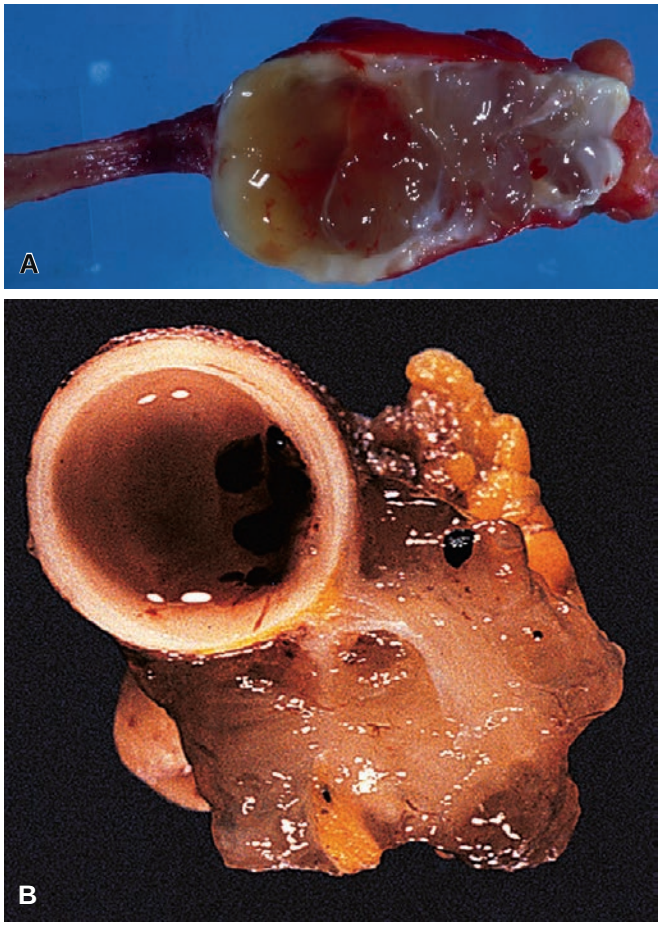

Figure 16.34 **A,** Low-grade appendiceal mucinous tumor featuring a markedly dilated appendiceal lumen and thin wall. **B,** Another case showing a markedly dilated appendix with extension of mucin into the mesoappendix (**A,** Courtesy of Dr. George F. Gray, Jr.)

neoplasms with mural changes such as disruption of the muscularis mucosae, mural atrophy with fibrosis of the mucosa and muscularis mucosae, and/or with extra-appendiceal mucin are best classified as LAMN rather than adenomas.[148,149,151]

Low-Grade Appendiceal Mucinous Neoplasm

Historically, in an attempt to avoid nomenclature confusion as well as correlate histologic features with biologic behavior, some authorities classified the entire spectrum of low-grade mucinous tumors from adenoma to low-grade mucinous tumors with extra-appendiceal mucin as LAMN.[119,150] More recent classification schemes have reinstated the term adenoma/cystadenoma, as previously discussed, recognizing that these lesions are cured by appendectomy as long as the entire appendix is evaluated and no histologic risk factors for recurrence are identified. Currently, most authorities use the term LAMN to indicate those appendiceal mucinous tumors that have features portending at least some increased risk of peritoneal dissemination.[148,149,151]

Similar to adenomas, these lesions may be grossly unremarkable or produce a cystically dilated appendix filled with mucin (Fig. 16.34A). Grossly visible mucin on the serosal surface or in the mesoappendix (Fig. 16.34B) is an important finding and, if present, should be carefully documented and submitted entirely in order to establish the presence or absence of extra-appendiceal neoplastic epithelium.[148–151]

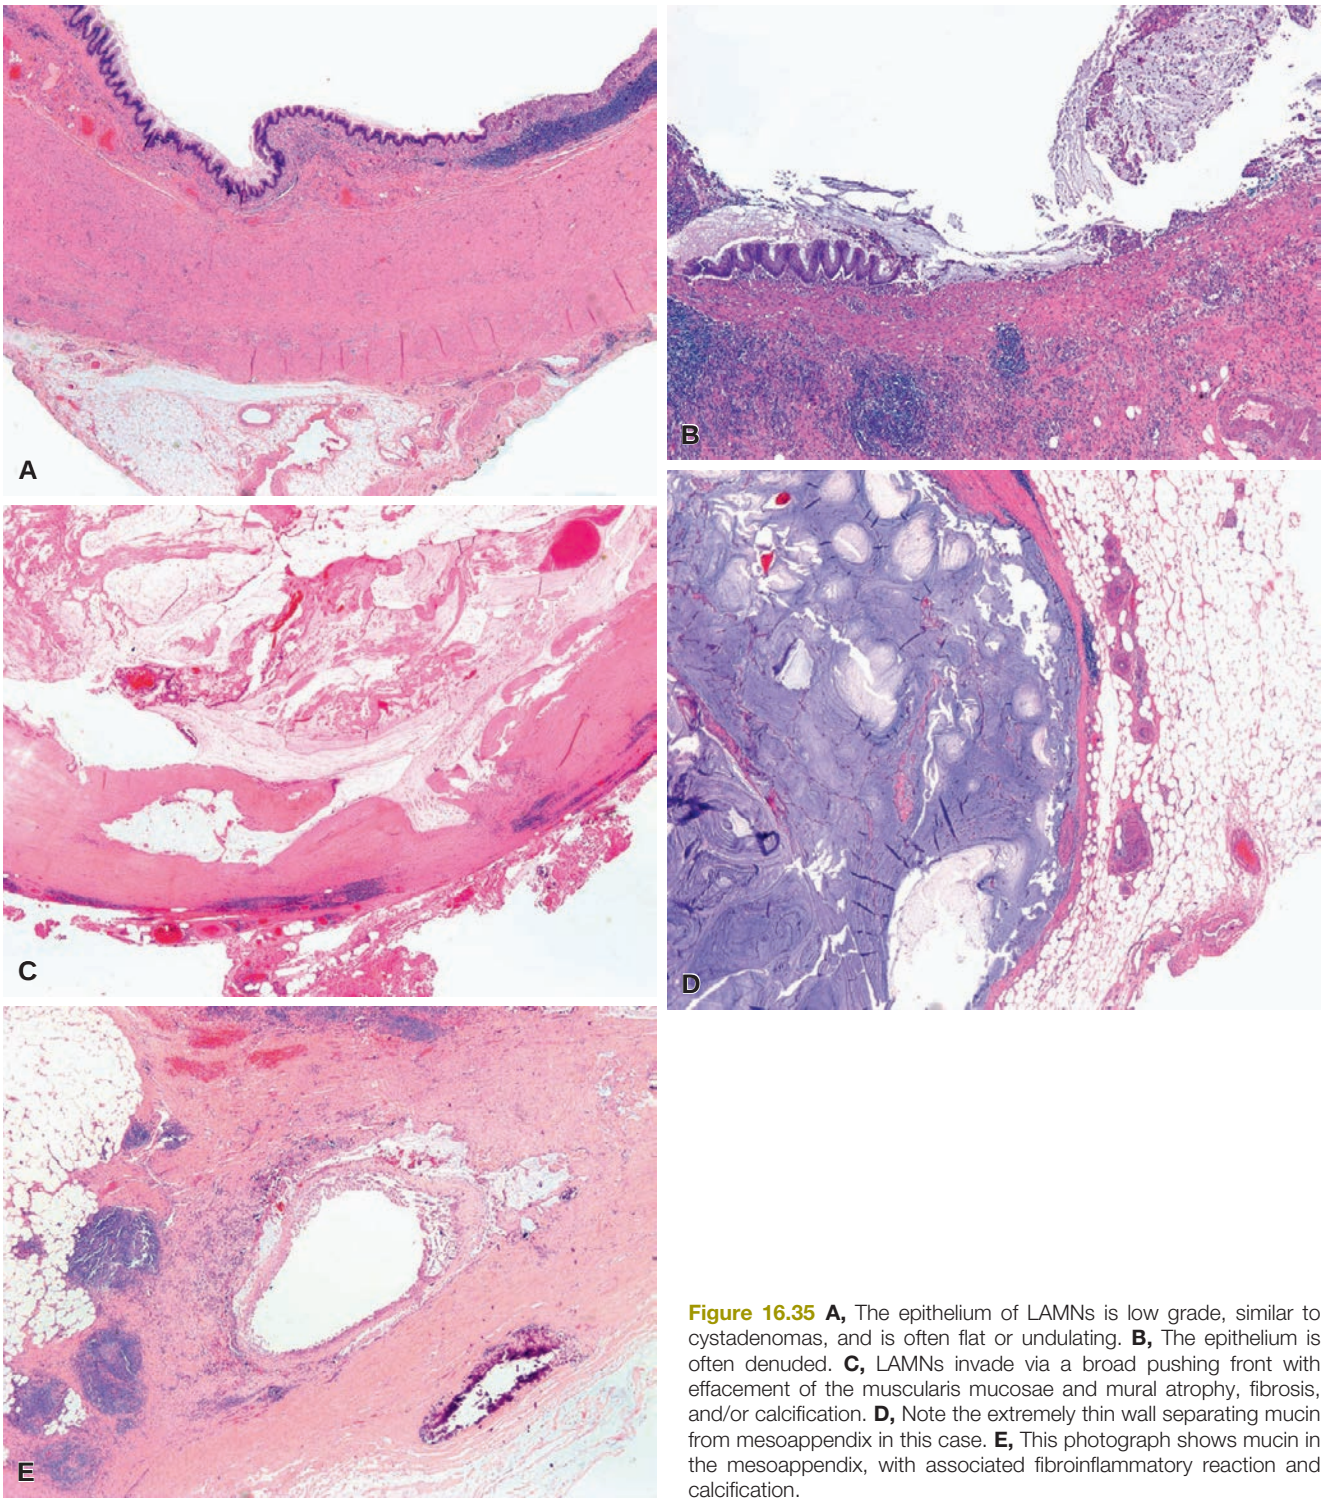

Figure 16.35 **A,** The epithelium of LAMNs is low grade, similar to cystadenomas, and is often flat or undulating. **B,** The epithelium is often denuded. **C,** LAMNs invade via a broad pushing front with effacement of the muscularis mucosae and mural atrophy, fibrosis, and/or calcification. **D,** Note the extremely thin wall separating mucin from mesoappendix in this case. **E,** This photograph shows mucin in the mesoappendix, with associated fibroinflammatory reaction and calcification.

The low-grade epithelium of LAMNs is similar to cystadenomas and is characterized by tall mucinous epithelial cells in a villous or flat configuration (Fig. 16.35A).[148–151] The villi are usually slender with straight edges. The epithelium is almost completely denuded in many cases, and multiple sections may be required to find neoplastic epithelium (Fig. 16.35B).[121,151] LAMN have a distinct manner of invasion of the appendiceal wall, which features a broad pushing front (rather than infiltrative neoplastic glands with desmoplasia) with effacement of the muscularis mucosae and mural atrophy, fibrosis, and/or calcification (Fig. 16.35C and D).[150] These tumors may dissect through the wall to create diverticulum-like outpouchings or even overtly perforate the organ (leading to the historical term 'ruptured adenoma,' which does not reflect the biologic potential of these tumors) (Fig. 16.35E). Mucinous neoplasms with high-grade cytologic features should not be classified as LAMN. If confined to the mucosa, they may be classified as adenomas, as

above; otherwise, they should be classified as mucinous adenocarcinoma (see subsequent section).

LAMN confined to the appendix are virtually always cured by appendectomy,[148] and recent studies have shown that even involvement of the margin by neoplastic epithelium or acellular mucin does not portend recurrence of disease.[152] Tumors with either acellular mucin in the peritoneal cavity, or neoplastic epithelium outside the appendix but confined to the right lower quadrant, have a low risk of progression to widespread pseudomyxoma peritonei, particularly if all of the extra-appendiceal mucin is evaluated histologically to exclude the presence of neoplastic epithelium in the former scenario.[148,153] Even so, approximately one-third of patients with extra-appendiceal neoplastic epithelium confined to the right lower quadrant may progress to disseminated peritoneal disease leading to death,[148,153] and because of this, some authors have previously classified tumors with any extra-appendiceal involvement by cellular mucin as low-grade mucinous adenocarcinomas.[126,151]

Management of patients with extra-appendiceal mucin limited to the periappendiceal region is controversial. Patients should have all grossly visible peritoneal mucin removed for histologic evaluation and then undergo radiographic surveillance to evaluate for development of mucinous ascites.[151,153] There are currently no data to support cytoreductive surgery with intraperitoneal chemotherapy as a preventive measure, and right colectomy offers no survival benefit over appendectomy.[154,155]

A number of benign lesions can mimic LAMN. Retention cysts are rare and usually smaller than 2.0 cm. The mucosa has often sloughed but when retained is atrophic or attenuated, lacking the undulating and/or villous features of LAMN as well as the low-grade cytologic atypia. Although retention cysts can rupture, the mucin is acellular and does not recur following appendectomy.[119,126] Reactive or hyperplastic appendiceal mucosa should not be mistaken for a mucinous neoplasm, particularly when associated with a retention cyst or diverticulum. Appendiceal diverticula, also discussed previously, can occur in association with mucinous adenomas as well as in non-neoplastic appendices.[156] Diverticula that complicate mucinous adenomas can be confused with the "pushing front" of a low-grade appendiceal neoplasm, particularly if the diverticulum is colonized by neoplastic epithelium, and ruptured diverticula may also be confused with LAMN with extra-appendiceal mucin (Fig. 16.10C).[74] Features favoring diverticulum over LAMN include the presence of non-neoplastic epithelium, continuity of mural epithelium with that lining the lumen of the lesion, and an intact, normal-appearing muscularis propria. Another extremely unusual condition associated with mucus production in the appendix is myxoglobulosis, also known as "caviar appendix."[119,157] In this condition, the appendiceal lumen contains numerous ovoid globules composed of mucus (Fig. 16.36), which are occasionally calcified. Histologically, the globules consist of laminated mucin surrounding an eosinophilic, granular core. The pathogenesis is unclear, but it is believed that this change represents organized mucin that has detached from the wall.

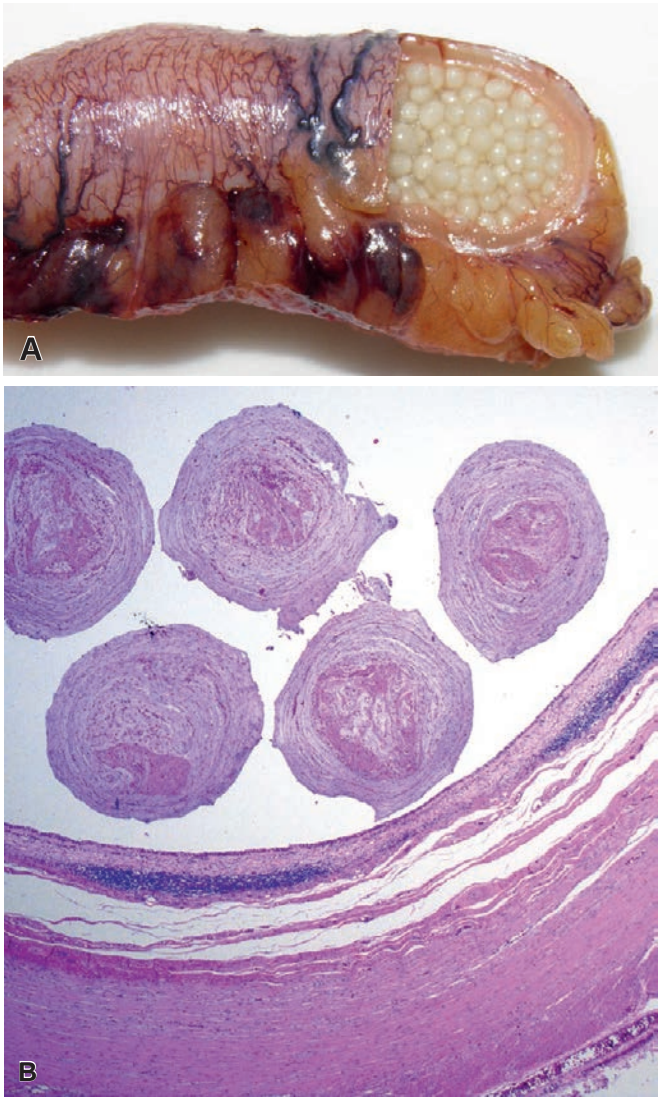

Figure 16.36 **A,** Myxoglobulosis, or "caviar appendix," features numerous ovoid globules composed of mucus within the lumen. **B,** Histologically, the globules are composed of laminated mucin surrounding a granular eosinophilic core. (Photographs courtesy of Dr. Ian Brown.)

Mucinous Adenocarcinoma and Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a descriptive term, characterizing mucin accumulation in the peritoneal cavity due to spread of a mucinous neoplasm.[151,158] Most cases develop secondary to spread of low-grade mucinous tumors of the appendix, although rare cases are associated with origins from other sites (e.g. ovary).[158,159] Widely disseminated pseudomyxoma peritonei results in the formation of innumerable gelatinous nodules and, in time, often causes death through infection, intestinal obstruction, or invasion of the surrounding structures such as the bladder, abdominal wall, and intestine (Fig. 16.37A). It may also involve the outer aspect of the spleen[160] and extend through the diaphragm to produce *pseudomyxoma pleurii*.[161] Finally, it can extend into inguinal and other hernia sacs; as a matter of fact, it is not rare for the disease to be first diagnosed on histologic examination of the contents of a herniorrhaphy operation.[162,163]

The peritoneal tumor deposits are generally morphologically similar to the primary appendiceal neoplasm.[150,164] Low-grade lesions (often associated with LAMN) consist of mucin pools containing scant strips of low-grade mucinous epithelium with rare mitoses, often in a background of hyalinized collagen bands and reactive fibrosis around mucin pools (Fig. 16.37B).[150,164] Peritoneal mucinous tumors with high-grade features, such as solid cell clusters that display nuclear enlargement and hyperchromasia, single cell necrosis, and mitotic activity, are more often associated with a mucinous adenocarcinoma (Fig. 16.37C and D).[150,164] The high-grade epithelium is often more abundant than in low-grade lesions and may be accompanied by destructive tissue invasion and/or a desmoplastic tissue response and lymph node metastases. These high-grade neoplasms

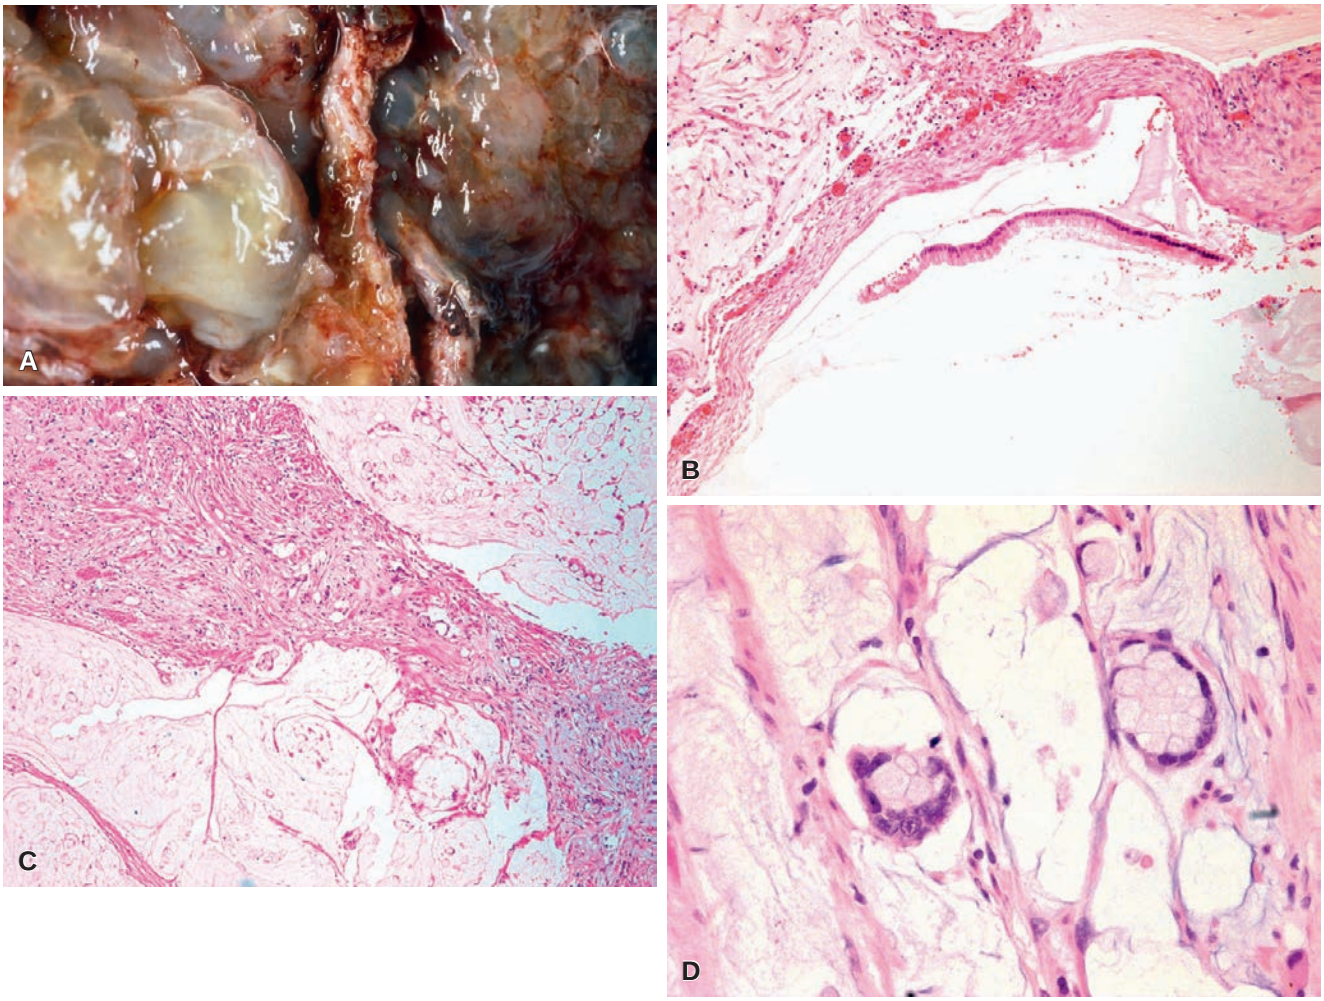

Figure 16.37 **A,** Gross photograph from a debulking procedure for pseudomyxoma peritonei. **B,** In this case, strips of low-grade epithelium float within pools of mucin. **C,** This case of pseudomyxoma peritonei with high-grade features shows invasion of the fibrous bands surrounding the mucin pools, as well as signet ring cells and marked nuclear atypia **(D)**. (**A,** Courtesy Dr. George F. Gray, Jr.)

often represent spread from a small bowel, colon, or pancreatic primary rather than a primary appendiceal tumor.[150,164] Some appendiceal neoplasms do show discordant histologic features in the primary appendiceal lesion and the peritoneal tumor deposits,[148,150] and progression from low-grade to high-grade histology has been seen in patients who fail therapy and/or have multiple tumor recurrences.[165,166]

The term *disseminated peritoneal adenomucinosis* has been proposed for this extremely well-differentiated form of disease, reserving the term *peritoneal mucinous carcinomatosis* for those cases in which the cytoarchitectural atypia is greater.[164,167] Although the distinction is of prognostic significance, it should be realized that these refer to different grades of malignancy and that calling them *adenomucinosis* may lead to an underestimation of their potentially aggressive behavior.[168]

Appendiceal mucinous neoplasms and pseudomyxoma peritonei typically express cytokeratin 20, CDX-2, and MUC2; cytokeratin 7 is variably positive.[169,170] Appendiceal adenomas, LAMN, and mucinous adenocarcinomas frequently show *KRAS* mutations, but they do not typically harbor abnormalities in *BRAF*, or *APC*, or show microsatellite instability.[151,171–173]

Most patients with peritoneal mucinous adenocarcinoma experience multiple tumor recurrences requiring intervention over time, leading to extensive intra-abdominal adhesions that ultimately prohibit further therapy.[174] Aggressive modern therapeutic approaches consist of a combination of surgery, directed towards complete cytoreduction, and hyperthermic intraoperative intraperitoneal chemotherapy (HIPEC) plus additional cycles of early postoperative intraperitoneal chemotherapy. The natural history of disease is dictated by tumor grade and pathologic stage[175]; 5-year survival rates of 86% are achievable among low-grade tumors that are treated with this approach, compared to 50% for high-grade tumors.[151,176,177] Although these aggressive modalities show promise, there is significant morbidity and mortality.

This topic would not be complete without addressing the entity known as *"mucocele."* In the appendiceal disease historically designated as such, the appendix shows either focal or diffuse globular enlargement, and the lumen is dilated and contains large amounts of glairy mucus. In our opinion, the term *mucocele* should not be used, because it is merely descriptive and tells nothing about the underlying cause of the mucin accumulation (which can range from a benign to frankly malignant and aggressive process). What matters is the nature of the underlying lesion, not the fact that abundant mucin is being produced by it. Making a diagnosis of "mucocele" is equivalent to using the term "hematocele" for any blood-containing lesion, regardless of whether the underlying lesion is a hematoma, a cavernous

hemangioma, an angiomatoid malignant fibrous histiocytoma, or an angiosarcoma.

Neuroendocrine Tumors

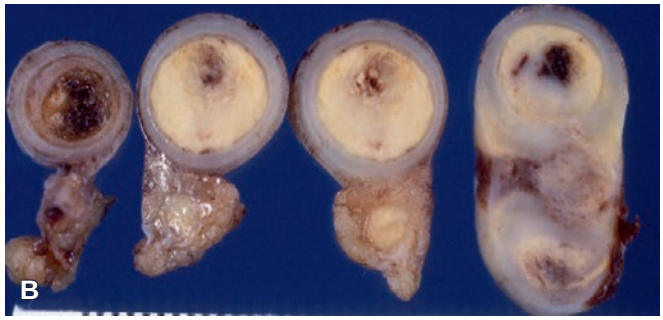
Well-differentiated NETs (formerly known as carcinoid tumors) are the most common type of appendiceal tumor.[178] They are identified in less than 1% of appendectomy specimens[141] and are more common among adults than children, although they can present at any age.[179] These lesions tend to occur in a slightly younger age group than NETs at other sites in the gastrointestinal tract and show a slight female predominance, although these features may at least in part reflect the frequency of acute appendicitis among young patients and women undergoing gynecologic surgery.[180] In most cases they are incidental findings at appendectomy for another reason, but they may be found associated with acute appendicitis as a result of obstruction of the lumen. Exceptionally, they have been found to secrete ACTH and result in a clinical picture of Cushing syndrome.[181] Carcinoid syndrome secondary to appendiceal carcinoid tumor is extremely rare.[182]

In terms of location within the appendix, the great majority of appendiceal NETs occur at the tip/distal third of the organ. The majority of tumors measure less than 1.0 cm in diameter and only rarely measure 2.0 cm or more.[141,183] Grossly, the tumors are firm, grayish white, and fairly well circumscribed but not encapsulated (Fig. 16.38). They acquire a characteristic yellow color after formalin fixation. When sufficiently large, those located at the tip often result in a typical "bell clapper" configuration of the appendix.

Morphologically, the vast majority of appendiceal NETs are serotonin-producing enterochromaffin (EC) cell tumors, similar to their counterparts in the jejunoileum. Previously, these tumors have been known as "classic" carcinoid tumors. EC cell tumors are composed of unencapsulated, tightly packed solid nests ("insulae") of small monotonous cells with occasional acini (Fig. 16.39),[141] which harbor luminal material that is positive for periodic acid–Schiff stain, but do not contain mucin. Other admixed architectural patterns are occasionally seen.[141] Tumor cells contain abundant amphophilic, often granular, cytoplasm and are both argentaffin and argyrophil positive.[141,184] The nuclei are typically round with coarse "salt and pepper" chromatin and small nucleoli; mitotic figures are rare. Occasional tumors display degenerative-type nuclear atypia with hyperchromasia and multinucleation, which has no bearing on behavior. A retraction of the tumor periphery from the stroma is usually evident and sometimes prominent. Invasion of the appendiceal muscle wall and lymph vessels is the rule, and spread to the peritoneal surface is not rare.

There is little question that the cells of most EC cell (classic carcinoid) tumors have morphologic, immunohistochemical, and ultrastructural features similar to those of the EC cells normally located at the base of Lieberkühn glands, but there is still debate over whether the tumors arise from these cells or from phenotypically similar cells located in the lamina propria and submucosa in close association with nerves, which sometimes form discrete units known as *subepithelial neuroendocrine complexes*, first identified by Masson. Because of this, it has been postulated that tumor cells found within intra-appendiceal nerves may be more closely related to tumor histogenesis than a manifestation of neoplastic perineural spread.[185–187]

EC cells are strongly immunoreactive with chromogranin A, synaptophysin, and serotonin.[141,184] Pankeratin staining tends to be weak, and both CK7 and CK20 are usually negative.[143] The tumors characteristically express CDX2, as a marker of midgut derivation.[188] The tumor cells are intimately associated with a population of S-100 protein–positive Schwann-like cells, probably belonging to the intra-appendiceal nerves mentioned previously.[185] Most EC cell tumors show a very low Ki-67 proliferation index (<1%).[189]



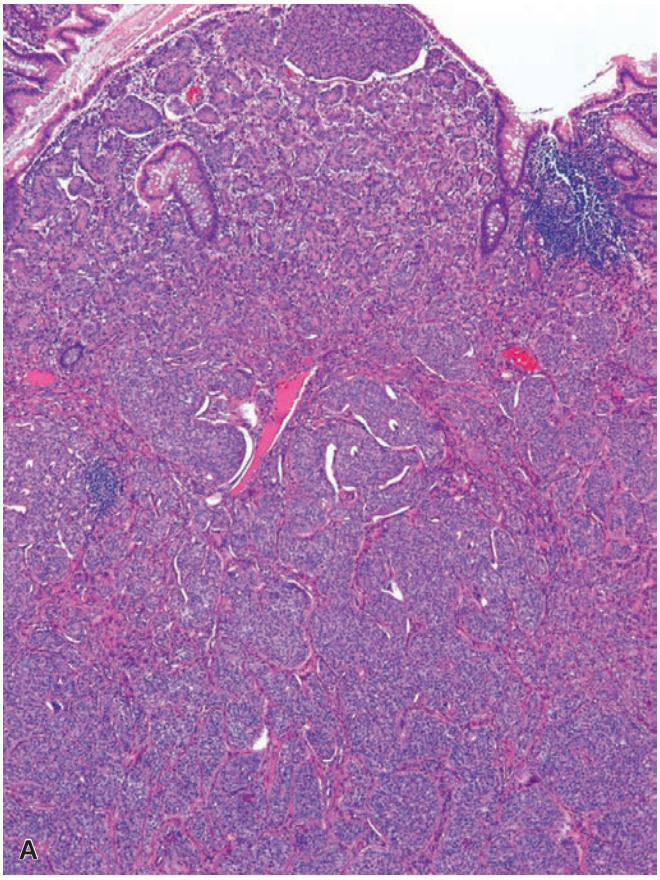


Figure 16.38 Gross Appearance of Well-Differentiated Neuroendocrine Tumor (Formerly Carcinoid Tumor) of the Appendix. These tumors are white-yellow and characteristically located in the tip **(A)**; they are well circumscribed but not encapsulated and may extend into the periappendiceal soft tissues **(B)**. (Courtesy Dr. George F. Gray, Jr.)

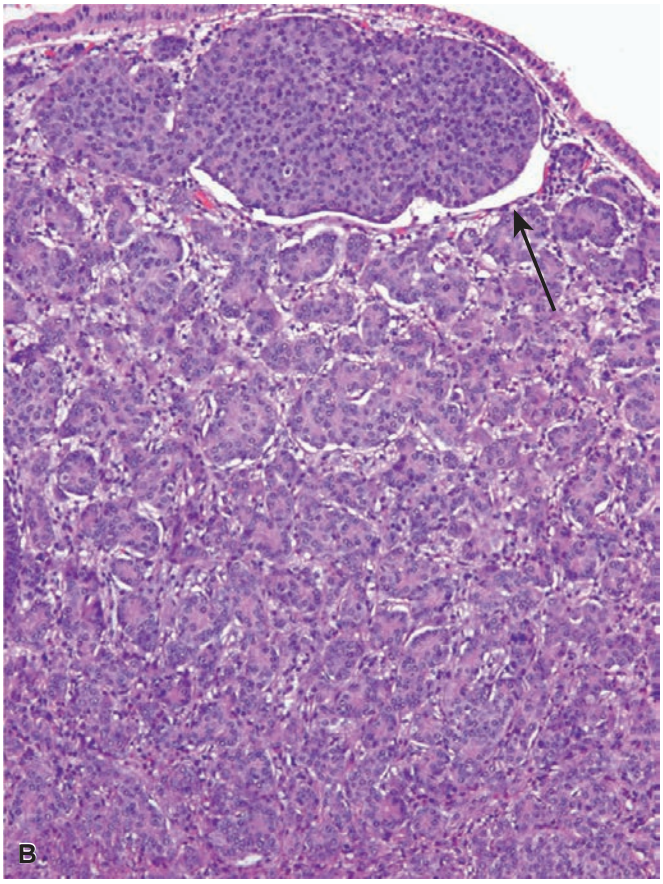
Approximately 10%–20% of appendiceal NETs are composed of enteroglucagon (L) cells. These tumors are characterized by glandular structures rather than solid nests[190,191] and have therefore been referred to as tubular carcinoids in the past. These tumors are typically small (2–3 mm) and composed of trabeculae and cords of cytologically bland tumor cells (Fig. 16.40). Some tumors display a predominantly acinar, or tubular, growth pattern,[190] contributing to their previous classification as tubular carcinoids. Although small amounts of inspissated mucin can be seen in the lumens, the cytoplasm is predominantly mucin negative.[141,191] Small red basophilic neuroendocrine granules may be visible; on occasion, these granules are large and acidophilic, simulating those of Paneth cells, but true Paneth cells are not a feature of tubular carcinoids.[141] The tumor cells are argyrophilic but argentaffin negative[184]; they are immunoreactive for chromogranin B, synaptophysin, glucagon,



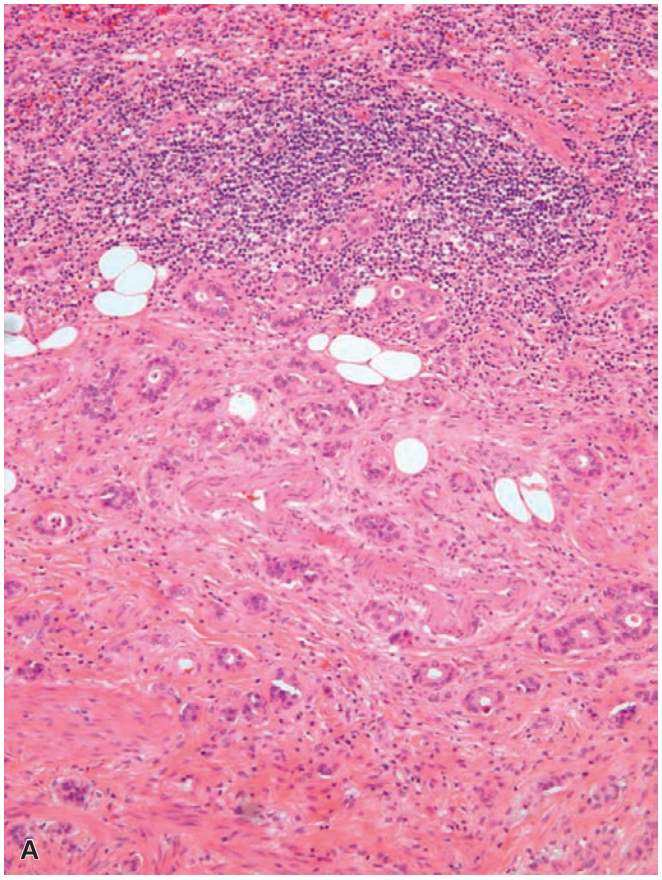


Figure 16.39 **A,** The majority of appendiceal NETs are composed of uncapsulated, tightly packed solid nests (insulae) of small monotonous cells with eosinophilic or amphophilic cytoplasm. **B,** Nuclei are uniform, small, and round, with speckled or "salt and pepper" chromatin. Lymphovascular invasion is typical *(arrow)*.

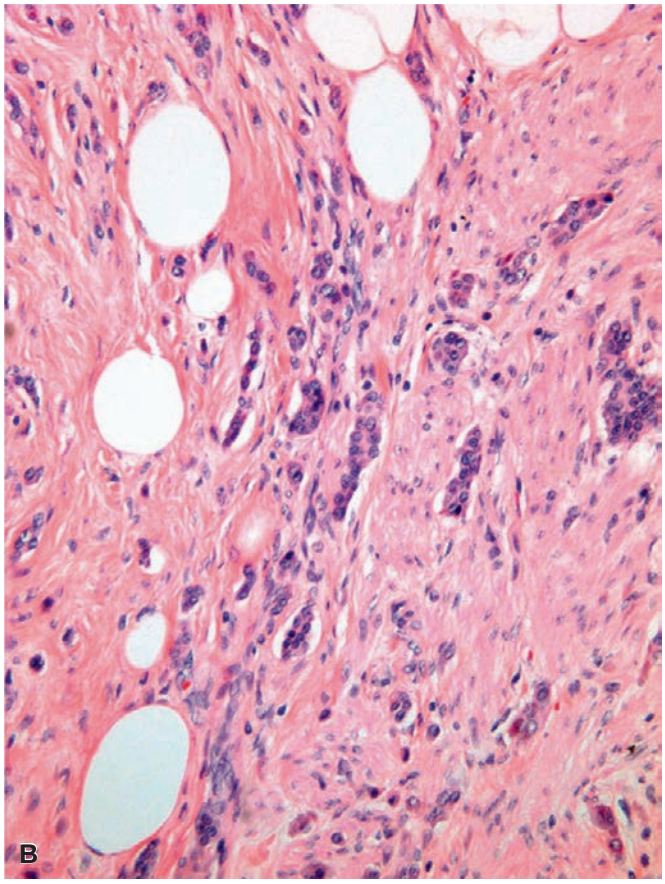

Figure 16.40 **A,** L-cell NETs, formerly known as tubular carcinoids, are composed of trabeculae and cords of neoplastic cells that may be mistaken for a carcinoma. **B,** Small red acidophilic neuroendocrine granules may be present.

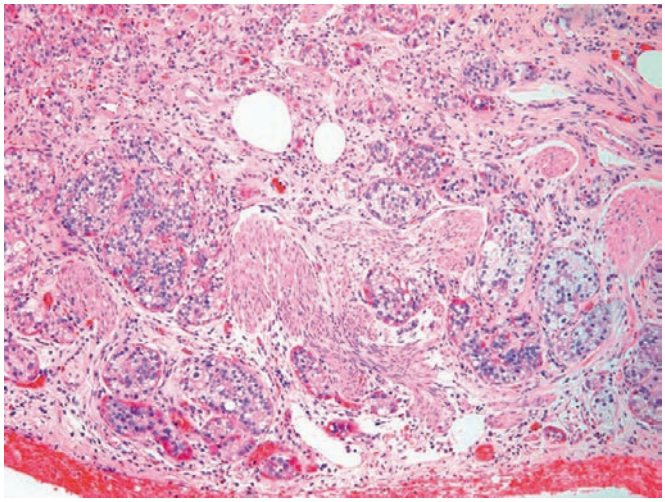

Figure 16.41 This well-differentiated NET has striking clear cytoplasm as well as eosinophilic neuroendocrine cells.

immunoglobulin A, pancreatic polypeptide, peptide YY, and CEA but typically do not stain for chromogranin A.[184,185,190] The Ki-67 proliferation index is also very low. Because of the infiltrative growth pattern and the lack of chromogranin A expression, as well as the fact that they variably express CK7 and CK20,[192] tubular carcinoids may be mistaken for metastatic carcinoma, but the lack of mitoses and nuclear atypia, orderly arrangement, and origin at the base of the glands of otherwise normal mucosa should lead to the correct diagnosis and avoid confusion with a primary or metastatic adenocarcinoma.

Occasional appendiceal NETs exhibit cells with clear cytoplasm and/or cytoplasmic vacuolization (Fig. 16.41). These tumors are referred to as lipid-rich or clear cell NETs, and this appears to represent a degenerative phenomenon in otherwise typical EC cell tumors. Clear cell NETs express general neuroendocrine markers but do not express mucins.[193,194]

Tubular carcinoids are typically minute and pursue a benign clinical course.[141] The behavior of most classic carcinoid tumors of the appendix is very indolent, especially when small, as fewer than 1% of tumors less than 2.0 cm metastasize.[141] Metastatic spread is usually associated with tumors greater than 2 cm in diameter, allowing for the occasional exception,[195] and even then often limited to the regional lymph nodes. Management decisions are largely based on tumor size. Most authors agree that simple appendectomy is adequate therapy for carcinoid tumors measuring less than 1 cm, provided that the margin is negative. Right hemicolectomy with lymph node dissection is generally reserved for tumors measuring more than 2 cm, given the greater likelihood of regional lymph node metastases and vascular invasion.[196,197] The treatment of carcinoid tumors measuring 1–2 cm and/or accompanied by mesoappendiceal invasion remains controversial. Completely resected tumors may be treated with appendectomy and clinical follow-up, although some favor a more radical approach in young patients.[183,196] Features suggestive of aggressive behavior (e.g. positive margin, invasion of the mesoappendix, vascular invasion, mitotic activity, and high Ki-67 labeling) may also prompt right colectomy and lymph node dissection,[197,198] although most studies have failed to show a survival benefit to extensive surgery. Given the importance of the previously mentioned factors in the therapeutic decision-making process, this information should be included in the pathology report. Approximately 18% of appendiceal NETs have associated malignancies elsewhere in the GI tract, so imaging and/or colonoscopy should be considered as well in the evaluation of these patients.[197]

Before leaving the subject of NETs of the appendix, we should mention some vanishingly rare entities that have primarily been documented as individual case reports. True primary small cell neuroendocrine carcinoma of the appendix is extremely rare,[199] as is mixed adenocarcinoma/neuroendocrine carcinoma (MANEC).[200] Rare cases of combined classical carcinoid/goblet cell carcinoid have also been described, as previously discussed.[147] Primary gangliocytic paraganglioma of the appendix has also been reported.[201]

Other Tumors and Tumor-Like Lesions

Müllerian Lesions

Endometriosis (Fig. 16.42A and B) involves the appendix in a significant minority of women with gastrointestinal endometriosis. Patients may present with signs and symptoms of acute appendicitis, although many are asymptomatic.[14,202] Appendiceal endometriosis may result in intussusception,[92] and, exceptionally, appendiceal rupture, particularly during pregnancy.[203,204] Appendiceal endometriosis can also lead to obstruction of the lumen with a mucocele-like distal dilation.[14,205] Rare reports of dysplastic changes arising in the context of appendiceal endometriosis have occurred, raising the possibility that any neoplasm of müllerian origin arising from endometriosis could present as an appendiceal tumor.[14,206] *Endosalpingiosis* (Fig. 16.42C and D) is typically an incidental finding as well,[14] although it can occasionally mimic a well-differentiated adenocarcinoma on frozen section evaluation, and has been reported to cause both a rectosigmoid stricture and a cystic mass.[207,208] The mucinous variant of benign müllerian glandular lesions, endocervicosis, has not been described in the appendix but conceivably could occur.[14] Rare cases of ectopic decidual reaction *("deciduosis")* have been reported in the appendix as well (Fig. 16.42E).[209]

Mesenchymal Tumors

Granular cell tumors,[210,211] *PEComas*,[212] *inflammatory fibroid polyps*,[213] and *schwannomas*[214] rarely involve the appendix and are similar to their counterparts found elsewhere in the GI tract. *GIST* can rarely involve the appendix as a primary site (Fig. 16.43)[214,215]; many of the reported cases have featured skeinoid fibers. There have also been isolated reports of appendiceal *leiomyoma* and *leiomyosarcoma*.[14,214]

Malignant lymphoma can involve the appendix as a primary site, although it is quite rare. Many different types of lymphoma have been reported in the appendix, primarily as case reports, including *Burkitt lymphoma*, *myeloid sarcoma*, and *mantle cell lymphoma*, some of which presented with the clinical picture of acute appendicitis.[14,215–218]

Kaposi sarcoma involving the appendix of HIV-infected individuals and resulting in acute appendicitis has been reported.[219]

Metastases to the appendix are rare and usually originate in carcinomas of the gastrointestinal tract, breast, or female genital tract (Fig. 16.44).[220–222]

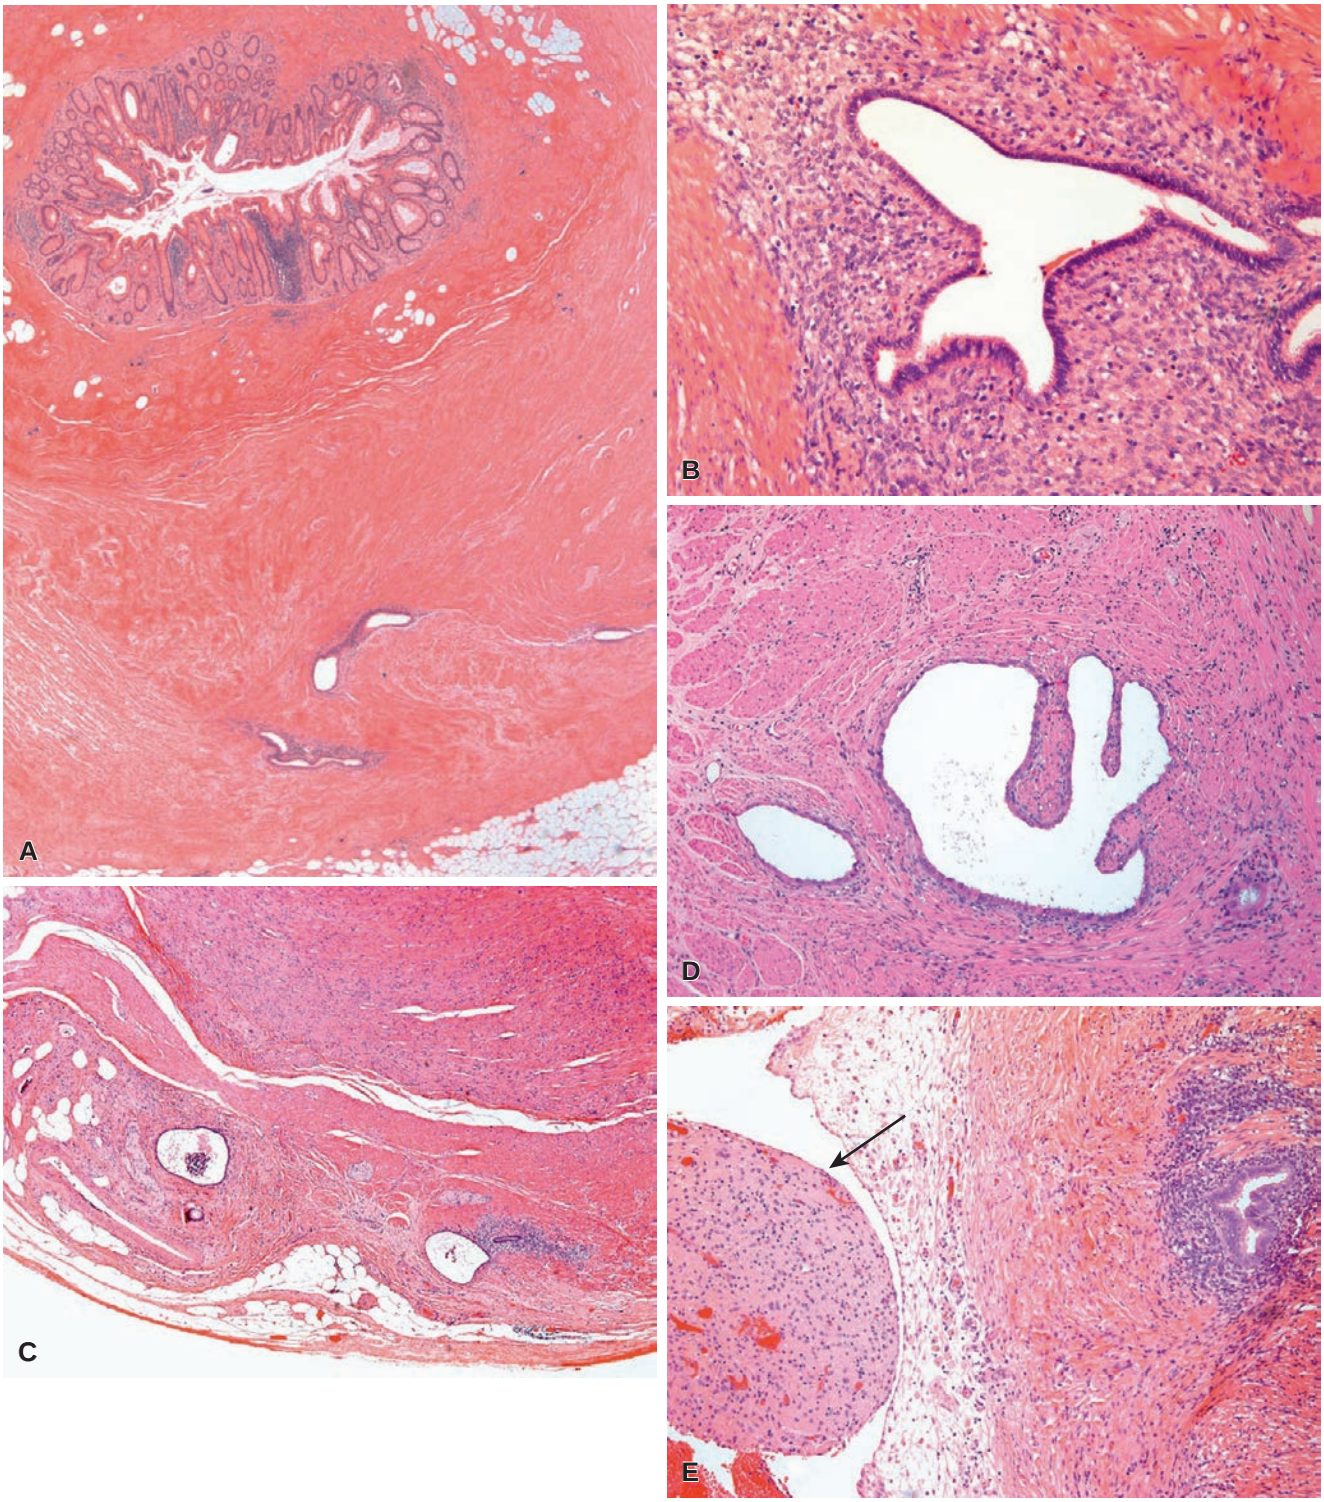

Figure 16.42 **A** and **B,** Endometriosis, characterized by endometrial glands and stroma, in the wall of the appendix. Endosalpingiosis in the outer wall of the appendix **(C)**; cilia are visible at higher power **(D)**. A focus of ectopic decidualization is seen on the left (**E,** *arrow*), while a focus of endometriosis is seen on the right.

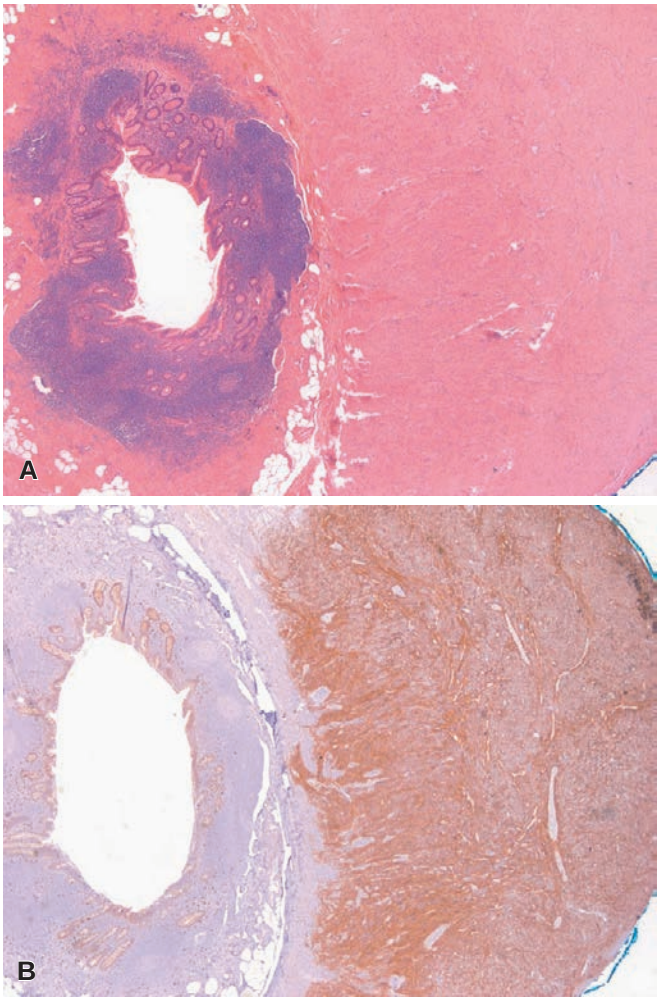

Figure 16.43 A primary GIST arising in the wall of the appendix **(A)**, confirmed by CD117 immunostaining **(B)**.

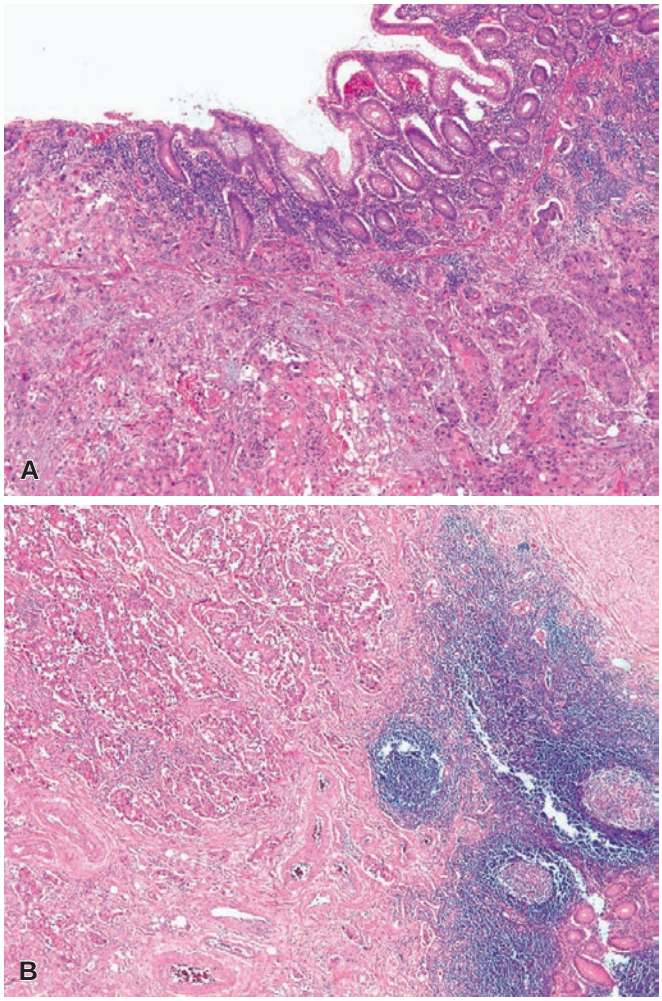

Figure 16.44 **A,** Metastatic squamous cell carcinoma from the cervix. **B,** Metastatic high-grade serous carcinoma from the ovary.

Normal Anatomy of the Large Bowel

The large bowel comprises the terminal 1–1.5 m of the gastrointestinal tract and is divided into the following regions: cecum, ascending (right) colon, transverse colon, descending (left) colon, sigmoid colon, and rectum. The hepatic flexure is at the junction of the ascending and transverse colon, and the splenic flexure is at the junction of the transverse and descending colon. The rectum forms the distal 8–15 cm of extraperitoneal large bowel that lies within the pelvis and ends at the anal canal.

The large bowel wall is composed of four layers: mucosa, submucosa, muscularis externa (propria), and serosa (or, in the rectum, perimuscular tissues). The mucosa has three components: epithelium, lamina propria, and muscularis mucosae. The mucosal surface is covered by a single layer of low columnar to cuboidal epithelium into which the crypts of Lieberkühn open. This surface epithelium is composed of absorptive cells (with basally located nuclei, mucin-negative acidophilic cytoplasm, and luminally directed apical striated borders) and goblet cells (which synthesize, store, and secrete mucin granules). Lymphocytes and occasional eosinophils may be present between the surface epithelial cells, which rest on a continuous thin basement membrane.[1] The crypts have a tubular, test tube-like shape and are arranged parallel to each other. Branching of these glands occurs very rarely; its presence is usually an indication of chronic disease. It should be distinguished from the cloverleaf-like structure resulting from the opening of several crypts into a single innominate groove.[2]

The crypt epithelium contains mature absorptive cells and goblet cells similar to those in the surface epithelium, but, in addition, it features immature and undifferentiated precursor cells, endocrine cells, and Paneth cells. Both precursor and endocrine cells predominate at the base of the crypts.[3] As in the small intestine, the precursor cells are the progenitors of all other types of epithelial mucosal cells. Paneth cells, identified by their numerous eosinophilic secretory granules (much larger than those of most neuroendocrine cells), contain lysozyme, epidermal growth factor, and other substances. They are normally present only in the cecum and proximal right colon; their occurrence elsewhere in the colon is a sign of metaplasia, usually secondary to chronic mucosal injury.[4] Immunohistochemically, the epithelial cells of the normal colonic mucosa stain for CK8, 18, 19, and 20 but not CK7.[5]

The lamina propria contains a few lymphocytes (both T and B cells), plasma cells, histiocytes, and mast cells scattered in a network of collagen fibers, smooth muscle bundles, vessels, and nerves.[6] Intramucosal ganglion cells can also be seen, isolated or in clusters, but they carry no pathologic significance.[7] In other instances one finds scattered multinucleated stromal giant cells of presumed myofibroblastic nature, similar to those seen more frequently beneath squamous-lined mucosal membranes.[8] *Lymphoglandular complexes* are normal structures formed by deep crypt epithelium surrounded by lymphoid follicles that extend from the mucosa through the muscularis mucosae into the submucosa.[9] The *pericryptal fibroblast sheath* is a collection of fibroblasts or myofibroblasts located around the crypts and at the most superficial portion of the lamina propria.[10]

The macrophages in the lamina propria may contain brown pigment consisting of hemosiderin (usually as the result of prior mucosal hemorrhages) or "pseudomelanin" (as the consequence of ingestion of anthracene-type laxatives).[11] The latter condition, if

Abstract

The colon is one of the most common sites of the gastrointestinal tract biopsied during endoscopic evaluation. The majority of colonic biopsies are performed to exclude either inflammatory or preneoplastic or neoplastic processes. The most common forms of colitis encountered include inflammatory bowel disease (both ulcerative colitis and Crohn disease) and infectious colitis, ischemic colitis, and lymphocytic/collagenous colitis. In addition, a variety of polyps can arise in the colon or rectum, most commonly hyperplastic polyps, adenomatous polyps, and sessile serrated polyps/adenomas. The most common neoplastic process is colonic adenocarcinoma, often arising in patients with previous documented preneoplastic polyps.

extensive enough to be detectable grossly, is referred to as *melanosis coli*.[12] Macrophages containing mucin ("muciphages") are a normal finding and should not be confused with the cells of Whipple disease or with signet ring cancer cells.[13] When grouping in clusters, they have been dignified with the name *colonic histiocytosis*, but they are not the manifestation of a disease entity. Rather, they are probably the expression of a previous unimportant local injury.[14] Histochemically they may contain neutral or acidic mucin, mainly of the sialomucin type.[15]

The lamina propria vessels consist of capillaries (regularly distributed) and lymph vessels (limited to the region immediately above the muscularis mucosae).

The submucosa is composed of loose connective tissue having cell constituents similar to the lamina propria. It also contains the submucosal neural plexus of Meissner. The muscularis externa (propria) includes a circular inner layer and a longitudinal outer layer, with the myenteric neural plexus of Auerbach lying between them. The serosa is composed of a single layer of flattened to cuboidal mesothelial cells and the subjacent fibroelastic tissue.

Interstitial cells of Cajal are scattered throughout the wall, as they are in other portions of the gastrointestinal tract.

The large bowel is supplied by branches of the superior mesenteric artery (from the cecum to the splenic flexure) and the inferior mesenteric artery (distal to the splenic flexure). The lower portion of the rectum is irrigated by the middle and inferior rectal arteries, which are branches of the internal iliac arteries.

The lymphatic drainage of the colon is mainly through the mesentery into the paracolic groups of lymph nodes located along the marginal vascular arcades. Subsequent stations are the intermediate nodal groups (more proximal, at the level of major arterial branches), the central or principal lymph nodes (adjacent to the superior and inferior mesenteric arteries), and the entire para-aortic chain. The lymphatic drainage of the rectum is toward the inferior mesenteric artery nodes, the superior hemorrhoidal chain, and the hypogastric and common iliac nodes.

Hirschsprung Disease and Related Disorders

Hirschsprung disease is a common congenital disorder (1 in 5000 newborns) that results from lack of coordinated propulsive movement of the distal portion of the large bowel due to the loss of intrinsic inhibitory innervation.[16] This is caused by the absence of parasympathetic ganglion cells in the intramural and submucosal plexuses, which in turn may be caused by either failure of migration from the neural crest or by immune-mediated neuronal necrosis (Fig. 17.1).[17] It is diagnosed during the first year of life in most patients, but it may present later, occasionally even in adulthood.[18] Approximately 80% of the patients are male; 10% have Down syndrome, and another 5% have other serious neurologic abnormalities.[19] Cases have also been associated with intestinal atresia[20] and anorectal malformations.[21] Familial cases have also been described.[22] Hirschsprung disease is currently regarded as a genetic disorder with a complex pattern of inheritance. As many as eight genes can be involved, with the *RET* and *EDNRB* genes apparently playing major roles.[22,23] In the total colonic aganglionosis form of Hirschsprung disease, *RET* germline mutation is found in greater than 70% of cases.[23,24]

The symptoms usually begin shortly after birth, with abdominal gaseous distention, delayed meconium passage, and tight anus. With the passage of time, the large bowel proximal to the lesion undergoes dilation of the lumen and hypertrophy of the muscular wall, whereas the diseased segment is narrowed (Fig. 17.2). Mucosal prolapse may be seen at the junction between the ganglionic and aganglionic

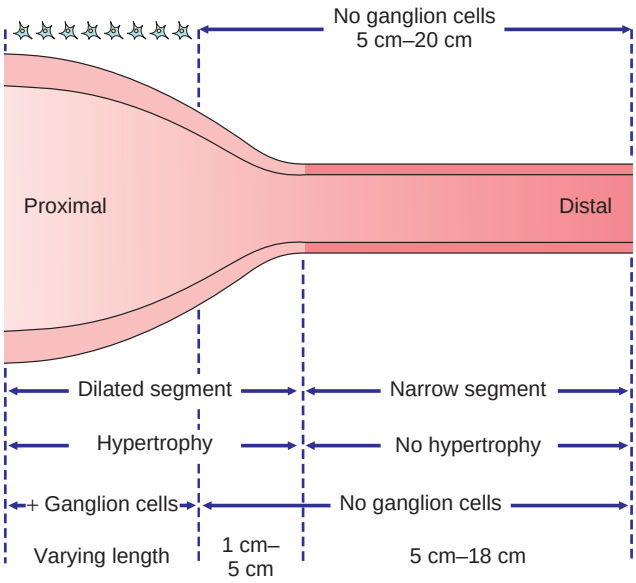

Figure 17.1 Schematic diagram of gross and microscopic changes in 15 cases of Hirschsprung disease.

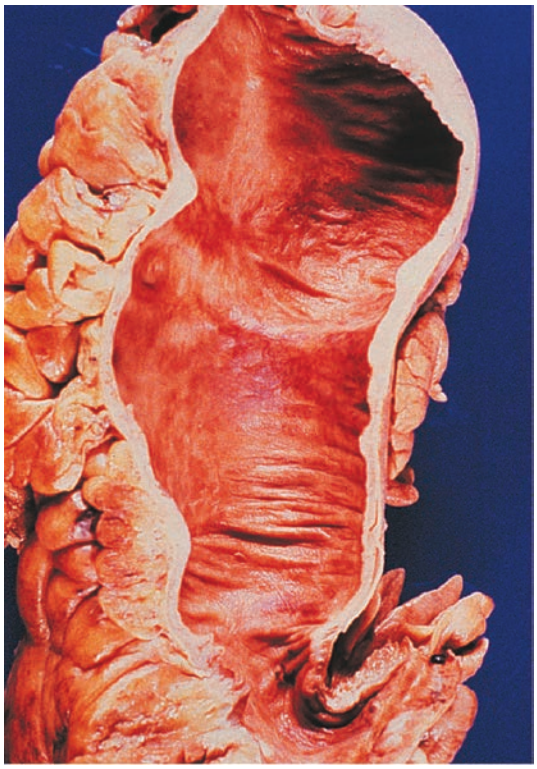

Figure 17.2 Gross Specimen of Hirschsprung Disease. The proximally dilated segment of bowel has been resected.

bowel, particularly in older patients.[25] The most important complications are acute intestinal obstruction and enterocolitis.[26,27]

Microscopically, the hallmark of the disease is the *absence* of ganglion cells (aganglionosis) in *both* plexuses of a segment of bowel.[28] This is associated with the presence of hypertrophied, disorganized, nonmyelinated nerve fibers of both adrenergic and nonadrenergic type in the aganglionic segment, which apparently fail to properly

innervate the muscle layers of the bowel.[29,30] There may also be an altered distribution of the interstitial cells of Cajal,[31] fibromuscular dysplasia in the arteries located in the transitional zone between the aganglionic and the dilated segments,[32] and hyperplasia of lymphoglandular complexes (the latter as an expression of secondary diversion colitis).[33]

Depending on the extent and location of the aganglionic segment, several forms of the disease have been recognized:

1. *Classic form:* The aganglionic segment begins in the distal colorectum and extends for a considerable distance in the adjoining proximal dilated bowel.
2. *Short-segment form:* The aganglionic segment involves the rectum and rectosigmoid for a distance of only a few centimeters.
3. *Ultrashort-segment form:* In this variant, the aganglionic segment is so short that the diagnosis can be missed if the biopsy is taken too high.[34]
4. *Long-segment form (total colonic aganglionosis):* Here the abnormality is more extensive, involving most or all of the large bowel, and occasionally even extending to the small bowel.[35] These patients present with symptoms of intestinal obstruction without megacolon.
5. *Zonal colonic aganglionosis:* Only a short segment of bowel is involved. In contrast to all other forms, ganglion cells are present not only above but also *below* the aganglionic segment.[36,37]

The traditional approach to morphologic documentation of Hirschsprung disease has been the biopsy procedure described by Swenson et al., in which a full-thickness segment of the muscular wall of the rectum is excised and examined for the presence of ganglion cells in the myenteric plexus.[16] Since ganglion cells are normally scanty near the internal anal sphincter, the standard guideline is that the biopsy should be taken at a point 2 cm above the anal valve in infants and 3 cm in older children,[38] even if some authors believe that biopsies taken at 1–1.5 cm from the anal valves may also be adequate.[34] The presence of squamous or transitional epithelium in a specimen indicates that the level of the biopsy is too low. Although this procedure is highly accurate, it requires technical skill, and general anesthesia and may lead to complications. For these reasons, "suction" or mucosal rectal biopsies are now typically done to confirm a diagnosis.[39] These are based on the premise that the limit of aganglionosis in Hirschsprung disease coincides closely in the submucosal and myenteric plexus, as shown by the careful microscopic mapping studies of Gherardi.[40] The ganglion cells of the submucosal plexus are smaller and more irregularly distributed than those located intermuscularly, and their identification requires expertise, patience, and the performance of serial sections in the biopsy obtained. Another abnormality that ought to be looked for is the presence of large (40 µm or greater) submucosal nerve trunks, since they correlate closely with the absence of ganglion cells.[41] Yunis et al. found that, in experienced hands, the mucosal biopsy is a simple and effective method for the exclusion of Hirschsprung disease.[42] These biopsies also can be evaluated with acetylcholinesterase histochemical stain, which highlights a marked increase in thick nerve fibers throughout the lamina propria and muscularis mucosae in patients with this disorder (Fig. 17.3).[43] In problematic cases, it has been shown that the determination of the acetylcholinesterase–butyryl-cholinesterase ratio may be helpful.[44] A number of immunohistochemical techniques have been reported to be useful in the diagnosis of this disease, including neuron-specific enolase, PGP 9.5, neurofilaments, microtubule-associated ("Tau") and MAP-2 proteins, antisynaptic vesicles 171 B.5, Neu N, BMPRIA, ret oncoprotein, cathepsin D (which highlights the presence of hypertrophied nerve fibers and the absence of ganglion cells) and S-100 protein (which shows absence of the normal perigangliionic satellite cells and accentuates the enlarged nerve bundles).[45–48] Yet another promising marker is calretinin, whereby loss of calretinin-immunoreactive nerves is characteristic of Hirschsprung disease,[49] a stain we have found to be most useful in our practice.

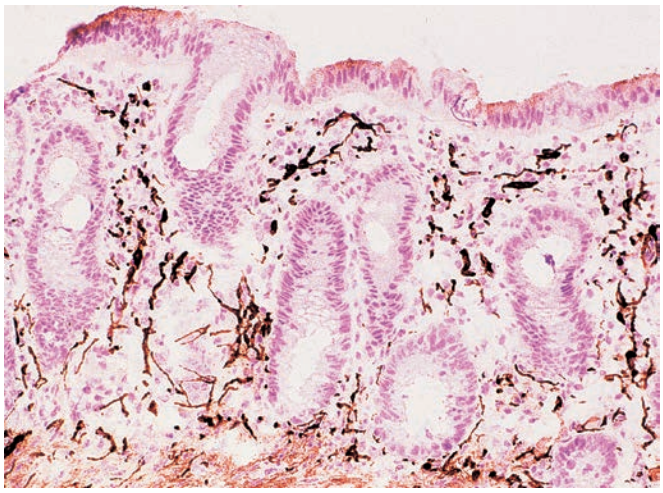

Figure 17.3 Colonic mucosa stained for acetocholinesterase from a patient with Hirschsprung disease. There is a marked increase in the number of nerve fibers in the lamina propria.

The ganglion cells present in the proximal segment, which appear normal by both hematoxylin and eosin (H&E) and the generic neuronal stains listed previously, may still fail to react for colonic neuropeptides such as VIP, GAL, SP, NPY, CGRP, and Met-ENR. It has been suggested that these abnormalities of enteric innervation may be responsible for the unsatisfactory postoperative results seen in approximately 20% of the cases.[50]

Another interesting finding is the marked elevation of class II major histocompatibility antigens in the aganglionic area (not present in patients with chronic constipation resulting from other causes), suggesting an underlying autoimmune mechanism for the disease.[51]

Frozen section is routinely used for documenting the absence of ganglion cells and determining the level of transection of the bowel at surgery. This procedure is facilitated if the surgeon gives the pathologist a rectangular piece of the entire muscular wall, so that the tissue can be properly oriented. For frozen section evaluation to be reliable, the tissue should be at least 4 mm long, and multiple serial sections should be taken. Even under these ideal circumstances it should be understood that the inaccuracy rate is relatively high, significantly more so than for frozen section diagnoses in general.[52]

The most common operations for the treatment of Hirschsprung disease are Swenson proctectomy with pull-through of ganglionic bowel to the anus, the Duhamel side-to-side anastomosis of ganglionic bowel with the aganglionic rectal stump, and the Soave endorectal pull-through, in which the rectal mucosa is stripped away and the ganglionic bowel brought down to the anus.[53,54]

Occasionally, successfully operated patients develop a recurrence of obstructive symptoms and are found to have aganglionosis in pulled-through bowel that had previously been shown to be ganglionated.[55]

Hypoganglionosis is a disputed entity in which there is a deficiency rather than an absence of ganglion cells.[56,57] It should be remembered that a decrease of ganglion cells is usually present at the junction between the dilated and aganglionic bowel in conventional Hirschsprung disease.

Intestinal neuronal dysplasia (neuronal colonic dysplasia, hyperganglionosis) is another controversial entity or entities included

in the vague group of disorders generically designated as pseudo-Hirschsprung disease.[58] Hyperplasia of the myenteric nerves is accompanied by giant ganglia, isolated ganglion cells in the submucosa, and an increase in acetylcholinesterase staining;[59] it has been described in association with von Recklinghausen disease and multiple endocrine neoplasia.[60,61] However, the entity is far from well defined, and its diagnosis should be reserved for the rare florid cases that occur in the absence of associated obstruction or other known entities and should be made only if multiple biopsies, including ample submucosa or transmural sections (preferably the latter), are available.[62]

Chronic idiopathic intestinal pseudo-obstruction is a syndrome in which symptoms of intestinal obstruction are present in the absence of mechanical obstruction. It has been attributed to an abnormal physiology of the bowel propulsive system. Loss of CD117-positive (presumably interstitial cells of Cajal) and CD34-positive cells has been found in a subset of these cases.[63] Staining for BCL2 is said to be a useful means of evaluating the presence of immature enteric ganglion cells that are allegedly present in this and some of the other nebulous conditions listed in this section.[64]

Slow transit constipation is yet another colonic mobility disorder characterized by delayed movement of stools through the colon. The mean number of interstitial cells of Cajal and enteric neurofilaments are said to be considerably reduced in this condition, particularly in the inner circular muscle layer.[65]

Megacolon can also result from **cytomegalovirus (CMV) infection** and **Chagas disease** as the result of acquired abnormalities of the neural plexuses.[66] In the latter condition there is a cytotoxic T cell–rich inflammatory infiltrate of the enteric plexuses accompanied by degeneration of ganglion and glial cells.[67,68]

Diverticulosis

Most cases of diverticulosis are acquired and occur in patients over the age of 40 years. Clinical evidence of diverticulosis is seen in slightly over 10% of the individuals in this age group, but surgical complications develop in only 10% of them.[69] Naturally, the incidence of diverticulosis at autopsy is higher; in a study from Australia, 45% of 200 examined large bowels had diverticula.[70] There have been reports of diverticula occurring in children, in young patients with Marfan, Williams–Beuren, or Ehlers–Danlos syndrome, and in association with polycystic renal disease.[71–73]

Diverticulosis shows a remarkable geographic difference in its frequency. It is common in North America, Europe, and Australia but uncommon in Asia, Africa, and parts of South America.[74] The main protective factor seems to be a high-residue diet, although the evidence is not conclusive.[75] This type of diet is thought to act by diminishing the degree of colonic segmentation, which is the mechanism responsible for mucosal herniation. The disease is characteristically multiple and preferentially involves the left colon. In the previously mentioned autopsy study from Australia, the sigmoid colon was affected in 99% of the specimens.[70] This was the only area of involvement in 41% of the cases; in 30%, the disease involved the descending colon; in 4%, the transverse colon; and in 16%, the entire colon. The rectum is only rarely affected. The distribution of the disease is different in patients from the Far East, in whom there is a greater frequency of right-sided involvement.[76]

As seen radiographically and grossly, the diverticula are located on the mesenteric and lateral aspects of the bowel (Figs. 17.4 and 17.5). They have a flask-like shape and may be filled with feces or mucin. Some extend into the appendices epiploicae and bulge over the serosa, but they may still be difficult to recognize at the time of surgery in obese persons. The muscular wall of the bowel always appears abnormal in the area of diverticulosis. The teniae are

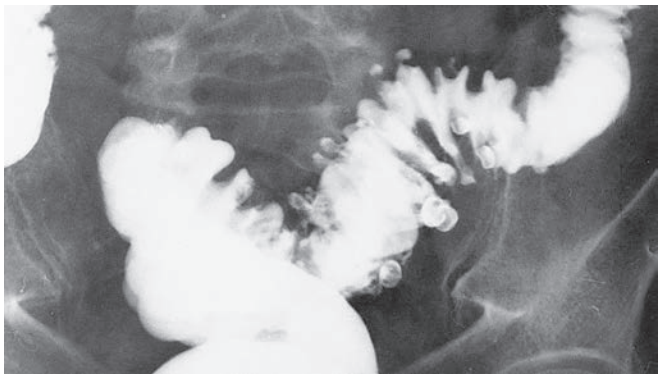

Figure 17.4 Classic radiographic appearance of diverticulosis.

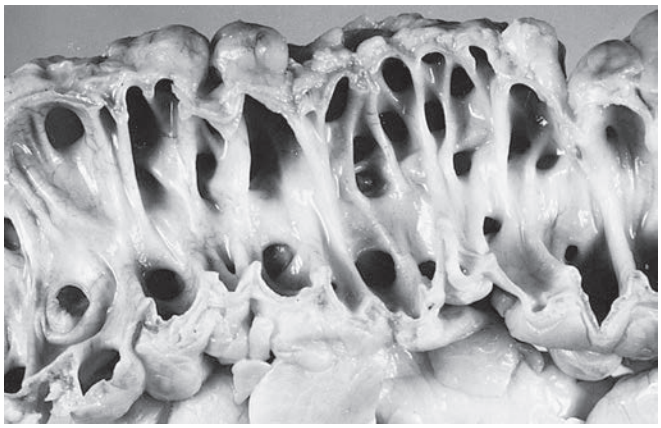

Figure 17.5 Extensive diverticulosis of the sigmoid colon with segmentation and shortening of bowel. Openings of diverticula can be clearly seen. The circular muscle is thick and corrugated.

Figure 17.6 Whole-mount section of colonic diverticular disease.

prominent, with an almost cartilaginous look. The circular layer is also thickened, with a corrugated appearance corresponding to interdigitating processes of the muscle.[77] Microscopically, the diverticulum lacks a muscle layer except for residual bundles of muscularis mucosae (Fig. 17.6). The adjacent bowel, including the myenteric plexus, shows no appreciable abnormalities. Polypoid prolapsing mucosal folds may occur, probably resulting from a combination of venous congestion and mucosal redundancy caused by the spastic contraction of the muscle coat.[78]

Cecal diverticula may be of two types. One, usually multiple, is similar in all aspects to diverticula of the left colon and is often associated with them. The other, thought to be congenital, is solitary

and unassociated with diverticular disease elsewhere; it is usually located on the medial wall of the cecum near the ileocecal valve and contains an external muscle layer.[79]

The main complications of diverticulosis are hemorrhage, perforation, and diverticulitis. The bleeding, which is right sided in about half of the cases and which may be massive, results from rupture of one of the colonic nutrient vessels that run on the side of the diverticulum.[80] Arteriographic and microangiographic techniques have shown a characteristic asymmetric rupture of the vessel toward the lumen of the diverticulum precisely at its dome or antimesenteric margin.[81]

Perforation of the diverticulum may lead to a pericolic or pericecal abscess, which in later stages evolves into an indurated mass that may be confused with carcinoma clinically and radiographically. The abscess may drain into bladder or adjacent bowel and result in fistula formation (*"dissecting diverticulitis"*), producing a double tracking effect on x-ray studies. Rarely, this fistulous tract may extend into the perineum, scrotum, buttocks, hip, or even lower extremities.[82] Acute free perforation into the abdominal cavity is rare. Sometimes the release of mucin contained within the diverticula results in a pericolic mucocele-like formation. Exceptionally, hyaline rings ("pulse granulomas") similar to those seen more often in the oral cavity are found in the areas of perforation.[83]

Diverticulitis manifests radiographically with sawtoothed serrations and a narrowed lumen. It may resemble carcinoma, but the segment involved is usually longer and the mucosa is intact. Microscopically, there is acute or chronic inflammation in—but mainly around—the base of the diverticulum (Fig. 17.7). Sometimes there is granulomatous inflammation around the diverticulum that can closely simulate Crohn disease. Not uncommonly, there is a chronic colitis limited to the sigmoid colon in areas near diverticula that are indistinguishable from idiopathic inflammatory bowel disease (IBD) in the absence of clinical and endoscopic data (see next section).[84–86] The inflammation can spread into the mesentery and result in panniculitis, not to be confused with sclerosing mesenteritis.

Pain, a common symptom of diverticular disease, may be secondary to these inflammatory changes; however, it may also be present in the absence of diverticulitis and is probably induced by the muscle abnormalities. Parenthetically, chronic corticosteroid therapy may lead to free perforation of the colon and closely simulate the picture of diverticulosis with diverticulitis.[87] Exceptionally, a polyp or carcinoma is found contained within a diverticulum.[88]

Acute uncomplicated diverticulitis can often be treated successfully with antibiotics alone.[89] Surgical resection is often performed in patients with complications of diverticulitis such as hemorrhage, ulceration, perforation, abscess formation, fistulae, strictures, obstruction, and pylephlebitis.[90] Prompt resection for patients with free diverticular perforation and spreading peritonitis may be required. Not surprisingly, morbidity and mortality rates are higher in these instances than when resections are performed for uncomplicated acute diverticulitis.[91] Other indications for surgery are repeated attacks of diverticulitis while on a good medical regimen and the development of urinary symptoms. The latter may be the manifestation of an impending sigmoid–vesical fistula.

Colitis

The term *inflammatory bowel disease*—sometimes preceded by the qualifier *idiopathic*—is employed for a group of inflammatory disorders currently thought to be associated with a number of susceptibility genes leading to defects in the epithelial barrier function, and activation of the mucosal immune system driven by the presence of normal luminal flora (commensal bacteria and their products).[92,93] The two main members of this group are ulcerative colitis and Crohn disease. However, as discussed later, distinction between these forms of IBD may be impossible in some cases (Table 17.1).

Table 17.1 Comparison of clinical and pathologic features between ulcerative colitis and Crohn disease

FEATURE	ULCERATIVE COLITIS	CROHN DISEASE
Clinical Features		
Rectal bleeding	Common	Uncommon
Abdominal mass	Very rare	10-15%
Abdominal pain	Usually left-sided	Usually right-sided
Sigmoidoscopy	Abnormal in 95%	Abnormal in <50%
Free perforation	10-15%	<5%
Colon carcinoma	5-10%	Very rare
Anal complications	Very rare	75% (fissures, fistulas)
Pathologic Features		
Distribution	Diffuse, predominantly left-sided Mucosal, some submucosal	Patchy, predominantly right-sided Transmural
Fissures	Absent	Common
Fistulas	Absent	Common
Rectal involvement	Virtually always	<50%
Ileal involvement	Backwash in pancolitis	>50%
Pyloric gland metaplasia	Uncommon	Common
Granulomas	Crypt rupture	True granulomas in >50%

Ulcerative Colitis

Ulcerative colitis occurs with equal frequency in both sexes. It appears most often in patients between 20 and 30 years of age; however, it can occur at any age, including in childhood.[94,95] The etiology remains unknown. There is increasing evidence that susceptibility is inherited, although the genetic contribution does not seem to be as important as for Crohn disease. The duration is usually prolonged, with many remissions and exacerbations; nutritional deficiencies and anemia are common accompanying features.

Ulcerative colitis is characteristically a left-sided disease that begins in the rectosigmoid colon. In some cases, it remains localized to the rectum *(ulcerative proctitis)*, but in most instances it spreads proximally, sometimes to involve the entire colon *(pancolitis)*.

The gross appearance of the lesions varies with the stage of the disease (Fig. 17.8). In the acute form, the mucosal surface of the bowel is wet and glaring from blood and mucus, and petechial hemorrhages are often seen. Various-sized ulcers of irregular configuration then appear. Some of these ulcers undermine the mucosa so that mucosal bridges with an underlying inflammatory infiltrate develop. Extensive longitudinal ulcers, especially if connected by transverse ulcers, are *not* a feature of ulcerative colitis and are more characteristic of Crohn disease. Elevated sessile reddish nodules, known as *pseudopolyps*, are often seen in an otherwise flat surface (Fig. 17.9). They are typically small and multiple. Rarely, they may have a filiform configuration; sometimes they attain a giant size, thus raising the clinical and radiographic suspicion of carcinoma.[96]

In the more advanced stages of the process, the entire bowel becomes fibrotic, narrowed, and shortened. The cicatricial stenosis associated with an inflammatory mass may result in an erroneous clinical and radiographic diagnosis of carcinoma. If the colon has become defunctionalized with an ileostomy or colostomy before the colectomy, it may show extreme narrowing of the lumen, striking atrophy of all the components of the wall, and a marked increase in pericolic fat. In the quiescent stage, ulceration is absent, the mucosa is atrophic, and there may be extensive submucosal fat deposition. In some cases the mucosa may appear grossly normal.

Microscopically, ulcerative colitis is primarily a mucosal and submucosal disease.[97,98] In the acute phase, there is an increase in the number of inflammatory cells in the lamina propria, including basal plasmacytosis. Crypt abscesses (i.e. collections of neutrophils in the glandular lumen) appear; these are preceded by accumulation of these cells at the base of the crypts (Figs. 17.10–17.12). This leads to a progressive destruction of the crypts, which show a marked decrease in cytoplasmic mucus and irregular shapes, resulting from a combination of atrophic and regenerative changes. These regenerative changes are also manifested by nuclear enlargement and increased mitotic activity; the latter is no longer limited to the lower portion of the crypts, as in the normal mucosa. Paneth cells, usually absent

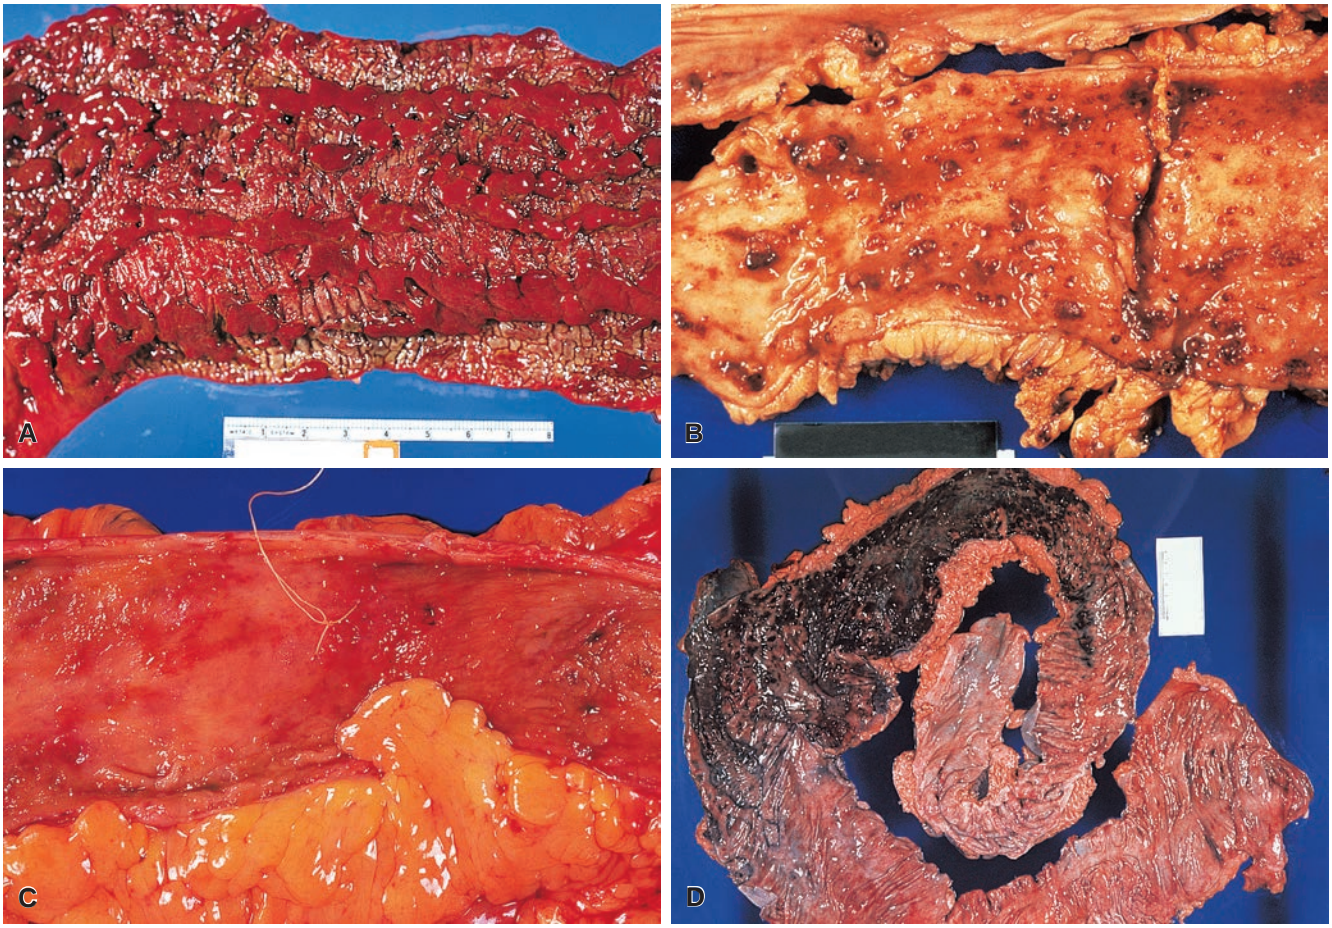

Figure 17.8 Various Gross Appearances of Ulcerative Colitis. beyond the right colon in normal individuals, appear as an expression of metaplasia, and are an indicator of chronic colitis.

The stromal inflammatory infiltrate of ulcerative colitis is composed of neutrophils, lymphocytes, plasma cells, a few histiocytes and other "accessory immune" cells, scattered eosinophils, and mast cells.[99,100] As a rule, granulomas containing epithelioid and multinucleated giant cells are absent, this being an important criterion in the differential diagnosis with Crohn disease. However, crypt-associated intramucosal granulomas may supervene in ulcerative colitis as a result of crypt rupture.[101] The infiltrate may be accompanied by numerous lymphoid

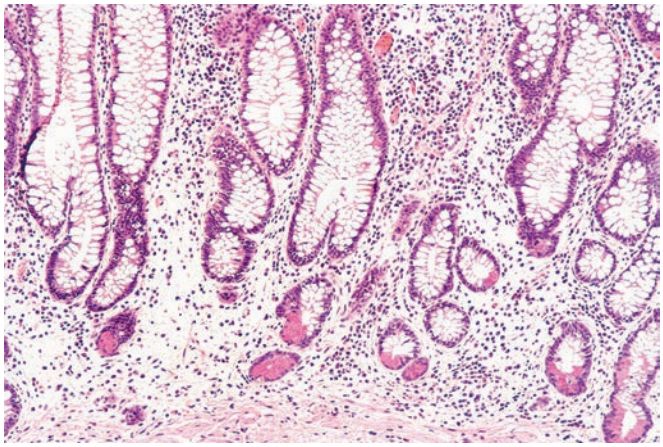

Figure 17.12 Chronic changes in ulcerative colitis characterized by crypt architectural distortion and Paneth cell metaplasia.

follicles, particularly in the rectum, and may lead to marked distortion of the crypts. Blood vessels are dilated, and mucosal capillary thrombi may be seen.[102] The inflammation may remain above the muscularis mucosae or extend into the submucosa. Ulcers and granulation tissue may be prominent and can result in pseudopolyps composed of granulation tissue mixed with inflamed and hyperemic mucosa. In some instances, the mucosal regeneration acquires a villous configuration reminiscent of small bowel mucosa.[103] Depending on the stage of the disease, the submucosa may appear normal or inflamed, hyperemic, infiltrated by fat, or fibrosed; sometimes it contains glands that have herniated through gaps in the muscularis mucosae, which often appears hypertrophic.[104] In approximately 10% of cases, the submucosal arteries show features of endarteritis obliterans, with or without thrombosis. The muscularis mucosae may appear reduplicated, but the muscularis externa is usually normal or slightly hypertrophic.[105]

As already stated, in the quiescent or resolving stage of the disease, the mucosa may appear grossly normal, with nearly total restoration of the mucin content. However, subtle microscopic abnormalities are often detected in the form of branching and irregular glands (rather than parallel, evenly spaced glands), a gap between the base of the crypts and the muscularis mucosae, the appearance of Paneth cells and hyperplasia of neuroendocrine cells. However, there are cases where medical therapy can induce a return to histologically normal mucosa, without any vestiges of prior mucosal injury.[106,107] It should also be noted that pediatric patients may show a near normal or even (very rarely) a completely normal rectum at first diagnosis.[108,109]

Ulcerative colitis can spread to other portions of the gastrointestinal tract. The ileum is involved in approximately one-fifth to one-third of the cases. This involvement (sometimes referred to as *backwash ileitis*) is superficial, mild, of little clinical importance, and typically occurs in continuity with the colonic disease; it rarely spreads more than 10 cm from the ileocecal valve and may be accompanied by dilation of the lumen.[110,111] Rare cases of diffuse *duodenitis* in ulcerative colitis patients have been described.[112]

Interestingly, the ileal stoma of proctocolectomized patients may develop colonic metaplasia and ulcerative colitis-like lesions, including inflammatory polyps.[113] Similar changes have been described in pelvic ileal reservoirs (ileal pouches) constructed in patients with ulcerative colitis *(postcolectomy pouchitis)*.[114] In turn, the defunctioned rectum may show changes that can simulate Crohn disease and are thought to result from a combination of defunctioning and of active ulcerative colitis.[115]

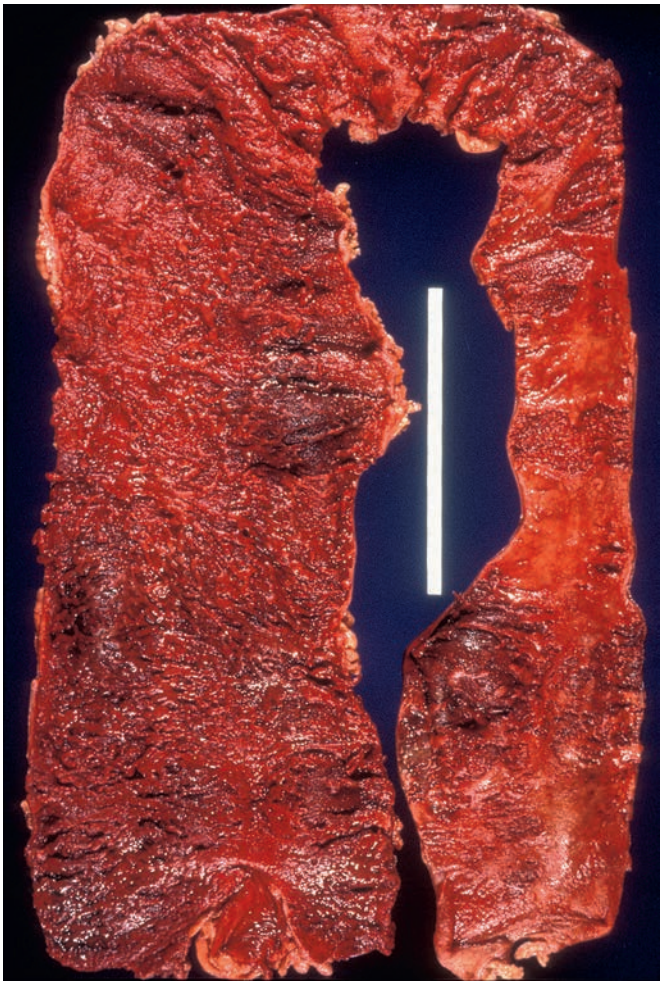

Figure 17.13 Fulminant ulcerative colitis complicated by toxic megacolon.

The vermiform appendix is affected in 20%–60% of cases; this may occur in continuity with adjacent involved cecum or as a skip lesion.[116,117] In the anal canal, there is often involvement of the glandular epithelium, and sometimes there are hyperplastic changes of the transitional mucosa.[118] Anal lesions are seen in 10% of cases; they may consist of midline dorsal fissures, skin excoriations, acute perianal and ischiorectal abscesses, or rectovaginal fistulas.

Some patients with ulcerative colitis have associated liver disease. This may consist of fatty infiltration, abscess, cirrhosis, sclerosing cholangitis, pericholangitis, and—rarely—carcinoma of the biliary tract.[119,120] Patients in whom the latter complication occurs are younger than those developing carcinoma de novo.[120]

Other distant manifestations of ulcerative colitis include arthritis, uveitis, pyoderma gangrenosum, and limited forms of Wegener granulomatosis.[121] These are usually limited to patients with extensive colonic involvement and appear only exceptionally in those with disease limited to the rectum.

Local complications of ulcerative colitis are perforation with peritonitis and abscess, toxic megacolon (Fig. 17.13), venous thrombosis (most often in the iliac vein), and carcinoma (discussed in the next section).

The treatment of ulcerative colitis, depending on its extent, severity, and duration, includes sulfasalazine therapy, local or systemic steroid therapy, and total colectomy.[122–124]

Carcinoma and Dysplasia in Ulcerative Colitis

The incidence of carcinoma of the large bowel is markedly increased in patients with ulcerative colitis.[125,126] The overall incidence of this complication is probably in the vicinity of 2%, which represents only 1% of all cases of colorectal carcinoma in the general population.[127] Risk factors include patients with extensive colitis, those with disease for greater than 7–10 years, young age of colitis onset, and primary sclerosing cholangitis.[128–131]

Studies have emphasized the atypical gross appearance of the carcinoma developing in ulcerative colitis, its more even distribution in the large bowel, its frequent multiplicity (10%–20% of the cases), its tendency to occur in younger persons, and the fact that the site of origin is almost always a flat rather than a polypoid mucosa.[132,133] Carcinoma may also develop in the rectal cuff or pouch following ileoanal pouch anastomosis.[134,135]

The earliest gross change is often represented by a thick mucosa with a finely nodular or velvety surface configuration. Microscopically, most of these tumors are adenocarcinomas of varying degrees of differentiation. The proportion of poorly differentiated and mucinous carcinomas is higher than for tumors arising in uninflamed mucosa, but rare low-grade well-differentiated tubuloglandular forms also exist.[136] It has been traditionally assumed that carcinomas developing in this setting carry an ominous prognosis; however, in several series with control subjects from a population without colitis matched by stage and microscopic grade, no difference in survival between the two groups has been found.[137–139]

The development of adenocarcinoma is always accompanied—and probably always preceded—by dysplastic changes of the colorectal mucosa. These dysplastic changes, which tend to occur in flat atrophic mucosa, should be distinguished from the more common regenerative changes that are often seen in inflamed mucosa.[140] As a rule, the diagnosis of dysplasia should not be made in areas of active inflammation. The evaluation of these changes is difficult and somewhat subjective,[141] but, when properly done, it has been successful in identifying a population at high risk for developing colorectal carcinoma.[142] The presence of dysplastic changes does not necessarily indicate that the patient harbors an invasive carcinoma elsewhere in the bowel. Similarly, the absence of such changes does not guarantee that the patient is free of carcinoma elsewhere. A standardized classification of dysplasia has been recommended,[143] using the following terminology (Figs. 17.14–17.17):

1. Negative for dysplasia
2. Indefinite for dysplasia

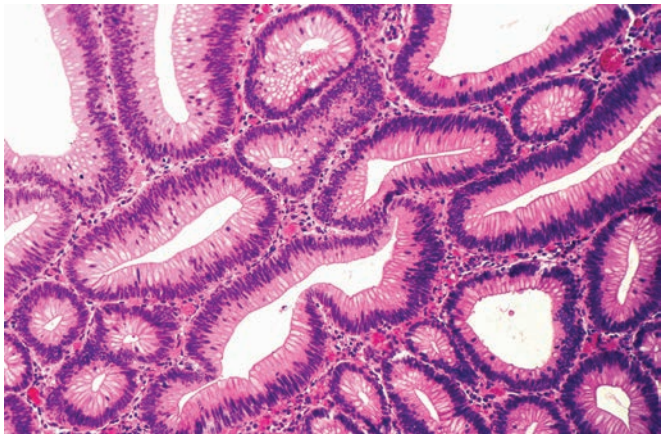

Figure 17.14 Focus of polypoid low-grade dysplasia in ulcerative colitis. The focus is histologically indistinguishable from a sporadic tubular adenoma.

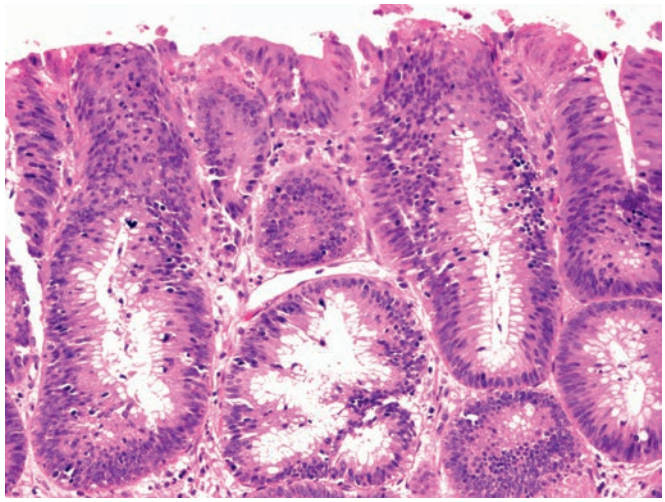

Figure 17.15 Focus of flat low-grade dysplasia in ulcerative colitis.

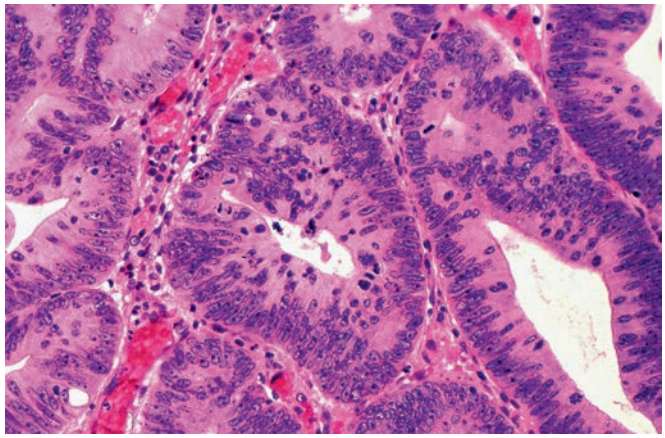

Figure 17.16 Flat high-grade dysplasia in ulcerative colitis characterized by marked cytologic atypia and architectural complexity.

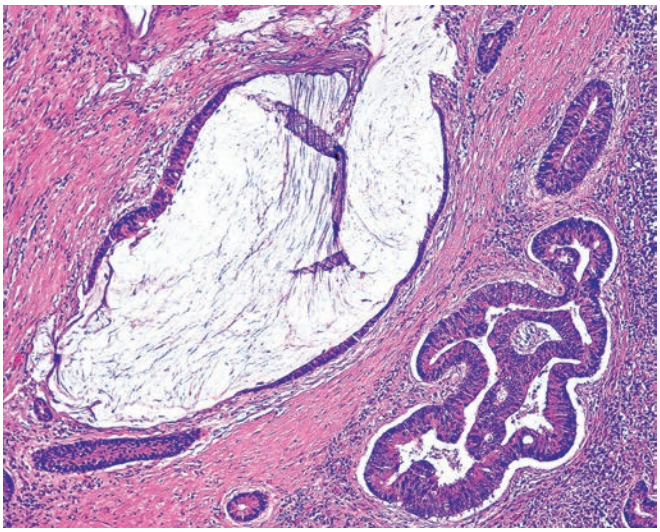

Figure 17.17 Invasive adenocarcinoma with abundant extracellular mucin arising in a colon affected by ulcerative colitis.

3. Positive for dysplasia, low grade
4. Positive for dysplasia, high grade

Pathologic diagnosis directly impacts patient management. Patients with a diagnosis of indefinite for dysplasia are treated with maximal medical therapy to reduce inflammatory changes and are brought back for repeat biopsy in a shorter period of time than those whose biopsies are negative for dysplasia. The implications of biopsies with low-grade or high-grade dysplasia in part depend on the endoscopic appearance of the area in question. For polypoid lesions, most cases can be treated by endoscopic polypectomy, even those with high-grade dysplasia.[144–146] However, most patients with flat high-grade dysplasia, and many with flat low-grade dysplasia (especially if multifocal), opt for colectomy.[145] Histologically, it is not possible to reliably distinguish a sporadic adenoma arising in a field of IBD from IBD-related polypoid dysplasia. By immunohistochemistry, IBD-related dysplasia tends to show strong staining for p53 and absent or weak staining for β-catenin,[147] as well as Ki-67 staining above the basal two-thirds of the crypt.[148] However, there is overlap with the patterns seen in sporadic adenomas, thereby limiting the clinical utility of these markers.

At the molecular level, the aberrations encountered in the dysplastic glands have included *TP53* mutation,[149,150] *KRAS* mutation,[151] and microsatellite instability (MSI).[151] It has also been found that ulcerative colitis patients with dysplasia and/or carcinoma have a much greater degree of genomic instability in both their dysplastic and nondysplastic mucosa than those lacking morphologic features of dysplasia/carcinoma.[152]

An interesting issue is whether the immunohistochemical and molecular alterations of the dysplastic lesions in ulcerative colitis (and therefore the mechanisms leading to its appearance and progression) are the same as or different from those operating in colorectal adenomas (which, of course, can be present in the large bowel affected by ulcerative colitis).[153–155] Although the results from the various groups are not always congruent, a consensus is beginning to emerge that flat dysplastic lesions in ulcerative colitis patients show substantial differences from de novo colorectal adenomas, whereas the polypoid dysplastic lesions in the same patients are very similar if not identical to the de novo lesions.[155–157]

The presence of these immunohistochemical or molecular alterations may be helpful in confirming the presence of dysplasia and eventually contribute to its grading, but at the present time this determination is largely based on the appearance of the epithelium in routinely stained sections. The surveillance protocols that have been devised for patients with ulcerative colitis, recommended to be started after 8–10 years of extensive colitis and after 15 years of left-sided colitis, depend on the skill and experience with endoscopic and microscopic features on the part of the gastroenterologist and pathologist, respectively.[158,159] Whether this close surveillance is actually truly beneficial and cost-effective remains controversial.[160] It needs to be emphasized in this regard that the absence of dysplasia in a colorectal biopsy does not exclude the possibility of the patient developing adenocarcinoma in the future.

Other colorectal malignancies that rarely occur in association with ulcerative colitis are various types of *neuroendocrine neoplasms*[161] and *malignant lymphoma*, particularly in the setting of immunosuppressive therapy.[162,163]

Crohn Disease

Crohn disease, originally described as a small bowel disorder, is now known to involve the large bowel in approximately 40% of all cases, with or without a concomitant ileal component. The etiology remains undetermined. Susceptibility to the disease is inherited, suggesting a genetic contribution to its development.[164] Bacterial infection and the gastrointestinal "microbiome" are also hypothesized to be important in the pathogenesis of this disease.[165]

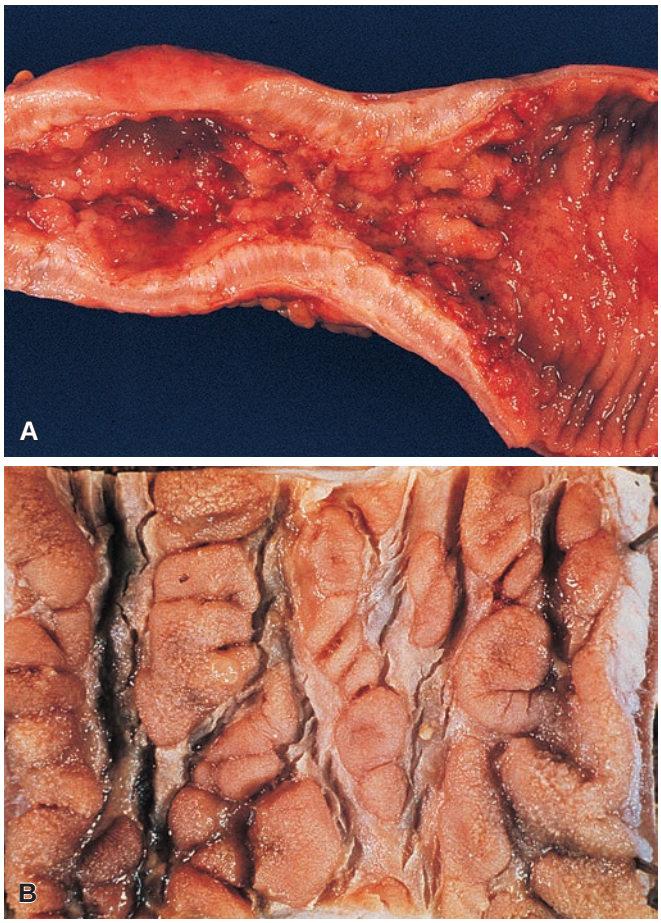

Figure 17.18 Gross Appearance of Crohn Disease of the Large Bowel. **A,** Segmental involvement with transmural inflammation and a stricture. The appearance is similar to that seen in small bowel Crohn disease. **B,** Typical cobblestone appearance.

Grossly, segmental distribution of the lesions (with "skip" areas that can be demonstrated radiographically), and preference for the right side of the colon are two important diagnostic features. Other gross findings of significance include stricture formation, fissuring, a cobblestone appearance, transmural involvement, and fat wrapping (Fig. 17.18). The ulcers (fissures) are linear, serpiginous, and discontinuous, with an intervening normal or edematous (but not markedly abnormal) mucosa. Often, they run longitudinally for long distances and are connected by short transversal ulcers (Fig. 17.19). Healing of this process leads to long rail-track scars. Sometimes, pseudopolyps (of the usual filiform or giant type) and mural bridging lesions develop similar to those seen in ulcerative colitis.[96,166] The microscopic appearance of Crohn disease in the large bowel is not qualitatively different from that seen in the small bowel. Fissures, noncaseating sarcoid-like granulomas (present in 40%–60% of cases), and transmural involvement are the typical triad of colonic Crohn disease. The mucosa has a relatively normal appearance and retains a significant amount of mucus, even in areas immediately adjacent to ulcerations. The presence of a well-defined focus of inflammatory cells surrounded by noninflamed and histologically normal mucosa is particularly suggestive of Crohn disease, as is the predominance of inflammatory infiltrate deep into the mucosa and extending into the submucosa. However,

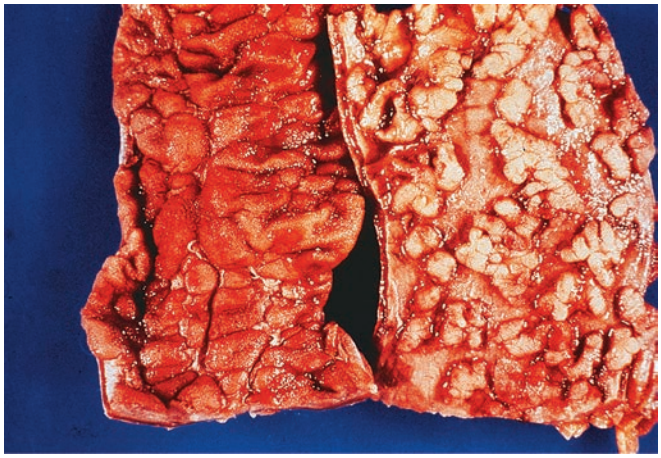

Figure 17.19 Comparison between pseudopolyps in ulcerative colitis *(right)* and the cobblestone pattern of Crohn disease *(left)*.

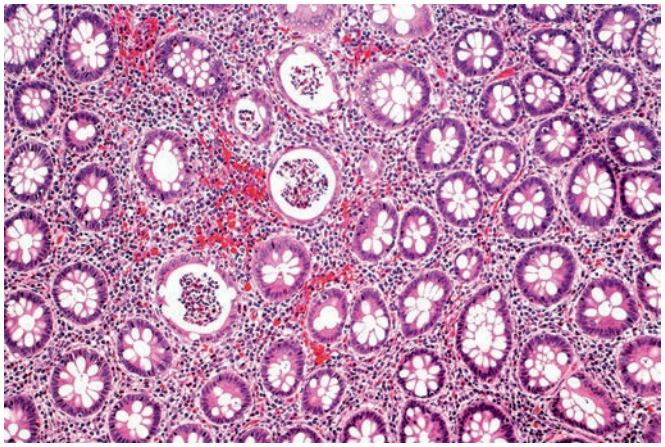

Figure 17.21 Patchy active inflammation in mucosa involved by Crohn disease with crypt abscesses.

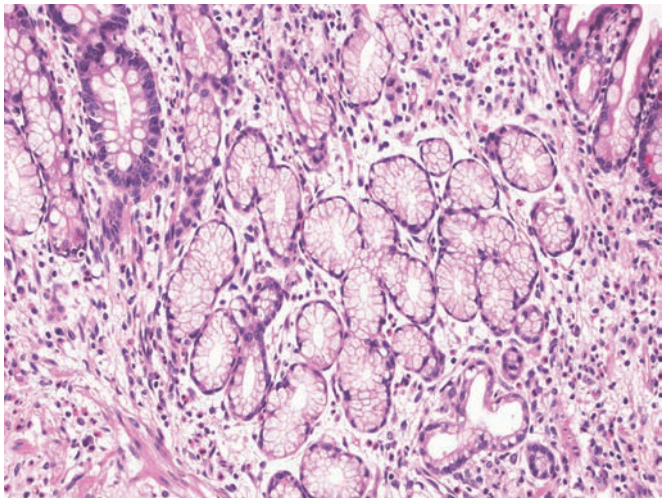

Figure 17.20 Focus of pyloric gland metaplasia in mucosa involved by Crohn disease.

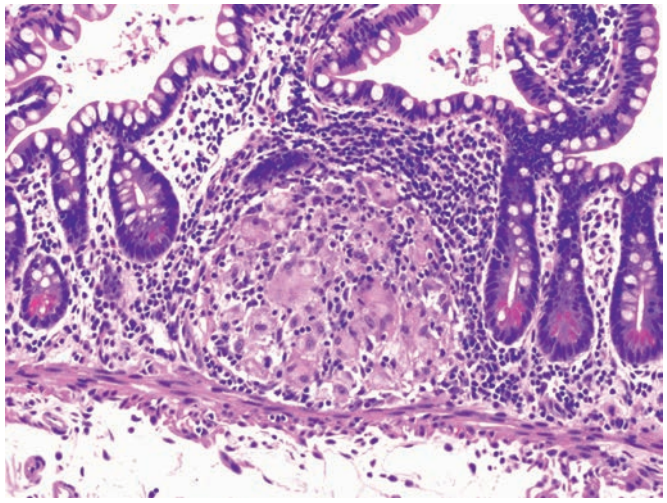

Figure 17.22 Crohn disease with a mucosal granuloma in the ileum.

on occasions the disease is superficial (i.e. limited to the mucosa and submucosa); in these instances, the cobblestone pattern is more diffuse and more finely nodular than is seen in classic Crohn disease.

The main features to look for in an endoscopic biopsy are patchy mucosal inflammation, granulomas, preservation of the goblet cell population, pyloric gland metaplasia, and maintenance of the architecture of the glands (Figs. 17.20–17.23). Serial sections may be necessary to demonstrate granulomas.[167] A rectal biopsy may be normal or show minor nonspecific changes, and a microscopically normal rectal biopsy in a definite case of colitis strongly favors Crohn disease over ulcerative colitis in the untreated setting.[168] If a colon involved by Crohn disease contains diverticula, the inflammatory process often spreads to them, making distinction from diverticulitis very difficult.[169] As previously mentioned, diverticular-associated colitis may have a Crohn-like pattern. Thus, inflammatory changes away from diverticula are the most useful finding in distinguishing these inflammatory conditions.

The ileum is involved in approximately 50% of cases of colonic Crohn disease.[168] Anal lesions are seen in 75% of cases and may present as chronic fissures, fistulas, and ulceration, and they can be

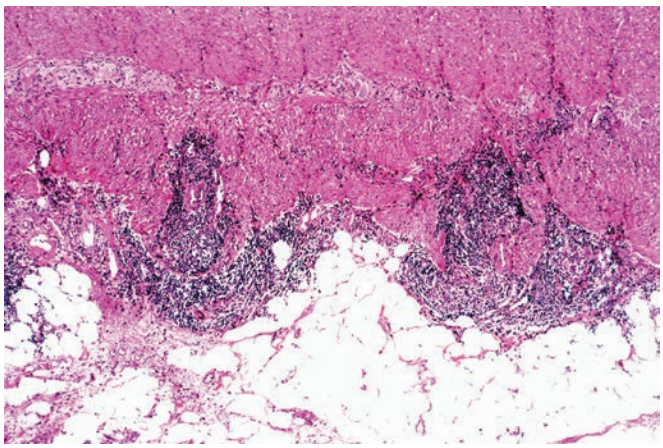

Figure 17.23 Resection specimen of Crohn disease showing transmural lymphoid aggregates.

the first clinical manifestation of Crohn disease.[170] The regional lymph nodes are often enlarged. Microscopically, they do not differ significantly from those in patients with ulcerative colitis, except for the occasional presence of granulomas.

One of the most common complications of Crohn disease is the formation of fistulas, arising on the basis of fissuring. Although perianal fistulas can be seen in both Crohn disease and ulcerative colitis, internal fistulas are virtually pathognomonic of the former.

Other complications of Crohn disease include skin ulceration (of perianal skin, around colostomies and ileostomies, and elsewhere) and toxic megacolon.[171] In a series of 615 patients with Crohn disease studied at the Cleveland Clinic, the overall incidence of toxic megacolon was 4%.[172] No cases were found when the disease was limited to the small bowel, but megacolon developed in 2% of patients with ileocolic disease and in 11% when the disease was limited to the colon. It should be pointed out that if the bowel is removed at the time when a toxic megacolon has developed (fulminant colitis), it may be impossible to determine the nature of the underlying disease.[173] Specifically, the criterion of transmural inflammation as a differential diagnostic point loses its significance in areas that are deeply ulcerated.

The other important complication of Crohn disease is the development of carcinoma, most commonly in the colon or rectum.[174] Although the incidence is much lower than for ulcerative colitis, there is no longer any doubt that the risk is substantially higher than for the normal population.[175] As in ulcerative colitis, the malignancy can be difficult to identify grossly, and it can also be accompanied and/or preceded by dysplastic changes of the colonic mucosa.[176,177] The criteria for the recognition and nomenclature of dysplasia are the same in both conditions.[143] In addition, a peculiar hyperplastic mucosal change is sometimes found in large bowels affected by Crohn disease and may be another form of dysplasia characteristic of this setting.[178]

The majority of patients with Crohn disease of the large bowel eventually require surgical excision of the disease; the decision as to which operation to perform depends on the extent and site of the disease, the presence of perianal involvement, and the age of the patient.[179]

Indeterminate Colitis

The distinction between ulcerative colitis and colorectal Crohn disease can be very difficult. For many years, the presence of a chronic inflammatory disease of the large bowel not attributed to a specific organism was equivalent to a diagnosis of ulcerative colitis. It is now apparent that many of these cases actually represent examples of colonic Crohn disease. The clinical, radiographic, and morphologic differences between these two diseases have now been clearly delineated. Alas, this exercise has rendered apparent the fact that none of the criteria are pathognomonic for either condition and that in approximately 15% of cases (particularly fulminant colitis) features of both conditions are present, so that the differential diagnosis becomes impossible.[180] The term *indeterminate colitis* has been proposed for this hybrid group.[180,181] On long-term follow-up, most cases will behave like ulcerative colitis and very few will later develop features of Crohn disease.[182] The occurrence of these indeterminate cases, the occasional coexistence of typical Crohn disease of the small bowel and ulcerative colitis of the large bowel in the same patient, the development of Crohn disease-like complications in patients with ulcerative colitis after proctocolectomy and ileal pouch-anal anastomosis, and the occurrence of both diseases in the same family[183] suggest that perhaps the distinction between these two entities has been too rigidly drawn. In any event, there are enough clinical and pathologic differences in the majority of cases to justify a separation that has prognostic and therapeutic implications. As a corollary, it is important not to use the term indeterminate colitis as a wastebasket diagnosis in biopsy specimens.

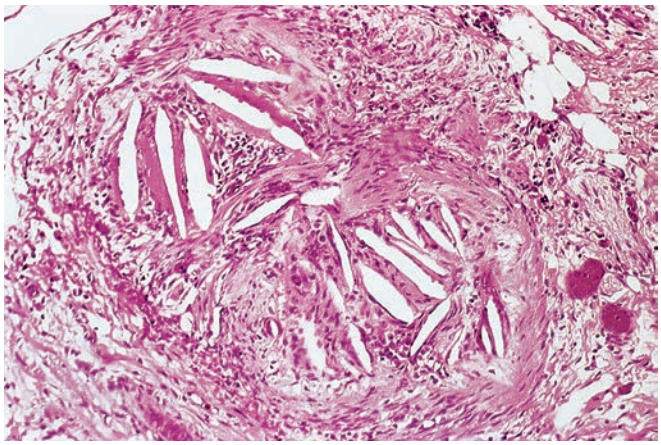

Figure 17.24 Cholesterol emboli in mesenteric vessels which resulted in ischemic colitis.

Ischemic Colitis

Ischemic colitis most often occurs in patients over 50 years of age, and the usual predisposing factors are arteriosclerosis, diabetes, and vascular surgery.[184] It may also be seen in younger patients in association with collagen vascular diseases (i.e. scleroderma and rheumatoid arthritis),[185] polyangitis granulomatosis,[186] idiopathic lymphocytic phlebitis,[187,188] amyloidosis,[189] and as a complication of birth control pill[190] or cocaine use.[191] Arteriosclerosis may lead to ischemic colitis by intrinsic obstruction of colonic vessels or by atheromatous embolism (Fig. 17.24).[192] The process usually manifests itself by sudden onset of bleeding and abdominal pain. It is a segmental disease, the splenic flexure being the classic site of involvement because of its relative paucity of blood supply; however, other sites, including the rectum, can be involved. The typical radiographic signs are gas within the bowel wall and "thumbprinting."[193] Radiographic, endoscopic, and intraoperative confusion with carcinoma may occur. Grossly, pseudopolyps may be present in addition to ulcers and fibrosis. Microscopically, there is ulceration covered by granulation tissue, which may extend into the submucosa and surround individual smooth muscle fibers of the muscularis mucosae. Hemosiderin is abundant. Hyaline thrombi can be seen in the lumen of small vessels. Cholesterol crystals, when present in the vascular lumen, support a diagnosis of atheroembolism. Fissures, lymphoid follicles, and granulomas are absent, but crypt abscesses may be seen. Microscopic features suggestive of ischemic necrosis are full-thickness mucosal necrosis in the acute stage, and hyalinization of the lamina propria, hemorrhage, and atrophic microcrypts in the healed phase (Fig. 17.25).[193] One can encounter bizarre stromal cells,[194] atypical reactive changes in the epithelial cells mimicking dysplasia,[195] and isolated goblet cells simulating neoplastic signet ring cells. One may encounter similar changes with ischemic-type features in the mucosa proximal to an obstructive lesion, usually a neoplasm.[196]

Aggressive management is of crucial importance to minimize the damage to the ischemic colon. Surgical intervention is indicated if there is evidence of peritonitis, transmural infarction, or perforation.[197]

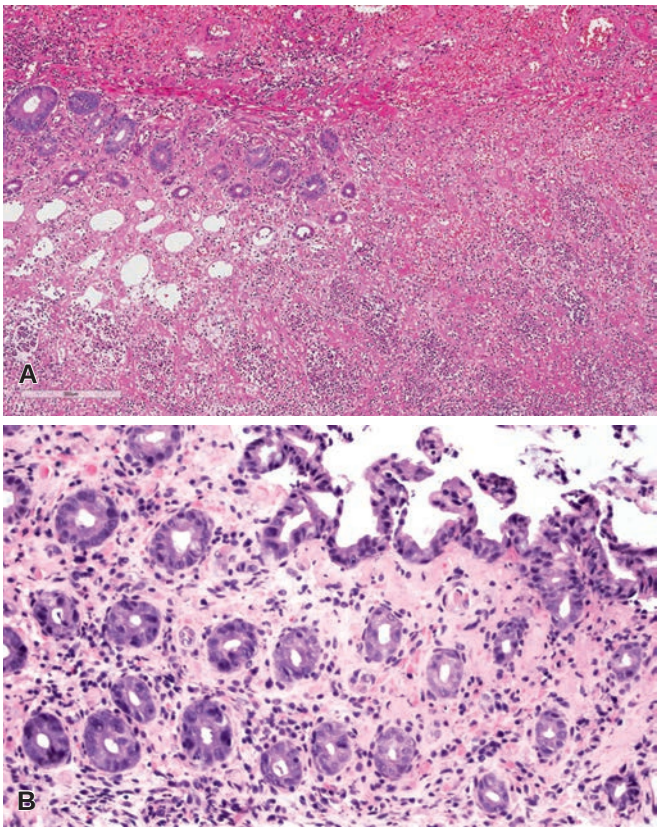

Figure 17.25 Ischemic Colitis. A, Mucosal erosion associated with regenerative epithelial changes and lamina propria hyalinization characteristic of ischemic colitis. **B,** High-power view of lamina propria hyalinization.

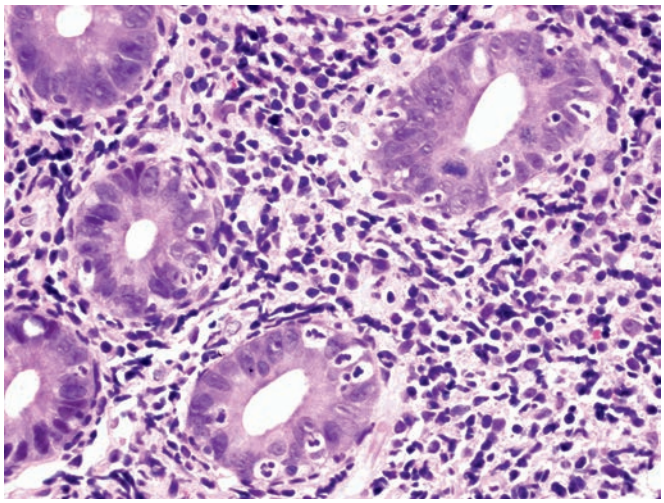

Figure 17.26 Acute self-limited colitis with patchy neutrophil-mediated crypt injury.

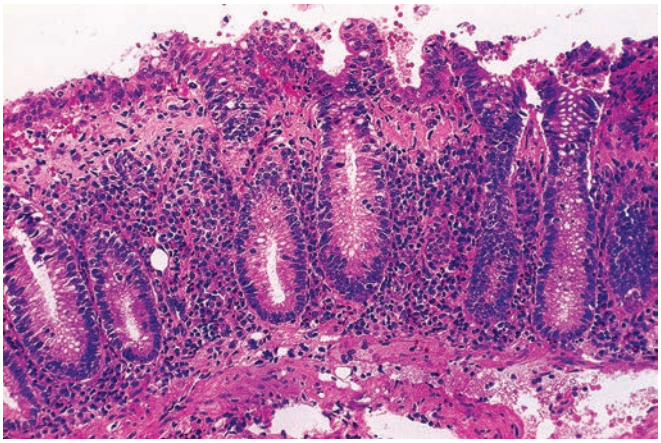

Figure 17.27 Collagenous colitis showing expanded lamina propria, lymphocyte-mediated surface injury, and subepithelial thickening of the collagen table.

Other Types of Colitis

Acute infectious-type colitis (acute self-limited colitis) is a self-limited diarrheal illness thought to be caused by infectious agents, particularly *Campylobacter, Escherichia coli* (especially with 0157:H7), *Salmonella*, and *Shigella*; however, in over half of the cases the etiology remains undetermined.[198] Microscopically, there is inflammatory infiltration of the lamina propria, edema, hyperemia, and hemorrhage with neutrophil-mediated crypt injury (Fig. 17.26). These changes may be difficult to distinguish from an early stage of ulcerative colitis, and a follow-up biopsy may be necessary to separate the two.[199] Infections by *Salmonella* and *Shigella* organisms are particularly well known for their capacity to simulate ulcerative colitis clinically and radiographically.[200] Acute inflammation out of proportion to chronic features should suggest an infectious etiology. Conversely, crypt distortion and plasma cell infiltration in the basal portion of the mucosa favor a diagnosis of ulcerative colitis.[201,202] The distinction between the two conditions is easier if the biopsy is taken within the first 4 days from the onset of symptoms.[198]

Allergic colitis and **proctitis** are related to foods (particularly cows' milk) and are seen more commonly in infants and children.[203,204] They present with rectal bleeding, sometimes accompanied by diarrhea. The main microscopic abnormalities on rectal biopsy are mucosal edema and marked eosinophilic infiltration. The eosinophils tend to aggregate around lymphoid nodules; others are located within crypts resulting in crypt abscesses, and there may be infiltrates within bundles of muscularis mucosae.[205,206] The eosinophilic infiltrates may be patchy, and thus multiple biopsies are recommended for their detection.[204]

Collagenous colitis usually presents clinically in middle-aged women with chronic watery diarrhea.[207] Endoscopic and radiographic studies are often normal. Microscopically, there is apical expansion of the lamina propria by plasma cells, lymphocytes, and eosinophils, usually without crypt distortion (Fig. 17.27), although rarely there may be minor crypt irregularities that can mimic IBD.[208] There is lymphocyte-mediated surface injury associated with thickening of the subepithelial collagen table, typically measuring 10 µm or greater.[209] The collagen thickening is often greatest in the right colon and is typically patchy; therefore, it can be missed on endoscopic biopsy, resulting in a diagnosis of lymphocytic colitis (described later).[210] Lymphocytes and neutrophils may be present in the crypts. A *pseudomembranous* form of collagenous colitis has been described.[211]

An immune pathogenesis and a relationship with celiac disease have been postulated.[212,213] It has been further suggested that nonsteroidal anti-inflammatory drugs may play an etiologic role in some of these cases,[214] although other drugs including proton pump inhibitors have also been implicated.[215] The clinical course is benign, and microscopic resolution may occur,[216] but the course tends to be relapsing and remitting.[217,218] Rare cases have been reported in association with colonic carcinoma.[217]

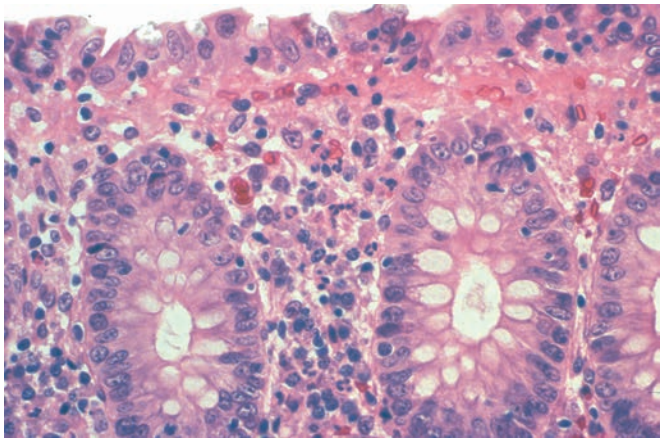

Figure 17.28 High-power view of lymphocyte-mediated surface injury in a case of lymphocytic colitis.

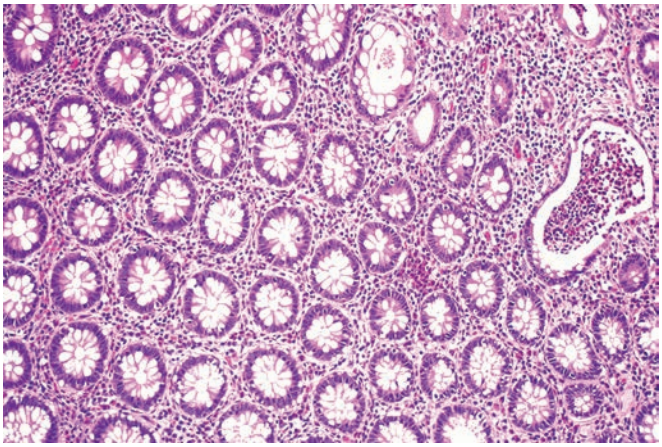

Figure 17.29 Focal active colitis pattern of injury.

Lymphocytic colitis appears to be closely related to collagenous colitis.[210,219,220] There are occasional transitions between these two disorders, which have been grouped by some under the term *watery diarrhea–colitis syndrome.*[221,222] The main microscopic differences between the two conditions are the absence of a thickened collagenous layer and the greater prominence of intraepithelial lymphocytes in lymphocytic colitis (Fig. 17.28).[223,224] Changes morphologically indistinguishable from lymphocytic colitis have been consistently found in large bowel biopsies of patients with celiac disease, further suggesting a pathogenetic relationship between these two disorders.[225,226]

The terminal ileum may be involved in cases of collagenous or lymphocytic colitis.[227] Rare cases of lymphocytic colitis containing scattered multinucleated giant cells in the subepithelial region have been described.[228,229]

It is clear that lymphocytic colitis represents a heterogeneous group of disorders, all of which result in an epithelial lymphocytosis.[230] In some instances, the microscopic features of lymphocytic colitis have been seen in patients later found to have Crohn disease.[231] It should also be mentioned that colonic biopsies taken in patients with *Brainerd diarrhea* (a chronic watery diarrhea of presumed infectious etiology characterized by acute onset and prolonged duration) show a microscopic appearance similar to that of lymphocytic colitis but usually lacking surface degenerative changes.[232] It is also likely that certain drugs (for example anti-seizure medications and nonsteroidal anti-inflammatory drugs) can induce this pattern of injury.[233,234]

Focal active colitis refers to a pattern of injury commonly seen in colorectal biopsy specimens characterized by focal crypt and surface epithelial injury mediated by neutrophils associated with a focal increase of inflammatory cells in the lamina propria (Fig. 17.29). It represents a pattern of injury rather than a specific diagnosis; most cases correlate clinically with infectious-type colitis, but other causes include bowel preparation, medication-induced injury, ischemia, and even Crohn disease, especially when this pattern is seen in children.[235–237]

Pseudomembranous colitis is due, in most instances, to a toxin produced by *Clostridium difficile*.[238,239] A substantial number of cases have been associated with the use of antibiotics, particularly lincomycin and clindamycin.[240] However, it should be kept in mind that not all pseudomembranes are secondary to an infection, as they may be seen in collagenous colitis, IBD, ischemia, and secondary to mucosal prolapse. Florid cases of this condition may be difficult to distinguish from ulcerative colitis and Crohn disease on clinical and radiographic grounds. Acute abdomen may be the presenting manifestation.[241] The thickening of the wall can be appreciated by CT and sonographic techniques.[242] Grossly, discrete yellow–white mucosal plaques are seen (Fig. 17.30). The distinguishing microscopic feature is a "focal explosive mucosal lesion" characterized by the presence of a mushroom-like mass of mucus and neutrophils attached to the surface of the mucosal glands (Fig. 17.31).[243] The mucosa immediately adjacent to these changes is remarkably normal. The wall may show massive edema, probably resulting from vascular

injury.[244] Intramucosal signet ring cells may be present and potentially be overinterpreted as evidence of a signet ring carcinoma.[245] Emergency surgery may be needed for complications, including colonic perforation and toxic colitis.[246]

Diversion colitis is an inflammatory bowel disorder resulting from diversion of the fecal stream by ileostomy or colostomy. The pathogenesis is unknown, but the removal of short-chain fatty acids present in the fecal stream is suspected to play an important role.[247,248] The disease occurs in adults as well as in children, and the abnormalities range from minimal mucosal friability to gross ulcerations.[249] Microscopically, the most common changes are mild to moderate lamina propria expansion, predominantly by plasma cells, crypt abscesses, and follicular lymphoid hyperplasia.[250] Aphthous ulcers are present in the most severe cases.[251] Of all these changes, lymphoid follicular hyperplasia is the most common and prominent.[252] These abnormalities quickly revert after reanastomosis.

Neonatal necrotizing enterocolitis is a condition primarily affecting infants who either are premature or have had exchange transfusions.[253] A few cases have followed thrombosis of the abdominal aorta,[254] suggesting that ischemia is an important risk factor. The condition may also be seen as a complication of Hirschsprung disease.[255] Most cases begin in the first week of life and are manifested by abdominal distention, the disappearance of bowel sounds, and the passage of small amounts of blood-stained stool.[256] The area of maximal involvement is usually the terminal ileum and ascending colon. The mucosa becomes necrotic and may partially slough off. Small submucosal gas-filled cysts are often present and can be seen radiographically and represent an important diagnostic sign (Fig. 17.32).[257] Bowel perforation may occur necessitating emergent surgery and resection of the affected segment.[258]

Ecchymotic colitis is the name sometimes given to a rare condition seen in neonates resulting in isolated rectal bleeding. It is characterized endoscopically by ecchymotic mucosal lesions and microscopically by a predominantly neutrophilic inflammation, foci of hemorrhage, and sometimes foci of pneumatosis. The etiology is unknown,[259] but it may be pathogenetically linked to necrotizing enterocolitis.

Amebic colitis can closely simulate ulcerative colitis or Crohn disease on clinical grounds.[260] The classic endoscopic appearance is that of discrete areas of ulceration covered by exudate, with normal intervening mucosa; however, many cases depart from this description. Amebiasis may involve any part of the bowel, but it has a predilection for the cecum and ascending colon (Fig. 17.33). In some cases the entire large bowel is involved, and there may even be extension into the terminal ileum.[261] Perforation occurs in 5%–10% of the cases.

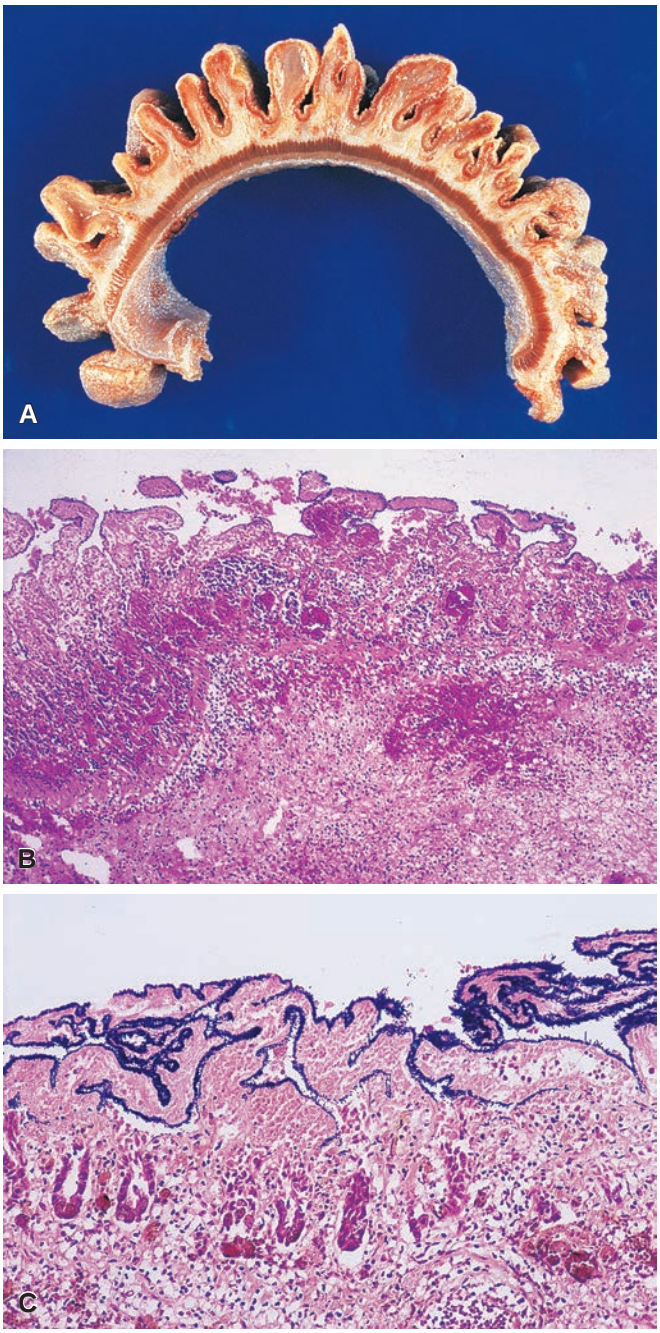

Figure 17.32 Necrotizing Enterocolitis. A, Gross appearance with mucosal necrosis and numerous small gas-filled cysts within the wall. **B,** Low-power microscopic appearance showing extensive ulceration, necrosis, and hemorrhage. **C,** Gram stain showing coating of the ulcerated surface by organisms.

The microscopic appearance of a rectal biopsy is rather nonspecific, although the relative paucity of inflammatory cells beneath the ulcer and the flask shape of the ulcer itself should alert the pathologist to consider this diagnosis. Confirmation rests on the identification of trophozoites of *Entamoeba histolytica*, which can be seen in H&E slides, although the inexperienced observer may confuse them with macrophages (and vice versa). Typically, the parasites are surrounded by an artifactually clear space. They are round or ovoid, measure 6–40 nm in diameter, and contain an abundant cytoplasm with a distinctive vacuolated appearance and relatively small, perfectly round

Figure 17.33 Amebic Colitis. Multiple, undermined ulcers are present in the cecum and ascending colon. (Courtesy of Dr. R.A. Cooke, Brisbane, Australia, from Cooke RA, Stuart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

nuclei with prominent nuclear borders and a central karyosome. The organisms can also be demonstrated with periodic acid–Schiff (PAS) and immunoperoxidase stains, both in sections and in smears.[262] Erythrophagocytosis by the trophozoites is usually present. Some cases present as a fulminant colitis, which can be difficult to distinguish from fulminant IBD.[263]

Tuberculosis may involve the gastrointestinal tract in the presence of minimal pulmonary disease.[264] The usual location is the ileocecal region, and a mass can be palpated in approximately half of the cases ("tuberculoma").[265] Grossly, there is ulceration with diffuse fibrosis extending through the wall, causing stenosis and obstruction. Coexistent tuberculous peritonitis is seen in rare cases. Microscopically, typical granulomas are usually present, which can be caseating, noncaseating, suppurative, or fibrous (healed).[266] Vasculitis may be present.[267] In some instances, a nonspecific, diffuse, chronic inflammation with fibrosis without granulomas is seen focally or—very rarely—as the sole pattern.[266] Demonstration of acid-fast bacilli, either by stain of the sections or by culture, is needed to establish a diagnosis. It should be remembered that the large majority of cases of granulomatous disease of the ileocecal area seen in the United States and western Europe represent examples of Crohn disease[268]; features favoring tuberculosis over Crohn disease are caseation and coalescence of the granuloma, whereas longitudinal ulcers favor Crohn disease.[269] Most patients with secondary ulcerating tuberculosis of the colon can be treated medically; surgery, sometimes in the form of ileocolectomy, is reserved for the large cecal tuberculomas.

CMV colitis is seen with increased frequency in immunocompromised patients, such as transplant recipients and individuals affected by AIDS.[270,271] It is also significantly associated with steroid-refractory ulcerative colitis.[272,273] The disease has a predilection for the ileocecal region and may be accompanied by extensive ulceration and rarely forms a discrete mass.[274] Inclusion bodies are found mainly in cells located in the wall or lining the lumen of submucosal vessels showing features of vasculitis, but they may also be seen in fibroblasts and epithelial cells. The diagnosis can be confirmed immunohistochemically (Fig. 17.34), which can be complemented by PCR in some cases.[275] Surgical resection may be necessary in cases resulting in massive hemorrhage.

HIV-infected patients may also develop colitis caused by *Pneumocystis*,[276] *Histoplasma*[277] adenovirus,[278] and *Toxoplasma*.[279] In addition, it has been suggested that HIV itself may be responsible for some cases of chronic colitis in this population.[280]

Strongyloides colitis can clinically mimic ulcerative colitis and cause the death of the patient if untreated.[281] Features seen in this form of colitis include skin lesions, distal attenuation of the disease, a predominance of eosinophils, less severe crypt distortion and frequent involvement of the submucosa.[281]

Behçet colitis is characterized by multiple ulcers of various sizes, shapes, and depths involving any portion of the large bowel and is accompanied by lymphocytic vasculitis of the submucosal veins[282]; it may closely resemble the appearance of Crohn disease.[283]

Graft-versus-host disease (GVHD), occurring in patients who have received bone marrow allografts, manifests in the gastrointestinal tract primarily as colitis.[284] Microscopically, there is focal crypt epithelial cell apoptosis, a feature that is thought to signify cell-mediated cytolysis (Fig. 17.35).[285] Crypt abscesses may also be present. Severe disease may lead to loss of crypts, sloughing of the mucosa, and formation of inflammatory polyps.[286] In the chronic phase there is architectural distortion (villiform surface with crypt branching and atrophy) similar to that seen in idiopathic IBD.[287] The histology of acute GVHD can be simulated by cytoreductive agents and viral infections, particularly CMV. In addition, these changes can be closely mimicked by patients taking mycophenolate mofetil, a T-cell inhibitor frequently used in the treatment of acute allograft rejection. However, histologic features favoring mycophenolate-induced injury over GVHD include lack of endocrine aggregates in the lamina propria, lack of apoptotic microabscesses and eosinophils greater than 15 per 10 HPF.[288] Similar changes are also seen in patients with AIDS.

Neutropenic enterocolitis (NEC) is a rare complication of neutropenia that occurs secondary to the administration of chemotherapy, usually for hematologic malignancies.[289] It may also occur in the setting of autologous or bone marrow transplantation for solid organ malignancies.[290] In most cases, chemotherapy has been delivered within 30 days of onset, and most patients have neutrophil counts below 1500 cells/mm^3.[291] Patients may present with gastrointestinal bleeding, fever, diarrhea, right lower quadrant pain, or even a mass. The process most commonly affects the terminal ileum and right colon. *Typhlitis* refers to hemorrhagic necrosis of the cecum.[292] Grossly, the affected areas are dilated, congested, and sometimes hemorrhagic. The mucosa shows hemorrhage and often necrosis without significant acute inflammation. Bacterial infection and ischemic injury likely also play a pathogenetic role.

Other Non-Neoplastic Lesions

Colonic atresia is much less common than atresia of the small bowel.[293,294] Most patients require early surgical intervention, but long-term outlook is excellent.

Heterotopic gastric epithelium, salivary gland tissue, and respiratory mucosa may be rarely found in the rectum.[295–297] The lesions typically present as sessile polypoid masses.

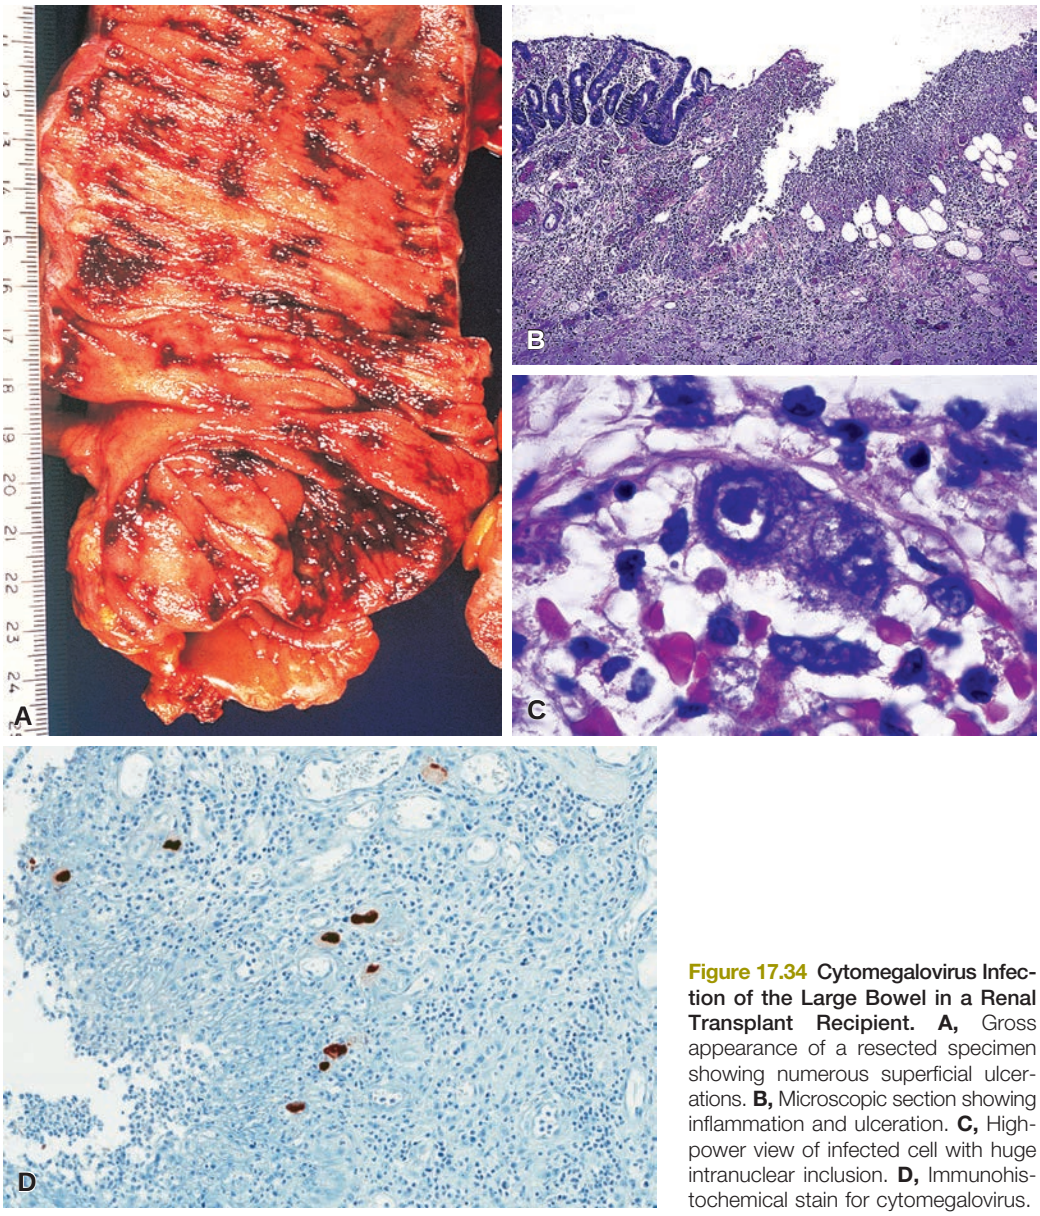

Figure 17.34 Cytomegalovirus Infection of the Large Bowel in a Renal Transplant Recipient. A, Gross appearance of a resected specimen showing numerous superficial ulcerations. **B,** Microscopic section showing inflammation and ulceration. **C,** High-power view of infected cell with huge intranuclear inclusion. **D,** Immunohistochemical stain for cytomegalovirus.

Neuronal storage diseases of various types are accompanied by changes in the ganglion cells of the submucosal and myenteric plexuses, so that the conditions may be diagnosed by rectal biopsy.[298,299]

Melanosis coli is the name given to a condition in which macrophages filled with a lipofuscin-like pigment ("pseudomelanin") are found within the lamina propria.[11] If they are numerous enough, the mucosa acquires a brown-to-black color which can be seen at endoscopy (Figs. 17.36 and 17.37). Interestingly, adenomatous polyps that may be present in such a mucosa may not show any pigmentation. Melanosis coli has been associated with the ingestion of anthracene laxatives,[12] but it can also be seen in patients without this history. Increased apoptosis seems to be the pathogenetic mechanism responsible for the change.[300] It should be mentioned here that other pigments sometimes seen in specimens from this region include India ink and methylene blue used as endoscopic tattoo agents.[301]

Endometriosis may involve the wall of the large bowel, induce secondary smooth muscle hypertrophy, and result in almost complete obstruction of the bowel lumen.[302] Microscopically, endometrial glands and stroma are seen surrounded by proliferated smooth muscle and clusters of hemosiderin-laden macrophages (Figs. 17.38 and 17.39). The overlying epithelium may show various types of inflammatory and ulcerative changes that may simulate IBD or solitary rectal ulcer syndrome in a biopsy specimen.[303,304] Some cases can involve the overlying mucosa and can closely simulate a primary colorectal adenoma.[305]

Neoplastic transformation can supervene in these endometriotic foci, usually in the form of endometrioid adenocarcinoma but also müllerian adenosarcoma and endometrial stromal sarcoma.[306,307] In some cases, immunostains with CDX-2 and PAX-8 can be helpful in distinguishing these tumors from a primary colorectal neoplasm.

Amyloidosis can involve the large bowel and be diagnosed on rectal biopsy.[308] The detection rates are comparable to those obtained by renal biopsy and better than those achieved by liver biopsy. It is important for the specimen to include the submucosa, for this can be the only place of amyloid deposition.[309] If the amyloid deposition is mainly beneath the epithelium, the appearance may

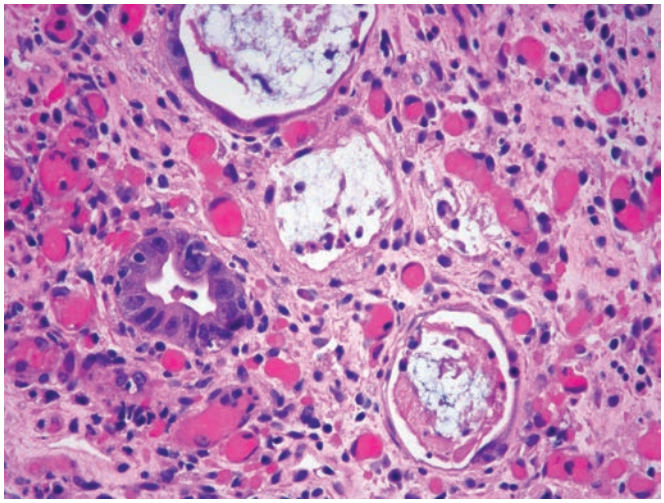

Figure 17.35 High-power view of graft-versus-host disease with characteristic scattered apoptotic cells.

Figure 17.36 **Melanosis Coli. A,** The change begins sharply at the level of the ileocecal valve. **B,** Large bowel diffusely involved by melanosis coli. There is also a carcinoma which is not involved by the melanosis.

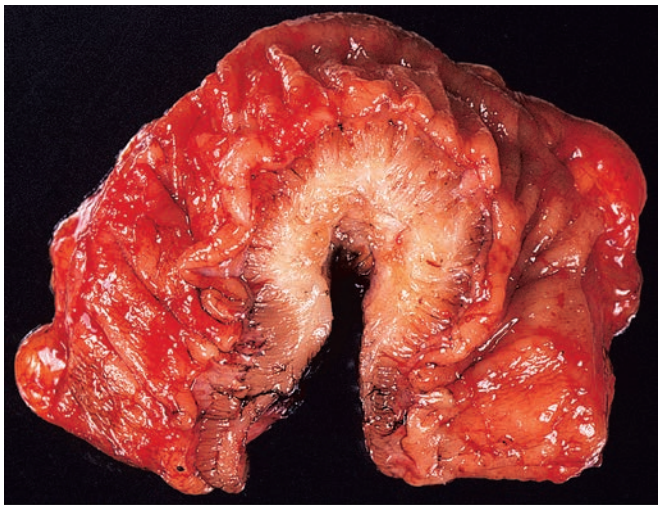

Figure 17.38 Endometriosis of the large bowel showing thickening of the wall associated with muscular hypertrophy resulting in partial obstruction.

simulate that of collagenous colitis.[310] Occasionally, amyloid deposition results in ischemic changes in the colon. Amyloidosis can be simulated by **elastotic and elastofibromatous depositions** in the muscularis mucosae and submucosa, a lesion which is of no clinical significance.[311]

Volvulus of the large bowel is a rare cause of acute abdominal obstruction.[312] Approximately 25%–40% of cases occur in the cecum.[313] Prompt surgical intervention is imperative. Gangrene is found in approximately 25% of cases at the time of exploration and is a definite indication for resection.

Malakoplakia can involve the colon diffusely (Fig. 17.40).[314] Most patients are adults, but cases in infants have been described.[315] Malakoplakia can occur in association with other conditions, including colonic adenocarcinoma,[316] immunodeficiency syndromes,[317] and ulcerative colitis.[318]

Barium granulomas can occur as a consequence of barium enema. The barium may escape through a break in the mucosa produced by infection, tumor, foreign body, or trauma and induce a

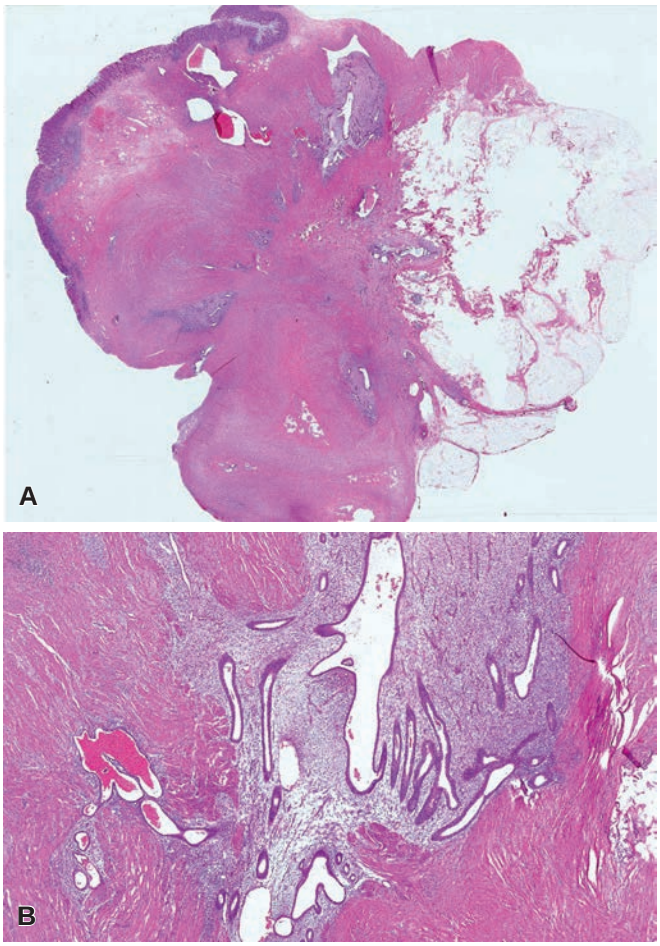

Figure 17.39 Endometriosis. A, Low-power view of endometriosis. **B,** High-power view of endometriosis showing endometrial glands surrounded by endometrial stroma.

granulomatous reaction. The crystals, which may remain in the tissues permanently, are easily visible under polarized light.[319]

Radiation changes in the colon and rectum can be accompanied by bizarre cellular changes in the crypt epithelium. Inflammation is also present, sometimes in the form of crypt abscesses; eosinophils may be numerous.[320] These acute changes usually subside within 1–2 months. Late changes include arterial stenosis due to the subendothelial accumulation of macrophages (Fig. 17.41). Severe radiation changes include ulceration, necrosis, hemorrhage, and perforation (Fig. 17.42).[321] In some cases, the degree of radiation-induced atypia may mimic adenocarcinoma.

Solitary cecal ulcers have an unknown etiology, and their microscopic appearance is completely nonspecific.[322,323] Most patients are middle-aged to elderly and present with hematochezia and right-sided abdominal pain.

Pneumatosis cystoides intestinalis occurring in infants is usually seen as a component of necrotizing enterocolitis and often has a fatal outcome.[324] Exceptionally, it occurs in association with cystic fibrosis.[325] In adults it may present as an idiopathic finding or in association with mechanical intestinal obstruction, chronic lung disease, or scleroderma.[326] When not associated with other abnormalities, it follows a chronic and indolent clinical course, although in some instances it may produce signs of intestinal obstruction and lead to an incorrect radiographic diagnosis of carcinoma. Grossly, polypoid grapelike masses formed by submucosal gas-filled cysts

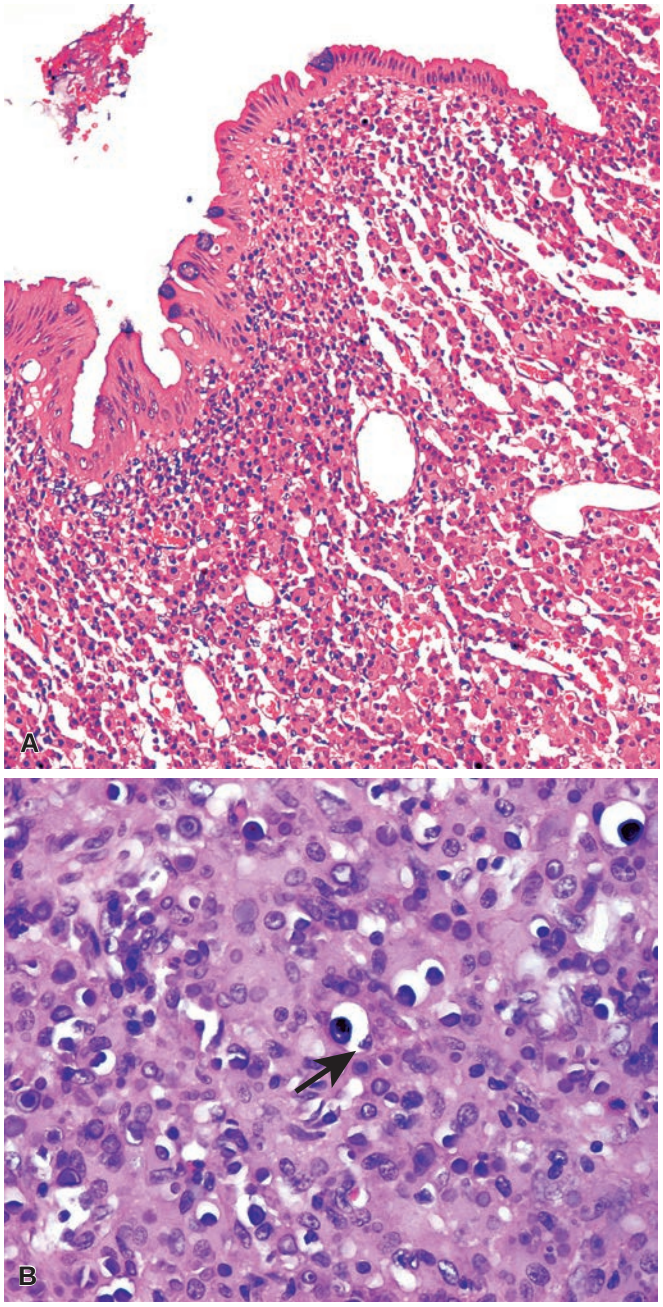

Figure 17.40 Malakoplakia. A, Low-power view showing packing of the lamina propria by a histiocyte-rich infiltrate. **B,** High-power view showing numerous histiocytes and rare Michaelis–Gutmann bodies (arrow).

protrude through the mucosa (Fig. 17.43). Microscopically, the cysts are lined by foreign body–type multinucleated giant cells (Fig. 17.44). The overlying mucosa may show cryptitis, crypt abscesses, chronic inflammation, and granulomas (i.e. changes that may mimic IBD, particularly Crohn disease).[327] The arrangement of the giant cells around intact, partial, or collapsed cysts is a key diagnostic feature.[328] It is believed that the gas is generated in the lumen or within inflamed crypts, from where it penetrates through the muscularis mucosae to accumulate in the form of submucosal cysts. Some authors have suggested a lymph vessel origin for the cysts, as the pericystic tissue stains for podoplanin.[329]

Mucosal pseudolipomatosis is the name given to the lesion in which small gas-filled cysts are limited to the lamina propria of the

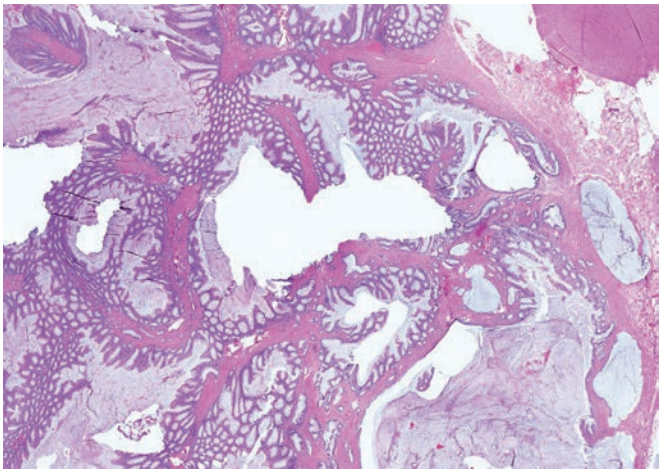

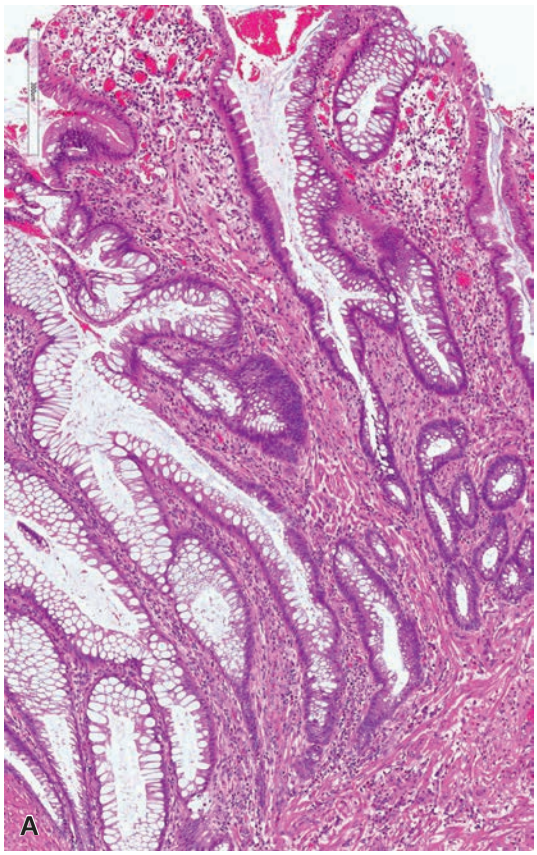

Figure 17.45 Low-power view of colitis cystica profunda.

mucosa, resulting in an endoscopic appearance that simulates lipomatosis.[330] This presumably occurs secondary to gas introduced into the mucosa at the time of endoscopy.[331]

Colitis cystica profunda is a non-neoplastic condition characterized by the presence of intramural mucus-containing cysts in the colon and rectum. It may present as a single polypoid mass or involve extensive areas of the bowel.[332] The localized form is typically located in the rectum, 5–12 cm from the anal margin, and presents as a plaque, nodule, or polyp and is associated with chronic proctitis.[333] This form is often associated with mucosal prolapse (solitary rectal ulcer syndrome; see later).

The diffuse form of colitis cystica profunda is in most cases the result of inflammation and ulceration of the bowel, as seen in ulcerative colitis, Crohn disease, or irradiation change[334]; the ulceration provides the means by which mucosa can extend along granulation tracts and thus form lakes of mucus in the submucosa. This disease may be easily mistaken for a mucinous carcinoma; however, the mucin production in colitis cystica profunda is not accompanied by epithelial atypia, tends to be round as opposed to infiltrative, and only rarely extends beyond the submucosa (Fig. 17.45).

Mucosal prolapse, sometimes referred to as "solitary rectal ulcer syndrome," presents as a (usually) solitary ulcerated or polypoid lesion located 4–18 cm from the anal margin.[335–337] The usual symptoms are the passage of blood and mucus via the rectum, an alteration in bowel habits, and pain. Microscopically, there is intercryptal erosion, hyperplasia of the crypts (some of which have a peculiar diamond shape), a tendency toward villous configuration, obliteration of the lamina propria by fibroblasts, elastin, and smooth

muscle cells from the muscularis mucosae, a reduction in the number of lymphocytes and plasma cells, and thickening of the muscularis mucosae with splaying of its fibers (Fig. 17.46).[337,338] Some cases are associated with colitis cystica profunda. The lesion referred to as inflammatory cloacogenic polyp is also a variation on this same theme, and some have grouped all of these changes as components of the *mucosal prolapse syndrome*.[339]

It is important to be aware of the fact that mucosal prolapse may occur secondary to an adjacent or underlying lesion such as endometriosis or primary or metastatic neoplasms.[340]

Enterocolic lymphocytic phlebitis is characterized by a circumferential, predominantly lymphocytic infiltration of small submucosal and/or subserosal veins, with sparing of the arteries. Some have proposed this lesion could be part of the IgG4-related family of diseases.[341,342] It also may be seen in the setting of diversion colitis in patients with IBD.[343]

Rosai–Dorfman disease can exceptionally involve the large bowel, usually associated with other extranodal manifestations of the disease.[344,345] Histologically, it resembles the lesion at other more typical sites (Fig. 17.47).

Fibrosing colonopathy is a rare condition seen in patients with cystic fibrosis who have been treated with high-strength enzyme replacement.[346] Morphologically, the affected colon has a cobblestone appearance, submucosal fibrosis, thickening of the muscularis externa, chronic mucosal inflammation, and mucosal eosinophilia.[347]

Tumors

Epithelial Polyps

The colorectal polyps included in this discussion are those of epithelial origin, which represent the large majority. They can be divided into several broad categories—adenomatous and serrated polyps. The latter category includes the exceedingly common hyperplastic polyp, as well as traditional serrated adenoma (TSA) and sessile serrated polyp (SSP)/sessile serrated adenoma.

Adenomatous polyps (tubular adenomas) are distributed regularly throughout the large bowel,[348] with 40% located in the right colon, 40% in the left colon, and 20% in the rectum, their frequency rising with age.[349] Blacks have a lower prevalence than whites. Most

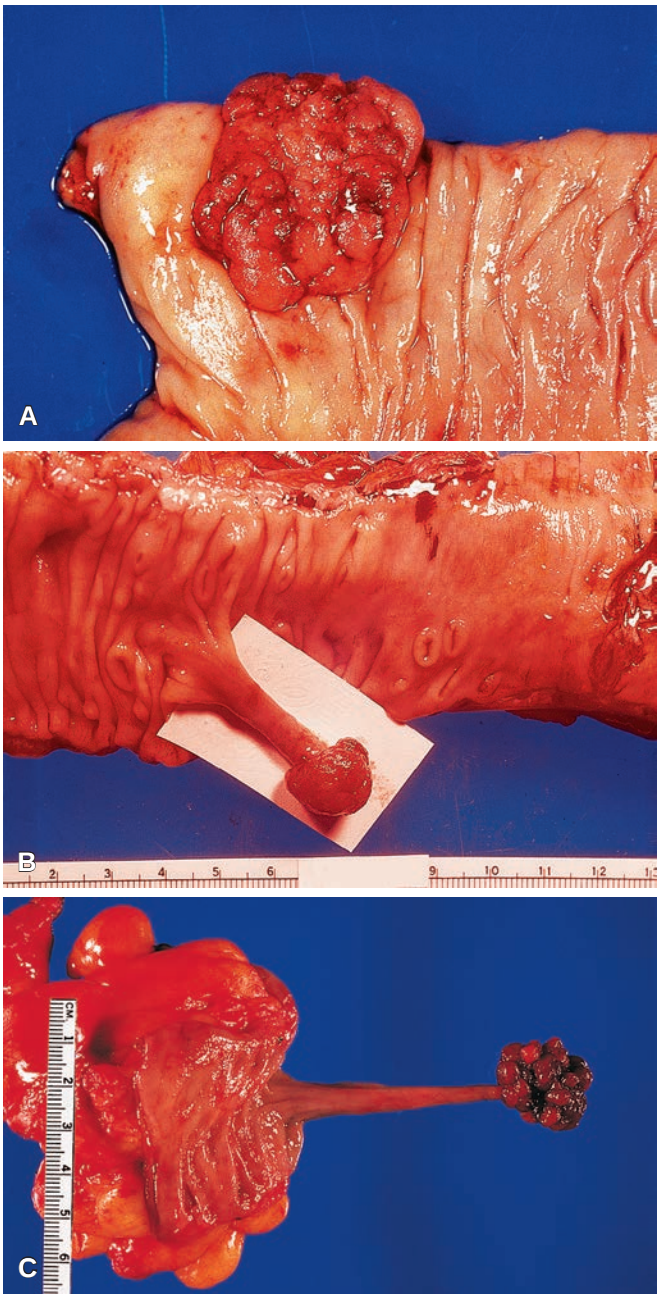

Figure 17.48 **Various Gross Appearances of Colonic Adenomatous Polyps. A,** Polyp with a sessile growth. **B** and **C,** Pedunculated polyps.

polyps are asymptomatic, but they may result in bleeding from twisting or vascular obstruction.[350] If large enough, they may cause changes in bowel habits or rarely intussusception. Grossly, most measure less than 1 cm in diameter. They may be sessile or pedunculated and single or multiple (Fig. 17.48). When multiple, they have a tendency to cluster.[351] When pedunculated, they may have a short or a long stalk attached by a narrow base. When sessile, they may be protruding, flat, or depressed (in which case the term "polyp" is a misnomer).[352] Flat and depressed lesions have been described with increasing frequency, particularly by Japanese authors using advanced microscopic techniques.[353]

Microscopically, there is an increase in the number of glands and cells per unit area compared to the normal mucosa (Fig. 17.49). The cells are crowded, contain enlarged hyperchromatic nuclei, and

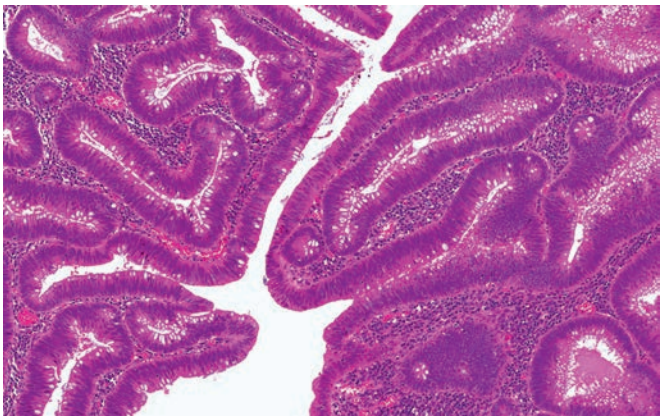

Figure 17.49 Tubular adenoma with characteristic low-grade dysplastic appearance.

have an increased number of mitoses, some of which may be atypical.[354] Mucin production is highly variable but usually decreased. The basement membrane is not thickened.

Focal areas of villous configuration are not infrequent in adenomatous polyps (Fig. 17.50).[355] Those with a villous component comprising 25% or more of the polyp are considered *tubulovillous adenomas*, and those with a villous component comprising 75% or more of the polyp are *villous adenomas*. The larger the polyp, the greater the frequency of a villous component.[356]

The degree of atypia seen in adenomatous polyps is related to increasing age, number of polyps per patient, size of the polyps, and presence of villous changes.[348] All adenomas have at least low-grade dysplasia (by definition), but some have more severe cytologic alterations and should be labeled as having high-grade dysplasia.

The term *carcinoma in situ* is not recommended, as this simply represents the upper end of the high-grade dysplasia spectrum (Fig. 17.51). Although the presence of a villous component and degree of dysplasia are known to be subject to significant interobserver variation,[357] they should still be assessed and reported, as the gastroenterology society guidelines still require their reporting in order to recognize when a patient has an "advanced adenoma," which necessitates closer endoscopic surveillance.[358]

Sometimes clusters of dysplastic glands in an adenomatous polyp are seen beneath the muscularis mucosae and may lead to a mistaken diagnosis of malignant transformation, a process often referred to as "pseudoinvasion" (Fig. 17.52). This is not an uncommon event; as a matter of fact, it may be more prevalent than true malignant transformation. The features that allow its recognition are as follows[359]: (1) the cytologic features of the misplaced glands are similar to those on the surface; (2) the glands are surrounded by inflamed loose stroma (lamina propria) and scattered bundles of muscularis mucosae, rather than the desmoplastic reaction associated with invasive carcinoma; and (3) there are abundant hemosiderin deposits around the dysplastic glands. Some of the glands may become cystic, rupture, and result in the formation of mucin lakes (colitis cystica profunda). This process tends to occur in larger polyps and likely occurs in areas of weakening of the muscularis mucosae where blood vessels penetrate, resulting in prolapse of epithelial elements in the submucosa.

Rarely, adenomatous polyps may exhibit morular formation,[360] focal squamous metaplasia,[361] cytoplasmic clear cell changes,[362] a minor component of Paneth cells,[363] multinucleated epithelial giant cells,[8,364] a population of neuroendocrine cells (Fig. 17.53),[365] malakoplakia in the polyp stroma,[366] osseous metaplasia,[367] or the presence of metastases from another site within the polyp.[368]

Figure 17.50 Adenomatous Polyp. A, Gross appearance of a polyp with tubulovillous features. **B,** Microscopic appearance of a tubulovillous adenoma.

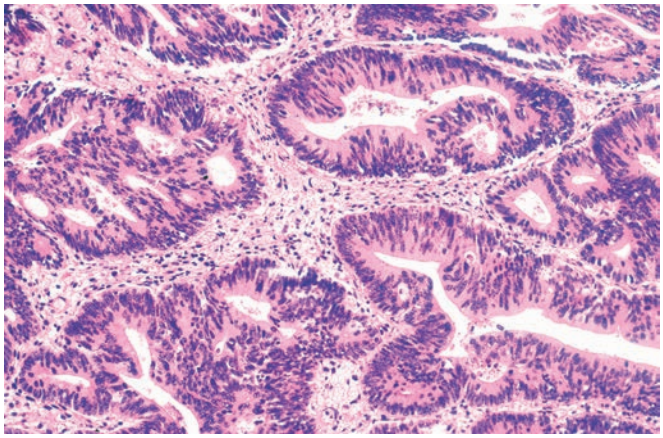

Figure 17.51 Adenoma with high-grade dysplasia showing a complex growth pattern, often formerly referred to as "carcinoma in situ," a term which is discouraged from being used.

"Aberrant crypts" were originally described in experimental animals exposed to colonic carcinogens and were identified by methylene blue stains of whole-mount preparations and probably represent the earliest identifiable "adenomatous" change.[369,370] They seem to be more numerous in colons harboring carcinoma than in those devoid of malignancy.[371,372]

The standard treatment for adenomatous polyps is polypectomy, followed by repeated colonoscopy.[373]

A **serrated (sawtoothed)** architecture is the common morphologic denominator of a group of polypoid colorectal lesions that have gained attention in recent years and which have generated an evolving terminology which at long last seems to be agreed upon by most involved in the field. The paradigmatic member of this group (and by far most common) is the **hyperplastic polyp**. This lesion is characteristically sessile and small, rarely exceeding 5 mm in diameter.[374] If pedunculated and/or large (particularly if located in the right colon), the possibility of it belonging to another member of the group of serrated polyps (SSP; see later) should be strongly considered. If a careful gross examination of the colonic mucosa is made, hyperplastic polyps will be found in 15%–30% of adult individuals.[375] Microscopically, elongated glands with intraluminal infoldings are seen, giving rise to the sawtoothed configuration that constitutes its morphologic signature and which is supposedly due to inhibition of apoptosis (Fig. 17.54).[376] Mitotic activity is increased only at the base, paralleling the pattern of the normal mucosa, and showing a striking contrast with that seen in adenomas. The epithelial cells have an inconspicuous basal nucleus and abundant cytoplasm filled with mucin. The basement membrane beneath the surface epithelium is often thickened, a change that can be easily appreciated on routine-stained sections. The surface epithelium has a micropapillary appearance and is often infiltrated by "nuclear dust."

In recent years, it has become obvious that many lesions diagnosed in the past as hyperplastic polyps are actually **SSPs**, also known has **sessile serrated adenomas**. Although there has been tremendous controversy over which name is most appropriate, the World Health Organization (WHO) recognizes both terms as equivalent.[377] We prefer the term SSP in our practice and, as such, this is the nomenclature that will be used for this discussion.

This polyp was first brought to attention by Longacre and Fenoglio-Preiser in 1990 as "serrated adenoma."[378] The same lesion was later defined in a detailed morphologic study by Torlakovic and Snover in 1996, when they coined the term "sessile serrated adenoma."[379] Subsequent studies clearly identified this lesion as preneoplastic and linked it to the serrated pathway of colorectal cancer,[380–384] which comprises approximately 15% of all colorectal carcinomas, particularly in elderly females and in the right colon.[385] At the molecular level, this pathway is associated with MSI, *BRAF* mutations, and excessive methylation (CIMP:CpG island methylator phenotype).[386,387]

SSPs are more likely to be larger and right sided than are hyperplastic polyps[385]; however, morphologic features should dictate this separation (described later), as there are rare SSPs that are relatively small (less than 5 mm) and/or left sided.[388] As the name implies, these lesions have a sessile endoscopic appearance and do not typically

have a pedunculated growth pattern. In fact, their recognition can be quite subtle and can even be overlooked by the endoscopist.[389]

Morphologically, SSPs can be recognized both by their architectural and cytologic features, although the former are generally more reproducible in arriving at a diagnosis.[390,391] SSPs virtually always show either basal crypt dilatation or lateral spread of crypts at the base of the mucosa, or both (Fig. 17.55).[385] In addition, many show excessive serrations, sometimes all the way to the base of the mucosa, as well as prominent submucosal fat. Some show an inverted (pseudoinvasive) growth pattern with penetration of crypts into the submucosa, although this pattern may also be seen in hyperplastic polyps. Cytologic features are subtle and less reliable in distinguishing SSPs from hyperplastic polyps. SSPs often show an upward migration of the proliferative zone into the middle or upper-third of the crypts, whereas this zone is restricted to the lower one-third of the crypts in hyperplastic polyps.[385]

A small percentage of SSPs progress to true cytologic dysplasia, which commonly resembles a conventional tubular adenoma (Fig. 17.56). These foci are usually sharply demarcated from the underlying

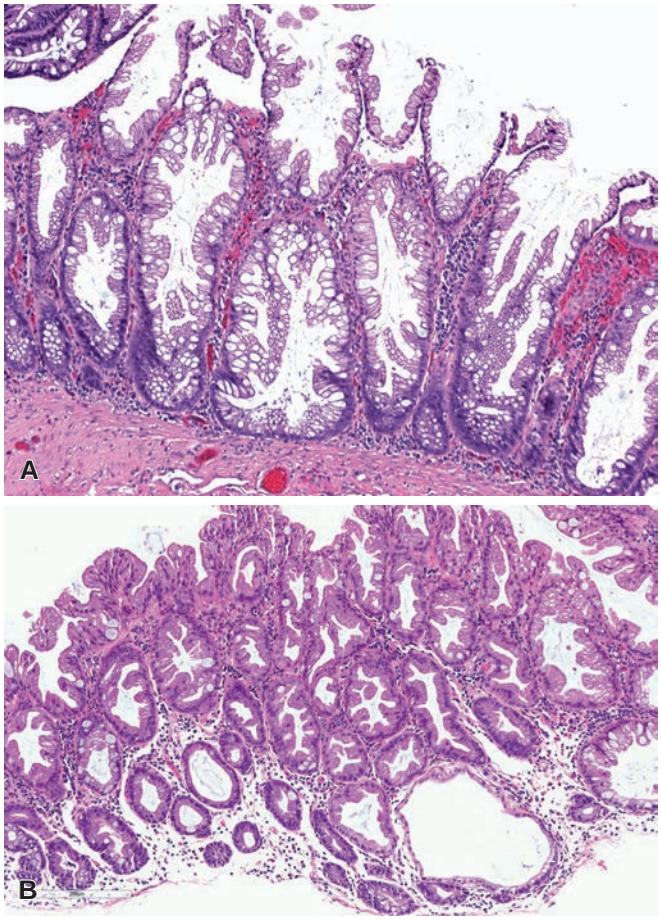

Figure 17.55 Sessile Serrated Polyp. A, Characteristic anchor-shaped crypts at the base of the mucosa in a sessile serrated polyp. **B,** Dilation of crypts at the mucosal base characteristic of sessile serrated polyp.

SSP. In years past, such areas were often interpreted as representing a mixed hyperplastic polyp—tubular adenoma, but we now know this represents what the WHO refers to as an SSP with cytologic dysplasia.[377] The dysplastic area can on occasion resemble a TSA, described further later. Although most dysplastic foci are low grade, some develop high-grade dysplasia and a small subset develops invasive adenocarcinoma. Some have even suggested this progression to invasive cancer may occur rapidly following development of cytologic dysplasia and, as such, it is recommended that the endoscopist ensure complete excision of this lesion and consider earlier (1–3 years) follow-up endoscopy[385,392]

Immunohistochemically, there is typically loss of MLH1 staining in the dysplastic foci, a feature that is not typical of sporadic adenomas.[393] In addition, these dysplastic foci retain *BRAF* mutations, which are also found in the adjacent SSPs.[393] **Serrated polyposis syndrome (SPS)** is the name endorsed by the WHO for what was formerly known as "hyperplastic polyposis,"[377] as it is now known these polyps are actually predominantly SSPs rather than hyperplastic polyps. The 2010 WHO criteria for SPS include any of the following features: (1) At least five serrated polyps proximal to the sigmoid colon, with two or more greater than 10 mm in greatest dimension, (2) any number of serrated polyps proximal to the sigmoid colon in an individual with a first-degree relative with SPS, and (3) more than 20 serrated polyps of any size throughout the colon.

Interestingly, studies have found hypermethylation not only in the serrated polyps but also in the nonpolypoid intervening mucosa.[394] Most cases of SPS are sporadic, and germline mutations have not been identified.[385] Patients with this syndrome clearly have an increased risk of colorectal carcinoma, which is often multifocal.[395] As such, these patients are generally followed with close colonoscopic surveillance and consideration for an extended colectomy when polyps become unmanageable endoscopically or cancer intervenes.[392]

TSA has also been a somewhat controversial lesion but clearly is the least common of the colorectal serrated polyps. Despite similarities to SSP in name, TSAs are distinct endoscopically as well as pathologically and at the molecular genetic level.[385] The exact relationship between TSA and the serrated colorectal neoplasia pathway is uncertain, but as of now, it appears to not be a lesion that is central to the pathogenesis of serrated colorectal neoplasia.

TSAs are relatively uncommon, comprising less than 1% of all colorectal polyps.[396] Most are small and left sided, but of course exceptions occur. Patients with TSAs seem to be at higher risk of metachronous polyps than patients with conventional adenomas.[397]

Histologically, these lesions tend to be uniform throughout, often with a villiform ("filiform") appearance.[391,398] The cytoplasm is often distinctly eosinophilic, with centrally or basally located uniform slightly hyperchromatic pencillate nuclei, with infrequent mitoses (Fig. 17.57). A characteristic feature is the "ectopic crypt foci," which are abortive attempts at new crypt base formation high in the polyp.[398] However, this feature can also be in tubulovillous/villous adenomas and is not entirely specific for TSA.[399]

As previously mentioned, TSA-like areas can be identified in the background of an SSP. Additionally, some cases of TSA harbor areas of conventional adenomatous dysplasia.[391] At the molecular level, TSAs are heterogeneous, with some showing evidence of *BRAF* mutations, while others harbor *KRAS* mutations.[391] Interestingly, a large molecular study of TSAs from Australia found that *BRAF*-mutated TSAs were more frequently proximal and were exclusively associated with a precursor polyp when compared to *KRAS*-mutated TSAs.[391] Malignant progression is rare and is associated with *TP53* mutation and activation of the Wnt pathway.[400]

Juvenile (retention) polyp is the most frequent colonic polyp seen in children, but approximately one-third of cases occur in adults.[401] Traditionally, it has been described as single and located in the rectosigmoid area; however, increased use of endoscopy has shown that in many cases more than one polyp is present and that a high proportion of them occur proximal to the sigmoid colon.[402] The lesion usually presents with rectal bleeding;

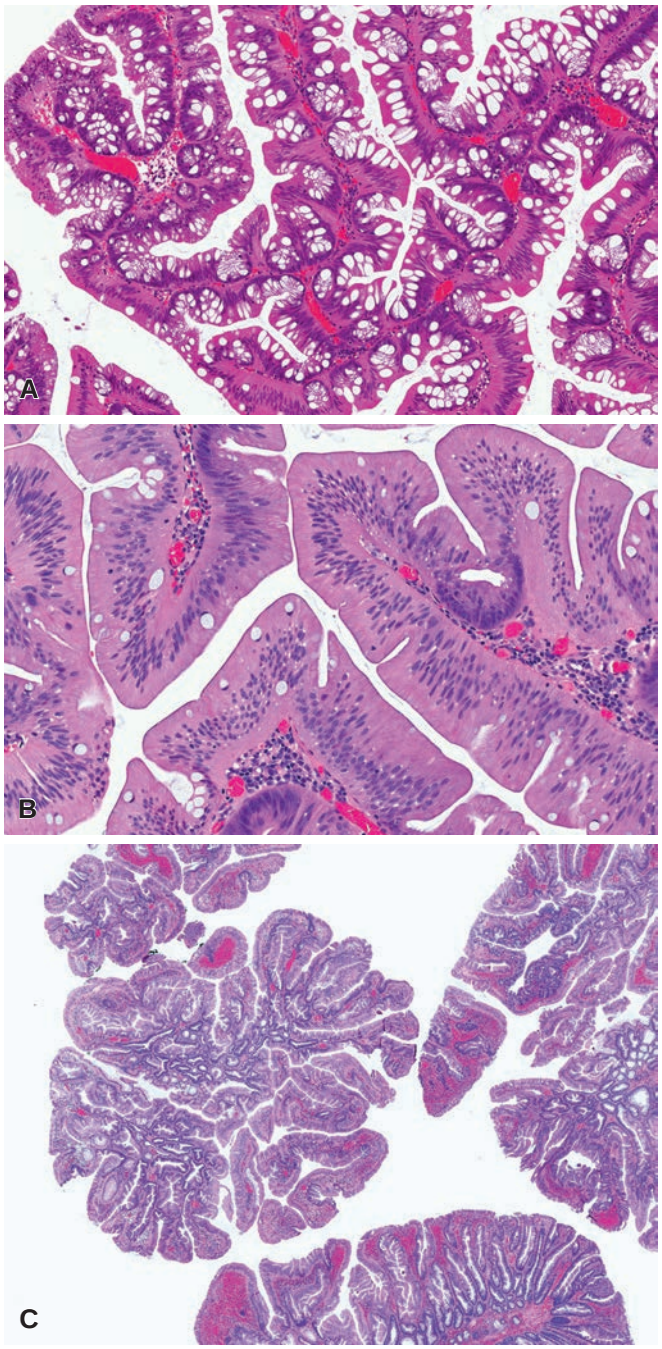

Figure 17.57 Traditional Serrated Adenoma. A, Lateral ectopic crypts in a traditional serrated adenoma. **B,** Apically located cytoplasmic eosinophilia is a characteristic feature. **C,** Most cases of traditional serrated adenoma show villiform architecture which can be mistaken for a tubulovillous adenoma.

autoamputation is common, the polyp being sloughed off and passed per rectum.

Grossly, juvenile polyp has a granular, red surface and a cystic, lattice-like appearance on cross section (Fig. 17.58). Microscopically, ulceration and granulation tissue are often seen at the surface and are associated with regenerative changes which can be confused with dysplasia. Beneath, there are cystically dilated glands filled with mucus, devoid of atypical features, and separated by an inflamed and edematous stroma (Fig. 17.59). Hyperplastic mucosal changes are present in approximately 20% of cases. As the name indicates, juvenile (retention) polyps have been traditionally regarded as non-neoplastic.[403] However, the occasional presence of foci of low- or high-grade dysplasia and of genetic alterations (such as *KRAS* mutations) raises some questions as to their true nature.[404] As noted later, some arise in the setting of juvenile polyposis syndrome.

Peutz–Jeghers polyps are practically always seen as part of a syndrome[405] (see later) and have microscopic features similar to their more common counterparts in the small bowel. Lack of cellular atypia, disorganization of glands, the occurrence of several cell types (including Paneth cells), and the presence of smooth muscle fibers from the muscularis mucosae (which give the lesion

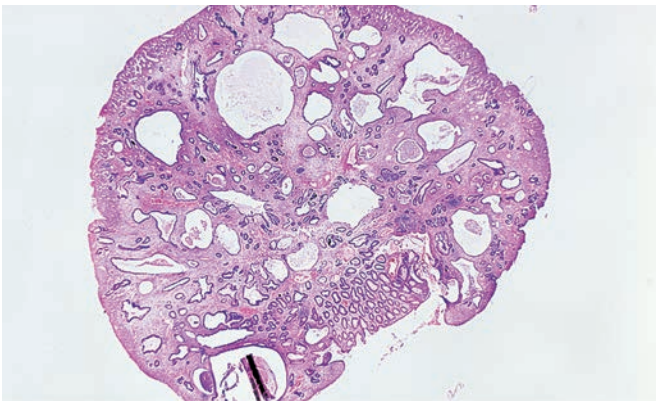

Figure 17.59 Whole-mount view of a juvenile (so-called retention) polyp.

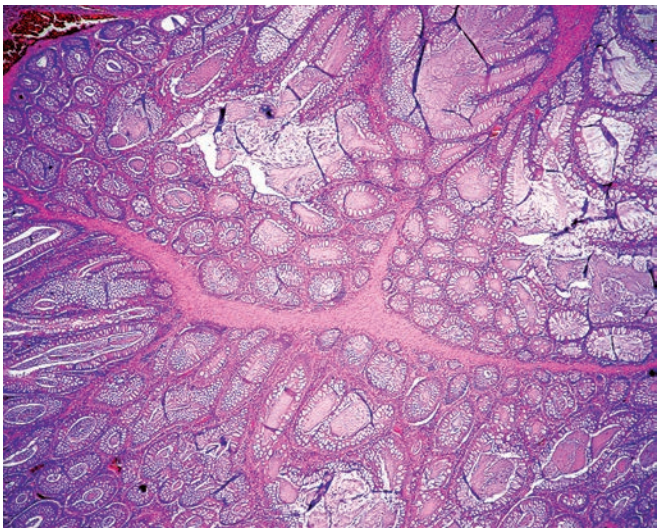

Figure 17.60 Peutz–Jeghers Polyp. There are ramifying bundles of smooth muscle and an absence of dysplasia.

a "hamartomatous" appearance) are the most important features (Fig. 17.60).[406] This pattern of glandular disorganization and epithelial misplacement simulating invasion should not be confused with malignancy.[407]

Polyposis Syndromes

Familial adenomatous polyposis (FAP; also known as polyposis coli) is characterized by the presence of hundreds or thousands of polyps throughout the bowel. The microscopic appearance of most of the individual lesions is indistinguishable from sporadic adenomatous polyps, but some look like "colonic aberrant crypts," flat adenomas, depressed adenomas, or villous adenomas.[408,409] This inherited condition shows autosomal dominant inheritance with a high degree of penetrance.[410] The responsible gene *(APC)* has been localized to chromosome 5q21.[411] A small percentage of cases is caused by germline mutation of the base-excision repair gene *MYH*.[412] The tumors in FAP become manifest much earlier than the usual adenomatous polyp, usually in the second decade of life.[413] Molecular techniques can be used for the presymptomatic diagnosis of this disorder through demonstration of germline mutations in the relevant genes.[414–416]

Radiographically and grossly, the bowel is studded with polyps ranging from very slight elevations of the mucosa to relatively large

Figure 17.61 Radiograph of familial adenomatous polyposis involving the entire bowel.

Figure 17.62 Gross appearance of familial adenomatous polyposis. The entire large bowel is involved by innumerable small polyps.

masses (Figs. 17.61 and 17.62). The presence of several adenomatous polyps in a patient does not necessarily indicate the presence of FAP. A minimum of 100 polyps needs to be present before such a diagnosis can be assumed on morphologic grounds.

KRAS mutations are found in approximately one-fourth of these polyps, the frequency being similar to that seen in sporadic cases.[417]

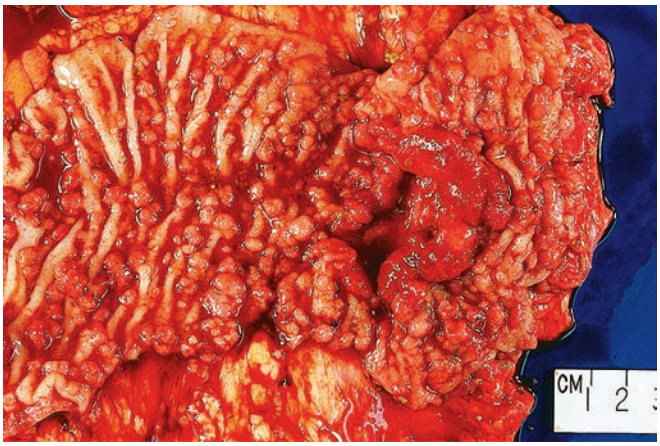

Figure 17.63 Familial adenomatous polyposis complicated by adenocarcinoma.

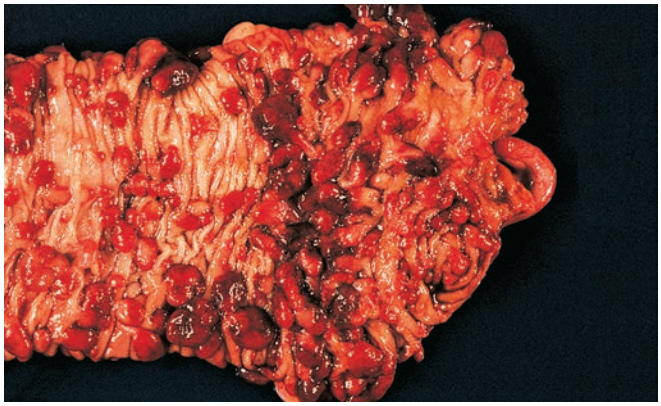

Figure 17.64 Juvenile Polyposis. The marked hyperemic quality is a characteristic feature of these lesions.

These mutations are also increased in the morphologically normal mucosa.[418]

FAP can involve other portions of the gastrointestinal tract, such as stomach and small bowel.[419] It should be remembered, however, that most polypoid lesions of the ileum seen in patients with this disorder represent foci of lymphoid hyperplasia and that many of the gastric lesions in these same patients are fundic gland polyps.[420]

If FAP is left untreated, one or more carcinomas will develop in the large bowel in nearly all patients (Fig. 17.63). Carcinomas arising in a background of FAP occur, on average, 20 years earlier than the ordinary colorectal carcinomas, most of them becoming manifest in the early thirties; therefore, prophylactic colectomy at 20–25 years of age is recommended.[419] If the surgery performed is a total colectomy followed by ileal pouch–anal anastomosis, close monitoring of the rectal cuff and ileal pouch is indicated because of the possibility of development of polyps and carcinoma at these sites.[421]

Carcinomas developing in other organs, such as the gallbladder, pancreas, thyroid, and adrenal gland, have also been reported in this disorder.[422–425] The thyroid carcinomas developing in these patients have a distinct microscopic appearance characterized by cribriform and morular formations.[426] Other described associations with FAP include hepatoblastoma,[427] multiple endocrine neoplasia,[426] nasopharyngeal angiofibroma,[428] and Sertoli cell tumors.[429]

In the variant of FAP known as *hereditary flat adenoma syndrome*, the polyps are flat rather than elevated, usually number less than 100, and exhibit a right-sided predominance.[430] The chromosomal abnormality is in the same gene *(APC)* as in ordinary FAP,[431] and the affected individuals may develop the same types of upper gastrointestinal tract lesions.[432]

Gardner syndrome is a variant of FAP characterized by the presence of numerous large bowel adenomas, multiple osteomas of the skull and mandible, multiple keratinous cysts of the skin, and soft tissue neoplasms, especially fibromatosis.[433] Most of the fibromatoses are intra-abdominal and develop following surgical intervention.[434] These lesions show coexistence of somatic and germline mutations of the *APC* gene, suggesting that inactivation of both alleles of this gene is involved in their development.[435] Because of the variable degree of penetrance, only one of the extracolonic manifestations may be present, such as fibromatosis. Adenomatous polyps may also be present in the small bowel and stomach. The potential for development of large bowel carcinoma is no different from typical FAP. In addition, patients with this syndrome can develop carcinomas of the small bowel, particularly in the periampullary area.[436]

Turcot syndrome, a variant of hereditary nonpolyposis colorectal cancer (HNPCC, also known as Lynch syndrome), is the name given to the odd combination of colorectal adenomatous polyps and brain tumors, usually glioblastomas.[437] This is an entity genetically distinct from FAP, with a recessive pattern of inheritance,[438] resulting from germline mutations in the mismatch repair (MMR) genes.[439,440] Muir–Torre syndrome is also considered to be a variant of HNPCC associated with tumors of sebaceous glands.[440,441]

SPS (mentioned earlier in this chapter) is characterized by the presence of multiple serrated polyps, especially SSP, some of them of large size and sometimes accompanied by adenocarcinoma.[442]

Juvenile polyposis is defined by the presence of multiple juvenile polyps throughout the bowel. This condition, which can be life threatening,[409] is associated with the development of adenomatous polyps and adenocarcinoma of the large bowel, duodenum, stomach, or pancreas (Fig. 17.64).[401] Some of the polyps in this disorder have combined juvenile and adenomatous features.[443] Some cases are associated with ganglioneuromatous proliferation.[444] The genetic defect in juvenile polyposis has been found to be inherited inactivating mutations of the *SMAD4* or *BMPR1A* genes, this inactivation being limited to the stromal cells.[445]

Cronkhite–Canada syndrome is a nonhereditary disorder in which multiple colorectal polyps of the juvenile type are associated with ectodermal changes (alopecia, nail atrophy, and hyperpigmentation).[446,447] The polyps associated with this syndrome are less commonly pedunculated than other juvenile polyps (Fig. 17.65).[448] Adenomatous changes and colorectal carcinoma may also develop in these patients.[449]

Peutz–Jeghers syndrome patients may feature, in addition to the typical Peutz–Jeghers polyps that define the syndrome (see previous discussion), adenomatous polyps with a marked degree of atypia. Some of these patients develop colorectal adenocarcinoma.[450] The syndrome is due to germline mutations of the *LKB1* gene.[451]

Cowden syndrome (multiple hamartoma syndrome) is an autosomal dominant illness characterized by mucocutaneous stigmata (facial trichilemmomas, acral keratoses, and oral mucosal papillomas), colorectal polyps, and an increased incidence of malignancy in various sites (breast, thyroid, renal, and uterine, among others).[452] The polyps have hamartomatous features, with disorganization and proliferation of the muscularis mucosae, but they differ microscopically from the polyps of Peutz–Jeghers syndrome.[409,453] The syndrome is due to germline mutation in the *PTEN* gene.[454]

Relationship With Carcinoma and Treatment

Colonoscopic polypectomy results in a lower-than-expected incidence of colorectal carcinoma in the population subjected to that procedure, providing support to the current practice of searching for and removing adenomatous polyps.[455] When possible, adenomas should be removed in toto, preferably in one piece. This allows a proper orientation of the specimen, so that in the presence of focal carcinoma the extent of the tumor and the relationship to the polypectomy margin can be assessed (Fig. 17.66). This determination is of great importance in deciding whether further surgery is indicated or whether endoscopic polypectomy is adequate therapy.

Malignant colorectal polyps should be assessed for the following features:

1. Tumor differentiation
2. Angiolymphatic invasion (lymphovascular invasion [LVI])
3. Adequacy of excision

Endoscopic polypectomy can be performed for those malignant colorectal polyps that are either well or moderately differentiated (i.e. not poorly differentiated), lack angiolymphatic invasion (although this assessment can be exceedingly difficult and subject to significant interobserver variability),[456] and have a free polypectomy margin.[457–459] Again, there is some disagreement as to what constitutes a tumor-free polypectomy margin. While some studies advocate for a 2-mm margin,[460] others require only 1 mm, and still others would consider a lesion as completely excised if the tumor is not seen at the cauterized polypectomy margin.[461]

In reality, the specimens obtained with endoscopic resection are often fragmented and difficult to orient. When a focal carcinoma is present in a polyp, it may be impossible to determine the adequacy of excision. In such circumstances, surgical excision is often indicated.

If a proximally located lesion is very large, a small endoscopic biopsy may fail to detect the area of malignant transformation if present; therefore such a lesion may be best treated by anterior resection of a segment of bowel.

The term **intramucosal adenocarcinoma** is a controversial one when used in the context of colorectal neoplasms. This refers to a neoplasm that has penetrated the basement membrane into the lamina propria or muscularis mucosae but not below (Fig. 17.67). As such, stromal desmoplasia, the best indicator of submucosal invasion, is absent. In the situation of an intact polyp with intramucosal adenocarcinoma that has been completely excised, endoscopic polypectomy is adequate therapy since there is no risk of lymphatic dissemination given the absence of lymphatic channels in the colorectal mucosa.[462] However, if the lesion is fragmented or from a larger incompletely excised lesion, we used the diagnostic term "at least intramucosal adenocarcinoma" with a comment that invasion still could be present in the remainder of the unexamined lesion remaining in the patient. In this situation, bowel resection with removal of regional lymph nodes is often indicated.[463–465]

We believe that following the rather conservative recommendations presented herein will help avoid subjecting patients with colorectal polyps to unnecessarily radical, costly, and potentially dangerous procedures. Obviously, a thorough pathologic evaluation is of paramount importance in this determination.[466]

Carcinoma

General Features

Carcinoma of the large bowel is common in northwest Europe, North America, and other Anglo-Saxon areas, but low in Africa,

Asia, and some parts of South America.[467,468] In the United States, it is the third most common cancer among men and women and the second leading cause of death from cancer. At the same time, it is by far the most curable form of carcinoma of the gastrointestinal tract. Males and females are affected equally, and the mean age at diagnosis is in the sixth to seventh decades of life. Cases occurring in the young (<40 years of age) are usually located in the distal colon and rectum and tend to show features associated with aggressive behavior or are associated with one of the hereditary colorectal cancer syndromes.[469]

The cause and pathogenesis of colorectal carcinoma are related to both environmental and genetic factors. The former are largely dietary, particularly in terms of fats and animal protein; they are related to their influence on the intestinal microflora and ultimately on the chemical composition of the intraluminal content.[470] Specifically, there is a close association between beef consumption, the ingestion of large amounts of animal fat, and the incidence of colorectal carcinoma; however, the issue is complex, and the precise nature of the relationship is far from established.[471]

The genetic factor manifests itself in a variety of ways. The most obvious is the high predisposition for colorectal carcinoma in patients with FAP (nearly 100% by age 50 years see previous discussion), other forms of polyposis (to a much lesser degree; see previous discussion), and in those with the HNPCC syndrome *(Lynch syndrome)* and related nonpolyposis associated hereditary conditions.

The issues of the relationship between epithelial polyps and colorectal carcinoma and the sequence of molecular alterations that have been detected in these lesions have already been discussed. Patients with IBD have a definite predisposition to colorectal carcinoma, but they comprise only a small percentage of the patients with colorectal carcinoma in the general population.[158] Some cases of colorectal carcinoma occur as a late complication of pelvic irradiation, usually for carcinoma of the cervix.[472] A few others have been reported as arising at ureteral implantation sites.[473]

Hereditary Nonpolyposis Colorectal Cancer Syndrome (Lynch Syndrome) and Other Familial Forms of Colorectal Cancer

HNPCC is due to germline mutations in one of the genes responsible for repair of DNA mismatches, most commonly *MLH1*, *MSH2*, *MSH6*, and *PMS2*, resulting in high levels of MSI.[474] There is a 50% risk of developing colorectal carcinoma for a first-degree relative of an affected patient in the direct genetic lineage.[475] The carcinomas most commonly involve the proximal colon. Patients with HNPCC are also at an increased risk for the development of malignant tumors at other sites, such as liver (cholangiocarcinoma), uterine corpus, urinary bladder, renal pelvis, ureter, pancreas, and several other organs.[476]

A variation on the theme of HNPCC is represented by colorectal carcinoma-prone families who have right-sided flat adenomas. The number of polyps is intermediate between that in FAP and that in classic HNPCC; the carcinomas, most of which are also right sided, occur at a later age than in the other two conditions.[477]

In **familial colorectal carcinoma** (defined by the presence of two or more first-degree relatives with this tumor), the risk for first-degree relatives of affected individuals is increased threefold.[430] Mutant alleles of the *HRAS*-1 minisatellite may predispose to this condition.[478]

The colorectal carcinomas that arise in HNPCC tend to show several of the following features, none of which can, however, be regarded as pathognomonic: young patient age, right-sided location, mucinous features, poor differentiation (solid or medullary appearance), tumor-infiltrating lymphocytes, lack of "dirty" necrosis, and presence of a Crohn-like inflammatory reaction.[479,480] Interestingly, the adenomatous polyps occasionally present in the colon of patients with HNPCC also tend to be infiltrated by lymphocytes.[481]

The approach (molecular vs. immunohistochemistry) to assessing tumors for HNPCC has been the topic of innumerable publications and debate. While both techniques are sensitive and specific for MMR deficiency, neither technique is perfect, and they should be viewed as complementary.[474] There are both technique and interpretive issues with immunohistochemical staining for MLH1, MSH2, MSH6, and PMS2, but in general, the recognition of good internal control staining can help to identify these technical issues. A normal staining profile indicates a low likelihood of HNPCC. An abnormal profile (besides loss of MLH1 and PMS2) should result in a germline evaluation for HNPCC. If there is concurrent loss of staining for MLH1 and PMS2, we test for *BRAF* V600E mutations and/or MLH1 methylation, which, if abnormal, indicates a low likelihood of HNPCC.[482]

Which tumors to test has also been the topic of debate. The Revised Bethesda Guidelines (accounting for age, tumor histology, family history) has been estimated to miss up to 30% of Lynch-associated tumors.[483,484] The Jerusalem criteria suggest testing colorectal cancers in all patients less than 70 years of age, although it has been estimated to miss approximately 10% of these tumors.[474,485] Others perform universal screening, usually assessing for MMR deficiency by immunohistochemistry.

Clinical Features

Carcinomas of the large bowel may present with rectal bleeding, changes in bowel habits (such as diarrhea alternating with constipation), anemia resulting from chronic blood loss, and vague abdominal pain. Intestinal obstruction is common when the tumor is situated in the left colon and rare for tumors in the cecum or ascending colon. Perforation may rarely occur, either at the site of the carcinoma or in the cecum as a result of distention caused by an obstructing rectosigmoid carcinoma. The endoscopic appearance is usually characteristic, but some inflammatory lesions may simulate carcinoma, and some undifferentiated carcinomas may have an innocent appearance.

Unfortunately, the previously mentioned symptoms are often indicative of advanced disease; therefore, many attempts have been made over the years to detect tumors at an earlier stage. One such procedure is the performance of appropriately timed endoscopic examinations of both men and women over 40 years of age.[486] Stool examination for occult blood also has proved to be an efficient and inexpensive way of detecting cases of early, asymptomatic carcinoma.[487]

Carcinoembryonic antigen (CEA) is a glycocalyx-related antigen that has been detected in the serum of 72%–97% of patients with colorectal carcinoma.[488] It disappears after resection of the tumor and reappears in the event of recurrence or metastases. Higher values are found in tumors that have spread beyond the bowel wall, in poorly differentiated neoplasms, and in tumors associated with angiolymphatic and perineurial invasion.[489] Elevated circulating levels of CEA also occur in carcinomas of the stomach, pancreas, breast, lung, prostate gland, and thyroid (medullary carcinoma). Serum CEA is practically never elevated in normal individuals, but high values can be found in patients with chronic liver or renal disease.[489] Unfortunately, the test is often negative during the early stages of colorectal carcinoma and is, therefore, not an effective screening tool. Its main utility rests in the monitoring of therapy, in the early detection of metastases, and as an indicator for second-look

Cooke, Brisbane, Australia, from Cooke RA, Stuart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

surgery.[488,490] Recently, *KRAS* mutation screening by chip-based DNA hybridization has shown promise as a potential tool in this regard.[491]

Site and Gross Features

Approximately 50% of all carcinomas occur in the rectosigmoid area, although their relative incidence seems to be decreasing[492]; a shift in location toward the proximal colon during the past few decades has been noted.[493] Right-sided tumors are associated with older age at presentation.[494] Multicentric carcinomas are found in 3%–6% of the cases.[495]

Grossly, most colorectal carcinomas are either polypoid or ulcerative/infiltrating (Fig. 17.68). The former presents as a bulky mass with well-defined, rolled margins, and a sharp dividing line with the normal bowel. The latter has a less elevated surface and is centrally ulcerated. A particular variant of this tumor type, well documented in the Japanese literature, is referred to as "flat" or "depressed" carcinoma and is thought to arise de novo rather than through malignant transformation of an adenoma.[496] These flat carcinomas have a greater tendency for deep invasion with lymphovascular permeation than the more common polypoid types.[497]

In general, there is good correspondence between the gross and the microscopic margins of the tumor. Extensive lateral superficial spread of the type often seen in the stomach is very rare in colorectal tumors, but it does occur.[498] On cross section, grayish white tissue is seen replacing the bowel wall. The edges may be well demarcated or with finger-like projections extending from the main mass. Highly mucinous tumors have a gelatinous, glaring appearance, and layers of mucus may separate the layers of bowel wall.

Important features to evaluate at the time of gross inspection are whether the tumor is confined to the wall or whether it has extended to the pericolic tissues, whether gross invasion of veins is present, and whether the remainder of the colon shows other carcinomas or polyps of any type.

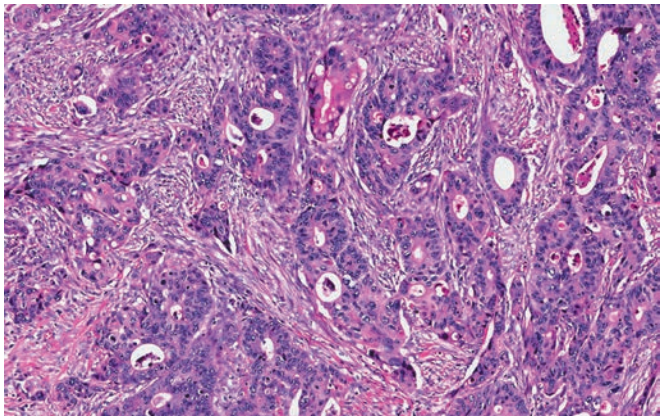

Figure 17.69 Microscopic appearance of an invasive colonic adenocarcinoma characterized by stromal desmoplasia.

Microscopic Features

The usual malignant tumor of the large bowel is a well-to-moderately differentiated adenocarcinoma secreting variable amounts of mucin. The tumor cells represent a combination of columnar and goblet cells, with occasional participation of neuroendocrine cells and the exceptional occurrence of Paneth cells.[499] The carcinoma consistently elicits an inflammatory and desmoplastic reaction, which is particularly prominent at the edge of the tumor (Fig. 17.69). Most of the inflammatory cells are T lymphocytes,[500] but B lymphocytes, plasma cells, histiocytes, and S-100 protein–positive dendritic cells may also be present.[501] Occasionally there are numerous eosinophils, a feature thought to be due to interleukin-5 production.[502]

The tumor surface may have a papillary or villous configuration, to be distinguished from a residual villous adenoma described previously and the micropapillary pattern described later. The tumor

may be seen invading all the layers of the bowel and extending into the pericolic fat, permeating perineurial spaces, and invading veins. The latter feature, which is of prognostic significance, can be better appreciated with stains for elastic fibers (Verhoeff–van Gieson or Movat stain).[503]

The edge of the tumor may show foci of a residual adenoma, but more commonly one identifies a reactive hyperplastic alteration in the glands, which appear taller, more tortuous, and with more goblet cells than the normal mucosa (so-called transitional mucosa).[504]

Histochemical and Immunohistochemical Features

Histochemically, the large majority of colorectal carcinomas are positive for mucin stains. Immunohistochemically, the main mucin protein cores expressed by conventional colorectal adenocarcinoma are MUC1 and MUC3 (as opposed to MUC2 in mucinous carcinoma).[505] There is also expression of MUC13, particularly in poorly differentiated tumors.[506] Recently, the serrated pathway of colon cancer has been found to be associated with increased expression of MUC2, MUC5AC, and MUC6.[507]

Colorectal adenocarcinomas are invariably positive for cytokeratin (CK), with the most common pattern being positivity for CK20 and negativity for CK7.[508] The reverse pattern is extremely rare, which is helpful in distinguishing colorectal adenocarcinoma from adenocarcinomas of other sites, such as lung and ovary.[509] However, aberrant patterns of immunoreactivity (such as positivity for CK7) can be found in some colorectal carcinomas, particularly those that are poorly differentiated.[510,511] Reactivity for CEA is also the rule, and failure to demonstrate CEA in an adenocarcinoma makes a colorectal origin unlikely.[512] The positivity for this marker is equally distributed throughout the cell surface in most cases, as opposed to the polar distribution seen in normal mucosa and in the better differentiated tumors.[513] A variety of monoclonal antibodies to different epitopes of the CEA molecule are available, but those that recognize epitopes of group 1 or 2 have been found to have the greatest degree of sensitivity and specificity.[508]

CDX2 is a caudal-type homeobox gene that encodes a transcription factor that plays an important role in the proliferation and differentiation of intestinal epithelial cells. It is found by immunohistochemistry in the overwhelming majority of colorectal carcinomas,[514] but it can also be expressed in primary mucin-producing carcinomas of ovary, bladder, and lung, as well as pancreaticobiliary adenocarcinomas.[515]

Tumor-associated glycoprotein 72 (TAG-72), recognized by monoclonal antibody B72.3, is present in virtually all invasive colorectal carcinomas but also in the majority of hyperplastic and adenomatous polyps and even in normal mucosa; however, the frequency of reactivity and the pattern of expression vary depending on the condition.[516]

Other markers consistently expressed by colorectal carcinoma regardless of differentiation are villin (a cytoskeletal protein associated with the axial microfilament bundles of brush border microvilli),[517] cathepsin B (a lysosomal cysteine proteinase),[518] neuropilin-1 (a molecule normally present in the developing nervous system), SRCA2 (an ATPase crucial to many cell functions),[519] and cadherin-17 (also known as liver-intestine cadherin).[520] Calretinin can be expressed by a minority of colorectal adenocarcinomas (especially the undifferentiated ones), a fact to be remembered in the differential diagnosis with mesothelioma.[521]

A high percentage of colorectal carcinomas show immunoreactivity for human chorionic gonadotropin (hCG)[522]; this seems particularly common in mucinous and poorly differentiated tumors.[523] Estrogen and progesterone receptors are usually absent or are present in a small minority of tumor cells.[524] Racemase, a marker for prostatic adenocarcinoma, is expressed in over half of colorectal adenocarcinomas, a potential source of misdiagnosis.[525]

Molecular Genetic Features

The identification of several types of familial colorectal carcinoma has led to the discovery of some of the genetic alterations associated with (and presumably pathogenetically responsible for) these tumors.[526] It was subsequently shown that somatic mutations of these genes also occur in sporadic colorectal cancer, such as *APC* and MMR genes.[527,528] The model still standing for colonic carcinogenesis is that proposed by Fearon and Vogelstein in the late 1980s,[529] but it has become increasingly obvious that many variations exist and that not all colorectal cancers follow the same genetic pathway during carcinogenesis. Specifically, DNA MMR deficiencies with resulting MSI has been found to be an important alternate pathway, present in approximately 15% of cases; it operates in HNPCC[530,531] and in sporadic carcinomas that are usually right sided and arising from serrated polyps (serrated pathway).[532,533]

Tumors associated with MSI tend to be mucinous or poorly differentiated, with a prominent host response, a circumscribed growth pattern, and right-sided location. The presence of tumor-infiltrating lymphocytes has been found to be one of the best histologic predictors of MSI.[479,534] It has been further pointed out that differences may exist depending on the specific type of MMR gene involved.[535]

Oncogenes that commonly show somatic mutations in colorectal carcinomas include *KRAS*, *BRAF*, *PIK3*, and *CTNNB1* (β-catenin gene).[536] For example, mutations of the *KRAS* oncogene have been found in about 40% of colorectal carcinomas, particularly metastatic lesions.[537,538] Its presence has been correlated with a lack of response to anti-epidermal growth factor receptor (EGFR) therapy.[539,540]

β-Catenin, which is associated with APC protein, is dysregulated either as a result of *APC* mutation (>70%) or *CTNNB1* (β-catenin gene) mutation (2%–5%), resulting in aberrant nuclear localization of the molecule as demonstrated by immunohistochemistry in a high proportion of cases.[541]

Tumor suppressor genes that are commonly involved in colorectal carcinomas include *TP53*, *APC*, *DPC4/SMAD4*, *DCC*, *CDKN1B*, and *MCC*.[528] Mutations of *TP53* have been detected by molecular techniques in the majority of colorectal carcinomas[542] and have been correlated with the immunohistochemical overexpression of the protein coded by the abnormal gene, albeit imperfectly. Decreased expression of CDKN1B (p27) has been associated with poor outcome.[543,544]

Other Microscopic Types

Mucinous carcinoma is a special type of colorectal carcinoma in which large lakes of extracellular mucin are formed, mixed with collections of tumor cells (Fig. 17.70).[545] According to the WHO, by definition, these mucinous foci should constitute at least half of the tumor mass. They represent up to 10% of all colorectal cancers.[546] At the molecular level, they show a high rate of MSI.[547] These tumors secrete distinct *O*-acylated forms of mucin containing the MUC2 protein core.[548,549] They usually have an exophytic shape and should not be equated to the pure signet ring carcinomas described later. Mucinous carcinomas are also more frequently associated with adenomas elsewhere in the colorectum than are conventional adenocarcinomas[550] and tend to present at a more advanced stage.[551]

The relationship between mucinous subtype and survival is not clear cut, with some studies showing a worse prognosis when compared to conventional colorectal carcinoma and others showing no significant difference.[552–554] This subtype does have a propensity

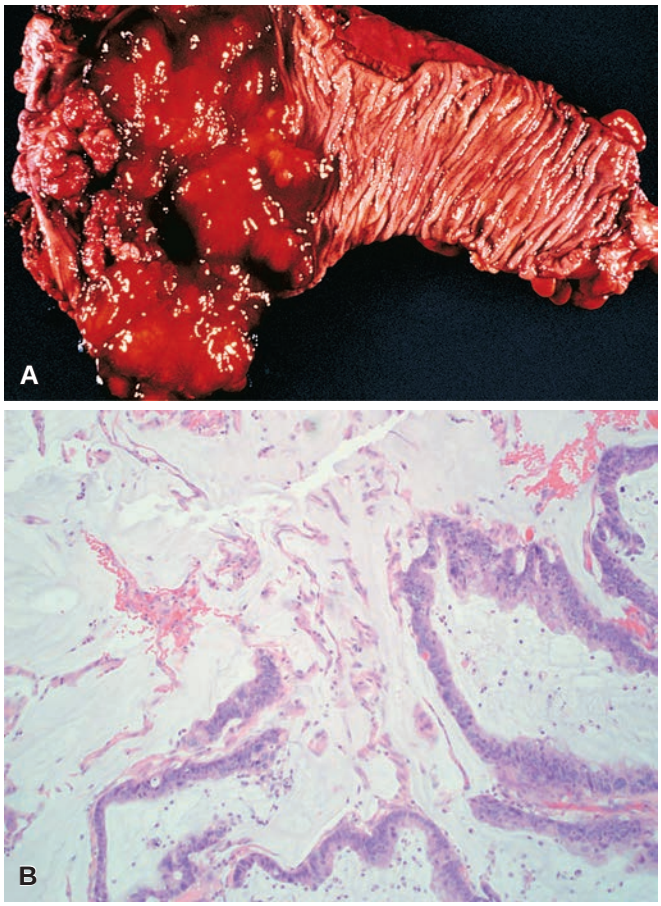

Figure 17.70 Mucinous Adenocarcinoma. A, Gross appearance of a mucinous adenocarcinoma of the rectum. **B,** Microscopic appearance of mucinous adenocarcinoma.

to invade adjacent viscera[555] as well as to develop peritoneal implants.[556] They are also more likely to develop lymph node metastases beyond the pericolonic region.[555] Greenson et al. found that mucinous tumors that are MSI low or stable are more likely to behave in an aggressive manner.[479]

Signet ring carcinoma is a rare form of colorectal carcinoma (up to 1% of all colorectal cancers) that usually affects young patients. Similar to mucinous carcinomas, about one-third of the cases are MSI high.[557] Like its more common gastric counterpart, signet ring carcinoma usually presents grossly as a diffuse infiltration of the wall, although it has also been described arising in an adenomatous polyp (Fig. 17.71).[558] By definition, more than 50% of the tumor should be composed of signet ring cells, regardless of the amount of extracellular mucin. Microscopically, the tumor grows in a diffuse fashion, with little if any glandular formation. Most or all of the mucin is intracellular, in contrast to that seen in mucinous carcinoma. This intracellular accumulation of mucin results in displacement of the nucleus and a typical signet ring configuration of the cells. Metastases tend to develop in lymph nodes, the peritoneal surface, and the ovary rather than the liver. The pattern of spread is mainly in the form of peritoneal dissemination, and the prognosis is extremely poor.[559] The possibility of the colorectal lesion representing a metastasis from a gastric or mammary primary lesion should always be investigated before a diagnosis of primary signet ring carcinoma is made.[560] Immunohistochemically, a CK7−/CK20+ profile favors a colorectal primary, whereas CK7+/CK20− favors a metastasis.[561] Colorectal signet ring carcinoma also expresses MUC2, MUC5AC, and CDX2, its overall profile being different from the homologous tumor in the breast but quite similar to that in the stomach.[562]

As mentioned earlier in this chapter, care should be exercised in distinguishing signet ring carcinoma from the benign signet ring change that may accompany pseudomembranous colitis and other inflammatory conditions.[563]

In some cases of mucin-producing colorectal adenocarcinomas, there is an admixture of extracellular and intracellular mucin formation, resulting in a mixed mucinous–signet ring carcinoma.[553] The greater the signet ring component, the worse the outcome. It is therefore useful to specify the presence and percentage of signet ring cells in mucinous tumors.[564]

A **micropapillary pattern** may be identified in about 20% of colorectal adenocarcinomas, a phenomenon analogous to the more familiar one seen in some carcinomas of breast, bladder, lung, and other organs.[565,566] This finding is associated with a greater frequency of angiolymphatic and perineural invasion and lymph node metastases and therefore of decreased survival (Fig. 17.72).[566,567]

Serrated adenocarcinoma has been recently proposed as a morphologically distinct type of colorectal adenocarcinoma, backed by some molecular findings. As one might expect, it is linked to the serrated pathway and precursor serrated lesions (SSP).[568] It is described

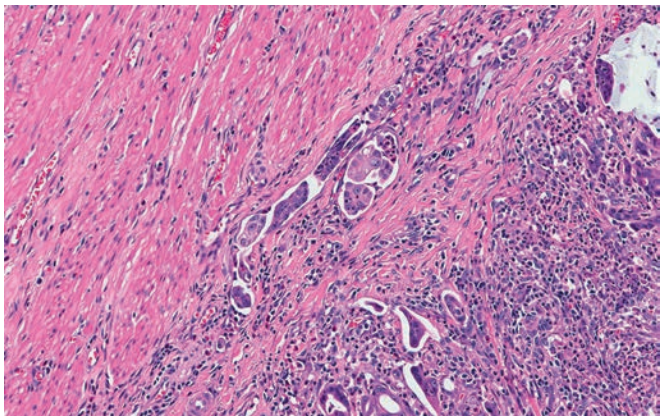

Figure 17.72 Poorly differentiated adenocarcinoma with micropapillary features and prominent angiolymphatic invasion.

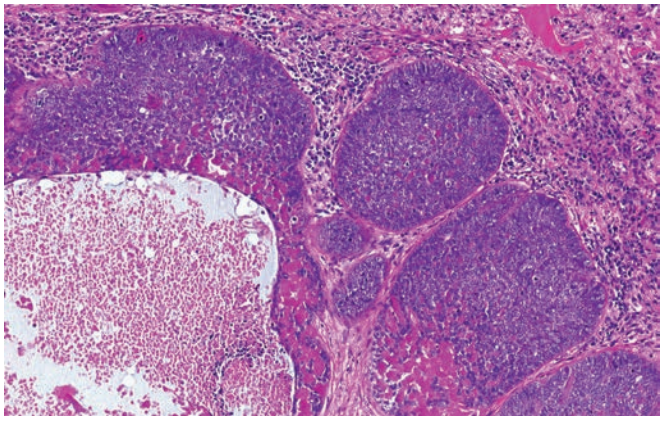

Figure 17.73 Characteristic appearance of basaloid squamous cell carcinoma arising in the anus.

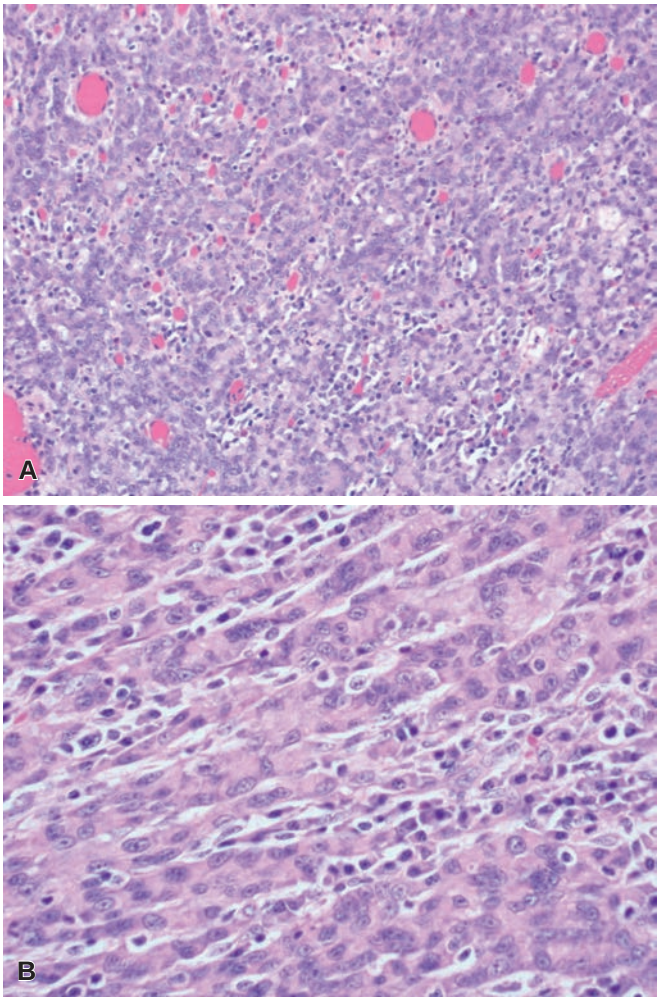

Figure 17.74 Characteristic appearance of so-called medullary carcinoma.

as showing a serrated, mucinous or trabecular pattern of growth, abundant eosinophilic cytoplasm, chromatin condensation, preserved polarity, and no necrosis.[569] It accounts for approximately 7.5% of all colorectal cancers and up to 10%–15% of proximally located tumors.[570,571]

There appear to be two distinct subtypes of serrated carcinomas. The more common are those arising in the proximal colon from SSPs and are MSI high. The less common type arise in the distal colon from TSAs and are MSI low or stable.[570] It should be noted that although it is believed that most proximal MSI-high cancers arise from SSPs, only a minority of these tumors actually show serrated features in the malignant component.[569,571]

Basaloid (cloacogenic) carcinoma, similar to its counterpart in the anal canal, has been reported on a few occasions in the colorectum, as proximally as the splenic flexure (Fig. 17.73).[572]

Clear cell carcinoma is not a specific entity but rather a minor morphologic variant of adenocarcinoma in which the accumulation of glycogen results in a clear appearance of the cytoplasm.[573]

Hepatoid adenocarcinoma can arise in the colon, the appearance being similar to that of its more common gastric counterpart.[574]

Medullary adenocarcinoma usually presents in the cecum or right colon of females.[575] Some cytoarchitectural features suggest neuroendocrine differentiation, but neuroendocrine markers are negative.[576] The tumor is composed of polygonal cells arranged in sheets, trabeculae, or an organoid pattern. The cells have vesicular nuclei, prominent nucleoli, abundant cytoplasm, and numerous tumor-infiltrating lymphocytes (Fig. 17.74).[577] The differential diagnosis includes poorly differentiated adenocarcinoma; in contrast to the latter, medullary carcinoma shows consistent loss of staining for MLH1 and CDX2.[578] Instead, it is usually immunoreactive for MUC1, MUC2, and TF3.[578] It also stains much more frequently for calretinin than poorly differentiated adenocarcinomas.[578] The behavior is not nearly as aggressive as the morphologic appearance might suggest.[577] Genetically, most of these tumors are characterized by MSI.[579,580]

Sarcomatoid (spindle cell) carcinoma is similar in appearance to that of its counterpart in many other organs, and its behavior is, as one would expect, very aggressive.[581,582] These are more common in elderly patients.

Squamous differentiation may be present in colorectal carcinoma. It is more common in cecal neoplasms but may be seen in tumors from any other area of the large bowel.[583] In most instances, the squamous component is associated with glandular elements *(adenosquamous carcinoma)*, but occasionally it is seen in a pure form *(squamous cell carcinoma)*.[584] An association has been noted between squamous changes in colorectal carcinoma and ulcerative colitis.[585] Some are associated with the production of parathyroid hormone-related protein and paraneoplastic hypercalcemia.[586] Several studies have failed to find a pathogenetic role for HPV.[584,587] The possibility of upward extension or submucosal metastasis from a carcinoma of the anal canal should be considered for squamous tumors located

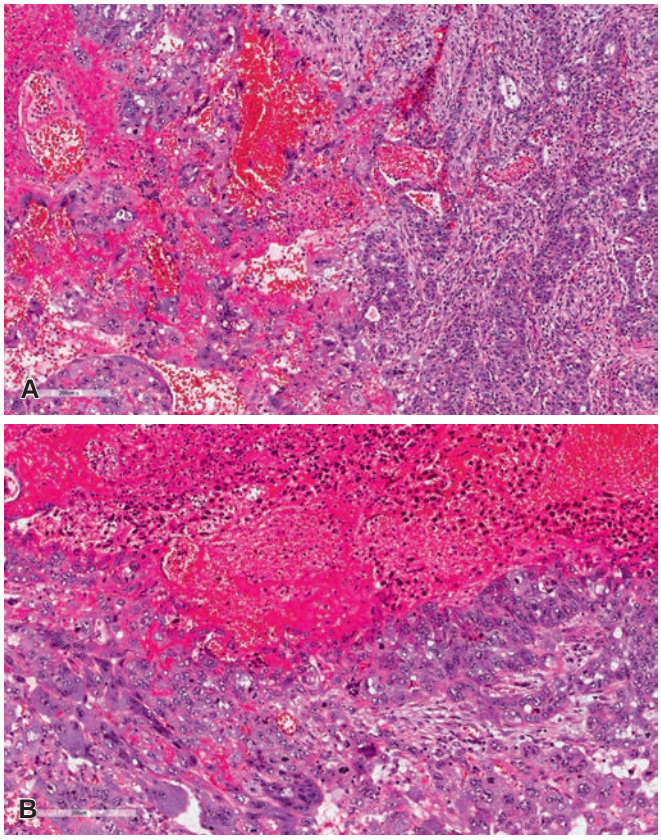

Figure 17.75 **Mixed Adenocarcinoma-Choriocarcinoma. A,** Low-power view showing an admixture of adenocarcinoma and choriocarcinomatous elements. **B,** High-power view of a focus of choriocarcinoma in a mixed tumor.

in the low rectum. Metastases from another site (especially the lung) should also be excluded, as should the presence of a squamous-lined fistula tract.

Trophoblastic differentiation can occur focally in colorectal adenocarcinoma, as it does in tumors of stomach and gallbladder (Fig. 17.75). hCG can be demonstrated immunohistochemically in the tumor cells.[523] Occasionally the entire tumor has the appearance of a choriocarcinoma.[588] This phenomenon should be distinguished from the more common finding of hCG positivity in morphologically conventional adenocarcinomas.

Glassy cell carcinoma, similar to its homolog in the uterine cervix, has been rarely described in the large bowel.[589]

Neuroendocrine differentiation may manifest itself in a variety of ways, as it does elsewhere in the gastrointestinal tract:

1. As *scattered neuroendocrine cells* in otherwise typical adenocarcinomas (particularly of the mucinous type), a feature that does not seem to independently influence the prognosis or natural history of these tumors.[590,591] This occurs in 15%–50% of all adenocarcinomas, as detected immunohistochemically or by hybridization procedures for neuroendocrine markers such as chromogranin.[592] This phenomenon seems to be more frequent after chemotherapy and radiotherapy, a fact which suggests that it might be induced by these treatment modalities.[593]
2. In the form of tumors with a *mixed composition*, in which typical adenocarcinoma intermingles with a component exhibiting clear-cut neuroendocrine differentiation. By definition, each component should comprise at last 30% of the tumor.[594] The existence of these tumors is explained by assuming an origin from endodermally derived multipotential cells located at the base of the crypts, which during the course of neoplastic transformation undergo differentiation along several different pathways.[595]
3. In the form of tumors showing throughout the appearance of a *neuroendocrine carcinoma* but having a more organoid appearance and being composed of larger cells than the small cell carcinomas *(large cell neuroendocrine carcinoma)*.[596]
4. In the form of *small cell neuroendocrine carcinoma*, a tumor having a microscopic appearance similar to that of its pulmonary homonym (Fig. 17.76).[596,597] Most of the cases are located in the right colon.[598] Electron microscopy usually reveals a few dense-core secretory granules in the cytoplasm, and immunohistochemical techniques show positivity for neuron-specific enolase and other neuroendocrine markers such as synaptophysin, although stains for chromogranin may be negative due to the low density of neurosecretory granules.[599] The entire tumor may have this appearance, or there may be foci of glandular differentiation, with or without mucin production.[596] Squamous differentiation may also be present.[598] Some of these small cell carcinomas arise

in the setting of a precursor adenoma.[596] The prognosis is poor, with early metastases to lymph nodes and liver.[596,598]

5. In the form of typical *carcinoid tumors (well-differentiated neuroendocrine tumor [WDNET])*, discussed later in this chapter.

Rhabdoid features can be seen in adenocarcinoma of the cecum and other portions of the large bowel[600,601]; as in other sites, this pattern is predictive of aggressive clinical behavior.

Oncocytic adenocarcinoma of the rectum has been reported occasionally, sometimes after preoperative chemoradiation or developing from a villous adenoma with oncocytic changes.[343] They should be distinguished from tumor cells with squamous metaplasia and from plain oxyphilic tumor cells.

Biopsy

A positive biopsy should always be obtained before radical surgery for colorectal carcinoma is undertaken. In large lesions, it is advisable to perform several biopsies from diverse areas; those from the center may show only granulation tissue, and those from the very periphery may contain only hyperplastic (so-called transitional) colonic epithelium. A sometimes more difficult (but just as critical) determination once a carcinoma has been recognized is to ascertain its location and extent. Obviously, the significance of the finding is markedly different if the fragment of tissue with adenocarcinoma was taken from the tip of a pedunculated polyp or from the side of a large ulcerated mass. Close communication with the endoscopist and surgeon, intact biopsy of an adequate size and depth, and proper orientation of the specimen are essential requisites for this determination.

Staging, Grading, and Prognostic Factors

In 1937, Dukes proposed his famous staging system for rectal carcinomas that also can be applied to carcinomas of the colon.[602] It is still widely used in one form or another because of its direct relationship with prognosis, as it is clear that the anatomic extent of tumor (pathologic stage) is the single most important predictor of clinical behavior for colorectal carcinoma.

A number of staging systems have been proposed since that time but, at least in North America, the TNM staging system is the most widely used (Tables 17.2 and 17.3). Depth of invasion (T) is critically important in this evaluation. *Tis* encompasses high-grade dysplasia and intramucosal adenocarcinoma (invasion into the lamina propria or muscularis mucosae but not beyond). T1 and T2 refer to invasion into the submucosa and muscularis propria, respectively. Those that invade into the subserosal adipose tissue or the nonperitonealized pericolic or perirectal soft tissue are T3. Some have found subclassification of T3 tumors based upon distance of tumor invasion beyond the muscularis propria to be of prognostic significance (pT3a less than 1 mm; pT3b 1–5 mm, pT3c 5–15 mm, pT3d greater than 15 mm).[603] Finally, invasion of the visceral peritoneum and invasion of adjacent structures constitute T4a and T4b, respectively. Several studies have found penetration of the visceral peritoneum (serosal involvement) to be an important adverse prognostic indicator.[604,605] However, it can be challenging to determine the status of peritoneal involvement in some cases.[606]

Regional lymph node involvement (N) is also a critical prognostic parameter. At least 10 (and ideally 12) lymph nodes should be examined in specimens which have not been subjected to neoadjuvant therapy.[607] Some have found the ratio of involved lymph nodes to the total number of lymph nodes to be an important prognostic factor.[608,609] A difficult problem can be distinguishing a pericolonic tumor deposit (PTD) from an involved lymph node, as the former is associated with an even poorer prognosis.[610,611] PTDs can be recognized by their irregular outline of tumor in the fat (away from the leading edge of the tumor), with no evidence of residual lymph node tissue. Involvement of common iliac and external iliac lymph nodes is considered evidence of distant metastasis (M1).[612]

Isolated tumor cells are defined as single or small clusters of tumor cells in a lymph node measuring ≤0.2 mm. *Micrometastases* are defined as tumor deposits in a lymph nodes greater than 0.2 mm but ≤2 mm. The former are considered N0, and the latter are considered N1(mic) or M1(mic) for regional and nonregional lymph nodes, respectively. The prognostic significance of these two categories is not entirely clear,[613,614] although there are emerging data to suggest the negative prognostic impact of micrometastases.[615–617]

There are a number of other important prognostic variables that will be highlighted here. As mentioned elsewhere in this chapter, *tumor subtype* is prognostically important, as mucinous, signet ring, and undifferentiated carcinomas are more clinically aggressive tumors. *Tumor grading* is important in that high-grade tumors (which have less than 50% gland formation) are more aggressive than low-grade tumors (which have ≥50% gland formation). The latter category encompasses both well- and moderately differentiated tumors.[618]

Vascular invasion, in particular, *extramural venous invasion*, has been found to be an important independent adverse indicator.[619,620] Given the notorious difficulty of recognizing this feature, some have advocated the use of elastin stains to increase sensitivity and specificity.[621] This finding has been estimated to be present in approximately 25% of all colectomy specimens for colorectal carcinoma. The relationship between lymphatic invasion and outcome is far less clear.[622]

The nature of the invasive margin of the tumor also has significance. Tumors with an "expanding" border with smooth rounded contours have a less aggressive clinical course than those with an infiltrative margin.[623] Interestingly, tumors with an expanding border have also been associated with MSI-high phenotype.[624,625] Tumor budding, defined as five tumor cells or less that detach from the tumor at the advancing edge and infiltrate into the desmoplastic stroma, is also a recently identified negative prognostic factor.[626,627] It also seems to correlate with risk of nodal metastasis in malignant colorectal polyps.[628]

Adequacy of surgical excision is also an important prognostic factor. Not only should one document the proximal and distal resection margins, but the radial (circumferential) margin in colorectal cancers is of clinical importance. In a seminal study done in 1986, Quirke et al. found positive radial margins in 27% of rectal resection specimens, and tumor recurrence occurred in almost all of those patients.[629] Subsequent studies confirmed the importance of this margin on recurrence and overall survival.[630] As such, these patients are treated by total mesorectal excision, which removes the mesorectal envelope[631] and potentially also resects unrecognized PTDs in the perirectal adipose tissue.[632]

Other prognostic factors include patient age (poorer prognosis in very young and very old patients)[633]; gender (better prognosis in females)[633]; serum CEA levels greater than 5.0 ng/mL (adverse indicator)[634]; bowel wall perforation (adverse indicator)[635]; prominent lymphoplasmacytic infiltrate at the advancing edge of the tumor, including a Crohn-like lymphoid reaction (favorable indicator)[636,637]; perineural invasion (adverse indicator)[638] and prominent tumor angiogenesis (adverse indicator)[639] Innumerable immunohistochemical, flow cytometric and molecular markers, far too numerous to be reaccounted here (e.g. fascin, HLA-DR, p16, HCG, BCL2, DNA ploidy, cell proliferation index, Claudin1), have been purported to be prognostic indicators, but none of these has reached the point of becoming part of routine clinical practice, aside from some of the previously mentioned molecular markers (e.g. MMR genes and

Table 17.2 Definitions of AJCC TNM

Primary Tumor (T)	
T CATEGORY	**T CRITERIA**
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ, intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosa but not into the muscularis propria)
T2	Tumor invades the muscularis propria
T3	Tumor invades through the muscularis propria into pericolorectal tissues
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structures
Regional Lymph Nodes (N)	
N CATEGORY	**N CRITERIA**
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three regional lymph nodes are positive (tumor in lymph nodes measuring ≥0.2mm) or a number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	One regional lymph node is positive
N1b	Two or three regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the subserosa mesentery or nonperitonealized pericolic or perirectal/mesorectal tissues
N2	Four or more regional nodes are positive
N2a	Four to six regional nodes are positive
N2b	Seven or more regional nodes are positive
Distant Metastasis (M)	
M CATEGORY	**M CRITERIA**
M0	No distant metastasis by imaging; no evidence of tumor in distant sites or organs (This category is not assigned by pathologists.)
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one site or organ is identified without peritoneal metastasis
M1b	Metastasis to two or more sites or organs is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastasis

proteins, *KRAS*). Most studies have found that MMR deficiency is associated with an improved outcome independent of other clinical and pathologic variables.[640–643] This has particular clinical significance for stage 2 and 3 disease, as these patients do not seem to benefit from 5-FU chemotherapy.[644] In fact, studies have also found that 5-FU may have deleterious effects in patients with MMR-deficient tumors.[645] Many studies have also found 18qLOH or *DCC* loss to be adverse prognostic indicators.[646,647]

Spread and Metastases

The most common sites of metastatic involvement of colorectal carcinoma are regional lymph nodes and liver. If there is tumor present in the lymph nodes, it is necessary to examine the tissue in the immediate vicinity of nodes, for tumor frequently extends beyond the lymph node capsule to invade surrounding veins.

Because of the great prognostic significance of lymph node metastases, it is important that the search for lymph nodes is thorough, whether done in the fresh or fixed specimen, with or without clearing of the fat in which the nodes are embedded. Sometimes the metastases will be present only in lymph nodes measuring 1 or 2 mm.[607]

Liver metastases are more common in tumors showing evidence of blood vessel invasion.[648] Other relatively common metastatic sites include peritoneum, lung, and ovaries. The incidence of ovarian metastases is high enough to justify the performance of a prophylactic

bilateral oophorectomy in a postmenopausal woman at the time of resection of the colorectal tumor. Rare metastatic sites include central nervous system, bone, testis, uterus, and oral cavity. Some of the metastases from colorectal adenocarcinoma can closely simulate primary tumors of the respective organs. This is particularly true for the ovary, in which the metastasis can be the form of initial presentation and be misdiagnosed as a primary endometrioid (including its secretory variant) or clear cell carcinoma.[649,650] Immunohistochemical and molecular studies can be helpful in this differential, as previously discussed. Secondary invasion of the bladder can simulate a primary tumor of this organ,[651] involvement of the prostate may be misinterpreted as a primary prostatic adenocarcinoma,[652] and intrabiliary growth in the liver may mimic a primary neoplasm of the biliary tract.[653]

Treatment

The standard therapy for colorectal carcinoma is surgical resection, the type of surgery obviously depending on the site of the tumor. For carcinoma of the cecum or ascending colon, ileocolectomy is the treatment of choice. Tumors located below the peritoneal reflection have been traditionally treated by an abdominoperineal resection.[654] Sphincter-preserving procedures are very effective if the cases are carefully selected.[655] Carcinomas located in other areas of the large bowel are treated by anterior resection, the extent of the operation being such as to remove the potentially involved lymph nodes. Local recurrence sometimes develops at the anastomotic line from tumor cells apparently implanted on the raw surface at the time of operation. Regular endoscopic examinations in the first year after surgery are important for the detection of potentially curable recurrences.[656]

Neoadjuvant therapy has become the treatment of choice for T3, T4, or node-positive rectal cancers.[657] Complete pathologic response (no residual tumor) is seen in up to 30% of patients.[658] Pathologic downstaging after therapy is associated with improved survival,[659] so a thorough pathologic evaluation of the tumor, tumor margins, and lymph nodes is essential. Only residual viable tumor cells should be considered as residual neoplasm (as opposed to necrotic tumor), and one often sees prominent ulceration, fibrosis, hemosiderin deposition, foamy macrophages, and mucin pools in these specimens.[660] Acellular mucin pools should not be considered as evidence of residual tumor and do not seem to be associated with a worse outcome.[661]

A significant number of patients with colorectal carcinoma develop liver metastases, a poor prognostic indicator.[662] In selected patients, resection of liver metastases has been found to prolong survival, especially for those in which a greater than 1 cm tumor-free margin can be obtained.[663]

Well-Differentiated Neuroendocrine Tumor (Carcinoid Tumor)

For many years, the term carcinoid tumor was used to describe well-differentiated neuroendocrine neoplasms arising in the tubal gut. In 2010, the WHO endorsed the term WDNET to distinguish these lesions from the more aggressive poorly differentiated neuroendocrine carcinomas, which encompasses small cell and large cell neuroendocrine carcinomas.[664,665] Although the term well-differentiated neuroendocrine carcinoma was used for "carcinoid tumors" that had metastasized, WDNET is a WHO-endorsed name which is independent of tumor stage. Using Ki-67 proliferation index and mitotic index, WDNETs are graded as grade 1 (Ki-67 index <3% and mitotic index <2/10 HPF) or grade 2 (Ki-67 index 3%–20% or 2–20 mitotic figures/10 HPF). Very rarely, WDNETs are grade 3 based upon Ki-67 or mitotic index, but there are insufficient data to understand the clinical behavior of these rare tumors.

The tumors are quite uncommon in the colon and are most common in the cecum.[666] They tend to be larger than 2 cm and behave in a clinically aggressive fashion. Rare examples secrete serotonin, in some cases resulting in the classic carcinoid syndrome.[667]

Rectal WDNETs are far more common (Fig. 17.77). They are often found as incidental polyps at endoscopy done for other reasons[668] and most are less than 0.5 cm at the time of discovery.[669] It is very uncommon for tumors less than 1 cm to metastasize, but the risk of metastasis is substantial for rectal WDNETs greater than 2 cm.[668] Many can be treated by endoscopic polypectomy provided the margin can be assessed. However, those tumors that are ulcerated or show invasion of the muscularis propria often require surgical excision, especially if greater than 1 cm. Rarely, WDNETs may arise in the setting of IBD, and such lesions may be multicentric.[161]

Grossly, it may appear as a flat and slightly depressed plaque or as a polypoid lesion.[670] One of its most distinctive features is the yellow color that it acquires after formalin fixation. Microscopically, invasion of the stroma by small uniform cells growing in a ribbon or festoon fashion is seen. This may be associated with crypt cell proliferative micronests (presumably the precursor lesion).[671] A minor tubular and/or acinar component associated with mucin production may also be present.[672] Immunohistochemically, they stain for the panendocrine markers (neuron-specific enolase, chromogranin, synaptophysin) and for a variety of peptide hormones.[673] Somatostatin, glucagon, substance P, and peptide YY are the ones most commonly represented, but gastrin/cholecystokinin, calcitonin, and pancreatic polypeptide have also been demonstrated in some

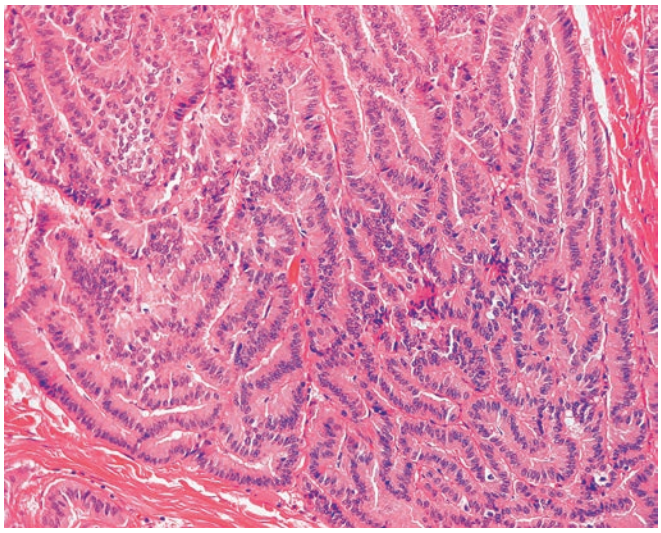

Figure 17.77 Rectal Carcinoid Tumor. The trabecular arrangement is typical of well-differentiated neuroendocrine tumors in this location.

cases.[674,675] Many of the tumors are polyhormonal.[674] Negativity for CDX2 and TTF-1 is the rule.[676] Rectal WDNETs have also often been found to exhibit immunoreactivity for CEA,[673] hCG,[677] and prostate-specific acid phosphatase.[678] The latter, whether real or the result of a cross reaction, is of practical importance because metastatic prostatic carcinoma may enter in the differential diagnosis with WDNET; the distinction is made (among other reasons) because the latter is consistently negative for prostate specific antigen.[678]

Malignant Lymphoma and Related Lesions

Malignant lymphomas are less frequently found in the large bowel than in the small bowel or stomach.[679] Some of the cases of large bowel lymphoma have been seen in immunosuppressed patients (HIV infected or transplant recipients) or in patients with ulcerative colitis.[680,681] These tumors can occur anywhere in the colorectum. They may produce prominent mucosal folds, ulceration, a large mass or a solitary polyp, or multiple small polyps distributed throughout the colorectum that may also extend to the small bowel *("lymphomatous polyposis")*.[682,683] The regional lymph nodes are involved in approximately half of the cases.

Colorectal malignant lymphomas are nearly always of non-Hodgkin type.[679] Most of the low-grade tumors are thought to belong to the mucosa-associated lymphoid tissue (MALT)-type category. They often show evidence of plasmacytic differentiation.

Other types of colorectal lymphoma include mantle cell lymphoma (Fig. 17.78),[684] anaplastic large cell lymphoma,[685] angioimmunoblastic T-cell lymphoma,[686] and Hodgkin lymphoma.[687]

As already stated, some cases of colorectal lymphoma present in the form of innumerable small polyps *("lymphomatous polyposis")*; it was initially thought that this presentation was more common with mantle cell lymphoma,[688] but it has also been documented with follicle center cell lymphoma,[689] MALT-type lymphoma,[690] and large cell lymphoma.[691]

Lymphoid polyps of benign (reactive) nature are sometimes found in the rectal area, sometimes designated as *lymphoid hyperplasia, pseudolymphoma,* and *"rectal tonsil."*[692] They appear as soft, superficial polyps usually covered by an intact, gray, smooth mucosa. The patient may complain of a mass, bleeding, or prolapse. Microscopically, these lesions are located in the lamina propria or submucosa and are made up of lymphoid tissue with follicle formation, a lobular pattern, and germinal centers. They may distort the muscularis mucosae and even extend to the muscularis propria. Nondestructive lymphoepithelial lesions may be present.[692] In a superficial or small biopsy, they can be incorrectly diagnosed as malignant lymphoma. Local excision is curative.

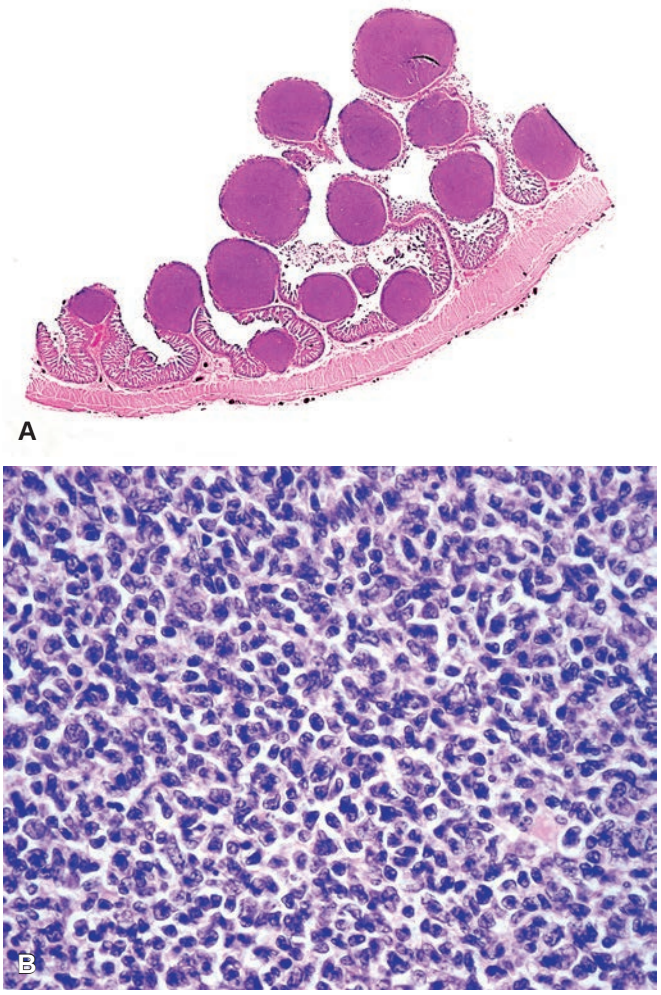

Figure 17.78 Mantle Cell Lymphoma of the Large Bowel. A, Whole-mount view showing characteristic "lymphomatous polyposis" appearance. **B,** High-power view of the neoplastic cells showing irregularity of their nuclear contours.

Langerhans cell histiocytosis can involve the gastrointestinal tract and be diagnosed in an endoscopic biopsy.[693] It can occur in adults or children, and there seems to be a female predominance.[694] Pediatric cases more often show evidence of systemic disease, which imparts a poor prognosis.

Other hematolymphoid disorders that occur in the colorectal region include *true histiocytic sarcoma,*[695] *follicular dendritic cell tumor,*[696] and *mast cell sarcoma*.[697]

Gastrointestinal Stromal and Smooth Muscle Tumors

The general features of gastrointestinal stromal tumors (GISTs) are discussed in the Stomach chapter and will not be repeated here. They are far less common in the colon when compared to the stomach and small bowel, although anorectal GISTs are a bit more common

than those arising in the colon.[698–700] However, compared to other portions of the GI tract, true smooth muscle tumors are relatively more common.

Colonic GISTs tend to occur in adults, and many are overtly histologically malignant (high risk) with marked cytologic atypia, necrosis, prominent mitotic activity, and mucosal invasion.[700] Most are predominantly spindled and stain for CD117, DOG1, and CD34. Anorectal GISTs are also predominantly spindled but appear more cytologically bland when compared to their colonic counterparts. Despite the low-grade appearance, they are deceptively aggressive and tend to recur, sometimes multiple times, emphasizing the need for an aggressive surgical approach.[698]

True smooth muscle tumors, both leiomyomas and leiomyosarcomas, can arise anywhere in the colon or anorectal region. The most common type is the leiomyoma which arises from the muscularis mucosae (leiomyomatous polyp), usually in the rectum or sigmoid colon.[701]

These superficial leiomyomas are small, sharply circumscribed, and lack mitotic activity and necrosis. They also generally lack atypia, although occasional examples containing bizarre hyperchromatic nuclei ("symplastic leiomyomas") do occur.[701] Smooth muscle tumors situated higher up in the colon have a higher incidence of malignancy.[700] Some present as polypoid lesions, and these tend to behave less aggressively than those arising as bulky intramural masses.[700]

Neural Tumors and Related Conditions

Neuromas, neurofibromas, and **(diffuse) ganglioneuromas** can occur in association with von Recklinghausen disease,[702,703] with multiple endocrine neoplasia (MEN) type 2b, or in the absence of either condition (Fig. 17.79). Most of these cases appear to arise from the neural plexuses in the bowel wall (transmural type), but others with a predominantly mucosal distribution *(mucosal type)* have been reported, sometimes in association with juvenile polyps, adenomatous polyps, and/or adenocarcinoma.[704,705]

Schwannomas can also occur in the colon and rectum and appear similar to the schwannomas arising elsewhere in the gastrointestinal tract with a characteristic peripheral lymphoid rim and strong S-100 protein staining (Fig. 17.80).[706] A few are of the *plexiform* or *epithelioid* varieties,[707] with even rarer cases with an EMA-positive perineural component *(hybrid perineurioma-schwannoma)*.[708] A further variant on the theme is the "*mucosal Schwann cell hamartoma,*" which presents as a solitary small sessile polypoid lesion, strongly positive for S-100 protein (Fig. 17.81). In contrast to the above lesions, it is not associated with von Recklinghausen disease.[709]

Benign fibroblastic polyp is the term originally proposed for a small polypoid lesion of the large bowel composed of cytologically bland spindle cells in the lamina propria which displace the normal glands and which were said to have a fibroblastic phenotype.[710,711] A subsequent study found that these lesions are composed of perineurial cells in view of their common immunoreactivity for EMA and claudin-1 and, as such, these lesions are now regarded as **mucosal perineuriomas** (Fig. 17.82).[711] A similar proliferation of perineurial cells is commonly identified in SSPs and is presumably a secondary, reactive proliferation inasmuch as they lack *BRAF* mutations which are typically found in the serrated proliferations.[712]

Other Tumors and Tumorlike Conditions

Tumorlike conditions of large bowel include the *inflammatory myoglandular polyp*, a pedunculated polypoid lesion (usually solitary) of the left (especially sigmoid) colon, characterized by submucosal

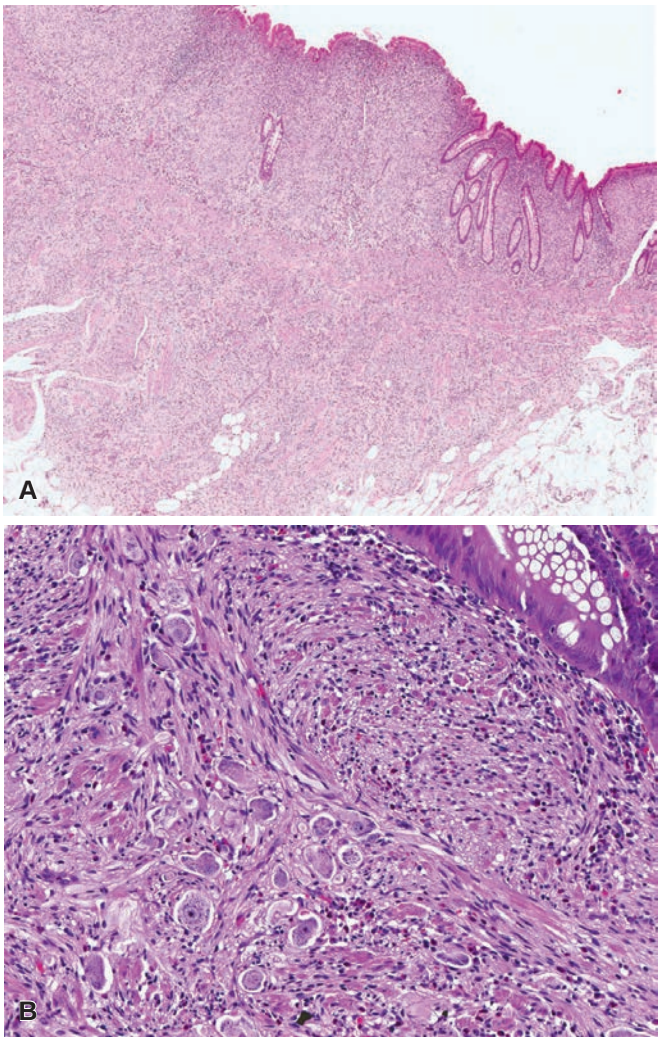

Figure 17.79 Colonic Neural Neoplasms. A, Diffuse-type ganglioneuroma involving the wall of the colon. **B,** High-power view of a polypoid ganglioneuroma.

granulation tissue, proliferation of smooth muscle, and hyperplastic glands with occasional cystic dilation.[713,714]

Another tumorlike condition is represented by the *bizarre stromal cells* sometimes present in polyps and ulcers of the gastrointestinal tract. The bizarre cells are characterized by a pyramidal shape and a strongly basophilic cytoplasm. They probably represent reactive myofibroblastic cells and should not be confused with malignant cells.[715]

Three pseudomalignant vascular conditions are the *florid vascular proliferation* that can develop secondarily to intussusception and muscular prolapse (Fig. 17.83),[716] *pyogenic granuloma (lobular capillary hemangioma)*,[717] and the exceptionally rare *reactive angioendotheliomatosis*.[718] All of these benign processes can be mistaken for an angiosarcoma.

Two other tumorlike processes that can involve this region are *xanthogranuloma*[719] and *reactive nodular fibrous pseudotumor*, a serosal-based proliferation of keratin-positive submesothelial fibroblasts.[720,721]

Vascular ectasias of the right colon are increasingly recognized as an important cause of lower intestinal bleeding in the elderly. They have also been designated as angiomas, angiodysplasias, and arteriovenous malformations, these various names reflecting the

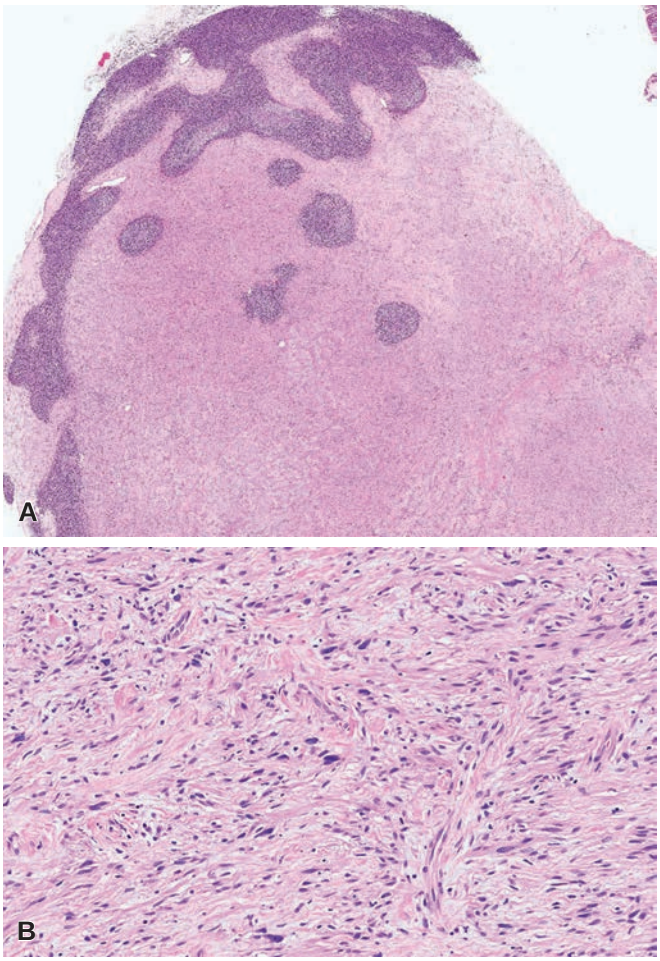

Figure 17.80 Colonic Schwannoma. A, Low-power view showing characteristic lymphoid rim surrounding the neoplastic cells. **B,** High-power view of cells with a schwannian appearance. Scattered degenerative atypical cells are characteristic.

uncertainty about their nature.[722,723] An acquired (degenerative) pathogenesis seems likely for most cases. The lesions are often small, multiple, and easily demonstrated by arteriography but may be difficult to identify in a colonic biopsy or after they have collapsed following colectomy[724]; injection with silicone rubber or other compounds followed by clearing of the specimen shows them dramatically.[725] Associated cholesterol emboli can lead to infarct and bowel perforation. Vascular ectasias should be distinguished from the *colonic varices* that may be seen as a complication of portal hypertension.[726]

Dermoid cysts have been described arising in the colon[727] and have identical histologic features to those arising elsewhere.

Hemangiomas rarely involve the large bowel. Most are of the cavernous type and may be multicentric.[728,729] Others are of cellular type and occur in infants.[730]

Lipomas of the large bowel are rare; they are invariably submucosal and therefore may intussuscept or be associated with mucosal prolapse.[731] Lipomas can also present in the form of multiple polyps in the colon.[732] **Lipomatosis** of the ileocecal valve or other portions of the colon (probably a non-neoplastic condition) may be mistaken radiographically for a tumor.[733]

Lymphangioleiomyomatosis can involve the colon in a diffuse fashion and be confused with leiomyomatosis[734]; HMB-45 immunoreactivity is a key to the diagnosis. **Angiomyolipoma/PEComa** is a tumor of HMB-45–positive smooth muscle cells that can occur in the large bowel, both in its conventional and epithelioid forms.[735] Although most are clinically benign, some are malignant, particularly those with marked nuclear atypia with diffuse pleomorphism and mitotic activity.[735]

Granular cell tumor can involve the colon or rectum, sometimes in association with similar tumors in other portions of the gastrointestinal tract.[736]

Melanoma of the anorectal region most commonly represents an upward extension or metastasis of tumors originating in the anal canal.[737]

Kaposi sarcoma can involve the large bowel; occasionally, the disease may initially present with intestinal symptoms and simulate the appearance of ulcerative colitis, particularly in AIDS patients.[738] As in other locations, these lesions stain for HHV8, allowing for reliable diagnosis.

Angiosarcoma can present as a solitary or multicentric mass and may be spindled or epithelioid.[739] These lesions reliably show strong nuclear staining for ERG and membranous immunoreactivity for CD31.

Metastatic tumors to the large bowel occur as a part of a disseminated process. These tumors form disk-like areas in which there is a central area of ulceration; the normal mucosa extends to the ulcer, giving indirect evidence that the metastatic focus began in the submucosa. This phenomenon is particularly common in malignant melanoma and primary carcinoma of the lung. Prostatic carcinoma can extend into the rectum and simulate a primary rectal neoplasm in a rectal biopsy.[740]

Metastatic malignant mesothelioma can involve the colon and even present as multiple colonic polyps.[741] Of course renal cell carcinoma may also metastasize to the large bowel. The differential diagnosis between primary and metastatic carcinoma involving the bowel is greatly aided by CDX2 immunostaining, which is consistently strongly positive in the former and negative in most of the others, allowing for the usual exceptions.[742]
