Preface

It is a daunting task to continue the incredible tradition of Drs. Rosai and Ackerman's work on this monumental surgical pathology textbook. No single pathologist is capable of tackling the complexities of modern surgical pathology, as the depth and breadth of knowledge required to write such a comprehensive textbook grows with each passing year. In light of this, we decided that a team approach was necessary to uphold the excellent tradition of this textbook and, hence, the 11th edition of *Rosai and Ackerman's Surgical Pathology* was born. The four of us were truly humbled to be invited to continue this tradition, as were our colleagues who joined the team. It was clear to us from the inception that our goal was to maintain Dr. Rosai's style and singular voice as best we could. We are hopeful the reader will notice a continuity of style with the previous editions. Nevertheless, it is impossible to emulate Dr. Rosai's unique voice as the only surgical pathologist in the world who could write multiple editions of this textbook.

The previous edition of *Rosai and Ackerman's Surgical Pathology* was published in 2011. Much has changed in surgical pathology since then, including identification of new entities, reappraisal of older entities, and increasingly sophisticated ancillary techniques, including immunohistochemistry and molecular diagnostics as tools commonly applied in the everyday practice of surgical pathology. We recognized the need for additional help from a number of expert colleagues in different areas of surgical pathology; we are truly grateful to the many authors who have contributed their time and energy to this project. As eloquently stated by Dr. Rosai in the preface of the 10th edition, "A constant attempt has been made to preserve as much as possible the pragmatic flavor initially given to this work by its peerless begetter, Dr. Lauren V. Ackerman."

Each of us is truly grateful to the countless staff pathologists, pathology residents, and fellows at each of our respective institutions who have helped us complete this textbook. We would like to thank Drs. Rahul Jawale, Lani Clinton, Youran Zou, Ryan Berry, Sara Hawes, Hannah Goyne, Ankur Sangoi, Christopher Przybycin, and Amy McKenney for their superb assistance with reviewing and proofreading the text. We would also like to sincerely thank Ms. Kathleen Ranney and Ms. Beth Minors for their outstanding administrative assistance—none of this work would be possible without them. Finally, we would like to thank Ms. Asmita Shirali for her efforts in representing the group of editors.

Most of all, we would like to thank Dr. Juan Rosai for allowing us the opportunity to follow in his enormous footsteps. It goes without saying that Dr. Rosai has been and remains one of the legendary giants of the field of surgical pathology, and it is our greatest professional honor to be able to carry on his tradition in the form of the 11th edition of *Rosai and Ackerman's Surgical Pathology*.

Preface
to the First Edition

This book can be only an introduction to the vast field of surgical pathology: the pathology of the living. It does not pretend to replace in any way the textbooks to general pathology, its purpose being merely to supplement them, assuming that the reader has a background in or access to those texts. The contents are not as complete as they might be because emphasis has been placed on the common rather than the rare lesions and are, to a great extent, based on the author's personal experiences. This book has been written for the medical student as well as for those physicians who are daily intimately concerned with surgical pathology. This must of necessity include not only the surgeon and the pathologist, but also those physicians in other fields who are affected by its decisions, such as the radiologist and the internist. Gross pathology has been stressed throughout with an attempt to correlate the gross findings with the clinical observations. The many illustrations have been selected as typical of the various surgical conditions, although in a few instances the author has been unable to resist showing some of the more interesting rare lesions he has encountered. Concluding each chapter there is a bibliography listing those references which are not only relatively recent and readily available, but also those which will lead the reader to a more detailed knowledge of the subject.

Dr Zola K Cooper, Assistant Professor of Pathology and Surgical Pathology, has written one of the sections on Skin, and Dr David E Smith, Assistant Professor of Pathology and Surgical Pathology, has written the chapter on Central Nervous System. Both of these members of the Department are particularly well qualified for their respective roles because of their background and present responsibilities in these fields. Their efforts on my behalf are most gratefully acknowledged.

Many members of the Surgical Staff at Barnes Hospital have given much help both knowingly and unwittingly. I am particularly grateful to Dr Charles L Eckert, Associate Professor of Surgery, for letting me bother him rather constantly with my questions and for giving freely of his experience. Dr Richard Johnson, who succeeded me as Pathologist at the Ellis Fischel State Cancer Hospital, agreeably made available all the material there, and Dr Franz Leidler, Pathologist at the Veterans Hospital, has been most cooperative.

Thanks must be given to Dr HR McCarroll, Assistant Professor of Orthopedics, for constructively criticizing the chapter on Bone and Joint, and to Dr California Waldron for helping me with the chapters related to the Oral Cavity. Among other faculty friends and colleagues who were especially helpful, I would like to mention Dr Carl E Lischer, Dr Eugene M Bricker, Dr Heinz Haffner, Dr Thomas H Burford, Dr Carl A Moyer, Dr Evarts A Graham, Dr Robert Elman, Dr Edward H Reinhard, Dr J Albert Key, Dr Glover H Copher, Dr Margaret G Smith, and Dr Robert A Moore. Mr Cramer K Lewis, of our Department of Illustration, has been very patient with my demands, and his efforts and skill have been invaluable. Miss Marion Murphy, in charge of our Medical Library, and her associates gave untiringly of their time.

Because of recent advances in anesthesia, antibiotics, and pre- and postoperative care, modern surgery permits the radical excision of portions or all of various organs. There is a need today for contemplative surgeons, men with a rich background in the fundamental sciences, whether chemistry, physiology, or pathology. The modern surgeon should not ask himself, "Can I get away with this operation?" but rather, "What does the future hold for this patient?" It is hoped that this book may contribute in some small fashion toward the acquisition of this attitude.

Lauren V Ackerman MD
St. Louis, Missouri, 1953

Introduction: The Legacies of Dr. Lauren V. Ackerman and Dr. Juan Rosai

1

Jesse K. McKenney

Excellence is an art won by training and habituation. We do not act rightly because we have virtue or excellence, but we rather have those because we have acted rightly. We are what we repeatedly do. Excellence, then, is not an act but a habit.

—Aristotle

The continuous success of this book since the first edition appeared in 1953 is a testament to the incredible careers of Dr. Lauren Ackerman and Dr. Juan Rosai and their unrelenting pursuit for excellence. We find it fitting to begin this 11th edition with their personal stories, so that younger generations will understand the magnitude of their impact on our field of surgical pathology.

Lauren V. Ackerman, MD

Dr. Lauren Ackerman was born in Auburn, New York in 1905. After completing studies at Hamilton College in 1927 and a year of work as an engineer, he entered medical school at the University of Rochester where he received his degree in 1932. At the recommendation of his medical school mentor, Dr. George Whipple, he traveled to the West Coast and completed training in internal medicine at the University of California, San Francisco (a decision that certainly had great influence on his approach to surgical pathology). After working as an Assistant Professor of Medicine focusing on pulmonary disease and autopsy correlation, Dr. Ackerman decided to pursue pathology. From 1936 to 1939 he was a pathology resident at Pondville Hospital in Wrentham, MA, where he studied under the legendary Dr. Shields Warren and developed his lifelong interest in tumor pathology.

In 1940, Dr. Ackerman became the Director of Laboratories at Ellis Fischel State Cancer Hospital in Columbia, MO. With the combination of his clinical background in internal medicine, his growing experience with tumor histology, and a commitment for nothing short of excellence, he helped to shape a model cancer hospital. During this time, he wrote his groundbreaking oncology textbook, with co-author Dr. Juan del Regato, *Cancer: Diagnosis and Treatment*, which served as the premier reference for a generation of oncologists through multiple editions. It was also during his time in Columbia that he described verrucous carcinoma, based on correlation with the unexpected local clinical aggressiveness of the tumor that seemed incongruous with the bland histologic features.

In 1948, Dr. Ackerman was recruited to Washington University in St. Louis as pathologist-in-chief at Barnes Hospital where he spent the next 25 years. During this phase of his career, his influence on other pathologists was enormous. He played a major role in the evolution of surgical pathology into a field that was focused on the clinical implications of histologic findings with regard to prognosis and therapy. Dr. Juan Rosai reminisced on his first experience with an Ackerman case conference; he thought he had entered the wrong room because of the thorough discussion of clinical history and imaging studies that was taking place. Dr. Ackerman codified his approach to the practice of surgical pathology in 1953 with publication of the first edition of this book, *Surgical Pathology*, which greatly increased the worldwide reach of his teaching and has had long-lasting impact on the evolution and current strength of our discipline. In 1973, Dr. Ackerman moved to the Department of Pathology of SUNY at Stony Brook, where he continued to practice pathology for 20 more years until his death at the age of 88.

During his career spanning over 50 years, Dr. Ackerman received enumerable awards for his professional contributions, including the Janeway Medal from the American Radium Society (1970), the Fred W. Stewart Award of the Memorial Sloan Kettering Cancer Center (1986), and the Gold-Headed Cane from the American Association of Pathologists and Bacteriologists (1987). In 1990, the new Surgical Pathology Laboratory at Washington University was dedicated in honor of Lauren V. Ackerman, MD, and, at that time, he also received the Distinguished Service Award from Washington University. In

1992, he received the Prix de Paris Award in recognition of his work at the Institut Gustave-Roussy in Villejuif.

One would be remiss discussing Dr. Ackerman without paying homage to his wit, which "by report" sometimes bordered on irreverent or even abrasive. During one particular dinner, he was given the task of choosing the table's wine, which he certainly enjoyed. After being told that the restaurant did not have either of the first two bottles of wine he requested, he asked for "the list of wines you actually have… not the list of wines you wish you had." On another occasion, after witnessing a young trainee order a "scotch and coke," he noted "I bet you like Tchaikovsky." One can only imagine his response to an improperly handled gross specimen.

Despite all of Dr. Ackerman's accomplishments, his most impressive legacy may be the lasting influence of surgical pathologists he trained. At the time of his death, Dr. Leon Sokoloff, professor emeritus of pathology and orthopedics at Stony Brook said, "He, more than anyone else, changed the character of anatomical pathology by directing the focus toward surgical pathology." The fact that so many leaders in academic surgical pathology emerged from Washington University is a testament to his mentorship and ability to inspire. His emphasis on the ideal that care of the patient be the driving force in surgical pathology continues on. It is unlikely that any practicing surgical pathologist today has not been trained or influenced by one of Ackerman's disciples.

Juan Rosai, MD

Giovanni "Juan" Rosai was born in Poppi, Italy (a small town in Tuscany) in 1940 and emigrated to Argentina with his parents at the age of eight. He attended the School of Medicine at the University of Buenos Aires where he met his first mentor in pathology, Dr. Eduardo Lascano. At the time of his graduation, the Hospital Regional Mar del Plata had just opened with the first formal residency programs in Argentina. Dr. Rosai became their only pathology resident, and he handled every surgical case and autopsy under the tutelage of Dr. Lascano, who had also moved to the new facility. At the time that a complex political situation ended the existence of the teaching hospital, Dr. Rosai met Dr. Lauren Ackerman, who was giving a talk at a medical conference in Buenos Aires. That meeting led to an acceptance of a residency with Dr. Ackerman at the Washington University in St. Louis, where Dr. Rosai completed training and remained as faculty until 1974. Dr. Rosai subsequently led several departments of pathology in the United States, first as: Director of Anatomic Pathology at the University of Minnesota (1974–1985), Director of Anatomic Pathology at Yale University (1985–1991), and Chairman of Pathology at Memorial Sloan Kettering (1991–1999). After a 35-year career in the United States, Dr. Rosai returned to Italy to serve as Chair of Pathology at the Cancer Institute of Milan.

Throughout his career, Dr. Rosai has made enumerable contributions to the field of pathology. His landmark descriptions of distinct entities include Rosai-Dorfman disease (sinus histiocytosis with massive lymphadenopathy), desmoplastic small round cell tumor, sclerosing angiomatoid nodular transformation of the spleen, and spindle epithelial tumor with thymus-like differentiation of the thyroid (SETTLE). To date, he has published over 400 articles, as well as 52 books, book chapters, and monographs. He served as editor in chief for the third series of the AFIP Fascicles and was the founding editor in chief of *The International Journal of Surgical Pathology*. He personally authored two of the third series AFIP Fascicles: *Tumors of the Thymus* and *Tumors of the Thyroid Gland* and edited a book on the history of surgical pathology in America, *Guiding the Surgeon's Hand*. A recent educational milestone was the creation of *The Juan Rosai Collection of Surgical Pathology Seminars,* an open online resource that includes digital images of the original slides and an annotated discussion representing nearly 1500 seminars and over 18,000 individual cases. Of course, one of Dr. Rosai's most renowned contributions has been the authorship of *Rosai and Ackerman's Surgical Pathology*, which he took over for Dr. Ackerman in 1981. Handling this task as a single author will probably stand as one of the monumental accomplishments of modern surgical pathology education and is a feat that we are quite sure will never be duplicated. *In this 11th edition our goal is to preserve what we can of his voice and influence, while acknowledging that there is no one among us who could singlehandedly create this work.*

Dr. Rosai has received numerous professional awards and honors over his career. These include Doctorate Honoris Causa from the University of Bologna (Italy), the University of Santiago de Compostela (Spain), the National University of Cordoba (Argentina), and the University of Ioannina (Greece). He is a Life Trustee of the American Board of Pathology and served for many years creating the Anatomic Pathology examination. His lifetime of service to the United States and Canadian Academy of Pathology (USCAP) and the International Academy of Pathology (IAP) has been acknowledged with the Maude Abbot Lectureship (USCAP 1995), the Distinguished Pathologist Award (USCAP 2010), and the Golden Medal Award (IAP 2011). Other recognition includes an Honorary Membership in the Royal College of Pathologists (England 2001) and the Fred Waldorf Stewart Award of the Memorial Sloan Kettering Cancer Center (New York 2006).

Personal stories can tell measures about a person's abilities, and Dr. Rosai's many trainees over the years all describe in near identical detail an otherworldly consult sign-out experience. On a typical day, as an unusual consult case was reviewed under the microscope (which could be from anywhere on the body), Dr. Rosai would ask someone to pull a specific box of slides off of the wall and another to retrieve a specific file folder containing manuscripts and notes. Of course, the lesions represented by the slides within the box were identical to the case under discussion and the folder contained relevant

articles and personal thoughts. For those with a love of surgical pathology, one cannot imagine a more magical and enlightening experience.

Dr. Rosai is known by many from the hundreds of educational lectures given over his career. His lectures often include philosophical discussions about current tumor classification with an admixture of historical antecedents that clarify the evolution of a specific topic. Of course, he is also masterful at presenting key diagnostic features and pitfalls for everyday practice. The delivery of these lectures is difficult to describe on the written page, but his wit and grace (combined with his incredible depth of knowledge) create a dynamic live experience that is seldom duplicated in surgical pathology conferences. His lectures still create an anticipatory buzz wherever he is speaking.

Today, Dr. Rosai maintains an active diagnostic surgical pathology consultation practice in Milan, Italy at the International Center of Oncologic Pathology Consultations of the Centro Diagnostico Italiano and also serves as a consultant surgical pathologist for ARUP laboratories in Salt Lake City, Utah. His academic activities continue as evidenced by his contributions to four new manuscripts in 2016, covering thyroid and neuroendocrine neoplasia. Dr. Rosai is one of the most distinguished surgical pathologists of the 20th century for his incredible (and unmatched) breadth and depth of knowledge, service to the field, and his remarkable ability to make us all better pathologists.

Introduction to Dermatopathology

The entities described in this section are a select group taken from the large number of diseases that affect the skin. They have been chosen to encompass the types of non-neoplastic material generally seen in surgical pathology laboratories. Many of the infrequently biopsied, histologically nonspecific, and rare dermatoses are excluded. Their characteristics are described in texts devoted wholly to dermatopathology and in the dermatologic literature.[1–12]

The fact that isolated histopathologic analysis has distinct limitations becomes more evident in the evaluation of the reactive processes associated with diseases of the skin than in most other organs. It is imperative that the clinical differential diagnosis be correlated with the gross and microscopic observations to render a clinically meaningful diagnosis.[13]

Skin biopsies are often small and have minimal gross changes. Ideally, the lesion should be examined by the pathologist on the patient, but, in lieu of this, an accurate clinical description and differential diagnosis should accompany each biopsy. With the ease of digital photography, the inclusion of a clinical image can be extremely useful in the interpretation of the biopsy findings. All biopsies should be taken from grossly characteristic areas. It is a waste of time and money to biopsy ruptured bullae, secondarily infected or heavily scratched areas, or the incipient or involuting lesion. Multiple biopsies may be advisable when the lesions present differing forms and stages. In diseases in which the expected changes are quantitative rather than qualitative (i.e. hyperkeratosis, acanthosis, increase in dermal thickness), the evaluation of these changes is best made by taking a punch biopsy also of clinically normal skin nearby, which represents the best possible control. Formalin, 10% buffered, is an adequate and widely available fixative. Bouin and Zenker fixatives may be used but have no unique merits. Incisional and punch biopsies can be kept from curling during fixation by placing them on a piece of file card prior to immersion. When the specimen is 0.3 mm or less in diameter, it is best processed into paraffin in one piece. It may then be sampled at various levels in the block. This prevents loss of tissue during the facing-up of the

Abstract

This chapter focuses on inflammatory diseases, infectious diseases, and miscellaneous disorders of the skin. For inflammatory disorders of the skin, the entities are classified according to reaction patterns. Entities with significant epidermal change are categorized into spongiotic, psoriasiform, and interface patterns. For entities without significant epidermal change, they are classified into perivascular, nodular and diffuse, palisading granulomatous, and sclerosing patterns. Panniculitis is subdivided into septal and lobular patterns, and bullous disease is divided into subepidermal and intraepidermal bullous dermatoses. Infections are categorized by nature of the infectious agent. At the end of the chapter is a group of miscellaneous disorders that are not easily classified in the aforementioned groups.

Keywords

scleroderma/morphea,
panniculitis,
vesiculobullous disease,
infection,
pyoderma gangrenosum

block and allows more adequate sampling. These technical niceties prevent delays, mishaps, and some mistakes.

Normal Anatomy

The skin or integument is a complex organ with many functions and with three main anatomic components: epidermis and skin adnexa, melanocytic system, and dermis and subcutis.[14–17]

The epidermis is a stratified squamous epithelium that differentiates to form the outer protective layer of keratin. It is composed of keratinocytes arranged in four layers: basal, squamous (prickle, malpighian), granular, and cornified (horny). The basal cells are the mitotically active cells that give rise to all other keratinocytes; they contain low-molecular-weight keratin and are separated from the dermis by a continuous basal layer, to which they are attached by hemidesmosomes. The basal membrane is a complex antigenic structure that plays an important role in many cutaneous diseases.[18] The dermoepidermal junction is thrown into undulating folds of interlocking ridges of epidermis (rete ridges) and dermal papillae. Thus the undersurface of the epidermis seen in whole mounts presents an anastomosing and reticulated pattern of ridges and valleys. The pattern and size of these ridges vary from area to area. With age, they diminish in size, and the dermoepidermal junction becomes flattened.

The squamous layer is composed of several layers of cells, which become larger, more flattened, and more eosinophilic as they approach the surface. This correlates with the intracytoplasmic accumulation of filaments, which are the precursors of keratin, and a diminution of ribosomes. Some cells in the squamous layer exhibit a clear, vacuolated cytoplasm (sometimes resulting in nuclear indentation), which should not be confused with melanocytes or Paget cells. Melanocytes and Paget cells, unlike vacuolated keratinocytes, have cytoplasm clinging to their nuclei. When the cells are separated, as a result of fixation and dehydration or intercellular edema, these areas of attachment are seen via the light microscope as fine spiny ("intercellular") bridges, with a dot-like structure at their center (Bizzozero nodule), representing the desmosome. The epidermal cells are not a syncytium, and true intercellular bridges do not exist. Destruction of these attachments causes the cells to lose their cohesion. This process, termed acantholysis, is seen in pemphigus vulgaris and related diseases. The granular layer is composed of one to three layers of flattened cells containing keratohyaline granules. These coarse, intensely basophilic granules are rich in histidine and represent the precursors of the protein filaggrin, which is responsible for the aggregation of keratin filaments. The cornified layer contains multiple layers of polyhedral cells that have lost their nuclei and that are arranged in a basket-weave pattern (except for the acral regions, in which this layer is thick and compact). The skin from the palms and soles features an additional layer—the stratum lucidum—located between the granular and the cornified layers and appearing as a homogeneous eosinophilic zone.

The major proteins of basal keratinocytes are keratins 5 and 14, which form an extensive network of 10-nm cytoskeletal filaments. As keratinocytes differentiate, they downregulate this pair of keratins and switch on expression of other pairs, the nature of which is dependent on the site. In the epidermis, terminally differentiated keratinocytes express keratins 1 and 10.

The keratinization cycle usually takes 30–45 days. Many dermatoses result in alterations in the pattern and speed of this process. Abnormal keratinization may be manifest by hyperkeratosis, in which the stratum corneum is thickened, usually in association with a more prominent granular layer, or by parakeratosis, in which the cells of the stratum corneum retain their nuclei and the granular layer is diminished or absent.

Certain descriptive terms are applied to alterations in the pattern of the epidermis. It may become *atrophic* or thinned with age or disease. It may be thickened, and as it proliferates the rete ridges extend deeper into the dermis, a process known as *acanthosis*. Outward overgrowth of the epidermis accompanied by elongation of the dermal papillae is *papillomatosis*. A degenerative process in which the basal cells become vacuolated, separated, and disorganized is called *liquefactive* or *hydropic degeneration*. Various combinations of these changes are seen in the dermatoses, and this descriptive jargon allows succinct communication.

In addition to keratinocytes, the normal epidermis contains melanocytes, Langerhans cells, and Merkel cells. Melanocytes are described in more detail in the chapter on cutaneous neoplasms. Langerhans cells are bone marrow–derived dendritic cells whose function is to present antigens to immunologically competent T cells. They are scattered throughout the upper part of the squamous layer and are difficult to identify in routinely stained sections. Ultrastructurally, they have a characteristic organelle—the Birbeck granule—a rod-shaped structure with zipper-like striations and sometimes a bulbous end. Immunohistochemically, they express CD1a, langherin, and S-100 protein; they have receptor sites for the Fc portion of the immunoglobulin G (IgG) molecule and the third component of complement.[15]

Merkel cells, also extremely difficult to identify in hematoxylin and eosin (H&E) sections and even with special stains, are concentrated in the glabrous skin of the digits, lips, outer root sheath of hair follicles, and tactile hair disks. Ultrastructurally, they contain cytoplasmic dense core (neurosecretory-type) granules, often arranged beneath the cell membrane or located within unmyelinated neurites. Spinous processes projecting from the cytoplasm anchor these cells to adjacent keratinocytes. Immunohistochemically, Merkel cells are reactive for neuron-specific enolase (NSE), neurofilaments, keratin (including CK20), chromogranin, and synaptophysin.[15,19,20]

The skin adnexa are represented by the hair follicles, sebaceous glands, sweat (eccrine) glands, and apocrine glands. The hair follicle, sebaceous gland, erector pili muscle, and (in certain regions) the apocrine gland constitute a functional complex known as the *pilar unit*.

The hair follicle is responsible for the formation of hair, a cyclic process that proceeds in three phases: *anagen* or growing phase, *catagen* or involuting phase, and *telogen* or resting phase. The mitotically active cells of the hair follicles lining the dermal papilla are the matrix (generative) cells. These cells give rise to the hair shaft and the *inner root sheath*. The outer layer of the latter structure is surrounded by a layer of large clear (glycogen-rich) cells known as the *outer root sheath*. At the level of the isthmus, these cells undergo an abrupt type of keratinization, which occurs without the interposition of a granular layer; this is referred to as *trichilemmal keratinization* and, by extension, the layer itself is known as the *trichilemmal sheath*. By contrast, the keratinization in the infundibular portion of the follicle is similar to that of the adjacent epidermis. It is not unusual to find *Demodex* folliculorum mites, clumps of *Staphylococcus epidermidis*, and yeasts of *Malassezia* (formerly *Pityrosporum*) inside the pilar infundibulum.

The sebaceous glands are lobulated structures containing an outer layer of germinative cells that, as they differentiate, move toward the inside and accumulate intracytoplasmic lipid droplets. These result in a typical multivacuolated appearance, with multiple indentations of the centrally located nucleus. The excretory duct of the sebaceous glands opens into the infundibulum of the hair follicle.

Sweat glands are of three types: *eccrine* (responsible for thermoregulation and therefore the only "true" sweat glands), *apocrine*, and *mixed* (apoeccrine glands). Eccrine sweat glands are tubular structures with a secretory and an excretory portion. The secretory coil, located

in the deep dermis or sometimes in the subcutis, is composed of secretory cells (further divided into clear and dark cells) and myoepithelial cells. The excretory portion is composed of a dermal (straight) and an intraepidermal (spiral) portion, the latter also known as the *acrosyringium*.

Although the apocrine glands are concentrated in the axillae, groin, and perineum, they also occur in small numbers on the face and elsewhere. Like eccrine glands, they have a secretory and an excretory component. It is the former that gives them their highly characteristic appearance. The cells have an abundant acidophilic cytoplasm, which may contain lipid, iron, and lipofuscin.

Immunohistochemically, the various epithelial components of eccrine and apocrine glands stain for carcinoembryonic antigen (CEA), epithelial membrane antigen (EMA), keratin, S-100 protein, the enzyme carbonic anhydrase, ferritin, secretory immunoglobulin, and pregnancy-specific β-I-glycoprotein (SPI). In addition, apocrine glands express the marker known as gross cystic disease fluid protein (GCDFP)-15.[21] The myoepithelial cells stain for actin, calponin, caldesmon, S-100 protein, and Sox10.[21–28]

The epidermal adnexa are seldom the sites of primary changes. However, diagnostic changes do occur: heterotopias as in nevus sebaceous of Jadassohn, in which apocrine glands are found in the scalp; pigmentation of eccrine gland basement membranes in argyria and hemochromatosis; atrophy, as in scleroderma; duct obstruction with subsequent retention, as in the various forms of miliaria; and deposition of aggregates of granules of mucoprotein in the eccrine gland cells in myxedematous patients.

The dermis is a connective tissue structure composed of collagen and elastic fibers bathed in ground substance and containing adnexal structures, vessels, and nerves. It is divided into two layers: adventitial and reticular. The adventitial dermis comprises the superficial layer located immediately beneath the epidermis—the papillary dermis—and that located around adnexal structures—the periadnexal dermis.[15]

The *adventitial dermis* is largely composed of a delicate network of collagen fibers (mainly type I, with a scattering of type III or "reticulin" fibers), whereas the *reticular dermis* is made up of thick bundles of type I collagen intermixed with thick elastic fibers.

The thickness of the dermis varies considerably from area to area; it is particularly thick in the back, a feature that is sometimes misinterpreted as being abnormal in biopsies.

The subcutaneous tissue (subcutis) is composed of lobules of mature adipose tissue separated by thin bands of connective tissue interlobular septa. The dermal blood vessels are divided into a deep plexus (located in the reticular dermis) and a superficial plexus (located in the papillary dermis), with communicating vessels in between. From the superficial vascular plexus, capillary loops extend into the dermal papillae. The acral skin contains specialized arteriovenous anastomoses—the *Sucquet–Hoyer canals*—surrounded by a row of modified smooth muscle—the *glomus cells*—which have a round shape, clear cytoplasm, and well-defined cytoplasmic borders. The lymphatics of the skin are also divided into a deep and a superficial plexus.

Specialized nerve end organs present in the skin are the *Wagner–Meissner corpuscles* (with a tactile function; mainly located in the papillary dermis of the palms and soles) and *Pacinian corpuscles* (sensitive to pressure; mainly located in the deep dermis and subcutis of weight-bearing areas). With age, and more so in areas exposed to sunlight, the collagen and elastica undergo structural and tinctorial changes called *solar (actinic) elastosis*. These changes should not be attributed to some suspect disease and should be distinguished from pathologic connective tissue changes, such as increased dermal mucin deposition.

The dermis is the site of inflammatory reactions. In normal skin, a few fibroblasts, macrophages, mast cells, lymphocytes, and dermal dendrocytes are present. The latter represent a population of mononuclear dendritic cells located in the papillary and upper reticular dermis and are thought to function as antigen-presenting cells. They express the coagulation factor XIIIa (also known as fibrin stabilizing factor) and are known to increase in number in a large number of inflammatory and neoplastic disorders.[29]

The perivascular and periadnexal spaces and the papillary layer of the dermis are the usual sites in which inflammatory cells aggregate. Certain dermatoses, such as lichen planus and chronic discoid lupus erythematosus, have distinct patterns of inflammatory reaction. Others, such as urticaria pigmentosa, have a specific cellular population. Changes in the nerves, visible in sections stained with H&E, are infrequent but when present are of note (see section on leprosy).

Inflammatory Dermatoses

As previously mentioned, a thorough and detailed discussion of inflammatory dermatoses is beyond the scope of this text and the reader should seek texts devoted to dermatopathology for a complete discussion of inflammatory diseases of the skin. Nevertheless, biopsies of inflammatory diseases are still encountered with relative frequency by surgical pathologists. Therefore some familiarity with these entities is necessary. Approaching inflammatory dermatoses based on the pattern of inflammation is a rational approach that results in more refined diagnoses. Multiple different patterns exist. For the purposes of this text, a simplified approach will be used. Broadly speaking, the inflammatory reaction patterns can be divided into five groups: (1) dermatoses with significant epidermal changes, (2) dermatoses with dermal inflammation without significant epidermal change, (3) sclerosing diseases, (4) panniculitis, and (5) immunobullous/vesiculobullous disease. These will be discussed in turn. There are also a variety of diseases with specific etiologies (e.g. infections) and miscellaneous disorders that will be described separately at the end of the chapter.

Inflammatory Dermatoses With Epidermal Change

There are three primary patterns within this group: spongiotic, psoriasiform, and interface dermatitis. Spongiotic dermatitis is characterized by the accumulation of edema fluid within the epidermis, resulting in the epidermal keratinocytes being pulled apart by hydrostatic forces. The psoriasiform pattern is characterized by epidermal acanthosis (hyperplasia) without significant spongiosis. There is often overlap between these patterns. The interface pattern is characterized by a dermal infiltrate, either lichenoid or perivascular, that is associated with damage to the epidermis along the dermoepidermal junction with basal vacuolization and dyskeratotic keratinocytes. Select entities within these groups will be discussed.

Spongiotic Dermatitis

Spongiotic dermatitis is a reaction pattern that is most commonly seen in the clinical spectrum of eczematous dermatitis, including allergic contact dermatitis, nummular dermatitis, atopic dermatitis, dyshidrotic eczema, stasis dermatitis, and eczematous drug reactions. All of these dermatoses are characterized by the presence of intraepidermal edema (spongiosis). Histologically, these entities resemble one another and differentiating them relies on knowledge of the clinical presentation rather than histologic features in most cases. That being said, this group of clinical disorders is frequently biopsied and have common histologic features.[29]

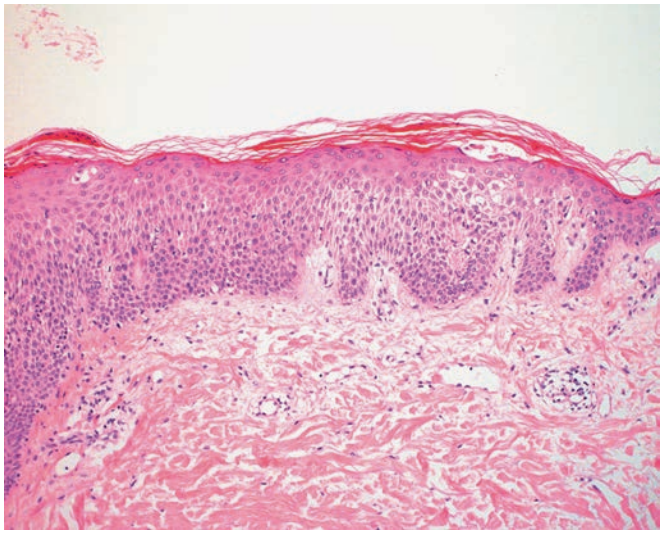

Figure 2.1 Acute Spongiotic Dermatitis. The stratum corneum is largely normal, and there is intraepidermal edema *(spongiosis)* and a superficial perivascular inflammatory infiltrate.

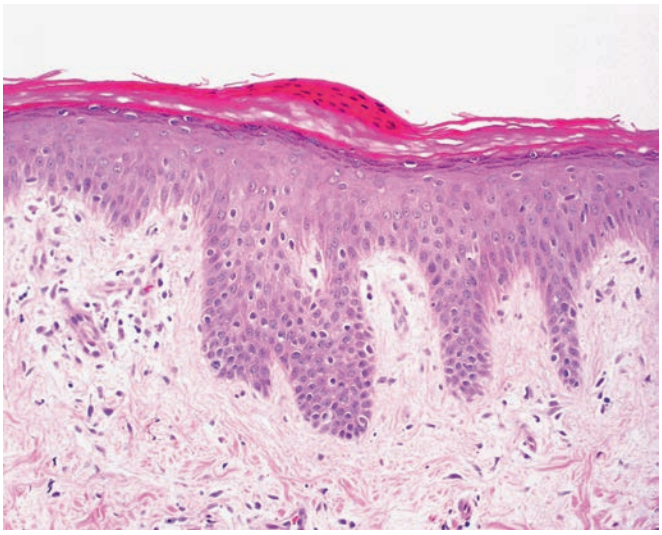

Figure 2.3 Chronic Spongiotic Dermatitis. There is compact hyperkeratosis, a thickened granular layer, minimal spongiosis, and a sparse perivascular infiltrate.

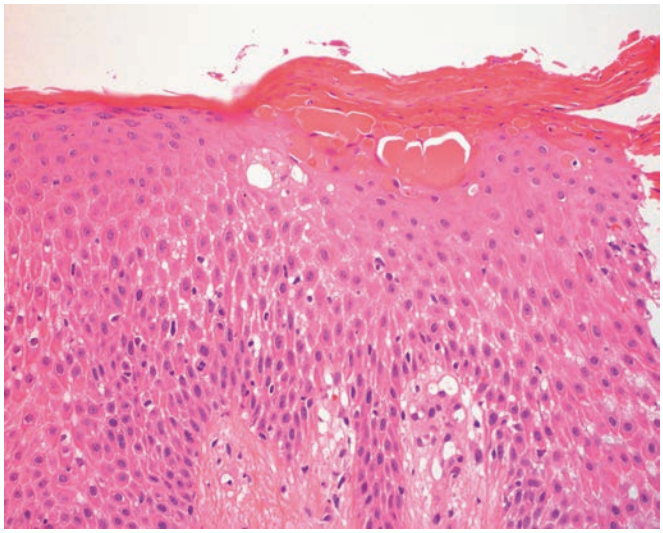

Figure 2.2 Subacute Spongiotic Dermatitis. The epidermis is acanthotic and spongiotic with overlying parakeratosis.

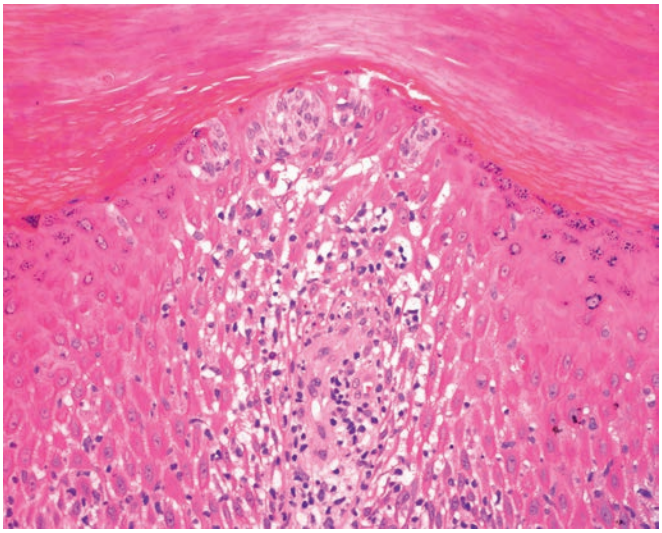

Figure 2.4 Langerhans Cell Microabscess. Intraepidermal collections of Langerhans cells are often found in allergic contact dermatitis.

The histologic features are somewhat dependent on when the biopsy is taken during the disease process. The range of histologic features can be divided into three phases, although one should recognize that these phases exist along a continuum. In *acute spongiotic dermatitis*, there is accumulation of edema fluid in the epidermis, sometimes with spongiotic microvesicle formation. The stratum corneum often retains its normal basket-weave configuration or may have some focal parakeratosis. Acanthosis is absent or mild. Within the dermis there is a variable superficial perivascular infiltrate of lymphocytes often admixed with eosinophils (Fig. 2.1). In the *subacute* form, there is associated parakeratosis, often with a diminished granular layer, acanthosis of the epidermis, variable spongiosis, and a similar superficial perivascular dermal inflammatory infiltrate (Fig. 2.2). In the *chronic* phase, there is often compact hyperkeratosis, a thickened granular layer, acanthosis, minimal spongiosis, and mild superficial inflammatory infiltrate (Fig. 2.3). The subacute and chronic phases can have significant histologic overlap with entities in the psoriasiform dermatitis category. In addition to spongiosis, there is variable parakeratosis, hyperkeratosis, and irregular acanthosis.

Allergic Contact Dermatitis

Allergic contact dermatitis is a common entity that is biopsied with some frequency. Typical examples of common allergens include detergents, nickel, and plants, such as poison ivy, but a whole host of potential allergens exist. Microscopically, it is a spongiotic dermatitis that is indistinguishable from other forms of spongiotic dermatitis. Some cases have Langerhans cell microabscesses in the epidermis (Fig. 2.4). This is a clue to possible allergic contact dermatitis but is not entirely specific.

Nummular Dermatitis

Nummular dermatitis presents as round to oval plaques, commonly on the extremities. Clinically, it may get confused with psoriasis.

Microscopically, most cases show features of subacute spongiotic dermatitis. Clues that help to distinguish it from psoriasis include serum in the parakeratotic scale, epidermal spongiosis, and, when present, eosinophils in the dermal infiltrate.

Atopic Dermatitis

This is a chronic eczematous dermatitis that runs in families and is associated with allergic rhinitis and asthma. It is infrequently biopsied and typically shows features of a subacute to chronic spongiotic dermatitis.

Dyshidrotic Eczema

Also called pompholyx, this is a recurrent dermatitis that affects the hands and feet, and many are in actuality an allergic contact dermatitis. Clinically, it often has a vesicular appearance. Microscopically, it resembles a typical spongiotic dermatitis. Spongiotic microvesicles are relatively common. It is important to exclude a dermatophyte infection, especially in lesions from the feet.

Eczematous Drug Reactions

A small subset of drug eruptions may be eczematous in nature. Histologically, they are not distinguishable from other forms of spongiotic dermatitis. Rather correlation with onset related to a medication is required.

Summary

As a general rule, pathologists can render only a descriptive diagnosis of spongiotic dermatitis because the histologic features themselves are not specific. That being said, it is important to exclude more specific diagnoses, such as psoriasis and dermatophyte infection, which can have overlapping features and are discussed later. If information is known about the clinical presentation, a more specific diagnosis can be suggested in a comment.

Stasis Dermatitis

A more distinct form of dermatitis that can have either a spongiotic or psoriasiform pattern is stasis dermatitis. Stasis dermatitis occurs on the lower legs of older and/or obese patients. Often it is bilateral but sometimes presents as an isolated lesion that can mimic a neoplasm clinically.[30] Microscopically, it is associated with variable acanthosis and spongiosis. The key feature is the presence of a lobular proliferation of relatively thick-walled blood vessels in the papillary dermis (Fig. 2.5). Frequently there are extravasated erythrocytes and siderophages. In longstanding cases there may be significant dermal fibrosis with an associated fibroblastic proliferation, called *acroangiodermatitis*, a condition that can superficially mimic Kaposi sarcoma.[30] It should be remembered that other forms of eczematous dermatitis, such as contact dermatitis, can be superimposed on patients with underlying stasis change.

Psoriasiform Dermatitis

The most common entities in this group include psoriasis and lichen simplex chronicus/prurigo nodularis. This group is characterized by prominent epidermal hyperplasia. That being said, there may be considerable overlap with subacute to chronic spongiotic dermatitis, which also is associated with epidermal hyperplasia. In that regard, placing subacute to chronic spongiotic dermatitis in the spongiotic pattern is somewhat arbitrary.

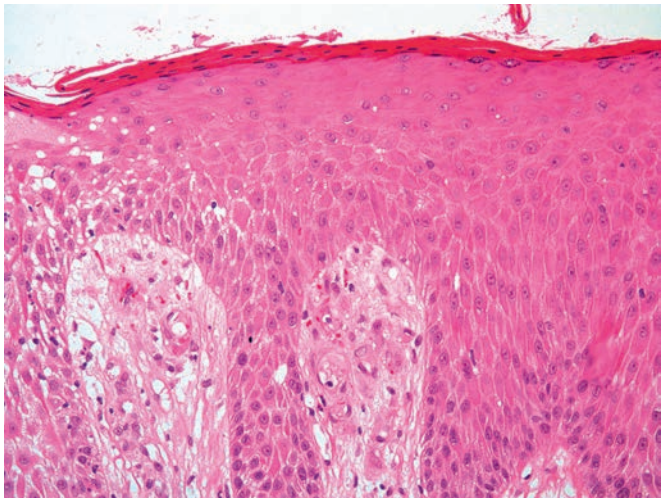

Figure 2.5 Stasis Dermatitis. Within the superficial dermis there is a lobular proliferation of relatively thick-walled vessels with hemorrhage and overlying spongiosis in the epidermis.

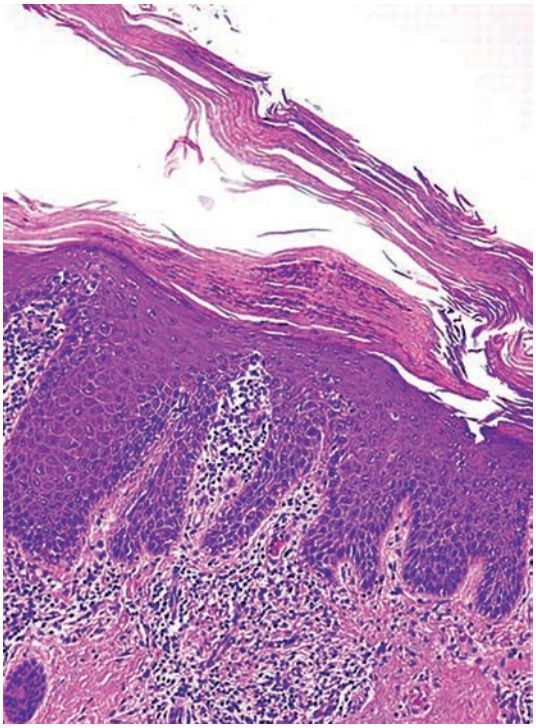

Figure 2.6 Typical Appearance of Psoriasis. Note the engorgement of papillae and Munro microabscesses.

Psoriasis

Psoriasis is one of the more common dermatoses. Estimates of its incidence vary between 0.5% and 1.5% of the population.[31] In its most common form, *psoriasis vulgaris*, it is a chronic, bilaterally symmetric, nonpruritic lesion formed by erythematous plaques covered by fine silvery scales.[32–34] Typically, it involves the extensor surfaces, such as the elbows, knees, back, and scalp. Generalized lesions also occur. The morphologic characteristics are those of uniform acanthosis of the epidermis with prominent parakeratosis and attenuation of the epidermis overlying the dermal papillae, a feature known as "suprapapillary thinning" (Fig. 2.6). Within the

parakeratosis and sometimes the epidermis, there are collections of neutrophils. Within the dermal papillae, the capillaries are dilated and tortuous. There is also a polymorphic inflammatory infiltrate composed of lymphocytes, macrophages, and neutrophils.[35] Psoriasis may also be induced by tumor necrosis factor-α inhibitors, typically in the setting of inflammatory bowel disease.[35] In our experience, drug-induced psoriasis in this setting often has eosinophils, in contrast to conventional psoriasis in which eosinophils are typically absent. Eosinophils are usually absent with the exception of drug-induced forms of psoriasis, usually secondary to tumor necrosis factor-α inhibitors. The hyperproliferation appears to be caused by overexpression of cytokines (e.g. tumor necrosis factor-α, interferon gamma, and various interleukins), as well as chemokines and chemokine receptors (e.g. CCL2, CCL3, CCL4, CXCL1, CXCL8), suggesting a Th1 disorder.[36,37]

Other variants of psoriasis lack the prototypical uniform hyperplasia but will be discussed in this section. *Pustular psoriasis* is a variant in which the subcorneal abscesses are particularly prominent.[31,32,36,38] In pustular psoriasis, there is less prominent epidermal hyperplasia. *Guttate psoriasis* is a special type of psoriasis that is characterized by a rapid onset of small papules and plaques, typically after an antecedent streptococcal pharyngitis. It lacks the epidermal hyperplasia, and the granular layer is often retained. It is characterized by discrete mounds of parakeratosis with collections of neutrophils overlying the epidermis (Fig. 2.7).[38]

The differential diagnosis of psoriasis typically centers on subacute forms of spongiotic dermatitis, usually nummular. In contrast to spongiotic dermatitis, the epidermis in psoriasis is more uniformly acanthotic and the parakeratosis is "dry," lacking the serum present in the overlying crust scale in spongiotic dermatitis. Psoriasis also typically lacks eosinophils (with the exception noted previously), which are frequently present in spongiotic dermatitis. Dermatophyte infections can have similarity to psoriasis. Both have collections of neutrophils in the parakeratosis, but dermatophyte infections usually lack the uniform acanthosis and may have eosinophils in the infiltrate. A periodic acid–Schiff (PAS) or Gomori methenamine silver (GMS) stain can help with this differential diagnosis. *Pityriasis rubra pilaris* is a rare disorder that can closely resemble psoriasis with a similar pattern of acanthosis and parakeratosis. However, collections of neutrophils in the parakeratotic scale are not seen. Finally, partially treated psoriasis may lack some of the typical histologic features. The presence of dilated and tortuous papillary dermal blood vessels can be a clue in partially treated psoriasis. As in all inflammatory dermatoses, clinical correlation is essential.

Lichen Simplex Chronicus and Prurigo Nodularis

Lichen simplex chronicus and *prurigo nodularis*, sometimes clinically referred to as neurodermatitis, are ends of a spectrum of a dermatosis that are the result of persistent excoriation rather than inflammation. They are often seen in patients with medical conditions that result in pruritus (e.g. renal failure) and in a subset of patients with psychiatric disorders.[39] They present as plaques (lichen simplex chronicus) or nodules (prurigo nodularis). The clinical location is a clue to the diagnosis in that lesions are only seen in areas that can be readily reached. This condition is most commonly encountered on the extremities, abdomen, genitalia, and scalp, but they may present at any easily accessible location on the body. Lichen simplex chronicus involving perianal and genital skin is often biopsied with a clinical diagnosis of lichen sclerosus. These disorders can also be seen as a complication of a chronic eczematous process, such as a persistent contact dermatitis (see earlier).

Microscopically, they demonstrate marked acanthosis of the epidermis, marked hyperkeratosis, a thickened granular layer, and vertical fibrosis of the papillary dermal collagen (Fig. 2.8).[40] Occasional cases may show pseudoepitheliomatous hyperplasia or focal parakeratosis. Typically, there is little inflammation unless it is superimposed on an underlying chronic eczematous process.

Interface Dermatitis

Interface dermatitis is characterized by basal vacuolization and dyskeratosis. The presence of dyskeratotic keratinocytes is important, as some cases of spongiotic dermatitis have basilar spongiosis that mimics vacuolar change. Broadly speaking, interface dermatitis can be grouped in two patterns: lichenoid and perivascular, although entities within this group may have overlapping features.

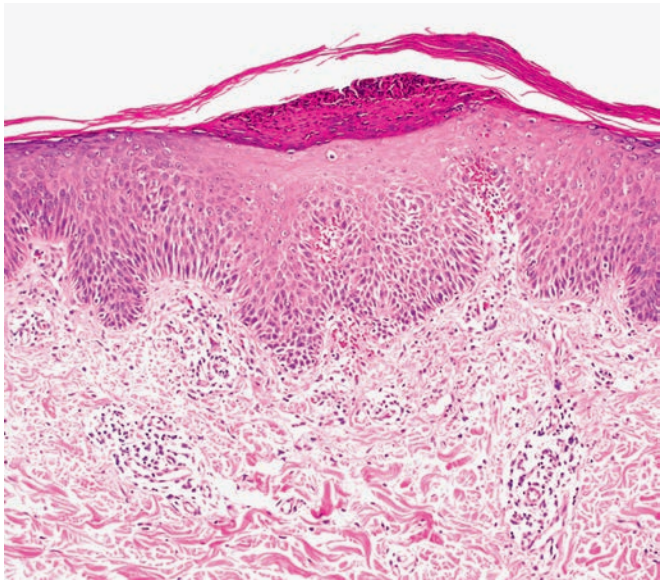

Figure 2.7 Guttate Psoriasis. Note the discrete mound of parakeratosis with overlying collections of neutrophils.

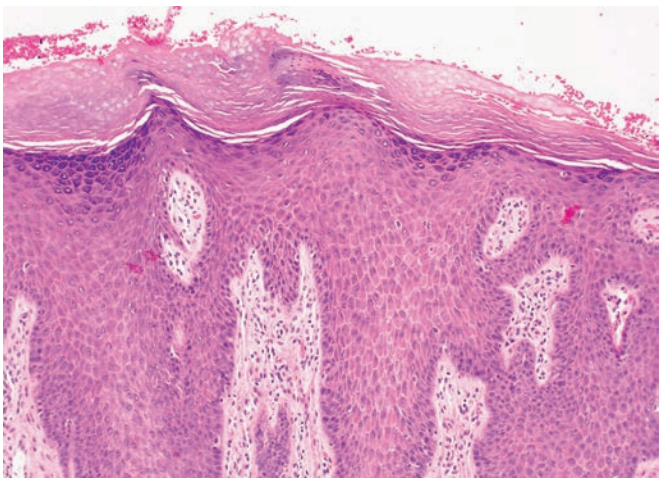

Figure 2.8 Lichen Simplex Chronicus. There is compact hyperkeratosis overlying an acanthotic epidermis with a thickened granular layer. Vertically oriented, thickened collagen bundles are present in the superficial dermis.

Interface Dermatitis With Perivascular Pattern

Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrosis

This group of disorders forms of spectrum of dermatoses that are histologically similar. Specific diagnosis requires knowledge of the clinical presentation.[41,42] *Erythema multiforme* is a self-limiting episodic eruption that usually affects acral surfaces and oral mucosa of young adults. It is associated with herpes simplex virus and *Mycoplasma* infections, as well as a variety of medications.[41,42]

Stevens-Johnson syndrome and *toxic epidermal necrolysis* involve both mucosa and epidermis. By definition, Stevens-Johnson syndrome affects ≤10% of the total body surface area and toxic epidermal necrolysis ≥30% of the body surface area, leaving an intermediate category between the two ends of the spectrum. Both Stevens-Johnson syndrome and toxic epidermal necrolysis are almost invariably triggered by adverse reactions to medications. They are considered true emergencies, and there is an associated mortality rate ranging from 10% to 40%. Recognition of Stevens-Johnson syndrome and toxic epidermal necrolysis is therefore critical because these patients may need to be managed in specialized burn units.

Microscopically, all of these entities show similar features. There is interface change characterized by basal vacuolization of the epidermis and frequent necrotic keratinocytes at all levels of the epidermis with exocytosis of lymphocytes into the overlying epidermis (Fig. 2.9).[43] In some cases there is complete necrosis of the epidermis. There is typically a relatively sparse to mild superficial perivascular lymphocytic infiltrate that may contain a few eosinophils.[44] The infiltrate is typically disproportionately mild compared with the amount of epidermal damage. Reactive epidermal changes, such as acanthosis, parakeratosis, and hyperkeratosis, are notably absent, and this absence is a clue to differentiating this group from other dermatoses with interface change. Some cases may have a bullous appearance due to detachment of the epidermis secondary to the marked interface change.[45]

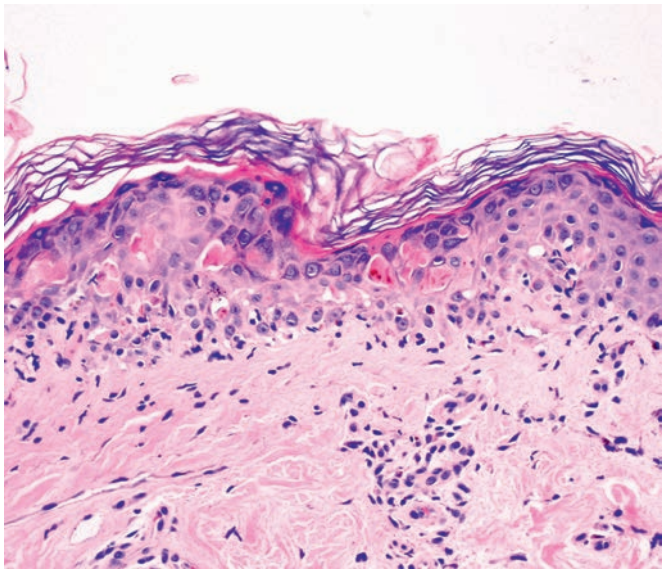

Figure 2.9 Erythema Multiforme. There is interface change with basal vacuolization, numerous dyskeratotic keratinocytes, and a sparse perivascular infiltrate.

Graft-Versus-Host Disease

Graft-versus-host disease is an important cause of morbidity and mortality following bone marrow transplantation. The acute form is characterized microscopically by vacuolization of the basal layer, spongiosis, and individual cell necrosis, associated with mononuclear cell infiltration of the upper dermis (Fig. 2.10).[46,47] Sometimes these epidermal changes occur in the absence of an inflammatory infiltrate.[47] The amount of inflammation seems to be the most important prognostic determinator.[48] This has been quantitated through the Lerner grading system, which has a high degree of interobserver concordance,[49] but which is of limited use in predicting the likelihood of a skin rash progressing to a clinically more significant disease.[50] In this system, grade 1 acute graft-versus-host disease is characterized by basal vacuolization with a superficial perivascular lymphocytic infiltrate without dyskeratotic keratinocytes. Grade 2 has the features of grade 1 graft-versus-host disease but with dyskeratotic keratinocytes and satellite cell necrosis. Grade 3 is associated with cleft formation between the epidermis and dermis, and grade 4 is characterized by complete loss of the epidermis. In general, most cases of acute graft-versus-host disease are grade 2.

The chronic form of graft-versus-host disease has been divided into a predominantly lichenoid form and sclerodermoid form.[51,52] In lichenoid chronic graft-versus-host disease the epidermis shows thickening of the granular layer like lichen planus, but the inflammatory infiltrate is usually less dense. The sclerodermoid form is essentially indistinguishable from scleroderma/morphea with marked sclerosis of dermal collagen.

Lupus Erythematosus

Cutaneous lupus erythematosus can be divided into the chronic/discoid, acute/systemic, and subacute forms.[53–55] *Chronic discoid lupus erythematosus* is a relatively common condition with a distinct preference for women, presenting as delimited erythematous to hyperkeratotic to atrophic patches and plaques on the face, neck, scalp, and, less frequently, the arms and trunk (Fig. 2.11). *Systemic lupus erythematosus* is an immune-mediated disease caused by antibodies to homologous and heterologous DNA. It manifests a protean symptomatology usually characterized by fatigue, fever, arthritis, various cutaneous lesions of which the erythematous bimalar

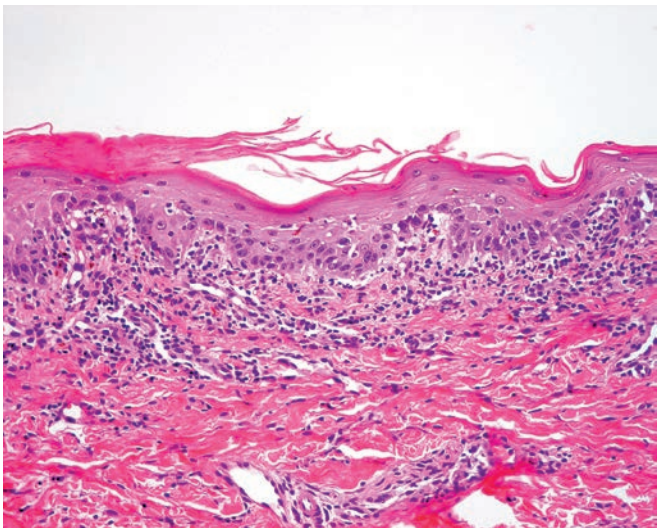

Figure 2.10 Microscopic changes of acute graft-versus-host reaction.

Figure 2.11 Extensive facial lesions of chronic discoid lupus erythematosus.

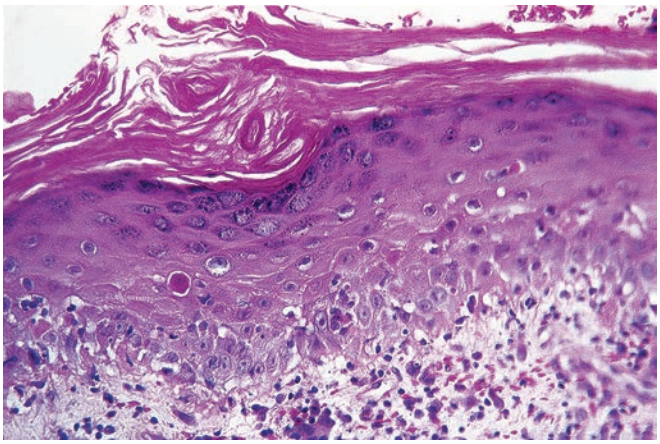

Figure 2.12 Lesion of chronic discoid lupus erythematosus showing hyperkeratosis and interface change with hydropic degeneration along basal layer.

"butterfly" blush is most common, signs of renal involvement, lymphadenopathy, and panserositis. Sunlight may cause exacerbations. *Subacute lupus erythematosus* usually presents as plaques, often annular, on sun-exposed skin of the extremities and trunk. The face is usually spared. Histologically, there is overlap between the subtypes. They all have basal vacuolization with interface change and scattered dyskeratotic cells associated with a superficial or superficial and deep perivascular lymphocytic infiltrate with increased dermal mucin. In the discoid form there is often follicular plugging, epidermal atrophy, a thickened basement membrane, and periadnexal inflammation (Fig. 2.12).[55–58] Eosinophils are absent, and their presence argues against the diagnosis.[59] *Tumid lupus erythematosus* is a form of chronic lupus erythematosus without interface change and may represent the same process that has also been termed *Jessner lymphocytic infiltration of the skin*.[58] Clusters of CD123-positive plasmacytoid dendritic cells are present in lupus erythematosus and their presence can support the diagnosis.[60]

Direct immunofluorescence will show the presence of immunoglobulins (usually IgG and IgM) and so-called membrane attack complex (C5b, C6, C7, C8, and C9) in approximately 90% of specimens obtained from clinically involved skin of patients with either systemic or chronic discoid lupus erythematosus.[61,62] The deposition consists of coalescing clumps along the dermoepidermal junction, resulting in the formation of an irregular band (so-called *lupus band test*), a finding that is not entirely specific for this entity.[63] Clinically uninvolved areas will show deposition of immunoglobulins in approximately half of the patients with systemic lupus erythematosus but no deposition of the membrane attack complex.[61,64] Direct immunofluorescence may be helpful in selected cases but is generally not necessary to establish the diagnosis. Histologic examination and correlation with clinical history usually allows accurate diagnosis.

Dermatomyositis

Dermatomyositis is an inflammatory disorder affecting skeletal muscle and skin, characterized clinically by proximal, symmetric muscle weakness, and cutaneous lesions. There are cutaneous forms without muscle involvement, termed dermatomyositis sine myositis. Microscopically, the skin changes may be those of a nonspecific chronic dermatitis or may acquire features very similar to those of systemic lupus erythematosus, although typically with less inflammation.[65,66] By immunofluorescence, features favoring dermatomyositis over lupus erythematosus are a negative "lupus band test" and deposition of C5b–q (the membrane attack complex of complement).[64] Biopsies of the afflicted muscles show distinct myositis with necrosis of myofibers, fragmentation, phagocytosis, and some sarcolemmal nuclear proliferation. In the later stages, fibrosis, fat infiltration, and fascicular atrophy appear.[67,68]

Much has been written about the incidence or coincidence of adenocarcinoma with dermatomyositis.[69–71] A review of the literature carried out by Williams many years ago found that 15% of dermatomyositis patients had neoplasms of the stomach, breast, ovary, lung, or colon. Remissions of the dermatomyositis have occurred following resection of the neoplasm.[71] Therefore careful investigation of adults with dermatomyositis for undetected carcinoma is certainly worthwhile. However, in the majority none will be found.

Interface Dermatitis With Lichenoid Pattern

Lichen Planus

Lichen planus is a pruritic, violaceous, subacute to chronic, papulosquamous dermatitis of unknown etiology (Fig. 2.13).[72–74] It usually involves the flexor surfaces of the arms and the legs, but it may be found in many other sites. Lesions may be confined to the oral mucosa, or they may precede or accompany the skin changes.[75] Histologically, the well-developed lesions are rather distinct (Fig. 2.14). The epidermis is hyperkeratotic, the granular layer is prominent, and the hyperplastic epithelium forms irregular sawtooth acanthotic pegs. Within the dermis there is a dense band-like (lichenoid) lymphocytic infiltrate that may contain a few eosinophils and histiocytes. Dyskeratotic keratinocytes, also referred to as *Civatte bodies*, are often seen in the basal layer and sometimes also in the upper dermis and malpighian layer. On occasion, subepidermal cleavage occurs with the formation of bullae. In oral lichen planus, there is may be parakeratosis, subtle formation of keratohyaline granules. Prominent hyperkeratosis and hypergranulosis are absent in *oral lichen planus*. Histologically, the dyskeratotic cells and absence of atypia in oral lichen planus assists in distinguishing it from dysplasia (see Chapter 4). Clinicopathologic variants of lichen planus include bullous, pemphigoid, hypertrophic, atrophic, and follicular (lichen planopilaris) forms.[76–79]

A morphologic pattern akin to that of lichen planus and designated as lichenoid dermatitis, lichenoid tissue reaction or

Figure 2.13 Clinical Appearance of Lichen Planus Affecting the Dorsum of the Hand. One of the lesions has been biopsied.

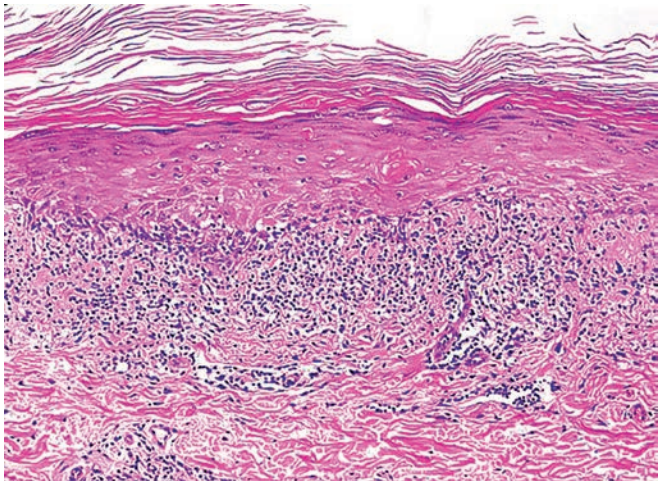

Figure 2.14 Microscopic Appearance of Lichen Planus. There is orthotopic hyperkeratosis, hypergranulosis, basal vacuolization, and a band-like inflammatory infiltrate with melanophages.

interface dermatitis can be seen in a variety of conditions, including lichenoid drug eruptions (see later), lichenoid actinic keratosis, benign lichenoid keratosis, solitary lichen planus, lupus erythematosus, acute graft-versus-host reaction, and several other conditions.[80–87] A lichenoid reaction is the rule in regressing melanoma (a notorious pitfall) and can also be seen in the epidermis overlying a dermatofibroma.[88,89]

Lichenoid Drug Eruption

Lichenoid drug eruptions present as widespread papular eruptions. A variety of agents can trigger lichenoid drug eruptions, including common agents, such as thiazide diuretics. The eruption can develop soon after ingestion of the drug or weeks after.

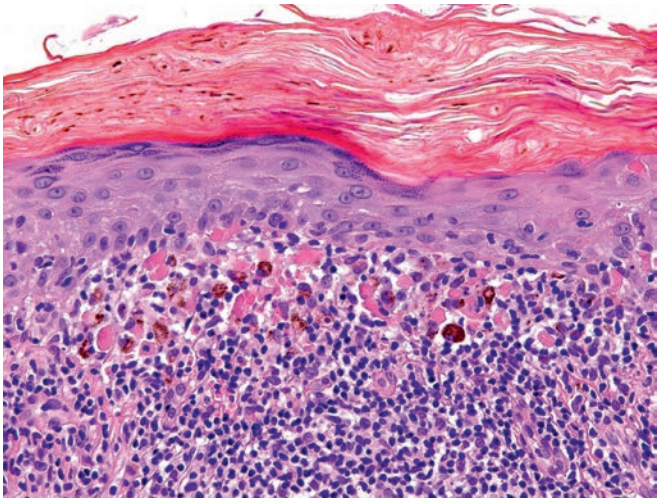

Figure 2.15 Lichenoid Tissue Reaction. Lichenoid drug reactions resemble lichen planus, but typically have parakeratosis, which is usually absent in lichen planus. (Courtesy of Dr Fabio Facchetti, Brescia, Italy.)

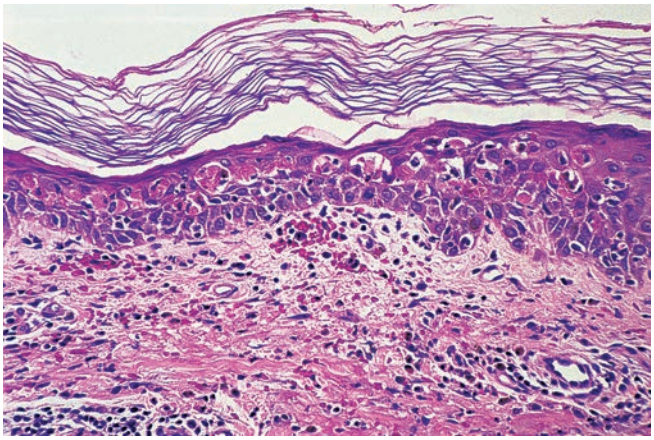

Figure 2.16 Fixed Drug Eruption. The infiltrate is rich in eosinophils and is accompanied by necrotic keratinocytes.

Microscopically, lichenoid drug eruptions are very similar to lichen planus. There is a lichenoid lymphocytic infiltrate with prominent epidermal damage. The epidermis has a thickened granular layer. The presence of parakeratosis and conspicuous eosinophils help to distinguish lichenoid drug eruption from lichen planus (Fig. 2.15).[80,87]

Fixed Drug Eruption

Fixed drug eruption is an unusual localized type of adverse medication reaction that recurs in the same location on subsequent exposures.[90–93] Microscopically, it is an interface dermatitis with a lichenoid or perivascular infiltrate and basal vacuolization with dyskeratotic keratinocytes (Fig. 2.16). The overlying stratum corneum usually has a normal basket-weave configuration but may have some parakeratosis. The infiltrate contains lymphocytes, histiocytes, and eosinophils. Melanophages are frequently present.

Pityriasis Lichenoides

Pityriasis lichenoides occurs in two clinical forms: *pityriasis lichenoides acuta et varioliformis acuta* (PLEVA; also known as *Mucha-Habermann disease*) and *pityriasis lichenoides chronica* (PLC).[94–97] The etiology is uncertain but may be related to a hypersensitivity reaction to various

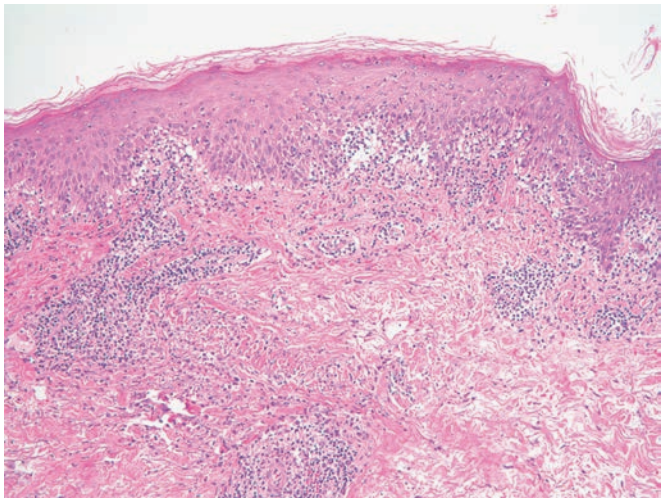

Figure 2.17 Pityriasis Lichenoides Et Varioliformis Acuta. There is interface change with basal vacuolization and a superficial and deep lymphocytic infiltrate with papillary dermal hemorrhage.

infectious agents or drugs.[98–100] It has also been associated with autoimmune disease. PLEVA is associated with the appearance of numerous, small papules that ulcerate and heal, leaving behind smallpox-like (varioliformis) scars. The eruption is predominately on the extremities but may also involve the trunk and buttocks. In PLC the eruption is characterized by brownish-red papules that typically do not result in scarring. Some patients may have overlapping features of both PLEVA and PLC.

Histologically, pityriasis lichenoides shows overlapping features of a lichenoid interface dermatitis and a perivascular interface dermatitis.[101,102] The features somewhat depend on the timing of the biopsy during the evolution of the disease. In fully developed, nonulcerated lesions of PLEVA, there is a superficial perivascular to lichenoid infiltrate with an accompanying wedge-shaped perivascular infiltrate extending into the underlying dermis. There is interface change with basal vacuolization, dyskeratosis, and papillary dermal hemorrhage (Fig. 2.17). The hemorrhage is likely due to a lymphocytic vasculitis, and vasculitic changes can sometimes be seen. In addition to interface change, the epidermis is spongiotic with parakeratosis-prominent exocytosis of lymphocytes and often exocytosis of erythrocytes. Although some authors prefer to classify this as a lymphocytic vasculitis, considering it in the family of interface dermatitis is prudent given the more consistent histologic findings of interface damage. In older lesions, the epidermis may be completely ulcerated. From a pathologic standpoint, ulcerated lesions are histologically nonspecific. Early lesions may show considerably less interface and epidermal change. PLC is similar to PLEVA but with less pronounced histologic features.[102] There is less interface damage, less inflammation, and little to no hemorrhage. Again, a given patient may have lesions that histologically span the spectrum of both PLEVA and PLC.

The differential diagnosis includes other interface dermatitides, as outlined previously. PLEVA has a distinct clinical presentation, which aids in its diagnosis. PLEVA also typically has extravasation of erythrocytes, which is not a conspicuous feature of the aforementioned entities. The presence of spongiosis helps to distinguish it from chronic interface dermatitides, such as lupus erythematosus. Lichen planus and lichenoid drug eruptions have a lichenoid pattern without a deeper perivascular extension. Graft-versus-host disease has much less inflammation. As with all inflammatory diseases, knowledge of the clinical presentation is very helpful.

However, one entity may have a very similar clinical presentation to PLEVA: lymphomatoid papulosis (LYP).[103–106] LYP is actually considered an indolent T-cell lymphoma. There are multiple different histologic types, ranging from type A to E.[107–111] Types A, B, and C are the classic forms. Type A can show considerable histologic overlap with PLEVA but also has numerous large, atypical $CD30^+$ lymphocytes that are not seen in PLEVA admixed within the infiltrate. Type B LYP resembles mycosis fungoides microscopically. Type C histologically resembles cutaneous anaplastic large cell lymphoma, with sheets of large atypical, $CD30^+$ lymphocytes. The primary way to differentiate types B and C LYP from their mimics is knowledge of the clinical history of waxing and waning papulonecrotic lesions.

Inflammatory Dermatoses With Dermal but Not Epidermal Change

This section will encompass a wide variety of entities and by necessity is somewhat superficial, mostly concentrating on more common dermatoses. The patterns discussed will include perivascular, nodular and diffuse, palisading granulomatous and sclerosing dermatoses.

Perivascular Dermatoses

This pattern is typified by an inflammatory infiltrate that is predominantly in a perivascular distribution. Some entities in this pattern will have overlapping features with the nodular and diffuse pattern. This further highlights how inflammatory diseases and their patterns are on a biologic continuum that we by necessity categorize as discrete entities.

Dermal Hypersensitivity Reactions

Dermal hypersensitivity reaction is a somewhat wastebasket term that encompasses a variety of entities, most commonly morbilliform drug eruptions, urticaria, and arthropod bite reactions. Although clinically distinct, these entities may be histologically indistinguishable. Morbilliform drug eruptions tend to be widespread, erythematous maculopapular eruptions associated with ingestion of a new medication, although sometime it may take weeks after initiation of a new medication, complicating the clinicopathologic correlation. Urticaria, or hives, classically presents as transient wheals that resolve in 24 hours, although occasionally they may be more persistent. Arthropod bite reactions may present as solitary lesions or numerous papules.

Morbilliform drug eruptions are the most common type of adverse medication reaction.[112] They are usually characterized by a mild superficial or superficial and deep, perivascular mixed inflammatory infiltrate of lymphocytes with a few eosinophils (Fig. 2.18). Some cases may show mild basal vacuolization, therefore overlapping with the interface pattern. *Urticaria* is almost identical with a mild perivascular infiltrate of lymphocytes, eosinophils, and sometimes neutrophils.[113,114] In urticaria, there may also be margination of neutrophils in the vascular lumens. In chronic cases, there may be subtle vascular damage resulting in urticarial vasculitis.[113,115] *Arthropod bite reactions* have a similar pattern of inflammation with eosinophils but typically a denser inflammatory infiltrate (Fig. 2.19). In the setting of underlying hematologic malignancies, such as chronic lymphocytic leukemia, reactions to arthropod assaults can be quite pronounced.[116]

Vasculitis

There is a large group of cutaneous diseases in which the basic alteration is an inflammatory change in the wall of the dermal and/

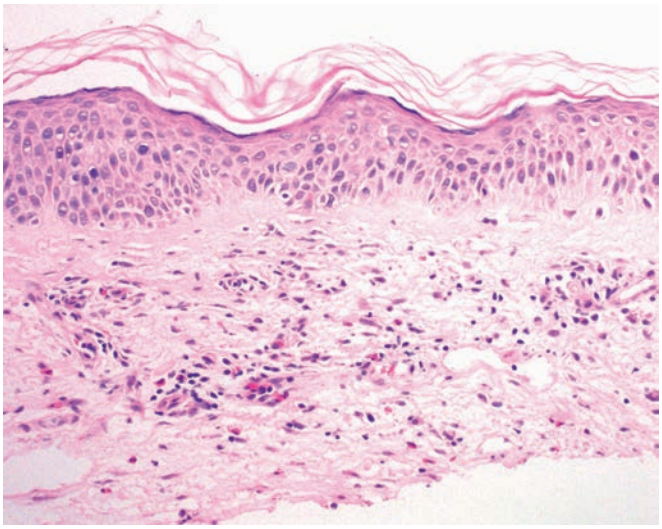

Figure 2.18 Morbilliform Drug Eruption. The epidermis is relatively normal. Within the dermis there is a mild perivascular infiltrate of lymphocytes and eosinophils.

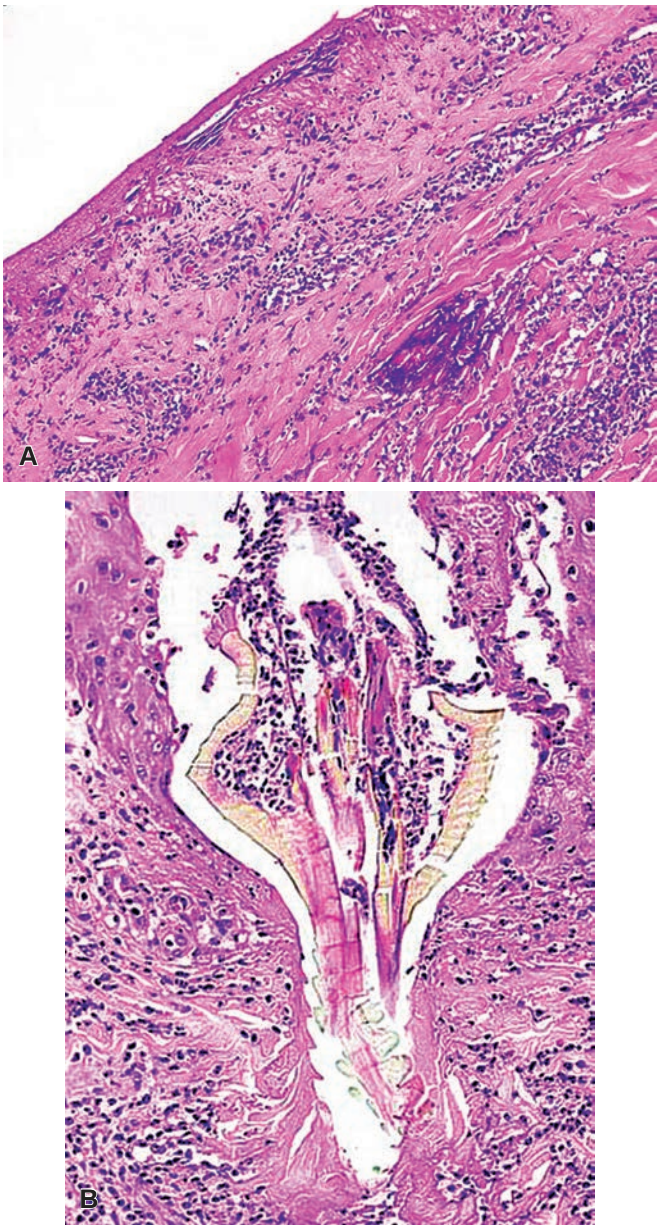

Figure 2.19 Arthropod Bite. A, Heavy inflammatory dermal infiltrate around necrotic focus. **B,** Section of the arthropod. (Courtesy of Dr Raffaele Gianotti, Milan, Italy.)

or subcutaneous vessels (i.e. a vasculitis).[117–120] The mechanism is in all likelihood immune mediated for the majority of them, through the action of immune complexes.[121,122] The disease can be restricted to the skin or also involve internal organs; if limited to the skin, it may be generalized or localized to a single focus.[123] The vessels involved may be the capillaries of the papillary dermis, arterioles, and venules of the deep dermis and subcutaneous tissue, or deep-seated medium-sized vessels. Erythrocytes extravasation is a constant feature.

The inflammatory infiltrate can be predominantly neutrophilic (usually accompanied by leukocytoclasis), lymphocytic, eosinophilic, or granulomatous.[124,125] Necrotizing changes (usually of fibrinoid type) of the vessel wall may be present or absent. Secondary changes in the overlying epidermis and in the sweat glands are frequent.[126] Direct immunofluorescence often shows granular deposits of immunoglobulins, complement, and fibrin in and about vessel walls, although with the exception of Henoch-Schönlein purpura, direct immunofluorescence plays little role in the diagnosis.[127,128]

Taking into account all of the foregoing features, morphologic classifications of cutaneous vasculitides have been proposed that correlate well with a variety of clinical conditions.[125,129–131]

Leukocytoclastic (neutrophilic, allergic) *vasculitis* is a neutrophilic vasculitis of small vessels accompanied by fibrinoid necrosis and leukocytoclasis (Fig. 2.20).[125] It usually presents as purpuric palpable lesions, most commonly on the lower part of the legs. Systemic involvement, particularly of the kidneys, is frequently found in the form known as Henoch-Schönlein purpura (IgA vasculitis).[128,132] *Henoch-Schönlein purpura* resembles conventional leukocytoclastic vasculitis but on direct immunofluorescence has prominent perivascular deposits of IgA and variable deposits of complement C3. Other distinct subtypes of leukocytoclastic vasculitis are those associated with chronic idiopathic urticaria, hypocomplementemia, and essential mixed cryoglobulinemia.[133,134] The presence of systemic disease is more likely when the vasculitis extends deeply into the reticular dermis or subcutaneous fat,[135] but in general the morphologic features of the systemic and the purely cutaneous form are the same.[136–138]

Etiologic agents include infections, foreign proteins, chemicals, drugs, and a variety of diseases. Some patients with acute leukemia develop cutaneous vasculitis, the suggestion having been made that the vascular injury is mediated by the leukemic blasts.[139]

Involvement of larger vessels, often accompanied by necrotizing changes, is seen in allergic granulomatosis of Churg and Strauss, polyarteritis nodosa (systemic or limited to the skin), giant cell arteritis, and granulomatosis polyangiitis (formerly Wegener granulomatosis).[140–143] Prominent vascular involvement without necrotizing changes is also seen in the cutaneous lesions of lymphomatoid granulomatosis, a form of B-cell lymphoma.[144,145] Angiodestruction can be seen in type E LYP.[110]

Other entities associated with vascular injury that do not fit in the category of leukocytoclastic vasculitis include pigmented purpuric dermatosis, perniosis, malignant atrophic papulosis, and segmented hyalinizing vasculitis (atrophie blanche of Milian).

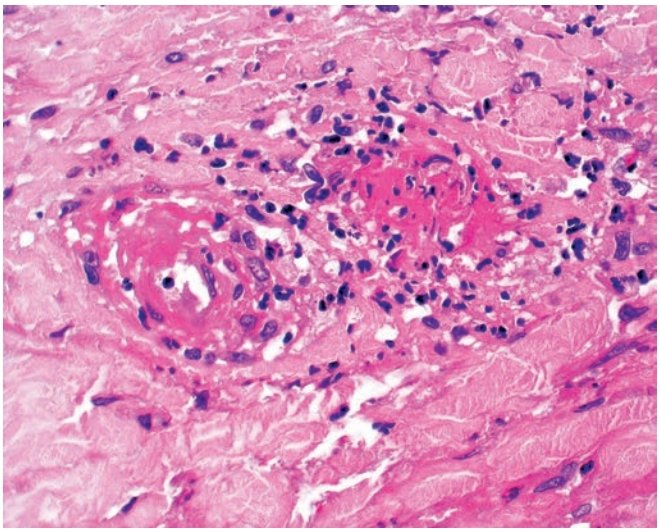

Figure 2.20 Acute Necrotizing Changes in Leukocytoclastic Vasculitis.

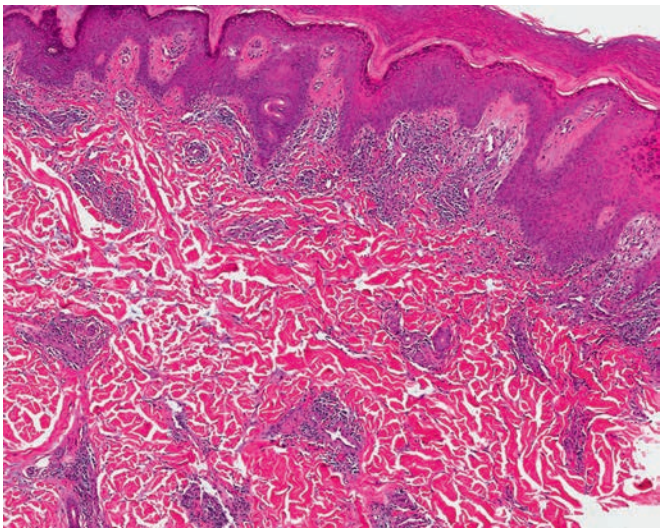

Figure 2.22 Perniosis is characterized by a superficial and deep perivascular lymphocytic vasculitis.

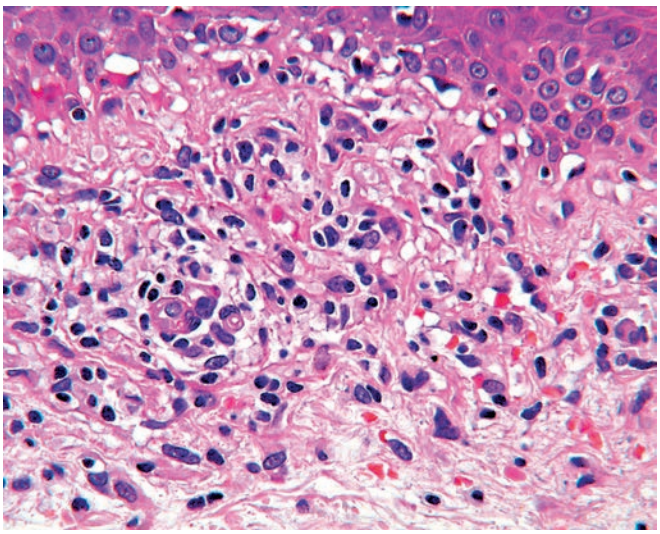

Figure 2.21 Chronic Non-Necrotizing Vasculitis in Pigmented Purpuric Dermatosis.

Pigmented Purpuric Dermatosis

Pigmented purpuric dermatosis has a variety of clinical forms, the most common of which is *Schamberg disease*. Schamberg disease most commonly presents in men and is characterized by asymptomatic, bilateral purpura and petechiae, most commonly involving the lower extremities. Clinically, it may be confused with leukocytoclastic vasculitis but lacks the indurated nature of the lesions seen in leukocytoclastic vasculitis. Microscopically, it consists of a superficial perivascular infiltrate of lymphocytes with extravasated erythrocytes and sometimes siderophages (Fig. 2.21).[146,147] The vessels can show endothelial swelling, and the condition is considered by some a form of lymphocytic vasculitis, although fibrinoid necrosis of vessels is not seen.

Perniosis/Chilblains

Perniosis usually occurs in cold, damp weather and most commonly presents as painful, erythematous nodules on the fingers or toes. It is a form of lymphocytic vasculitis. Microscopically, there is a superficial and deep perivascular and perieccrine lymphocytic infiltrate (Fig. 2.22). The vessels often demonstrate fibrinoid change that has been described as having a fluffy appearance. Papillary dermal edema is often marked.[148,149]

Malignant Atrophic Papulosis (Degos Disease)

This disorder usually occurs in young adult men and is characterized by papules and patches with a central, depressed white area surrounded by an erythematous rim. It has been associated with lupus erythematosus and may represent a reaction pattern rather than a distinct entity. Microscopically, the main change is an ischemic, wedge-shaped infarct of the skin resulting from intimal proliferation of a deep-seated arteriole with or without a lymphocytic infiltrate.[150–152]

Atrophie Blanche

In atrophie blanche (segmented hyalinizing vasculitis) the dermal capillaries show focal endothelial proliferation, marked thickening of the wall by PAS-positive eosinophilic hyaline material, and eventually occlusion of the lumen by a fibrin thrombus (Fig. 2.23).[153,154] This condition has been associated with a variety of hypercoagulable states, and the presence of numerous thrombosed vessels should prompt the pathologist to recommend an appropriate evaluation to exclude those possibilities.

Calciphylaxis

Calciphylaxis usually presents in patients with chronic renal failure as bilateral, painful ulcers involving the thighs. Involvement of the breasts, buttocks, and penis has also been described. This is a medical emergency with a mortality rate greater than 50%.[155–157] Histologically, most of the findings are in the subcutis. Therefore it is important that any diagnostic biopsy be of adequate depth. Calciphylaxis is characterized by calcium deposition in small- to medium-sized arterioles, associated with thrombosis and extensive fat necrosis of the subcutis (Fig. 2.24). The calcium deposits are usually evident in routine H&E sections, but von Kossa stains may be useful in selected cases. Vascular thrombosis of vessels in the overlying dermis may also be seen.

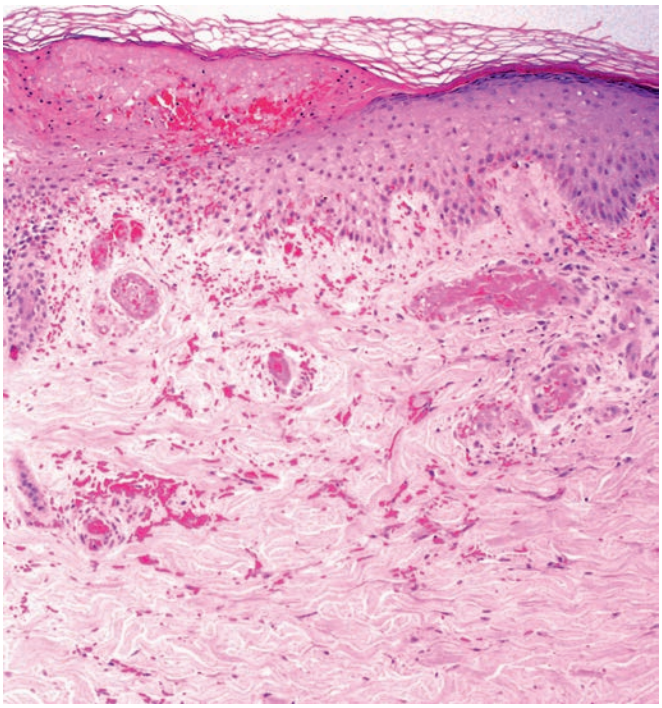

Figure 2.23 Atrophie blanche is characterized by intravascular fibrin thrombi without a true vasculitis.

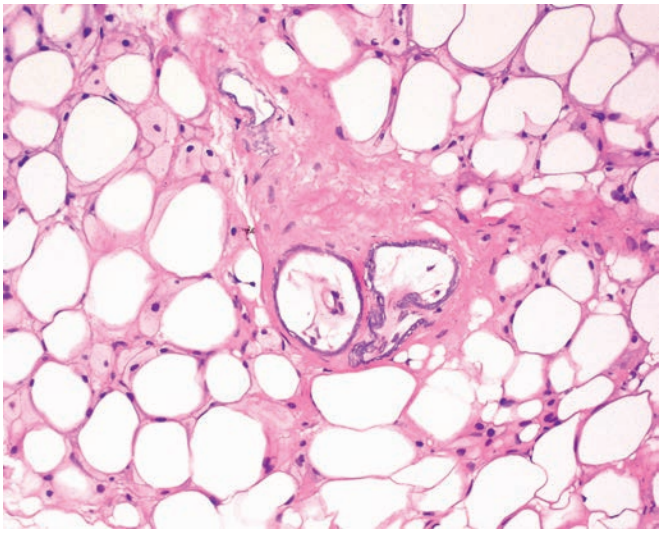

Figure 2.24 Calciphylaxis. There is calcium deposition affecting vessels in the subcutis and associated fat necrosis.

Mastocytosis

Mastocytosis of the skin can manifest in the form of *urticaria pigmentosa*, (solitary) *mastocytoma*, *diffuse and erythrodermic cutaneous mastocytosis*, and *telangiectasia macularis eruptiva perstans*.[158–161] Urticaria pigmentosa, accounting for approximately 80% of cutaneous mastocytosis, usually has its onset during childhood in the form of multiple brown macules.[158,162] On occasion, it makes its first appearance in adults.[162] The brown macules may be diffusely distributed or, less frequently, may be single.[160,163] When the lesions are stroked, the skin urticates because of the release of histamine.

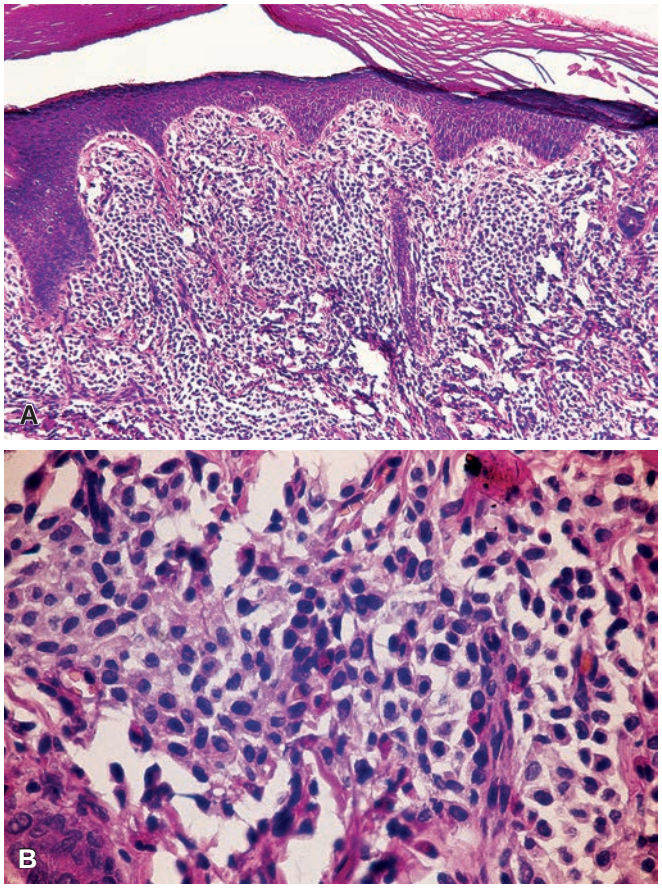

Figure 2.25 Urticaria Pigmentosa. A, Diffuse dermal infiltrate of mast cells admixed with eosinophils. **B,** High-power view of the infiltrate. (Courtesy of Dr Raffaele Gianotti, Milan, Italy.)

Systemic mastocytosis accounts for approximately 20% of cases and may have involvement of the spleen, liver, bone marrow, and lymph nodes, with or without cutaneous lesions.[164,165] Most behave in an indolent fashion, but aggressive forms with a malignant clinical course, including mast cell leukemia, do occur. In general, it is not possible on morphologic grounds to distinguish urticaria pigmentosa with systemic involvement from that having skin disease only,[166] but expression of CD2 or CD25 on mast cells is more common in patients with systemic disease.[167] Aberrant expression of CD30 is also associated with more aggressive disease.[168]

The diagnosis of mastocytosis in a skin biopsy can be easily missed unless the cytologic features of mast cells in sections stained with H&E are remembered (Fig. 2.25).[169] Some of the cells have large, pale nuclei, distinct cytoplasmic boundaries, and a faintly granular cytoplasm. Others are elongated and closely simulate fibroblasts or perithelial cells. Mast cells can be highlighted with toluidine blue, Giemsa, or Leder cytochemical stains. They can also be highlighted with immunohistochemical stains for tryptase, calretinin, and CD117 (c-kit) (Fig. 2.26).[170–173] The mast cells are often admixed with eosinophils, a feature that may induce confusion with Langerhans cell histiocytosis, but the latter often has involvement of the epidermis and is positive for S100 protein, langerin, and CD1a. Mutations of KIT have been documented in a significant proportion of cases.[174,175] Therefore patients with systemic disease may respond to treatment with imatinib mesylate.[176,177]

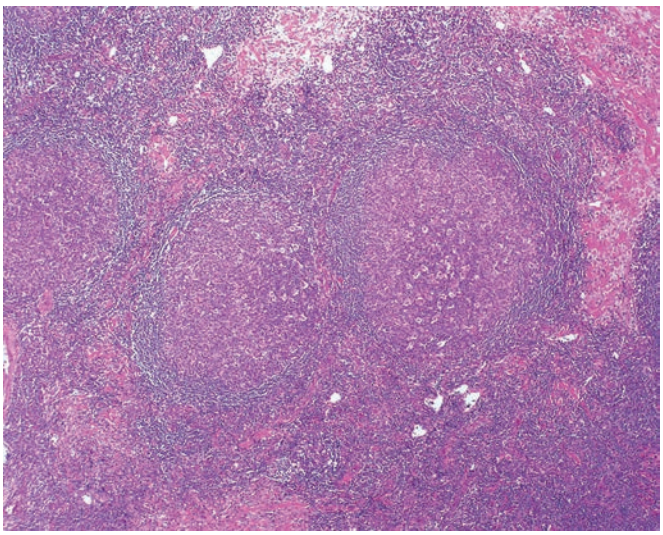

Figure 2.29 Cutaneous B-Lymphoid Hyperplasia. Reactive germinal centers with frequent tingible body macrophages may be present.

Nodular and Diffuse Dermatoses

Entities in this reaction pattern involve the dermis that is not concentrated around vessels. In selected entities there can be histologic overlap with perivascular inflammatory dermatoses.

Acute Febrile Neutrophilic Dermatosis (Sweet Syndrome)

Acute febrile neutrophilic dermatosis, most commonly referred to as *Sweet syndrome*, is characterized by acute onset of fever, leukocytosis, arthralgias, and erythematous plaques that often involve the extremities and face. It is most common in middle-aged women, but any age group can be affected.[178] It can be associated with underlying inflammatory bowel disease, connective tissue disease, infection, and, in a small subset, malignancies, usually hematologic malignancies but also solid tumors.[178,179] Microscopically, there is a dense infiltrate of neutrophils in a nodular to sheet-like pattern (Fig. 2.27). Leukocytoclasis is common, but vascular damage is not a feature, distinguishing it from leukocytoclastic vasculitis, described previously.[180,181] There may be prominent dermal edema, sometimes giving rise to a bullous appearance to the process.[182]

B-Cutaneous Lymphoid Hyperplasia

B-cutaneous lymphoid hyperplasia, also known as *lymphocytoma cutis* and *pseudolymphoma*, most commonly presents in the head and neck as solitary erythematous to violaceous plaques or nodules in adults.[183] Although most cases are idiopathic, such triggering agents as arthropod bites, *Borrelia* infections, drugs, and jewelry have all been implicated.[184,185]

Histologic examination reveals a nodular to sheet-like lymphoid proliferation that can mimic a B-cell lymphoma (Fig. 2.28). Lymphoid follicles with reactive germinal centers containing centroblasts, centrocytes, and tingible body macrophages may be present (Fig. 2.29).[186–188] These are surrounded by a proliferation of small reactive

Figure 2.30 Clinical Appearance of Granuloma Faciale. The lesion appears as thickened purplish patches.

T-cells. The B-cells in the lymphoid follicles can be highlighted by stains for CD20, bcl-6, and CD10. The interfollicular cells are largely negative for these markers. Stains for CD21 will highlight an intact dendritic network in the germinal centers.

The main differential diagnosis includes cutaneous marginal zone lymphoma and cutaneous follicle center lymphoma, which are discussed in more detail in the chapter on cutaneous neoplasms. Briefly, in cutaneous marginal zone lymphoma there is a sheet-like proliferation of monocytoid B cells with variable numbers of monotypic plasma cells in the interfollicular zone. The monocytoid B cells disrupt reactive follicles, resulting in expansion of the follicular dendritic network. The neoplastic B cells may also have aberrant CD43 expression. In primary cutaneous follicle center lymphoma, the germinal centers are more monomorphous with few to no tingible body macrophages.

Granuloma Faciale

Granuloma faciale typically presents on the face of adults as a thickened, purplish brownish patch, which clinically may be confused with infected nevus, tumor, or sarcoid (Fig. 2.30).[189] For this reason, it is often excised or biopsied, and acquaintance with its histologic appearance is helpful. The generally unaltered epidermis is separated from the zone of dermal inflammation by a narrow band of uninvolved dermis. The inflammatory reaction is nodular to sheet-like and formed by lymphocytes, histiocytes, neutrophils, and often large numbers of eosinophils. The infiltrate is frequently prominent, and there is overlap with entities with a nodular or diffuse pattern of inflammation, such as acute febrile neutrophilic dermatosis and arthropod bite reactions. It is considered a chronic vasculitis, and in early lesions evidence of a leukocytoclastic vasculitis may be present (Fig. 2.31).[190] It has been suggested that eosinophilic angiocentric fibrosis of the larynx and other portions of the sinonasal tract is the mucosal equivalent of cutaneous granuloma faciale. Indeed, they look very similar microscopically and can coexist.[191]

Erythema elevatum diutinum shares some morphologic features with granuloma faciale and is thought to be pathogenetically related to it.[192,193] It generally presents in systemically ill patients as bilaterally symmetrical plaques, papules, or nodules, often over the dorsa of joints. Microscopically, it initially presents as a leukocytoclastic vasculitis and later resolves with storiform or concentric fibrosis that imparts a more diffuse pattern to the inflammatory process.[194] In contrast to granuloma faciale, eosinophils are scanty or absent. Sometimes the disease has a nodular quality that mimics a neoplastic process.[195]

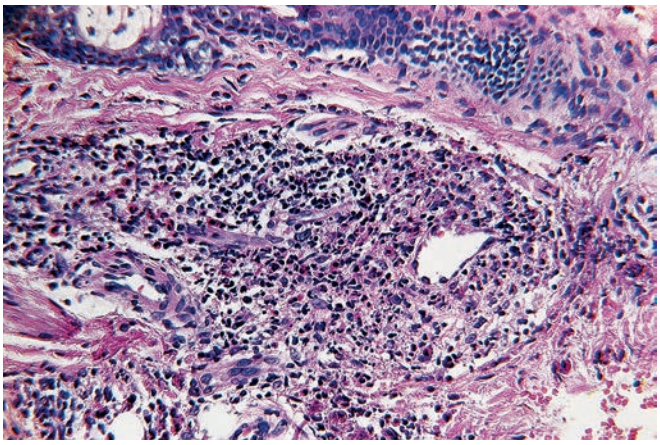

Figure 2.31 Vascular changes in granuloma faciale.

Sarcoidosis

Sarcoidosis can present as an acute self-limiting disease, chronic cutaneous disease, or systemic disease that also involves lymph nodes and viscera. The clinical manifestations of cutaneous sarcoidosis are multifarious, earning the disease a site among the "great imitators in medicine."[196,197] Clinically, the cutaneous manifestations of the disease vary a great deal from case to case. The lesions can be single or multiple and can range from macules to large plaques and nodules.[196–199]

Microscopically, the dermis is infiltrated by nests and clusters of noncaseating epithelioid granulomas almost devoid of associated inflammatory cells (Fig. 2.32). In particular, Langhans giant cells are scarce. The often-mentioned asteroid bodies, seen in giant cells, and the calcified Schaumann bodies are uncommon and nonspecific.

Sarcoidosis is a diagnosis of exclusion, inasmuch as granulomas with an identical microscopic appearance can also appear in the skin in a variety of infectious diseases, including tuberculosis, atypical mycobacteriosis, and syphilis; as a reaction to zirconium, beryllium, and tattoos; and as a secondary change in malignant lymphoma. Therefore, at a minimum, stains for infectious organisms should be performed the first time a biopsy from a given patient with possible sarcoidosis is encountered.

Palisading Granulomatous Disease

This group of disorders is characterized by a histiocytic infiltrate that surrounds zones of altered collagen. Granuloma annulare and necrobiosis lipoidica are the prototypical examples in this category.

Granuloma Annulare

Granuloma annulare occurs most frequently on the dorsum of the hands and arms as circinate or grouped clusters of pink nodules with slight central depressions (Fig. 2.33). Occasionally, the disease

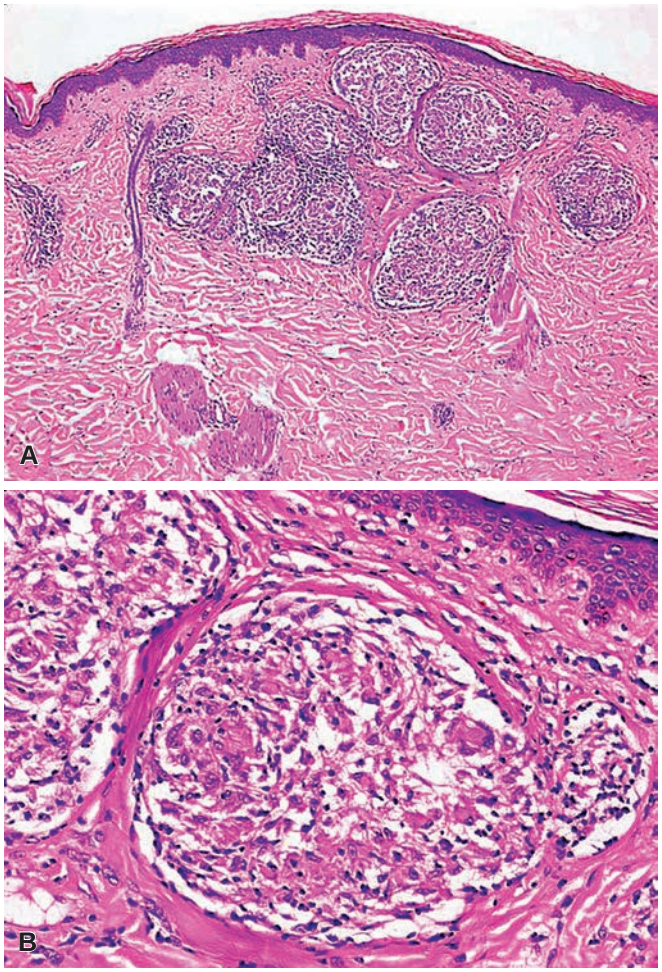

Figure 2.32 **A and B,** Low- and Higher-Power Views of Cutaneous Sarcoidosis.

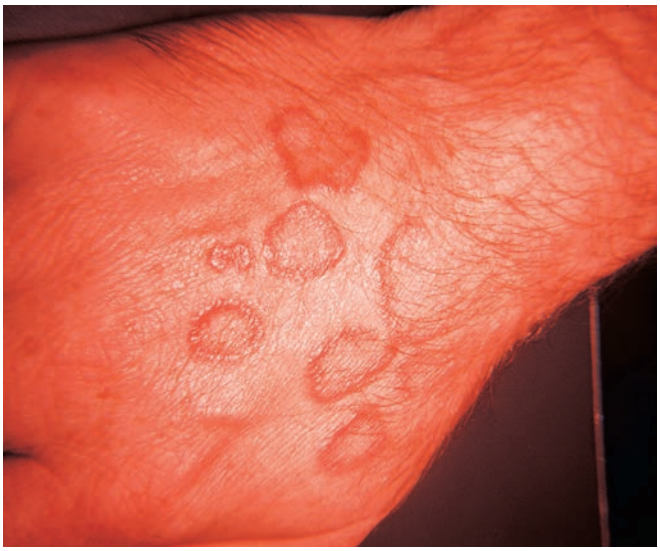

Figure 2.33 Clinical Appearance of Multiple Lesions of Granuloma Annulare of Dorsum of Hand.

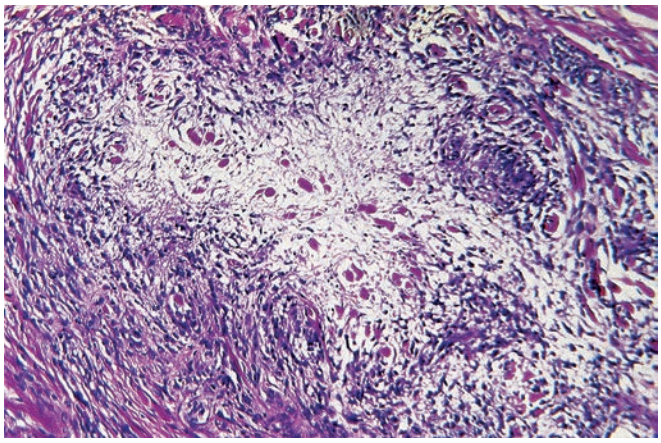

Figure 2.34 Typical Lesion of Granuloma Annulare, With Palisading of Histiocytes Around "Necrobiotic Collagen" Center.

is generalized.[200] Associated systemic diseases are present only exceptionally.[201,202] Histologically, the key component of the lesion is the so-called necrobiotic or palisading granuloma.[203] This is characterized by a well-demarcated zone of disintegrating extracellular material with the appearance of collagen mixed with dermal mucin and cellular debris that is found in the mid-dermis surrounded by a cuff of radially oriented fibroblasts mixed with lymphocytes and histiocytes (Fig. 2.34). Occasional foreign body giant cells and foci of vasculitis may be found. In many lesions the palisading granuloma is not as well developed and has a more interstitial pattern.[204] Multiple sections may be necessary to arrive at a specific diagnosis in this setting.

Immunohistochemically, the "histiocytes" of granuloma annulare stain for vimentin and lysozyme but not for other histiocytic markers, such as HAM-56 or KP-1 (CD68).[205] Ultrastructural studies have shown a prominent component of degenerated elastic (rather than collagen) fibers.[206] Isolated, large, rather deep, necrobiotic collagen granulomas are sometimes seen on the extremities or occiput in children[204] and sometimes in adults.[207,208] They have been referred to as deep, subcutaneous, or giant granuloma annulare and as pseudorheumatoid nodule.[209,210]

An entity histologically similar to granuloma annulare that occurs on heavily sun-damaged skin has been designated as *O'Brien actinic granuloma*, *Miescher granuloma*, and *annular elastolytic giant cell granuloma*.[211,212] Histologically it is almost identical to conventional granuloma annulare and is considered by some to represent the same disease, just occurring in sun-damaged skin. The presence of elastic fibers in the giant cells, as seen by light and electron microscopy, is one of its most important distinguishing features.[213–215]

The subcutaneous nodules of rheumatoid arthritis and rheumatic fever share with granuloma annulare the presence of the necrobiotic collagen granuloma, but the combination of clinical and microscopic features usually allows an easy distinction.[209,216] Rheumatoid nodules are usually deeper and the central zone of the palisading granuloma contains fibrin rather than dermal mucin.

Necrobiosis Lipoidica

Necrobiosis lipoidica typically presents as atrophic, yellow, depressed plaques involving the lower legs (Fig. 2.35).[217,218] Necrobiosis lipoidica is associated with diabetes mellitus and hypothyroidism, but the association with underlying endocrine disordered is less frequent than originally thought.[219] Although most cases involve the legs, presentation outside this location may occur.[219–221] Microscopically,

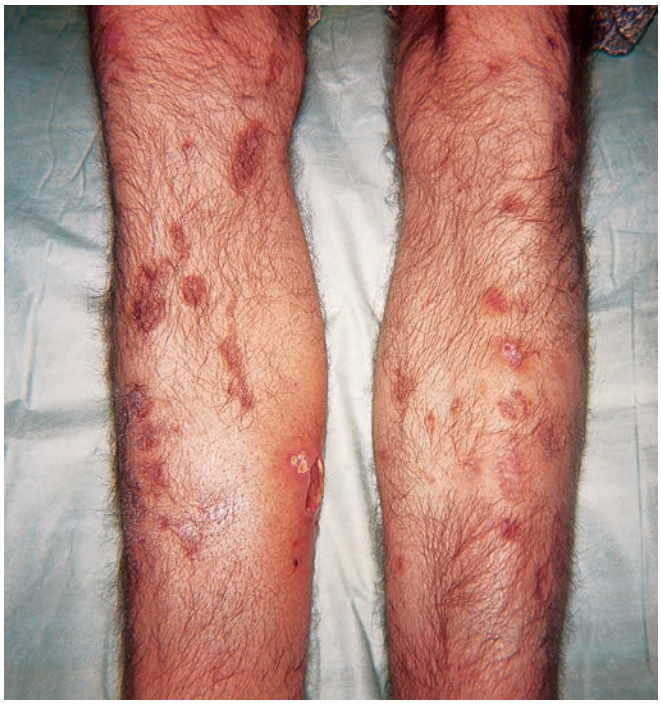

Figure 2.35 Clinical Appearance of Lesions of Necrobiosis Lipoidica.

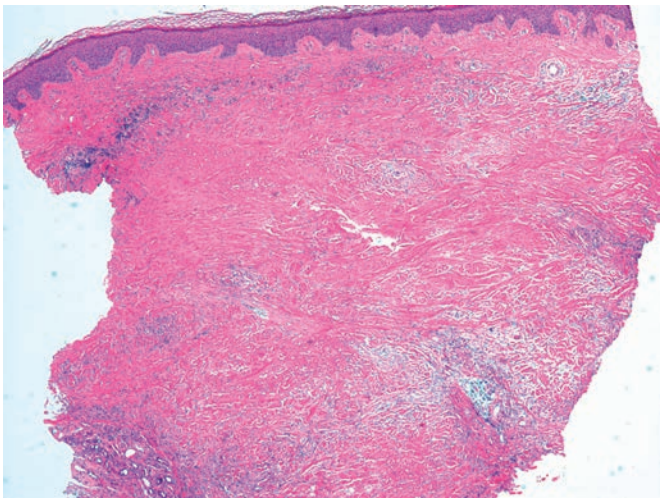

Figure 2.36 **Necrobiosis Lipoidica.** Tiered arrangement of inflammatory cells and altered collagen.

ill-defined areas of disintegrating dermal collagen are seen surrounded by a lymphohistiocytic infiltrate, often arranged in a tiered or layered pattern (Fig. 2.36).[220,221] This has been likened to the appearance of a layer cake or bacon. Lymphoid aggregates with plasma cells are typical (Fig. 2.37). Thickening of the blood vessel wall is usually prominent. It may also have a deeper component with the features of septal panniculitis. Granuloma annulare tends to have a more circumscribed pattern of palisading granulomas and plasma cells are typically absent in granuloma annulare. In addition, in contrast with granuloma annulare, stains for mucin and immunoreactivity for lysozyme tend to be negative, although these stains are not generally necessary to distinguish these entities.[222] The differential diagnosis also includes *necrobiotic xanthogranuloma*, a disease occurring in the head, neck, and trunk of patients in association with paraproteinemia.[223]

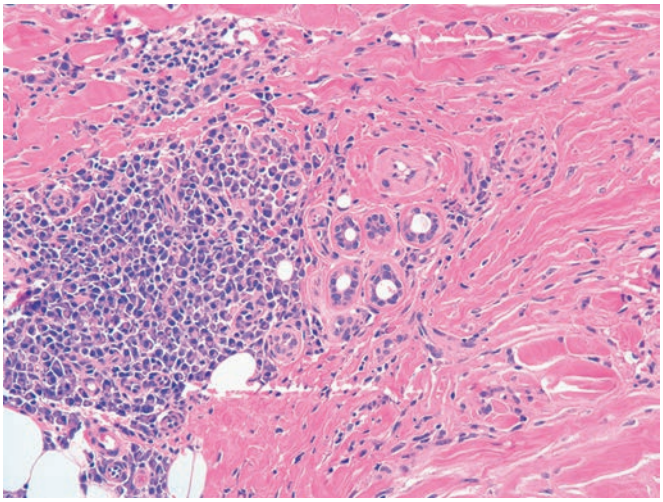

Figure 2.37 Necrobiosis lipoidica usually has lymphoplasmacytic aggregates.

Sclerosing Disorders

This group of disorders is characterized by dermal sclerosis, usually with comparatively little inflammation. Included in this group are scleroderma/morphea, eosinophilic fasciitis, and lichen sclerosus.

Scleroderma/Morphea

Scleroderma is manifest in two distinct forms: *localized scleroderma*, or morphea, and *systemic scleroderma*, in which the skin, particularly of the face, the upper trunk, hands, and arms (acrosclerosis), the esophagus, the heart, and the lungs are diseased.[224–226] Most patients are adults, but the disease can also present in childhood.[227,228] Morphea is the most common form of scleroderma in childhood.[229] Sometimes, visceral disease typical of systemic scleroderma occurs in the absence of cutaneous involvement. A few cases of morphea have been associated with generalized or systemic disease.

The dominant microscopic change in scleroderma is an increase in the amount of collagen, which is morphologically, ultrastructurally, and biochemically unremarkable.[230,231] The relative proportions and distribution of type I and type III collagens are also closely similar to those found in the normal dermis.[232] The histologic appearance is that of enlarged, swollen collagen fibers with a decrease in the normal spacing between the collagen bundles of the reticular dermis (Fig. 2.38). The sclerosis may extend in depth to encircle the secretory coils of the eccrine sweat glands. Concomitantly, the epidermis becomes atrophic. Varying amounts of a mild lymphoplasmacytic infiltrate may be seen in the dermis. In well-developed lesions, the infiltrate may be absent or present at the leading deep edge of the sclerotic change. Early lesions may have little collagen change and a superficial and deep perivascular lymphoplasmacytic infiltrate, suggesting that the fibrosis may represent a secondary phenomenon.[233,234] One should not mistake the normally relatively thick collagen bundles of the back for scleroderma. The collagen bundles of the back will still have retained spaces between the fibers. Dystrophic calcification may occur in scleroderma, and in some patients the dominant patterns is that of acrosclerosis preceded by, or associated with, Raynaud phenomenon.

Scleroderma is usually distinguishable from lichen sclerosus (discussed in more detail later) by the depth of dermal involvement, but in some cases coexisting features of lichen sclerosus

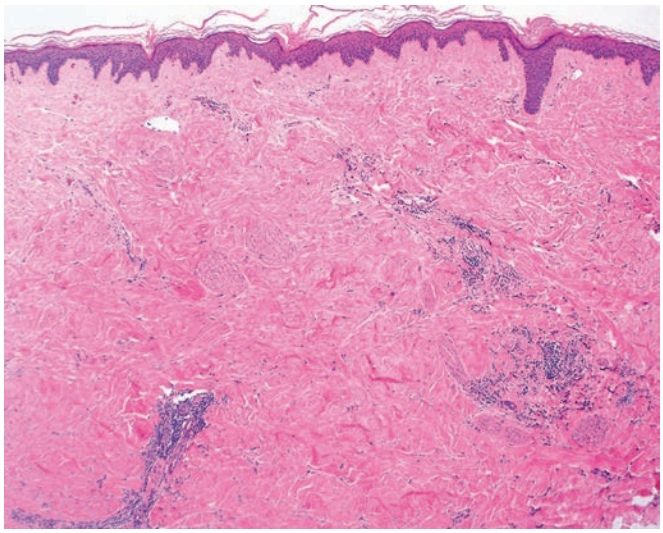

Figure 2.38 Scleroderma. Thickened collagen bundles with decreased spaces between the collagen bundles of the reticular dermis.

may be present and the diseases may represent a spectrum.[235] Scleroderma should also be differentiated from eosinophilic fasciitis (see later).

Eosinophilic Fasciitis

Eosinophilic fasciitis (Shulman disease) is characterized clinically by swelling, tenderness, and stiffness of an extremity, often involving the lower forearm and sometimes associated with carpal tunnel syndrome and peripheral eosinophilia.[235–239] The most important difference between scleroderma and eosinophilic fasciitis on histologic grounds is that in the latter condition there is marked inflammation and thickening of the deep fascia (with or without eosinophils), whereas in scleroderma this structure tends to show minimal or no abnormalities.

Lichen Sclerosus

Lichen sclerosus, also called *lichen sclerosus et atrophicus*, occurs most often on the anogenital areas, upper trunk and neck, and flexor surface of the wrist. When this disease is located in the vulva or glans penis, it is also designated as *kraurosis* and *balanitis xerotica obliterans,* respectively. The disease occurs most commonly in women, often at or around menopause, but it can also be seen in children and young adults.[240] The lesions present as white papules and plaques with a wrinkly surface. Patients have an increased risk of development of high-grade squamous intraepithelial lesions of the differentiated or simplex type, and squamous cell carcinoma in the affected sites, but the risk is relatively low (<10%). The etiology is unknown, but there is a strong association with autoimmune disorders and a link with HLA DQ7.[241] The microscopic features vary depending on the timing of the biopsy. Early lesions may demonstrate an interface dermatitis that can mimic lichen planus.[242] More established lesions have the characteristic edematous, homogenization of the papillary dermis with atrophy of the overlying epidermis (Fig. 2.39). A variable perivascular to lichenoid lymphocytic infiltrate is frequently at the leading edge of the dermal change. Varying degrees of non-necrotizing vasculitis may be seen.[243] As previously mentioned, lichen sclerosus should be distinguished from scleroderma/morphea, although the two diseases may coexist and distinction may not always be possible.[234,244]

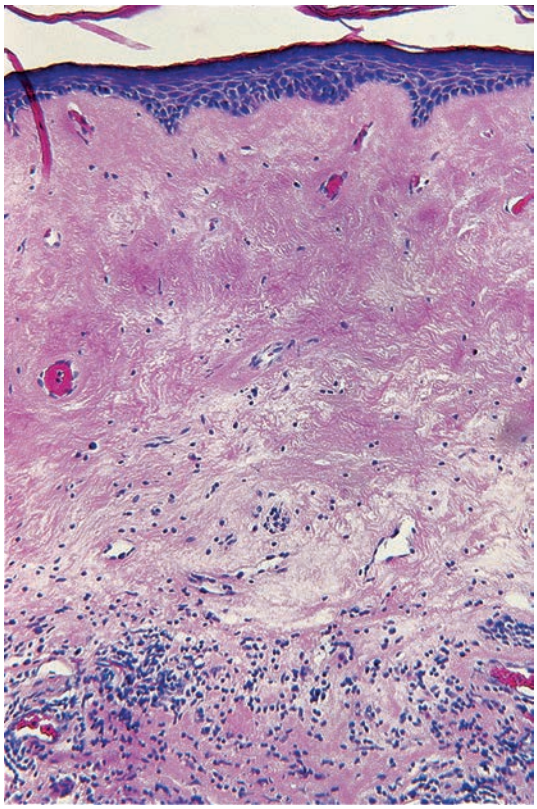

Figure 2.39 Lichen Sclerosus.

Panniculitis

Panniculitis exists in a predominantly septal or lobular pattern, although there is considerable histologic overlap in both of these patterns. It is important to examine the biopsy at low magnification to assess for where the predominant pattern of inflammation/alteration of the subcutis is present. Erythema nodosum is the prototypical septal panniculitis, whereas nodular vasculitis is the prototypical lobular panniculitis.

Erythema Nodosum

Erythema nodosum is the most common form of primary panniculitis, accounting for approximately 70%–80% of cases of panniculitis. The lesions present as painful, red, subcutaneous nodules on the anterior surface of the legs.[245] Typically, they involute within a few days or weeks, leaving slightly depressed pigmented areas. They do not ulcerate, as do the lesions of erythema induratum. It seems certain that the pathogenesis is immune mediated, but the precise mechanism is unknown.[246] In an old series of a British population with erythema nodosum, 45% of the patients had antecedent streptococcal infections, 6% had tuberculosis, 36% had sarcoid, and 13% had a variety of lesions.[247] Several other infectious agents can be involved.[248] Some cases are associated with chronic ulcerative colitis and others with Behçet syndrome.[249–253] In the endemic areas of the United States, coccidioidomycosis is a common antecedent.

Histologically, the junction of the dermis and the subcutis is inflamed. An inflammatory infiltrate extends along the fibrous septa between the fat and about the vessels of the dermis (Fig. 2.40). There is usually spillover into the adjacent lobules, but it is concentrated at the periphery. The composition of the inflammatory infiltrate

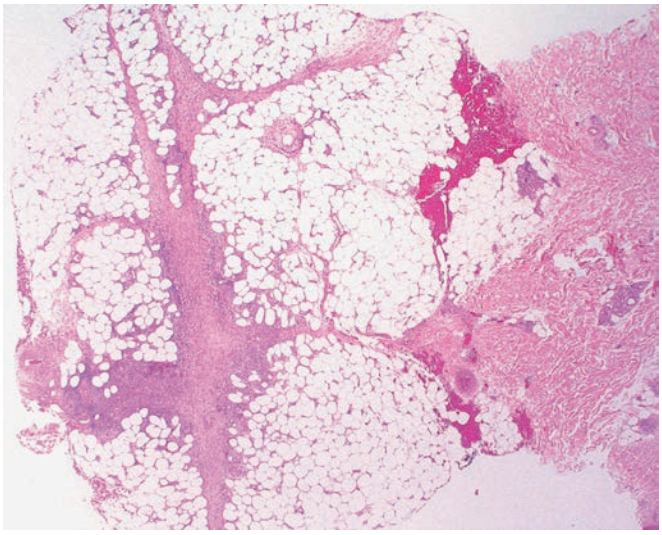

Figure 2.40 Erythema Nodosum. The inflammation predominantly affects the subcutaneous septae.

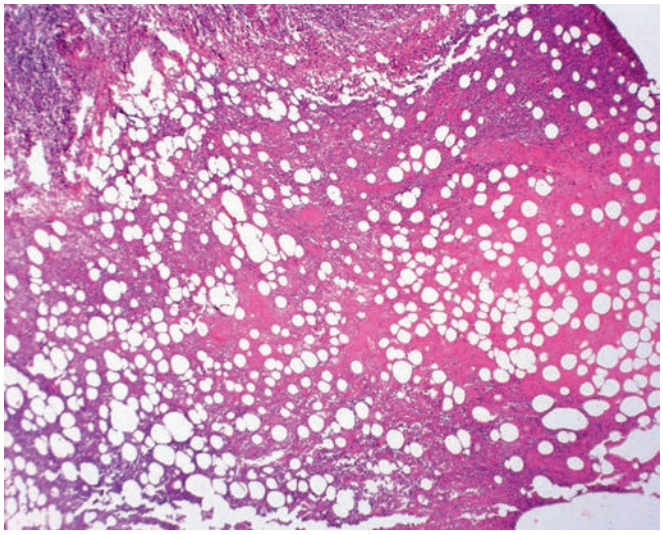

Figure 2.42 Nodular Vasculitis/Erythema Induratum. The inflammation predominantly affects the subcutaneous lobule.

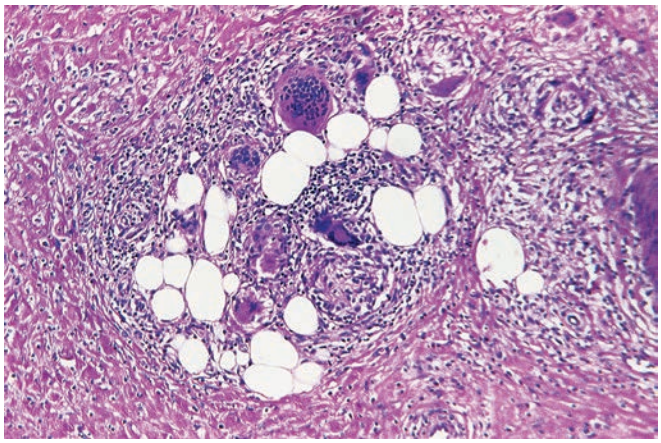

Figure 2.41 Panniculitis With Scattered Multinucleated Giant Cells in Erythema Nodosum.

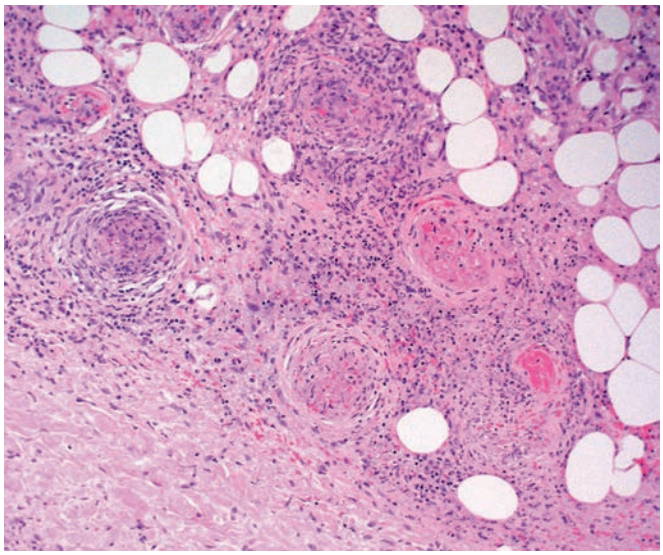

Figure 2.43 Vasculitis in Nodular Vasculitis.

depends largely on the age of the lesion. It may be predominantly neutrophilic, lymphocytic, or histiocytic, with isolated giant cells or noncaseating granulomas (Fig. 2.41).[245,254–256] A characteristic lesion seen in the early stages of the disease is represented by a cluster of small histiocytes radially arranged around a central cleft (Miescher radial granuloma).[255]

Nodular Vasculitis/Erythema Induratum

Both terms are used for the same condition. This condition usually presents on the calves of young to middle-aged women.[257] They present as painful violaceous nodules that may be complicated by ulceration. Some cases represent a manifestation of underlying tuberculosis (Bazin disease) and is a form of tuberculin hypersensitivity.[258] Acid-fast bacilli are not seen in special stains, but mycobacterial DNA has been found in these lesions by polymerase chain reaction (PCR) by some authors but not by others.[259] In the United States, most cases of erythema induratum are idiopathic and are not related to underlying tuberculosis. The etiopathogenesis of this disease and its relation to tuberculosis remain controversial.

Nodular vasculitis/erythema induratum is predominantly a lobular panniculitis, although some septal involvement may also be seen (Fig. 2.42). The inflammatory infiltrate is variably composed of lymphocytes, histiocytes, and neutrophils. Granulomas may be present. In most cases there is an associated leukocytoclastic vasculitis involving medium-sized vessels of the septum or lobule (Fig. 2.43).[257] The differential diagnosis includes erythema nodosum and infection. Erythema nodosum has a distinctly different clinical presentation, lacks the vasculitis, and is predominantly a septal panniculitis. Infectious processes usually lack the associated vasculitis, but infectious stains should be used if there is a question of infection.

Lipodermatosclerosis

Lipodermatosclerosis, or sclerosing panniculitis, is a type of panniculitis that is the result of chronic venous insufficiency. It occurs in elderly or morbidly obese patients and presents as woody

induration of the lower legs.[260,261] Microscopically, unlike other panniculitides, it is relatively noninflammatory. There is lobular alteration of the fat, with hyalinization, microcyst formation, and membranocystic fat necrosis that has been compared with the appearance of frost on a windowpane (Fig. 2.44). The septa are typically spared. The overlying dermis usually shows evidence of stasis change. It may also be seen as a result of vascular compromise due to radiation therapy.[261]

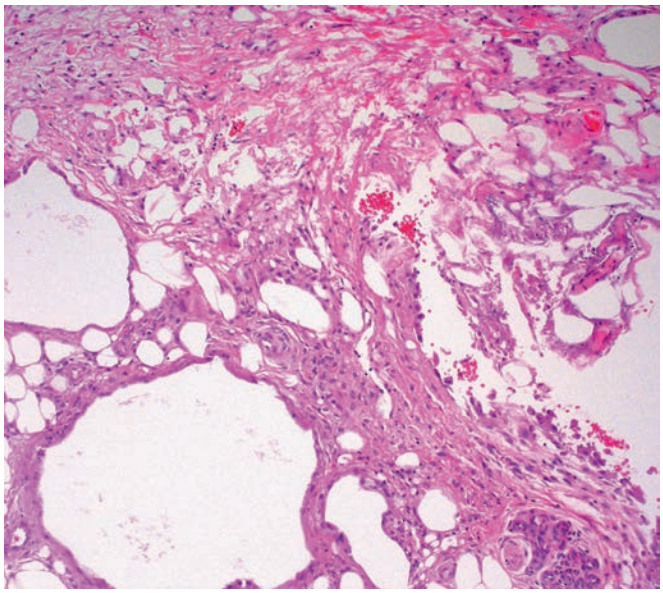

Figure 2.44 **Membranocystic Fat Necrosis of Lipodermatosclerosis.**

Vesiculobullous Diseases

The key morphologic features in the microscopic evaluation of vesiculobullous lesions are the level of the plane of separation and the type of cellular change seen, particularly the presence or absence of acantholysis—as masterfully described in the classic monograph by Lever[262] (Table 2.1), now supplemented by their immunofluorescent pattern (Table 2.2). Vesicles and bullae (large vesicles) are divided according to their location into subepidermal and intraepidermal, which in turn may be suprabasal or subcorneal. In making this distinction, one should be aware that a bulla that was originally subepidermal can become intraepidermal because of regrowth of epithelium across its base, a process that can be very rapid. Actually, large intraepidermal bullae unassociated with acantholytic changes should be suspected of being healed subepidermal bullae. Biopsying early lesions (<24 hours old) minimizes this problem. Biopsies for complimentary direct immunofluorescence studies should be perilesional and submitted in Michel's solution rather than formalin. A complete discussion of the wide range of bullous dermatoses is beyond the scope of this text, but selected entities will be emphasized.

Subepidermal Bullous Disease

Subepidermal bullous dermatoses include a wide range of entities, including *bullous pemphigoid, cicatricial pemphigoid, epidermolysis bullosa*

Table 2.1 Grouping of cutaneous bullous diseases according to the location and mechanism of formation of the bullae

INTRAEPIDERMAL	SUBEPIDERMAL
Subcorneal/Glandular	**Basal Keratinocyte Necrosis, Cytologic, or Damage**
Miliaria crystalline	Epidermolysis bullosa simplex
Staphylococcal scalded skin syndrome	Thermal injury (some)
Pemphigus foliaceus and variants	Erythema multiforme
Bullous impetigo	Herpes gestationis
IgA pemphigus	**Epidermal Basement Membrane Zone Destruction or Disruption**
Subcorneal pustular dermatosis	
Erythema toxicum neonatorum	Lamina lucida
Transient neonatal pustular melanosis	Bullous pemphigoid
Acropustulosis of infancy	Cicatricial pemphigoid
Spinous	Herpes gestationis
Spongiotic dermatitis	Dermatitis herpetiformis
Friction blister (may extend into dermis)	Linear IgA dermatosis
Miliaria rubra	Epidermolysis bullosa acquisita
Incontinentia pigmenti	Porphyria cutanea tarda
IgA pemphigus	Epidermolysis bullosa letalis (junctional)
Epidermolytic hyperkeratosis	Suction blister
Hailey-Hailey disease	Thermal injury (some)
Suprabasal	Sublamina densa
Pemphigus vulgaris and variants	Cicatricial pemphigoid
Paraneoplastic pemphigus	Linear IgA dermatosis
Darier disease	Epidermolysis bullosa dystrophica
	Epidermolysis bullosa acquisita
	Bullous systemic lupus erythematosus
	Dermal
	Penicillamine-induced blisters (iatrogenic)

Ig, Immunoglobulin.

Table 2.2 Usual immunofluorescence patterns in the various types of vesicobullous dermatoses.*

DERMATOSIS	PRINCIPAL IMMUNOREACTANT	LOCATION	PATTERN
Pemphigus			
All types except below	IgG	ISR	Lace-like
IgA type	IgA	ISR	Lace-like
Paraneoplastic type	IgG C3, IgG C3, IgG	ISR EBMZ EBMZ	Lace-like Linear Granular
Bullous pemphigoid	C3, IgG	EBMZ	Linear
Cicatricial pemphigoid	C3, IgG	EBMZ	Linear
Herpes gestationis	C3	EBMZ	Linear
Epidermolysis bullosa acquisita	C3, IgG	EBMZ	Linear
Bullous systemic lupus erythematosus	C3, IgG C3, IgG	EBMZ EBMZ	Linear Granular
Dermatitis herpetiformis	IgA	EBMZ	Granular
Linear IgA dermatosis	IgA	EBMZ	Linear
Erythema multiforme	C3, IgM C3, IgM	EBMZ Vessels	Granular Granular

*It should be noted that immunoglobulins other than those listed above may also be present, although less commonly and less intensely.
EBMZ, Epidermal basement membrane zone; Ig, immunoglobulin; *ISR*, intercellular squamous region.

Figure 2.45 Clinical Lesions of Dermatitis Herpetiformis. Note the small size of the vesicles and their symmetric distribution.

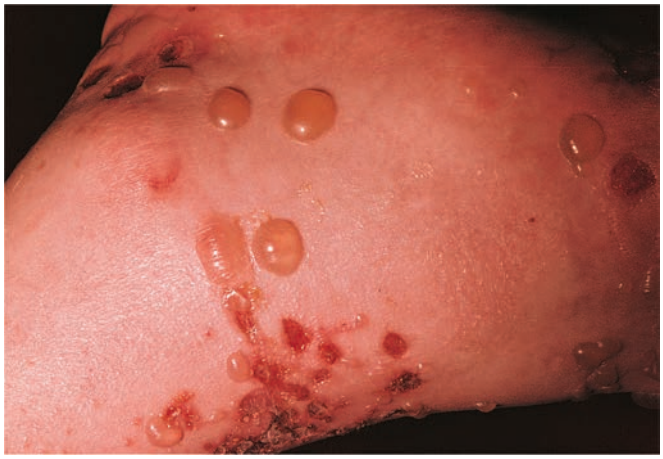

Figure 2.46 Clinical Appearance of Bullous Pemphigoid. Large bullae are present, some of which have ruptured.

dermatitis herpetiformis, and *porphyria cutanea tarda* (Figs. 2.45 and 2.46).[263] They can also be seen as a secondary event in any dermatosis associated with liquefactive degeneration of the basal layer, such as lupus erythematosus, erythema multiforme, scleroderma, and lichen planus (see earlier).[264]

Microscopically, a distinction between these various subepidermal processes is not always possible; however, careful evaluation of a set of criteria as seen in routinely stained sections results in a high level of concordance with the clinical diagnosis (see Tables 2.1 and 2.2).[265]

Bullous Pemphigoid

A number of clinical forms exist. The most common form, *generalized cutaneous pemphigoid*, presents as tense blisters involving the skin of older patients.[265,266] In a minority, there may also be mucosal involvement.[267] The most consistent histologic features of bullous pemphigoid is a subepidermal blister above the basement membrane that contains numerous inflammatory cells, including frequent eosinophils, in the blister cavity (Fig. 2.47). Direct immunofluorescence on specimens submitted in Michel's solution will reveal linear deposition of

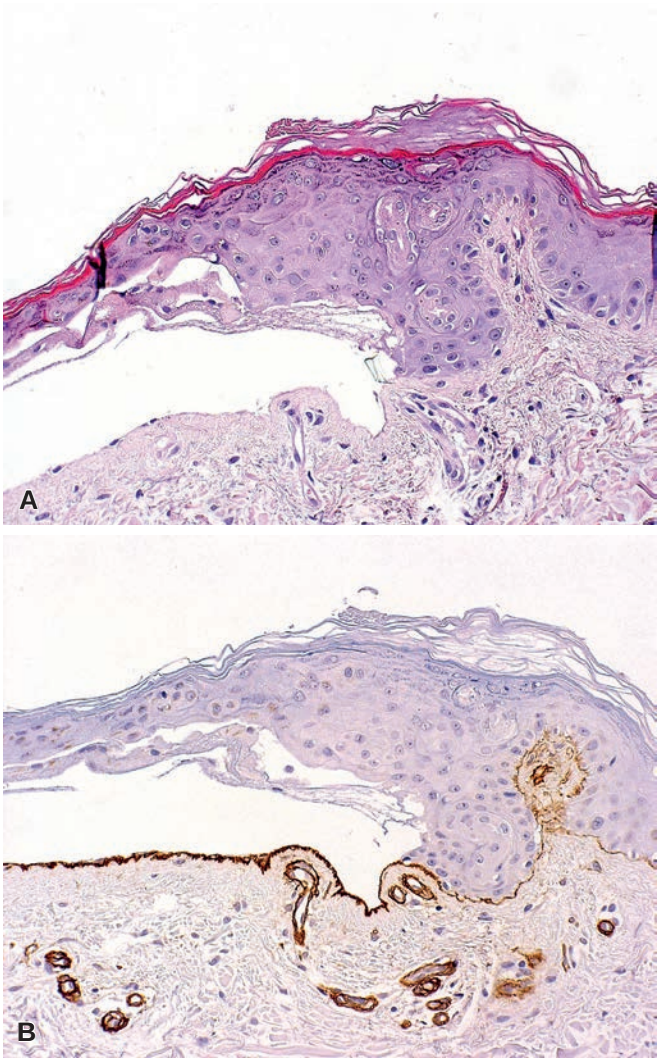

Figure 2.47 **A,** Bullous pemphigoid. A net separation is present between the epidermis and dermis, with protrusion of dermal papillae into the bulla. The inflammatory infiltrate is very scanty. **B,** Immunostaining for type IV collagen shows that the basement membrane is at the base of the bulla. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

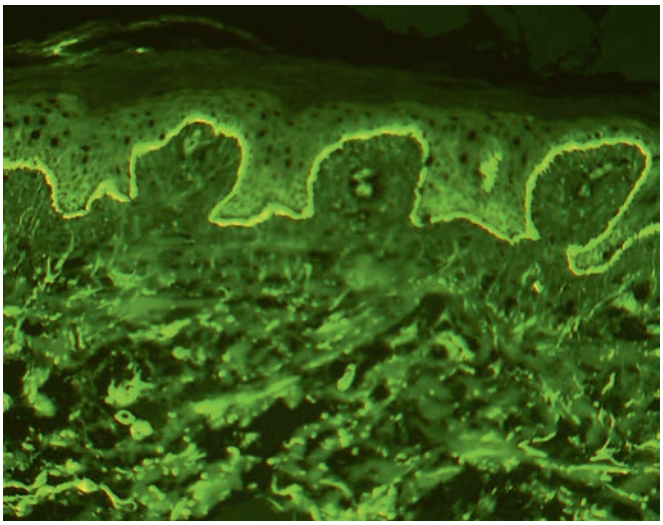

Figure 2.48 Linear deposition of complement C3 in bullous pemphigoid.

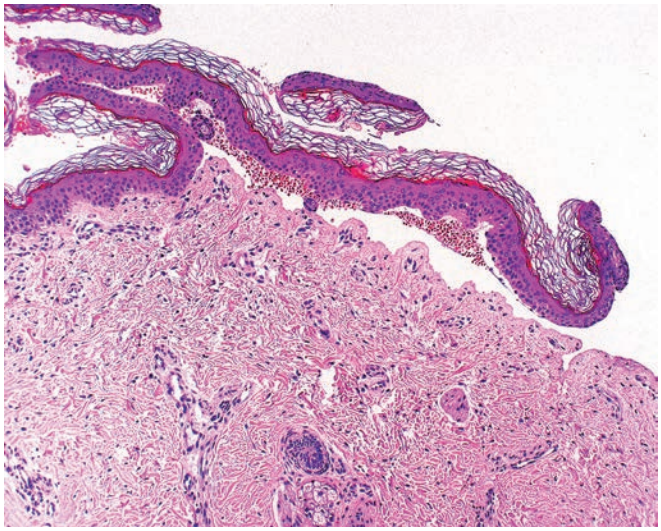

Figure 2.49 Clean subepidermal bulla of epidermolysis bullosa.

complement C3 and usually IgG along the basement membrane zone (Fig. 2.48).

Cicatricial Pemphigoid (Mucous Membrane Pemphigoid)

This rare form of pemphigoid involves ocular and oral mucosa and is often associated with scarring, especially ocular lesions.[266,267] Involvement of genital mucosa is relatively common in female patients with this condition. Histologically, they can be indistinguishable from generalized cutaneous pemphigoid, but the inflammatory infiltrate is often much less intense. In older or recurrent lesions, an underlying scar is often present. Direct immunofluorescence is similar to bullous pemphigoid, although IgA deposits may also be seen in a minority of cases.

Epidermolysis Bullosa Acquisita

There are multiple different variants and only the classical variant will be discussed.[268–272] Patients present with marked skin fragility at sites prone to trauma, such as the hands. Patients easily develop blisters and erosions, and milia are frequently present.

Microscopically, cell-poor subepidermal blisters are characteristic, although occasional cases will show some inflammatory cells in the blister cavity (Fig. 2.49). By direct immunofluorescence, linear deposits of IgG and complement C3 are present, similar to pemphigoid. Salt-split skin preparations examined with direct immunofluorescence will demonstrate the immune deposits on the floor of the blister in epidermolysis bullosa acquisita rather than the roof of the blister in pemphigoid.[272]

Dermatitis Herpetiformis

Dermatitis herpetiformis usually presents in young adults as an intensely pruritic papulovesicular eruption often on extensor surfaces. Clinically, it is closely related to celiac disease. Histologically, the most useful criterion for the diagnosis of dermatitis herpetiformis is the presence of papillary microabscesses forming a multilocular subepidermal bulla (Fig. 2.50).[273] Direct immunofluorescence demonstrates granular deposits of IgA along the basement membrane zone that are typically

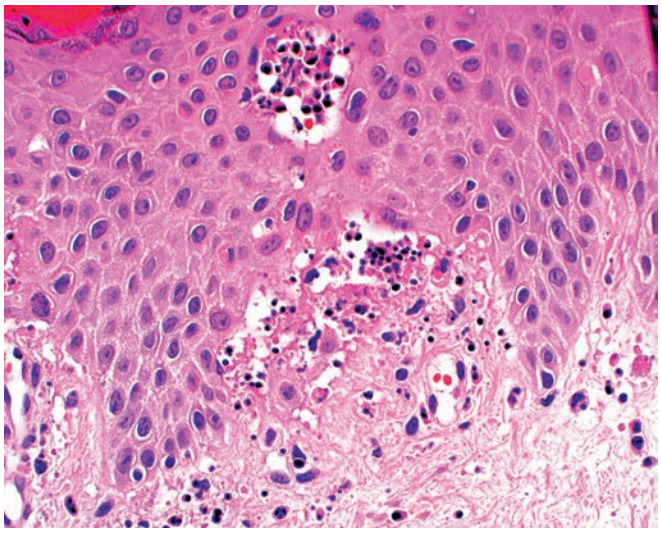

Figure 2.50 Typical appearance of early lesion of dermatitis herpetiformis.

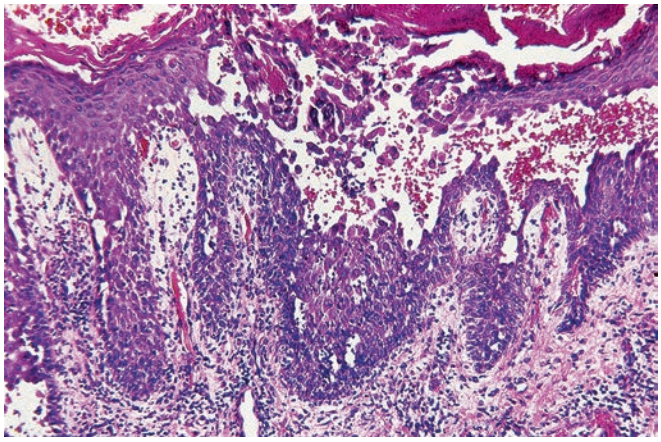

Figure 2.51 Pemphigus Vulgaris. The bulla is in a suprabasal location.

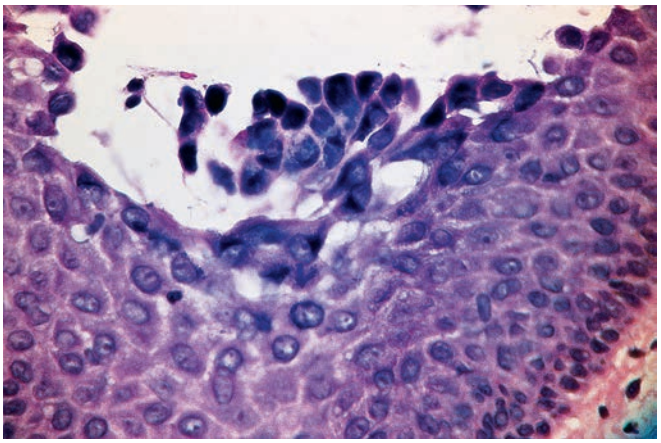

Figure 2.52 Pemphigus Erythematosus. The acantholytic cells are in a superficial location.

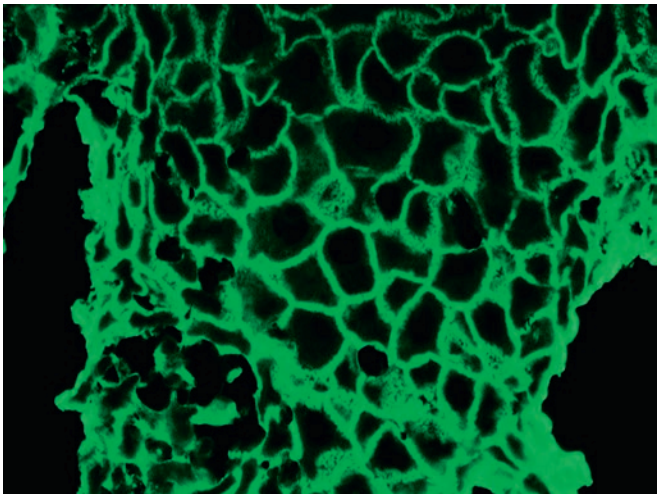

Figure 2.53 Immunofluorescent Demonstration of Anti-Pemphigus Vulgaris Antibody.

more intense in the dermal papillae. *Linear IgA disease* can be histologically and clinically indistinguishable from dermatitis herpetiformis.[274] Like dermatitis herpetiformis, it is characterized by subepidermal blisters with neutrophils along the dermoepidermal junction. It differs by having a linear pattern of IgA deposition along the dermoepidermal junction. Linear IgA bullous dermatosis is frequently triggered by adverse drug reactions.[274]

Intraepidermal Bullous Disease

Intraepidermal bullous dermatoses are characterized by acantholysis and intraepidermal blisters. These disorders include a variety of conditions, including the pemphigus group (pemphigus vulgaris, pemphigus vegetans, pemphigus foliaceus and pemphigus erythematosus), Darier disease, Hailey-Hailey disease, and Grover disease.

Pemphigus

The pemphigus group consists of a variety of related diseases. In *pemphigus vulgaris* and *vegetans*, the pattern of acantholysis results in a cleavage plane just above the basal layer (Fig. 2.51), whereas in *pemphigus foliaceus* and *pemphigus erythematosus* the split is in or just below the granular layer (Fig. 2.52).[262,275–277] Indirect immunofluorescent stains performed with sera of patients with pemphigus demonstrate the presence of antiepithelial autoantibodies in most cases, although the test may be negative in the early stages (Fig. 2.53).[278,279] In addition, IgG and complement C3 can be detected in more than 90% of cases in the epidermal intercellular spaces by a direct immunofluorescence technique.[280] These autoantibodies directed against desmogleins play an important role in the pathogenesis of pemphigus.[281–286] Some cases of pemphigus are seen in association with internal organ malignancies (paraneoplastic pemphigus).[286–288] A statistically increased incidence of internal malignancies has been observed in patients with pemphigus, in addition to the well-known association between pemphigus and thymoma.[288]

Acantholysis can be seen in several other dermatologic conditions, such as *familial benign pemphigus* or *Hailey-Hailey disease* (often located in inguinal folds and clinically resembling candidiasis and condylomas),[289] viral vesicles, the pemphigus-like lesions induced by D-penicillamine,[290] actinic keratosis, and the type of squamous cell carcinoma arising from it (adenoid or pseudoglandular), *Darier disease, warty dyskeratoma*, and *transient acantholytic dermatosis (Grover disease)*. The latter is characterized by transient edematous and

excoriated papules and vesicles located predominantly on the trunk, thought to be the result of the combined action of heat and sweating.[291–293] According to Chalet et al. the most important clue to the diagnosis is the association of acantholysis and spongiosis.[293] In addition, focal acantholytic dyskeratotic changes (sometimes limited to a single rete ridge) totally devoid of clinical significance can be found in association with a variety of localized lesions, such as dermatofibroma, basal cell carcinoma, melanocytic nevus, and malignant melanoma.[294,295]

In subcorneal pustular dermatosis, the vesicles are just beneath the keratin layer, as they are in *impetigo contagiosa*.[296,297] Another subcorneal vesicular lesion that has been mistaken clinically for junctional nevus is the blood blister, in which the erythrocytes are trapped beneath the thick stratum corneum of the toes or fingers. This has been termed talon noir and is commonly seen in athletes.[298]

Infections

Viral Diseases

The viral lesions of skin most commonly seen histologically are warts and condylomas. Molluscum contagiosum and herpesvirus infections are also commonly biopsied.

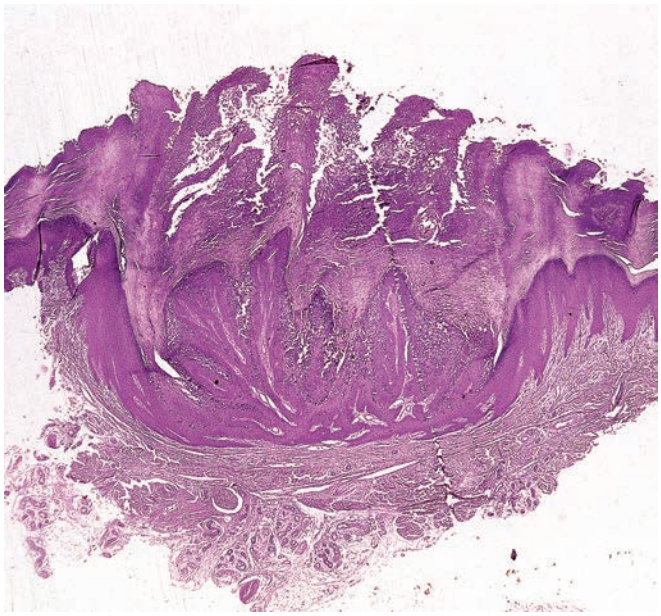

Figure 2.54 Verruca Vulgaris. The lesion is cup-shaped and highly keratotic.

Warts

Warts are cutaneous (and sometimes mucosal) lesions caused by one of the several human papilloma viruses (HPVs), papovavirus.[299–301] Several variants of warts occur, depending primarily on the HPV subtype, but also on the anatomic features of the region.[302–304] *Verruca vulgaris* (generally associated with HPV-2) usually occurs on the hands as an elevated, hard, rough, flesh-colored lesion. The top may be peeled off, leaving a pink granular surface. *Verruca plantaris* occurs on the sole of the foot, is covered by a callus, and is often painful. *Verruca plana* (usually associated with HPV-10) is, as its name indicates, a flatter lesion usually seen in crops or clusters on the face and hands. Flat warts disseminated throughout the body are a feature of the genetically determined *epidermodysplasia verruciformis*.[305,306] *Condyloma acuminatum* or "venereal wart" (usually caused by HPV-6 and HPV-11) occurs around the anus and vulva, on the glans penis, and sometimes in other mucosal membranes, such as the oral cavity. Genital warts with increased risk for developing dysplasia and subsequent carcinoma are predominantly caused by HPV-16 and HPV-18.

The histologic characteristics of these lesions are those of focal epidermal hyperplasia manifested by hyperkeratosis and parakeratosis, varying degrees of acanthosis, and (except for verruca plana) papillomatosis (Fig. 2.54). A trichilemmal type of keratinization may be present.[307] Distinct vacuolization of the cells in the upper portion of the malpighian layer is a feature in early lesions; some of these abnormal cells have large cytoplasmic eosinophilic aggregates. Smaller vacuolated cells with pyknotic nuclei may also be seen in the lower portions of the thickened stratum corneum. In condyloma acuminatum, acanthosis may be florid, and tangential cuts can show isolated nests of squamous cells surrounded by inflamed dermis. Care should be taken not to overdiagnose such lesions as squamous cell carcinoma. Older verrucae may not show the microscopic changes that allow their recognition; they may appear simply as papillomas or keratoses. Flat warts undergoing involution exhibit marked mononuclear dermal and intraepidermal inflammation associated with degenerative epidermal changes.[308,309] The viral nuclear inclusions are basophilic, Feulgen positive, and DNase resistant. They can be demonstrated immunohistochemically and with an in situ hybridization techniques.[310] The eosinophilic cytoplasmic masses are not made of viral material but rather represent accumulations of tonofilaments.

Occasionally, benign or malignant skin tumors and tumor-like conditions of various types (e.g. seborrheic keratosis, squamous cell carcinoma in situ [Bowen disease], and invasive squamous cell carcinoma) are seen superimposed on HPV-induced lesions, suggesting a causal relationship.[311–313] In our experience, this is most common in elderly and immunocompromised patients (e.g. solid organ transplant patients). Epidermodysplasia verruciformis is another example.[314,315] Changes in keratin expression occur in the keratinocytes as a result of the viral infection, and further changes develop when a neoplastic process supervenes.[315,316]

Molluscum Contagiosum

Molluscum contagiosum is a skin disease produced by a *Molluscipoxvirus*, a virus specific to humans, present worldwide, and passed by direct skin to skin contact.[317,318] It occurs often in young individuals and may even be congenital.[319,320] Clinically, it is characterized by small, firm, usually multiple nodules that, when fully developed, have central cores from which white keratinous material can be expressed (Fig. 2.55). The microscopic picture is characteristic. The dermis is indented by a sharply delimited and lobulated mass of proliferating epithelium. As the cells differentiate within the mass, their cytoplasm gradually is filled by a faintly granular eosinophilic inclusion that displaces the nucleus and enlarges the cells (see Fig. 2.55). These molluscum bodies are formed of viral particles that are similar in size and mode of formation to the poxviruses.[321] Inflammation in the surrounding dermis is intense, sometimes in the form of an abscess[322] and sometimes in the form of a pleomorphic T-cell infiltrate that can simulate a lymphomatous/leukemic process.[323,324] Metaplastic ossification has been occasionally observed.[325]

Herpes Virus

Herpes zoster is a painful disease caused by the same virus that causes chickenpox (varicella). It may vary from relatively benign

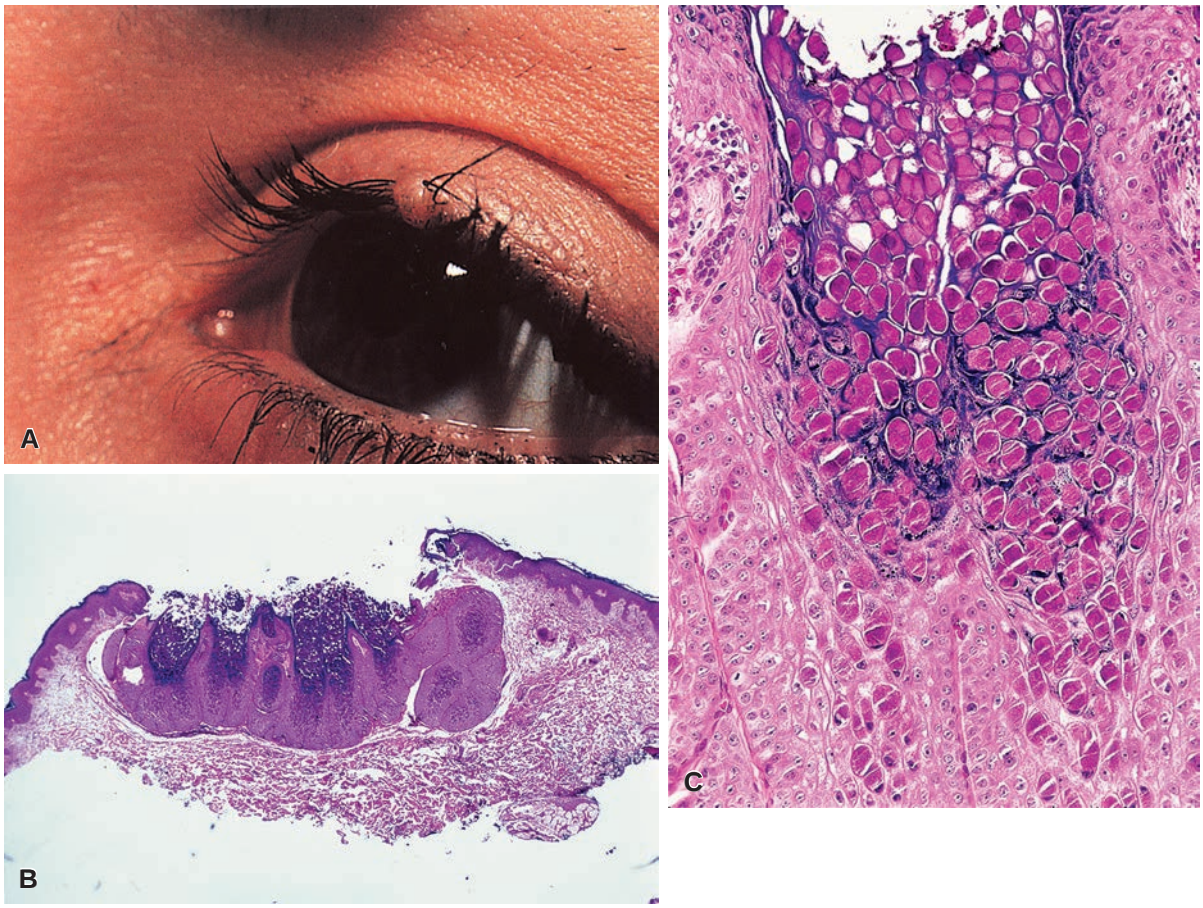

Figure 2.55 Molluscum Contagiosum. A, Clinical appearance of lesion located in eyelid. **B,** Low-power view of cup-shaped lesion. **C,** High-power view showing numerous molluscum bodies. (**A** courtesy Dr Carlos Ramos, Belleville, Illinois.)

pruritic lesions on the trunk, usually unilateral and in the distribution of a single dermatome, to severe involvement of the first division of the trigeminal nerve with herpetic keratitis and corneal ulceration.[326,327] Postherpetic neuralgia is the unpleasant sequela. Patients with leukemia and malignant lymphoma are particularly prone to develop herpes zoster infection.[328]

Oral and genital herpes are typically caused by herpes simplex virus 1 (HSV1) and HSV2, respectively, although either virus can be found in either location. Infection with both HSV1 and HSV2 results in recurrent, painful blistering eruptions.

The histopathologic features of varicella–herpes zoster are essentially identical to herpes simplex lesions, although it has been suggested that the lesions of zoster have a more prominent inflammatory infiltrate than herpes simplex lesions.[329] In both conditions, there are intradermal blisters with acantholysis and multinucleated keratinocytes with the characteristic intranuclear steel gray viral inclusions with peripheral margination of nuclear chromatin (Fig. 2.56). In some cases the dermal lymphocytic infiltrate can be of an intensity and atypia such as to simulate a malignant lymphoma.[330]

Bacterial Diseases

Folliculitis

The term folliculitis refers to an inflammatory process distributed around hair follicles and involving the follicular opening or adjacent perifollicular skin.[331] A fair number of cases are drug induced.[332] They have been divided microscopically into the following:

1. Infectious

   Superficial (usually suppurative): resulting from fungi, bacteria, syphilis, or viruses
   Deep (usually granulomatous): resulting from fungi or bacteria

2. Noninfectious

   Superficial (usually suppurative): acne vulgaris, rosacea, follicular mucinosis, steroid induced, etc.
   Deep (usually granulomatous): acne vulgaris (conglobate and keloidal forms), perforating forms, etc.
   Spongiotic: Fox-Fordyce disease, atopic dermatitis, pruritic folliculitis of pregnancy

3. Perifolliculitis

   Predominantly lymphocytic: lichen planopilaris, pityriasis rubra pilaris, rosacea, etc.
   Predominantly granulomatous: perioral dermatitis, rosacea, etc.

Demodex mites are more frequent in inflamed follicles than in normal ones, but it is not clear whether they play an etiologic role.[333] *Eosinophilic folliculitis*, as seen in adults and infants, is usually a human immunodeficiency virus (HIV)-related dermatosis.[334,335] The

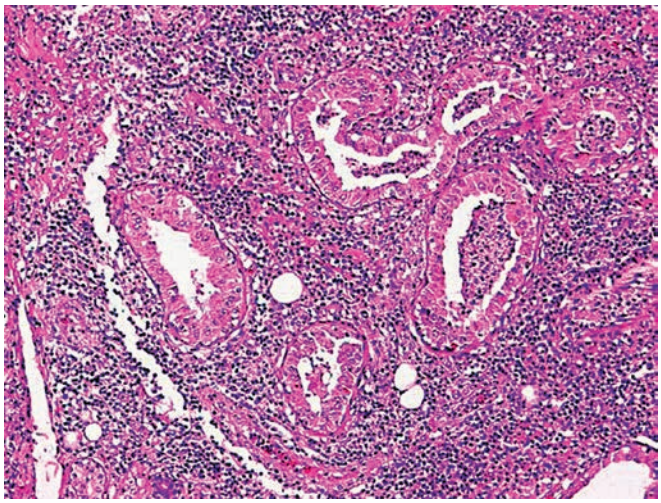

Figure 2.57 Hidradenitis Suppurativa. A heavy neutrophilic infiltrate is present around apocrine glands and in their dilated lumina. (Courtesy of Dr Raffaele Gianotti, Milano, Italy.)

Figure 2.58 Clinical Appearance of Lupus Vulgaris. The lesion presents in the form of an irregularly shaped red patch with elevated borders.

term *pseudolymphomatous folliculitis* has been proposed for a skin lesion usually located in the face and characterized histologically by a dense lymphocytic infiltrate of mixed nature centered around hair follicles, with infiltration of the follicular epithelium.[336] The suggestion has been made that some cases diagnosed as solitary sclerotic fibroma of the skin may be the end stage of a folliculitis.[337]

Hidradenitis Suppurativa

Hidradenitis suppurativa is caused by bacterial infection in and about apocrine glands, usually in the axilla but occasionally involving the perineum or vulva (Fig. 2.57).[338] Anaerobic organisms are the most important pathogens. Abscesses, sinuses, and perianal fistulas occur with subsequent scarring.[339] The process tends toward chronicity, and in refractory cases excision of the involved skin may be required.[340] The follicles into which the apocrine glands open are plugged by keratin and infection develops following stasis. At present, hidradenitis suppurativa is considered a disease of follicular occlusion (acne inversa) rather than a primary inflammatory/infectious process of apocrine glands.[341,342]

Tuberculosis and Atypical Mycobacteriosis

Cutaneous tuberculosis is an uncommon disease in the United States, although its incidence is on the rise.[343] It has various clinical and morphologic forms depending on the mode of entry and whether it is a primary or secondary infection.[343,344]

Lupus vulgaris is a reactivation type of tuberculosis. It generally involves the face, and the lesions are formed of red patches in which small, firm nodules reside (Fig. 2.58).[345] When pressed with a glass slide (diascopy), these nodules have a pale tan color. Microscopically, non-necrotic (sarcoid-like) and—less commonly—necrotic granulomas are found in the dermis (Fig. 2.59). Acid-fast bacilli are difficult to demonstrate but may be found. Cultures are recommended. The organisms can also be demonstrated with PCR methods.[346] Ulceration of the skin may occur. In longstanding cases, frank squamous cell carcinoma may arise from these lesions.

Papulonecrotic tuberculid is a skin lesion associated with tuberculosis but typically devoid of organisms; it is seen in both adults and children and is characterized microscopically by dermal necrosis, a poorly formed granulomatous infiltrate, vasculitis, and edema.[347,348] Rarely, the vasculitis is in the form of a nodular granulomatous phlebitis.[349]

Atypical mycobacteriosis can also affect the skin and result in a variety of lesions, including ulceration, abscesses, granulomas, diffuse histiocytic reactions, panniculitis, and rheumatoid-like nodules.[350–353]

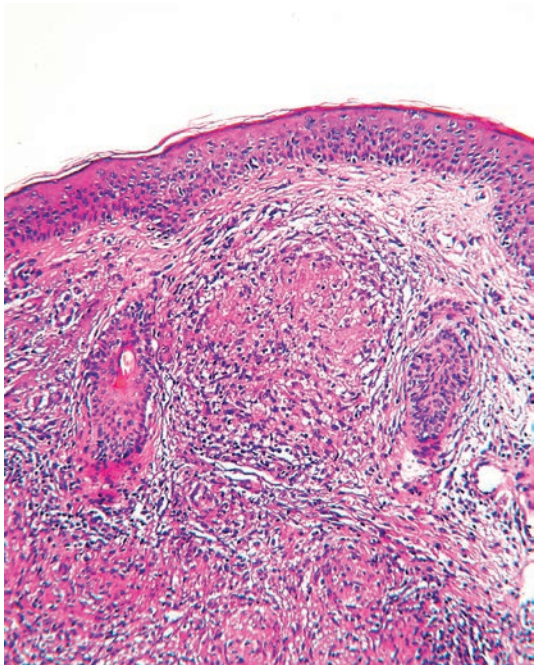

Figure 2.59 Tuberculosis of Skin (Lupus Vulgaris). Well-formed granulomas with necrotic centers are present in the dermis.

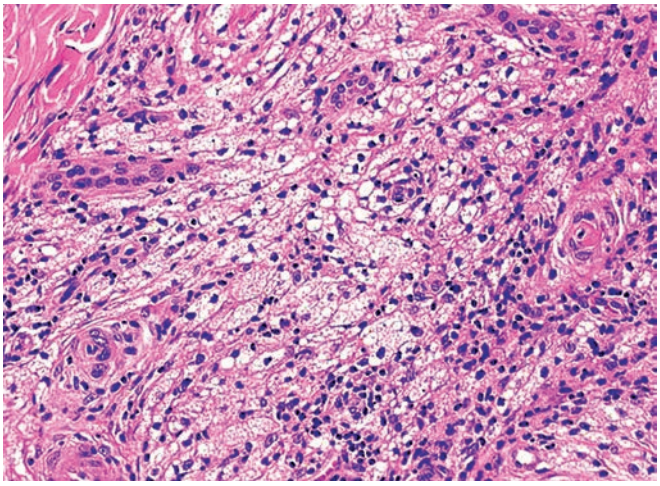

Figure 2.60 Lepromatous Leprosy. Large collections of foamy macrophages *(Virchow cells)* infiltrate the dermis.

Mycobacterium kansasii, M. marinum, and *M. ulcerans* are the organisms most commonly implicated.[350–353] Infection with atypical mycobacteria should be considered whenever routine bacterial cultures are negative.

Leprosy

In most regions of the United States, leprosy, or Hansen disease, is a rarity. However, an increased number of cases have been seen during as the result of the influx of immigrants from Asia and other regions of the world in which the disease is still endemic. Therefore the pathologist should consider it in the differential diagnosis of dermal granulomas and histiocytic tumors. In *lepromatous* and *dimorphic leprosy* the lepra or Virchow cells, filled with acid-fast bacilli, are plentiful (Figs. 2.60 and 2.61), whereas in *tuberculoid* and

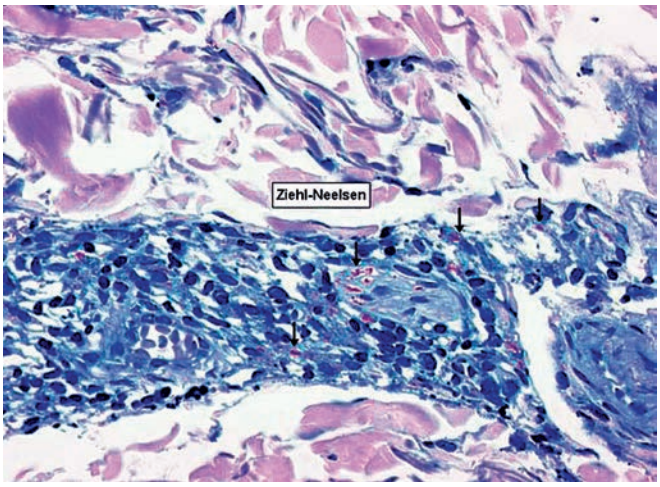

Figure 2.61 Acid-fast stain shows leprosy organisms *(arrows)* in a perineurial inflammatory infiltrate. (Courtesy of Dr Raffaele Gianotti, Milan, Italy.)

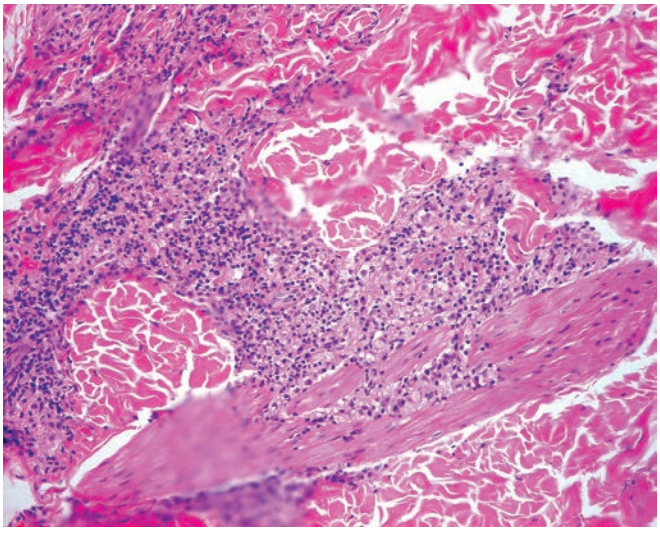

Figure 2.62 Infiltration of the Arrectores Pilorum Muscle by Inflammatory Cells. This is a diagnostic clue for the diagnosis of leprosy.

indeterminate leprosy, bacilli are very scanty.[354] As for tuberculosis, a PCR-based diagnosis of leprosy is now available.[355] A diagnosis of leprosy should be suspected whenever the granulomas or the lymphocytic infiltration is located in and around the cutaneous nerves or when seen infiltrating and destroying arrectores pilorum muscle (Fig. 2.62).[354,356] Histoid leprosy (a bad term) is regarded by most workers as a variant of lepromatous leprosy which follows resistance to dapsone therapy.[357] It presents clinically as sudden eruptions of dome-shaped nodules that can simulate keratoacanthomas or cutaneous metastases.[358] Microscopically, the dermis shows sheets of round to spindle-shaped histiocytes, with a pattern resembling benign fibrous histiocytoma.

Syphilis

The cutaneous lesions of secondary syphilis are of the maculopapular type and can be confused clinically with drug eruption, lichen planus, psoriasis, and other dermatoses (Fig. 2.63). Secondary syphilis can also present in the form of moth-eaten alopecia.[359] The microscopic

appearance can be nonspecific, especially in the macular lesions. The late papular lesions are more likely to exhibit the distinctive microscopic appearance of a dense perivascular or diffuse lichenoid infiltrate predominantly or almost exclusively composed of plasma cells (Fig. 2.64).[360] Noncaseating granulomas may also be present. The blood vessels characteristically show marked endothelial swelling and often proliferation. The cutaneous lesions of syphilis occurring in HIV-infected individuals do not differ significantly at the microscopic level from those seen in immunocompetent persons.[361]

Figure 2.63 Palmar Lesions of Secondary Syphilis.

Although the organisms can be detected by Steiner silver stains, immunohistochemistry is a significantly more sensitive and superior technique (Fig. 2.65).[362] Of interest, in primary syphilis, the spirochetes show a mixed epitheliotropic and vasculotropic pattern, whereas in secondary syphilis, the spirochetes are almost confined to lower levels of the epidermis in an intercellular distribution.[363] PCR methods to detect *Treponema pallidum* in biopsies and biologic fluid is also available.[364]

Lyme Disease

Lyme disease, a multisystem disorder caused by the spirochete *Borrelia burgdorferi*, is most commonly transmitted to humans by a tick

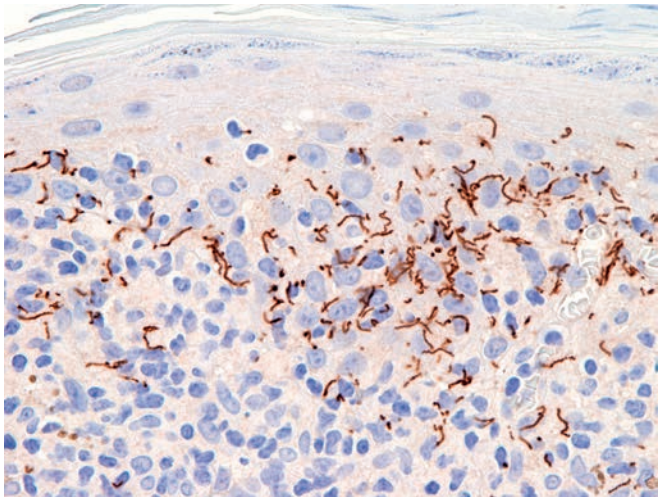

Figure 2.65 Numerous *Treponema* organisms are seen in this immunostain in a case of secondary syphilis. (Courtesy of Dr Fabio Facchetti, Brescia, Italy.)

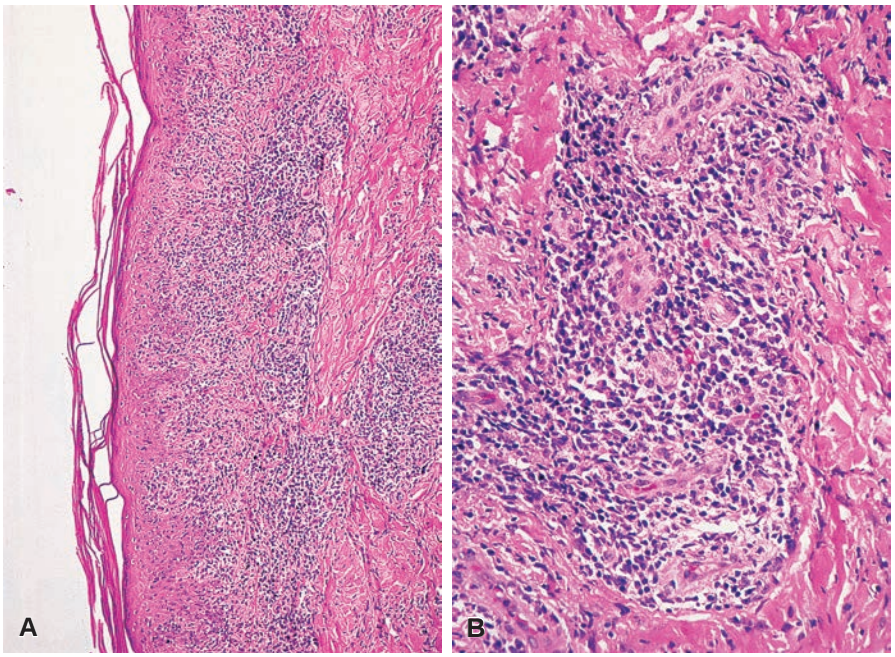

Figure 2.64 **Secondary Syphilis. A,** Low-power view showing a dense infiltrate predominantly affecting the upper dermis. **B,** High-power view showing markedly hyperplastic blood vessels surrounded by a lymphoplasmacytic infiltrate.

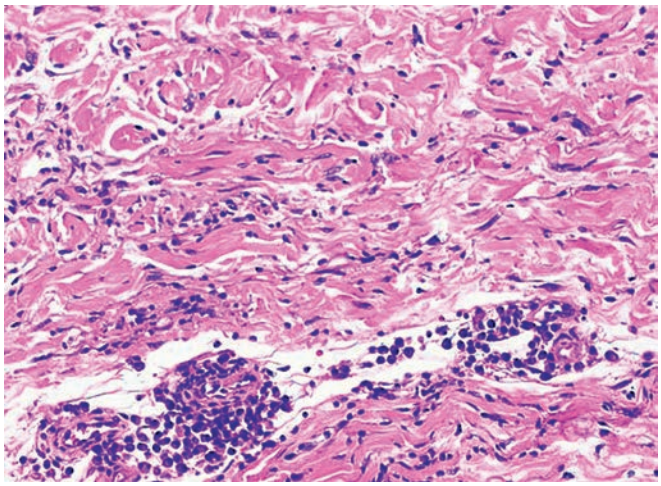

Figure 2.66 Lyme Disease. A perivascular infiltrate of lymphocytes and plasma cells is seen in the dermis.

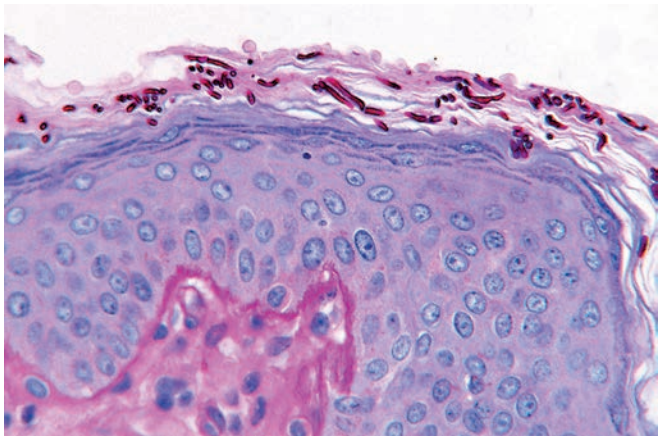

Figure 2.67 Dermatophytosis due to *Trichophyton*, demonstrated by periodic acid–Schiff stain.

bite.[365,366] It may be manifest in the skin as *erythema chronicum migrans* (currently regarded as pathognomonic of the disease), *acrodermatitis chronica atrophicans*, and *cutaneous lymphoid hyperplasia* ("borrelial lymphocytoma").[367–371] In the early stages the predominant microscopic finding is a superficial and deep perivascular infiltrate largely composed of lymphocytes but also containing plasma cells and/or eosinophils (Fig. 2.66). Spirochetes can be demonstrated with the Warthin-Starry silver stain.[372] The organisms have also been detected by PCR in synovial fluid.[373] Other organs that may be involved by Lyme disease in addition to skin include the heart, joints, and nervous system.

It has been suggested that some cases of morphea, lichen sclerosus et atrophicus, anetoderma, and atrophoderma of Pasini and Pierini may also be caused by borrelial organisms, but this remains controversial.[374,375]

Fungal Diseases

Tinea (Dermatophytoses)

In the dermatophytoses, the fungal spores and hyphae are found in the stratum corneum and in or about hair shafts (Fig. 2.67).[376] Mild epidermal changes, such as focal intercellular edema and varying amounts of dermal inflammation, may be seen. The fungal elements are readily seen in sections stained by the PAS or GMS methods. Occasionally, atypical clinical forms of tinea are biopsied, and the fungi are readily missed if not sought. Bacterial folliculitis and perifolliculitis may be superimposed on tinea of the scalp and beard. These lesions are known as *kerion celsi* and *sycosis barbae*, respectively, and may, on occasion, be mistaken for infected tumors. Histologically, cellulitis, abscesses, pseudoepitheliomatous hyperplasia, and a few fungi in the hair follicles and adjacent tissues are seen. A related disorder is *Majocchi granuloma (nodular granulomatous perifolliculitis)*, in which inflammation of dermal and subcutaneous tissue by dermatophytes is present; *Trichophyton rubrum* is the organism most commonly involved.[377]

It should be kept in mind that dermatophytes can be found superimposed on an inflammatory (pyoderma, scabies) or neoplastic lesion of the skin.[378] We have seen cases of mycosis fungoides that were missed originally because the atypical dermal lymphoid infiltrate was attributed to the fungi seen in the horny layer.

Figure 2.68 Clinical Appearance of North American Blastomycosis.

North American Blastomycosis

Isolated cutaneous blastomycosis is an uncommon lesion. Usually the skin lesion is secondary to pulmonary involvement, which may be subclinical.[379] Overall, approximately 20% of patients with blastomycosis have cutaneous lesions.[380] The causative organism, *Blastomyces dermatitidis*, is a spheric, double-contoured 12 µm ± 4 µm yeast. It reproduces by budding, and this characteristic allows its identification in sections. The skin lesions are slowly enlarging verrucous plaques in which numerous small abscesses are present (Fig. 2.68).[380] Microscopically, they are characterized by marked pseudoepitheliomatous hyperplasia and a mixed granulomatous and acute polymorphonuclear infiltrate (Fig. 2.69).[380] The accompanying pseudoepitheliomatous hyperplasia may cause diagnostic confusion with squamous cell carcinoma. The organism is generally found in giant cells. Smears and cultures are recommended diagnostic adjuncts (Fig. 2.70).

Chromoblastomycosis

Chromoblastomycosis is an indolent cutaneous disease with a verrucous or nodular gross appearance, often misdiagnosed clinically as carcinoma and therefore excised.[381–383] It is an occupation-related disease, mainly affecting individuals in tropical and temperate regions.[383] Hematogenous dissemination occurs very rarely.[384] The spores are

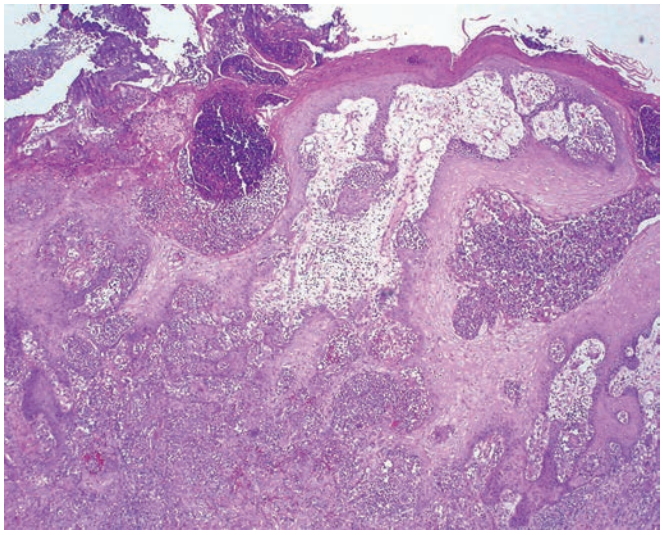

Figure 2.69 Blastomycosis. Pseudoepitheliomatous hyperplasia and dense neutrophilic infiltrate.

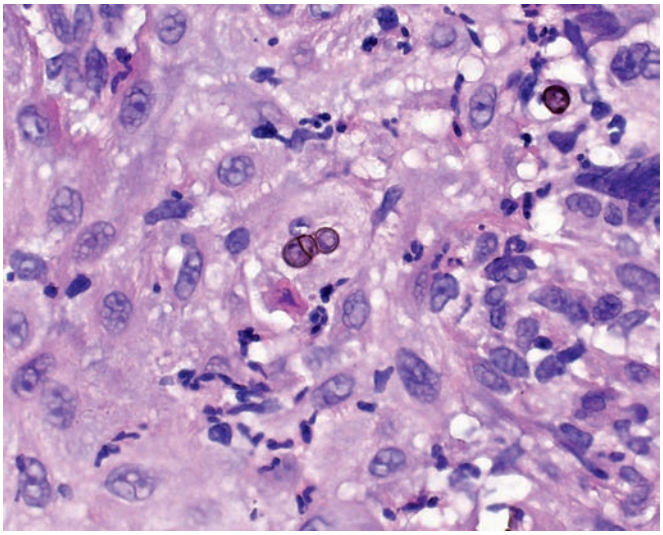

Figure 2.71 Chromoblastomycosis. Pigmented septate organisms.

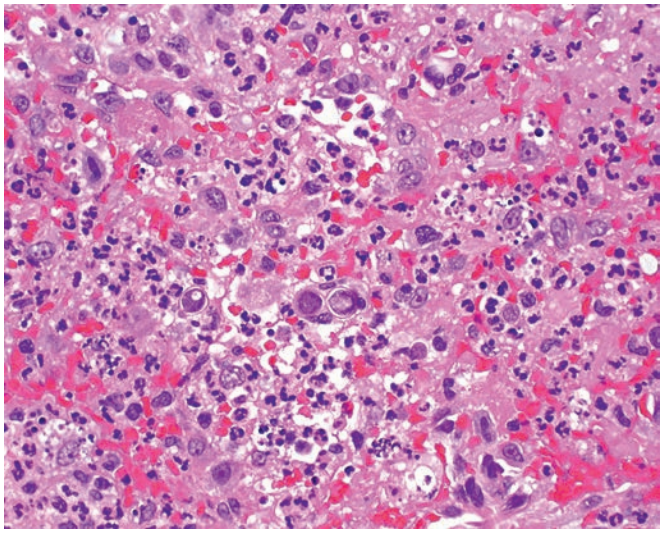

Figure 2.70 Blastomycosis. Budding yeast with thick refractile cell walls.

brown, hence their name, and the tissue reaction is similar to that seen in blastomycosis (Fig. 2.71). These fungi, closely related species of *Phialophora*, *Fonsecaea* and *Cladosporium*, multiply by cross wall formation and splitting. Their color, cross walls, and lack of budding distinguish them from *B. dermatitidis*. Sometimes, fungi with an identical appearance are found in subcutaneous abscesses.[385]

Miscellaneous Disorders

Foreign Body Reaction

Silica, talc, exogenous lipids, zirconium, beryllium, and aluminum induce granulomatous reactions within the dermis.[386–389] Residual particles of talc, silica, and lipids are demonstrable in tissue by routine or polariscopic microscopy. Beryllium, previously a component of the phosphorus in fluorescent lights, induces a distinct necrotizing and granulomatous reaction. Aluminum, used for vaccination and allergen desensitization, can induce a variety of changes in the injection site, including fat necrosis, panniculitis, prominent lymphoid follicle formation, and perifollicular lymphoid infiltrate. A clue to the diagnosis is the finding of histiocytes with a violaceous granular cytoplasm.[390]

Pyoderma Gangrenosum

Pyoderma gangrenosum is associated with a systemic disorder (such as inflammatory bowel disease) in approximately half of the cases.[391,392] It begins with an acute-phase necrotic pustule or furuncle and can evolve to a large and deep necrotic ulcer with a violaceous border and a surrounding halo of erythema.[392] Most lesions are found on the extremities. The majority are deeply seated, but they can also be superficial and vegetant.[393] Microscopically, the changes are those of hemorrhagic necrosis with abscess formation in the early stage and represented by a heavy infiltrate of lymphocytes and plasma cells in the late stage. Marked epidermal hyperplasia can be seen at the edges. The pathogenesis is probably immune mediated. Histologically, pyoderma gangrenosum does not have specific features but requires clinical correlation for diagnosis.

Elastosis Perforans

Elastosis perforans (serpiginosa) typically involves the back of the neck in adolescent boys.[394] Microscopically, clumps and strands of abnormally coarse elastic fibers penetrate the epidermis and produce a focal epidermal hyperplasia.[395,396] The altered elastica in the papillary dermis is easily missed and recognition usually requires elastic tissue stains.

Elastosis perforans needs to be distinguished from other perforating dermatoses, such as *reactive perforating collagenosis, perforating folliculitis*, and *Kyrle disease*.[397–400] The nosologic identity of the latter two disorders and their relationship to each other remains controversial. A high proportion of them are seen in patients with chronic renal failure (in hemodialysis) or diabetes mellitus.[401,402]

Pseudoxanthoma Elasticum

The dermal changes in *pseudoxanthoma elasticum* are manifestations of a heritable disease also having ocular and vascular lesions resulting from degeneration of elastic fibers and due to mutations of the

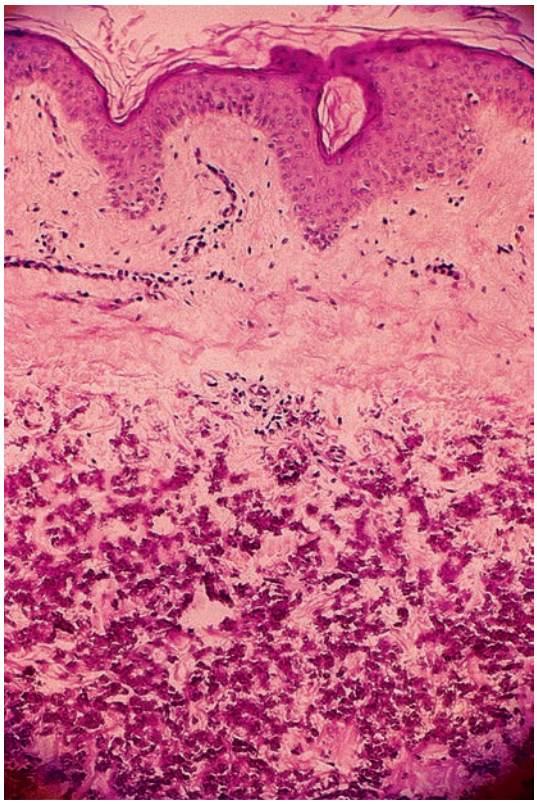

Figure 2.72 Pseudoxanthoma Elasticum.

Figure 2.73 **Clinical Appearance of Darier Disease.** The lesion typically affects the back and presents in the form of reticulated keratotic lesions.

ABCC/MRP6 gene (which codes for an ATP-binding protein).[403–405] Angioid streaks in the retina and degenerative changes in arteries leading to occlusion or rupture are described.[406] Yellow streaks and plaques of the skin, particularly in areas of creases, such as the neck, axillae, and groin, account for the name pseudoxanthoma. Histologically, the mid and lower dermis contains clumps and strands of altered, basophilic connective tissue that stain intensely with aldehyde fuchsin and Verhoeff elastic tissue stain (Fig. 2.72). The basophilic staining quality of the elastic material is due to dystrophic calcification of the fibers.

Cutaneous Mucinosis

Pretibial myxedema is characterized by sometimes large nodular lesions that occur on the legs of patients who are or have been thyrotoxic.[407] When particularly extreme, the disease has been referred to as *elephantiasic*.[408] The accumulation of mucopolysaccharides in the dermis is similar to that in the orbital tissues, which is caused by excess thyroid-stimulating hormone (TSH) secretion by the pituitary gland. Histologically, the dermal collagen is separated by aggregates of faintly basophilic material that stains with Mayer mucicarmine, Hale colloidal iron, and PAS (diastase resistant).

Other conditions associated with the deposition of large amounts of acid mucopolysaccharides in the dermis are the generalized myxedema of hypothyroidism, papular mucinosis (lichen myxedematosus), myxoid cyst, cutaneous focal mucinosis, and follicular mucinosis.[409–418] The latter condition is a reaction pattern of follicular epithelium that is particularly prominent in alopecia mucinosa but that can also be seen in a variety of other diseases, including mycosis fungoides.[419] Morphologically, the idiopathic and mycosis fungoides-related forms of the disease are similar; follow-up studies on patients with the idiopathic form have shown little or no progression toward mycosis fungoides, despite the presence in some cases of a clonal T-cell population.[419] *Cutaneous myxomas* (superficial angiomyxomas) are an important component of Carney complex, which also includes cardiac myxomas, spotty hyperpigmentation, and endocrine hyperactivity.[420]

Acanthosis Nigricans

Acanthosis nigricans manifests clinically as brown, velvety plaques most often found in the axillae, back of the neck, and other flexural areas. Two major forms exist, one associated with internal malignant neoplasms (particularly of the gastrointestinal tract) and the other with a heterogeneous group of disorders having as common denominator the presence of tissue resistance to insulin.[421–424] The latter form includes diabetes, obesity, and Cushing syndrome. Microscopically, the changes are similar in both types and are characterized by papillomatosis and hyperkeratosis (rather than by acanthosis and hyperpigmentation, as suggested by the name). In the cases associated with malignancy, the disease may be the result of production of epidermal growth factors by the tumor cells.[425,426]

Darier Disease

Although Darier disease has bullous features, it is not an autoimmune inflammatory bullous dermatosis. Darier disease is an uncommon genodermatosis caused by germline mutation of the *ATP2A2* gene.[427,428] It usually presents with a symmetrical distribution of keratotic reddish-brown papules over the seborrheic areas of the body (Fig. 2.73). Unilateral and localized variants have been described.[429] Microscopically, the skin lesions are characterized by suprabasal

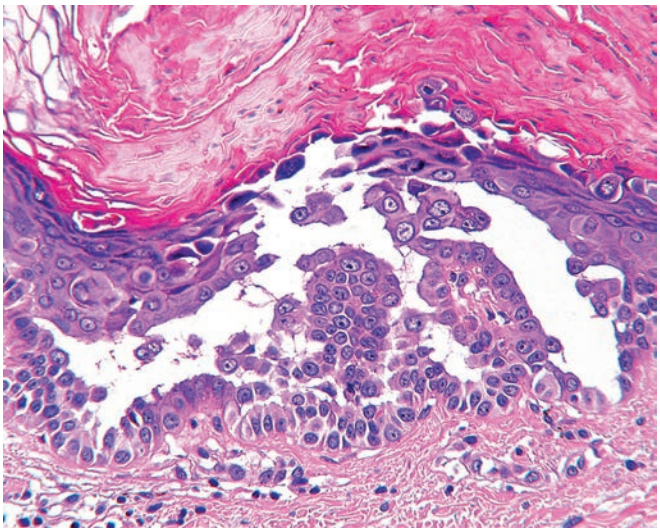

Figure 2.74 Darier Disease.

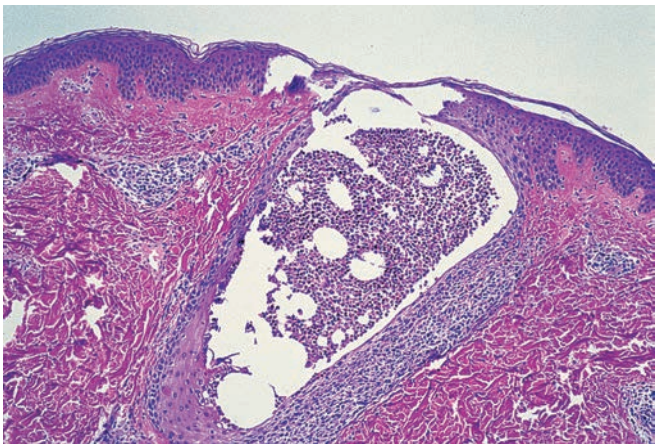

Figure 2.75 Eosinophilic Folliculitis in a Human Immunodeficiency Virus-Infected Patient.

clefts in which acantholytic cells called grains are found (Fig. 2.74).[430] The dermal papillae covered by a layer of basal cells form small villi at the base of the lesion. In addition, within the epidermis, large individually dyskeratotic cells called *corps ronds* are found. When the lesions are closely spaced, the skin assumes a verrucous appearance. The back is the most common site of involvement. The oral mucosa and hairless skin may be involved, showing that the disease is not limited to the hair follicle, as suggested by the synonym keratosis follicularis. *Warty dyskeratoma*, an isolated follicular lesion, is histologically similar but unrelated to Darier disease.

Dermatoses in HIV-Infected Patients

HIV-infected patients may develop a large variety of skin diseases, ranging from inconspicuous macular rashes to Kaposi sarcoma, the latter being the condition that contributed in the mid-1980s to the recognition of this immune deficiency syndrome.[431–434]

Non-neoplastic skin manifestations of HIV infection include the following:

1. Maculopapular eruptions. In acute HIV disease, approximately one-fourth of patients develop a maculopapular erythematous eruption in the trunk that may extend to involve the extremities. Microscopically, there is a nonspecific perivascular collection of lymphocytes and histiocytes in the upper dermis, sometimes associated with small papulovesicular foci with necrotic keratinocytes and a few neutrophils.[435,436]
2. Papular pruritic eruptions. These lesions, which may develop after the acute HIV phase, have a tendency for waxing and waning and can occur anywhere in the body. Microscopically, there is a superficial and mid-dermal perivascular lymphocytic dermatitis, often featuring eosinophils, acanthosis, and parakeratosis.[437]
3. Vasculitis. A few cases of leukocytoclastic vasculitis have been reported. Some have been said to be the direct result of HIV infection[438] and others of cytomegalovirus (CMV) infection.[439]
4. Folliculitis and syringitis. The clinical observation has been made that full-blown AIDS is often preceded by some manifestation of folliculitis.[440] Microscopically, the usual appearance is that of a mixed perifollicular chronic inflammatory infiltrate, sometimes associated with follicle rupture. In some cases the inflammation has a prominent eosinophilic component (HIV-associated eosinophilic folliculitis) (Fig. 2.75).[441] Herpetic syringitis (i.e. inflammation of the acrosyringium of the sweat glands) has been described, sometimes accompanied by squamous syringometaplasia.[442]
5. Seborrheic dermatitis. This common complication of HIV infection differs from that seen in immunocompetent individuals in that it tends to involve the trunk and extremities and is clinically more severe.[443,444] Microscopically, the changes depend on the stage of the lesion and are qualitatively similar to those seen in the usual form of the disease.
6. Psoriasis.
7. Drug reaction.
8. Parasitic (scabies), fungal (cryptococcosis, histoplasmosis, dermatophytosis), and bacterial (mycobacteriosis, syphilis, bacillary angiomatosis) infections.
9. Viral infections (other than these already mentioned). Herpes simplex occurs in approximately 20% of HIV-infected patients, usually in the form of a painful ulcer in the perianal or perioral regions (see Fig. 2.56).[445] Varicella–herpes zoster infection can be severe and widespread, sometimes with involvement of numerous dermatomes.[446,447] CMV may be detected in ulcerative lesions at mucocutaneous junctions. Other viral infections include measles,[448] molluscum contagiosum, oral hairy leukoplakia, and HPV-induced lesions (such as anal warts and bowenoid papulosis).[449]
10. Papular neutrophilic xanthoma. This HIV-associated lesion is characterized by collections of foamy macrophages, extracellular nuclear dust, and hyaline necrosis of collagen fibers.[450]

The skin is, contrary to the ubiquitous simplistic concept, a remarkably heterogeneous organ. The nodular lesions (hamartomatous, reactive, and neoplastic) that occur in the skin are more numerous than those produced by any other organ. For example, the eccrine sweat gland alone gives rise to 10 or more histologically distinct adenomas. This diversity, combined with a body of descriptive data (clinical, histologic, histochemical, immunohistochemical, and ultrastructural) amassed over the past century and dispersed in varying literatures, produces confusion, chiefly in the area of nomenclature. Within the limits inherent in a textbook that covers a breadth of surgical pathology specialties, it is impossible to pursue finite segmentation, interesting and accurate as it may be. The more common lesions will be discussed in some detail and pertinent references provided for the rare lesions.

Most of the mesenchymal tumors that may involve the dermis are discussed in the chapter on soft tissues. Only those showing exclusive or preferential involvement of the skin are included in this chapter.

Abstract

This chapter focuses on cutaneous tumors and tumorlike conditions of the skin. Epidermal tumors, adnexal tumors, melanocytic tumors, neuroendocrine tumors, cutaneous soft tissue tumors, and lymphoproliferative/hematopoietic lesions will be covered.

Keywords

Seborrheic keratosis,
squamous cell carcinoma,
basal cell carcinoma,
adnexal tumor,
melanocytic nevus,
melanoma,
Merkel cell carcinoma,
dermatofibrosarcoma protuberans,
atypical fibroxanthoma,
lymphoma

Epidermis

Seborrheic Keratosis

Seborrheic keratoses are common, benign, pigmented, predominantly basal keratinocytic proliferations occurring chiefly on the trunk of adults. They may be single or multiple. The sudden appearance of, or increase in the number and size of, seborrheic keratoses in association with internal malignant disease is known as the *Leser–Trélat sign*.[1]

Grossly, the lesions of seborrheic keratosis protrude above the surface of the skin, are soft, and vary in color from tan to black. The single, heavily pigmented seborrheic keratoses may be confused clinically with malignant melanoma.

Microscopically, the number of epidermal basal cells is greatly increased, presumably as a result of a maturation defect. The acanthotic pattern is the most frequent, in which a thick layer of basal cells is seen interspersed with pseudohorn cysts (Fig. 3.1). Some of these cells contain melanin, as the result of transfer from neighboring melanocytes. Other microscopic variants of seborrheic keratosis are the *hyperkeratotic*, *adenoid*, *acantholytic*,[2] and *desmoplastic*. The latter may simulate invasive squamous cell carcinoma.[3] *Psoriasiform keratosis* is a recently described condition combining features of seborrheic keratosis and psoriasis, the true nature of which still needs to be determined.[4,5]

Immunohistochemically, the keratinocytes of seborrheic keratosis invariably express low-molecular-weight keratin but often exhibit a deficiency of the high-molecular-weight keratins.[6,7]

In *irritated seborrheic keratosis*, squamous metaplasia is pronounced, often in the form of so-called squamous eddies. This phenomenon, presumably arising from the acrotrichia, should not be overdiagnosed as basosquamous carcinoma.[8] It does not seem to be related to human papilloma virus (HPV).[9] Instead, HPV can be identified in the seborrheic keratosis-like lesions of patients with *epidermodysplasia verruciformis*[10,11] and in those exhibiting bowenoid changes.[12,13] The latter should probably be interpreted as condylomas rather than as true seborrheic keratoses.[14]

Malignant skin neoplasms of various types (particularly basal cell carcinoma) may be seen contiguous or adjacent to lesions of seborrheic keratosis.[15] Seborrheic keratoses are genetically stable but frequently have mutations in a variety of oncogenes in the *FGFR3-RAS-mitogen-activated protein kinase (MAPK)* pathway but not tumor suppressor genes.[16]

Benign Lichenoid Keratosis

Benign lichenoid keratosis (lichenoid keratosis, lichen planus–like keratosis) presents as a solitary lesion, most commonly on the trunk or extremities of middle-aged and older patients. Clinically, they are often confused with basal cell carcinomas. Microscopically, the epidermis is acanthotic with hyperkeratosis and a thickened granular layer in association with a dense lichenoid lymphocytic infiltrate with interface change reminiscent of lichen planus.[17]

Acrochordon

Acrochordon is the preferred name for a common and inconsequential skin lesion also known as fibroepithelial papilloma, fibroepithelial polyp, fibroma molle, and skin tag. As these various names indicate, it is a polypoid lesion composed of varying amounts of stroma covered by a papillomatous epidermis. A clue to the diagnosis is the absence of adnexal structures in the underlying dermis.

A distinctive variant of this exophytic fibroepithelial process is represented by the *acquired (digital) fibrokeratoma*, characterized by collagenous protrusions covered by hyperkeratotic epidermis, usually occurring around interphalangeal joints but sometimes in other sites.[18]

Actinic Keratosis

In that portion of the epidermis exposed to sunlight, chiefly that of the near ultraviolet (UV) spectrum, a sequence of atrophic, hyperplastic, and eventually dysplastic changes known as actinic keratosis may develop.[19] The term "senile" keratosis, often used as a synonym, is inappropriate. An increased incidence of these changes has been found in renal transplant recipients, particularly in the lip region.[20] Histologically, actinic keratoses involve the interfollicular epidermis, sparing the follicular apparatus and the intraepidermal portion of the sweat duct, as demonstrated in the classic article by Pinkus.[21] The stratum corneum is replaced by a parakeratotic scale. Excessive production and accumulation of this scale lead to the formation of cutaneous horns. The granular layer is generally absent except at and about the follicular orifices. The malpighian layer shows disorderly maturation, as well as individually dysplastic and dyskeratotic cells (Fig. 3.2). Morphologic variations on the theme of actinic keratosis include basaloid proliferations resembling early basal cell carcinomas, changes along the dermoepidermal junction resembling lichen planus

Figure 3.1 Seborrheic keratosis with mild pigmentation in the skin of a senior pathologist. Pseudohorny cysts are evident.

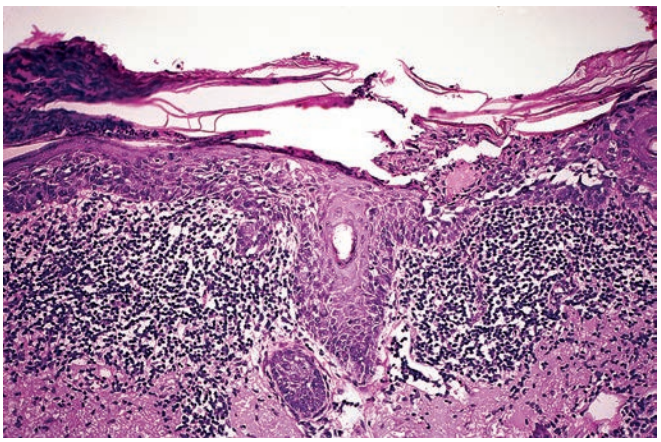

Figure 3.2 Actinic Keratosis. Note the hyperparakeratosis, moderate malpighian atypia, and dermal inflammatory infiltrate.

(lichenoid actinic keratosis), suprabasal acantholysis producing vesicles similar to those of pemphigus vulgaris, a marked degree of keratinocytic atypia throughout the malpighian layer (bowenoid actinic keratosis), and the presence of large atypical clear cells (pagetoid actinic keratosis).[22] Not infrequently, the basal melanocytes participate in the proliferation and atypia, resulting in a combination of actinic keratosis and actinic melanosis. Such cases appear clinically as heavily pigmented lesions.[23]

The papillary dermis is often chronically inflamed, and basophilic degenerative changes are prominent in the elastic fibers (solar elastosis). In florid forms of actinic keratosis, the atypical epithelial proliferation produces irregularly elongated acanthotic ridges, and this process extends down the external root sheaths of the hair follicles. In such cases, the differential diagnosis with superficially invasive squamous carcinoma inevitably arises.

Accumulation of p53 protein, presumably as a result of mutation, has been found in almost three-fourths of actinic keratosis lesions and found to correlate with the degree of atypia.[24] Genetically, mutation of TP53 is found in 50% of cases, being less frequent than in cutaneous squamous cell carcinoma.[25] The mutations in TP53 are predominantly C to T transitions, in keeping with ultraviolet radiation damage.[25] In addition, loss of heterozygosity at multiple chromosome sites is common.[26,27] Progression to squamous cell carcinoma may be mediated by inactivation of INK4A (p16).[28]

Actinic keratoses may be treated by a variety of methods—freezing, superficial curettage, application of antineoplastic chemotherapeutic agents, and surgical excision. Excision is unnecessarily radical therapy except for the more florid and infiltrative types and those not responding to topical 5-fluorouracil.[29]

Cutaneous Horn

Cutaneous horn (cornu cutaneum) is the traditional picturesque term for a protruding skin lesion largely composed of keratin and resembling a horn in shape.[30] The lesion can reach a gigantic size and truly resemble an animal horn.[31] Because the clinical appearance of cutaneous horn can result from a variety of diseases, cutaneous horn should not be used as a pathologic term. Most cases are caused by actinic keratosis, but others may be the result of verruca, seborrheic keratosis, inverted follicular keratosis, or squamous cell carcinoma.[32] The keratin formed is usually of epidermal type, but occasionally it has trichilemma-like features (i.e., it contains deep red granules). When this is the case, the lesion has been referred to as trichilemmal keratosis, verrucous trichilemmal tumor, and trichilemmal horn.[33,34]

Bowen Disease

Bowen disease is a form of squamous cell carcinoma in situ that consists clinically of indolent, scaly, erythematous plaques occurring predominantly on non-chronically sun-exposed skin (Fig. 3.3). Histologically, the lesions show a variety of atypical epithelial changes, such as cytoplasmic vacuolization, nuclear hyperchromasia, multinucleated keratinocytes, individual cell dyskeratosis, and increased number of mitoses, including atypical forms (Fig. 3.4). The maturation pattern is markedly altered (as made very apparent with the Mib-1 stain),[35] but some surface flattening and keratinization are almost always present. Extension of the process into the eccrine sweat glands may occur.[36] In its fully developed stage, Bowen disease can be regarded as a carcinoma in situ of the skin or as a form of squamous intraepidermal neoplasia, a concept supported by the presence of mutant p53 protein,[37,38] and of distinct aneuploidy in flow cytometric studies.[39] It should be emphasized that the diagnosis of Bowen disease is a clinicopathologic one.[40] Lesions showing similar microscopic changes but located in sun-exposed areas and having the clinical

Figure 3.3 Clinical Appearance of Bowen Disease. A slightly elevated red patch of irregular contours is seen. This clinical appearance conforms to the syndrome originally described by Bowen.

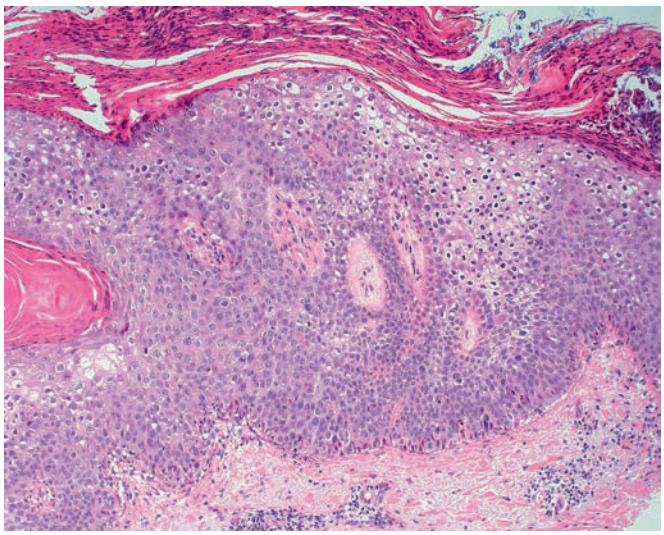

Figure 3.4 Microscopic Appearance of Bowen Disease. The atypia involves the full thickness of the epithelium. This example also has focal clear cell change.

appearance of actinic keratosis should not be diagnosed as Bowen disease but rather as *bowenoid actinic keratosis*. An important difference between the two conditions is that in actinic keratosis there are atypical squamous cells in the lower portions of the epidermis including the basal layer, whereas in Bowen disease there are atypical squamous cells in all portions of the epidermis but with preservation of the basal cells, which are arranged in palisades. Differences can also be appreciated at the immunohistochemical level.[41]

Occasionally, lesions of Bowen disease have a papillated appearance,[42] others show a verrucous–hyperkeratotic pattern, and still others contain large atypical clear cells simulating Paget disease *(pagetoid Bowen disease)*[43]; even more rarely, the latter two processes coexist.

Some studies have shown an apparent increase in the incidence of visceral cancer in patients with Bowen disease,[44,45] but others have failed to document such an association. Because arsenic is capable of inducing hyperplastic and dysplastic epidermal changes that may lead to the development of invasive squamous cell carcinoma, this element has been looked for in lesions of Bowen disease, but the search has proved inconclusive.[46]

Squamous Cell Carcinoma

General Features

The large majority of squamous cell (epidermoid) carcinomas of the skin are actinically induced,[47–49] one of the postulated pathogenetic mechanisms being the induction of TP53 mutations by ultraviolet light (Fig. 3.5).[50] The incidence of this tumor is directly related to the amount of exposure to the sun and the lack of pigmentation of the skin. Blond, blue-eyed, fair-skinned people living in Texas have a higher incidence of skin cancer than do their counterparts in Minnesota. Squamous cell carcinoma in black people is a very rare disease. In urban populations, frankly invasive squamous cell carcinoma is uncommon, whereas in rural populations it is common.[51] Nearly all of these actinic-induced tumors are preceded and accompanied by lesions of actinic keratosis.[52]

Squamous cell carcinomas of the skin can also be seen as a complication of the following:

1. Xeroderma pigmentosum, a genetically determined condition characterized by a diminished capacity for DNA repair following ultraviolet light irradiation.[53,54] These patients may also develop basal cell carcinomas and malignant melanomas.
2. Epidermodysplasia verruciformis, a generalized virally induced dermatosis.[55,56]
3. Cutaneous scars of various types: from burns (Marjolin ulcer), x-rays, epidermolysis bullosa, chronic osteomyelitic sinuses, necrobiosis lipoidica, acne aggregata seu conglobata, or hidradenitis suppurativa.[57–64]
4. Chemical exposure: arsenic, coal tars, soot, and a variety of oils and distillation products.[46]
5. Immunocompromise. In organ transplant recipients the carcinomas are often associated with severe actinic keratosis or, less commonly, widespread warts.[65,66] HPV has been detected in these lesions.[67,68] The clinical course can be very aggressive.[69] In the human immunodeficiency virus (HIV)-infected population there is an increased risk for both squamous cell and basal cell carcinoma.[70] The tumors tend to be larger, less differentiated, and more deeply invasive.[71]
6. PUVA-treated psoriatic patients, in whom the risk is dose dependent.[72,73]
7. Ichthyosis,[74] epidermal nevus,[75] porokeratosis,[76] and congenital lymphedema.[77,78] Only a few cases have been reported in each of these disorders.

Smoller et al.[79] have shown that an "activated" keratinocyte phenotype—characterized by a particular staining pattern for ψ-3, involucrin, filaggrin, and keratins—is the common denominator for the conditions that predispose to squamous cell carcinoma.

Microscopic Features

More than 80% of squamous cell carcinomas are well differentiated and, as such, produce large amounts of keratin (Fig. 3.6). Some of this is seen in the form of horn pearls, particularly in the better differentiated tumors; characteristically, keratohyaline granules within

Figure 3.5 Squamous Cell Carcinoma. A, Tumor of the face with rolled edges and depressed center. **B,** Tumor of the leg with exophytic appearance.

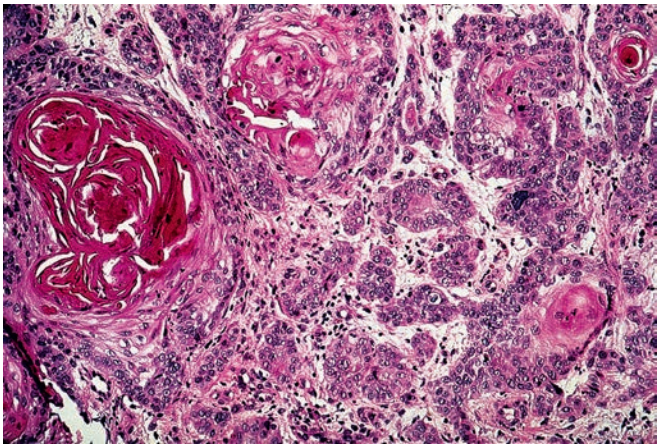

Figure 3.6 Deeply invasive, well-differentiated squamous cell carcinoma.

these pearls are sparse or absent. So-called intercellular bridges can be found with ease in most cases. The pattern of growth may be polypoid or even papillary[80] or may have a deep penetrating quality. Sometimes the tumors are cup-shaped in the manner of keratoacanthomas.

Invasion of the dermis is sine qua non for the diagnosis, but this may be a very subjective evaluation in the early stages. A lesion interpreted by some as florid actinic keratosis may be interpreted by others as a superficially invasive squamous cell carcinoma.[81,82] This is a reflection of the fact that actinic keratosis and squamous cell carcinoma are part of a continuous spectrum of squamous neoplasia. Fortunately, the issue is of no great practical importance, because the treatment and prognosis for these borderline lesions are essentially the same.

Squamous cell carcinoma may contain a population of non-neoplastic dendritic melanocytes, with transfer of some of the melanin granules into the cytoplasm of the tumor cells (pigmented squamous cell carcinoma); this phenomenon is analogous to that seen more commonly in basal cell carcinoma.[83]

Occasionally, the tumor has a clear cell appearance throughout, raising the differential diagnosis with a variety of adnexal tumors,[84,85] as well as suggesting the possibility that the change may reflect an abortive attempt at trichilemmal differentiation in the squamous cell carcinoma.[86] Even more rarely, the tumor may have a component of signet ring cells.[87]

Immunohistochemical and Molecular Genetic Features

Squamous cell carcinomas of the skin exhibit immunoreactivity for high-molecular-weight keratins, involucrin (a precursor of the cross-linked envelope protein of the stratum corneum), epithelial membrane antigen (EMA), and often also carcinoembryonic antigen (CEA) and p63.[88–91] Poorly differentiated tumors can also be immunoreactive for vimentin.[92] In contrast to basal cell carcinomas, squamous cell carcinomas tend to be negative for Ber-EP4 and CD10.[93–95] Basement membrane components, such as laminin and type IV collagen, can be found surrounding some of the tumor nests.[96]

Accumulation of p53 protein has been detected in close to half of cases.[97]

Up to 90% of cutaneous squamous cell carcinomas harbor the TP53 mutation, with frequent C→T or CC→TT transitions as signatures of ultraviolet radiation–induced mutagenesis.[98] The frequent presence of the TP53 mutation in the precursor lesion actinic keratosis, as well as normal-looking epidermal cells adjacent to squamous cell carcinoma, suggests that this genetic alteration is an early event in carcinogenesis.[98] Inactivation of the RB/P16 pathway through mutation or promoter hypermethylation of INK4A also appears to play a role.[99,100] Recent studies also implicate activation of the NF-κB pathway to contribute to the malignant phenotype of cutaneous squamous cell carcinoma.[101–103] Activating mutations in HRAS and KRAS are found in 46% and 4%–12% of cases, respectively.[104,105] Promoter hypermethylation of the E-cadherin gene CDH1 is reported in 95% of cases.[100]

Other Microscopic Types

Spindle squamous cell carcinoma (metaplastic sarcomatoid squamous cell carcinoma) usually occurs in sun-exposed areas and is relatively common in the lip (Fig. 3.7). The differential diagnosis includes malignant melanoma and atypical fibroxanthoma. Continuity of tumor cells with the basal layer of the epidermis, foci of clear-cut squamous change, and high-molecular-weight keratin immunoreactivity are the most important distinguishing features.[106–108] Vimentin is consistently coexpressed by these tumors.[109] *Carcinosarcoma* is the term used when there is a sharp segregation between the epithelial and the sarcoma-like components.[110] When the distinction between spindle cell carcinoma and a mesenchymal tumor is not possible (a not uncommon occurrence), the noncommittal term *sarcoma-like tumor of the skin* may be used.[111]

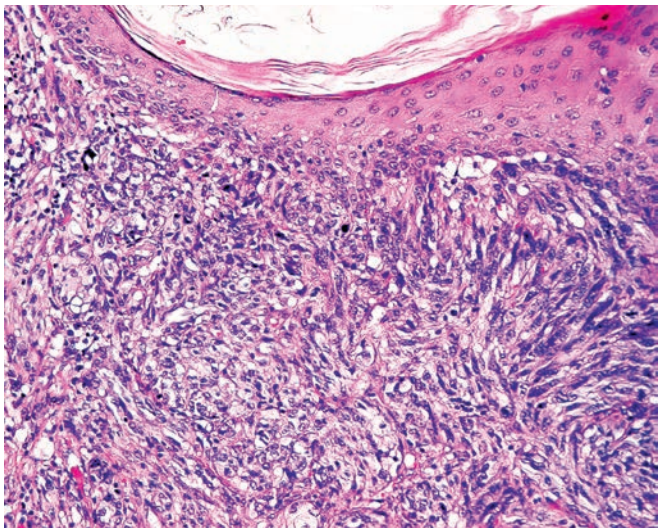

Figure 3.7 Squamous cell carcinoma with spindle metaplastic features.

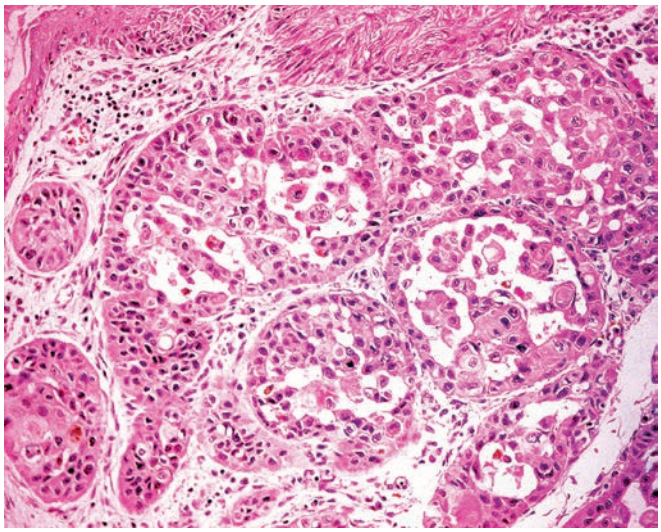

Figure 3.8 Adenoid (acantholytic) squamous cell carcinoma, resulting in a pseudoglandular appearance.

Adenoid (pseudoglandular; acantholytic) *squamous cell carcinoma* results from acantholysis (i.e., lack of cell cohesiveness caused by a desmosomal defect) (Fig. 3.8). Sometimes the pattern simulates an angiosarcoma (pseudoangiosarcomatous carcinoma).[112,113] Nearly all cases occur in sun-exposed areas, and many are associated with actinic keratosis with acantholysis. Immunohistochemically, there is a preferential reduction of the cell adhesion molecule syndecan-1.[114] The differential diagnosis includes primary and metastatic adenocarcinoma, true adenosquamous carcinoma of the skin (a rare aggressive neoplasm that exhibits squamous differentiation and mucin production),[115,116] and mucoepidermoid carcinoma (an even rarer tumor of probable sweat gland derivation).[117]

Figure 3.9 Verrucous Carcinoma of Skin. A, Typical appearance of lesion located in sole of foot. **B,** Papillomatous growth associated with hyperkeratosis and pushing type of invasion into the underlying dermis. (Courtesy Dr Daniel Santa Cruz, St. Louis.)

Verrucous carcinoma is an extremely well-differentiated type of squamous cell carcinoma, also known in the skin as carcinoma or *epithelioma cuniculatum*.[118,119] It appears as an ulcerated, fungating, and polypoid mass with openings of sinus tracts onto the skin surface. Most cases are located in the sole of the foot (Fig. 3.9). Local invasion is the rule, and extension to bone is frequent, but nodal metastases are exceptional.[120,121] It is regarded as the cutaneous counterpart of the more common verrucous carcinoma of the oral cavity and other mucosal membranes, and, like them, it may be positive for HPV.[122]

Treatment

Complete excision remains the treatment of choice for most squamous cell carcinomas.[123,124] Careful pathologic examination, including inked surgical margins, allows identification of those cases in which the tumor has been transected. Depending on the size and location of the tumor and the general condition of the patient, alternative therapies include curettage and electrodessication, cryotherapy, and radiation therapy.[47]

Prognosis

The overall prognosis of squamous cell carcinoma is excellent, particularly for the actinic-induced tumors.[125] Superficially invasive cancers (less than 1.5 cm) metastasize only occasionally.[126] Even in lesions larger than 2 cm with unequivocal invasion into the reticular dermis, the incidence of regional lymph node metastases is less than 5%. The best prognostic factors are staging, level of dermal invasion, and vertical tumor thickness.[127,128] In one series, all tumors that recurred were 4 mm or more thick and involved the deep half of the dermis or deeper; all tumors that proved fatal were at least 1 cm in maximum thickness, and most extended into the subcutaneous fat or beyond.[127] In another series, the prototypical metastatic squamous cell carcinoma had a width of at least 1.5 cm, a vertical tumor thickness of at least 2 mm, poor differentiation, desmoplasia, and a mixed inflammatory infiltrate.[129] The presence or absence of actinic keratosis at the edge of a squamous cell carcinoma is not as useful a predictor of behavior as tumor thickness or level of invasion.[130]

Pseudoepitheliomatous Hyperplasia

At sites of trauma, chronic irritation, and ulcers, the reparative hyperplasia of the epidermis may produce seemingly invasive tongues of epithelial cells. This abnormality, known as *pseudoepitheliomatous* (pseudocarcinomatous) *hyperplasia*, can also be caused by mycotic infections (particularly North American blastomycosis), bromoderma, pyoderma vegetans, tuberculosis, syphilis, granular cell tumor, and melanocytic lesions (particularly Spitz nevi but also malignant melanoma).[131,132] The epithelial proliferation is generally associated with a dermal fibroblastic and vascular proliferation and a prominent acute or subacute inflammatory infiltrate. Characteristically, the proliferating strands of epithelium are thin, markedly elongated, anastomosing, and heavily infiltrated by inflammatory cells (Fig. 3.10).[133]

Clear separation of pseudoepitheliomatous hyperplasia from squamous cell carcinoma is not always easy. The width of the strands (thin in hyperplasia and broad in carcinomas) and the degree of keratinocytic atypia (greater in the carcinoma) are the main distinguishing features. It should be kept in mind that the presence of an intraepidermal inflammatory infiltrate, no matter how heavy, does not rule out the diagnosis of squamous cell carcinoma. We have seen several cases with clear-cut architectural and cytologic features of carcinoma that were repeatedly underdiagnosed as pseudoepitheliomatous hyperplasia because of their association with a prominent lymphocytic, neutrophilic, eosinophilic, or granulomatous infiltrate.

Basal Cell Carcinoma

General Features

Basal cell carcinoma derives its name from the cytologic similarity of the tumor cells to the normal basal cells of the epidermis and the

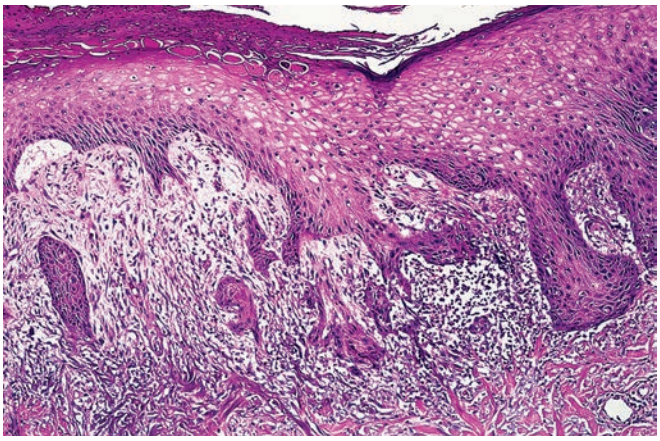

Figure 3.10 Pseudoepitheliomatous hyperplasia following removal of a benign nevus.

Figure 3.11 Gross appearance of basal cell carcinoma of forehead. The lesion is nodular and pigmented.

traditional belief that it arises from them. In our opinion, all basal cell carcinomas attempt to differentiate toward adnexal structures (particularly pilosebaceous units), but most of them remain at a stage so primitive as to render this recognition not immediately apparent.[134] The belief that basal cell carcinomas represent primitive "adnexal" carcinomas has been voiced over the years by several authors[135,136] and is supported by the marked immunohistochemical similarities that exist between basal cell carcinoma and tumors of indubitable hair follicle derivation,[137–141] among them the common immunoreactivity for CD10.[142] Some authorities who initially denied the concept have now gone as far as flatly stating that basal cell carcinoma is a trichoblastic carcinoma.[143]

Basal cell carcinoma is the most frequent form of skin cancer; it occurs predominantly on sun-exposed skin[144] in direct proportion to the number of pilosebaceous units present therein, a feature supporting the previously stated histogenetic interpretation.[145,146] Fair-skinned, blue-eyed persons engaged in outdoor occupations suffer a higher incidence of these tumors.[147,148] Synchronous and metachronous tumors are frequent.[149] Exceptionally, children and young adults are affected.[150,151]

Basal cell carcinomas may also develop in sunlight-protected skin,[152] in nevus sebaceus of Jadassohn, in the lower leg in association with chronic venous stasis and other preexistent conditions,[153–155] over arteriovenous malformations,[156] and following arsenic ingestion, x-ray exposure, skin injury, chickenpox scars, tattoos, hair transplantation scars, and immune suppression.

The clinical appearance of basal cell carcinoma is as variable as its histologic patterns. *Nodular*, *ulcerative*, *superficial*, *erythematous*, *sclerosing* (morphea-like), and *keloidal* forms occur (Fig. 3.11).[144,157]

Basal cell nevus syndrome *(Gorlin syndrome)* is characterized by multiple basal cell carcinomas, palmar pits, calcification of dura, keratocysts of the jaws, skeletal anomalies, and occasional abnormalities of the central nervous system, mesentery, and endocrine organs (Fig. 3.12).[158,159] Microscopically, the basal cell carcinomas in this setting exhibit a broader spectrum of subtypes than the sporadic tumors.[160,161] The syndrome should be suspected when basal cell carcinomas are seen in young people who have multiple tumors, many of which are of the superficial multicentric type and in which osteoid is an occasional finding. It is caused by a germline inactivating mutation in the *PTCH1* gene located at chromosome 9q22.3–q31.[160] Mutations in *PTCH1* are also found in a significant number of sporadic basal cell carcinomas.[144]

Figure 3.12 Multiple basal cell carcinomas in the skin of the back of an elderly patient.

Microscopic Features

As stated in the preceding section, basal cell carcinomas arise from basally located cells of the epidermis and pilosebaceous units and differentiate incompletely in the direction of adnexal (primarily follicular) structures.[162] Epidermal attachment is present in nearly all cases. The tumors may have solid, cystic, adenoid, keratotic, pigmented, infiltrating, and sclerosing (morphea-like) patterns (Fig. 3.13).[144,163,164] The keratotic pattern probably represents an expression of differentiation toward the infundibular portion of hair follicles, has no clinical significance, and should be distinguished from so-called basosquamous carcinoma.

The nests of basal cell carcinoma show prominent palisading and are surrounded by a typical loose stroma, which contains myofibroblasts and often exhibits myxoid change.[144,165] Cleft-like retraction spaces, some of artifactual nature and others resulting from the accumulation of stromal mucin, are often seen between

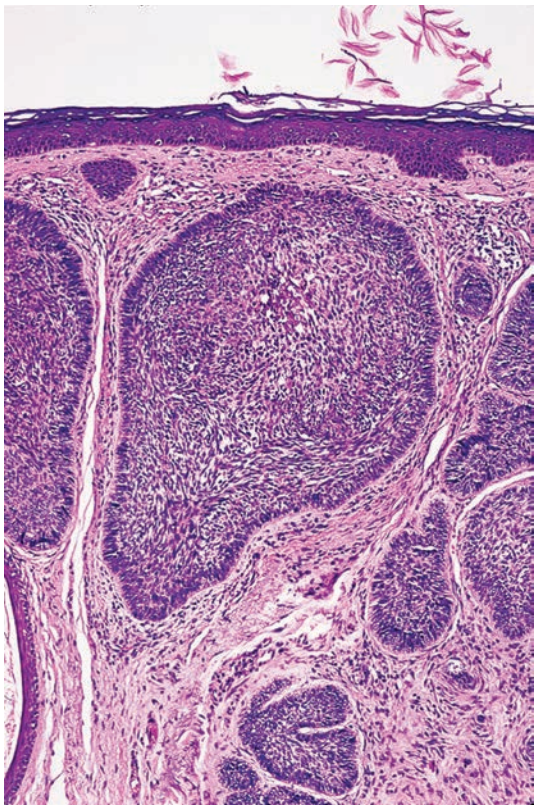

Figure 3.13 Typical nodular appearance with peripheral palisading of cutaneous basal cell carcinoma.

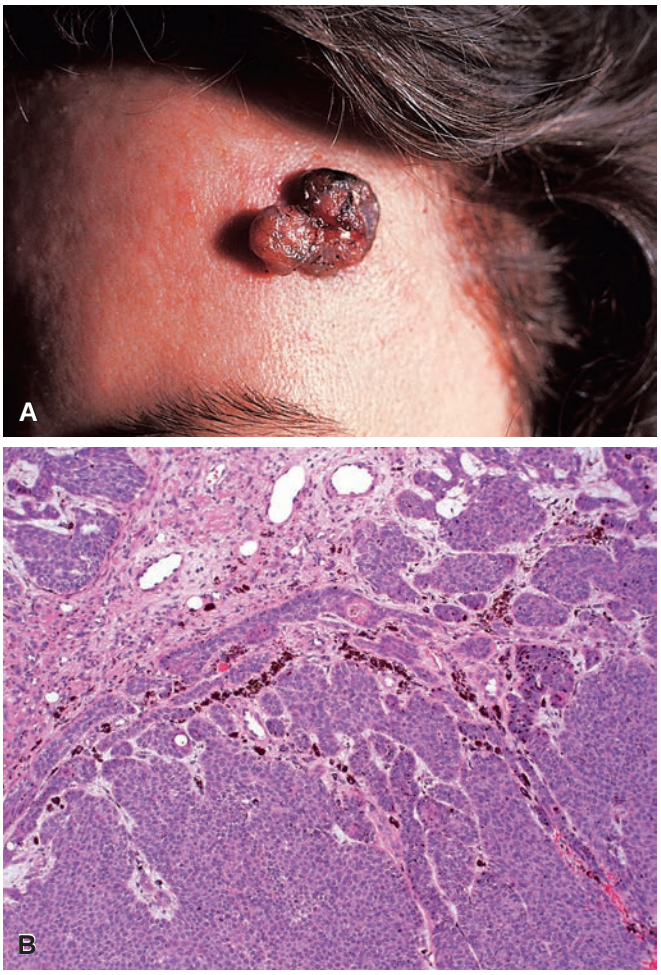

Figure 3.14 **A** and **B,** Clinical and microscopic appearance of pigmented basal cell carcinoma. Melanin is largely present in macrophages located in the stroma between tumor lobules.

the epithelial nests and the stroma.[166] Melanin can accumulate in dermal macrophages between the tumor nests and result in a "pigmented" appearance clinically and histologically (Fig. 3.14). Langerhans cells can also be present.[167] Intercellular amyloid material is not infrequent, sometimes accompanied by the deposition of immunoglobulins.[168,169] Oval to spindle tumor cells with hyaline eosinophilic cytoplasm have been found in a few cases[170] and interpreted by some authors as evidence of myoepithelial differentiation (see also section "Other Microscopic Types" later).[171] Mitotic activity (sometimes accompanied by atypical forms), marked atypia with the appearance of bizarre ("monster") tumor cells, and giant cell formation may occur, but there is no convincing evidence that any of these features carries prognostic significance.[144,172–174] In other instances the atypia is present in the reactive stromal cells and is equally inconsequential.[175] The stroma may undergo osseous metaplasia, sometimes to a considerable degree[176]; in other instances, it may contain peculiar collagen crystal-like structures.[177]

Rarely, matrical (shadow cell formation), eccrine, or sebaceous differentiation or markedly thickened basement membrane is seen in otherwise typical basal cell carcinoma, further supporting the close relationship of these tumors with adnexal structures.[178–182] Perineurial or endoneurial invasion by tumor cells is rarely present and is more common in the infiltrating/morpheaform variants.[183] Sometimes, a basal cell carcinoma is seen adjacent to a benign melanocytic nevus, the juxtaposition being a coincidental event.[184]

The differential diagnosis of basal cell carcinoma includes the areas of highly organoid basaloid proliferation sometimes seen in the epidermis overlying dermatofibromas[185] and the more atypical foci of basaloid proliferation that may be found in association with actinic keratosis and Bowen disease (see respective discussions).

Histochemical and Immunohistochemical Features

Immunohistochemically, the cells of basal cell carcinoma are positive for keratin (particularly low-molecular-weight type)[7,186,187] but usually negative for EMA, CEA, and involucrin.[88,90] Other markers commonly expressed are CD10 (as mentioned previously), Ber-EP4, and androgen receptors.[188] The basement membrane that surrounds the tumor nests reacts with antibodies against laminin, types IV and V collagen, and bullous pemphigoid antigen.[189,190] The pattern of staining for these markers tends to be attenuated and discontinuous, as an expression of the disruption of this structure.[191,192] This feature is more prominent in the aggressive tumors.[193]

A suggestion was made some years ago that basal cell carcinomas may show neuroendocrine differentiation, with immunoreactivity for CD56, chromogranin, and synaptophysin[194]; although the relatively common finding of argyrophilia may seem to support this contention, immunoreactivity for neuroendocrine markers, such as chromogranin or neuron-specific enolase (NSE), is uncommon.[195,196] Importantly, basal cell carcinoma is negative for cytokeratin 20, which allows distinction from Merkel cell carcinoma and trichoepitheliomas, which typically have scattered retained Merkel cells in the tumor islands.[197] It has been shown that most basal cell carcinomas stain for Ber-EP4, whereas most squamous cell carcinomas do not.[93,94,198] They also

commonly express BCL2, a feature of alleged value in the differential diagnosis with actinic keratosis and squamous cell carcinoma.[199,200]

Molecular Genetic Features

More than 80% of basal cell carcinomas overexpress p53 protein,[201] and this figure is even higher in the more aggressive types (see later). Clonal chromosome aberrations are frequent, most often represented by the numerical changes +18, +9, +20, +7, and +5.[202] Dysregulation of the Hedgehog pathway is a key pathogenetic event in basal cell carcinoma.[203] In the absence of Hedgehog ligands, protein patched homolog 1 (encoded by *PTCH1*) normally inhibits the transmembrane protein Smoothened (encoded by *SMOH*), leading to a cascade that represses expression of the Hedgehog downstream target genes. In basal cell carcinomas, inactivating somatic mutation and allelic loss of *PTCH1*, the gene implicated in the basal cell nevus syndrome, are common (67% and 53% of cases, respectively).[204–207] In 10% of cases, activating mutations of *SMOH* are present instead.[206,208] These genetic changes result in activation of the Hedgehog pathway. A recent study has successfully used GDC-0449, a small-molecule inhibitor of smoothened, for treatment of advanced basal cell carcinoma.[209] Vismodegib and sonidegib, both inhibitors of the Hedgehog pathway, have activity against basal cell carcinoma with significant antitumor effect in large unresectable tumors and rare cases of metastatic basal cell carcinoma.[210] Mutation in *TP53* is found in approximately 30%–40% of cases.[205,206] Presence of trisomy 6 has been correlated with the metastatic potential of the tumor.[211]

Other Microscopic Types

Superficial basal cell carcinoma arises in skin with sparse, fine hairs and epidermis that is thin, such as that of the trunk. It grows chiefly in a lateral direction, beneath a relatively flat epidermis, and exhibits a high recurrence rate.[144,212,213]

Basosquamous (metatypical) carcinoma has the general configuration of a basal cell carcinoma, but it also contains atypical squamous cells. This variant is more aggressive than conventional basal cell carcinoma. A high proportion of the metastasizing basal cell tumors belong to this type, which should be distinguished from the keratotic form of basal cell carcinoma.[214,215]

Granular cell basal cell carcinoma contains tumor cells with cytoplasmic granules analogous in every way to those seen in granular cell tumor of the dermis and other locations.[216,217] No clinical significance is ascribed to this variety.

Clear cell basal cell carcinoma contains tumor cells with prominent cytoplasmic vacuoles[218–220]; in other cases the tumor cells may even have a signet ring configuration,[221] perhaps indicative of myoepithelial cell differentiation.[222]

Infundibulocystic basal cell carcinoma is a variant of basal cell carcinoma in which evidence of hair follicle differentiation is much more evident and advanced than in the ordinary type; it could be viewed as being situated between the latter and trichoepithelioma in terms of the differentiation spectrum.[223]

Fibroepithelioma of Pinkus (fibroepithelial tumor; Pinkus tumor) often occurs on the back (Fig. 3.15). It has been traditionally regarded as a polypoid variant of basal cell carcinoma, and it has been suggested that the fibroadenoma-like pattern of this tumor is the result of eccrine duct spread.[224] Other authors view it as a "fenestrated" variant of trichoblastoma.[225] To us, this tumor provides yet another piece of evidence of the intimate relationship of basal cell carcinoma with the pilosebaceous unit.

Sarcomatoid basal cell carcinoma is a relatively new variant, characterized by areas of conventional basal cell carcinoma intimately admixed with heterologous bone formation (termed osteosarcomatous differentiation by the authors).[226] Its behavior does not seem particularly aggressive.

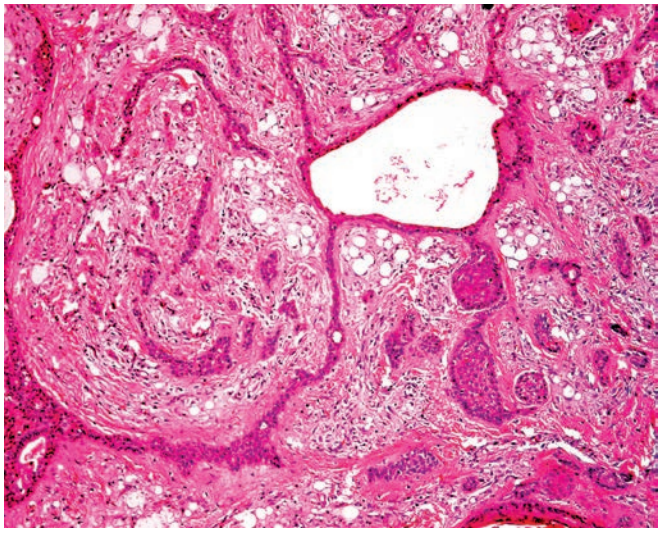

Figure 3.15 Highly organoid appearance of fibroepithelioma of Pinkus.

Spread and Metastases

Basal cell carcinoma usually grows in a slow and indolent fashion. However, if untreated, the tumor may invade the subcutaneous fat, skeletal muscle, and bone *("ulcus rodens")*. Tumors of the face may invade skull, nares, orbit, or temporal bone via the auditory canal. They can thus reach the central nervous system and produce lethal meningitis. Microscopically, the locally more aggressive tumors tend to show loss of peripheral palisading and a dense, fibrous stroma rather than a loose myxoid stroma.[227] At a statistical level, they also show decreased expression of syndecan-1[228] and BCL2,[229] greater expression of p53,[230] higher AgNOR count,[231] and higher incidence of aneuploidy[232] than the others.

In terms of location, local recurrence is more common in tumors of the nasolabial fold, inner canthus, and postauricular region.[163] This is probably the combined result of the highly irregular infiltrative pattern that these tumors often exhibit, and the fact that in these locations the distance to the surgical margins tends to be rather close.[233,234] In general, the microscopic appearance of the recurrence is not substantially different from that of the original tumor.[235] Distant metastases are extraordinarily rare, but more than 100 cases have been reported.[236–238] These include cases associated with the basal cell nevus syndrome.[239] Approximately 60%–75% of these metastases involved the regional lymph nodes, and the others affect such organs as lung, bone, and liver. Metastases in basal cell carcinoma are more likely in the basosquamous types, in those with perineurial spread, and in tumors located on sunlight-protected skin.[152]

Treatment

Excision, curettage and desiccation, and irradiation used appropriately cure most basal cell carcinomas.[123,148,240,241] Even when these tumors extend to the margin of surgical excision (an occurrence of approximately 5% in large series), only one-third will show evidence of recrudescence over the ensuing 2–5 years.[242] Thus immediate reexcision is not always indicated under these circumstances. Actually, it has been suggested that evaluation of the pattern of tumor growth (widely dispersed vs. tightly clustered nests) is a better predictor of local

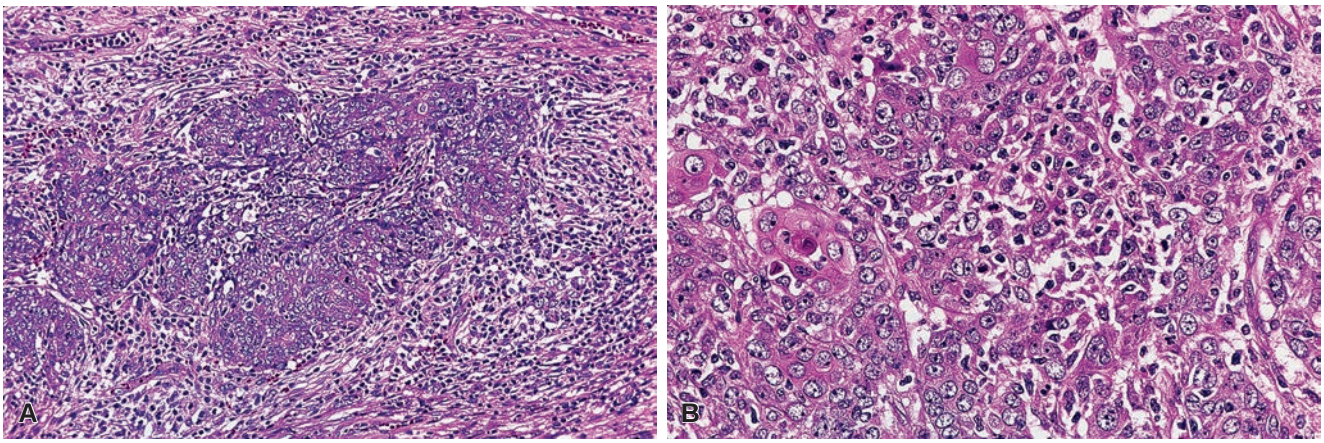

Figure 3.16 **A** and **B,** Low- and high-power views of lymphoepithelioma-like carcinoma.

recurrence than presence or absence of tumor at the surgical margins.[243]

Recurrent basal cell carcinomas can be treated with radiation therapy or surgical reexcision.[244] In some institutions, these recurrent tumors (and increasingly, many others, whether recurrent or not) are being treated by a procedure known as Mohs micrographic surgery.[245–247] In this setting the Mohs surgeon reviews complete en face surgical margins by frozen section, to ensure complete evaluation of the margins intraoperatively. In the United States, this technique has been advocated for certain basal cell carcinoma subtypes and for basal cell carcinomas in cosmetically sensitive locations.[241] While there is literature that supports the concept that this results in a decrease in local recurrence, use of this technique does need to be balanced with cost because it is significantly more costly than conventional excision for a relatively indolent tumor.

Skin Adnexa

The large majority of skin adnexal tumors differentiate only along one adnexal line, and this results in the formation of reasonably distinct types whose structure, cytochemistry, and immunohistochemistry can be correlated with those of the corresponding adnexa or even a subdivision thereof.[248–253] However, because all cutaneous adnexa share the same origin, it is not surprising that the tumors arising from them have many features in common, not only among themselves, but also with those of surface epidermal type. As a matter of fact, it is not unusual to find evidence of differentiation along two or more adnexal lines in different tumors occurring in the same individual or sometimes even within the same neoplasm, whether benign or malignant.[254–257] The tumors described as cutaneous adnexal carcinomas with divergent differentiation are an expression of the latter phenomenon.[258]

Lymphoepithelioma-like carcinoma of the skin may also represent a primitive adnexal neoplasm. As the name indicates, this lesion shows a morphologic resemblance to the tumor of the upper respiratory tract that bears that name, but it also exhibits features suggestive of early sweat gland and/or follicular differentiation (Fig. 3.16).[259,260] It does not seem to be related to Epstein–Barr virus (EBV).[261]

Eccrine Sweat Glands

Eccrine Poroma

Eccrine poromas occur chiefly on the palms and soles but have been reported in many other sites. They often show a moat and hillock pattern and, histologically, are characterized by a sharp junction between the proliferating, nonpigmented, small keratinocytes and the adjacent epidermis (Fig. 3.17). Within these cords and nests, ducts and sharply outlined squamous islands may be formed.[262] The tumor may be purely intraepidermal, purely intradermal (also referred to as *dermal duct tumor*), or (more commonly) involve both areas.[263] Purely intraepidermal poromas have been described in the past as *hydroacanthoma simplex*.[264] Heavily pigmented and clear cell variants of this tumor have been reported.[265] Ultrastructural, enzymatic, histochemical, and immunohistochemical studies show that the predominant cell of eccrine poroma has features similar to those of the eccrine gland acrosyringium.[266,267] However, cases have been described with divergent differentiation toward apocrine structures.[268] EMA immunoreactivity is consistently present, and this stain helps in identification of duct lumens.[269] The dermis beneath often shows a distinct proliferation of reactive vessels and some inflammation. The main differential diagnosis of eccrine poroma is with basal cell carcinoma and seborrheic keratosis.

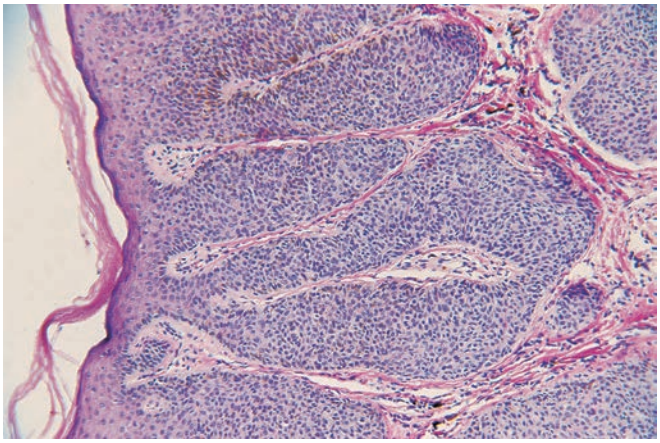

Figure 3.17 **Eccrine Poroma.** The tumor characteristically grows in the form of cords and nests of small tumor cells attached to the epidermis.

Eccrine poroma should also be distinguished from *acrosyringeal adenomatosis* (eccrine syringofibroadenoma), a peculiar condition in which papular lesions spread gradually and symmetrically to cover large areas of the body. Microscopically, they are formed by a diffuse proliferation of acrosyringium-related cells in the epidermis and dermis.[270,271]

Figure 3.18 Hidradenoma. The lesion is lobulated and shows a prominent clear cell component.

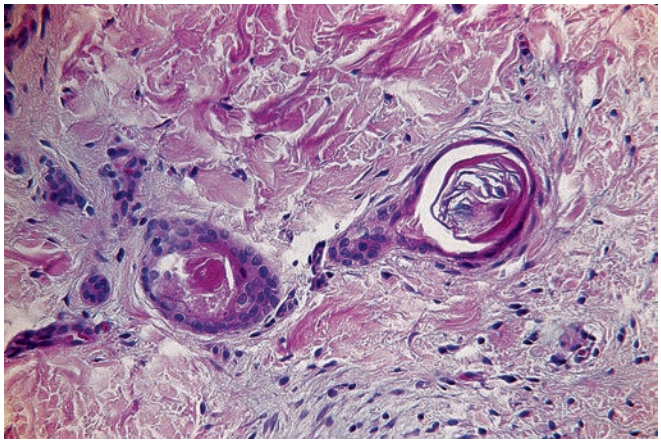

Figure 3.19 Syringoma. Small glandular structures with little "tails" are typical of this entity.

The behavior of eccrine poroma is benign, but a malignant counterpart of the tumor, known as eccrine porocarcinoma, exists.[272]

Hidradenoma

Hidradenoma, also known as *eccrine acrospiroma*, arises from the distal excretory duct.[273] It forms nodules with occasional cystic foci high in the dermis (Fig. 3.18). Some of the proliferating cells are cytologically similar to those of the poroma. Others have an abundant clear cytoplasm (hence the other synonym, *clear cell hidradenoma*), and still others exhibit prominent squamous metaplasia.[274] Immunohistochemically, there is reactivity for keratin, EMA, CEA, S-100 protein, and vimentin, although immunostains are not necessary for the diagnosis.[275] Johnson and Helwig[276] regard eccrine poroma as a subtype of eccrine acrospiroma (hidradenoma), although they are widely considered distinct entities currently. The differential diagnosis of hidradenoma can include glomus tumor because of the presence in both entities of round clear cells and marked vascularity; the distinction between the two entities is easily made by immunohistochemical evaluation.[275]

Syringoma

Syringomas are generally multiple, yellowish, papulonodular lesions that occur chiefly on the neck and face (particularly lower eyelids) of women. Other forms are *vulvar* syringoma, *acral* syringoma (limited to the dorsal proximal and middle phalanges of the hand), and *eruptive* syringoma (see later). Microscopically, these tumors are formed by clusters of small ducts lined by epithelium two cells thick, occasionally with comma-shaped extensions (Fig. 3.19). A clear cell variety has been described, resulting from intracellular accumulation of glycogen.[277]

The ultrastructural[278] and histochemical (enzymatic)[279] findings indicate that syringomas are of eccrine rather than apocrine nature. Specifically, the pattern of cytokeratin expression suggests differentiation toward the portion of the sweat duct located in the uppermost portion of the dermis and lower portion of the epidermis (sweat duct ridge).[280]

Eruptive syringoma appears as multiple yellow–brown papules on the neck, anterior trunk, axillae, shoulder, anterior surfaces of the arms, abdomen, and pubic areas of young people[281]; the process may be reactive rather than neoplastic.[282]

Mixed Tumor (Chondroid Syringoma) and Myoepithelioma

Mixed tumors are benign, nodular, nonulcerated tumors that occur predominantly on the face, head, and neck but also on the extremities and trunk.[283] Histologically, immunohistochemically, and ultrastructurally, their appearance is comparable to that of mixed tumors of salivary gland origin.[284–286] This includes the presence of cells with an abundant hyaline cytoplasm.[287,288] Sometimes, eosinophilic globules with radiating fibrillary structures are seen within and around the lumina, their appearance being analogous to that seen in collagenous spherulosis of the breast.[289,290] Immunohistochemically, the inner layer cells express cytokeratin, CEA, and EMA; the outer cell layers show variable staining for myoepithelial markers, such as vimentin, S-100 protein, actin, calponin, p63, and glial fibrillary acidic protein.[291–294] Although most of these tumors are thought to be of eccrine type, a variety exhibiting clear-cut evidence of apocrine differentiation has been well documented; this is often admixed with follicular and sebaceous components.[295,296] Despite the occasionally atypical appearance of the cartilaginous component, the large majority of these tumors are benign.

Tumors having a similar myoepithelial cell component but lacking the epithelial element are known as *myoepitheliomas* (Fig. 3.20)[297]; some of these behave in a malignant fashion, apparently with a higher frequency than the homologous salivary gland neoplasms.[293]

Tumors with an appearance similar to cutaneous chondroid syringomas and myoepitheliomas can also arise in the deep soft tissue.[298]

Cylindroma

Classically, *cylindroma* of the skin has been described as a large, multicentric tumor of the scalp (turban tumor) (Fig. 3.21). In fact, the majority of these slow-growing adenomas are solitary and small, and approximately 10% occur on sites other than the head and neck.[299] Exceptionally, they are seen in association with microscopically identical tumors in the major salivary glands.[300] Microscopically, the heavy accumulation of basement membrane material around and within the tumor lobules is the most important distinguishing feature (Fig. 3.22). The ultrastructural and immunohistochemical features indicate differentiation toward the intradermal coiled duct

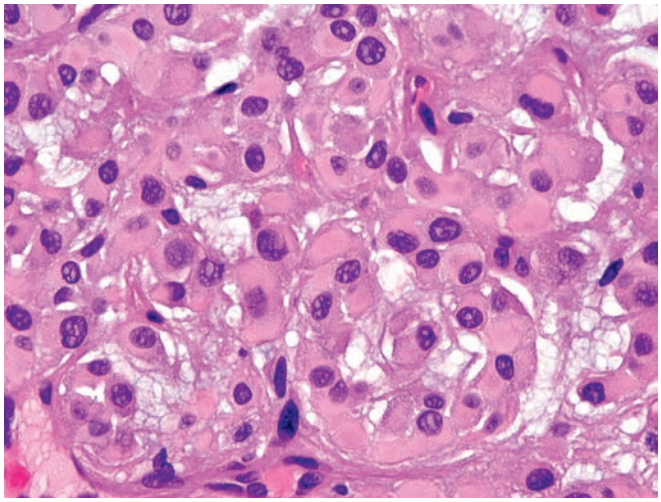

Figure 3.20 Myoepithelioma of skin consistent with sweat gland origin. The tumor cells have a typical hyaline cytoplasm. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

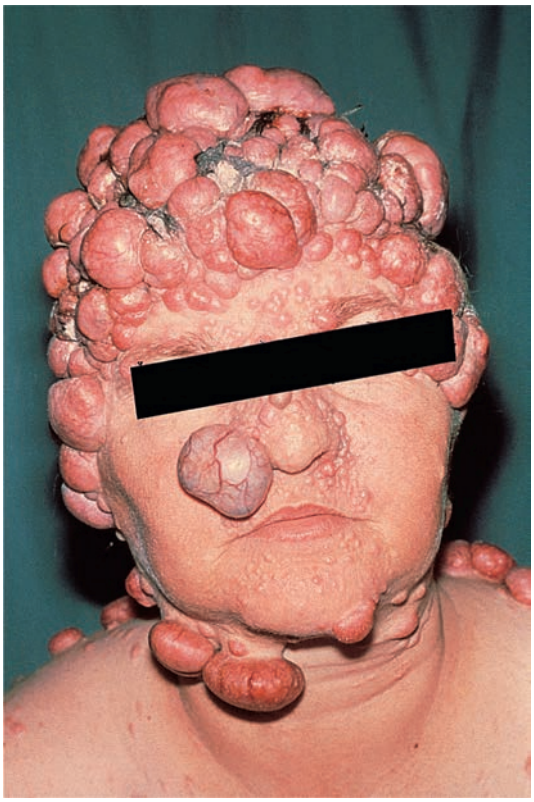

Figure 3.21 Clinical appearance of multiple dermal eccrine cylindroma extensively involving the scalp and other sites of the head and neck. This is sometimes referred to as turban tumor.

region of eccrine sweat glands,[301–303] provide evidence for the participation of myoepithelial cells,[304–306] and are very similar to those of eccrine spiradenoma.[307] Sometimes, features of cylindroma and eccrine spiradenoma coexist in the same lesion *(spiradenocylindromas)*.[308,309] Several examples of eccrine cylindroma undergoing malignant transformation are on record.

Multiple cylindromas are caused by a mutation in the *CYLD* gene, found on chromosome 16; both copies of this tumor-suppressor gene must be inactivated for the syndrome to occur.[310]

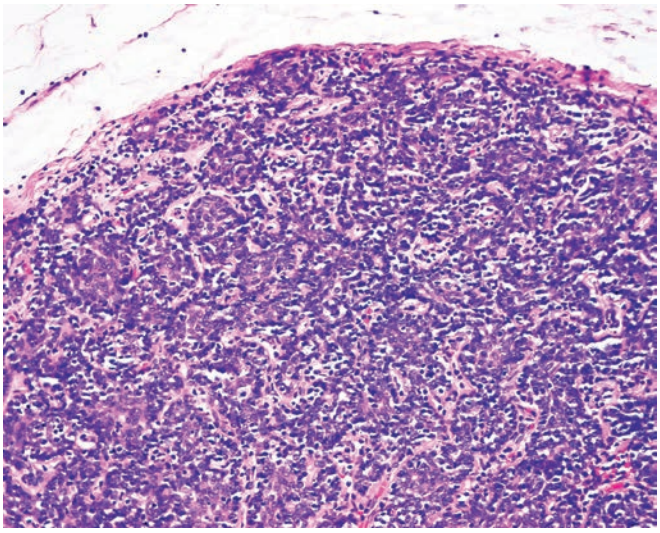

Figure 3.23 Eccrine Spiradenoma. The lesion is highly cellular and infiltrated by lymphocytes.

Spiradenoma

Spiradenomas are sharply delimited, lobular sweat gland adenomas that can occur almost anywhere in the body and can be extremely painful. They originate from the lower portion of the eccrine duct and are microscopically very cellular (Fig. 3.23).[311,312] The scanty cytoplasm and marked cellularity may lead the unwary to an erroneous diagnosis of malignancy.[313] We have seen them confused with synovial sarcoma and with metastatic carcinoma. They can also be confused clinically and microscopically with vascular tumors because of their high degree of vascularity (Fig. 3.24).[314] Ultrastructural and immunohistochemical studies have shown that these tumors contain an admixture of epithelial (secretory) and myoepithelial cells.[315–317]

In some spiradenomas, a heavy infiltration by lymphocytes (mainly of T-cell type) is present between the tumor cells; the resulting appearance is reminiscent of a thymoma. The analogy is accentuated by the presence of perivascular spaces containing lymphocytes.[317]

The tumor entity known as *cutaneous lymphadenoma* (not to be confused with cutaneous lymphoepithelioma-like carcinoma; see earlier) seems to represent a closely related phenomenon. It presents as multiple rounded lobules of basaloid cells with some peripheral palisading, foci of keratinization, and sometimes duct formation,

Figure 3.24 Clinical appearance of eccrine spiradenoma of the knee associated with a prominent vascular component that resulted in a hemangioma-like appearance clinically.

which are admixed with an intense infiltrate of small lymphocytes.[318,319] The immunohistochemical profile of this tumor has suggested to some authors a histogenetic link with trichoblastoma.[320]

On rare occasions, eccrine spiradenoma shows a focal atypical adenomatous component, the significance of which has not yet been ascertained.[321] In other instances it has been seen to undergo transformation to a high-grade malignancy.[322]

Syringocystadenoma Papilliferum

Syringocystadenoma papilliferum is a verrucous, moist tumor that occurs chiefly on the scalp, neck, and face but may be found elsewhere on the skin. It is seen from childhood to senescence, and often there is a history of slow growth or of a recent change in a "birthmark." Microscopically, a glandular papillary proliferation connected to the skin surface is seen. Dense plasma cell infiltration is common. These plasma cells are predominantly of the IgG and IgA classes.[323,324] Juxtaposed nevus sebaceus was found in one-third and basal cell carcinoma in one-tenth of the patients reported in the classic article by Helwig and Hackney.[325]

A malignant counterpart of this neoplasm *(syringocystadenocarcinoma papilliferum)* has been described,[326] as well as a variant containing a prominent fibrous component, known as *eccrine syringofibroadenoma* and sometimes developing in peristomal skin.[327,328]

Papillary Eccrine Adenoma

Papillary eccrine adenoma is a distinctive sweat gland tumor, most often located on the distal extremities of black people.[329] Microscopically, tubular structures resembling eccrine ducts are seen; many are dilated and exhibit intraluminal papillomatosis. Local recurrence

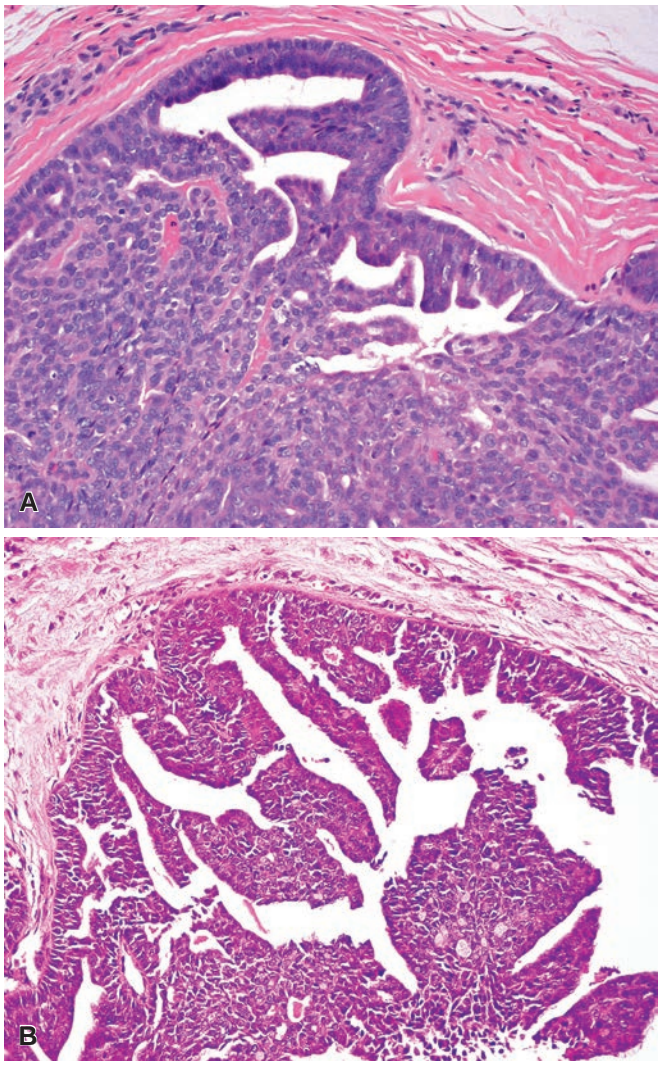

Figure 3.25 **Aggressive Digital Papillary Adenocarcinoma. A,** Primary tumor with areas of back to back glands as well as papillary areas. **B,** Metastatic tumor involving a lymph node.

may supervene, but none of the reported lesions has metastasized. Immunohistochemically and ultrastructurally, the pattern suggests differentiation toward the secretory epithelium of sweat glands.[330–333] The main differential diagnosis is with low-grade eccrine carcinoma.[334,335]

Digital Papillary Adenocarcinoma

Another sweat gland neoplasm with a marked predilection for the digits is *digital papillary adenocarcinoma*.[336,337] Formerly subdivided into adenoma and adenocarcinoma based on histologic features, it is now recognized that histologic features are not predictive of behavior and that all are considered carcinomas with metastatic potential.[337] Microscopically, tubuloalveolar and ductal structures alternate with areas of papillary projections protruding into cystic lumina (Fig. 3.25). The appearance is somewhat reminiscent of carcinoma of the breast. Local recurrence is common, and there is risk of metastasis to regional lymph nodes and the lungs.[337]

Clear Cell Acanthoma and Other "Acanthomas"

Degos clear cell acanthoma[328] is a morphologically distinct intraepithelial lesion composed of clear, glycogen-filled keratinocytes

associated with dermal inflammation. A minor melanocytic population may also be present.[338,339] Clear cell acanthoma is seen almost invariably in the leg of females, is occasionally multiple, and is thought to arise from intraepidermal eccrine ducts. Similar cytologic changes ("pale cell acanthosis") can be seen focally in seborrheic keratosis and several other skin disorders as an expression of a reaction pattern of epidermal epithelium.[340] As a matter of fact, clear cell acanthoma itself may be an exaggerated form of this process rather than a true neoplasm.

One could mention here that acanthoma is a generic term that has been used for "benign tumors of epidermal keratinocytes."[333] It comprises a large number of probably unrelated lesions, such as seborrheic keratosis, verrucous acanthoma, epidermolytic hyperkeratosis, warty dyskeratoma, acantholytic acanthoma, epidermolytic acanthoma, and large cell acanthoma.[333,335,341–345] Consequently, the term "acanthoma" has very little meaning when used without a qualifier.

Intraepidermal Epithelioma

The lesion traditionally known as *intraepithelial epithelioma of Borst–Jadassohn* is probably composed of a heterogeneous group of disorders, the two most common being irritated seborrheic keratosis and eccrine poroma (and related intraepidermal sweat gland tumors).[346,347]

Sweat Gland Carcinoma

Adenocarcinomas arising from eccrine glands constitute only a minute fraction of sweat gland neoplasms (Figs. 3.26 and 3.27).[348–350] Most occur in adults, but they have also been reported in children.[351] They can be very difficult to recognize at the microscopic level. Those with well-developed ductal differentiation simulate metastatic carcinoma, particularly from the breast,[352,353] a similarity highlighted by the fact that they can exhibit immunoreactivity for gross cystic disease fluid protein (GCDF-15) and estrogen receptor protein[354] (although usually not for HER2/neu)[355] The sweat gland carcinomas with large clear cells may resemble metastatic renal cell carcinoma,[356] and those with prominent basaloid formations may be confused with basal cell carcinoma.[357]

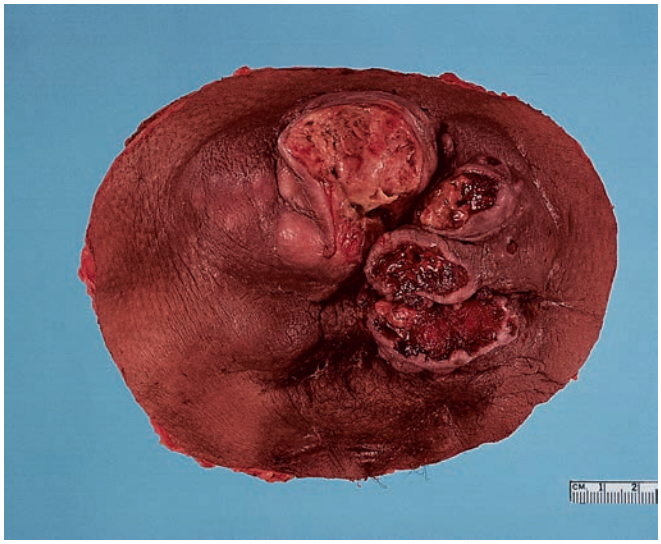

Figure 3.26 Gross appearance of resected specimen of sweat gland carcinoma of the axilla. The tumor grows in a multinodular fashion and shows several areas of ulceration.

Some sweat gland carcinomas retain morphologic features that allow them to be recognized as the malignant counterparts of the various types of sweat gland adenomas, as already alluded to in some of the previous sections.[358–360]

Porocarcinoma (malignant eccrine poroma) is the most frequent member of this group.[361,362] Most cases occur in the lower extremities, like their benign counterparts. Some of the lesions are pedunculated. Microscopically, the architecture is similar to that of eccrine poroma, but there is obvious atypia and high mitotic activity. Epidermotropism is a common feature of this tumor, the resulting picture being that of extramammary Paget disease.[363,364] Foci of squamous differentiation and clear cell features may be present.[365,366] Pigmentation may occur and lead to a mistaken diagnosis of malignant melanoma.[367] Metastases occur most frequently in the regional lymph nodes, this often following repeated local recurrences.[368]

Other distinct varieties of sweat gland carcinoma include malignant chondroid syringoma (malignant mixed tumor[369]) and the closely related myoepithelial carcinoma (Fig. 3.28),[297] malignant dermal cylindroma,[370,371] malignant syringoma (syringoid eccrine carcinoma),[372–374] hidradenocarcinoma (malignant acrospiroma),[360,375] digital papillary adenocarcinoma (see Fig. 3.25B),[337] and apocrine carcinoma.[376,377]

In addition to these presumably de novo lesions, eccrine acrospiroma, spiradenoma, syringoma, and cylindroma can undergo malignant transformation, the phenomenon manifesting clinically as enlargement of a cutaneous nodule of long standing.[378–382] This transformation is usually in the form of a high-grade carcinoma, including the variant known as sarcomatoid carcinoma or carcinosarcoma.[383]

Several other distinctive types of sweat gland carcinoma occur. One is *primary mucinous carcinoma*, often appearing in the scalp and the head and neck of elderly patients, especially involving the eyelids.[384–386] Its microscopic appearance resembles mucinous carcinoma of the breast by virtue of the presence of clusters of tumor cells floating in lakes of mucin. The similarity is reinforced by the fact that, on occasion, the mucinous pattern is associated with an infiltrating ductal pattern.[386] Both pure and mixed forms exist.[383,384] It appears likely to be related to *endocrine mucin-producing sweat gland carcinoma*, which shares clinical, morphologic, and immunophenotypic features.[387] The immunohistochemical profile of mucinous carcinoma suggests differentiation toward the eccrine secretory coil,[371,388] but some cases have been thought to exhibit apocrine-type features.[389,390] They may also contain a myoepithelial cell component, a useful feature in the differential diagnosis with metastatic carcinoma.[391]

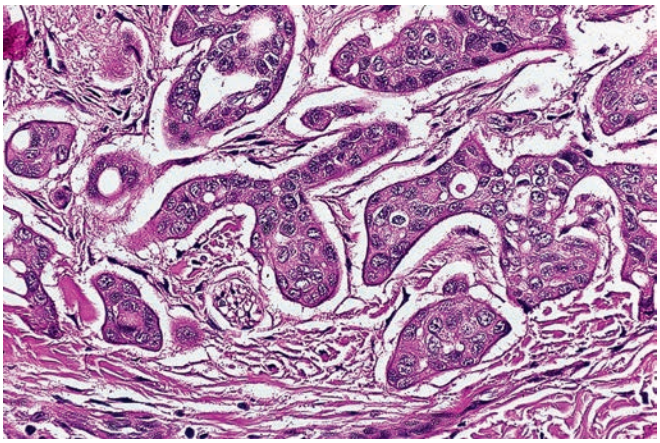

Figure 3.27 Typical branching configuration of sweat gland carcinoma.

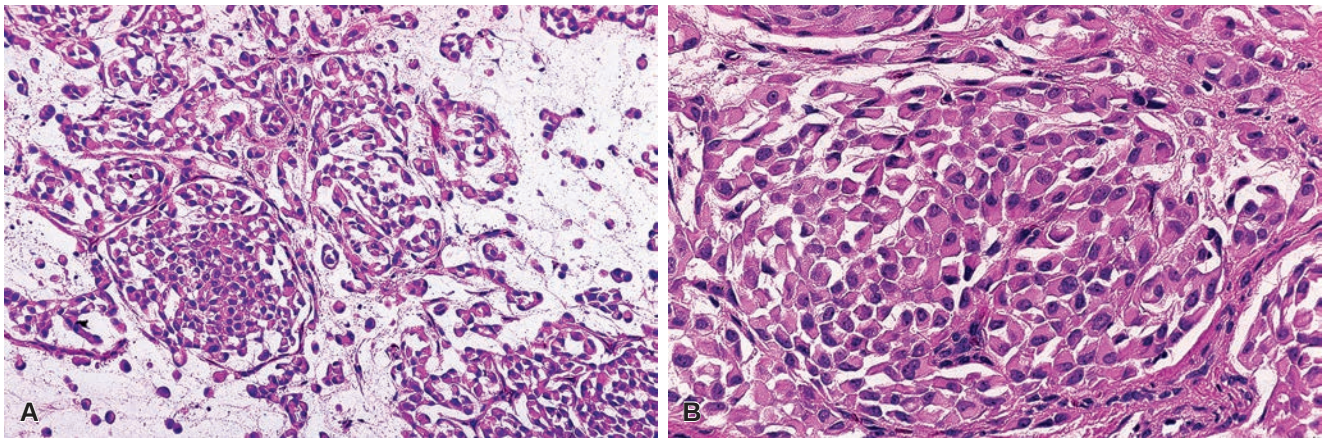

Figure 3.28 **A** and **B,** Sweat gland carcinoma of myoepithelial type located in the toe.

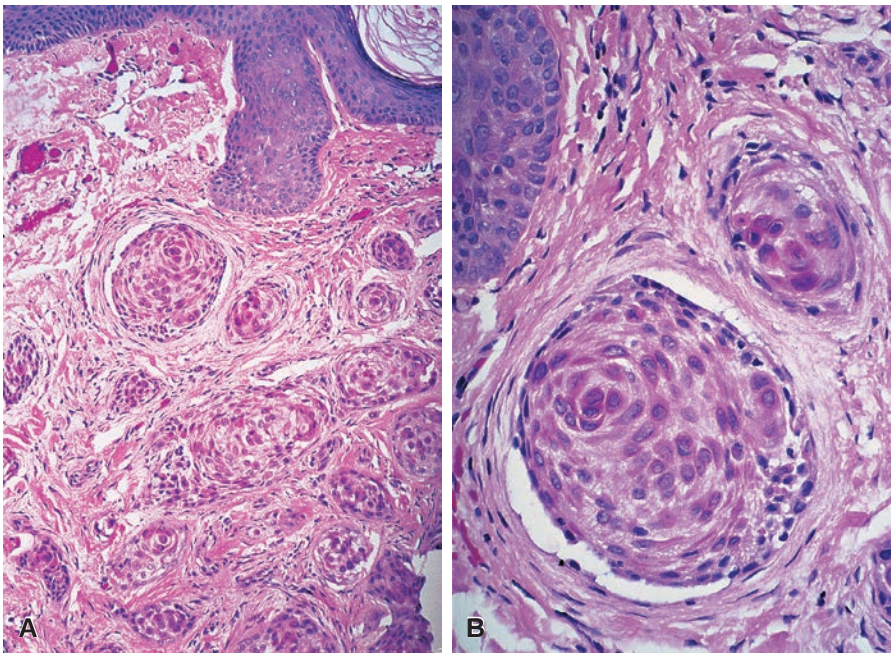

Figure 3.29 **A** and **B,** Microcystic adnexal carcinoma composed of nests of keratinocytes in a whorling pattern. This tumor was located in skin of upper lip in a 28-year-old woman.

This tumor should be distinguished from the even rarer primary *adenoid cystic carcinoma* and *mucoepidermoid carcinoma* of the skin, two tumors morphologically and immunohistochemically equivalent to the salivary gland neoplasms that bear those names.[392–396] More important, it should be distinguished from *mucinous syringometaplasia*, a non-neoplastic reactive change that can be accompanied by prominent epithelial hyperplasia.[397]

Another variant of sweat gland carcinoma, *microcystic adnexal carcinoma*, also termed *sclerosing sweat duct carcinoma*, appears as a slow-growing, indurated nodule or plaque, usually on the face.[398–400] The upper lip is a particularly common location. Microscopically and immunohistochemically, the tumor shares several features with benign syringoma and desmoplastic trichoepithelioma, and it may be impossible to distinguish on superficial biopsies.[401] Cords and nests of uniform keratinocytes, keratin-containing cysts, and foci of ductal differentiation are present (Figs. 3.29 and 3.30). Exceptionally, there is sebaceous differentiation.[402] The stroma has a dense, collagenous quality. There is often CK15 positivity, a potentially useful feature in the differential diagnosis with basal and squamous cell carcinoma.[403] The tumor has invasive properties, sometimes extending into the subcutaneous fat, perineurial spaces, and/or mandibular bone.[398–401,404] Recurrence is common, but metastases are extremely rare.[405]

Nearly all types of sweat gland carcinoma exhibit immunoreactivity for cytokeratin, CEA, and EMA, like their benign counterparts.[406,407]

Extramammary Paget Disease

Extramammary Paget disease results from the presence in the epidermis of carcinoma cells with signs of glandular differentiation. Concomitant involvement of eccrine glands and/or hair follicles is nearly always present, whereas dermal invasion is seen in a minority of cases, the frequency varying according to the location (extremely rare in the vulva and more common in the perianal region).[408] Cases limited to the epidermis are explained by postulating an origin from the intraepidermal portion of the sweat glands or from primitive basal cells with the capacity to differentiate toward glandular elements.[409,410]

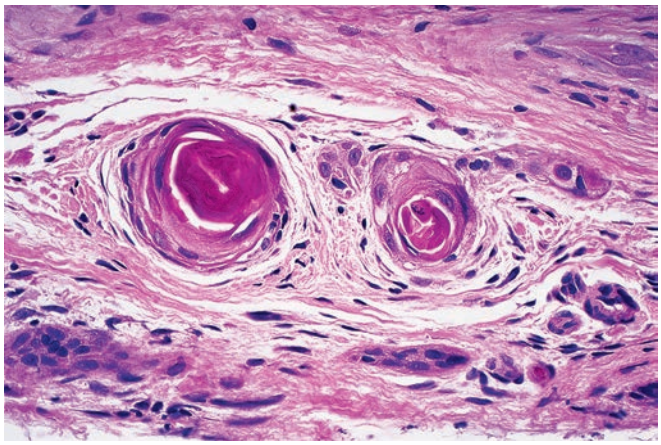

Figure 3.30 Microcystic adnexal carcinoma.

The labia majora, scrotum, and perineum are the most frequent sites, with adjacent areas following. The lesions are grossly circinate, annular, erythematous, and eczematoid plaques. Histologically, large, pale, vacuolated cells are seen concentrated just above the basal layer (Fig. 3.31). They may be single or arranged in rows, small nests, or glandular formations. A cleft-like separation is often seen between the Paget cells and the adjacent non-neoplastic keratinocytes. Electron microscopic examination shows that Paget cells are not altered keratinocytes or melanocytes but rather cells with glandular differentiation.[411] In contrast to Paget disease of the breast, the extramammary form is consistently positive for mucin stains.[412,413] Immunohistochemically, the tumor cells show reactivity for EMA, CEA, CK7, and CK19 (regarded as a marker or follicular stem cells)[414] and the types of low-molecular-weight cytokeratin present in simple epithelia (Fig. 3.31).[390,415–418]

The theme common to all forms of Paget disease is the origin of the tumor from epithelial cells with the capacity to differentiate toward the glandular structures of the region. These are the mammary glands in the breast, the apocrine glands in the vulva, and the perianal and/or rectal glands in the perianal region. This probably explains the fact that there is heterogeneity in the immunohistochemical profile of Paget disease depending on the site of occurrence but in concordance with that of the corresponding normal glands and adenocarcinomas of the region. Thus, vulvar Paget disease is positive for GCDFP-15 and hormone receptors (curiously, androgen rather than estrogen or progesterone)[416,419–421] and shows a pattern of lectin-binding sites similar to that of apocrine glands.[422,423] Conversely, perianal Paget disease often shows positivity for cytokeratin 20, a feature of colorectal glands.[421,424] Patients with perianal Paget disease that is positive for cytokeratin 20 usually have an underlying rectal adenocarcinoma with secondary involvement of the skin.

Complete surgical excision is the treatment of choice, but this may be difficult to achieve because of the ill-defined gross edges of the lesion.

The differential diagnosis of extramammary Paget disease includes pagetoid Bowen disease, pagetoid actinic keratosis, benign and malignant melanocytic lesions, metastatic epidermotropic carcinomas from breast and other sites,[425,426] and so-called clear cell papulosis.[427] Most of the reported cases of the latter condition have been in children younger than 4 years and have been characterized by multiple small whitish maculopapular lesions that, microscopically, are seen to contain pale cells with a similar immunohistochemical profile to that of Paget cells (Fig. 3.32).[428] These cells are probably related to the so-called Toker cells as seen in the nipple.

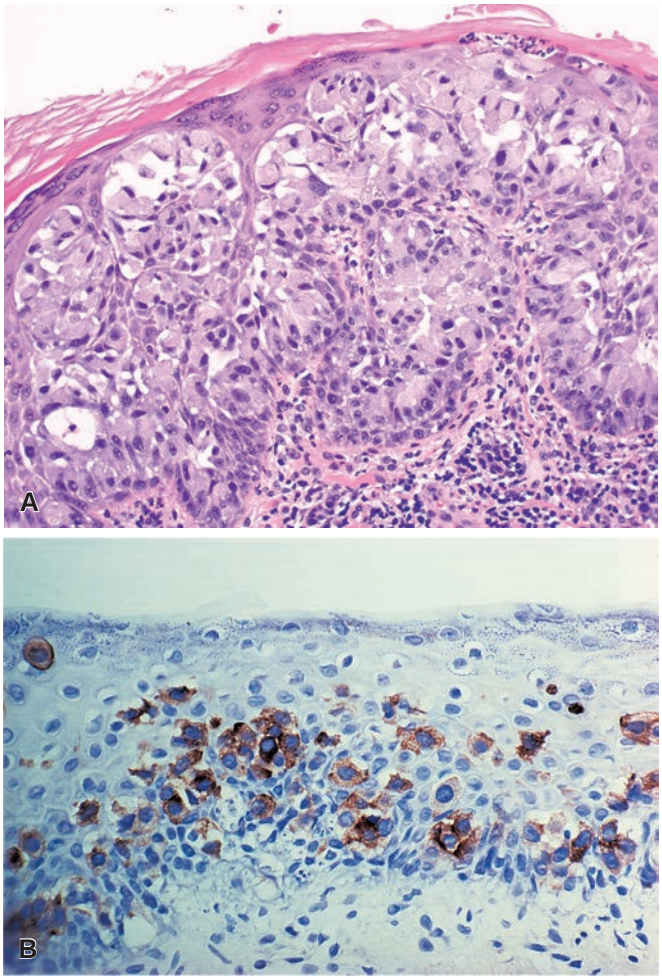

Figure 3.31 Extramammary Paget Disease of the Skin. A, The tumor consists of intraepidermal collections of neoplastic cells with small hyperchromatic nuclei and relatively abundant cytoplasm. The tumor cells typically spare the basal layer. **B,** Extramammary Paget disease immunostained for epithelial membrane antigen.

Apocrine Glands

It is possible that some of the sweat gland tumors already described, particularly syringocystadenoma papilliferum, cylindroma, and mixed tumor, exhibit apocrine differentiation.[429] As a matter of fact, the existence of eccrine and apocrine forms of the latter has been proposed. Furthermore, stains for the apocrine marker GCDFP-15 are often positive in sweat gland neoplasms.[429] However, tumors composed exclusively of apocrine glands are extremely rare.

Apocrine cystadenoma is discussed in a different section.

Tubular apocrine adenoma is characterized by dermal and subcutaneous tubular structures of apocrine type arranged in a lobular fashion.[430] The lesion is very similar to syringocystadenoma papilliferum.[431]

Papillary hidradenoma and *ceruminous adenoma* have been traditionally regarded as tumors of apocrine glands.

Sebaceous Glands

Sebaceous Hyperplasia

The most common nodular lesion of the sebaceous glands is due to hyperplasia. It occurs chiefly on the nose and cheeks of elderly persons, hence the name senile sebaceous hyperplasia or, preferably, *sebaceous hyperplasia*.[432] The lesion consists of enlarged but otherwise relatively normal sebaceous glands.

Nevus Sebaceus of Jadassohn and Epidermal Nevus

Nevus sebaceus of Jadassohn is a distinct clinicopathologic type of epithelial nevus.[433] It is composed of a hamartomatous conglomerate of large sebaceous glands associated with heterotopic apocrine glands, defective hair follicles, acanthosis, and papillomatosis (Fig. 3.33). The lesions occur on the scalp and face, are present from infancy, and gradually enlarge.[434] Basal cell carcinomas, a variety of adnexal tumors (particularly trichoblastomas) and, very rarely, squamous cell carcinomas can arise within this lesion.[435,436]

Epithelial nevi without an adnexal component are generically referred to as *epidermal nevi*. They are characterized microscopically by hyperkeratosis, papillomatosis, and acanthosis and are sharply demarcated from the adjacent skin. Several clinicopathologic varieties exist, one of them having a characteristic linear distribution *(linear epidermal nevus)*.[437] Histologically they are similar to seborrheic keratosis. The history of presence since childhood may be the only way to distinguish epidermal nevus from a seborrheic keratosis.

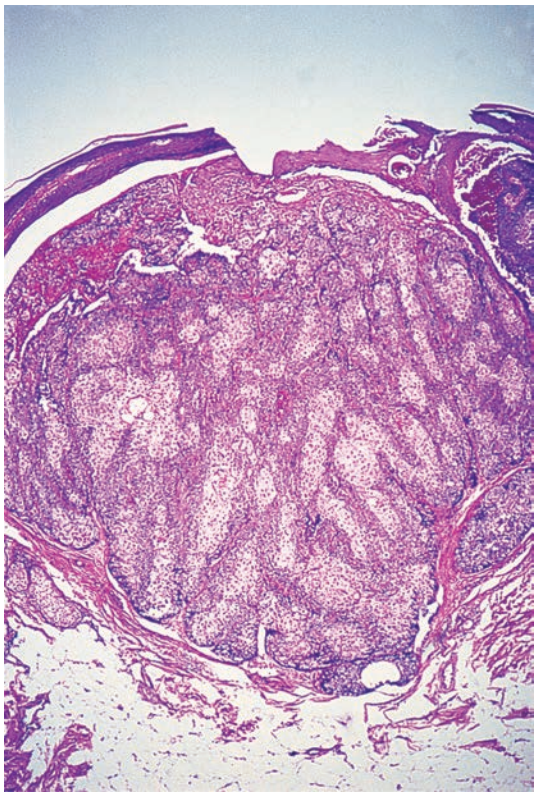

Figure 3.34 Sebaceous Adenoma. The tumor has a distinctly lobular architecture. The light and dark areas correspond to well-differentiated sebaceous cells and generative cells, respectively.

Sebaceous Adenoma

Sebaceous adenoma presents as a nodular lobulated growth with generative cells at the periphery and cells showing varying degrees of sebaceous differentiation toward the center (Fig. 3.34).[438] Although well differentiated, it lacks the distinctly organoid quality of sebaceous hyperplasia. It should be realized that the so-called sebaceous adenoma occurring on the face of patients with the tuberous sclerosis syndrome is not a sebaceous neoplasm but a fibrovascular proliferative process *("angiofibroma")* accompanied by a mild degree of sebaceous hyperplasia. *Sebaceoma* represents a morphologic variant of sebaceous adenoma in which the germinative basaloid cells predominate over

mature sebocytes but lacks the infiltrative growth of sebaceous carcinoma.[439,440] Some of these tumors have a pattern of growth vaguely mimicking that of carcinoid tumors.[441] Immunoreactivity for adipophilin is helpful for confirming the presence of intracytoplasmic lipid vesicles and hence sebaceous differentiation.[442]

Sebaceous Carcinoma

Bona fide sebaceous carcinoma is extremely rare.[438] Those occurring in the eyelids, in caruncles, and in the orbit may be more aggressive than those located elsewhere in the skin,[443,444] but an unfavorable clinical course can occasionally also be seen with the latter.[445] Some of the cases have followed irradiation therapy to the area,[446] and others have arisen in lesions of nevus sebaceus of Jadassohn.[447] Microscopically, sebaceous carcinomas exhibit, together with evidence of sebaceous differentiation, prominent atypia, increased mitotic activity, and invasive features (Fig. 3.35). The invasiveness criterion should be emphasized because sebaceous tumors with marked cellular atypia but good circumscription or encapsulation usually do well.[448] Immunoreactivity for keratin and cytokeratin, EMA, Leu-M1 (CD15), androgen receptor, and adipophilin is present in sebaceous carcinoma, whereas CEA and S-100 protein are absent.[442,449,450] Sebaceous carcinoma shows a greater expression of the Thomsen–Friedenreich (T) antigen than sebaceous adenoma, and it may show reactivity for androgen receptors, a feature that it shares with sebaceous adenomas.[450] Although other quantitative differences exist in the immunohistochemical profile between sebaceous adenomas and carcinoma, they are not sharp enough to be of great diagnostic assistance, and one must rely on histologic features to make the distinction.[451]

Sebaceous carcinoma should be distinguished from basal cell carcinomas with sebaceous differentiation,[452] and from squamous cell carcinomas accompanied by hydropic changes in the tumor cells.[453] Necrosis and lack of lymphoid cell reaction have been found to be associated with a more aggressive course.[454]

Sebaceous adenoma and carcinoma may be seen as a component of *Muir–Torre syndrome*, a clinical subset of hereditary nonpolyposis colorectal cancer syndrome which is caused by germline mutation in a mismatch repair gene, most commonly MSH2.[455–458] In this condition, multiple cutaneous tumors exhibiting varying degrees of sebaceous and hair follicle differentiation occur in association with multiple internal malignancies.[458–460] The tumors, whether benign or malignant, may have a cystic or keratoacanthoma-like growth pattern, which should be a clue to the association.[461,462] Because of the strong association of sebaceous neoplasm with Muir–Torre syndrome, it has been suggested that routine immunohistochemistry (looking for loss of mismatch repair protein expression) be performed in all sebaceous neoplasms regardless of the patient's age or other clinical characteristics.[458,463]

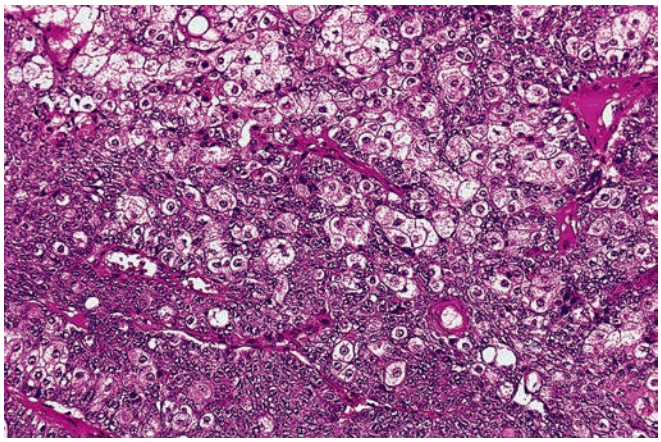

Figure 3.35 Sebaceous Carcinoma. The tumor is composed of an increased number of atypical basaloid cells with some cells exhibiting evident sebaceous differentiation.

Hair Follicles

A myriad of neoplasms, hamartomas, and cysts can develop from the hair follicle. In an exhaustive review of the subject, Headington[464] listed 26 entries, and several additional ones have been described since.[465–470] One could wonder how useful or sensible it will be to further continue this subdivision, which is largely irrelevant on clinical grounds, as opposed to using a more encompassing term, such as *benign trichogenic tumor*.[471] In any event, only the more common and better established varieties of hair follicle tumors will be described here.

Inverted Follicular Keratosis

The lesions of inverted follicular keratosis occur mostly on the face of elderly patients, the eyelid being a preferred location. Clinically, they present as a papule or nodule, practically always single, usually projecting from the surface. Microscopically, they resemble an endophytic seborrheic keratosis, with the most distinctive feature being the presence of squamous eddies (Fig. 3.36).[472] They usually have a papillomatous as well as an acanthotic inverted component. In contrast to keratoacanthoma, the borders are sharply outlined, and inflammation is usually lacking.[473]

The histogenesis and pathogenesis are controversial. Some view it as a unique keratotic lesion of the infundibular portion of the hair follicle (hence the name),[474] whereas others regard it as an irritated form of seborrheic keratosis or verruca vulgaris.[475]

Trichoepithelioma

Trichoepitheliomas are hair follicle tumors of long standing,[476] a good number of which occur in children.[477] They are often multiple, do not ulcerate, and may attain a huge size.[478] Some are seen in a familial setting.[479] Histologically, a stromal element surrounds abortive pilar differentiation (Fig. 3.37). The main differential diagnosis is with basal cell carcinoma, which is histogenetically a closely related tumor; the most helpful features are the frondlike arrangement of

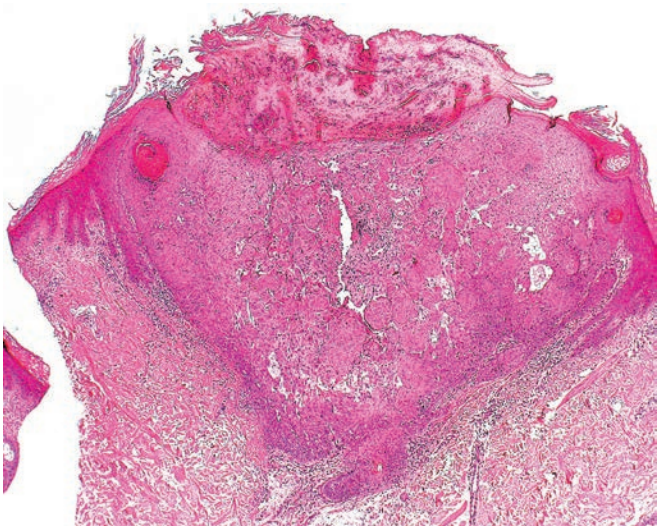

Figure 3.36 Inverted Follicular Keratosis. There are numerous "keratotic eddies."

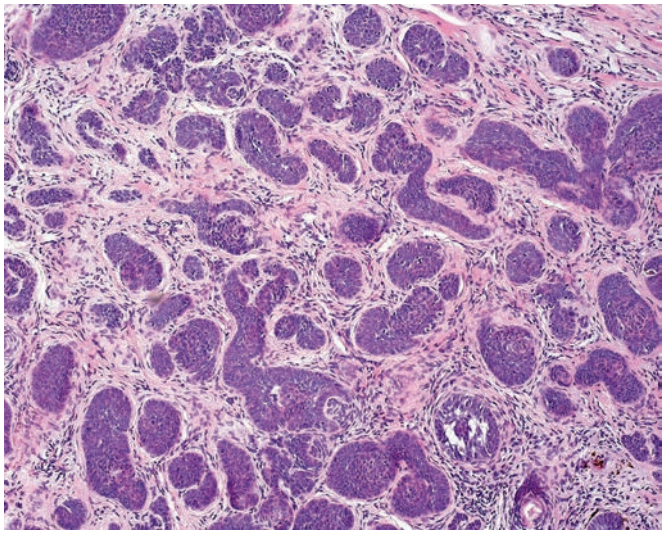

Figure 3.37 Organoid pattern in trichoepithelioma with islands of basaloid cells surrounded by a fibroblastic stroma. Focal papillary mesenchymal bodies are present.

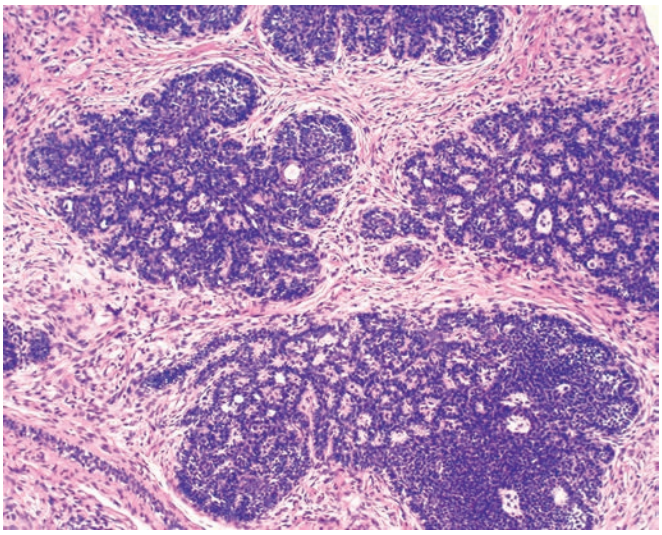

Figure 3.39 Trichoblastoma. This tumor is morphologically similar to trichoepithelioma and is composed of islands of basaloid epithelium surrounded by a fibroblastic stroma.

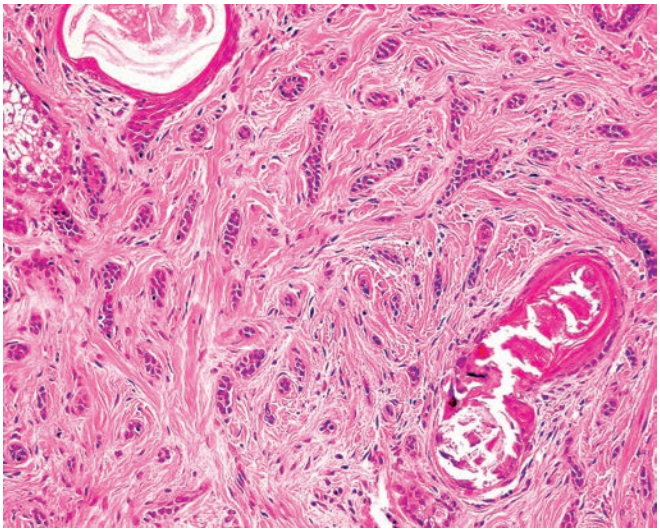

Figure 3.38 Desmoplastic Trichoepithelioma. This benign tumor is not to be confused with basal cell carcinoma.

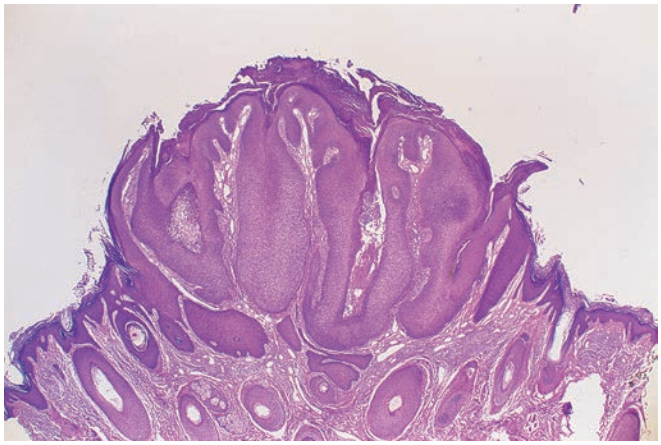

Figure 3.40 Trichilemmoma. The tumor presents as an endophytic lobular growth of glycogen-rich clear cells. (Courtesy Dr D Santa Cruz, St Louis.)

the basaloid cells, the presence of epithelial tracts comprising two or more layers of basaloid cells, and the formation of papillary mesenchymal bodies, which represent attempts to form the papillary mesenchyme responsible for hair follicle induction.[480] A variant of this tumor, appropriately known as *desmoplastic trichoepithelioma*, is accompanied by extensive fibrous proliferation that surrounds and distorts the epithelial islands (Fig. 3.38).[481] In contrast with the conventional form, this variant is usually single. Its main differential diagnosis is with the morphea-like form of basal cell carcinoma.[482] Immunostaining for cytokeratin 20 may be helpful because most trichoepitheliomas have retained, scattered Merkel cells, whereas they are absent in basal cell carcinomas.[197] Stains for bcl-2 have also been highlighted as a useful marker. In trichoepitheliomas, bcl-2 stains highlight the periphery of the tumor, whereas the staining pattern is diffuse in basal cell carcinoma.[140] Immunostaining for stromelysin-3 (a matrix metalloproteinase) is also said to be of help in this regard, in the sense of being always negative in desmoplastic trichoepithelioma and positive in most cases of basal cell carcinoma.[483]

Trichoblastoma

Trichoblastoma is a benign hair follicle tumor related to trichoepithelioma composed of aggregates of basaloid epithelial cells associated with a distinctive trichogenic stroma (Fig. 3.39). As already indicated, we view this tumor as being very closely related to basal cell carcinoma and trichoepithelioma; indeed foci of typical basal cell carcinoma may be present.[484] A prominent component of Merkel cells is usually present, and a clear cell variant has been described.[485] Like many other hair follicle tumors, it may undergo malignant transformation into a high-grade carcinoma, a sarcomatoid carcinoma (carcinosarcoma) and possibly a true sarcoma.[470,486,487]

Trichilemmoma

Trichilemmoma (tricholemmoma) is a benign solid tumor that presents as a lobular formation or plate-like growth of glycogen-rich clear cells, often surrounded by palisading and sometimes exhibiting central keratinization (Fig. 3.40). Multiple trichilemmomas are associated with acral keratoses, sclerotic fibromas of skin, papillomas

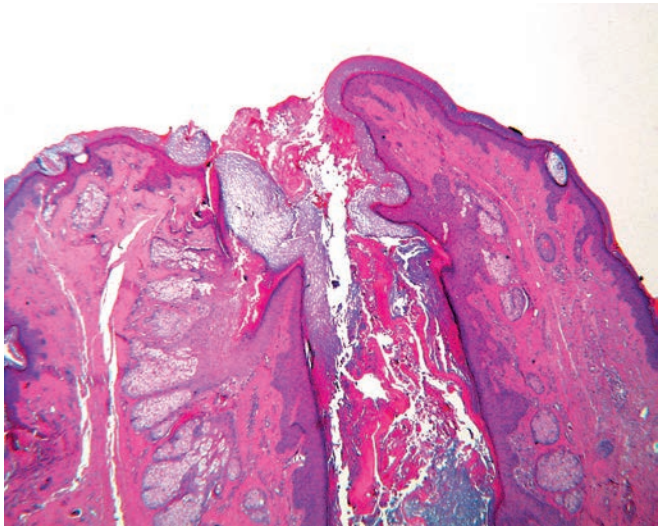

Figure 3.41 Highly organoid pattern of trichofolliculoma.

of the oral mucosa, and, occasionally, tumors of the breast, thyroid, and gastrointestinal tract—a condition known as Cowden disease or multiple hamartoma syndrome.[488,489]

A *desmoplastic* variety of trichilemmoma that simulates an invasive carcinoma has been described.[490] This variety still has tumor cells with clear cytoplasm with peripheral palisading typical of conventional trichilemmoma.

Trichilemmal (tricholemmal) carcinoma is a tumor that combines features of trichilemma-type keratinization with atypical features, such as brisk mitotic activity, invasion of reticular dermis, and ulceration.[491,492] The clinical course of trichilemmal carcinoma is very indolent, and the incidence of metastatic behavior is extremely low.[493,494]

Trichofolliculoma

Trichofolliculomas are solitary, nodular, highly organoid hamartomatous lesions that recapitulate the anagen, catagen, and telogen phases of the normal hair follicle. They should be distinguished from trichoepitheliomas and basal cell carcinomas.[495] Their characteristic dilated central follicle is surrounded by proliferating epithelium showing various stages of pilar formation (Fig. 3.41). Merkel cells are often present,[496] as they also are in other hair follicle tumors, such as trichoepithelioma and trichoblastoma.[197,497]

The occurrence of multiple fibrofolliculomas in association with trichodiscomas (another type of benign hair follicle tumor) and acrochordons (fibroepithelial polyps) constitutes a genetically determined syndrome.[498]

Keratoacanthoma

Keratoacanthoma typically presents as a dome-shaped lesion with a central crater filled with keratin (Fig. 3.42). It occurs in males 3 or 4 times more frequently than in females. When compared with conventional squamous cell carcinoma of the skin, keratoacanthoma is seen to occur in a somewhat younger population and to have a similar but not identical site distribution.[499] The most important microscopic feature is the architecture of the lesion as seen on cross section on low-power examination: overhanging edges, a keratin-filled crater, and hemispheric shape that is buttressed by a normal-appearing epidermis (Fig. 3.43). Cytologic criteria are of less use in the differential diagnosis with conventional squamous cell carcinoma.[500]

Figure 3.42 Clinical appearance of keratoacanthoma.

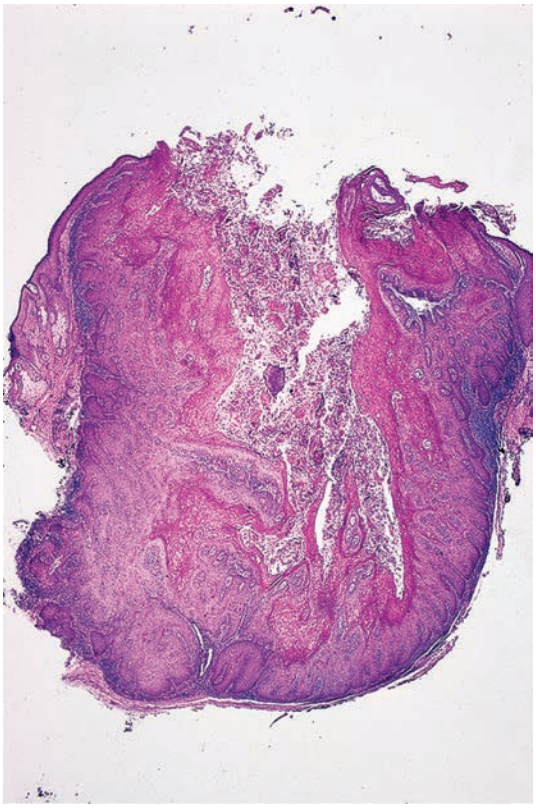

Figure 3.43 Low-power appearance of keratoacanthoma.

Most of the epithelium is well differentiated, with abundant ground-glass cytoplasm, but nuclear abnormalities and mitotic activity can be prominent. The growing edge is usually of the pushing type, a feature accentuated by the heavy rim of inflammatory cells, in which eosinophils may be prominent. However, in some instances there is extension into the underlying skeletal muscle, perineurial invasion,

or even blood vessel invasion.[501–503] It should be noted that eosinophilic infiltration can also occur in squamous cell carcinoma and may actually be more frequent in it.[504] Florid proliferation of sweat ducts entrapped by the keratoacanthomas is a common feature of probable reactive nature.

Many special techniques have been used in the differential diagnosis between keratoacanthoma and conventional squamous cell carcinoma. These include immunohistochemical staining for filaggrin (a histidine-rich protein normally present in the granular and horny layers of the epidermis),[505] transforming growth factor alpha expression,[506] vascular cell adhesion molecule (VCAM) and intercellular adhesion molecule (ICAM),[507] MIB-1 expression,[508] proliferating cell nuclear antigen (PCNA) distribution,[509] DNA content,[510,511] p53 expression,[510,512,513] P2X7 expression (a marker for the initiation of apoptosis),[514] microsatellite instability, and loss of heterozygosity,[515] but it is doubtful whether any of these achieves a sharp separation between the two entities (perhaps simply because such a sharp morphologic separation does not exist). Keratoacanthomas are molecularly distinct from squamous cell carcinomas, but these studies have not to date revealed a simple means to distinguish keratoacanthoma from squamous cell carcinoma.[516]

Keratoacanthoma is thought to represent a proliferation of the infundibular portion of hair follicles rather than of the epidermis. In its most typical form, it arises from previously normal skin, grows rapidly for 4–6 weeks, and then undergoes spontaneous regression over the following 4–6 weeks to leave a slightly depressed, annular scar.[517] However, many variations exist. Some lesions grow slowly, some lesions do not regress spontaneously, some develop at the site of previous trauma,[518] and some lesions (referred to as *actinic keratoacanthomas*) are seen in sun-exposed skin in association with typical changes of actinic keratosis.[519] Some have been reported in association with inflammatory dermatoses, congenital skin lesions, genetic diseases, and scars. Some patients have numerous eruptive lesions *(Grzybowski type)*, and others have multiple ulcerating tumors with atypical distribution *(Ferguson–Smith type)*.[520] Some lesions considered keratoacanthomas may actually represent a subtype of well-differentiated squamous cell carcinomas or perhaps misdiagnosed squamous cell carcinoma, as supported by the chromosomal aberrations they exhibit.[521] This would explain the fact that, occasionally, lesions with the characteristic clinical and microscopic features of keratoacanthoma have been found to grow to huge sizes and/or to metastasize to regional lymph nodes, particularly when the patient's immunity is impaired.[522,523] However, to state that keratoacanthoma is simply a squamous cell carcinoma is to ignore its distinctive clinical behavior and molecular differences from conventional squamous cell carcinoma. At the very least, it should be regarded as a distinct/(abortive) subtype of squamous cell carcinoma. Similarly, to insist that keratoacanthoma is always a benign squamous proliferation[524] is to ignore all the other clinical, biologic, and behavioral evidence pointing towards a neoplastic process.[525–528]

In closing, yet another manifestation of this process should be mentioned. This is the so-called *subungual keratoacanthoma*, thought to arise from the nail matrix, which presents as a rapidly growing mass in the tip of a finger or toe, often associated with a lytic cup-shaped defect of the distal phalanx.[529,530]

Keratinous Cyst

Keratinous cysts have been known for many years as sebaceous cysts, a misnomer born of a mistaken gross interpretation of the cyst content and perpetuated by uncritical repetition.[531,532]

Two types of keratinous cyst occur, with occasional hybrid forms. The more common (90%), known as the *epidermal* or *epidermoid type*, is lined by cornified epithelium, has a distinct granular layer,

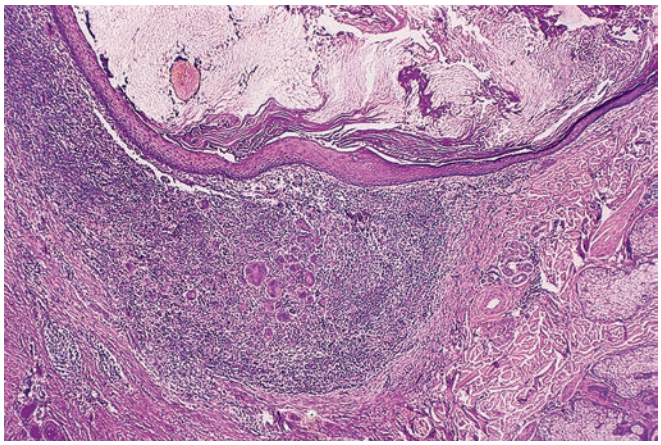

Figure 3.44 Keratinous cyst of epidermal type with secondary inflammation.

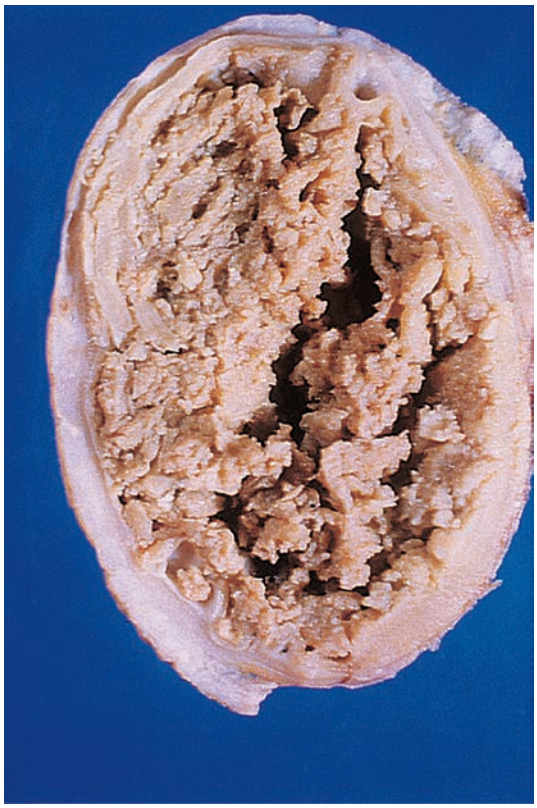

Figure 3.45 Gross appearance of keratinous cyst of trichilemmal type. Grumous material composed of pilar-type keratin occupies the lumen.

and contains lamellated keratin without calcification (Fig. 3.44). Although some of these cysts (particularly those located in the fingers)[533] result from traumatic inclusion of the epidermis—hence the term *epidermal inclusion cyst*—the majority probably arise from cystic dilation of the infundibular portion of hair follicles. A few of these cysts exhibit seborrheic keratosis–like changes in their wall.[534]

The other keratinous cyst is the *pilar*, or *trichilemmal type*, (Fig. 3.45).[535,536] It occurs preferentially on the scalp and is microscopically characterized by a trichilemmal type of keratinization, that is, sudden keratinization without the formation of a granular layer and an uneven interphase between the keratinized and nonkeratinized cells (Fig. 3.46). The keratin inside the cyst is not lamellated, some of the nuclei

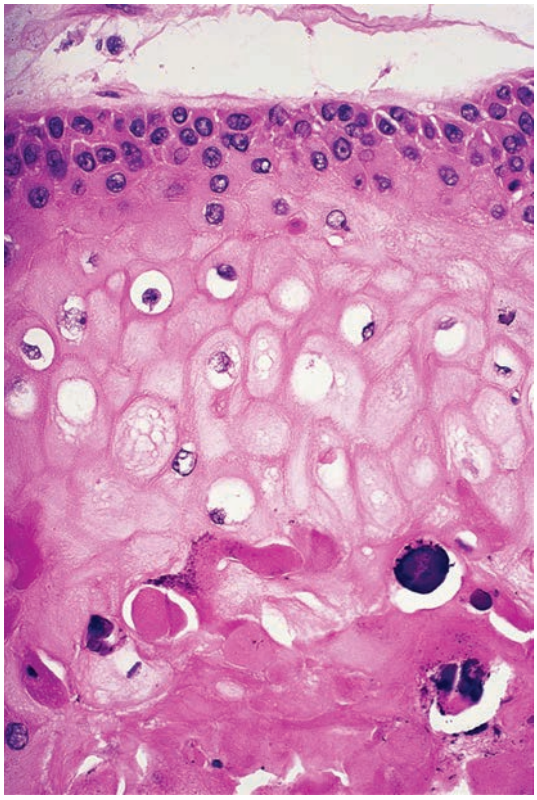

Figure 3.46 Keratinous cyst of pilar type showing trichilemmal pattern of keratinization.

are retained, and focal calcification is frequent. Ultrastructural and immunohistochemical studies also support a trichilemmal derivation for this lesion.[537]

HPV (usually type 57 or 60) has been found in cases of keratinous cysts of palmoplantar and other locations, suggesting that it may play an etiologic role.[538]

Other Cutaneous Cysts

Several other varieties of cutaneous cysts occur, sometimes in combination.[539–541] Although some of them are not of hair follicle derivation, they are listed here for comparison purposes.

1. *Dermoid cyst*. These are microscopically similar in most respects to keratinous cysts of the epidermal type except for the fact that they contain hair adnexa in their wall opening into the cavity.[542] Most of them are found in the face of children near the eyebrow, along lines of embryonic closure.
2. *Steatocystoma*. This is lined by a thin layer of stratified squamous epithelium resembling the ductal portion of a sebaceous gland; lobules of sebaceous glands and small hair follicles are present and the cyst lining has a crenulated appearance. It may occur as a solitary lesion,[543] as multiple lesions on the face,[544] or in the more common disseminated form known as *steatocystoma multiplex*.[545]
3. *Hydrocystoma* (solitary or multiple, usually on the face) and *apocrine cystadenoma*. Both of these are lined by a layer of sweat duct–like epithelium, which usually has apocrine features.[546,547]
4. *Cutaneous ciliated cyst (cystadenoma)*. This is usually seen in the extremities of young females shortly after puberty and is thought by some to be of müllerian derivation.[548–550] Rare cases have been described in males.[551]

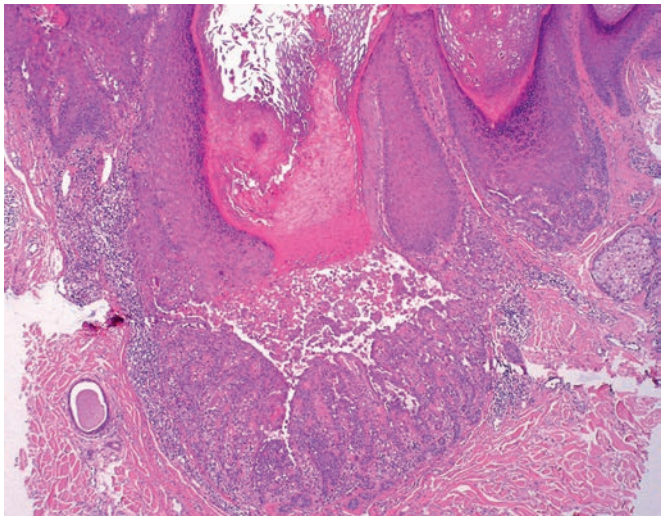

Figure 3.47 Warty Dyskeratoma. There is an inverted proliferation of keratinocytes with prominent acantholysis.

5. *Vellus hair cyst*. This presents as small, multiple, eruptive cysts over the chest wall and extremities of young individuals. It is lined by a layer of flattened, follicular sheath epithelium and contains numerous vellus hairs and soft keratinous material.[552]
6. *Pigmented follicular cyst*. This is a hyperpigmented lesion with epidermal-type keratinization, which contains laminated keratin, many pigmented hair shafts, and some growing hair follicles.[553]
7. So-called *bronchogenic cyst*. This is usually discovered at birth or soon thereafter in the suprasternal notch.[554] The lining is made up of pseudostratified columnar ciliated epithelium. Despite its name, the lesion is probably of branchial cleft derivation rather than of bronchial origin.[555] Therefore a more appropriate name would be *branchiogenic cyst*.

Warty Dyskeratoma

Warty dyskeratoma is a small papulonodular lesion usually occurring in sun-exposed skin and characterized microscopically by a peculiar follicular acantholysis and dyskeratosis (Fig. 3.47). Despite the microscopic similarities with Darier disease, it does not represent an isolated manifestation of the latter (which is not a follicle-based process). Instead, it is probably a primary proliferative process of hair follicles, which has been viewed either as the follicular counterpart of actinic keratosis *(isolated follicular keratosis)* or, more likely, as a sui generis follicular neoplasm *(follicular dyskeratoma)*.[556]

Proliferating Pilar Tumor (Proliferating Trichilemmal Cyst)

Pilar tumor represents the neoplastic counterpart of the pilar (trichilemmal) cyst, and it therefore exhibits the same predilection for the scalp and base of neck of women.[557] All types of transitional forms can be found between the ordinary pilar cyst and the full-blown proliferating pilar tumor. In some instances the pilar tumor presents as a mural nodule in a lesion having otherwise the appearance of a pilar cyst, and in others the two lesions coexist in the same individual.[558] The overlying epidermis is usually uninvolved, but in some cases the lesion opens into the surface. Proliferating pilar tumor can reach huge proportions (Fig. 3.48).[559] These lesions should not be misinterpreted as squamous cell carcinomas arising from sebaceous cysts.

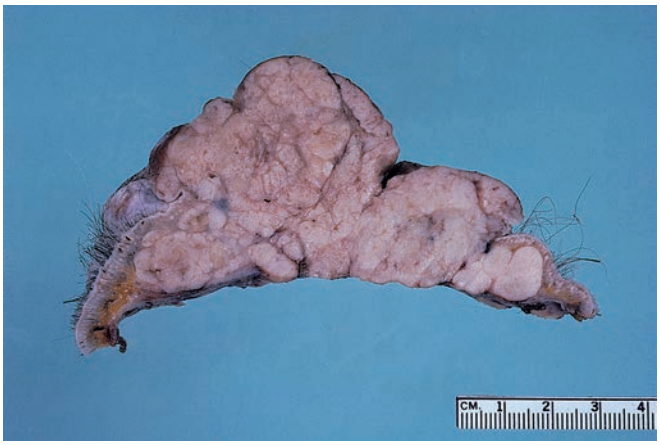

Figure 3.48 Cut surface of a proliferating pilar tumor. It has a multinodular appearance, with both an exophytic and an endophytic component.

Figure 3.49 Low-power appearance of proliferating pilar tumor. The lobulated contour is characteristic.

Microscopically, pilar tumors have a predominantly solid appearance and generally pushing borders. Interlacing bands of squamous epithelium exhibiting trichilemma-type keratinization are characteristic (Fig. 3.49). Nuclear atypia may be prominent, and some irregularities at the interphase between epithelium and stroma can be observed. Sometimes focal invasion of the stroma is identified.[560] This lesion is neoplastic rather than hyperplastic, a hypothesis supported by the finding of nondiploid DNA content in some of the cases.[561] The behavior is generally benign; several instances of local recurrence have been reported, but metastases are exceptionally rare.[562,563] The few well-documented instances of metastases have occurred in tumors with clear-cut malignant microscopic features.[564–566] The malignant component may have the appearance of a focal trichilemmal carcinoma or, exceptionally, a spindle cell (sarcomatoid) carcinoma.[559,567,568]

Pilomatrixoma

Pilomatrixoma (pilomatricoma), formerly known as *calcified epithelioma of Malherbe*, is a nodular, benign tumor arising from the hair matrix (Fig. 3.50). It occurs predominantly in children and young adults, and most of the cases are located on the head, neck, and upper extremities.[569] Microscopically, it is composed of solid nests of small basaloid cells that may lead to a mistaken diagnosis of basal cell carcinoma,[570] particularly on cytologic examination.[571,572] The key

Figure 3.50 Gross appearance of pilomatrixoma.

feature is the fact that these basaloid cells undergo abrupt keratinization, leading to the formation of "ghost" and "shadow" cells (Fig. 3.51). Pigmentation may occur as a result of colonization by melanocytes.[573] Foreign body reaction, calcification, and ossification are common secondary events. This may be accompanied by extramedullary hematopoiesis.[574] Transepidermal elimination or perforation can occur.[575] The histochemical, immunohistochemical, and ultrastructural features are in keeping with an origin from the hair matrix.[576–579] Most cases of pilomatrixoma show activating mutations of the β-catenin gene *CTNNB1*.[580] It should be remarked that focal features of hair matrix differentiation can sometimes be seen in lesions other than pilomatrixoma.[581]

Cases of pilomatrixoma with atypical histologic features and a tendency for local invasiveness and local recurrence have been designated as *aggressive* pilomatrixomas.[575,582] *Malignant* pilomatrixoma *(pilomatrix carcinoma)* exhibits cytologic atypia, an infiltrating border, transitions to squamous cells, clear cells, necrosis, and mitoses.[583] Cytologic atypia and infiltration are the key features, as mitotic activity may be prominent in typical pilomatrixomas. Sarcomatoid features may be present.[584] Local recurrence is common, and metastases to distant sites can occur.[580,585–588]

Nails

Because the nail bed epithelium is comparable to the outer root sheath or trichilemma of the hair follicle,[589] it follows that if a malignant tumor were to develop from it, that tumor should resemble a trichilemmoma or a trichilemmal carcinoma. Inevitably, such tumors have now been described, under the terms of *onychomatricoma* and *onycholemmal carcinoma*.[590–592] In retrospect, it is possible that some cases reported in the old literature as squamous cell carcinoma, verrucous carcinoma, or keratoacanthoma of the nail bed belong to the same category.

Melanocytes

Melanocytes are neural crest–derived cells located in the basal layer of skin, hair follicles, most squamous-covered mucosal membranes,

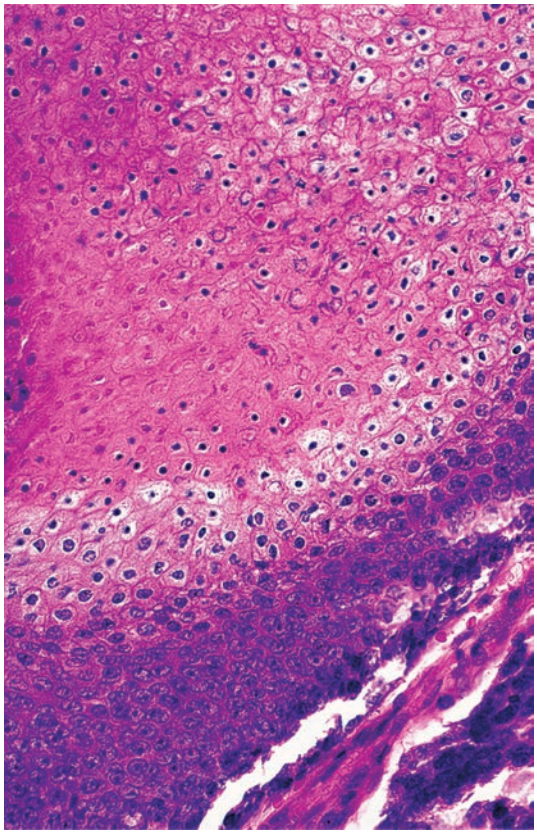

Figure 3.51 Microscopic Appearance of Pilomatrixoma. The basal cells keratinize as does cortex of hair (without granular layer) and produce "ghost" cells.

leptomeninges, and several other sites. Their function is to produce an insoluble pigment known as melanin, using tyrosine as a substrate, and to transfer this product through the process of cytocrinia to the adjacent epithelial cells. The neuroectodermal origin of melanocytes, proposed many years ago by Masson and others,[593] has been supported by a variety of techniques, among which the chick–quail chimera of Le Douarin is the most elegant and convincing, at least for this particular cell type.[594]

The ratio of melanocytes to keratinocytes in the epidermal basal layer varies from 1 : 4 to 1 : 10, depending on the site of the body. Racial differences in skin pigmentation are due to differences in the amount of melanin contained in the keratinocytes rather than the number of melanocytes. The functional unit composed of a melanocyte and the adjacent keratinocytes receiving melanin from it is referred to as the epidermal–melanin unit.

Normal melanocytes with scant pigment appear as pale cells in routinely stained sections (hence the former name "Masson clear cells"), but other intraepidermal clear cells are of keratinocytic nature.[595] Melanocytes possess slender cytoplasmic processes (dendrites) that emanate from the cell body and extend between keratinocytes; these become particularly apparent when containing increased melanin pigment through either increased production or a block in the transfer mechanism.

Melanocytes are generally positive for melanin stains (such as the Fontana–Masson silver stain), tyrosinase, DOPA reaction, S-100 protein, NSE, Mart-1/MelanA (A103), microphthalmia transcription factor (MiTF), Sox10 (a neural crest transcription factor crucial for specification, maturation, and maintenance of Schwann cells and melanocytes), PAX3 (a transcription factor with an important role in the development of melanocytes during embryogenesis), and vimentin; the intensity of these reactions shows marked variability, possibly depending on the functional status of the cell.[596–601] Stains for neurofilaments and glial fibrillary acidic protein are negative.[602] Stains for HMB-45 are generally negative in normal resting melanocytes but positive in activated melanocytes, including those of some nevi and malignant melanoma.[603,604] Keratin is another marker that is consistently absent in normal melanocytes but sometimes expressed aberrantly in their neoplastic counterparts. Other melanocytic markers are discussed in the section on malignant melanoma.

Ultrastructurally, the hallmark of the melanocyte is the melanin-synthesizing organelle known as the *melanosome*. The development of this Golgi-derived structure, which has a specific appearance in its fully developed form because of the striated appearance of its electron-dense content, is preceded by the ultrastructurally nonspecific *premelanosome* and followed by the mature melanin granule.

The term melanocyte should be reserved for the mature melanin-forming cell. Its immature counterpart is the *melanoblast*. Dermal macrophages with phagocytosed melanin are *melanophages*. *Nevus cell* and *nevocyte* are terms that have been traditionally used for the cells of benign ordinary nevi; some authors regard them as nothing but melanocytes and have suggested abandoning the term altogether.[605] We fear that this may be too simplistic a view of the origin and nature of these cells.

Nevi

The word *nevus* (*Leucoraja naevus,* birthmark) can be properly applied to any circumscribed growth of the skin of congenital nature. However, in common practice it is usually used as a synonym for *mole* (L. moles, a shapeless mass) to designate a localized benign abnormality of the melanocytic system. The adjectives *melanocytic* (which we prefer), *nevocellular*, and *pigmented* refer specifically to this type of nevus.

Melanocytic nevi are usually acquired, in the sense that they become clinically apparent after the first year of life. Most of them will appear between the second and sixth years, and nearly all will have become manifest by the age of 20 years. They follow a rather predictable evolution, which only rarely is upset by some dramatic event, such as spontaneous regression, activation, or malignant transformation.[606] Their proliferative activity roughly correlates with the age of the patient.[607] Every white person has a variable number of nevi, the average being between 20 and 30.[608] Their distribution frequency is different from that of malignant melanoma. They are much more common in the skin of the head, neck, and trunk, whereas a high percentage of malignant melanomas occur in the lower extremities. Nevi of every conceivable size, shape, and degree of pigmentation occur, and they may be more or less hairy. Nevi have been variously classified, but it is best to divide them according to the location of the melanocytes inasmuch as their position bears a definite relationship to the likelihood of malignant transformation and perhaps to their histogenesis.

It has been suggested that melanocytic nevi straddle the fence between malformation (hamartoma) and neoplasia.[609] However, the finding that these lesions are clonal and that they exhibit loss of heterozygosity speaks in favor of a neoplastic nature.[610,611] In melanocytic nevi, activating mutations of *BRAF* are frequent, most commonly T1799A (V600E) mutation.[612–614] *NRAS* mutation is uncommon, and *CDKN2A* mutation is not found.[613]

Masson suggested that the ordinary compound mole has a dual origin from intraepidermal melanoblasts, some of which become intradermal through the Abtropfung (dropping off) process, and dermal Schwann cell–related dermal cells.[615,616] Many ultrastructural, histochemical, immunohistochemical, and experimental studies support his proposal that the cells from the upper portion of

compound nevi have melanocytic properties, whereas those in the deep portion have features strongly suggesting differentiation toward specialized peripheral nerve structures.[617–619]

The overwhelming majority of nevi are located in the skin, but they can also be found in any mucosal membrane covered by squamous epithelium (see respective sections). Clusters of benign nevus cells can also be seen in the dermis, subcutaneous tissue, and in the capsule of lymph nodes, the axillary region being the most common location for the latter event.[620,621] These nests, which typically do not penetrate into the node itself, should not be confused with metastatic malignant melanoma, a mistake particularly likely to occur when they are found in specimens from axillary lymphadenectomy or sentinel node biopsy performed because of cutaneous melanoma.

Junctional, Intradermal, and Compound Nevi

Ordinary nevi are classified according to the location of the nevus cells in relation to the major epidermal and dermal landmarks. *Junctional nevus* is defined as a nevus in which the melanocytic proliferation is restricted to the basal portion of the epidermis ("junctional" area). Nevi of the palms and soles are frequently of the junctional type,[622] with most of the intraepidermal melanocytes concentrated in the skin furrows.[623] Grossly, junctional nevus is flat or slightly elevated, non-hairy, and fawn colored. Microscopically, it is characterized by the presence of melanocytic nests ("theques") on the epidermal side of the dermoepidermal junction (Fig. 3.52). Malignant melanomas may arise from this lesion.

Lentigo simplex is generally regarded as the first phase in the evolution of common nevi ("nevi incipientes") and therefore a precursor of junctional nevus. It consists of a proliferation of melanocytes in the epidermal basal layer, and it differs from junctional nevus in that the melanocytes are individually arranged rather than in theques. Multiple lentigines occur in Peutz–Jeghers syndrome, centrofacial lentiginosis, Moynahan syndrome, LEOPARD syndrome, Carney syndrome, and xeroderma pigmentosum.[624] Basal cell hyperpigmentation microscopically resembling lentigo is commonly seen in the epidermis overlying dermatofibromas (see section on dermatofibroma). Exceptionally, a nevus or a melanoma is found on top of a dermatofibroma.[625]

Intradermal nevus is the term given to a nevus in which all the melanocytes are in the dermis. This is the common adult type of nevus. It may be papillomatous, pedunculated, or flat, and it is often hairy. Microscopically, small nests or bundles of melanocytes are seen in the upper dermis, with a tendency to concentrate around pilosebaceous units.[626] The degree of pigmentation and cellularity varies widely. The lower half of the lesion tends to be less cellular and less pigmented and is composed of spindle cells with fibrillary cytoplasm arranged in bundles.[616] Sometimes, structures resembling tactile (Wagner–Meissner) corpuscles are present. Although these areas are immunohistochemically different from neurofibromas,[627] we favor the interpretation that they represent the expression of the neural component of the nevus; it is hard for us to dismiss these highly organoid structures as simply the result of atrophy, as others have done.[628] Occasionally, a storiform pattern of growth is present in this deep portion, establishing a link—at least on morphologic grounds—with the dermal tumor known as storiform neurofibroma.[629,630] Multinucleated melanocytes can be seen scattered throughout the nevus, particularly in the upper half; many of these cells have a characteristic "mulberry" shape. Ultrastructurally and immunohistochemically, the intradermal nevus cells are surrounded by basement membrane components.[631,632] Malignant melanomas rarely arise from purely intradermal nevi, although a few convincing examples are on record.[633]

Compound nevus combines the features of the junctional and intradermal types, i.e., it has both an epidermal and a dermal component. The percentage of nevi with junctional changes decreases as the age of the patient increases.[634] As for the other types of nevi, the amount of melanin deposition is highly variable and sometimes very abundant (hypermelanotic nevus)[635]; as a general rule, it is concentrated in the superficial half of the lesion, particularly the intraepidermal portion. As with other nevi, lymphocytes and other mononuclear cells may be seen at the base of the lesion[636]; they tend to be in clusters rather than exhibiting the bandlike quality more commonly seen in melanoma.

The microscopic appearance of nevi shows some interesting variations depending on the site in which they occur. Nevi of the palms and soles tend to remain junctional throughout life. Nevi of the scalp often exhibit a prominent neural component. Nevi located on the vulvar skin (vulvar or genital nevi) tend to have larger, more irregularly shaped, and more irregular theques than those located elsewhere, and they have a tendency to be accompanied by lentiginous melanocytic hyperplasia; because of these features, they can be misdiagnosed as malignant melanomas.[637,638] Other body sites prone to harbor nevi with atypical features are breast, flexural skin, and acral region, especially ankle.[639–641]

Many morphologic variations have been observed in otherwise typical compound or intradermal nevi. These include the presence of marked sclerosis (desmoplastic or sclerotic nevus),[642] nodular myxoid changes,[643] amyloid deposition, elastosis, metaplastic bone in the stroma; folliculitis and abscess formation; association with keratinous cysts[644] and psammoma bodies; cytoplasmic vacuolization (sometimes resulting in lipoblast-like cells); oncocytic changes[645]; and eczematous or focal acantholytic keratotic changes in the overlying or adjacent epidermis.[646,647]

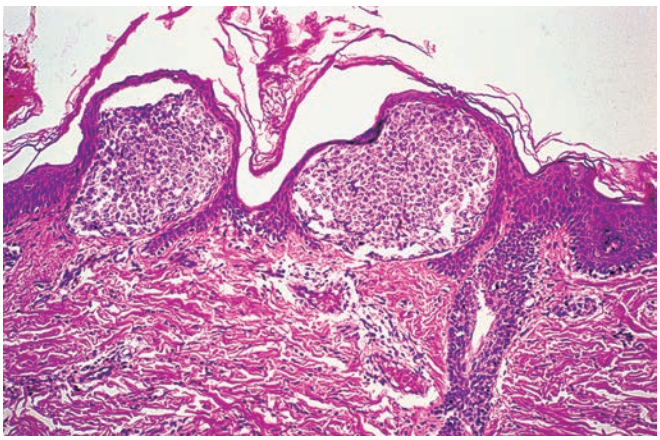

Figure 3.52 Typical Junctional Nevus. Two large theques of melanocytes expand the basal layer of the epidermis.

Blue Nevi and Related Lesions

Blue nevus of the *ordinary (usual, common)* type is usually small and located in the head, neck, or upper extremity.[648] Microscopically, it is characterized by an ill-defined deep dermal proliferation of elongated and/or dendritic dermal melanocytes, sometimes extending into the subcutis. Melanin pigment is usually abundant (Fig. 3.53), although hypopigmented variants occur. There is a band of uninvolved dermis between the epidermis and the lesion, and junctional activity is consistently absent. Blue nevi are sometimes misdiagnosed as benign fibrous histiocytomas because the melanin present in them is misinterpreted as hemosiderin. They are positive for melanin

stains, S-100 protein, and all other melanocytic stains, including HMB-45.[649]

Blue nevi have also been reported in the sclera, hard palate,[650] breast, vagina, cervix,[651] prostate,[652] spermatic cord, and lymph nodes.[653] Blue nevi do not show *BRAF* and *NRAS* mutations, as found in conventional melanocytic nevi, but instead show frequent somatic mutations (83%) in the heterotrimeric G protein alpha subunit, *GNAQ*, a gene also frequently implicated in uveal melanoma. The mutations occur in codon 209 in the RAS-like domain, resulting in constitutive activation.[630]

The differential diagnosis of blue nevus includes dermatofibroma (if the melanin pigment is mistaken for hemosiderin) and—more importantly—metastatic melanoma from the skin or eye, which can simulate it closely.[654,655]

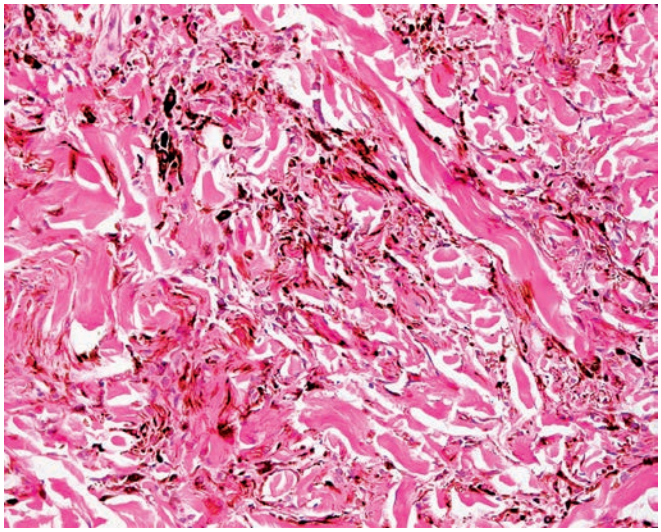

Figure 3.53 Blue Nevus of the Ordinary Type. The cells are spindle-shaped and heavily pigmented.

Cellular blue nevus is a distinctive variety of blue nevus, often clinically suspected of being malignant because of its large size and intense pigmentation.[656,657] The most common locations are the buttock and sacrococcygeal areas; less common sites include the scalp, face, and dorsa of hands and feet.[657] Microscopically, these lesions are extremely cellular, with a pushing border that has been likened to the silhouette of a dumbbell. Extension into the subcutis is the rule, and pigment can be easily found. They differ microscopically from malignant melanomas by the absence of junctional activity, epidermal invasion, peripheral inflammation, and necrosis; the presence of pushing margins, biphasic pattern, fasciculation, and neuroid structures; the inconspicuousness of the nucleoli; and the relative lack of atypia and mitotic figures (Fig. 3.54).[657]

Morphologic variations that cellular blue nevi can exhibit on occasion include the presence of a prominent cellular stroma between the tumor nests (*desmoplastic* cellular blue nevus),[658] focal balloon cell change,[659] paucity of pigmentation (*amelanotic* cellular blue nevus),[660] and degenerative changes in the stroma, including pseudoangiomatous foci (*ancient* blue nevus).[661]

Immunohistochemically, cellular blue nevi are positive for S-100 protein, Melan-A, and HMB-45. Some congenital cellular blue nevi have also been found to be reactive for CD34.[662] Like other melanocytic nevi, cellular blue nevi do not exhibit chromosomal aberrations on analysis by comparative genomic hybridization.[663]

The behavior of cellular blue nevus is nearly always benign, but a few cases with local recurrence or involvement of regional lymph nodes have been documented.[657] However, even these patients are cured by excision of the primary lesion and involved nodes, in the sense that the disease does not progress further.

These cases should be distinguished from malignant melanoma arising from cellular blue nevus and from a type of malignant tumor that has most of the morphologic features of cellular blue nevus but that exhibits a malignant behavior.[664–666] The latter, which has also been referred to as *blue melanoma*, is more common in the scalp and foot (especially heel). Microscopic features that should raise this possibility in a lesion with the architectural features of a cellular blue nevus are marked nuclear atypia, numerous mitoses, atypical

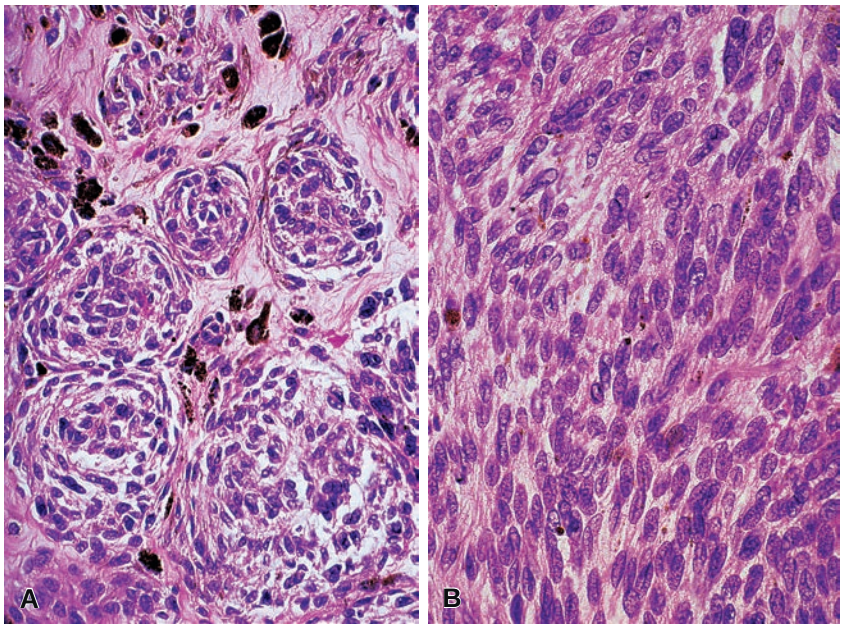

Figure 3.54 Large Cellular Blue Nevus. A, A distinct nesting pattern is present, with most of the melanin being located in macrophages situated in the intervening stroma. **B,** Numerous oval to spindle tumor cells with indistinct nucleoli. There is no mitotic activity.

mitoses, necrosis (sometimes with palisading at the edges), and the occurrence of epithelioid tumor cells.[665,667] It has been claimed that malignant blue nevi have higher AgNOR counts and higher proliferative activity (as measured by PCNA) than cellular blue nevi.[668] Melanomas resembling blue nevi have molecular abnormalities similar to conventional melanoma when interrogated by fluorescence in situ hybridization (FISH).[669] Melanomas arising in blue nevi have also been demonstrated by FISH to have chromosomal alterations associated with conventional melanoma in the malignant component.[670]

Cellular blue nevi with architectural and/or cytologic atypia but not sufficient to be placed in one of the two former malignant categories have been designated as *atypical*,[671] a term which has been violently attacked by some authorities.[672] In a series of nine cases, there were no recurrences or metastases, indicating that a conservative diagnostic and therapeutic approach is justified for these morphologically borderline lesions, especially considering the fact that the agreement rate for the diagnosis of "atypical cellular blue nevus" remains distressingly low.[673]

Both ordinary and cellular blue nevi are usually immunoreactive for S-100 protein, HMB-45, and the other melanocytic markers,[649,674] but exceptions occur.[675]

Variations on the theme of either ordinary or cellular blue nevus include cases forming large plaques (up to 17 cm in diameter),[676] cases with a target-like appearance,[677] and cases in which there is a second component of ordinary type (junctional, compound, or intradermal). The latter represents the most common type of *combined nevi*.[678,679]

Epithelioid blue nevus is a multicentric familial form of blue nevus that is part of the Carney complex together with cardiac myxoma, psammomatous melanotic schwannoma, and other abnormalities. Microscopically, these nevi are heavily pigmented, poorly circumscribed dermal lesions composed of two types of melanocyte: one intensely pigmented and globular, and the other lightly pigmented, polygonal, and spindle.[680] Epithelioid blue nevi can also be seen outside the Carney complex,[681,682] and their status as a distinct subtype of blue nevus has been questioned.[683] The observation has been made that epithelioid blue nevus is morphologically indistinguishable from so-called *animal-type melanoma*, and the proposal has been made to designate this allegedly distinct type of low-grade malignant tumor as *pigmented epithelioid melanocytoma*.[684]

Paraganglioma-like dermal melanocytic tumor is likely to represent another variation in the theme of cellular/epithelioid blue nevus. It is usually found in the extremities of adult females, is centered in the dermis, and presents as a nodule composed of nests of clear to amphophilic oval cells with mild atypia and low mitotic activity, apparently devoid of melanin at the hematoxylin and eosin (H&E) level but expressing all the usual melanocytic markers at the immunohistochemical level. The evolution of the few reported cases has so far been benign.[685]

Other benign skin lesions containing deeply seated dendritic melanocytes include *mongolian spot* (an ill-defined area of bluish discoloration, up to several centimeters in size, usually in the lumbosacral region), *Ota nevus* (located in the ophthalmomaxillary area), *Ito nevus* (located in the shoulder region), and *Sun nevus* (a bilateral speckled pigmentation of the zygomatic region in Chinese people).[686,687]

Spitz Nevus and Related Melanocytic Tumors

Spitz nevus (spindle and/or epithelioid cell nevus) characteristically occurs before puberty, but it may also appear in adult life.[688–690] The most typical presentation is in the form of a raised, pink or red nodule in the skin of the face that clinically resembles a hemangioma. It may be multiple, in either a clustered *(agminate)* or disseminated

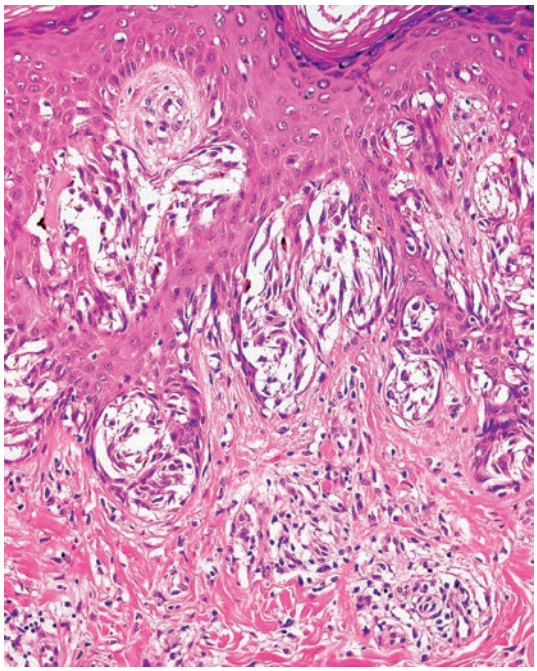

Figure 3.55 Spitz Nevus of Spindle Cell Type. This example is predominantly junctional in location.

fashion[691]; this should not be mistaken for the satellite lesions of malignant melanoma.

Microscopically, most Spitz nevi are of the compound type, with a prominent intraepidermal component. Approximately 5%–10% are junctional, and 20% or more are intradermal.[692,693] They are composed of spindle cells, epithelioid cells, or an admixture of both.

The spindle cell variant is characterized by cigar-shaped cells with large nuclei and prominent nucleoli (Fig. 3.55). The cells of the epithelioid type have similar nuclei and a large, polygonal cytoplasm with distinct borders (Fig. 3.56). A variant of the latter is a multinucleated giant melanocyte containing up to 10–20 nuclei. Mitoses are found in approximately half of the cases,[694,695] but atypical mitoses are exceptional. Pigmentation is usually scanty, but a deeply pigmented variant (often of recent onset and located on the proximal extremities of young adults) exists; this is referred to as *pigmented spindle cell nevus (Reed nevus)* and is regarded by many authors as a separate entity from Spitz nevus (Fig. 3.57).[696–699]

Sometimes, Spitz nevi of predominantly dermal location are accompanied by an extensive stromal desmoplasia, which encircles the individual cells and simulates an invasive pattern (*desmoplastic* Spitz nevus).[700] This feature is more commonly seen in adults, which adds to the diagnostic difficulty. Other features occasionally present in Spitz nevi are predominantly intraepidermal growth (*pagetoid* Spitz nevus),[701] invasion of lymph vessels,[702] florid pseudoepitheliomatous hyperplasia (Fig. 3.58),[132] "tubular" pattern of growth,[703] plexiform pattern of growth (*plexiform* Spitz nevus),[704,705] halo reaction,[706] and prominent vasculature (*angiomatoid* Spitz nevus).[707] Features that favor a diagnosis of Spitz nevus over one of malignant melanoma are symmetric shape; sharp lateral demarcation; maturation in depth; arrangement of the spindle cells perpendicularly to the skin surface; presence of tadpole and multinucleated giant cells; lack of upward epidermal spread of single melanocytes (see earlier); presence of telangiectasia, edema, and fibrosis; presence of eosinophilic hyaline bodies along the dermoepidermal junction thought to be made of basement membrane material (Kamino bodies); and lack of ulceration.[708–712] In addition, the cytoplasm of benign

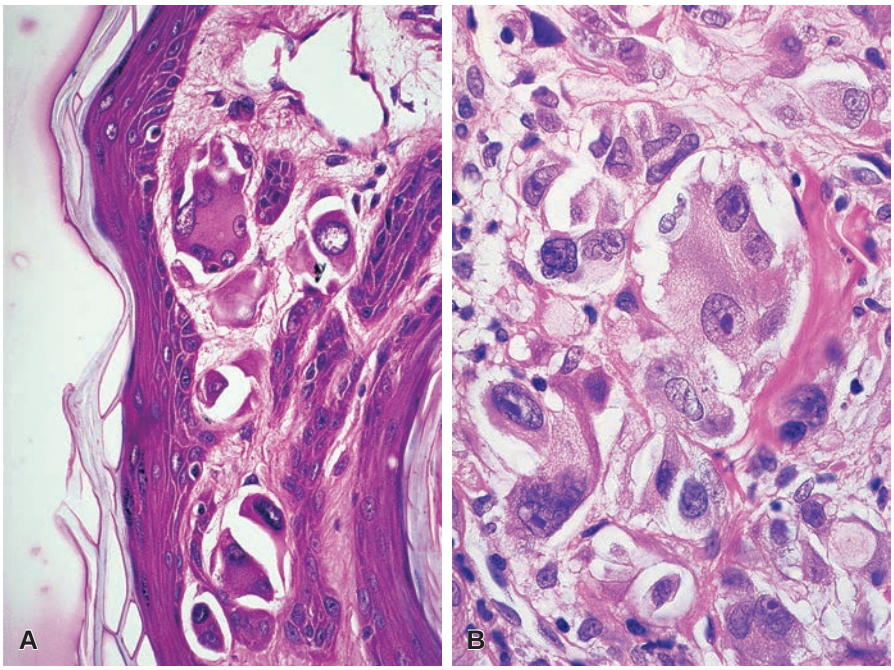

Figure 3.56 **A** and **B,** Spitz nevus of epithelioid type. The tumor cells feature large size, polygonal shape, occasional multinucleation, and a strongly eosinophilic cytoplasm.

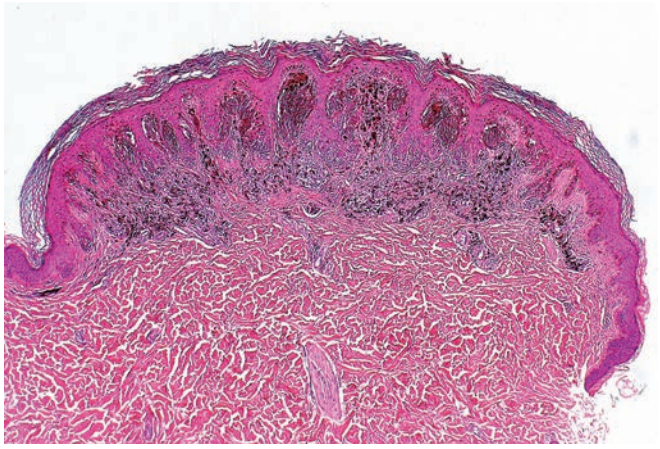

Figure 3.57 **Reed Nevus.** The tumor is heavily pigmented, in contrast to the usual type of Spitz nevus.

epithelioid nevi has a homogeneous acidophilic ground-glass appearance, whereas that of melanoma cells tends to be more irregular in configuration and staining reaction. An additional feature said to be in favor of the diagnosis of melanoma is so-called consumption of the epidermis, as defined by thinning of the epidermis with attenuation of the basal and suprabasal layers and loss of rete ridges in the areas of direct contact with neoplastic melanocytes.[713] Unfortunately, immunohistochemical stains have proved of very little value in this important differential diagnosis.[714] Immunostains for S100A6 protein expression have been touted as an effective adjunct in the differential diagnosis, but this has not widely been adopted.[715] Consistent immunostaining for p16 in desmoplastic Spitz nevus has been reported to differ from the infrequent p16 staining (18.2%) in desmoplastic melanoma, but there remains overlap.[716] Unfortunately, the same can be said for other immunohistochemical stains, and immunohistochemistry is at best supportive in nature but not reliably discriminatory.

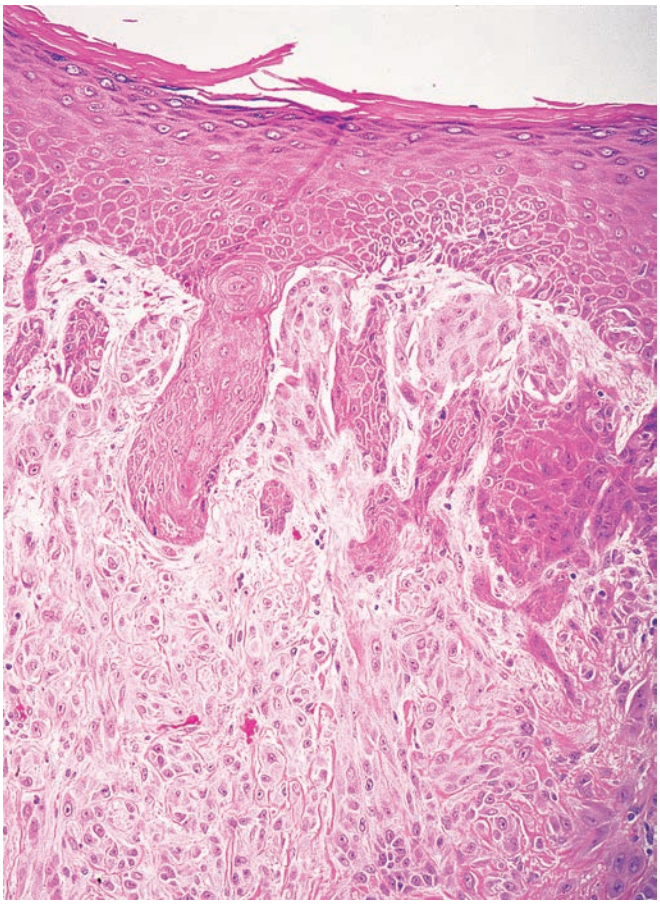

Figure 3.58 Spitz nevus of the spindle cell type that is predominantly intradermal.

Comparative genomic hybridization shows that most cases of Spitz nevi do not exhibit chromosomal aberrations, and only 25% show gain of chromosome 11p.[717] *HRAS* (located on 11p) mutations are common in cases with 11p abnormality.[718] In contrast to malignant melanoma, mutations in *BRAF* and *NRAS* genes are not typically found in Spitz nevus.[719] More recently, kinase fusions involving *ROS1*, *NTRK1*, *ALK*, *BRAF*, and *RET* have been described in Spitz nevi, atypical Spitz tumors, and spitzoid melanomas, suggesting that these genetic rearrangements may impart particular histologic features.[699,720,721]

The behavior of Spitz nevi is almost uniformly benign, but local recurrences may result from incomplete excision; these may show greater architectural irregularities than the original lesion.[722] That being said, several cases of "Spitz nevi" associated with regional lymph node involvement have been reported.[712,723] These "malignant Spitz nevi" tend to be large and deep, with pushing penetration of the dermis and subcutis. None of the patients reported by Smith et al.[125] went on to develop distant disease. However, we have seen a clinically and histologically typical case of Spitz nevus in the cheek of a young girl previously affected by acute leukemia that recurred locally, then metastasized to a regional node, and eventually led to widespread metastases and death.[724]

The argument as to whether or not malignant Spitz tumor exists is largely semantic. There is no question—as the cases previously described illustrate—that, on occasion, cutaneous melanocytic tumors with morphologic features of Spitz tumor behave in a malignant fashion. Whether one calls them malignant Spitz tumor, Spitz-type malignant melanoma, or spitzoid melanoma is immaterial, but to call them malignant melanomas without a qualifier does not fully convey the clinicopathologic identity of this rare but important entity.[725] In this scheme, and following a reasoning similar to that adopted for cellular blue nevus (see previous section), Spitz nevi that show worrisome microscopic features not sufficient to place them in a straightforward malignant category have been designated as *atypical Spitz tumors* or *melanocytic tumors of uncertain malignant potential (MELTUMP)*.[726–728] At a practical level, one should be aware of the fact that a significant percentage of these borderline tumors (especially those in the Spitz category; 33%–50% of the cases) show involvement of the sentinel nodes.[729–731] None of the patients reported by Smith et al.[724] went on to develop distant disease, and therefore may not truly represent malignancy despite involvement of lymph nodes. However, aggressive tumors with Spitz features have resulted in mortality. Recently, it has been demonstrated that a subset of atypical Spitz tumors with homozygous deletion of 9p21 are aggressive tumors worthy of being considered a type of spitzoid melanoma.[732]

A recently described subset of atypical Spitz tumors have deletions of *BAP1*. This results in intradermal tumors composed of large epithelioid melanocytes admixed with more conventional appearing melanocytes. An inflammatory infiltrate is frequently present. These appear to be benign, but patients with germline mutations of *BAP1* are prone to development of melanoma.[733] This further highlights how the group of lesions that have been designated Spitz tumors is biologically and molecularly diverse.

Congenital Nevus

Congenital nevus differs from the more common acquired variety because of its generally larger size (Fig. 3.59); tendency to involve the reticular dermis and subcutaneous tissue; single cell permeation of dermal collagen bundles; and involvement of skin adnexa, arrector pili muscles, nerves, and vessels.[734–736] However, there are too many exceptions to allow for an absolute distinction based on microscopic criteria alone.[734] Neuroid differentiation, such as the formation of Wagner–Meissner-like corpuscles, is common. The term *neuronevus*

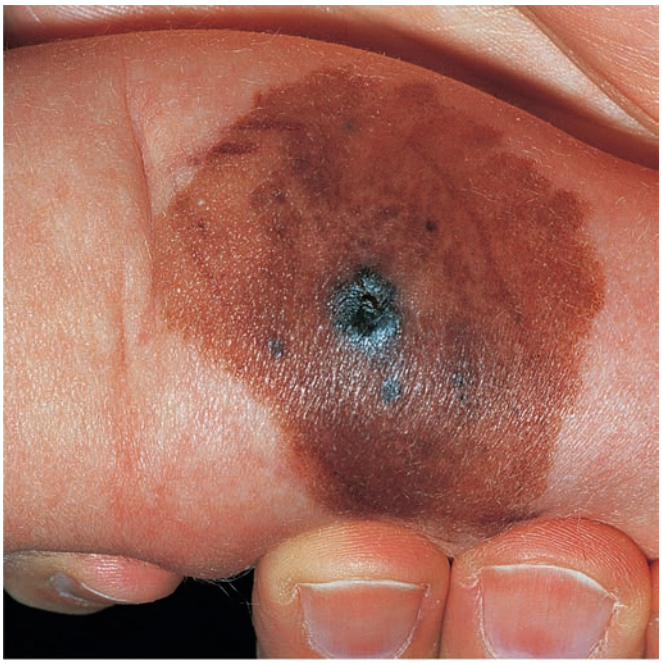

Figure 3.59 Congenital nevus with central hyperpigmented area. This corresponded microscopically to a pagetoid intraepidermal proliferation of melanocytes.

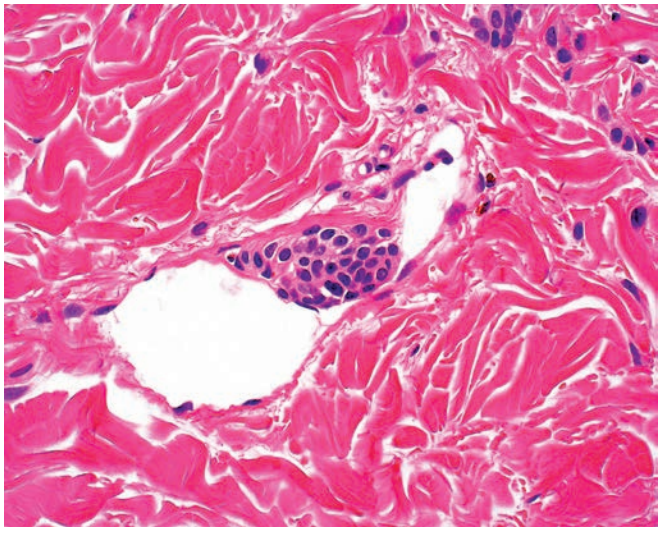

Figure 3.60 Vascular involvement in congenital nevus. This is not a sign of malignancy.

has been applied to congenital (and some acquired) nevi in which this feature is particularly prominent. When looking at these formations, one marvels at the fact that some authors deny the participation of specialized peripheral nerve structures in the formation of these lesions. The arrangement of round nevus cells in and around vessel walls may simulate the appearance of a glomus tumor (Fig. 3.60).[737] In some cases a nodular or hyperpigmented area develops within the nevus, which may be a cause of great concern both clinically and histologically. These proliferative nodules may show pagetoid intraepidermal proliferation of melanocytes, simulating the appearance of superficially spreading melanoma,[738] but typically regress if left alone.[739] Some congenital nevi also resemble melanoma at the clinical level, especially when located in acral sites[740] or when growing in a very rapid fashion.[741]

Like most melanocytic nevi, and in contrast to Spitz nevi and blue nevi, congenital nevi commonly show *BRAF* mutation.[614] There are no chromosomal aberrations.

Giant congenital nevus is a variant of congenital nevus characterized by its extensive size, its surface area being by definition 144 cm^2 or larger. It has also been defined as a nevus that measures more than 20 cm in diameter in an adult or that occupies 20% or more of the body surface area.[742] It has a tendency to distribute along a dermatome and often has a "bathing trunk" or "garment" configuration. It is also referred to as *giant pigmented nevus* and *giant hairy nevus*. It may involve a whole extremity, the entire scalp, and most of the trunk and even extend into the placenta.[743] It is often associated with smaller ("satellite") nevi and with nevi in mucosal membranes.[744] When in the scalp, it may result in convoluted folds of greatly thickened skin; this is known as *cerebriform* congenital nevus and is the usual histologic substratum of so-called *cutis verticis gyrata*.[745] Its microscopic appearance is qualitatively similar to that of the more common (non-giant) congenital nevus; occasionally, it has a component of pigmented large epithelioid cells similar to those seen in epithelioid blue nevus.[746]

Giant congenital nevus is sometimes associated with meningeal or cerebral melanosis (so-called *neurocutaneous melanosis or melanocytosis*),[747,748] or it may occur as a component of *melanophakomatosis*, together with numerous satellite nevi. Dissemination to the peritoneal surface by ventriculoperitoneal shunting has been exceptionally observed.[749] Neurocutaneous melanosis may give rise to malignant melanoma of the skin or central nervous system and to related malignant neuroectodermal tumors with a variety of patterns, including malignant peripheral nerve sheath tumor (MPNST), so-called *cutaneous malignant melanotic neurocristic tumor*, rhabdomyosarcoma, liposarcoma, and round cell or spindle cell undifferentiated forms.[750–753] Exceptionally, this malignancy occurs outside the region of the congenital nevus.[754,755] Whether the smaller congenital nevi are also subject to an increased risk of malignant transformation has not yet been established with certainty.[756,757]

Active, Dysplastic, and Atypical Nevi

Active nevus ("hot nevus") is a term that has been applied to benign melanocytic nevi that show prominence of the junctional component and hyperplasia of individual basal melanocytes, often associated with increased overall cellularity and dermal inflammatory infiltrate. Activation of nevi, thus defined, has been reported as a result of sunlight exposure[758] or ultraviolet irradiation,[759] in pregnancy,[760,761] following the use of contraceptive pills, in association with malignant melanoma elsewhere in the skin,[762] in recurrent nevi,[763] and sometimes for no obvious reason. It has been suggested that HIV infection is yet another cause of melanocytic activation.[764] Exceptionally, a myriad of "eruptive" nevi with the microscopic signs of activation unassociated with any recognizable cause will appear in an adult.[765]

Dysplastic nevus remains a highly controversial concept.[766] This lesion seems to blend or at least exhibit some morphologic similarities with the phenomenon of activation of nevi as already described. In its better-defined form, it occurs as a genetically determined syndrome in families prone to develop malignant melanoma (dysplastic nevus syndrome).[767,768] The nevi are clinically atypical, with a relatively large size (>5 mm), irregular outline, and variegated appearance; they appear in adolescence and continue to develop in adult life (Fig. 3.61).[769,770] Microscopically, most dysplastic nevi are compound nevi exhibiting marked lentiginous proliferation of melanocytes at the dermoepidermal junction, with or without nests. The latter are irregularly sized and shaped. These nests bridge adjacent rete ridges, which are themselves of irregular shape and orientation. If a dermal component is present, the junctional component is seen to extend beyond its lateral margins. The dermis shows eosinophilic and lamellar fibroplasia, focal perivascular lymphocytic infiltrate, and vascular dilation.[771,772] These features, collectively referred to as *architectural atypia*, are usually matched by a mild to moderate degree of cytologic atypia, manifested by nuclear hyperchromasia, prominent nucleoli, and dusty melanin pigment.[773] The melanocytes can be spindle shaped or epithelioid; the former tend to be arranged parallel to the skin surface (Fig. 3.62).[774]

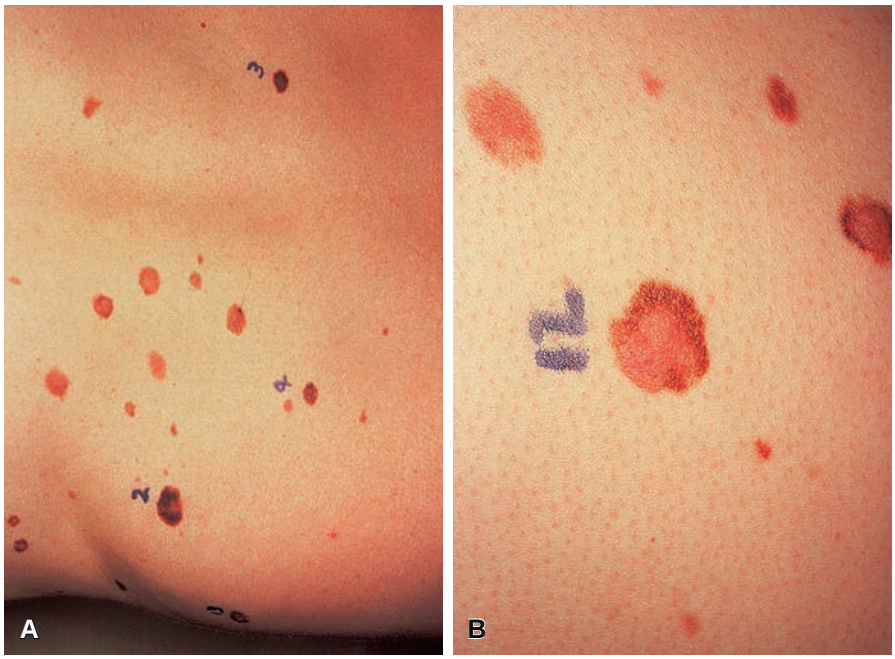

Figure 3.61 **A** and **B,** Clinical appearance of dysplastic nevi in patient with the dysplastic nevus syndrome. These nevi are large, have an irregular outline, and feature a variegated appearance. (Courtesy Dr D Santa Cruz, St Louis.)

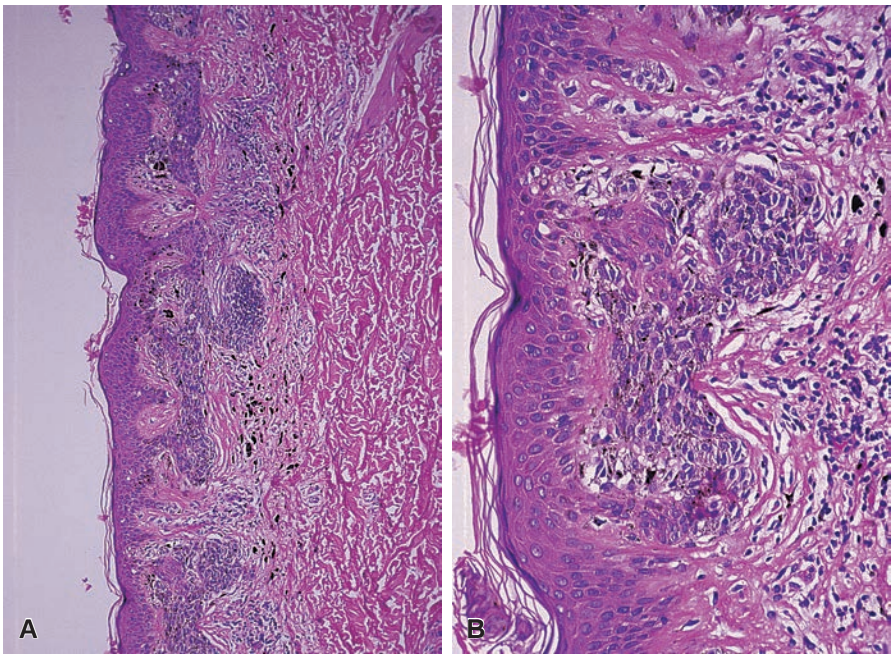

Figure 3.62 **A** and **B,** So-called dysplastic nevus. There is dermal fibrosis, inflammation, and a proliferation of melanocytes at the dermoepidermal junction, with bridging of rete ridges.

Proposals have been made to grade dysplastic nevi depending on the severity of atypia, but the criteria are far from standardized.[775–777] It has been further suggested that the degree of atypia in these nevi correlates with the risk for developing melanoma.[778] It should be remarked that only a minority of the clinically atypical nevi fulfill the microscopic criteria for dysplastic nevus.[779,780]

Ultrastructurally, a variety of melanosomal alterations have been described in these lesions.[781] DNA ploidy studies have shown that nearly all dysplastic nevi are diploid,[755] despite previous claims to the contrary.

Although the importance of having identified a familial syndrome with a predisposition toward melanoma cannot be overemphasized, the application of this concept to the solitary pigmented lesions remains questionable in terms of morphologic criteria, molecular markers, and biologic significance.[782–785] On the basis of present evidence, we think that solitary melanocytic nevi with "dysplastic" features should be regarded as clinically benign. That being said, many clinicians advocate conservative reexcision of dysplastic nevi with moderate to severe dysplasia. At the very least those patients probably should have continued clinical surveillance.

A more general approach to the problem can be taken by acknowledging the fact that one encounters, not infrequently, a melanocytic nevus (usually of the compound type) with atypical changes of the intraepidermal component. If the atypia is of a degree such as to indicate the emergence of a bona fide malignant neoplasm, we designate such a lesion as an in situ malignant melanoma arising in a compound nevus. For the considerably more common cases in which the atypia is below the threshold of melanoma (fully acknowledging the subjective nature of this determination), descriptive terms can be used. A descriptive diagnosis such as "atypical junctional or compound melanocytic proliferation" or "nevus with cytologic atypia" can be used as long as the pathologist acknowledges the diagnostic uncertainty and recommends that the lesion be conservatively but completely reexcised, comforted by the knowledge that a complete surgical excision will be curative in practically every instance.

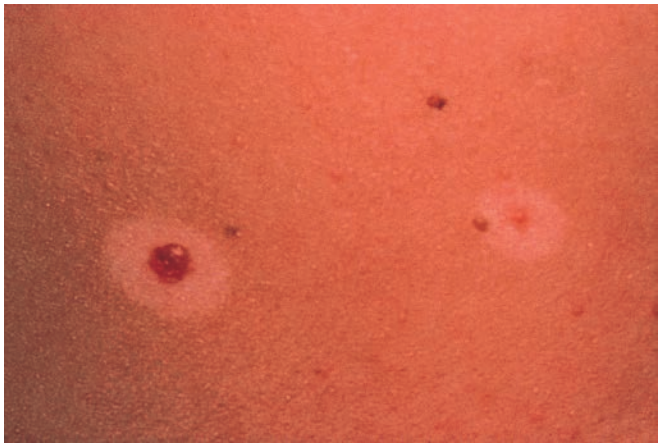

Figure 3.63 **Typical Clinical Appearance of Halo Nevus.** Heavily pigmented center is surrounded by sharply defined oval area of depigmentation. Pigmented nevus may be situated in center, as here, or be eccentric. (Courtesy Dr AW Kopf, New York.)

Other Nevi

Halo nevus (leukoderma acquisitum centrifugum) is the clinical term used to describe a melanocytic nevus surrounded by a zone of depigmented skin (Fig. 3.63).[786] It is most commonly found on the trunk of young patients, and it can be multiple.[787] Microscopically, it is characterized by a heavy infiltration of the nevus by lymphocytes and histiocytes and is thought to represent the expression of a host immune response (Figs. 3.64 and 3.65). The lesion can be confused with melanoma, lymphoma, and dermatitis. Ultrastructurally, melanocytes in various stages of degeneration can be identified amid the lymphohistiocytic elements.[787] It should be mentioned that malignant melanoma may also be surrounded by a halo of depigmented skin.[788] However, in this instance the halo tends to be irregular, and the pigmented spot is usually off center.

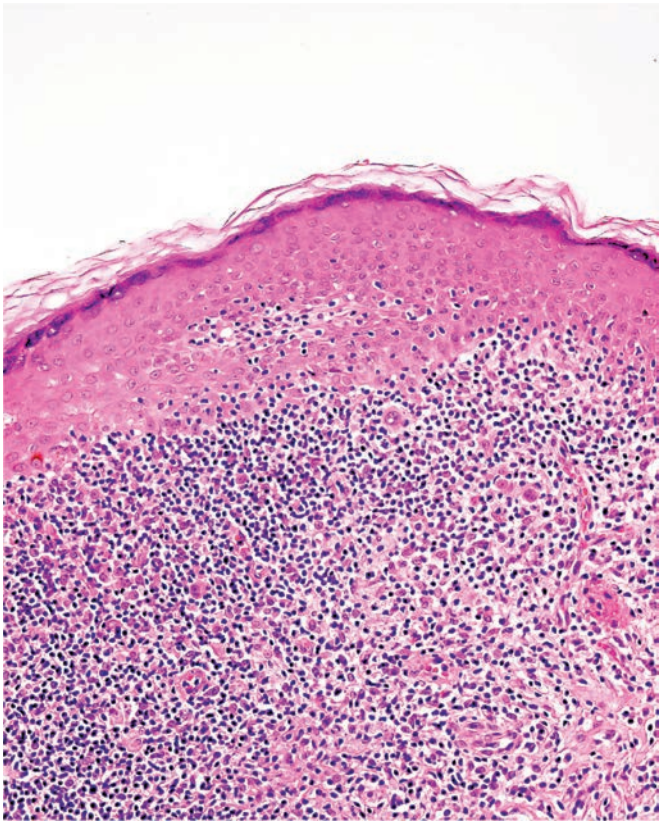

Figure 3.64 Halo Nevus. The low-power view is that of an inflammatory dermal nodule.

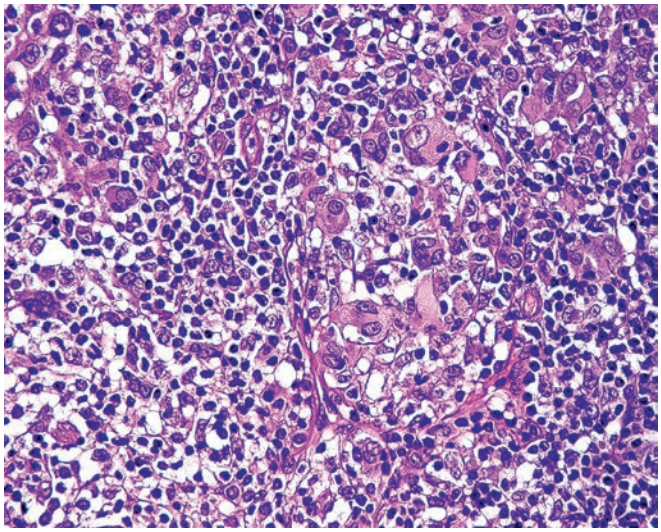

Figure 3.65 Halo Nevus. High-power view showing residual melanocytes amid a heavy inflammatory infiltrate.

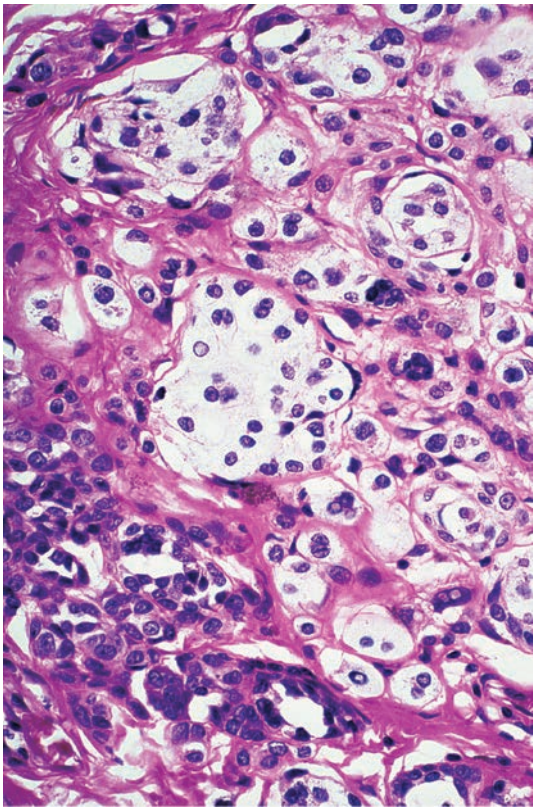

Figure 3.66 Balloon Cell Nevus. The tumor cells are arranged in nests and have a voluminous pale cytoplasm.

Balloon cell nevus is another unusual variety of nevus, identified by the presence of large pale melanocytes with foamy cytoplasm, perhaps the result of a biochemical alteration in melanin synthesis (Fig. 3.66).[789] Balloon cells also can occur in blue nevi and malignant melanomas.[790]

Cockarde nevus is characterized clinically by a concentric pattern of pigmentation; a central pink to darkly pigmented papule is surrounded by a stippled pigmented circle, with a clear zone in between.[791] Microscopically, the central lesion is a junctional or compound nevus without inflammatory changes, the peripheral portion (ring) shows multiple junctional melanocytic nests, and the intermediate zone is basically unremarkable.

Deep penetrating nevus is the name given to a variant of compound nevus morphologically similar to blue nevi, in which the dermal component extends deeply into the reticular dermis and sometimes even into the subcutaneous fat.[792] The junctional component is usually inconspicuous, whereas the dermal component is cellular, nested or fascicular, abundantly pigmented, and cytologically mildly atypical. Mitoses are nil, and there is little or no inflammatory infiltrate. Sometimes deep penetrating nevus is seen admixed with other types of nevi, as a form of combined nevus.[793]

Treatment

Because every white adult has, on average, 20–30 nevi, it is obvious that specific indications are needed for their removal, other than those dictated by cosmetic considerations. The presence of a junctional component per se is not an indication; most plantar and palmar nevi are junctional, but they are too common and the possibility of malignant transformation too remote to warrant routine removal.[794,795] Definite indications for excision include the appearance of a pigmented lesion in an adult, chronic mechanical irritation of a nevus, or the appearance of any of the following changes in a preexisting nevus: deepening of pigmentation or spread of the pigment beyond the gross confines of the lesion, appearance of flat areas of depigmentation within the nevus, appearance of a red inflamed zone around the nevus, rapid growth, ulceration, itching, oozing of serum, or bleeding with trivial trauma.[796]

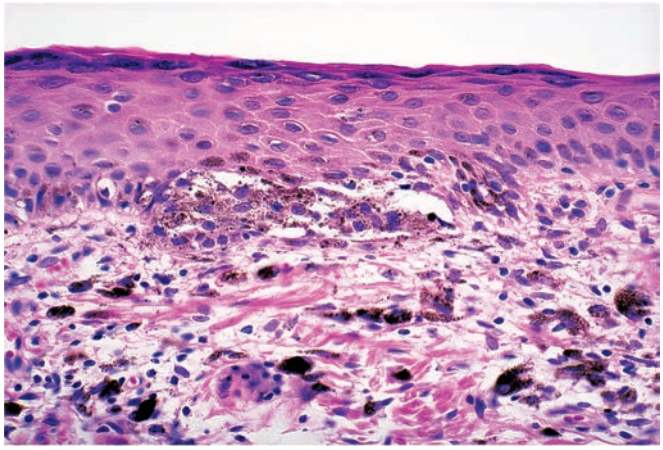

Figure 3.67 Recurrent Nevus Following Shave Excision. There is an irregular proliferation of melanocytes along the dermoepidermal junction, associated with some dermal fibrosis and clusters of melanin-laden macrophages. This lesion should not be overdiagnosed as malignant melanoma.

Removal of a nevus should be carried out with a cold knife rather than a cautery to prevent the distortion of tissue and peculiar staining reactions associated with the latter. Incomplete removal may result in local recurrence.[797–799] The recurrent lesion often shows junctional activity, even if this feature was not present in the original excision.[800] This, together with the nuclear enlargement and nucleolar prominence that often accompany these recurrences, has sometimes resulted in a mistaken diagnosis of malignant melanoma with regression (Fig. 3.67).[763,801] Parenthetically, another pseudomalignant feature that may be seen in a reexcision skin specimen is the growth of squamous epithelium in the perineurial spaces, mimicking perineurial invasion.[802]

Early surgical removal of the giant form of congenital nevus is also recommended because of their greater tendency to undergo malignant transformation; unduly large lesions have to be excised in the course of several sessions.

Malignant Melanoma

General Features

The large majority of melanomas are associated with sunlight exposure and thought to be due to ultraviolet radiation.[803,804] Therefore, most are found in the head and neck area and on the lower extremities, the latter location being particularly more common in women.[805,806] Rare but well-known locations of cutaneous melanomas are the subungual region ("melanotic whitlow")[807–809] and the palms and soles. White people, particularly those of fair complexion, red hair, and a tendency to burn or develop freckles after exposure to sunlight,[810] are particularly susceptible to the development of melanomas. The few melanomas developing in blacks tend to occur in the palms, soles, nail beds, or mucous membranes.

The overwhelming majority of melanomas arise after puberty. However, there is no question that they can also occur in children.[811–816] Most of these melanomas have the same microscopic pattern as those in adults and, therefore, can be distinguished in most cases on morphologic grounds from Spitz nevi.[817,818]

The presence of a large number of melanocytic nevi represents a risk factor for melanoma, even if these nevi are not of the dysplastic type.[819–821] The genetically determined disease *xeroderma pigmentosum* predisposes to the development of melanoma. Cases of melanoma have been reported in association with type I Recklinghausen disease[822] and in solid organ transplant recipients, the latter setting also associated with increased lethality.[823,824]

Malignant melanomas can present as multiple primary tumors.[825,826] In a series of 712 patients with melanomas, 38 (5.3%) had more than one primary melanoma: 24 had 2 primary lesions, 11 had 3, 2 had 4, and one had 8.[827] The prognosis was more dependent on the type and stage of the largest lesion than on the number of primary lesions. Multiple primary melanomas should be distinguished from the admittedly controversial phenomenon of nevus activation in patients with melanomas.[762]

The existence of hereditary forms of malignant melanoma has been known for a long time.[828] Members of melanoma-prone families often exhibit numerous atypical melanocytic lesions ("dysplastic nevi") that serve as a cutaneous marker of those at higher risk.[829] A proportion of cases of hereditary melanoma are caused by germline inactivating mutation in *CDKN2A* on chromosome 9p21 (encoding two tumor suppressor gene products, p16INK4a and p14ARF) or less commonly, activating mutation in *CDK4*.[830–835] Germline mutations in the tumor suppressor gene *BAP1* have been associated with an increased risk for developing cutaneous and uveal melanoma, as well as malignant mesothelioma.[836–838]

The fact that malignant melanomas can develop from nevi can be no longer denied, but the exact percentage is not clear. It is obvious that only an infinitesimal portion of acquired nevi become malignant. The percentage is higher for congenital nevi and for dysplastic nevi, but the exact figures are again unknown. Remnants of dysplastic nevi are said to be present in anywhere from less than 5% to almost half of all melanomas, this wide range undoubtedly reflecting the difficulties in distinguishing lateral melanoma spread from a preexisting precursor lesion.[839]

Clinical Appearance and Major Clinicopathologic Types

For the purposes of clinical and microscopic description, it is useful to divide melanomas into different types. The most common forms of melanoma can be divided into four categories[840-844] while acknowledging the fact that the clinicopathologic or prognostic differences among them are not as sharp as originally claimed.[845,846] These categories are *lentigo maligna* melanoma, *superficially spreading* melanoma, *nodular* melanoma, and *acral lentiginous* melanoma. A high degree of accuracy in the differential diagnosis among these types is possible on the basis of location and gross appearance.[847]

Lentigo maligna (Hutchinson freckle) typically occurs in the sun-exposed areas of elderly white persons, most commonly on the cheek.[848,849] It is a flat, slowly growing lesion, its color varying from tan to black.[850] Microscopically, it is characterized by a proliferation of atypical melanocytes in the basal layer, distributed individually as well as in nests (Fig. 3.68). Retraction of the cytoplasm is common and pleomorphism may be prominent.[850] Upward migration is less prominent than in other types of melanoma. The proliferation of atypical basal melanocytes in the deep portion of the rete ridges can simulate invasion, especially in a tangential section. It is advisable to be very conservative in the evaluation of this lesion, just as one should be in actinic keratosis. When confined to the epidermis, it is considered *lentigo maligna*, a form of melanoma in situ. When a dermal component is present, the term *lentigo maligna melanoma* is used. The term *lentiginous melanoma* has been proposed for a lesion that seems to us to represent a variation in the theme of lentigo maligna, but this terminology is not widely used.[851,852]

Another type of invasive melanoma that can develop within lentigo maligna is *desmoplastic melanoma* (see later).[853] This tumor tends to recur locally, as well as to metastasize distantly.[854] It can also be seen in connection with other pigmented lesions.[855]

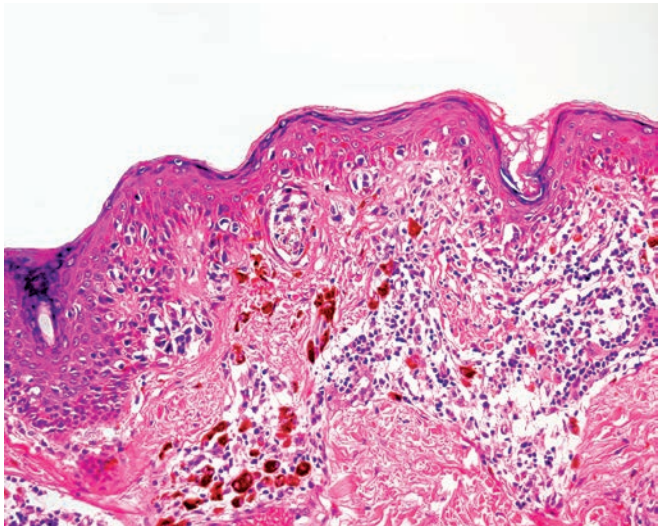

Figure 3.68 So-Called Lentigo Maligna. The atypical melanocytes are present along the basal layer individually and in theques.

Figure 3.69 Clinical appearance of melanoma of superficially spreading type. The nodular light area corresponds to a focus of amelanotic malignant melanoma featuring deep dermal invasion.

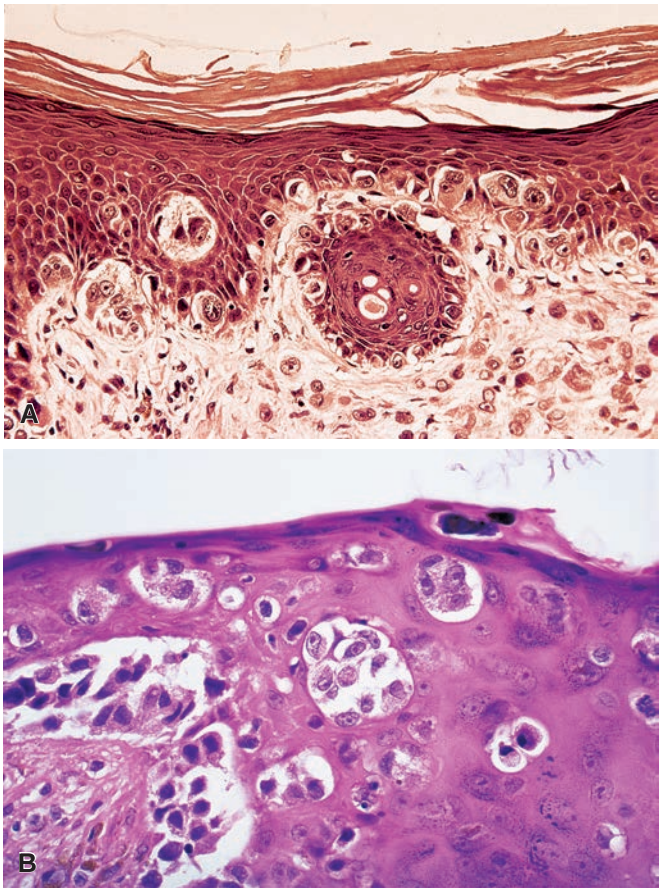

Figure 3.70 A, Pagetoid appearance of melanocytes in superficially spreading malignant melanoma. **B,** Malignant melanoma showing transepidermal migration. There is also individual necrosis of neoplastic melanocytes. Some of the melanin has reached the horny layer (so-called pigmented parakeratosis).

Superficial spreading melanoma is the most common form of melanoma. It has also been previously called premalignant melanosis and pagetoid melanoma, and it can occur anywhere on the body surface. It has a variegated appearance, the colors including hues of tan, brown, black, blue, pink, and white. The telltale color of early superficially spreading melanoma is most frequently a shade of blue admixed with tan, brown, or dark brown.[847] The surface is slightly elevated, and the margins are barely palpable (Fig. 3.69). The white areas correspond to areas of spontaneous regression; they are related to tumor size but not to the level of invasion or prognosis.[856] Pink and blue areas also correspond to areas of tumor regression, associated with dermal fibrosis and accumulation of melanin-laden macrophages. The borders of the lesion are irregular and usually include a prominent indentation or notch. Deep invasion generally is accompanied by the appearance of an elevated nodule on the surface. Microscopically, the noninvasive areas are composed of uniform atypical melanocytes with nest formation and pagetoid appearance (Fig. 3.70).

Nodular melanoma can present as a smooth nodule covered by normal epidermis, as an elevated blue–black plaque, or as a polypoid, frequently ulcerated mass.[857] A lateral flat component is not seen clinically or microscopically. This type of melanoma affects all body surfaces, is usually of short duration, and occurs in a younger age group than either of the foregoing two categories.

Acral lentiginous melanoma has an intraepidermal component of lentiginous type, which is similar in many respects to that seen in lentigo maligna.[844,846,858] In contrast to the latter, however, the intraepidermal melanocytes tend to be dendritic and bizarre, the involved epidermis is markedly hyperplastic rather than atrophic, and the papillary dermis in this region is widened and inflamed. Tumors with these features have been seen on the palms, soles, subungual areas, mucocutaneous junction of the oral and nasal cavities, and anus.[859] This type of melanoma is more common in blacks and Asian people.[860,861]

The clinical differential diagnosis of malignant melanoma includes a wide variety of lesions, particularly those containing melanin or hemosiderin pigment: benign nevi of various types, benign fibrous histiocytoma, inflamed or thrombosed hemangioma, pigmented seborrheic keratosis, and pigmented basal cell carcinoma.[862] Conversely, malignant melanomas that are amelanotic or covered by a thick layer of keratin can simulate a pyogenic granuloma or a callus, respectively.

Microscopic Features and Other Melanoma Types

The typical example of malignant melanoma is easily identified microscopically because of its junctional activity; prominent melanin

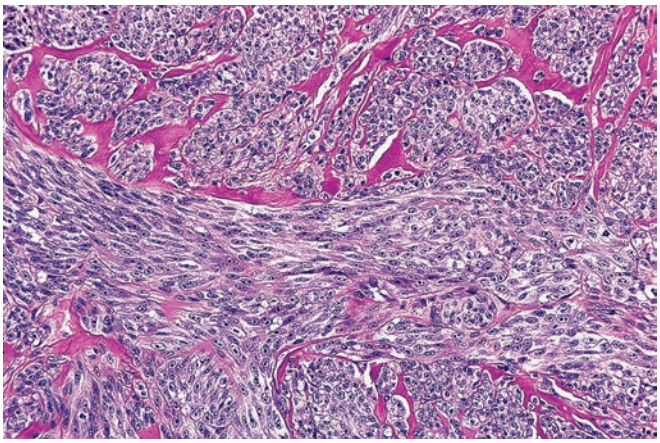

Figure 3.71 Malignant melanoma in the region of the Achilles tendon showing prominent spindling. This is a common finding in tumors at this site.

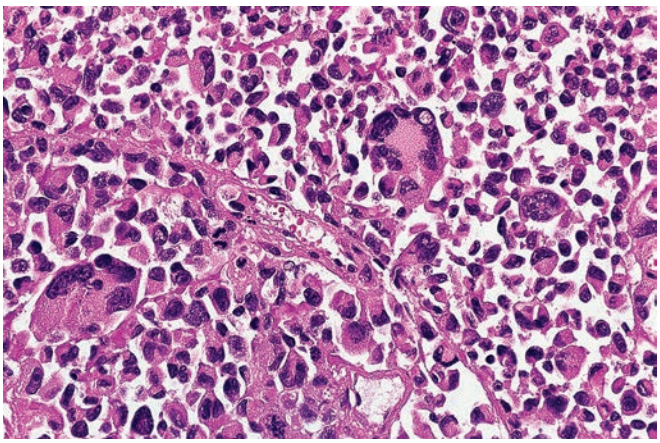

Figure 3.72 Melanoma containing highly anaplastic tumor cells.

pigmentation; invasion of the surrounding tissue; marked cytologic atypia; nuclear grooves, folds, and pseudoinclusions; large eosinophilic nucleoli; and abundant mitotic figures, some of them atypical.[863] Alas, this is not always the case. As a matter of fact, malignant melanoma is notorious for the great microscopic variability that it may exhibit.[864–866] The cells can be epithelioid, spindle shaped, or extremely bizarre ("monster cells").[867] Their size can range from small (lymphocyte-like)[868] to spindled to giant multinucleated forms (Figs. 3.71 and 3.72). The cytoplasm can be eosinophilic, basophilic, foamy, of signet ring type,[869,870] rhabdoid,[871–873] oncocytic[874] or completely clear (balloon cell melanoma).[875] Melanin can be abundant, scanty, or absent (amelanotic melanoma).

Sometimes the amount of melanin production is so massive as to obscure the cellular details; such cases have been inelegantly called *animal-type melanoma* on the grounds that they resemble melanocytic neoplasms in horses and other mammals.[876] Their behavior is that of low-grade neoplasms, with the potential for local recurrence, nodal metastases, and very exceptionally distant metastases.[877] The claim has been advanced that this animal-type melanoma is the same entity as epithelioid blue nevus, and the proposal has been made to rename it *pigmented epithelioid melanocytoma*.[687]

The pattern of growth of melanoma may be pseudoglandular, pseudopapillary, peritheliomatous, hemangiopericytoma-like, resembling Spitz nevus (spitzoid melanoma), rosette-like, trabecular (Fig. 3.73), verrucous (nevoid or pseudonevoid melanoma) (Fig. 3.74), carcinoid-like, or follicular (i.e., centered in the hair follicle and the

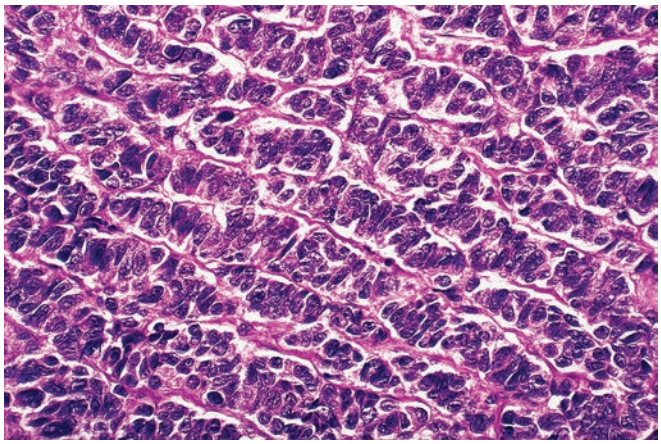

Figure 3.73 Prominent trabecular pattern of growth in melanoma.

adjacent dermis).[866,878–884] The tumor can be accompanied by marked fibroblastic response, myxoid changes (Fig. 3.75),[885,886] osteoclast-like giant cells,[887–889] Touton-like giant cells,[890] pseudoepitheliomatous hyperplasia of the overlying epidermis,[131] and a variety of divergent differentiations, including osteocartilaginous, rhabdomyoblastic, and neuroendocrine.[891–894] Occasionally, formations suggesting differentiation toward Schwann cells, tactile corpuscles, ganglion cells, and other neuroid structures are observed.[895–897] Sometimes the lymph node and other metastases of a melanoma acquire an appearance that is practically indistinguishable from that of an MPNST.[898] The knowledge that MPNSTs rarely metastasize to lymph nodes is helpful in the distinction.

Desmoplastic melanoma, which has already been mentioned, represents a distinct subtype of spindle cell melanoma.[899] The head and neck is the most commonly affected region.[900] This is an important subtype of melanoma because of the fact that it can be easily misdiagnosed, sometimes with serious consequences. An overlying junctional component consisting of melanocytic hyperplasia to lentigo maligna is frequently, but not invariably, present. The dermal component is formed of spindle cells arranged in short fascicles surrounded by a heavy desmoplastic stroma. The tumor cells can be very scanty and not overly atypical. The difficulty is compounded by the fact that these cells are positive for S-100 protein but usually not for HMB-45, Melan-A, or any of the other more specific melanoma markers, while sometimes acquiring mesenchymal markers, such as actin.[901,902]

Desmoplastic melanomas can be "pure" or represent a portion of an otherwise conventional melanoma.[903] More cellular examples with less collagenous stroma are better regarded as spindle cell melanoma rather than desmoplastic melanoma. The differential diagnosis of desmoplastic melanoma includes hypertrophic scar (which may contain S-100 protein–positive cells),[904] atypical fibroxanthoma, spindle squamous cell carcinoma, and peripheral nerve sheath tumors. Clues to the diagnosis at the H&E level are focal fascicular pattern of growth, deep invasion, infiltration of nerves, and lymphoid aggregates at the tumor periphery (sometimes so prominent as to resemble cutaneous lymphoid hyperplasia/pseudolymphoma), and the presence of a lesion with the features lentigo maligna in the overlying epidermis (Fig. 3.76).[905] Alas, many of these features will often be absent in the individual case. *Neurotropic melanoma* is a variant of desmoplastic/spindle cell melanoma growing in a peripheral nerve sheath pattern, either because the tumors invade preexisting nerves or because they differentiate along peripheral nerve structures.[906–909] Along these lines, it is interesting that spindle cell melanomas have often been found to express the p75 neurotrophin

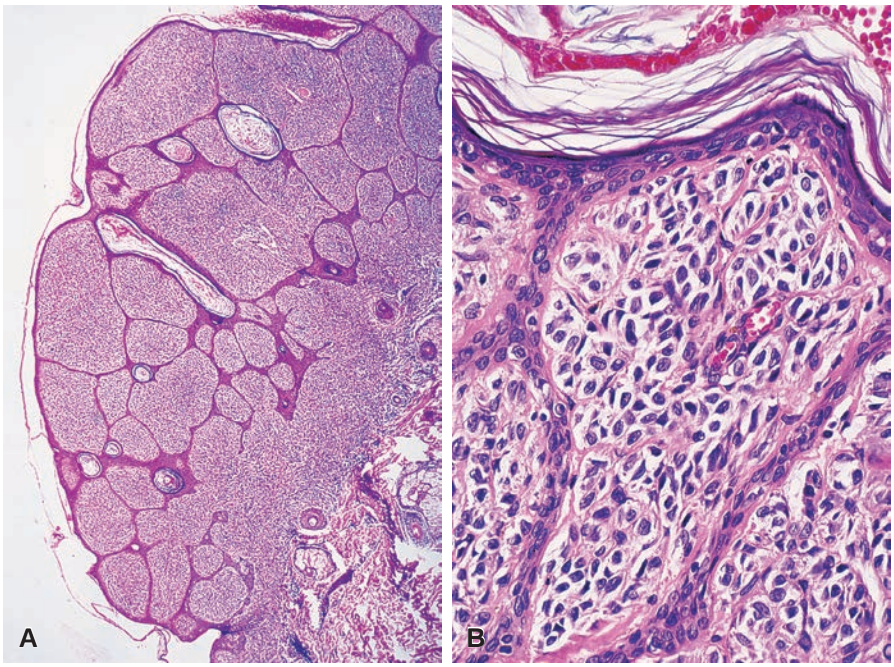

Figure 3.74 Malignant Melanoma With Nevoid Pattern of Growth. A, Low-power view showing a polypoid configuration suggestive of a benign intradermal nevus. **B,** High-power view showing only minimal atypicality of the tumor cells. This tumor recurred locally and eventually metastasized to regional lymph nodes. (Slide contributed by Dr Paul Duray, Bethesda, MD.)

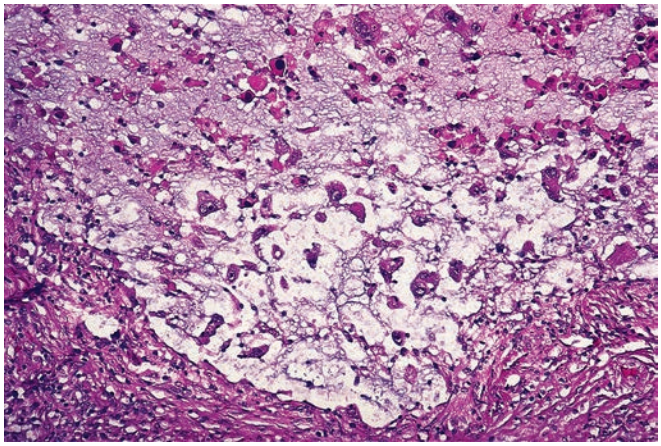

Figure 3.75 Myxoid Changes in Malignant Melanoma. This secondary alteration is more common at metastatic sites but can also be seen in the primary lesion.

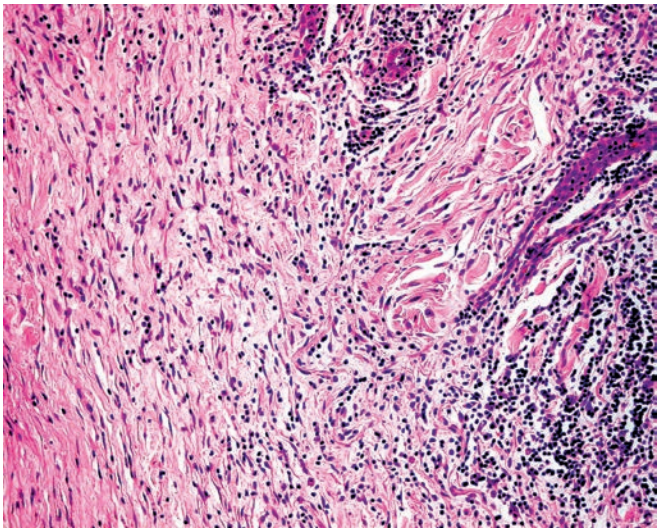

Figure 3.76 Desmoplastic Malignant Melanoma. The spindle cells have a deceptively bland appearance. The collections of lymphocytes are a characteristic feature.

receptor and nerve growth factor receptor (NGFR) (a marker of schwannian differentiation), two features further supporting a differentiation along neural lines.[910,911]

Borderline or *minimal deviation melanoma* is yet another proposed subtype of melanoma, a controversial concept that includes the previously cited verrucous and spitzoid melanoma, as well as a halo nevus–like type.[912–914] As a result of all these variations, malignant melanoma can simulate carcinoma, various types of sarcoma, malignant lymphoma, and several other neoplasms.

Nearly all primary melanomas exhibit an intraepidermal component ("junctional activity") during their initial phase. Therefore a melanoma lying entirely within the dermis should be suspected of being metastatic. However, many well-documented cases of primary intradermal melanoma exist, the possible explanations for their occurrence being total regression of the intraepidermal component or origin from an intradermal nevus. When encountering a purely intradermal primary melanoma, it should be distinguished from *cutaneous clear cell sarcoma*.[915]

At a practical level, there are two major diagnostic challenges in this field. The first is how to identify as melanoma an obviously malignant tumor when melanin formation is not apparent in routine sections. Features suggestive of melanoma in H&E sections are: cells with abundant acidophilic, finely granular cytoplasm; pseudonuclear inclusions; a combination of epithelial and spindle cell patterns of growth; a fascicular arrangement of tumor cells; and pseudoalveolar arrangement. Special stains, immunohistochemical stains, and

ultrastructural examination are of great utility in establishing the diagnosis in difficult cases (see next section). The other important diagnostic problem is the determination of whether a skin lesion of obvious melanocytic nature is benign or malignant. Benign lesions most commonly overdiagnosed as melanomas are Spitz nevi (especially the desmoplastic type of pure epithelioid nevus), halo nevi, activated and dysplastic nevi, vulvar (genital-type) nevi, and nevi that have recurred following incomplete excision. Conversely, the type of melanoma that is more likely to be underdiagnosed as benign is a level I or II superficially spreading type, especially if occurring in sites such as the plantar and the subungual regions.[916–918] We have found the criteria listed here to be the most useful for the identification of early malignant melanoma.[919,920] Unfortunately, none of them is pathognomonic. The diagnosis of melanoma can be made only on the basis of a combination of features.

1. Poor circumscription (lack of cohesiveness) of the intraepidermal melanocytic component. The nests are not as sharply defined as those of benign lesions, and the individual cells within the nests are separated from each other. A related phenomenon of similar diagnostic significance is subepidermal cleft formation, i.e., the presence of clefting of at least 0.3 mm in length between the epidermal layer and the underlying melanocytic proliferation.[921]
2. Lateral extension of individual melanocytes. Benign lesions usually exhibit a sharp cutoff, whereas in most malignant lesions there is a trailing off of atypical melanocytes spreading from the center of the lesion.
3. Extension of melanocytes, individually and in nests, throughout the malpighian layer and within adnexal epithelium. This phenomenon of transepidermal migration results in a pagetoid appearance of the lesion, hence the term "pagetoid melanoma" that is sometimes used. The melanin pigment can reach the horny layer, a process known as pigmented parakeratosis; this is rare in benign nevi, but appears with some frequency in some variants of benign lentigo and in "activated" benign lesions.
4. Size variation, shape variation, and confluence of melanocytic nests.
5. Asymmetry. This pertains to many of the items described in this list, such as lateral extension, the extent of the dermal component, architectural features of the nests, cell type, the distribution and appearance of the melanin, and the degree of inflammation and fibrosis.
6. Lack of maturation of dermal melanocytes. In benign nevi, the nests and individual melanocytes become smaller with descent into the dermis, whereas this is usually absent in melanoma.
7. Melanocytic atypia, evidenced by the prominence of nuclei and nucleoli and an increase of the nucleocytoplasmic ratio.
8. Mitotic activity. Most benign nevi have a very small number of mitotic figures, although some spindle and epithelioid cell nevi may contain many. The presence of atypical mitoses and dermal mitoses (especially deeply located) are strong indicators that the lesion is malignant. The same is true for the presence of mitoses in the dermal component of melanocytic lesions other than Spitz nevi. Some benign and malignant melanocytic lesions are associated with marked hyperplasia of the epidermis: in these cases, one should be careful to distinguish mitoses in keratinocytes from mitoses in melanocytes.
9. Melanocytes with an abundant clear cytoplasm having a finely dispersed ("dusty") chromatin. This has been interpreted as a sign of degeneration and is a particularly useful sign.
10. Necrosis of individual melanocytes. This phenomenon should be distinguished from the eosinophilic hyaline bodies (Kamino bodies) seen most often in Spitz nevi.
11. Dermal infiltrate of chronic inflammatory cells, mainly lymphocytes. This is particularly prominent in early lesions and tends to have a bandlike distribution instead of the patchy appearance usually seen in irritated nevi.

So far, no completely reliable ultrastructural, immunohistochemical, or molecular genetic features distinguishing between benign and malignant melanocytic lesions have been described.[922] At the ultrastructural level, there is a greater tendency for abnormal melanosome formation in malignant melanomas than in the benign lesion, but there is a great degree of overlap.[923]

Histochemical and Immunohistochemical Features

At the outset, it should be restated that all of the markers listed in this section are useful (to a greater or lesser degree) to distinguish normal or neoplastic melanocytes from other cell types, but none of them is of great utility in the separation between benign and malignant melanocytic neoplasms.

Melanin stains are silver based and rely on the reducing properties of melanin granules. These argentaffin stains (of which the Fontana–Masson is the most widely used) are particularly useful in two situations: detecting finely dispersed granules that are not immediately apparent in H&E sections or demonstrating (when used in conjunction with a negative iron stain) that the brown pigment seen in the routine sections is melanin rather than hemosiderin.

Immunohistochemically, the typical melanoma is reactive for S-100 protein, HMB-45, Melan-A, tyrosinase, MiTF, and SOX10.[599,924–926] Positivity for S-100 protein, although nonspecific, is of greater practical importance because it is negative in many of the tumors that enter in the differential diagnosis (Fig. 3.77).[927,928] This reactivity is both nuclear and cytoplasmic and is present in more than 90% of the cases.[929] However, it should be noted that melanomas (particularly in their metastases) can lose their immunoreactivity for S-100 protein (and most of the markers discussed next) as a consequence of phenotypic dedifferentiation.[930–932]

HMB-45 is a much more specific marker than S-100 protein (Fig. 3.78).[603] It is particularly useful when the differential diagnosis includes a nonmelanocytic tumor that can also be S-100 protein positive, such as breast carcinoma.[933] It may be detected in S-100 protein–negative melanomas, but on the whole it is less sensitive than the latter. It recognizes a premelanosomal glycoprotein (gp100) related to the tyrosinase system, which explains why it may be negative in undifferentiated amelanotic neoplasms.[934–937]

Melan-A (Mart-1; A103) is a melanocyte differentiation antigen originally identified as a target for cytotoxic T cells, which is detected with the monoclonal antibody A103. It is positive in approximately

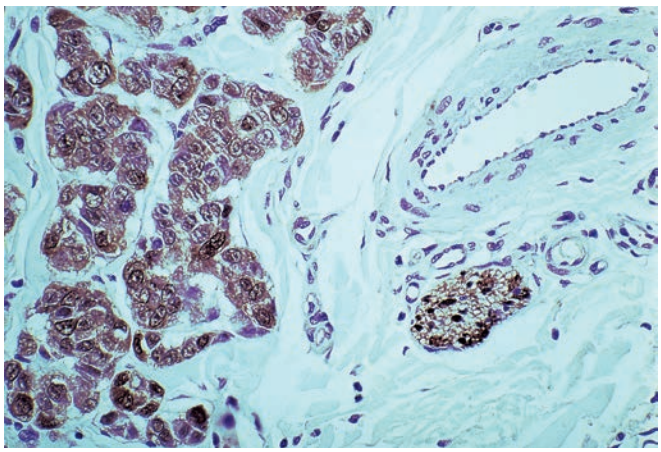

Figure 3.77 Malignant melanoma of skin immunostained for S-100 protein. Strong nuclear and cytoplasmic reactivity is present.

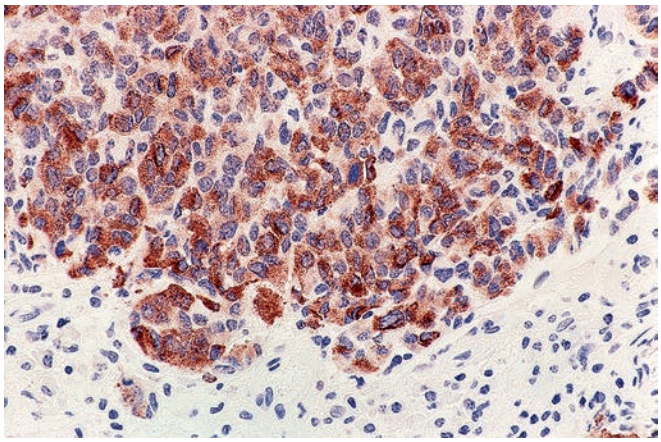

Figure 3.78 HMB-45 immunoreactivity in melanoma.

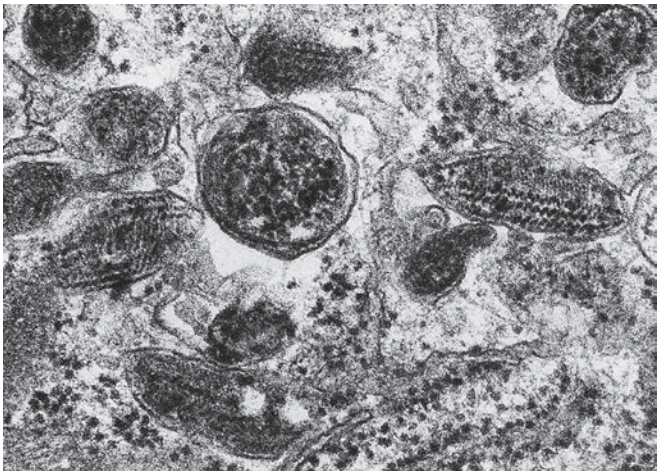

Figure 3.79 Stage 2 and stage 3 melanosomes with characteristic lattice arrangement in malignant melanoma of skin metastatic to lung (×81,000).

80% of melanomas and has become a widely used marker for this tumor; however, it also stains steroid-producing cells from adrenal cortex, ovary, and testis and the tumors originating from them.[597]

Tyrosinase is a key enzyme for the production of melanin from tyrosine; it can be detected with conventional enzyme histochemical methods (which require fresh tissue) but now also with immunohistochemistry or reverse transcription-polymerase chain reaction (RT-PCR) in paraffin-embedded material.[596,938,939] At the immunohistochemical level, the positivity is in the range of 80%–90%.

MiTF is a nuclear protein needed for the development and postnatal viability of melanocytes, through its function as a master regulator of extracellular signals. It stains nearly all melanomas of conventional type,[598] but—like most other markers—it fails to stain most spindle cell/desmoplastic melanomas,[940] despite early statements to the contrary; furthermore, it can also be positive in a variety of nonmelanocytic spindle cell tumors, including dermatofibroma and smooth muscle tumors.[940]

SOX10 is a nuclear transcription factor that is widely expressed in melanocytic and nerve sheath tumors. It stains nearly all melanocytic tumors, including desmoplastic melanomas, but will also stain myoepithelial cells.[602,926]

SM5-1 and *PNL2* are two relatively new antibodies said to offer significant advantages in terms of sensitivity, a claim that needs independent confirmation.[941,942]

MAGE-1 (melanoma antigen-encoding gene) has also been introduced as a sensitive marker for melanoma, but its diagnostic utility seems very limited.[943,944] NK1/C3 has also been advocated for the identification of melanoma but suffers from considerable cross-reactivity with many other neoplasms.[945,946]

NSE also stains melanoma cells, in keeping with the neuroectodermal nature of these cells, but the stain is of little practical utility. *WT1* is negative in most nevi and positive in most melanomas (including the desmoplastic variety), but its potential utility is diminished by the fact that most Spitz nevi and a third of dysplastic nevi are also positive.[947]

It is important to recognize that, contrary to previous claims, a significant number of melanomas exhibit immunoreactivity for low-molecular-weight keratins (such as those demonstrated with the CAM 5.2 antibody)[948,949]; some cases are also positive for CEA, EMA, α1-antichymotrypsin, and CD68 (KP-1).[948–952]

Electron Microscopic Features

Electron microscopy has previously contributed greatly to the confirmation of a diagnosis of malignant melanoma through the identification of melanosomes and the less specific premelanosomes (Fig. 3.79),[953–955] and it still may in rare cases, but its diagnostic utility is of limited value following the advent of immunohistochemistry.[956] The utility of this technique was brought dramatically to light in a case we examined in an axillary lymph node, which was very suggestive of melanoma in the H&E section but which was negative for S-100 protein and HMB-45 while being positive for low-molecular-weight keratin. Ultrastructurally, the tumor cells had well-developed melanosomes and lacked epithelial features. A regressed primary tumor in the adjacent skin was later detected.

Molecular Genetic Features

Cytogenetic or comparative genomic hybridization studies reveal aberrations of multiple chromosomes in malignant melanoma, whereas they are absent in melanocytic nevi, except some cases of Spitz nevi showing gain of 11p alone.[957] The commoner changes include losses of 6q, 8p, 9p, and 10q and gains of 1q, 6p, 7, 8q, 11q, 17q, and 20q.[957] Of interest, the patterns of chromosomal aberrations seem to differ markedly depending on anatomic location and sun-exposure pattern; for example, acral sites have significantly more aberrations involving chromosomes 5p, 11q, 12q, and 15, whereas lentigo maligna melanomas or melanomas occurring on severely sun-damaged skin show more frequent losses of 17p and 13q.[957]

In melanomas, the MAPK signaling pathway and PTEN/AKT pathway are commonly activated by somatic alterations in the involved genes (Fig. 3.80).[958,959] For the MAPK pathway, there are documented alterations in *KIT* (mutation or amplification in 0%–40%), *NRAS* (mutation in 20%), *BRAF* (mutation in 60%, at a frequency similar to that of melanocytic nevi except Spitz nevi), and *MiTF* (amplification in 20%).[958–961] Of note, in melanomas occurring in acral and chronic sun-damaged skin, *BRAF* and *NRAS* mutations are uncommon, whereas *KIT* alteration is relatively common.[962,963] On the other hand, *KIT* alteration is very rare in melanomas occurring in skin without chronic sun damage.[963] For the PTEN/AKT pathway, *PTEN* shows inactivation by deletion, hypermethylation or mutation in 50% of cases, and *AKT* shows amplification or activation in 60% of cases.[959] This information provides the theoretical framework for targeted therapy to abrogate the pathways (see Fig. 3.80).[959,964]

CDKN2A, the gene implicated in the genesis of some hereditary melanomas, shows inactivating mutation or allelic loss in a small proportion of cases of sporadic melanomas but in almost all melanoma

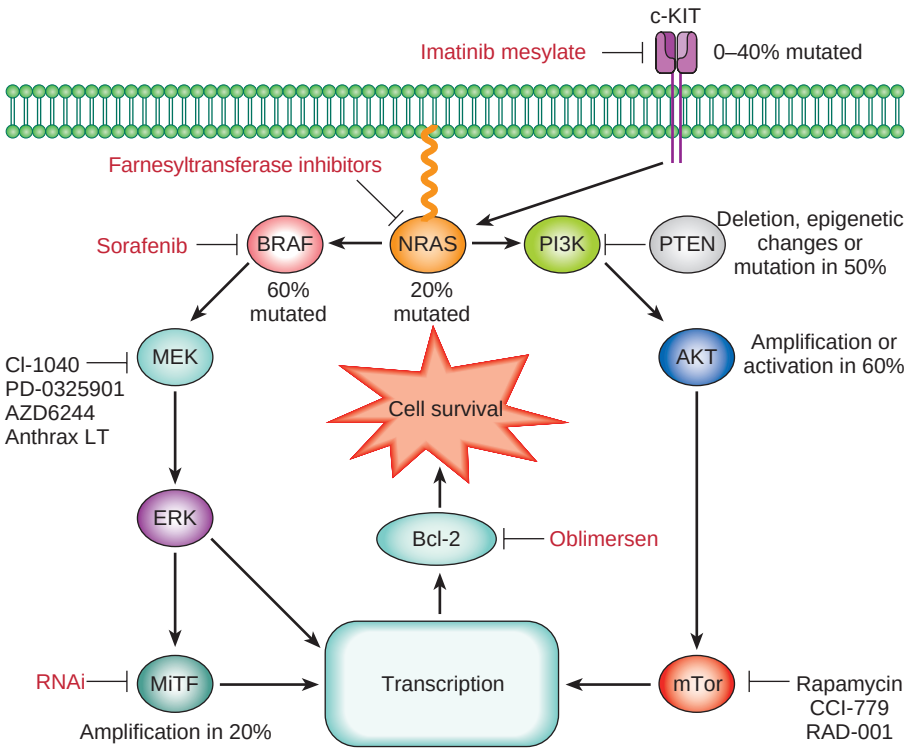

Figure 3.80 Targeted Therapies in Melanoma. Advances in our understanding of the genetics of melanoma have led to the development of targeted therapeutic agents that are directed at commonly observed molecular aberrations in melanoma involved in tumor proliferation and resistance to chemotherapy. *MiTF*, Microphthalmia transcription factor. (Adapted from Singh M, Lin J, Hocker TL, Tsao H. Genetics of melanoma tumorigenesis. *Br J Dermatol*. 2008;158(1):15–21.)

cell lines.[965–968] Mutations in telomerase reverse transcriptase (TERT) promoters are common in melanomas with *CDKN2A* and *BRAF* alterations and in melanomas from intermittently and chronically sun-exposed sites.[969] The combination of *TERT* promoter and *BRAF* mutations is associated with more aggressive behavior.[970]

FISH technique can aid in the distinction between melanoma and nevi by detecting chromosomal aberrations associated with melanoma looking for gain in 6p, loss in 6q, and gain in 11q to support the former diagnosis.[971–974] The discriminatory utility of FISH seems improved with additional probes directed against 9p21 and 8q24.[974] However, not all melanomas have chromosomal aberrations detectable by this technique, and the technique may not have the same degree of sensitivity or specificity in ambiguous lesions.[975] A genetic signature assay has been developed that appears to behave with a similar degree of sensitivity and specificity to FISH on non-ambiguous lesions, but it remains to be seen how well it will perform in routine practice.[976]

Biopsy and Frozen Section

Whenever feasible, an elliptical excisional biopsy with narrow margins (down to the subcutaneous fat) constitutes the best procedure for the initial evaluation of suspicious pigmented skin lesions.[977] However, that is a relatively uncommon practice. Fortunately, there is no evidence that incisional biopsy of a malignant melanoma increases the probability of spread.[978,979] Punch biopsies or incisional biopsies are indicated for extensive lesions (such as giant congenital nevi or lentigo maligna) or for lesions located in certain areas (such as the subungual region). If the lesion proves malignant, a reexcision should be carried out. In experienced hands, the diagnosis of malignant melanoma by frozen section is reliable.[980–982] However, one can hardly justify its routine use on practical grounds, other than for the evaluation of surgical margins.[983] That being said, it is more desirable to evaluate margins on permanent sections.

Regression

Partial regression is a common feature in melanoma. Total regression is much less common, but numerous cases in which the primary tumor regressed completely after giving rise to nodal and distant metastases have been documented.[984–986] This phenomenon may also explain some apparent discrepancies between expected and observed prognosis based on tumor thickness[987,988] and also the fact that in 5%–15% of patients with metastatic melanoma the primary tumor is never found.[989,990]

Clinically, spontaneous regression of melanoma is often heralded by the sudden onset of an irregular halo around the tumor. Microscopically, the early stage of regression is characterized by a dense infiltrate of lymphocytes similar to that seen in spontaneously disappearing nevi. This change may be partial or complete. In the late stage, vascular scar tissue with a variable number of melanin-laden macrophages is present (Fig. 3.81). Several distinctive clinical patterns result from this process. It has been pointed out that only melanomas with an intraepidermal component have been found to undergo spontaneous regression.[991]

Atypical In Situ Melanocytic Lesions

One of the most controversial aspects in the pathology of the melanocytic system is the evaluation and nomenclature of atypical

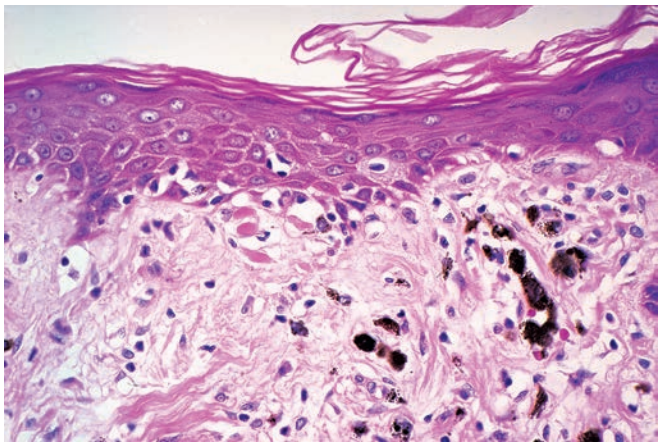

Figure 3.81 Area of Regression in Malignant Melanoma. There is extensive dermal fibrosis, epidermal atrophy, numerous dermal melanophages, and dyskeratotic cells in the dermoepidermal junction. Viable tumor was present in other areas.

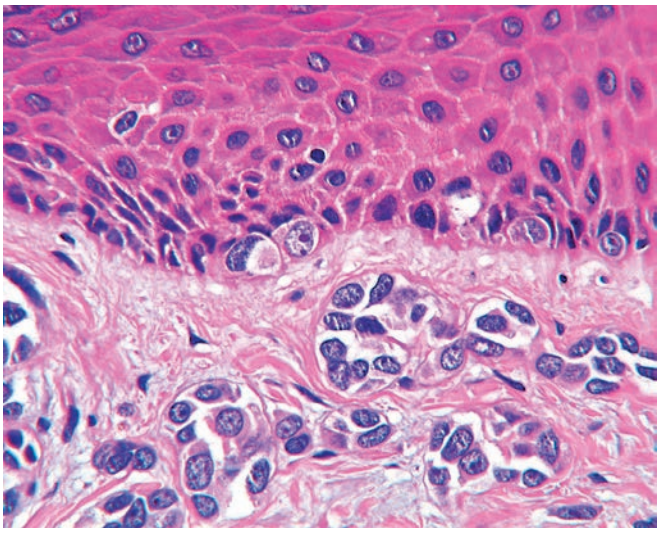

Figure 3.82 Metastatic malignant melanoma with secondary epidermal involvement.

melanocytic lesions that are limited to the epidermis. Such changes may be seen at the periphery of an obvious malignant melanoma,[992,993] in the epidermal component of a compound nevus, or as an isolated finding. Terms such as *atypical* (intraepidermal, premalignant) *melanocytic hyperplasia*, *lentiginous dysplastic nevus*, *melanocytic dysplasia*, *melanocytic intraepidermal neoplasia (MIN)*, *premalignant melanosis*, and *melanoma in situ* have been used for this process, depending on location, some variations in morphologic appearance, and—most of all—the observer's bias.[992–997] In such a situation, it is important to word your report in a way to ensure proper treatment of the patient so that the lesion is completely excised if there is significant concern about the biologic potential regarding the lesion. As mentioned previously, lesions falling short of criteria for melanoma in situ should be diagnosed descriptively with such terms as intraepithelial atypical melanocytic proliferation and intraepithelial melanocytic neoplasia, with the recommendation of complete but conservative reexcision.[998]

Spread and Metastases

Malignant melanoma spreads by growing along the dermoepidermal junction and upper dermis and later by invading the deep dermis and eventually the subcutis and deeper structures, the latter feature being evaluated in a semiquantitative manner by determining the Clark level and Breslow thickness (see later). The deeper the melanoma extends into the dermis or subcutis, the higher the risk of metastasis. Metastases in regional lymph nodes are common even if the nodes appear clinically negative (see next section).

Distant metastases occur most often in the liver, lungs, gastrointestinal tract, bone, and central nervous system but can occur anywhere, including within other tumors.[999,1000] At autopsy, metastases to the heart are found in one-half of the patients.[1001] A certain pattern in the distribution of these metastases, presumably related to the embryologic origin of the organs involved, has been noted.[1002] Cutaneous metastases are also common. Many of them are located close to the tumor ("satellite nodules"), suggesting a lymphatic rather than a blood vessel mechanism. Cutaneous and subcutaneous metastases located between the site of the primary tumor and the regional lymph node are referred to as "*in-transit metastases*." Both satellite nodules and in-transit metastases are usually indicators of disseminated systemic disease.[1003] Cutaneous metastases from melanoma can be difficult to distinguish from a primary lesion because the metastases may develop a secondary intraepidermal component ("epidermotropic" metastases) (Fig. 3.82).[1004] A useful differential feature is the fact that in metastatic carcinoma melanoma with secondary intraepithelial spread, the dermal component is much wider than the epidermal one, whereas the opposite is generally true for the primary lesion.[1005] However, some epidermotropic metastatic malignant melanomas are primarily intraepidermal, simulating malignant melanoma in situ.[1006] Phenotype profile comparison between the primary melanoma and its metastasis usually shows a close concordance, but some markers are lost in the latter as a side effect of tumor progression.[1007]

The behavior of malignant melanoma is very unpredictable. Deaths from metastatic melanoma have been documented 15 years or more after the initial therapy.[1008] Conversely, some patients with widespread satellite nodules in one extremity may survive for many years without evidence of tumor spread beyond that extremity. Immunologic factors likely play a role in the varying behavior of individual tumors. Although the interactions between the tumor and the immune system are incompletely understood, expression of PD-L1 appears to play an important role in the ability of melanoma to downregulate immunosurveillance and contribute to the development of metastasis.[1009,1010] Current therapeutic strategies using immune checkpoint inhibitors are showing great promise in the treatment of this disease.[1011–1014]

Sentinel Lymph Node

The performance of sentinel lymph node biopsy in melanoma has become routine.[1015,1016] This procedure is based on the mechanistic concept that the pattern of metastatic spread of melanoma to the nodes is orderly, and that if the sentinel node (defined as the first node on the direct lymphatic drainage path from the primary tumor) is negative, the likelihood is very high that this will also be true for the other nodes of that region (especially if the tumor burden in the sentinel node is considerable and/or the primary tumor has a high Breslow thickness).[1017,1018] Therefore, if the sentinel node is positive, a lymphadenectomy is carried out. Although there are strong voices of dissent,[1019] most workers in the field maintain that sentinel node biopsy is an accurate staging procedure and a powerful prognostic indicator.[1020–1022]

Sentinel node biopsy is recommended for all melanomas measuring 1 mm or more in thickness or in thinner melanomas with dermal mitotic figures or ulceration.[1023] The node is identified with a dye or an isotope[1024] and sent to the pathology department, where preferably it will be submitted in toto for paraffin embedding serial sectioning, rather than subjecting it to frozen section, acknowledging the fact that discrepant opinions exist regarding the usefulness of the latter procedure in this situation.[1025] In our practice, we do not do frozen sections on sentinel lymph nodes for metastatic melanoma.

Controversy also exists as to the best method for the pathologic evaluation of the sentinel node that will ensure a high detection rate while preventing the other activities of the histology laboratory coming to a full halt. In general, the recommendation is for the examination of a certain number of H&E step sections plus one or more immunostains.[1026–1028] Following an exhaustive pathologic study of 105 sentinel lymph node procedures carried out at the Memorial Sloan Kettering Cancer Center, we concluded that the performance of three levels at 250-µm intervals, each level being composed of a set of three sections stained with H&E, S-100 protein, and HMB-45, will detect the overwhelming majority of the nodal metastases present.[1029] At the Sydney Melanoma Unit, four sequential sections of both halves of each node are examined; the first and fourth sections are stained with H&E, the second is stained for S-100 protein, and the third section is stained for HMB-45.[1030] We would regard as the absolute minimum the performance of three "step" H&E sections (with approximately 10 discarded sections in between) plus one immunostain, among which we and most others prefer HMB-45 (Fig. 3.83).[1031] The addition of immunostains for SOX10 can also be useful in the evaluation of sentinel lymph nodes. Perhaps it should be added here that there is no evidence of a predilection of metastatic melanoma for a particular region of the node.[1032]

It remains to be seen whether molecular techniques for the detection of isolated tumor cells (such as the RT-PCR procedure for tyrosinase) will be a useful adjunct to the combined morphologic and immunohistochemical method just described.[1033,1034] Currently, these methods are not the standard of care and should be considered investigational.

The differential diagnosis of metastatic melanoma to lymph node includes benign nevus cells (nodal nevi) and histiocytes.[1035] Benign nevus cell inclusions are usually limited to the nodal capsule (although they can also be intraparenchymal),[1036] have a typical semilunar shape, lack nuclear atypia, and stain for S-100 protein and Melan-A but weakly or not at all for HMB-45, IMP3, or MIB-1 (Ki-67).[1037,1038] Histiocytes and other cells of the accessory immune system can be a problem because of their immunoreactivity for S-100 protein and occasional positivity for HMB-45, as well as the fact that melanomas can be positive for some of the histiocyte-associated markers.[1039,1040] However, histiocytes should lack nuclear atypia and be positive for CD68/PG-M1 (which melanoma cells usually are not).[1040] Immunostains for SOX10 can help in this situation because melanocytes are positive for SOX10 and histiocytes are not.[1041]

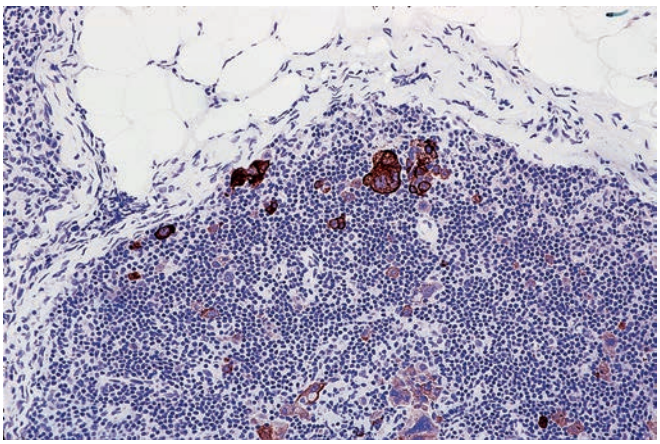

Figure 3.83 Isolated melanoma cells in sentinel lymph node, demonstrated with HMB-45 immunostain.

Treatment

The treatment of choice of most malignant melanomas is wide excision of the primary lesion.[1042] A margin of 3 cm or perhaps even 1 cm is probably sufficient for the average-sized tumor, even if some surgeons in the past have recommended a margin of 5 cm.[1042–1046] Balch et al.[1047] recommended a margin of 2 cm for thin melanomas (less than 0.76 mm in thickness) and a margin of 3–5 cm for thicker lesions, but even this proposal has been questioned in view of the fact that survival in melanoma is unrelated to the width of the margins, irrespective of the width of the tumor.[1048–1051] Indeed, the same group of authors has shown that even in intermediate-thickness melanoma (1–4 mm), a surgical margin of 2 cm is sufficient.[1052] In a randomized clinical trial, Thomas et al.[1053] found that a 1-cm margin for thick (>2 mm) melanomas was associated with a significantly greater risk of regional recurrence than a 3-cm margin but that the overall survival rate was the same.

If the regional lymph nodes are clinically considered to be involved, a radical lymph node dissection should be performed. Removal of clinically negative lymph nodes has always been a very controversial subject. Some authors have been in favor of the procedure based on the finding of microscopic foci of malignant melanoma in almost a fourth of clinically negative nodes.[1054] However, most series have failed to show an improvement of survival in the patients so treated.[1055–1057] A prospective randomized study of stage I melanoma of the limbs showed no differences in survival between the patients who had regional node dissection at the time of the original excision and those who had it only when clinically detectable metastases appeared.[1058–1060] As already indicated in the preceding section, the field has been revolutionized with the introduction of the sentinel lymph node biopsy as a guide for planning therapy and gauging prognosis.

Topical imiquimod appears to be a viable option for treatment of lentigo maligna, especially in patients with persistently positive margins or who are poor surgical candidates.[1061] For disseminated disease, interleukin, biochemotherapy, and interferon have given good results but only in a small percentage of patients.[1062,1063] More recently, targeted therapy directed against melanomas with specific mutations has shown significant effect. Vemurafenib targets the V600E *BRAF*–mutated melanomas, and imatinib mesylate has activity against melanomas with activating *KIT* mutations.[1014,1064,1065] As previously mentioned, checkpoint inhibitors targeting CTLA-4 and PD-1/PD-L1 have shown significant efficacy in the adjuvant setting.[1010–1014]

Prognosis

The death rate for malignant melanoma is still unacceptably high if one considers the fact that this lesion is diagnosable at a stage when it can be cured in nearly every instance. In a series of nearly 3000 patients with melanoma in Norway, published in 1977, the overall 5-year relative survival rate was approximately 60%.[1066] There are many clinical and pathologic factors that have been studied in regard to their influence on prognosis.[1067,1068] Before subjecting the reader to this imposing list, we should mention as an introduction that an analysis of 17,600 patients with melanoma showed that in the tumor (T) staging category, the most powerful predictors of

survival were tumor thickness (Breslow level) and ulceration.[1069] This large study is a powerful validation of the seminal work of Dr. Clark and colleagues and Dr. Breslow.[1070–1072]

Clark and colleagues noted a correlation of adverse prognosis depending on the anatomic level of the skin involved by melanoma. The level of invasion *(Clark's level)* is defined as: *level I* epidermis (melanoma in situ), *level II* papillary dermis, *level III* filling the papillary dermis, *level IV* reticular dermis, and *level V* subcutis.[1073] A direct relationship exists between the level of invasion and the incidence of lymph node metastases and therefore the prognosis.[1074] In one series, regional node metastases were present in 32% of the patients with level III invasion, 67% with level IV, and 66% with level V[1075,1076]; patients with level I and level II did not undergo node dissection, but none of them had clinical evidence of metastases. In the series of Wanebo et al., the 5-year disease-free survival after surgery was 100% in patients with level II invasion, 88% in those with level III, 66% in those with level IV, and 15% in those with level V.[1077,1078]

The concept of anatomic level of invasion was refined in a quantitative manner by Dr. Breslow.[1071,1072] The tumor is measured with an ocular micrometer at right angles to the surface of the adjacent normal skin, from the top of the granular layer of the overlying epidermis or from the ulcer base over the deepest point of invasion to the deepest invasive tumor cells in ulcerated tumors. In the original version, the system assigned the melanomas into low-, intermediate-, and high-risk categories depending on whether their depth is less than 0.76 mm, between 0.76 and 1.5 mm, or greater than 1.5 mm, respectively.[1073] The 5-year disease-free survival is 98% for the first group, 44%–63% for the third, and somewhere in between for the second.[1073,1077–1079] In one series, the 3-year actuarial incidence of subsequent regional metastases in patients initially treated by wide local excision of the melanoma was 0% for lesions less than 0.76 mm, 25% for 0.76–1.50 mm lesions, 51% for 1.51–3.99 mm lesions, and 62% for lesions greater than 4 mm in thickness.[1079]

Note should be taken of the fact that, in recent publications (including the new staging system of melanoma), the groups are divided according to 1-mm increments rather than in the fashion originally devised by Breslow and his followers.[1073] Due to its more reproducible nature, measuring thickness has largely supplanted the use of Clark's level, although the original work of Dr. Clark and colleagues was seminal in our understanding of pathologic staging of melanoma.[1070]

In addition to thickness, the presence of ulceration—however minimal—has emerged as one of the most important prognostic factors in melanoma, as reflected in the AJCC staging system.[1073] The prognostic value remains after the tumor is matched with nonulcerated lesions by thickness, type, and stage.[1080,1081]

Most authors have shown a relationship between dermal mitotic activity and prognosis independently from other parameters.[1082] As a matter of fact, a study of 3661 patients from a single center showed that tumor mitotic rate is a more powerful prognostic indicator than ulceration.[1083] Even a single dermal mitotic figure in a thin melanoma (≤1.0 mm) should prompt consideration of sentinel lymph node biopsy.[1023] In the current staging system, dermal mitoses upstage the tumor stage in thin (pT1) melanomas but not for thicker melanomas.[1073] It should be noted that mitotic figures in melanocytes within the epidermis of adnexal epithelium are not used in determining the mitotic rate. It should also be pointed out that pathologists should assess for mitotic figures as they would routinely and to not go to exhaustive efforts by multiple deeper levels or special stains as the prognostic information is based on routine practice.

Other factors associated with prognosis:

1. *Gender*. In one large series,[1067] the 5-year survival rate was 50.5% for males and 70.5% for females. This improved survival for females results from a variety of factors, such as location and depth of invasion.[1084] However, it seems to remain somewhat better even after these factors have been corrected.
2. *Age*. It has been claimed that younger age is associated with a more favorable prognosis in males but not in females.[1085] One study has shown the adverse prognostic significance of old age, but this is at least partially due to the large percentage of thick melanomas in this age group.[1086]
3. *Pregnancy*. This remains a controversial subject. Isolated case reports have strongly suggested an adverse effect, but several large studies showed no statistical differences in prognosis.[1087,1088] Perhaps part of the difficulty resides in the fact that this alleged influence may be dependent on the stage of the melanoma. Shiu et al.[1089,1190] found no statistical difference in stage I disease but a significantly lower survival rate in pregnant patients (29%) with stage II lesions as compared with nonparous (51%) or nulliparous (55%) patients. Parenthetically, malignant melanoma cells do not contain hormone receptors at the immunohistochemical level, and this also applies to pregnant patients.[1087]
4. *Anatomic location*. Rogers et al.[1091] have defined the following as high-risk sites: scalp, mandibular area, midline of trunk, upper medial thighs, hands, feet, popliteal fossae, and genitalia. These differences may be attributable to their association with thickness. Subungual melanomas have a notoriously bad prognosis, which is probably largely due to their late detection.
5. *Clinicopathologic type*. Early articles describing the three major types of malignant melanoma claimed a better prognosis for lentigo maligna melanoma, a worse prognosis for nodular melanoma, and an intermediate prognosis for superficially spreading melanoma.[1070,1092] More recent studies have shown that, once depth of invasion is entered into the equation, most of these differences are erased. The behavior of acral lentiginous melanoma is particularly aggressive, but again this may be the consequence of its propensity for deep invasion and ulceration: in the series of Coleman et al.,[1093] the average 3-year survival rate was 11%.
6. *Cytologic features*. Whether the melanoma cells are spindle, epithelioid, or any other shape seems to bear no direct relationship to the prognosis.[1094,1095]
7. *Cell proliferative activity*. Melanomas have been stained for cell proliferation markers, such as MIB-1 (Ki-67) and PCNA, the latter rarely used at present. A relationship has been demonstrated between this parameter and the thickness of the tumor, but there is controversy as to whether it offers independent prognostic information.[1096–1099] We do not recommend routine use of proliferative markers in the assessment of melanomas.
8. *Dermal inflammatory infiltrate*. It has been found that a dense lymphocytic infiltrate around the melanoma is associated with a better prognosis, particularly if the lymphocytes are closely intermingled with the neoplastic melanocytes ("tumor-infiltrating lymphocytes").[1100,1101] The intensity of this reaction has been graded using the odd terminology brisk, non-brisk, and absent and found to have a strong predictive value in melanomas with a vertical growth phase.[1102] Conversely, the presence of numerous plasma cells in the infiltrate is said to correlate with an increased probability of lymph node metastases.[1103] Although some of the significance of these findings may diminish after correcting for tumor thickness, tumor infiltrating lymphocytes have been shown to be an independent prognostic factor.[1104]
9. *Regression*. The significance of regression is controversial. It has been claimed that the presence of focal areas of regression in a malignant melanoma may modify the significance of the level or thickness of the residual tumor (Fig. 3.81). Regression, even

if focal, may explain why relatively superficial melanomas exhibiting focal regression may be associated with an incidence of lymph node metastases higher than that expected on the basis of these determinations.[988] However, other studies have failed to confirm this claim.[1105–1107] These discordant results likely reflect our poor understanding of the complex interactions of melanoma with the immune system.

10. *Angiotropism*. Angiotropism (defined not as conventional blood vessel invasion but as growth of melanoma cells along the external surface of blood vessels) has been found to be a predictor of local recurrence and in-transit metastases.[1108]
11. *Microscopic satellites*. The presence of microscopic satellites, defined as tumor nests greater than 50 µm in diameter separate from the main tumor mass, shows a high association with regional lymph node metastases and therefore with prognosis.[1109]
12. *Metastases to sentinel node*. The prognostic value of this procedure is well established and may constitute the reason why its performance has become so ubiquitous. Among cases with positive sentinel nodes, the prognosis is related to the tumor burden and to the presence of extranodal extension.[1110,1111] It has been suggested that isolated HMB-45 or Melan-A-positive cells do not impact behavior,[1112] but this has not been widely accepted and currently any amount of tumor involving a lymph node is still considered significant.[1073]

Other Pigmented Skin Lesions

There are several types of benign and (less commonly) malignant skin lesions that are neither melanocytic nevi nor malignant melanoma.

Hyperpigmentation, whether regional or generalized, is the result of stimulation of melanocytes by a variety of stimuli, such as sunlight, heat, drugs, hormones (as in pregnancy), dietary deficiency (as in kwashiorkor), metabolic disorders (such as Gaucher disease), scars, and a variety of dermatoses (generically referred to as postinflammatory hyperpigmentation).[1113] The only microscopic change (rarely seen because of the infrequency of biopsies in this group of conditions) is increased pigmentation of basal melanocytes, accompanied by increased transfer of melanin into the adjacent keratinocytes and melanophages in the dermis.

Ephelis (freckle) arises in sun-exposed skin of susceptible individuals and shows microscopically mild hyperpigmentation of basal melanocytes and basal keratinocytes, associated with a normal epidermal *architecture.*

Solar lentigo shows elongation of rete ridges and increased pigmentation of the basal and suprabasal layers; this lesion is related to keratosis rather than to simple lentigo, and it may have a reticulated appearance (Fig. 3.84).[1114]

Café au lait spot, as seen in Recklinghausen disease but also in other genetically determined diseases and in 10% of the general population, is characterized microscopically by basal hyperpigmentation of the epidermis and, at the ultrastructural level, by the presence of macromelanosomes.

Becker nevus, typically seen in the shoulder, chest, or lower back, shows increased epidermal pigmentation associated with mild acanthosis and sometimes hypertrichosis. Some Becker nevi have an increased number of smooth muscle bundles in the dermis.[1115]

Pigmentation can also occur in several types of nonmelanocytic skin neoplasms because of increased activity of melanocytes or increased retention of pigment in the epithelial cells. The most striking example is *melanoacanthoma*, in which dendritic melanocytes and keratinocytes participate in the formation of this benign lesion, which some authors regard as an entity and others (including ourselves) as a variant of seborrheic keratosis.[1116]

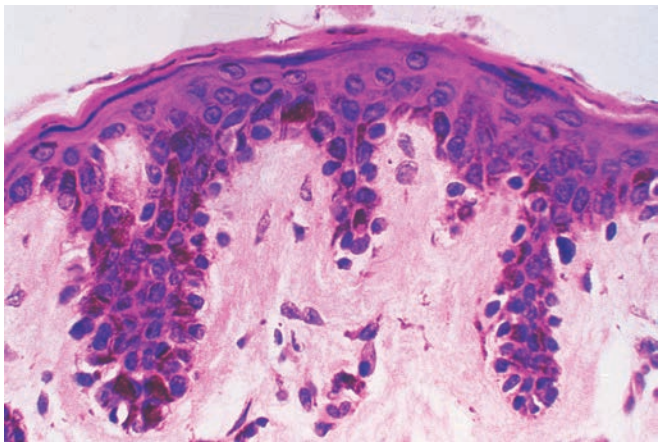

Figure 3.84 Microscopic Appearance of Solar Lentigo. There is elongation of rete ridges associated with hyperpigmentation of the basal layer.

Malignant basomelanocytic tumor is a rare lesion having a dual neoplastic cellular composition, one of melanocytic and the other made up of basal cell carcinoma–like cells.[1117,1118] The basal cell component of these tumors tends to be of high grade. In one of the reported cases, the tumor metastasized as a malignant melanoma.[1119] *Malignant squamomelanocytic tumor* is another lesion having a dual neoplastic population, one (like the former) of melanocytic nature and the other made up of squamous cell carcinoma–like keratinocytes.[1120,1121]

Other lesions that may be heavily pigmented are ordinary seborrheic keratosis, acrochordon, dermatosis papulosa nigra, actinic keratosis, Bowen disease and bowenoid papulosis, basal cell carcinoma, and some adnexal tumors (particularly trichoepithelioma, pilomatrixoma, and eccrine poroma). In pigmented basal cell carcinoma, both participation of dendritic melanocytes and retention of pigment in the neoplastic epithelial cells occur.

Neuroendocrine Cells

Merkel Cell Carcinoma

Merkel cell carcinoma is the currently preferred term for a distinctive cutaneous malignancy originally described as trabecular carcinoma,[1122,1123] but now referred to as Merkel cell carcinoma.[1124,1125] It occurs mainly in adults and elderly individuals, with rare cases described in children.[1126] The face and extremities are the most common locations (Figs. 3.85 and 3.86).[1127,1128] Clinically, it appears as a nodular, sometimes ulcerated lesion with a reddish or violaceous hue. Microscopically, the tumor is centered in the dermis or sometimes in the subcutaneous tissue, with the overlying epidermis being usually uninvolved.[1129] The monotonous nature of the dermal round cell infiltrate and the diffuse pattern of infiltration of the subcutaneous fat are responsible for its occasional misdiagnosis as malignant lymphoma (Fig. 3.87).[1130,1131] The pattern of growth can also be trabecular, but it is rare for this to be the predominant feature (hence the inappropriateness of the term trabecular carcinoma).[1132] The diagnosis of Merkel cell carcinoma can be made on the basis of the cytologic features as seen in a good H&E-stained slide (Fig. 3.88). The cytoplasm is scanty but visible as a thin acidophilic rim; the nuclei are round and vesicular, with a typically fine granular ("dusty") chromatin and multiple nucleoli. Mitotic figures and fragmented nuclei (probably as the result of apoptosis) are plentiful. Necrosis may be present, sometimes accompanied by the Azzopardi phenomenon (hematoxyphilic staining of vessel walls and fibrous

Figure 3.85 Merkel Cell Carcinoma. This unfortunate patient had involvement of almost the entire face by an extensively ulcerated neoplasm that failed to respond with chemotherapy after an initial diagnosis of malignant lymphoma.

Figure 3.86 Merkel Cell Carcinoma Involving the Hand. This particular lesion was associated with Bowen disease of the overlying epidermis.

septa).[1133] The stroma often contains proliferated vessels with plump endothelial cells, a feature that these tumors share with many other malignant neoplasms having a primitive neural phenotype.[1133,1134]

Merkel cell carcinoma can be seen in association with in situ or invasive squamous cell carcinoma, with duct-like structures of eccrine type, and with basal cell carcinoma-like areas, suggesting that it originates from a multipotential stem cell of ectodermal derivation.[1076,1135–1138] Rarely, it exhibits focal or extensive intraepidermal pagetoid spread (Fig. 3.89).[1139] Even more rarely, the entire tumor can be intraepidermal, either pure or associated with squamous cell carcinoma in situ.[1140,1141]

Exceptionally, Merkel cell carcinoma can show foci resembling leiomyosarcoma, rhabdomyosarcoma, or atypical fibroxanthoma, either in the primary tumor or in the recurrences as a result of dedifferentiation/divergent differentiation.[1142–1144] The differential diagnosis includes the reciprocal phenomenon, i.e., rhabdomyosarcomas with aberrant expression of neuroendocrine markers.[1145]

When examined ultrastructurally, the tumor cells are seen to contain dense-core neurosecretory granules (sometimes arranged immediately beneath the cell membrane) and tightly packed perinuclear intermediate filaments (Fig. 3.90).[1130,1146,1147] Filament-rich rigid spinous processes ("cytoplasmic spikes") similar to those seen in normal Merkel cells have been detected in a few cases.[1148–1150]

Immunohistochemically, positivity for low-molecular-weight keratin, neurofilaments, and NSE is usually obtained (Fig. 3.91).[1151–1154] Notably, the positivity for keratin is predominantly for cytokeratin 20[1154,1155] and often has a distinct perinuclear dot-like quality, a feature found only exceptionally in small cell carcinomas of internal organs (we have seen it in isolated cases of neuroendocrine tumors of the salivary gland, pancreas, and thyroid).[1156] The consistent positivity for CK20 and neurofilaments and the negativity for TTF-1 (allowing for the inevitable exceptions)[1157,1158] are important in the differential diagnosis with metastatic small cell neuroendocrine carcinoma of

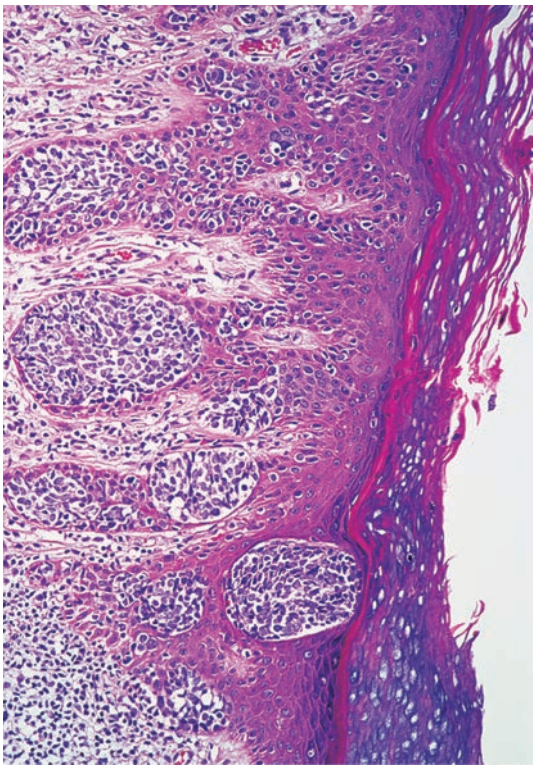

Figure 3.89 Merkel cell carcinoma showing marked degree of epidermotropism. (Slide contributed by Dr Philip LeBoit, San Francisco.)

lung.[1090,1159–1161] However, exceptions occur, such as cases that are positive for CK7 while negative for CK20.[1162]

In addition to the markers just listed, cases of Merkel cell carcinoma have shown reactivity for chromogranin, synaptophysin, vasoactive intestinal peptide, pancreatic polypeptide, calcitonin, substance P, somatostatin, ACTH, other peptide hormones, PAX-5 (a B-cell related transcription factor and therefore a potential source of confusion with lymphoma),[1163] TdT (the same warning applies),[1164,1165] glypican-3,[1166] and CD117.[1167–1169]

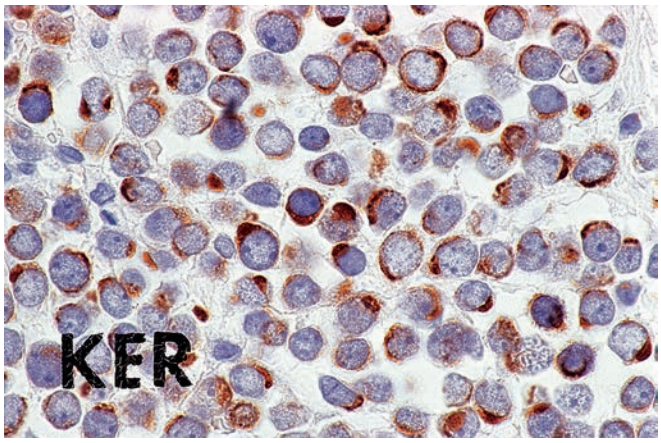

Figure 3.91 Dot-like immunoreactivity for keratin in Merkel cell carcinoma.

A most interesting development has been the demonstration that a new polyoma virus is clonally integrated in the genome of the majority of Merkel cell carcinomas, with truncating mutations in the viral large T antigen gene.[1170] This can be demonstrated by PCR or immunohistochemistry.[1171,1172] The virus is present in approximately 75%–80% of the cases in the United States, but much less frequently in cases from Australia, where UV radiation is the more important etiologic factor.[1173]

Merkel cell carcinoma is an aggressive neoplasm. Regional nodal metastases are common, and distant metastases also occur, particularly to the lungs, liver, and bones,[1174,1175] but also to unusual sites, such as the testis.[1176] Occasionally, a morphologically and genetically typical Merkel cell carcinoma is found in a lymph node (most often inguinal) in the absence of a primary skin tumor.[1177] The most likely explanation for this occurrence is spontaneous regression of the primary tumor (a phenomenon analogous to that which has been well documented in melanoma).[1178–1180]

Previously, the recommended treatment for Merkel cell carcinoma was wide resection of the primary site and regional lymph node dissection.[1181,1182] Current guidelines incorporate the use of sentinel lymph node biopsy with lymph node dissection reserved for patients with positive sentinel lymph nodes or obvious metastasis at presentation.[1183] Radiation therapy can be effective as an adjunct,[1183–1186] and chemotherapy has been used for metastatic tumors.[1183,1186–1188] Locoregional recurrence carries an ominous prognostic significance.[1189]

Other Neuroendocrine Tumors

Sometimes, tumors with an appearance similar to pulmonary small cell neuroendocrine carcinoma and large cell neuroendocrine carcinoma[1190] are found in the skin. They probably represent morphologic variants of Merkel cell carcinoma, but the possibility of a metastasis from an internal organ should always be ruled out.[1191] Like otherwise typical Merkel cell carcinomas, these neuroendocrine carcinomas of skin may show divergent differentiation along skeletal muscle or other mesenchymal lines.[1192]

Most cases reported in the past as peripheral neuroblastomas of skin fit into the category of Merkel cell carcinoma; others are clearly different and of unquestionable neural derivation.[1193] Still others belong to the Ewing sarcoma and Ewing sarcoma-like family of tumors.[1194] Carcinoid tumors of both insular and trabecular types, allegedly primary in the skin, have also been reported.[1195–1197] These should be distinguished from skin metastases from carcinoid tumor of internal organs, particularly lung.

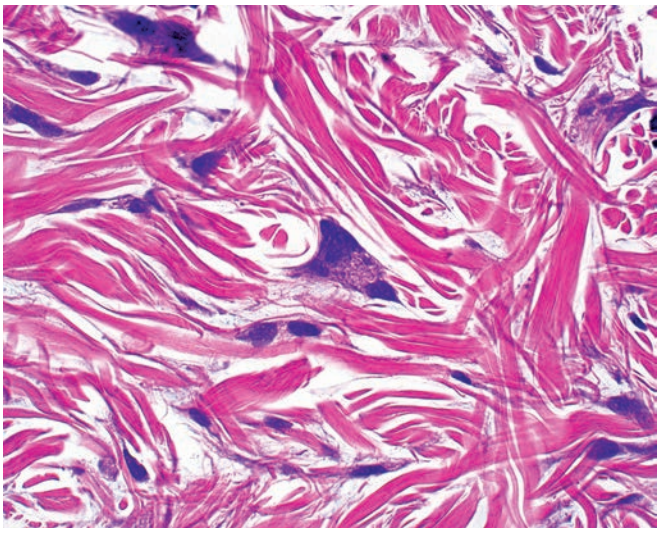

Figure 3.94 Pleomorphic Fibroma. A large triangular cell with hyperchromatic nuclei is encased within dense fibrous tissue.

Dermis

Fibroblastic Tumors and Tumorlike Conditions

Keloid is an abnormal pattern of dermal reaction to injury that results in an unusual hypertrophic scar, seen most commonly in African-American persons (Fig. 3.92). The earlobe is one of the most common locations. It is characterized by the formation of wide acidophilic bands of collagen, with seven fibroblasts and myofibroblasts running in parallel between them (Fig. 3.93).[1198–1200] The immunohistochemical profile also shows some differences.[1201] This distinction is useful in estimating the probability of recrudescence, which is much higher for keloids than for hypertrophic scars. Another differential diagnosis is with so-called keloidal dermatofibroma, in which an otherwise typical dermatofibroma exhibits an area similar to keloid in its superficial portion.[1202] A keloid-type change is sometimes also seen as a complication of acne ("acne keloidalis").[1203] In keloids that have been injected with steroids, a common treatment, pools of mucinous material can be found.[1204]

Acrochordon (soft fibroma, fibroepithelial polyp, cutaneous tag) is a non-neoplastic polypoid lesion composed of a loose connective tissue core covered by a normal to slightly hyperplastic (sometimes hyperkeratotic) epidermis. The absence of adnexal structures in the underlying dermis is a clue to the diagnosis.

Pleomorphic fibroma has a denser collagenous background, and it contains scattered bizarre cells with hyperchromatic nuclei and stellate cytoplasm, usually unaccompanied by mitotic activity (Fig. 3.94)[1205]; the lesion is the cutaneous equivalent of the more common polypoid lesion seen in squamous-covered mucosal membranes, such as nasal cavity, oral cavity, and urogenital tract[1206] (see respective chapters). It is probably closely related to giant cell collagenoma[1207] but distinct (also on immunohistochemical grounds) from dermatofibroma with monster cells.[1208] Other variations on the theme of benign pseudosarcomatous polypoid lesions of the skin have been described.[1209]

Fibrous papule of the face appears clinically as a solitary, dome-shaped, firm lesion that is frequently mistaken for basal cell carcinoma, clinically. The nose is by far the most common site (hence the alternative term "fibrous papule of the nose").[1210] Microscopically, there are increased vessels with a dilated lumen separated by a fibroblastic stroma containing stellate and sometimes multinucleated cells similar to those of pleomorphic fibroma.[1211] The numerous hair follicles are surrounded by a concentric array of collagen fibers. Expression of NKI/C3 is common.[1212] This lesion, which anatomically is best described as an angiofibroma, should be distinguished from a fibrosing (involuting) melanocytic nevus, a not always easy but practically inconsequential task.[1213]

Sclerotic fibroma (storiform collagenoma) is characterized by the heavy deposition of collagen with a so-called wood-grain pattern in a markedly hypocellular lesion having well-circumscribed outlines.[1214] The collagen is predominantly of type I,[1215] and there is expression of CD34.[1216] This is probably a heterogeneous condition, with some of the cases representing the end stage of a folliculitis.[1217] Multiple fibromas of the face, scalp, and subungual region are seen in tuberous sclerosis, together with angiofibroma of the face and "shagreen patches" in the lumbosacral region. Multiple sclerotic fibromas are also a marker for Cowden disease.[489]

Collagenous fibroma (desmoplastic fibroblastoma) is a different lesion from sclerosing (sclerotic) fibroma despite the misleadingly similar terminology. It is typically subcutaneous, sometimes associated with fascial involvement, and is characterized microscopically by bland stellate and spindle-shaped fibroblasts embedded in a collagenous or myxocollagenous matrix.[1218–1220]

Dermatomyofibroma (cutaneous myofibroma) is a benign cutaneous, plaque-like proliferation of fibroblasts and myofibroblasts (the identity of the latter having been confirmed ultrastructurally) centered in the deep dermis and subcutis.[1221] It is most commonly found in and

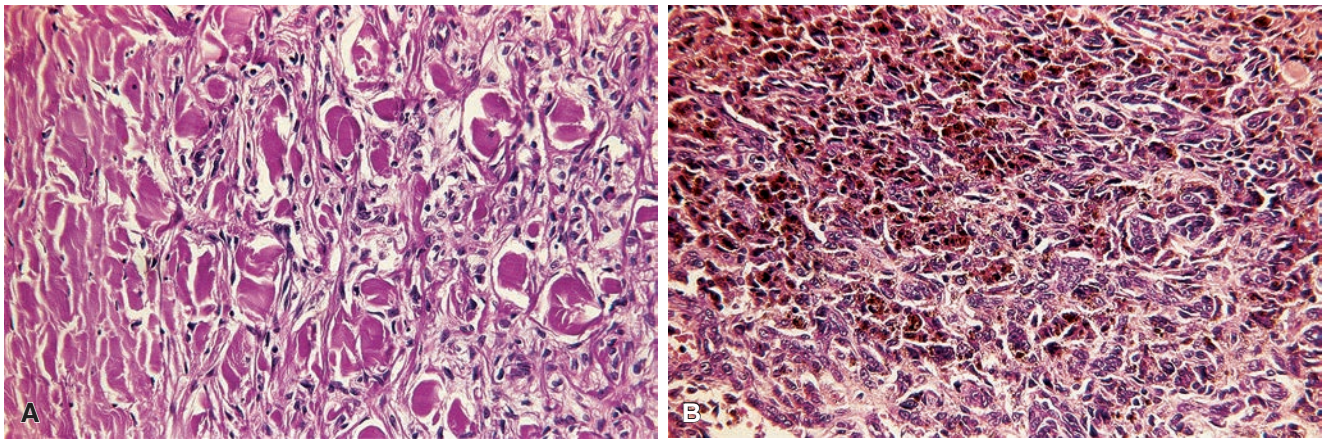

Figure 3.95 Benign Fibrous Histiocytoma of Skin. The tumor depicted in **A** is predominantly fibrous, whereas that shown in **B** is mainly composed of hemosiderin-laden macrophages.

around the shoulder of young women.[1222–1224] When hemorrhagic, it may simulate plaque-stage Kaposi sarcoma.[1225] Focal positivity for smooth muscle actin and CD34 is the rule. The behavior is benign.[1226] It may be related to the recently described fibroblastic connective tissue nevus which has significant histologic and immunophenotypic overlap.[1227]

Solitary fibrous tumor and *nodular fasciitis* have been reported in the skin, their microscopic appearance being similar to those of their more common deep-seated counterparts.[1228,1229] However, some lesions reported to be cutaneous solitary fibrous tumors may in fact be spindle cell lipomas with little mature adipose tissue.[1230]

Fibrohistiocytic Tumors and Tumorlike Conditions

Benign Fibrous Histiocytoma

Benign fibrous histiocytoma (also known as dermatofibroma, histiocytoma, and sclerosing hemangioma) refers to a spectrum of firm, nodular, nonencapsulated, often pigmented lesions that occur chiefly on the extremities.[1231,1232] Clinically, they may be single or multiple and have a flat, polypoid, or depressed shape. Most of them are less than 1 cm in diameter, but some can reach huge proportions. When heavily pigmented, they may be confused clinically with nevi, malignant melanoma, Kaposi sarcoma, and other vascular tumors. On transection, they are usually solid and rather well circumscribed but not encapsulated, the color ranging from white to yellow to dark brown, depending on the relative amounts of fibrous tissue, fat, and hemosiderin. Microscopically, there is a cellular fibroblastic-like proliferation with varying amounts of collagen deposition, admixed with a variable number of macrophages, most of which may contain fat (thereby acquiring a foamy appearance) or hemosiderin. Some of these histiocytes are multinucleated and may acquire the features of Touton giant cells. Much more rarely, they have osteoclast-like features, with or without accompanying bone formation.[1233,1234] Mitotic activity and MIB-1–measured proliferative index are typically low.[1235]

The lesion is characteristically centered in the upper dermis, but it can involve the deep dermis and occasionally extend into the subcutis.[1236–1238] The fibrohistiocytic proliferation is set in a fine vascular network, which can be very prominent (Fig. 3.95). The presence of this vascular component is responsible for this lesion having been regarded in the past as a sclerosing hemangioma and

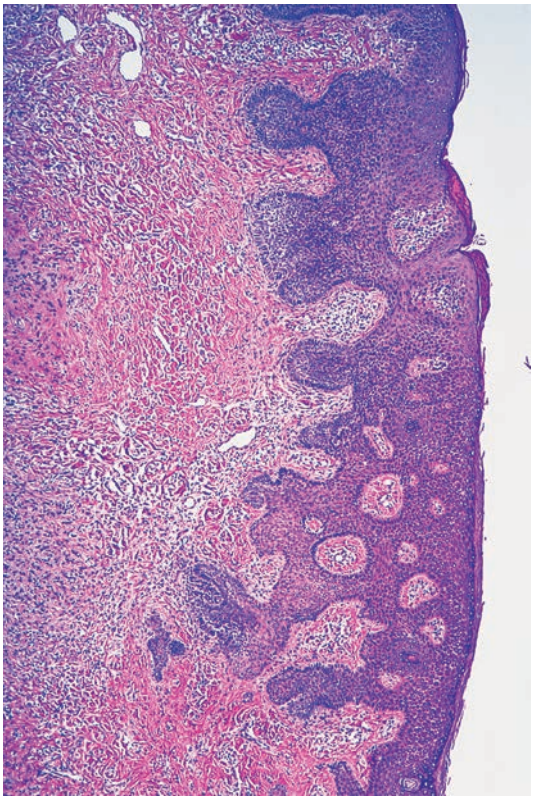

Figure 3.96 Benign Fibrous Histiocytoma. This lesion is associated with basaloid proliferation of the overlying skin. This change does not represent a basal cell carcinoma.

for the fact that it is still occasionally misdiagnosed as Kaposi sarcoma, especially when occurring in HIV-infected individuals. Focal storiform features may be seen, but they are rarely as well developed as in dermatofibrosarcoma protuberans (DFSP).

The overlying epidermis is often acanthotic but can be normal or atrophic. Sometimes there is a proliferation of hair germ–like structures in the basal layer of the epidermis (follicular induction), and rarely a full-blown basal cell carcinoma develops (Fig. 3.96)[1239,1240]; the epidermal growth factor receptor is said to play a role in this interesting phenomenon.[1241] More rarely, there is sebaceous hyperplasia[1242] or even a squamous cell carcinoma in situ.[1243]

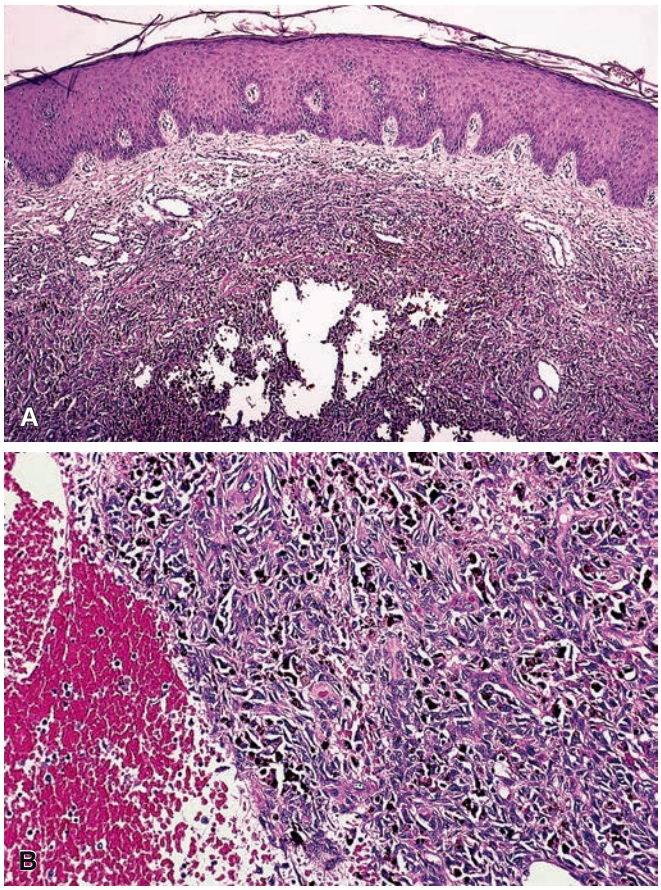

Figure 3.97 **Aneurysmal Fibrous Histiocytoma. A,** Low-power appearance. The empty space in the center of the lesion was occupied by blood. **B,** Higher-power view, showing recent and old hemorrhage.

Morphologic variations of dermatofibroma include prominent palisading similar to that seen in peripheral nerve tumors,[1244] keloid-like changes,[1202] myxoid changes,[1245] granular cells,[1246–1248] markedly lipidized cells,[1249] clear cells,[1250,1251] balloon cells,[1252] signet ring cells,[1253] diffuse eosinophilic infiltrate,[1254] and lichenoid, erosive, and ulcerated features.[1255] Sometimes two or more of these variations coexist.[1256] Marked focal cellular atypia (manifested by the presence of "monster cells"),[1257–1259] extreme cellularity (sometimes associated with necrosis),[1260] and the presence of large cystic changes filled with blood may also occur. The latter lesion, referred to as hemorrhagic, aneurysmal (Fig. 3.97), or angiomatoid, should be distinguished from the *angiomatoid fibrous histiocytoma* seen in deeper sites in younger patients (see chapter on soft tissue tumors).[1261,1262] Due to nomenclature similarity with angiomatoid fibrous histiocytoma, a completely different neoplasm, the use of the term *angiomatoid* when describing benign fibrous histiocytomas with hemorrhage is strongly discouraged. *Epithelioid* fibrous histiocytoma (epithelioid cell histiocytoma) is yet another variation on the theme, characterized by the presence of large "angulated" epithelioid cells as the main constituent (Fig. 3.98).[1263–1266] This tumor is notorious for its ability to simulate vascular and melanocytic neoplasms.[1266] This variant has rearrangements of *ALK*, and immunohistochemical stains can be a useful adjunct to the diagnosis.[1267]

Immunohistochemically, dermatofibromas are positive for factor XIIIa, a proenzyme known to be present in so-called dermal dendrocytes,[1268,1269] and for HMGA1/HMGA2 (members of the high mobility group protein family genes).[1270] In contrast with DFSP, they are negative for CD34.[1268,1270,1271] Another group of markers that

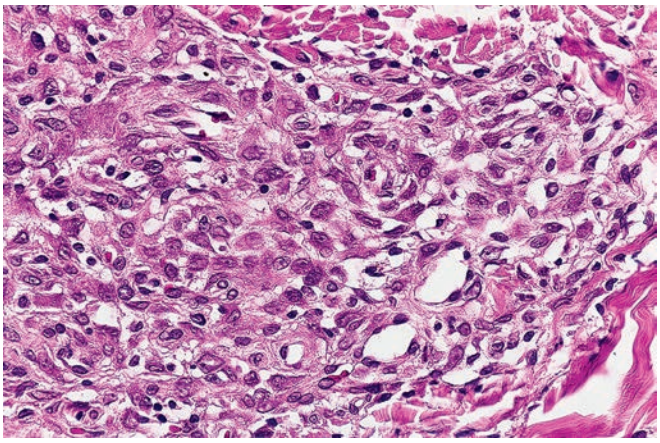

Figure 3.98 Epithelioid fibrous histiocytoma.

dermatofibromas often exhibit are those associated with smooth muscle/myofibroblastic differentiation, such as actin, desmin, and myosin; this is not generally known and has led to misdiagnoses, such as leiomyoma or—worse—leiomyosarcoma.[1272,1273] However, truth be told, immunohistochemical stains are rarely needed in the diagnosis of dermatofibromas, except in partially sampled lesions in superficial biopsies.

There was a longstanding controversy as to whether dermatofibroma is a neoplastic or reactive condition, but the occurrence of aggressive and even metastasizing forms of the disease (see later) and the evidence of clonality at the molecular level have effectively disproven the idea that dermatofibromas are reactive in nature.[1274–1276]

The behavior of dermatofibroma is generally very indolent, to the extent that local recurrence is very rare even if the margins are inadequate. However, cases with locally aggressive behavior and even with distant metastases are on record.[1277–1281] This is seen more commonly with lesions located in the face and those exhibiting deep extension into the subcutaneous tissue and/or cellular fascicles of mitotically active spindle cells, but it remains an exceptionally rare occurrence, and histologic features are not predictive of aggressive behavior. It does appear that dermatofibromas with metastatic potential may have increased chromosomal aberrations compared with conventional dermatofibromas, but these changes are not reflective in histologic features and are not practical for routine use.[1282,1283]

Atypical Fibroxanthoma

Atypical fibroxanthomas are nodular, sometimes ulcerated tumors that typically occur on the sun-exposed skin of elderly persons and are often clinically confused with cutaneous carcinomas (Fig. 3.99).[1284–1286] Histologically, the tumor is often polypoid and ulcerated, especially when occurring at the classical sites (Fig. 3.100). Bizarre tumor cells are seen scattered within a spindle cell stroma with varying amounts of inflammation (Fig. 3.101). Mitoses are plentiful, some of them being atypical. However, in some instances there is little pleomorphism and a predominance of spindle cells.[1287] The overlying epidermis may be normal, atrophic, hyperplastic, or ulcerated, but by definition it should not show continuity with the tumor. Morphologic variations include tumors with pigmentation,[1288] with osteoclast-like giant cells,[1289,1290] with clear cells,[1291,1292] (which should be distinguished from other dermal clear cell mesenchymal neoplasms),[1293] and with granular cells.[1294,1295]

Immunohistochemically, the various components of the lesion may show reactivity for vimentin, actin, calponin, h-caldesmon, CD68 (detected with monoclonal antibody KP-1), α1-antitrypsin,

Figure 3.99 Clinical appearance of atypical fibroxanthoma. The lesion is characteristically elevated, reddish, and ulcerated.

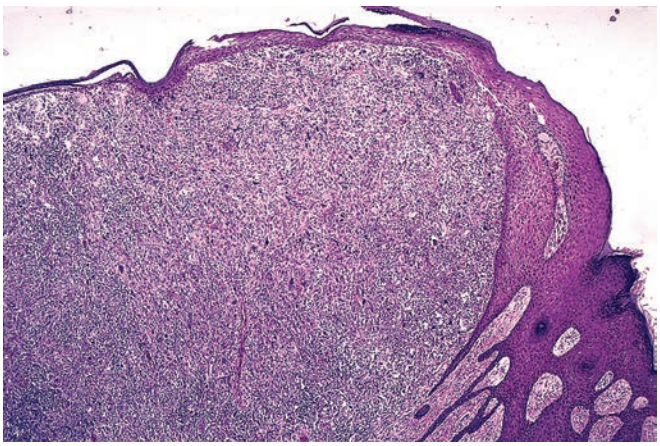

Figure 3.100 Low-power view of atypical fibroxanthoma. The lesion is typically polypoid and ulcerated.

α1-antichymotrypsin, cathepsin-B, FXIIIa (focal), S-100 protein (focal), CD10, CD117, and CD99 and negativity for keratin, EMA, and desmin.[1296–1301] From a practical standpoint, the absence of any keratin expression and absence of diffuse S100 protein expression is more important than any positive marker. There are rare reports in the literature of so-called keratin-positive atypical fibroxanthomas, which in our opinion are more likely sarcomatoid squamous cell carcinomas.[1302]

Despite the bizarre microscopic features that suggest a high-grade lesion, atypical fibroxanthomas are relatively indolent lesions that are usually cured by local excision.[1303] However, some cases have resulted in local recurrence, and a few have metastasized.[1304,1305]

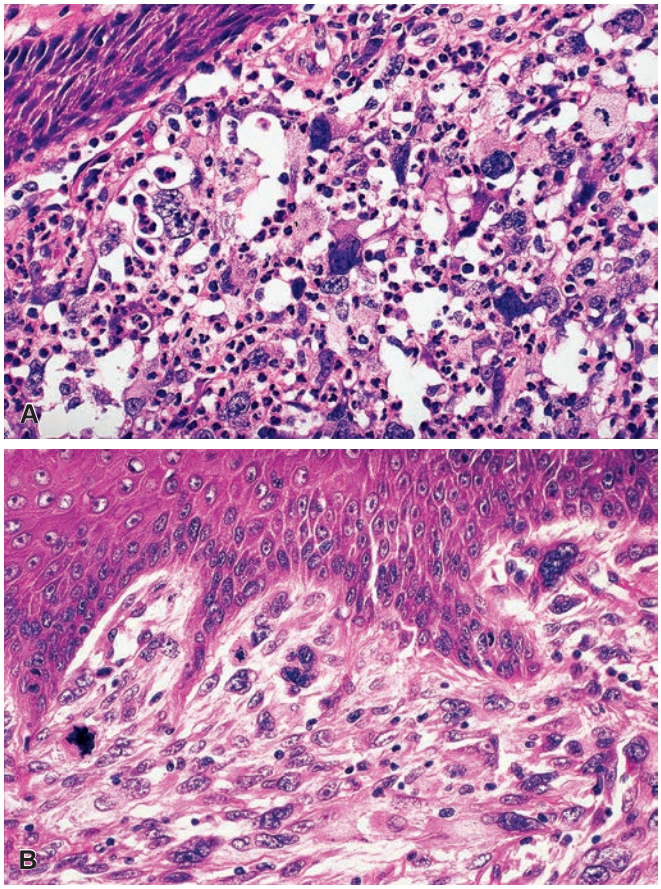

Figure 3.101 **A** and **B,** High-power views of atypical fibroxanthoma, showing highly anaplastic cells in the dermis surrounded by an inflammatory infiltrate.

Factors that portend aggressive behavior and possible metastases in atypical fibroxanthoma are vascular invasion, extension into deep tissues, tumor necrosis, local recurrence, and history of immunosuppression,[1304] but rare cases without these features may behave in an aggressive fashion.[1305] Cases with the aforementioned histologic features are probably best classified as *pleomorphic dermal sarcoma*, a tumor that shares demographic features with atypical fibroxanthoma but is infiltrative and has a significant risk of metastasis.[1306]

Dermatofibrosarcoma Protuberans

DFSP are slow-growing, nodular, polypoid neoplasms that are found almost exclusively in the dermis, from which they often invade the subcutaneous tissue (Fig. 3.102). However, sometimes they are entirely subcutaneous, with little or no dermal involvement.[1307] Most of the cases occur in adults, but they have also been seen in infancy and childhood.[1308] As a group, these tumors are much larger than benign fibrous histiocytomas; however, the diagnosis of DFSP should not be made or ruled out on the basis of size alone. Microscopically, the appearance of radial whorls of spindle cells producing the storiform or cartwheel pattern is characteristic although not pathognomonic (Fig. 3.103). Other features of diagnostic importance are the high cellularity, monomorphic appearance, diffuse infiltration of subcutaneous fat (Fig. 3.104), lack of foamy or hemosiderin-laden macrophages and/or multinucleated giant cells, and lack of peripheral collagen trapping characteristic of dermatofibroma. Myxoid features can be present focally and sometimes be the dominant feature of the tumor.[1309–1311] Bundles of plumper spindle cells of myoid

Figure 3.102 Gross appearance of dermatofibrosarcoma protuberans, showing typical bulging above the skin.

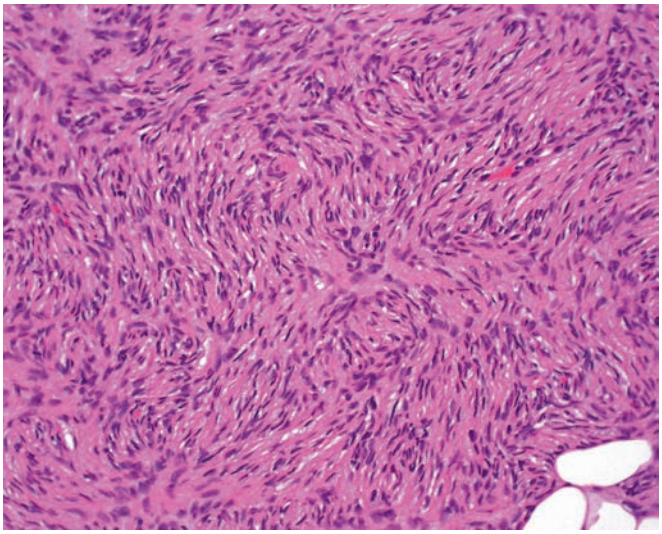

Figure 3.103 Storiform or cartwheel pattern of dermatofibrosarcoma protuberans.

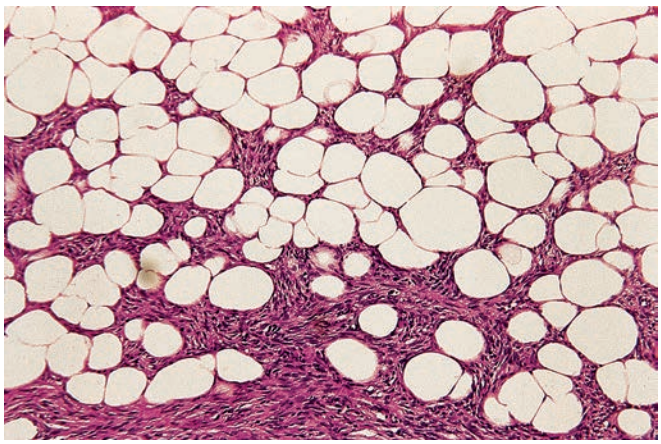

Figure 3.104 Typical pattern of invasion of subcutaneous fat by dermatofibrosarcoma protuberans.

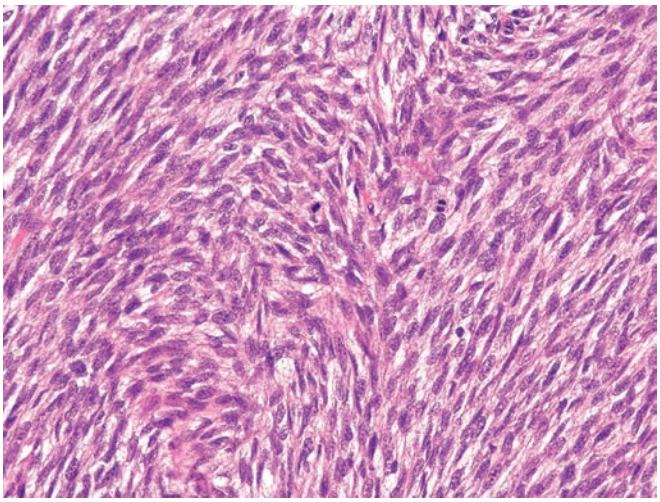

Figure 3.105 Fibrosarcomatous area in a dermatofibrosarcoma protuberans. A storiform pattern of growth is no longer evident in this component. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

appearance can be seen.[1312] Regressive areas with atrophy may also occur, and these are likely to be underdiagnosed.[1313,1314] Granular cell change may be present in areas.[1315]

Immunohistochemically, these tumors are positive for vimentin, actin (focally and inconstantly), and CD34 (strongly and consistently).[1316,1317] Conversely, they are negative for S-100 protein, HMB-45, keratin, and Factor XIIIa (although some dendritic cells that are reactive for the latter marker are usually found).[1268,1298,1318]

Cytogenetically, DFSP shows supernumerary rings derived from chromosome 22 or a linear translocation in the same chromosome in the form of *t*(17;22)(q22;q13), both of them leading to the gene fusion *COL1A1* with *PDGFB*.[1319,1320] This molecular alteration is also found in the morphologic variants of this tumor, including the high-grade areas (fibrosarcomatous transformation) when present.[1321,1322] Detection of the gene fusion by RT-PCR or FISH is helpful for confirming a diagnosis of DFSP in difficult cases.[1322]

The natural history of DFSP is characterized by an extremely high tendency for local recurrence following limited resection.[1323,1324] Very rare instances of metastases to regional nodes and/or internal organs have also been documented.[1325,1326] Thus, DFSP is generally placed in the category of tumors of intermediate malignancy.[1327]

DFSP and *giant cell fibroblastoma of infancy* are related tumors representing ends of a spectrum. This is supported by the occurrence of hybrid or combined tumors, either simultaneously or sequentially and by their common molecular alterations.[1328–1331]

DFSP can undergo fibrosarcomatous transformation, the latter areas acquiring the typical herringbone appearance of that tumor type and no longer exhibiting a storiform pattern of growth (Fig. 3.105). There has been an argument as to whether this morphologic change is reflected in a more aggressive clinical form,[1332–1334] but most recent evidence indicates that it does.[1335] Occasionally, the tumor progression is toward a more pleomorphic neoplasm with the appearance of an undifferentiated pleomorphic sarcoma (referred to historically as malignant fibrous histiocytoma).[1336,1337]

Pigmented DFSP (Bednar tumor, pigmented storiform neurofibroma) is a neoplasm having the overall appearance of an ordinary DFSP but containing, in addition, a variable (but usually small and patchy) population of dendritic cells containing large amounts of melanin pigment (Fig. 3.106).[1338] Although this finding obviously raises the possibility of schwannian/melanocytic derivation, the tumor is negative for S-100 protein and other melanocyte-related

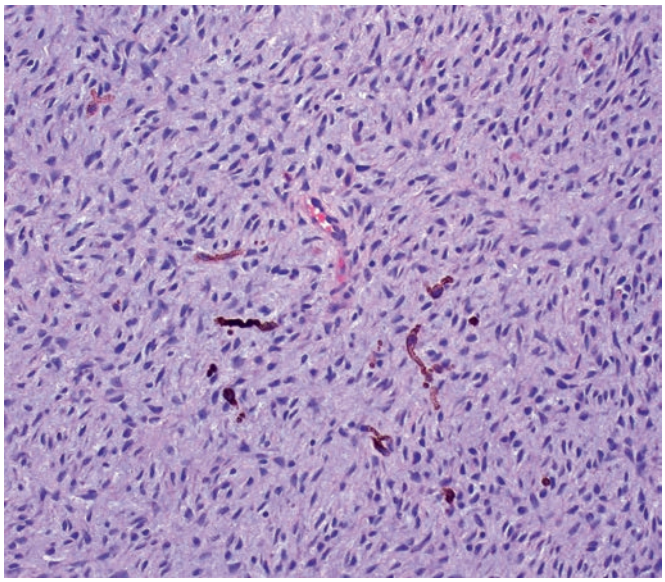

Figure 3.106 Pigmented dermatofibrosarcoma protuberans (Bednar tumor).

markers and should not be equated with malignant melanoma of conventional, desmoplastic, or soft tissue (clear cell sarcoma) types. The similarity with DFSP extends even to the occasional development in Bednar tumor of fibrosarcomatous areas and of distant metastatic spread.[1339]

Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma) and Pleomorphic Dermal Sarcoma

Undifferentiated pleomorphic sarcoma, a tumor morphologically analogous to the tumor traditionally called pleomorphic-storiform type of malignant fibrous histiocytoma, can sometimes present as a superficial tumor. This term should probably be restricted to those tumors that infiltrate deeply into the subcutis, fascia, or muscle and arise outside of the head and neck.[1306,1340] Some of the reported cases have occurred in chronic ulcers or scars,[1341] and others have shown the features of the myxoid variant (myxofibrosarcoma).[1342,1343] They should not be confused with atypical fibrous histiocytoma/dermatofibroma with monster cells, tumors that have marked cytologic atypia but overall features of dermatofibromas.[1257,1258,1344] A more detailed discussion of these entities is present in the chapter on soft tissue tumors. The term *pleomorphic dermal sarcoma* has been suggested for pleomorphic sarcomas that arise in sun-damaged skin of the head and neck of elderly patients.[1306] As previously mentioned, they differ from atypical fibroxanthoma by having an infiltrative growth pattern, necrosis, and perineural invasion. Of these features, infiltrative growth is the most important. These tumors have a relatively high rate of recurrence and metastatic rate of approximately 10%, with metastases most commonly involving the skin of the head and neck. The possibilities of sarcomatoid squamous cell carcinomas and spindle cell melanoma should be excluded with appropriate cytokeratin stains and a stain for S100 protein or SOX10.[1306]

Xanthoma

Xanthomas are non-neoplastic nodules resulting from the accumulation of fat-laden histiocytes in the dermis and subcutis or deeply in the tendons, synovium, and bone (Fig. 3.107). They are usually periarticular and few in number, but disseminated forms occur.[1345]

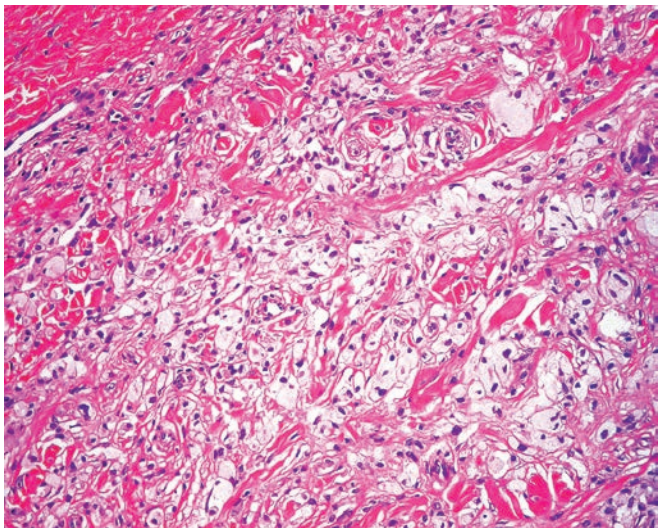

Figure 3.107 Cutaneous xanthoma showing ill-defined collection of foamy macrophages in the dermis.

They are often associated with hyperlipidemia, either primary (familial) or secondary to diabetes mellitus, hypothyroidism, multiple myeloma, malignant lymphoma, leukemia, and obstructive liver disease. Flat xanthomas of the eyelid, referred to as *xanthelasma*, show a similar microscopic appearance. Only a minority of these patients have hyperlipidemia. *Papular xanthoma* is usually found in the trunk or extremities of males.[1346] In *eruptive xanthoma*, there is an abrupt onset of crops of yellowish papules with erythematous halos on the extensor surfaces. It can be confused with granuloma annulare at the microscopic level.[1347] In *verruciform xanthoma*, there is a papillomatous, verruca-like change of the overlying epidermis.[1348,1349]

Xanthogranuloma

Xanthogranuloma occurs most often in the skin, but it can also be found in the subcutaneous tissue, skeletal muscle,[1350,1351] ocular globe, peripheral nerves,[1352] testis,[1353] breast,[1354] and other sites.[1350,1351,1355,1356] It usually presents in infants *(juvenile xanthogranuloma)*, but it also occurs in adults, having in them a slightly different microscopic appearance.[1357] The upper part of the body is most commonly involved. The skin lesions are multiple in approximately 20% of cases[1358]; adult cases are more often solitary. Glaucoma and amblyopia, caused by involvement of the iris and ciliary body, can sometimes be seen as the initial manifestation of the disease. It has been reported in association with type 1 neurofibromatosis, epilepsy, Niemann–Pick disease, urticaria pigmentosa, and cytomegalovirus (CMV) infection.[1357]

Microscopically, the lesion is characterized by a histiocytic proliferation that in later stages is accompanied by foamy and Touton giant cell forms (Figs. 3.108 and 3.109). Lymphocytes, eosinophils, proliferating vessels, and fibroblasts may also be present. Ultrastructurally, the histiocytes do not contain Birbeck granules; some have instead a variable number of cytoplasmic lipid vacuoles.[1358] Immunohistochemically, most cases show positivity for CD68, α1-antichymotrypsin, lysozyme, and other histiocytic markers, whereas S-100 protein is essentially negative.[1359,1360] The lesion is thought to be a proliferation of (non-Langerhans) cells belonging to the so-called accessory immune system, whether conventional macrophages or plasmacytoid monocytes.[1361–1363] Xanthogranulomas with scanty foamy macrophages and giant cells may closely mimic malignant melanoma, but xanthogranulomas are negative for melanocyte-specific

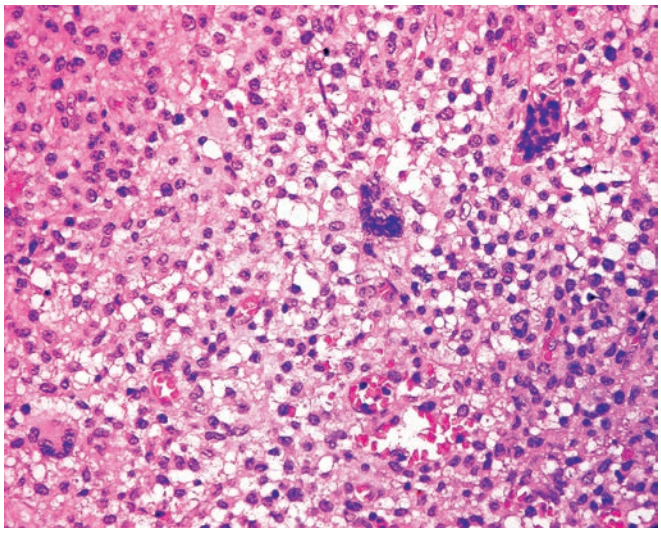

Figure 3.108 Juvenile Xanthogranuloma. Scattered multinucleated histiocytes are seen among numerous mononuclear elements.

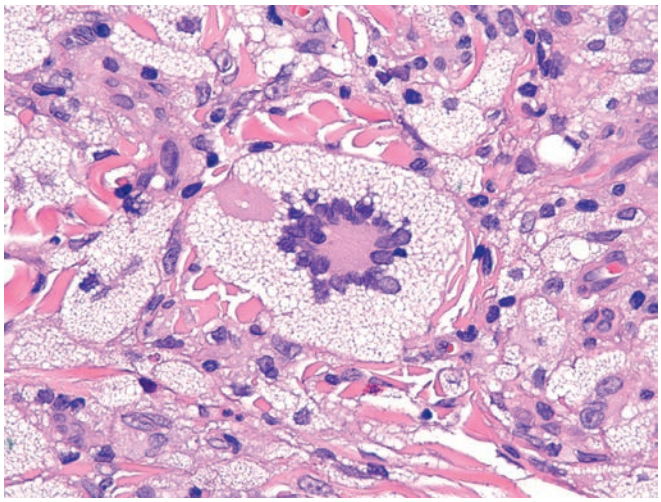

Figure 3.109 A spectacular Touton giant cell in a case of juvenile xanthogranuloma. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

markers like Melan-A.[1364] There is a variant of xanthogranuloma predominantly composed of spindle cells; solitary and generalized forms have been described.[1365]

Other Histiocytic Proliferations

Many other types of histiocytic infiltrates of the skin occur, a high percentage of them in children.[1358,1366,1367] *Giant cell reticulohistiocytoma* can present in a solitary or multicentric form, the latter sometimes associated with articular involvement ("lipoid dermatoarthritis").[1368,1369] Microscopically, there is an infiltration of mononuclear and multinucleated histiocytes with a characteristic ground-glass cytoplasm, admixed with other inflammatory cells.[1370] Immunohistochemically, the main proliferating cells have markers of histiocytes, with an important secondary component of dermal dendrocytes.[1371,1372] Some authors believe that reticulohistiocytoma and multicentric reticulohistiocytosis represent different entities.[1373]

In *Langerhans cell histiocytosis*, scattered ordinary histiocytes are seen admixed with eosinophils and S-100 protein– and CD1a-positive Langerhans cells, the latter defining the nature of the disorder, covered elsewhere in this text. Invasion of the epidermis by the infiltrate is an important diagnostic sign.

Figure 3.110 Clinical Appearance of Rosai–Dorfman Disease of the Skin. In this case the lesion presented in the form of multiple elevated erythematous nodules.

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) may involve the skin (Figs. 3.110 and 3.111).[1374] In some instances the diagnosis is obvious because of the presence of prominent cervical lymphadenopathy; however, in the majority of cases the cutaneous lesions represent the predominant or exclusive manifestation of the disease.[1375–1378]

Smooth Muscle Tumors

Leiomyomas of skin can be divided into three distinct types: the *genital* leiomyoma located in the nipple or scrotum; the multiple superficial nodules of *nevoid* or *hamartomatous* type derived from arrectores pilorum muscle (*pilar* leiomyoma)[1379]; and the *solitary angioleiomyoma* (vascular leiomyoma), which is usually subcutaneous rather than dermal (see soft tissue chapter).[1380]

Cutaneous leiomyomas can be very painful. Microscopically, they show intersecting fascicles of smooth muscle, without atypia, mitotic activity, or necrosis. Occasionally, scattered bizarre hyperchromatic nuclei are present both in angioleiomyomas[1381] and pilar leiomyomas.[1382] As in analogous situations in other parts of the body, these tumors—which behave in a benign fashion—are variously called pleomorphic, symplasmic, or atypical. *Familial cutaneous leiomyomatosis* is a genetically determined condition, sometimes associated with a distinct morphologic type of renal cell carcinoma, a condition associated with mutations in fumarate hydratase.[1383,1384]

Leiomyosarcomas are larger, more cellular, cytologically atypical, mitotically active and may contain areas of necrosis.[1385–1387] Some of them exhibit a prominent vascular pattern, suggesting that they may represent the malignant counterpart of vascular leiomyoma.[1388]

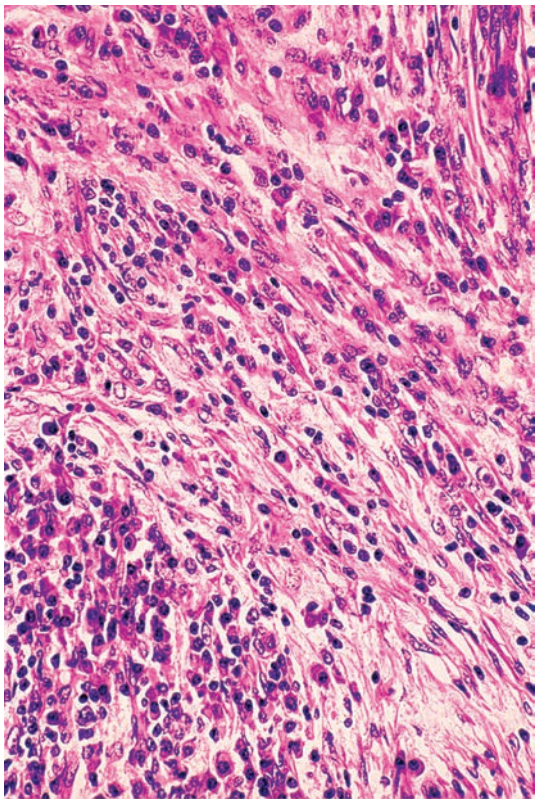

Figure 3.111 Microscopic Appearance of Cutaneous Rosai–Dorfman Disease. A polymorphic infiltrate composed of lymphocytes, plasma cells, and histiocytes is present. As is often the case in extranodal lesions, there is a moderate degree of fibrosis.

Others have clear cell ("leiomyoblastomatous") features[1389,1390] and still others have a desmoplastic quality.[1391] Cutaneous leiomyosarcomas may recur, but they metastasize only exceptionally if at all, in stark contrast with their subcutaneous counterpart.[1386,1392,1393] Some have argued that the name should be changed to "atypical intradermal smooth muscle tumor" to reflect the indolent nature of the tumor.[1394] However, this approach has been questioned, suggesting that this approach may inject a proliferation of confusing and ultimately meaningless nomenclature.[1395] Multiple smooth muscle tumors in HIV-infected patients are associated with EBV and appear to be biologically different from other cutaneous leiomyomas.[1396] No such association has been found in similar tumors in immunocompetent individuals.[1397]

Skeletal Muscle Tumors

Rhabdomyomatous mesenchymal hamartoma (striated muscle hamartoma) is a benign process of infants usually located centrally on the chin or near the ala of the nose, sometimes in association with other congenital abnormalities. Microscopically, the lesion is formed by a central core containing bundles and individual fibers of skeletal muscle and other mesenchymal elements.[1398,1399] Occasionally, lesions with a similar appearance (and also of presumed choristomatous or hamartomatous nature) present as multiple nodules in the skin.[1400,1401]

Adult rhabdomyoma has been reported in the lip and eyelid.[1402]

Primary cutaneous rhabdomyosarcomas are rare. Tumors arising in young patients tend to be of the embryonal or alveolar type, whereas those arising in older adults are usually pleomorphic rhabdomyosarcomas.[1403] Cutaneous rhabdomyosarcomas, like their deep soft tissue counterparts, can be aggressive neoplasms.[1403] Rhabdomyosarcoma can also arise in represent the malignant component of a congenital melanocytic nevus.[1404]

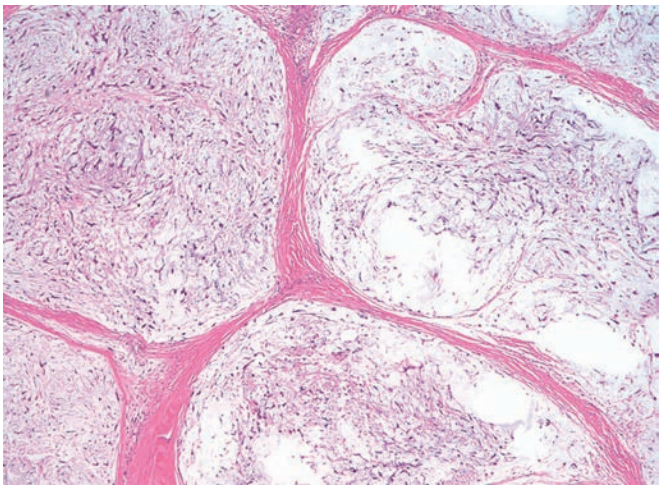

Figure 3.112 Dermal Nerve Sheath Myxoma. The tumor is characterized by bland spindled cells arranged in discrete myxoid nodules separated by fibrous septae.

Peripheral Nerve Sheath Tumors

Of the various types of peripheral nerve sheath tumor, those with a predilection for cutaneous (dermal)—as opposed to subcutaneous or deeper—involvement are *neurofibroma*, *granular cell tumor* (not all of which are neural),[1405,1406] *dermal nerve sheath myxoma* (myxoid neurothekeoma), and *palisaded encapsulated neuroma* (solitary circumscribed neuroma).[1407] The first two tumors are discussed in the chapter on soft tissue tumors, but it should be mentioned here that dermal neurofibromas can result in proliferation of entrapped sweat glands or folliculosebaceous structures, which can be confusing,[1408] and that reexcision specimens may show a reparative perineurial proliferation which may simulate perineurial invasion by tumor.[1409,1410]

Dermal nerve sheath myxoma (myxoid neurothekeoma) is characterized by distinct nests of spindled to slightly epithelioid cells in a myxoid stroma separated by fibrous septa (Fig. 3.112).[1411–1413] It is a benign tumor but prone to local recurrence if incompletely excised. This tumor is positive for S100 protein, unlike the unrelated cellular neurothekeoma (see later).

The so-called *cellular neurothekeoma* was originally considered an entity related to dermal nerve sheath myxoma due to overlapping histologic features. The tumor is composed of a nested population of epithelioid cells within a somewhat hyalinized stroma (Fig. 3.113). Some myxoid stroma may be present. It was originally thought to be related to dermal nerve sheath myxoma due to the overlapping appearance of the nested pattern. However, convincing evidence of true nerve sheath differentiation is lacking, and there is growing consensus that cellular neurothekeoma is best considered a fibroblastic/fibrohistiocytic tumor.[1414–1416] Cellular neurothekeoma is negative for S-100 protein, Melan-A, and HMB-45; positive for S-100A6, protein gene product (PGP) 9.5, MiTF, NKI/C3, NSE, and CD10; and variable for smooth muscle actin.[1414–1420] The combination of NKI/C3 and CD10 may be the most helpful positive stains, although neither is tremendously specific.[1420] Cellular neurothekeoma can be confused with malignant melanoma and other melanocytic tumors,[1343,1421] particularly when exhibiting atypical features.[1420,1422] We have seen several cases in which typical cellular neurothekeoma areas blended with a pattern very similar to that of plexiform

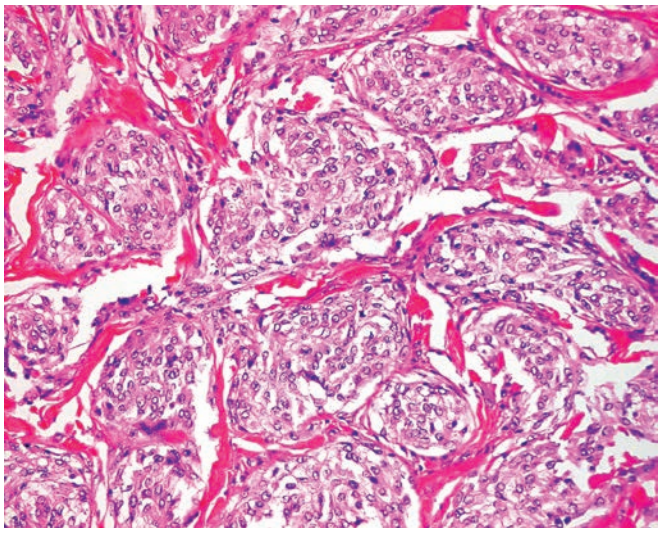

Figure 3.113 Cellular Neurothekeoma. The tumor cells are arranged in compact nests.

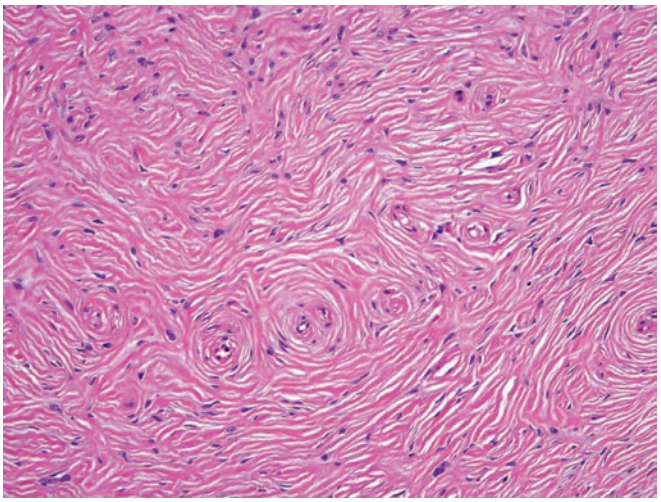

Figure 3.115 Cutaneous Perineurioma. The very elongated shape of the tumor cells and the whorling arrangement are typical features of this benign peripheral nerve sheath tumor. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

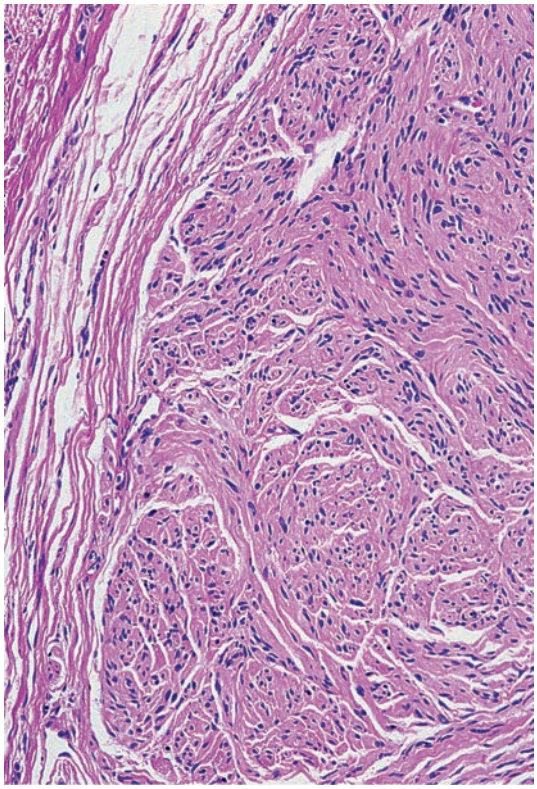

Figure 3.114 Palisaded Encapsulated Neuroma. The fascicular pattern is well developed. This lesion should not be confused with leiomyoma of skin.

fibrohistiocytic tumor, suggesting a relationship between the two entities, although a relationship has not been definitively proven.[1423] The behavior is generally benign. Local recurrences have been rarely described, but no instances of metastatic spread.[1415,1416]

Palisaded encapsulated neuroma (solitary circumscribed neuroma) presents as a small solitary papule, usually located on the face.[1424] Microscopically, it is a spindle cell lesion exhibiting varying degrees of nuclear palisading and characteristic intratumoral clefts (Fig. 3.114).[1425] Occasionally, the cells are epithelioid rather than spindle.[1426] Misinterpretation of this lesion as a schwannoma or leiomyoma is common. Immunohistochemically, the spindle cells are strongly reactive for S-100 protein, in keeping with their presumed schwannian nature.[1427,1428] Axons can be demonstrated with special stains, distinguishing it from schwannoma.

Epithelial sheath neuroma is a most peculiar skin lesion characterized by a proliferation of nerve fibers coated by squamous epithelium.[1429,1430] This process probably represents an unusual reactive process with squamous metaplasia of the nerve sheath.

Perineurioma can occur in the skin and soft tissues with a variety of patterns: *epithelioid* (often misdiagnosed as epithelioid histiocytoma), *sclerosing* (which simulates a fibroma and is usually acral in location), *reticular*, and *plexiform* (Fig. 3.115).[1431–1434] EMA immunoreactivity is an important clue to the diagnosis.

Although the large majority of MPNSTs are located in the deep soft tissues, cutaneous examples have been described in patients with or without type I Recklinghausen disease.[1356,1435,1436] In MPNST, a precursor neurofibroma remnant is often present.

Vascular Tumors and Tumorlike Conditions

A large variety of tumors and ectasias arising from blood and lymph vessels of the skin exists,[1437,1438] and several new types have been described.[1439] Most of these lesions are discussed in the chapter on soft tissue tumors. Only those features pertaining to their cutaneous location will be mentioned in this section.

Hemangioma

The more distinctive types of benign blood vessel tumors of skin[1440] are *capillary* hemangioma, *infantile* hemangioma (benign [infantile] hemangioendothelioma) (Fig. 3.116), *cavernous* hemangioma, *angiokeratomas* of various types,[1441] *verrucous* hemangioma,[1442] *acral arteriovenous tumor/arteriovenous hemangioma* (Fig. 3.117),[1443,1444] *microvenular* hemangioma (Fig. 3.118),[1445–1447] *glomeruloid* hemangioma (Fig. 3.119; a distinctive vascular proliferation rich in hyaline globules, seen in Castleman disease associated with the POEMS [polyneuropathy, organomegaly, endocrinopathy, monoclonal plasma proliferative disorder, skin changes] syndrome),[1448–1451] *papillary* hemangioma (also containing hyaline globules),[1452,1453] *hobnail* hemangioma (targetoid hemosiderotic hemangioma) (Fig. 3.120),[1454,1455] *acquired*

elastotic hemangioma,[1456] *symplastic* hemangioma,[1457] *cutaneous epithelioid angiomatoid nodule*,[1458] *glomus tumor*, and *myopericytoma* (see chapter on soft tissue tumors).[1459]

Spider angioma, venous lake, capillary aneurysm, angioma serpiginosum, and the lesion of hereditary hemorrhagic telangiectasia are not true neoplasms but rather telangiectatic processes of either hamartomatous or acquired nature.[1356] This may also be true for some of the lesions listed in the preceding paragraph.

Lymphangioma

Cutaneous lymphangiomas usually present in infancy, the majority being present by the age of 5 years.[1459] Sites of predilection are the neck, axilla, breasts, chest, buttocks, and thighs. The lesions are divided into *superficial* (lymphangioma circumscriptum), *deep* (lymphangioma cavernosum), and *cystic* (cystic hygroma) varieties (Fig. 3.121). Recurrence develops in about 25% of cases.[1460] This is apparently caused by the presence of large muscle-coated lymphatic cisterns lying deep in the subcutis and feeding the superficial vesicles.[1461]

Benign lymphangioendothelioma is the name that has been proposed for the benign lymph vessel tumor originally described as acquired progressive lymphangioma.[1462,1463] It presents as a bruise-like lesion and simulates angiosarcoma because of the presence of anastomosing vascular channels. However, atypia of endothelial cells is totally absent.[1464] Before this diagnosis is made, care should be exercised in ruling out the lymphangioma-like form of Kaposi sarcoma.[1465,1466]

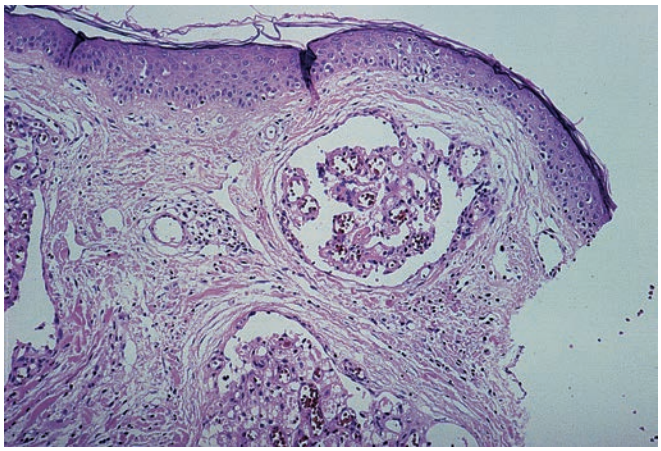

Figure 3.119 Glomeruloid hemangioma in a patient with POEMS syndrome. Microscopic appearance of the individual lesions is reminiscent of renal glomeruli.

Figure 3.122 Clinical appearance of typical pyogenic granuloma.

A curious condition mentioned here despite the fact that it is not a lymph vessel neoplasm is *cutaneous intralymphatic histiocytosis*. As the name indicates, this process is characterized by the presence of dilated lymph vessels packed with CD68-positive histiocytes, usually seen in patients with rheumatoid arthritis.[1467,1468]

Pyogenic Granuloma

Pyogenic granuloma (granuloma pyogenicum, lobular capillary hemangioma) presents clinically as a rapidly growing polypoid red mass, surrounded by a collarette of thickened epidermis. The fingers and lips are the most common locations (Fig. 3.122). Sometimes it appears in connection with a keratinous cyst.[1469] Microscopically, there is vascular proliferation, edema, and inflammation. The epidermis is thinned and sometimes ulcerated at the top, and there is acanthosis and hyperkeratosis at the sides (Fig. 3.123). The most distinctive feature is the so-called vascular (capillary) lobule, a central branching vessel, surrounded by a hypercellular proliferation of newly formed endothelial and perithelial cells (Fig. 3.124).[1470,1471] High cellularity and abundant mitotic activity may be present (particularly in lesions of the lips), but these are not indicative of an aggressive behavior.[1472,1473] The lesion is self-limited, and spontaneous regression is the rule. Excision is usually curative, although some examples located on the trunk may recur as multiple satellites.[1474] Lobular capillary hemangioma can also occur in a disseminated form,[1475] develop within port-wine stains,[1476] be located in the deep dermis or subcutaneous tissue,[1477] or present as an intravascular proliferation.[1478] Deeply seated lesions usually lack the edema and inflammation seen in the more superficial examples.

Acquired Tufted Angioma

Acquired tufted angioma (angioblastoma) typically presents as multiple red plaques on the shoulders and upper back of children and

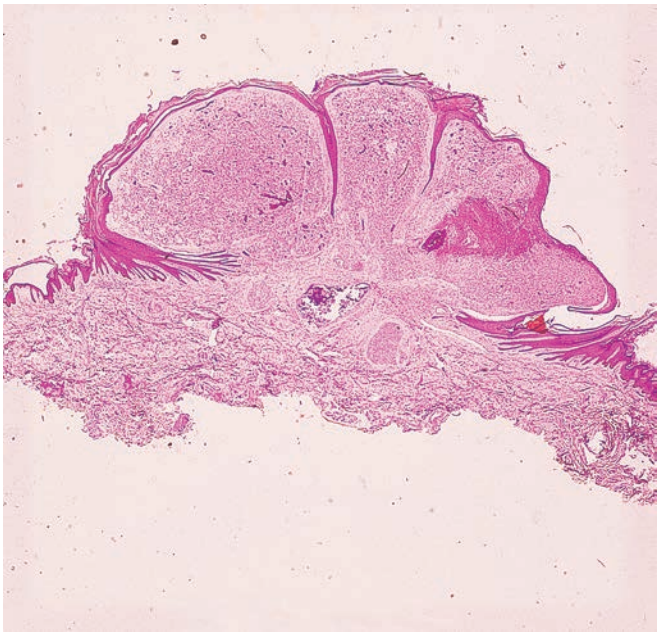

Figure 3.123 Low-power microscopic view of typical pyogenic granuloma.

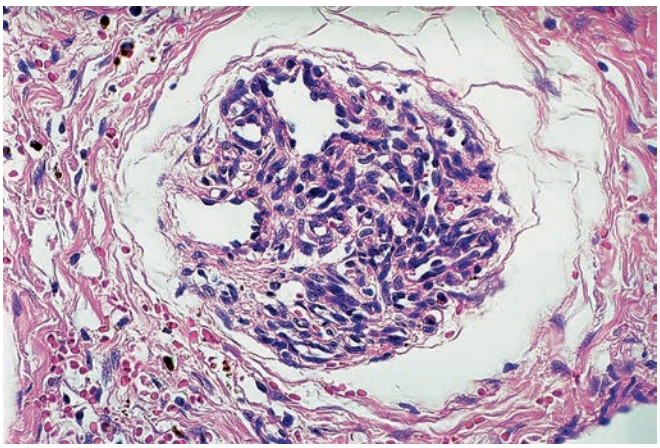

Figure 3.124 So-Called Capillary or Vascular Lobule. This formation is almost always an indicator of a benign process.

adolescents and is characterized microscopically by multiple vascular lobules, which tend to be more cellular than those of pyogenic granuloma and to have a semilunar vessel at the periphery rather than a more open one at the center.[1479,1480] Acquired tufted angioma shares histologic and immunophenotypic features with kaposiform hemangioendothelioma and is likely part of the spectrum of that tumor.[1481]

Masson Hemangioma

Masson hemangioma (vegetant intravascular hemangioendothelioma; Masson pseudoangiosarcoma; intravascular papillary endothelial hyperplasia) is in all likelihood the result of exuberant organization and recanalization of a thrombus.[1482] It may develop in a previously normal vessel as a result of trauma, or it may superimpose itself on a pyogenic granuloma or cavernous hemangioma.[1483–1485] It is characterized microscopically by a papillary proliferation of endothelial cells (which are plump but lack atypia) located entirely within the lumen of a dilated vessel. The core of the papillae has a deeply acidophilic quality, resulting at least in part from fibrin deposition.

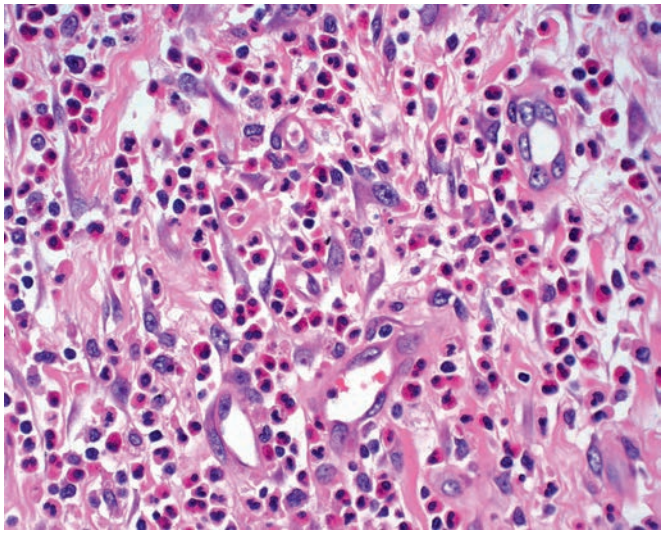

Figure 3.125 Epithelioid hemangioma is benign cutaneous vascular tumor largely composed of vessels lined by epithelioid endothelial cells. An associated infiltrate of eosinophils and lymphocytes is usually present.

The immunohistochemical profile of the predominant element is that of activated endothelial cells.[1486]

Epithelioid Hemangioma

Epithelioid hemangioma (histiocytoid hemangioma, angiolymphoid hyperplasia with eosinophilia) presents clinically as inflammatory-looking nodules, the head and neck (particularly the periauricular region) being the preferred locations.[1487,1488] Despite earlier claims to the contrary, this disease is clearly distinct from Kimura disease.[1410,1489,1490] Microscopically, a central area of proliferated blood vessels is infiltrated and surrounded by a heavy inflammatory infiltrate rich in eosinophils and containing lymphoid follicles with germinal centers. In a variation of the theme, the proliferation may acquire a lobular solid pattern that has been termed *cutaneous epithelioid angiomatous nodule*.[1458] The defining feature of this entity is the peculiar epithelioid or histiocytoid appearance of the endothelial cells (Fig. 3.125). Sometimes the inflammatory infiltrate is nil or absent.[1491] These lesions, as they occur in the skin, are of an indolent nature, and there is controversy as to whether they are reactive or neoplastic.[1492] They represent the "benign" end of the spectrum of a family of vascular proliferations having as a common denominator the presence of epithelioid (histiocytoid) endothelial cells, which also includes epithelioid hemangioendothelioma and epithelioid angiosarcoma.[1493] A distinction among these entities is possible in the majority of the cases on the basis of location (most epithelioid hemangiomas are cutaneous, whereas most epithelioid hemangioendotheliomas and angiosarcomas are not), cellularity, atypia, and some architectural features.[1494] That being said, epithelioid hemangioendothelioma[1495,1496] and epithelioid angiosarcoma[1497] can occur in the skin, whereas tumors with the appearance of epithelioid hemangioma can be seen in deep sites, such as bone.[1498]

Kaposi Sarcoma

In its classic form, Kaposi sarcoma is infrequent in the United States but relatively common in some regions of the Mediterranean basin and even more so in equatorial Africa, where it comprises 10% of all malignant tumors.[1499–1501] The incidence of Kaposi sarcoma in the United States increased several hundred-fold during the 1980s through

Figure 3.126 Clinical Appearance of Kaposi Sarcoma. A, Diffuse violaceous lesions in skin of foot and ankle. This is the most common location of the classic form. **B,** Early lesion of Kaposi sarcoma in an HIV-infected patient.

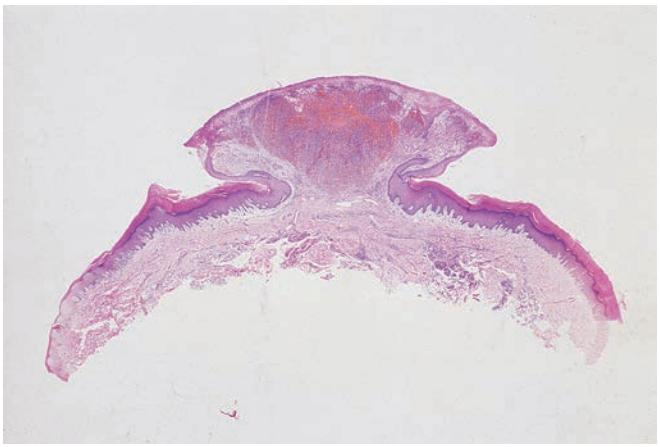

Figure 3.127 Low-power view of a lesion of Kaposi sarcoma having a prominent polypoid shape that simulates pyogenic granuloma.

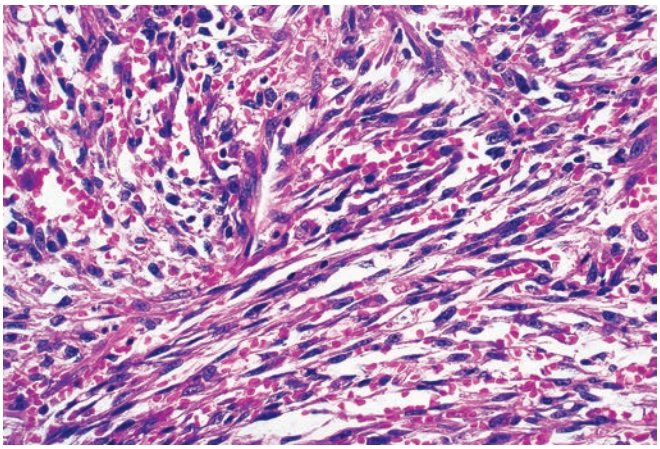

Figure 3.128 Microscopic Appearance of Kaposi Sarcoma. Elongated spindle cells showing minimal atypia are separated by slits containing red blood cells.

its occurrence in the acquired immunodeficiency syndrome (AIDS) population and, to a lesser degree, in persons with other forms of immunosuppression, such as organ transplant recipients.[1500–1504] An association with the systemic form of Castleman disease and with angioimmunoblastic lymphadenopathy (two disorders of the immune system) has also been reported.[1505,1506] In patients with AIDS, Kaposi sarcoma is predominantly a feature of the homosexual population, although it has also been seen in heterosexual drug users.[1507]

In classic Kaposi sarcoma, the disease manifests itself by multiple blue dermal plaques or nodules starting on the feet and legs (Fig. 3.126).[1500,1501] These nodules progress up the extremity and occasionally assume a pedunculated appearance reminiscent of pyogenic granuloma (Fig. 3.127). By angiographic techniques, clinically inapparent subcutaneous nodules can be identified. Temporary control is effected by irradiation, chemotherapy, or, if the lesion is sharply delimited, excision. The course of Kaposi sarcoma is variable although usually prolonged. Some elderly persons die of intercurrent disease. An increased incidence of malignant tumors, particularly of lymphoid type, has been documented.[1508] In patients in whom the disease runs its full course, widespread visceral involvement may be found.[1509] Lymph nodes and the gastrointestinal tract are the organs most commonly involved.[1510] Visceral involvement can precede the development of skin lesions or occur in their absence.[1511] Indicators of poor outcome in classic Kaposi sarcoma are immunosuppression and age greater than 50 years.[1512,1513]

Other clinical forms of Kaposi sarcoma have been described in African cases.[1514] In the AIDS population, the lesions of Kaposi sarcoma have a more erratic distribution, a wider variety of clinical appearance, and a more rapidly aggressive clinical course,[1515,1516] with frequent involvement of the lymph nodes, lung, and/or gastrointestinal tract.[1517]

Microscopically, the most typical feature of Kaposi sarcoma is the presence of spindle cells forming slits containing red blood cells (Fig. 3.128). Mitotic activity is only moderate, and pleomorphism is usually absent. Admixed in this lesion are lymphocytes, hemosiderin-laden macrophages, and other inflammatory cells. Variously sized hyaline bodies, which are periodic acid–Schiff (PAS) positive, are often seen in the cytoplasm of the proliferating cells and sometimes extracellularly. These probably represent the result of ingestion and degradation of erythrocytes and—although diagnostically useful—are not specific for Kaposi sarcoma.[1518,1519]

In early lesions, the spindle proliferation may be limited to the papillary dermis and to the vascular plexus with the neoplastic vessels

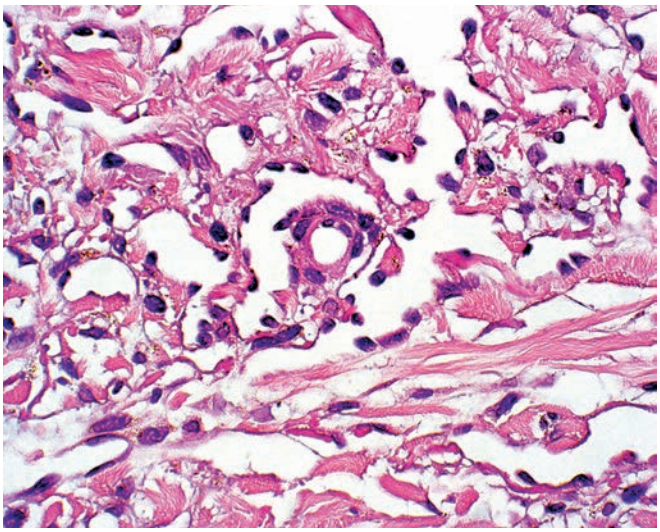

Figure 3.129 Early changes of Kaposi sarcoma, manifested by vascular proliferation in the dermis. These changes often center around skin adnexae.

dissecting around dermal structures, such as the secretory coil of sweat glands or blood vessels (Fig. 3.129).[1520] This has been termed the promontory sign. The changes can be very subtle and limited to a few irregularly dilated vascular spaces and aggregates of plumper (epithelioid) cells[1521]; at this stage, the microscopic appearance may be nondiagnostic in the absence of doing immunostains for human herpesvirus 8 (HHV8) (see later).

Histochemical, immunohistochemical, and ultrastructural studies have shown that Kaposi sarcoma is derived from endothelial cells,[1522] probably of lymphatic origin.[1523,1524] Indeed, FVIII-related antigen, CD31, CD34, angiotensin-converting enzyme, thrombomodulin, leukocyte adhesion molecule-1, and other endothelial markers have been detected in at least some of the cases,[1525–1528] The consistent immunoreactivity for podoplanin (D2-40), a lymphatic endothelial marker, provides additional support for the lymphatic nature of the lesion.[1524,1529]

The most important recent development in this field has been the discovery that HHV8 is present in almost 100% of Kaposi sarcoma lesions, whether HIV-related, classic, endemic, or iatrogenic.[1530] HHV8, also known as Kaposi sarcoma–associated herpesvirus (KSHV), is a gamma-herpesvirus closely related to EBV.[1531] It is believed to be necessary but not sufficient to cause the disease, with immunosuppression playing a major contributory role. Parenthetically, HHV8 is also involved in the pathogenesis of multicentric Castleman disease and primary effusion lymphoma.[1532–1534] Immunostains for HHV8 latent nuclear antigen are consistently positive in Kaposi sarcoma and are a valuable tool in confirming the diagnosis (Fig. 3.130).[1535–1537]

There is controversy concerning the pathogenesis of Kaposi sarcoma, particularly whether it should be regarded as a multicentric hyperplastic or as a neoplastic process.[1538] The fact that nearly all these lesions have been found to be diploid on flow cytometric studies[1539] would seem to favor the former mechanism, which could be mediated by the action of oncogenes and growth factors that stimulate local angiogenesis.[1540–1542] The clonal nature of the lesions and their sometimes markedly aggressive behavior favor instead a neoplastic nature.[1543,1544] Remarkably, it has been shown that post-transplant Kaposi sarcoma originates from the seeding of donor-derived progenitors.[1545] More recently, it has been shown that Kaposi sarcoma in individual patients is actually a multiclonal process, arguing again in favor of a reactive/infectious rather than neoplastic process.[1546]

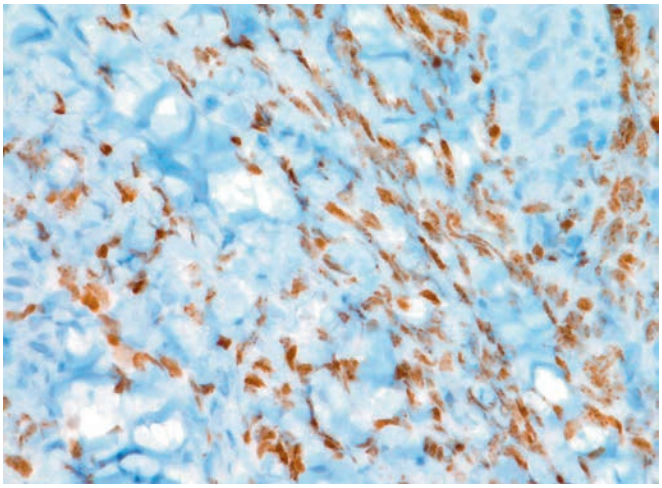

Figure 3.130 Immunoreactivity for HHV8 latent nuclear antigen.

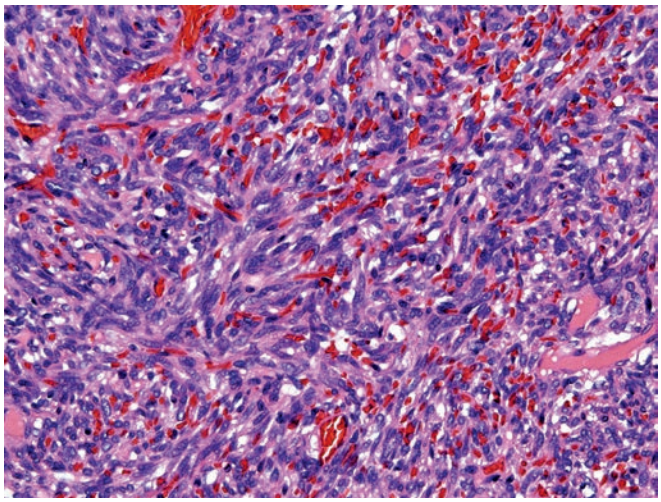

Figure 3.131 Kaposiform Hemangioendothelioma in an Infant. The lesion is composed of uniform spindled cells arranged in fascicles. There are no hyaline bodies and the tumor cells are negative for HHV8. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

In terms of differential diagnosis, benign lesions that can be microscopically confused with Kaposi sarcoma include arteriovenous malformations, acroangiodermatitis, pyogenic granuloma and other vascular proliferations exhibiting a lobular pattern of growth (such as tufted angioma), intranodal hemorrhagic spindle cell tumor with amianthoid fibers (nearly always located in inguinal nodes), bacillary angiomatosis, pigmented purpuric dermatosis, kaposiform hemangioendothelioma (Fig. 3.131), and the predominantly vascular or hemorrhagic forms of benign fibrous histiocytoma.[1474,1547–1551]

Bacillary Angiomatosis and Verruga Peruana

Bacillary angiomatosis is due to infection by a rickettsia-like organism of the *Rochalimaea* species now known as *Bartonella henselae*.[1552,1553] The cutaneous lesions, which present clinically as reddish papules and nodules, are characterized microscopically by lobules of capillaries with plump (epithelioid or histiocytoid) endothelial cells (Fig. 3.132A).[1554] Thus, this entity shows some of the architectural features of pyogenic granuloma and some of the cytologic features of epithelioid hemangioma. Clues to the diagnosis are represented by clusters of neutrophils (many of them fragmented) and the presence

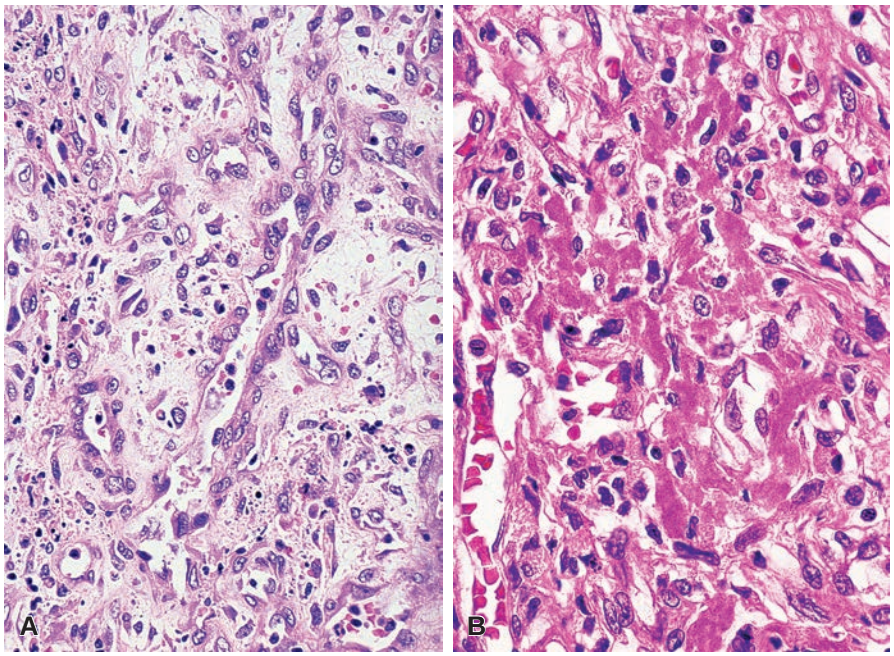

Figure 3.132 Bacillary Angiomatosis. A, Note epithelioid appearance of the endothelial cells in the proliferating vessels and neutrophilic infiltrate with marked karyorrhexis. **B,** An amphophilic granular material is seen in the stroma, due to the accumulation of myriads of microorganisms.

of a granular purplish-staining extracellular material (see Fig. 3.132B). The latter results from the accumulation of a myriad of organisms, as demonstrated with silver stains, immunohistochemistry, or electron microscopy.[1555–1557]

Bacillary angiomatosis can also involve soft tissues (sometimes in the absence of skin disease),[1558] lymph nodes,[1559] and internal organs.[1560,1561] It can also be seen in association with Kaposi sarcoma.[1562]

The differential diagnosis of bacillary angiomatosis includes verruga peruana, another vascular proliferative process induced by an infectious organism, in this instance *B. bacilliformis*.[1563] Identification of Rocha-Lima inclusions is the most important clue for the diagnosis of this disease, which is endemic to Peru.

Angiosarcoma

Angiosarcoma of the skin is largely restricted to sun-damaged skin of the head and neck of elderly persons,[1564–1566] if the varieties associated with longstanding lymphedema or radiation therapy are excluded.[1567–1569] It characteristically presents as a violaceous flat lesion of ill-defined margins, on which elevated nodules may develop.[1570] Occasionally, the tumor acquires a verrucous appearance because of hyperplasia of the overlying epidermis.[1571] Microscopically, three distinct patterns are seen, singly or in combination: undifferentiated foci, which can simulate carcinoma or malignant melanoma; freely anastomosing channels lined by atypical endothelial cells, surrounding skin adnexa, and dissecting dermal collagen fibers; and areas resembling Kaposi sarcoma (Fig. 3.133).[1565,1572] The tumor cells have ultrastructural and immunohistochemical features of endothelial cells, although these can be lost in the poorly differentiated tumors.[1570,1573,1574]

Occasionally, the tumor cells have an epithelioid morphology *(epithelioid angiosarcoma)*.[1497,1575,1576] This tumor should be distinguished from epithelioid hemangioendothelioma and—more importantly—from epithelioid hemangioma.[1494] In contrast to Kaposi sarcoma, flow cytometric studies of angiosarcoma show a nondiploid pattern.[1576] Angiosarcoma is a slow growing but highly aggressive neoplasm that stubbornly recurs following surgery or radiation therapy to involve extensive areas of the scalp and face and eventually metastasizes to the regional lymph nodes, the lung, and other organs.[1555,1571] Older patient age, anatomic site, necrosis, and epithelioid features correlate with increased mortality.[1577] Any vascular lesion of the skin diagnosed as angiosarcoma in a young patient or not located in the head and neck should be suspected of being something else and, more often than not, a benign process.[1578] Tumors notorious for their ability to simulate angiosarcoma are squamous cell carcinoma,[113] epithelioid sarcoma,[1579] and pseudoangiomatous atypical fibroxanthoma.[1580]

A distinctive and increasingly common type of angiosarcoma is that developing following irradiation to the area, usually as part of the therapy for breast carcinoma.[1581,1582] It can be viewed as analogous to post-mastectomy angiosarcoma (Stewart–Treves syndrome, see Chapter 36), from which it differs because of its shorter latency period and lack of association with lymphedema. Its morphologic appearance is similar to that of de novo angiosarcoma, its main differential diagnosis being with the *atypical vascular lesion*, a lesion that often accompanies it and precedes it, and which may on occasion therefore be seen as its precursor.[1583] The distinction, which can be very difficult because of the considerable overlap, is mainly based on the greater degree of atypia seen in the full-blown angiosarcoma.[1584] A particularly treacherous feature in this situation is the capillary (vascular) lobule pattern of postradiation angiosarcoma.[1585] Whereas in all other situations we are aware of this as a sign of benignancy, when seen in the context of a postradiation atypical vascular lesion it is an indicator of the high probability of an angiosarcoma developing (if it has not already).[1586] Recently, it has been shown that amplification of *MYC* and expression of MYC is a consistent feature of postradiation angiosarcoma that is not seen in atypical vascular lesion.[1587] It should be stressed that this same feature is not typically seen in conventional angiosarcomas.

Retiform hemangioendothelioma is a distinctive vascular tumor of intermediate malignancy that resembles well-differentiated

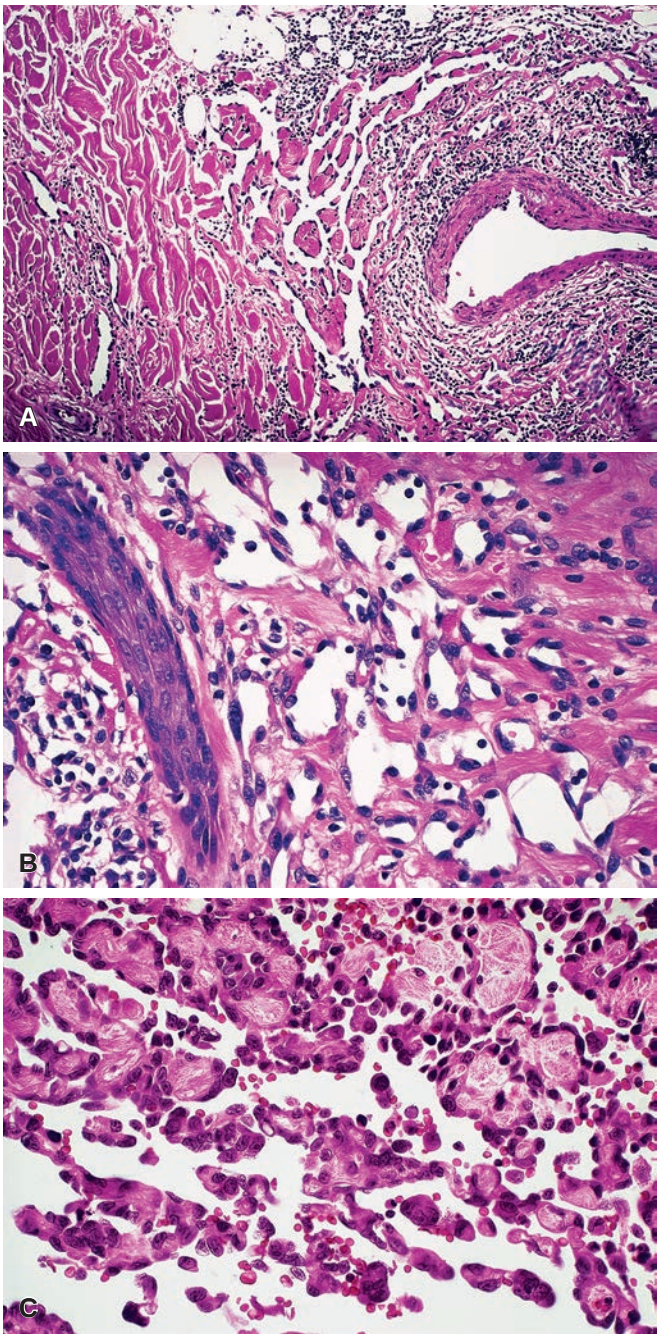

Figure 3.133 Angiosarcoma of Skin. A, Dissection of dermal collagen fibers by neoplastic vessels. **B,** Freely anastomosing vessels lined by atypical cells. **C,** Papillary projections.

angiosarcoma. It usually occurs in the distal extremities of young individuals, sometimes associated with hyperkeratotic changes in the overlying epidermis.[1588] Microscopically, there is a complex ("retiform") network of vessels in the dermis and subcutaneous tissue, lined by endothelial cells having round (lymphocyte-like) nuclei and scanty cytoplasm. These cells protrude into the lumen of the neoplastic vessels in a hobnail fashion. Similar areas are sometimes seen in angiosarcomas, but here they are accompanied by a greater degree of atypia and pleomorphism. Immunohistochemically, retiform hemangioendotheliomas are positive for CD31, CD34, and FVIII-related antigen but usually not for the lymph vessel markers D2-40 and vascular endothelial growth factor receptor-3 (VEGFR-3).[1589]

Lymphoid Tumors and Tumorlike Conditions

Cutaneous Lymphoid Hyperplasia

Cutaneous lymphoid hyperplasia (also known as lymphoplasia, lymphadenoma, lymphocytoma benigna cutis, lymphadenosis benigna cutis, and Spiegler–Fendt sarcoid) was briefly discussed in the section on inflammatory diseases of the skin. It will also be discussed here as it figures prominently in the differential diagnoses of cutaneous lymphomas. It occurs predominantly on the face as solitary violaceous nodules or plaques, most commonly in women.[1590] It probably represents a response to trauma, insect bites, and other undetermined stimuli.[1591] Microscopically, the infiltrate is predominantly composed of lymphocytes and histiocytes in the dermis (Fig. 3.134).[1592] Classically, the upper portion of the dermis is more involved than the deep dermis, but this is not a consistent feature. The morphologic and immunoarchitectural features of the lesion are very similar to those of reactive lymph nodes.[1593] Cases in which the lymphoid infiltrates centers around follicles have been designated *pseudolymphomatous folliculitis*.[1594] They can be associated with hyperplasia of hair follicles and other adnexal structures. Although the latter finding favors benignancy, it can also occur in cutaneous lymphoma.[1595]

Microscopically, features are variable. Most cases show a top-heavy, wedge-shaped infiltrate with a distinct grenz zone.[1596,1597] In some cases, there are distinct lymphoid follicles composed of CD20-positive B cells with or without germinal centers typically surrounded by a population of reactive CD3-positive T cells. When present the germinal centers are frequently polarized and contain tingible body macrophages, which can aid in the distinction form cutaneous follicle center cell lymphoma (see later) (Fig. 3.135).[1513,1598]

The primary differential diagnostic considerations include primary cutaneous marginal zone lymphoma and primary cutaneous follicle center lymphoma, discussed in more detail later. Histologic features that have traditionally been used to favor a diagnosis of lymphoid hyperplasia over one of malignant lymphoma are the following: multiplicity of cell types, including plasma cells and eosinophils; formation of lymphoid follicles, with or without germinal centers; polarized germinal centers (when germinal center formation is present); tingible body macrophages; vascular proliferation; predominantly perivascular or periadnexal distribution of the infiltrate; and

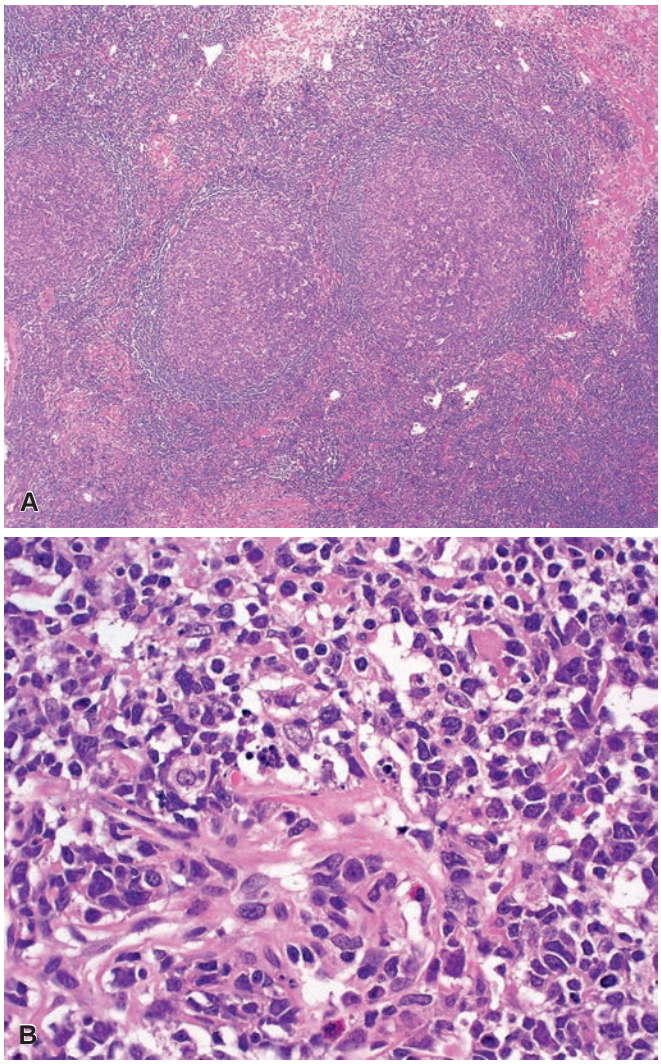

Figure 3.135 **A,** In this case of cutaneous lymphoid hyperplasia, there are distinct reactive germinal centers with a polarized appearance surrounded by a reactive proliferation of T-cells. **B,** The reactive germinal centers contain tingible body macrophages.

prominent epidermal hyperplasia.[1513,1596–1599] Immunohistochemistry is also valuable. By immunohistochemistry, the germinal centers retain immunoreactivity for BCL6 and CD10 but do not show coexpression of BCL2. The CD20-positive B cells do not show aberrant expression of CD43. Immunostains for CD21 can highlight intact dendritic cell networks in the reactive germinal centers.[1513,1598–1600] Plasma cells in the infiltrate lack light chain restriction by immunohistochemistry.[1598] The germinal centers in reactive lymphoid hyperplasia have a high Ki-67 nuclear labeling index. In selected cases clonality studies may be pursued, and cutaneous lymphoid hyperplasia is typically polyclonal. Molecular genetic analysis may be useful for the differential diagnosis with malignant lymphoma.[1598,1601]

Most lesions of cutaneous lymphoid hyperplasia are characterized by a benign clinical course, with resolution following antibiotic, steroid, or x-ray therapy or resolving spontaneously. However, some cases have been documented to progress to malignant lymphoma.[1602,1603]

Other clinically benign lymphocytic infiltrates that can microscopically simulate malignant lymphoma are related to molluscum contagiosum,[1604] syphilis,[1605] nodular scabies,[1606] and actinic reticuloid.[1607] Those that simulate microscopically the appearance of mycosis fungoides have been generically referred to as cutaneous pseudo–T-cell lymphomas.[1608,1609]

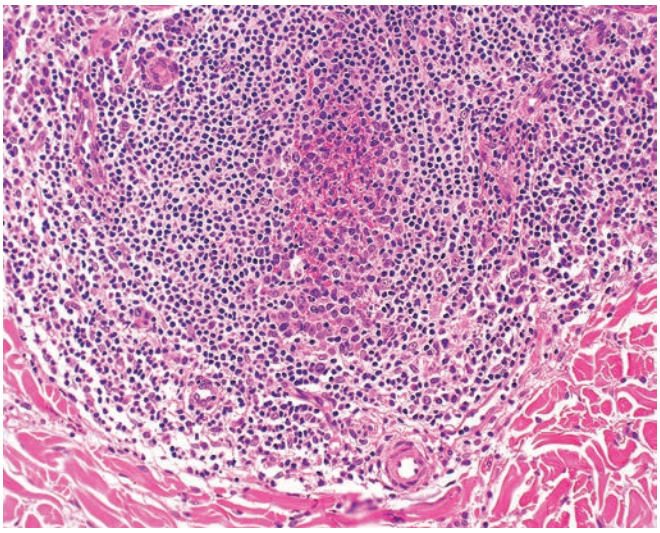

Figure 3.136 **Marginal Zone B-Cell Lymphoma of Skin.** There is a proliferation of neoplastic monocytoid tumor cells colonizing a germinal center.

Primary Cutaneous Marginal Zone Lymphoma

Primary cutaneous marginal zone lymphoma usually arises on the extremities or trunk, with a predominance in young males.[1513] Microscopically, primary cutaneous marginal zone lymphoma has a nodular to diffuse pattern and the epidermis is uninvolved. The infiltrate is predominantly composed of marginal zone cells (centrocyte-like cells), monocytoid B cells and plasma cells. Reactive germinal centers may be present, and they are frequently colonized by the neoplastic monocytoid B cells (Fig. 3.136).[1513,1600] In the lymphoplasmacytic variant, the majority of cells are lymphoplasmacytoid and plasma cells with few monocytoid B cells. The plasmacytic variant is composed predominantly of plasma cells.

The neoplastic cells express CD20 and CD79a, and stains for CD79a often highlight more of the neoplastic cells, including plasma cells.[1513] Stains for BCL6 and CD10 are negative, helping to distinguish it from primary cutaneous follicle center lymphoma. Stains for CD21 can highlight disrupted dendritic cell networks in reactive germinal centers colonized by the neoplastic cells.[1513,1610] The plasma cells are light chain restricted by immunohistochemistry (>3 : 1 kappa:lambda or >1 : 1 lambda:kappa), and the neoplasm demonstrates clonality by molecular testing.[1513,1598,1600,1603]

The primary differential diagnosis includes cutaneous lymphoid hyperplasia and primary cutaneous follicle center lymphoma. Primary cutaneous marginal zone lymphoma has larger, pale-staining cells that colonize germinal centers. Sheets of CD20- and CD79a-postive lymphocytes outside the germinal centers also favor primary cutaneous marginal zone lymphoma, as does light chain restriction of the plasma cell component. Distinguishing primary cutaneous marginal zone lymphoma from primary cutaneous follicle center lymphoma can be challenging. The germinal centers in the latter are neoplastic and typically lack tingible body macrophages. The interfollicular B cells in primary follicle center lymphoma are positive for BCL6. Cutaneous involvement by underlying chronic lymphocytic leukemia/small lymphocytic lymphoma can also be a consideration. The neoplastic B cells of this latter condition coexpress CD5, unlike primary cutaneous marginal zone lymphoma. Secondary involvement

by extranodal marginal zone lymphoma can be histologically indistinguishable. Expression of CD43 on the neoplastic cells favors secondary cutaneous involvement.

Primary cutaneous marginal zone lymphoma has an excellent prognosis with a greater than 90% 5-year survival. Most patients can be treated with localized therapy, either excision or radiation therapy.[1598]

Primary Cutaneous Follicle Center Lymphoma

Most patients present with an erythematous to violaceous nodule on the head and neck (most common site) or trunk (Fig. 3.137). Women are more commonly affected. Microscopically, this lymphoma may be follicular, diffuse, or follicular and diffuse (Fig. 3.138).[1513,1611,1612] In the follicular pattern, the tumor is composed of neoplastic follicles with a combination of centrocytes, centroblasts, and immunoblasts. The neoplastic follicles lack polarization and lack tingible body macrophages. The surrounding mantle zone is reduced to absent. In the diffuse pattern, the neoplastic cells have a sheet-like pattern in the dermis. Some cases have a combination of neoplastic follicles and a sheet-like pattern of neoplastic cells.

By immunohistochemistry, the neoplastic cells are positive for CD20, CD79a, and BCL6. Occasional cases are also positive for BCL2 and CD10. The tumor cells are negative for MUM1. Unlike the nodal counterpart, it is rare to see a *t*(14;18) in primary cutaneous follicle center lymphoma. Molecular studies typically reveal a clonal population of B-cells.[1598,1610–1612]

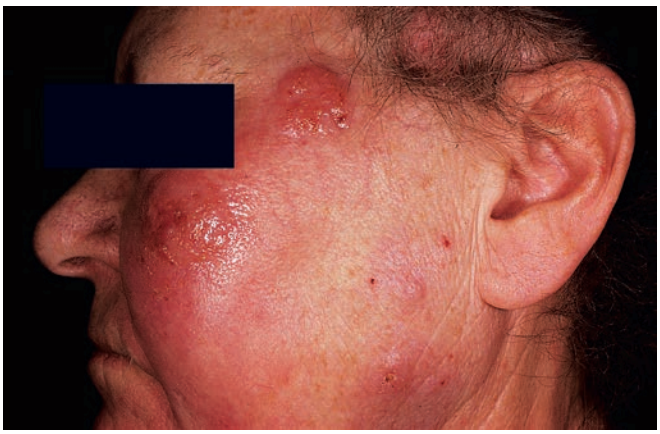

Figure 3.137 Malignant Lymphoma of Skin. The lesion appears in the form of markedly erythematous nodules on the face.

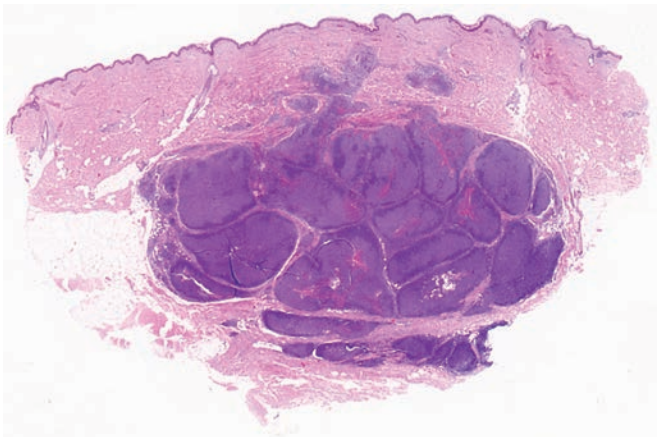

Figure 3.138 Panoramic view of follicular lymphoma of the skin, showing its deep location, nodular architecture, and sparing of papillary dermis and epidermis.

In the follicular and combined and diffuse and follicular patterns, the differential diagnosis includes cutaneous lymphoid hyperplasia and cutaneous marginal zone lymphoma.[1513,1610–1612] Cutaneous lymphoid hyperplasia is more heterogeneous with admixed eosinophils and plasma cells. The germinal centers in cutaneous lymphoid hyperplasia tend to be polarized and have tingible body macrophages. In cutaneous marginal zone lymphoma, the germinal centers are reactive in nature, like in cutaneous lymphoid hyperplasia. The neoplastic cells are negative for BCL6 in cutaneous marginal zone lymphoma. In the diffuse pattern, a rare aggressive form of cutaneous B-cell lymphoma, *diffuse large B-cell lymphoma, leg type* needs to be considered. This lymphoma usually presents on the lower legs of older patients. It consists of a sheet-like proliferation of enlarged centroblasts and immunoblasts. The tumor cells of diffuse large B-cell lymphoma, leg type are positive for MUM1, which is negative or only focally positive in primary follicle center lymphoma. BCL6 and CD10 immunoreactivity favor primary cutaneous follicle center lymphoma. It is also prudent to exclude the possibility of secondary cutaneous involvement by systemic follicular lymphoma, generally accomplished by a clinical examination.[1513,1610–1612]

Like primary cutaneous marginal zone lymphoma, primary follicle center lymphoma has an excellent prognosis with a greater than 90% 5-year survival. Surgical excision or radiotherapy are effective means of treatment.[1513]

Mycosis Fungoides and Related Peripheral T-Cell Lymphomas

Mycosis fungoides is a distinct clinicopathologic type of peripheral T-cell lymphoma and the most common cutaneous lymphoma subtype (Fig. 3.139).[1542,1613–1617] The large majority of cases occur in adult and elderly individuals, but adolescents and young adults can also be affected.[1617,1618] Traditionally, mycosis fungoides is divided into three stages: *premycotic*, *mycotic*, and *tumorous*. In the premycotic stage, the skin is erythematous, scaly, and pruritic. Clinical variations characterized by solitary, follicular, granulomatous, pustular, bullous, hyperkeratotic, verrucous, and hypopigmented forms exist.[1615,1616,1619–1626]

In the premycotic stage, the microscopic appearance may be nondiagnostic and represented by a nonspecific psoriasiform dermatitis.[1627] In the mycotic stage, infiltrative plaques appear, and biopsies show a polymorphous inflammatory infiltrate in the dermis that contains small numbers of frankly atypical lymphoid cells.[1628] These cells may invade the epidermis to form Pautrier microabscesses or, more often, to line up individually along the epidermal basal layer (Figs. 3.140 and 3.141).[1629] The latter finding, if unaccompanied by spongiosis, is strongly suggestive of mycosis fungoides. The lymphoid infiltrate may be predominantly located around hair follicles and can be accompanied by follicular mucinosis.[1630–1633] In rare instances there is infiltration of the eccrine sweat glands.[1634] In the tumorous stage, dense infiltrates of atypical lymphoid cells expand the dermis. The characteristic cell of mycosis fungoides is a small- or medium-sized lymphocyte with a cerebroid nucleus. This term refers to the highly irregular contour of the thick nuclear membrane, which results in an appearance somewhat reminiscent of brain convolutions (Fig. 3.142).[1635] Thin, well-prepared sections are necessary to identify this feature. These cerebroid cells are of T-cell type; their phenotype is usually that of helper T cells (CD4+), but sometimes it is suppressor/cytotoxic (CD8+) or aberrant.[1636,1637] Interestingly, several differences in antigen expression have been found between intraepidermal and intradermal lymphocytes.[1638–1640] In advanced stages of the disease, these cells may express CD15.[1641]

Figure 3.139 Clinical appearance of mycosis fungoides showing infiltrative plaques over virtually entire body.

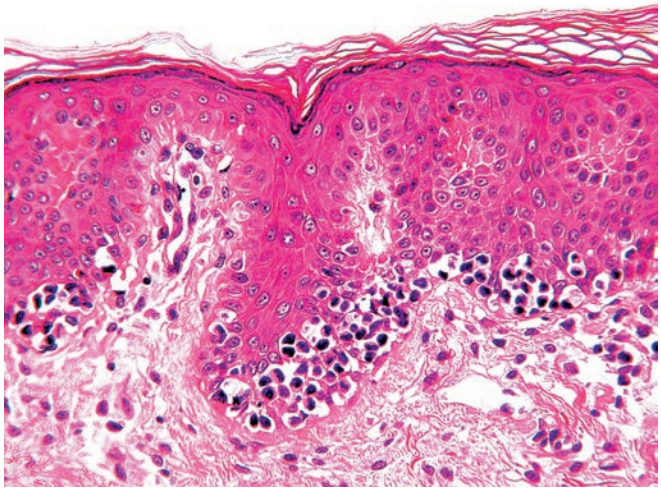

Figure 3.140 Epidermotropism of neoplastic lymphoid cells in mycosis fungoides.

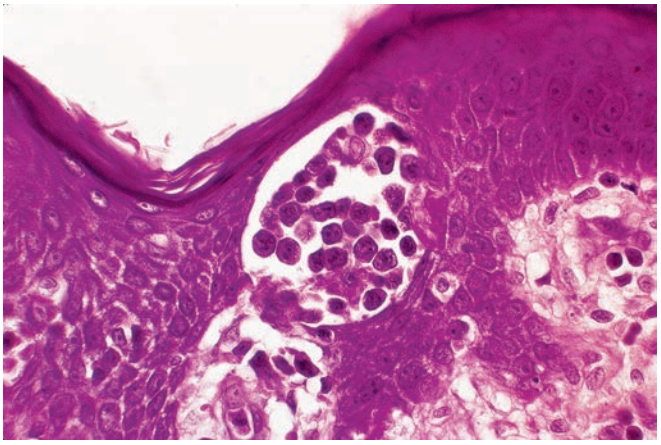

Figure 3.141 So-called Pautrier microabscess in mycosis fungoides.

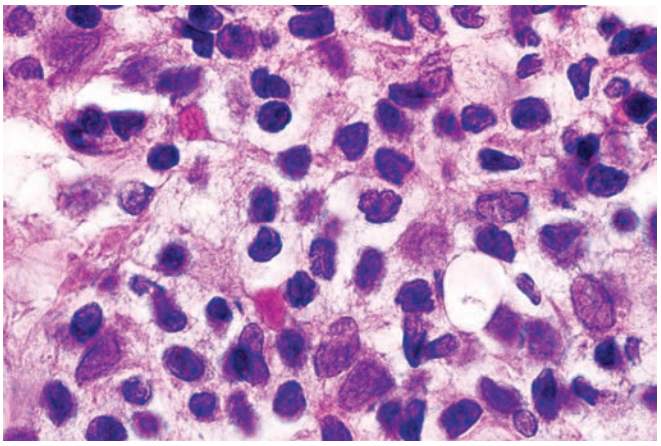

Figure 3.142 High-power view of mycosis fungoides cell, showing marked nuclear irregularities.

Although the presence of cerebroid cells is necessary to make a diagnosis of mycosis fungoides, they are not pathognomonic of the disease. Scattered cells with these nuclear features can be seen in other lymphomas and in some types of spongiotic acute and chronic dermatitis.[1642–1645] Conversely, it should be noted that a reactive B-cell component (with plasma cells and follicle formation) can accompany the T-cell neoplastic infiltrate of mycosis fungoides.[1639]

On the basis of immunocytochemical studies of the T-cell population performed, it has been suggested that loss of the T-lineage antigens CD2, CD3, CD5, and CD7 occurs in neoplastic T lymphocytes but not in reactive conditions.[1646–1648] Greater diagnostic assistance is provided by molecular studies (such as the analysis of T-cell receptor genes) for the identification of T-cell clones in skin biopsy specimens from patients with early disease.[1649–1651] It should be pointed out that other processes such as pityriasis lichenoides can have an abnormal clone of T-cells.[1652,1653] Therefore clonality by itself is not diagnostic. The histologic features must be analyzed in the appropriate clinical context, and significant weight is given to the clinical information in order to arrive at a diagnosis of mycosis fungoides, especially in early lesions.[1654]

The course of mycosis fungoides is usually protracted over a period of years. Clinical signs associated with poor prognosis are the presence of generalized plaques or tumors, diffuse erythema, and lymphadenopathy.[1655,1656] A correlation exists between the histologic findings and the clinical course,[1657] which applies primarily to the number and cytologic features of the neoplastic T cells, but the prognostic significance of the microscopic features as seen in a single biopsy is negligible.[1658] Parenthetically, Langerhans cells have been implicated in the pathogenesis of the disease, together with dermal dendrocytes.[1638,1659]

In approximately one-half to two-thirds of patients with mycosis fungoides of the skin, involvement of lymph nodes and internal viscera occurs. In most instances, the internal disease is microscopically still recognizable as mycosis fungoides by the polymorphism of the infiltrate and, most important, the cerebroid quality of the

nuclei of the tumor cells.[1660,1661] The internal infiltrates of mycosis fungoides can be found in the lymph nodes, lung, spleen, liver, kidney, bone marrow, central nervous system, and practically every other organ.[1661–1663]

Sepsis is a frequent terminal complication. The forms of therapy for disease limited to the skin include total skin electron beam irradiation, topical chemotherapy, and PUVA.[1664] More recently, targeted therapies are also being incorporated into the management of mycosis fungoides.[1665]

Sézary syndrome is a variant of mycosis fungoides characterized clinically by infiltrative erythroderma with pruritus, lymphadenopathy, and the presence of large or small cerebroid cells (Sézary and Lutzner cells, respectively) in the peripheral blood.[1666–1668] PAS-positive cytoplasmic granules are present in their cytoplasm. The distinction between mycosis fungoides and Sézary syndrome is to some extent artificial because circulating cerebroid cells of the same phenotype are found in approximately 20% of patients with mycosis fungoides. However, minor morphologic differences exist, such as a smaller number of cerebroid cells in the epidermis and fewer lymphocytes aligned within the basal layer, which may render the diagnosis more difficult.[1669]

Woringer–Kolopp disease (pagetoid reticulosis) is another T-cell cutaneous proliferative disorder which is characterized morphologically by a monomorphic intraepidermal infiltrate of cells with cerebroid nuclei, indistinguishable from those of the usual mycosis fungoides and Sézary syndrome.[1670,1671] The lesion presents clinically as a solitary erythematosquamous patch, typically on the extremities. The evolution is extremely slow.

Lymph Nodes in Mycosis Fungoides

Lymphadenopathy is common in patients with mycosis fungoides. The pathologic changes may be those of dermatopathic lymphadenitis, involvement by mycosis fungoides, or both.[1672,1673] The distinction between these processes can be extremely difficult to make. Preservation or distortion of the nodal architecture and the number of atypical lymphoid cells in T cell–dependent paracortical areas are the two most important diagnostic features.[1674,1675] Immunophenotyping and determination of clonal rearrangement of T-cell receptor genes offer a more sensitive and reliable means to make the distinction. (see Chapter 37).[1676,1677]

Lymphomatoid Papulosis and Anaplastic Large Cell Lymphoma

Lymphomatoid papulosis (LYP) is the original term given to a self-healing, recurrent papular eruption with a generally indolent clinical course and characterized microscopically by a polymorphic dermal infiltrate usually located superficially (Figs. 3.143 and 3.144). There are multiple different histologic types, ranging from type A to E.[1678–1682] Types A, B, and C are the classic forms. Type A can show considerable histologic overlap with pityriasis lichenoides et varioliformis acuta (PLEVA), discussed previously in the section on inflammatory dermatoses. It is composed of a superficial and deep perivascular mixed infiltrate with numerous large, atypical CD30+ lymphocytes admixed with avariable numbers of lymphocytes, eosinophils, and/or neutrophils (Fig. 3.145). Type B LYP resembles mycosis fungoides microscopically. Type C histologically resembles cutaneous anaplastic large cell lymphoma, with sheets of large atypical, CD30+ lymphocytes. More recently, types D and E have been described. Type D LYP has the typical clinical presentation of LYP but histologically and immunophenotypically resembles cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma.[1683] Knowledge of the clinical presentation is the only way to reliably distinguish these

Figure 3.143 Clinical Appearance of Lymphomatoid Papulosis. Multiple lesions are present, the larger ones showing ulceration.

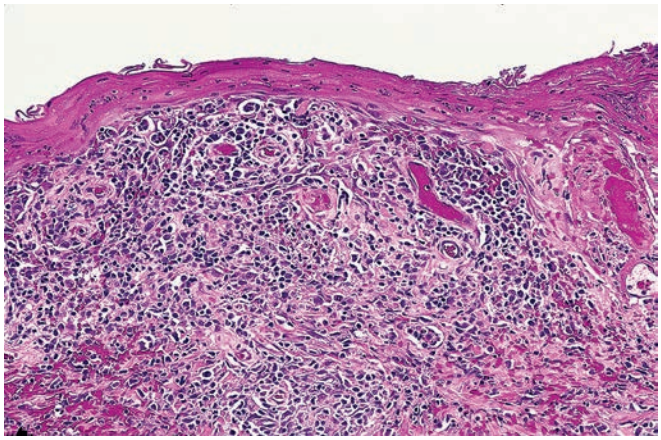

Figure 3.144 Low-power view of lymphomatoid papulosis showing heavy dermal infiltrate with epidermal thinning.

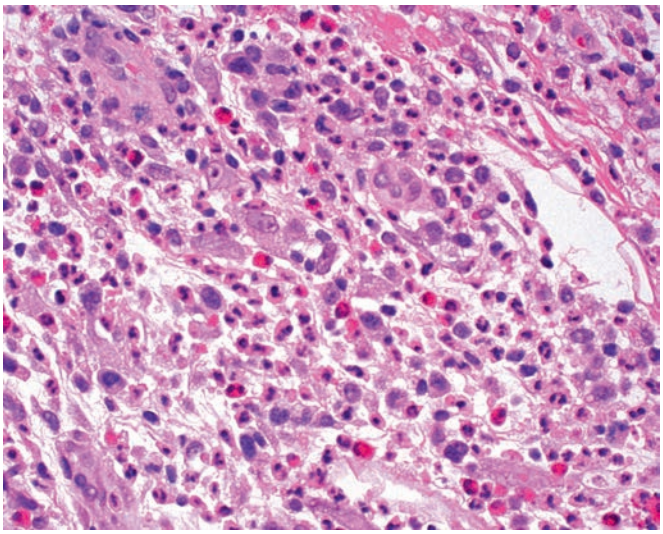

Figure 3.145 Lymphomatoid Papulosis Type A. High-power view, showing large atypical lymphoid cells admixed with eosinophils.

entities. Type E LYP is associated with a perivascular infiltrate of atypical CD30-positive and often CD8-positive lymphocytes with destruction of the vessel wall. Clinically, patients develop ulcers and large eschar-like lesions that eventually resolve spontaneously in this rare form of LYP.[1681]

The nature of LYP has been controversial. It was originally regarded either as a specific dermatosis or as a variant of PLEVA (Mucha–Habermann disease). The fact that there is a clonal population of T cells,[1684,1685] and that in 10%–20% of cases there is an association with, or evolution into, an obvious malignant lymphoma[1686] supports the current classification of LYP as a CD30-positive lymphoproliferative disorder closely related to anaplastic large cell lymphoma.[1687,1688]

The histologic differential diagnosis of LYP is variable. As previously mentioned, type A LYP can be confused with PLEVA or an arthropod bite reaction, although these conditions do not typically have significant numbers of CD30-positive atypical lymphocytes.[1689] Type B LYP histologically resembles mycosis fungoides. Type C LYP is indistinguishable from anaplastic large cell lymphoma (see later). Type D LYP is indistinguishable from cutaneous aggressive epidermotropic CD8+ cytotoxic T-cell lymphoma. In type E LYP, other forms of angioinvasive T-cell lymphoma need to be considered. This highlights the critical importance of correlation of the histologic findings with clinical presentation to arrive at an accurate diagnosis in LYP.[1690]

Anaplastic large cell lymphoma of skin presents clinically as solitary or multiple, often ulcerated skin lesions, and it affects predominantly elderly males.[1679,1688] Some cases have occurred in a post-transplant setting.[1691] Microscopically, there is a diffuse dermal and subcutaneous infiltration by a polymorphic infiltrate containing large anaplastic tumor cells with an appearance similar to those described in LYP.[1679,1688,1692] Pseudoepitheliomatous hyperplasia is a common accompanying feature.[1693] Morphologic variants include myxoid, sarcomatoid, and neutrophil-rich.[1694–1696]

The large lymphoid cells show strong positivity for CD30 in the form of diffuse membrane staining, as well as a paranuclear dot-like reaction in the Golgi area. Lineage markers are usually of T-cell type, but they can also be null.[1695,1697] They are by definition not of B-cell type, but it should be noted that some cutaneous large B-cell lymphomas are CD30 positive.[1698]

Three clinicopathologic forms of anaplastic large cell lymphoma are recognized: *primary cutaneous*, *primary systemic ALK+*, and *primary systemic ALK–*.[1688,1695,1699] The primary cutaneous form is associated with a good prognosis, as secondary systemic dissemination is only rarely observed. In contrast to systemic ALK+ anaplastic large cell lymphoma, the chromosomal translocation t(2;5), which generates the chimeric NPM–ALK transcript, is not found in primary cutaneous anaplastic large cell lymphoma.[1688,1700–1702] Instead, 20%–57% of cases show DUSP22-IRF4 translocation.[1703–1707] Rarely this translocation is seen in LYP.[1706,1707]

It needs to be pointed out that the presence of CD30-positive atypical lymphoid cells in a skin lesion is not diagnostic of LYP/anaplastic large cell lymphoma, inasmuch as they can also be seen in a variety of non-neoplastic cutaneous infiltrates.[1708]

Other Malignant Lymphomas

Other forms and subtypes of T-cell lymphoma that involve the skin are adult T-cell leukemia–lymphoma, subcutaneous panniculitis-like T-cell lymphoma, extranodal natural killer (NK)/T-cell lymphoma, nasal type; cutaneous γ/δ+ T-cell lymphoma, primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoma, primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma and primary cutaneous peripheral T-cell lymphoma, unspecified.[1688]

Subcutaneous panniculitis-like T-cell lymphoma is characterized by a primary involvement of the subcutaneous tissue (Fig. 3.146).[1688,1709]

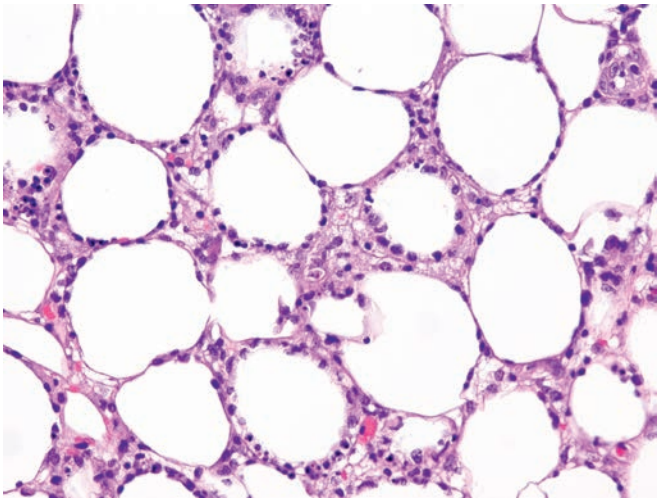

Figure 3.146 Panniculitis-Like T-Cell Lymphoma. Note the rimming of individual melanocytes by atypical lymphoid cells. (Courtesy Dr Fabio Facchetti, Brescia, Italy.)

The predominant phenotype is CD3+/CD4–/CD8+/β-F1+ (TCR α/β subtype)/CD56–.[1688,1710–1712] Rimming of adipocytes by the neoplastic lymphocytes is an important morphologic, albeit not totally specific, clue.[1713] There is significant histologic overlap with cutaneous γ/δ+ T-cell lymphoma, but this subcutaneous lymphoma has a γ/δ TCR and is CD3+/CD4–/CD8–/CD56+.[1688] The distinction is not trivial as subcutaneous panniculitis-like T-cell lymphoma is indolent with an excellent 5-year survival and cutaneous γ/δ+ T-cell lymphoma is a very aggressive lymphoma.

Primary cutaneous CD4+ small/medium-sized pleomorphic T-cell lymphoproliferative disorder usually presents as a solitary nodule with a dermal infiltrate of small- to medium-sized atypical lymphocytes that represent a proliferation of neoplastic follicular T-helper cells. In addition to being positive for CD4, they express CXCL-13 and PD-1.[1688] This is an indolent tumor, and some have questioned its inclusion as a true cutaneous lymphoma.[1714] Due to its indolent behavior, it has been reclassified as a lymphoproliferative disorder rather than a true lymphoma.[1715]

Lymphoblastic lymphoma is very uncommon, but it represents the predominant type of cutaneous lymphoma in children.[1716–1718]

Blastic plasmacytoid dendritic cell neoplasm (also known as blastic NK cell lymphoma) is a CD4+/CD56+/CD123+ systemic malignancy with frequent cutaneous involvement and a highly aggressive clinical course.[1719–1723]

Hodgkin lymphoma of the skin is exceptionally rare and presents in most instances as papules and nodules forming distally to involved lymph nodes; they are an indication of stage IV disease and probably result from retrograde lymphatic spread.[1724] A few well-documented cases of primary Hodgkin lymphoma of the skin have been reported,[1725,1726] some of them in HIV-infected patients,[1726] but many of the cases published in the past under this rubric were examples of LYP or cutaneous anaplastic large cell lymphoma.

True histiocytic and *Langerhans cells sarcomas* of the skin exists,[1727–1729] but most cases previously reported as malignant histiocytosis would probably be reclassified as anaplastic large cell lymphoma at present.

Intravascular (angiotropic) lymphoma is the currently preferred term for the disease originally described as malignant (systemic, proliferating, neoplastic) angioendotheliomatosis and characterized by accumulations of large, round, malignant cells in the lumen (and sometimes wall) of vessels (Fig. 3.147).[1730] The cutaneous and neurologic manifestations dominate the clinical presentation, but the disease may present initially in the uterine cervix, prostate, nasal cavity, bone, skeletal muscle, or other sites.[1731,1732] It was originally

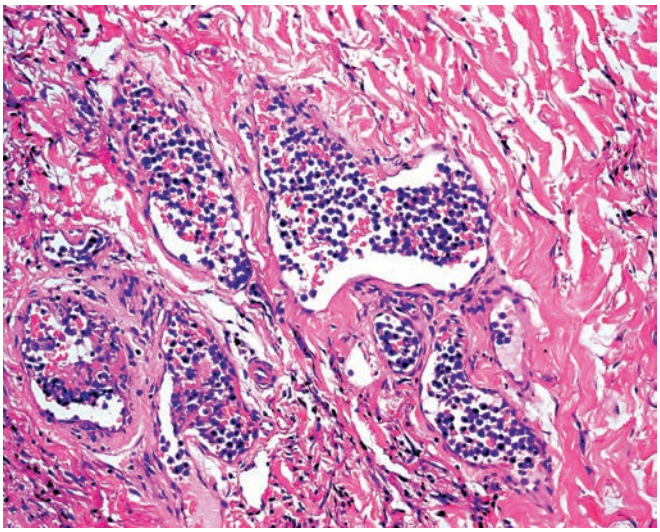

Figure 3.147 Angiotropic Malignant Lymphoma. The dermal vessels are packed with malignant lymphoid cells.

regarded as a systemic malignancy of vascular endothelium, but immunocytochemical studies have shown that it represents an angiotropic form of malignant lymphoma, usually of B-cell but sometimes of T- or NK-cell type, the latter being usually associated with EBV infection.[1733–1736] The term "angiotropic lymphoma" should not be equated with that of "angiocentric lymphoma," a T- or NK-cell malignancy with a different organ distribution and microscopic appearance (see Chapter 7).

Leukemia

Involvement of the skin in the form of multiple papules or nodules ("leukemia cutis") occurs in approximately 10% of patients with monocytic leukemia, 8% with chronic lymphocytic leukemia, and 5% with chronic granulocytic leukemia.[1737–1739] Most patients have an abnormal blood count at the time of diagnosis, but in some instances the skin lesions represent the first clinical manifestation of the disease and are accompanied by a normal peripheral blood ("aleukemic" forms).[1738,1739] Granulocytic leukemia of skin is usually a manifestation of recurrence in treated patients or a late development in association with widespread dissemination.[1740] Rarely, the disease manifests initially as multiple tumors in the skin: these cases tend to be misdiagnosed as large cell lymphoma.[1741] In chronic lymphocytic leukemia, the dermal infiltrate can be perivascular and periadnexal, nodular/diffuse, or bandlike.[1742] Immunohistochemical evaluation plays an important role in the identification of this process.[1743,1744] This includes the use of TdT and lymphocyte lineage markers for acute lymphoblastic leukemia, myeloperoxidase for acute myelogenous leukemia, and lysozyme (muramidase), the latter seemingly the most sensitive for acute myelogenous leukemias.[1743,1744]

It is well to remember that a large proportion of the skin lesions occurring in leukemic patients are histologically nonspecific inflammatory reactions and are not caused by infiltration by neoplastic cells.[1745] This includes leukemic vasculitis, although in this condition it is not clear whether the cells infiltrating the vessel walls are reactive or neoplastic.[1746]

Other Primary Tumors and Tumorlike Conditions

Endometriosis can present in women of reproductive age in the skin of the umbilicus or groin without antecedent surgery. When present in other cutaneous sites, there is nearly always an associated surgical scar.[1747] Microscopically, the combination of endometrial glands and stroma is characteristic; the lesion should not be confused with a sweat gland tumor or, worse, with a metastatic adenocarcinoma. Marked hemorrhage or myxoid decidual changes in the stroma may render the recognition difficult and lead to an overdiagnosis of malignancy.[1748,1749]

Meningioma can occur as a skin nodule, either in the scalp or along the vertebral axis, with or without an associated skin defect (see Chapter 46). *Hamartoma of the scalp with ectopic meningothelial elements* (rudimentary meningocele) is pathogenetically related to meningioma of the skin; it appears as a scalp nodule, usually during infancy, and is characterized by a dermal and subcutaneous proliferation of polygonal to spindle meningothelial cells, sometimes arranged in whorls and sometimes dissecting collagen fibers in a fashion reminiscent of angiosarcoma (Fig. 3.148). Psammoma bodies and islands of cartilage may be present. A long cleft is sometimes seen in the center of the lesion, in keeping with its presumed malformative pathogenesis. The ectopic meningothelial cells are immunoreactive for vimentin, EMA, and p63 and negative for CD31 and FVIII-related antigen.[1750–1752]

Nasal glioma is a form of glial heterotopia that is seen in neonates at the root of the nose, sometimes immediately beneath the skin (see Chapter 4).[1753]

Ganglioneuroma can exceptionally present as a primary cutaneous neoplasm.[1754]

Osteoma cutis of skin is not a neoplasm but rather a reactive process. It can be seen as metaplastic ossification of other lesions, such as pilomatrixomas or melanocytic nevi, or the result of inflammatory processes, often linked to prior acne.[1755,1756]

Metaplastic synovial cyst (synovial metaplasia of the skin) is a peculiar postsurgical intradermal cystic formation associated with transepidermal fistulas and lined microscopically by tissue resembling hyperplastic synovium.[1756–1759] The rare *cutaneous ganglion cyst* probably has a similar pathogenesis.[1760]

Inflammatory pseudotumor presents as a small, deeply seated dermal nodule; microscopically, it has a fibrosed (sometimes hyalinized) and vascularized center containing a polymorphic infiltrate rich in plasma cells surrounded by a rim of lymphoid follicles, the overall appearance resembling a lymph node on low-power examination.[1761] The process is probably truly inflammatory and not related to so-called inflammatory myofibroblastic tumor.

PEComa, an unusual tumor of melanocytic and smooth muscle differentiation related to angiomyolipoma, can rarely present in a superficial (cutaneous or subcutaneous) location.[1762–1764] As in other sites, they may be predominantly composed of clear cells. They should be distinguished from metastatic renal cell carcinoma, true melanocytic lesions, and other clear cell mesenchymal neoplasms.[1293]

Soft tissue-type tumors of various types can sometimes present as cutaneous (dermal) neoplasms. In addition to those that have already been mentioned, the list includes spindle cell lipoma,[1765] pleomorphic liposarcoma,[1766] giant cell tumor,[1767] Ewing sarcoma/primitive neuroectodermal tumor (PNET),[1768] synovial sarcoma,[1769] and clear cell sarcoma[915] to highlight a few.

Metastatic Tumors

In men, the most common sources of metastatic tumor to the skin are lung (25%), large bowel, skin (melanoma), kidney, and upper aerodigestive tract. In females, the breast is the most common source (69%), followed by the lung, skin (melanoma), kidney, and ovary.[1770–1772] Unusual sites include adrenal gland, liver, pancreas, uterus, and thyroid.[1773–1776] Most cases are multiple and appear as firm, nonulcerated nodules.[1776] When solitary, they may be misdiagnosed

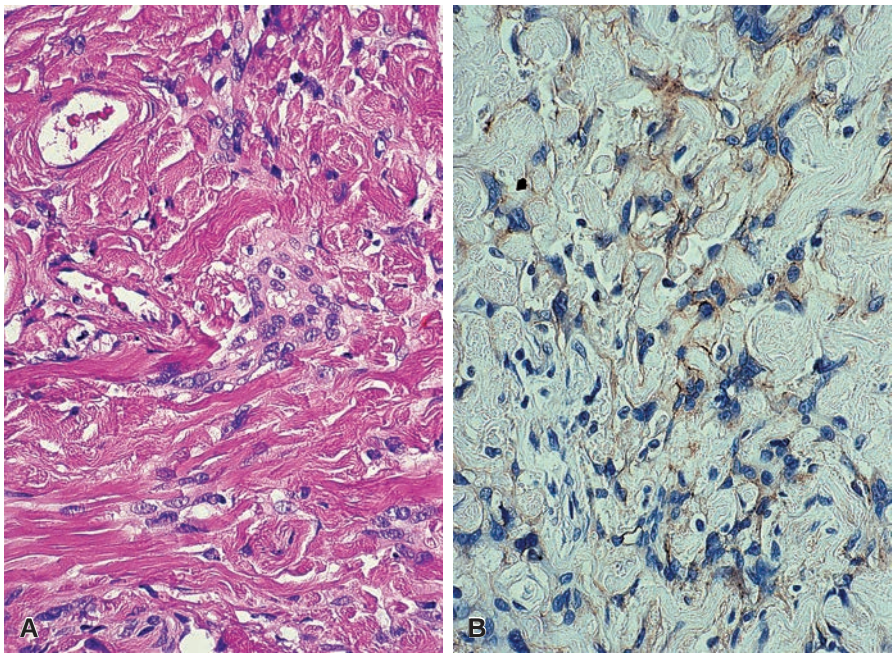

Figure 3.148 Hamartoma of the Scalp With Ectopic Meningothelial Elements. A, Meningothelial cells are present in the deep dermis, some of them arranged in clusters and others individually among collagen fibers. **B,** Positive immunostain for epithelial membrane antigen (EMA).

as primary skin tumors (Fig. 3.149). This is particularly true for renal cell carcinoma, which is often misinterpreted as a sweat gland tumor; the presence of dilated sinusoidal vessels, extravasated red blood cells in the glandular lumina, and nuclear atypia should suggest the correct diagnosis.[1777,1778] Immunostains for markers such as PAX8 can aid in recognition of metastatic renal cell carcinoma.[1779,1780] Occasionally, metastatic signet ring carcinomas from the stomach or other sites elicit a brisk fibroblastic reaction with storiform features, thus closely resembling the appearance of a DFSP. Staining with antibody HIK1083 (which detects gastric O-glycan) is useful in the distinction between cutaneous metastases of gastric carcinoma (positive) and primary sweat gland carcinoma (negative),[1781] whereas podoplanin (D2-40), p63, and p40 have been proposed as a means to distinguishing sweat gland carcinoma (positive) from metastatic carcinoma from various sites (negative).[1782–1784]

The metastatic tumor may be predominantly confined to lymphatic vessels. This is especially true in metastatic carcinomas of the breast, which can impart a diffuse erythematous appearance to the affected skin (so-called inflammatory carcinoma) (Fig. 3.150). Occasionally, the metastatic dermal nodules invade the overlying epidermis, simulating the appearance of a primary tumor ("epidermotropic carcinomas").[1785,1786] Another source of error is the solitary cutaneous metastasis from a small cell carcinoma of the lung, endocrine tumor of the pancreas, or carcinoid tumor of the small bowel that is misdiagnosed as Merkel cell carcinoma or some other primary neuroendocrine carcinoma of skin, but Merkel cell carcinoma is positive for cytokeratin 20.[1787]

The most common sites for skin metastases are the chest and abdomen, followed by the head and neck; location in the extremities is rare. Those metastases situated in the scalp can be associated with alopecia ("alopecia neoplastica"). The interesting observation has been made that the skin metastases tend to be close to the site of the primary tumor: chest in lung carcinoma, abdominal wall in gastrointestinal tumors, and lower back in renal cell carcinoma.[1771]

Figure 3.149 Squamous cell carcinoma of uterine cervix metastatic to skin of arm.

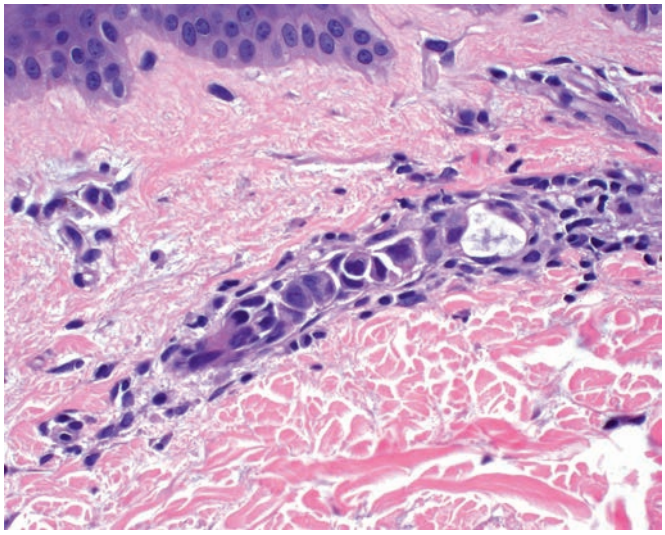

Figure 3.150 Metastatic Adenocarcinoma of Breast to Skin. The tumor cells are filling the vascular lumen of a dermal lymphatic vessel.

Oral Cavity and Oropharynx

Normal Anatomy

The oral cavity and oropharyngeal region represent the upper portion of the digestive tract; in addition, the oropharynx constitutes a portion of the upper respiratory tract. The oropharynx and hypopharynx share many of the diseases of the two adjacent digestive tract organs—oral cavity and esophagus—whereas the nasopharynx shares them with the two other components of the upper respiratory tract, that is, the nasal cavity and paranasal sinuses.

For the purposes of the topographic characterization of lesions that occur in this area (particularly squamous cell carcinoma), the oral cavity and oropharyngeal region is divided into the following regions: (1) *lip*, including only the vermilion surface and comprising an upper and lower lip joined at the commissures of the mouth; (2) *floor of the mouth*, a U-shaped area bounded by the lower gingiva and the oral tongue; (3) *oral tongue*, defined as the portion of the tongue anterior to the circumvallate papillae; (4) *buccal mucosa*, which covers the inner surface of the cheeks and lips; (5) *gingiva* (alveolar ridge), the mucosa covering the mandible or maxilla from the gingivobuccal gutter to the origin of the mobile mucosa; (6) *retromolar trigone*, a small triangular surface behind the third molar covering the ascending ramus of the mandible; (7) *hard palate*, a semilunar area located between the upper alveolar ridge and the mucous membrane covering the palatine process of the maxillary bones; (8) *base of the tongue*, bound anteriorly by the circumvallate papillae, laterally by the glossotonsillar sulci, and posteriorly by the valleculae; (9) *tonsillar area*, which includes the anterior and posterior tonsillar pillars and the tonsillar fossa; (10) *soft palate*; and (11) *pharyngeal walls.*[1,2]

The surface epithelium of this region is of stratified squamous type throughout, with greater depth than the epithelium of the skin. It lacks hair follicles and sweat glands but may contain scattered sebaceous glands, melanocytes, and Merkel cells.[3] It keratinizes in the areas most exposed to mastication (gingivae, hard palate, and dorsum of tongue) but not in others. The lamina propria is composed of loose connective tissue and contains mucous and serous glands of minor salivary gland type. Minor but distinctive variations exist among the various areas of this region.

The oral cavity and oropharynx are the sites of numerous diseases, both congenital and acquired, affecting a large variety of tissues and systems. Only those that occur commonly enough to be of interest to the surgical pathologist are discussed here. For a more thorough discussion of these diseases and the rarer diseases, the reader is referred to specialized textbooks on the subject.[3–6]

Abstract

This chapter reviews pathology of the upper aerodigestive tract. The chapter is organized by subsite beginning with the oral cavity/oropharynx followed by sinonasal cavities, larynx, and trachea. Each subsite section discusses the relevant anatomy and histology, followed by non-neoplastic and neoplastic entities.

Keywords

Oral cavity neoplasms,
oropharyngeal neoplasms,
sinonasal neoplasms,
laryngeal neoplasms

Congenital Abnormalities

Dermoid cysts are seen in the midline of the floor of the mouth. Although present at birth, they may become evident only later when secondarily inflamed.[7] They are lined by squamous epithelium and contain skin adnexa.[8] **Heterotopic gastric** or **intestinal epithelium** has been reported in the tongue and floor of the mouth, sometimes resulting in cystic formations.[9] Minute **cysts of odontogenic origin** are commonly seen in the alveolar and palatal mucosa of newborns and older infants; they need not be biopsied. Nodules of **heterotopic nerve tissue** in the palate or parapharyngeal space, mainly composed of glial elements and ependyma-lined clefts, have been reported as *glial choristomas*[10,11]; in rare cases, a neoplasm may arise from them.[12] **White sponge nevus,** an autosomal dominantly inherited disease, is characterized by large white plaques in the oral mucosa with preferential involvement of the buccal mucosa (Fig. 4.1). Mutations of the keratin 4 or 13 genes, which are expressed in the malpighian layer of the mucosa, is responsible for the clinical and histologic abnormalities. Microscopically there is striking intracellular glycogen accumulation throughout the malpighian layer with overlying parakeratosis (Fig. 4.2).[13] **Fordyce granule** refers to the presence of normal sebaceous glands inside the oral cavity, a very common occurrence. Sometimes these glands undergo hyperplastic changes and appear as discrete nodules.[14] The entity **lingual thyroid** is discussed in Chapter 8.

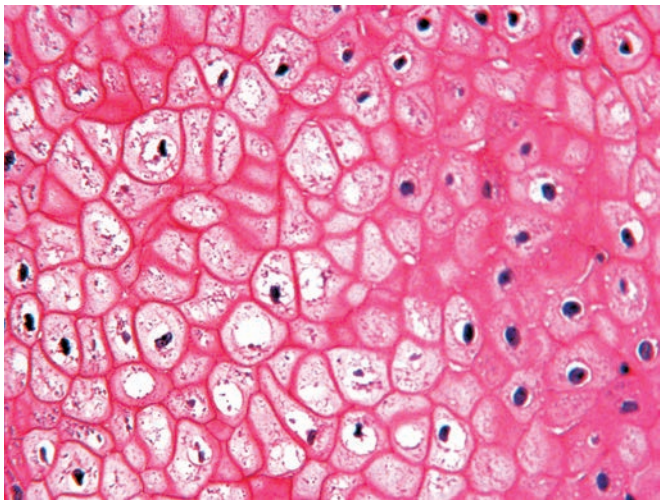

Figure 4.2 White Sponge Nevus. There is a marked pallor of the cytoplasm due to intracellular edema.

Although it does not represent a congenital anomaly, the occurrence of **epithelial nests** in intraoral sensory nerve endings should be mentioned here.[15,16] Their importance relates to the fact that pathologists unaware of their existence might easily confuse them with perineurial invasion by squamous cell carcinoma. These formations are normally occurring neuroepithelial structures of alleged receptor function, known by anatomists as the *organ of Chievitz*, Chievitz paraparotid organ, and juxtaoral organ (Fig. 4.3).[17] They lie deep to the internal pterygoid muscle near the pterygomandibular raphe and are associated with small branches from the buccal nerve. These structures can undergo nodular hyperplasia.[18]

Inflammatory Diseases

Chronic inflammatory lesions of nonspecific type are produced in the oral cavity by ill-fitting denture, ragged, sharp teeth, and poor dental hygiene. Removal of the offending agent allows the pathologic process to subside. Microscopically, a combination of hyperplastic epithelium (including pseudoepitheliomatous hyperplasia), fibrous tissue, and inflammatory cells in varying proportions is seen. In a classic article, Bhaskar et al.[19] described 341 such cases, all associated with the use of dentures, under the term *inflammatory papillary hyperplasia*; 82.7% of the lesions were located in the palate. Localized overgrowth of the epithelium with or without ulceration is frequent, and it is not rare to see large pseudotumors made up of fibrous tissue and chronic inflammatory cells, among which plasma cells may be prominent. Lesions in which the fibrous proliferation predominates are sometimes referred to, somewhat inaccurately, as *irritation fibromas*. Scattered stellate and multinucleated giant cells can be seen throughout the fibrous tissue, in which case the term *giant cell fibroma* has been used.[20,21]

Geographic tongue (benign migratory glossitis, glossitis migrans) is a relatively common condition (affecting 1%–2% of the population) of unknown cause, which is usually asymptomatic. Most patients are adults, but it has also been seen in children. It often occurs in association with fissured tongue. Clinically, it appears as an erythematous flat zone on the dorsum of the tongue resulting from loss of the filiform papillae (Fig. 4.4). The microscopic appearance is that of a psoriasiform process; there is acanthosis with migration of neutrophils throughout the epithelium to form microabscesses near the surface, accompanied by a mild inflammatory infiltrate in the lamina propria.[22]

Tuberculosis is a rare lesion within the oral cavity. It is usually seen on the tongue as a painful ulcer, but it also may occur on the buccal mucosa. It nearly always is associated with advanced pulmonary disease. Microscopically, there are typical tubercles.[23]

Syphilis may produce a gumma in the tongue or palate appearing as a painless indurated mass. Microscopically, there are granulomas with giant cells, numerous plasma cells, and prominent vascular changes.

Histoplasmosis can occur anywhere in the oral cavity and can closely simulate squamous cell carcinoma on clinical examination. Indurated ulcers, nodular lesions, or verrucous masses can be present. The usual microscopic appearance is that of a granuloma, although sometimes only a nonspecific inflammatory reaction is seen. Special stains (Gomori methenamine silver or periodic acid–Schiff [PAS]–Gridley) are necessary for the identification of the fungi.[24]

Crohn disease can involve the oral cavity and pharynx, sometimes as the initial manifestation.[25,26] Oral lesions develop in about 6% of patients with Crohn disease at some stage of this disorder. The

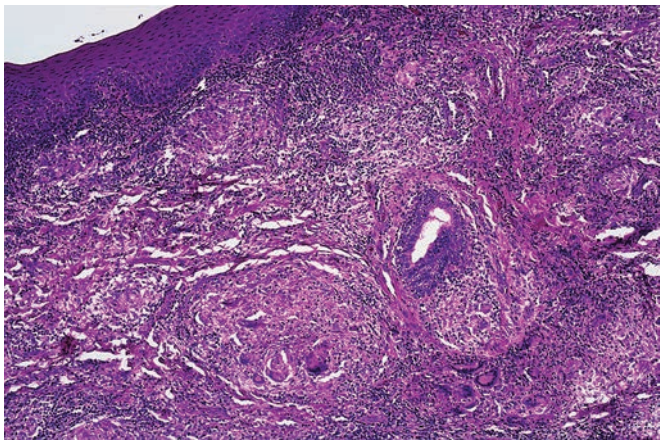

Figure 4.5 Lip Biopsy in a Patient With Melkersson–Rosenthal Syndrome. Numerous non-necrotizing granulomas are seen beneath a normal epithelium.

most common locations are lips, gingiva, vestibular sulci, and buccal mucosa.[26] The lesions can manifest as edema, ulcers, or in the form of a polypoid papulous hyperplastic mucosa. Microscopically, there are edema, dilation of lymph vessels, chronic inflammation, scattered giant cells, and, rarely, noncaseating granulomas.[27]

Sarcoidosis may affect the oral mucosa, gingiva, tongue, hard palate, and major salivary glands. Random biopsy of the lower lip has been successfully used to support a diagnosis of sarcoidosis; in a series of 75 consecutive patients, noncaseating granulomas were found by this procedure in 58%.[28]

Melkersson–Rosenthal syndrome is composed of the triad of orofacial swelling, peripheral facial nerve paralysis, and plicated tongue. *Cheilitis granulomatosa* is probably an abortive variant of this syndrome, the etiology and pathogenesis of which remain obscure.[29] Microscopically, there is a granulomatous inflammation primarily involving the stroma of the lip (Fig. 4.5). The differential diagnosis includes sarcoidosis and Crohn disease.

Granulomatous tonsillitis is occasionally found in specimens of tonsillectomy performed because of chronic recurrent tonsillar enlargement; in most cases, no specific organism is recovered, and the course is benign.[30]

Waldeyer ring lymphoid hyperplasia is a common symptomatic complication of HIV infection. Characteristically, the process is accompanied by a scattering of multinucleated giant cells adjacent

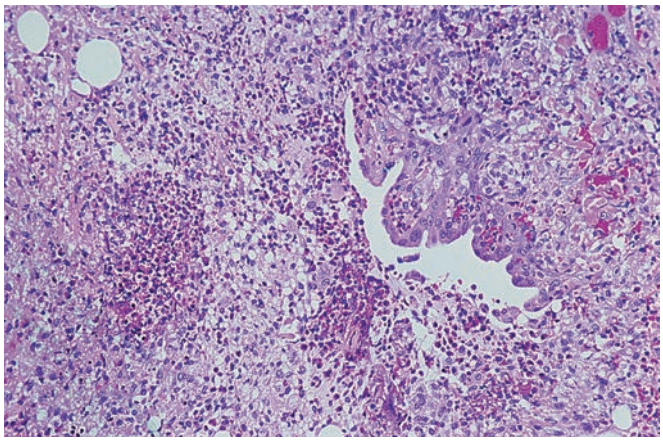

Figure 4.6 Tongue Ulceration With Eosinophilia. A mixed inflammatory infiltrate rich in eosinophils is present.

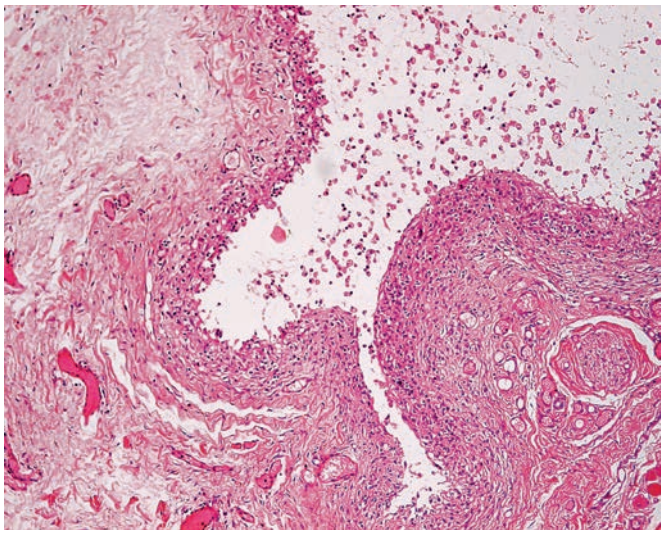

Figure 4.7 Extravasation Mucocele. The lining of the mucus-filled cyst is made up of histiocytes rather than epithelial cells.

to the tonsillary crypt of surface epithelium.[31] These cells, which harbor significant amounts of HIV, exhibit histiocytic markers and probably belong to the accessory immune system.[32]

Granulomatosis with polyangiitis (Wegener) may manifest in the oral cavity as a red to purple hyperplastic gingiva; in about 5% of the cases this is the first manifestation of the disease.[33] On microscopic examination, there are epithelioid histiocytes, giant cells, eosinophils, pseudoepitheliomatous hyperplasia, and, in rare cases, vasculitis.[34]

Behçet disease affects primarily skin, oral mucosa, and eyes and is characterized microscopically by a leukocytoclastic vasculitis.[35] **Cytomegalovirus infection** can manifest in the oral cavity as an ulcerated lesion.[36]

Tongue ulceration with eosinophilia (eosinophilic ulcer; ulcerative eosinophilic granuloma; traumatic ulcerative granuloma with stromal eosinophilia [TUGSE], Riga–Fede disease) may mimic carcinoma clinically.[37] Microscopically, it shows a polymorphic inflammatory infiltrate rich in eosinophils, extending into the submucosa, muscle, and minor salivary glands[38] (Fig. 4.6). The initiating event is presumably traumatic (crush injury to the tongue muscle), hence its alternative designation as *traumatic (ulcerative) granuloma*.[39] Some cases have shown T-cell receptor rearrangement and/or CD30 immunoreactivity, but the clinical behavior is benign.[40]

Chronic graft-versus-host disease (GVHD) frequently involves the oral cavity and presents with xerostomia if the salivary glands are involved as well as with lichen planus-like lesions involving the buccal mucosa and tongue.[41] Histologically, the mucosal lesions demonstrate intracellular edema with basal cell degeneration, scattered dyskeratotic cells, and a lichenoid chronic inflammatory infiltrate.

Pulse granuloma, an odd lesion also known by a variety of synonyms, is discussed in Chapter 5.

Other Non-Neoplastic Lesions

Leukoedema presents as a diffuse opalescent lesion of the cheek mucosa that can extend to the lips; microscopically, the main alteration is vacuolization or intracellular edema of the malpighian cells, a change of a probably degenerative nature.[42]

Diffuse fibrous hyperplasia of the gingiva has been traditionally described as a complication of diphenylhydantoin (Dilantin) therapy, but most cases seen today are genetically inherited, idiopathic, or associated with other drugs, such as cyclosporin A.[43,44] The gingival thickening can be so extreme as to necessitate surgical removal.

Oral submucosal fibrosis, as seen mainly in Indians and Pakistanis, is a reactive process characterized microscopically by subepithelial fibrosis and chronic inflammation, accompanied by hyalinization and loss of vascularity.[45] The overlying epithelium may be either atrophic or hyperplastic and is often hyperkeratotic. The pathogenesis is unknown. The disease is thought to predispose the patient to the development of squamous cell carcinoma.[46]

Mucous cyst (mucocele), when applied to a lesion of the oral cavity, has been used for two different processes. The first and more common is referred to as *extravasation mucocele* and represents a focus of stromal reaction to spillage of mucus from a traumatically injured minor salivary gland.[47] It is often seen in young individuals, the lower lip being the classic location, and the microscopic pattern is that of granulation tissue surrounding one or more spaces containing mucin[48] (Fig. 4.7). Sometimes the cysts are very superficial and simulate vesicobullous diseases clinically.[49]

The second type, named *retention mucocele*, occurs most often in older patients and in other locations in the oral cavity, such as the floor of the mouth and the inside of the cheek. Microscopically, a mucus-filled cyst completely lined by cylindric, cuboidal, or flattened epithelial cells is seen.[50]

An anatomic variant of either extravasation or retention mucocele is known as *ranula* when it occurs as a blue-domed cyst in a sublingual location, and as *plunging ranula* when it extends into the neck above the hyoid bone.[51,52]

Oral focal mucinosis is the oral counterpart of the more common cutaneous focal mucinosis[53]; this condition is located in oral cavity sites other than the lip and lacks the granulation tissue wall and inflammatory cells consistently seen in extravasation mucocele.

Necrotizing sialometaplasia is a reactive condition involving minor or—less commonly—major salivary glands; its importance lies in the fact that it can be confused histologically with squamous cell or mucoepidermoid carcinoma.[54,55] The disease usually presents as an ulcerating lesion of the hard palate characterized by vascular proliferation, prominent inflammatory infiltrate, and partial necrosis of salivary glands, associated with regeneration and squamous metaplasia of the adjacent ducts and acini. Cases also have been described in the nasal cavity, gingiva, lip, hypopharynx, and maxillary sinus. The morphologic changes are somewhat similar to those seen in this region after radiation therapy. The pathogenesis is probably ischemic, and some cases have been seen as a complication of

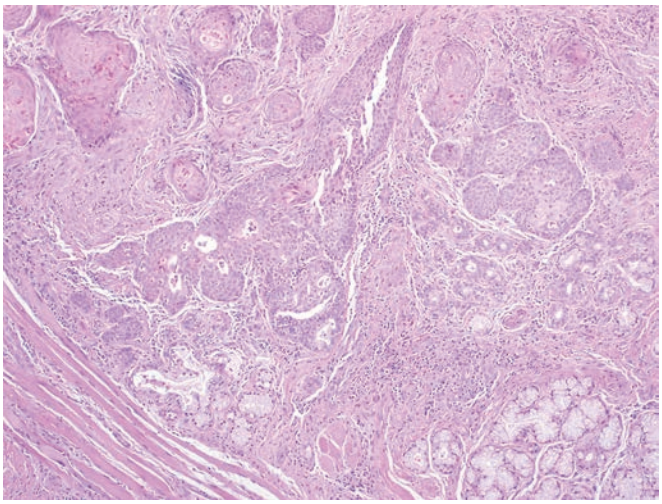

Figure 4.8 Necrotizing sialometaplasia. The retained lobular configuration is an important diagnostic clue.

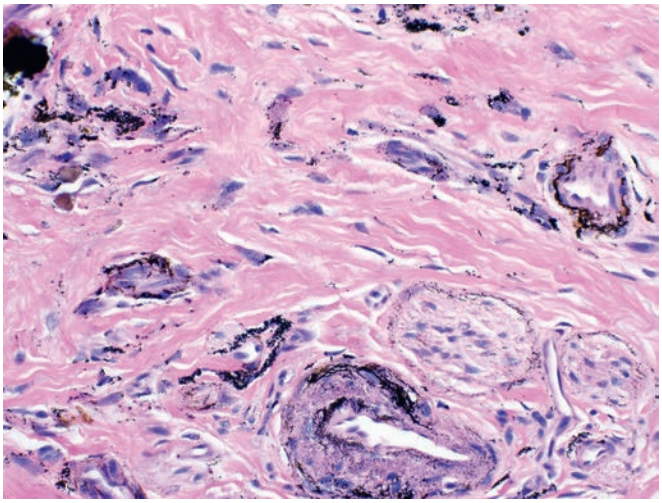

Figure 4.9 Amalgam Tattoo. The pigment is seen surrounding vessels and nerves as well as adhering to the connective stroma fibers.

vasculitis and other primary vascular disorders. The lobular configuration that these lesions exhibit on low-power examination is an important sign in the differential diagnosis with squamous cell carcinoma[56] (Fig. 4.8). The presence of calponin-positive myoepithelial cells is a supporting diagnostic feature.[57,58]

Amyloidosis of the tongue may be an isolated event (localized amyloidosis) but is often involved as a manifestation of systemic amyloidosis.[59] Only in a small proportion of cases are the deposits extensive enough to result in clinically evident disease in the form of diffuse macroglossia or a localized tumor.[60,61] Patients with lingual amyloidosis should be worked up for systemic disease; 15% of those with systemic disease will have underlying multiple myeloma.

Amalgam tattoos result from amalgam alloys being inadvertently deposited in subepithelial connective tissues of the gingiva, buccal mucosa, and/or alveolar ridge. They appear as blue-black macules ranging from 1 to 20 mm.[62] They are typically biopsied to rule out melanocytic lesions. Histologically, fine golden-brown or black granules are deposited on connective tissue fibers and around vessels and nerves (Fig. 4.9). Larger particles can be seen in foreign body giant cells.

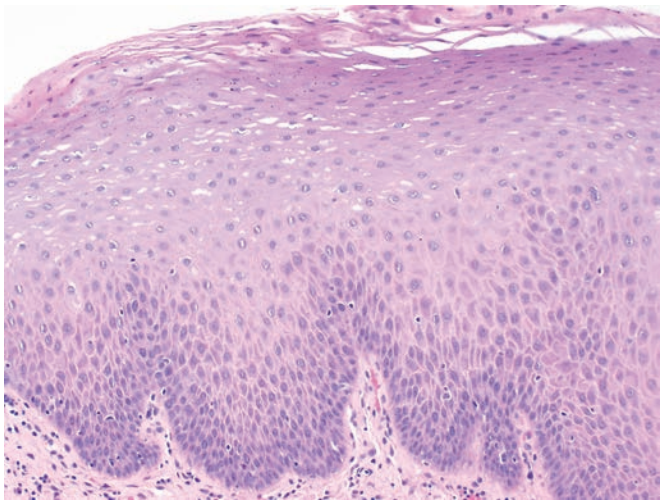

Figure 4.10 Keratosis Without Dysplasia.

Dermatologic disorders of various types can involve the oral cavity, including *lichen planus* (but beware of lichenoid dysplasia, see next section),[63,64] *lupus erythematosus*,[64] and *pemphigus vulgaris*.

Tumors and Tumorlike Conditions of Surface Epithelium

Intraepithelial Squamoproliferative Lesions

It has been rightly pointed out that the lesions grouped under this generic term "continue to be among the most widely discussed, reclassified, and semantically tortured conditions in the medical literature."[65] Part of the problem resides in the fact that different clinical and pathologic terms have been introduced haphazardly over the years and that the correlations between them—although certainly present, as will be shown later—are less than perfect. Among the clinical terms, **leukoplakia** remains the most widely used.[65,66] It has been defined as "a white patch or plaque, not less than 5 mm in diameter, that cannot be removed by rubbing and cannot be classified as any other diagnosable disease," and it implies nothing about the histologic appearance. It is equivalent to the term *keratosis* as used more often at other sites (such as larynx) and is sometimes subclassified (always on clinical grounds) as homogeneous, nonhomogeneous (speckled; nodular; erythroleukoplakia), erythroplakia (which is red rather than white), and proliferative verrucous leukoplakia.[65,67] The most common location of leukoplakia, as defined previously, are the buccal gingival gutter and tongue.

At the histopathologic level, terms such as keratosis, squamous hyperplasia, and verrucous hyperplasia have been used interchangeably, the choice depending on minor architectural differences but mainly on personal preference. When *dysplasia* is present, this is added to the diagnosis and the changes are graded as *mild*, *moderate*, and *severe*, the latter merging with squamous cell carcinoma in situ (CIS) and therefore often grouped with it, as it is at other sites (Figs. 4.10–4.13).[68,69] The microscopic criteria for the diagnosis of severe dysplasia/CIS are the same as for other mucosal membranes: epithelial disarray with full-thickness atypia, no flattening or horizontal elongation of the surface layer, and a basement membrane that appears intact in routinely stained sections.

The atypical proliferative changes characteristically involve the surface epithelium, but they can also extend to the ducts of minor salivary glands. When the dysplastic changes are accompanied by hyperkeratosis, prominent granular layer, irregular basal layer,

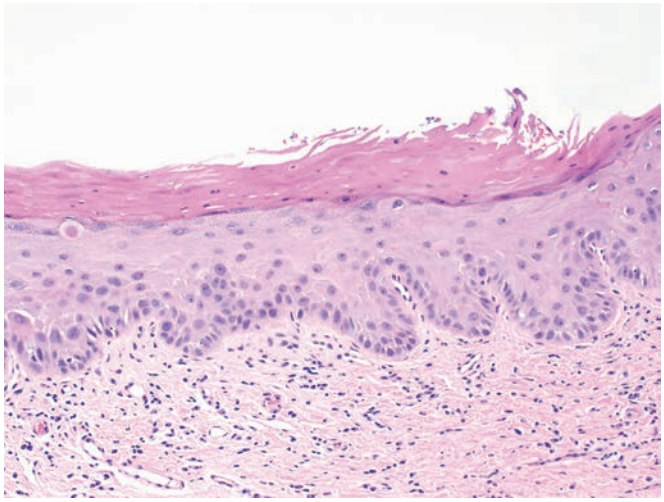

Figure 4.11 Mild Dysplasia.

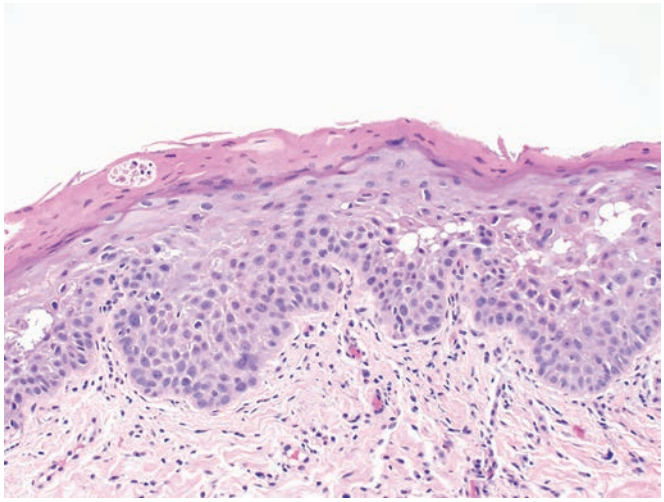

Figure 4.12 Moderate Dysplasia.

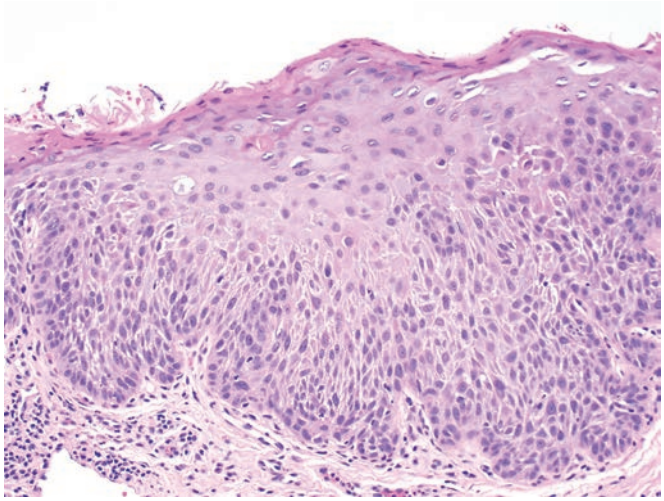

Figure 4.13 Severe Dysplasia.

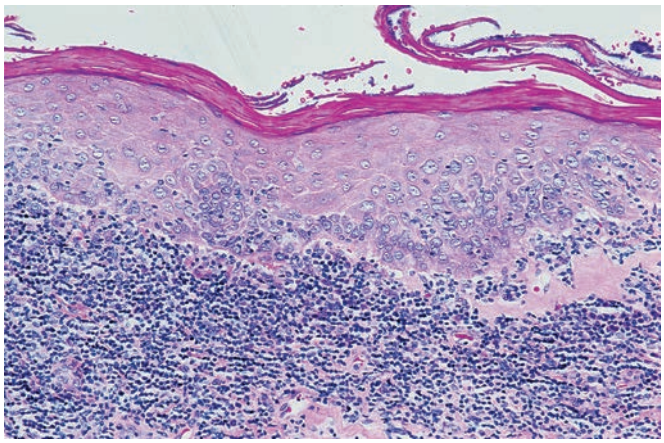

Figure 4.14 Lichenoid Dysplasia. There is a bandlike lymphocytic infiltrate beneath the squamous epithelium, with some infiltration of lymphocytes in the lower third. This lesion is commonly underdiagnosed.

Table 4.1 Classification of keratosis

GENERIC TERM	QUALIFIERS	DYSPLASIA
Keratosis	Papillary	Absent
	Lichenoid	Mild
	Verrucous	Moderate
	Proliferative verrucous	Severe/CIS

Examples:
- Keratosis, with no dysplasia
- Keratosis, lichenoid, with mild dysplasia
- Keratosis, with severe dysplasia/CIS

CIS, Carcinoma in situ.

sawtoothed rete pegs, and bandlike lymphocytic infiltrate, the condition is referred to as *lichenoid dysplasia* (Fig. 4.14).[70] Because of the often subtle degree of the dysplastic changes, this condition is frequently underdiagnosed as lichen planus, a mistake that may have serious consequences.[71,72]

The alternative terminology that has been proposed for this group of lesions is that of *oral intraepithelial neoplasia* (*OIN*), grade I (equivalent to mild dysplasia), grade II (equivalent to moderate dysplasia), and grade III (equivalent to severe dysplasia/CIS). Until the latter terminology is widely adopted (and there is no sign that it will happen soon), our preference is to use *keratosis* as the generic term, to qualify it if indicated and—most importantly—to indicate the presence and degree of dysplasia, according to the scheme in Table 4.1. It should be acknowledged that, no matter what terminology is used, the determination is subjective and marred by a marked degree of interobserver variability.

At the immunohistochemical level, the main distinction between keratosis without and with dysplasia is a quantitative one: whereas in the former the expressions of keratin 19, p53, and proliferation-related antigens (such as Ki-67) are all limited to the basal layer, in the latter they are also expressed in suprabasal cells. A similar distinction is appreciated with $p16^{INK4A}$, the protein product of a tumor suppressor gene.[73] Of these markers, Ki-67 (MIB-1) seems the most consistent and therefore the most useful for the identification and grading of the dysplasia.[74] DNA ploidy studies have shown that

about one-third of "leukoplakic" lesions are hyperploid or aneuploid but that the relationship of this parameter with the grade of dysplasia is poor.[75,76] Overexpression of p53 has been found in only a small minority of dysplasias, in keeping with the known late occurrence of this event in the carcinogenesis chain.[77] In summary, no immunohistochemical marker, or set of markers, is adequate in making a diagnosis of dysplasia or grading dysplasia but, in conjunction with the morphology, can be useful as an adjunctive measure in making these distinctions.

In terms of clinicopathologic correlations, severe dysplastic changes are much more likely to be present in lesions with the clinical appearance of erythroplakia than those of homogeneous leukoplakia, with erythroleukoplakia occupying an intermediate position.[78] Thus, of 158 "early" asymptomatic squamous cell carcinomas studied by Mashberg et al.,[79] 143 (90.5%) had red velvety ("erythroplastic") components, whereas only 10 (9.8%) had white components; only four lesions were solely white, and there was no color distinction between in situ and invasive carcinoma. The presence of induration almost guaranteed the presence of stromal invasion.

There is also a correlation between the location of the leukoplakia and the chance of finding dysplastic changes microscopically; the probability of dysplasia is much higher for lesions located in the floor of the mouth.[80]

The most important issue concerning this group of lesions is the likelihood of them evolving into invasive carcinomas of either squamous or verrucous type. There is no question that this prediction is more accurate when made on the basis of the severity of the dysplasia as judged microscopically than when attempted on the basis of clinical features. If all cases fitting the clinical definition of leukoplakia are included, the incidence of subsequent malignancy is very low. Pindborg et al.[81] followed 248 patients with oral leukoplakia (mostly of the speckled type) for 1–10 years and found that only 4.4% developed squamous cell carcinoma. In Einhorn and Wersäll's series[82] of 782 patients with a mean follow-up of 11.7 years, the incidence of invasive carcinoma was 2.4% after 10 years and 4% after 20 years. Most other series quote figures ranging from less than 1% to 6%.[83]

From a microscopic standpoint, the implicit assumption is that the greater the atypia, the higher the premalignant potential. It is, however, important to remember that some squamous cell carcinomas of the mouth present without any evidence of adjacent or preceding dysplasia[68] and that a lesion with the features of severe dysplasia/CIS may simply be the peripheral expression of an invasive carcinoma that has not been properly sampled.

There is hope that some special procedure will eventually allow a more accurate and reproducible prediction of the premalignant potential of these lesions.[84]

Actinic cheilitis is the equivalent in the lip vermilion of actinic keratosis of the skin on morphologic, pathogenetic, and behavioral grounds; it should therefore not be equated with the leukoplakic–dysplastic conditions within the oral cavity previously discussed. An increased prevalence of dysplastic and malignant lip lesions has been documented in renal transplant recipients and other immunosuppressed individuals.[85]

Oral/Oropharyngeal Lesions and Human Papilloma Virus

The oral cavity can be the site of a variety of human papilloma virus (HPV)-related lesions, some of which are microscopically and behaviorally analogous to those located in the genital tract.[86] These include *focal epithelial hyperplasia (Heck disease)*,[87] *verruca vulgaris*,[88] *condyloma acuminatum*,[89] and the relatively common *squamous papilloma*[90] (Fig. 4.15).

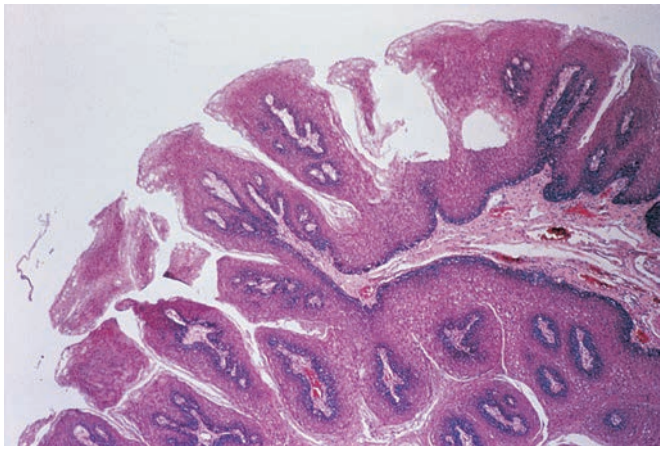

Figure 4.15 Squamous Papilloma of the Oral Cavity.

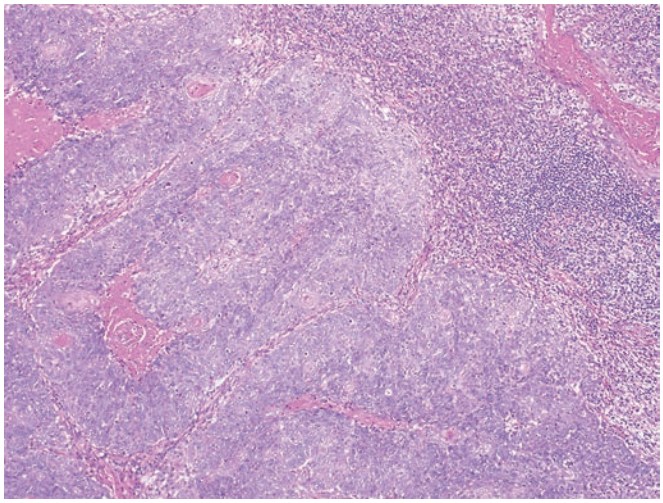

Figure 4.16 Infiltrative lobules composed of poorly differentiated basaloid cells with focal keratinization (so-called non-keratinizing squamous cell carcinoma) are typical of HPV-related oropharyngeal squamous cell carcinomas.

Heck disease presents clinically as a well-circumscribed, sessile, pale elevation of the buccal mucosa. Microscopically, the most prominent feature is the presence of balloon cells in the malpighian layers. The balloon cells often demonstrate irregular nuclear karyorrhectic degeneration resembling mitotic figures (mitosoid bodies) that are suggestive of the diagnosis. This disorder is more common among Native Americans and Eskimos.[87]

The verrucae, condylomas, and papillomas often exhibit koilocytosis as a sign of cytopathic effect.

An etiologic role for HPV has also been suggested for verrucous carcinoma[91] and squamous cell carcinoma, including some of its precursors (high-grade dysplasia/CIS) and variants, but these are inconsistent findings.[92] The benign oral lesions are statistically associated with HPV types 2, 4, 6, 11, 13, and 32, and the malignant ones with HPV types 16, 18, and 33.[86,93,94] Among the carcinomas, those with the highest incidence of HPV detection are the poorly differentiated nonkeratinizing squamous cell carcinomas of the oropharynx (palatine and lingual tonsil) seen in sexually active young individuals (Fig. 4.16).[95–97] Parenthetically, many of the latter tumors express p16 protein, a surrogate marker for high-risk

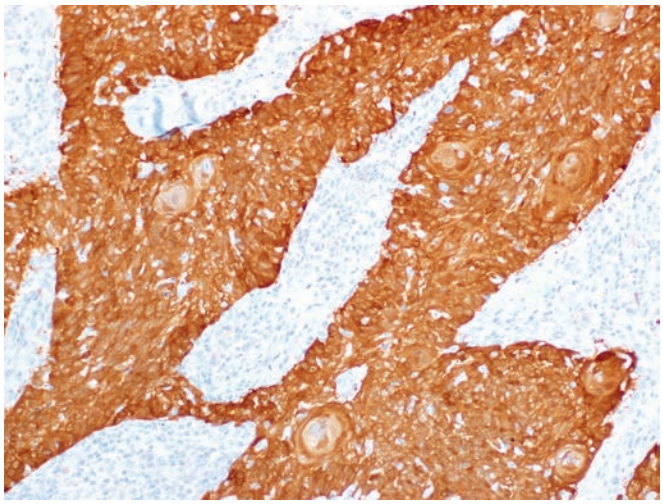

Figure 4.17 A p16 immunohistochemical stain is strongly positive in the entire tumor including both nuclear and cytoplasmic staining. This pattern of staining, in conjunction with the morphology, supports that this is a high-risk HPV-related carcinoma.

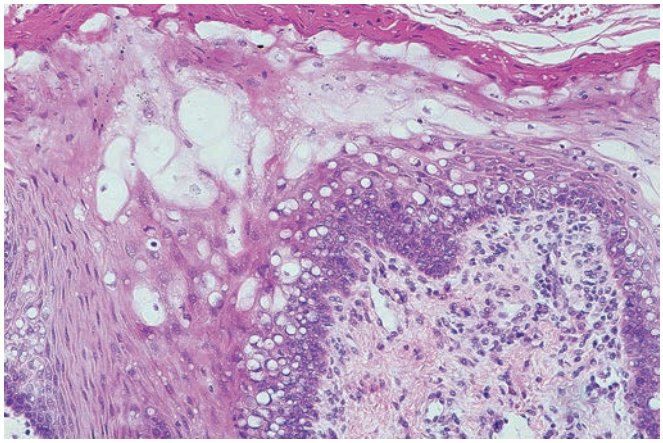

Figure 4.18 Hairy Leukoplakia. There is prominent ballooning of the squamous cells in the upper half of the epithelium, associated with mild inflammation in the underlying stroma.

HPV infection (Fig. 4.17).[98] HPV-positive oropharyngeal cancers are also more likely to exhibit a "basaloid" morphology and to have cystic lymph node metastasis.[99] It is important to recognize these cancers as they are associated with a favorable response to chemoradiation therapy and are associated with a much improved survival compared with conventional squamous cell carcinoma of the head and neck.

Not all squamous papillomas of the oral cavity are virally induced. Some may be the result of mechanical irritation, and others (although possibly viral related) are genetically determined, such as those occurring as a component of Cowden syndrome.[100,101]

Hairy leukoplakia was originally thought to be associated with HPV but is now believed to be due to Epstein–Barr virus (EBV) lytic infection.[102,103] This lesion develops in patients with HIV infection and is characteristically located along the lateral edges of the tongue.[104] Microscopically, it shows parakeratosis, acanthosis, and intranuclear inclusions in keratinocytes, associated with ballooned or ground-glass cytoplasm (Fig. 4.18).[105,106] There is a high incidence of superinfection by *Candida* organisms.

Squamous Cell Carcinoma

General Features

Practically speaking, cancer of the oral cavity mucosa is synonymous with squamous cell (epidermoid) carcinoma. Known predisposing factors vary according to the location of the tumor. Most carcinomas of the oral cavity are strongly associated with tobacco use, and there is a synergistic effect with alcohol. For carcinoma of the lip, they include sunlight, fair complexion, and—to less extent—smoking and mechanical irritation.[107] Transplant recipients and HIV-positive patients are also at an increased risk, presumably as a result of immunosuppression.[108,109] This risk is greater among younger patients.[109] Interestingly, carcinomas developing in HIV-positive individuals are only infrequently associated with HPV infection.[108]

Oropharyngeal carcinomas have been related mainly to tobacco and alcohol, but also to syphilis, oral sepsis, iron deficiency, oral candidiasis, and Fanconi anemia.[110–114] Currently, most oropharyngeal squamous cell carcinomas are now known to be related to infection with high-risk HPV. Most cases occur in men over the age of 50, although the relative incidence among women and younger patients seems to be increasing.[92,115–118]

Location

In a large series from the M.D. Anderson Cancer Center in Houston, Texas,[119] the location of squamous cell carcinomas within the oral cavity was listed as follows: lip, 45%; tongue, 16%; floor of mouth, 12%; buccal mucosa, 10%; lower gingiva, 12%; and upper gingiva and hard palate, 5%. Of the lip tumors, over 90% involved the lower lip. In a careful study of early asymptomatic squamous cell carcinomas of the oral cavity proper, Mashberg and Meyers[120] found that the overwhelming majority of them occurred in three locations: floor of the mouth (especially at the papilla at the Wharton duct exit), soft palate–anterior pillar–retromolar complex, and ventrolateral aspect of the mobile portion of the tongue (Fig. 4.19). These "high-risk areas" have in common a lining of thin nonkeratinized squamous epithelium, with short or absent rete ridges and a narrow lamina propria.

Multiplicity of tumors is common; in such cases, the tongue is one of the most commonly affected sites.[121] Patients with carcinoma of the oral cavity have a 100-fold probability of developing a second primary tumor in the region.[122] The chances of this occurrence are particularly high when the carcinoma is associated with dysplastic changes elsewhere in the oral cavity, which are the morphologic indicators of the important biologic phenomenon known as *field cancerization*.[123]

The analysis of the karyotype and pattern of *TP53* mutation in these multiple tumors has shown that in some cases they are clonally related (taken to indicate that they represent metastases from a single lesion), whereas others—probably the majority—are truly multiple primary tumors.[124,125]

Microscopic Features

Intraoral squamous cell carcinomas range widely in their degree of differentiation. Histologic evidence of squamous differentiation is typically manifest as intercellular bridges and/or squamous pearls. Those located at the base of the tongue or in the tonsil tend to be undifferentiated and solid with less prominent evidence of keratinization, thereby creating diagnostic confusions with large cell malignant lymphoma. Perineurial and vascular invasion are common. The epithelium adjacent to the invasive tumor often shows dysplastic changes of various degrees, all the way to CIS.[126] Some variations in the microscopic appearance of this tumor exist. A few squamous cell carcinomas are massively infiltrated with mature eosinophils, a feature that may create diagnostic

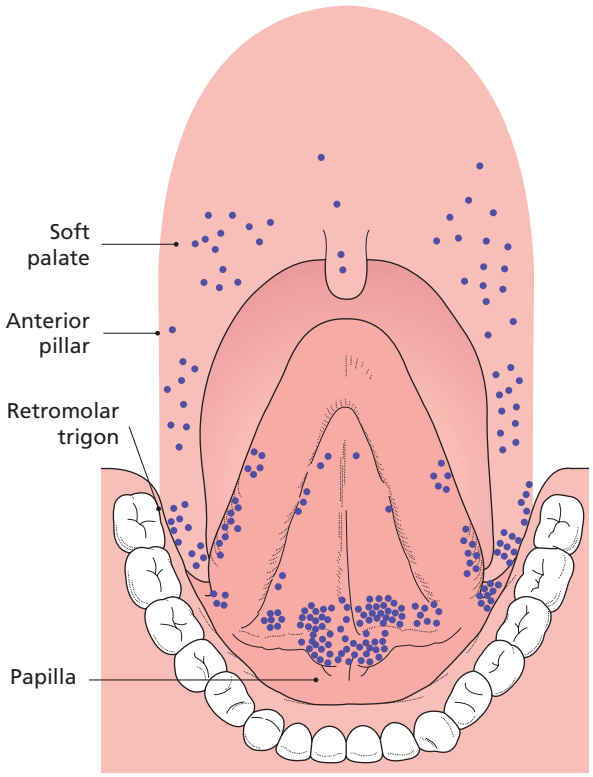

Figure 4.19 Scattergram indicating site of origin of over 200 asymptomatic early squamous cell carcinomas. Note concentration of lesions around papilla at exit of Wharton duct, ventrolateral aspect of tongue, lingual aspect of retromolar trigone, anterior pillar, and soft palate. (Adapted from Mashberg A, Meyers H. Anatomic site and size of 222 early asymptomatic oral squamous cell carcinomas. A continuing prospective study of oral cancer. II. *Cancer*. 1976;37:2149–2157.)

difficulties and that is said to be associated with an improved prognosis.[127,128]

Histochemical and Immunohistochemical Features

Immunohistochemically, these tumors are invariably positive for keratin. In the study by Suo et al.,[129] all cases expressed CK8 and 19, most expressed 5/6 and 13 (the latter only in the metastases), and none expressed CK20.

For the special features of the tonsillar tumors associated with cystic metastases in cervical lymph nodes, see under "Spread and Metastases."

Molecular Genetic Features

The most common oncogene alterations identified in oral squamous cell carcinoma involve p16 (approximately 80% of the cases), p53 (50%, with mutation being more common in smokers), cyclin D1 (30%), p63 (30%), phosphatase and tensin homolog (PTEN) (10%), Rb (<10%), and epidermal growth factor receptor (EGFR, <10%).[115,130,131] The critically altered pathways include p53 (inactivation by mutation, HPV-16 E6 protein inhibition, or aberrations of other genes in the pathway), EGFR (frequent overexpression through gene amplification, transcriptional activation or mutation in ligand-binding domain), signal transducer and activator of transcription 3 (STAT3) and vascular endothelial growth factor receptor (VEGFR).[132] There are ongoing clinical trials on the usefulness of drugs that specifically target these pathways, such as EGFR inhibitor and VEGF or VEGFR inhibitor.[132]

Evaluation of these changes has led to the proposal of a model of molecular progression, which is conceptually appealing but which should be viewed only as a working hypothesis.[133,134]

Gene expression profiling studies have identified transcriptional signatures in oral squamous cell carcinomas that are said to predict the overall survival, recurrence-free survival, and likelihood of lymph node metastasis.[135–137]

Biopsy, Cytology, and Frozen Section

Dentists have the best opportunity to discover early lesions of the oral cavity, especially those in "hidden" sites such as the posterolateral tongue. It is their responsibility to examine the oral cavity carefully and to refer patients with suspicious lesions for proper evaluation and possible biopsy.[121] The diagnosis is usually obvious in a well-taken sample. A biopsy specimen that is often much more difficult to interpret is the one taken from an abnormal-appearing mucosa sometime after irradiation therapy has been completed for an invasive squamous cell carcinoma. Under these circumstances, it is better to refrain from making a diagnosis of carcinoma unless there is definite stromal invasion, because from a cytologic standpoint it is often challenging to distinguish residual CIS from radiation atypia. Generally speaking, it is better to wait a minimum of 4–8 weeks after completion of the therapy before taking a new biopsy.

Fine-needle aspiration is a very convenient and efficient way to confirm the presence of cervical lymph node metastases. As mentioned, p16 immunohistochemistry is helpful in supporting the diagnosis of metastatic oropharyngeal squamous cell carcinoma if positive.

The main role of frozen section in oropharyngeal squamous cell carcinoma is in the evaluation of surgical margins.[138] A good correlation has been found between presence or closeness of the tumor at the margin and the probability of local recurrence and mortality.[139]

Spread and Metastases

The pattern of direct spread of oropharyngeal carcinoma is dictated by the anatomic features of the primary site.[2] Carcinoma of the lip invades adjacent skin, the orbicular muscle, and—when advanced—the buccal mucosa, the adjacent mandible, and the mental nerve. Tumors of the floor of the mouth penetrate early beneath the mucosa into the sublingual gland, into the midline muscles, and extend toward the gingiva and mandible.[140] Tumors of the oral tongue, which usually arise on the lateral surfaces and ventral side, tend to remain localized for long periods but eventually invade the floor of the mouth, mandible, and root of the tongue, resulting in fixation of the organ. Tumors of the buccal mucosa invade the underlying muscles and may eventually penetrate into the skin. Tumors of gingiva extend quickly into the periosteum, the adjacent buccal mucosa, and the floor of mouth. Tumors of the hard palate may spread into the underlying bone, but extension into the maxillary antrum is very rare. Tumors of the retromolar trigone spread to adjacent buccal mucosa, anterior tonsillar pillar, maxilla, pterygomandibular space, medial pterygoid muscle (resulting in trismus), and buccinator muscle.

Invasion of the mandible usually involves the body of the bone, from which it may spread to the ramus; direct invasion of the latter structure may also occur, particularly after radiation therapy.[141] Metastases occur primarily by the lymphatic route, the distribution of lymph node involvement depending on the location of the primary tumor.[142] The more anterior the tumor, the lower the position of the cervical nodal metastasis. Carcinomas of the base of the tongue and oropharynx tend to metastasize to the upper cervical (jugulodigastric; level II) lymph nodes. These metastases are notoriously cystic and frequently present before the identification of the primary carcinoma.

Metastases to the posterior triangle region (level V) are rare; they occur in only 6% of the oropharyngeal tumors and 1% of the oral tumors.[143] Features of the primary tumor associated with the likelihood of nodal metastases in the neck are location (higher for the posterior portion of the tongue and oropharynx, intermediate for the anterior portion of the tongue, and lower for the lip, floor of mouth, cheek mucosa, hard palate, and gingiva), poor microscopic differentiation, and depth of invasion.[144,145] Lip carcinomas associated with metastases tend to be wide, deep, not well differentiated, and accompanied by an inflammatory and desmoplastic response.[146]

Occasionally, the cervical node metastases from these squamous cell carcinomas undergo cystic degeneration. This, plus the well-differentiated nature of the lesion, may easily lead to a mistaken diagnosis of branchial cyst with malignant transformation ("branchial carcinoma").[96] The occult primary lesion is often located in the lingual or palatine (faucial) tonsil, and it may take 10 years or more for it to be detected.[147] Another peculiar morphologic pattern that squamous cell carcinoma can exhibit when metastasizing to cervical nodes is that of an extensive foreign body giant cell reaction around clumps of keratin, without viable tumor cells; this is particularly common if the tumor has been previously irradiated.[148]

Treatment

The two pillars of therapy for oropharyngeal carcinoma are surgery and radiation therapy, used either singly or in combination.[149] For most early stage lesions, the results of irradiation and surgery are very similar, so that the final decision as to which to use often depends on factors such as functional and cosmetic results, the patient's general status, and the physician's bias.[150,151] Advanced cases are treated by a combination of radiation therapy and chemotherapy.[115] Most other sites are treated with primary surgery for resectable cases with adjuvant radiation therapy with or without concomitant chemotherapy. Patients with unresectable tumors can be treated with radiation or chemoradiation therapy with palliative intent.

The treatment of metastatic squamous cell carcinoma to the cervical lymph nodes without detectable primary is largely dependent on the specific location of the lymphadenopathy.[152]

Prognosis

Listed below are the most important prognostic determinants in carcinomas of the oral cavity.

1. **Location**. The overall 5-year survival rates are about 90% for carcinomas of the lower lip; 60% for tumors of the anterior tongue; 40% for tumors of the posterior tongue, floor of mouth, tonsil, gingiva, and hard palate; and 20%–30% for tumors of the soft palate.[144,153] However, these figures are heavily influenced by, and largely dependent upon, the tumor stage. HPV-related oropharyngeal squamous cell carcinomas are associated with a favorable outcome compared with conventional head and neck squamous cell carcinoma.
2. **Stage**. As usual, this parameter is of the utmost significance. Thus, the recurrence-free 5-year survival rates for "mucosal cancer" of this region in a series of over 3000 cases were: stage I, 91.0%; stage II, 77.2%; stage III, 61.2%; stage IVA, 32.4%; stage IVB, 25.3%; stage IVC, 3.6%.[154]
3. **Grade**. This parameter has proved to be of independent prognostic value.[155] It has been noted that grading of the deep invasive margins of the tumor provides better prognostic information than grading of the entire tumor.[156]
4. **Depth of invasion**. This is an important factor, at least in some locations.[144,157] This feature is incorporated into the staging systems and often dictates whether a lymph node dissection will be performed, especially for oral cavity carcinomas.
5. **Tumor size**. This feature does not correlate closely with clinical outcome, except for the very small tumors.[158]
6. **Tissue eosinophilia**. Intense infiltration of the carcinoma by eosinophils is said to be a favorable prognostic factor.[159]
7. **Lymph node involvement**. Naturally, presence of lymph node metastases is an important prognostic criterion and, as such, it is a key feature of the staging system. Extracapsular spread (i.e., spread of the metastases beyond the lymph node capsule) is an indicator of a further decrease in survival rates being associated with higher rates of locoregional failure.[156]
8. **High-risk HPV**. HPV-16 and -18 positivity in squamous cell carcinomas of the oral cavity and other head and neck sites has been recognized to be a powerful indicator of improved survival.[160] In a recently completed study, it was confirmed that tumor HPV status is a strong and independent prognostic factor for survival among patients with oropharyngeal cancer.[161] This survival advantage is tempered in those individuals who smoke.
9. ***P21* gene**. Overexpression of this gene (the product of which is the downstream regulatory protein of *TP53*) was found to be an independent indicator of unfavorable prognosis in lingual squamous cell carcinoma.[162]
10. **p16**. Overexpression of p16 was found by Kato et al. to be a favorable prognostic factor in oropharyngeal carcinoma.[163] This is related to the fact that p16 is a surrogate marker for high-risk HPV, a known favorable prognostic factor.

Verrucous Carcinoma

Verrucous carcinoma (Ackerman tumor) is a variant of well-differentiated squamous cell carcinoma endowed with enough clinical, pathologic, and behavioral peculiarities to justify its being regarded as a specific tumor entity.[164,165] The oral cavity is its classic location, but this lesion also has been reported in the larynx, nasal cavity, esophagus, penis, anorectal region, vulva, vagina, uterine cervix, and skin (particularly in the sole of the foot). Within the oral cavity, the most common sites are the buccal mucosa and lower gingiva.[166] Most patients are elderly males, and there is a close connection with the use of tobacco, especially chewing or snuff dipping.[167] Grossly, it presents as a large, fungating, soft papillary growth that tends to become infected and slowly invades contiguous structures (Fig. 4.20). It may grow through the soft tissues of the cheek, penetrate into the mandible or maxilla, and invade perineurial spaces. Regional lymph node metastases are exceedingly rare and are presumably related to an undetected well-differentiated conventional squamous cell component. Distant metastases have not been reported.

The microscopic diagnosis of verrucous carcinoma may be difficult because of its well-differentiated character. A superficial biopsy will

Figure 4.20 Gross Appearance of Verrucous Carcinoma With Extensive Involvement of the Tongue.

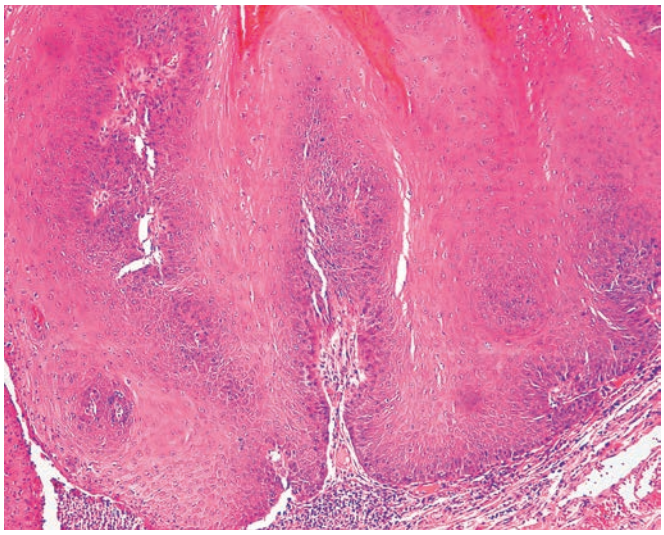

Figure 4.21 Verrucous Carcinoma of Tongue. Extremely well-differentiated squamous rete pegs push into the underlying stroma.

show only hyperkeratosis, acanthosis, and benign-appearing papillomatosis. Sections of an adequate biopsy show swollen, rounded, and voluminous rete pegs that extend into the deeper tissues (Fig. 4.21). Additional features include parakeratin plugs (invaginations) and a band of lymphoplasmacytic inflammation at the advancing front. The most important differential feature with squamous cell carcinoma is the good cytologic differentiation *throughout* the tumor. Dr. Lauren Ackerman, who first described the entity, used to express this fact by stating: "If a lesion looks cytologically like carcinoma, it is not verrucous carcinoma." Significantly, in about one-fifth of the cases, cytologically identifiable foci of squamous cell carcinoma occur within a lesion that looks otherwise like a verrucous carcinoma, hence the importance of thorough sampling.[168] These *hybrid* (*verrucous–squamous*) *tumors* are said to be associated with a higher recurrence rate than pure verrucous carcinomas.[168]

Resection is the treatment of choice. If surgery is inadequate, the tumor will recur.[164] Radiation therapy is not recommended, since it may alter the nature of the tumor to a highly malignant, rapidly metastasizing, poorly differentiated squamous cell carcinoma.[169] This has occurred in as many as 30% of the cases in some series, the average postirradiation interval being 6 months.

It is likely that most of the cases reported in the past as *oral florid papillomatosis* represent early and noninvasive stages of verrucous carcinoma. Along the same lines, the similar if not identical conditions known as *verrucous hyperplasia*, *proliferative verrucous leukoplakia*,[170] *verrucous keratosis*, and *leukoplakia verrucosa* can be regarded as precursor lesions of verrucous carcinoma, from which they are distinguished by the fact that the verrucous process is *superficial* to the adjacent squamous epithelium.

Other Microscopic Types

Carcinomas of surface epithelial origin other than squamous cell carcinoma of either the conventional or verrucous carcinoma types include the following:

1. **Adenoid (pseudoglandular) squamous cell carcinoma**. This tumor exhibits a pseudoglandular or alveolar appearance because of acantholysis. Most examples are located in the lip and, like their more common cutaneous counterparts, are associated with, and probably induced by, actinic radiation; however, a few have been seen in the gingiva or tongue, where an actinic pathogenesis cannot be invoked.[171]
2. **Adenosquamous carcinoma**. In contrast to the type listed previously, the rare adenosquamous carcinoma shows areas of squamous differentiation admixed with others having true glandular differentiation.[172] Some of these cases may be of minor salivary gland derivation, but they are substantially different from mucoepidermoid carcinomas.[173]
3. **Basaloid squamous cell carcinoma**. This is an aggressive variant of squamous cell carcinoma that has a predilection for the upper aerodigestive tract (oral cavity, oropharynx, esophagus, and larynx) but also occurs in other sites such as lung.[174] In basaloid carcinoma, areas with obvious squamous differentiation are admixed with solid tumor islands composed of undifferentiated basaloid cells that exhibit peripheral palisading and a thick basement membrane (Fig. 4.22).[175] Small cystic spaces containing mucoid or hyaline material are present, resulting in a resemblance to adenoid cystic carcinoma. The prominence of basal lamina material is one of the most striking attributes of this tumor at both the ultrastructural and immunohistochemical level. Immunoreactivity for high-molecular-weight keratin (detected with the 34βE12 antibody) and p63 is a consistent feature of this tumor.[176] Occasional examples have a spindle cell component.[177] The differential diagnosis includes minor salivary gland tumors (particularly adenoid cystic carcinoma)[178] and peripheral ameloblastoma.

   Adenoid cystic carcinoma shows a lower nuclear grade and exhibits focal glandular differentiation, whereas basaloid squamous cell carcinoma shows squamous differentiation. Both adenoid cystic carcinoma and basaloid squamous cell carcinoma are immunoreactive for 34βE12 and p63.[154]

   HPV-16 is detectable in the large majority of oropharyngeal basaloid squamous cell carcinomas, but only in few of those arising in other sites. The absence of HPV-16 in these tumors is associated with a decreased overall survival.[160]
4. **Papillary squamous cell carcinoma.** This is an uncommon variant in the oral cavity. It is seen most frequently in the oropharynx and larynx of elderly individuals and shows a frequent association with HPV infection.[179] Papillary squamous cell carcinoma of the oral cavity and oropharynx is associated with a good prognosis.

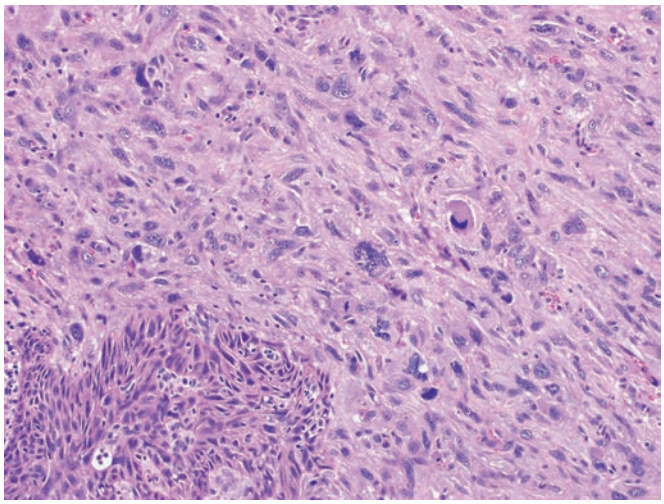

Figure 4.23 Spindle Cell (Sarcomatoid) Carcinoma. The island in the bottom left is clearly identifiable as squamous cell carcinoma, whereas the remaining component has a pleomorphic sarcoma-like appearance.

5. **Spindle cell (sarcomatoid) carcinoma**. This may appear as an ulcerated and infiltrative mass or as a polypoid growth in the lip, tongue, or other portions of the oral cavity. Sometimes the sarcoma-like formation blends with areas of obvious squamous cell carcinoma or represents the recurrence of what originally was an obvious squamous cell carcinoma (Fig. 4.23).[180] Other tumors are associated with squamous CIS or severe dysplasia. These findings, plus a wealth of electron microscopic, immunohistochemical, and molecular data, indicate that the sarcoma-like component represents a metaplastic change of an originally epithelial neoplasm.[181] Immunostains helpful in the distinction between sarcomatoid carcinoma and sarcoma (in the sense of favoring the former if positive) are keratin 5/6, epithelial membrane antigen (EMA), membranous epithelial cadherin, and nuclear p63.[182] Unfortunately, even a broad panel of epithelial immunohistochemical markers will be negative in a significant percentage of cases.

   The sarcoma-like component may look like an undifferentiated pleomorphic sarcoma or fibrosarcoma of soft tissue or it may show evidence of specific mesenchymal differentiation, particularly along muscle lines.[183] The nodal and distal metastases of this tumor may be purely carcinomatous, have a mixed appearance as in the primary neoplasm, or, in rare cases, be entirely composed of sarcoma-like elements. The prognosis is closely related to the stage and depth of invasion and is not significantly different from ordinary squamous cell carcinoma of equivalent stage and thickness.[184]
6. **Small cell carcinoma**. The appearance is similar to that of the homonymous lung carcinoma.[185] It may be pure or associated with a squamous component and its behavior is very aggressive.[186]
7. **Lymphoepithelioma-like carcinoma**. A tumor microscopically similar to the lymphoepithelioma of the nasopharynx and tonsil is occasionally found in the oral cavity or oropharynx.[187,188]
8. **NUT (midline) carcinoma**. This newly recognized type of carcinoma is defined by a molecular genetic alteration, but its diagnosis can be suspected on the basis of its clinicopathologic features.[189] Clinically it affects midlines structures, particularly those in the head and neck areas. Most of the initial reported cases were in children and young adults, but they were subsequently seen in all age groups. The most typical morphologic pattern is represented by foci of undifferentiated carcinoma showing islands of keratinization, *with a sharp interphase between the two*, accentuated by the immunohistochemical profile (CK8/18 positive in the undifferentiated areas and CK5/6 or p63 positive in the keratinizing areas). Prior to its recognition, this tumor was usually interpreted as sinonasal undifferentiated carcinomas, poorly differentiated squamous cell carcinoma, small cell carcinomas, or the basaloid squamous cell carcinomas.[189]

   At the molecular level, the tumor is defined by rearrangement of the *NUT* gene on chromosome 15q14.[190] The diagnosis is confirmed by documenting nuclear expression of NUT in the nuclei of the undifferentiated cells by immunohistochemistry (with the C52 monoclonal antibody) or by detecting the chromosome translocation *BRD4-NUT* or one of its variants (such as *BRD3-NUT*) by fluorescent in situ hybridization or reverse transcriptase-polymerase chain reaction (RT-PCR).[190,191] This tumor runs an extremely aggressive clinical course but has been found to respond well to the chemotherapeutic regimen used for Ewing sarcoma/primitive neuroectodermal tumor (PNET).[192]

Tumors and Other Lesions of Minor Salivary Glands

Minor salivary glands, present in practically all compartments of the oral cavity, participate in many of the diseases affecting their major counterparts, a feature that can be exploited for diagnostic purposes. Thus biopsy of the lower lip has shown involvement of the minor salivary glands in cases of *cystic fibrosis*[193] and *Sjögren syndrome*[194] and has also been used to diagnose end-stage *chronic GVHD*.[195]

Adenomatoid hyperplasia is a term used for a localized hyperplastic process of minor salivary glands appearing clinically as a nodule, usually in the hard palate but occasionally in the retromolar area.[196]

Intraoral minor salivary glands can give rise to a variety of benign and malignant tumors. The hard palate is the most common location, but similar tumors also occur in the soft palate, cheek, tonsil, floor of the mouth, tongue, lip (usually the upper), gingiva, and jaw. It is important to remember that tumors arising in the deep lobe of the parotid gland may present as primary intraoral masses. With a few exceptions, minor salivary gland tumors are morphologically analogous to those located in the major glands[197,198]; however, they differ from the latter in their relative incidence and, to some extent, in their natural history.[199]

Pleomorphic adenomas (benign mixed tumor), which constitute over 75% of all parotid neoplasms, make up about half of the salivary gland tumors of the palate but are otherwise similar to major salivary gland pleomorphic adenomas.[200–202] They may be overdiagnosed as malignant because of increased cellularity, nuclear atypia in the often predominant myoepithelial component (see under "Myoepithelioma"), or pseudoepitheliomatous hyperplasia of the overlying mucosa.[203]

Adenoid cystic carcinoma, mucoepidermoid carcinoma, and **polymorphous low-grade adenocarcinoma** (see later section) comprise the large majority of intraoral malignant salivary gland tumors, in contrast to the more even distribution of tumor types seen in the parotid gland. Rare cases of **acinic cell carcinoma** and of **epithelial–myoepithelial carcinoma** (to be distinguished from pure myoepithelioma, see later) have also been described.[204,205] The prognosis of adenoid cystic carcinoma is said to be better when the tumor is located in the palate than when arising in the parotid or submandibular gland,[201] but this may be at least partially due to the inclusion among the palatal tumors of some cases of

polymorphous low-grade adenocarcinomas. The prognostic difference among the various morphologic subtypes of this tumor, which has been noted for the major salivary gland, seems to apply also to this location.[206] Of the salivary gland tumors located in the lip, about 80% are benign. Among the malignant types, adenoid cystic carcinoma and mucoepidermoid carcinoma are the most frequent.[207]

Some types of salivary gland tumor occur predominantly or, in some instances, almost exclusively in the minor salivary glands of the oral cavity. They include the following:

1. **Canalicular adenoma**. This tumor, characterized by a canalicular pattern of growth (Fig. 4.24), has a predilection for the upper lip, buccal mucosa, and palate (often at the junction between the hard and soft regions), where it is sometimes confused with adenoid cystic carcinoma.[202,208,209] In contrast to adenoid cystic carcinoma, canalicular adenomas are diffusely positive for S-100 and demonstrate only focal and weak p63 staining if positive.
2. **Myoepithelioma**. This lesion, composed of hyaline or plasmacytoid cells, usually involves the hard palate (Fig. 4.25). The differential diagnosis includes plasmacytoma, oncocytoma, and even skeletal muscle neoplasms. Despite its high cellularity and the occasional presence of atypical hyperchromatic nuclei and intravascular tumor cells, the behavior is generally benign.[210,211]
3. **Sialadenoma papilliferum**. This is a papillary tumor of the oral cavity, usually located in the hard palate or buccal mucosa and characterized microscopically by a biphasic composition. An exophytic mass of well-differentiated squamous epithelium is seen covering a glandular component consisting of cleft-like cystic spaces lined by cuboidal or columnar epithelium; some of these glands may contain oncocytic cells, and others may exhibit squamous metaplasia.[212] The stroma is usually rich in plasma cells. The appearance is reminiscent of both Warthin tumor of the parotid gland and papillary syringocystadenoma of skin, both at the light and electron microscopic level.
4. **Inverted ductal papilloma**. This tumor has a pattern of growth similar to that of inverted papilloma of the nasal cavity. It appears clinically as a small submucosal mass in the oral cavity of adults. Microscopically, there are complex invaginations formed by well-differentiated, predominantly squamous epithelium–associated microcysts, occasional mucous cells, and a lining of columnar cells. The behavior is benign.[213]
5. **Clear cell carcinoma.** This is a low-grade carcinoma that predominantly occurs in intraoral minor salivary glands of adults.[214] The palate is most frequently involved, but all oral sites can be involved such as alveolar ridge, tongue, tonsil, floor of mouth, and buccal mucosa. Microscopically, they are composed of sheets or nodules of large polygonal cells with abundant cytoplasmic glycogen and lacking in atypia or mitotic activity (Fig. 4.26). The stroma can be hyalinized and paucicelluar or composed of a cellular spindled myofibroblastic stroma. The cells are positive for keratin and p63 with variable S-100 staining. They may be associated with recurrence and regional lymph node metastasis, but they rarely metastasize distantly or result in death. Recently these tumors have been shown to have a consistent *EWSR1-ATF1* fusion.[215]
6. **Polymorphous low-grade adenocarcinoma.**[216,217] This is the currently preferred term for a low-grade malignant tumor that has also been called *low-grade papillary adenocarcinoma*,[218,219] *terminal duct carcinoma*,[220] and *lobular carcinoma*.[221] Adult females are most

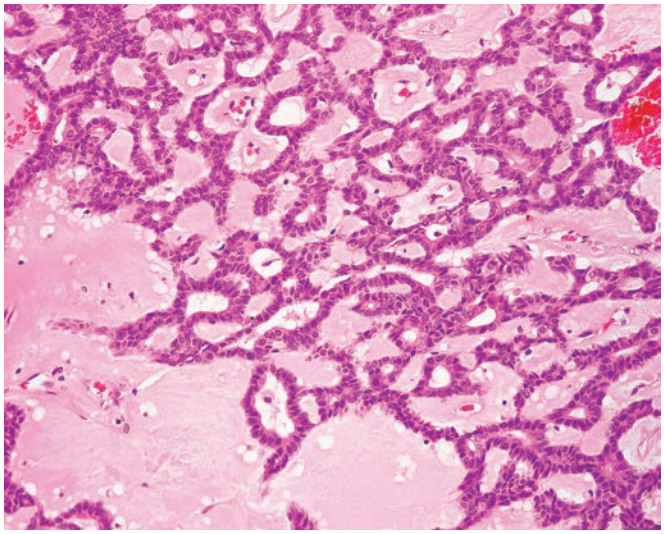

Figure 4.24 Canalicular Adenoma. This type of benign salivary gland tumor is particularly common in the lip.

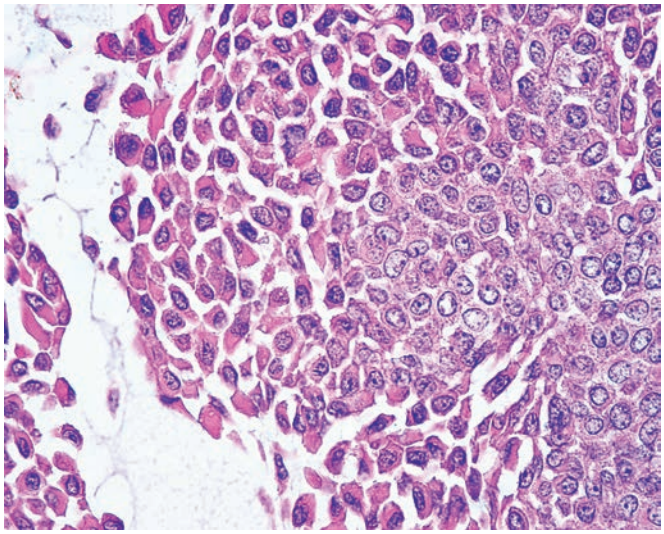

Figure 4.25 Myoepithelioma exclusively composed of so-called hyaline or plasmacytoid cells.

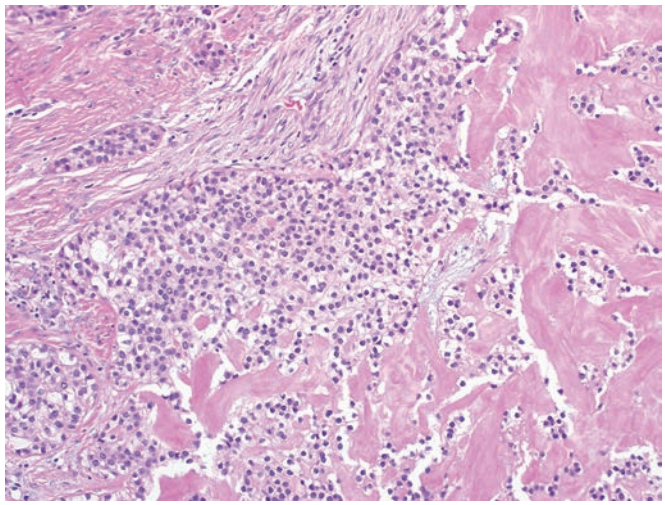

Figure 4.26 Clear Cell Carcinoma of Minor Salivary Glands. These typically arise in intraoral minor salivary gland and are composed of irregular islands composed of large clear cells associated with a hyalinized to spindled stroma.

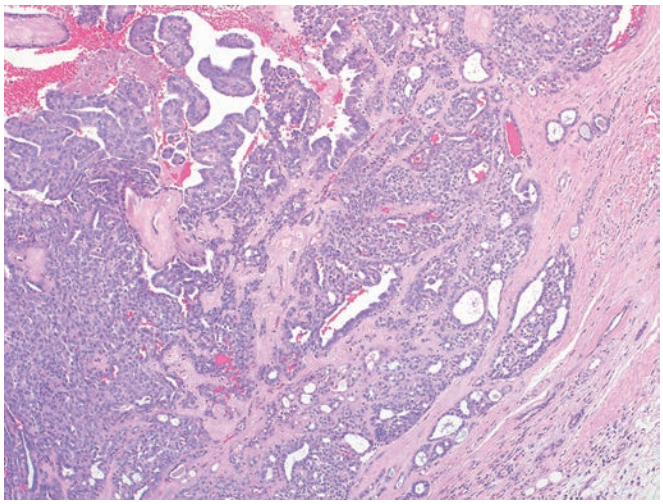

Figure 4.27 Polymorphous Low-Grade Adenocarcinoma. At low power, multiple architectural patterns can be seen including solid, tubular and papillary in this example.

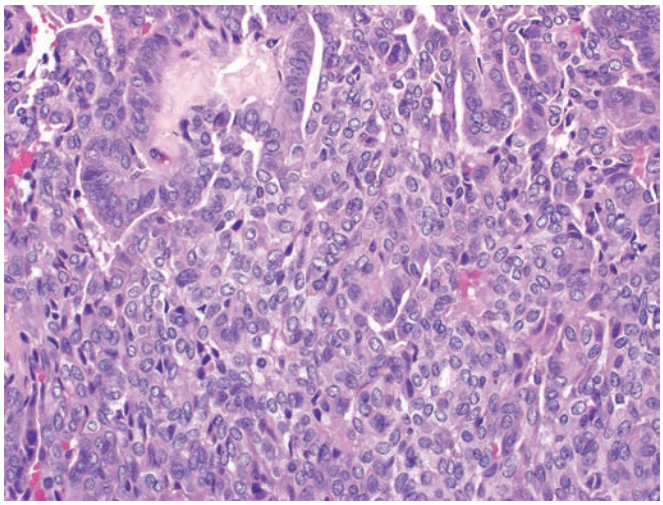

Figure 4.28 Polymorphous Low-Grade Adenocarcinoma. The cells are monotonous with oval nuclei containing pale chromatin, somewhat resembling the nuclei seen in papillary thyroid carcinoma.

commonly affected.[216] The palate is the most common location, but all intraoral sites can be involved. Polymorphous low-grade adenocarcinoma is the second most common type of salivary gland carcinoma in this location following adenoid cystic carcinoma.[222] Microscopically, there is uniformity of cell type but a marked variation in architectural patterns, which is responsible for the various names that this tumor has received.[223] Tubular, cribriform, papillary, solid, and fascicular formations may appear, with frequent combinations and transitions (Figs. 4.27 and 4.28). The tumor nuclei are typically oval with pale chromatin and occasional nuclear grooves imparting a resemblance to papillary thyroid carcinoma. The periphery of the tumor has invasive features, sometimes in an Indian-file pattern, which has led to a strained analogy with invasive lobular carcinoma of the breast. Perineurial invasion is also common and may have a targetoid appearance. Mitotic activity is inconspicuous. Extensive S-100 protein immunoreactivity is present, suggesting possible derivation from intercalated ducts.[224] They are often p63 positive, but the staining is focal and of variable intensity. C-kit is often positive in polymorphous low-grade adenocarcinoma, limiting its utility in the differential diagnosis. The differential diagnosis includes benign mixed tumor, canalicular adenoma, basal cell adenoma (all of which lack infiltrative features), and in particular adenoid cystic carcinoma.[220] However, the last lacks the plump and columnar cells of polymorphous low-grade adenocarcinoma, as well as its papillary and fascicular growth patterns. In addition, adenoid cystic carcinomas are not diffusely S-100 positive and have diffuse strong p63 staining in the myoepithelial/basal cell component. The behavior of this tumor is that of a low-grade malignancy. In one series of 69 cases, recurrences developed in 12% and regional lymph node metastases in 10%, but there were no distant metastases, and there was only one tumor-related death.[224] In another series, consisting of 164 cases, 97.6% of the patients were either alive or had died of other diseases.[216] Tumors with a conspicuous papillary component are associated with a higher incidence of lymph node metastases.[217] Rarely, polymorphous low-grade adenocarcinoma may undergo transformation to a high-grade tumor.[225,226] A majority of polymorphous low-grade adenocarcinomas have recently been shown to have *PRKD1* activating mutations.[227]

The recently described *cribriform adenocarcinoma of minor salivary glands* (cribriform adenocarcinoma of the tongue) is mentioned here despite its obscure histogenesis and also because its differential diagnosis includes several types of salivary gland tumor. Morphologically, it resembles the solid and follicular variants of papillary thyroid carcinoma (to the point of raising the possibility of an origin from the thyroglossal duct anlage), but thyroglobulin stains are negative.[228] Some consider this a variant of polymorphous low-grade adenocarcinoma due to significant histologic and immunophenotypic overlap. This is supported by recent molecular evidence demonstrating translocations involving the *PRKD1* gene and the related *PRKD2* and *PRKD3* genes.[227] In contrast to polymorphous low-grade adenocarcinoma, cribriform adenocarcinoma of minor salivary glands most often arises in the tongue base and more often presents with cervical lymph node metastasis. Despite this latter fact, they are associated with an overall favorable prognosis.

The treatment of minor salivary gland tumors is primarily surgical. It has been emphasized that the first excision should be the most definitive and comprehensive and that treatment of recurrent disease is rarely curative.[229] Postoperative irradiation is generally recommended for all high-grade malignancies, including adenoid cystic carcinoma.[229]

Tumors of Odontogenic Epithelium

Peripheral ameloblastoma is a tumor of the oral cavity, not involving bone but exhibiting microscopic features of ameloblastic differentiation (Fig. 4.29). As a matter of fact, its appearance is indistinguishable from that of ameloblastoma of the jaw (see Chapter 5).[230] Most of the reported cases have occurred in the gingiva, and several have been published in the past as basal cell carcinomas. A desmoplastic variety has been described.[231] Theoretically, peripheral ameloblastomas could arise from remnants of the dental lamina within the gingiva ("rests of Serres") or from surface epithelium that has retained the capacity to differentiate along odontogenic structures. They are more indolent than their counterparts in the jaw and are generally cured by local excision.[230]

Tumors of Melanocytes

Ephelis and **lentigo** (melanotic macules) can present as solitary lesions of the oral cavity, usually the lower lip.[232] They are more

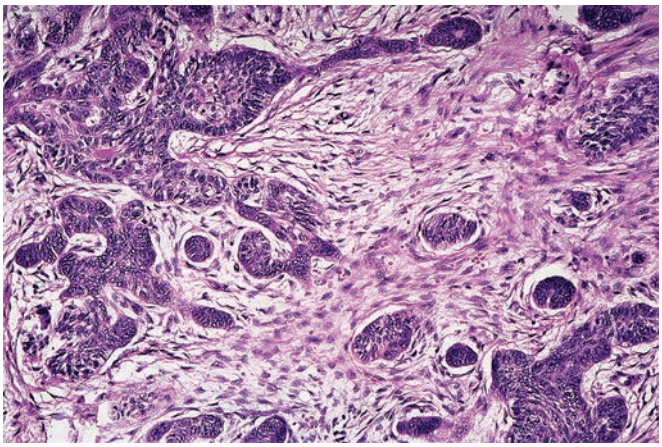

Figure 4.29 Peripheral Ameloblastoma. This tumor connected with the lining epithelium of the gingival mucosa and did not involve the jawbones but is otherwise identical to intraosseous ameloblastomas.

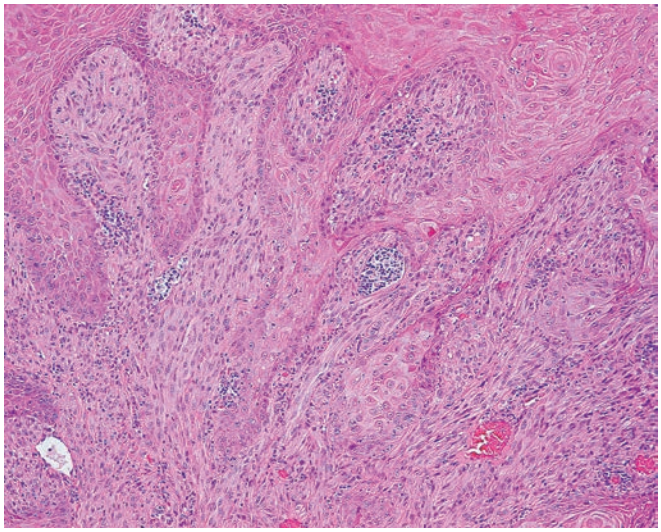

Figure 4.30 Spitz nevus of tongue accompanied by intense pseudoepitheliomatous hyperplasia of the overlying squamous epithelium.

common in females and are characterized microscopically by hyperpigmentation of the basal layer, associated in the case of lentigo with elongation of the rete ridges. The term *melanoacanthoma* has been used when the melanocytic proliferation extends above the basal layer and is found intimately admixed with the keratinocytes.[233] Multiple pigmented macules of the lip are one of the components of the Peutz–Jeghers syndrome and Carney complex. The presence of pigmented patches within the oral cavity (usually located in the hard palate or gingiva) is known as **melanosis**.

Melanocytic nevi may involve the lips and, in rare cases, the inside of the oral cavity.[234–236] In one series, there were 3 junctional, 30 compound, 32 submucosal (equivalent of the cutaneous intradermal), and 6 blue nevi.[237]

Spitz nevus may involve the tongue and be associated with pseudoepitheliomatous hyperplasia of the overlying squamous epithelium, to a degree that may simulate both malignant melanoma and squamous cell carcinoma (Fig. 4.30).[238]

Malignant melanoma of the oral cavity is particularly common in people of Japanese and black African origin. The hard palate and gingiva are the most common locations.[239] Both pigmented and amelanotic varieties occur.[240] Some of the tumors have desmoplastic features, especially when occurring in the lower lip. These are often underdiagnosed because of their scarce cellularity and sometimes less than prominent atypia. The diagnosis should be suspected in the presence of a spindle cell proliferation in the lamina propria with a fascicular pattern of growth, particularly if accompanied by prominent clusters of lymphocytes in the peripheral portion.[241] The diagnosis is supported by the S-100 protein positivity; however, this is usually accompanied by negativity for Melan-A and HMB-45.[242] Conventional melanoma, by contrast, is usually positive for all three markers.[242]

Oral "melanosis" adjacent to the area of invasive melanoma is found in about 30% of the cases; in most instances, there is some degree of atypia in this intraepithelial component. Lymph node and distant metastases are common, and the prognosis is extremely poor.[243] The histologic parameters used for predicting prognosis of cutaneous melanomas do not apply as well.[244]

Tumors and Tumorlike Conditions of Lymphoid Tissue

Benign nodules made of mature small lymphocytes, with or without an admixture of histiocytes, are not uncommon in the oral cavity. They may represent enlarged buccal lymph nodes or hypertrophic buccal tonsils, or may be associated with cystic glandular structures (*"lymphoepithelial cysts"*).[245] The most prominent of these benign lymphoid proliferations occur in the palatine tonsils and are designated *lymphoid polyps* or *pseudolymphomas*, but it is better to avoid the latter term.[246]

Malignant lymphoma most commonly occurs in the Waldeyer ring, particularly in the palatine and lingual tonsil, but it can also develop in the gingival area, buccal mucosa, palate, or lips. Most patients are in their sixth or seventh decade, but cases have been reported in younger patients and even in children.[247] The typical clinical presentation is that of a soft, bulky mass covered by normal or ulcerated mucosa. Microscopically, most cases are of B-lineage and follicular center cell origin, of large size and with a generally diffuse pattern of growth.[248–252] In about 40% of the cases, there is evidence of disease outside the oral cavity, particularly in the cervical lymph nodes and gastrointestinal tract.[253] A high proportion of the latter represent cases of marginal zone lymphoma.[249,254] T-cell lymphomas can also occur in this location[255] (including mycosis fungoides[256]), as well as anaplastic large cell lymphomas.

As for malignant lymphomas elsewhere, clinical staging and microscopic typing are the two most important prognostic factors.[248]

Plasmacytomas can occur in the soft tissues of the oral cavity, although not so commonly as in the upper air passages.[257] It is important to distinguish them from the more common *plasma cell granulomas* of reactive nature,[258] including so-called *mucous membrane plasmacytosis*[259] or *plasma cell mucositis*.[260] These disorders are composed of mature plasma cells, have a mixture of other inflammatory cells, and are associated with fibrosis. Immunohistochemical staining for immunoglobulin light chains may help in this differential diagnosis as plasmacytomas will demonstrate a monoclonal population of either kappa- or lambda-expressing cells.

Hodgkin disease presenting initially in the oral cavity is extremely rare, but several reported cases are on record.[261] Most of them were located in the Waldeyer ring, and there was a predilection for the lymphocyte-rich classical subtype.[262]

Leukemia of acute myelocytic or myelomonocytic type is associated with gingival involvement in about 4% of the cases, with or without concomitant skin involvement.[263] In rare cases, oral cavity disease is the first manifestation of extramedullary myeloid sarcoma.[264]

Langerhans cell histiocytosis can involve the oral cavity, either as an isolated focus or as an expression of multisystem disease.[265]

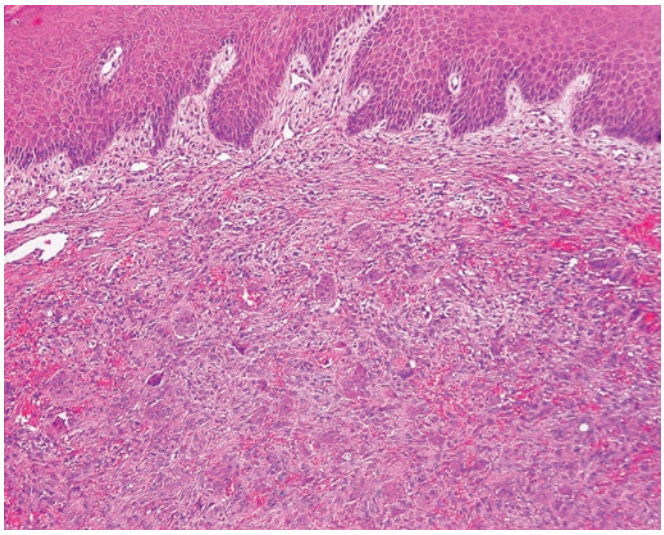

Figure 4.31 Peripheral giant cell granuloma beneath a slightly hyperplastic squamous epithelium.

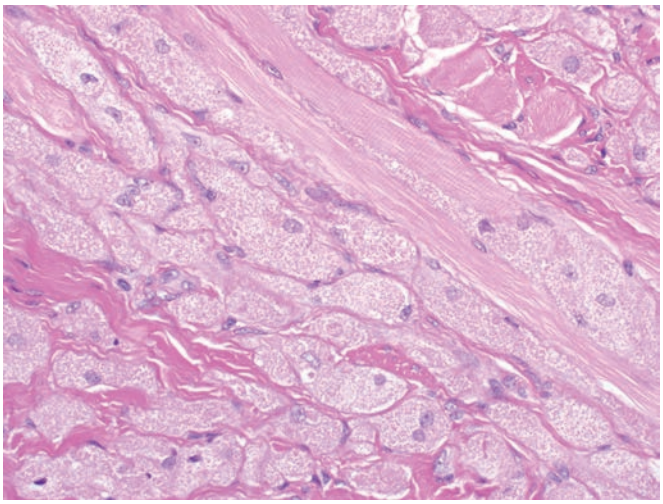

Figure 4.32 Granular Cell Tumor. The lesion shows an infiltrative pattern with growth along muscle fibers. The cells are large and polygonal with abundant granular eosinophilic cytoplasm.

Although most often found in the gingiva, the lesions can also affect the hard palate.[266]

Follicular dendritic cell tumors (dendritic reticulum cell tumors) and **histiocytic sarcomas** have been observed in the palate and tonsil.[267] These are fully discussed in Chapter 37.

Other Tumors and Tumorlike Conditions

Hamartomas of the tongue blend with some of the congenital malformations mentioned previously. They are predominantly submucosal and can be roughly divided according to their predominant composition into neurovascular, smooth muscle predominant, fat predominant, and smooth muscle and fat containing.[268]

Peripheral giant cell granuloma (giant cell epulis) is seen in all age groups and is more common in females.[269] Maxilla and mandible are affected with equal frequency. A soft-to-firm mass forms in the gingiva, often displaces adjacent teeth, and may erode the underlying bone. Microscopically, the lesion shows numerous osteoclast-like giant cells, a cellular highly vascularized stroma, and, at times, small amounts of neoformed osteoid and bone (Fig. 4.31). This common lesion is benign and probably of reactive nature.

Peripheral ossifying fibroma is a reactive lesion composed of a proliferation of bland fibroblasts with a collagenous stroma that may contain dystrophic calcification and reactive bone, the latter typically located at the deep aspect. Most occur in young adults, but a wide age range is described.[270] They occur in the gingiva, particularly near the incisors, and present as sessile mucosal covered nodules often with ulceration. Although benign, recurrences occur in about 20% of patients, necessitating excision down to the periosteum to prevent such an event.

Granular cell tumor can involve any portion of the oral cavity, the tongue being the most common site (and the one in which it was originally described by Abrikosoff) (Fig. 4.32). The overlying epithelium often shows florid pseudoepitheliomatous hyperplasia.[271] An exceptionally rare malignant counterpart of this lesion has also been described.[272] A lesion morphologically similar to granular cell tumor is seen occasionally in the gingiva of newborn infants and is called *congenital (granular cell) epulis* (Fig. 4.33). This lesion occurs almost exclusively in females and behaves in a benign fashion even if incompletely excised.[273] Histologically, it is comprised of sheets of large polygonal cells with abundant granular eosinophilic cytoplasm. The tumor has a prominent vascular stroma, and they do not induce pseudoepitheliomatous hyperplasia, features which differ from granular cell tumor. Ultrastructural studies have suggested a mesenchymal (fibroblastic, pericytic, or smooth muscle) rather than an odontogenic origin.[274,275] Staining for S-100 protein, NGFr/p75, and PGP 9.5 is negative, in contrast to the adult form of this lesion.[276]

Figure 4.33 Clinical Appearance of Congenital Granular Cell Epulis. (Courtesy of Dr. R.A. Cooke, Brisbane, Australia; From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

Verruciform xanthoma presents in middle-aged persons as a raised, granular, or verrucous lesion of the oral cavity, usually in the gingiva or alveolar ridge.[277,278] Collections of foamy macrophages in the lamina propria are covered by a verrucous and acanthotic epithelium (Fig. 4.34). The lesion is probably a reactive process rather than a true neoplasm.

Congenital dermoid (hairy polyp) is a rare congenital malformation arising from the oropharynx or nasopharynx. Microscopically, the lesion is polypoid and composed of epidermis, hair follicles, sebaceous glands, and eccrine sweat glands. Adipose tissue, smooth muscle, striated muscle, and cartilage may be present within the polyp core.[279] Excision is curative.

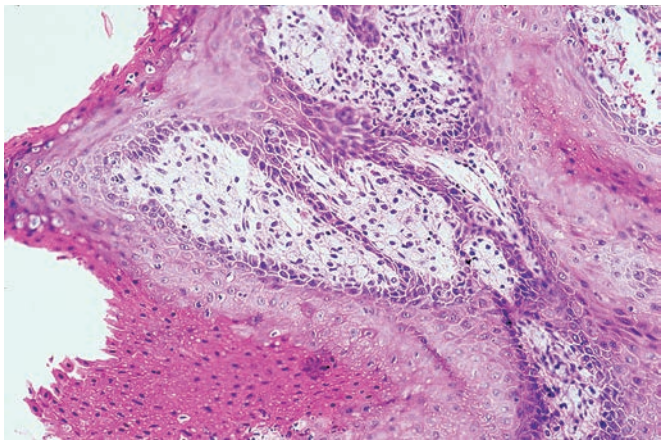

Figure 4.34 Verruciform Xanthoma. Clusters of foamy macrophages are seen expanding the stroma beneath a hyperkeratotic epithelium.

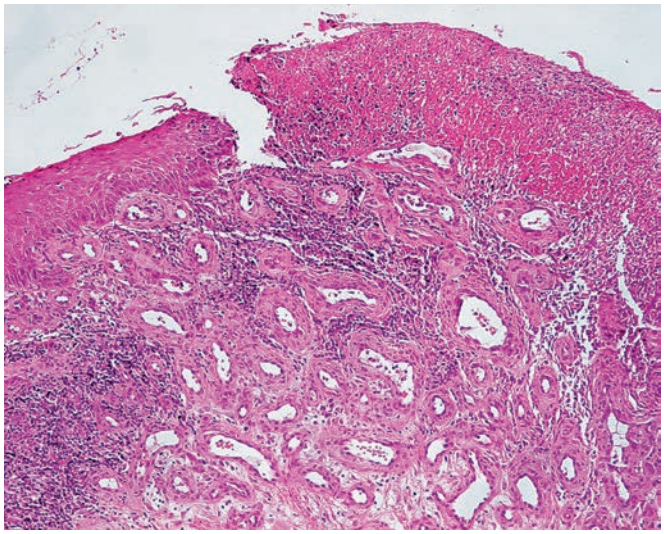

Figure 4.35 Pyogenic Granuloma. Numerous neoformed vessels are separated from each other by an inflamed and edematous stroma. The overlying mucosa is partially ulcerated.

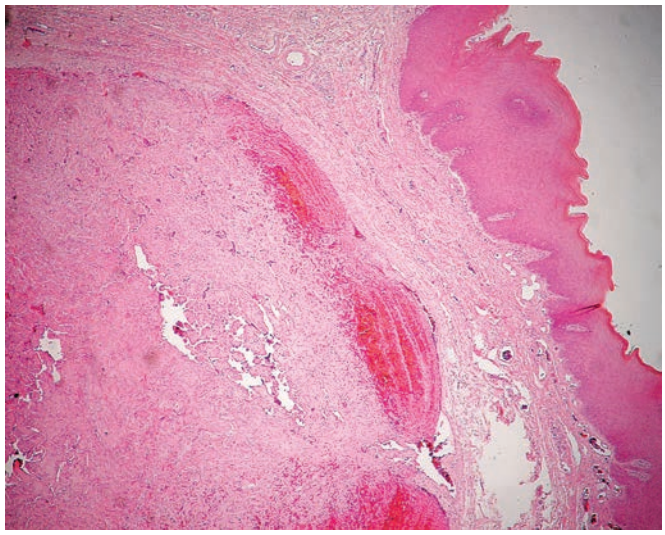

Figure 4.36 Intravascular Papillary Endothelial Hyperplasia. Remnants of the original thrombus can be seen in the more superficial portion of the nodule.

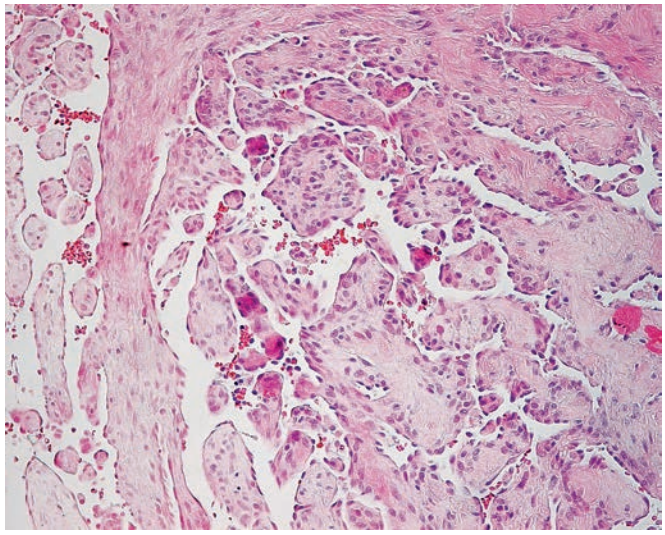

Figure 4.37 Intravascular Papillary Endothelial Hyperplasia. Papillary projections lined by endothelial cells are seen within the vascular lumen.

Vascular proliferations of the oral cavity are benign in the vast majority of cases. Two of the most common types are probably not even neoplastic, although their ability to simulate a malignant process is not to be underestimated.[280] The first is *pyogenic granuloma (lobular capillary hemangioma)*, which appears as an elevated, dark red lesion that may or may not be ulcerated (Fig. 4.35).[281] Large masses of proliferating endothelial and perithelial cells are separated by an edematous stroma containing inflammatory cells, imparting a lobular configuration to the vascular proliferation. Characteristically, the covering epithelium makes a collarette and almost meets at the base of the lesion. The lesion may regress completely or heal as a residual fibrous mass or fibroepithelial papilloma.[282] An identical lesion occurring during pregnancy has been referred to as granuloma gravidarum or pregnancy tumor.[283]

The second most common benign and probably non-neoplastic intraoral vascular lesion is *intravascular papillary endothelial hyperplasia (Masson hemangioma)*. It can occur de novo or be superimposed on a preexisting hemangioma (Figs. 4.36 and 4.37).[284] Both this lesion and pyogenic granuloma occur most commonly in the lip, their features sometimes overlapping.[280]

Benign vascular tumors are largely represented by *hemangiomas* and *lymphangiomas*.[285] Most of these are located in the tongue, where they can result in soft cystic masses large enough to interfere with speech and mastication. Microscopically, most of these lesions have markedly dilated ("cavernous") vascular or lymphatic channels. The treatment is surgical. *Tonsillar lymphangiomatous polyps* present as unilateral tonsillar masses composed of dilated lymph channels covered by hyperplastic squamous epithelium, resulting in a typical polypoid configuration.[286] Other benign or borderline vascular tumors that may present intraorally are *glomus tumor*,[287] *epithelioid hemangioma* (angiolymphoid hyperplasia with eosinophilia) (Fig. 4.38),[288,289] and *epithelioid hemangioendothelioma*.[290]

Kaposi sarcoma of the oral cavity can be seen in individuals with HIV infection and sometimes represents the first manifestation of the disease. The palate is the most common site. Clinically, the lesions may appear as small, well-delineated macular lesions or as larger, infiltrative nodules.[291] Microscopically and immunohistochemically, the features are generally similar to those of its cutaneous

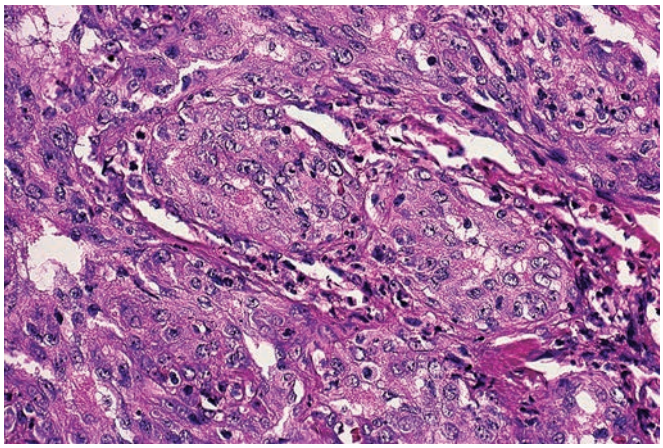

Figure 4.38 Epithelioid Hemangioma of Soft Tissues of Oral Cavity. This lesion tends to be overdiagnosed as a malignant vascular neoplasm and sometimes is confused with carcinoma.

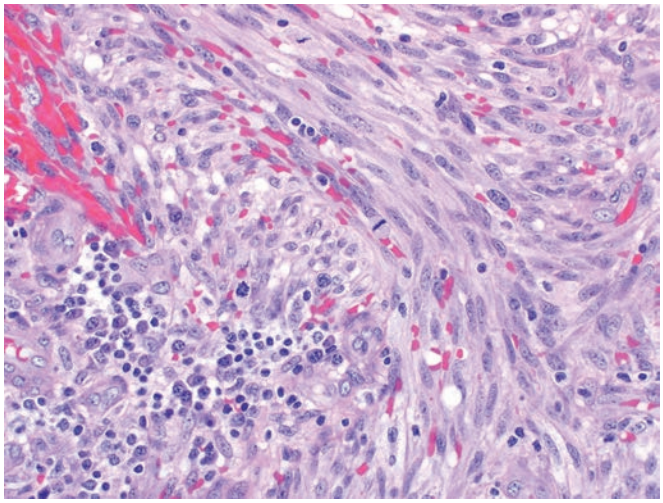

Figure 4.39 Kaposi Sarcoma of Oral Cavity. Atypical spindle cells form slit-like vascular channels containing red blood cells.

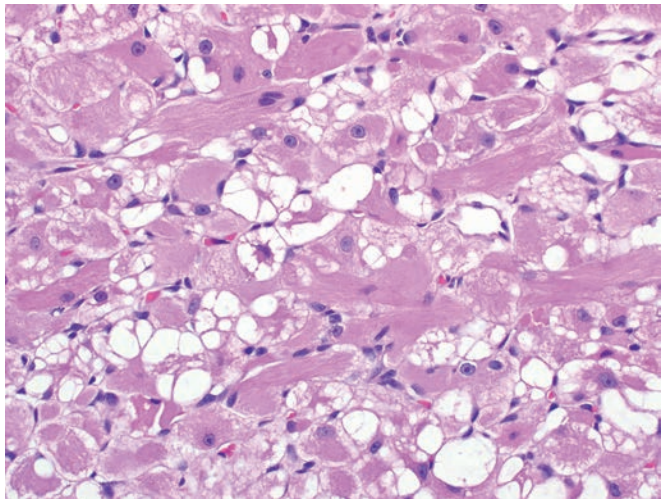

Figure 4.40 Adult Rhabdomyoma of Oral Cavity. Large eosinophilic cells contain cytoplasmic vacuoles, some of which resemble "spider cells." Cross striations can be seen focally in many cases.

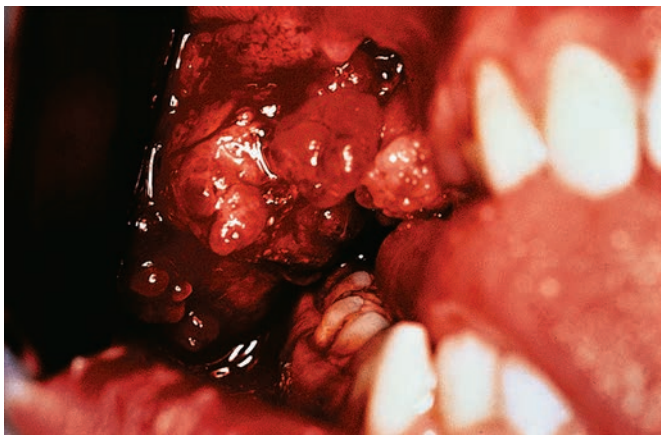

Figure 4.41 Clinical appearance of embryonal rhabdomyosarcoma of oral cavity in an infant.

counterpart (Fig. 4.39).[292] *Angiosarcoma* of the oral cavity is very rare.[293–295] Before making a diagnosis of angiosarcoma in the oral cavity (particularly if the lesion is in the lip or tongue), the much more likely possibility of a benign vascular process of one of the types previously described should be considered.[280]

Solitary fibrous tumor may present in the oral cavity as a well-circumscribed submucosal mass; the behavior of the reported cases has been benign.[296]

Rhabdomyomas have a special predilection for the oral cavity and neck. The floor of the mouth is the most common location,[297,298] but they also occur in the tongue.[299] Both adult and fetal forms have been described, as well as intermediate ("juvenile") forms.[300] The adult type is the most common and is usually well circumscribed and may be multiple.[301] It may recur locally and display cytogenetic abnormalities, features more in keeping with a neoplastic than a hamartomatous process.[302] Histologically, they are composed of sheets of very large eosinophilic cells with a low nuclear-to-cytoplasmic ratio. Cytoplasmic vacuolization results in a characteristic "spider" cell morphology, and cross striations can be seen (Fig. 4.40). Fetal rhabdomyomas resemble embryonal rhabdomyosarcoma but typically are circumscribed and lack cytologic atypia and mitotic activity.

Embryonal rhabdomyosarcomas have been described in the tongue and most other oral sites in children (Figs. 4.41 and 4.42).

Peripheral nerve tumors and tumorlike conditions of the oral cavity and pharynx include *schwannoma* (often located in the tongue),[303,304] *neurofibroma*,[305] *traumatic neuroma* (sometimes containing mature ganglion cells),[306] and the *multiple mucosal neuromas* seen as a component of multiple endocrine adenomatosis type IIb. These lesions resemble plexiform neurofibromas and may be found in the lips, tongue, conjunctiva, nasal cavity, and larynx.[307] They are made up of all the elements of the normal nerve, including a thickened EMA-positive perineurial layer.[308] *Malignant peripheral nerve sheath tumors* of the oral cavity, some of which are pigmented, have also been described.[309]

Other **benign soft tissue tumors** that have been reported in this location are *lipoma* (including variants such as myxoid lipoma, spindle cell lipoma, sialolipoma,[310] and lipoma with osseous and chondroid metaplasia)[311–314] *chondroma*,[315] *angiolipoma*,[316] and *PEComa*.[317]

A unique intraoral neoplasm exhibiting myxochondroid features has been termed *ectomesenchymal chondromyxoid tumor*; most have occurred in the anterior tongue (Fig. 4.43).[318] Microscopically, they are characterized by a lobular proliferation of oval and spindle cells in a chondromyxoid background. Immunohistochemically, the tumor

cells are reactive for glial fibrillary acidic protein (GFAP) and keratin and less frequently for smooth muscle actin and S-100 protein (but not for EMA and desmin). These are benign tumors that tend not to recur following excision.

Synovial sarcomas can occur as primary tumors in the pharynx, tonsil, cheek, tongue, or palate of young adults[319,320]; the main differential diagnosis is with salivary gland tumors, particularly cellular pleomorphic adenoma, epithelial–myoepithelial carcinoma, and carcinoma ex pleomorphic adenoma (Fig. 4.44).

Other reported sarcoma types of the oral cavity include **alveolar soft part sarcoma,**[294] **extraskeletal osteosarcoma,**[321] **fibrosarcoma** (Fig. 4.45), and **liposarcoma/atypical lipomatous tumor** (including the dedifferentiated form of the latter).[322,323]

Metastatic tumors may present as primary intraoral masses. The gingiva is the classic location, with or without bone involvement. The lung is the most common site of the primary lesion.[324,325] Metastatic renal cell carcinoma can masquerade clinically and microscopically as a pyogenic granuloma. Other sites for the primary tumor include breast, kidney, skin (melanoma and squamous cell carcinoma), prostate, endometrium, large bowel, and pleura (mesothelioma).[326–329]

Respiratory Tract

Normal Anatomy

The nasal cavity, paranasal sinuses, and nasopharynx form a functional unity that is reflected in the commonality of the pathologic processes that involve the region. This is particularly the case for the first two sites, which are often grouped under the term *sinonasal*.

The two main types of epithelia lining these structures are stratified squamous and respiratory-type pseudostratified columnar. The interphase between them is sharp in some areas, whereas in others there is an intervening zone of transitional (intermediate) epithelium. The latter resembles the urothelium of bladder and related structures at the light microscopic level but is ultrastructurally distinct from it.[1]

Each of these types of epithelia has its own distinctive cytokeratin profile as evaluated immunohistochemically.[330]

Numerous submucosal seromucinous glands are present throughout; they are particularly numerous in the region of the eustachian tube opening in the nasopharynx. Focal oncocytic metaplasia of these glands is common with advancing age. In *melanocytic oncocytic metaplasia*, a pigmented patch is seen around the eustachian tube

in which oncocytic metaplasia of the seromucinous glands is associated with melanin pigmentation.[331]

The roof of the nasal cavity contains the olfactory mucosa. In the normal human fetus this mucosa extends to the midportion of the nasal septum and onto the superior turbinate in a continuous fashion, whereas in adults many of these areas are replaced by respiratory epithelium.[332] The olfactory mucosa consists of three types of cell: olfactory nerve cells (bipolar cells whose axons pass through the cribriform plate to end in the olfactory bulb); sustentacular or supporting cells (microvilli-containing cylindrical cells); and basal cells (basally located small conical cells thought to be stem cells). Beneath the mucosa lie the olfactory glands of Bowman.[333]

Organized lymphoid tissue is present throughout the nasopharynx, which forms part of the Waldeyer ring. In addition to the pharyngeal tonsil (commonly referred to as the adenoid), lymphoid cells are abundant in the rim of the eustachian tube opening *(Gerlach tonsil)*. Conversely, lymphoid cells are scanty in the sinonasal region.

Inflammatory (Including "Allergic") Polyp

Nasal polyps are not true neoplasms. Their formation is associated with inflammation, allergy, or mucoviscidosis. Clinically, they appear as soft exophytic masses that extend laterally from the mucosa into the anterior part of the middle meatus.[334] Bilaterality is the rule. With time, they can fill the entire nasal cavity and even extend upward into the cranial cavity.[335] A morphologically similar type of polyp can be seen arising from one of the paranasal sinuses; this is referred to as *choanal polyp* and is subdivided according to its specific location into antrochoanal (the most common), sphenochoanal, and ethmoidochoanal.[336] Microscopically, the polyps are composed of a loose myxoid or hyaline stroma surrounding mucous glands and are covered by respiratory epithelium, which often exhibits foci of squamous metaplasia. They are infiltrated by lymphocytes, plasma cells, mast cells, neutrophils, and eosinophils.[337] Among the lymphocytes, there is a predominance of CD8+ (suppressor/cytotoxic) over CD4+ (helper/inducer) cells.[338] The eosinophils are immunoreactive for E62 (an activation marker), suggesting that they play a role in the pathogenesis of these polyps.[339] Eosinophils are not restricted to the polyps having a presumed allergic pathogenesis, although they are more numerous in them (Fig. 4.46).[340] Prominent thickening of the basal membrane is a common accompanying finding.

Occasionally, the stromal cells are large and pleomorphic, with bizarre hyperchromatic nuclei, and can simulate rhabdomyosarcoma or other malignancies (Fig. 4.47).[341] These cells are of a reactive nature and are similar to those sometimes seen in polyps of the oral cavity, vagina, and other mucosa-covered sites. Choanal polyps may show a prominent component of dilated vessels ("angiomatous or angiectatic polyps"), sometimes associated with thrombosis and infarct.[342]

From 6% to 10% of patients with mucoviscidosis (cystic fibrosis) develop polyps in the nasal cavity and paranasal sinuses. Therefore children presenting with nasal polyps should be investigated for this genetically determined condition. Microscopically, the polyps differ from the ordinary variety by the presence of large cystic glands with inspissated secretion in their lumina, degranulation of mast cells, preponderance of acid mucin, lack of extensive infiltration by eosinophils, and scanty submucosal hyalinization.[343,344] Nasal polyps can also develop as a complication of mucopolysaccharidosis (Hurler–Scheie syndrome).[345]

Local recurrence is common following the surgical removal of sinonasal polyps, probably because of persistence of the inciting pathogenetic factors.

Other Inflammatory Lesions

Chronic sinusitis has been traditionally divided into purulent and nonpurulent types. The maxillary sinus is by far the most commonly involved site. The disease is caused by various microbial organisms. The main microscopic features are inflammatory infiltrate, edema, glandular hyperplasia, basement membrane thickening, and squamous metaplasia.[346] Eosinophils may also be present and are occasionally numerous.[347] The underlying bone may show thickening and remodeling, with prominent osteoblastic rimming and fibrosis of the bone marrow spaces.

Mucocele of the maxillary sinus represents a complication of chronic sinusitis in which the accumulation of inflammatory exudate and the mucin secreted by the hyperplastic glands lifts the epithelial lining of the sinus and the periosteum away from the underlying bone. It is also sometimes referred to as *pseudocyst*.[348] The process gradually expands the cavity and causes destruction of contiguous bones, to the point that it can be mistaken for a malignant neoplasm.

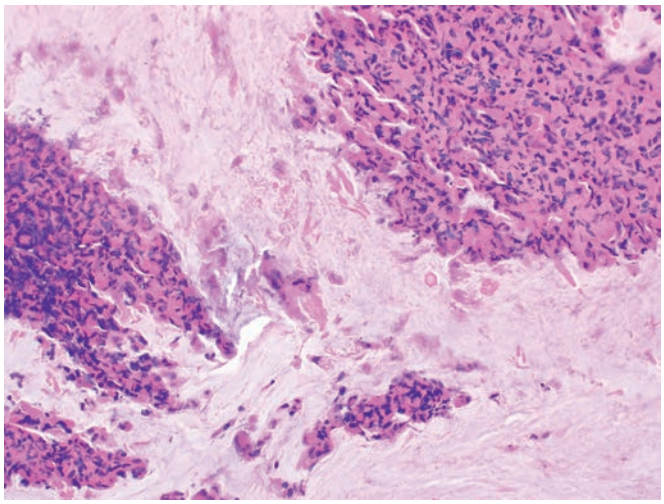

Figure 4.48 Allergic mucin with aggregates of eosinophils and sloughed epithelial cells. Within the acellular mucin, numerous Charcot–Leyden crystals are seen.

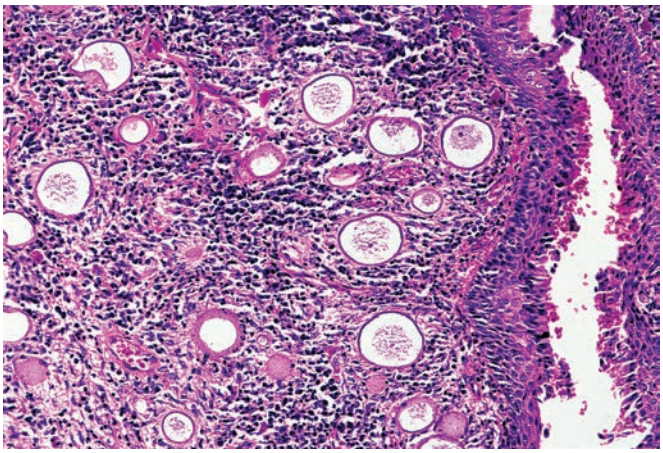

Figure 4.49 Rhinosporidiosis. Large globular cysts are present surrounded by a heavy inflammatory reaction.

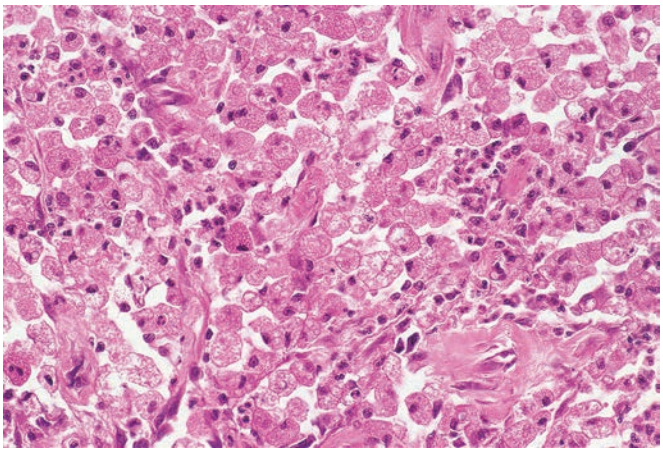

Figure 4.50 Rhinoscleroma. The infiltrate is mainly of histiocytic character, some of the cells having foamy features. The main differential diagnosis is with nasal involvement by Rosai–Dorfman disease.

Mycotic infections of the upper respiratory tract are usually located in the paranasal sinuses.[349] *Mucormycosis* is one of the most frequent, but other organisms such as *Aspergillus* can be involved as well. It usually occurs in association with poorly controlled diabetes mellitus, especially when complicated with ketoacidosis. It is also seen in the immunocompromised population. The infection may result in the formation of noninvasive mycetomas/fungus balls or spread rapidly to involve orbit and brain ("invasive fungal sinusitis").[350,351] In mucormycosis, the organisms characteristically invade blood vessels and cause thrombosis, hemorrhage, and infarction.

Allergic fungal sinusitis is a term used for an infection of the sinus caused by *Aspergillus*, *Curvularia*, or other fungal organisms that results in the formation of so-called allergic mucin (Fig. 4.48), made up of pools of mucin-containing sloughed epithelial cells, eosinophils, Charcot–Leyden crystals, and fungal hyphae[352–354] Allergic fungal sinusitis is not to be equated with *paranasal mucocele*, which results from the accumulation of mucus in a sinus because of obstruction.[355]

Rhinosporidiosis is an inflammatory disease endemic in India, but it has also been reported in other parts of the world.[356] It is characterized by hyperplastic polypoid lesions of the nasal cavity and—rarely—other mucous membranes. The diagnosis is readily made by the identification of numerous globular cysts measuring up to 200 nm in diameter (Fig. 4.49). Each of these cysts represents a thick-walled sporangium containing numerous spores. The precise nature of this organism remains enigmatic.[357] Molecular studies indicate that *Rhinosporidium seeberi* clusters with a novel group of fish parasites referred to as the DRIP clade (*Dermocystidium*, rosette agent, *Ichthyophonus*, and *Psorospermium*), near the animal–fungal divergence.[358]

Tuberculosis can involve the nasal cavity, nasopharynx, or paranasal sinuses. Many of the cases are associated with cervical lymphadenopathy; most seem to represent an isolated upper respiratory tract infection rather than secondary spread from pulmonary infection.[359]

Sarcoidosis may first present with nasal manifestations and may result in perforation of the septum.[360]

Rhinoscleroma (scleroma) is an inflammatory disease of the nose, pharynx, and larynx caused by an organism of the *Klebsiella* group. Microscopically, the predominant cells are foamy macrophages (Mikulicz cells) and plasma cells (Fig. 4.50). Vasculitis, ulceration, and pseudoepitheliomatous hyperplasia may be present.[361] The organisms can be identified using PAS or Hotchkiss–McManus stains or by an immunocytochemical technique.[362]

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) can affect various head and neck sites, including the nasal cavity (in the form of polyps), paranasal sinuses, and nasopharynx. Concomitant cervical nodal involvement may or may not be present.[363,364]

Granulomatosis with polyangiitis (Wegener granulomatosis) in its classic form is a rapidly progressive condition in which nasal involvement is accompanied by pulmonary and renal disease. Microscopically, a leukocytoclastic vasculitis with geographic necrosis surrounded by palisaded histiocytes, lymphocyte-poor granulomatous reaction, and epithelial ulceration is seen.[365]

In one series,[366] vasculitis, necrosis, and granulomatous inflammation *together* were seen in only 16% of head and neck biopsy specimens; both vasculitis and granulomatous inflammation were seen in 21%, and vasculitis and necrosis in 23%. In another series,[367] the nasal biopsy was diagnostic of granulomatosis with polyangiitis in 53% of the patients; samples larger than 5 mm in greatest diameter were more likely to contain diagnostic features than smaller samples. Elastic tissue stains are helpful in identifying remnants of badly damaged vessels. Granulomatosis with polyangiitis should be

distinguished from tuberculosis and other specific infections; from malignant lymphoma, especially natural killer (NK)/T-cell lymphoma; from so-called eosinophilic angiocentric fibrosis (see later); from cocaine-induced lesions[368]; and from other immune-mediated diseases, such as lupus erythematosus.

It should be remembered that granulomatosis with polyangiitis is not a lymphocyte-rich process, whether in the upper respiratory tract or in the lung; therefore a biopsy from the sinonasal region containing a dense lymphocytic infiltrate renders such a diagnosis less likely, and the alternative possibility of a malignant lymphoma is a real one.[369]

Eosinophilic angiocentric fibrosis is an inflammatory disease of unknown cause characterized by a perivascular "onion-skin" fibrosis and a mixed inflammatory infiltrate rich in eosinophils.[370] There are no granulomas, necrosis, or vasculitis. It has been viewed as the mucosal counterpart of granuloma faciale and can involve any portion of the upper respiratory tract.[371]

Myospherulosis is an iatrogenically induced granulomatous condition of the nose and paranasal sinuses. It is a form of lipogranuloma that develops after hemostatic packing with petrolatum-based ointments and gauze, and is microscopically analogous to a disease previously described in the subcutaneous tissues of East Africans.[372] Microscopically, its distinctive feature is the presence of large tissue spaces containing saclike structures with brown "spherules" resembling fungi (Fig. 4.51). It turns out that these mysterious formations are simply erythrocytes that have been altered and clumped by the action of the petrolatum.[373]

Tumors

Sinonasal (Schneiderian) Papilloma

Sinonasal papillomas are benign neoplasms of the sinonasal respiratory mucosa (the schneiderian membrane) most commonly presenting with nasal congestion, nasal obstruction, and/or epistaxis. Most cases are seen in adult men, but they can also occur in children.[374] In rare cases, they may extend into the cranial cavity.[375] Many adjectives have been attached to them, such as inverted, cylindrical cell, transitional, squamous, and schneiderian. There are three distinct clinicopathologic subtypes: exophytic (fungiform), inverted, and oncocytic. Excluded from this group are the verrucous hyperkeratotic squamous papillomas arising from the stratified squamous epithelium lining the nasal vestibule, which are analogous to tumors occurring elsewhere in the skin. In contrast to inflammatory polyps, sinonasal papillomas are unilateral in the large majority of cases.[376] Microscopically, papillomas are composed of proliferating columnar and/or squamous epithelial cells, with an admixture of mucin-containing cells and numerous microcysts (Fig. 4.52).[377] The microcysts are typically filled with neutrophils (neutrophilic microabscesses) and epithelial transmigration of neutrophils is a distinct histologic feature (Fig. 4.53). Downward growth into the sinonasal seromucous glands results in the inverted growth pattern of inverted papillomas. Some tumors are partially or entirely composed of swollen, granular, eosinophilic cells with features of oncocytes (oncocytic papilloma) (Fig. 4.54).[378] Occasional mitoses are present in the basal layer. Atypia is mild to moderate, and there is an orderly maturation pattern. The dual composition of columnar and squamous cells is also apparent at the immunohistochemical level, in the sense that there is expression of keratin corresponding to both cell types.[379] The inverted and oncocytic papillomas occur almost exclusively on the lateral nasal wall and are unilateral.

Figure 4.52 Sinonasal Papilloma With Inverted Pattern of Growth.

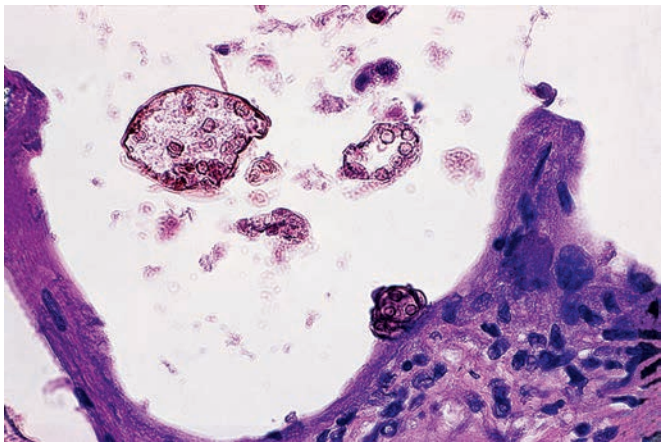

Figure 4.51 Myospherulosis of paranasal sinus following an operation in the region for fibromatosis. A "bag" containing round structures is seen floating in a tissue cavity surrounded by fibrous tissue.

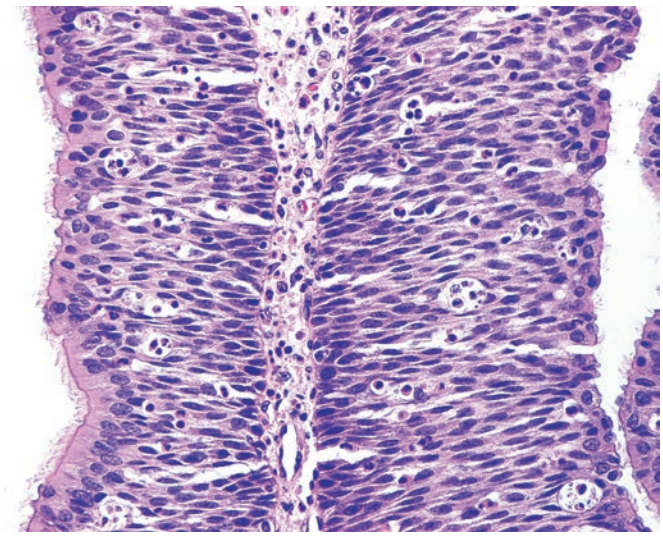

Figure 4.53 Stratified Lining by Cylindrical Cells in Sinonasal Papilloma. Note the transmigration of neutrophils and neutrophilic microabscesses.

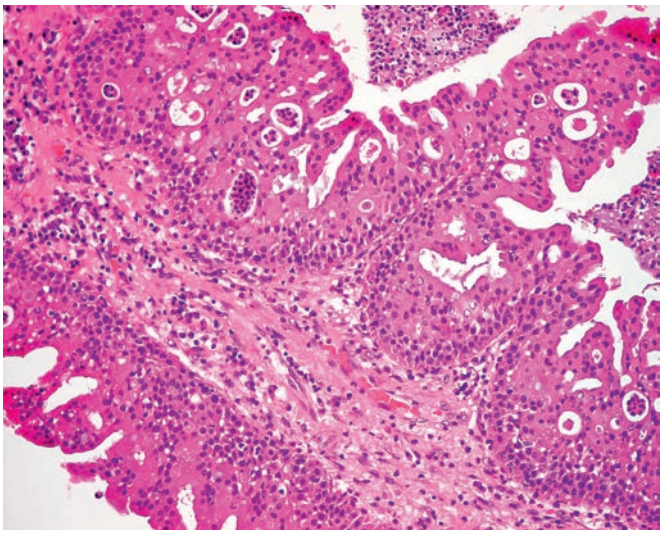

Figure 4.54 **Sinonasal Papilloma Lined by Oncocytic Epithelium.** Note the transmigration of neutrophils and neutrophilic microabscesses.

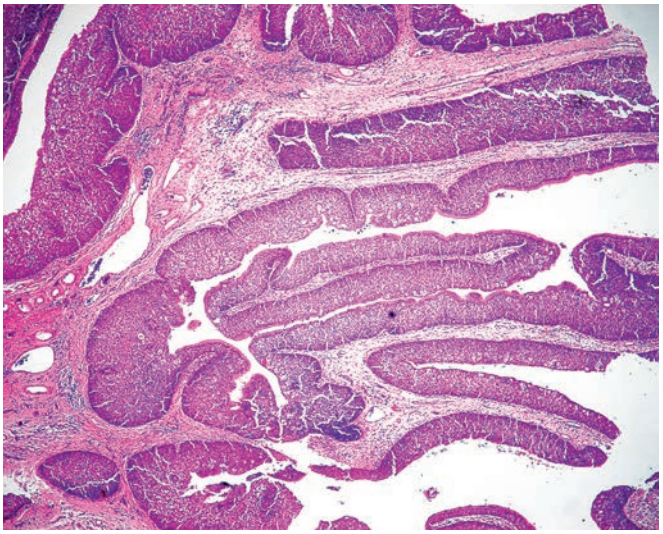

Figure 4.55 **Sinonasal Papilloma With Exophytic (Fungiform) Pattern of Growth.**

Papillomas arising in the nasal septum are usually exophytic and mushroom shaped ("fungiform" or "everted"). They are lined by similar epithelium as inverted papillomas but are arranged in exophytic fronds with a thin central core of connective tissue (Fig. 4.55). They lack the neutrophilic microabscesses and epithelial transmigration of neutrophils seen in inverted and oncocytic papillomas.

Sinonasal papillomas have a tendency to recur, this feature being particularly common with the inverted and oncocytic types.[377] They also have a complex and often misunderstood relationship with malignancy, most commonly squamous cell carcinoma, which may manifest in three ways:

1. Development of obvious carcinoma months or years after the excision of a papilloma, with or without recurrences of the papilloma in the interim.[380] This event occurs in about 3% of all papillomas and is associated with a 25% survival rate.
2. Presence of focal invasive carcinoma in an otherwise typical papilloma at the time of the first excision.[381] This complication, seen in about 3% of the cases, is associated with an excellent prognosis.
3. Occurrence of a tumor having a pattern of growth very similar to that of papilloma but with subtle cytologic features indicative of malignancy (see next section). The survival rate for this group is as poor as for carcinoma developing after excision of a papilloma (that is, in the neighborhood of 25%).

Many studies have been done in recent years with in situ hybridization or PCR techniques demonstrating the presence of HPV in sinonasal papillomas, even if the detection rate varied considerably.[382–384] HPV 6/11 has been the type most often detected.[385] In several of the series the incidence of positivity was notably higher for the fungiform than for the inverted papillomas, which often show histologic evidence of viral infection in the form of koilocytosis.[382,386] Despite early claims to the contrary,[387] EBV is not present in sinonasal papillomas.[382] A recent study demonstrated activating EGFR mutations in 88% of inverted papillomas and 77% of squamous cell carcinomas arising in inverted papillomas. These were not identified in oncocytic or exophytic papillomas, implicating a distinct role of activating EGFR mutations in inverted papilloma pathogenesis.[388]

The treatment of sinonasal papillomas is surgical removal. CT scanning is routinely used in management planning. The standard therapy has been lateral rhinotomy and en bloc excision of the lateral nasal wall, followed by removal of all the mucosa in the ipsilateral paranasal sinuses.[389] Endoscopic sinus surgery approaches are now replacing open surgical resection as the mainstay of therapy for inverted and oncocytic papillomas.[390] Exophytic papillomas can be conservatively excised.

Sinonasal Carcinoma

General Features

Sinonasal carcinomas are an uncommon group of tumors responsible for less than 1% of cancer deaths in the United States.[391] A marked left-sided preponderance has been noted for ethmoid tumors, suggestive of an exogenous pathogenesis.[392] An occupational group known to be at an increased risk is nickel refiners.[391] Studies from Europe, Australia, and North America have shown that another profession at risk is that of woodworkers, with most of the tumors in this group being adenocarcinomas.[393–396] In contrast to sinonasal papilloma, only a small minority of the carcinomas of this region that have been investigated for evidence of HPV infection have yielded positive results; most of these positive cases are of the cylindrical cell carcinoma type (see below).[397] They lack evidence of EBV infection, regardless of their histologic subtype.[398]

Location and Spread

Intranasal carcinomas occur more commonly in the vestibule and lateral wall and only rarely in the septum.[399–401] In one series of paranasal sinus tumors, 76% occurred in the ethmoid sinus, 16% in the sphenoid sinus, and 2% in the frontal sinus.[402] Sinonasal carcinomas often are diagnosed late in their course, when extensive bone destruction is already present. Intranasal tumors may extend into the medial wall of the antrum, ethmoid sinuses, orbit, anterior skull bone, and upper lip. Tumors of the infrastructure of the maxillary sinus spread inferiorly into the alveolar process or gingivobuccal sulcus, anteriorly into the soft tissues of the cheek beneath the zygoma, or medially into the nasal cavity and hard palate. Those of the suprastructure may extend superiorly and medially into the orbit, ethmoid sinus, and cribriform plate; posterolaterally into the pterygoid space, sphenoid sinus, or base of the skull; anterolaterally into the zygoma; or posterolaterally into the infratemporal fossa.[2]

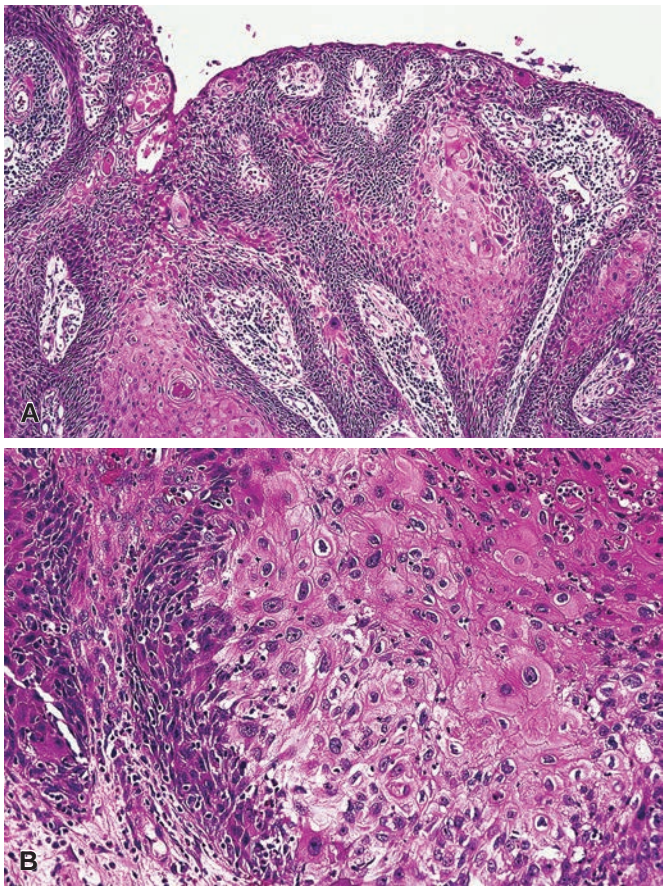

Figure 4.56 Low- **(A)** and high- **(B)** power views of sinonasal keratinizing squamous cell carcinoma.

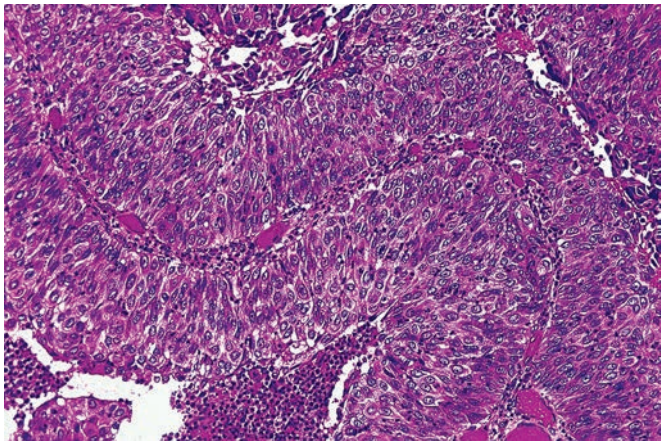

Figure 4.57 Nonkeratinizing squamous cellinonasal carcinoma of "transitional" type.

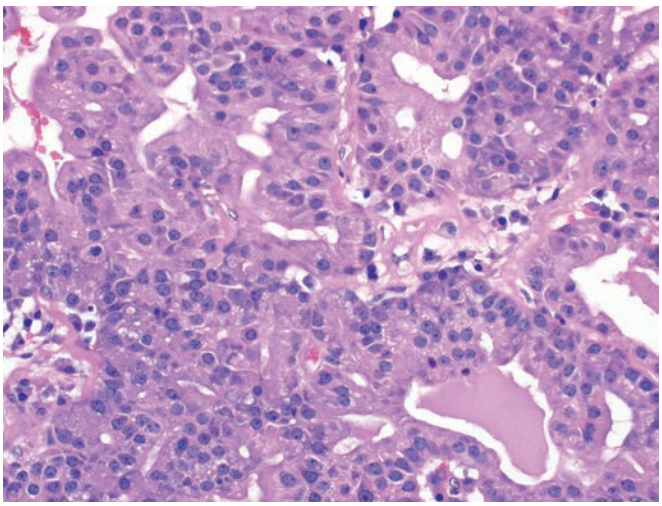

Figure 4.58 Low-grade nonintestinal type sinonasal adenocarcinoma with complex arborizing tubular and papillary pattern and extremely well-differentiated cytologic appearance.

Microscopic Features

Conventional squamous cell carcinoma (the term often preceded by the qualifier ***keratinizing***) is the most common microscopic type of sinonasal carcinoma, as already shown in the monumental study by Ringertz in 1938.[403] Most of the cases are high-grade lesions, with varying degrees of keratinization (Fig. 4.56).[404]

Nonkeratinizing squamous cell carcinoma (transitional; cylindrical; schneiderian) carcinoma is closely related to conventional squamous cell carcinoma. The cells have scant cytoplasm imparting a basaloid appearance of typically have occasional keratin pearl formation. Foci of intracellular mucin production may be present. The proliferation often has an undulating or ribbon-like growth pattern. In most instances the microscopic diagnosis is obvious because of the atypicality and stromal infiltration. In others the identification is more difficult because the growth pattern is similar to that of a papilloma in the sense that stromal invasion is not immediately apparent. The differential diagnosis must be made on the basis of cellular abnormalities, such as gross disturbance of polarity, increased mitotic rates, and atypical nuclear changes (Fig. 4.57).[377,405] However, mitoses and some degree of nuclear hyperchromasia also can be present in benign lesions such as inverted papillomas.

The differential diagnosis of keratinizing and nonkeratinizing squamous cell carcinoma also includes the sometimes bizarre atypical epithelial changes that can develop following chemotherapy.[406]

Verrucous carcinoma, basaloid squamous cell carcinoma, and **sarcomatoid carcinoma (spindle cell carcinoma, carcinosarcoma)** are three types of malignant tumor that have been rarely observed in the sinonasal region. They are similar in all regards to their more common counterparts in the upper digestive tract and larynx.

Adenocarcinomas of the sinonasal tract can be of salivary gland type or of non-salivary gland type. The latter are divided into intestinal type and nonintestinal type. Adenocarcinoma without a specific salivary gland pattern usually arises on the middle turbinate or in the ethmoid sinus and from there extends laterally into the orbit and upward into the anterior cranial fossa. These tumors may arise from the surface epithelium (the majority) or from the subjacent seromucous glands.[407,408] Microscopically, nonintestinal-type adenocarcinomas show a wide range of differentiation and patterns, most of them having a well-differentiated seromucinous composition and tubulopapillary architecture (Figs. 4.58 and 4.59).[408,409] These low-grade adenocarcinomas can be distinguished from benign mimics by the lack of a myoepithelial layer, presence of infiltrative growth, and complex growth pattern. High-grade nonintestinal-type adenocarcinomas more often have a solid growth pattern with marked nuclear atypia, necrosis, and high mitotic activity.

Intestinal-type sinonasal adenocarcinomas have an appearance strongly reminiscent of colorectal carcinoma or adenoma, including the presence of goblet cells.[410–413] Others resemble small intestinal mucosa, with the formation of resorptive, goblet, Paneth, and

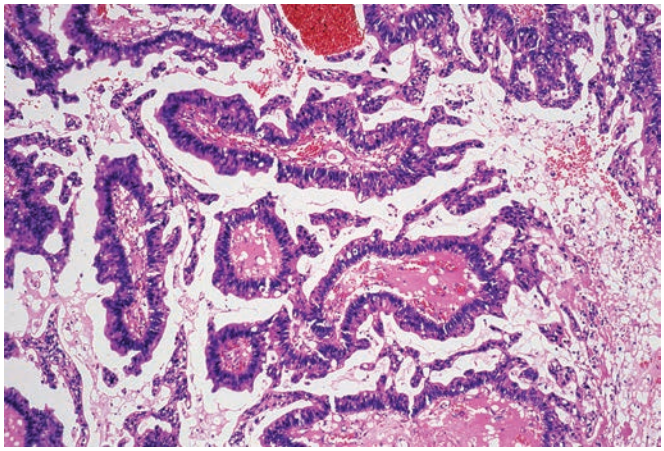

Figure 4.59 Nonintestinal Type Adenocarcinoma of the Nasal Cavity. The tumor is well differentiated and has a distinctly papillary configuration.

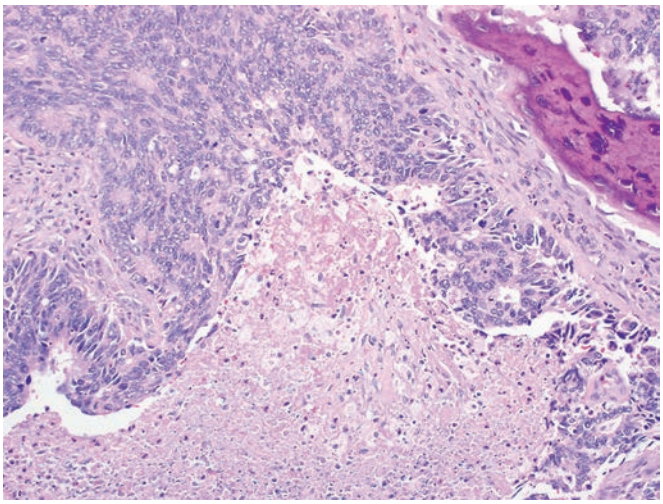

Figure 4.61 Moderately differentiated ITAC resembled conventional colorectal adenocarcinoma with "dirty" necrosis.

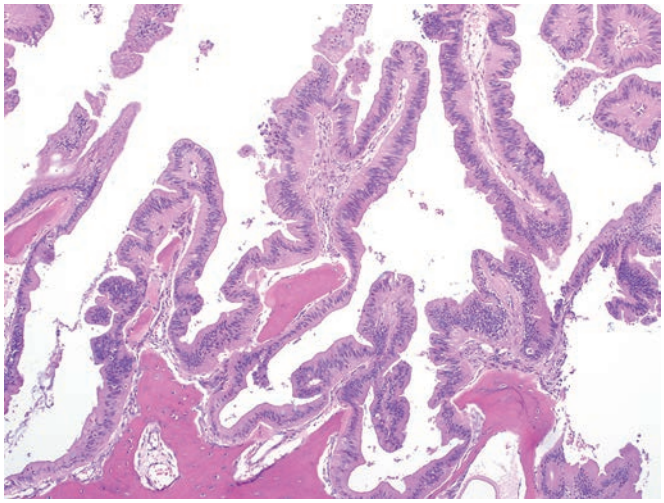

Figure 4.60 Well-Differentiated Intestinal-Type Sinonasal Adenocarcinoma (ITAC). The lesion resembles a villous adenoma of the colon. Note the bone invasion at the bottom.

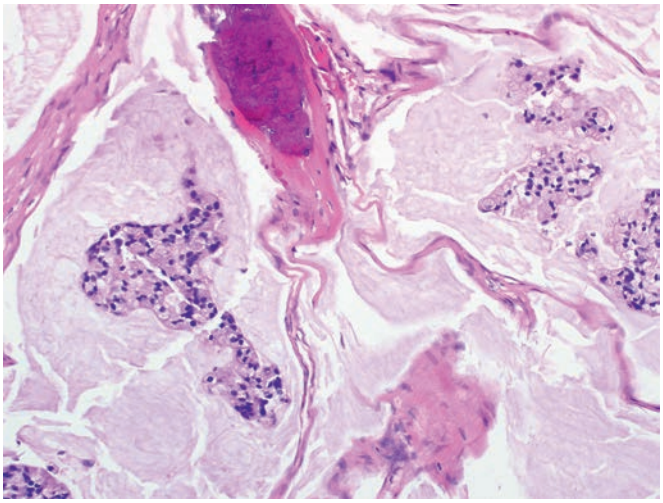

Figure 4.62 Mucinous ITAC typically consist of pools of mucin with malignant cells either within the mucin or lining the mucous pools.

neuroendocrine cells.[414] In rare cases the latter component is present in the form of atypical carcinoid, resulting in the formation of a composite neoplasm. Tumors that resemble colonic adenomas are considered well differentiated (Fig. 4.60) and those that resemble typical colorectal adenocarcinoma are considered moderately differentiated (Fig. 4.61). Those with a solid growth pattern are considered poorly differentiated. Finally, some tumors are considered mucinous if they resemble mucinous colorectal adenocarcinoma or if they have a signet ring cell morphology (Fig. 4.62). The morphologic similarities between colorectal adenocarcinoma and sinonasal intestinal-type adenocarcinomas are matched immunophenotypically (with positivity for CK20, CDX2, villin, and MUC2)[415–417] but usually not at the molecular level in terms of *KRAS* and *TP53* abnormalities.[418] Sinonasal adenocarcinomas are locally aggressive tumors, with a propensity for local recurrence.[419] Lymph node metastases are rare. Low-grade (well-differentiated) tumors typically have an indolent course, whereas high-grade tumors have a very poor outcome.

Small cell neuroendocrine carcinoma has a morphologic, immunohistochemical, and ultrastructural appearance similar to that of its pulmonary homolog.[420] The main differential diagnosis is with undifferentiated (anaplastic) carcinoma (see below) and with olfactory neuroblastoma.

Sinonasal undifferentiated (anaplastic) carcinoma (SNUC) of the nasal cavity or paranasal sinuses is characterized microscopically by nests, trabeculae, and sheets of medium-sized cells having a high mitotic rate, extensive necrosis, and prominent vascular invasion.[421] SNUC does not show evidence of neuroendocrine, squamous, or glandular differentiation.[399,422] SNUC express simple keratins (CK7, CK8, and CK19) but are negative for complex keratins (CK14 and CK5/6) and neuroendocrine markers. They present in adults as locally advanced sinonasal or skull-based tumors and are associated with a median survival of under 2 years. ***NUT midline carcinoma*** accounts for a proportion of cases conventionally diagnosed as SNUC; the diagnosis has to be confirmed by immunostaining with a NUT-specific antibody or by molecular techniques.[191]

Treatment and Prognosis

The recommended treatment for most sinonasal carcinomas is a combination of surgery and radiation therapy with or without

chemotherapy.[423] The 5-year survival rates with this modality have been in the neighborhood of 60%.[424] Relapse occurs almost always within 2 years after the initial treatment. As usual, the most important prognostic factor is tumor stage.[425] In a multivariate analysis of a large retrospective cohort, extension to the pterygomaxillary fossa and invasion of the dura remained independent prognostic factors.[424]

Histology-wise, it would seem that adenocarcinoma carries a slightly better prognosis than squamous cell carcinoma.[424] As mentioned, among the adenocarcinomas, there is a relationship between degree of differentiation and prognosis.[425] Tubulopapillary tumors showing minimal atypia run an indolent clinical course.[411] The prognosis of high-grade adenocarcinoma, SNUC, and NUT midline carcinoma are extremely poor.[426]

Nasopharyngeal Carcinoma

General Features

Squamous cell carcinoma of the nasopharynx is a leading cause of death for large populations in Southeast Asia and, to less degree, in northern Africa,[427,428] The age–incidence curve is bimodal, with a peak occurring between 15 and 25 years and another between 60 and 69 years.[429] Cases showing familial aggregation have been reported both in the United States and in the Southeast Asia.[430] The accumulated evidence strongly suggests that this tumor results from the combined action of genetic predisposition, environmental factors, and the EBV.[431–433] Specifically, it has been proposed that tumor initiation requires EBV expression but that the induction of preneoplastic events and maintenance of tumor-cell phenotype require critical cellular genes.[434] It should be noted that the association with EBV is much stronger in endemic areas (such as Southeast Asia) than in other parts of the world.

Within the tumor, the EBV DNA is homogeneous and clonal with regard to terminal repeat sequences.[435] Expression of specific viral messenger RNAs or gene products is consistently detected within all of the tumor cells.[436]

The virus can be demonstrated in the tumor tissue with in situ hybridization and immunohistochemical techniques, the former being much more reliable (Fig. 4.63).[437,438] It has also been detected with the PCR technique in materials obtained by fine-needle aspiration of metastatic cervical nodes.[439] The virus has been found in all microscopic types of nasopharyngeal carcinoma—including cases exhibiting glandular differentiation—although with different frequencies (see below). The consistent detection of IgG antibodies (which are directed against the early EBV antigen) and of IgA antibodies (which are directed against the capsid viral antigen) has been used in the United States to support a presumptive diagnosis of nasopharyngeal carcinoma.[440] However, the presence of 30% false-positive results for the former test and 9%–18% for the latter indicates that the diagnosis of nasopharyngeal carcinoma cannot be based solely on serologic tests. These tests have also been used in areas with a high incidence of nasopharyngeal carcinoma as a risk predictor. In one such study, carried out in Taiwan, in which almost 10,000 men were enrolled, blood samples were examined for IgA antibodies against EBV-specific capsid antigen and neutralizing antibodies against EBV-specific DNase. It was found that the risk for cancer development was 4.0 for subjects with one marker and 32.8 for subjects with both markers, as compared with subjects with neither marker.[441] Increasingly, assay of plasma EBV DNA is used in place of serologic studies to aid in diagnosis, prognostication, assessment of post-treatment residual tumor load, and detection of relapse of nasopharyngeal carcinoma.[442]

Gross Features

Grossly, the tumor may be very difficult to detect. Random ("blind") biopsies from the nasopharyngeal area should be taken whenever the diagnosis is suspected, particularly from the fossa of Rosenmüller.[443]

Microscopic Features

Microscopically, the crucial distinction to be made in nasopharyngeal carcinoma is between tumors that show clear-cut evidence of keratinization and those that do not.[444] The former, designated **keratinizing squamous cell carcinomas**, do not show as high an association with EBV as the others and occur in an older age group (Fig. 4.64).[445] The tumors in the second category, which represent the large majority, have been designated **nonkeratinizing carcinomas** and are subdivided into *differentiated* and *undifferentiated* types.[446] The former have a stratified or pavemented arrangement and well-defined cell margins and are histologically identical to sinonasal nonkeratinizing squamous cell carcinomas (Fig. 4.65). The latter exhibit a syncytial appearance and indistinct cell margins (Fig. 4.66). A high proportion of these tumors (particularly in the undifferentiated subgroup) is accompanied by a prominent inflammatory infiltrate rich in lymphocytes, a fact responsible for the designation

lymphoepithelioma that these neoplasms have traditionally received. The term is a misnomer inasmuch as the lymphocytic population is not neoplastic. As a matter of fact, it may be accompanied by other inflammatory cells, such as plasma cells, eosinophils, and—on rare occasions—epithelioid histiocytes and multinucleated giant cells; however, the term "lymphoepithelioma," inaccurate as it may be, should perhaps be retained in view of the characteristic appearance of this neoplasm.

Two patterns of growth may be seen in undifferentiated nasopharyngeal carcinoma, sometimes in combination. The first, referred to as *Regaud type*, consists of well-defined aggregates of epithelial cells surrounded by fibrous tissue and lymphoid cells (Fig. 4.67). In the second, designated as *Schmincke type*, the neoplastic epithelial cells grow diffusely and are closely intermingled with inflammatory cells. The latter type is apt to be confused with large cell malignant lymphoma (Fig. 4.68). Careful examination of the tumor cell nuclei should establish the diagnosis in most instances. The nuclei of undifferentiated nasopharyngeal carcinoma are characteristically large and vesicular, with a smooth outline and a single, large, sharply etched eosinophilic nucleolus. The nuclei of malignant lymphoma are usually more irregularly shaped, the chromatin is coarser, and the nucleoli are smaller and either basophilic or amphophilic. Occasionally, the tumor cells have an oval or spindle shape that may be confusing (Fig. 4.69). Amyloid globule deposition is not uncommon in nasopharyngeal carcinoma.[447]

An in situ carcinoma component can be identified in only a minority of cases. Even rarer but well documented is the nasopharyngeal carcinoma that is *entirely* in situ (nasopharyngeal intraepithelial lesion).[448]

Rare microscopic forms of nasopharyngeal carcinoma include **basaloid squamous cell carcinoma**[449] and **papillary adenocarcinoma**.[450] The adenocarcinomas may be of salivary gland type (the most common) or arise from the surface epithelium.[451] The latter are papillary, mucin producing, immunoreactive for keratin and carcinoembryonic antigen (CEA), and associated with an excellent prognosis.[450] Rare examples of nasopharyngeal adenocarcinoma closely mimic the appearance of papillary thyroid

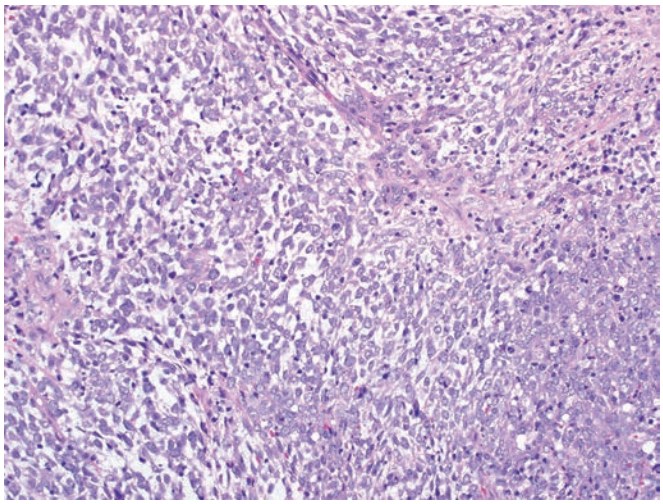

Figure 4.69 Undifferentiated nasopharyngeal carcinoma composed of oval and spindle tumor cells.

carcinoma and can even be immunoreactive for TTF-1 (but not for thyroglobulin).[452]

Immunohistochemical Features

Immunohistochemically, nasopharyngeal carcinoma (including the lymphoepithelioma type) shows reactivity for keratin (always), EMA (usually), and CEA (occasionally).[453,454] Thus keratin is the most reliable marker for the identification of this neoplasm. About 10% of the cases stain for CD30, a potential source of misdiagnosis.[455] A population of S-100 protein–positive dendritic cells may also be present.

Electron Microscopic Features

Ultrastructurally, tonofilaments and complex desmosomes are present in the tumor cells.[456] The electron microscopic features suggest an origin from the cells of the basal layers of pseudostratified and stratified epithelia.[457]

Molecular Genetic Features

The etiology of nasopharyngeal carcinoma is complex, involving genetic susceptibility, EBV infection, and exposure to chemical carcinogens. Multiple somatic genetic and epigenetic changes are required for tumor development.[458] *EBV-LMP1* appears to be the principal oncogene—it is required for cell immortalization and is present in 80%–90% of the tumors.[459] In the carcinoma cells, there is upregulation of cellular proliferation pathways such as the Akt pathway, mitogen-activated protein kinases, and the Wnt pathway. Cell adhesion is compromised due to abnormal E-cadherin and β-catenin function. Aberrations in cell cycle are due to dysregulation of factors such as P16, cyclin D1, and cyclin E. Anti-apoptotic mechanisms are also upregulated.[460]

Allelic loss of chromosome 3p (particularly the 3p21.3 region) is found in 95%–100% of nasopharyngeal carcinomas, indicating that this region harbors tumor suppressor genes that are important in tumorigenesis. Several genes have been implicated, including *RASSF1A*, *LTF*, *BLU*, and *LARS2*.[460] Another common site of allelic loss is 9p21, implicating the *P16*, *P15*, and *P14/ARF* genes.[458] Downregulation of E-cadherin is common, and results from aberrant promoter methylation of the E-cadherin gene.[459] While P53 is commonly overexpressed, the *TP53* gene is usually not mutated.

Some oncogenes are found to be variably overexpressed, sometimes attributable to gene amplification, such as *A20/TNFAIP3* (6q23), *BCL2* (18q21), *CCND1* (11q13), *EGFR* (7p12), *EVI1* (3q26), *HER2* (17q12), *HRAS* (11p15), *NRAS* (1p13), *ID1* (20q11), *INT2/FGF3* (11q13), *NMYC* (8q24), and *PIK3CA* (3q26).[458]

Staging and Grading

Several staging systems for nasopharyngeal carcinoma have been proposed. In a comparative study, it was concluded that the system devised by Ho was the best predictor of prognosis.[461]

Spread and Metastases

Nasopharyngeal carcinoma arising from the fossa of Rosenmüller frequently extends to the paranasopharyngeal space, from which it can grow along the perineurial space of the trigeminal nerve.[462]

Nasopharyngeal carcinoma has a great propensity to metastasize to regional nodes; in fact, the appearance of unilateral cervical lymphadenopathy is the most common form of presentation. A unique feature of nasopharyngeal carcinoma is its propensity to metastasize to the posterior cervical triangle (level V) and many patients present with bilateral level V metastases. Microscopically, these nodal metastases may closely simulate a large cell lymphoma. Diagnostic clues include the focal (predominantly sinusal) nature of the involvement and the large vesicular nuclei with a single prominent nucleolus. In some cases the metastatic tumor is accompanied by a marked infiltration by eosinophils, which may result in a mistaken diagnosis of Hodgkin lymphoma.[463] In other cases the lymph node metastases are accompanied by a granulomatous reaction with varying degrees of necrosis (Fig. 4.70).[464] In yet others,

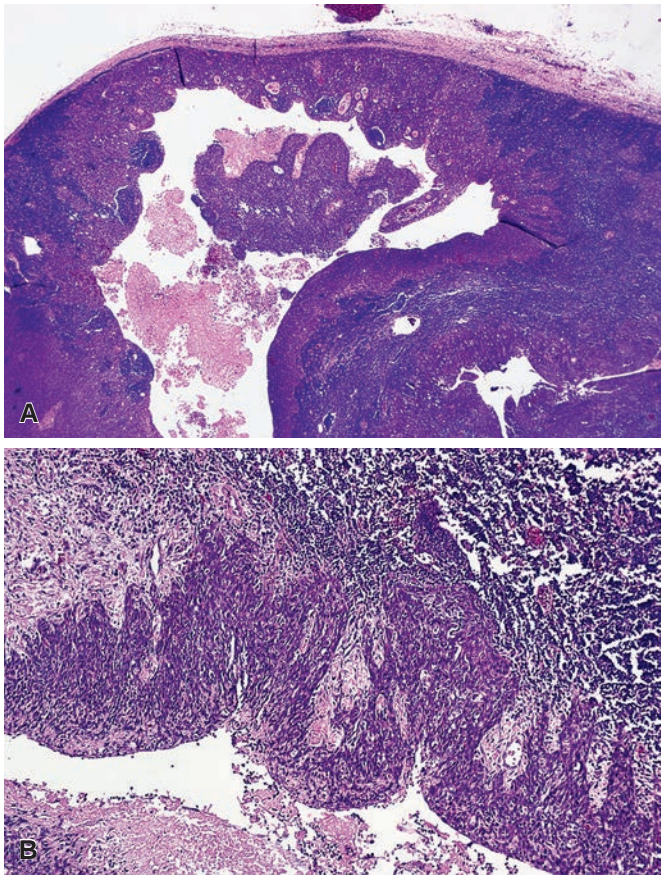

Figure 4.71 **A** and **B,** Cystic metastasis of nasopharyngeal undifferentiated carcinoma to cervical lymph node simulating the pattern of growth of branchial cleft cyst.

it undergoes marked cystic changes, simulating a benign branchial cleft cyst (Fig. 4.71).

Metastases can also develop in distant sites, such as the skeletal system.[465]

Treatment and Prognosis

The treatment of choice for nasopharyngeal carcinoma is radiation therapy, which some authors suggest combining with chemotherapy.[466] In a series of over 5000 cases from Hong Kong, complete remission after radiation therapy was obtained in 83%; the overall actuarial 10-year survival rate was 43%, and the corresponding failure-free survival was 34%.[467] Survival is significantly affected by patient age (better in young individuals), clinical staging,[468,469] and the location of the regional metastases (better for homolateral rather than contralateral metastases and for metastases that are limited to the upper neck as opposed to the lower cervical regions). Cranial nerve, orbit, and intracranial involvement confer a particularly unfavorable prognosis.[468]

At a microscopic level, survival has been found to be worse for the keratinizing squamous cell carcinoma than for the others.[470,471] For the latter category, it has been claimed that the prognosis is worse for tumors exhibiting one or more of the following features:

1. Marked anaplasia and/or pleomorphism[472]
2. High cell proliferation rate (measured with mitotic count or with proliferation-related immunomarkers)[473]
3. Lack of lymphocytic infiltrate[472]
4. High density of S-100 protein–positive dendritic cells[472]
5. High microvessel count[474]
6. HER2/neu overexpression.[474]

Salivary Gland Tumors

Tumors of minor salivary gland origin occur in the nasal cavity as well as in the sinuses but much less commonly in the nasopharynx. Their relative frequency conforms to the density and distribution of the seromucous (salivary gland type) glands of the region—hence their predilection for the nasal (septum and turbinates) or ostial regions.[475] Of the paranasal tumors, the majority are found in the maxillary sinus antrum. Of 37 cases reviewed by Rafla,[476] 21 were in the antrum, 9 in the ethmoid, 5 in the nasal fossa, and 2 in the sphenoid. Most tumors of the paranasal sinuses are malignant; **adenoid cystic carcinoma** is the most common variety.[476] Like its more common counterpart in the major salivary glands, this tumor may undergo dedifferentiation.[477]

In the nasal cavity there is a relatively high proportion of benign neoplasms in the form of **pleomorphic adenoma** (benign mixed tumor). The large majority arise from the mucosa overlying the bony or cartilaginous septum.[478] Their microscopic appearance is similar to that of their homologs in the major salivary glands, but they are unencapsulated in minor salivary gland sites.[479] Recurrence is rare if adequately excised and rare cases may undergo malignant transformation (carcinoma ex pleomorphic adenoma).

Several other types of salivary gland tumor have been reported in the sinonasal region, including **mucoepidermoid carcinoma**, **acinic cell carcinoma**, and **epithelial–myoepithelial carcinoma**, and **myoepithelioma**.[475] Most are low-grade lesions, but local recurrence is a common event given the difficulty in obtaining tumor-free margins in this location.[475] In contrast to the oral cavity, polymorphous low-grade adenocarcinomas are very uncommon in the sinonasal region.

Salivary gland anlage tumor is the term proposed for a distinctive polypoid lesion of the nasopharynx that presents at birth or soon thereafter with respiratory distress. Microscopically, it is characterized by a biphasic pattern of squamous nests and duct-like structures at the periphery of the lesion that blend into solid nodules centrally (Fig. 4.72). It is a benign, perhaps hamartomatous process, but it can be life-threatening because of its location.[481]

Neurogenous and Related Tumors and Tumorlike Conditions

Encephaloceles and **glial heterotopias** (commonly called *nasal gliomas*) are related malformational tumorlike conditions usually affecting newborns and older infants.[482] They may present as subcutaneous masses at the base of the nose or as intranasal polyps. Microscopically, they are composed of mature glial tissue, with occasional multinucleated glial cells that may simulate neurons (Fig. 4.73). Immunohistochemically, there is reactivity for both S-100 protein and GFAP. In some cases a true neuronal component is also present. Associated bony defects are the rule with the encephaloceles, but they are unusual with the glial heterotopias, a feature to be evaluated at the time of removal or with preoperative imaging.

Meningiomas located intracranially may invade the sphenoid or frontal sinuses secondarily. They can also present as primary intranasal or paranasal masses.[483] The key diagnostic features are a whorled growth pattern, psammoma bodies, and a combined EMA, progesterone receptor, and vimentin immunoreactivity.

Astrocytomas and other glial tumors can also extend into the root of the nasal cavity from their initial intracranial location.[484]

Olfactory neuroblastoma (esthesioneuroblastoma) is a specific type of malignant neuroectodermal tumor arising from neuroepithelial

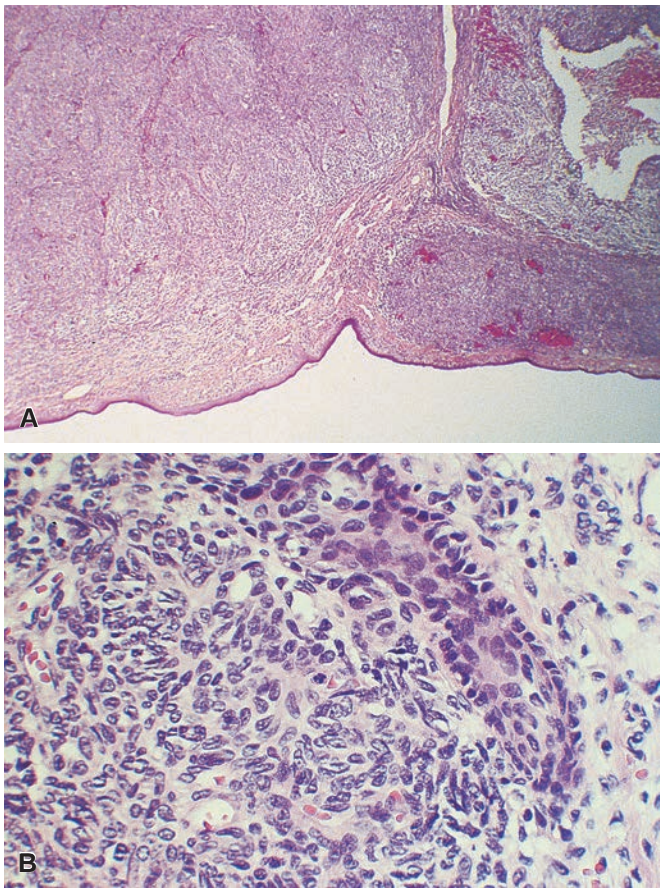

Figure 4.72 Salivary Gland Anlage Tumor. A, The solid, multinodular growth with a focal cyst is the characteristic appearance of this polypoid growth. **B,** A solid focus is composed of stromal cells with interspersed small duct-like structures. Solid or duct-like structures adjacent to the nodules are typically present in the loose fibrous stroma between the solid nodules.

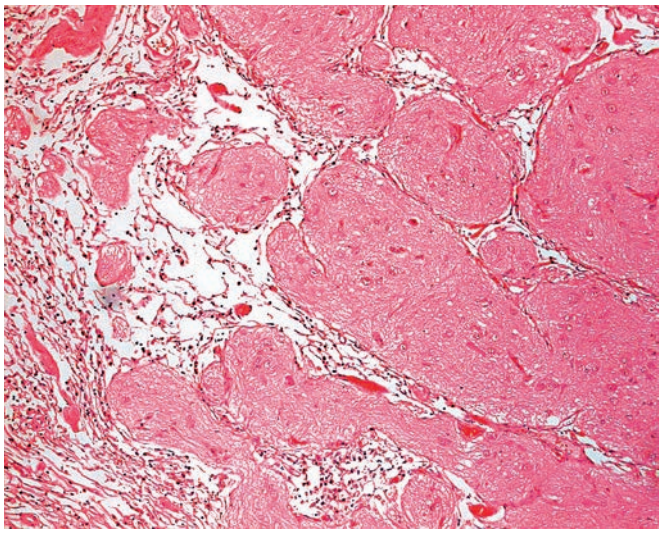

Figure 4.73 Glial Heterotopia in Nasal Cavity.

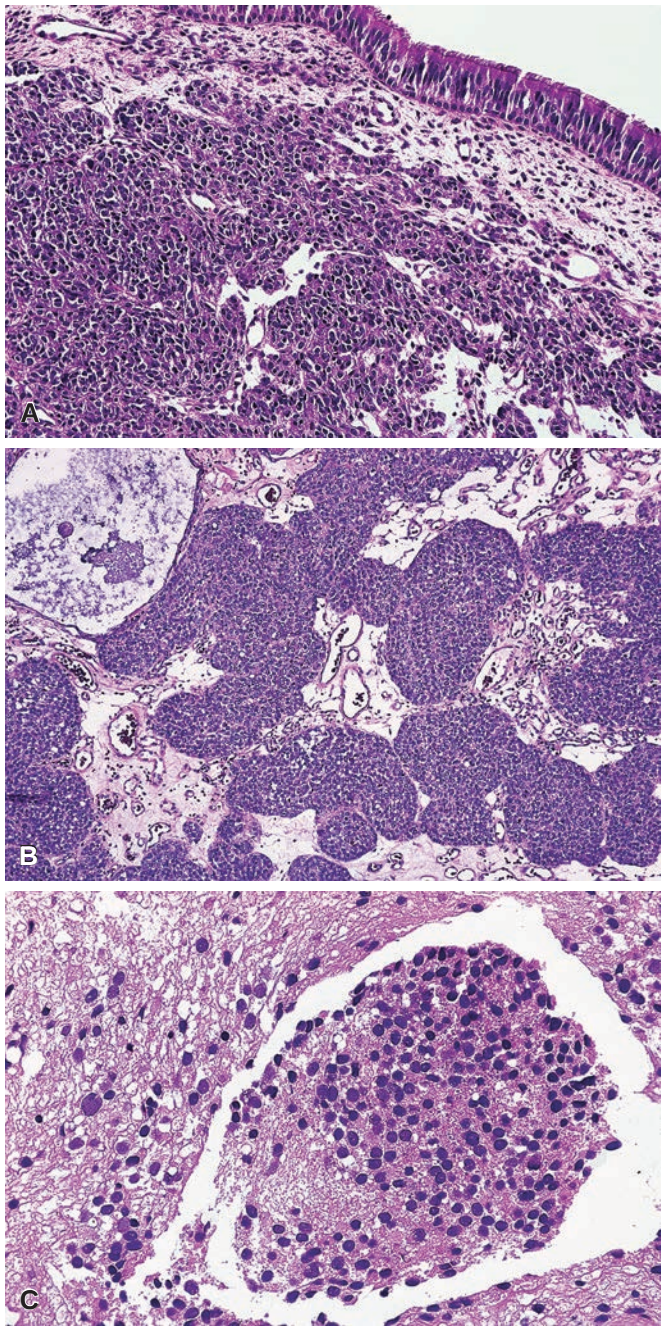

Figure 4.74 Olfactory Neuroblastoma. Both **A** and **B** show a lobular pattern of growth. The tumor depicted in **C** shows typical neurofibrillary background.

elements in the olfactory mucosa.[485] Olfactory neuroblastoma shows a wide range of age distribution (3–79 years), the median age being about 50 years.[486] Grossly, the tumor appears as a reddish gray, highly vascular polypoid mass of generally soft consistency located in the roof of the nasal fossa. Rare cases have been described as arising in the nasopharynx, maxillary sinus, and ethmoid sinus.[487] Microscopically, several patterns have been described, which often merge with each other (Fig. 4.74).[488] The most easily recognizable and common appearance is that of a cellular tumor arranged in lobules and composed of uniform small cells with round nuclei, scanty cytoplasm, indistinct nuclear membranes, and a prominent eosinophilic fibrillary or reticular background, similar to that seen

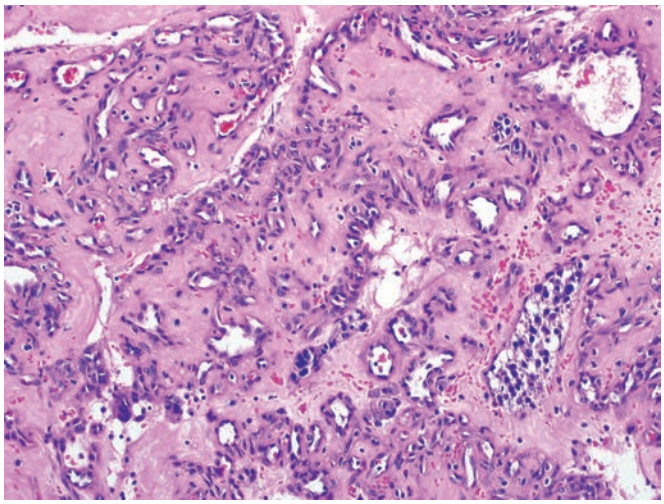

Figure 4.75 Olfactory neuroblastoma associated with a striking lobular proliferation of blood vessels. This proliferation is a feature often seen in neuroepithelial and neuroendocrine neoplasms and may be mistaken for a vascular neoplasm. Note the small foci of residual olfactory neuroblastoma.

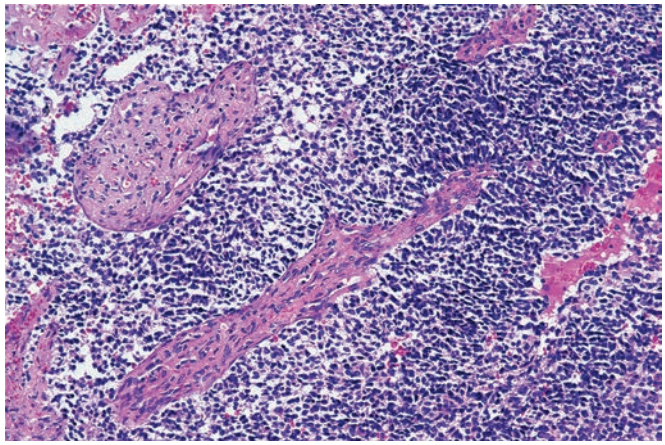

Figure 4.76 Some high-grade olfactory neuroblastomas resemble small cell carcinoma of the nasal cavity. The lesion is extremely cellular and monotonous, with no obvious evidence of neural differentiation.

in some other neurogenic tumors (such as ganglioneuroblastoma) (see Fig. 4.74C). Rosettes (actually pseudorosettes) of the Homer Wright type may be present (and identifiable in cytologic preparations[489]) in up to 30% of tumors, but differentiation into mature ganglion cells takes place only in rare cases.[490] True neural rosettes (Flexner–Wintersteiner) are also uncommon being present in only about 5% of tumors. Fibrovascular stroma may be abundant and separates the tumor cells in distinct lobular pattern. The vascular proliferation can be so florid as to obscure the true nature of the tumor (Fig. 4.75).[491] Melanin may in some cases be found in the cytoplasm of the tumor cells.[492] The differential diagnosis of tumors with this appearance includes malignant lymphoma, plasmacytoma, embryonal/alveolar rhabdomyosarcoma, and the Ewing sarcoma/PNET tumor family (see later).

In other examples the tumor cells are larger, have more abundant cytoplasm with less fibrillary stroma, and grow in solid nests, thus exhibiting an epithelial appearance. This type is often confused with SNUC, nasopharyngeal carcinoma, and small neuroendocrine carcinoma. The suggestion has been made that these two patterns may correspond to two different tumor types, the former being similar (although not identical) to *neuroblastoma* and the latter being similar to *small cell neuroendocrine carcinoma* (Fig. 4.76) (see p. 297).[493] The fact that in some of these tumors there is a component of adenocarcinoma or squamous cell carcinoma (so-called dedifferentiated olfactory neuroblastoma) would seem to support this contention. Other authors have described a similar morphologic dichotomy but favored the existence of a spectrum of differentiation rather than the existence of two separate neoplasms, in view of the many shared ultrastructural and immunohistochemical features.[494] These considerations notwithstanding, in most cases the distinction between olfactory neuroblastoma and small cell neuroendocrine carcinoma is possible and that it has significant therapeutic connotations.[495] Strong expression of cytokeratin is a useful marker in distinguishing these two as olfactory neuroblastoma are invariable negative or show weak and focal staining.

Another contentious issue has been the relationship between olfactory neuroblastoma and tumors in the Ewing sarcoma/PNET family. Despite early claims to the contrary, it has been shown that olfactory neuroblastoma lacks the *EWS–FLI1* gene fusion that characterizes the latter, and therefore it should be considered distinct from it.[496]

Historically, catecholamines have been demonstrated in olfactory neuroblastoma by fluorescent techniques after formaldehyde vapor or glyoxylic acid treatment,[497] whereas the enzyme dopamine β-hydroxylase and the hormone ACTH have been detected by biochemical and immunocytochemical methods.[498] Parenthetically, a case has been described of Cushing syndrome secondary to olfactory neuroblastoma.[499] Other substances detected immunohistochemically in the tumor include synaptophysin, chromogranin, CD56, neuron-specific enolase, neurofilaments, and Hu (Fig. 4.77).[494,500–502] As mentioned, cytokeratin reactivity is uncommon and, when present, is typically weak and focal. In addition, S-100 protein has been found in isolated cells, often surrounding the tumor nests (sustentacular cells), and GFAP has been detected in scattered astrocyte-like cells.[501]

Electron microscopy shows the consistent presence of neurofilaments, neurotubules, and dense-core neurosecretory cytoplasmic granules and may be of help in difficult cases.[503]

Olfactory neuroblastoma shows complex karyotypic changes.[504] An array-based comparative genomic hybridization study showed that gene copy gains are more common than losses, with the most changes being gains at 7q, 9p, 20p/q, and Xp/q and losses at 2q, 6q, 22q, and Xp/q.[505]

The behavior of olfactory neuroblastoma is mainly characterized by local invasiveness into the paranasal sinuses, nasopharynx, palate, orbit, base of skull, and brain.[506] Distant metastases occur in about one-fifth of cases, the most common sites being the cervical lymph nodes and lungs. The 5-year survival rate is between 50% and 66%.[507,508] Late recurrence is common. This tumor has been shown to be radiosensitive, and a combination of surgery and radiation therapy offers the best chances of cure.[507,509,510] From the surgical standpoint, endoscopic removal results in outcomes comparable to those obtained with open surgery.[511] A four-tiered grading system proposed by Hyams shows poor interobserver reproducibility and poor correlation with prognosis. Most olfactory neuroblastomas can be segregated into low and high grade based on the previously mentioned features. Systemic spread is more common in the high-grade (small cell neuroendocrine carcinoma-like) tumors than among the low-grade (neuroblastoma-type) neoplasms.[495]

Carcinoid tumor has been found in rare cases to present as an intranasal or paranasal sinus tumor. These well-differentiated neuroendocrine tumors can show marked immunophenotypic overlap

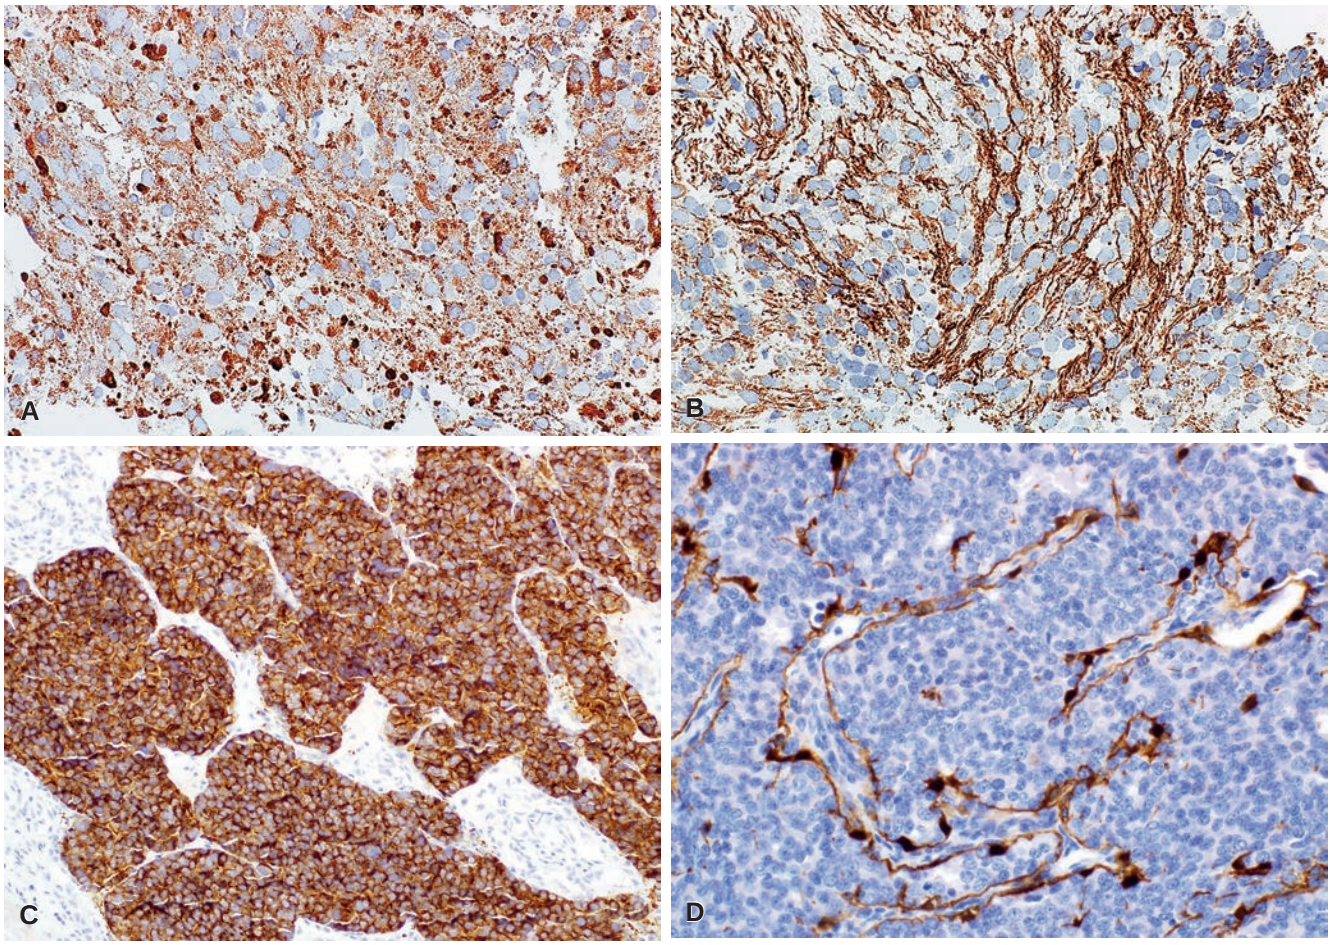

Figure 4.77 Olfactory Neuroblastoma. A, Chromogranin; **B,** neurofilament; **C,** synaptophysin; and **D,** S-100 protein.

with olfactory neuroblastoma but will invariably express cytokeratin as opposed to olfactory neuroblastoma.

Pituitary adenoma can present as a primary lesion of the nasopharynx, sphenoid sinus, or nasal cavity, presumably arising from ectopic anterior pituitary-like cells. These tumors, which are typically of the chromophobe type, should be distinguished from pituitary adenomas that have extended downward from the sella through the sphenoid bone.[512] One should suspect the diagnosis when confronted with a ribbony or rosettoid pattern of growth and a prominent delicate vascularized stroma.[513] These tumors will express cytokeratins, neuroendocrine markers and typically one or more pituitary hormones. Null cell (pituitary hormone negative) cases are common though.

Paragangliomas have been reported both intranasally and in the nasopharynx.[514] These are morphologically and immunophenotypically identical to those occurring elsewhere and lack the fibrillary stroma that is characteristic of olfactory neuroblastoma.

Peripheral nerve tumors of the sinonasal region are extremely rare.[515] They presumably arise from the ophthalmic and maxillary branches of the trigeminal nerve and from branches of the autonomic nervous system. The most common type is the schwannoma, which may cause diagnostic problems because of hypercellularity and the fact that—in contrast to its more common counterpart in the soft tissue—it is often unencapsulated.[516] Neurofibromas (including the plexiform variety) and malignant peripheral nerve sheath tumors have also been observed.[517] Some of the latter have exhibited focal skeletal muscle differentiation ("Triton tumor").[517] Some peripheral nerve tumors occur in association with neurofibromatosis 1 (von Recklinghausen disease).

Tumors of Melanocytes

Primary sinonasal malignant melanomas usually present as solid polypoid growths.[518] Their most common location is the nasal cavity, followed by antrum, ethmoid, and frontal sinuses.[518] They arise from melanocytes located in the epithelium and stroma of the respiratory mucosa.[519] Most sinonasal melanomas are easily recognizable microscopically, but some can be missed because of their lack of pigmentation, pleomorphic features, pseudopapillary configuration, or prominent spindle cell appearance (Fig. 4.78).[518,520] Occasional examples have shown prominent myxoid features[521] and others have been accompanied by metaplastic bone formation.[522] The epithelial basal layer should be searched for the presence of theque-like growth or "junctional" activity to support a diagnosis of primary sinonasal melanoma. However, this features is often obscured the presence of surface mucosal ulceration. Immunohistochemically, these tumors are reactive for vimentin, S-100 protein, Melan-A (Mart-1), and HMB-45, that is, they have a profile similar to that of their cutaneous counterparts. The prognosis is extremely poor, with most patients dying of metastatic tumor in less than 5 years.[518,523]

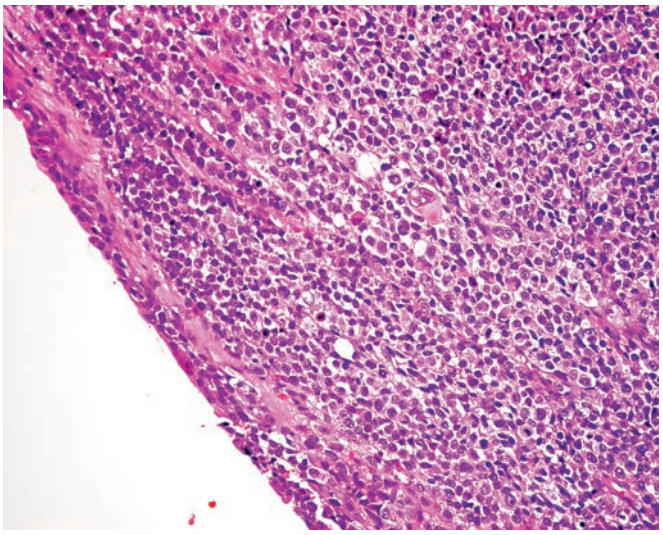

Figure 4.78 Malignant Melanoma of Nasal Cavity. The diffuse pattern of growth and lack of pigmentation often result in misdiagnoses.

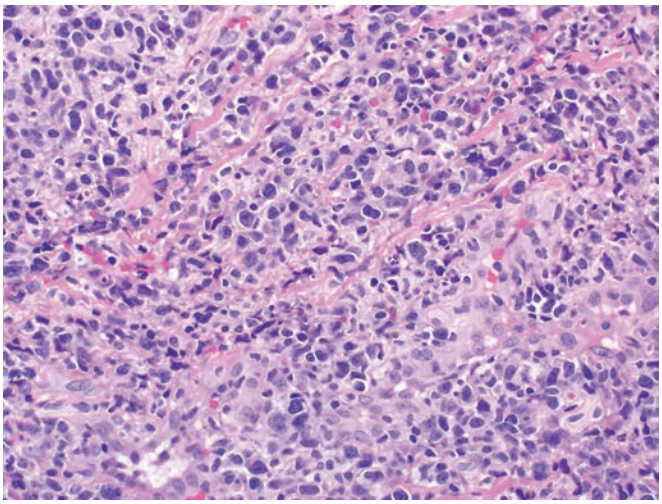

Figure 4.80 Most extranodal NK/T-cell lymphomas are composed of a heterogeneous proliferation of atypical lymphocytes.

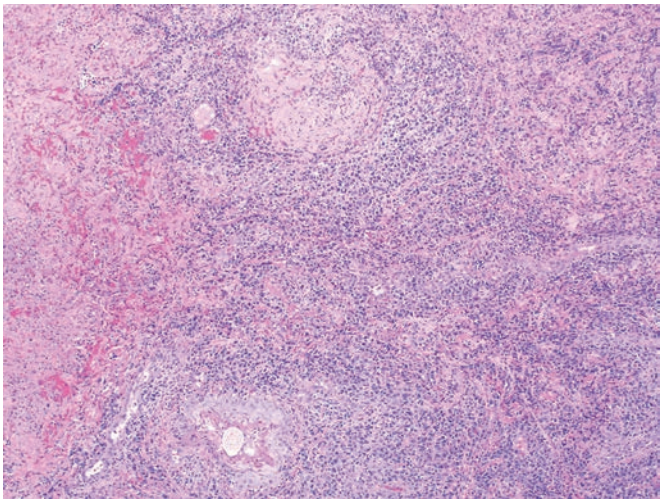

Figure 4.79 Extranodal NK/T-cell lymphoma demonstrating necrosis *(left)* and vessel involvement *(upper center)* with focal pseudoepitheliomatous hyperplasia *(bottom left)*.

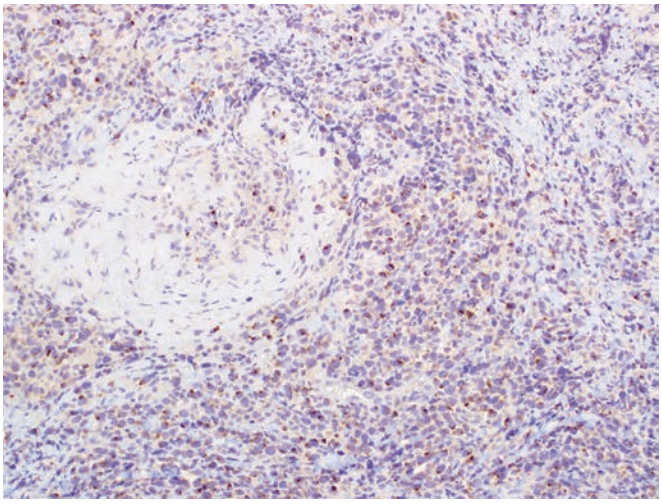

Figure 4.81 Immunohistochemical demonstration of NK marker expression such as TIA-1 help to confirm the diagnosis.

Lymphoid Tumors and Tumorlike Conditions

Malignant lymphoma can present initially as a mass in the sinonasal region or nasopharynx.[524,525] Nearly all cases are of non-Hodgkin type[526,527] and the large majority fall into one of three categories: (1) NK/T-cell type; (2) B-cell type; and (3) peripheral T-cell type.[528] There is a marked geographic difference in their relative frequency: B-cell lymphomas predominate in series from the United States and Western Europe, whereas NK/T-cell lymphomas are prevalent in series from the Far East and Latin America.[528–531]

Extranodal NK/T-cell lymphoma is a distinct clinicopathologic entity which is highly associated with EBV.[442] Morphologically, it is characterized by a broad cytologic spectrum, ranging from small or medium-sized to large transformed cells (Figs. 4.79 and 4.80).[532] Necrosis is nearly always present. Angioinvasion by tumor cells is a very frequent and diagnostically important feature, sometimes accompanied by epitheliotropism reminiscent of that seen in mycosis fungoides. An admixture of reactive histiocytes, some exhibiting erythrophagocytosis, is a frequent feature. Because of the remarkable pattern of blood vessel involvement, this type of lymphoma is sometimes referred to as *angiocentric lymphoma*. However, angiocentric growth is not always present, while it can also be seen in other types of lymphoma. The immunophenotype of NK/T-cell lymphoma is characteristic: positive for cytoplasmic CD3 (as detected in paraffin sections), CD2, and CD56 but usually negative for surface CD3 (as detected by flow cytometry or on frozen section).[533] Cytotoxic markers, such as TIA-1 (Fig. 4.81) and granzyme B, are detectable in most cases.[534] Tumors with a similar phenotype occurring at other extranodal sites (such as skin, subcutaneous tissue, gastrointestinal tract, and testis) or in the lymph nodes themselves are referred to as nasal-type NK/T-cell lymphoma. While CD56 positivity is a key diagnostic feature, it should be kept in mind that this can also be seen in other lymphoma types and in a variety of nonlymphoid neoplasms, including Ewing sarcoma/PNET.[535] It has been hypothesized that the necrotizing features of this tumor type are mediated by perforin and the Fas–Fas ligand (CD95/CD95L) mechanism.[536] There is also frequent overexpression of P53.[537]

In extranodal NK/T-cell lymphomas, the T-cell receptor genes are usually not rearranged, but they are rearranged in a proportion

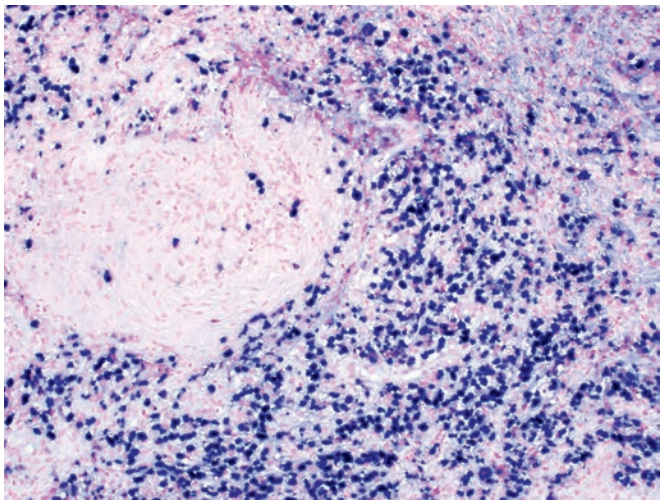

Figure 4.82 The atypical lymphocytes are positive for EBER confirming the presence of Epstein–Barr virus. Note the EBER positive cells in the vessel on the left.

Figure 4.83 **A,** A young female with a clinical diagnosis of lethal midline granuloma. **B,** Same patient a few years later. There was no evidence of systemic disease at the time. This unfortunate individual died a few weeks after this second photograph was taken.

of cases with the cytotoxic T-cell rather than the genuine NK-cell phenotype.[538] There is a consistent association with EBV, which is practically a definitional feature.[539] The most reliable way to demonstrate EBV is in situ hybridization for EBV early RNA (EBER), whereby clusters and sheets of cells exhibit nuclear labeling (Fig. 4.82). This can aid in the differential diagnosis, including in the distinction from reactive lymphoid infiltration (EBER negative) and from other lymphoma types with CD56 expression (usually EBER negative).[540]

The commonest genetic changes are −6q21 (with *PRDM1* being the most likely target gene), −17p11–p13, +1q31–qter, and +20pter–qter.[541,542] Recurrent chromosomal translocations have not been recognized.

It has become apparent that a high percentage of cases of so-called *lethal midline granuloma* (a clinical syndrome characterized by slowly progressive ulceration and destruction of the nose and paranasal cavities, with frequent erosion of the soft tissues, bone, and cartilage of the region) (Fig. 4.83) are due to NK/T-cell lymphoma.[543] In the past, these cases have been diagnosed with terms such as polymorphic reticulosis,[543] malignant histiocytosis,[544] and midline malignant reticulosis. Other cases having the clinical features of lethal midline granuloma represent particularly aggressive examples of granulomatosis with polyangiitis. Still others have been found to be the result of cocaine abuse and are characterized microscopically by nonspecific inflammation and necrosis without vasculitis.[545,546] A clue to this possibility is the presence of polarizable foreign material with an associated giant cell reaction.

Although nasal NK/T-cell lymphomas had been linked by some authors to pulmonary lymphomatoid granulomatosis (because of their angiocentric qualities, association with EBV, and other shared morphologic features) under the term *angiocentric immunoproliferative lesion*, this is no longer thought to be appropriate in view of the current belief that lymphomatoid granulomatosis is an EBV-linked B-cell lymphoma with a florid T-cell reaction.

B-cell lymphoma of the sinonasal region usually presents as a large cell lymphoma with a diffuse pattern of growth and a relatively monomorphic appearance. It is much more common in the paranasal sinuses than in the nasal cavity (an important point in the differential diagnosis with NK/T-cell lymphoma) and constitutes the most common type of sinonasal lymphoma in the United States and western Europe.[547] Burkitt lymphoma is the predominant form of sinonasal lymphoma in the pediatric US population.[548]

Peripheral T-cell lymphoma is uncommon in the sinonasal region and does not express CD56 and usually lacks the necrotizing and angiocentric features of NK/T-cell lymphoma.[549] In contrast to the latter, it usually lacks an association with EBV and shows rearrangement of the T-cell receptor gene.[549]

The behavior of sinonasal lymphoma is difficult to assess because of the fact that one of its major types (NK/T-cell) has been only recently defined, that some of the reported series do not include a thorough immunophenotypic evaluation, and that many cases of NK/T-cell lymphoma go unrecognized for years. In the Far East (where NK/T-cell lymphoma predominates), about 70%–80% of patients with sinonasal lymphoma present with stage IE or IIE disease, have a complete response rate of 75%, and a 2-year overall survival of 50%.[528] In one series from the United States (where B-cell lymphoma is prevalent), the overall survival rate was 52%.[550]

Plasmacytoma (extramedullary plasmacytoma) arising in the nasal cavity or nasopharynx may present primarily as a soft bleeding mass.[551] Microscopic examination shows a monomorphic infiltration by plasma cells which can range in appearance from mature to immature and anaplastic.[257] Amyloid deposition among the neoplastic cells is sometimes present. Approximately 10%–20% of patients with apparently solitary plasmacytomas of the upper air passages subsequently develop disseminated myeloma. In some patients, this process takes 10 or more years to become manifest. Local control of the disease can usually be achieved with radiation therapy.[552]

Angiotropic (intravascular) lymphoma is not to be confused with angiocentric (NK/T-cell) lymphoma (see Chapter 37). In this condition, the neoplastic lymphocytes are predominantly within the lumen of the vessels rather than infiltrating the vessel wall and are usually of B lineage. This unusual type of lymphoma can present initially as an intranasal lesion.[553]

Hodgkin lymphoma presenting as a primary disease in this region is exceptional, but isolated cases of this occurrence have been reported.[554]

Myeloid (granulocytic) sarcoma has been seen limited to the sinonasal region and simulating malignant lymphoma in routinely stained sections.[555]

Pseudolymphoma (reactive lymphoid hyperplasia) may present as a polypoid intranasal mass.[556]

Angiofibroma (Nasopharyngeal Angiofibroma)

Angiofibroma occurs almost exclusively in males between 10 and 25 years of age[557]; however, well-documented cases in older patients are on record. Several cases have been reported in patients with familial adenomatous polyposis (FAP), but alterations of the *APC* gene have not been found in the tumors.[558] The great predilection for young males strongly suggests that this lesion is androgen dependent, a theory confirmed by the fact that stromal and endothelial nuclear immunostaining for androgen receptors is found in 75% of cases; by contrast, very few are positive for progesterone receptors and estrogen receptors.[559] It has also been found that nasopharyngeal angiofibroma contains protein basic fibroblast growth factor (bFGF)[560] and that there is a strong nuclear expression of β-catenin.[561] Concordant with this latter feature, sporadic (not associated with FAP) angiofibromas often have activating mutations of the *CTTNB* gene.[562]

This neoplasm arises from a distinctive erectile-like fibrovascular stroma located in the posterolateral wall of the roof of the nose, where the sphenoidal process of the palatine bone meets the horizontal ala of the vomer and the root of the pterygoid process of the sphenoid bone. Because of this, these are now simply referred to as angiofibroma instead of nasopharyngeal angiofibroma. Grossly, it presents as a polypoid mass that bleeds severely on manipulation and biopsy (Fig. 4.84). It can grow to occlude the involved nares completely. It may protrude below the free edge of the soft palate, extend into the antrum, and grow to the external orifice of the nares, posteriorly into the nasopharynx, or even into the orbit and cranial cavity.[556] Selective carotid arteriograms were often used to determine the gross confines of the tumor, but this method has been replaced by noninvasive techniques such as CT scan and MRI.

Microscopically, nasopharyngeal angiofibroma is composed of an intricate mixture of blood vessels and fibrous stroma (Fig. 4.85). The latter varies from loose and edematous, with stellate fibroblasts and numerous mast cells, to a dense, acellular, and highly collagenized tissue. The latter is particularly striking and diagnostic. The cellularity varies between tumors but is often homogeneous in a given tumor. The vessels range from capillary size to venous size; the larger vessels

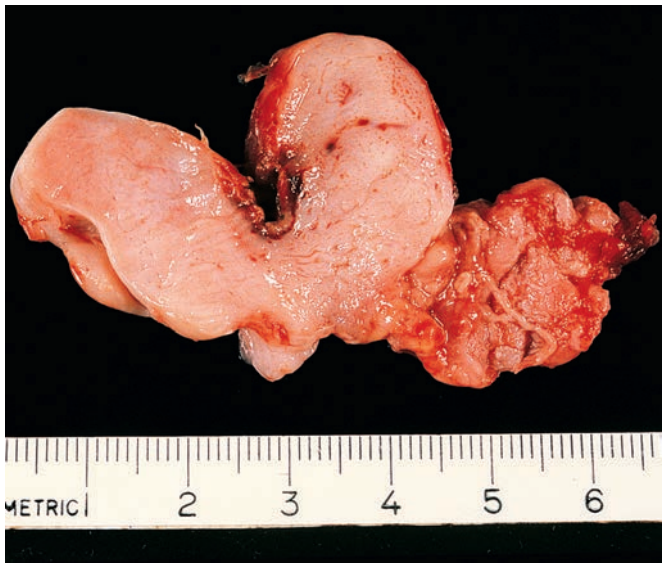

Figure 4.84 Nasopharyngeal Angiofibroma. The cut surface shows the characteristic spongy appearance and well-circumscribed outline.

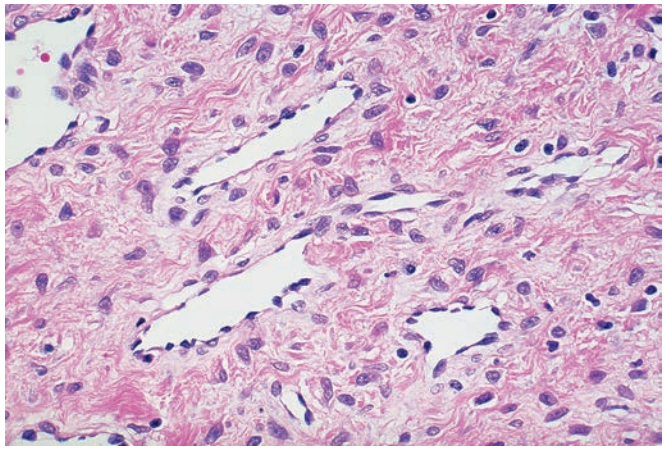

Figure 4.85 Nasopharyngeal Angiofibroma. The dense fibrous quality of the stroma and the numerous thin-walled vessels are characteristic of this entity.

are located at the base of the lesion, whereas the smaller capillary-like vessels with plump endothelial cells are particularly common at the "growing edge" of the tumor.[563] The large vessels may have an irregular or incomplete smooth muscle coat, but they lack elastic fibers. Many examples have a "hemangiopericytomous" vascular pattern. It is important to distinguish angiofibromas from lobular capillary hemangiomas because of the different natural history of these lesions. In general, hemangiomas are accompanied by less fibrous tissue, show some degree of lobulation, and their vessels do not have the "erectile tissue" appearance so characteristic of nasopharyngeal angiofibroma. Location of the tumor is very important in this regard; a diagnosis of angiofibroma should be questioned for any tumor not located in the area described in the preceding paragraph, and particularly for those limited to the nasal cavity. Solitary fibrous tumors can be confused with angiofibromas, but they are much more cellular with marked variations in cellularity and denser collagen bundles.

There is no doubt that some large angiofibromas regress after puberty, especially after incomplete surgical removal or radiation

therapy. Spontaneous total regression, however, is very rare[564]; therefore, in a patient with symptoms, treatment is indicated. There is controversy as to whether surgery or radiation is the treatment of choice, but most writers favor surgical resection for early lesions.[565,566] Preoperative embolization is used in most cases to control intraoperative and perioperative bleeding.[567] Radiation therapy or even chemotherapy may be necessary for more advanced and aggressive tumors.[568] Most post-therapy recurrences develop within the first year.[569] Meticulous removal of the angiofibroma is essential to prevent recurrence, particularly the portion of the tumor which infiltrates the pterygoid canal and basisphenoid.[570] A multidisciplinary approach may be necessary to achieve cure.[571] A few cases of sarcomatous transformation after radiation therapy have been described.[572]

Other Tumors and Tumorlike Conditions

Dermoid cysts are dorsal developmental anomalies located in the midline and histologically composed of benign ectodermal and mesodermal elements. Most are located in the subcutaneous tissue of the supraorbital ridge and nose and less commonly in the glabella and columella. Rare examples occur in the paranasal sinuses. They may be associated with bony defects and sinus tracts.[573] They can extend intracranially and result in CNS infection.[574]

True teratomas have been reported in the sinuses and nasopharynx of infants and children. The large majority are histologically mature and clinically benign.[575]

Nasal chondromesenchymal hamartoma is a benign and probably non-neoplastic process which presents as an intranasal or paranasal polypoid mass in infants and occasionally in older children and adults.[576,577] It is composed microscopically of mature cartilage, myxoid stroma, and aneurysmal bone cyst-like formations, and it has been regarded as the upper respiratory tract homolog of chest wall mesenchymal hamartoma.

Respiratory epithelial adenomatoid hamartoma (REAH) is the cumbersome name that has been proposed for a well-differentiated proliferation of glands lined by ciliated epithelium originating from the mucosal surface; the glands often have a thickened basement membrane (Fig. 4.86). The most common location they arise from is the nasal septum, particularly along its posterior aspect.[578] Although originally described as a hamartomatous condition, REAH is now thought by some to be a neoplastic process and possibly related to low-grade (nonintestinal) sinonasal adenocarcinoma.[579]

Vascular tumors are relatively common and include a large variety of types. Care must be taken to not over diagnose the normal heavily vascularized connective tissue of the nasal cavity as a vascular neoplasm. *Lobular capillary hemangioma* is a common tumor of the nasal cavity, where it can reach a large size (Fig. 4.87). This tumor is often misinterpreted as a nasopharyngeal angiofibroma, or—worse—as an angiosarcoma, the latter because of the marked cellularity and high mitotic activity that it may exhibit. Detection of a *lobular* pattern of growth within the lesion (as opposed to freely anastomosing vascular channels) is a key diagnostic feature. Support for the diagnosis is obtained by the immunohistochemical demonstration of the presence of CD31-positive endothelial cells and actin-positive prethelial/smooth muscle cells, the latter predominating.[580]

Glomangiopericytoma *(sinonasal-type hemangiopericytoma, hemangiopericytoma-like tumor)* is a vascular mesenchymal neoplasm that is clinically and histologically distinct. They may arise either in a paranasal sinus or in the nasal cavity, the latter predominating.[581,582] The clinical diagnosis is often that of allergic polyp. Microscopically, the lesions appear vascular and highly cellular, but they have little atypia, necrosis, or mitotic activity (Fig. 4.88). The cells are ovoid or spindled with monotonous nuclei and scant amounts of pale eosinophilic cytoplasm. They array around staghorn-type vessels in areas and are associated with a patchy inflammatory infiltrate and extravasated red blood cells. The proliferation of spindle cells are arranged in short fascicles, but other patterns such as storiform and whorled patters can be seen. A distinct features is the presence of an acellular, hyalinized zone located around small blood vessels (Fig. 4.89). Cytologic atypia, mitotic activity, and necrosis are not present. Immunohistochemically, there is strong reactivity for vimentin, smooth muscle actin, and muscle specific actin.[582] The cells are negative for S-100 and desmin and typically for CD34. CD34 is very focal in the rare cases that are positive. Ultrastructurally, the most consistent features are basal lamina material enwrapping the individual cells, tapered cytoplasmic extensions, and orderly bundles of filaments.[582] Most view this tumor as being closer to Stout's original concept of hemangiopericytoma than most other tumors that have received this term, in the sense that it is composed of vascular myoid cells similar to glomus cells.[583] Glomangiopericytomas

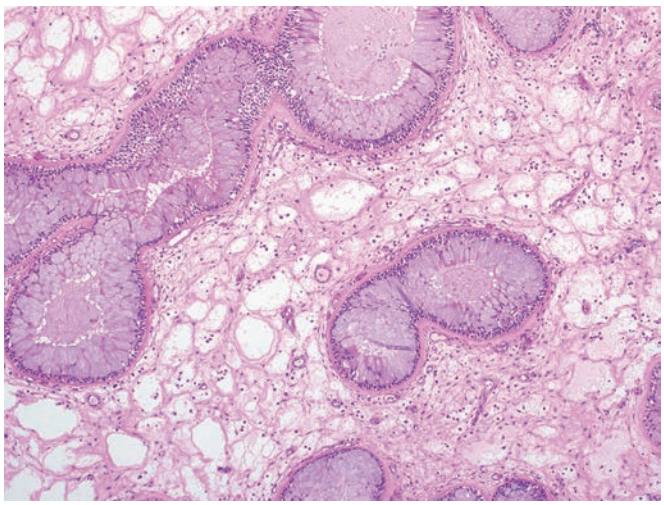

Figure 4.86 Respiratory Epithelial Adenomatoid Hamartoma. While these resemble inverted papillomas, the epithelial lining consists of normal surface respiratory mucosa with thickened basement membranes.

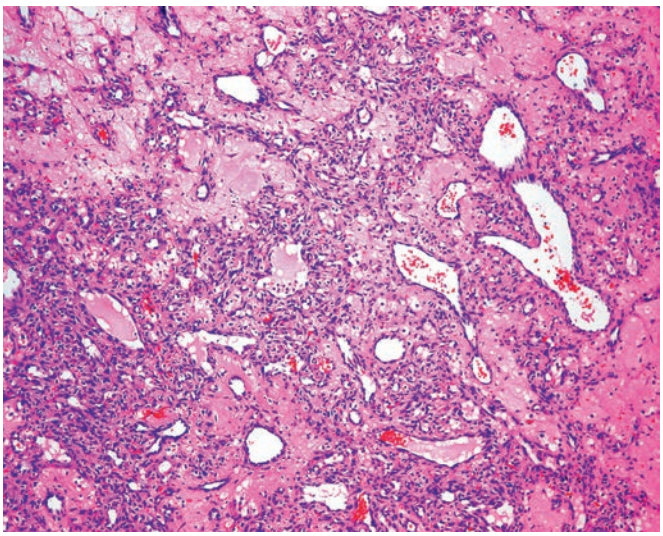

Figure 4.87 Lobular Capillary Hemangioma of Nasal Cavity. Numerous capillary lobules are seen. This lesion should not be confused with nasopharyngeal angiofibroma.

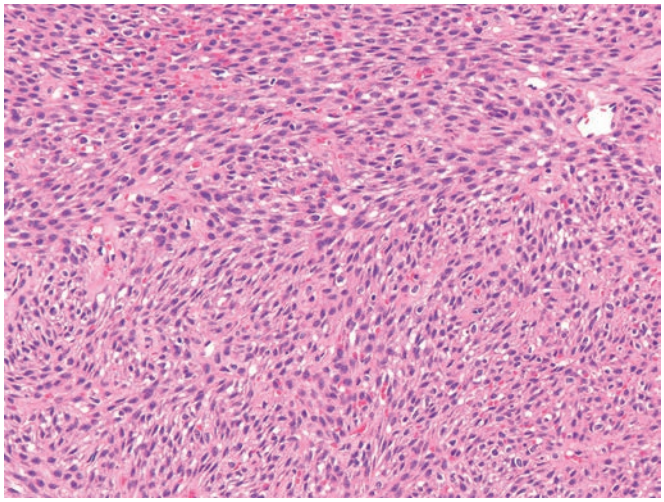

Figure 4.88 Glomangiopericytoma (Hemangiopericytoma-Like Tumor) of Nasal Cavity. Predominantly oval tumor cells arrange themselves around blood vessels forming small fascicles.

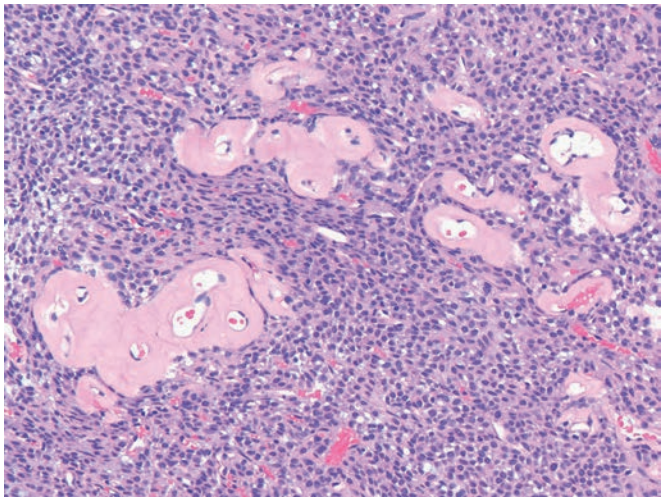

Figure 4.89 Perivascular hyalinization is frequently seen in glomangiopericytomas.

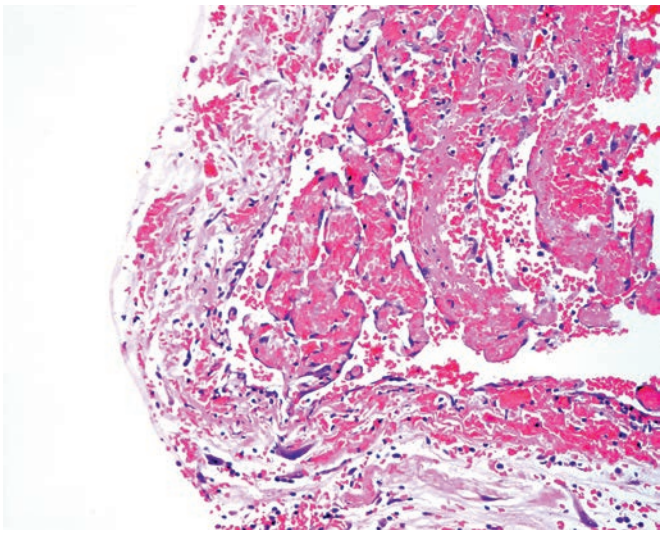

Figure 4.90 So-Called Masson Hemangioma (Papillary Endothelial Hyperplasia). The intraluminal papillary fronds have a fibrin core and are covered by endothelial cells.

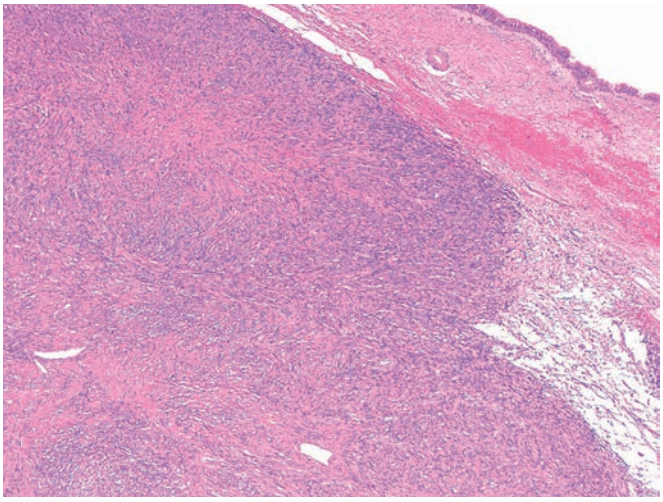

Figure 4.91 Solitary Fibrous Tumor of Paranasal Sinus. The tumor is highly vascularized and shows an alternation of hypercellular and hypocellular foci.

are low-grade lesions that tend to have an excellent long-term prognosis. Local recurrences may develop, but metastases do not occur.[581,582]

Other vascular tumors of the region include *hemangioma*, *lymphangioma*, conventional *glomus tumor*, *Masson hemangioma* (Fig. 4.90) (papillary endothelial hyperplasia), *angioleiomyoma* (vascular leiomyoma), *Kaposi sarcoma*, and the exceptionally rare *angiosarcoma*.[584] Before making the latter diagnosis in the nasal cavity, other possibilities should be considered, such as a particularly florid form of lobular capillary hemangioma, the reactive vascular changes in cocaine abusers,[585] and the prominent angiectatic changes sometimes seen in nasal polyps.[342]

Solitary fibrous tumor (formerly hemangiopericytoma) is uncommon in the upper respiratory tract accounting for less than 0.1% of neoplasms. Most occur in adults, and all sites can be affected, with the nasal cavity and paranasal sinuses being most frequent. They are morphologically, genetically, and immunohistochemically analogous to non-sinonasal solitary fibrous tumors (Figs. 4.91 and 4.92).[586] Most behave in a benign fashion but recurrences can be seen especially in lesions that have been inadequately excised. Rare cases may have histologic and clinical features of a high-grade malignancy.

Low-grade sinonasal sarcoma with neural and myogenic features (biphenotypic sinonasal sarcoma) is a recently described spindle cell sarcoma occurring in the sinonasal region and demonstrating immunophenotypic evidence of both neural and myoid differentiation.[587] Most patients are adults, and there is a female predilection. Morphologically, they are infiltrative and highly cellular being composed of uniform spindle cells arranged in fascicles with a herringbone-type appearance. They are usually associated with a benign respiratory epithelial proliferation with cystic change that is likely hyperplastic in nature. They uniformly express S-100 protein and actin, typically in a patchy distribution. Cytokeratin and desmin can be focally positive in rare cases. The original authors reported two of their tumors to have the chromosomal translocation t(2;4) resulting in a *PAX3-MAML3* fusion.[588] Nearly half of patients will develop recurrence, but none have developed metastasis or died of disease.

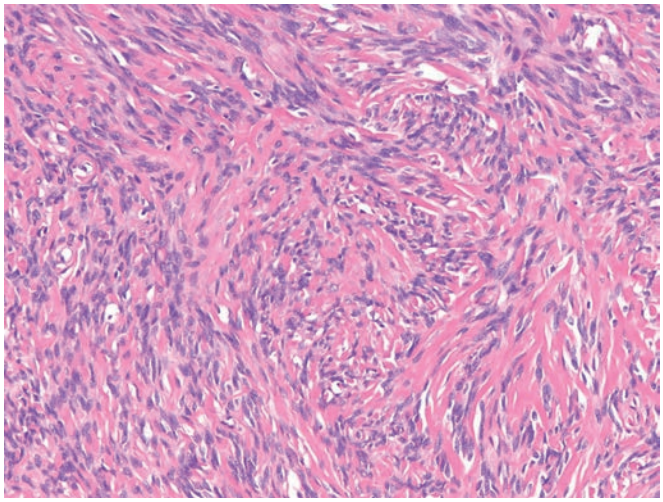

Figure 4.92 Solitary Fibrous Tumor of the Nasal Cavity. Bland spindle cells associated with ropey collagen bundles arranged in short fascicles are typical.

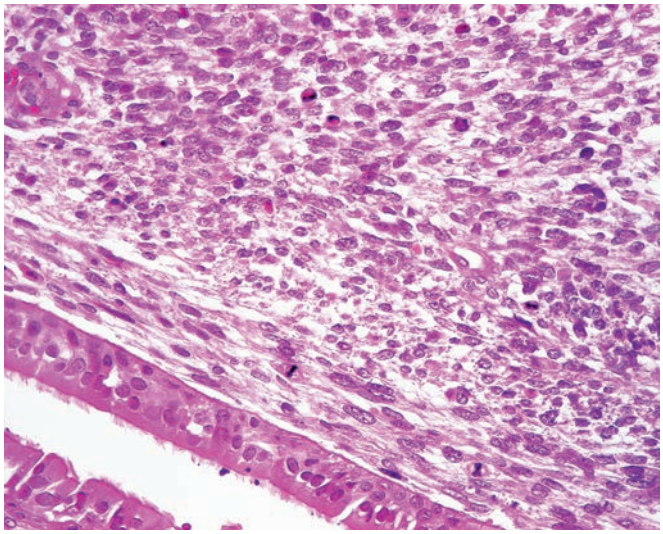

Figure 4.93 Embryonal Rhabdomyosarcoma of Nasopharynx. The lesion is extremely cellular and mitotically active.

Ameloblastoma having a microscopic appearance indistinguishable from that of its more common counterpart in the jaw can present as a primary tumor in the sinonasal tract, predominantly located in the maxillary sinus. The fact that there is often continuity of the tumor with the surface epithelium suggests that most of these tumors are primary in this region rather than extensions of jaw neoplasms.[589] As such, they are analogous to the peripheral ameloblastomas of the oral cavity (see Chapter 5). The differential diagnosis includes sinonasal extension of craniopharyngioma, the nature of which should be apparent on MRI or CT scan.[589]

Chordoma of the sphenoid region is another example of a primary cranial/intracranial tumor that can secondarily invade the nasopharynx.[590]

Rhabdomyosarcoma of the embryonal type is one of the three most common types of nasopharyngeal malignancy in children, the other two being lymphoepithelioma and malignant lymphoma (Fig. 4.93).[591] Both embryonal and alveolar rhabdomyosarcoma can also develop in the sinonasal tract in adults.[592] The alveolar type (including its solid variant) is the most common[593]; it often develops clear cell changes because of glycogen accumulation, thus simulating other neoplasms. They most frequently arise in the ethmoid sinus followed by the maxillary sinus and nasopharynx. They are genetically and immunophenotypically identical to alveolar rhabdomyosarcoma occurring elsewhere and are associated with a poor prognosis.

Teratocarcinosarcoma (teratoid carcinosarcoma) is a unique sinonasal tract neoplasm that combines features of carcinosarcoma and teratoma, the latter including primitive neuroepithelial elements with well-formed rosettes and fetal-type squamous differentiation (Fig. 4.94).[594] The histogenesis remains uncertain, but it has been proposed on the basis of cytogenetic, ultrastructural, and immunohistochemical observations that it represents a neuroectodermal tumor with divergent differentiation.[595,596] Most patients are adults, and the prognosis is poor, with 60% of the patients not surviving beyond 3 years.[597]

Soft tissue tumors of this region include, in addition to the entities already described, the following types: osseous and fibro-osseous lesions,[598] cartilaginous tumors,[599] smooth muscle tumors,[600,601] fibroblastic and myofibroblastic tumors (fibromatosis, "fibromas," and fibrosarcomas),[602] myxomas,[603] adipose tissue tumors,[604] fibrous histiocytomas,[605] synovial sarcomas,[320] extraskeletal Ewing sarcoma/PNET (Fig. 4.95),[606] phosphaturic mesenchymal tumor,[607] and desmoplastic small cell tumor.[608]

Follicular dendritic cell tumor/sarcoma is a malignant neoplasm arising from the follicular subset of the dendritic/reticulum cells family. Its features are similar to those of its more common counterpart in the lymph nodes. In the nasopharynx, its misdiagnosis as lymphoepithelioma-like carcinoma is likely. The nucleoli are not as large or eosinophilic as in the latter, and there is immunoreactivity for CD21 and/or CD35 instead of keratin.[609] Some cases have arisen against a background of Castleman disease of the hyaline–vascular type.[610]

Metastatic tumors to this region are exceptional, but well-documented cases are on record. As usual, renal cell carcinoma, malignant melanoma, and breast carcinoma head the list.[611]

Larynx

Normal Anatomy

The larynx is a complex organ composed of various stromal and epithelial tissues. The supraglottic portion is derived from the third and fourth branchial pouches, whereas the glottis and subglottis originate from the sixth branchial pouch. The major cartilages of the larynx (cricoid, thyroid, and arytenoids) are of hyaline type, whereas the epiglottis is of elastic type, with numerous fenestrations. Calcification of the thyroid and cricoid cartilages increases with age; the thyroid cartilage also undergoes ossification.

The larynx is usually divided into three major compartments:

1. **Supraglottic**, which extends from the tip of the epiglottis to the true cord and includes the aryepiglottic folds, false vocal cords, and ventricles (including its saccules)
2. **Glottic**, which extends from the top of the true vocal cords and extends caudal for 1 cm and consists of the true vocal cords and the anterior commissure that bridges them anteriorly
3. **Subglottic**, which is the area between the lower border of the glottis (where the squamous epithelium ends) and the inferior border of the cricoid cartilage.

The epithelium of the normal larynx varies from stratified squamous to respiratory-type ciliated, depending on the location, according to the scheme outlined in Table 4.2.

The junction between the two epithelial types may be abrupt or separated by a transitional zone. Patches of squamous epithelium are frequently seen within the respiratory-type epithelial regions;

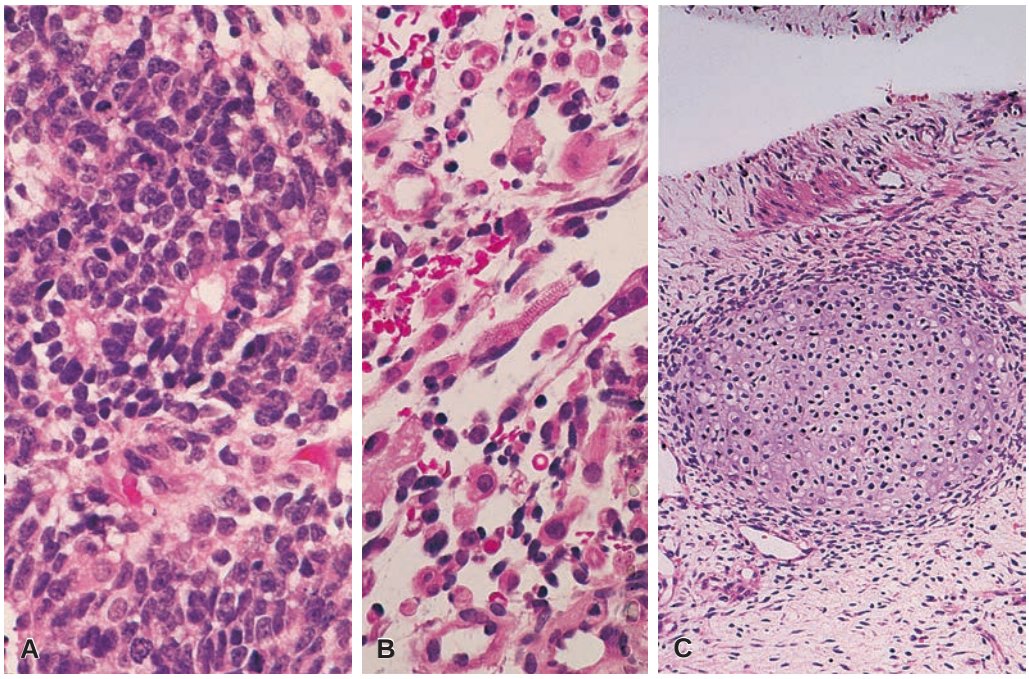

Figure 4.94 Teratocarcinosarcoma of Sinonasal Region. This composite photomicrograph shows three different components: **A,** adenocarcinomatous with neural-type rosette formations; **B,** myosarcomatous areas; and **C,** cartilaginous foci. (Courtesy of Dr. Dennis K. Heffner, Washington, DC.)

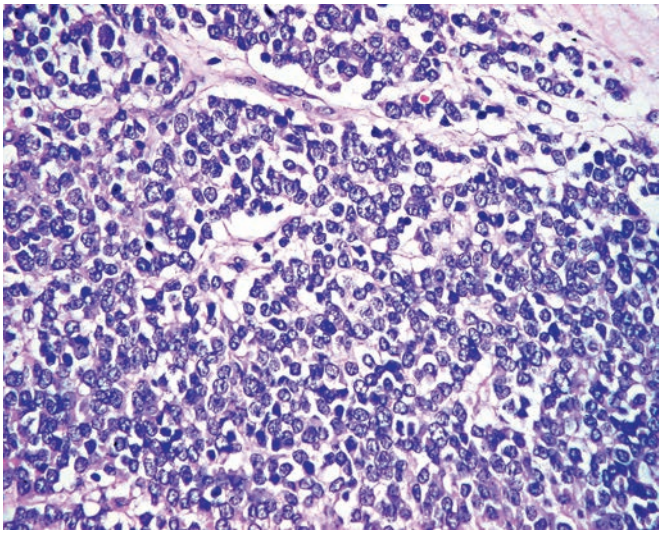

Figure 4.95 Ewing Sarcoma/PNET of Sinonasal Region. This tumor type is distinct from olfactory neuroblastoma.

Table 4.2 Classification of the laryngeal epithelium

Epiglottis	
Lingual (anterior) surface	Stratified squamous
Laryngeal (posterior) surface	Mixed stratified squamous and respiratory type
Larynx	
Supraglottic portion	Respiratory type
Glottis	Stratified squamous
Intraglottic portion	Respiratory type

these are particularly prominent in smokers. Dendritic melanocytes may be seen in the basal layer, particularly in blacks.

Seromucinous glands are present in most of the larynx; these often show oncocytic metaplasia in older individuals.[612]

Reinke space is the term used for the lamina propria of the true vocal cord, bound by the base of the squamous epithelium on one side and the vocal ligament on the other. It contains a few capillaries but lacks lymph vessels.

Biopsy specimens from the larynx may show *normal* or *metaplastic cartilaginous formations* that can be confused with cartilaginous neoplasms. One is the *vocal process of the arytenoid cartilage*, which may be seen as a sharply circumscribed nodule of uniformly mature elastic-type cartilage in biopsies from the posterior portion of the true cord. Another is *chondroid metaplasia* of the true cord, a common asymptomatic finding in the mid or posterior portion of this structure; it is characterized by blurred margins and a peripheral zone of myxoid connective tissue.[613]

Two pairs of paraganglia are normally found in the larynx, sometimes in ectopic or aberrant positions.[614]

It is not unusual to find microscopic islands of *thyroid tissue* within the fibrous capsule of the larynx and trachea, just external to the cricothyroid membrane.[615]

Cysts and Laryngocele

The two most common types of **cyst** of the larynx have been divided by DeSanto et al.[616] according to their mechanism of formation into *saccular* (24%) and *ductal* (75%). The former arise from cystic distention of the laryngeal saccule. They are usually large and deep and are often found inside the ventricle. Saccular cysts differ from laryngoceles only in that they contain mucus, whereas the latter

contain air as they still are connected to the endolarynx. Ductal cysts, which are the result of dilation of mucous glands, are small and superficial and are usually located in the true cord or epiglottis. Both types can be lined by either squamous or respiratory epithelium or a combination of both. Saccular cysts may be a cause of neonatal airway obstruction.[617]

A third type of laryngeal cyst, which probably represents a subtype of the ductal cyst, is referred to as *oncocytic cyst* (oncocytic papillary "cystadenoma") because of the fact that it is lined partially or completely by oncocytes.[618] Papillary infoldings are usually present, but the condition is regarded as a metaplastic and hyperplastic change rather than a true neoplasia. In rare cases the entire larynx is involved in a diffuse fashion by this process.[619] Oncocytic cysts have a tendency to recur.

A fourth type of laryngeal cyst is the *tonsillar cyst*.[620] It has squamous-lined crypt-like structures and abundant follicular lymphoid tissue in the wall.

The term **laryngocele** refers to an air-containing dilation of the tip of the laryngeal ventricle that communicates with the lumen of the ventricle by a narrow stalk.[621] The *internal* variety causes hoarseness, dyspnea, or reflex cough, whereas the *external* type appears as a soft mass in the lateral aspect of the neck. Combined forms occur. Laryngoceles may became infected and accumulate purulent material *(laryngopyoceles)*.

Inflammation

Chronic (nonspecific) laryngitis can be the result of infection, overuse of the voice, exposure to chemical or physical agents, or irritation by tobacco and alcohol. Microscopically, a lymphocytic infiltrate is seen beneath the mucosa with an inconstant admixture of plasma cells and histiocytes, accompanied by some hyperplasia of the overlying epithelium.

Acute epiglottitis (acute supraglottitis) is a relatively rare but potentially lethal disease because of respiratory tract obstruction caused by massive edema. It is usually a disease of children but also occurs in adults.[622] It is a bacterial infection, and *Haemophilus influenzae* type B is the most common organism involved. Grossly, the epiglottis appears red and edematous; microscopically, there is an intense acute inflammatory infiltrate associated with edema that extends to the adjacent soft tissues.

Tuberculosis of the larynx begins with edema of the posterior interarytenoid space, from which it spreads to the epiglottis, aryepiglottic fold, and vocal cords.[623,624] It can simulate carcinoma on laryngoscopic examination. Imaging studies of the chest may show active advanced tuberculosis, although not as frequently as in the past.[625] Laryngeal biopsy shows typical granulomas, with or without caseation necrosis, but granulomas can be poorly formed. Demonstration of acid-fast bacilli or their DNA sequences is necessary to document the diagnosis.

Histoplasmosis and **blastomycosis** are the two most common types of mycotic laryngitis in the United States.[626] In histoplasmosis, the early lesions are frequently located in the vocal cords and epiglottis.[24] A granulomatous lesion involving *only* the anterior portions of the larynx (especially the epiglottis) or having associated oral lesions is more likely to be histoplasmosis than tuberculosis. **Aspergillosis** and **cryptococcosis** may also involve this organ.[627,628] **Actinomycosis** of the larynx is extremely rare; only a handful of cases have been reported.[629] Several of these mycotic infections (particularly histoplasmosis and blastomycosis, but also aspergillosis) can induce a marked pseudoepitheliomatous hyperplasia of the overlying epithelium that can be confused microscopically with carcinoma.

Leprosy of the larynx is not rare in areas of the world where the disease is endemic.[630]

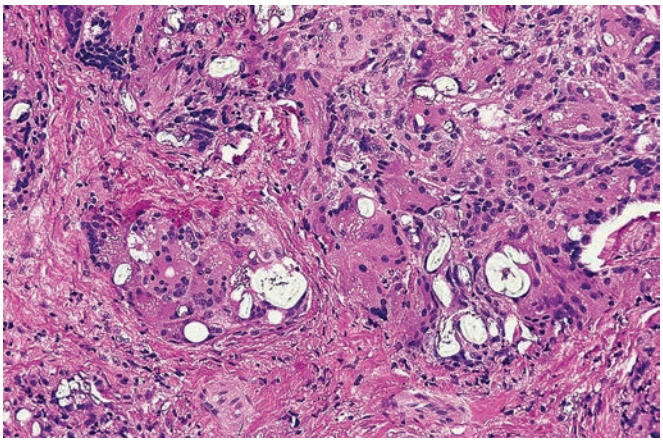

Figure 4.96 So-Called Teflonoma of Larynx. A foreign body giant cell reaction is seen around Teflon fragments. These are polarizable using polarized light microscopy.

Crohn disease can be accompanied by ulcerative and granulomatous lesions in the larynx, particularly the epiglottis.[631]

Sarcoidosis can involve the larynx and has been reported to present as epiglottic enlargement.[632]

Laryngeal granulomas resulting from endotracheal trauma caused by intubation can occur bilaterally on the vocal process of the arytenoid cartilage and may be mistaken for a neoplasm. Injection of *Teflon* into paralyzed vocal cords, used as a means of augmentation in cases of recurrent nerve paralysis, may lead to the formation of an exuberant **foreign body granuloma** ("teflonoma") (Fig. 4.96).[633] Cases of laryngeal **malakoplakia** and **Kimura disease** have been described.[634,635] **Radiation changes** may present in the form of granulation tissue–type reactions with bizarre mesenchymal cells that can simulate malignancy.[636] **Arthritis** of the cricoarytenoid joint is commonly associated with generalized rheumatoid arthritis.[637] **Pemphigus vulgaris** may rarely involve the supraglottic larynx.[638] **Gout** may result in the deposit of tophi in the true vocal cords.[639] **Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy)** can affect the subglottic region and trachea.[362]

Vocal Cord Nodule and Contact Ulcer

Vocal cord (laryngeal) nodule represents a peculiar noninflammatory reaction to injury causing hoarseness, which is seen more commonly in people who misuse their voices. It occurs chiefly on the anterior third of the vocal cords and has also been called singer's nodule, amyloid tumor, vocal cord polyp, and varix.

The microscopic appearance varies depending on the stage of evolution, as carefully recorded in the classic article by Ash and Schwartz on the subject (Fig. 4.97).[640] In the early stages, there is edema and proliferation of young fibroblasts (myxoid stage). Later, dilated blood vessels and hyalinization of the stroma appear (fibrous stage). Cases with a prominent vascular component may be mistaken for hemangioma (vascular stage). The hyaline stage was previously designated as "amyloid tumor." This is a misnomer because the material is fibrin rather than amyloid. Mixed types occur as well.

Contact granuloma (contact ulcer, granulomatous ulcer, intubation granuloma, posterior commissure ulcer) is a lesion sometimes erroneously equated with laryngeal nodule but having a different presentation, microscopic appearance, and behavior. Most are caused by severe phonotrauma, gastroesophageal reflux disease, and intubation. It is almost always found at the level of the posterior commissure, in the area of the vocal process of the arytenoid cartilage, at a site

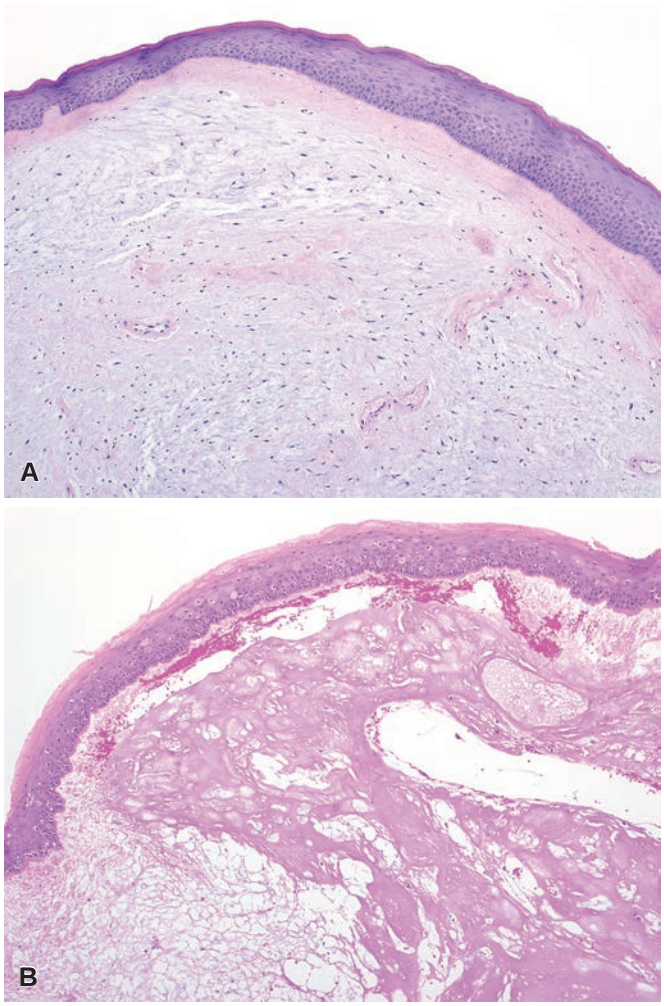

Figure 4.97 Vocal Nodule. The lesion shown in **A** has a fibromyxoid quality, whereas that depicted in **B** has fibrinoid features.

where the amount of subepithelial stroma is scantier. Microscopically, it has the appearance of exuberant granulation tissue; it is often confused with a pyogenic granuloma but lacks the characteristic lobular pattern of the latter.[641] The epithelium may be ulcerated or exhibit hyperplastic changes, sometimes of a pseudoepitheliomatous degree (Fig. 4.98).[642] The lesion stubbornly recurs after local excision but eventually subsides. Conservative management is strongly recommended, inasmuch as the trauma associated with the surgical excision can induce further recurrences.

Other Non-Neoplastic Lesions

Amyloidosis may involve the tracheobronchial tree as a localized phenomenon.[643] It is usually asymptomatic but may result in hoarseness and bleeding. The false vocal cords are the most common site, but any portion of the larynx can be involved, often in a multifocal fashion. Monoclonal light chain deposition can be detected in most cases. The disease can recur locally and become systemic or multicentric, but none of the patients studied by Thompson et al.[644] developed myeloma or lymphoma.

Eosinophilic angiocentric fibrosis is a peculiar inflammatory lesion of the upper respiratory tract thought to represent a mucosal variant of granuloma faciale and which occurs more commonly in the nasal cavity[369]; some of the reported cases have involved the

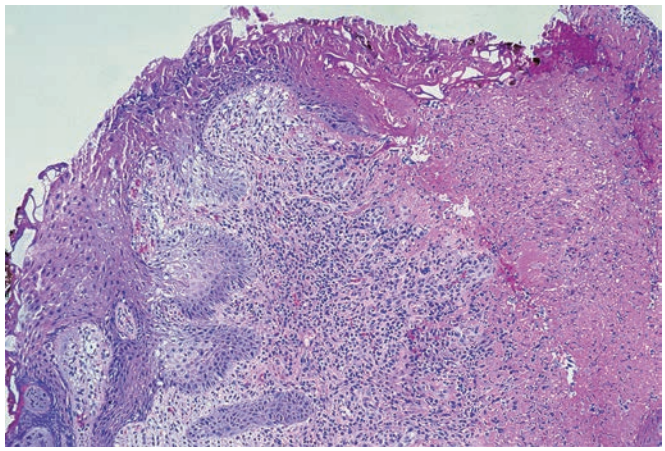

Figure 4.98 Contact Ulcer of Larynx. A polypoid mass is seen resulting from a heavily inflamed stroma covered by a partially ulcerated epithelium.

subglottic region of the trachea and the larynx.[645] The differential diagnosis includes granulomatosis with polyangiitis, Churg–Strauss syndrome, and specific infections.

Focal mucinosis has been rarely reported in the larynx and other portions of the upper aerodigestive tract.[646]

Necrotizing sialometaplasia similar to that more commonly seen in the oral cavity can occur in the larynx.[647]

Tumors and Tumorlike Conditions

Papilloma and Papillomatosis

Juvenile laryngeal papillomas present in children or adolescents with multiple papillary tumors on the true cords, from which they may spread to the false cords, epiglottis, subglottic area, and in rare cases, even the trachea and bronchi. When extensive, papillomatosis may cause extreme respiratory difficulty and even death (Fig. 4.99).

The viral etiology of juvenile laryngeal papillomatosis has been proven by ultrastructural examination,[648] immunohistochemical demonstration of HPV antigens,[649] and in situ hybridization.[650,651] Viral DNA has also been found in uninvolved sites in patients with active disease and also in patients in remission.[651] The types of HPV that have been specifically associated with laryngeal papillomas are HPV-11 and HPV-6.[652]

The microscopic appearance is that of a papillary or acanthotic growth of well-differentiated squamous cells that retain an orderly maturation pattern (Fig. 4.100).[653] Mitotic activity is common, and some degree of koilocytosis and mild nuclear atypia are the rule (Fig. 4.101). When the process involves the respiratory mucosa, the maturation pattern, which is constant in the squamous epithelium, is not so apparent. This may lead to an overdiagnosis of CIS. Mild chronic inflammation and hyperemia are usually present beneath the epithelium.[654]

These tumors tend to recur over a long period. It has been pointed out that the recurrences occur more often at junctions of stratified squamous and respiratory-type epithelium.[654] Treatment has included hormones, HPV vaccines, cautery, cryosurgery, CO_2 laser, interferon, and photodynamic therapy, with mixed but generally limited results.[655,656] In cases with very extensive involvement, laryngectomy may become necessary.

Rarely, squamous cell carcinoma develops in association with laryngeal papillomatosis. In practically all the reported cases of this complication, irradiation therapy had been administered previously

Figure 4.99 Extensive Papillomatosis in an 18-Year-Old Boy. The patient had had almost 50 resections of this process, beginning at 7 years of age, and finally died of suffocation.

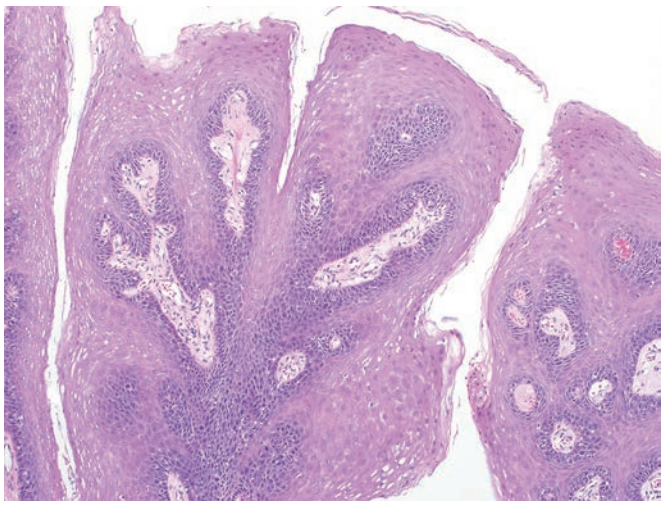

Figure 4.100 Squamous papilloma of larynx with a typical arborizing papillary appearance.

for the papillomas; however, a few cases have been documented in which malignancy developed in the absence of radiation therapy.[657] The carcinoma is usually located in the larynx, but in cases with extensive papillomatosis of the tracheobronchial tree, it may also be found in the trachea or bronchi.[658] Interestingly, in all of the reported cases of juvenile-onset respiratory papillomatosis complicated by the development of pulmonary squamous cell carcinoma, HPV-11 was identified in association with the malignant tumor.[659]

Adult laryngeal papillomas have a male predominance, are most commonly solitary, show a greater degree of inflammatory reaction, do not tend to spread, and recur less frequently than the juvenile form. As for the juvenile form, the involved viral types are usually HPV-6 and HPV-11.[662]

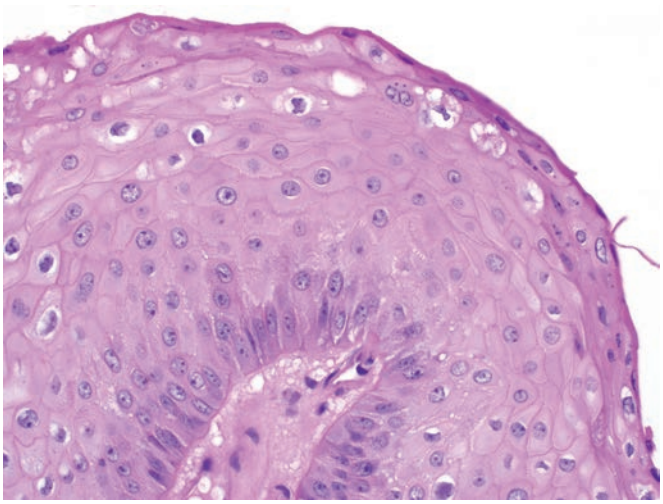

Figure 4.101 Squamous papillomas show an orderly pattern of maturation with koilocytes near the surface.

Verruca vulgaris is another HPV-related lesion that may occur in the larynx and be confused with squamous cell or verrucous carcinoma.[663]

Squamous Intraepithelial Lesions

Keratosis of the larynx involves most commonly the true cords and interarytenoid area. It is also designated as simple hyperplasia, epithelial hyperplasia, squamous hyperplasia, and leukoplakia, even if the latter term is not used as often by the clinicians as in the oral cavity. It often occurs in smokers, singers, and others who use their voices excessively. Patients may complain of hoarseness, and laryngoscopic examination may show white thickening of the involved areas. Presence of reddening should alert the clinician to the possible existence of a more significant lesion (dysplasia/CIS, see later). Cases of keratosis that exhibit an undulating warty configuration are referred to as *verrucous keratosis* or *papillary keratosis*. Microscopically, benign keratotic lesions are characterized by hyperkeratotic epithelium (often with a granular layer) and acanthosis, without atypia.

As in other sites, cases of keratosis characterized by varying degrees of cellular atypia, loss of normal maturation, and loss of stratification are grouped under generic terms such as *squamous intraepithelial lesion* (*SIL*), *squamous intraepithelial neoplasia* (*SIN*), and *laryngeal intraepithelial neoplasia* (*LIN*), these embracing the traditional categories of dysplasia and CIS. These changes are graded on the basis of the degree of nuclear abnormalities (including changes in polarity)[664] and the level of the epithelium showing loss of stratification. The World Health Organization (WHO) Classification of Tumors described and illustrated the criteria for their grading system (referred to as the "dysplasia system") as follows[665] (Figs. 4.102 to 4.105):

1. **Mild dysplasia.** The nuclear abnormalities are slight and are most marked in the basal third of the epithelial thickness. They are minimal in the upper layers where the cells show maturation and stratification. A few mitoses may be present in the parabasal layers. Keratosis and chronic inflammation are usually present.
2. **Moderate dysplasia.** The nuclear abnormalities are more marked than in mild dysplasia, and nucleoli tend to be prominent. These changes are most marked in the lower two-thirds of the epithelial thickness. Moderate nuclear abnormalities may persist up to the surface, but cell maturation and stratification are evident in the upper layers. Mitoses are present in the parabasal and intermediate layers. The lesion may be associated with keratosis.

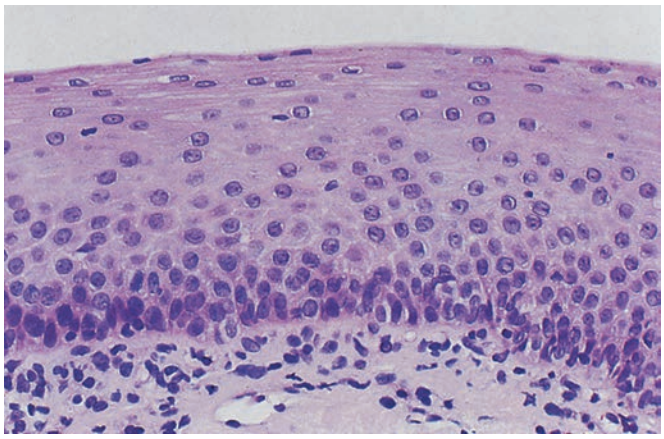

Figure 4.102 Mild Dysplasia of Larynx. There is mild nuclear atypia with retained maturation and stratification of upper layers. (From Shanmugaratnam K, Sobin H. *Histological Typing of Tumours of the Upper Respiratory Tract and Ear*. 2nd ed. New York, NY: Springer; 1991.)

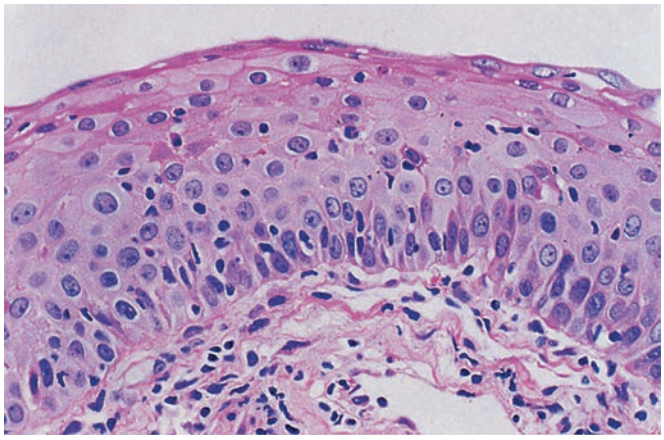

Figure 4.103 Moderate Dysplasia of Larynx. There is moderate nuclear atypia with prominent nuclei, but the stratification of the upper layers is retained. (From Shanmugaratnam K, Sobin H. *Histological Typing of Tumours of the Upper Respiratory Tract and Ear*. 2nd ed. New York, NY: Springer; 1991.)

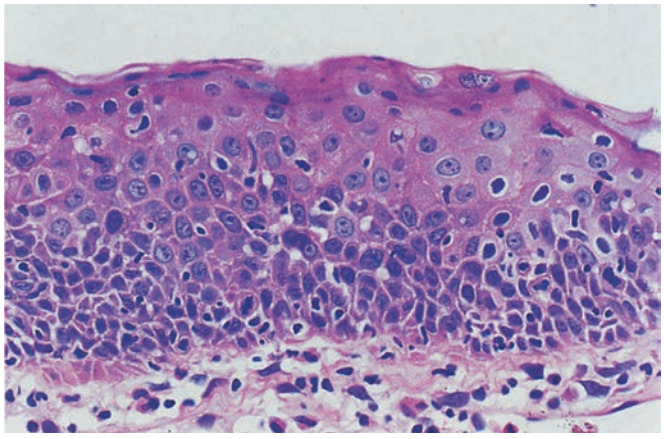

Figure 4.104 Severe Dysplasia of Larynx. There is severe nuclear atypia and increased mitotic activity, associated with some maturation and stratification of the most superficial layers. (From Shanmugaratnam K, Sobin H. *Histological Typing of Tumours of the Upper Respiratory Tract and Ear*. 2nd ed. New York, NY: Springer; 1991.)

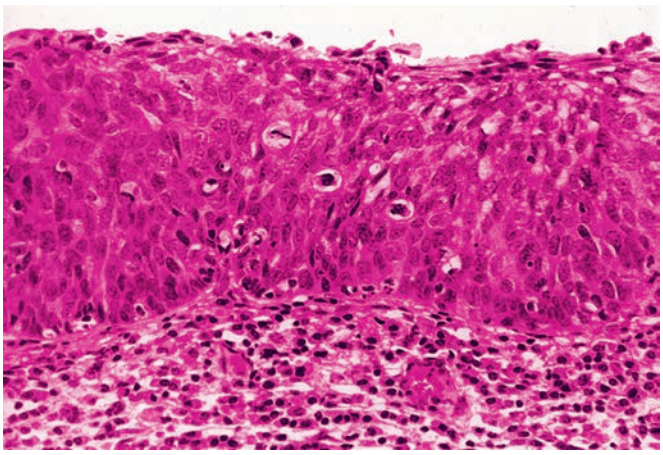

Figure 4.105 Squamous Cell Carcinoma in situ of Larynx.

3. **Severe dysplasia.** The epithelium shows marked nuclear abnormalities and loss of maturation involving more than two-thirds of the epithelial thickness with some of the stratification of the most superficial layers. Nuclear pleomorphism is common, and some of the cells may have bizarre nuclei. In some areas the nucleoli are very prominent, but in others all the nuclei are hyperchromatic. Mitoses are present high up in the epithelium, and atypical mitoses may be found. The presence of some maturation and stratification of the cells in the most superficial layers distinguishes the lesion from CIS. The lesion is frequently associated with keratosis.
4. **CIS.** A lesion in which the full thickness of the squamous epithelium shows the cellular features of carcinoma without stromal invasion.

It should be noted that the WHO scheme reproduced here makes a distinction between severe dysplasia and CIS (discussed later), whereas in most other sites these two conditions are currently grouped because of the considerable difficulty in distinguishing them consistently and because of their seemingly similar natural history.

Most cases of CIS of the larynx are composed of keratinized cells (spinous or well-differentiated type), whereas a minority are formed of basal-like cells similar to those seen in CIS of the uterine cervix (basal type). There is no evidence that these two subcategories differ from the point of view of their clinical significance.

Papillary CIS is a variant of CIS characterized by papillary fronds with a fibrovascular stroma covered by squamous epithelium with cytologic features similar to those seen in the conventional variety.[665] Going back to the latter, it needs to be pointed out again that its boundaries with severe dysplasia are very blurred, to the point that the two diagnoses should be regarded as essentially equivalent for clinical purposes. It should also be kept in mind that a lesion of dysplasia/CIS may simply represent the peripheral portion of an invasive carcinoma. Indeed, about 75% of invasive squamous cell carcinomas of the larynx have an associated in situ component.[666]

An alternative grading system, referred to as the Ljubljana classification, divides the classes as follows[667,668]:

1. Squamous hyperplasia
2. Basal–parabasal hyperplasia
3. Atypical hyperplasia
4. CIS.

The first two categories are viewed as benign, the third as potentially malignant, and the fourth as actually malignant. The authors stress the lack of significance of the presence of a surface keratin

layer in the differential diagnosis between CIS and lesser lesions, an important difference with the WHO scheme. The Ljubljana types are not easily translatable into those in the WHO system, and no compelling evidence has been brought forward that this system will improve the admittedly unsatisfactory rate of interobserver agreement with the WHO system[669] or that it can provide more accurate prognostic information.

A third proposal is that of a binary system, by which lesions are divided as follows[662]:

1. Hyperplasia/keratosis, SIN I (low grade)
2. SIN II (high grade).

A correlation exists between the grade of dysplasia/CIS and the incidence of aneuploidy,[68] immunohistochemical reactivity for EGFR,[663] cell proliferation (as measured by Ki-67 immunostaining),[670] and expression of the P53 product.[670] Obviously, the most important question in this group of patients is the estimation of the risk for the development of invasive squamous cell carcinoma. On the whole, the risk is rather small, but this is probably because there is a great predominance of patients with low-grade lesions. In a classic study by McGavran et al.,[671] of 84 patients with laryngeal keratosis with varying degrees of dysplasia followed between 5 and 15 years, only three developed carcinoma and only one of these patients died as a result. In the series of Hellquist et al.,[672] 7% of the patients with mild dysplasia progressed to more severe dysplasia or carcinoma, 24% of those with moderate dysplasia progressed to CIS or invasive carcinoma, and 25% of those with severe dysplasias progressed to invasive carcinoma. Similar results were obtained by Gillis et al.[673] and Kambic et al.[674] In the series of Stenersen et al.,[664] 46% of untreated CIS developed invasive carcinoma within 4 years. The progression of the disease can be very slow; it is not unusual for patients to have documented CIS for 5 years or more without an invasive component developing in this period.[675] None of the special techniques that have been applied to these lesions up to now has proved superior to simple morphologic assessment, as subjective and unsatisfactory this assessment may be.

The treatment of these conditions needs to be individualized in the basis of the patient's age, reliability, extent of the lesion, and—last but not least—the presence and degree of microscopic changes of dysplasia/CIS. Cases of keratosis without dysplasia or mild dysplasia can be simply watched.[676] Cases with more significant changes can be treated with vocal cord stripping, endoscopic laser resection, extensive surgery, or radiation therapy.[677]

Invasive Carcinoma

General Features

Carcinoma of the larynx accounts for 2.2% of all cancers in men and 0.4% in women. Most patients are in their fifth decade of life or beyond, but cases occurring in much younger patients are on record.[678] A large majority of the patients are males; however, the incidence in females is increasing. Smoking is the main risk factor, this risk being enhanced by heavy alcohol consumption.[679,680] In some studies, up to 25% of laryngeal squamous cell carcinomas harbor HPV, most commonly HPV-16, and less commonly HPV-18.[681] The high-risk HPV seems to be biologically relevant in a subset of laryngeal carcinogenesis, manifesting with viral integration in the cancer cell genome and increased expression of P16 protein. The HPV-associated cancers tend to occur in younger patients who are nonsmokers.[682] In general, HPV now appears to have a minor role in overall laryngeal carcinogenesis.

Interestingly, a difference in the incidence of the location of the tumor within the larynx has been found depending on the site of residence of the patient.[2] Hoarseness is a common early symptom for glottic tumors but not for those located elsewhere.

Patients with laryngeal carcinoma are at an increased risk for the development of a second tumor in the upper aerodigestive tract or lung.[122]

The "T" classification for cancer of the larynx is based on a combination of clinical, endoscopic, and radiologic parameters.

Types, Spread, and Therapy

Spread of laryngeal carcinoma can be accurately predicted from the site of origin and knowledge of the anatomic barriers produced by the different laryngeal compartments.[2] Accordingly, these tumors have been traditionally divided, depending on their location, into four major types (Figs. 4.106–4.109). This classification has been largely based on laryngoscopic evaluation, but the use of CT scan and MRI has resulted in greater accuracy. MRI is more sensitive but less specific than CT in detecting cartilage invasion by tumor; it

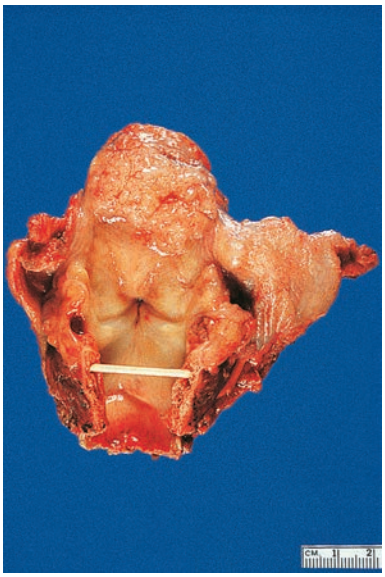

Figure 4.106 Supraglottic carcinoma of the larynx replacing most of the epiglottis.

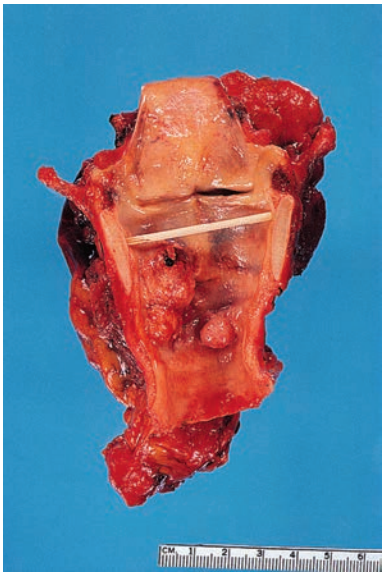

Figure 4.107 Subglottic carcinoma appearing as multiple polypoid masses.

tends to overestimate it, whereas CT tends to underestimate it.[683] The four types are as follows:

1. **Glottic** (60%–65% of all cases). These tumors arise from the true vocal cords, the anterior third of the glottis being the most common location. They tend to remain localized for long periods because of the surrounding cartilaginous wall and the paucity of lymphatic vessels in Reinke's space. In time they may spread across the anterior commissure to the opposite cord, posteriorly to involve the arytenoids, superiorly to involve the supraglottic portion, inferiorly to extend into the subglottic area, and anteriorly to penetrate the thyroid cartilage with subsequent growth into the soft tissues of the anterior neck. In one series, ipsilateral lymph node metastases were not found in any of 41 T1 lesions and in only 7.3% of T2 tumors[684]; therefore prophylactic lymph node dissection is not indicated.

   Early cases can be treated by irradiation therapy with excellent results.[685] If irradiation fails, surgery still saves most of the patients.[686] Small, superficially invasive squamous cell carcinomas of the true cord can also be cured by endoscopic removal (cordectomy) alone with results essentially identical to those obtained in CIS.[687] T2 glottic cancers can be treated by hemilaryngectomy.[688]

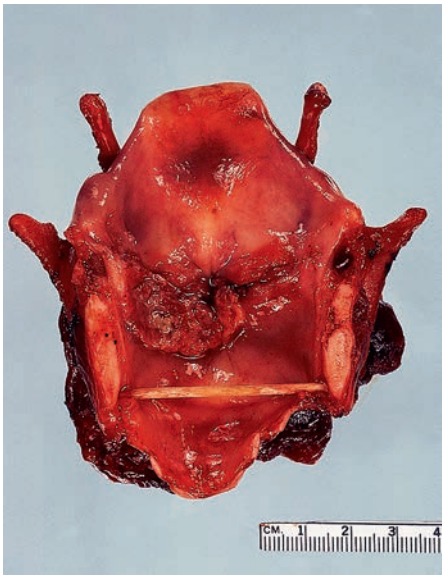

Figure 4.108 Gross appearance of transglottic carcinoma.

2. **Supraglottic** (30%–35% of all cases). These tumors involve the false cord, the ventricle (including those arising in a laryngocele), aryepiglottic fold, and/or the laryngeal or lingual surface of the epiglottis.[689] One-third of the supraglottic cancers arise from the latter structure. These tumors have a marked tendency to spread toward the pre-epiglottic space, but the oropharynx is protected by the thick hyoepiglottic ligament.[690] Only 1% of supraglottic carcinomas invade inferiorly to involve the glottis. Invasion of cartilage is also rare and is largely restricted to cases in which the cartilage had undergone osseous metaplasia.[691]

   The incidence of lymph node metastases averages 40%. About 20%–35% of patients with clinically negative nodes harbor occult metastases on microscopic examination.[2] Supraglottic tumors can be treated by irradiation or laryngectomy.[685]

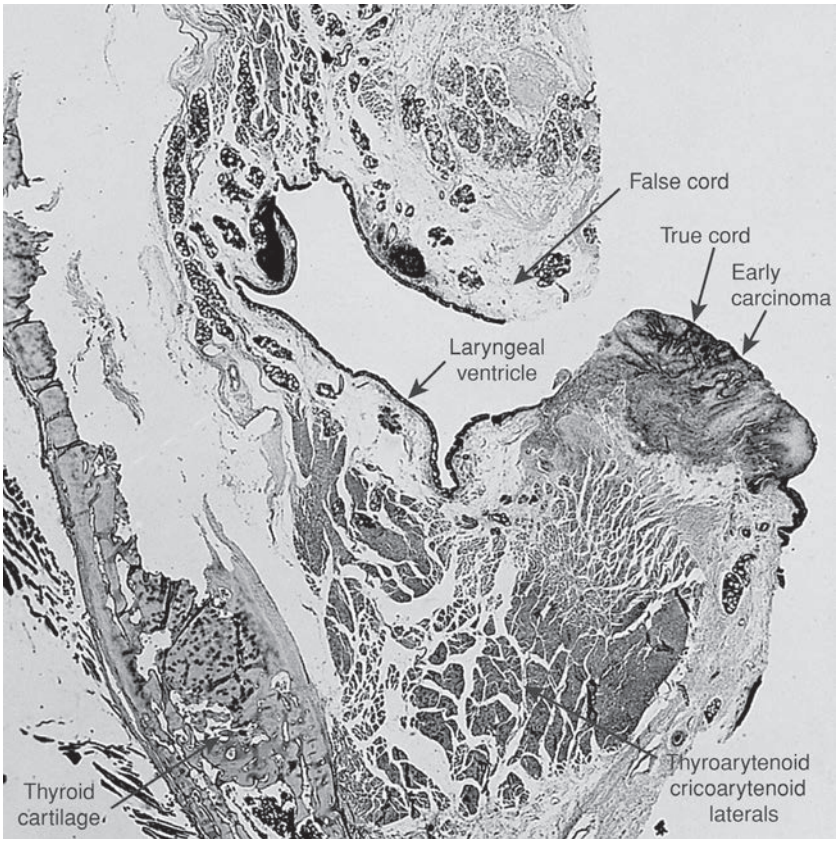

Figure 4.109 Superficial carcinoma of true vocal cord (glottic carcinoma), as seen in a sagittal section. This lesion is equally curable by resection or radiation therapy.

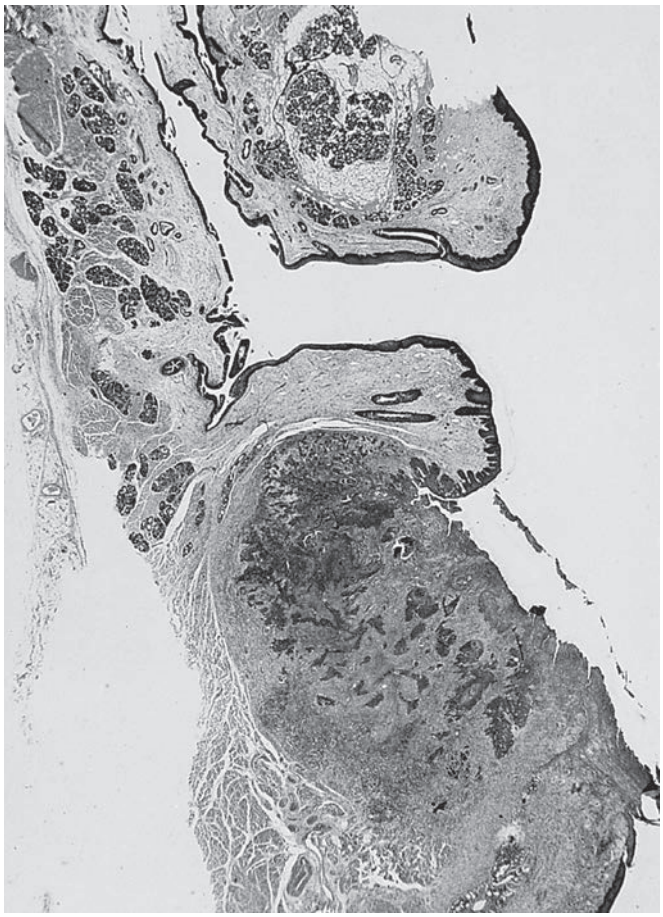

Figure 4.110 True Subglottic Squamous Cell Carcinoma in a 42-Year-Old Man. Hemilaryngectomy was performed. All margins were free. This was the third infraglottic carcinoma out of 600 consecutive laryngectomies.

3. **Transglottic** (less than 5% of all cases). This term is applied to cancers that cross the laryngeal ventricle.[684] They have the highest incidence of lymph node involvement (52%). Of 16 transglottic cancers examined by McGavran et al.,[692] five (31%) had clinically undetected node metastases. This figure indicates that elective lymph node dissection should be performed for tumors in this location, in addition to a total laryngectomy.[693]
4. **Subglottic** (infraglottic) (less than 5% of all cases). Under this category are included cancers involving the true cord with a subglottic extension of more than 1 cm (Fig. 4.110) as well as tumors entirely confined to the subglottic area. The latter are very unusual.[694] Lateral spread to the cricoid cartilage is the rule. Also common is destruction by tumor of the weak interthyrocricoid membrane, with invasion of the prelaryngeal wall and thyroid gland.[695] Because of the frequent extension to the trachea, this structure should be resected as distally as possible. Metastases to cervical nodes occur in 15%–20% of the cases, and metastases to paratracheal nodes occur in about 50%.[76] Therefore radical node dissection with clearance of paratracheal nodes is indicated.

   Tumors situated on the pyriform sinus or postcricoid areas are considered of hypopharyngeal origin.

   The most common sites of metastases from laryngeal carcinoma, regardless of site of the primary tumor, are the regional lymph nodes, followed by the lungs. Thyroid gland and jugular vein involvement are usually the result of direct extension; the latter is seen only in the presence of extensive nodal involvement and indicates a high probability of systemic dissemination.[696]

Pathologic Features

Grossly, laryngeal carcinomas are generally described as a protruding pink to gray mass that is often ulcerated. Vocal cord lesions tend to have a keratotic appearance.

Microscopically, over 90% of laryngeal carcinomas are of the squamous cell type. They are graded into well, moderately, and poorly differentiated on the basis of the degree of differentiation, cellular pleomorphism, and mitotic activity. Most glottic carcinomas are well to moderately differentiated, whereas a high percentage of those located in other regions of the larynx (particularly in the subglottis) are moderately to poorly differentiated. In general, the smaller the tumor, the better differentiated its appearance. Those neoplasms in which the stromal invasion is limited to the most superficial layers just below the basement membrane (according to some authors, within 0.5 mm from the basement membrane level) are designated as *superficially invasive*, *minimally invasive*, *microinvasive*, or *"early."* The last term should be avoided, not only because it may be inaccurate chronologically speaking, but also because it is used by clinicians with a somewhat different meaning; specifically, to indicate that the mobility of the cord is not impaired. Tumors involving the anterior commissure are treacherous in the sense that significant invasion may be clinically inapparent.

Occasionally, the tumor extends over a large surface of the larynx while retaining its superficial character.[697]

Papillary squamous cell carcinoma is a variant of squamous cell carcinoma with an exophytic pattern of growth and the features of CIS associated with foci of invasion. These foci can be inconspicuous and require thorough sampling for their identification. This tumor is distinguished from verrucous carcinoma on the basis of the cytologic atypia it exhibits. It shows a greater degree of association with HPV than ordinary squamous cell carcinoma, and it has a relatively good outlook (in contrast to its counterpart in the sinonasal region).[698]

The diagnosis of postirradiation persistence of squamous cell carcinoma is often difficult to make. If dysplastic or atypical cells are present but limited to the mucosa it is better to err on the conservative side because of the great difficulty in distinguishing tumor recurrence from postirradiation atypia.[68]

Molecular Genetic Features

The genetic changes of laryngeal squamous cell carcinomas are generally similar to those of squamous cell carcinomas of other head and neck sites. Multiple genetic alterations are necessary to drive the progression from a normal cell to invasive cancer.[699] Allelic losses of 3p (harboring *FHIT*), 9p21 (harboring *CDKN2A*), and 17p13 (harboring *TP53*) are considered to be early events in carcinogenesis, since they are found in 60%–80% of cases of preneoplastic lesions and invasive carcinomas.[699,700] Other common genetic changes include gains or amplifications of 3p, 5p, 8q, 11q13 (harboring *CCND1*, among others), and 18p, and losses of 5q, 8p, 11q23–24, 13q, and 18q. A proportion of cases strongly express transforming growth factor alpha (TGF-α, a ligand for EGFR), with activation of the EGFR pathway and associated with a very poor prognosis.[701]

The HPV-associated subgroup appears to be genetically different. There is strong immunohistochemical expression of p16, *TP53* gene mutation is generally absent, and allelic losses at 3p, 9p, and 17p are uncommon.[699]

Other Microscopic Types

Verrucous carcinoma (Ackerman tumor) is a rare variant of squamous cell carcinoma with a distinctly polypoid pattern of growth and an

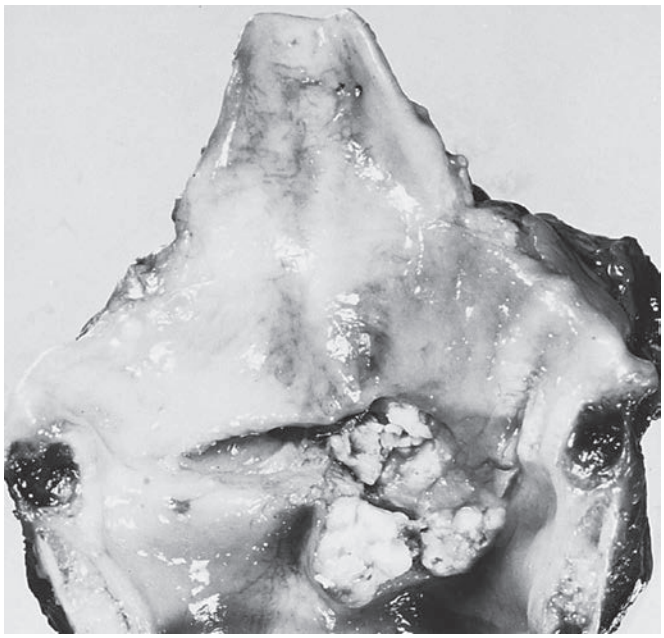

Figure 4.111 Verrucous carcinoma of larynx with obliteration of right vocal cord and extension into subglottis. (From Kraus FT, Perez-Mesa C. Verrucous carcinoma. Clinical and pathologic study of 105 cases involving oral cavity, larynx, and genitalia. *Cancer*. 1966;19:26–28.)

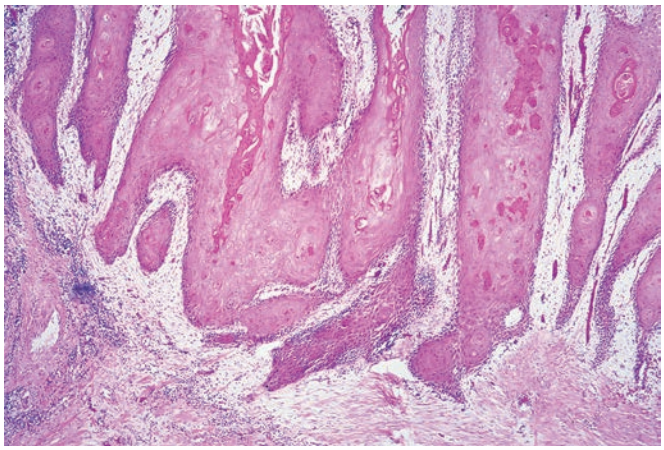

Figure 4.112 Verrucous Carcinoma. Well-differentiated tongues of squamous epithelium impinge on the underlying stroma.

extremely well-differentiated microscopic appearance (Figs. 4.111 and 4.112).[702] Like its counterpart in the oral cavity and other locations, it may show extensive local invasion but practically never metastasizes.[169] HPV sequences have been demonstrated both in the tumor and in adjacent normal tissues in some studies but not in others.[703] Verrucous carcinoma should be distinguished from the verrucous form of keratosis (verrucous hyperplasia). The differential diagnosis is based on the presence or absence of invasion and can therefore be impossible to make on a small biopsy.[649] Sometimes verrucous carcinoma coexists with conventional squamous cell carcinoma *(hybrid carcinoma)*.[704] The primary treatment of verrucous carcinoma is surgical. Radiation therapy may be followed by anaplastic transformation of the tumor.[705] Hybrid carcinomas should be treated as conventional squamous cell carcinomas.

Small cell (neuroendocrine) carcinoma is an unusual type of laryngeal carcinoma (less than 0.5% of all cases) that most often

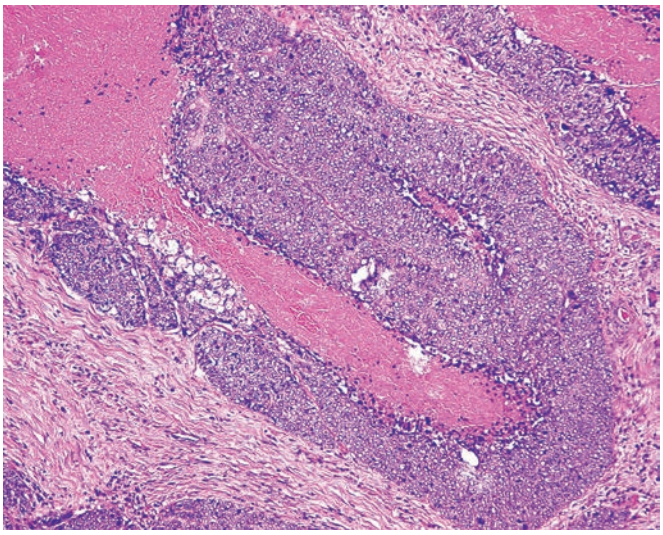

Figure 4.113 Basaloid Squamous Cell Carcinoma of Larynx. The basophilic staining quality and the high-grade nature of the tumor are evident with central comedonecrosis.

presents in the sixth and seventh decades in men who are heavy smokers.[706] Although all laryngeal sites can be involved, most (>90%) arise in the supraglottic larynx. Its microscopic appearance is identical to that of its pulmonary counterpart. Like the latter, it usually contains a few dense-core secretory granules on ultrastructural examination and exhibits a variable (sometimes very scanty) degree of immunoreactivity for neural/neuroendocrine markers.[707] As in other sites, it may be pure or associated with other patterns.[708] Cervical, nodal, and distal metastases are very common, and the prognosis is poor.[708] It should be distinguished from atypical carcinoid/large cell neuroendocrine carcinoma.

Basaloid squamous cell carcinoma is a highly malignant laryngeal tumor characterized by areas of typical in situ and/or invasive squamous cell carcinoma associated with nests of small crowded cells (Fig. 4.113). These cells have hyperchromatic nuclei, scant cytoplasm, small cystic spaces, necrosis, prominent hyalinization, and peripheral palisading.[175] The overall appearance suggests an attempt of differentiation toward adnexal (glandular) structures. This tumor, which also occurs in the tongue, pharynx, and esophagus, should not be confused with true adenoid cystic carcinoma, which has a different clinical course.[178] Most of the patients with basaloid squamous cell carcinoma are heavy smokers who present with advanced disease and sometimes with other primary tumors in the area.[709] The supraglottic larynx is preferentially involved. The behavior is extremely aggressive.[174]

Lymphoepithelioma-like carcinoma (lymphoepithelial carcinoma) of the larynx is often accompanied by (and sometimes presents initially with) cervical lymph node metastases. Alterations of *TP53* are common, but no relationship with EBV has been found. The clinical course is aggressive.[710]

Adenosquamous carcinoma consists of conventional squamous cell carcinoma and adenocarcinoma. The squamous component is typically invasive but can be *in situ*. The adenocarcinoma component is typically at the base of the tumor. Adenosquamous carcinoma has the same demographics as conventional squamous cell carcinoma but appears be more aggressive.

Sarcomatoid carcinoma (spindle-cell carcinoma; carcinoma with sarcoma-like stroma; carcinosarcoma; pseudosarcoma) is a peculiar neoplasm with a high predilection for the upper aerodigestive tract.[711] Tumors of this type located in the larynx, as elsewhere, often have

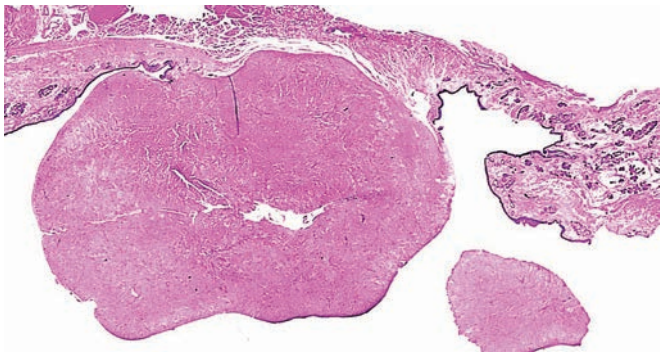

Figure 4.114 Whole mount of laryngeal sarcomatoid squamous cell carcinoma, showing typical polypoid shape.

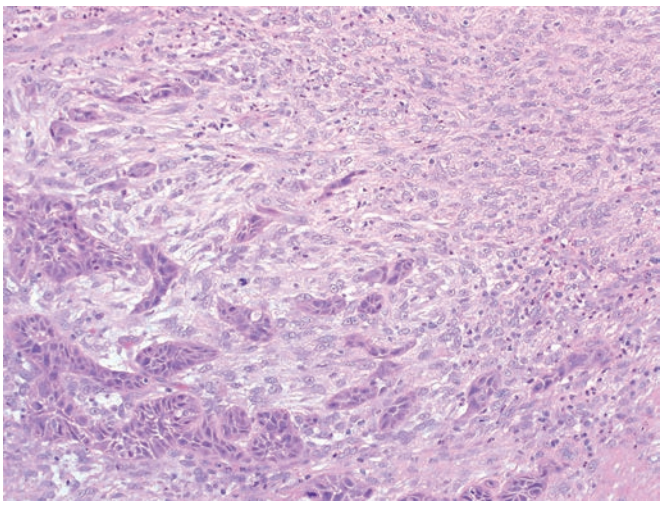

Figure 4.115 Sarcomatoid carcinoma of larynx with conventional squamous cell carcinoma at the bottom left.

a polypoid configuration[712] (Fig. 4.114) and may simulate a laryngeal polyp. Most are located in the supraglottic region. Microscopically, they have an element of squamous cell carcinoma (often inconspicuous and frequently in situ) and a pleomorphic sarcoma-like or fibrosarcoma-like component, which makes up the bulk of the lesion. The sarcomatoid component may be so bland as to simulate granulation tissue or have a bizarre appearance reminiscent of so-called malignant fibrous histiocytoma, malignant giant cell tumor of soft parts, or osteosarcoma (Fig. 4.115).

Lymph node metastases may be composed of the carcinomatous component alone, both patterns as in the primary tumor, or—in rare cases—the sarcoma-like elements exclusively. Whether the sarcoma-like stroma is of mesenchymal derivation or a carcinoma in disguise has been a matter of controversy since the entity was first defined in the classic paper by Lane.[713] Current evidence strongly favors the latter interpretation. Immunohistochemical markers of epithelial differentiation such as keratin and p63 are detected in at least some of the spindle cells in most cases, even in those with a relatively monomorphic appearance.[714] However, a significant number of cases are completely negative for epithelial markers. Thus a high index of suspicion is required for sarcomatoid malignancies involving the mucosal surface. The presence of a conventional squamous cell carcinoma component or overlying CIS/dysplasia should suggest the possibility of sarcomatoid carcinoma. The fact that the two tumor components harbor the same *TP53* mutation and share a variety of chromosome markers is further proof of their common pathway of tumorigenesis.[181,715]

Surgical excision is the treatment of choice.[712] The prognosis is better for the polypoid tumors than for deeply invasive neoplasms with similar microscopic features.[184] Stage by stage, it does not seem to be significantly different from that of conventional squamous cell carcinoma.[714]

Prognosis

The factors found to be of prognostic significance in laryngeal squamous cell carcinoma are the following:

1. *Clinical stage* and *site*. These two factors are interrelated and are therefore usually evaluated together.[716] The approximate 5-year survival rates for the different types are the following, allowing for the usual differences from series to series:

   Glottic: 80%
   I: 90%; II: 85%; III: 60%; IV: less than 5%
   Supraglottic: 65% (with those located in the aryepiglottic folds having the worst prognosis)[717]
   I: 85%; II: 75%; III: 45%; IV: less than 5%
   Transglottic: 50%
   Subglottic: 40%

   Among the T1 glottic tumors, the microinvasive type needs to be segregated from the others because its natural history is basically equivalent to that of CIS (in a manner analogous to that operating between microinvasive and in situ squamous cell carcinoma of the uterine cervix).
2. *Microscopic grade*. While this parameter is related to the clinical stage of the tumor, it has been shown that it is an independent prognostic determinator.[718]
3. *Field size*. Among T1 glottic carcinomas treated with radiation therapy, a large tumor field size is associated with an increased risk of local recurrence.[719]
4. *Lymph nodes*. In patients with metastatic lymph nodes, the prognosis is affected by the number of involved nodes, their size, and the presence or absence of extranodal extension.[720]
5. *Host reaction*. It has been claimed that a high density of S-100 protein–positive Langerhans cells in the tumor stroma is a favorable prognostic sign.[721]
6. *Keratin expression*. No prognostic significance seems to be attached to the type of keratin expression by the tumor, as evaluated immunohistochemically.[722]
7. *p53 overexpression*. It has been proposed that this parameter is an independent prognostic factor,[723] the claim has not been substantiated by others.[724]
8. *Survivin expression*. A high level of expression of this marker is said to be associated with p53 accumulation and poor survival.[725]

Salivary Gland–Type Tumors

The most common form of salivary gland–type tumor of the larynx is **adenoid cystic carcinoma**.[726] Almost all of these tumors are located in areas other than the true vocal cords, in keeping with the distribution of normal salivary glands in the region. They grow slowly but eventually prove fatal in most instances.[727] This tumor should be distinguished from the more rapidly growing basaloid squamous cell carcinoma.

Other neoplasms in this category include mucoepidermoid carcinoma,[728] acinic cell carcinoma,[729] benign mixed tumor (pleomorphic adenoma),[730] and myoepithelial neoplasms.[731,732]

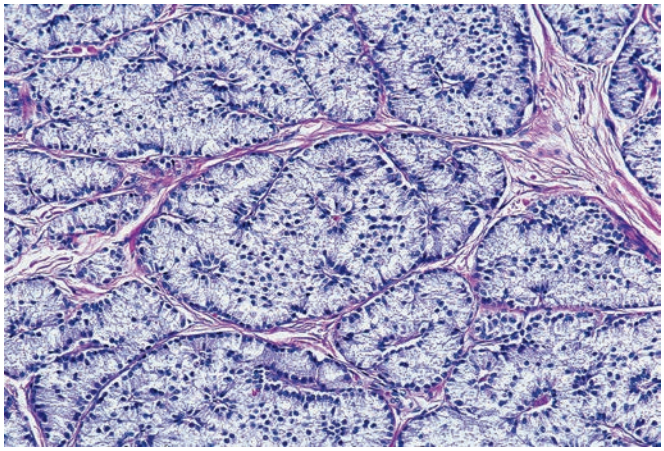

Figure 4.116 Carcinoid tumor of the larynx showing marked cytoplasmic clear change.

Neuroendocrine Tumors

In addition to the already mentioned small cell neuroendocrine carcinoma, the larynx can be the site of several other types of neuroendocrine tumor.[733,734]

Carcinoid tumor of the *typical* variety, which is very rare in this location, looks in all respects like its more common bronchial counterpart at the morphologic, immunohistochemical, and ultrastructural levels.[735] Some are predominantly composed of oncocytic cells *(oncocytic carcinoid tumors)*,[736] others have an appearance indistinguishable from that of medullary thyroid carcinoma[737] (but are negative for TTF-1),[738] and still others are composed of clear cells (Fig. 4.116). Most of these tumors are located in the supraglottic region, particularly in the arytenoid and aryepiglottic folds.[739] The prognosis for true laryngeal carcinoid tumors is generally good.

The larynx is much more commonly the site of *atypical carcinoid tumor* (moderately differentiated neuroendocrine carcinoma) and *large cell neuroendocrine carcinoma*.[734,740] Both of these tumor types are characterized by pleomorphism, mitotic activity, and necrosis (Fig. 4.117). The distinction between them, not always attempted in the articles that have been written on the subject, is made using the same guidelines as those used for the homonymous pulmonary tumors. Argyrophilia, immunoreactivity for chromogranin and synaptophysin, and presence of dense-core neurosecretory granules on ultrastructural examination are the rule.[741,742] They are also positive for cytokeratin and up to 80% express calcitonin but, in contrast to medullary thyroid carcinoma, they are typically negative for TTF-1. Most patients are elderly males with a history of heavy smoking. Nearly all tumors are located in the supraglottic region, particularly on the arytenoid cartilage.[743] They run an aggressive clinical course, with frequent metastases to lymph nodes and distant sites. Mortality is approximately 50%.

Paraganglioma of the larynx is usually located in the supraglottic region, from where it often extends to the ipsilateral aryepiglottic fold.[744] However, it can also present as a subglottic tumor.[745] Metastases have been documented in about a fifth of the reported cases, but these studies might include lesions that could be classified as atypical carcinoid tumors. Most tumors are nonfunctioning.[746] Calcitonin and vasoactive intestinal peptide (VIP) have been detected in some of the cases, in addition to the usual panendocrine markers.[747] In contrast to carcinoid tumors and other types of neuroendocrine carcinoma, they are keratin negative. Sustentacular cells, which are immunoreactive for S-100 protein and GFAP, are present at the periphery of the nests and constitute an important diagnostic sign.[748]

Other Tumors and Tumorlike Conditions

Hemangioma of the larynx characteristically presents in infants as a sessile, poorly circumscribed mass in the subglottic area, immediately beneath the true vocal cord. Symptoms of upper respiratory tract obstruction may be severe. One-half of the patients have associated hemangiomas in the skin, an important diagnostic sign. Biopsy can precipitate massive bleeding. Treatment modalities include endoscopic excision with CO_2 laser, systemic steroids, interferon, and intralesional corticosteroid injection with short-term intubation.[749] Hemangiomas of the larynx are exceptionally also seen in adults.[750]

Angiosarcoma can present as a polypoid mass in the epiglottis (Fig. 4.118) or elsewhere in the larynx. Some of the reported cases have been associated with previous radiation to the area.[751]

Granular cell tumor may involve the true cord or other sites in the larynx.[752] Some of the reported cases have been in children. Most are located posteriorly. They are small and yellow and are covered by epithelium. The clinical diagnosis is usually that of laryngeal papilloma or nodule. Their microscopic appearance is typical, but they can be mistaken microscopically for invasive squamous cell carcinoma because of the pseudoepitheliomatous hyperplasia that often accompanies this lesion.

Myofibromatosis of the larynx in the neonate may result in severe laryngeal obstruction.[753]

Inflammatory myofibroblastic tumor (inflammatory pseudotumor) can involve the larynx and be confused with a clinically more aggressive process, particularly spindle cell (sarcomatoid) carcinoma.[754]

Rhabdomyoma has a predilection for the head and neck area, including the larynx. Cross striations are often found in the tumor cells, in addition to characteristic "spinder" cells and peculiar crystal-like intracytoplasmic particles. The adult type is more common than the fetal variety.[56]

Rhabdomyosarcoma also occurs; it is mostly restricted to infancy and childhood and is almost always of the embryonal variety, including the botryoid subtype.[756] The larynx is a common location for pleomorphic rhabdomyosarcoma. This is an aggressive variant of rhabdomyosarcoma that is restricted to adults.

Leiomyomas and **leiomyosarcomas** are extremely unusual; some of the former have been of epithelioid or atypical (bizarre) types.[757,758]

Cartilaginous tumors are the most common mesenchymal neoplasms of the larynx.[759,760] They usually arise from the cricoid cartilage and appear posteriorly in the subglottic region (Figs. 4.119 and 4.120). Chondrosarcomas far outnumbers cases of laryngeal chondroma. Goethals et al.[761] classified four of their 22 cases as *chondromas* and all of the others as *chondrosarcomas* by applying

the microscopic criteria used for the homonymous skeletal tumors; none of the tumors metastasized, and only six recurred locally. Although subsequently there have been reported cases with pulmonary metastases, these findings indicate that surgery should be as conservative as possible for cartilaginous neoplasms occurring in this location, nearly all of which are well differentiated.[762] Rarely, chondrosarcomas may be of the clear cell variety or exhibit dedifferentiated foci.[763,764] Although they are rare, well-documented cases of chondroma do arise in the larynx. In contrast to chondrosarcomas, these are small (<1–2 cm) tumors without any chondrocyte atypia. Laryngeal cartilaginous tumors should be distinguished from the non-neoplastic condition known as *chondrometaplasic nodules.*[762]

Osteosarcomas also occur; they should be distinguished from chondrosarcomas with osseous metaplasia and from sarcomatoid carcinomas (carcinosarcomas).[765]

Lipoma of the spindle cell variety was reported in the larynx by Nonaka et al.,[766] and **hibernoma** has been seen in the pre-epiglottic area.[767]

Well-differentiated liposarcoma (atypical lipomatous tumor) can present as a pedunculated laryngeal mass, almost always located in the supraglottic portion of the hypopharynx.[768] As in other sites it can undergo dedifferentiation.[769]

Undifferentiated pleomorphic sarcomas (malignant fibrous histiocytoma) of the larynx also have been described,[770] but one wonders how many of them actually represent sarcomatoid carcinomas in which the epithelial component (which may be very inconspicuous) has either been overlooked or else has been destroyed by tumor ulceration.

Isolated cases of **giant cell tumor**,[771,772] **aneurysmal bone cyst**,[773] osteoblastoma,[774] **polypoid xanthoma**,[775] **solitary fibrous tumor**,[776] and **synovial sarcoma**[777] have been reported.

Malignant melanoma can be primary in the larynx,[778] but the possibility of metastasis should always be ruled out before entertaining such a diagnosis.

Lymphoid tumors and tumorlike conditions can also involve the larynx, although the event is rare.[779] Reported cases include non-Hodgkin lymphoma (including the "lethal midline granuloma" type of probable NK/T-cell nature), and plasmacytoma. Although the latter lesion may be initially localized, dissemination is likely to occur.[780] Plasmacytoma should be distinguished from chronic inflammation and so-called *mucous membrane plasmacytosis*, a reactive condition of unknown cause. *Acute leukemia* can present initially with laryngeal obstruction.[781]

Metastatic tumors to the larynx can arise from various sites; skin (melanoma), kidney, breast, and lung are the most common.[782]

Trachea

Non-Neoplastic Lesions

Chondromalacia is characterized by necrosis and softening of the tracheal cartilage. It may result in fibrous strictures and tracheal deformation owing to the collapse of the necrotic plates of cartilage. It may be due to the ischemic damage and mechanical effects induced by prolonged intubation, prior infection, tumors, trauma, vasculitis, and relapsing perichondritis. Cases in which no inciting factor can be identified are referred to as *idiopathic tracheal stenosis*.[783]

Tracheopathia osteochondroplastica presents as multiple submucosal nodules composed of mature bone and cartilage.[784] Its etiology is unknown.

Amyloidosis of the tracheobronchial tree is characterized by the formation of solitary or multiple nodules and is usually asymptomatic.

Figure 4.121 Extensive Papillomatosis of Trachea and Bronchi.

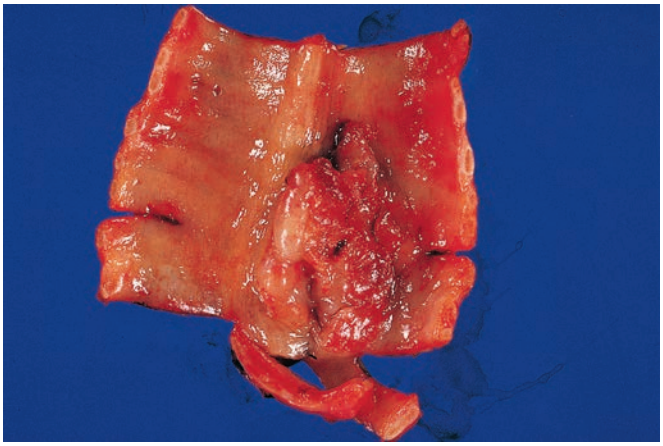

Figure 4.122 Squamous Cell Carcinoma of Trachea Growing as a Polypoid Mass. The tumor was treated by segmental resection.

Necrotizing sialometaplasia similar to that more commonly seen in the palate has been described in the trachea after prolonged translaryngeal intubation.[785]

Rheumatoid nodules are occasionally seen in the trachea of patients with rheumatoid arthritis.[786]

Tumors

Papilloma and **papillomatosis** of the trachea are morphologically similar to the homonymous lesions seen in the larynx (Fig. 4.121). Cases seen in conjunction with laryngeal lesions usually begin in infancy and have a very low incidence of malignant transformation. Those limited to the trachea and bronchi usually begin in adulthood and have a greater tendency for malignant change.

Squamous cell carcinoma is the most common primary malignant tumor of the trachea (Fig. 4.122).[787] The majority arise in adult (mean age of 65) men and preferentially involve the lower third of the trachea. The clinical course is rapid, and the prognosis is poor. The primary treatment is surgical, usually consisting of circumferential resection of the involved segment with end-to-end anastomosis.[788] Radiation therapy is used for advanced cases. Tumor extension into the thyroid gland and lymph vessel invasion are two important unfavorable prognostic factors.[789]

Adenoid cystic carcinoma is the second most common type of primary tracheal malignancy. Its appearance is similar to that of the

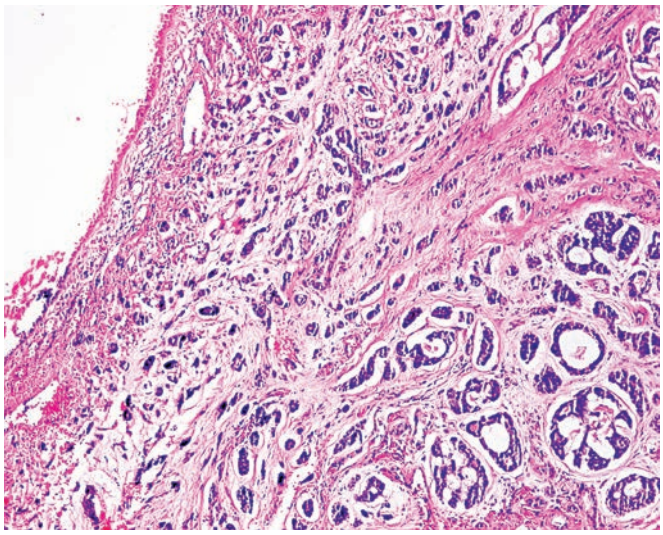

Figure 4.123 Adenoid cystic carcinoma of trachea growing beneath normal epithelium and showing typical cribriform pattern of growth.

homonymous tumor in the major salivary glands (Fig. 4.123). Most cases are located in the upper third of the trachea with equal sex incidence and occur in younger individuals (mean age 45–50) compared with squamous cell carcinoma.[790] The clinical course is very slow, but the long-term prognosis is poor.

Small cell (neuroendocrine) carcinoma has an appearance and a behavior similar to that of the bronchial tumor of the same type, an extension from which should always be considered in the differential diagnosis.

Adenocarcinoma (mucin-producing) and **lymphoepithelioma-like carcinoma** have been observed in the lower third of the organ.[790]

Carcinoid tumor may arise in the trachea and be cured by segmental resection with primary reconstruction.[791]

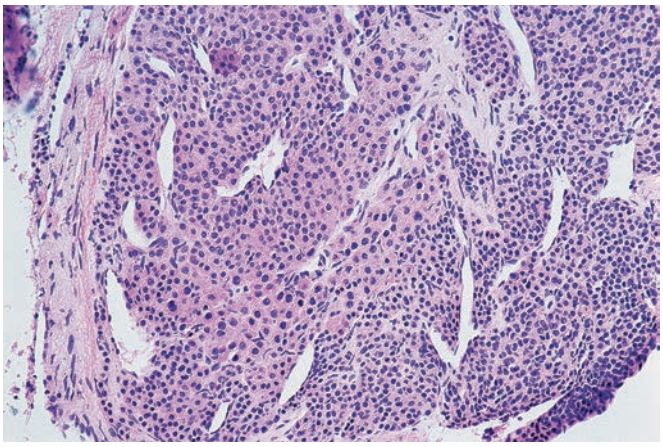

Figure 4.124 Glomus Tumor of Trachea. The microscopic appearance is identical to that of the homonymous tumor of the skin.

Benign mixed tumors (pleomorphic adenomas) and other salivary gland-type tumors occur, but not nearly as often as adenoid cystic carcinoma.[792]

Other primary tumors of the trachea, all exceptionally rare, include glomus tumor (Fig. 4.124)[793] (including its oncocytic variety),[794] solitary fibrous tumor (hemangiopericytoma),[795] juvenile hemangioma,[796] granular cell tumor,[797] "fibromyxoma," schwannoma,[798] paraganglioma,[799] benign clear cell tumor ("sugar tumor"),[800] fibrosarcoma,[788] benign and malignant fibrous histiocytoma,[801] plasmacytoma, and malignant lymphoma.[802] Hodgkin lymphoma can present initially as a tracheal mass as a result of invasion from adjacent nodes.

Secondary tumors are much more common than primary neoplasms. Most of them arise in the bronchi, esophagus, or larynx and involve the trachea by direct extension. Metastasis to the trachea is uncommon with most being from breast, skin, kidney, and colorectal primaries.

Normal Anatomy

In most respects, the microscopic features of the mandible and maxilla differ in no significant way from those of any other bones. Their peculiarity is derived from their close proximity to the mucosal surface of the oral cavity and the fact that they enclose the odontogenic apparatus, a highly specialized structure that gives rise to a large variety of malformative, inflammatory, and neoplastic conditions.

The odontogenic compartment is unique in the sense that it contains primitive embryonic structures from early fetal development to approximately 25 years of age. They have a combined ectodermal and mesodermal derivation; the mesodermal component has the added peculiarity that it originates from the neural crest (the so-called *ectomesenchyme*).[1]

The odontogenic development as seen in a tooth germ is a striking example of reciprocal inductive phenomena between two different types of tissue. The first is composed of an invagination of the ectodermally derived primitive oral cavity *(dental lamina)*, which subsequently acquires a bell shape and develops along its inner (concave) aspects a layer of cuboidal to columnar cells, the *ameloblasts*, which are responsible for the secretion of enamel matrix. At this stage, it is also referred to as the *enamel organ*.

The second component, which is mesodermally derived and enclosed within the previously described bell, is formed by the *dental papilla*, having initially the appearance of a loose myxoid mesenchyme and later undergoing a maturation of its outer aspect (i.e. that contiguous to the ameloblastic layer) that results in the emergence of *odontoblasts* (i.e. the cells responsible for the formation of the dentinal matrix).

An increase in the cellularity of the dental papilla adjacent to the maturing ameloblastic (enamel-forming) epithelium subsequently leads to the formation of the *dental sac* or *follicle* surrounding the developing tooth, which is in turn responsible for the formation of a dense fibrous sheath enveloping the tooth roots known as *periodontium*. In addition, the inner cells of this sac become *cementoblasts* and deposit cement over the newly formed dentin, whereas the more peripheral cells of this structure are thought to become osteoblasts and to contribute to the production of alveolar bone.

The major extracellular components of the tooth are dentin, enamel, and cementum. *Dentin* is easily recognized because of its radially striated appearance caused by the presence of innumerable minute canals (the *dentinal tubules*) containing cytoplasmic processes from the odontoblasts. When these canals are absent, it may be difficult to distinguish between atypical poorly mineralized dentin (dentinoid) and osteoid. *Enamel* consists of thin rods or prisms that on cross section are separated by concentric lines *(lines of Retzius)*. *Cementum* is very similar to bone in physicochemical characteristics and is indeed regarded as a special type of bone. It may be cellular or acellular, and it is identified microscopically mainly because of its intense basophilia. When less than entirely typical, its distinction from conventional bone may become impossible. It must be recognized that cementum-like material may be encountered in parts of the skeletal system other than the maxilla or mandible, in which participation of odontogenic tissue would seem out of the question.

The presence of rounded, strongly basophilic *cementicles* within the periodontal ligament is a normal feature.

The *dental pulp* has a myxoid hypocellular appearance that is similar to that of myxoma and that sometimes can be confused with

Abstract

This chapter reviews the development of teeth and the normal anatomy and histology of teeth and gnathic bones. Inflammatory disorders and nonodontogenic tumors are discussed as well. Odontogenic tumors and jaw cysts are reviewed using the general classification adopted by the WHO. Disorders of the temporomandibular joint are also discussed.

Keywords

Odontogenic tumors,
nonodontogenic tumors

it. It differs from the latter grossly because of its most compact appearance and microscopically because a layer of odontoblasts may be recognizable at the periphery. Sometimes a thin layer of eosinophilic dentin is seen adjacent to the layer of odontoblasts.

Nests of odontogenic epithelium (with or without their associated mesenchymal counterpart) are normally found in the jaw and gingiva and have the potential to develop into cysts or tumors. Those nests located in the alveolar mucosa and resulting from the breakup of the dental lamina are referred to as *rests of Serres*, whereas those embedded within the periodontium are known as *rests of Malassez*.

Another source of cysts and tumors in this region is related to the breakdown of ectodermal lining cells during the union or fusion of the various embryonic processes of the region, through the formation of entrapped epithelium-lined nests.

The surgical pathology of the maxilla and mandible encompasses the spectrum of pathology, because both systemic and unique diseases occur in these locations. This discussion concentrates on commonly encountered and surgically related conditions of the jaws. A more detailed discussion of these conditions, as well as of others that are less common, may be found in specialized texts.[2–7]

Inflammatory Diseases

The majority of inflammatory conditions of the jaws have a dental origin. Untreated dental caries eventually leads to inflammation of the pulpal or soft tissue portions of teeth that are unable to respond and heal adequately. This results in inflammation of the cancellous bone and connective tissue surrounding the dental root apices that follows a predictable, albeit variable, clinical and pathologic course.

Periapical granuloma appears as a lytic lesion at the apex of a nonvital tooth and is ordinarily detected in a dental roentgenogram. Grossly, the lesion rarely measures over 1.5 cm in diameter. Microscopically, it consists of a rounded collection of acute and chronic inflammatory cells rich in histiocytes and surrounded by dense fibrous tissue. Degeneration can occur in the center, leading to cavity formation and the development of a *radicular* or *periapical* cyst resulting from stimulation of the rests of Malassez.[8]

Pulse granulomas may be seen in areas of chronic periostitis. These ring-like structures enclose vegetable particles, giant cells, other inflammatory cells, and bundles of collagen fibrils (Fig. 5.1). This inconsequential microscopic oddity, variously referred to as *hyaline ring–like structures*, *lentil granuloma*, *oral vegetable granuloma*, and *giant cell hyaline angiopathy*, has given rise to numerous theories about its nature, as can be deduced from the names it has received.[9,10] The two leading hypotheses are a reaction to legume parenchymatous cells at various stages of digestion ("pulse" being the edible seed of legumes), and a degenerative change in vessel walls resulting from localized vasculitis. The former explanation seems much more reasonable. Structures of similar appearance have been described in many other sites, including gallbladder, rectum, fallopian tube, skin, and prostate.[11]

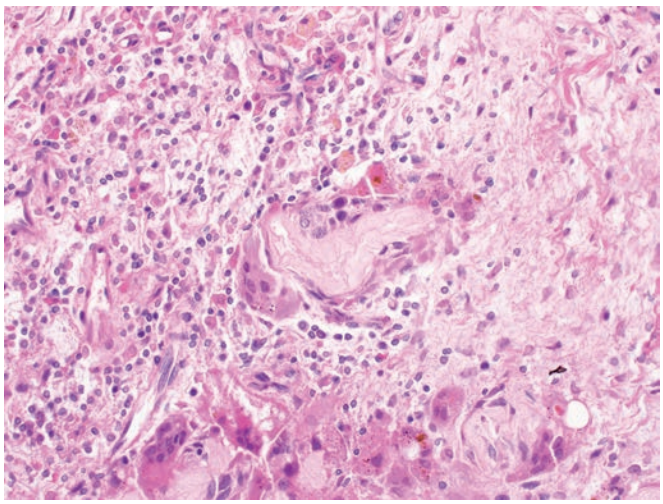

Figure 5.1 Pulse granuloma. Foreign body giant cells surround residual plant material (pulse) with associated fibrosis and chronic inflammation.

Osteomyelitis of the jaws of bacterial etiology usually represents an additional consequence and extension of dental or periodontal infection.[12] Acute, subacute, and chronic forms exist. Some of the chronic forms are of the sclerosing *(Garré)* type.[13] Hematogenous osteomyelitis is encountered more rarely. Symptoms such as pain, fever, and soft tissue swelling or redness in later stages are usually present. Smooth, regular, and atrophic loss of the covering mucosa is a late finding, and the exposed bone appears dull and devitalized. Radiographic features of osteomyelitis are subtle, irregular, ill-defined, and predominantly radiolucent lesions. A *sequestrum* is more often identified at the time of surgical exploration than during examination of x-ray films. Acute suppurative inflammation and resorptive scalloping of margins of nonvital bone within a large portion of maxilla or mandible are the main microscopic findings of acute and subacute osteomyelitis. *Staphylococcus aureus* is the organism most commonly cultured. Anaerobic bacteria have also been demonstrated to be important.[14] Tuberculosis, mucormycosis, aspergillosis, and candidiasis have also been causally identified in osteomyelitis of the jaws.[15]

Chronic forms of osteomyelitis generally appear histologically as benign fibro-osseous lesions with patchy chronic inflammation. The diagnosis often depends on the constellation of clinical, radiographic, and histologic findings. Another form of osteomyelitis of the jaw is that associated with the so-called SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis).[16] This variety is nonsuppurative and antibiotic therapy is usually not effective.[16]

Osteonecrosis of the jaw bones can be seen following radiation therapy (osteoradionecrosis)[17] or in patients being treated with bisphosphonates (osteochemonecrosis, bisphosphonate-related osteonecrosis).[18] The mandible is affected more commonly than the maxilla and the lesions present as a painful mucosal ulcer with exposed underlying dead bone. Pathologic fractures may occur in the weakened bone. They are histologically similar with necrotic bone surrounded by acute and chronic inflammatory cells with superimposed colonization by oral microbial flora.

Simple Bone Cyst

Simple bone cyst usually occurs in young patients as a sharply outlined, unilocular, radiolucent mass (Fig. 5.2). It is usually located in the body or symphyseal area of the mandible and can assume a large size.[19] In older patients it may also involve the maxilla.[20] It is also known as *traumatic*, *solitary*, or *hemorrhagic cyst*, but there is a history of trauma in only one-half of the cases, and the content of the cyst is rarely hemorrhagic. Actually, little is observed within the cavity at surgery in the typical case; this feature is analogous to that seen in solitary (unicameral) bone cysts, of which simple bone cyst may be the gnathic counterpart. Morphologically, the cavity is entirely intraosseous and not lined by epithelium. Surgical samples from the periphery show instead a delicate fibrovascular lining of unremarkable appearance. A few osteoclast-like giant cells and hemosiderin-laden macrophages may be present. Surgical exploration with thorough curettage is the treatment of choice and is typically curative.

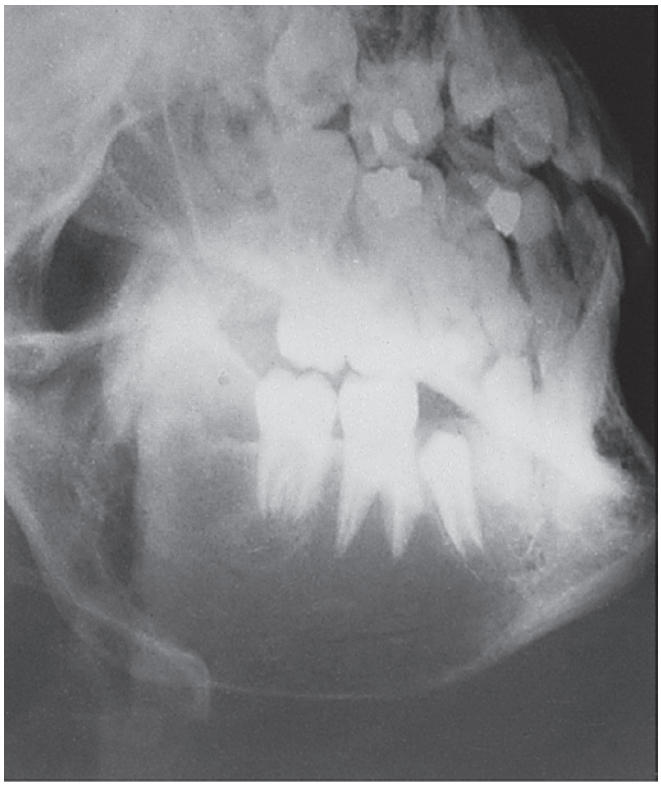

Figure 5.2 Simple bone cyst of mandible in an 11-year-old girl. Note thin shell of remaining bone at the inferior aspect of the mandible.

The differential diagnosis of simple bone cyst includes aneurysmal bone cyst (particularly when the latter is associated with a benign fibro-osseous lesion) and so-called *latent bone cavity*, a symptomless open cavity situated below and behind the inferior dental canal near the angle of the mandible and often containing salivary gland tissue.[21]

Central Giant Cell Lesion and Other Giant Cell-Containing Lesions

Lesions of the jaws that feature large numbers of osteoclast-like, multinucleated giant cells include the following major entities: central giant cell lesion (granuloma), cherubism, giant cell tumor (osteoclastoma), fibro-osseous lesions, the bone lesion of hyperparathyroidism (brown tumor), hereditary hyperparathyroidism–jaw tumor syndrome, and aneurysmal bone cyst. **Central giant cell granuloma** is by far the most common. Its pathogenesis is unknown. Because a history of trauma is often ascertained, it has been suggested that it is the result of the organization of slow, minute, recurrent hemorrhages, hence the alternative name *reparative giant cell granuloma* coined by Jaffe in his classic paper on the subject.[22] A benign neoplastic nature seems a more likely explanation given the fact that some do recur.

This condition affects children and young adults, predominantly females, and occurs almost twice as frequently in the mandible as in the maxilla, particularly in the anterior region.[22,23] It produces a lytic lesion of the bone, which microscopically shows large numbers of multinucleated giant cells, hemosiderin, a cellular vascular stroma, and often new bone formation (Figs. 5.3 and 5.4). The osteoclast-like giant cells have a patchy distribution, usually associated with areas of hemorrhage. Cases have been reported in association with central odontogenic fibroma.[24]

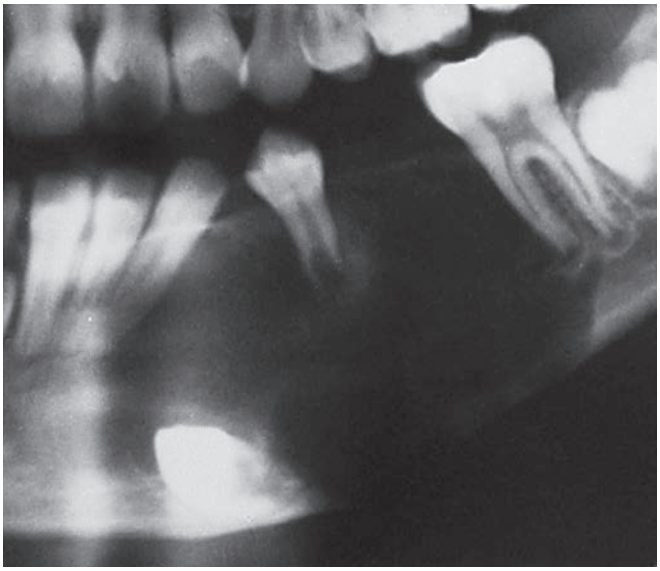

Figure 5.3 Radiographic appearance of recurrent central giant cell granuloma in a 10-year-old girl. The inferior border of mandible has been eroded and the involved teeth are displaced.

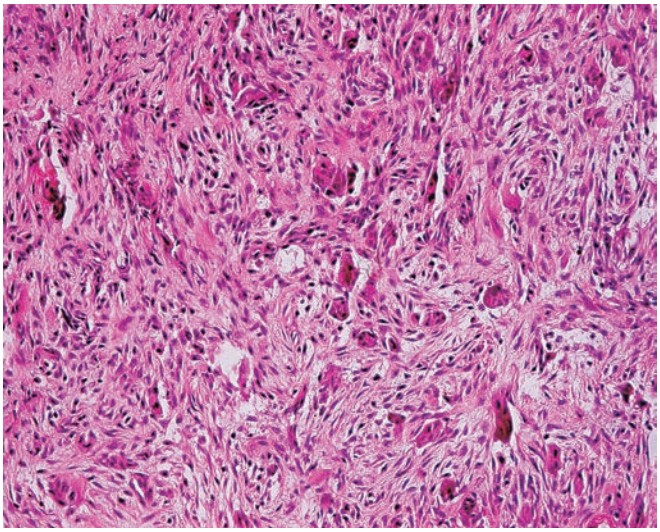

Figure 5.4 Central giant cell granuloma. Osteoclast-like giant cells are scattered within a fibroblastic matrix.

These lesions are treated by surgical removal or thorough curettage.[25,26] Recurrence, which occurs in approximately one-fourth of the cases, is treated similarly but only after the diagnosis has been confirmed.

Cherubism (hereditary and intraosseous fibrous swellings of the jaws) is indistinguishable microscopically from the lesions of central giant cell granuloma.[27] However, the bilateral presentation of mandibular and maxillary involvement in a young individual with an autosomal dominant mode of inheritance, the sometimes more delicate fibrovascular stroma with less consistent bone formation, and the differing behavior and response to treatment clearly justify a nosologic separation between the two. The gene responsible for cherubism has been mapped to chromosome 4p16.3,[28] and identified as encoding c-Abl–binding protein SH3BP2.[29]

Hyperparathyroidism,[30] aneurysmal bone cyst, and other conditions containing areas resembling giant cell granuloma (especially

at the periphery) may also constitute a basis for histologic misinterpretation. Fortunately, these are encountered much less commonly and are usually associated with additional clinical or laboratory information that aids delineation.[31] Giant cell tumor only rarely, if ever, occurs in the jaw bones.

Benign Fibro-Osseous Lesions

Several types of tumor and tumorlike conditions composed of benign fibro-osseous tissue exist. Their histologic features are very similar, whereas their clinical behavior can be very different.[32] Their accurate diagnosis depends on an integration of the microscopic picture with the medical, family, and dental history, the radiographic and operative appearance, skeletal survey, and laboratory tests; furthermore, it may need to be revised on the basis of the course of the disease and response to treatment. The pathologist who relies on histology alone for the interpretation of these lesions is less likely to contribute to the successful management of these patients. Common benign fibro-osseous lesions of the jaw bones are listed in Box 5.1.

Fibrous Dysplasia and Related Lesions

Fibrous dysplasia can be polyostotic or monostotic, the microscopic appearance of the two forms being essentially the same. The polyostotic form may be accompanied by pigmented skin lesions, endocrine dysfunction presenting with precocious puberty in females, and other anomalies *(McCune–Albright syndrome)*. Both monostotic fibrous dysplasia and Albright syndrome are associated with a somatic mutation of the *GNAS1* gene.[33,34] Fibrous dysplasia confined to jawbones is sometimes referred to as the *craniofacial form* of the disease. Approximately 10% of patients with monostotic fibrous dysplasia present with involvement of the craniofacial skeleton. In contrast, a vast majority of those with polyostotic disease have involvement of the craniofacial bones. Congenital or hereditary fibrous dysplasia in siblings has been reported[35] and should not be confused with cherubism.

Clinically, painless and sometimes dramatic swellings of the maxilla or mandible are observed that are characteristically unilateral. Young individuals are usually affected, the mean age at time of diagnosis in most series being from 25 to 35 years. The lesions tend to become static as skeletal maturity is reached. The radiographic appearance varies from cystic or radiolucent to sclerotic or radiopaque, and the margins tend to be ill-defined.

The histologic appearance of fibrous dysplasia in its usual, most recognizable form is characterized by the presence of curvilinear

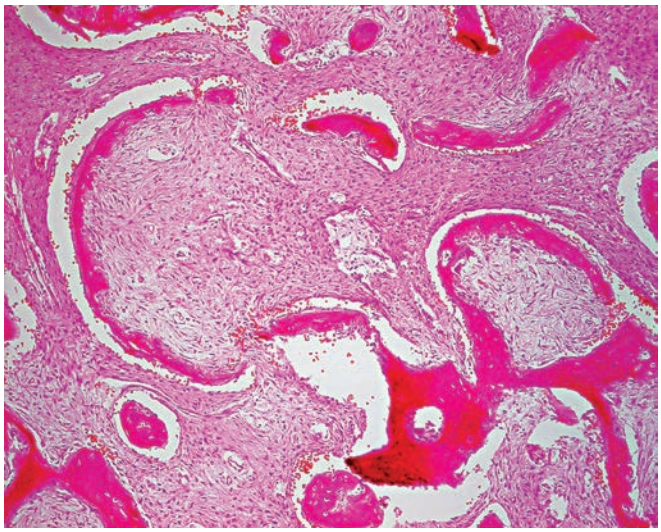

Figure 5.5 Fibrous dysplasia. Curvilinear bone trabeculae are surrounded by a dense fibrous stroma. Osteoclasts are lacking.

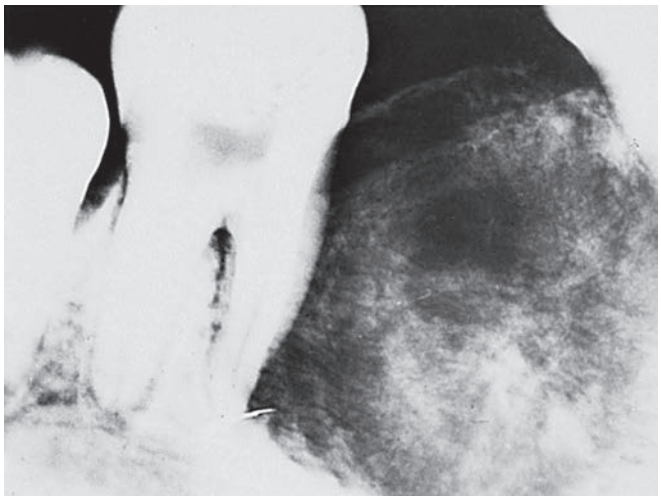

Figure 5.6 Ossifying fibroma in a 17-year-old girl. Note the sharp border of the lesion. (Courtesy of Dr. C.A. Waldron, Atlanta.)

trabeculae of woven or immature bone within a proliferating benign fibroblastic stroma (Fig. 5.5). Osteoblastic rimming of these trabeculae is usually absent, but its presence focally (particularly at the periphery of the lesion) does not rule out a diagnosis of fibrous dysplasia. Two main morphologic variations on this theme are represented by lesions in which there is deposition of either lamellar bone with prominent osteoblastic rimming or rounded psammoma-like masses resembling cement. These two variations can be seen in lesions of the craniofacial skeleton but are typically not seen in lesions involving the long bones.

Ossifying fibroma (cementifying fibroma, cemento-ossifying fibroma) is a benign neoplasm occurring in the tooth-bearing regions of the jaw bones.[36–39] They occur most often in the mandible of adults, and there is a female predilection. They present as an expansile lytic or mixed lytic-sclerotic bone lesion or are discovered incidentally in imaging studies and are well demarcated in contrast to fibrous dysplasia (Figs. 5.6 and 5.7). Histologically, they consist of a collagenous spindled stroma associated with varying amounts and types of mineralized tissues (Fig. 5.8). These can include

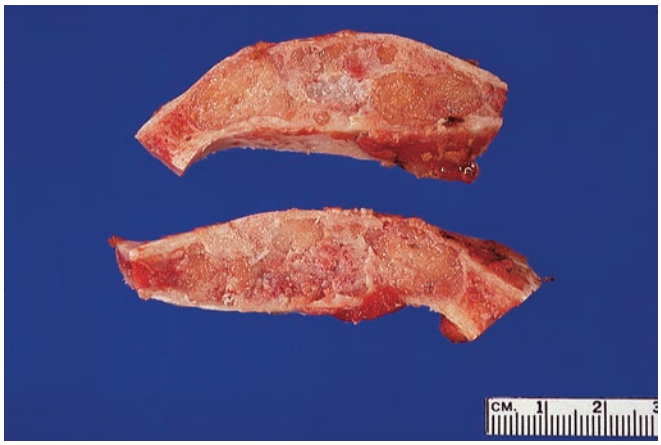

Figure 5.7 Gross appearance of ossifying fibroma. The lesion is hard, whitish, and well defined.

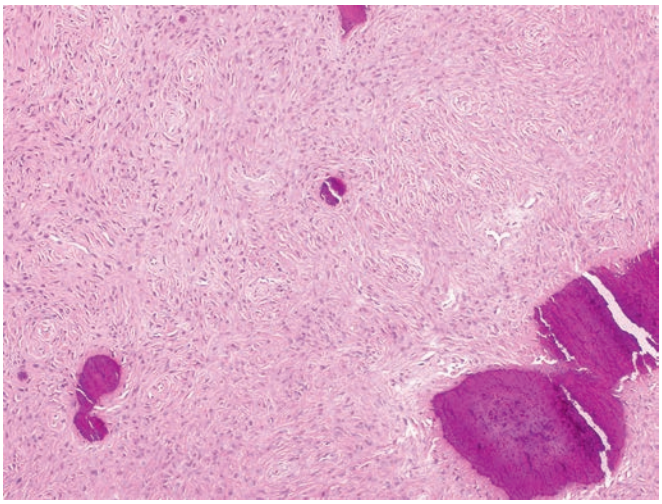

Figure 5.8 Conventional ossifying fibroma is less homogeneous compared to fibrous dysplasia and contains irregular globoid bone with a bland cellular spindled stroma.

globules of dense bone, trabeculae of woven or lamellar bone, and cementum-like calcifications. In contrast to fibrous dysplasia, there is less histologic uniformity in a given lesion; however, significant histologic overlap exists requiring correlation with imaging and clinical findings.

Two variants of ossifying fibroma have been described, and these typically present in children with rapidly growing bone tumors of the craniofacial skeleton. As such, they have been referred to as "aggressive" and "juvenile" ossifying fibroma. They are the psammomatoid and trabecular variants, but they may be unrelated to conventional ossifying fibroma. The *psammomatoid ossifying* fibromas usually occur in older children and involve the periorbital bones and paranasal sinuses preferentially but do occur in the mandible.[40] Radiologically, they are well circumscribed and typically lytic. Histologically, there is a cellular, benign, spindled stroma associated with numerous, round, basophilic ossicles that resemble psammoma bodies (Fig. 5.9). Simple excision is the treatment of choice, but lesions can recur. *Trabecular ossifying fibromas* occur in younger children and present with a rapidly growing tumor involving the maxilla most often followed by the mandible.[41] Microscopically, they consist of a cellular spindled stroma with bundles of osteoid that matures

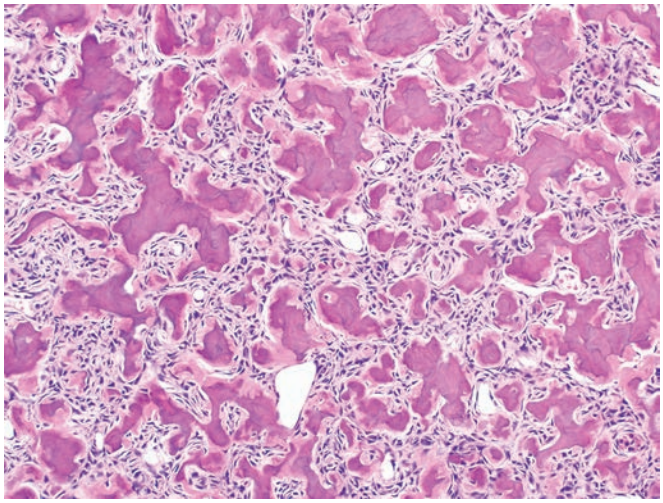

Figure 5.9 Psammomatous ossifying fibroma are more cellular and have psammoma-like ossicles and trabeculae.

to woven bone and lamellar bone with a zonal-type appearance. Stromal hemorrhage and aggregates of osteoclast are scattered throughout. Aneurysmal bone cyst changes and cystic degeneration are not uncommon. They are treated by simple excision but frequently recur.

It seems likely that all of these lesions might have a periodontal ligament origin. Overall, these lesions show a marked predilection for females and for the molar–premolar region of the mandible. Some authors have stressed the importance of separating fibrous dysplasia from the ossifying fibroma group of lesions because the latter are better-demarcated lesions that are more amenable to surgical enucleation or to curettage.[38,42,43] These practical considerations justify a segregation for therapeutic and prognostic purposes, which are backed by immunohistochemical and molecular genetic data. Thus, fibrous dysplasia (whether gnathic or extragnathic) has been found to exhibit a much stronger immunoreactivity for osteocalcin and to consistently harbor mutations of the *GNAS1* gene, whereas ossifying fibroma does not.[44]

Osseous Dysplasias (Cementoma) and Related Lesions

There are additional fibrous and ossifying, calcifying, or cementifying conditions of the jaws that may be linked to fibro-osseous lesions because of their histologic resemblance, although some of them may be of odontogenic nature.

Osseous dysplasia (periapical, focal, and florid) is a relatively common disorder, being detectable radiographically in 0.3% of the adult population. It is usually multiple and asymptomatic, is limited to small regions surrounding apices of teeth, and ordinarily does not require treatment. It is thought to be of periodontal ligament origin and non-neoplastic in nature.[45] An autosomal dominant form of this disorder has been described.[46]

Mandibular incisor regions of black female adults usually are involved, but there are some differences among the three variants. Occasionally, a single tooth is affected, and this may become a surgical specimen. Periapical osseous dysplasia occurs in middle-aged black women and involves the apex of a single tooth, usually a mandibular incisor. Focal osseous dysplasia is similar to the periapical type but involves multiple teeth in the posterior mandible. Florid osseous dysplasia is similar to the focal type except that multiple jaw quadrants are involved and the lesions are more often

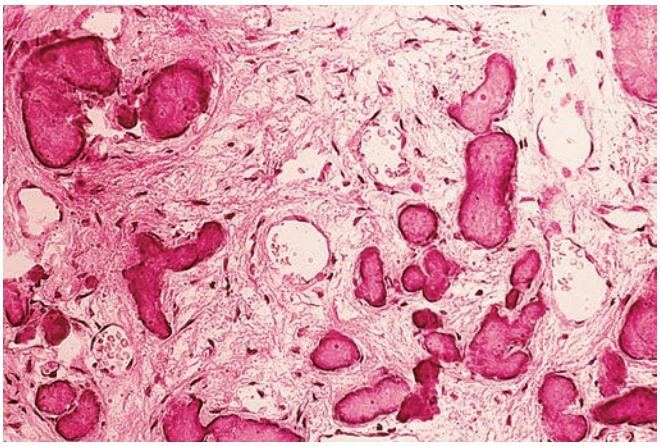

Figure 5.10 Periapical cemental dysplasia. (From Pindborg JJ, Kramer IRH, Torloni H. *Histological Typing of Odontogenic Tumours, Jaw Cysts, and Allied Lesions*. Geneva: World Health Organization, 1971.)

symptomatic. Microscopically all three are identical; the most typical feature is the presence of curvilinear trabeculae ("ginger root" pattern) or irregularly shaped cementum-like masses set within a vascular stroma (Fig. 5.10). The main differential diagnosis is with ossifying fibroma, which is well-circumscribed and shows thin isolated trabeculae with prominent osteoblastic rimming; however, significant histologic overlap exists.[2,47]

Benign osteoblastoma can occur in the jaw, sometimes in intimate relationship to a dental root surface.[48] When the latter is the case, the alternative designations of *(benign) cementoblastoma* and *true cementoma* are sometimes used (Figs. 5.11 and 5.12).[49]

The clinical course is usually innocuous, the lesion often stabilizing as a heavily calcified nodule. However, the fact that some lesions are locally aggressive indicates that surgical excision is the treatment of choice.

Figure 5.12 Typical radiographic appearance of cementoblastoma. A dense, homogeneous mass is seen in continuity with the tooth root. (Courtesy of Dr. C.A. Waldron, Atlanta.)

Microscopically, this lesion features irregular osteoid and bone formation (or cementum) within proliferative fibrovascular connective tissues.[37] Plump benign-appearing osteoblasts are seen rimming the newly formed trabeculae (Fig. 5.13). Osteoblastomas exhibiting a prominent epithelioid configuration of the osteoblasts are referred to as *aggressive* and are regarded by some as low-grade (nonmetastasizing) malignancies given the increased rate of recurrence.

Other lesions of the jaw featuring bone or cementum formation within proliferative fibrous connective tissue include solitary **large** or **"gigantiform" cementomas**,[50] and **osteomas** (especially those observed in patients with Gardner syndrome).[51] Inflammatory lesions of the jaws during their sclerotic or healing phases and Paget disease also enter in the differential diagnosis.[52]

Epithelial Cysts

Epithelium-lined cysts of the maxilla or mandible are among the more commonly encountered jaw diseases from both the clinician's and the pathologist's perspective.[19] Most cannot be identified specifically on the basis of their histologic appearance alone. Therefore, integration of radiographic, surgical, and microscopic findings is necessary to reach a specific diagnosis.

Two major categories of epithelial cyst exist: odontogenic and fissural (nonodontogenic). *Odontogenic* cysts arise from the odontogenic epithelium and are located within the jaw (or, rarely, in the adjacent soft tissues). *Fissural (nonodontogenic) cysts* are thought to arise from epithelial inclusions within soft or bony portions of the region that lack the embryologic and tooth-forming heritage of odontogenic epithelium. They occur along embryologic fissure lines

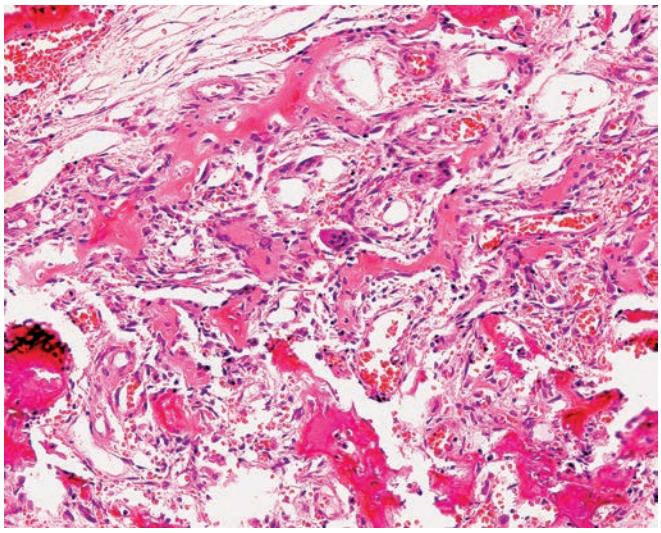

Figure 5.13 Cementoblastoma. Numerous neoformed osteoid trabeculae are lined by osteoblasts and separated by a highly vascularized matrix.

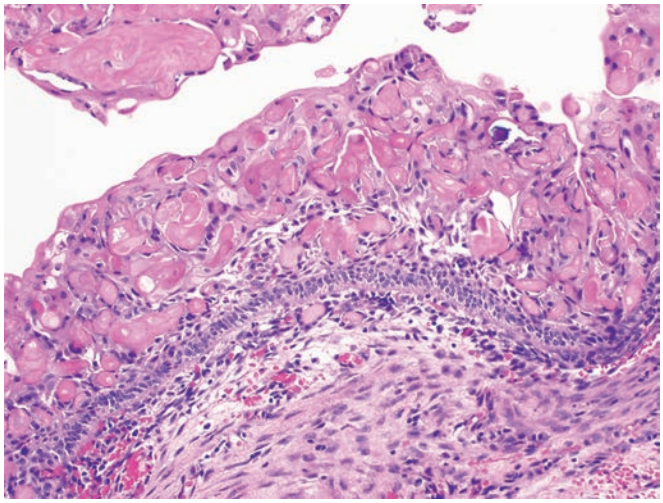

Figure 5.14 Calcifying cystic odontogenic tumor (CCOT). The epithelial cells resemble cystic ameloblastoma but the presence of ghost keratinocytes, some of which calcify, easily distinguish CCOT from ameloblastomas which lack them.

and, therefore, usually occur outside of the jaw bones. Several subtypes of these two major categories are listed in Box 5.2.

Dentigerous cysts surround or are associated with unerupted teeth and usually are found in young adults. They are found in almost 1% of individuals having complete dental roentgenograms and are often discovered incidentally.[53] They arise from alterations of reduced enamel epithelium after development of enamel and are associated with the tooth crown, at least initially. They develop from fluid accumulating between the crown of the tooth and the reduced enamel epithelium which is just beneath the dental follicle connective tissue. Swelling and, rarely, pain are symptoms, but they occur late or with infection and inflammation.

Microscopically, the uncomplicated dentigerous cyst has a thin fibrous wall (dental follicle connective tissue) lined by stratified squamous epithelium.[53] Secondary changes in the form of chronic inflammation, ulceration, reactive hyperplasia, metaplasia (squamous and mucinous), calcification, and clusters of histiocytes containing hemosiderin and lipofuscin are common.[54] Dysplasia and carcinoma can also develop in them, but this is exceedingly uncommon.[55] Although uncommon, they are more likely to give rise to cystic ameloblastomas.

Surgical excision is the treatment of choice for dentigerous cysts. Recurrence is very unusual. When it occurs, incomplete removal or the alternative possibilities of keratocystic odontogenic tumor and early or cystic examples of ameloblastomas should be considered.

Eruption cyst is a subtype of dentigerous cyst that may be unilateral or bilateral, single or multiple. It presents as a gingival swelling above erupting primary or, rarely, permanent teeth. Surgical exposure of the affected tooth reveals a subacutely inflamed and hemorrhagic cyst wall lined by usually thin and nonkeratinizing stratified squamous epithelium.

Gingival cysts of newborn infants *(Bohn nodules)* present as minute cystic or nodular formations; they are seen in most neonates and gradually disappear, usually in a matter of weeks. Microscopically, they are lined by stratified squamous epithelium that are sometimes parakeratotic.[56] Occasionally, gingival cysts are seen in adults.

Lateral periodontal and **botryoid odontogenic cysts** probably represent cystic remnants of the dental lamina. They are remarkable by virtue of their anatomic location, usually apposing gingival or root surfaces of teeth in adults.[57] Mandibular premolar regions are the most frequent sites of occurrence. They are usually unilocular but can present as a multilocular cyst. The latter have been termed botryoid odontogenic cysts. Microscopically, they are lined by an extremely thin stratified squamous epithelium, one or two layers thick.[58] Small nodular collections of glycogen-containing epithelial clusters can be seen, especially in the botryoid odontogenic cysts.

Calcifying cystic odontogenic tumor (keratinizing and calcifying odontogenic cyst, Gorlin cyst) is characterized by a cyst lining of ameloblastic epithelium with prominent basal palisading and large masses of keratinized "ghost" cells (Fig. 5.14). The ghost cells undergo varying degrees of dystrophic calcification. Some of the cells may exhibit clear cell changes, and others may contain melanin pigment.[59] The epithelium can induce dentinoid matrix production in the underlying stroma. Some examples show a remarkable similarity with ameloblastoma and craniopharyngioma, from which they are distinguished by the presence of the characteristic ghost cells and dentinoid, respectively.[60,61] It has been proposed that lesions in which

Figure 5.15 Periapical/radicular cyst demonstrating continuity with pulp canal of nonvital tooth.

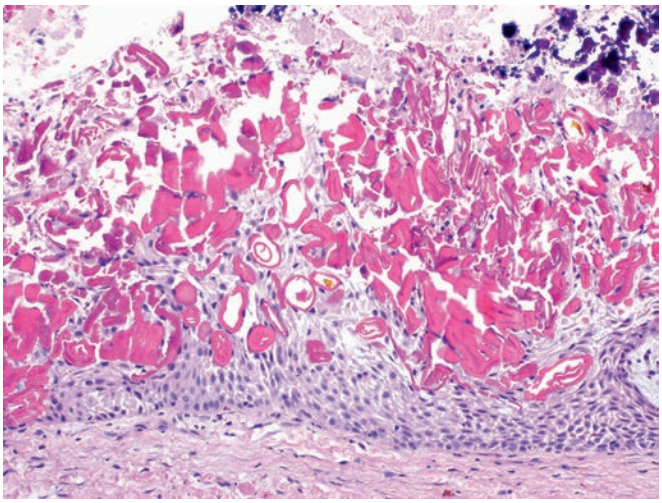

Figure 5.17 Periapical/radicular cyst with numerous intraepithelial eosinophilic Rushton bodies.

this proliferation is solid represent the neoplastic counterpart of the calcifying cystic odontogenic tumor, and the term *dentinogenic ghost cell tumor* has been proposed for them.[62,63] Indeed, it may well be that all of the lesions in this category are tumors exhibiting varying (and sometimes very extensive) degrees of cystic change, a possibility supported by the common presence of molecular alterations in the form of β-catenin gene mutations.[64] Aberrant nuclear accumulation of β-catenin is a characteristic finding, attributable to the presence of somatic mutations in the encoding gene *CTNNB1*.[64] Enucleation is the treatment of choice which is associated with a very low recurrence risk.

Radicular or periapical cysts are a sequela of dental inflammatory disease and represent the most frequently encountered cyst of the jaws.[8] They occur in all age groups but are more commonly diagnosed during the third and fourth decades. Those observed within the maxilla or the mandible after tooth extraction are called *residual cysts*. Radiographically, periapical cysts present as a well-circumscribed radiolucency at the apex of affected nonvital teeth (Figs. 5.15 and 5.16). Microscopically, they are lined by stratified squamous epithelium, the thickness of which varies according to the degree of inflammation present. Ulceration is common, and epithelium may be difficult to identify. When present, it may exhibit metaplasia, calcification, and hyaline (Rushton) bodies (Fig. 5.17). The inflammatory infiltrate in the wall may be acute, chronic, or mixed. Aggregates of cholesterol crystals, foamy macrophages, multinucleated giant cells, and plasma cells are common. The cyst usually is easily curetted from the surrounding bone, and recurrence is rare. At surgery, the cyst may be found attached to the apex of the extracted tooth.

Keratocystic odontogenic tumor (odontogenic keratocyst) constitutes approximately 10% of cysts of the jaw and ordinarily can be diagnosed on the basis of their histologic features.[65,66] Although they can occur in any portion of the jaw, most are found in the posterior mandibular regions. They have been divided into *solitary* or *primordial* (90%) and *multiple* (10%). The latter are a component of the nevoid basal cell carcinoma syndrome *(Gorlin syndrome)*, together with cutaneous nevoid basal cell carcinomas, palmar/plantar pits, calcification of the falx cerebri, cutaneous epidermoid cysts, and numerous types of skeletal abnormalities.[67,68] This syndrome is transmitted by an autosomal dominant gene having high penetrance and variable expressivity.[69,70] Germline mutation of the human homologue of *Drosophila* patched *(PTCH1)*, a tumor suppressor gene located at 9q22.3–q31, is the underlying molecular defect in this syndrome.[71]

Keratocysts occur most frequently in the third molar region of the mandible (Figs. 5.18 and 5.19). The mean age of the patients is 40 years. The cysts are more frequently multilocular and more commonly associated with swelling and pain than are dentigerous cysts.

Grossly, the cyst cavity contains a cheesy material consisting of keratinous debris that, when flushed away, reveals a white, subtly wrinkled surface. Microscopically, the epithelial lining is of uniform thickness and approximately 5–7 cells thick. It is a parakeratinized

Figure 5.18 Radiograph demonstrating portion of maxillary odontogenic keratocyst in a 15-year-old with a 2-week history of facial swelling.

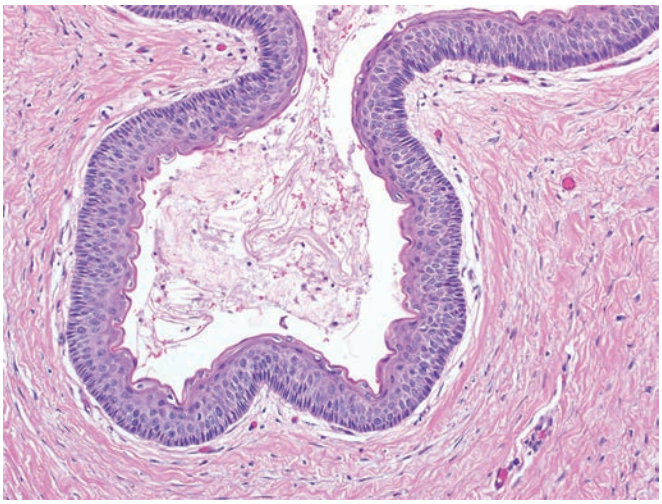

Figure 5.19 Odontogenic keratocyst. Note the corrugated parakeratinized surface and prominent palisaded basal cell layer.

squamous epithelium with prominent palisading of the basal cell layer and a wavy, corrugated, or mildly verrucous surface of parakeratin. Secondary inflammation can obscure these characteristic histologic findings. Small "daughter" cysts and basaloid odontogenic rests can be seen in the connective tissue stroma. These should be separated from the cystic lesions exhibiting an orthokeratinized lining, on the basis of less aggressiveness associated with the latter *(orthokeratinized odontogenic cysts)*.[72,73] The majority of keratocystic odontogenic tumors have been found to harbor chromosomal abnormalities, supporting the supposition that they are of neoplastic nature, resulting in the renaming of the entity from "odontogenic keratocyst."[74,75] The Sonic Hedgehog *(SHH)* signaling pathway plays

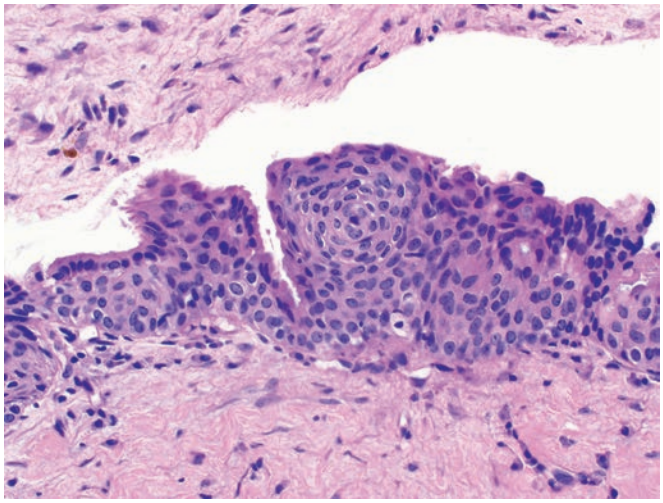

Figure 5.20 Glandular odontogenic cysts can be unilocular or multilocular. They are lined by squamoid epithelial cells with occasional thickened plaques. Other features include eosinophilic surface cells, mucous cells, and intraepithelial glandular lumens.

a critical role in tooth development. *PTCH1* combines with Smoothened *(SMO)* to form a receptor complex for the *SHH* ligand. Inactivating mutation and allelic loss of *PTCH1* resulting in aberrant activation of the *SHH* signaling pathway represent the key genetic event of both sporadic and nevoid basal cell carcinoma syndrome-related keratocysts.[76,77]

Keratocystic odontogenic tumors have a high rate of recurrence, which has ranged from 23% to 60% in the various series.[78] This has been variously attributed to technical difficulties with curettement due to the multilocularity of the cysts and the friability of the material, presence of epithelial remnants in the wall, and budding of the epithelial lining within the cyst wall.

Glandular odontogenic cysts (sialo-odontogenic cysts) are most often seen in adults and have a predilection for the anterior jaw, especially the mandible. They can be unilocular or multilocular and have a recurrence risk similar to keratocystic odontogenic tumors. Microscopically, they are lined by stratified squamous epithelium with eosinophilic cuboidal surface cells in areas (Fig. 5.20). They contain mucous cells and duct-like structures as well and can therefore be confused with mucoepidermoid carcinoma.[79] Small nodular collections of glycogen-containing epithelial clusters can be seen, similar to those in lateral periodontal/botryoid odontogenic cysts.

Nasolabial (Klestadt or **nasoalveolar) cyst** predominantly occurs in females and is commonly bilateral. Originally thought to arise from epithelial rests at the embryologic junction of the globular, lateral nasal, and maxillary processes, development from the caudal end of the nasolacrimal rod or duct is currently favored.[80] The nasoalveolar cyst occurs near the base of the nostril, outside the alveolar process of the maxilla. It eventually obliterates the nasolabial fold and gently presses its way toward the nasal mucosa. Microscopically, the lining may be of stratified squamous or respiratory type.

Nasopalatine duct (incisive canal) cyst may be intraosseous or be located within the soft tissues of the palatine papilla. It represents cyst formation of embryologic remnants of the incisive canal joining the oral and nasal cavities[81] and is the most common type of fissural or nonodontogenic cyst. Microscopically, it is lined by respiratory or stratified squamous epithelium (sometimes pigmented) or a combination of both.[82] Frequently, the nasopalatine neurovascular bundle is present in the stroma adjacent to the cyst epithelium, as well as minor salivary gland, adipose, and cartilage tissues.

Odontogenic Tumors

Odontogenic tumors are neoplasms of the jaws which differentiate toward tooth structures. Despite their rarity, there is a great variety of types, with numerous transitional forms. This has resulted in many classification attempts, beginning with the histologic scheme proposed by Broca in 1867. Thoma and Goldman[83] in 1946 classified them histogenetically into epithelial, mesodermal, and mixed, whereas Pindborg and Clausen[84] in 1958 stressed the phenomenon of induction (as a mechanism of differentiation) over histogenesis. Subsequent authors have slightly rearranged these types and added a few, most of which are included in the current classification scheme from the World Health Organization (WHO).[2]

The following grouping (Box 5.3) presents odontogenic tumors in a simplified fashion for the general surgical pathologist. It emphasizes their clinical behavior, which is benign for most types.

It should be noted that peripheral (extraosseous) equivalents of most central odontogenic tumors have been described, located in the mandibular or maxillary gingiva, arising either from the surface mucosa or from dental lamina nests in the submucosa, or in the sinonasal tract.[85]

Benign Odontogenic Tumors

Adenomatoid Odontogenic Tumor (Adenoameloblastoma)

Adenomatoid odontogenic tumor is a benign lesion that probably arises from the odontogenic epithelium of the dental lamina complex or its remnants.[86,87] It is more common in females, occurs most frequently in the second decade of life, and the most frequent location is the anterior maxilla.[86] It is often associated with an unerupted canine tooth ("follicular" type) (Fig. 5.21), but it can also be extrafollicular and may appear cystic radiographically.[88] A peripheral variety of this tumor exists.[87] Although the tumor expands, it is not invasive and does not recur after conservative surgical therapy.[89]

Grossly, it is rounded and predominantly solid with cystic areas. Some are very cystic to the point of simulating an odontogenic cyst. The low-power microscopic appearance is that of a multinodular tumor composed of cuboidal to columnar cells forming small nests

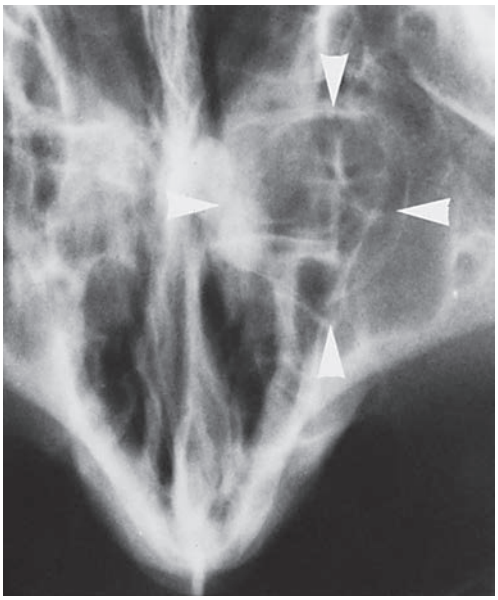

Figure 5.21 Adenomatoid odontogenic tumor of maxilla in an edentulous patient. Radiographically, a dentigerous cyst is suggested *(arrows)*.

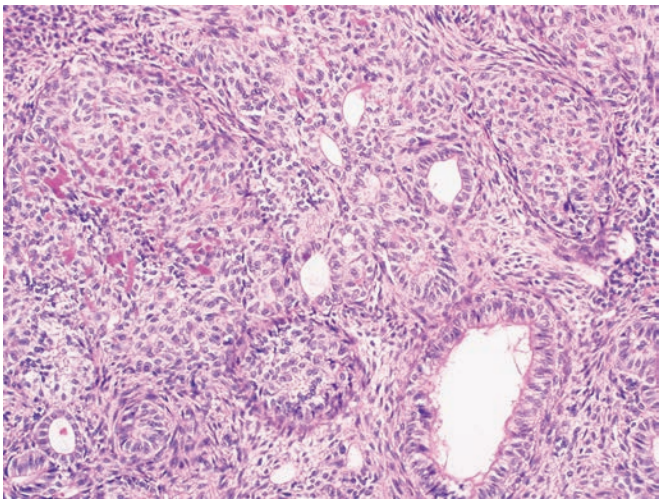

Figure 5.22 Adenomatoid odontogenic tumor. Gland-like structures are present with more cellular solid areas. Eosinophilic tumor droplets are present on the left.

with occasional duct-like structures. The duct-like structures are filled with eosinophilic material or are empty, and the outer cells can demonstrate reverse polarization (Fig. 5.22). Some tumors can have so-called convoluted structures, which are similar to the duct-like structures except that they are lined by very tall columnar cells arranged in a convoluted manner. Homogeneous zones of hyaline material and calcified deposits may be scattered throughout the epithelial lining.[2,90,91] Between the solid epithelial nodules, the epithelial cells often have a more cystic configuration and there is little stroma. The lesion is typically surrounded by a thick fibrous capsule.

Calcifying Epithelial Odontogenic Tumor

Calcifying epithelial odontogenic tumor (Pindborg tumor) occurs more commonly in the fourth and fifth decades.[92] There is no gender

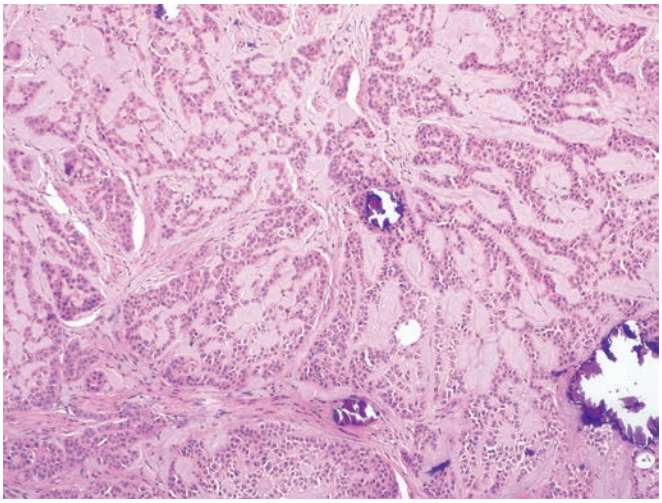

Figure 5.23 Calcifying epithelial odontogenic tumor. Nests of eosinophilic epithelial cells are set within an amyloid stroma with areas of dystrophic calcification.

predilection. Most of the reported cases have arisen in the mandibular premolar–molar area in association with an embedded tooth,[93] and a few have been found peripherally located in the gingiva.[94]

Grossly it is usually solid, but a cystic variety has been described.[95] Microscopically, the tumor is composed of closely packed polyhedral epithelial cells accompanied by variable amounts of stroma (Fig. 5.23). The epithelial cells frequently demonstrate nuclear pleomorphism and have abundant eosinophilic cytoplasm. Some tumors contain a predominance of clear cells. Although the nuclei demonstrate pleomorphism, they typically lack mitotic activity. Intracellular degeneration results in numerous spherical spaces filled with eosinophilic homogeneous material that in time becomes calcified. This has been shown to be amyloid or a substance with similar physicochemical properties.[96,97] Some tumors are quite cellular with minimal amyloid, whereas others are paucicellular and rich in amyloid. Despite the name, some tumors are actually noncalcified. High activity of alkaline phosphatase and adenosine triphosphatase has been found in the cytoplasm, an enzyme histochemical profile similar to that of the stratum intermedium cells of the normal dental germ.[98] Hybrids of this neoplasm and adenomatoid odontogenic tumor have been described.[99]

Calcifying epithelial odontogenic tumor may be invasive and recur locally, but on the whole it is a less aggressive lesion than ameloblastoma.[2] Small tumors can be enucleated but larger lesions require resection with tumor-free margins. Exceptional instances of metastasis to regional lymph nodes and to the lungs have been reported.[100]

Squamous Odontogenic Tumor

Squamous odontogenic tumor is a very rare benign neoplasm that occurs over a wide age range and has a predilection for the anterior maxilla and posterior mandible. Tumors in the former location tend to recur more often due to incomplete removal.[101–103] Radiographically, the lesion appears as a well-circumscribed semicircular radiolucency between the roots of teeth and surrounded by a sclerotic border. Microscopically, it is composed of nests and islands of well-differentiated squamous epithelium lacking atypia or mitotic activity, located within a collagenous stroma of low to moderate cellularity (Fig. 5.24).[102] An extraosseous variety of this tumor has been described.[101]

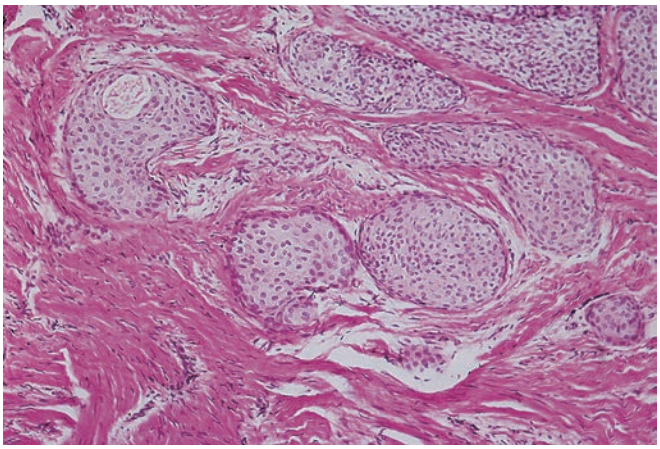

Figure 5.24 Squamous odontogenic tumor. Well-defined nests of monotonous clear cells are separated by an abundant collagen stroma.

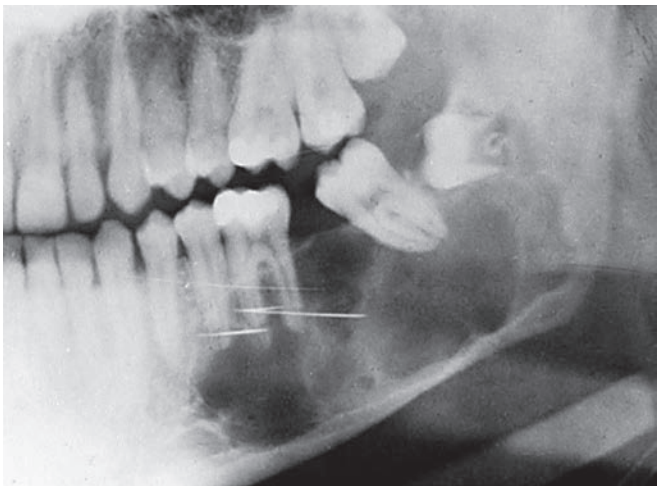

Figure 5.25 Radiographic appearance of ameloblastic fibroma of mandible in a 17-year-old youth. The defect is multilocular but suggests irregularity.

Ameloblastic Fibroma

Ameloblastic fibroma often resembles a cyst radiographically (Fig. 5.25). In contrast to ameloblastoma (the tumor with which it is most commonly mistaken), ameloblastic fibroma usually occurs in a young age group, rarely being seen in individuals older than 21 years of age. It is usually solid, although a cystic variety has been described.[104]

Microscopically, it is composed of strands and buds of ameloblastic epithelial cells embedded in a cellular myxoid connective tissue stroma (Fig. 5.26). The presence of this mesenchymal component is the main distinguishing feature with ameloblastoma. Hard tooth structures such as dentin may be present (ameloblastic fibrodentinoma), but this does not impart a biologic difference.[105] For the most part, the cells composing the epithelial strands are cuboidal and two cell layers thick. Only occasionally a stellate reticulum is present, but larger aggregates are often found as well. A *granular cell variety* of ameloblastic fibroma has been described.[106] Ameloblastic fibro-odontoma consist of an ameloblastic fibroma with areas resembling small odontomas.

The clinical behavior of ameloblastic fibroma and ameloblastic fibro-odontoma is benign. Therefore, and in contrast to ameloblastoma, simple curettage is usually adequate.[107]

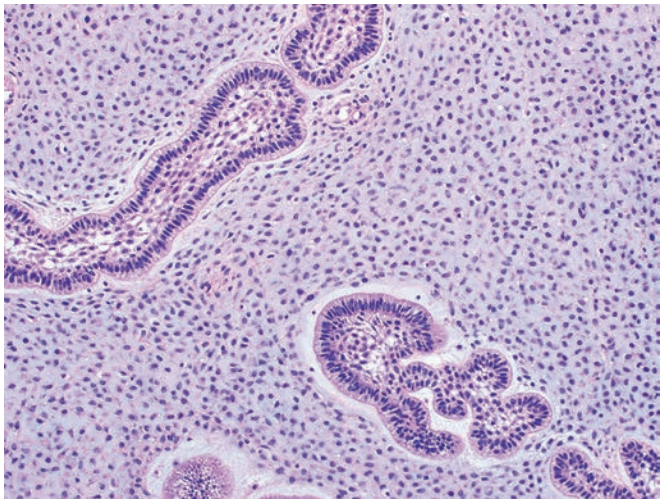

Figure 5.26 Ameloblastic fibroma. The neoplastic fibrous stroma encloses thin strips of ameloblastic epithelium.

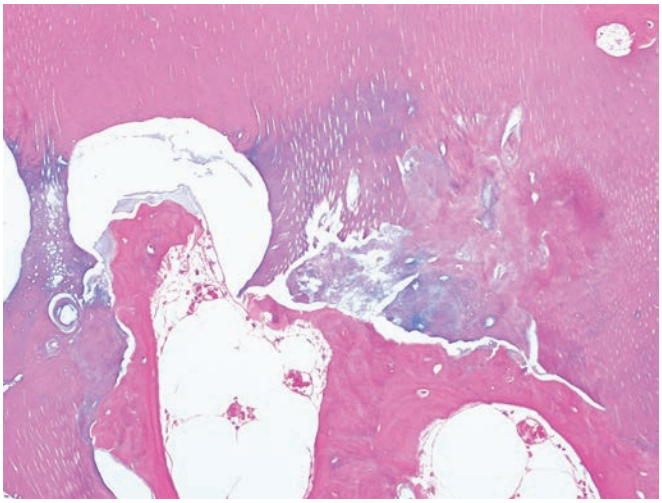

Figure 5.28 Complex odontomas contain a disorganized proliferation of enamel, dentin, and cementum (bone).

Figure 5.27 Radiograph illustrating benign complex odontoma involving posterior maxilla of a 16-year-old girl. Note molar superiorly and absence of one molar.

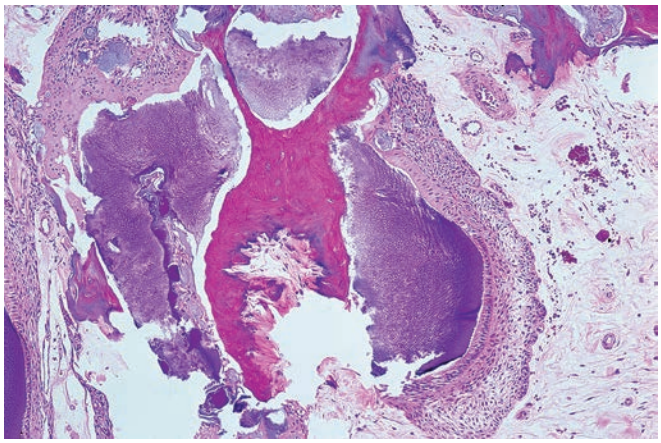

Figure 5.29 Compound odontomas are more organized than complex odontomas having the appearance of a misshapen tooth.

Odontoma

Odontomas are defined as odontogenic tumors featuring production of calcified parts of teeth. They are the most common odontogenic tumor. They occur in the tooth-bearing regions of the mandible or maxilla. Two main subtypes of odontoma are recognized.

Complex odontoma is an architecturally disorganized lesion, with a variety of calcified patterns but not enough coordinated production of enamel, dentin, or cementum to reach a point where an actual tooth can be identified (Fig. 5.27). It is more frequent in molar areas of the mandible in female patients (Fig. 5.28). Although the tumors occasionally achieve considerable proportions, they are entirely benign and usually represent incidental findings in routine radiographic examinations.

Compound odontoma exhibits a higher degree of differentiation than does complex odontoma, so that the individual lesion characteristically consists of masses of small misshapen teeth known as *denticles* (Fig. 5.29). Most lesions have only a few of these structures, but cases containing as many as 2000 (!) are on record. Compound odontomas behave in an entirely benign fashion. They are more commonly encountered in the anterior regions of the jaws and are more frequent in the maxilla than in the mandible.

Odontoameloblastoma

Odontoameloblastoma (ameloblastic odontoma, odontoblastoma) is a solid or cystic lesion characterized by the presence of a prominent epithelial component resembling ameloblastoma in addition to dental hard and soft tissues, such as enamel and dentin (Fig. 5.30).[2,108] The presence of dental hard tissues distinguished this lesion from ameloblastoma. Some have considered it a variant of odontoma, but it appears to be a distinct entity.[109] It is generally benign, but on occasion it behaves aggressively and recurs locally after conservative surgical removal.[2] Therefore, it is typically treated in a similar manner as ameloblastoma.

Odontogenic Myxoma, Myxofibroma, and Fibroma

Myxoma of the jaws is generally regarded as of tooth germ origin and specifically derived from the dental papilla, hence the qualifier *odontogenic* usually applied to it.[110] It may be associated with

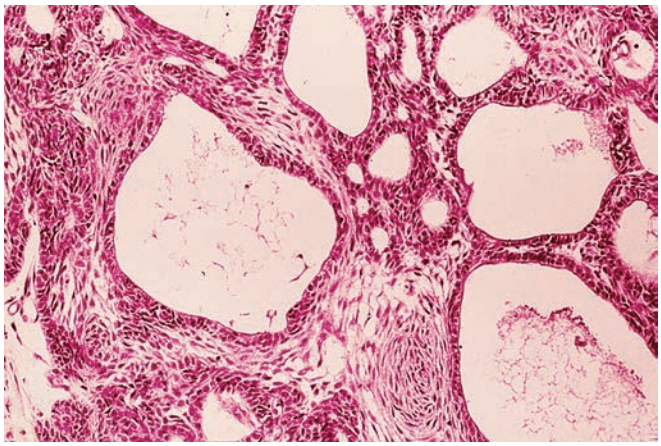

Figure 5.30 Odontoameloblastoma. (From Pindborg JJ, Kramer IRH, Torloni H. *Histological Typing of Odontogenic Tumours, Jaw Cysts, and Allied Lesions*. Geneva: World Health Organization; 1971.)

Figure 5.31 Radiograph illustrating a large recurrent odontogenic myxoma of mandible in male adult.

malformed or missing teeth. Approximately 60% occur during the second or third decades, and there is an equal incidence of mandible and maxilla involvement. Radiographically, these tumors often present as lytic lesions, but they can attain a large size and result in marked facial deformity. Recurrence after conservative removal is not unusual, probably because of its poorly defined margins (Fig. 5.31).[111] Therefore, resection with tumor-free margins is indicated. Small lesions can be more conservatively excised.

Microscopically, myxoma consists of loose stellate cells with long, branching, eosinophilic cytoplasmic processes that are set within a paucivascular myxoid stroma (Fig. 5.32). Occasionally, strands of odontogenic epithelium thought to represent rests of Malassez are noted. Spicules of bone trabeculae are often entrapped by this infiltrative tumor. The myxoma cells are immunohistochemically reactive for vimentin and often smooth muscle actin but are negative for S-100 protein. In contrast to intramuscular myxoma, activating mutations in the *GNAS1* gene are not found.[112]

Odontogenic myxoma can be closely simulated microscopically by the normal dental papilla of an unerupted tooth. Although the

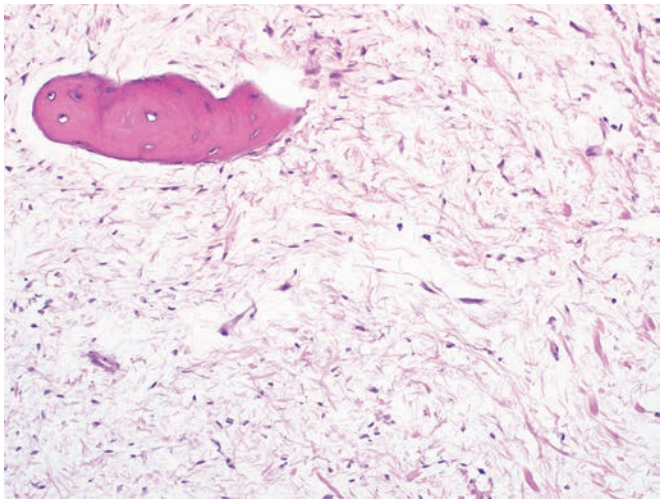

Figure 5.32 Odontogenic myxoma. The lesion is highly myxoid, hypocellular, and devoid of atypia. Native bone trabeculae are entrapped indicative of infiltrative growth.

histology can be similar, the clinical and radiographic appearances easily distinguish these two processes.

Odontogenic fibroma differs microscopically from myxoma by the presence of fibrous tissue and the more frequent occurrence of odontogenic epithelial rests.[113] This lesion occurs most frequently in the mandible and displays a female predilection.[114] Tumors in which the myxomatous and the fibrous components are equally represented can be designated as *myxofibromas*.[115] Cases combining features of odontogenic fibroma and central giant cell granulomas exist (see p. 276).[116] Odontogenic fibroma can be simulated microscopically by the normal dental follicle around the crown of an unerupted tooth (see p. 276).[113,117] In contrast to myxomas, they tend not to recur and can be treated more conservatively.

Peripheral counterparts of these lesions occurring in the gingiva have been described.[118]

Borderline Odontogenic Tumors

Ameloblastoma

General and Clinical Features

Ameloblastoma is the most common of the epithelial odontogenic tumors,[119] but it is still comparatively rare, comprising approximately 1% of tumors and cysts arising in the jaws. It may arise from the epithelial lining of a dentigerous cyst, from the remnants of the dental lamina and enamel organ, or from the basal layer of the oral mucosa, sometimes in a multicentric fashion.[120]

Ameloblastoma appears most commonly in the third to fifth decades, but it has also been described in children.[121] No gender or racial preference has been noted. More than 80% occur in the mandible, with 70% of these arising in the molar–ramus area. The usual radiographic appearance is that of a lytic expansile lesion. Clinical duration may range from a few weeks to 50 years (Fig. 5.33). The diagnosis can be made by fine-needle aspiration. Some arise in the maxillary sinus and have no connection with the maxillary bone.

Morphologic Features

Traditionally, ameloblastoma has been divided into solid and (multi) cystic types, but this distinction is arbitrary inasmuch as nearly all ameloblastomas demonstrate some degree of cystic change (Fig. 5.34). Therefore, they are now grouped together as solid/

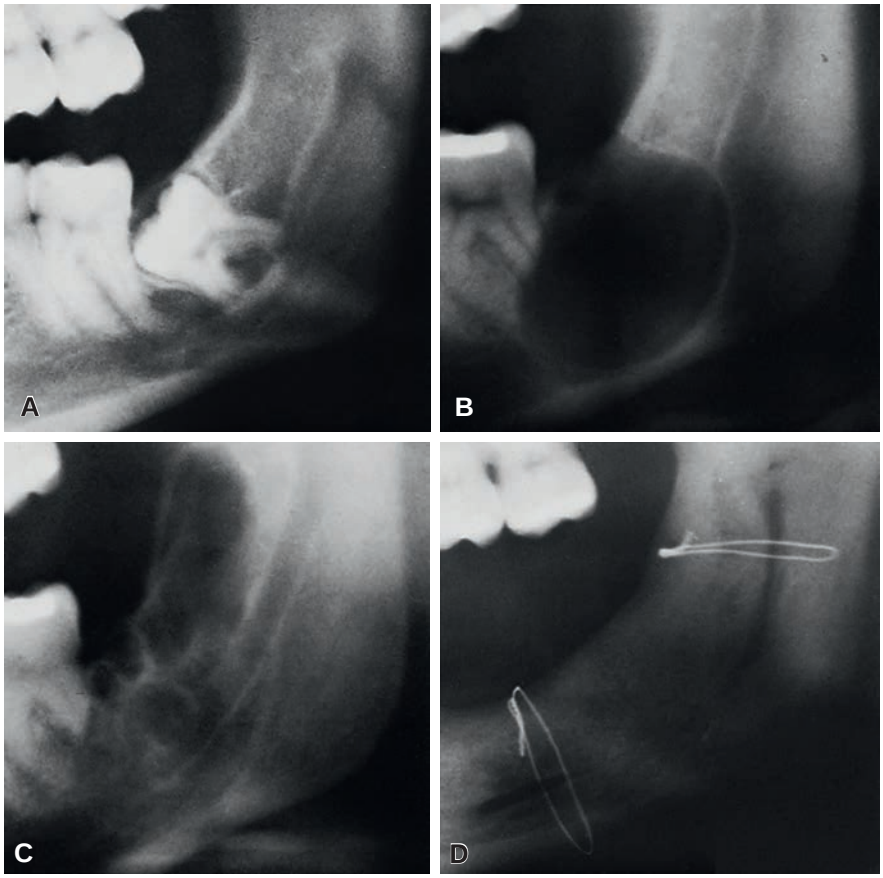

Figure 5.33 Four radiographs illustrating history of ameloblastoma associated with impacted third molar tooth in a 19-year-old female patient. **A** (April 1971), Subtle, atypical radiolucency can be discerned below tooth. Tooth was surgically removed. No surgical specimen was obtained. **B** (September 1974), Routine dental roentgenogram revealed residual or recurrent cystic lesion. Surgical curettage was performed and "early" ameloblastoma demonstrated. No further treatment was given. **C** (February 1978), Multilocular radiolucency of more typical character. Tumor was resected. **D** (December 1978), There is no evidence of residual tumor. (Courtesy of Dr. William Randall and Dr. Clark Borstad, Minneapolis.)

Figure 5.34 Gross appearance of ameloblastoma showing an expansile solid and cystic mass in the posterior mandible and ramus.

multicystic ameloblastomas. Microscopically, many subtypes or patterns have been described: follicular, plexiform (Fig. 5.35), acanthomatous (Fig. 5.36), basaloid, granular cell (Fig. 5.37), and desmoplastic.[122–126] Two or more types may coexist within the same tumor, and there is little evidence to suggest that one subtype is more aggressive than another.

The two predominant patterns are follicular and plexiform. In the follicular type, there is an attempt to mimic the dental organ epithelium. The outermost cells resemble those of the inner dental epithelium of the developing tooth follicle (i.e. the ameloblastic layer). The cells are tall columnar, with polarization of the nuclei away from the basement membrane. The plexiform pattern demonstrates irregular masses and interdigitating cords of epithelial cells but otherwise are similar to the follicular type.[2,127] The central portion of the epithelial island is composed of a loose network of cells resembling stellate reticulum. Squamous metaplasia within the stellate reticulum gives rise to the acanthomatous type and is a common histologic finding. The epithelial islands demonstrate little inductive influence on the fibrous connective tissue stroma. Enamel and dentin are not formed by ameloblastoma. The desmoplastic variant is uncommon and is characterized by dense sclerotic stroma with compressed islands of ameloblastoma. They tend to lose the polarization of the peripheral palisaded columnar cells and the stellate reticulum appears more condensed and cellular.

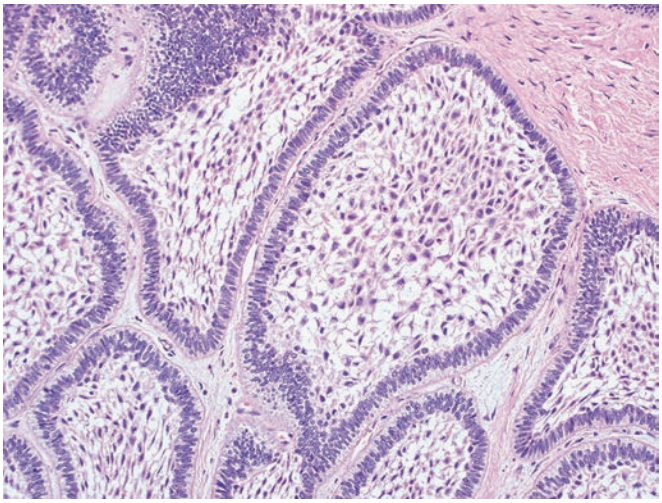

Figure 5.35 Ameloblastoma exhibiting the classic "follicular" appearance with central stellate reticulum and peripheral palisaded columnar cells with so-called reverse polarization.

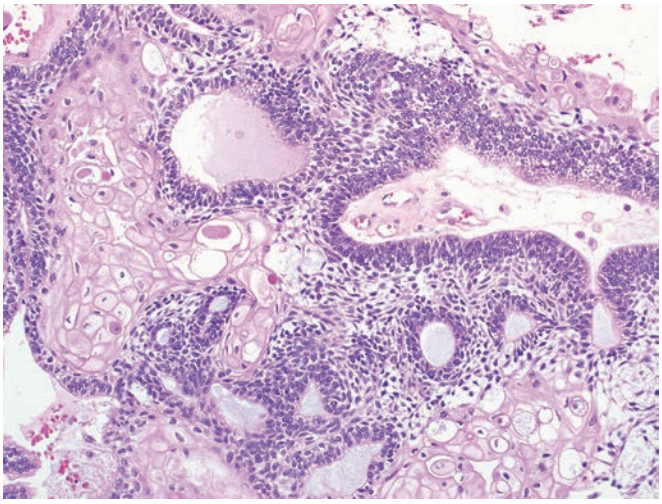

Figure 5.36 Acanthotic ameloblastoma. Ameloblastic epithelium surrounds large keratin-filled cavities.

Immunohistochemical and Molecular Genetic Features

Immunohistochemically, the tumor cells exhibit strong reactivity for keratin and are surrounded by a continuous layer of laminin in a pattern similar to that seen in the developing tooth.[128] The major keratins expressed are CK5 and CK14, whereas coexpression of CK8, CK18, and CK19 is a feature of the cells in the stellate reticulum-like areas.[129] Notably, calretinin has been found to be positive in the overwhelming majority of solid and multicystic ameloblastomas (as well as in the unicystic tumors, see later).[130] The staining, which is almost always restricted to the stellate reticulum-like epithelium, may be of diagnostic aid for the identification of these tumors, particularly in the differential diagnosis with keratocyst, which is consistently negative for this marker.[131]

Granular cell ameloblastoma is positive for keratin and negative for S-100 protein, in keeping with its ameloblastic nature and in contrast to the ordinary granular cell tumor; however, and like the latter, it is also positive for CD68, indicating that the granular cell change here is also due to lysosomal overload.[132]

Ameloblastoma commonly shows aberrant nuclear accumulation of β-cateinin.[64,133,134] To explain this phenomenon, mutations of genes involved in the Wnt signaling pathway have been sought. Mutations in the β-catenin gene *CTNNB1* are rare, mutations in the *APC* gene are found in 0%–50% of cases, and mutations in *AXIN1* and *AXIN2* are absent.[64,133–135] Gene expression profiling studies reveal overexpression of the oncogene *FOS* and tumor necrosis factor (TNF) receptor 1 *(TNFRSF1A)*, as well as underexpression of a variety of genes, such as genes for *SHH*, TNF receptor-associated factor 3 *(TRAF3)* and transforming growth factor (TGF)-β_1 *(TGFB1)*.[136] Recently, somatic activating *BRAF* V600E mutations have been identified in 62% of ameloblastomas in a large series of 80 tumors.[137] *BRAF* VE1 immunohistochemical stain was 100% sensitive and specific in these mutated cases. *BRAF*-mutated tumors show lower recurrence risk. Mutually exclusive somatic activating mutations of FGFR2 were also identified, as well as rare mutations of SMO, CTNNB1, PIK3CA, and SMARCB1.

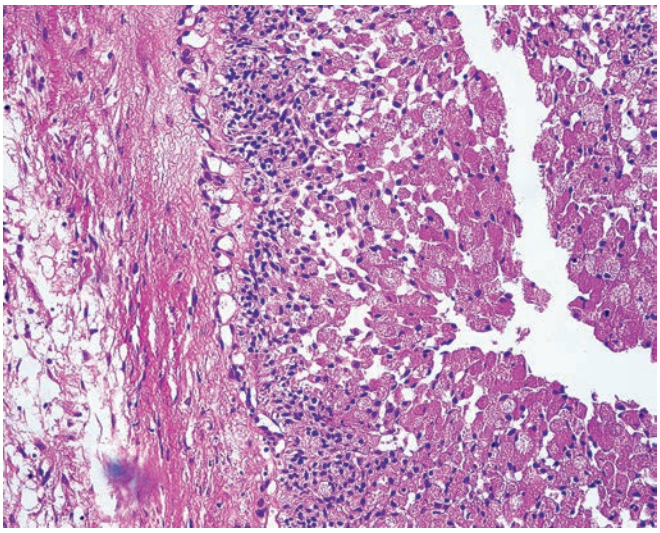

Figure 5.37 Granular cell ameloblastoma. Most of the tumor cells in the stellate reticulum area have an abundant, deeply granular cytoplasm.

Spread and Metastasis

Ameloblastoma has invasive properties and a tendency to recur. As such, they are treated by complete surgical resection with tumor-free margins.

Furthermore, distant metastases have been documented in rare instances, especially to the lungs but also to the central nervous system.[138,139] The term *malignant ameloblastoma* is accepted by the WHO for those metastasizing tumors that retain the typical morphology of ameloblastoma (as opposed to ameloblastic carcinoma, see next section). In the majority of these cases, the distant metastases have been preceded by several local recurrences.[140]

Differential Diagnosis

A particularly vexing problem in this area is the differential diagnosis between focal reactive hyperplasia in a dentigerous cyst and so-called *unicystic ameloblastoma*, the latter representing either ameloblastic transformation from a dentigerous cyst or a predominantly cystic form of ameloblastoma. In unicystic ameloblastomas that have ameloblastomatous epithelium confined to the cyst lining (so-called luminal and intraluminal types), simple enucleation is effective treatment. If ameloblastomatous epithelium extends into the underlying stroma of a unicystic ameloblastoma (so-called mural type), they should be treated like conventional solid/multicystic ameloblastomas because they have a recurrence risk.

The minimal criterion for the diagnosis of ameloblastoma under these circumstances is the finding of a palisaded basal layer with

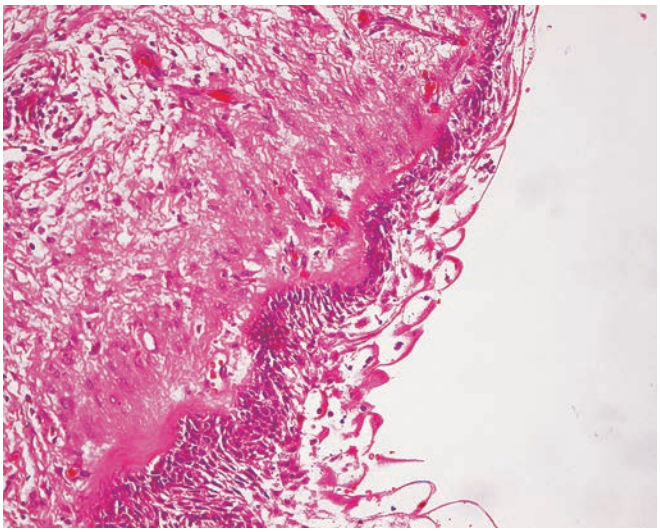

Figure 5.38 Unicystic ameloblastoma fulfilling the minimum criteria for this entity, which should be distinguished from reactive epithelial changes in a radicular cyst.

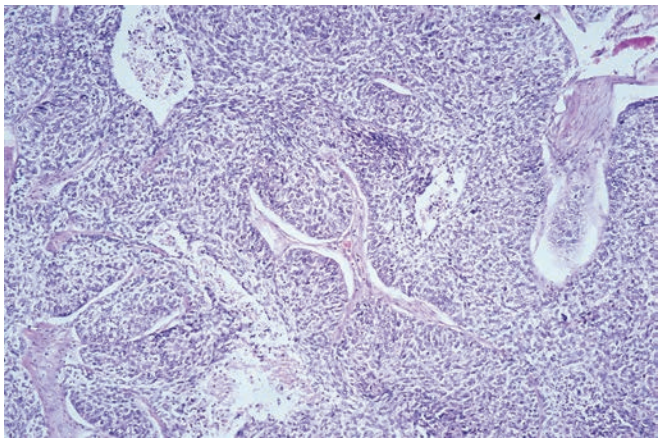

Figure 5.39 Ameloblastic carcinoma. The geographic configuration of the tumor nests and the overall basophilic staining quality give this lesion a distinctly basaloid quality. Other areas had a more typical ameloblastoma appearance.

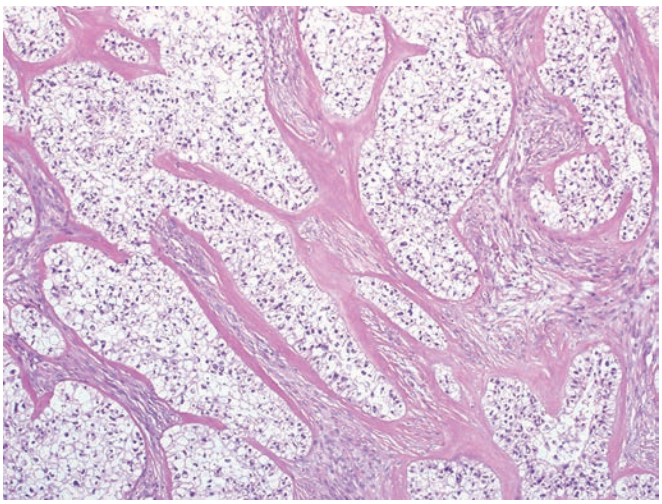

Figure 5.40 Clear cell odontogenic carcinoma. Infiltrative nests of large polygonal clear cells are set within a hyalinized to cellular spindled stroma.

stellate reticulum-like epithelium above (Fig. 5.38).[141,142] Immunoreactivity for calretinin may help to support the diagnosis.[143] Enucleation of the lesion is usually curative, but local recurrence may develop, particularly if there are ameloblastic islands embedded in the cyst wall.[144]

Malignant Odontogenic Tumors

Ameloblastic Carcinoma

Ameloblastic carcinoma is defined as a tumor having the overall microscopic architectural features of ameloblastoma but also manifesting malignant morphologic features, such as lack of differentiation, hypercellularity, marked nuclear atypia, numerous mitotic figures, vascular invasion, and neural invasion (Fig. 5.39).[145] It is possible that at least some of the reported *intraosseous squamous cell carcinomas* of the jaw represent ameloblastic carcinomas with a marked degree of squamous change[146–148]; others appear to arise in keratocysts and other types of odontogenic cyst.[149] Hypermethylation of *P16* may mediate the malignant transformation of ameloblastoma.[150] These are aggressive tumors with approximately one-third resulting in distant metastasis and death.

Odontogenic Carcinoma

Odontogenic carcinoma is a generic term used for primary intraosseous carcinomas thought to be of odontogenic origin, either de novo or through the malignant transformation of an odontogenic cyst.[151] The term is generally restricted to carcinomas other than those having an ameloblastoma-like pattern (see previous section) and is usually accompanied by a qualifier.

Clear cell odontogenic carcinoma is a rare epithelial lesion of the jaw of putative odontogenic origin that may simulate a clear cell carcinoma of salivary gland type or of metastatic origin. The clear cells are arranged in nests surrounded by a mature collagenous stroma, are devoid of mucin, and contain glycogen (Fig. 5.40).[152] These tumors are morphologically and immunophenotypically very similar to clear cell carcinoma of minor salivary gland origin. In support of their relatedness is that a majority of clear cell odontogenic carcinomas demonstrate the *EWSR1-ATF1* fusion identified in clear cell carcinoma of minor salivary gland origin.[153] Although originally regarded as benign, it is now considered malignant, with occasional examples having metastasized to regional lymph nodes.[154,155]

Sclerosing odontogenic carcinoma is characterized by the presence of small nests and thin cords of small polygonal epithelial cells, occasionally clear and relatively monomorphic, often exhibiting skeletal muscle and neural infiltration, embedded in an abundant sclerohyaline stroma.[156]

Ghost cell odontogenic carcinoma is the malignant variant of dentinogenic ghost cell tumor. These are rare tumors whose behavior is difficult to predict but, overall, are associated with a 73% 5-year survival.[157]

Ameloblastic Fibrosarcoma

Ameloblastic fibrosarcoma (odontogenic sarcoma; odontogenic fibrosarcoma) shows histopathologic features similar to those of ameloblastic fibroma but differs from it by virtue of cytologic atypia and increased cellularity of the mesenchymal component with diminution or absence of the epithelial component, and aggressive

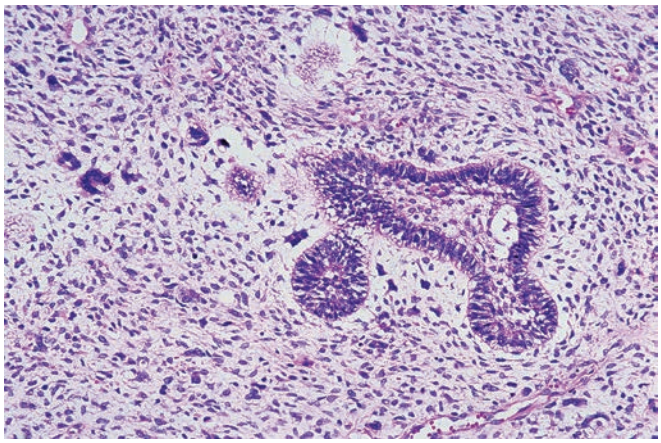

Figure 5.41 Ameloblastic fibrosarcoma. Islands of well-differentiated ameloblastic epithelium are separated by a neoplastic stroma showing marked pleomorphism and mitotic activity.

Figure 5.42 Radiograph illustrating cystlike appearance of aneurysmal bone cyst of mandible in a 19-year-old man.

clinical behavior (Fig. 5.41).[158,159] Sometimes these features appear in recurrences of tumors originally diagnosed as ameloblastic fibromas.

Pain is a common symptom, in contrast with most other odontogenic tumors. Death follows extensive local recurrence and extension. Distant metastases from this tumor are exceptionally rare.

Cases combining features of ameloblastic carcinoma and ameloblastic fibrosarcoma *(ameloblastic carcinosarcoma)* have been described, sometimes arising in ameloblastic fibroma.[160]

Other Tumors and Tumorlike Conditions

Paget disease of the mandible and maxilla can occur as a dominant clinical expression of a generalized process or as the only localization in the monostotic form of the disease. The process may be complicated by the appearance of osteosarcoma or giant cell tumor. Actually, the possibility of Paget disease should always be investigated when either of these two neoplasms is found in the jaw. As a note of caution, normal cementicles within the periodontal ligament should not be confused with Paget disease.

Langerhans cell histiocytosis (eosinophilic granuloma; histiocytosis X) of bone has a marked predilection for the jaw—more often the mandible—where it can cause a localized ragged zone of destruction (see Chapter 37).[161]

Aneurysmal bone cyst can produce massive expansion of the mandible. Radiographic studies reveal a multiloculated lytic lesion with fluid-fluid levels (Fig. 5.42). Because of its high content of giant cells, the lesion can be confused microscopically with central giant cell granuloma.[162]

Benign tumors of the jaw include, among others, hemangioma of either cavernous or Masson type,[163] benign peripheral nerve tumors,[164] nonossifying fibroma (not to be confused with the ossifying fibroma),[165] desmoplastic fibroma (which has a definite predilection for the mandible and histologically resembles desmoid fibromatosis),[166] chondromyxoid fibroma,[167] chondroblastoma,[168] the already mentioned osteoblastoma, osteochondroma (often located in the coronoid process of the mandible),[169] and osteoma. The last lesion occurs almost exclusively in the jaw and is present in more than 80% of patients with Gardner syndrome.[170]

Salivary gland tumors may present as primary intraosseous masses, usually in the mandible. Mucoepidermoid carcinoma is the most common type[171]; other types include adenoid cystic carcinoma, acinic cell carcinoma, and hyalinizing clear cell carcinoma.[172]

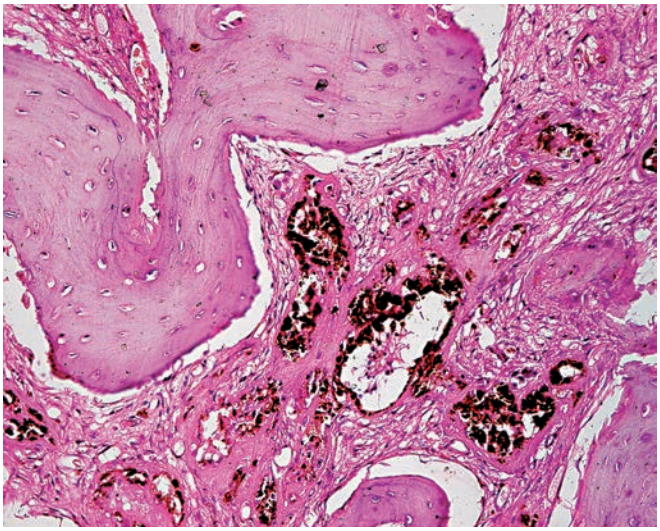

Figure 5.43 Melanotic neuroectodermal tumor of infancy. The neoplastic islands located between the bone trabeculae contain abundant melanin pigment.

Meningioma has been seen in the mandible, presumably arising from ectopic nests of arachnoidal cells or related perineurial cells.[173] Most are of the meningothelial, fibroblastic or transitional types histologically.

Melanotic neuroectodermal tumor of infancy (melanotic progonoma; retinal anlage tumor) is a rare neoplasm of neuroectodermal derivation previously thought to arise from odontogenic epithelium (Figs. 5.43 and 5.44).[174,175] The maxilla is the most common location; however, it also occurs in the mandible, skull, long bones, epididymis, mediastinum, and soft tissues of extremities. They are composed of a dual population of small round neuroblastic cells arranged in nests and surrounded by melanin-containing epithelial cells that are separated by a dense fibrous stroma. The small neuroblastic cells are positive for NSE and CD57, often with expression of synaptophysin and GFAP. The epithelial cells are positive for cytokeratin, HMB-45, and vimentin. Ultrastructural studies and the demonstration of both neuronal differentiation and

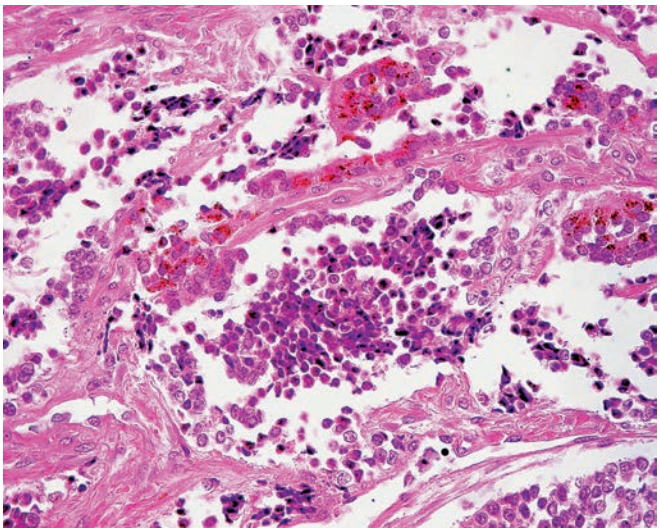

Figure 5.44 Melanotic neuroectodermal tumor of infancy. This example shows the classic pattern of neuroblast-like cells surrounded by larger melanin-containing epithelial cells.

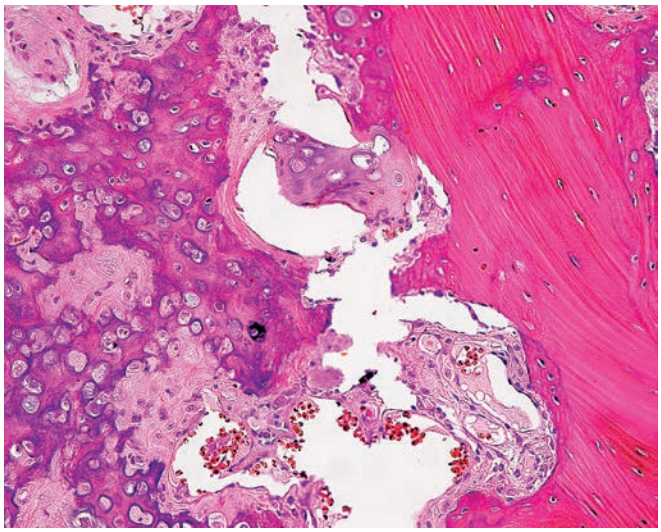

Figure 5.46 Osteosarcoma of jaw. The neoplastic bone *(left)* is clearly distinguishable from the residual normal bone *(right)*.

Figure 5.45 Gross appearance of a destructive osteosarcoma of mandible.

vanillylmandelic acid production have confirmed the neural nature of this neoplasm.[176] The behavior is generally benign, but some cases with aggressive local behavior and a few that have resulted in distant metastases have been documented.[177]

Myofibroma is another proliferative process that may involve the mandible of infants or children.[178] Morphologically they resemble those seen in soft tissue sites. They can be solitary bone tumors or can be associated with other sites of involvement in the multicentric form of myofibromatosis.

Osteosarcoma is the most common primary malignant tumor of the jaw. The mandible is affected slightly more often than the maxilla (Fig. 5.45).[179] The majority of the maxillary tumors occur in the alveolar ridge.[180] Most cases arise de novo, but others represent complications of radiation therapy, Paget disease, or fibrous dysplasia.[181] The majority are of the usual intramedullary type, but parosteal examples have been reported.[182] Microscopically, most have a conventional appearance, with many exhibiting a prominent chondroblastic component (Fig. 5.46). Others have a telangiectatic quality that may lead to confusion with aneurysmal bone cyst.[183] The prognosis for osteosarcoma of the jaw is, as a group, more favorable than for osteosarcoma of long bones. It is best for the tumors located in the mandibular symphysis and worst for those involving the maxillary antrum.[184] Multimodality therapy similar to that used for osteosarcomas of the extremities is used for them.

Chondrosarcoma of the jaw shows a marked predilection for the maxilla.[185] It can be central or peripheral, and microscopically it may exhibit conventional, mesenchymal, or dedifferentiated features.[186]

Ewing sarcoma/primitive neuroectodermal tumor (PNET) can present as a primary tumor of the jaw; most of the reported cases have been located in the maxilla.[187]

Kaposi sarcoma of the oral cavity may erode the underlying jawbone; in exceptional cases it presents as a primary intraosseous lesion.[188]

Other reported cases of sarcoma of the jaw are *leiomyosarcoma*,[189] *rhabdomyosarcoma*,[190] *myofibroblastic sarcoma* (myofibrosarcoma),[191,192] *malignant peripheral nerve sheath tumor*[193] (including its melanotic variant[194]), *angiosarcoma* (including the epithelioid variant[195]), and *pleomorphic undifferentiated sarcoma* (malignant fibrous histiocytoma).[196] The last is a very aggressive neoplasm, similar to those arising in deep soft tissues.

Malignant lymphoma that involves the jaws is nearly always of the non-Hodgkin type.[197] In adults, most cases represent diffuse large B-cell lymphoma, whereas in children there is a predominance of Burkitt lymphoma.[198] The high frequency of jaw involvement in the latter is well known.[198]

Hodgkin lymphoma with primary presentation in the jaw is a curiosity; less than a handful of cases have been reported.[199]

Acute leukemia may involve the jaw and oral cavity in children, sometimes as the initial sign of the disease.[200]

Plasma cell neoplasms can present in the jaw, either as part of a generalized process (multiple myeloma) or as the only manifestation of the disease (plasmacytoma).[201]

Direct invasion of the mandible by squamous cell carcinoma of the oral cavity is not uncommon. Extension along the mandibular canal, which contains the inferior alveolar nerve, artery, and vein, can be seen at a great distance from the primary tumor.[202]

Metastatic tumors to the jaw in adults most often originate from breast, lung, large bowel, prostate, kidney, thyroid, or testis.[203,204] In children, metastases to the jaw originate most frequently from adrenal neuroblastoma, embryonal rhabdomyosarcoma, and Wilms tumor.[205,206]

The tooth-bearing area of the body and molar regions of the mandible are the most frequent sites for these metastases, possibly because of greater blood supply in these regions. In approximately half of the cases, oral metastasis is the first sign of systemic disease. Swelling, pain, and anesthesia are the most common symptoms.[205,207,208]

Diseases of the Temporomandibular Joint

Hypoplasia of the mandibular condyle may be unilateral or bilateral. It is characterized by facial asymmetry and abnormality of function. It often represents diminished or retarded development and may be associated with anomalies of the ear or temporal bone and with macrostomia. It may also be the result of acquired conditions, especially mandibular fracture or other traumas during the growth period.

Hyperplasia of the mandibular condyle usually manifests as an isolated finding in the form of unilateral facial enlargement in adults, but it may be also seen in association with hemihypertrophy. Grossly, the condyle appears larger than normal. Microscopic examination reveals a thick and irregular layer of hyaline or fibrohyaline cartilage covering the articular surface of the condyle. This disease is probably related to, if not identical with, *synovial chondromatosis* or *osteochondromatosis*.[209,210] When the cellularity of the cartilaginous nodules is marked, the possibility of overdiagnosing the case as chondrosarcoma exists.

Tophaceous pseudogout (tumoral calcium pyrophosphate dihydrate crystal deposition disease [CPDCDD]) results from the deposition of calcium pyrophosphate dihydrate crystals.[211] Microscopically, the presence of chondromyxoid tissue with atypical chondrocytes can result in a mistaken diagnosis of chondrosarcoma. The identification by polarized light of birefringent crystals associated with a granulomatous reaction is the clue to the diagnosis (Fig. 5.47).[212] The chemical nature of the crystals can be confirmed by crystallography, but this is not typically necessary from a diagnostic standpoint.[213]

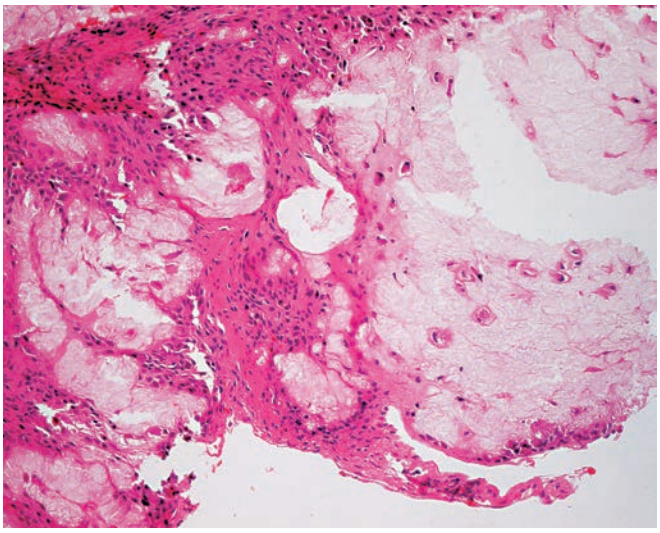

Figure 5.47 Tophaceous pseudogout. The lobules of deposited soft tissue uric acid have the appearance of slightly atypical cartilage and are surrounded by foreign body giant cells.

Traumatic, inflammatory, and degenerative conditions may all result in the so-called *temporomandibular joint pain–dysfunction syndrome*. The features of this syndrome include limitation of jaw movement with discomfort or pain, tenderness of masticatory muscles, and, sometimes, clicking of the joint during mastication. The gross and microscopic anatomy of joint components (capsule, articulating portions of the mandibular condyle, and the meniscus) display markedly altered relationships in such instances. Less altered, individual components of the temporomandibular joint, such as a meniscus or condylar head, may be surgically removed and submitted for pathologic examination. Although it is sometimes possible to demonstrate specific inflammatory or degenerative conditions of this joint, such as rheumatoid arthritis, osteoarthritis (osteoarthrosis), or osteochondromatosis, in most cases the pathologic features are nonspecific.[214]

Tenosynovial giant cell tumor (pigmented villonodular synovitis) can occur in the region of the temporomandibular joint. Lack of familiarity with this fact, coupled with the high cellularity of the lesion, may result in overinterpretation as a malignant process.[215]

Other conditions that have been reported in the temporomandibular joint include osteoma and osteoblastoma, ganglion and synovial cyst, aneurysmal bone cyst, epidermal inclusion cyst, hemangioma, nonossifying fibroma, Langerhans cell histiocytosis, and plasma cell myeloma.[215]

Normal Anatomy

The major salivary glands are the paired parotid, submandibular (submaxillary), and sublingual glands. The parotid gland weighs 14–28 g, the submandibular gland weighs 7–8 g, and the sublingual gland weighs 3 g. The main duct of the parotid gland (Stensen duct) empties into the oral cavity opposite the crown of the second maxillary molar. The main ducts of both the submandibular glands (Wharton duct) and sublingual glands (Bartholin duct) open in the floor of the mouth, on each side of the frenulum of the tongue. Several minor sublingual gland ducts (Rivinus ducts) drain into the main duct or empty into the oral cavity along the plica sub lingualis on either side of the frenulum.

The parotid gland is composed of a broad superficial lobe and a smaller deep lobe, with the facial nerve running between, and artificially separating, the two lobes. Variations of this anatomy and the distribution of the facial nerve occur.[1]

Minor salivary gland tissue is present in many other locations in the head and neck region, where it may give rise to inflammatory conditions, benign tumors, and malignant tumors. They are found in the lips (more in the upper than the lower lip), gingiva, floor of mouth, cheek, hard and soft palates, tongue, tonsillar areas, oropharynx, and upper respiratory tract.

Microscopically, salivary glands are compound exocrine glands composed of a ductal and an acinar portion, the latter of either serous or mucinous type.[2] The parotid gland is exclusively serous, the submandibular gland is mixed with serous predominance, and the sublingual gland is mixed with mucinous predominance. Minor salivary glands can be pure mucinous (anterior tongue, palate), pure serous (posterior tongue), or mixed (lip, buccal, sinonasal tract, nasopharynx). The intercalated ducts and acini represent the terminal portion of the system (ductoacinar unit). Under normal conditions, rare sebaceous glands are annexed to the duct system in the parotid and, less commonly, the submandibular glands. The reserve cells of the intercalated ducts are the source of regeneration of the acinar tissue and the terminal duct system and are thought to be the progenitors (together with the closely apposed myoepithelial cells) of most salivary gland tumors.[3] However, it has been pointed out that basal

Abstract

This chapter reviews the normal anatomy and histology of the three paired major salivary glands and the minor salivary glands. Inflammatory disorders and developmental disorders of salivary glands are briefly discussed. Salivary gland tumors make up for most of the chapter content, using the general classification adopted by the WHO. However, certain neoplasms are discussed together as they relate to differential diagnosis.

Keywords

salivary gland neoplasms,
salivary gland inflammation

and luminal cells at all levels of the duct system and even acinar cells are capable of DNA synthesis and mitosis, and therefore they all have the potential to give rise to neoplasms.[4]

Immunohistochemically, the luminal cells stain for low-molecular-weight keratin (including CK7), CD117, carcinoembryonic antigen (CEA), and epithelial membrane antigen (EMA). The intercalated duct luminal cells are also positive for lysozyme but not for S-100 protein.[5] Serous acinar cells are positive for low-molecular-weight keratin and DOG-1.[6] The myoepithelial cell component can show some minor differences in its immunohistochemical profile depending on its location, but this is an inconsistent finding: in the parotid gland the myoepithelial cells express mainly calponin and h-caldesmon; in the submaxillary glands they also express smooth muscle actin; and in the minor salivary glands there is an additional expression of smooth muscle myosin heavy chain. Myoepithelial cells also stain for p63, p40, CD10, and maspin, as do the basal cells.[7]

The lymphoid tissue of the parotid region is represented by small nodes located near or within the parotid gland and by scattered lymphoid cells located in the connective tissue around the acini and ducts. The latter are part of the mucosa-associated lymphoid tissue (MALT).[8] Periparotid lymph nodes often contain benign salivary gland inclusions. No lymph nodes are present within the submandibular or sublingual glands.

Heterotopia

Heterotopia of salivary gland tissue has been divided into *intranodal* and *extranodal* types.[2] The intranodal variety is more frequent. Almost all lymph nodes located within or near the parotid gland in infants contain salivary gland tissue. The finding is not as prevalent in adults, but it is still very frequent. The salivary gland tissue is usually located in the medullary portion of the node and is predominantly composed of intercalated and intralobular ducts; it may also contain acini (mainly of serous type) and small ducts of immature type.[9]

Extranodal heterotopia has been divided into *high* and *low* forms, depending on its location in the head and neck region. Sites of high heterotopia include the mandible, ear, palatine tonsil, mylohyoid muscle, pituitary gland, and cerebellopontine angle; these are probably all the result of abnormalities in the embryonic migration of the salivary glands. Low heterotopia is related to the branchial pouches and is found in association with cysts and sinuses in the lower neck and in the thyroid gland.[10,11] The most common location is along the medial border of the right sternomastoid muscle near the sternoclavicular joint. In this location, the ectopic glands can secrete saliva onto the skin during feeding.

Heterotopic salivary tissue is subject to the same pathologic changes as its orthotopic counterpart, including cystic formation, oncocytic metaplasia, ductal hyperplasia, and neoplasms.[9] Among the latter, Warthin tumor is the most frequent, but several other benign and malignant types have been described.[12]

Sialolithiasis

Calculi may form in the major ducts of the submandibular, sublingual, and parotid glands, sometimes in a multicentric and bilateral fashion.[13] They are more common in the submandibular gland than in the parotid gland, presumably because in the former the saliva is more saturated with calcium salts and the duct is longer with a sharp upward angle prior to its termination onto the floor of the mouth (Fig. 6.1).[14] Rarely, they affect minor salivary glands.[15] Some of the stones have a foreign body or bacterial nidus. Others do not have an identifiable nidus, are laminated, and are composed of the crystalline compound carbonate apatite.[16] The formation of calculi

Figure 6.1 Sialolithiasis with secondary chronic sialadenitis. A large stone is blocking a major salivary duct.

blocks secretion and produces swelling of the distal salivary gland tissue. If ductal obstruction persists, the gland becomes inflamed and atrophic as acinar tissue is destroyed. With obstructed ducts of the submandibular and sublingual glands, marked induration can occur in the floor of the mouth that may be mistaken for neoplasm by palpation. The duct orifices become erythematous and swollen. Radiographic examination may demonstrate a radiopaque mass, and sialography will show partial or total blockage of the duct. The stones can also be demonstrated by ultrasound.[17] Microscopic examination of glands that have been affected by stones shows dilation of ducts with intraluminal neutrophils, at times squamous metaplasia of the epithelium, moderate to prominent chronic inflammation, and a variable destruction of acinar tissue (Fig. 6.2). Degenerative changes in the secretory and myoepithelial cells are also apparent at the immunohistochemical and ultrastructural levels.[18]

The treatment of symptomatic sialolithiasis consists of surgical removal or disintegration of the calculus. The latter is achieved with techniques such as intracorporeal or extracorporeal shock-wave lithotripsy.[19] In most cases the gland can be preserved, but surgical resection is occasionally necessary.[20]

Sialadenitis

Acute sialadenitis can be localized to one salivary gland (usually parotid or submandibular) or be the expression of a systemic infection. *Viral* sialadenitis (rarely seen as a surgical specimen or biopsy) can be caused by paramyxovirus (mumps), cytomegalovirus, Epstein–Barr virus (EBV), coxsackievirus, and influenza A and parainfluenza viruses.[21] *Acute suppurative sialadenitis* is generally caused by *Staphylococcus aureus*, *Streptococcus* species, and gram-negative bacteria. Dehydration, malnutrition, immunosuppression, and sialolithiasis are

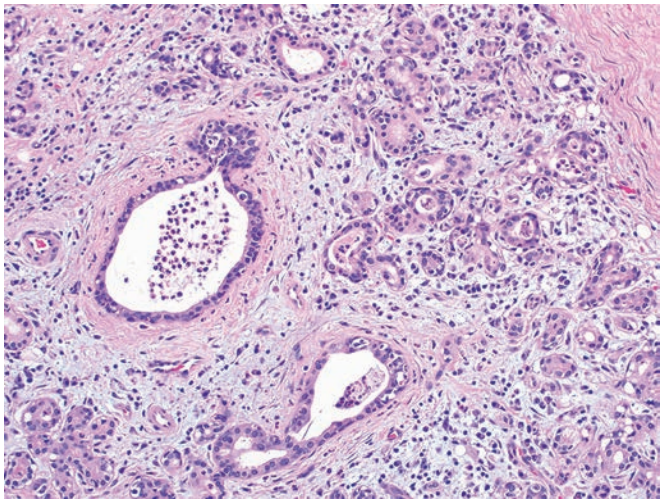

Figure 6.2 Obstructive sialadenitis associated with submandibular gland sialolithiasis. The parenchyma is atrophic with mixed acute and chronic inflammation including intraluminal neutrophils.

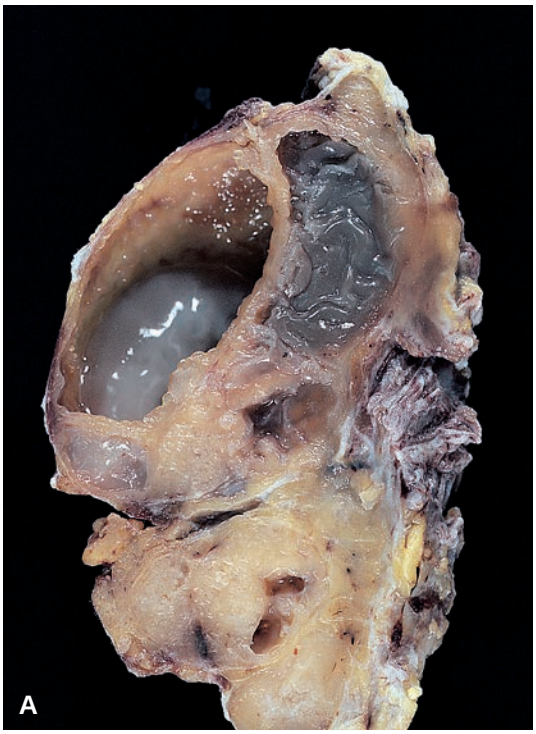
predisposing factors. Once an abscess has formed, surgical drainage may be necessary (Fig. 6.3).[21]

Chronic sialadenitis in the form of mild lymphocytic infiltration of the major salivary gland unaccompanied by clinical symptoms is relatively common. Some cases are of focal obstructive nature and are accompanied by various degrees of parenchymal atrophy, fibrosis, and microliths[22]; others, more common in females, are age related, have a high statistical association with rheumatoid arthritis and Sjögren syndrome, and are probably immune mediated.[23,24] In clinically apparent cases, sialolithiasis is the most common cause.

Kuttner tumor is a chronic sclerosing sialadenitis of the submandibular gland.[25,26] This disorder, which is usually unilateral, is characterized by a plasmacytic and lymphocytic periductal infiltrate eventually leading to encasement of ducts in thick fibrous tissue. The lobular architecture is preserved and obliterative phlebitis is frequently seen. The lymphocytes that infiltrate the epithelial component are mainly B cells. The plasma cells contain abundant immunoglobulin G4 (IgG4), suggesting that Kuttner tumor is part of the widening spectrum of IgG4-associated diseases.[27,28] Cases in which the lymphoid infiltrate is very florid can simulate marginal zone B-cell lymphoma.[29] Surgical excision may be necessary in some cases.[30]

Sclerosing polycystic adenosis is characterized by the presence of a discrete mass (usually in the parotid gland) formed by fibrohyaline stroma enclosing dilated and hyperplastic ductal and acinar structures (Fig. 6.4). Apocrine-like metaplasia and transluminal bridges with a cribriform pattern of growth are present.[31,32] The appearance resembles that of sclerosing adenosis and fibrocystic disease of the breast. Some of the epithelial cells contain large, brightly eosinophilic cytoplasmic granules. The behavior is characteristically indolent.[33] Although initially reported as a reactive inflammatory process, most authors now believe this is a low-grade neoplasm,[34] and a study with the HUMARA technique has shown that the disease is of clonal nature.[35]



Granulomatous sialadenitis is uncommon and can result from tuberculosis, fungal infection, sarcoidosis, or duct obstruction from calculi or malignant tumors. In the latter instance, the granulomas result from rupture of ducts and may contain small pools of mucin.[36] A *xanthogranulomatous* variant of sialadenitis has also been described.[37]

Kimura disease can involve the salivary glands (especially the parotid) by spread from adjacent lymph nodes.[38]

Benign Lymphoepithelial Cysts and HIV-Related Lesions

Benign lymphoepithelial cysts are lesions of the parotid or upper cervical lymph nodes characterized by unilocular or multilocular cystic formations lined by glandular or squamous epithelium surrounded by a florid lymphoid hyperplasia with prominent germinal centers.[39] The amount of the lymphoid component is variable,[40] and the cyst lining is often infiltrated by lymphocytes.[41] This is likely an acquired process resulting from the proliferation of branchial pouch-derived or analogous epithelium (e.g. intranodal salivary gland inclusions) induced by the lymphoid hyperplasia, probably through a specific interaction between the epithelial cells and a subset of lymphocytes.[42] Other examples of this phenomenon in the head and neck area are branchial cleft cyst, the branchial cleft cyst-like formations sometimes seen in Hashimoto thyroiditis, and multilocular thymic cyst.

Another salivary gland lesion that merits mention in this context is **human immunodeficiency virus (HIV)-associated lymphoepithelial cyst** (Fig. 6.5).[43,44] The morphologic changes in

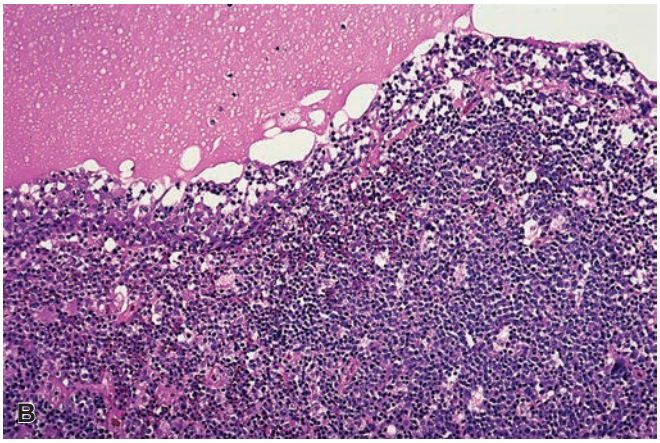


Figure 6.5 **A,** Lymphoepithelial cysts in parotid gland removed from an HIV-infected patient. The solid tan areas correspond to infiltration by lymphoid tissue. **B,** Lymphoepithelial cyst of parotid gland in an HIV-infected patient. Note the lymphocytic infiltration of the epithelium.

this condition include multiloculated lymphoepithelial cysts similar to those previously described, solid lymphoepithelial lesions (so-called epimyoepithelial islands) similar to those seen in Mikulicz disease (see next section), and a combination of both.[44,45] These lesions can be unilateral but are often bilateral. The more prominent the combination of these changes, the more likely that HIV infection is the causative factor. Three-dimensional reconstructions have shown that the cysts arise from the intralobular duct system rather than from intraparotid lymph nodes.[46]

The lymphoid follicles of HIV-induced salivary gland disease show a prominent network of follicular dendritic cells and numerous intrafollicular CD8+ lymphocytes. The follicular dendritic cells show a strong expression of HIV-1 major core protein and HIV-1 RNA, indicating that there is active replication of the virus within them.[47]

There are two other polycystic diseases of the salivary glands that need to be mentioned here for differential diagnosis purposes. The first is *polycystic (dysgenetic) disease*, a developmental disorder so far reported only in females and characterized by bilateral parotid gland enlargement.[48,49] The lesion is characterized by small epithelial cysts replacing most of the parotid gland parenchyma with small foci of residual acini interspersed throughout. The other is the already mentioned *sclerosing polycystic adenosis*. One should also keep in mind that some neoplasms of salivary gland may undergo prominent cystic changes. This is particularly true of mucoepidermoid carcinoma, acinic cell carcinoma, basal cell adenoma, sebaceous lymphadenoma, and, occasionally, benign mixed tumor.

Lymphoepithelial Sialadenitis (Mikulicz Disease) and Sjögren Syndrome

Lymphoepithelial sialadenitis (Mikulicz disease, benign lymphoepithelial lesion) most often presents as a slowly increasing and eventually striking enlargement of the salivary and/or lacrimal glands. This enlargement is usually bilateral and symmetric, but it can also be unilateral and localized, at least at the clinical level. If an infection develops, the process may subside only to recur when the infection is gone.

Grossly, the gland is enlarged and whitish, sometimes admixed with occasional cysts (Fig. 6.6A). Microscopically, the two cardinal changes are marked lymphoid infiltration and so-called epimyoepithelial islands.[50] This combination of findings has been used to create a synonym for the disease associated with a catchy acronym, that is, *myoepithelial sialadenitis* (*MESA*), recently modified to *lymphoepithelial sialadenitis (LESA)*.[51] The lymphoid tissue contains numerous well-formed germinal centers and is composed of a mixed population of B and T lymphocytes, accompanied by scattered histiocytes and dendritic cells. The so-called epimyoepithelial islands appear as solid epithelial nests surrounded and infiltrated by lymphoid cells, which are mainly of monocytoid B type (see Fig. 6.6B). A hyaline substance is deposited between the cells, which is shown ultrastructurally to represent basement membrane material, including type IV collagen.[52] The nature of the cells within the islands, that is, whether ductal, basal or myoepithelial, remains a controversial subject.[53,54] Current evidence suggests a lack of myoepithelial cell participation, which—if true—would make the term "epimyoepithelial islands" inaccurate and the alternative "lymphoepithelial lesions" more appropriate.[55]

LESA can remain localized to the salivary gland but more often is a manifestation of a generalized symptom complex known as **Sjögren syndrome**, the other components of which are keratoconjunctivitis, xerostomia, rheumatoid arthritis, and hypergammaglobulinemia.[56] In this condition, lymphoid infiltrates similar to those present in the major salivary glands are also seen in the lacrimal glands and minor salivary glands of the oral cavity. This fact is of diagnostic utility, in the sense that biopsy of the labial glands is often used to document the diagnosis of this condition.[57] It should be noted, however, that so-called epimyoepithelial islands are usually scanty or absent at these sites. Occasionally, the lymphoid infiltrates extend to other organ systems, such as lymph nodes, lung, kidney, bone marrow, skeletal muscle, skin, or liver.[58]

The etiology of LESA, with or without Sjögren syndrome, remains enigmatic. The incidence of the disease is markedly increased in HIV-infected patients. As a matter of fact, there is a marked morphologic similarity (and probably a close pathogenetic relationship) between Sjögren syndrome as seen in this population and the HIV-related changes described in the previous section. Interestingly, a chronic lymphocytic sialadenitis morphologically very similar to Mikulicz disease occurs in hepatitis C virus (HCV)-related chronic liver disease.[59]

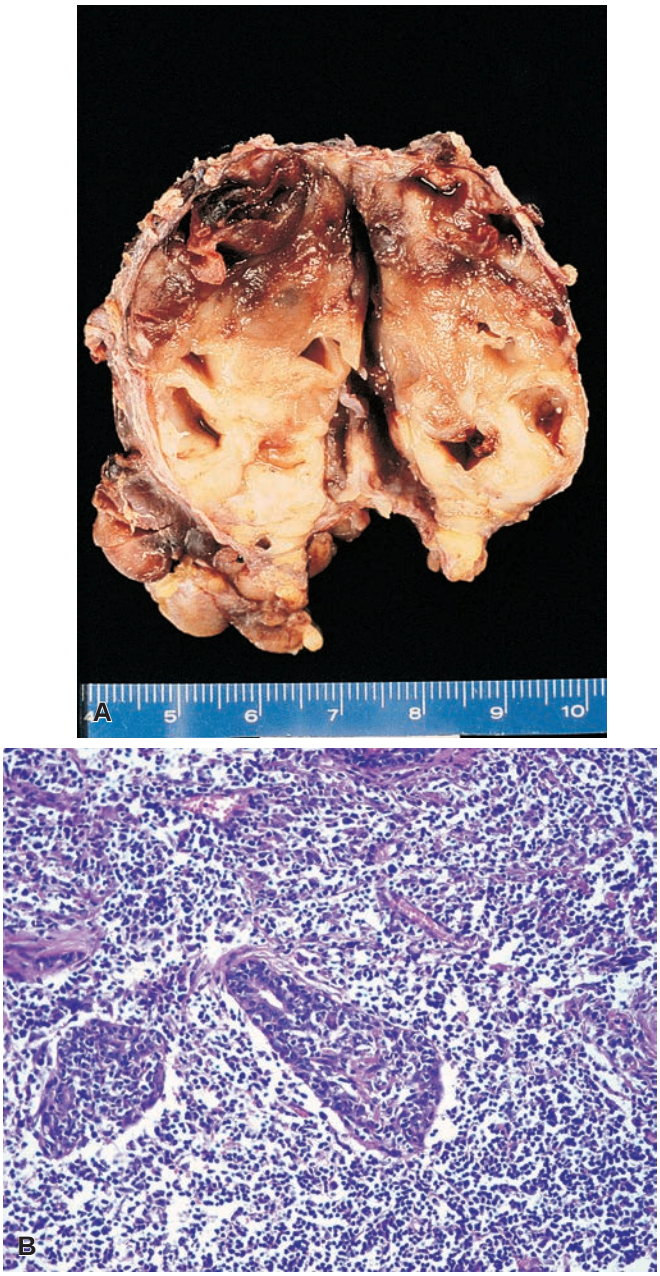

Figure 6.6 **A,** Gross appearance of lymphoepithelial sialadenitis (LESA) of parotid gland. There is a combination of solid areas resulting from infiltration by lymphocytes and small cystic formations representing dilated ductal lumina. **B,** Prominent proliferation of duct epithelium in a patient with LESA disease.

The prevalent view is that LESA is a systemic autoimmune process. In the typical case the lymphocyte population is polytypic, in keeping with a reactive process. However, this population may undergo small clonal expansions, detectable on Southern blots.[56,60–62] In some cases, these evolve into full-blown lymphomas, whether in the salivary gland or in extraglandular locations.[62,63] Some of these are large B-cell lymphomas (often with an immunoblastic appearance), whereas others are small lymphocytic lymphomas with or without plasmacytoid features (see later), and exceptional cases of Hodgkin lymphoma and peripheral T-cell lymphoma have been reported.[64–66] When one of these lymphoma types develops, there is usually not much difficulty in identifying it. The vexing problem is how to interpret the usual case of LESA that is composed of a morphologic mature ("benign-looking") lymphocytic population, especially if a monotypic component has been detected with molecular techniques. Is it a reactive, possibly autoimmune process with a tendency to evolve into a recognizable malignant lymphoma, or is it a malignant lymphoma already?[67–69] Some authors have taken the latter view and have placed LESA in the ever-expanding MALT lymphoma category, mainly on the basis of the molecular findings. It seems to us that to label a process as malignant at a stage at which it shows neither clinical nor morphologic signs of malignancy is neither conceptually nor medically sound.[51] At the present state of knowledge, it is probably wiser to restrict the diagnosis of lymphoma to those cases showing some *morphologic* evidence of such. The most important feature in this regard is the number and distribution of the monocytoid B cells. The presence of these cells outside of the lymphoepithelial lesions, and especially as broad anastomosing strands, is in favor of lymphoma; the same is true for sheets of plasma cells, with or without Dutcher bodies.[70,71] In fact, probably the earliest morphologic feature of MALT lymphoma arising in LESA is the presence of a "halo" of pale-staining sheets of monocytoid B cells surrounding the "epimyoepithelial" islands.

Irradiation Effect

The submandibular glands, which are often included in the field of irradiation for tumors of the oral cavity, swell and become firm as a result of the therapy. These changes may be mistaken clinically for metastatic carcinoma in submandibular lymph nodes and sometimes have led to unnecessary radical surgery. Not surprisingly, these changes are frequently seen in cervical lymph node dissection specimens in patients previously treated with radiation therapy. Microscopic examination shows atrophy of acinar elements with associated fibrosis and chronic inflammatory cells in the stroma. The lining of the duct epithelium may show prominent squamous metaplasia and degenerative-type atypia.

Other Non-Neoplastic Lesions

Lymphoid disorders of reactive nature can involve the intraparotid lymph nodes and be confused clinically with a primary salivary gland tumor. These include nonspecific follicular hyperplasia, healed abscesses, and granulomatous inflammations, such as those produced by cat-scratch disease.

Amyloidosis may involve the salivary gland as part of a generalized process or as a localized pseudotumoral mass ("amyloid tumor"), and it may result in the sicca syndrome.[72]

Nodular fasciitis can present as a primary intraparotid or periparotid lesion; its microscopic appearance is identical to that of its more common soft tissue counterpart.[73]

Inflammatory pseudotumor is composed of a predominant population of myofibroblast-like cells in an edematous and inflammatory background.[74] As in other sites where this entity occurs, there is a question as to whether it may represent a neoplastic condition, hence the alternative designation of *inflammatory myofibroblastic tumor*.

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) can involve the major salivary glands, with or without accompanying lymph node enlargement.[75]

Intercalated duct hyperplasia of major salivary glands may coexist with salivary gland tumors of various types (especially epithelial–myoepithelial carcinomas) and with chronic parotitis.[5] It is composed of intercalated duct epithelium and therefore different from the adenomatoid acinar hyperplasia found predominantly in intraoral salivary glands.[76] It has been suggested that intercalated duct

hyperplasia may be a precursor lesion of some salivary gland neoplasms (see next section).

Epithelial Tumors

Classification

The classification of salivary gland tumors has proved a most difficult and frustrating exercise. If anything, it is even more complex than that of the somewhat related breast and sweat gland tumors. One of the major stumbling blocks is that most of the salivary gland tumors arise from—or differentiate toward—the same cell lines: epithelial (ductal and/or acinar) and abluminal (myoepithelial and/or basal cell). This results in a considerable overlap at all levels, compounded by the fact that each of these cells can undergo a variety of metaplastic changes (e.g. oncocytic, clear cell, sebaceous, squamous, chondroid). In addition, with some exceptions, these lesions are uncommon. The World Health Organization (WHO) classification stresses the distinction between benign and malignant tumors (i.e. adenomas and carcinomas).[77–79] In this chapter, a somewhat different approach has been used. The tumors have been grouped, whenever possible, according to their predominant line of differentiation; this has been followed by a discussion of the benign and malignant members within each group.

Tumors With Stromal Metaplasia

Pleomorphic Adenoma (Benign Mixed Tumor)

Pleomorphic adenoma is the most common neoplasm of the salivary glands. It is most frequent in women in the fourth decade of life, but it can be seen in children and in elderly persons of either gender.[80] It is approximately 10 times more common in the parotid than in the submandibular gland and is very rare in the sublingual gland. In the parotid gland, most tumors arise within the superficial lobe, from either the tail (50%) or the anterior portion (25%). The remaining 25% arise from the deep lobe and often present as a parapharyngeal mass.[81] They are also seen in various minor salivary gland sites (e.g. palate).

Grossly, the tumor forms a rubbery, tan-white, firm mass with a bosselated surface and may grow to a large size but are usually between 2 and 5 cm (Fig. 6.7). The consistency depends on the relative amount of epithelial cells and stroma and the type of the latter. Although the tumor tends to be well circumscribed, small extensions (so-called pseudopodia) can often be seen protruding into the adjacent normal tissue. Islands of cartilage can be recognized by their glistening, translucent appearance. In rare cases, foci of mature bone are identified.

The typical pleomorphic adenoma has a biphasic appearance resulting from the intimate admixture of epithelium and stroma (Figs. 6.8 and 6.9). Most of the epithelial component is of a glandular nature, but foci of squamous metaplasia are common, sometimes accompanied by keratinized epithelial plugs in the lumen. The neoplastic glands have a lining composed of two cell types, the basally located cells displaying morphologic features of myoepithelial and basal cells.[82] They may be cuboidal, oncocytic, clear, spindled, or "hyaline" (see Fig. 6.8).[83] The latter cells are also referred to as plasmacytoid myoepithelial cells and are frequently seen in pleomorphic adenomas. The stroma may have a nonspecific myxoid appearance, sometimes containing abundant elastic tissue[84] or extensive adipose tissue[85]; however, areas of clear-cut cartilaginous differentiation are usually found. There is convincing morphologic, ultrastructural, immunohistochemical, and molecular evidence to suggest that these mesenchymal elements share the same origin as the epithelial cells[86–88] and that they represent modified myoepithelial cells.[89] Ultrastructurally, a continuum of cytoplasmic features from epithelial to mesenchymal cells is also present.[90–92]

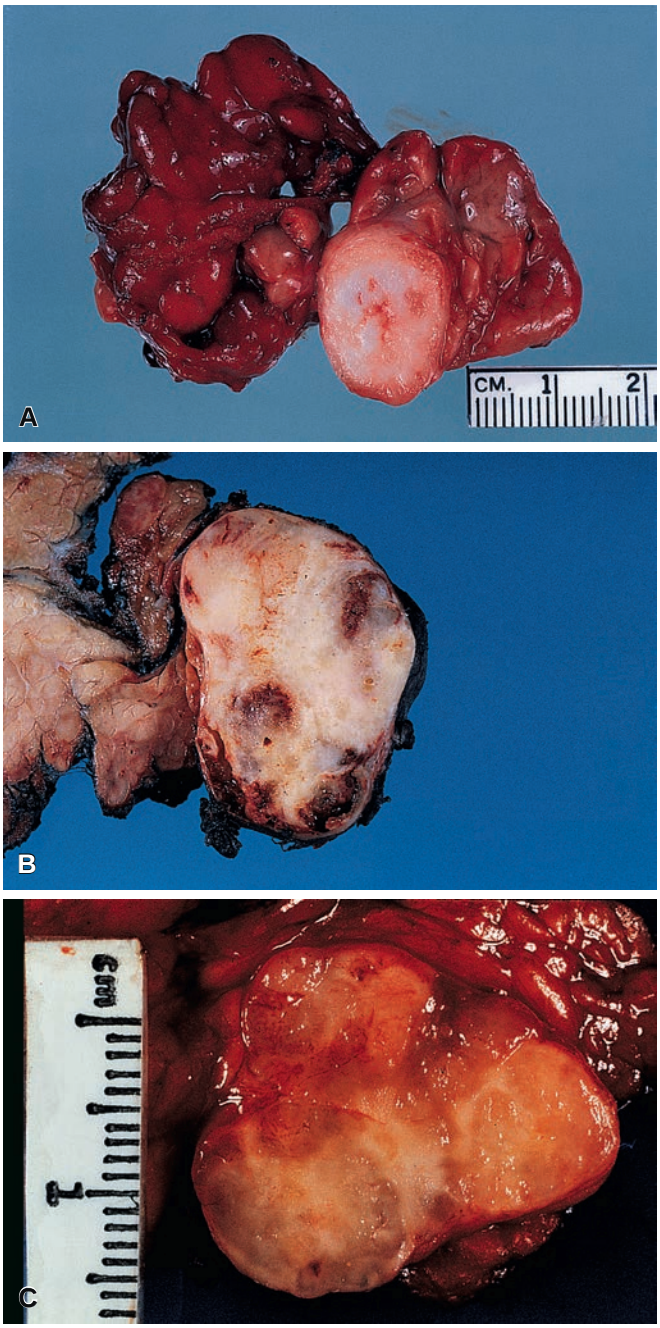

Figure 6.7 A–C, Gross appearance of three benign mixed tumors of parotid gland. Note the sharply outlined character and predominantly solid cut surface. The tumors shown in **A** and **B** have a glistening surface indicative of cartilaginous differentiation, whereas the tumor in **C** has a more myxoid or gelatinous appearance.

Additional stromal changes seen in pleomorphic adenoma include osseous metaplasia and areas of fibrosis. Cutaneous adnexal differentiation can be seen in pleomorphic adenomas, especially those arising in the palate and lip.[93] This is most commonly manifest as trichilemmal differentiation, infundibulocystic structures, and trichohyalin granules. Other substances sometimes found in pleomorphic adenomas include tyrosine-rich crystalloids in the myxoid

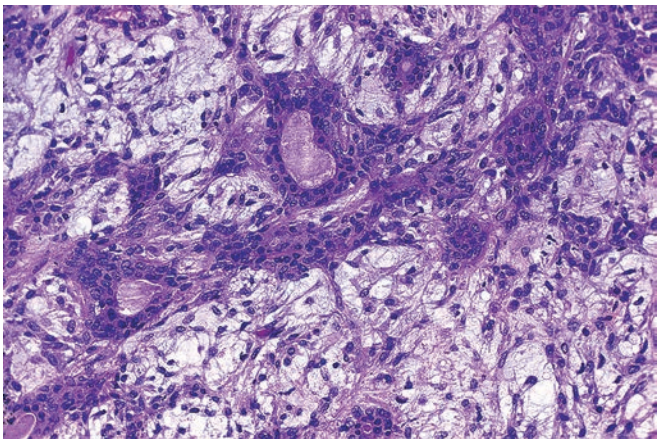

Figure 6.8 Microscopic appearance of benign mixed tumor. Epithelial and myoepithelial cells can be easily distinguished.

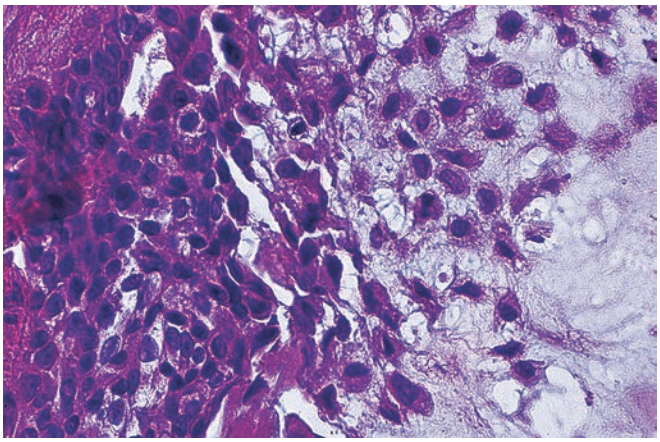

Figure 6.9 Benign mixed tumor. The myoepithelial cells are undergoing cartilaginous metaplasia and appear to "melt" into the chondromyxoid stroma they are producing.

areas,[94,95] collagenous spherules,[96] calcium oxalate crystals, intraductal birefringent crystalloids of unknown chemical composition,[97] and melanin.[98]

Some benign pleomorphic adenomas are extremely cellular, the tumor cells being either round or spindle shaped (Fig. 6.10). Others may show cytologic atypia in the form of scattered large hyperchromatic nuclei (which have been shown to be polyploid).[99] Follow-up studies have indicated that these tumors do not behave differently from the ordinary variety. The rarity of mitotic figures and absence of necrosis aid in the differential diagnosis with true malignant neoplasms. Something similar can be said of pleomorphic adenomas with foci that superficially resemble the adenoid cystic carcinoma pattern. The presence of these foci does not influence the prognosis and therefore should be disregarded.

Immunohistochemically, the ductal epithelial component is positive for keratin, EMA, and CEA. The keratins most frequently expressed are CK7, CK8/18, and CK19 (with or without CK14) in the luminal cells of the tubular structures, and CK14 in the abluminal cells.[100] The myoepithelial component is immunoreactive for low-molecular-weight keratins (CK7, CK8/18, and CK14), actin, myosin, other smooth muscle-specific proteins, p63, p40, and sometimes S-100 protein.[101–106] The latter marker is also strongly expressed in the cartilaginous areas and in subpopulations of the epithelial ductal cells. The demonstration in some of the tumors of glial fibrillary

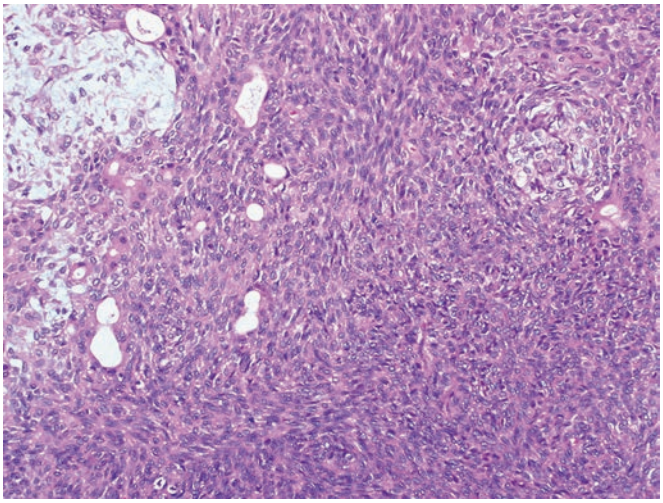

Figure 6.10 Benign mixed tumor with a markedly hypercellular appearance.

acidic protein and astroprotein, two glial markers, is more difficult to explain[107,108]; it has been suggested that it is the result of cross-reactivity with other intermediate filaments of similar structure and chemical composition.[109] Regardless of the reason for this occurrence, it seems to be related to the capacity of this tumor for cartilaginous differentiation, and it therefore may be useful in the differential diagnosis with adenoid cystic carcinoma and basal cell adenoma, in which such a differentiation does not occur.[110]

Cytogenetically, pleomorphic adenoma shows distinctive chromosomal translocations involving 8q12 or 12q13–15.[111,112] The *PLAG1* gene at 8q12 can be fused with *CTNNB1* (β-catenin), *LIFR* (leukemia inhibitory factor receptor), or *SII* (transcription elongation factor SII), or is overexpressed due to intrachromosomal 8q rearrangements.[25,113–115] The *HMGA2* gene at 12q13–15 can be fused with *FHIT* (fragile histidine triad) or *NFIB* (nuclear protein involved in transcriptional regulation).[116,117] Overexpression of p53 or mutation in the *TP53* gene is rare in pleomorphic adenoma, in contrast to its malignant counterpart.[118]

The *recurrence rate* of pleomorphic adenoma depends almost entirely on the adequacy of the primary excision, as several classic studies have conclusively demonstrated.[119] Recurrence is very high if the tumor is removed by a simple enucleation (Fig. 6.11). This is because small inconspicuous nodules (pseudopodia) attached by threadlike filaments of neoplastic tissue may be present surrounding the main mass.[120] They may have the shape and appearance of lymph nodes and may be mistaken for nodal metastases by both the surgeon and the pathologist. If the tumor is enucleated, these small remnants may be left behind and will provide the nidus for recurrence.[121] Most of these recurrences will appear during the first 18 months after surgery, but others supervene over an exceedingly long period (50 years or more). Because of this, long-term follow-up is essential. It has been proposed that patients with tumor spillage at operation or residual tumor left behind should have radiation therapy immediately to minimize the possibility of recurrence.[122] Usually the microscopic pattern of the recurrent tumor exactly mimics that of the original neoplasm (Fig. 6.12). Surgery for recurrent tumor often fails. In approximately one-fourth of cases, further recurrences develop, often in the form of multiple foci.[123] The proper therapy for pleomorphic adenoma is its total surgical removal, along with a margin of normal salivary tissue that surrounds it. For the tumors located in the superficial lobe of the parotid gland, which represent the majority, the standard surgery is a superficial parotidectomy with

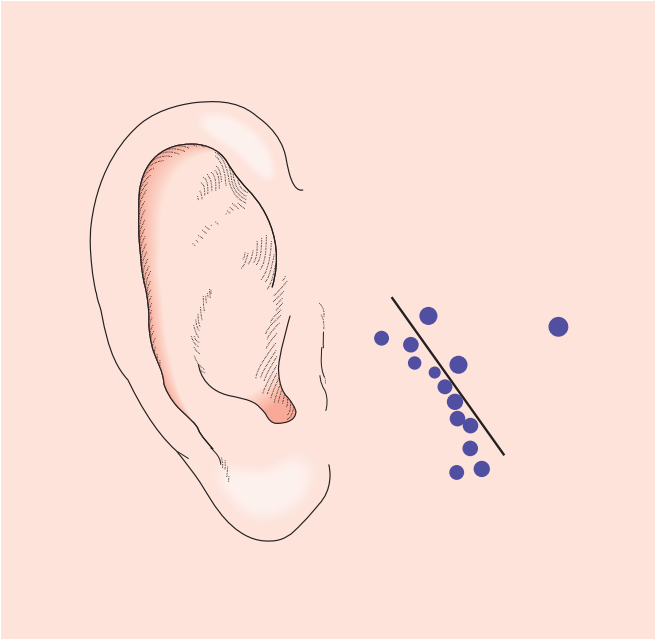

Figure 6.11 Distribution of recurrent tumor nodules (shown as *dots*) as demonstrated by careful histologic study of reexcision of benign mixed tumor of parotid gland, which at time of first operation had apparently been enucleated. Surgical scar measured 3.5 cm. (Courtesy of Dr. F. Leidler, Houston.)

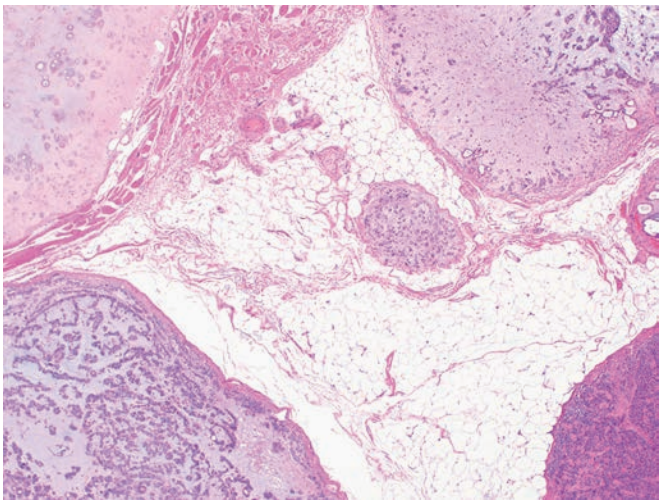

Figure 6.12 Recurrent benign mixed tumors typically appear as multiple small tumors distributed in residual gland tissue, as well as periglandular soft tissue.

preservation of the facial nerve. The incidence of recurrence after this procedure is almost zero, and the long-term prognosis for properly treated pleomorphic adenoma is excellent.

Under rare circumstances, a pleomorphic adenoma of ordinary microscopic appearance will metastasize to the lymph nodes, lungs, bone, or other organs, with the metastases appearing as benign as the original tumor ("benign" metastasizing pleomorphic adenoma).[124,125] Some of these cases have occurred in immunologically compromised patients and have followed a rapidly aggressive clinical course.[126] Usually these metastases are preceded by one or more local recurrences.[127] Curiously, a good number of these metastases have presented as isolated masses in the kidney.[128]

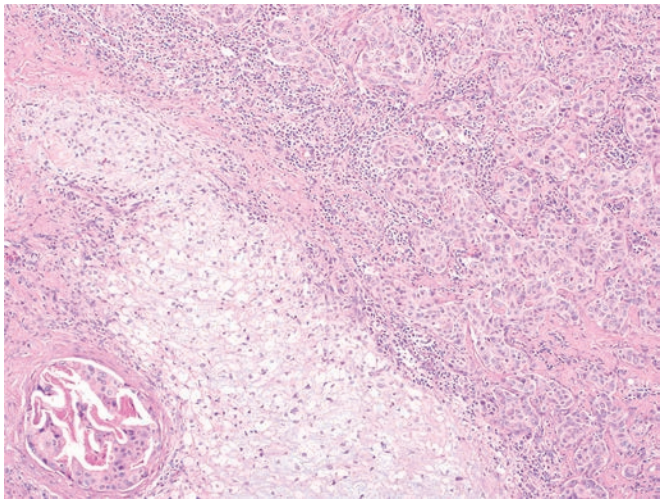

Figure 6.13 Benign mixed tumor with area of malignant transformation in the form of poorly differentiated carcinoma (*upper right* and *bottom left*). As with this tumor, the histology of the carcinoma is most often salivary duct carcinoma.

Malignant Mixed Tumor

Two major categories of malignant mixed tumor exist.[129,130] The first and more common can be viewed as a malignant transformation of a preexisting pleomorphic adenoma (carcinoma ex pleomorphic adenoma). This complication occurs in approximately 5%–10% of these neoplasms.[131] Clinical features that suggest this event in a long-standing tumor are sudden increase in growth, pain, and facial paralysis.[132,133] Documentation that a malignant salivary gland tumor arose from a preexistent pleomorphic adenoma may be difficult to obtain. The clinical history, although suggestive of the process, is not by itself diagnostic. It is necessary to have microscopic evidence of a previously existing benign tumor or to have benign and malignant tumor in the same neoplasm. This may require thorough sampling of the tumor. Sometimes the preexisting benign lesion is represented only by a totally hyalinized round nodule surrounded by carcinoma. Features said to indicate a greater likelihood of malignant transformation of a pleomorphic adenoma are submandibular (as opposed to parotid) location, long duration, older patient age, large tumor size, and—at the microscopic level—prominent zones of hyalinization and a moderate degree of mitotic activity.[134]

The malignant component of this tumor typically has an epithelial appearance usually comparable to that of the luminal cells, less commonly that of the myoepithelial cells, or both (Fig. 6.13). It has been stated that these malignant areas often assume the appearance of one of the well-recognized variants of salivary gland carcinoma (such as mucoepidermoid carcinoma or adenoid cystic carcinoma), but salivary duct carcinoma and adenocarcinoma, not otherwise specified (N.O.S.) type, appear to be the most common.[135] For example, in the series of Tortoledo et al.,[130] the malignant component was classified as salivary ductal carcinoma in 13 cases, undifferentiated carcinoma in 10, terminal duct carcinoma in 9, myoepithelial carcinoma in 3, and unclassified in 2. Most of the tumors have a poorly differentiated appearance. As a matter of fact, whenever a high-grade adenocarcinoma that is difficult to classify is found in the salivary gland, the possibility of it having arisen from a pleomorphic adenoma should be considered.[135] In a high percentage of early cases the malignant change is restricted to foci of intraductal carcinoma, with an intact layer of neoplastic myoepithelial cells on the outside.[136]

In most cases, the immunohistochemical profile of the malignant cells is comparable to that of the ductal luminal cells of the benign component.[137] In the malignant areas there is often overexpression of *TP53* (as a result of mutation) and of *HER2*.[138–140] However, this is also true in a small subset of pleomorphic adenoma lacking malignant change.[141] Genetic alterations that mediate malignant transformation may include amplification of genes at 12q13–15 (including *CDK4*, *HMGA2*, *MDM2*), *TP53* mutation, or *HER2* amplification.[142–144]

LiVolsi and Perzin[129] have pointed out that if the cytologically malignant foci are found entirely within a pleomorphic adenoma (i.e. intracapsular or in situ) they are not associated with clinical malignancy if the tumor is completely excised. Only when invasion occurs beyond the capsule of the original neoplasm will the lesion potentially behave clinically in a malignant fashion. For invasive tumors, the extent of invasion beyond the capsule is of importance: minimally invasive (≤1.5 mm from the tumor capsule) versus widely or frankly invasive (<1.5 mm), as defined by the WHO.[7] In one series, all patients whose malignant neoplasms extended for more than 8 mm beyond the capsule died of tumor.[130] Therefore, the importance of thorough sampling cannot be overemphasized. The prognosis also depends on the histologic type of carcinoma, the microscopic grade (which is related to the former), and the proliferative index.[130,145]

The most common sites of metastases are regional lymph nodes, lungs, bone (especially the vertebral column), and abdominal organs.[146]

The second type of malignant mixed tumor has a biphasic composition similar to that of pleomorphic adenoma, but both the epithelial and the mesenchyme-like elements have a malignant appearance, the former often in the form of a ductal carcinoma and the latter in the form of chondrosarcoma or undifferentiated pleomorphic sarcoma. Because no preexisting benign tumor is found, the designation of *carcinoma ex pleomorphic adenoma*, which has been suggested as an alternative term for malignant mixed tumor, is inappropriate.[133] Names such as *true malignant mixed tumor* and *carcinosarcoma* have been proposed instead.[147–149] This is an aggressive, often rapidly lethal neoplasm.

Tumors With Oncocytic (Oxyphilic) Change

Oncocytes or oxyphilic cells are large ductal epithelial cells with a granular, deeply eosinophilic cytoplasm crowded with mitochondria.[150] Their number in the normal salivary gland increases with age, and their secretory activity is minimal, suggesting that they are the expression of a degenerative change.[151] Sometimes one finds multiple parotid cysts lined by oncocytic epithelium, associated with tyrosine crystals in the lumen.[152] In other instances, oncocytes form well-defined clusters scattered throughout the gland. It is not clear whether these clusters represent an exaggeration of the age-related hyperplastic process or the emergence of a neoplasm, an uncertainty reflected by the terms that have been used to designate this process: *oncocytosis*,[153] *multinodular oncocytoma*,[154] *multinodular oncocytic hyperplasia*, and *multifocal adenomatous oncocytic hyperplasia*.[155,156]

The two major tumor types composed of oncocytes are oncocytic adenoma and Warthin tumor.[157,158] There are no transitional forms between these two tumors, suggesting that their pathogenesis is different.

Oncocytic Adenoma and Oncocytic Carcinoma

Oncocytic adenoma (oncocytoma; oxyphilic adenoma) is defined, since the classic works of Hamperl, as a benign tumor exclusively composed of oncocytic cells.[159] The majority occur in the parotid, but they are also well documented in the submandibular gland.[160] In one large series, 20% of patients had either a history of radiation therapy to the region or of long-term occupational exposure.[161] Grossly, the tumor presents as a solid, well-circumscribed mass, usually small and with a characteristic tan or brown color (Fig. 6.14). Microscopically, it is composed of large cells with small, central, round nuclei and abundant granular acidophilic cytoplasm (Fig. 6.15). Ultrastructurally, the cytoplasm is packed with mitochondria (Fig. 6.16). Mitotic figures are absent, and cellular transition from

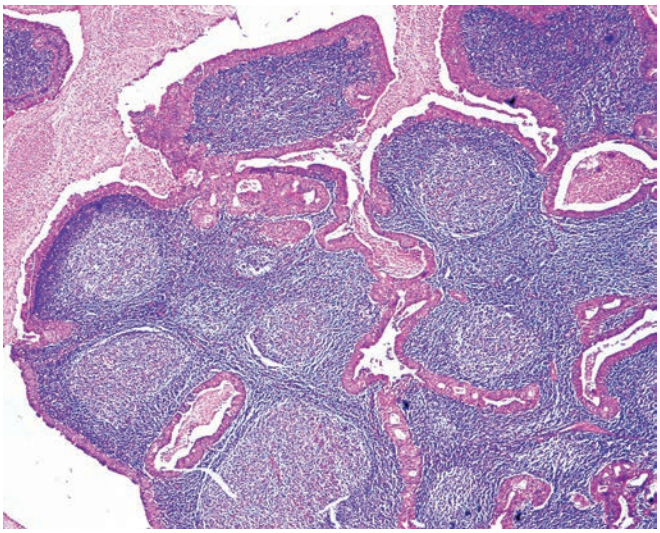

Figure 6.18 Low-power appearance of Warthin tumor. Germinal centers are very prominent.

normal lining cells of the ducts may be seen. Occasionally, the cells undergo a clear change as a result of cytoplasmic glycogenation. The lumen of the glandular spaces formed by these tumors may contain psammoma bodies[162] or tyrosine-rich crystals.[163] Focal collections of oncocytes may be present in the adjacent normal gland. Local excision is usually curative.[164] The tumor cells diffusely express keratin, and p63 highlights a subset of the cells in a distribution suggestive of basal-type cells.[165] The latter is helpful in distinguishing oncocytic adenoma from metastatic renal cell carcinoma, which are always p63 negative.

The presence of cytoplasmic mucin or of mucin-containing cystic spaces is not a typical feature of oncocytic adenoma but can be seen occasionally; such a finding should raise the suspicion that the tumor is an oncocytic variant of mucoepidermoid carcinoma (see later). Occasionally, multiple oncocytic nodules, often with clear cell change, can be appreciated. In these cases, the term *multinodular oncocytic* hyperplasia is appropriate.

Oncocytic carcinoma (malignant oncocytoma; oxyphilic carcinoma) is the malignant counterpart of oncocytic adenoma, a tumor type so rare as to represent a pathologic curiosity.[161] It is characterized by cytologic atypia, mitotic activity, and infiltrative growth. These are typically high-grade neoplasms with aggressive clinical behavior.

Warthin Tumor

Warthin tumor (cystadenoma lymphomatosum papilliferum) is found exclusively in the parotid gland and periparotid lymph nodes.[166] Warthin tumor is more common in males, and a near-universal relationship with smoking has been found.[167,168] It is often multicentric and is bilateral in 10%–15% of cases. It comprises 70% of all bilateral salivary gland neoplasms.[169] Grossly, it appears as a lobulated brown mass and has a typical multicystic appearance, with fluid-filled spaces filled with dark brown fluid (often likened to motor oil) (Fig. 6.17). Occasionally the entire tumor undergoes necrotic changes consistent with hemorrhagic infarct. These changes can occur spontaneously but are more common following fine-needle biopsy.[170]

Microscopically, lymphoid tissue is prominent, often with germinal centers; this has led to the time-honored suggestion that the lesion originates from excretory ducts located within intraparotid lymph nodes (Fig. 6.18).[171] This lymphoid stroma is predominantly composed of B lymphocytes,[172] but it also contains T lymphocytes, mast cells, and S-100 protein–positive dendritic cells.[173] Covering the surface of this lymphoid tissue are large epithelial cells with oncocytic features, similar in most respects to those seen in oncocytic adenoma (Fig. 6.19). These cells are arranged in two layers, with some morphologic and immunohistochemical differences between them.[174] The luminal cells are more columnar and the outer cells more polygonal. Both stain equally with keratin, and the outer cells are p63 positive, suggesting a basal cell phenotype. These oncocytic cells are also reactive for mitochondria-associated markers (Fig. 6.20).[175,176] The keratins

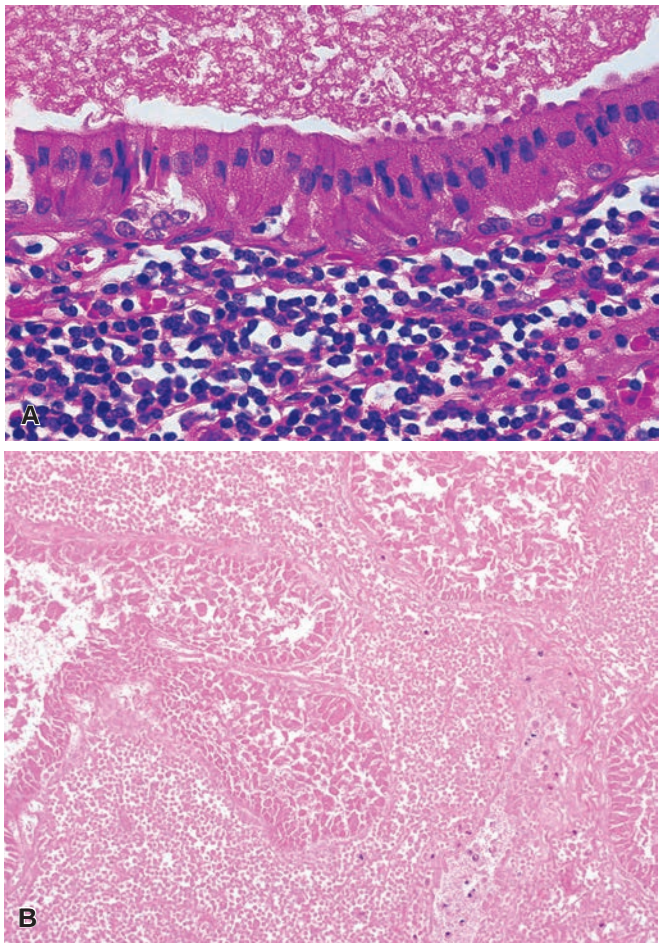

Figure 6.19 **A,** High-power view of the lining of one of the cysts of Warthin tumor. The epithelium is tall and oxyphilic, with a discontinuous layer of small cells at the base. The stroma beneath contains a monotonous lymphocytic infiltrate. **B,** Infarcted Warthin tumor following fine-needle aspiration. Ghost outlines of necrotic epithelial papillae can be seen adjacent to necrotic lymphocytic stroma.

expressed are those typical for columnar differentiation, that is, CK7, 8, 18, and 19.[177] Mucin-secreting cells and groups of sebaceous cells may also be present.[178,179] There is no evidence for a myoepithelial cell component.[180] Occasionally, the lymphoid component is scanty or absent.[166] By electron microscopy, the cytoplasm of the granular epithelial cells is packed with mitochondria.

The cases associated with infarct-like necrosis may exhibit focal squamous metaplasia (see Fig. 6.19B), sometimes with features analogous to those of necrotizing sialometaplasia in the oral cavity,[181] and are just as likely to be overinterpreted as squamous cell carcinoma.[182]

The typical treatment of Warthin tumor is surgical excision; the incidence of local recurrence is extremely low.

Malignant transformation of Warthin tumor is a rare event but has been documented both in terms of the lymphoid component evolving into malignant lymphoma[183–185] and the epithelial component evolving into adenocarcinoma, mucoepidermoid carcinoma, squamous cell carcinoma, oncocytic carcinoma, Warthin adenocarcinoma,[186] or Merkel cell carcinoma.[187–190]

Warthin tumor has been generally regarded as a true neoplasm, hence its inclusion in this section. However, some have made the suggestion that it may belong instead to the group of acquired multicystic reactive conditions of the head and neck that also includes benign lymphoepithelial cyst and other lesions of branchial pouch derivation.[42] The fact that the epithelial component of this lesion has been found to be polyclonal and that it tends to be associated with salivary ductal inclusions in parotid lymph nodes support this contention.[191,192] If this interpretation is correct, one should regard the parotid lesions having a multicystic oncocytic-lined component but lacking a lymphoid stroma *(oncocytic papillary cystadenomas)* as belonging to a different category.[166]

"Monomorphic" Adenoma

The outdated term *monomorphic adenoma* was originally proposed for any benign epithelial salivary gland tumor other than pleomorphic adenoma. It therefore included tumors as disparate as oncocytic adenoma, Warthin tumor, sebaceous lymphadenoma, canalicular adenoma, and basal cell adenoma.[193,194] The very inclusiveness of the term when so defined, and the fact that some people have used it instead as a synonym for only one member of the group (i.e. for basal cell adenoma), has resulted in confusion. Therefore it is probably advisable to regard monomorphic adenoma not as a specific pathologic diagnosis but rather as the expression of a nosologic grouping.[195] The term "monomorphic adenoma" does not appear in the new WHO classification of salivary gland tumors and should not be used as a specific pathologic diagnosis.[79]

Basal Cell Adenoma and Adenocarcinoma

Basal cell adenomas usually occur in adult patients, and there is a slight predilection for females.[196] Most cases occur in the

parotid but a few have been reported within periparotid lymph nodes, as well as in minor salivary gland sites.[197] Grossly, these tumors are encapsulated and often cystic; as a group, they tend to be smaller than pleomorphic adenomas. Microscopically, they are composed of basaloid epithelial cells, arranged in a variety of architectural patterns, and lacking in cartilage and chondromyxoid stroma. This acknowledges the fact that pleomorphic adenomas and basal cell adenomas have overlapping histology. Most basal cell adenomas have scattered ductal structures filled with eosinophilic secretions. The ducts often undergo cystic change. Surrounding the ducts are varying amounts of basaloid cells that may have a true basal cell immunophenotype, as well as true myoepithelial cells. Therefore, these tumors contain varying amounts of ductal, basal, and myoepithelial cells. An important distinguishing feature seen in most basal cell adenomas is the palisading at the periphery of the epithelial nests, also giving the tumor a "basaloid" appearance. The pattern of growth may be predominantly tubular, trabecular, cribriform, or solid.[195,198,199] In a variant of the latter designated as **membranous** or **dermal analogue tumor**, there is deposition of abundant basal lamina material around and within the epithelial nests, in a pattern nearly identical to that of the cutaneous sweat gland tumor known as eccrine dermal cylindroma (Fig. 6.21).[200,201] Actually, there have been cases of multiple dermal cylindromas coexisting with multiple parotid tumors with the same microscopic appearance.[202–204] Furthermore, the same cytogenetic abnormality in the chromosome 16q region has been found in the two tumors.[205] The mutated gene involved in this syndrome (Brooke–Spiegler syndrome) is the *CYLD* gene, which can also be mutated in sporadic basal cell adenomas.

Basal cell adenocarcinoma is the malignant counterpart of basal cell adenoma.[206–208] Like its benign counterpart, it can arise either in the major or the minor salivary glands.[209] It has a similar architecture and immunohistochemical profile,[210] but it differs by virtue of its infiltrative quality, perineurial spread, and vascular invasion, as well as a variable degree of cytologic atypia and mitotic activity. Although most basal cell adenocarcinomas are cytologically low grade, high-grade examples do occur. It also tends to express p53, BCL2, and epidermal growth factor receptor (EGFR), but this is not necessarily helpful in the diagnosis.[211] The parotid gland is the predominant site, and the peak incidence is in the sixth decade of life. Solid, membranous, trabecular, and tubular patterns of growth have been described. The aggressiveness of the tumor can be manifested by local recurrence or metastases to the lymph nodes and lung. Like its benign counterpart, it can be associated with dermal cylindromas in the Brooke–Spiegler syndrome.[206]

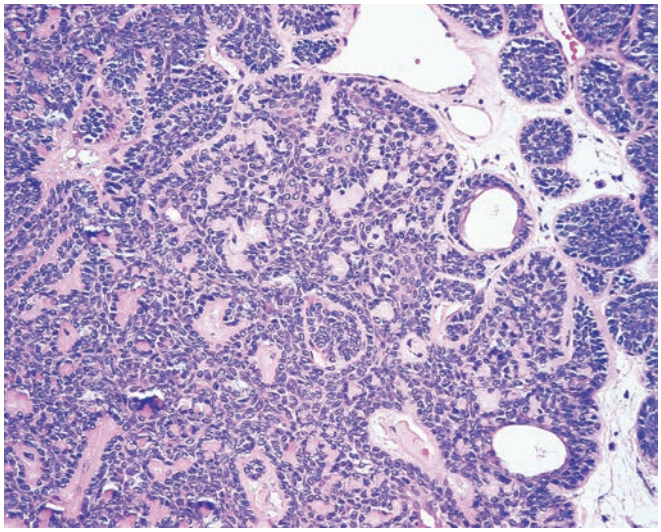

Figure 6.21 Basal cell adenoma of parotid gland. The appearance is reminiscent of that of a skin adnexal tumor (cylindroma).

Canalicular Adenoma

Another tumor formerly considered a variant of monomorphic adenoma is characterized by the presence of bilayered strands or ribbons of columnar epithelial cells separated by a loose, well-vascularized, paucicellular-myxoid stroma. This has been referred to as **canalicular adenoma** and is now regarded as an entity separate from basal cell adenoma[195,212] because of its unique morphology and immunophenotype and greater tendency to arise from intraoral minor salivary glands.[213] The "canalicular" description stems from the appearance imparted by the bilayered epithelial cells alternately opposing each other (Fig. 6.22). In some tumors, nodules of basaloid cells are present in between the columnar epithelial cells. A unique feature of canalicular adenomas is diffuse S100 reactivity. They are strongly positive for cytokeratin and have weak and focal staining

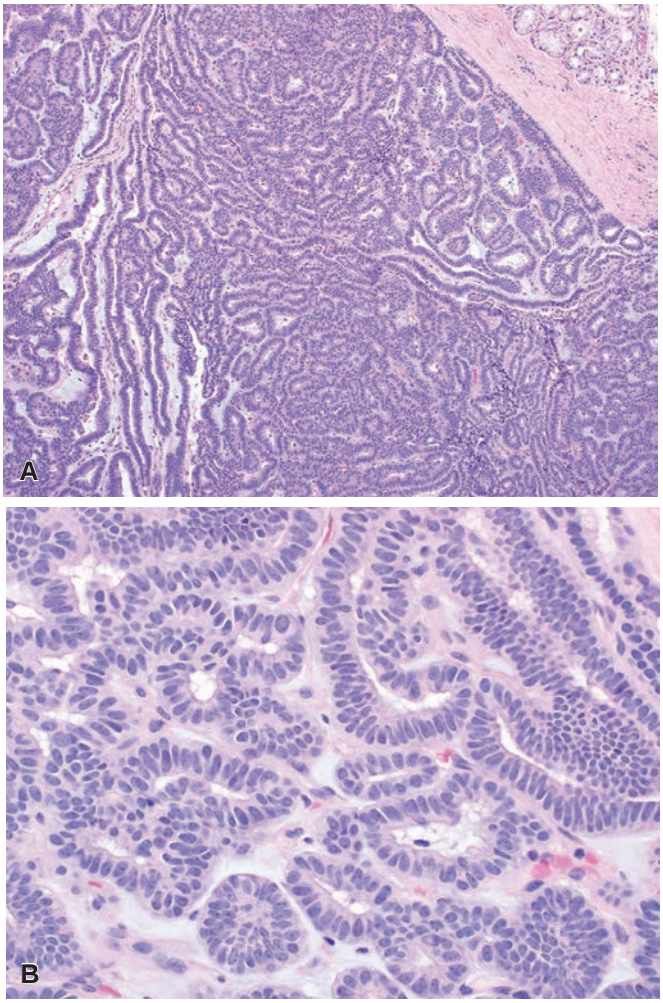

Figure 6.22 Canalicular adenoma of the buccal minor salivary glands. **A,** Parallel rows of columnar epithelial cells appose each other in areas imparting a beaded or canalicular pattern. The stroma is scant and predominantly myxoid. **B,** The columnar cells are uniform and cytologically bland.

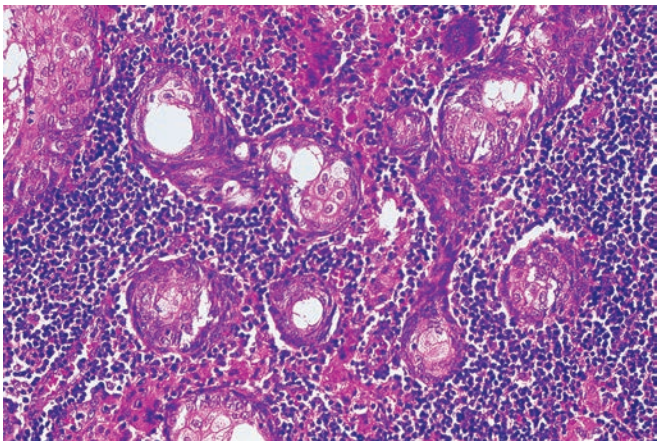

Figure 6.23 So-called sebaceous lymphadenoma. Ductal structures merge with well-differentiated sebaceous glands, which in turn are surrounded by a heavy lymphocytic infiltrate.

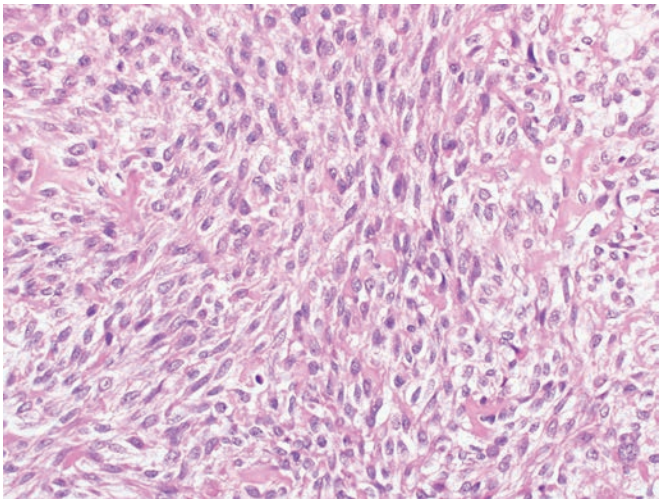

Figure 6.24 Spindle cell myoepithelioma of parotid gland. It would be very difficult to distinguish this tumor from a soft tissue neoplasm on purely morphologic grounds.

with p63 and myoepithelial markers at most. A vast majority of canalicular adenomas occur in the upper lip (80%) and buccal mucosa (10%) of adults. They are benign neoplasms that rarely recur with complete excision.

The main differential diagnosis of basal cell adenoma is with basal cell adenocarcinoma (see later discussion), pleomorphic adenoma, and adenoid cystic carcinoma.[214] Basal cell adenoma lacks the chondromyxoid mesenchyme-like component of pleomorphic adenoma. In contrast to adenoid cystic carcinoma, it is encapsulated and devoid of stromal and perineurial invasion. Immunohistochemically, the duct-lining cells express keratins and CEA with variable S-100 protein reactivity; the basaloid cells in the trabecular and solid areas express vimentin, actin, and p63, indicative of myoepithelial cell participation.[215,216] Basal cell adenoma behaves in a benign fashion, analogous to that of pleomorphic adenoma, and excision is curative. The recurrence risk is not as high as it is for pleomorphic adenomas with the exception of the membranous type in which up to 25% of tumors recur.

Malignant transformation of basal cell adenoma is a rare but well-documented event; the membranous type is said to be particularly at risk (up to 25%).[217] In six cases of this phenomenon reported by Luna et al.,[218] the malignant component was diagnosed as adenoid cystic carcinoma in three and as basal cell adenocarcinoma in the other three.

Tumors With Sebaceous Differentiation

Cells of a sebaceous type are often found within otherwise normal parotid glands. They are also found in a variety of salivary gland tumors. They are relatively common in Warthin tumor but may also appear in pleomorphic adenoma, mucoepidermoid carcinoma, adenoid cystic carcinoma, and epithelial–myoepithelial carcinoma.[219–222]

Benign tumors with a predominant sebaceous component have been designated as **sebaceous adenoma** when pure and **sebaceous lymphadenoma** when accompanied by a prominent lymphoid stroma (Fig. 6.23).[223,224] The latter tumor may present as a unilocular cystic mass on gross inspection.[225] When the tumor contains the same admixture of epithelial glandular cells and lymphocytes but lacks sebaceous differentiation, it is simply designated as *lymphadenoma*.[226,227] Rare malignant counterparts of these tumors exist; these have been called **sebaceous carcinoma** and **sebaceous lymphadenocarcinoma**, respectively.[223]

Tumors With Myoepithelial Differentiation

Myoepithelial cells are a component of many types of benign and malignant salivary gland tumors, particularly pleomorphic adenoma, epithelial–myoepithelial carcinoma, adenoid cystic carcinoma, and basal cell neoplasms.[228–231] Benign neoplasms composed exclusively of myoepithelial cells are referred to as **myoepitheliomas**.[232] Grossly, they are well circumscribed and typically encapsulated. A variety of morphologic types have been described: spindle cell, hyaline (plasmacytoid), epithelioid, and clear cell. However, it should be noted that combined and intermediate forms exist, and that the myoepithelial nature of the hyaline cell type has been questioned by some.[233]

The *spindle cell type* tumors have a stromalike appearance and can be confused with lesions of fibroblasts, Schwann cells, or smooth muscle cells (Fig. 6.24).[234] The *epithelioid type* is composed of uniform round cells with moderate amounts of cytoplasm. As with other myoepitheliomas, immunohistochemical demonstration of myoepithelial differentiation is required to confirm the diagnosis. In the variant known as *oncocytic myoepithelioma*, the cytoplasm has a granular oxyphilic quality. In all myoepitheliomas, collagen stroma is scanty, microcystic formations may be present, and various degrees of secondary myxoid change or lipomatous metaplasia of the stroma may be seen.[235,236] Collagenous crystalloids may be present in some tumors.[237] Ultrastructurally and immunohistochemically, microfilaments of both actin and keratin type can be demonstrated (Fig. 6.25).[238] Most myoepitheliomas also demonstrate p63 and p40 reactivity, whereas S100 can be positive or negative. The *hyaline (plasmacytoid) cell–type* tumors are composed of cells with eccentric nuclei, some degree of pleomorphism and hyperchromasia, but scanty or no mitotic activity. The cytoplasm is abundant, with a *diffuse* eosinophilia that is very different from the fine granular quality seen in oncocytes. The cell margins are polygonal and sharply outlined (Fig. 6.26). The appearance of hyaline cells may simulate that of neoplastic plasma cells or even skeletal muscle cells. Ultrastructurally, their main feature is the presence of abundant, uniformly dispersed microfilaments measuring 50–100 Å in diameter.[239] Although this type has ultrastructural evidence of myoepithelial differentiation, they are typically negative for traditional myoepithelial markers (actin, p63) but do stain with keratin and S-100. The *clear cell type* tumors are composed of sheets or nests of small cuboidal cells with moderate amounts

Figure 6.25 Electron micrograph of a myoepithelioma of parotid gland. Portion of a neoplastic myoepithelial cell illustrating *(left to right)* extracellular space with collagen fibrils and basement membrane, electron-dense attachment plaques on the cell membrane, linear arrays of 6-nm actin microfilaments, perinuclear bundles of tonofilaments (indicative of squamous metaplasia), and a portion of the nucleus. (×22,900.) (Courtesy of Dr. Robert A. Erlandson, Memorial Sloan-Kettering Cancer Center.)

of clear cytoplasm. These clear cells contain variable amounts of glycogen but no fat or mucin.

Immunohistochemically, in general, the neoplastic myoepithelial cells show reactivity for keratin, both forms of S-100 protein, p63, p40, actin, and, in some cases, vimentin, calponin, and myosin.[101,240–246] In this regard, it is important to point out that many myoepitheliomas fail to react with smooth muscle actin.[247] It is important to remember that there are differences in the immunohistochemical profile related to the myoepithelioma subtype, as well as a great deal of heterogeneity within each category.[244,248]

Most of the reported cases of spindle cell, epithelioid, and clear cell myoepitheliomas have occurred in the parotid gland, whereas most pure examples of hyaline myoepitheliomas have been described in minor salivary glands, particularly those in the palate.[249,250]

There is a range of differentiation among these tumors, with both benign and malignant variants represented. The majority of cases with a hyaline cell morphology have behaved in a benign fashion,[251] although well-documented exceptions exist.[249] Many malignant examples of the spindle cell and particularly of the clear cell types have been described.[252–256] Malignant tumors have been referred to as both malignant myoepithelioma and myoepithelial carcinoma. In general, these have been characterized by infiltrative growth, increased cellularity, mitotic activity, necrosis, and cytologic atypia.[251] A frequent growth pattern is composed of large invasive lobules with central necrosis. These malignant myoepitheliomas can arise de novo or as a malignant transformation of a myoepithelioma, benign mixed tumor, or a basal cell adenoma.[257,258] They are uncommon, accounting for approximately 2% of salivary gland malignancies. They are most common in the parotid gland but can be seen in all salivary gland sites. Although no formal grading system exists, tumors with high mitotic activity, necrosis, and pleomorphism tend to behave as high-grade carcinomas. Following treatment, approximately

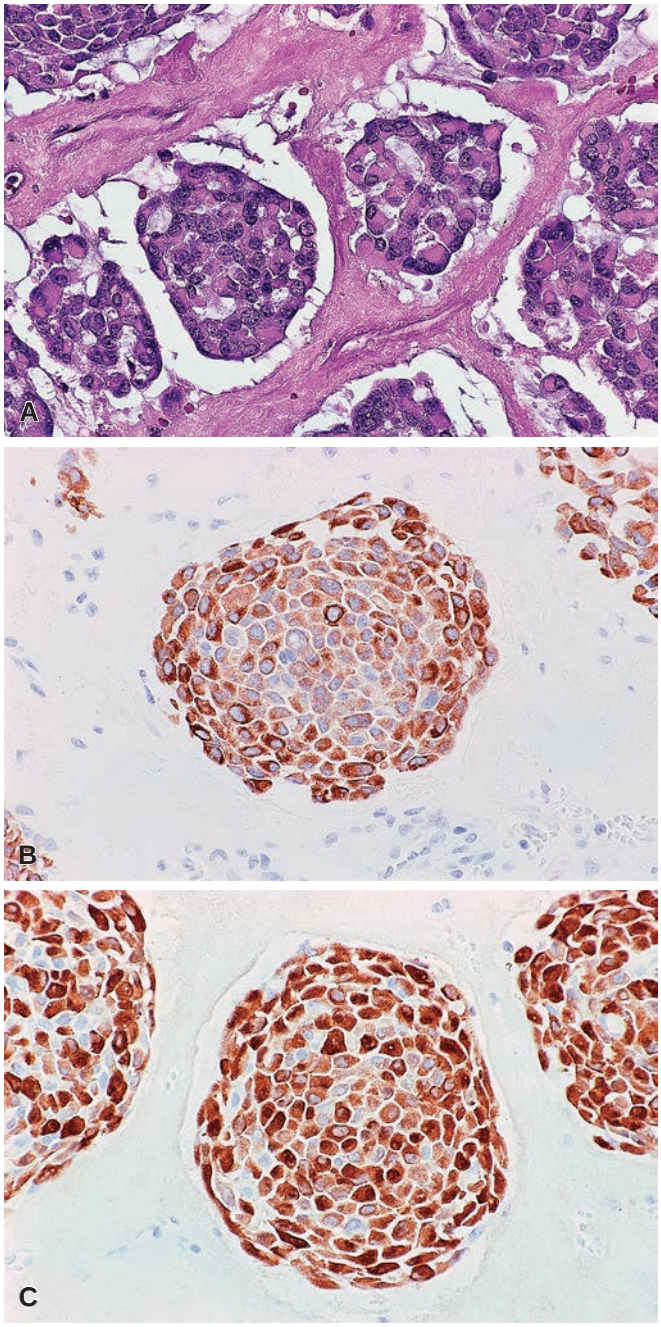

Figure 6.26 Myoepithelioma composed of so-called hyaline cells. (**A,** H&E; **B,** keratin; **C,** S-100 protein.)

one-third of patients will die of disease, one-third will be alive with disease, and one-third will be alive and disease free.[256] Although most myoepitheliomas are reportedly negative for *EWSR1* rearrangements,[259] clear cell myoepithelial carcinomas show *EWSR1* gene rearrangements in approximately 40% of cases.[260]

Tumors With Clear Cell Change

As is true in most other organs, clear cell–containing neoplasms of the salivary gland do not constitute a homogeneous or specific type.[261–264] In the presence of such feature, the differential diagnosis should include clear cell myoepithelioma and myoepithelial

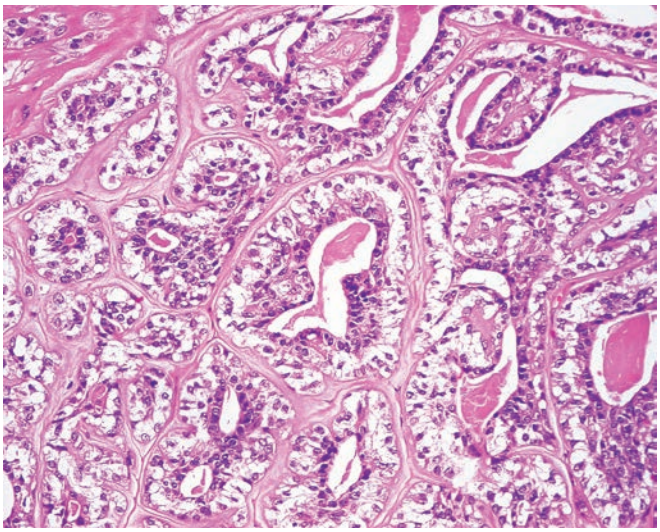

Figure 6.27 Epithelial–myoepithelial carcinoma. The myoepithelial component is represented by the cells with clear cytoplasm. Infiltrative growth was present in other areas of this tumor. Benign mixed tumors can have similar appearing areas, but they lack infiltrative growth.

carcinoma (positive for glycogen), sebaceous neoplasms (positive for fat), mucoepidermoid carcinoma (positive for mucin), acinic cell carcinoma, clear cell change in oncocytic tumors, and metastatic renal cell carcinoma.[265–267] There are some malignant salivary gland tumors composed of clear cells that cannot be placed into any of those categories and for which the descriptive term *clear cell* carcinoma has been used.[268,269] Most of these tumors occur in the oral cavity rather than in the major salivary glands and are accompanied by a prominent fibrohyaline stroma (hence the proposed term *hyalinizing clear cell carcinoma* for them).[268]

Epithelial–myoepithelial carcinoma is an uncommon salivary gland carcinoma that most often occurs in the parotid gland but can occur in other major salivary glands and minor salivary gland sites, especially the sinonasal region.[270] As the name implies, they are composed of a dual population of eosinophilic ductal cells surrounded by myoepithelial cells that most often have prominent clear cytoplasm (Fig. 6.27). The proportions of ductal and myoepithelial cells varies from tumor to tumor. The stroma can be scant but often contains variable amounts of myxoid and/or basement membrane–type material. Because most are low-grade, demonstration of infiltrative growth is required to make this diagnosis. Some tumors can have significant mitotic activity, pleomorphism, and necrosis. The invasive lobules are typically solid, but papillary and cystic growth patterns are not uncommon. Several "variants" have recently been described, including double clear, oncocytic-sebaceous, and apocrine.[270,271] In addition, some may arise in a preexisting pleomorphic adenoma (carcinoma ex pleomorphic adenoma). The ductal cells react with low-molecular-weight cytokeratin, whereas the myoepithelial cells react with high-molecular-weight cytokeratin, p63, p40, actin, and calponin. S-100 staining, as is often the case in salivary gland neoplasia, is unpredictable. Although approximately 40% of tumors recur, metastases are seen in only 15% (mostly cervical lymph nodes) and disease-related mortality is less than 10%, with 5-year survival rates of 80%.[270,272]

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common salivary gland malignancy. Most cases of mucoepidermoid carcinoma are located

Figure 6.28 Gross appearance of mucoepidermoid carcinoma. This particular tumor is entirely solid, without the cystic formations commonly seen in low-grade lesions.

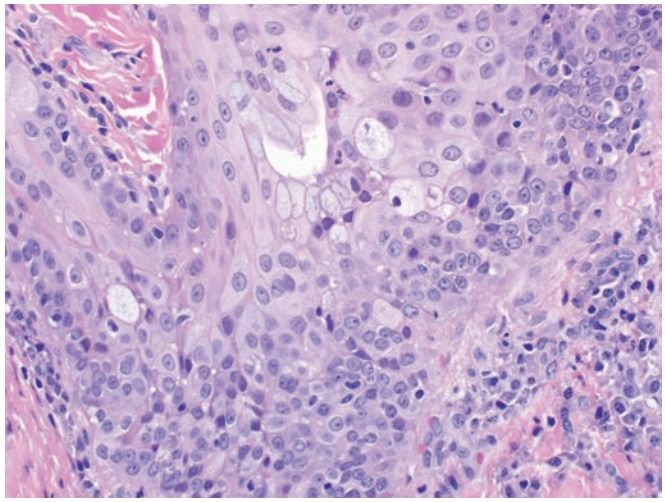

Figure 6.29 Mucoepidermoid carcinoma. Mucous, squamous, and intermediate cells can be seen.

in the parotid gland, and half of cases occur in the major salivary glands (Fig. 6.28).[273] They also arise from minor salivary gland sites with the palate, buccal mucosa, and tongue being relatively common sites. This lesion also represents the most common malignant salivary gland tumor in children.[80,274] Microscopically, three main cell types can be identified: mucin-producing, squamous (epidermoid), and intermediate (Fig. 6.29). The intermediate cells tend to predominate and are characterized as small cuboidal cells with minimal eosinophilic cytoplasm, resembling basal cells. The three cell types are

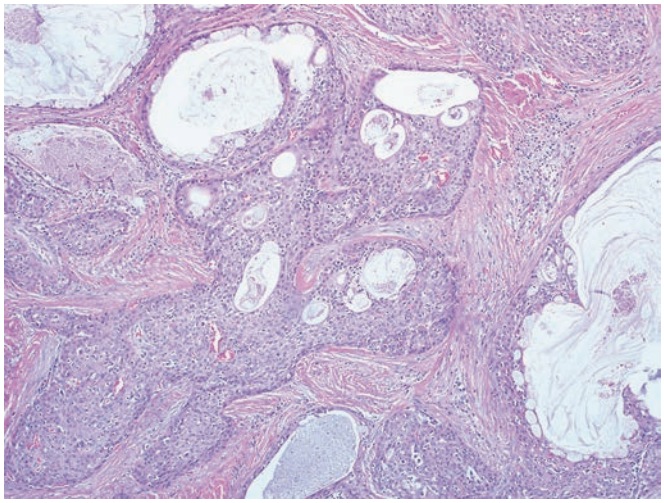

Figure 6.30 Low-grade mucoepidermoid carcinoma has a predominantly cystic areas as well as infiltrative growth.

present in variable proportions from tumor to tumor and can form sheets and nests with duct-like structures or cysts. The better differentiated forms present grossly as a relatively well-circumscribed mass with cystic areas containing mucinous material (Fig. 6.30). Microscopically, well-differentiated mucinous cells predominate in these low-grade lesions. The high-grade varieties are more solid and have a more infiltrative pattern of growth. In the high-grade tumors, squamous and intermediate predominate over the mucin-producing cells. It should be pointed out that marked nuclear atypia, frequent mitoses, extensive keratinization, and extensive necrosis are not typical of mucoepidermoid carcinoma of any grade. When these features are present, the alternative possibilities of poorly differentiated adenocarcinoma and adenosquamous carcinoma should be considered.[275]

Morphologic variants of mucoepidermoid carcinoma include forms with a component of sebaceous cells,[276] cases with prominent oncocytic change *(oncocytic mucoepidermoid carcinoma)*,[277–279] tumors with extensive clear cell change, forms with intense sclerosis of the stroma *(sclerosing mucoepidermoid carcinoma)*, and an extremely rare variant characterized by sclerosis, focal epidermoid features, and eosinophilic infiltration *(sclerosing mucoepidermoid carcinoma with eosinophilia)*, the latter being similar to the homonymous tumor of the thyroid gland.[7,280] In addition, cases of mucoepidermoid carcinoma with a dedifferentiated component have been reported, the change being accompanied by an accelerated clinical course.[281]

When the mucin or keratin formed by mucoepidermoid carcinoma escapes into the interstitial tissue, it causes an inflammatory reaction. Although true post-traumatic sialoceles and mucoceles certainly occur,[282] in the presence of mucin-filled cystic spaces in the parotid region the possibility of a well-differentiated mucoepidermoid carcinoma should always be ruled out by taking additional sections. Sometimes, extensive fibrosis accompanies the spillage of mucin.[283]

Immunohistochemically, simple mucin-type carbohydrate antigens (T, Tn, and syalosyl-Tn) have been detected in this tumor.[284] The mucins expressed by mucoepidermoid carcinoma include MUC1, MUC2, MUC4, MUC5AC, and MUC5B, but not MUC3 (which is expressed instead by adenoid cystic carcinoma; see later). Significantly, MUC1 predominates in the high-grade tumors, whereas MUC4 is more prevalent in low-grade tumors.[285,286]

In terms of keratin expression, the usual profile of mucoepidermoid carcinoma is CK7+/CK14+/CK20–.[287,288] The pattern of staining with these markers recapitulates that of normal striated duct cells.[289] Myoepithelial cell markers are usually negative and focal with weak staining if present.[289] The exception is p63, which is positive in the epidermoid and intermediate cells.

In a majority of cases of mucoepidermoid carcinomas, a distinctive chromosomal translocation t(11;19)(q21;p13), which fuses the *CRTC1* (formerly known as *MECT1*) gene with the *MAML2* gene, is found.[290–292] The translocation results in activation of the Notch pathway.[293] Of interest, mucoepidermoid carcinomas occurring in other sites, such as skin, breast, lung, and cervix, have also demonstrated the *CRTC1* translocation.[294–297] In 6% of cases, *CRTC3–MAML2* gene fusion is present instead of *CRTC1–MAML2*.[292] Mucoepidermoid carcinomas harboring *CRTC1–MAML2* or *CRTC3–MAML2* fusion exhibit a more favorable prognosis compared with those lacking the gene fusion.[291,292,298–300]

There is a marked difference in prognosis depending on the grade of the tumor, whether one uses the traditional two-tier system (low grade and high grade) or the three-grade scheme proposed by the Armed Forces Institute of Pathology (AFIP) authors, which is the one currently favored.[301–303] This is based on a weighted points system: cystic component less than 20%, 2 points; neural invasion, 2 points; necrosis, 3 points; four or more mitoses per 10 high-power fields, 3 points; anaplasia, 4 points. A total score between 0 and 4 defines a low-grade tumor, a score of 5–6 applies to an intermediate-grade tumor, and a score of 7 or more indicates a high-grade tumor.[304]

In the series reported by Jakobsson et al.[305] the determinate 5-year survival rate was 98% for the low-grade variety and 56% for the high-grade variety. Most of the latter tumors showed their malignant behavior within the first 5 years after surgery, in contrast with the continuous fall in survival rate over a 20-year period seen with adenoid cystic carcinoma and acinic cell carcinoma. In another series involving 69 cases, all but 2 of the 14 deaths and all 6 instances of distant metastases occurred in high-grade tumors, which were also associated with an increased incidence of local recurrence and regional lymph node metastases.[275] A correlation has also been found between prognosis and the following parameters: age (better in younger patients), gender (better in females), location (better in the parotid than in the submandibular gland), extraglandular extension, vascular invasion, necrosis, mitotic rate, cell proliferation as measured by MIB-1 antibody, DNA ploidy, and activation of the ERK-1/ERK-2 pathway.[301,302,306–308]

Acinic Cell Carcinoma and Mammary Analogue Secretory Carcinoma

Acinic cell carcinoma comprises 1%–3% of all salivary gland tumors. There is a male predominance and a peak incidence in the fifth decade of life, but there is a broad age distribution.[309] In fact, following mucoepidermoid carcinoma, it the second most common salivary gland malignancy in children. It is the most common bilateral salivary gland malignancy. A few familial cases have been described.[310] The majority (80%) are located in the parotid gland, but many examples in the minor salivary glands have been recorded.[311–313]

Grossly, the tumor presents as an encapsulated round mass with a solid, friable, grayish-white cut surface, usually measuring less than 3 cm in diameter.[309] Occasionally it undergoes marked cystic degeneration.

The microscopic appearance shows considerable variation from case to case. The pattern of growth may be predominantly solid, microcystic, papillary–cystic, or follicular.[309] There is also marked variability in the appearance of the tumor cells. The most characteristic cell, known as acinic, has a cytoplasmic appearance (granular and basophilic) and ultrastructural morphology analogous to that of acinic cells of normal salivary glands (Fig. 6.31).[314,315] The cytoplasmic granules demonstrate periodic acid–Schiff (PAS) positivity that is

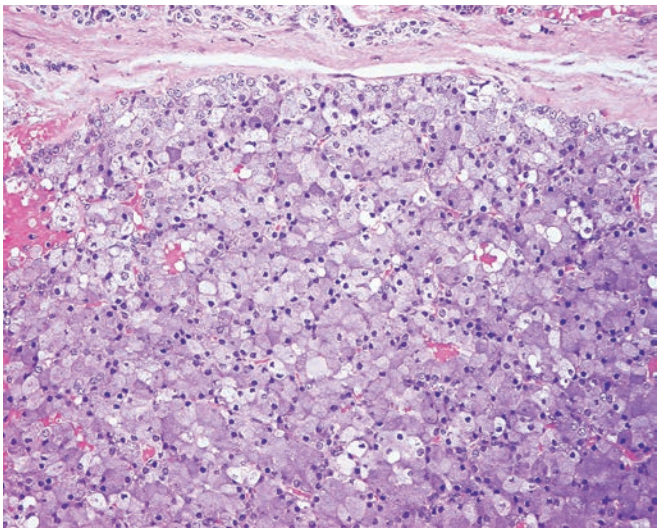

Figure 6.31 Acinic cell carcinoma. The cells have an abundant cytoplasm filled with basophilic zymogen granules.

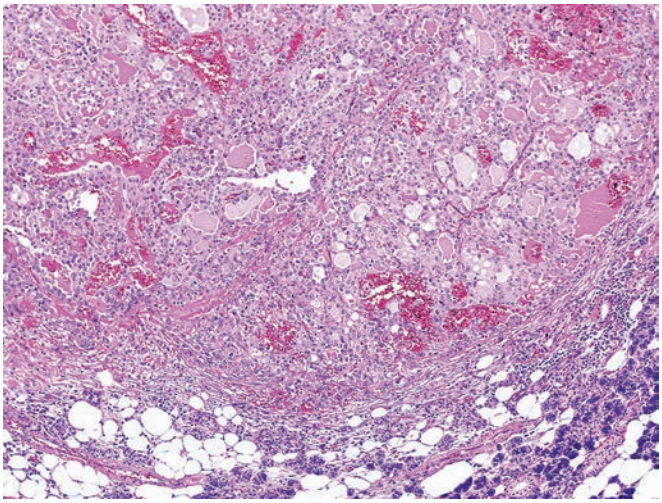

Figure 6.32 Mammary analogue secretory carcinoma of parotid gland. These low-grade infiltrative carcinomas are comprised of large nests with a microcystic appearance. The lumens are filled with eosinophilic to basophilic secretions.

resistant to diastase. Other cell types have been designated as intercalated duct, clear, vacuolated, and nonspecific glandular.[309] When the clear cell component predominates, the tumor acquires a "hypernephroid" appearance reminiscent of renal cell carcinoma. These clear cells do not contain fat or mucin but may have variable amounts of glycogen. However, focal mucin positivity can be encountered in the papillary–cystic or follicular areas.[316] The occurrence of these cytologic and architectural variations indicates that this neoplasm differentiates in the direction of the terminal ductular–acinar unit of the salivary gland, which includes secretory acinar (luminal) cells, intercalated duct cells, pluripotential reserve (basal) cells, and myoepithelial cells.[317] Lymphoid follicles with germinal centers may be prominent at the periphery of the tumor[318] and laminated concretions with the appearance of psammoma bodies may be seen within the lumina.[309]

Immunohistochemically, there is positivity for keratin and also focal reactivity for amylase, α1-antichymotrypsin, transferrin, lactoferrin, IgA, secretory component, and proline-rich protein.[319,320] Patchy S-100 protein reactivity can be seen in some tumors. Apical membrane reactivity for DOG-1 has been identified in acinic cell carcinomas and is helpful in distinguishing this tumor from its mimics.[6]

In a classic study of 37 cases reported by Eneroth et al.,[314] there was local recurrence in 11 cases and metastases in 7 cases; 4 recurrences were in regional lymph nodes. The determinate survival rate at 5 years was 89%, but it fell to 56% after 20 years. In a larger series reported by Ellis and Corio,[321] there was a recurrence rate of 12%, a metastatic rate of 7.8%, and a death rate of 6.1%. The regional lymph nodes are the most common site of metastases.[321]

Features of prognostic importance are pain or fixation, gross extraglandular invasion, desmoplasia, cytologic atypia, increased mitotic activity, and adequacy of initial excision.[322] The latter is of particular importance.[323,324] In the series of Perzin and LiVolsi,[324] recurrent tumor was found in 14 of 15 patients treated with limited local excision but in only 3 of 28 patients who had wide local excision. Local recurrence was associated with an increased incidence of locally uncontrollable and metastatic disease. Neck dissection does not appear warranted unless the nodes are clinically involved. The role of radiation therapy for this tumor remains controversial; most series have not shown clear-cut beneficial effects.[325]

A particularly ominous but fortunately rare event in acinic cell carcinoma is the emergence of an anaplastic (dedifferentiated) component in the form of a high-grade adenocarcinoma, poorly differentiated carcinoma, or undifferentiated carcinoma.[7,326] This development is associated with aneuploidy on flow cytometry, appearance of peculiar helioid inclusions at the ultrastructural level, and an accelerated clinical tempo.[327,328] *TP53* gene mutation and *HER2* amplification have not been detected in dedifferentiated acinic cell carcinoma.[329]

Mammary analogue secretory carcinoma is a recently described salivary gland carcinoma that was frequently diagnosed as acinic cell carcinoma but is now known to be a distinct entity that is identical to secretory carcinoma of the breast, confirmed by the morphologic, immunohistochemical, and genetic similarities between the two entities. The entity was reported by Skalova et al., taking advantage of the fact that mammary secretory carcinoma is associated with the t(12;15)(p13;q25) translocation leading to the *ETV6–NTRK3* gene fusion. Given the histologic similarity to acinic cell carcinoma, a key question, of course, was whether acinic cell carcinoma of salivary glands carried the same translocation. Reis-Filho et al.,[330] and Skalova et al.,[331] working with 14 suitable cases, found the same cytogenetic aberration *in all of them* (but not in conventional acinic cell carcinomas or other salivary gland tumors). On the basis of this remarkable finding, the authors postulated the existence of a distinct entity among salivary gland tumors that they proposed to call mammary analogue secretory carcinoma of salivary glands (MASC). Most occur in the parotid gland, but intraoral minor salivary gland sites can also be involved. Morphologically, the cases representing this new entity are characterized by the presence of microcystic and glandular spaces with abundant eosinophilic secretion positive for PAS, mucicarmine, MUC1, MUC4, and mammaglobin (Fig. 6.32). The cells have an apocrine appearance with vacuolated, eosinophilic cytoplasm and uniform vesicular nuclei with small nucleoli (Fig. 6.33). Similar to mammary secretory carcinoma of the breast, the cells are positive for cytokeratin, S-100 protein, BRST-2, and mammaglobin but negative for androgen receptor, p63, and DOG-1. They are low-grade carcinomas that recur in approximately 30% of cases but only rarely metastasize or result in death. Rare examples with high-grade transformation (dedifferentiation) have been described and behave more aggressively.

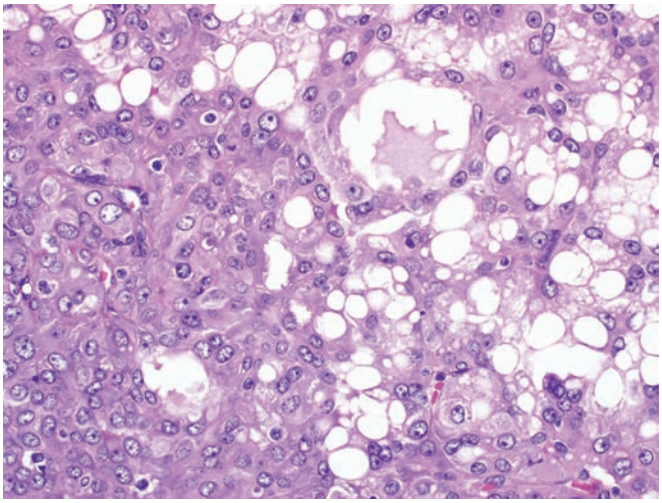

Figure 6.33 Mammary analogue secretory carcinomas contain monotonous cells with an apocrine appearance and vacuolated cytoplasm.

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is a generally slow-growing but highly malignant neoplasm with a remarkable capacity for recurrence. In the parotid gland it is less common than mucoepidermoid carcinoma and acinic cell carcinoma, but in the minor salivary glands it is the most common malignant tumor.

Grossly, it usually has a solid appearance and an infiltrative pattern of growth, although some examples can be well circumscribed. Microscopically, the typical adenoid cystic carcinoma has a pattern described as *cribriform:* nests and columns of cells of rather bland appearance are arranged concentrically around glandlike spaces ("pseudocysts") filled with homogeneous eosinophilic PAS-positive material or granular myxoid material (Figs. 6.34 and 6.35). Most of these are not true glandular spaces; they represent instead extracellular cavities containing reduplicated basal lamina material and mucin produced by the tumor cells (Fig. 6.36).[332] Small true glandular lumina are also formed. Indeed, identification of *both* pseudocysts and true glandular lumina is required to make a diagnosis of adenoid cystic carcinoma. The rare small glandular lumina are lined by a monolayer of eosinophilic epithelial cells. These are surrounded by varying amounts of small myoepithelial cells with scant cytoplasm and hyperchromatic, angulated nuclei. This tumor has a remarkable tendency for invasion of perineurial spaces, to the degree that the diagnosis of adenoid cystic carcinoma should be questioned if an adequate sample taken from the periphery of the tumor does not exhibit this feature (Fig. 6.37).[333]

Some adenoid cystic carcinomas have a predominantly *tubular* pattern of growth, whereas others are mainly *solid*[334,335] and yet others (exceptionally rare) are *sclerosing*.[336] The solid pattern is characterized by overgrowth of the epithelial (glandular) component and frequently displays more mitotic activity with increased cytologic atypia with or without small foci of necrosis. Combined patterns of growth are common, whether in the original tumor or in the recurrences (Fig. 6.38).[337]

Immunohistochemically, the tumor cells located in recognizable duct structures express a phenotype similar to that of the intercalated duct (positive for keratin, CEA, lysozyme, lactoferrin, α1-antichymotrypsin, S-100 protein, and CD117 [c-KIT]), and those around pseudocysts have a phenotype suggestive of myoepithelial cell differentiation (positive for S-100 protein, p63, and actin and variably positive for keratin).[338–343]

Cytogenetically, there is a high incidence of loss of heterozygosity (LOH) at chromosome 6q23–35.[344,345] Alterations of *TP53* are

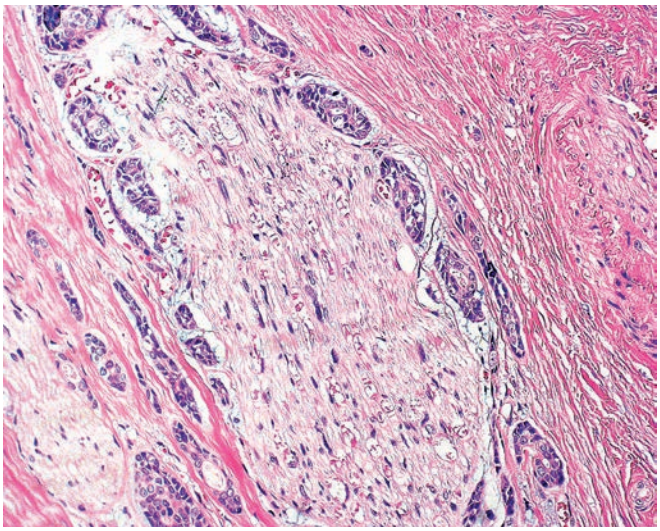

Figure 6.37 Adenoid cystic carcinoma with prominent perineurial invasion.

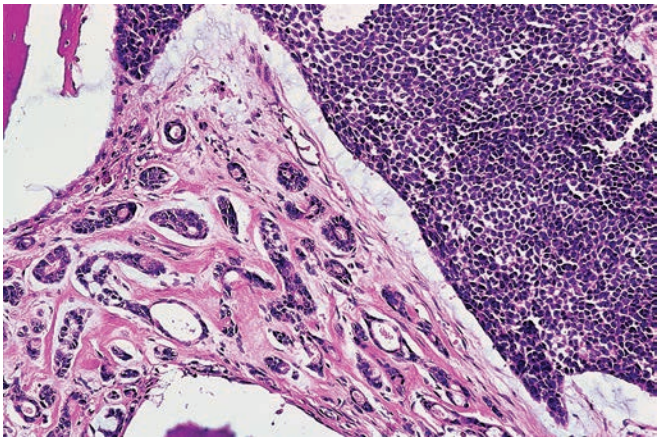

Figure 6.38 Adenoid cystic carcinoma combining tubular *(left)* and solid *(right)* features.

uncommon,[346] except in dedifferentiated cases (see later). A microarray analysis has demonstrated the common expression of genes indicative of myoepithelial differentiation, transcription factors 50 × 4 and AP-2y, and members of the Wnt/β-catenin signaling pathway.[347] A proportion of cases (approximately 30%) of adenoid cystic carcinomas exhibit a distinctive chromosomal translocation resulting in *MYB–NKIB* fusion.[348]

The differential diagnosis with benign mixed tumor can be difficult. Important points to remember are that adenoid cystic carcinoma is invariably invasive and often associated with perineurial invasion, and that chondromyxoid stroma and foci of squamous metaplasia are consistently absent. In addition, papillary growth and true cyst formation are not a feature of adenoid cystic carcinoma.

Another important differential diagnosis is with polymorphous low-grade adenocarcinoma, which is rendered easier by the realization that the latter is almost nonexistent in the *major* salivary glands. At the microscopic level, the nuclei of adenoid cystic carcinoma tend to be hyperchromatic and angulated rather than bland and uniform. Furthermore, as already stated, adenoid cystic carcinoma is usually strongly immunoreactive for CD117 (c-KIT), whereas polymorphous low-grade adenocarcinoma is either negative or shows a lesser intensity of staining.[343] The latter fact makes this stain suboptimal as a distinguishing feature. In contrast, diffuse S-100 protein staining would support a diagnosis of polymorphous low-grade adenocarcinoma over adenoid cystic carcinoma, whereas strong p63 staining would support the latter.

Because the prognosis of adenoid cystic carcinoma is greatly influenced by its pattern of growth, this feature has been used as a grading system.[334,349–351] In one series, the recurrence rate was 59% for the tubular tumors, 89% for the classic cribriform lesions, and 100% for the solid variety.[334] In another series in which a somewhat similar grading system was used, the cumulative survival rates at 15 years were 39%, 26%, and 5%, respectively.[351] The solid or anaplastic type of adenoid cystic carcinoma is associated with a higher incidence of metastases and a rapid clinical course.[349,352] Based on these findings, adenoid cystic carcinomas can be graded as follows: grade 1—tubular or mixed cribriform and tubular; grade 2—pure cribriform or those with a solid component less than 30%; grade 3—tumors with 30% or more solid component. A behavior just as aggressive (if not more so) is to be expected in the rare instances in which a conventional adenoid cystic carcinoma undergoes dedifferentiation or high-grade transformation,[353,354] an event that is accompanied by *TP53* gene mutation.[355] Other factors that influence the prognosis of adenoid cystic carcinoma are stage (very important), presence of tumor at the margins, anatomic site, size of the primary lesion, degree of atypia, and lymph node metastases.[334,351,356]

Adenoid cystic carcinomas frequently metastasize to the lungs. These metastases are usually silent, and it is not unusual to find multiple nodules in the chest x-ray film of a totally asymptomatic individual. Lymph node metastases are rare, at least at the time of the initial presentation; many of them seem to represent direct extension from the perinodal soft tissues rather than true embolic deposits.[357]

In the treatment of adenoid cystic carcinoma, a radical surgical approach should be used, no matter how well differentiated the tumor appears under the microscope.[358] Cures after tumor recurrence are very difficult to achieve. Radiation therapy is rarely curative, but it may improve results when combined with surgery,[349] and it may produce excellent temporary regression of inoperable recurrences.[350,359]

Salivary Duct Tumors

Salivary duct papilloma usually arises within minor salivary glands, but a few cases have been reported in the parotid.[360–363]

Salivary duct carcinoma is usually seen in elderly males, most commonly in the parotid gland but also in the submandibular gland.[250,364–366] Some cases develop on the basis of a preexisting pleomorphic adenoma and salivary duct carcinoma is the most common carcinoma seen in carcinoma ex pleomorphic adenoma. Microscopically, it resembles high-grade in situ and invasive apocrine ductal carcinoma of the breast, whether comedo, solid, cribriform, papillary, invasive micropapillary, mucinous (mucin-rich), the usual invasive form, or even sarcomatoid (Fig. 6.39).[7,367–375] In other words, it spans the same wide range of differentiation as its more common mammary counterpart.[376–378] The immunohistochemical profile is similar to that of a ductal-type adenocarcinoma and just as diverse as its morphologic appearance.[379] There is expression of keratin (including low- and high-molecular-weight keratins),[380] HER2/neu (approximately 40% of cases),[381,382] CEA, and EMA.[383,384] It also frequently expresses androgen receptors (approximately 90%) but negative for estrogen receptor. Some tumors express CD117 (c-KIT), GCDFP-15 (especially in the intraductal component), and prostate-specific antigen and other prostate-related markers.[385,386–388] They

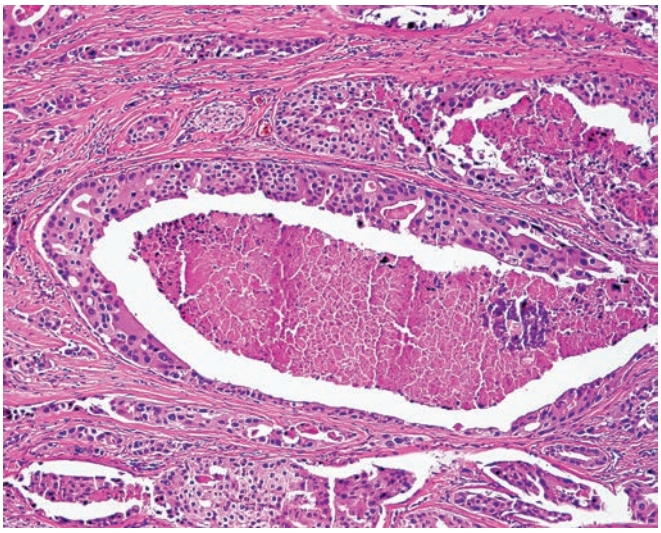

Figure 6.39 High-grade ductal-type carcinoma of parotid gland. There is some degree of cytoplasmic apocrine-like change.

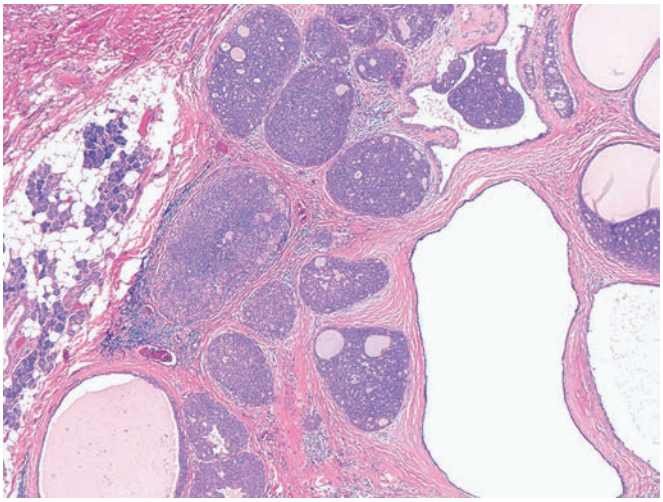

Figure 6.40 Low-grade cribriform cystadenocarcinoma of parotid gland. A mixture of solid and cystic nodules is typical.

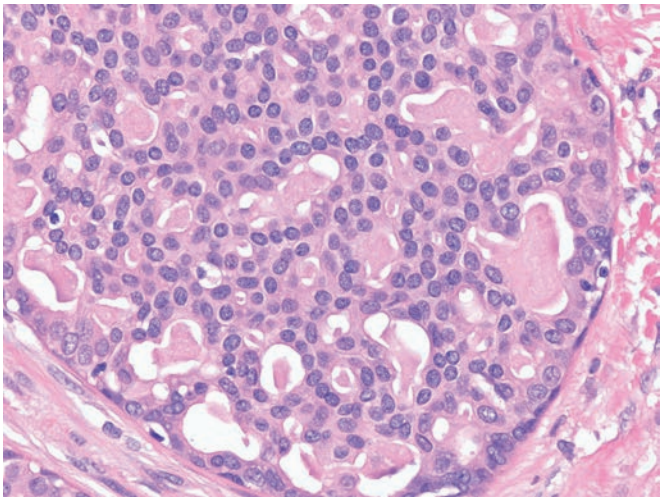

Figure 6.41 Low-grade cribriform cystadenocarcinomas resemble low-grade breast epithelial lesions, such as atypical ductal hyperplasia and low-grade ductal carcinoma in situ.

are negative for S-100 protein and p63 (rare weak positivity can be seen).[389]

Mutation of *TP53* is a common finding in salivary duct carcinoma, and *HER2* amplification is present is approximately one-third of cases.[365,382] Gene expression profiling study shows overexpression of apoptosis-related genes *CASP10* and *MMP11*.[390]

This high-grade carcinoma is markedly aggressive, with frequent metastases to both regional nodes and distant organs, and a mortality rate of 70%, with most patients dying within 3 years of diagnosis.[250,391] The presence of a micropapillary or sarcomatoid component is said to be associated with an aggressive behavior.[392] Rare pure intraductal tumors treated by simple excision recur frequently, either with the same intraductal pattern or as invasive tumor.[393,394]

It should be emphasized that the term "salivary duct carcinoma" refers to the pattern of growth of the tumor rather than to its anatomic location. Most reported carcinomas of Stensen duct have not been salivary duct carcinomas but rather mucoepidermoid, squamous cell, or undifferentiated carcinomas.[395]

Low-grade cribriform cystadenocarcinoma is a recently described indolent salivary gland carcinoma that resembles a spectrum of low-grade breast lesions ranging from atypical ductal hyperplasia to micropapillary and cribriform ductal carcinoma in situ (Fig. 6.40). Most occur in adults and are located in the parotid gland.[396] They were originally referred to as "low-grade salivary duct carcinoma,"[376] but this term should be avoided to obviate confusion with the aggressive salivary duct carcinoma. Most lesions are entirely in situ, based on both morphologic and immunohistochemical features. Small foci of infiltrative growth can be identified in rare lesions. The tumor is characterized by solid and cystic lobules composed of bland cuboidal cells with minimal mitotic activity. Some tumors have cells with prominent apocrine cytology.[375] The solid lobules contain numerous microcysts imparting a cribriform appearance (Fig. 6.41). The microcysts are filled with pale eosinophilic or basophilic secretions. The cystic lobules may contain both papillary and cribriform growth. The neoplastic cells are positive for keratin and S-100 protein but negative for p63 and myoepithelial markers. The latter highlight a single layer of myoepithelial cells in the majority of the tumor lobules. Androgen receptor and HER2/neu are negative. Given the low-grade cytology and in situ nature of the tumor, the prognosis is excellent, with low recurrence risk and only rare cases of metastasis, with essentially no disease-related mortality.

Polymorphous Low-Grade Adenocarcinoma

Polymorphous low-grade adenocarcinoma is usually restricted to the minor salivary glands of the oral cavity and is therefore discussed in Chapter 4.[397–399] Those occurring in the major salivary glands nearly always arise against a background of benign mixed tumor, but rare primary examples do occur.[400,401] The main differential diagnosis is with adenoid cystic carcinoma and benign mixed tumor.[402,403]

Cystadenocarcinoma (Papillary Cystadenocarcinoma)

Cystadenocarcinoma comprises less than 3% of all parotid tumors, but they also occur in the sublingual gland.[363,404] It may grow large and be accompanied by hemorrhage and necrosis. Similar cases have been described in the oral cavity.[405,406] Microscopically, the presence of invasive cystic nodules with well-defined papillary structures is the most important distinguishing feature. Mucin production is usually present, but there are no squamous or intermediate

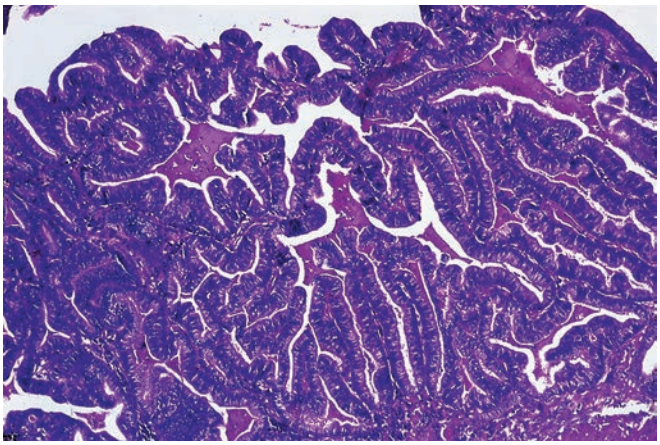

Figure 6.42 Papillary cystadenocarcinoma of parotid gland.

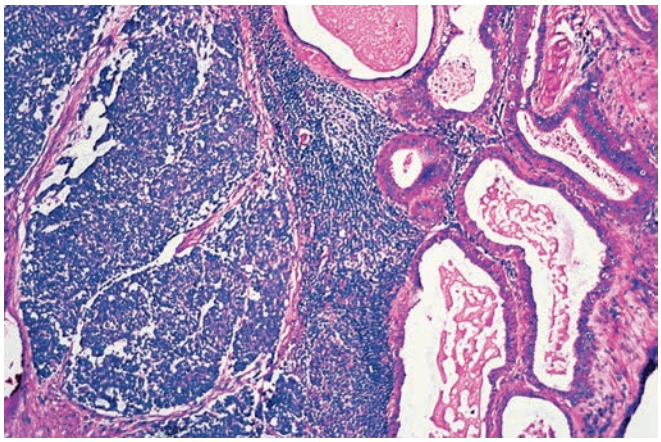

Figure 6.43 Collision between Warthin tumor *(right)* and small cell (Merkel cell) carcinoma *(left)*.

components (Fig. 6.42). If there is a prominent papillary component, the tumors can be designated as *(papillary) cystadenocarcinomas*.[407,408] Sometimes the malignant papillary component is a focal feature in an otherwise benign-looking mucinous cystadenoma.[409] The differential diagnosis includes mucoepidermoid carcinoma, acinic cell carcinoma, the papillary subtype of polymorphous low-grade adenocarcinoma, and metastatic carcinoma, particularly from the thyroid. Blanck et al.[404] divided their cases into high- and low-grade varieties based on the presence or absence of stromal invasion. The former had a poor prognosis, comparable with that of adenoid cystic carcinoma, whereas the latter did not differ prognostically from low-grade mucoepidermoid carcinoma.

Squamous Cell Carcinoma

Most squamous cell carcinomas in the parotid region represent metastases in the intraparotid lymph nodes of tumors located in the oral cavity, some other region in the upper aerodigestive tract, or the skin.[410]

True pure squamous cell carcinomas of the salivary gland are very rare. Some represent the malignant component of a mixed tumor; others are predominantly squamous cell types of high-grade mucoepidermoid tumors, as shown by their focal positivity for mucin stains. An in situ malignant ductal component has been occasionally encountered and can support the concept of primary salivary gland squamous cell carcinoma but could also represent secondary invasion from a metastasis.[411] These tumors grow rapidly and infiltrate surrounding structures. The treatment of choice is radical surgery, but radiation therapy is also effective. The overall 5-year survival rate in a series of 18 cases from the Mayo Clinic was 50%.[412]

Small Cell Carcinoma and Other Neuroendocrine Carcinomas

There are malignant tumors of the salivary gland that are entirely composed of a solid population of small cells with a darkly staining nucleus, high mitotic activity, and scanty cytoplasm.[413,414] Some of these tumors are indistinguishable from small cell carcinomas of the lung. They may be pure or associated with areas of glandular or squamous differentiation.[415–418] Ultrastructurally, dense-core granules consistent with endocrine differentiation are found in most but not all of the cases.[419] Immunohistochemically, all of the cases studied by two groups of authors[420,421] expressed one or more neuroendocrine markers, such as Leu7, neuron-specific enolase (NSE), chromogranin, or synaptophysin. Keratin (often dot-like pattern) and EMA are also regularly expressed.

In approximately half of the cases these tumors have been found to have features analogous to those of Merkel cell carcinoma of skin, including immunoreactivity for CK20 and polyomavirus.[421,422] Rarely, small cell carcinoma can be the malignant component arising in a background Warthin tumor (Fig. 6.43).[423] On the basis of the above findings, some authors have proposed to divide small cell carcinomas of salivary glands into Merkel cell type and pulmonary type, the latter being negative for CK20. It remains to be seen whether this distinction carries a clinical significance, but preliminary studies suggest that the Merkel cell type is associated with a better survival.[7,421] Overall, recurrence and metastasis occur in more than half of patients, with 5-year survival ranging from 15% to 50%.

Large cell neuroendocrine carcinoma of the salivary gland has also been described, the criteria for its recognition being the same as for the homologous lung tumor.[424]

Lymphoepithelioma-Like Carcinoma

Lymphoepithelioma-like carcinoma is the preferred term for a type of salivary gland carcinoma that has also been reported as a malignant lymphoepithelial lesion and lymphoepithelial carcinoma.[425–428] This tumor is particularly frequent among Eskimos and Chinese, in whom it may show evidence of familial clustering.[427,429] It presents as a unilateral mass, in either the parotid or submaxillary glands, in adult patients without any of the peripheral manifestations of Sjögren syndrome. Its low-power appearance is reminiscent of Mikulicz disease because of the mixture of epithelial solid islands and lymphoid tissue. However, high-power examination shows that the islands have malignant cytologic features throughout. The appearance is that of a nonkeratinizing large cell carcinoma, with occasional spindle-shaped areas, analogous by light and electron microscopy to the nasopharyngeal tumor classically known as lymphoepithelioma.[426,430] That the analogy may be more than morphologic is suggested by the fact that many of these patients have serologic evidence of EBV infection[427] and that EBV DNA has been found in the tumors by in situ hybridization and other molecular techniques.[431–434] Perineurial invasion may be present.[427] Immunohistochemically, there is strong positivity for keratin.[427] The reactive lymphoid tissue forms germinal centers and may exhibit focally a starry sky pattern. Regional lymph node metastases are very common, and distant metastases (particularly to the lung, liver, and bone) also occur.[429] Wide variations in mortality rates have been reported, but the overall outcome in the better documented cases seems to

be relatively good, with 5-year survival rates ranging from 75% to 85%.[427,435]

Other Primary Carcinomas

Some *adenocarcinomas* of salivary gland combine features of two histologically distinct types. They are referred to as **hybrid carcinomas**, and one of the two components is often of myoepithelial nature, but any combination of histologic subtypes is possible.[436,437] Other adenocarcinomas do not fit into any of the previously described patterns and are referred to as adenocarcinoma, N.O.S.[438,439] Following the description of salivary duct carcinoma, polymorphous low-grade adenocarcinoma, MASC, low-grade cribriform cystadenocarcinoma, and epithelial–myoepithelial carcinoma, the number of adenocarcinomas, N.O.S. has shrunk considerably.[438]

Malignant Lymphoma

Malignant lymphoma in the parotid region may arise from an intraparotid lymph node or in the gland itself. In the former instance, the histologic features and natural history of the disease are those of nodal lymphoma in general. When the salivary gland tissue is involved, this may represent the expression of disseminated involvement or, more commonly, a primary process of this organ. The large majority of primary lymphomas of salivary gland involve the parotid gland, but the submaxillary gland can also be affected.[440–443] Clinically, most present as unilateral masses. The large majority of salivary gland lymphomas are of B-cell derivation, most commonly MALT lymphoma, followed by follicular lymphoma and diffuse large B-cell lymphoma.[440,442,444]

Some salivary gland lymphomas are of follicular type and feature the t(14;18) characteristic of follicular lymphoma.[444,445] Some have sclerosing features and simulate chronic sclerosing sialadenitis (Kuttner tumor; but see later).[446] Others—the majority—are composed of small lymphocytes and cells resembling monocytoid B cells. These tumors are currently regarded as belonging to the MALT/marginal zone type.[447,448] They often arise against a background of Mikulicz disease or other immune-mediated diseases (see earlier).[444] They are characterized by a very slow evolution and an excellent long-term prognosis[444,447,449]; it is not unusual for recurrent disease to supervene in the contralateral parotid, skin, or in some other location a decade or more after the initial diagnosis.[450] In contrast, lymphomas composed of large cells run a rapidly progressive clinical course.[451]

Cases of malignant lymphoma have also been observed in association with Warthin tumor,[183,452] in transplant recipients,[453] and following chronic sclerosing sialadenitis (Kuttner tumor).[454]

Isolated cases of **plasmacytoma** of the salivary gland have been reported, some later developing typical radiographic bone changes of multiple myeloma.[455,456]

T-cell lymphomas of the salivary gland are rare but well documented.[457] These include tumors of T/natural killer cells. They may show prominent lymphoepithelial lesions and cannot therefore be reliably distinguished from B-cell tumors on morphologic grounds.[458]

Hodgkin lymphoma presenting as a primary salivary gland neoplasm is very rare.[459] Most cases so diagnosed in the past would probably be reclassified today.

Other Primary Tumors

Benign vascular tumors of blood vessel and lymph vessel type (lymphangiomas) occur in the parotid gland.[460]

Infantile (juvenile) hemangioma is the most common salivary gland tumor in infants and children.[461] It is often congenital and usually involves the parotid gland. It forms a diffuse soft mass without fixation to the overlying skin. Microscopically, it is made up of anastomosing thin-walled capillaries growing between salivary ducts and acini (Fig. 6.44). The solid proliferation of endothelial cells and the presence of mitotic figures may lead to a mistaken diagnosis of malignancy.[462] These lesions practically never become malignant and can regress spontaneously. Some of the cases have been associated with the Kasabach–Merritt syndrome.[463] Immunohistochemical reactivity for GLUT1 distinguishes this lesion from its mimics, particularly vascular malformations, because the former demonstrate diffuse cytoplasmic reactivity.[464] This distinction is important because infantile hemangiomas can be followed clinically without surgical intervention. Vascular malformations, in contrast, need to be treated because they tend to grow slowly over time.

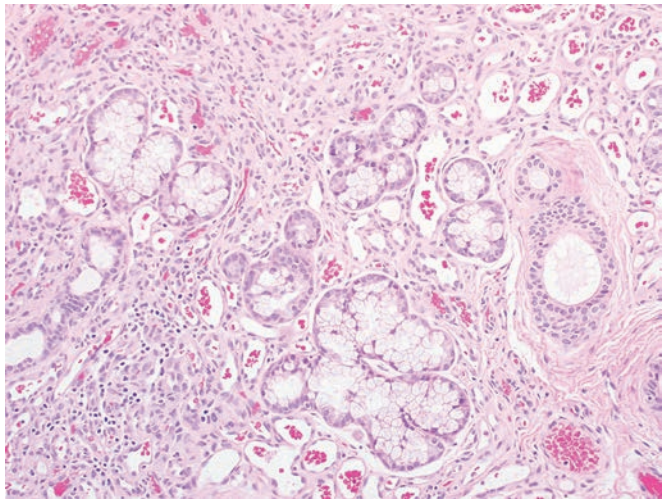

Figure 6.44 Infantile hemangiomas are composed of small capillary-sized blood vessels that infiltrate the glandular parenchyma.

Lipoma rarely involves the region of the parotid salivary gland.[465] It should be distinguished from *lipomatosis*, which is a diffuse nontumoral deposition of adipose tissue throughout the gland accompanied by enlargement of the organ. The latter has been seen in association with diabetes, cirrhosis, chronic alcoholism, malnutrition, and hormonal disturbances.[466] In some cases, this has been preceded by hypertrophy of the serous acinar cells, interstitial edema, and ductal atrophy, a process known as *sialosis* or *sialadenosis*.[467]

Schwannoma can arise from one of the fine radicles of the facial nerve and present clinically as a primary salivary gland tumor.[468] It is grossly encapsulated, and its microscopic appearance is similar to that of schwannomas elsewhere. Failure to recognize this neoplasm as benign may result in needless sacrifice of the facial nerve.

Adult rhabdomyoma often presents in the soft tissues of the submandibular area, but the gland itself is rarely affected.[469]

Solitary fibrous tumor has been reported in the parotid and in the submandibular gland.[470,471] Its histology and clinical course is similar to that of its soft tissue counterpart.[472]

Sialolipoma is a benign tumor composed of mature adipose tissue and glandular elements, which are probably entrapped.[473]

Granular cell tumor has been reported within the parotid gland.[474]

Sialoblastoma (embryoma) is a term used for an extremely rare, highly cellular epithelial parotid tumor of neonates and infants having an embryonal or "blastomatous" appearance.[475–477] The neoplastic cells typically are reactive for keratin, p63, S-100, and actin. The biologic behavior is difficult to predict on histologic

grounds. Some of the sialoblastomas have recurred locally, several had regional lymph node involvement, and one case resulted in lung metastases.[478]

Salivary gland anlage tumor is another congenital tumor of minor salivary gland type that has been described only in the nasopharynx.[479]

Sarcomas are very rare and need to be distinguished from epithelial, myoepithelial, and melanocytic tumors with a spindle cell pattern.[480] The types described in adults include *malignant peripheral nerve sheath tumor*, *fibrosarcoma*, *synovial sarcoma*, *Kaposi sarcoma*, *angiosarcoma*,[481] *Ewing sarcoma/primitive neuroectodermal tumor* (*PNET*), desmoplastic small round cell tumor,[482] and *undifferentiated malignant fibrous histiocytoma*.[480,483–486] In children, *embryonal rhabdomyosarcoma* can arise in the parotid region and can secondarily invade the gland.[487]

Metastatic Tumors

Most metastatic tumors to this region are centered in intraparotid or submandibular lymph nodes.[488] As the tumor grows, it closely mimics a primary neoplasm of the salivary gland. It should be remembered that the most common malignant tumor in the submandibular and parotid gland region is a metastatic carcinoma in the submandibular or parotid lymph nodes rather than a primary salivary gland carcinoma. The most common types are squamous cell carcinoma (from the upper aerodigestive tract or skin) and malignant melanoma (including the desmoplastic variant).[489–491] Of the distant tumors metastasizing to the major salivary glands, lung, kidney, and breast tumors are the most common.[488,492,493] Other reported sites include prostate and large bowel.[491,494]

General Features of Salivary Gland Tumors

Relative Incidence and Malignancy

Salivary gland tumors are 12 times more frequent in the parotid than in the submandibular gland, a difference that cannot be explained on the basis of gland size alone. The majority are benign and largely represented by the pleomorphic adenoma.[495,496]

In a series of 2632 salivary gland tumors reported by Eneroth,[497] the incidence of malignancy was 17% for the parotid gland, 38% for the submandibular gland, and 44% for the palate. The incidence of malignancy is highest for tumors of the sublingual gland and benign sublingual gland neoplasms are exceedingly uncommon.[495]

Most tumors of major salivary glands are unilateral and single. Bilaterality and multiplicity are common only in Warthin tumor but can also be seen with pleomorphic adenoma and acinic cell carcinoma.[498] Acinic cell carcinoma is the most common bilateral salivary gland malignancy.

Tumors of minor salivary glands can be found anywhere in the oral cavity, including the hard and soft palate, cheek, gingiva, tonsillar area, and tongue.[499] Their frequency seems to be approximately proportional to the amount of normal glandular tissue in this area, which may explain their marked predilection for the hard palate. They can also occur in the lip (particularly upper lip), nasal cavity and paranasal sinuses, ear, jaw, pharynx, larynx, trachea, and bronchi. Furthermore, tumors of the salivary gland type may arise from a variety of glandular structures, particularly breast and sweat glands.

Finally, salivary gland tumors of various types have been described as arising from lymph nodes located in or around the parotid gland, presumably on the basis of ectopic salivary tissue. Warthin tumor is by far the most common type, but examples of sebaceous lymphadenoma, pleomorphic adenoma, basal cell adenoma, acinic cell carcinoma, and mucoepidermoid carcinoma have also been reported.[197,500]

Little is known about the etiology of salivary gland tumors, and high-risk populations have not been identified except for the rare lymphoepithelioma-like carcinoma.[501] An increased incidence of benign mixed tumors and other neoplasms has been observed following therapeutic childhood irradiation,[502,503] and a possible increase in carcinomas (particularly of mucoepidermoid type) has been noted among atomic bomb survivors.[504]

In children, the most common salivary gland tumor is benign mixed tumor, but the proportion of malignant tumors is higher than in adults. Among the malignant neoplasms, mucoepidermoid carcinoma, adenoid cystic carcinoma, and acinic cell carcinoma are the most common.[80,505–507]

Clinical Diagnosis

Benign tumors of the salivary glands usually can be distinguished from the high-grade malignant varieties on the basis of their clinical and gross characteristics. The presence of facial nerve paralysis is almost diagnostic of malignancy. These criteria do not apply for the low-grade acinic cell carcinomas and mucoepidermoid carcinomas because their clinical presentation is usually indistinguishable from that of benign neoplasms. The reverse also may be true, although only in rare cases. Warthin tumor, for instance, may be clinically thought to be malignant because of its adherence to the skin.

Staging

A clinical staging system using the TNM classification scheme for major salivary gland tumors has been established. It is based on: size of the primary tumor, local extension with involvement of adjacent structures (bone, skin, ear canal, facial nerve, skull base, pterygoid plates, carotid artery), involvement of the regional lymph nodes (number, size, and laterality), and the presence or absence of distant metastases. Importantly, extraglandular extension is based on gross or clinical evidence and not microscopic evidence alone. Salivary gland carcinomas of minor salivary glands are staged according to the site from which they arise.

Biopsy and Cytology

Tumors of the submandibular gland are usually treated by removal of the gland without previous biopsy. For tumors of the parotid glands, several choices are available depending on the size and location of the tumor, clinical features, and expertise of the pathologist. Tumors involving the superficial parotid lobe lacking clinical features of malignancy can be properly handled by a superficial lobectomy with frozen section, any subsequent therapy depending on the diagnosis of the frozen section. Obviously malignant tumors with skin invasion can usually be diagnosed with a small incisional biopsy and treated accordingly. Other options are core needle biopsy and fine-needle aspiration. Although the former usually provides diagnostic material, the possibility of implantation along the needle track and the difficulty sometimes encountered in the differential diagnosis (particularly among adenoid cystic carcinoma, monomorphic adenoma, and benign mixed tumor) have resulted in a less than enthusiastic response from clinicians and pathologists. Instead, fine-needle aspiration has been used successfully by several European institutions (particularly the Karolinska Institute in Sweden) and has now become widespread in the United States (Figs. 6.45 and 6.46). The overall accuracy rate has been greater than 90% in most reported series.[508,509] The fine-needle aspiration procedure can induce necrotic and reparative changes in the tumor, particularly if composed

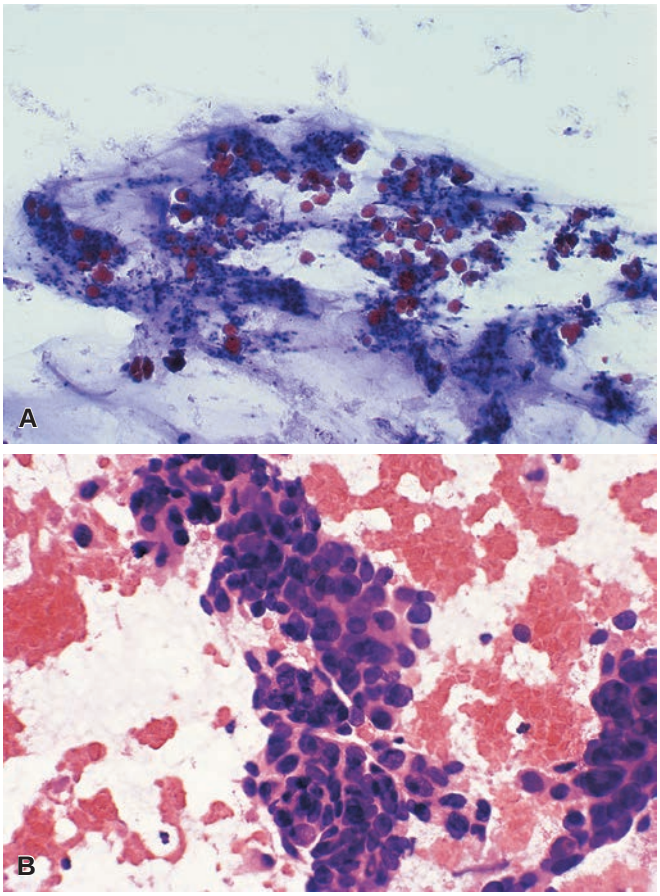

Figure 6.45 **A,** Fine-needle aspiration specimen from a benign mixed tumor of parotid. Clusters of benign-appearing epithelial cells are seen against a bluish myxoid matrix. Tyrosine-rich crystals are also present. **B,** Fine-needle aspiration of mucoepidermoid carcinoma of parotid gland. Most of the cells are of the so-called third cell type, and some exhibit focal squamous differentiation. (**A,** Courtesy of Dr. Maureen Zakowski, Memorial Sloan-Kettering Cancer Center.)

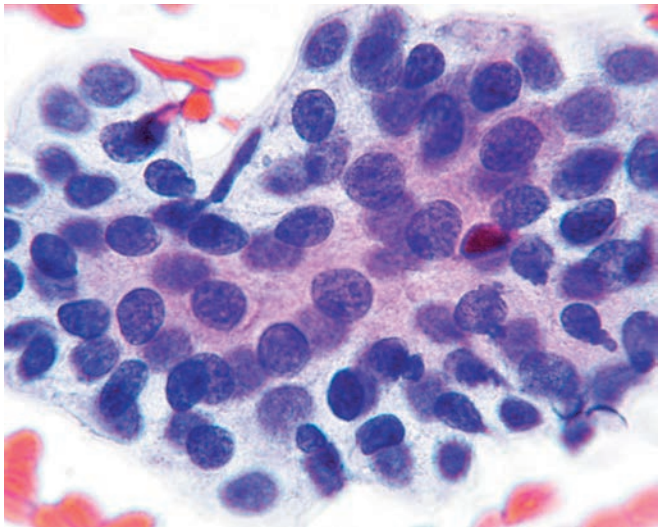

Figure 6.46 Typical appearance of adenoid cystic carcinoma on fine-needle aspiration. The nuclei are small and hyperchromatic. There is a pink amorphous basement membrane–like material, which corresponds to the "cylinders" seen in the histologic sections.

of oncocytes[510]; however, the subsequent microscopic evaluation of the case is not significantly compromised.[511]

Frozen Section

Intraoperative examination of salivary gland tumors is an accurate procedure that can help the surgeon determine the extent of the surgery needed, particularly for parotid neoplasms.[512,513] Obviously, the usefulness of this procedure depends on the expertise of the pathologist in providing accurate diagnoses and the wisdom of the surgeon in applying this information.[514]

Treatment

The extent of surgical treatment of parotid tumors is determined by their microscopic type, histologic grade, and the anatomic peculiarities of the parotid gland, particularly its intimate relationship with the facial nerve.[515,516]

Fortunately, most parotid pleomorphic adenomas arise from the superficial lobe, so a superficial or partial parotidectomy with preservation of the nerve can be performed; actually, the nerve can be preserved in selected cases even if the entire gland is removed.[517]

Most low-grade malignant tumors of mucoepidermoid or acinic cell type can be treated in a similar fashion. If the carcinoma is advanced and/or high grade, total parotidectomy with sacrifice of the facial nerve is usually necessary. If there is clinical evidence of nodal involvement, this procedure needs to be coupled with selective or radical neck dissection. Elective wide dissection should be considered in malignant tumors that are of high grade and/or larger than 4 cm.[518]

The surgical treatment of submandibular tumors, whether benign or malignant, is total removal of the gland. The recurrence rate of carcinomas of this particular gland is relatively high because of the close relation of the gland to the mandible.

Patients who develop postoperative recurrence of high-grade malignant salivary gland tumors do poorly; most have a relatively short survival, and subsequent treatment is effective in only one of four cases.

Radiation therapy has been used as the primary form of therapy in inoperable tumors and as a postoperative modality in cases selected on the basis of the microscopic features and surgical procedure.[519,520] There is evidence that this may result in a decrease in the incidence of local recurrence.[521–523]

Prognosis

The prognosis of salivary gland tumors is determined by the clinical staging, location, and microscopic features (Fig. 6.47).[524–527] Malignant tumors of the submandibular gland have a higher incidence of recurrence and metastases than parotid tumors of the same type.[528,529] For adenoid cystic carcinoma, the prognosis is best when located in the palate, intermediate when in the parotid gland, and worst in the submaxillary gland. For parotid malignant tumors, the presence of facial nerve paralysis is an ominous prognostic sign. In regard to microscopic types, the prognosis is best for the low-grade variants of mucoepidermoid and acinic cell carcinoma and worst for the high-grade variants of these tumors and for adenoid cystic carcinoma, malignant mixed tumor, salivary duct carcinoma, and squamous cell carcinoma. Additional prognostic parameters are discussed in connection with the respective tumor types.

Amplification of *HER2* oncogene[530] and p53 oncoprotein expression[531] have been claimed to correlate with aggressive behavior, but it is not clear that these parameters represent independent prognostic determinators.[142,532,533]

Tumors and tumorlike conditions, *273*

Introduction

Nearly all the diseases that can involve the ear also occur in other sites of the body. However, some of these diseases either have a predilection for the ear or pose special problems when occurring at this site. Only the features of these lesions as they pertain to their location in the ear will be discussed here. The general features of the various entities are dealt with in the respective chapters.

The reader is referred to the specialized books on the subject for an authoritative discussion of the specific diseases of this structure.[1–4]

Normal Anatomy

The ear is divided into the external, middle, and inner segments. The external ear consists of the auricle (pinna) and the external auditory canal, which is further divided into an outer (cartilaginous) portion and an inner (osseous) portion. Microscopically, both the auricle and the canal are covered by skin that differs little from that of the skin elsewhere, except for the fact that in the inner half of the canal the epidermis is very thin and lacks rete pegs. Adnexal structures are present in both areas; they are represented by hair follicles, sebaceous glands, and eccrine sweat glands in the auricle and by hair follicles, sebaceous glands, and a special type of apocrine sweat gland (known as *ceruminous glands*) in the canal, most of which are located in the outer third of this structure.

The inner portion of the canal is separated from the middle ear by the *tympanic membrane*, a thin fibrous structure lined by an attenuated layer of keratinizing squamous epithelium on the outer surface and by a single layer of cuboidal cells on the inner surface.

The middle ear (tympanic cavity) contains the three auditory ossicles (malleus, incus, and stapes); it connects with the pharynx through the eustachian tube and with the mastoid cavity and its contiguous pneumatic spaces. The middle ear proper and the mastoid are lined by a layer of flat epithelium; the eustachian tube is covered by tall ciliated epithelium, with smooth transitions between the two types.[5,6]

The inner ear, which is located in the medial portion of the temporal bone, contains the *cochlea* and the *vestibular labyrinth*. These structures are supplied by the eighth cranial nerve, which enters the region through the internal auditory canal together with the seventh nerve. The vestibular labyrinth includes the blind *endolymphatic sac*, which is located in the middle of the posteromedial plate of the petrous bone. It has an intraosseous *rugose* portion and a *distal* portion that lies within the dura. It is lined by a flat to low columnar epithelium resting on a well-vascularized stroma.[7] The sac is connected to the *utricle* and *saccule* (the two main membranous structures of the vestibule) by the *endolymphatic duct*, which passes across the petrous bone.

Diseases of External Ear

Non-Neoplastic Disorders

Congenital abnormalities of this region are common. *Preauricular sinuses*, *cysts*, and *fistulas* are derived from the first or second branchial clefts.[8,9] They are lined by squamous or respiratory epithelium and often contain lymphoid tissue in the wall. Cartilage and skin adnexa may also be present. Secondary inflammatory features are common.[8,9] The treatment is surgical, and recurrences are common.[10] *Accessory tragi* are unilateral or bilateral nodules present at birth, located anteriorly to the auricle in the pretragal area.[11] Like the previous lesions, they are the expression of a branchial cleft anomaly. Sometimes they are seen as a component of the oculoauriculovertebral syndrome (Goldenhar syndrome).[12] Microscopically they are composed of a covering of skin, numerous tiny, mature hair follicles, and a core of fibrofatty tissue that may contain cartilage.[13] Depending on the relative amounts of these components, these lesions can be variously misdiagnosed as papillomas, fibromas, or soft tissue

Abstract

This chapter reviews normal anatomy and histology of the external, middle, and inner ear compartments. Non-neoplastic and neoplastic pathologies of the external are discussed separately from those of the middle and inner ear.

Keywords

external ear,
middle ear,
inner ear

chondromas. *Ectopic salivary gland tissue* is not uncommon in the region of the middle ear; it can also be found in the external auditory canal.[14]

Keratinous cysts are common in and around the ear. Some are probably developmental anomalies related to the branchial cleft (see preceding discussion), and others are equivalent to those seen elsewhere in the skin and, as such, are either of infundibular hair follicle derivation or of epidermal inclusion type. They are all lined by keratinized squamous epithelium and filled by keratin of epidermal type. Keratinous cysts of pilar type are common in the periauricular area but not in the ear itself.

Cholesteatoma of the external auditory canal is composed of a cystic mass of keratinized squamous epithelium overlying an area of bone sequestration in the inner half of the canal. This rare condition should not be confused with cholesteatoma of the middle ear spaces or with *keratosis obturans*, a disorder characterized by a diffuse acanthosis and hyperkeratosis of the skin of the canal associated with underlying chronic inflammation.[15]

Malignant external otitis, also known as necrotizing granulomatous otitis, is usually caused by *Pseudomonas aeruginosa* and affects mainly elderly patients who have diabetes. It can also be due to fungi, particularly *Aspergillus*. Microscopically, it is characterized by a necrotizing inflammatory reaction involving skin, soft tissue, cartilage, and bone, with invasion of the skull base.[16]

Chondrodermatitis nodularis chronica helicis (Winkler disease) usually involves the upper portion of the helix in older patients, but it can also occur in the antihelix and in younger individuals. Clinically, it presents as a painful, small, round nodule, often covered by a crust.[17] It is often thought clinically to be squamous cell carcinoma or actinic keratosis. Microscopically, there is marked hyperkeratosis and parakeratosis, acanthosis, and hyperplasia of the epidermis, which can reach pseudoepitheliomatous degrees (Fig. 7.1). The center is usually ulcerated and covered by granulation tissue. The underlying inflammation reaches the perichondrium and is characterized by a mononuclear infiltrate and vascular proliferation. The latter may be so pronounced as to simulate a vascular neoplasm, particularly glomus tumor.[18]

Idiopathic pseudocystic chondromalacia results from degeneration of the auricular cartilage and is more commonly seen as a painless localized ear enlargement (sometimes bilaterally) in young males. Grossly, a cystic formation within the external auricular cartilage is filled with a watery fluid. Microscopically, the cyst has no lining, and there is no associated inflammation.[19]

Relapsing polychondritis is characterized by episodic painful inflammation of cartilage, most commonly in the outer and inner ear, nose, costochondral junctions, a variety of joints, and sometimes the cartilage of the respiratory tract.[20] Aortic insufficiency is a life-threatening complication. The external ear is affected in almost 90% of the patients, and it represents the initial site of involvement in one-third of the cases.[21]

Microscopically, there are degenerative changes in the cartilage (decrease in basophilic staining, loss of lacunae, and eventual replacement by collagen) and an inflammatory infiltrate that is neutrophilic initially and mononuclear in the late stages.[21] The etiology is unknown, but the detection in these patients of antibodies to type II collagen suggests an autoimmune mechanism.[22,23]

Nodular fasciitis can involve the external ear region; its morphologic appearance is similar to that seen at other soft tissue sites.

Localized disorders of the external ear formed by the accumulation of extracellular material include *keloid*, localized *amyloidosis*, uric acid tophi of *gout*, *elastotic nodules*, and *collagenous papules*. Elastotic nodules are small papules and nodules most commonly noted on the antihelix as a result of actinic damage. Microscopically, they are composed of dermal clumps of elastic tissue.[24] Collagenous papules are smooth, firm, small papules, located bilaterally on the inner aspects of the aural pinnae and, in rare cases, in the external auditory canal. Microscopically, there is a dense collagenous mass in which dilated vessels and scattered fibroblasts are identified.[25]

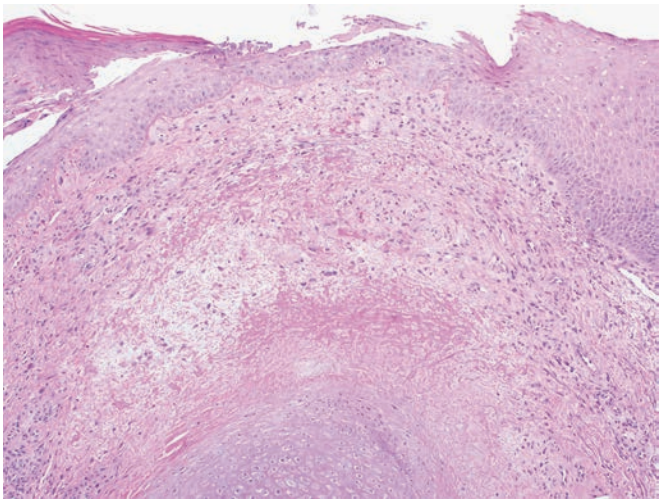

Figure 7.1 Chondrodermatitis Nodularis Helicis. There is fibrosis and vascular proliferation in the dermis, accompanied by pseudoepitheliomatous hyperplasia of the overlying epithelium. The perichondrium demonstrates fibrinoid degeneration.

Tumors and Tumorlike Conditions

Keratotic Lesions

The external ear is a common site for *seborrheic keratosis* and *actinic keratosis*. Some ear lesions designated as fibroepithelial papillomas or squamous papillomas are probably variants of seborrheic keratosis. Other *squamous papillomas* present as branching complex polypoid structures in the external auditory canal. Additional types of keratotic lesion that can occur at this site are *keratoacanthoma*, *inverted follicular keratosis*, *verruca vulgaris*, and *molluscum contagiosum*. It has been estimated that 8.5% of all keratoacanthomas involve the skin of the external ear.[26]

Basal Cell Carcinoma

Basal cell carcinoma is a common tumor of the auricle and external auditory canal, the ratio between the two sites being 5:1. In the auricle, basal cell carcinoma predominates over squamous cell carcinoma (although not as much as in the rest of the head and neck area[27]), the ratio being reversed in the external auditory canal. The microscopic features and behavior of this lesion are described in Chapter 3. If untreated, basal cell carcinomas of the canal may extend into the middle ear, mastoid, or even the cranial cavity.[28] These tumors may be treated with surgery or radiation therapy, the choice depending on the size and location.

Squamous Cell Carcinoma

Squamous cell carcinoma of the external ear comprises one-fourth of all squamous cell cutaneous carcinomas of the head and neck

Figure 7.2 This squamous cell carcinoma of the auricular concha required the removal of the entire external ear.

region.[29] Most patients are elderly. The tumors are more common in the auricle (particularly the helix) than in the canal. Many of the latter present clinically with symptoms of otitis.[30] Grossly and microscopically, they do not differ significantly from those seen elsewhere in sun-exposed skin (Fig. 7.2). Some are of the *adenoid (pseudoglandular)* variant, others belong to the *verrucous* type, and still others to the *spindle cell* (*sarcomatoid*) variant.[31,32] The pattern of local spread varies depending on the initial location of the tumor. Tumors of the helix spread initially along the helix and then anteriorly to the antihelix and posteriorly to the posterior surface of the ear; tumors of the antihelix spread concentrically; tumors of the posterior surface of the ear spread to the helix and along that structure.[33] Tumors at high risk for regional lymph node involvement are those with a depth of invasion greater than 8 mm or a depth of invasion between 2 and 8 mm in conjunction with destructive cartilage invasion, lymphovascular invasion or a "noncohesive" invasive front.[34] Tumors of the canal tend to invade bone and often destroy the tympanic membrane to penetrate into the middle ear. Like their basal cell counterparts, squamous cell carcinomas can be treated by either surgery (primary resection with or without neck dissection) or radiation therapy, the choice being determined by the size, location, and degree of invasiveness of the lesion.[35]

The prognosis is much better for tumors of the auricle than for those in the canal, a fact that is at least partially related to the earlier diagnosis of the former type of tumor.[33] In one series, tumor-related deaths occurred in only 1 of 17 patients with tumors of the auricle but in 11 of 21 patients with tumors of the canal.[36] Survival is directly correlated with tumor stage. The prognosis is particularly ominous for tumors of the inner portion of the canal exhibiting deep involvement of the temporal bone and beyond.[37]

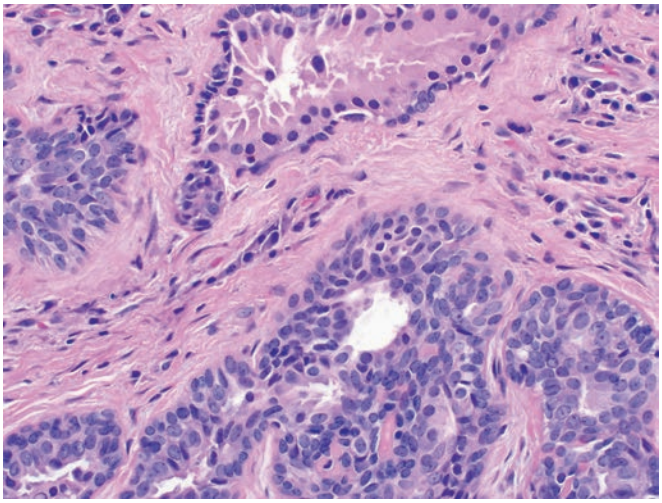

Figure 7.3 Ceruminous Adenoma. A benign biphasic epithelial proliferation is seen adjacent to normal ceruminous gland *(top center)*.

Adnexal Tumors

Almost any type of adnexal tumor can involve the skin of the external ear. One of the most common is *pilomatrixoma*, often seen in children and sometimes confused microscopically with basal cell carcinoma. Reported cases of adnexal tumors of this region include other types of *hair-follicle neoplasms*[38] and *sebaceous adenoma*.[39]

Adnexal tumors of the external auditory canal are generally assumed to be of ceruminous gland origin and include both benign and malignant neoplasms. The clinical presentation is similar, although the malignant tumors are more often painful and ulcerated.[40] Four major categories are recognized.

Ceruminous adenoma (ceruminoma) is sharply demarcated but not encapsulated. Variously sized glandular formations arranged in a back-to-back proliferation and lined by apocrine cells are seen microscopically (Fig. 7.3).[41] A myoepithelial layer can be discerned at the base. Mitotic figures, pleomorphism, necrosis, and invasiveness are lacking. Presence of cerumen pigment and positivity for CK7 and p63 are helpful in the differential diagnosis with other neoplasms of the region.[42]

Benign mixed tumor (pleomorphic adenoma, chondroid syringoma) has an appearance similar to that of its cutaneous or salivary gland counterpart. In some cases, the epithelial component exhibits apocrine features similar to those of adenoma.[43]

Syringocystadenoma papilliferum is morphologically equivalent to the tumor occurring elsewhere in the skin, particularly in the scalp. Connection with the surface of the canal is characteristic.

Ceruminous adenocarcinoma may be well differentiated and therefore difficult to distinguish from adenoma. The presence of more than occasional mitotic activity, pleomorphism, the absence of a myoepithelial layer, necrosis, and invasiveness are the main identifying features.[44] The main problem with this tumor is local recurrence; nodal or distant metastases are exceedingly rare.

Some adenocarcinomas of ceruminous gland origin, not surprisingly, are clinically and morphologically identical to salivary gland carcinomas. Adenoid cystic carcinoma and mucoepidermoid carcinoma are the most common histologic subtypes. It is important to exclude extension into the external auditory canal from an adjacent parotid gland primary before making a diagnosis of primary ear salivary gland carcinoma.

Adenoid cystic carcinoma has an appearance similar to that of its more common equivalent in the salivary glands (Fig. 7.4). Like

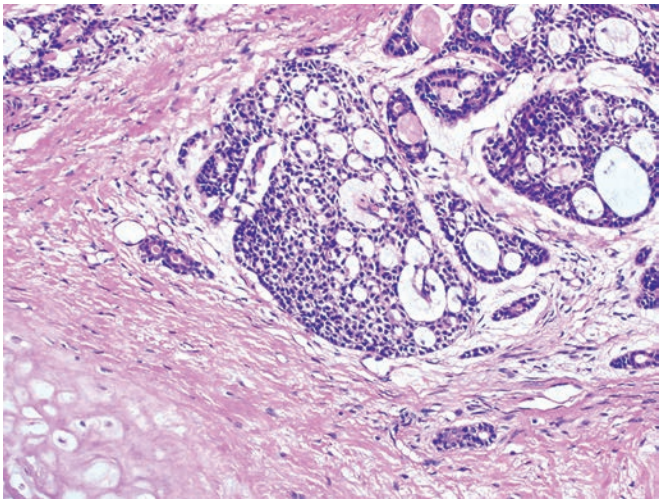

Figure 7.4 Adenoid cystic carcinoma growing beneath the epidermis of the external ear canal and infiltrating close to auricular cartilage *(bottom left)*.

the latter, it has a great tendency for local (including perineurial) invasion and distant (rather than nodal) metastases, particularly to the lungs but also to brain.[45] The death rate is approximately 50%. *Mucoepidermoid carcinomas* arising in the ear are typically low-grade but are otherwise similar to those occurring in the salivary glands.

The differential diagnosis of these tumors includes direct invasion from so-called adenomas and paragangliomas of the middle ear and adnexal tumors of the auricle. It is particularly important to distinguish the benign eccrine dermal cylindroma arising from the conchal portion of the auricle from adenoid cystic carcinoma arising from the canal.

Melanocytic Tumors

Melanocytic nevi of any of the known microscopic types can occur in the auricle or, less commonly, in the canal.[46] They may show some disturbing morphologic features, similar to those often seen in the acral, flexural, and genital areas (so-called nevi of special sites).[46]

Malignant melanomas of the external ear comprise approximately 10% of all melanomas of the head and neck region.[47] Nearly all are located in the auricle rather than in the canal.[48] The most common type is superficially spreading. Nodal metastases are to the upper cervical, intraparotid, or occipital groups, depending on the exact location of the tumor in the auricle.

Other Tumors

Osteoma of the external auditory canal presents as a solitary pedunculated osseous mass attached by a narrow pedicle to the tympanosquamous or tympanomastoid suture line of the temporal bone. Microscopically, it is formed by mature lamellar bone containing bone marrow and covered by keratinized squamous epithelium.[49]

Exostoses are sessile, often multiple and bilateral masses that seem to be particularly common in swimmers. Microscopically, the appearance is similar to that of osteoma except for the absence of bone marrow spaces.[49]

Cutaneous myxomas of the external ear (superficial angiomyxoma) occur in patients with Carney complex, sometimes bilaterally. Microscopically, they are nonencapsulated circumscribed nodules composed of scattered stellate and spindle cells set in a myxoid, capillary-rich matrix.[50] A mixed inflammatory infiltrate with a predominance of neutrophils is common and helps to distinguish this lesion from other superficial myxoid tumors. Entrapped epithelial buds, cords, and cysts are seen in approximately 25% of cutaneous myxomas. Although benign, there is a propensity for recurrence.

Vascular tumors and tumorlike conditions include *vascular leiomyoma (angioleiomyoma)*,[51] *epithelioid (histiocytoid) hemangioma* (also known as angiolymphoid hyperplasia with eosinophilia and having a predilection for the skin of the ear, external auditory canal, and periauricular region[52]), and the related *epithelioid angiomatous nodule*.[53] The neoplastic versus inflammatory nature of the last two entities remains debatable.

Other primary tumors of the external ear include *Merkel cell carcinoma*[54,55] and various types of soft tissue neoplasm, including *rhabdomyosarcoma*, *myxoid chondrosarcoma*,[56] and *peripheral nerve sheath tumors*.[57] As already mentioned, the canal can be secondarily involved by tumors of the middle ear or salivary gland.

Exceptionally, *malignant lymphoma* presents initially as an ear lesion.[58]

Diseases of Middle and Inner Ear

Non-Neoplastic Disorders

Developmental anomalies of the middle ear include the presence of brain tissue (as a manifestation of heterotopia or encephalocele)[59] and ectopic salivary gland tissue (sometimes designated as choristoma).[60]

Inflammatory polyp (aural polyp, otic polyp) arises in the middle ear on the basis of a chronic otitis media but often presents in the external auditory canal following perforation of the tympanic membrane. Microscopically, the appearance is that of chronically inflamed stroma, typically with features of granulation tissue. The overlying mucosa may be of columnar respiratory type (consistent with its middle ear origin) or squamous (as a result of metaplasia). Cystically dilated glands may be present in the stroma.

Inflammations of the middle ear (otitis media) are usually of a nonspecific nature microscopically.[61] Although no glands are present in the subepithelial connective tissue of the middle ear, surface invaginations induced by chronic inflammation can result in a pseudoglandular appearance when cut in cross section. This structure can also be involved by specific conditions, such as tuberculosis, aspergillosis, malakoplakia, and granulomatosis with polyangiitis (Wegener).[62,63] *Cholesterol granulomas* can be seen in any inflammatory process involving the middle ear that results in microhemorrhage. These result from a foreign body giant cell reaction to cholesterol crystals that derive from the breakdown of extravasated red blood cells. Morphologically, they appear as empty acicular spaces surrounded by a giant cell reaction and nonspecific chronic inflammation with fibrosis, fresh hemorrhage, and hemosiderin-laden macrophages (Fig. 7.5). They are commonly seen in association with other lesions such as cholesteatoma.

Tympanosclerosis results from dystrophic calcification of the tympanic membrane and/or middle ear mucosa secondary to recurrent bouts of otitis media. Histologically, there is dense mineralization of connective tissues which can undergo ossification. Severe cases can result in ossicular fixation and conductive hearing loss.

Cholesteatoma usually presents during the third or fourth decade, but it may appear at any age. It is the result of chronic otitis media and may involve the middle ear, peritympanic space, mastoid cavities, and petrous portion of the temporal bone. Grossly, the appearance is that of a cyst filled with a granular waxy material. Microscopically, the membrane that bounds the lesion peripherally

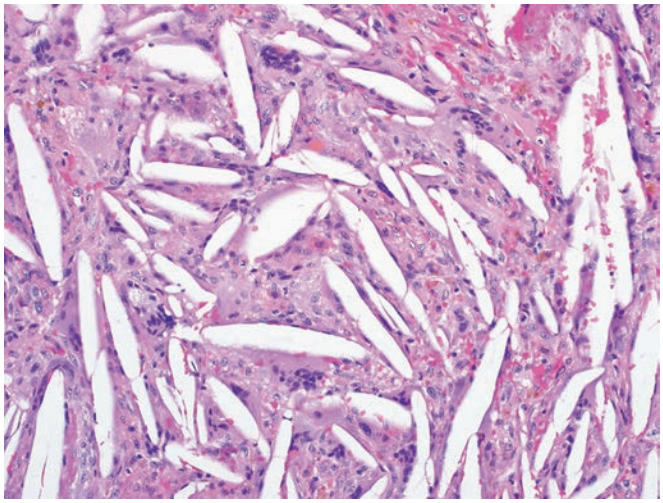

Figure 7.5 Cholesterol granuloma composed of inflammation with hemorrhage and cholesterol crystals with foreign body giant cell reaction.

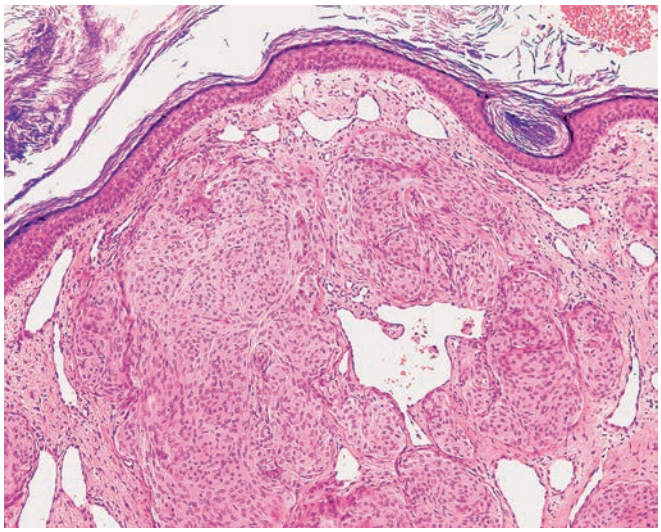

Figure 7.6 Meningioma of Ear. The appearance is identical to that of its counterpart in the central nervous system. Note the overlying cholesteatoma with middle ear epithelium replaced by keratinizing squamous mucosa.

is made up of keratinizing squamous epithelium, and the content is composed of keratin squames. Chronic inflammatory cells, cholesterol clefts, and foreign body–type giant cell granulomas are common. It should be noted that although *cholesterol granulomas* are often seen in the middle ear as a consequence of cholesteatoma, they may also occur independently from it as a result of hemorrhage or otitis media.

The pathogenesis of cholesteatoma is controversial; origin of the squamous epithelium from metaplasia of middle ear mucosa, migration from the external auditory canal, migration from the external surface of the tympanic membrane following a perforation, or retraction of the tympanic membrane into the middle ear have all been considered.[64] In the congenital form, the disease is thought to be the result of inclusions of squamous epithelium in the temporal bone. The matrix-degrading cysteine proteinase cathepsin K may be involved in the bone erosion often seen in this entity.[65]

The treatment is surgical and aimed at removal of the entire lesion, including the limiting membrane.[66]

Otosclerosis is a disorder of abnormal bone remodeling of unknown etiology. Genetic factors are clearly involved, but measles virus infection and autoimmunity may play contributory roles.[67,68] The typical and apparently unique site of involvement is the temporal bone. It is characterized by an initial bone resorption (otospongiosis) followed by bone production (otosclerosis).[69] This results in the formation of Paget disease–like woven bone with prominent cement lines.[70] The disease causes hearing loss because of fixation of the stapes footplate in the oval window. Usually, the only specimens received in the pathology laboratory are portions of the stapes head and crura, which are almost always unaffected by the disease.[70] Microscopic studies done on temporal bones at autopsy have revealed cases of "histologic otosclerosis" that were asymptomatic, but the incidence of this finding seems much lower (approximately 2.5%) than previously claimed.[71]

Tumors and Tumorlike Conditions

Paraganglioma

Paraganglioma of the glomus jugulare or glomus tympanicum is the most common neoplasm of the middle ear.[72] The general features of this tumor are discussed in Chapter 29. It can be found in the jugular bulb area, within the middle ear, in the external auditory canal, or around the eustachian tube.[73] In contrast to paragangliomas of other sites, those of the middle ear region have a marked predilection for females.[74] They can be familial, bilateral, or associated with paragangliomas elsewhere. Clinically, the typical presentation is that of a red mass protruding behind the tympanic membrane or extending in the canal. Profuse bleeding may be encountered at the time of biopsy. This tumor has a tendency to infiltrate adjacent bone; a few cases associated with distant metastases are on record. The initial treatment usually takes the form of local excision, but the incidence of local recurrence is greater than 50%.[74] Radiation therapy has also been used as an adjunct to surgery or as the primary treatment.[75]

Meningioma

Approximately 6% of all meningiomas arise from the surface of the petrous bone, from which they may invade this structure and reach the middle ear. In addition, meningiomas seemingly localized to the middle ear have been described.[76] The tumor may involve the external ear canal, mastoid cavity, or jugular fossa.[77] The microscopic appearance is described in Chapter 43 (Fig. 7.6). The treatment is surgical. The prognosis is substantially better for meningiomas limited to the middle ear than for those reaching this site through invasion of the petrous bone.

Schwannoma (Acoustic Neuroma)

The tumor traditionally known as acoustic neuroma is simply a schwannoma arising from the eighth (or sometimes the seventh) nerve, which grows within the internal auditory canal and can reach the middle ear. These are often submitted to the pathology department as tumors of the cerebello-pontine angle. Its features are described in Chapter 41. Nearly 90% of acoustic neuromas are solitary and not associated with neurofibromatosis 2 (NF2), whereas 5% are bilateral and not associated with NF2 and 4% are NF2 related.[78] The treatment is complete surgical resection, which is associated with a very low recurrence rate.

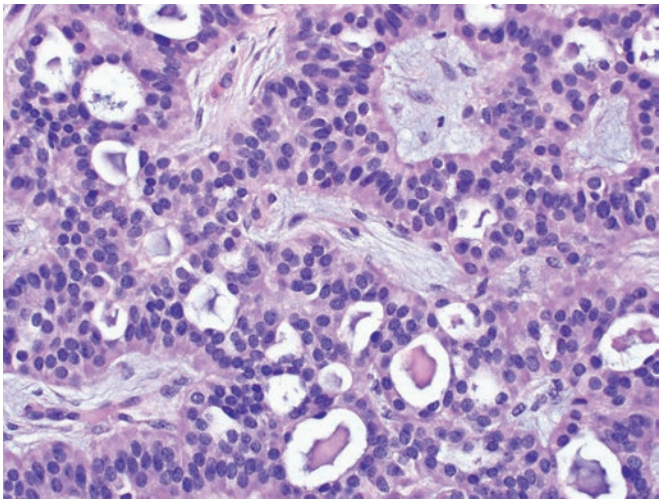

Figure 7.7 So-Called Middle Ear Adenoma. This tumor is closely related and perhaps identical to carcinoid tumor of the ear.

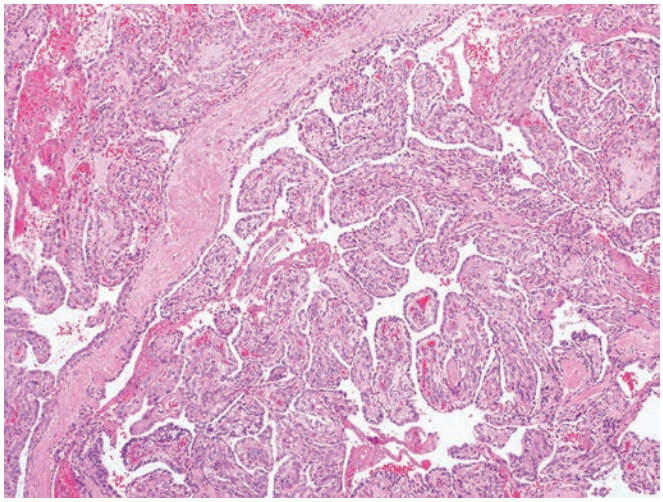

Figure 7.8 Endolymphatic Sac Tumor. The tumor forms papillary and glandular structures lined by clear cells. The papillary structures have well-vascularized connective tissue cores.

Middle Ear Adenoma (Carcinoid Tumor, Neuroendocrine Adenoma)

Middle ear adenoma is the term traditionally used for a distinctive tumor of the middle ear, mostly seen in patients between 20 and 40 years of age. Grossly, the lesion is grayish white and firm, not as vascular as paraganglioma, and relatively well circumscribed. Microscopically, the pattern of growth may be solid, glandular, or trabecular (Fig. 7.7).[79] The tumor cells are uniform, cuboidal or cylindrical, with a moderately abundant acidophilic cytoplasm that sometimes acquires plasmacytoid features.[80] Mitoses are exceedingly rare, pleomorphism is minimal, and necrosis is absent.

Histochemically, there may be intraluminal positivity for mucin and intracytoplasmic argyrophilia. Ultrastructurally, the tumor cells exhibit desmosomes and microvilli; in addition, membrane-bound dense-core granules are present in many of the tumor cells.[81] Immunohistochemically, positivity for keratin, neuroendocrine markers, and lysozyme has been described.[82,83]

The histogenetic problem posed by middle ear adenoma mainly concerns its possible neuroendocrine nature and relationship with the reported cases of **carcinoid tumors** of the middle ear.[84] The latter tumors have many cytoarchitectural features in common with middle ear adenoma but also exhibit undeniable evidence of neuroendocrine differentiation. Some authors like to view middle ear adenomas and carcinoid tumors as separate entities and regard the former as tumors of the middle ear mucosa.[83,85] However, a large number of studies performed in recent years have convincingly shown that these two tumors merge imperceptibly, in the sense of showing various degrees of combined exocrine and neuroendocrine differentiation.[86–90] As such, they could be regarded as analogous to adenocarcinoids or amphicrine neoplasms of other sites and are now all simply regarded as "middle ear adenomas." The presence of a neuroendocrine component is supported by the previously mentioned argyrophilia, demonstration of dense-core granules ultrastructurally, and reported immunoreactivity for neuron-specific enolase, chromogranin, synaptophysin, serotonin, and numerous peptide hormones (such as pancreatic polypeptide, glucagon, cholecystokinin, and leucine-enkephalin).[87] Rare cases associated with systemic manifestations (carcinoid syndrome) are also on record.

The treatment of choice of middle ear adenoma/carcinoid tumor is surgical excision. The prognosis is excellent, with only an occasional example of local recurrence.[87,89,90]

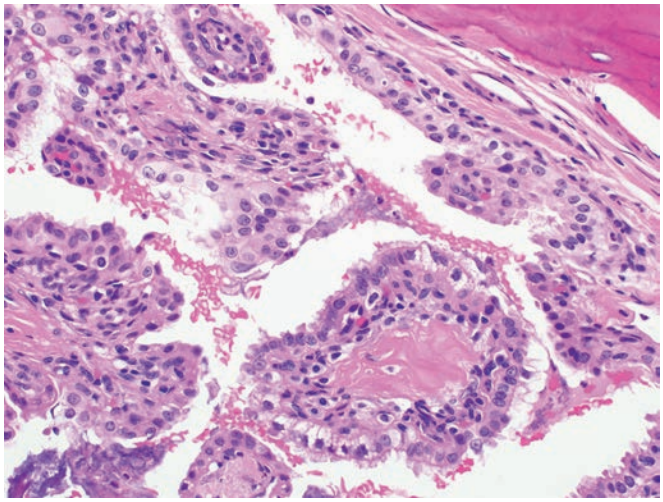

Figure 7.9 Endolymphatic Sac Tumor. The gland and papillary structures are lined by a monolayer of cytologically bland cells with clear cytoplasm, resembling the normal endolymphatic sac organ.

Endolymphatic Sac Tumor (Aggressive Papillary Middle Ear Tumor, Heffner Tumor)

Adenocarcinoma of the middle and inner ear has been a somewhat confusing and controversial entity.[91,92] The term has sometimes been used for papillary adenocarcinomas presenting in the middle ear and for papillary adenocarcinomas and "adenomas" arising in the temporal bone (aggressive papillary tumor of the temporal bone). Most of these lesions are now accepted as and referred to as endolymphatic sac tumors (ELSTs). ELST is an uncommon, locally aggressive but nonmetastasizing neoplasm arising from the endolymphatic sac of the petrous portion of the temporal bone. Most occur in adults and present with hearing loss often associated with tinnitus and vertigo. This is a low-grade papillary and glandular adenocarcinoma (Fig. 7.8) composed of uniform cuboidal cells with clear to acidophilic cytoplasm forming papillary structures that rest on a vascular stroma (Fig. 7.9). Cystic dilation of the glands often occurs, leading to a follicle-like appearance that is very reminiscent of that seen in thyroid tumors.[93–95] Tumors with prominent cytoplasmic clearing

simulate metastatic renal cell carcinoma. They stain positive for cytokeratin with variable GFAP and S-100 staining. They are negative for thyroglobulin and TTF-1. Gaffey et al.[96] who originally referred to this neoplasm as *aggressive papillary middle-ear tumor* (APMET), favored an origin from middle ear/mastoid epithelium. In a subsequent article, they showed that this lesion can occur in the setting of von Hippel–Lindau (VHL) disease, sometimes in association with a microscopically similar tumor in the broad ligament of presumed wolffian (mesonephric) origin.[97,98] APMET was shown to be closely related if not identical to the *low-grade adenocarcinoma of probable endolymphatic sac origin* reported by Heffner[99] and referred to by some as *Heffner tumor*.[100,101] Most of these are now accepted to be of endolymphatic sac origin with a strong association with VHL disease. Patients with ELSTs should be screened for VHL disease, and patients with the syndrome should be screened for ELSTs. Cases of this tumor occurring in the setting of VHL disease are typically bilateral and are associated with germline mutation of the *VHL* gene combined with loss of function of the wild-type allele through genetic deletion.[102] Interestingly, mutations or allelic deletions of the same gene have also been found in most sporadic tumors.[103,104]

ELST has a tendency to invade bone and the middle ear, from which it may spread to the cranial cavity, especially the posterior fossa. The treatment is surgical, but achievement of local control is difficult and associated with recurrences.[96]

Squamous Cell Carcinoma

Squamous cell carcinoma of the middle ear is exceedingly uncommon and typically presents in older patients with a history of long-standing ear discharge, which may be hemorrhagic and is usually associated with pain and hearing loss.[105] Rarely, the process is bilateral.[106] An etiologic role for chronic otitis media has long been suspected.[107] Grossly, the tumor fills the middle ear spaces, from where it may invade the bony walls of the mastoid ear cells, the bone septum that separates the ear from the carotid canal, the internal auditory meatus, the eustachian tube, and the external auditory canal. Eventually, it may reach the intracranial cavity and the soft tissues of the neck.[105] Microscopically, the tumor is an ordinary squamous cell carcinoma of various degrees of differentiation; in rare cases, it may be of *verrucous* type. The differential diagnosis includes secondary invasion of the middle ear by squamous cell carcinomas of the external auditory canal and the eustachian tube. The preferred form of treatment is a combination of surgery and radiation therapy. In the series by Michaels and Wells,[105] the 5-year survival rate was 39%.

Rhabdomyosarcoma

Rhabdomyosarcoma of the middle ear occurs almost exclusively in children. At the time of diagnosis, the tumor has often invaded the external canal, mastoid, and meninges.[108] CT scan is the best method to delineate the tumor and to detect intracranial spread. Microscopically, the neoplasms are most often of embryonal type, including the botryoid variety.[109] The microscopic features are described in Chapter 41 (Fig. 7.10). The treatment is a combination of surgery, radiation therapy, and multidrug chemotherapy.[109,110]

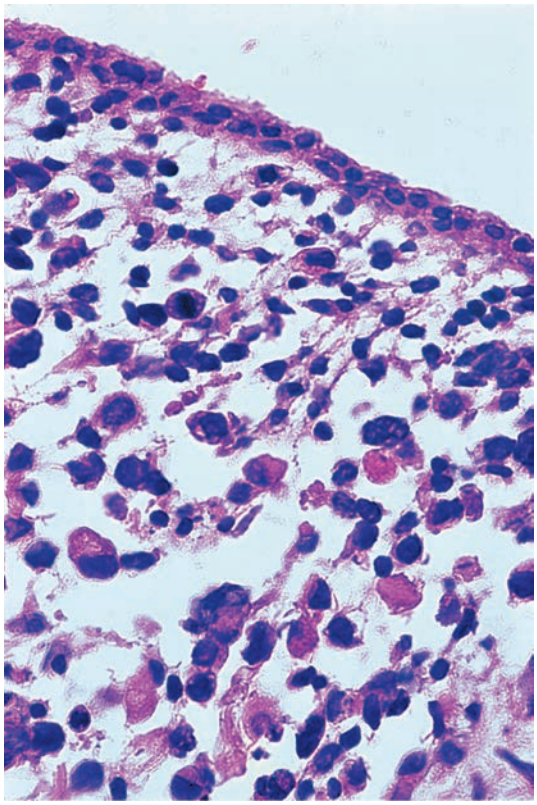

Figure 7.10 Embryonal Rhabdomyosarcoma of the Middle Ear. Neoplastic tumor cells are seen growing beneath a flattened epithelium. Most of the cell population is small, but there are larger elements (rhabdomyoblasts) with more abundant fibrillary acidophilic cytoplasm.

A few cases of rhabdomyosarcoma apparently localized to the external auditory canal have been reported.[109]

Other Primary Tumors

Rare benign primary tumors of the middle ear region include *lipoma*, *hemangioma*, *osteoma*, *ossifying fibroma*, *dermoid cyst* (in the eustachian tube), *teratoma*, and "*glioma*."[111–116] The middle ear can also be involved in cases of *Langerhans cell histiocytosis*.[117,118]

Metastatic Tumors

The temporal bone can be involved by malignant tumors arising elsewhere. This involvement can be in the form of direct extension from tumors of the pharynx, salivary glands, or central nervous system, or as blood-borne distant metastases. In the latter instance, the most common sites of the primary are breast, lung, and kidney.[119,120]

Normal Anatomy and Thyroid Gland Development

The thyroid *anlage* appears in the embryo as a midline structure at the site corresponding to the foramen cecum of the adult tongue. From here, it descends as a component of the thyroglossal duct along the midline to reach its final position in the mid neck.[1] Later, the hyoid bone is formed from the second branchial arch. The thyroglossal duct is usually situated *anteriorly* to this bone and is divided by it into a suprahyoid and an infrahyoid portion. In the normal course of events, the thyroglossal duct is obliterated and disappears, leaving as a vestige the pyramidal lobe in approximately 40% of normal individuals.[2] At the same time, the thyroid *anlage* expands laterally to form the thyroid lobes. Microscopically, cords and plates of follicular cells are formed by the 9th week, small follicular lumina appear by the 10th week, and colloid secretion becomes evident by the 12th week. By the 14th week, the gland consists of well-developed follicles lined by follicular cells and containing thyroglobulin-positive colloid in the lumen.

The development of the thyroid gland is controlled by the coordinated action of specific transcription factors such as TTF-1 (Nkx2-1), TTF-2 (FoxE1), PAX8, HHEX, and NKX2-5. Functional maturation requires the activity of thyrotropin (TSH), of the TSH receptor (TSHr) and of the TSHr downstream effector Gsα. Genetic alterations associated with *thyroid dysgenesis* (a term referring to the spectrum of thyroid organogenetic defects) include those of the TSH receptor gene *(TSHR)* in non-syndromic cases, while the Gsα gene *(GNAS)* and the thyroid transcription factors genes *PAX8*, *TTF-1 (Nkx2-1)*, *TTF-2 (FoxE1)*, and *NKX2-5* are typically associated with syndromes that include thyroid dysgenesis as one of the features.[3,4]

The normal adult thyroid gland is composed of two lobes joined by the isthmus, which lies across the trachea anteriorly, below the level of the cricoid cartilage. It is endowed with a rich lymphatic network, not always evident in hematoxylin and eosin (H&E) sections but clearly evident with the D2-40 immunostain.[5] The lymph vessels coalesce in the subcapsular region to give rise to collecting trunks that drain into the following nodes: (1) pericapsular; (2) internal jugular chain; (3) pretracheal, paratracheal, and prelaryngeal (the pretracheal node located near the isthmus is sometimes referred to as the Delphian node); (4) recurrent laryngeal nerve chain; and (5) retropharyngeal and retroesophageal. The anterosuperior mediastinal nodes are secondary to the recurrent laryngeal nerve chain and pretracheal groups, but studies have shown that dye injected into the thyroid isthmus can also drain directly into them.[6]

Microscopically, the thyroid gland is made up of round or oval follicles that vary considerably in size, with an average diameter of 200 µm. They are lined by a single layer of follicular cells whose shape ranges from flattened to low columnar, depending on their degree of activity.[5] The cytoplasm has a pale acidophilic or amphophilic staining quality; the greater the activity of the cell, the greater its amount. Follicular cells with abundant granular acidophilic cytoplasm are referred to as Hürthle cells (a misnomer), Askanazy cells, oxyphilic cells, or oncocytes. Ultrastructurally, this granularity

Abstract

The thyroid gland, from the Greek words *thyreos* (shield) and *eidos* (shape), is one of the largest endocrine organs, with a remarkable potential for growth and enlargement. Diseases due to altered parenchymal function and anatomic abnormalities of this gland are among the most common endocrine disorders in humans. Thyroid carcinoma is the most common endocrine malignancy, and both non-neoplastic and neoplastic abnormalities are a frequent source of specimens for surgical pathology laboratories. Thyroid nodules are highly prevalent and often require cytopathologic evaluation. The general theme is that of the "needle in the haystack": many are thyroid nodules, but few have malignant potential. Of the malignant tumors, few pose a significant threat to life, although some of them, like anaplastic carcinoma, are among the most aggressive forms of human cancer. While most thyroid tumors are sporadic, a few develop in a familial setting or in the context of well-defined tumor syndromes (medullary carcinoma and MEN2 being the prototypical examples for C-cells, follicular carcinoma and Cowden syndrome for follicular cells). Some thyroid lesions pose considerable diagnostic challenges, and Dr. J. Rosai used to quote the words of the famous French pathologist C. L. Pierre Masson (one of the fathers of surgical pathology): "Of all cancers, thyroid epitheliomas teach, perhaps, the greatest lesson of humility to histopathologists." Ancillary techniques, including immunohistochemistry and molecular diagnostics, may help resolve these difficult cases. This chapter covers the relevant topics in the routine surgical pathology practice of the thyroid gland.

Keywords

diffuse thyroid hyperplasia
nodular thyroid hyperplasia
thyroiditis
thyroid tumors
follicular thyroid adenoma
oncocytic (Hürthle cell) tumors
thyroid cancer
follicular thyroid carcinoma
papillary thyroid carcinoma
poorly differentiated thyroid carcinoma
anaplastic thyroid
carcinoma
thyroid molecular pathology
thyroid markers

is due to the accumulation of mitochondria. They can be detected immunohistochemically with antibodies directed against mitochondrial enzymes.[7]

The proliferative activity of follicular cells is related to age, being highest in the prenatal group and lowest in adults.[8]

The main ultrastructural features of follicular cells are abundant granular endoplasmic reticulum, a well-developed Golgi apparatus, lysosomes (particularly numerous in actively secreting cells, and mainly located toward the apical side, not to be confused with secretory granules), and numerous microvilli in the luminal border.[9]

The intraluminal colloid is pale staining, with scalloped borders in follicles with active secretory function and densely eosinophilic in inactive ones. In old age, it tends to be broken up in globular formations. It is variably periodic acid–Schiff (PAS) positive and alcianophilic, depending on the types and relative amounts of carbohydrate components present.[10] Birefringent *calcium oxalate crystals* may be found, always intraluminally, their number increasing with age.[11] Their presence is of practical utility in distinguishing thyroid from parathyroid tissue (which lacks them), particularly at the time of frozen section.[12] They occur in the normal gland and in many pathologic conditions, particularly benign ones.[11] They are thought to represent a sign of functional inactivity on the part of the follicles containing them.[11]

Collections of small follicles protruding into the lumen of larger follicles are commonly seen in actively secreting glands; they are referred to as *Sanderson polsters* and become prominent in hyperplastic conditions.[5]

Immunohistochemically, many markers have been documented in normal follicular cells, most of them being also expressed in well-differentiated tumors of these cells:

1. Reactivity for thyroglobulin, thyroid peroxidase (TPO), triiodothyronine (T3), and thyroxine (T4) is found both in the colloid and in the cytoplasm of the follicular cells. Thyroglobulin is the most widely used of these markers.[5] Less degree of reactivity is found in oncocytic (Hürthle) cells.
2. Immunoreactivity for the sodium iodide symporter (NIS), the ion channel protein that mediates active iodide uptake, is localized to the basolateral plasma membrane of follicular cells. NIS is expressed at higher level in the normal thyroid gland and in benign conditions than in carcinomas, where the localization of the protein is redirected to the intracellular compartment.[13] Pendrin and Anoctamin-1 (ANO1) (also known as Transmembrane Member 16A-TMEM16A or Discovered on GIST1-DOG1), the ion channel proteins that mediate the passive iodide efflux towards the follicular lumen are localized by immunohistochemistry to the apical plasma membrane of follicular cells.[14]
3. Thyroid transcription factor-1 (TTF-1) is expressed in normal follicular and parafollicular cells. It is an extremely useful marker for all types of primary and metastatic thyroid tumors (including medullary carcinoma), except for anaplastic carcinoma. TTF-1 is not expressed in normal, hyperplastic, or adenomatous parathyroid tissue.[5] It is expressed in the normal lung (bronchial cells and pneumocytes) and in most cases of lung carcinoma (including the small cell neuroendocrine type). TTF-1 is occasionally expressed in other sites, such as the normal and neoplastic female genital tract,[15] Wilms tumor,[16] and Merkel cell tumor.[17] Like TTF-1, PAX8 and TTF-2 (FoxE1) are also detectable by routine immunohistochemical methods in thyrocytes and tumors derived from them. PAX8 may be the best to demonstrate the thyroid origin of anaplastic carcinoma.[18]
4. Low-molecular-weight keratins: CK7, CK18, and (to less degree) CK8 and CK19.[19]
5. EMA (epithelial membrane antigen, MUC1).[20]
6. Vimentin.[21]
7. Estrogen and progesterone receptors.[22]
8. Blood group antigens.[23]
9. Metal-binding proteins: ceruloplasmin, lactoferrin, transferrin, metallothionein.[24]
10. Follicular cells are joined by tight junctions containing the known components of these structures, including occludin and the various claudins.[25]
11. The follicles rest on a basement membrane that is immunoreactive for laminin and type IV collagen.[26]

Many of the markers listed previously have been evaluated in normal tissues, benign tumors, and malignant tumors with the hope of finding significantly different values among these groups that could be exploited diagnostically, but the results have generally been those to be expected, that is, disappointing.

The other major epithelial component of the thyroid gland is represented by neuroendocrine cells known as C cells or parafollicular cells. The latter term is a misnomer because immunohistochemical and ultrastructural studies have shown that they occupy a predominantly and perhaps exclusively intrafollicular position. It has been generally believed that mammalian, like avian C cells, derive from the neural crest. Lineage tracing experiments have now provided substantial evidence that they develop under the influence of specific transcription factors (including TTF-1) from the pharyngeal endoderm of the IV pouch and ultimobranchial body (see Solid cell nests next).[27] Because of this fact, C cells are largely restricted to the middle and upper thirds of the lateral lobes along their central axes. The number of C cells varies according to age; they are more numerous in infancy and old age than in adults. Most adult glands contain no more than 10 C cells in a low-power microscopic field. In old age, they may form nodular aggregates.[28]

Ultrastructurally, C cells contain numerous dense-core granules of neurosecretory type. They are argyrophilic with the Grimelius reaction; metachromatic with toluidine blue; positive for lead hematoxylin; and immunoreactive for calcitonin, katacalcin, calcitonin gene–related peptide, neuron-specific enolase (NSE), chromogranins A and B, secretogranin II, and synaptophysin (Fig. 8.1).[5] They are also immunoreactive for carcinoembryonic antigen (CEA), although less so than their neoplastic counterparts in medullary carcinoma.[5]

Solid cell nests *(rests)* are believed to represent remnants of the ultimobranchial body, which in turn is derived from the branchial cleft pouch complex IV–V.[29] They measure 0.1 mm on average and can be detected in almost 90% of neonatal thyroid glands (Fig. 8.2).[30] Exceptionally they reach a large and even a "giant" (tumorlike) size.[31] They are mainly composed of polygonal or oval cells admixed

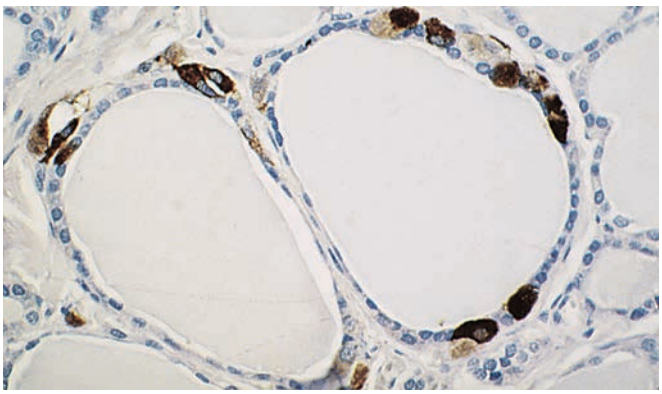

Figure 8.1 Immunoreactivity for calcitonin in thyroid C cells from a case of C-cell hyperplasia.

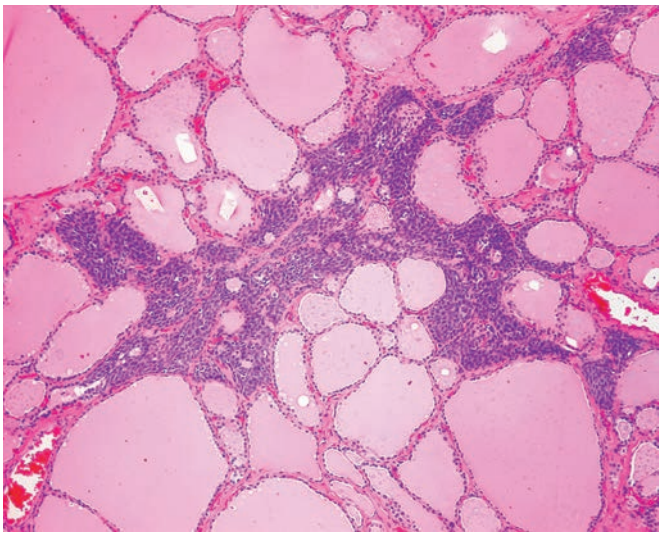

Figure 8.2 Solid cell rest. The irregular branching shape of the nodule is characteristic.

Figure 8.4 Thyroglossal duct cyst. The content of the cyst is gelatinous.

with occasional clear cells. Small glandular lumina containing a mucinous secretion are often present,[32] the nests thus acquiring a combined solid and cystic appearance. A substantial number of C cells may be seen around the nests, in keeping with the well-known relationship that these cells have with the ultimobranchial body.[32] Ultrastructurally, there are microfollicular structures, intracytoplasmic microvacuoles, and ciliated cells, in addition to lymphoid cells.[33] Immunohistochemically, solid cell nests are positive for high-molecular-weight keratin (recognized by the antibody 34bE12) and for CEA.[32,34] Their strong immunoreactivity for p63, telomerase expression, and proliferative activity suggest a stem cell origin.[34] Solid cell nests need to be distinguished from metaplastic follicles, nodular C-cell hyperplasia, and papillary microcarcinoma. Carcinoma of the thyroid showing thymus-like elements (CASTLE) may originate from solid cell nests.[35]

Focal collections of lymphocytes are seen at autopsy in the thyroid of approximately one-half of females and one-fourth of males; this finding is regarded as a subclinical manifestation of focal lymphocytic thyroiditis.[36] Microscopic manifestations of nodular hyperplasia have been reported at autopsy in one-fourth of the cases, but their frequency varies greatly depending on the geographic location of the population being investigated.[37]

Morphologic variations in the anatomy of the thyroid, several of them being the expression of branchial pouch remnants[38] and having no clinical significance, include:

1. Adipose metaplasia of the interfollicular stroma. Only exceptionally will this result in a clinically noticeable mass ("localized adiposity"), to be distinguished from lipoadenoma (see p. 295).[39]
2. Intrathyroidal islands of mature cartilage, presumably of branchial pouch derivation.
3. Intrathyroidal islands of ectopic thymus.[40]
4. Intrathyroidal parathyroid.[5]
5. Intrathyroidal bundles of skeletal muscle.[5]
6. Intrathyroidal salivary gland tissue.[41]
7. Perithyroidal pancreatic tissue, presumably a foregut remnant (see later).[42]
8. Accumulation of melanin-like pigment in the cytoplasm of follicular cells occurs in old age and may become massive after the administration of some medications, such as minocycline.[43] When intense, it is appreciable grossly and is referred to as *melanosis thyroidi* or—less pompously—as *black thyroid* (Fig. 8.3).[43,44] Some of the granules are of classic lipofuscin type, but most of them also contain colloid, thus becoming ambilysosomes.[44]

Congenital Abnormalities

Thyroglossal duct anomalies are the result of a localized persistence of the thyroglossal duct. This may be in the form of a sinus tract connected either to the foramen cecum or to the suprasternal notch, or in the form of a blind tubular structure.[45] It may be accompanied by a cystic dilation, as the result of secretion from the lining cells. When these cystic changes are prominent, the abnormality is designated as a thyroglossal duct cyst. Its usual location is the midline of the neck, in the region of the hyoid bone (Fig. 8.4).[45] Microscopically, the cyst is lined by pseudostratified ciliated or squamous epithelium which is often TTF-1 positive but thyroglobulin negative.[46] Mucous glands and thyroid follicles are commonly seen in the subjacent stroma. Secondary inflammation is common, particularly in cases accompanied by a sinus tract.[47] As a result, the epithelial lining may be partially absent, and the stroma may be infiltrated by inflammatory cells. Most cases are clinically evident during

childhood, but others become apparent only later in life. The treatment is surgical removal. To minimize recurrence, it is important to include in the excision the middle third of the hyoid bone and the entire length of any sinus tract that might be present.[48]

The thyroid tissue present in these anomalies can undergo malignant transformation, usually in the form of papillary carcinoma.[49,50] The prognosis is excellent after surgical removal, which does not need to include the thyroid gland. Other tumor types have been described, including oncocytic (Hürthle cell) carcinoma[51] and undifferentiated (anaplastic) carcinoma.[52]

Heterotopic thyroid tissue can be found not only as a component of thyroglossal duct cyst but anywhere along the course of the thyroglossal duct, sometimes as the sole abnormality (Fig. 8.5). The most frequent location is the base of the tongue, where it may result in difficulty in swallowing and respiratory obstruction, which in a few cases has proven fatal. At a microscopic (subclinical) level, lingual thyroid is found in 10% of normal individuals.[53] This heterotopic thyroid does not differ microscopically from that seen in the main gland. Sometimes a capsule is formed around it; in other instances, the follicles grow between the skeletal muscle of the tongue, a feature that may simulate invasion by tumor. Significantly, in 70% of patients with grossly evident lingual thyroid there is absence of the normal thyroid gland. Therefore, removal of the heterotopic thyroid tissue will lead to hypothyroidism, requiring subsequent medical replacement therapy.

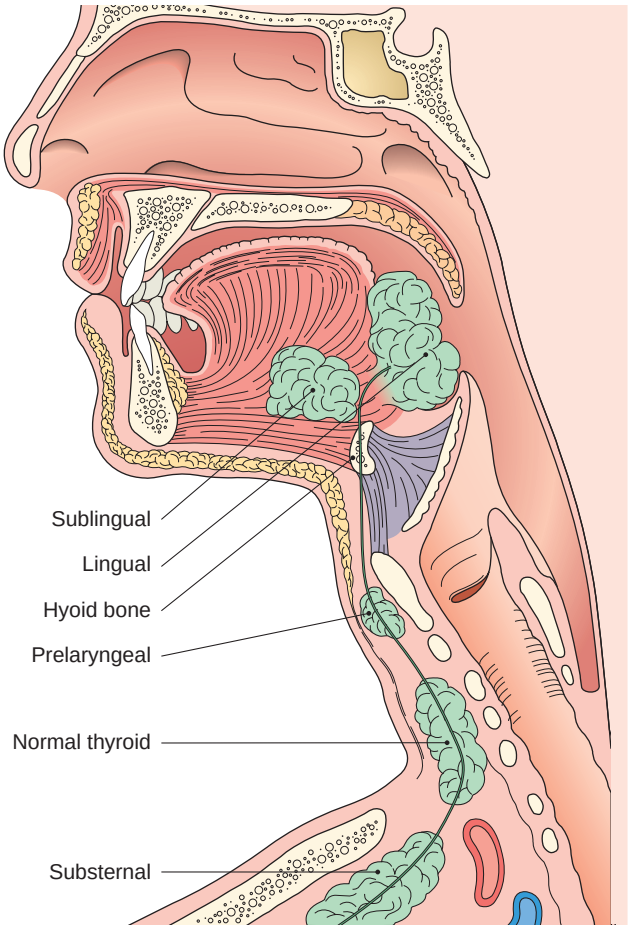

Figure 8.5 Distribution of heterotopic thyroid tissue. (From Lemmon WT, Paschal GW Jr. Lingual thyroid. *Am J Surg*. 1941;52:82–85.)

Other sites of heterotopic thyroid tissue are the anterior tongue, submandibular region, larynx, trachea, mediastinum (usually superior but sometimes posterior), and heart.[54–56] The common denominator in all these sites is their location in or close to the midline, the large majority being found in the so-called *Wölfler area*, described by anatomists as an isosceles triangle with the edge of the mandible at its base and the concavity of the aortic arch at its apex. The possible occurrence of heterotopic thyroid tissue in cervical nodes is discussed elsewhere.

More distant locations in which heterotopic thyroid tissue has been reported include the wall of the duodenum, gallbladder, region of the porta hepatis, adrenal gland, fallopian tube, vagina, and—last but not least—the ovary and other sites as a component of a teratoma (*struma ovarii* being the most spectacular example) (see Chapter 35).[57,58] Heterotopic thyroid tissue in any of these locations is subject to the same diseases that can affect the main gland, including inflammation, hyperplasia, and tumors. Thus, several cases of follicular carcinoma arising from lingual thyroid have been reported,[59] as well as numerous cases of carcinomas of various types arising in struma ovarii (see Chapter 35).[60,61]

Branchial pouch anomalies are not directly related to the thyroid but are discussed here because of their close proximity to the gland. They may present as a patent fistula, a simple sinus, a blind cyst, or an island of cartilage (Fig. 8.6).[62] They are located in the anterolateral region of the neck, their exact position depending on the specific branchial cleft involved. Those related to the *first pouch* appear in the preauricular area or beneath the posterior half of the mandible and may be connected to the external auditory canal. Those related to the *second pouch* appear just anterior to the sternocleidomastoid muscle in the mid neck and may have an open tract communicating with the pharynx near the superior fold of the tonsil. Those related to the *third and fourth pouches* are typically found in the lower neck, in a suprasternal or supraclavicular location. Some of these have been mislabeled as bronchogenic cysts in the past.[63,64]

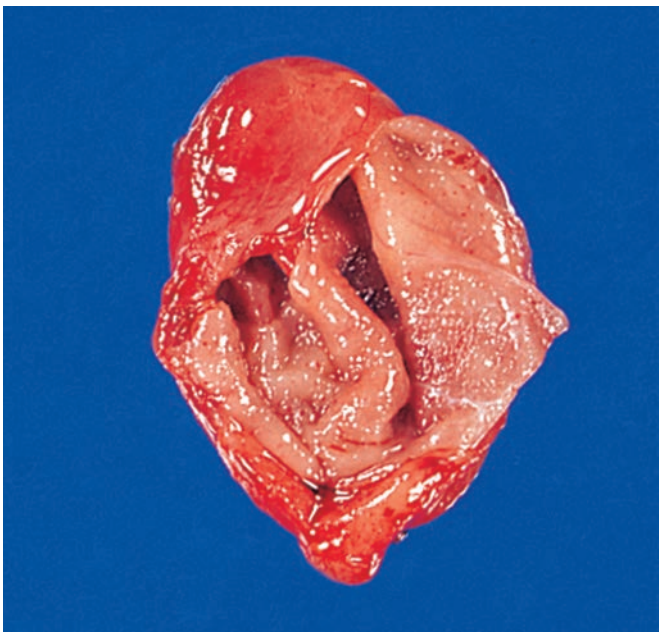

Figure 8.6 Branchial cleft cyst that has been partially opened to expose the inner surface, which is rendered irregular by the presence of innumerable hyperplastic lymphoid follicles.

The lining of these cysts and fistulous tracts is usually squamous epithelium, but columnar ciliated epithelium is also common. Abundant lymphoid tissue, often with germinal centers, is observed beneath. Cysts located in the lower neck may also contain mucinous, seromucinous, and sebaceous glands.[63,64] Secondary infection may complicate the microscopic picture. Squamous cell carcinomas arising in a branchial cleft cyst probably exist, but they are exceptionally rare.[65] Any cystic mass in the lateral neck containing squamous cell carcinoma must be considered a lymph node metastasis with cystic degeneration until proved otherwise, and a search for the primary tumor should be instituted, particularly in the upper aerodigestive tract.[66] Sites notorious for harboring small occult primary tumors include tonsil and posterior tonsillar pillar, retromolar trigone, tongue, and nasopharynx.

Similar comments pertain to the relationship of branchial cleft cysts and papillary carcinomas of thyroid type. Perhaps there exist cases of this tumor type arising in the ectopic thyroid tissue of branchial cleft cysts,[67] but there is no question that the overwhelming majority of the cystic lesions in the lateral neck containing a recognizable focus of papillary thyroid carcinoma represent lymph node metastases from a thyroid primary that have undergone secondary cystic change.

Branchial pouch–related structures are found within the thyroid in the form of the already mentioned solid cell nests (a remnant of the ultimobranchial body or branchial pouch complex IV–V) and—less commonly—in the form of heterotopic cartilage (sharply outlined and often kidney shaped),[68] thymic tissue, parathyroid glands, or epithelial-lined cysts with or without an associated lymphoid component.[69] Most of the latter—sometimes designated as *lymphoepithelial cysts*—are seen in glands affected by Hashimoto thyroiditis, but they can also be found in its absence.[70] Exceptionally, perithyroidal epithelial cysts have been found to contain pancreatic tissue in their wall, as representatives of foregut remnants.[42]

Parenthetically, the presence of normal, cystic, or neoplastic thymic tissue in the neck should also be viewed as the expression of branchial pouch–derived anomalies (see Chapter 12).

Thyroiditis

Acute Thyroiditis

Acute thyroiditis is usually of infectious nature.[71,72] It may be associated with acute infections of the upper aerodigestive tract (e.g., pharyngitis, tonsillitis), generalized sepsis, or major trauma to the neck with an open wound.[73] It tends to affect the malnourished infant, the debilitated elderly, and the immunocompromised patient. *Streptococcus haemolyticus*, *Staphylococcus aureus*, and *Pneumococcus* are the organisms most commonly responsible.[71,72] Other causes include gram-negative bacteria, fungi (particularly *Candida*), and *Pneumocystis*.[74] Viral infection is rare, but several cases of cytomegalovirus infection of the thyroid in patients with AIDS have been documented.[75]

Morphologically, the main changes in acute thyroiditis are neutrophilic infiltration and tissue necrosis. Nonsuppurative and suppurative forms exist, the latter sometimes evolving into an *abscess*.[76] The interesting observation has been made that a large number of cases of recurrent acute suppurative thyroiditis (especially when left sided) are secondary to the presence of a piriform sinus fistula,[77] a structure of presumably ultimobranchial body derivation.[78]

The best method to confirm the diagnosis of acute thyroiditis is a fine-needle biopsy with smear cytologic examination and cultures. The presence of a pyriform sinus fistula can be established by barium meal.[77]

Medical treatment of acute thyroiditis is usually effective, but abscesses need to be drained surgically. Cases associated with pyriform sinus fistula are best treated by fistulectomy.[77]

Granulomatous (de Quervain) Thyroiditis

Granulomatous thyroiditis, also known as de Quervain thyroiditis, giant-cell thyroiditis, subacute thyroiditis, subacute granulomatous thyroiditis, or painful subacute thyroiditis, typically presents in middle-aged women with sore throat, painful deglutition, and marked tenderness on palpation in the thyroid region, often associated with fever and malaise.[72] Once the initial process has subsided, pressure symptoms and/or mild hypothyroidism may develop. However, in the majority of cases there is complete resolution. Because of the sometimes asymmetric involvement of the gland, the disease may be clinically confused with carcinoma. Thyrotoxicosis with elevated serum levels of T4 and T3 in combination with marked suppression of radioactive iodide uptake are typical of the initial phase of this disease,[72] which has been found to be associated with the HLA-B35 haplotype.[79]

Grossly, the process usually involves the entire gland, but the enlargement is often asymmetric. In a typical case, the gland is enlarged to approximately twice its normal size. In the advanced stage, the involved areas are firm. In contrast to Riedel thyroiditis, there is usually little or no adherence to the surrounding structures.

Microscopically, areas of marked inflammation and granulomas containing foreign body giant cells are present. It is characteristic for these granulomas to surround follicles and for the multinucleated giant cells (most of which are of histiocytic nature) to engulf colloid (Fig. 8.7). The granulomas are not very distinct, and caseation necrosis is consistently absent. Areas of fibrosis are also seen, usually in a patchy distribution. Different stages of the same process may be seen in the same gland.[80] Strong immunoreactivity for CA19-9 is found in the late stage of the disease, whereas positivity for CEA in the center of the granuloma is a feature of the acute stage.[81]

The etiology is not known. Although the disease often follows an infection of the upper aerodigestive tract, the thyroiditis itself is of nonbacterial nature. A viral etiology has been often suggested on clinical and epidemiologic grounds but not conclusively proven.[72,82]

Other Granulomatous Inflammations

Palpation thyroiditis is the term that has been proposed for a relatively common, clinically insignificant, and grossly inconspicuous thyroid process (also known as multifocal granulomatous folliculitis)

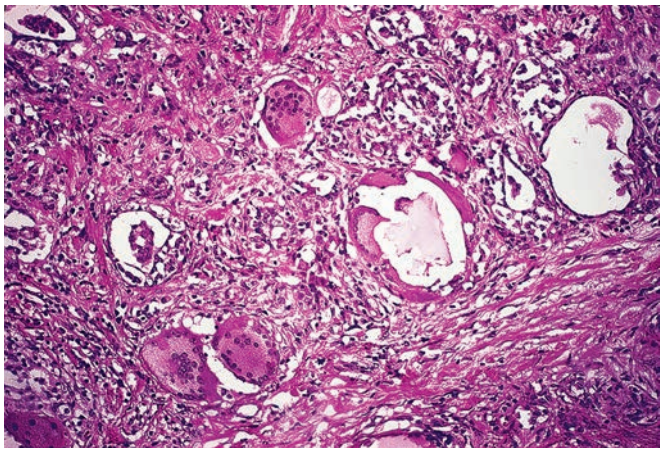

Figure 8.7 Granulomatous thyroiditis showing multiple granulomas centered in thyroid follicles.

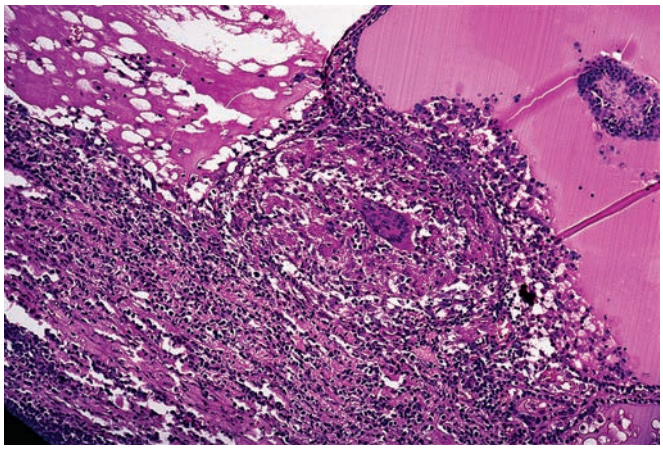

Figure 8.8 So-called palpation thyroiditis is a common incidental finding.

in which collections of histiocytes (some of them foamy), lymphocytes, and a few multinucleated giant cells are seen within the lumen of scattered thyroid follicles (Fig. 8.8).[83] In some of these follicles, the inflammatory infiltrate disrupts the epithelium and extends into the perifollicular region. These changes bear no relationship to granulomatous (de Quervain) thyroiditis. Rather, they seem to be the result of minor trauma to the gland, sometimes spontaneous and sometimes thought to be induced by vigorous palpation on physical examination, hence the term palpation thyroiditis.

Tuberculosis as a primary clinical manifestation within the thyroid gland is a pathologic curiosity.[84] In disseminated miliary tuberculosis, it is common for an occasional tubercle to occur within the gland. It is also possible for tuberculosis of cervical lymph nodes or larynx to involve the thyroid gland secondarily. Many of the cases diagnosed in the past as tuberculosis of the thyroid were actually examples of granulomatous (de Quervain) thyroiditis.

Sarcoidosis may involve the thyroid in the form of interstitial (rather than follicle-centered) noncaseating granulomas in patients with systemic disease. Occasionally it manifests initially as a thyroid mass.[85] Sarcoidosis has been associated with autoimmune thyroid disease (Graves disease and Hashimoto thyroiditis).[86]

Mycoses of various types have been described, most of them occurring in immunocompromised hosts.[87–89] In many of these cases, the tissue changes are characterized by necrosis and acute inflammation rather than granuloma formation.

Postoperative necrotizing granulomas, vaguely simulating rheumatoid nodules and morphologically similar to those more commonly seen in the prostate and bladder, have been observed within the thyroid.[90]

Autoimmune (Lymphocytic and Hashimoto) Thyroiditis

It is now widely accepted that the thyroid diseases traditionally known as lymphocytic thyroiditis and Hashimoto thyroiditis represent different phases or manifestations of an organ-specific, immune-mediated inflammatory disorder generically designated as *autoimmune thyroid disease*. The disorder is common, affects predominantly women, and it is characterized by the production of autoantibodies that alter thyroid function.[72,91,92] It is further believed that autoimmune thyroiditis is one of the two major forms in which autoimmune thyroid disease may manifest, the other being Graves disease.[93] In favor of this interpretation is the existence of cases sharing features of the two diseases (sometimes designated by the picturesque term *hashitoxicosis*), suggesting that one may evolve into the other.[94] According to this interpretation, there is an immune-mediated insult that leads initially to diffuse or nodular hyperactivity of the gland and eventually to exhaustion atrophy, manifested by diffuse oxyphilia of the follicular epithelium. Rarely the sequence is reversed, in the sense that Hashimoto disease with hypothyroidism is followed by Graves disease.[95]

The mechanisms leading to autoimmune thyroid disease are of both humoral and cellular nature. Circulating autoantibodies exist against thyroglobulin and other follicular cell antigens, notably TSHr. The leading pathogenetic event is the breakdown of immune tolerance caused by a combination of immunologic, genetic, and environmental factors. Available evidence indicates that autoimmunity is triggered by inflammatory events in the gland likely related to infection (viral or bacterial), or injury to the thyroid cells from toxins. The injured thyrocytes may exhibit new epitopes (or unmask hidden ones), causing the arrival of major histocompatibility complex (MHC) class II–positive antigen presenting cells (dendritic cells and different subclasses of macrophages). These cells present thyroid-specific antigens to naive lymphocytes within the regional lymph nodes, resulting in clonal expansion of CD4+ T cells, CD8+ cytotoxic T cells, and immunoglobulin (IgG) antibody–producing B cells that are autoreactive. These cells accumulate in the thyroid, resulting in thyroiditis. The intrathyroidal T and B cells, as well as antigen-presenting cells, produce numerous cytokines that alter the behavior of the follicular cells. These start expressing MHC class II, enabling the interaction with antigen-specific T cells that maintains and contributes to the autoimmune inflammatory process.[93,96–98] Genome-wide association studies (GWASs) have identified several susceptibility loci for autoimmune thyroid disease, some of which have been specifically linked to Graves disease (the *TSHR* single nucleotide polymorphism rs2268458) and Hashimoto thyroiditis (e.g., the *FoxE1* single nucleotide polymorphism rs965513).[99]

Morphologically, the common denominator of autoimmune thyroid disease in general and autoimmune thyroiditis in particular is the presence of *lymphocytic infiltration of the gland associated with germinal center formation*. Histologically, it is the *appearance of the intervening follicles that determines the category to which a given case belongs*: Graves disease when the follicles are diffusely hyperplastic, lymphocytic thyroiditis (in various forms) when they are relatively normal, and classic Hashimoto thyroiditis when follicles are lined by severely damaged cells showing extensive oncocytic change. Considerable confusion exists in the use of terminology, depending on whether the emphasis is on tissue inflammation or the clinical findings. Some authors use the term Hashimoto thyroiditis to include any autoimmune thyroid disease characterized by marked lymphocytic infiltration.[100] For practical purposes, autoimmune thyroiditis can be grouped histologically into "lymphocytic thyroiditis," when the evidence of parenchymal damage is limited, and "Hashimoto thyroiditis" when there is marked parenchymal damage, following the original description of the disease by Hakaru Hashimoto in 1912.[101] The practice of using the terms lymphocytic and Hashimoto thyroiditis synonymously is not recommended, one of the reasons being that a good correlation exists between the morphologic appearance of the follicular epithelium and thyroid function.[102,103]

Lymphocytic thyroiditis, thus defined, is characterized by lymphoid infiltration with limited evidence of parenchymal damage. As these forms of thyroiditis rarely require thyroidectomy, few studies have accurately described the histologic alterations following needle biopsy procedures.[102] Germinal centers are few, oncocytic changes are focal, follicular atrophy is absent (there may actually be signs of follicular hyperplasia), and fibrosis is mild or altogether absent. Several clinical entities fall into this category: *painless (or silent, or subacute lymphocytic) thyroiditis* that can be *sporadic*[104] or *postpartum*,[105] the "*juvenile form*" of lymphocytic/autoimmune thyroiditis,[106] and the initial phase in cases of *Hashitoxicosis*.[94] In patients with painless

(silent) thyroiditis, sporadic or postpartum, a transient hyperthyroid phase is followed by hypothyroidism and then, in the majority of cases, by resolution with return to a euthyroid condition.[72] The course of the juvenile form of autoimmune thyroiditis is variable.[106] Drug-induced thyroiditis after treatment with amiodarone and lithium has been related to autoimmunity. Immunomodulatory drugs, cancer immunotherapy, and cancer vaccines have immune-related side effects that include endocrinopathies and thyroiditis.[72,107]

The presence of focal lymphoid infiltration in the thyroid parenchyma is referred to as *focal lymphocytic thyroiditis (or nonspecific thyroiditis, or focal autoimmune thyroiditis)*. Most patients are euthyroid, but a minority has latent/subclinical hypothyroidism.[102] Collections of lymphocytes are common in thyroid glands removed for a variety of reasons and can be found around thyroid tumors (particularly papillary carcinoma), in thyroid glands that have been irradiated (radioactive iodine ablation or external beam therapy), and in autopsy series.[36] Autopsy studies indicate that the finding is more frequent in women, increases with age, and shows racial variation (more common in whites than in black or Japanese individuals). White females have the highest prevalence and the most pronounced increase with aging: focal lymphoid infiltration is found in approximately 55% of white women aged 80 years or older.[108]

Hashimoto thyroiditis, originally described in 1912 by Hakaru Hashimoto as struma lymphomatosa,[101] is characterized by extensive damage to the thyroid parenchyma. It is predominantly a disease of women over 40 years of age. It presents as diffuse firm thyroid enlargement, sometimes accompanied by signs of tracheal or esophageal compression. Initially the disease may be accompanied by mild hyperthyroidism and later by hypothyroidism.[72] At surgery, the thyroid gland is easily separated from other structures. The fascial attachment between the thyroid gland and the tracheal wall is, at times, slightly thickened, but there is no strong fixation (unlike Riedel thyroiditis). Because of the firm character of the lesion, it may be confused with carcinoma, but the diffuse involvement without adherence to the surrounding structures should be strong evidence against it. Grossly, the typical case shows diffuse and symmetrical enlargement of the gland. However, in some instances, one lobe is more enlarged than the other, and in others the disease has a distinctly multinodular quality. The consistency is firm but not stony hard as in Riedel thyroiditis. There is no extension of the process outside the gland. The cut surface is friable, vaguely or distinctly nodular or micronodular, yellowish gray, and greatly resembles a hyperplastic lymph node (Fig. 8.9). Colloid is not clearly discernible. Necrosis and calcification are absent. The texture of the parenchyma infiltrated by lymphoid cells results in a distinctive pattern on ultrasound examination characterized by reduced echogenicity.[100]

Microscopically, the two main abnormalities are lymphocytic infiltration of the stroma and oxyphilic change of the follicular epithelium (Fig. 8.10). The lymphoid tissue is distributed within and around the lobules, and it invariably exhibits large follicles with prominent germinal centers. Lymphocytes predominate, T cells predominating over B cells.[109] Plasma cells, histiocytes, and scattered intrafollicular multinucleated giant cells are also present. Ultrastructurally, some of these giant cells have been found to be of epithelial derivation, but most are of histiocytic nature.[110] The lymphoplasmacytic population has been found to be polyclonal by immunohistochemical and gene rearrangement studies.[109,111] Lymphatic vessels are increased in number and dilated, resulting in characteristic "cracking spaces" (Fig. 8.11).[112]

Most of the thyroid follicles are atrophic, but others show features consistent with regenerative hyperplasia.[113] Most or all of these follicles are lined by variably sized oncocytic (Hürthle) cells. The nuclei of these cells may show enlargement and hyperchromasia or, conversely,

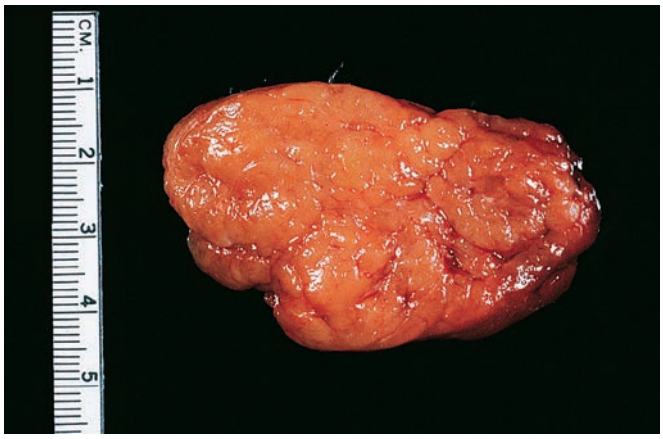

Figure 8.9 Cut surface of thyroid involved by Hashimoto thyroiditis. The appearance is reminiscent of a hyperplastic lymph node.

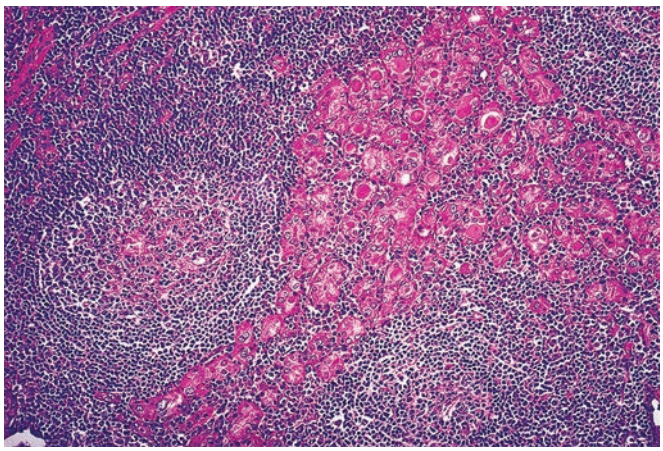

Figure 8.10 Hashimoto thyroiditis showing lymphoid follicles with prominent germinal centers and oncocytic follicular epithelium.

Figure 8.11 Dilated lymphatic vessels in Hashimoto thyroiditis result in characteristic "cracking spaces."

an optically clear appearance and overlapping quality reminiscent of that seen in papillary carcinoma. Immunohistochemically, the follicular cells of autoimmune thyroiditis show greater reactivity for keratin (particularly the high molecular weight types), S-100 protein, HLA-DR, and *N*-acetyl-α-D-galactosamine than the corresponding

normal cells, their immunohistochemical profile thus resembling that of the cells of papillary carcinoma. Biochemically, the oncocytic cells of Hashimoto thyroiditis have defects of cytochrome-c oxidase and the common 4977 base pairs deletion of mitochondrial DNA.[114]

Squamous nests and duct-like structures, thought to arise from metaplasia of follicular cells as a response to the chronic inflammatory injury (and possibly representing a manifestation of phylogenetic regression), are common and can reach sizable proportions (Fig. 8.12).[115] Rarely, large cysts lined by squamous epithelium and bordered by a row of lymphoid follicles are seen, their appearance being highly reminiscent of branchial cleft cysts (Fig. 8.13).[116] Parenthetically, similar cysts can also be seen in the absence of thyroiditis.[70]

In the typical case of Hashimoto thyroiditis, connective tissue is scarce, with slight or moderate thickening of the interlobular septa. In the *fibrous (or fibrosing) variant* of the disease, described by Katz and Vickery in 1974[117] and comprising approximately 10% of all cases, fibrosis is more extensive. In contrast to Riedel thyroiditis, this fibrosis is of dense hyaline type (instead of the active proliferative fibrosis seen in the latter) and does not extend beyond the thyroid capsule. In this regard, it should be remembered that Hashimoto and Riedel thyroiditis can exceptionally coexist.[118,119] The fibrous variant of Hashimoto thyroiditis can also be confused with carcinoma when the fibrosis is associated with epithelial islands showing squamous metaplasia.[117] It typically presents in older women, with hypothyroidism requiring prompt hormone replacement, and may evolve into a severe form of *thyroid atrophy*. In these cases the thyroid gland is not palpable and the symptoms of hypothyroidism are difficult to identify since they overlap with those of aging.[100]

A type of Hashimoto thyroiditis that shows partial overlap with the fibrous variant is the IgG4-related form. It is defined by an increased number of IgG4-positive plasma cells (greater than 20 IgG4-positive plasma/high-power field [×400] and IgG4/IgG ratios greater than 30% by immunohistochemistry). Compared with conventional Hashimoto thyroiditis the IgG4-related variant is associated with high titers of thyroid autoantibodies, runs a more aggressive course, shows greater ultrasound alterations with pronounced hypoechogenicity, develops at a younger age, has a lower female-to-male ratio. Histologically, the lympho-plasmacytic infiltration is extensive and there is a predominantly interfollicular pattern of fibrosis. Similar to the fibrous variant (and unlike Riedel thyroiditis) the inflammatory process does not extend to extrathyroidal tissues, nor is it typically associated with fibroinflammatory lesions in other sites.[100,120,121]

Although Hashimoto thyroiditis typically exhibits a diffuse appearance both grossly and microscopically, cases do occur in which a distinct nodularity is evident, the epithelial component of the nodules having a hyperplastic quality. This could be interpreted as the combination of Hashimoto thyroiditis and nodular hyperplasia, but in all likelihood the two abnormalities are pathogenetically related. A term such as *nodular Hashimoto thyroiditis* would therefore seem more appropriate to designate this relatively common occurrence. A variation on the theme is represented by the Hashimoto thyroiditis in which one or more distinct hyperplastic ("dominant") nodules exclusively composed of oncocytic (Hürthle) cells having either a follicular or a solid configuration are present. Some of these nodules are surrounded by a thick fibrous capsule and therefore fulfill the criteria for follicular, including oncocytic (Hürthle) cell, adenoma, even if their true neoplastic nature is debatable.

Hashimoto thyroiditis (and autoimmune thyroid disease in general) may be seen in association with lymphocytic inflammation

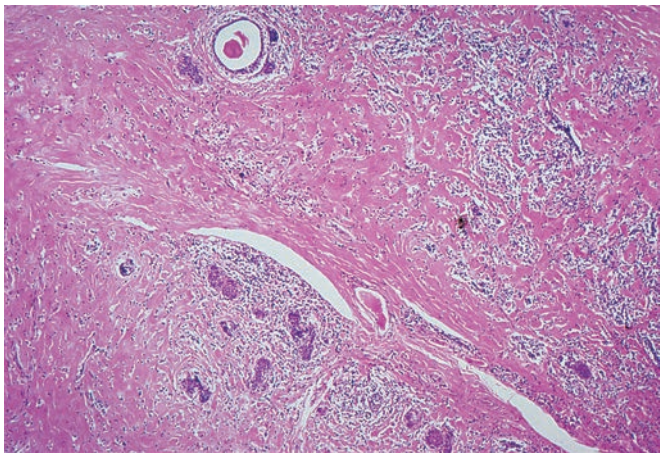

Figure 8.12 Hashimoto thyroiditis with extensive fibrosis, atrophy of follicular epithelium, and squamous metaplasia.

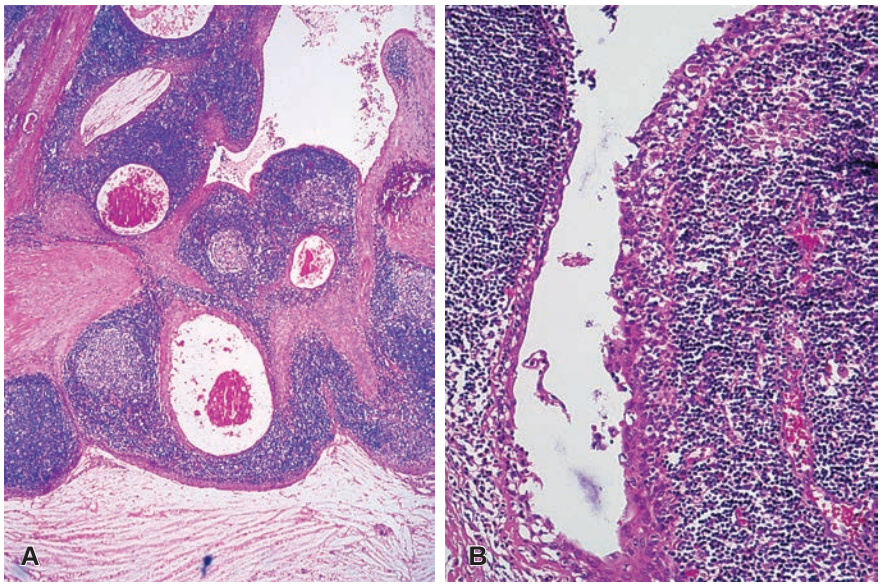

Figure 8.13 **A** and **B,** Hashimoto thyroiditis with branchial cleftlike cysts. In the high-power microphotograph (**B**) one can appreciate the infiltration by the lymphocytes of the lining epithelium.

of other organs, also on an autoimmune basis, as parts of autoimmune polyendocrine syndromes, namely Addison's disease (the combination being known as *Schmidt syndrome*) and diabetes mellitus.[122] Chronic autoimmune thyroiditis, Addison's disease, and type 1A diabetes are the distinctive features of *autoimmune polyendocrine syndrome type II* (the type I characterized by hypoparathyroidism and Addison's disease is not typically associated with thyroid disease). Hashimoto thyroiditis (and other autoimmune thyroid diseases) can also be associated with non-endocrine autoimmune disorders like vitiligo, pernicious anemia, myasthenia gravis, autoimmune gastritis, celiac disease, and hepatitis.[122]

Complications of Hashimoto thyroiditis include thyroid lymphoma,[123] oncocytic (Hürthle cell) neoplasms, and papillary carcinoma.[98] Their identification at an early stage may be extremely difficult. This probably explains the remarkable difference in the reported figures for these complications, particularly the latter two.[124] It is worth noting that follicular cells in Hashimoto thyroiditis can have loss of heterozygosity (LOH) at tumor suppressor gene loci[125] and can become karyotypically abnormal when they form proliferative nodules.[126] Also, the occurrence of sometimes striking nuclear clearing and overlapping in the follicular cells of Hashimoto thyroiditis is of interest; one wonders whether this might not represent a precursor (preneoplastic) stage of papillary carcinoma, as suggested by their similar phenotypic profile.[127] Additional evidence suggests that *RET/PTC* may provide a link between Hashimoto thyroiditis and papillary carcinoma. As a matter of fact, patients exposed to the Chernobyl radioactive fallout not only develop *RET/PTC*-driven papillary cancer but also chronic autoimmune thyroiditis; transgenic mice expressing *RET/PTC* show chronic thyroiditis in addition to papillary carcinoma; and—more importantly—low level *RET/PTC* rearrangement is commonly detectable in non-neoplastic thyrocytes of Hashimoto thyroiditis,[128–130] both in nodular and non-nodular areas of the inflamed gland.[128] This finding is intriguing given the established oncogenic potential of *RET/PTC*. It has to be pointed out that the rearrangement is present in very few cells,[128] that its identification requires highly sensitive methods[128–130] (that need therefore to be avoided for the molecular diagnosis of papillary carcinoma), and that the very restriction of the rearrangement to rare follicular cells does not necessarily anticipate the development of papillary carcinoma. The finding of oncogenic events in non-neoplastic cells is certainly not unique, a good example being the occurrence of *BCL2/JH* rearrangement (the molecular signature of follicular lymphoma) in rare lymphocytes in hyperplastic follicles.[131] Just as the identification of low-level *BCL2/JH* rearrangement does not establish per se a diagnosis of follicular lymphoma, the detection of low level *RET/PTC* does not establish papillary carcinoma. It rather supports the epidemiologic data showing that Hashimoto thyroiditis is associated with a small but real risk of developing papillary carcinoma, by providing a biologic link between the two. Incidentally, *BRAF* p.V600E mutations have not been detected in Hashimoto thyroiditis.[128,132] Medullary carcinoma has also been described in thyroid glands with Hashimoto thyroiditis, but the occurrence is probably coincidental.[133]

The treatment of Hashimoto thyroiditis depends on its severity. In mild cases no therapy is needed. In some instances, thyroid hormone is given to relieve hypothyroidism. In still others, surgery in the form of subtotal thyroidectomy is performed because of large size and/or pressure symptoms. Some cases of Hashimoto thyroiditis are treated surgically simply because they are clinically confused with a neoplastic process.[100]

Riedel Thyroiditis

Riedel thyroiditis, also known as Riedel struma, fibrous thyroiditis, and invasive thyroiditis was originally reported by Bernhard Moritz Riedel in 1896.[134] It is an extremely rare disorder that affects adult and elderly patients and shows a slight predilection for females. It presents with an ill-defined thyroid enlargement often associated with profound dyspnea. The lesion, which is extremely firm, binds the soft tissues of the neck in an iron collar (in the original description Riedel used the words *eisenharte*—iron hard—struma) and may compress the trachea to a slitlike state. Clinically, it is often thought to be carcinoma. In contrast to granulomatous thyroiditis, it is not preceded by an acute inflammatory process or by tenderness of the thyroid gland. The regional lymph nodes are not involved. Grossly, the process is asymmetric and involves only localized areas of the thyroid gland. The affected portion is stony hard and cuts with great resistance. Dense fibrous tracts extend from the thyroid capsule into adjacent muscle so that at surgery the tissue planes are obliterated. On cross section, areas with complete obliteration of the architecture alternate with others having a nearly normal appearance.

Microscopically, fibrous tissue completely replaces the area of the gland involved (Fig. 8.14). The fibrosis is the result of an active proliferative process of fibroblasts and myofibroblasts showing areas of storiform growth, and dense hyaline collagenization in the later stages of the disease. In the resected thyroid glands, hyalinization is frequently extensive, and skeletal muscle cells in the immediate area are often directly infiltrated by fibrous connective tissue. Giant cells are absent. The inflammation present is patchy and of mononuclear type, with a predominance of lymphocytes and plasma cells. The plasma cells are polyclonal, with numerous IgA- and IgG4-producing cells.[121,135] Collections of eosinophils may also be present. Medium-sized veins encased by the fibrosis typically show inflammation of their wall. This process of inflammatory phlebosclerosis is referred to as *obliterative phlebitis* and is important diagnostic feature (Fig. 8.15).[136] Elastic stain may be necessary to recognize fully obliterated veins. Arteries are less likely to be affected.[121]

Riedel thyroiditis is the prototypical manifestation of IgG4-related disease in the thyroid gland. IgG4-related diseases are a group of tumefactive fibro-inflammatory disorders (generically known as *inflammatory fibrosclerosis*) that can affect many organs and sites.[121,135] The group includes retroperitoneal or mediastinal fibrosis, sclerosing cholangitis, and—in the head and neck region—inflammatory pseudotumor of the orbit, eosinophilic angiocentric fibrosis, IgG4-related disease submandibular disease, and Mikulicz's disease.[121] IgG4 is a rare IgG idiotype, inefficient as antibody, with paradoxical anti-inflammatory properties. The diagnosis of IgG4-related diseases is based on distinctive histologic features (lymphoplasmacytic infiltrate, fibrosis—arranged at least focally in a storiform pattern,

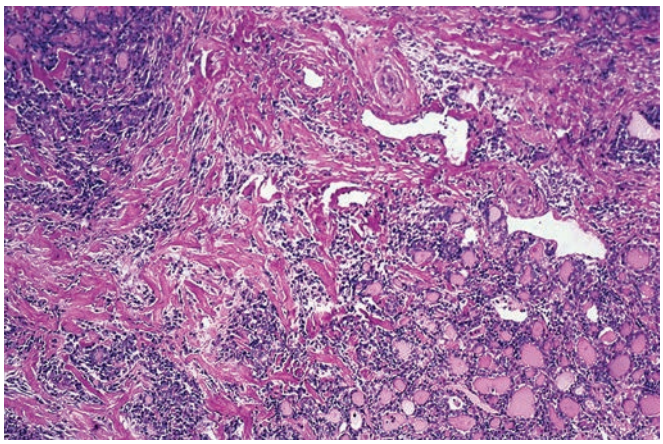

Figure 8.14 Riedel thyroiditis showing sclerosis, chronic inflammation, and parenchymal atrophy.

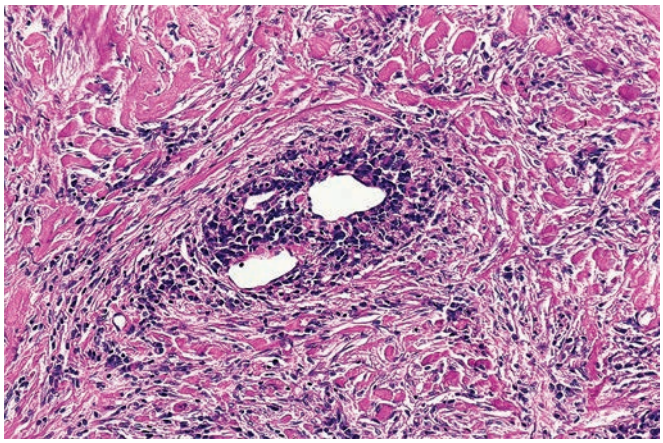

Figure 8.15 Inflammation of a vein in Riedel thyroiditis.

Figure 8.16 Multifocal sclerosing thyroiditis, macroscopic appearance. Multiple fibrotic foci are scattered throughout the bisected thyroid lobe *(arrows)*. (From Fellegara G, Rosai J. Gross appearance of multifocal fibrosing thyroiditis. *Am J Surg Pathol*. 2015;39(6):870.)

and obliterative phlebitis), and on the finding of numerous IgG4-positive plasma cells with an IgG4 to IgG ratio greater than 40% by immunohistochemistry.[121] IgG4-related fibro-inflammatory disorders develop (synchronously or metachronously) in other sites (e.g., the retroperitoneum) in 30%–40% of patients with Riedel thyroiditis.[135]

Riedel thyroiditis is different from granulomatous or Hashimoto thyroiditis, despite the existence of isolated instances in which the two diseases coexist.[118,119] While many cases of fibrous and some cases of conventional Hashimoto thyroiditis are IgG4 related, their histologic and clinical features are different, and they lack the extraglandular infiltration and systemic involvement by IgG4-related disorders in other sites that is typical of Riedel thyroiditis.[135] Riedel thyroiditis needs also to be distinguished from malignancies, particularly the paucicellular variant of anaplastic carcinoma (a challenging distinction in small biopsies), and from lymphoplasmacytic lymphoma.[121]

Steroid therapy has been effective in some cases (particularly those diagnosed at early stages), but most patients need surgical intervention to relieve the compression symptoms and to rule out the presence of carcinoma. The resection is quite difficult because no plane of cleavage exists and aggressive surgery is not recommended due to the risk of complications.[135]

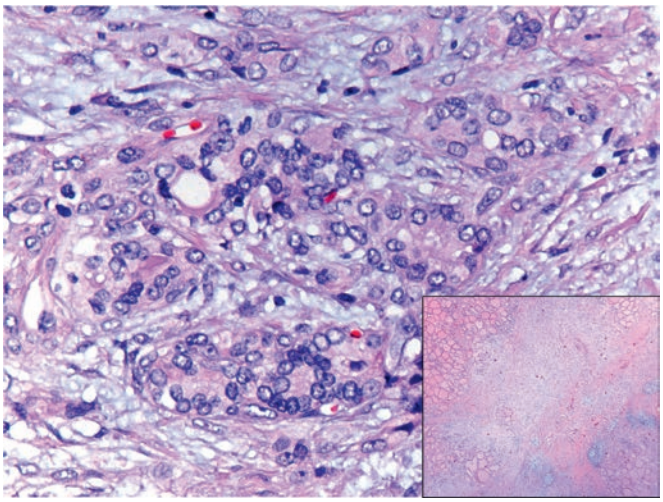

Figure 8.17 Multifocal sclerosing thyroiditis, microscopic appearance. *Reactive atypia* of follicular cells and "nodular fasciitis-like" stroma. The inset shows the irregular starlike fibrotic focus at low power.

Multifocal Fibrosing Thyroiditis

An uncommon but very distinctive form of thyroiditis has been recognized and designated multifocal fibrosing (or sclerosing) thyroiditis by Dr. Rosai in the course of his long and extensive activity as consulting pathologist. As the name implies the condition is characterized by one or more foci of fibrosis throughout the gland (typically foci are multiple, sometimes very numerous), having a stellate, radial configuration, and in a minority of cases a band-like appearance (Fig. 8.16).[137] The size of the foci is quite variable, with a mean diameter of 3 mm. On low power, the appearance can be indistinguishable from that of papillary microcarcinoma, but on high power it is possible to appreciate the lack of a neoplastic glandular component. Although the sclerotic foci are heterogeneous, the individual lesions are similar to each other in composition, characterized by a fibrotic poorly cellular center that merges with a cellular peripheral zone. Some of the follicular structures present at the periphery of the sclerotic focus (i.e., at the interface between the fibrotic core and the normal tissue), and to less extent those entrapped inside it, undergo reactive/regenerative changes (so-called *reactive atypia*) that simulates malignancy (Fig. 8.17). The thyroid follicles entrapped in the more central sclerotic areas are minute, with scant colloid. Those at the periphery appear hyperplastic, are surrounded by stroma that can have a nodular fasciitis-like appearance, and are lined by crowded thyrocytes with overlapping nuclei that sometimes display mild clearing and irregularities of the nuclear membrane contour. There are no nuclear pseudoinclusions or psammoma bodies.[137] *BRAF* p.V600E mutations have not been identified.[138]

The pathogenesis of multifocal fibrosing thyroiditis is obscure. The condition probably represents a peculiar host response to injury that stimulates a localized tissue response followed by a process similar to that of a healing scar. The condition develops predominantly in women (F/M = 12.75) and is often associated with nodular hyperplasia, Hashimoto thyroiditis, and Graves disease. In approximately 30% of cases it coexists with papillary microcarcinoma, and it is possible that some cases may represent a pre-neoplastic condition. As Dr. Rosai has pointed out, an association between fibrosis and malignancy has been reported in other organs (e.g., radial scar leading to ductal breast carcinoma).[137]

Hyperplasia

Hyperplastic disorders of the thyroid have been classified on the basis of their presumed pathogenesis, morphologic features, and

Table 8.1 Major types of thyroid hyperplastic disorders

NAME	MECHANISM	PATHOLOGY	FUNCTIONAL STATUS
Dyshormonogenetic Goiter	Genetically determined error in thyroid hormone synthesis	Nodular or (less frequently) diffuse hyperplasia	Hypothyroid
Graves Disease	Autoimmune	Diffuse hyperplasia	Hyperthyroid
Nodular Hyperplasia			
Endemic goiter	Iodine deficiency	Nodular hyperplasia (preceded by a transient phase of diffuse hyperplasia)	Usually euthyroid; sometimes hypothyroid
Sporadic goiter	Unknown	Nodular hyperplasia	Usually euthyroid; sometimes hyperthyroid or hypothyroid

clinical manifestations. In practice, three major forms of thyroid hyperplasia are recognized by combining these criteria (Table 8.1).

Dyshormonogenetic Goiter

Dyshormonogenetic goiter is a condition in which enlargement of the thyroid gland is due to defects in the synthesis of thyroid hormones. Thyroid dyshormonogenesis (thyroid hormone deficiency resulting from inborn errors of thyroid hormone synthesis) accounts for approximately 20% of cases of primary congenital hypothyroidism, the other 80% being the result of thyroid dysgenesis.[139] Some studies have shown that the incidence of primary congenital hypothyroidism with a normally located (eutopic) thyroid gland and milder dysfunction may be increasing, possibly due to changes in screening thresholds.[140] Dyshormonogenetic goiter is linked to mutations in genes that encode for proteins involved in the steps of thyroid hormone synthesis. Mutations in genes that cause defective iodide transport (*NIS/SCL5A5* encoding the Na/Iodide symporter and *SCL26A4/PDS* encoding pendrin), defective iodide organification (*TPO* encoding thyroid peroxidase, *DUOX2* encoding dual oxidase 2, *DUOXA2* encoding dual oxidase maturation factor 2), defects of thyroglobulin synthesis (*TG* encoding thyroglobulin), or dehalogenation deficiency (*IYD/DEHAL1* encoding iodotyrosine deiodinase) are well characterized. Disease phenotypes are inherited in an autosomal recessive manner and are not associated with other defects, other than deafness in Pendred syndrome (due to *SCL26A4/PDS* mutations).[139–141]

Grossly, the gland is enlarged and multinodular (Fig. 8.18). Microscopically, the most common alteration consists of hypercellular nodules exhibiting a variety of architectural appearances, with a predominance of solid and microfollicular patterns (Fig. 8.19).[142] In some cases there are papillary and insular formations. Fibrosis is a common finding, in some instances resulting in irregularities at the edge of the nodules that can simulate capsular invasion. Other common features include marked nuclear atypia and minimal amounts of colloid. A diagnostically important feature is the fact that the nuclear atypia (in the form of bizarre hyperchromatic nuclei) is present mainly in the tissue *between* the hyperplastic nodules rather than in the nodules themselves.[142] Mitotic figures are often seen, presumably as a result of the continuous TSH stimulation.[142] The suggestion has been made that there is some correlation between the specific molecular defect and the morphologic appearance of the gland.[143]

The histologic features of dyshormonogenetic goiter are characteristic enough that a pathologist may strongly suggest the diagnosis.[142] This is important given the need for genetic counseling to assess

Figure 8.18 Dyshormonogenetic goiter. Gross appearance. Note the multinodular quality and the hemorrhagic changes in the larger nodules. (Courtesy of Dr. Michael Kashgarian, New Haven, Connecticut.)

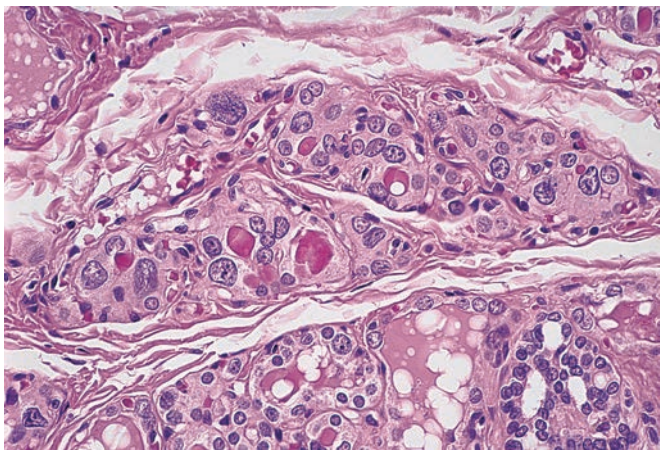

Figure 8.19 Dyshormonogenetic goiter. Microscopic appearance. The follicles are hyperplastic and lined by follicular cells with marked nuclear pleomorphism.

the risk of inheritance and recurrence in the family.[139] Cases of thyroid carcinoma have been reported in patients with dyshormonogenetic goiter, but the number of well-documented cases is very low.[144] Most have been of follicular type, and others have been incidental papillary microcarcinomas.[142] The reported follicular tumors have included adenomas (some developing after T4 replacement therapy) and carcinomas.[142,145]

Because dyshormonogenetic goiter is commonly associated with pleomorphism, hypercellularity, and mitotic activity of the follicular epithelium, one should be particularly strict with the criteria for the diagnosis of follicular carcinoma in this setting. Specifically, nothing short of clear-cut capsular or blood vessel invasion should be accepted.[142,146]

Graves Disease (Diffuse Toxic Goiter)

Graves disease (also known as Basedow disease, diffuse toxic goiter, and exophthalmic goiter) typically presents in young adult females with muscle weakness, weight loss, irritability, heat intolerance, fatigue, tachycardia, goiter, and often a great increase of appetite. It can also develop in children, in whom it constitutes the most common cause of hyperthyroidism. Atrial fibrillation may occur, particularly in older patients.[147,148] The enlargement of the thyroid gland is typically diffuse, but in case of iodide deficiency Graves disease may coexist with multinodular goiter. The goiter is palpable in the majority of hyperthyroid patients who are younger than 60 years, as opposed to less than 50% of older patients.[147]

Graves ophthalmopathy (or orbitopathy) develops in 25%–30% of patients. Cigarette smoking is a risk factor and has been associated with more aggressive ophthalmopathy.[149] This is an autoimmune disorder of the periorbital tissues that results in increased volume of both adipose tissue and extraocular muscles due to inflammation, the accumulation of hydrophilic glycosaminoglycans (typically hyaluronic acid) and related edema, and tissue remodeling with activation of lipogenesis and fibrosis.[149] Exophthalmos (or proptosis, i.e., protrusion of the eyeball) develops in approximately 60% of patients with ophthalmopathy, but imaging can identify subtle orbital connective tissue abnormalities in 70% of patients with Graves disease.[147,149]

Late clinical manifestations of Graves disease are localized dermopathy *(pretibial myxedema)* and so-called *thyroid acropachy*; the latter is characterized by swelling of the extremities and clubbing of fingers and toes resulting from periosteal new bone formation.[147,150]

Laboratory abnormalities include elevation of bound T4, free T4, or bound T3 levels and increased radioactive iodine uptake in the presence of low TSH levels.[147,148] A variant characterized by increased serum levels of T3 in the presence of therapy-induced low levels of T4 has been described as *T3-predominant Graves disease*.

Grossly, the gland shows a mild to moderate symmetric diffuse enlargement. It is succulent and reddish and has the consistency of pancreatic tissue (Fig. 8.20). The cut surface is uniformly gray or red, depending on the degree of vascularity (Fig. 8.21). In longstanding cases, the gland appears friable and dull yellow.

Microscopically, the follicles are markedly hyperplastic, with prominent papillary infolding that may cause confusion with papillary carcinoma (Fig. 8.22).[151,152]

The lining epithelium is columnar, with basally located normochromatic or hyperchromatic nuclei and a clear, sometimes microvacuolated basophilic or amphophilic cytoplasm that may contain fat and glycogen. These features are said to be even more prominent in T3-predominant Graves disease.[153] A variable number of oxyphilic cells may be present, suggesting a possible evolution toward Hashimoto thyroiditis. The colloid is pale and finely vacuolated, with prominent scalloping where it abuts the epithelium. The stroma contains aggregates of lymphoid tissue with germinal center formation

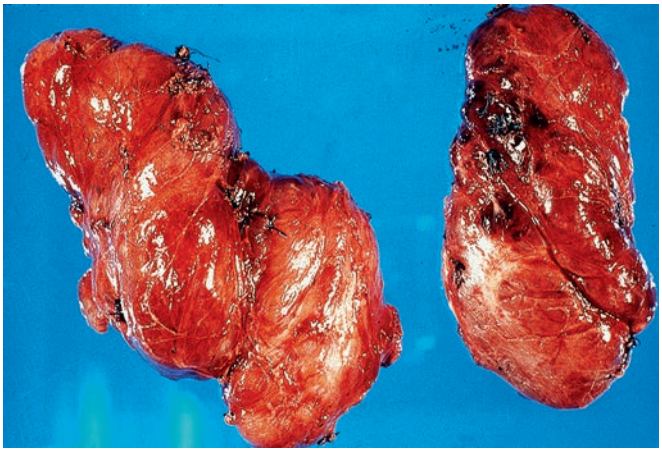

Figure 8.20 Outer aspect of diffuse thyroid hyperplasia in a patient with Graves disease. The gland is diffusely swollen and hyperemic.

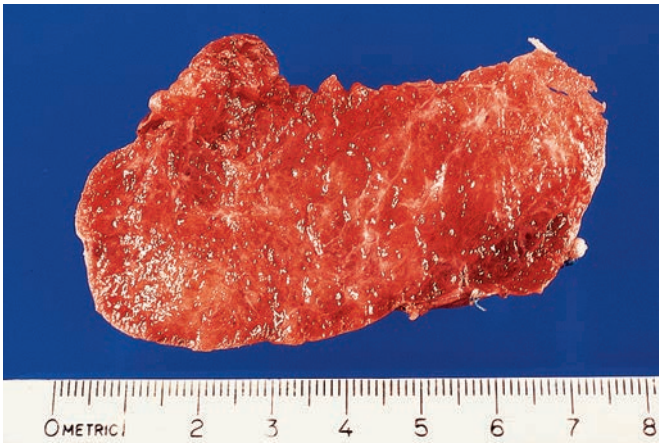

Figure 8.21 Cut surface of thyroid gland with diffuse hyperplasia, showing a hyperemic "juicy" appearance.

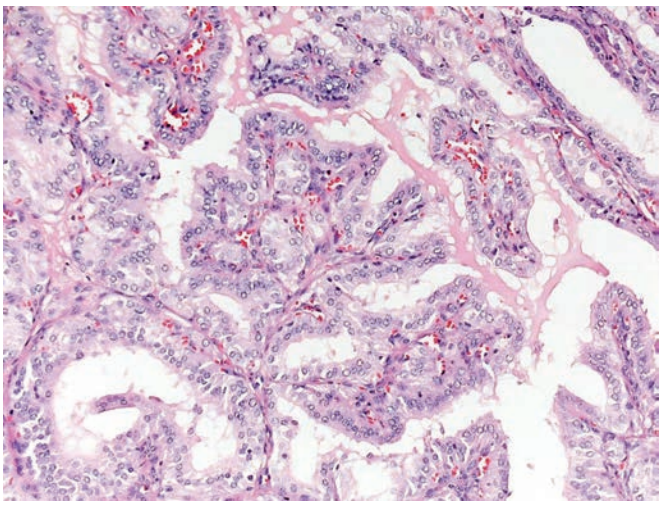

Figure 8.22 Hyperplastic papillae protruding into dilated follicles in diffuse hyperplasia.

(Fig. 8.23). Immunohistochemically, most of these lymphocytes are of T-cell type, the cytotoxic-suppressor subtype predominating in the follicles and the helper-induced subtype in the interstitium.[154] Mild fibrosis is present in longstanding cases. Hyperplastic follicles

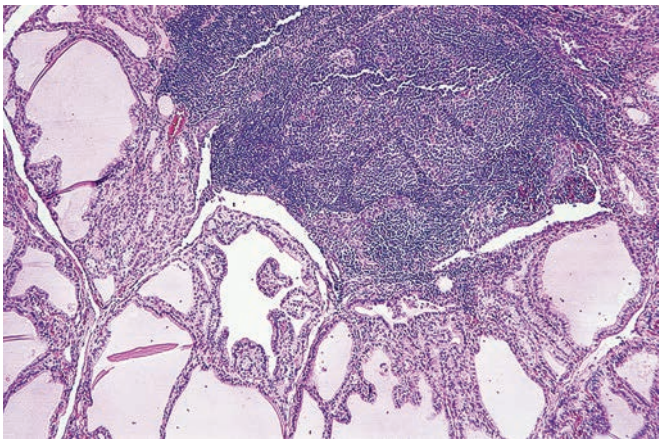

Figure 8.23 Lymphoid follicles with germinal centers and hyperplastic thyroid follicles in diffuse hyperplasia. Note the pale-staining quality of the colloid.

may be seen outside the thyroid gland, sometimes growing into the skeletal muscle of the neck. This may represent extrathyroid extension of the hyperplastic process or—more likely—the expression of hyperplasia in ectopic thyroid follicles, which in the normal situation are so small and scanty as to pass undetected.[155] Whatever the mechanism for their development, they should not be interpreted as evidence of malignancy.

Controversy still exists regarding the incidence, as well as the prognosis, of thyroid cancer associated with Graves disease (and hyperthyroidism in general, e.g., in the case of toxic multinodular goiter), but the numbers are such as not to influence the selection of therapy for Graves disease in the absence of palpable thyroid nodules.[156] Not surprisingly, incidental carcinomas have been found in the pathologic examination of thyroid glands removed for hyperthyroidism, their incidence varying from 1% to 10% in most reported series.[156] These figures are no higher than those reported in otherwise normal glands. Nearly all of the cases have been small papillary carcinomas without clinical significance, although some studies have suggested that carcinomas arising in patients with Graves disease may potentially be more aggressive.[156] The treatment of Graves disease may consist of antithyroid drugs such as propylthiouracil, methimazole, and carbimazole; ablation of the gland with radioactive iodine; or subtotal thyroidectomy.[147] The latter operation provides the specimen most commonly seen by the pathologist in this disorder. It should be noted that the microscopic picture described previously is rarely seen in their pristine state in these organs because of the changes that supervene as a result of therapy with antithyroid drugs and iodine or beta-blockers, which are given routinely in the preoperative period.[147] The glandular enlargement and the lymphoid infiltrate persist, but most of the hyperplastic changes in the follicles regress.[152,157,158] However, thorough sampling will usually reveal residual foci of hyperplasia. After surgery the thyroid remnants regenerate, so that a euthyroid status can be maintained, especially if the amount of thyroid tissue left is approximately 5 g on each side.[159] The greater the lymphocytic infiltration and the larger the number of oxyphilic cells in the operative specimen, the greater the chance that hypothyroidism will develop postoperatively.[160]

Glands treated with radioactive iodine show initially nuclear abnormalities, dissolution of some of the follicles, and vascular alterations. In later stages, nodularity, oncocytic changes, follicular atrophy, and fibrosis occur.[158,161,162] As a consequence, the long-term incidence of hypothyroidism is very high with this therapy. It should be noted that none of these treatments improves the ophthalmopathy associated with hyperthyroidism; rather, in some instances radioactive iodine treatment may provoke or worsen it.[147]

Graves disease is one of the two major forms in which *autoimmune thyroid disease* may manifest, the other being Hashimoto thyroiditis.

In Graves disease, thyroid-stimulating immunoglobulins activate TSHr, causing the overproduction of thyroid hormones and hyperthyroidism.[147,148] The T and B cells, as well as antigen-presenting cells infiltrating the thyroid parenchyma, produce numerous cytokines (including interleukins-1β, -6, and -12 and interferon-γ). These cytokines activate and sustain inflammation and alter the behavior of the follicular cells. Follicular cells start producing cytokines and expressing MHC class II molecules and CD40, allowing for productive interactions between thyroid epithelium and antigen-specific T cells that contribute to the autoimmune inflammatory process. Other antithyroid antibodies (e.g., anti-peroxidase) are also present but are not relevant for the development of the hyperthyroidism.[147]

The occurrence of an immune attack on the thyroid follicle is also evident on electron microscopic examination, which demonstrates deposits consistent with immune complexes in the follicular basement membrane.[163]

Genetic and environmental factors have been associated with the development of Graves disease, but the specific initiating events are unknown: infections and emotional stress are often reported in the patient history.[147,148,164] An increased incidence of Graves disease after irradiation to the neck for lesions such as Hodgkin lymphoma has been observed,[165] and cases have been reported in association with true thymic hyperplasia.[166]

Graves disease is only one of the many disorders—although by far the most common (80% of cases in iodide sufficient areas)[148]—that can lead to clinically evident hyperthyroidism, i.e., hyperfunction due high thyroid hormone levels caused by an increase in their synthesis and secretion by the thyroid parenchyma. Hyperthyroidism is not synonymous with *thyrotoxicosis,* the clinical hypermetabolic syndrome caused by increased free thyroxine-T4 and/or free triiodothyronine-T3 levels that may or may not be due to increased hormone synthesis and secretion by the thyroid. Other causes of hyperthyroidism include the following[148]: (1) "Toxic" sporadic (nodular) goiter; (2) "Toxic" follicular adenoma and the rare hyperfunctioning thyroid carcinoma. In these instances the hyperthyroidism is due to activating mutations in the gene encoding for the TSH receptor or in that for its associated Gsα subunit protein (with or without associated *EZH1* gene mutations); (3) TSH-secreting pituitary adenoma (hyperthyroidism due to stimulation by inappropriate TSH secretion); (4) Trophoblastic tumors (hydatidiform mole, choriocarcinoma) and human chorionic gonadotropin (hCG)-induced gestational hyperthyroidism. In these cases the hyperthyroidism is due to increased stimulation of the TSH receptor by hCG; (5) Struma ovarii (hyperthyroidism due to the autonomous function of thyroid tissue in the ovarian teratoma); (6) Iodine-induced hyperthyroidism (the Jod-Basedow effect—*jod* is the German word for iodine; hyperthyroidism after exposure to excessive amounts of iodide caused by increased hormone synthesis in patients with underlying thyroid disease, particularly those with multinodular goiter containing autonomously hyperfunctioning areas); (7) Familial and sporadic non-autoimmune hyperthyroidism due to gain-of-function germline mutations in the TSH receptor gene.

Thyrotoxicosis without hyperthyroidism is due to the release of stored, preformed iodothyronine hormones into the circulation (follicular cell damage with "hormone leakage") as seen in various types of thyroiditis (e.g., de Quervain or drug-induced thyroiditides), or due to excessive intake of exogenous thyroid hormones (iatrogenic or factitious).[148] *Amiodarone-induced thyroid disease* includes both thyrotoxicosis

and hypothyroidism. Amiodarone is a cardiac antiarrhythmic and antianginal drug containing a large amount of iodine (37% by weight) that is in part released in the blood. Amiodarone-induced thyrotoxicosis type I is a form of iodine-induced hyperthyroidism caused by the exposure to high amounts of iodine; amiodarone-induced thyrotoxicosis type II is due to the direct toxic effect of the drug on thyrocytes, characterized histologically by degenerative and destructive follicular lesions causing the release of iodothyronines, involutional changes, and fibrosis.[72,148,167] Amiodarone-induced hypothyroidism (due to iodine excess) occurs predominantly in patients with preexisting thyroid autoimmune disease.[72]

Autoimmune thyroid diseases like Graves disease and Hashimoto thyroiditis can be components of autoimmune polyendocrine syndromes and can also be associated with non-endocrine autoimmune disorders (e.g., vitiligo, pernicious anemia, myasthenia gravis, autoimmune gastritis, celiac disease, hepatitis).[122]

Nodular Hyperplasia

Nodular hyperplasia (multinodular hyperplasia, nodular or multinodular goiter, adenomatoid goiter, adenomatous hyperplasia) is the most common thyroid disease. Its development is influenced by environmental factors, the most important of which is iodine deficiency, and by genetic factors.[168]

In the form traditionally known as **endemic goiter**, the disease is due to low iodine content of the water and soil, and it can be largely prevented by the addition of iodine to common salt.[169,170] The deficiency in thyroid hormone production induced by iodine deficiency leads to increased TSH secretion, which results initially in a hyperactive thyroid with tall follicular epithelium and small amounts of colloid (so-called *parenchymatous goiter*) and later in follicular atrophy with massive storage of colloid, with or without nodularity (so-called *colloid goiter*). In these endemic areas, the frequency of the disease at post mortem examination is virtually 100%. Although endemic goiter is typically a disease of developing countries, iodine deficiency is a global public health problem and may cause goiter also in developed ones.[169,170]

In the form known as **sporadic (nodular) goiter**, which is the one most commonly seen in the United States and other developed parts of the world, the pathogenesis remains unclear. Mild dietary deficiency of iodine, slight impairment of hormone synthesis, natural goitrogens, smoking, and lack of selenium and iron have been variously suggested.[168] In most patients with nodular hyperplasia, the blood levels of TSH are not elevated. Some cases are associated with lymphocytic or Hashimoto thyroiditis and can be viewed as the nodular forms of these immune-mediated inflammatory diseases. Hereditary predisposition is polygenic and influenced by environmental factors. Single nucleotide polymorphisms at specific chromosomal loci (1p36, 15q21and 16q23) have been linked to thyroid volume by genomewide association studies (GWAS),[171] while polymorphisms at both thyroid-specific genes (encoding for TPO, thyroglobulin, sodium iodine symporter, pendrin, and TSHr) and non thyroid-specific chromosomal loci (e.g., MNG-1 at 14q31, MNG-2 at Xp22, MNG-3 3q26.1-q26.3) have been associated with nodular goiter.[172] Patients with DICER1 syndrome, a rare autosomal dominant cancer syndrome caused by inactivating germline mutations in the gene encoding DICER1, a ribonuclease (RNase) involved in the generation of mature miRNA species, develop pleuropulmonary blastoma, ovarian Sertoli-Leydig cell tumors, cystic nephroma of the kidney and multinodular goiter with adenomatous nodules, and sometimes thyroid carcinoma (often follicular variant papillary carcinoma).[173]

The prevalence of goiter in the general adult population of iodide-sufficient regions is 10% in women and 2% in men,[174] while thyroid nodularity is identified at autopsy in approximately 50% of cases.[175] Clinically, most patients are euthyroid and when first seen have a multinodular gland that may become very large, cause tracheal obstruction, and produce considerable disfigurement. In cases with a single, firm, dominant nodule, the clinical distinction from a true neoplasm becomes impossible. Hemorrhage within a nodule can cause sudden enlargement and pain. A small proportion of patients initially have clinical signs of hyperthyroidism, but the exophthalmos of Graves disease does not occur.[168]

Some cases of nodular hyperplasia are located substernally and enter in the differential diagnosis of superior mediastinal tumors (see Chapter 12). The morphologic changes are similar to those of the nodular form of endemic goiter. As in the latter, the degree of thyroid nodularity is directly related to the duration of the disease.[168,176] On occasion, one or more of the hyperplastic nodules appear in the lateral neck, anatomically separate from the main gland, sometimes simulating metastatic thyroid carcinoma[177]; these are referred to as *parasitic nodules*.

Grossly, the thyroid with nodular hyperplasia is enlarged and its shape distorted, one lobe being frequently larger than the other (Fig. 8.24). The thyroid capsule may be stretched but is intact. On cross section, multiple nodules are seen; most are devoid of a capsule (Fig. 8.25), but some may be partially or even completely encapsulated. Secondary changes in the form of hemorrhage, calcification, and cystic degeneration are common.

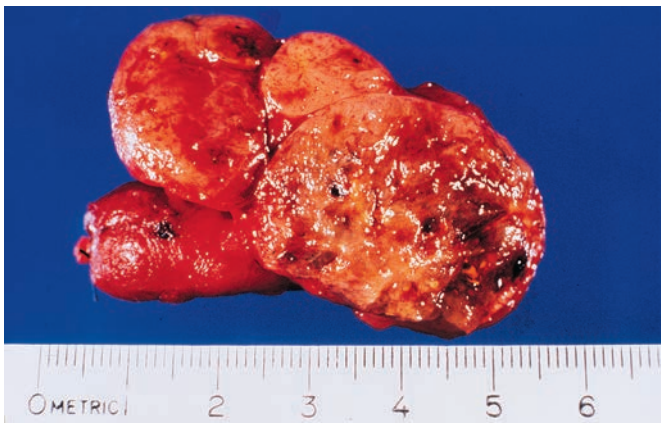

Figure 8.24 Nodular hyperplasia of thyroid gland, with secondary cystic and hemorrhagic areas.

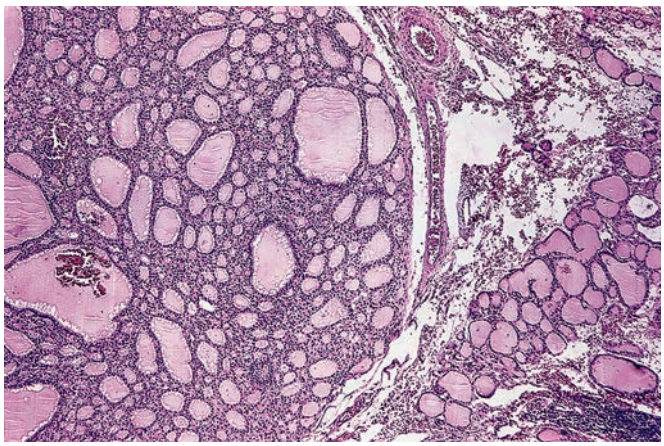

Figure 8.25 Low-power appearance of nodular hyperplasia. The hyperplastic nodules lack a capsule.

Microscopically, the appearance is very variable. Some nodules are composed of huge follicles lined by flattened epithelium, others are extremely cellular and hyperplastic, and still others are composed predominantly or exclusively of oncocytic (Hürthle) cells (Fig. 8.25). Some of the dilated follicles have a conglomerate of small active follicles at one pole (so-called *Sanderson polsters*) (Fig. 8.26). Others have papillary projections facing the lumen of a cystic follicle, a feature that may lead to confusion with papillary carcinoma (Fig. 8.27).[151]

It is not unusual to find, within a nodule predominantly composed of large dilated follicles, sharply outlined solid or microfollicular clusters of follicular cells. It has been suggested that nodular goiters grow by episodic replication of these clusters, which have been referred to as *foci of secondary proliferation*. The proliferative activity in these clusters overlaps with that of neoplastic nodules (follicular adenoma, follicular carcinoma, papillary carcinoma).[178]

Rupture of follicles leads to a granulomatous reaction to the colloid, with appearance of histiocytes and foreign body–type giant cells. Greatly thickened vessels with calcified media, areas of fresh and old hemorrhage, coarse fibrous trabeculation, foci of calcification, and osseous metaplasia may be seen as expression of regressive changes. Exceptionally, foci of extramedullary hematopoiesis are found in patients with known or occult primary myelofibrosis.[179]

Vascularization inside the nodules is usually prominent, sometimes accompanied by reactive endothelial hyperplasia[180] and exceptionally even by the presence of hyperplastic follicles within vascular lumina.[181] Obviously, the latter feature raises the differential diagnosis with angioinvasive follicular carcinoma. Although the distinction can be very difficult, if the overall appearance of the lesion is typical throughout of nodular hyperplasia (including the intravascular component), a benign diagnosis is justified. Conversely, the multinodular pattern of invasion of some widely invasive carcinomas (particularly Hürthle cell carcinomas) may simulate nodular hyperplasia.[177] A variable number of chronic inflammatory cells are present in the stroma in many of the cases, indicating the coexistence of chronic thyroiditis; the larger their number, the higher the incidence of postoperative hypothyroidism.[160] The presence of highly atypical nuclei in a case of nodular hyperplasia should raise the possibility of previous exposure to radioactive substances if present in the nodule themselves, and of dyshormonogenetic goiter if present between the nodules. It is not possible to predict on the basis of the morphologic appearance whether the patient has clinical or laboratory evidence of hyperthyroidism.

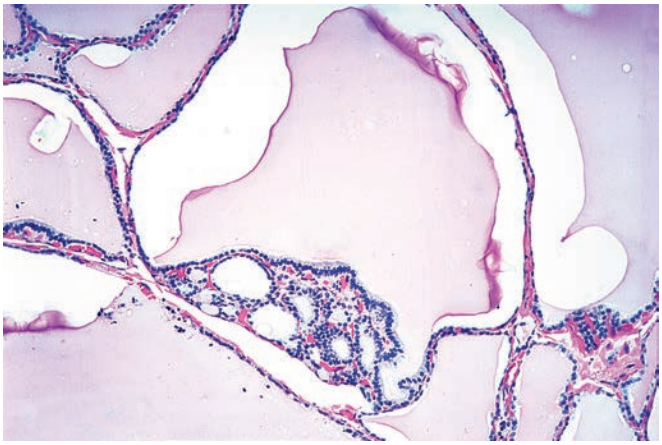

Figure 8.26 Nodular hyperplasia showing so-called Sanderson polster.

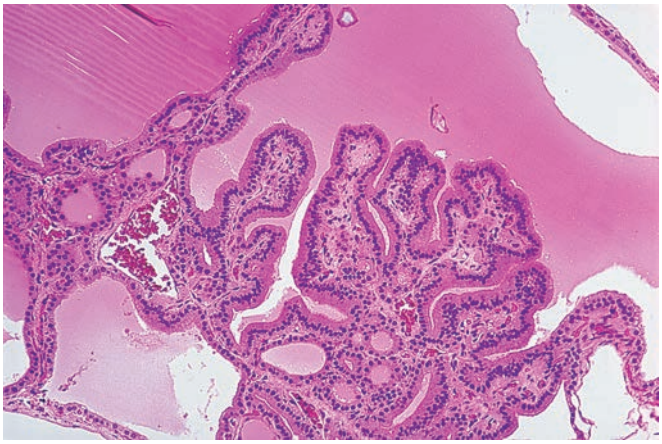

Figure 8.27 Nodular hyperplasia with benign papillary formations protruding toward the center of a cystically dilated follicle. Note the basal position of the nuclei.

The differential diagnosis between a dominant nodule from a case of nodular hyperplasia and a true adenoma is based on a set of admittedly arbitrary criteria. The adenoma is usually single, is totally surrounded by a capsule, is dissimilar from the remaining parenchyma, compresses the adjacent tissue, and is composed mainly of follicles that are smaller than those of the normal gland. The lesion of nodular hyperplasia is almost always one of many nodules, its encapsulation is incomplete, the follicular size is variable, some or all of the follicles are larger than those in the surrounding gland, and there is no compression of the adjacent parenchyma. In some cases, the distinction becomes impossible, inasmuch as lesions with the morphologic features of adenoma may be multiple and/or occur in a setting of nodular hyperplasia.

To address this, the clonality of hyperplastic nodules has been evaluated using X chromosome inactivation patterns: thyroid nodules, particularly the "dominant" adenomatous ones that develop in the background of nodular hyperplasia, may be monoclonal, even when they are partially or completely devoid of a fibrous capsule.[182] These studies have limitations given the large size of the embryonal X chromosome inactivation patch in the thyroid gland (approximately 0.5–1 cm^2),[183] but results consistent with a monoclonal cell population are identical to those obtained in many follicular adenomas (that are typically, but not always, clonal by X chromosome inactivation analysis).[184]

Most hyperplastic nodules have a normal karyotype. However, chromosomal DNA abnormalities detectable by conventional karyotyping and ploidy analysis occur in a minority of hyperplastic nodules, particularly in those with adenomatous features that frequently have extra copies of chromosome 7.[185] Activating mutations of the TSH receptor gene, typically associated with "toxic" adenomas, have been identified in hyperfunctioning, scintigraphically "hot" areas in multinodular goiter[184] and in microscopic, autoradiographically "hot" foci in approximately 30% of euthyroid goiters.[186] Activating *RAS* mutations occur in a few hyperplastic nodules.[184,187] These observations (monoclonal origin of some hyperplastic nodules, the occurrence of cytogenetic abnormalities, of aneuploidy and of oncogenic mutations) have been used to argue that hyperplastic nodules are in fact neoplastic.[184] They certainly reflect the difficulty in drawing the line between hyperplasia and neoplasia, a problem common to all endocrine proliferative lesions.

A longstanding and still unresolved issue is whether nodular hyperplasia is associated with an increased incidence of clinically significant carcinoma, particularly of the follicular type.[168] Suffice it to say that if such an increase really exists, it is small enough to be disregarded for practical purposes.

Mild asymptomatic cases of nodular hyperplasia require no treatment. Suppressive medical therapy with exogenous thyroid hormones is only moderately effective. If the enlargement is such that disfigurement or pressure symptoms develop, bilateral subtotal thyroidectomy is performed.[168]

Tumors

The majority of clinically apparent thyroid neoplasms are primary and epithelial. Traditionally, they have been divided into adenomas and carcinomas, the latter group incorporating the medullary carcinomas together with the more common lesions composed of follicular cells. From a histogenetic/differentiation standpoint, it is preferable to divide thyroid neoplasms into three major categories, depending on the cell types involved, and subdivide them into the various benign and malignant categories:

1. Tumors exhibiting follicular cell differentiation
2. Tumors exhibiting C-cell differentiation
3. Tumors exhibiting follicular and C-cell differentiation.

Lesions in the first category comprise more than 95% of the cases, the remainder being largely made up by tumors in the second category.[188]

Epithelial Tumors—Specific Types

Follicular Adenoma

Follicular adenoma is defined as a benign encapsulated tumor that shows evidence of follicular cell differentiation and lacks: (1) evidence of capsular, vascular, or any other type of invasion; and (2) the nuclear features of the papillary family of neoplasms. It is a common thyroid neoplasm. Most patients are euthyroid adults who initially have a thyroid lump, which on scan is usually "cold," sometimes "cool" or "warm," and only rarely "hot." The large majority of "hot" nodules are benign, but exceptions have been documented.[189]

By ultrasound, follicular adenomas are well circumscribed, usually solid, isoechoic or hypoechoic with a peripheral halo, similar to follicular carcinomas.[190]

Few of the tumors are associated with clinical hyperthyroidism (so-called *toxic* or *Plummer adenomas*).[191,192] The thyroid tissue outside hyperfunctioning nodules often contains intraluminal crystals of calcium oxalate, thought to be a sign of hypofunction.[189]

Adenomas are almost always solitary (except when occurring in genetically determined syndromes). They are characteristically surrounded by a generally thin capsule that is grossly and microscopically complete (Figs. 8.28 and 8.29). The architectural and cytologic features are different from those of the surrounding gland, which usually shows signs of compression. Adenomas may exhibit a variety of patterns, singly or in combination: normofollicular (simple), macrofollicular (colloid), microfollicular (fetal), and solid/trabecular (embryonal) (Fig. 8.30). The morphologic differences among these various patterns may be striking. They have no apparent clinical significance but elicit different differential diagnoses. Thus, as a general rule, the larger the follicles, the less likely that the lesion is a follicular adenoma or a follicular carcinoma (as opposed to a hyperplastic nodule or a papillary carcinoma with a predominantly follicular growth pattern). Instead, a predominance of solid/nesting/trabecular areas should alert one to the alternative possibilities of poorly differentiated or medullary carcinoma (which, however, are usually—but not always—clearly invasive).[193]

Mitoses are rare or absent in the follicular adenomas. They are not necessarily indicators of malignancy, but when they are present in appreciable numbers one should sample and examine the specimen with particular care. Secondary degenerative changes such as hemorrhage, edema, fibrosis, calcification, bone formation, and cystic degeneration are common, especially among the larger tumors. Sometimes the vessels in the capsule of adenomas (and also at the periphery of hyperplastic nodules) show prominent focal thickenings of their wall, referred to as *muscular cushions*.[194] Adenomas may exhibit papillary or pseudopapillary structures, which may prompt confusion with papillary carcinoma. Some authors have referred to these tumors as "papillary adenomas," a term that should be replaced with *follicular adenomas with papillary hyperplasia*.[195] The differential diagnosis, which

Figure 8.28 **A** and **B**, Gross appearance of two follicular adenomas. Both tumors show focal hemorrhagic areas.

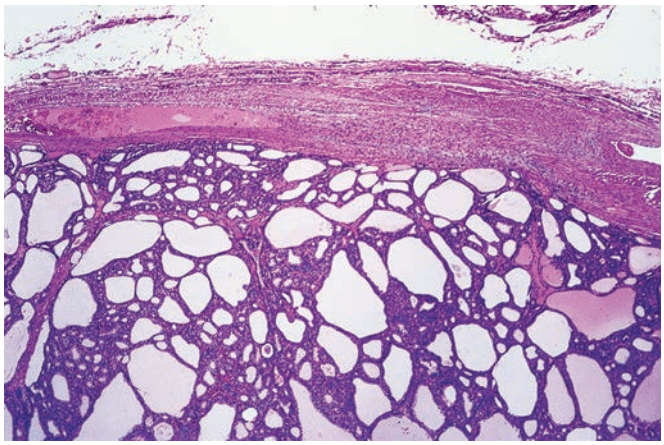

Figure 8.29 Intact fibrous capsule around a follicular adenoma.

includes hyperplastic nodules and encapsulated papillary carcinomas, is discussed later.

Some correlation exists between the microscopic appearance of a follicular adenoma and its activity as judged by the scan appearance.[196,197] In general, hyperfunctioning (hot) adenomas are more cellular and their cells have more abundant cytoplasm (and therefore a decreased nucleocytoplasmic ratio) than nonfunctioning (cold) tumors. However, the range of morphologic appearances that hot thyroid nodules can exhibit is wide, including less well-differentiated and oncocytic patterns. Hyperfunctioning follicular adenomas that are scintigraphically "hot" (and sometimes associated with overt hyperthyroidism, so-called *toxic* or *Plummer adenomas*) typically have activating mutations in the gene encoding the TSH receptor (*TSHR*) or in that encoding its associated Gsα subunit protein *(GNAS)*. *TSHR* mutations are more common (~50%–80%) than those of *GNAS* (~5%).[198,199] *EZH1* gene mutations have been identified in approximately 20%–30% of cases, nearly always in combination with *TSHR* or *GNAS* mutations, or with other presumed alterations in cAMP pathway genes.[200] It should also be remembered that hot thyroid nodules are usually but *not always* benign.[189]

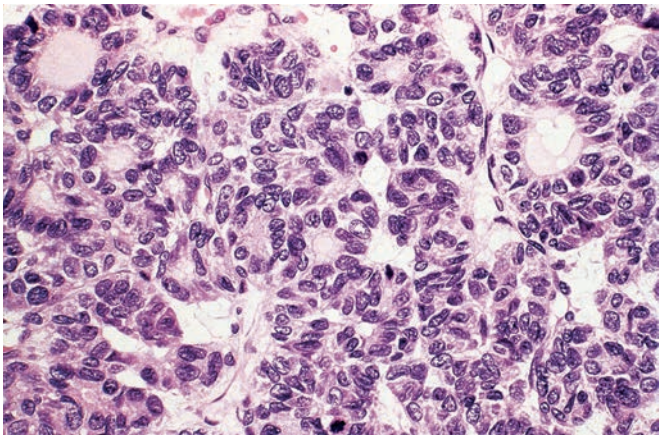

Figure 8.30 Microfollicular pattern of growth in a follicular adenoma.

The enzyme histochemical and immunohistochemical profile of adenomas mirrors that of the normal follicle.[201,202] There is reactivity for low-molecular-weight keratin, TPO, and thyroglobulin in the cytoplasm, for TTF-1 and PAX8 in the nuclei, and for laminin and other basement membrane components around the follicles.[26,202] The use of immunohistochemical markers in the differential diagnosis is discussed later. To date, no molecular test can reliably distinguish between follicular adenoma and follicular carcinoma, since genetic alterations (e.g., chromosomal abnormalities, activating *RAS* mutations, and *PAX8/PPARG* rearrangement) found in the former are also found, albeit with a higher prevalence, in the latter (Table 8.2). This points to a tumorigenic pathway common to all follicular neoplasms (adenomas and carcinomas) as opposed to papillary carcinoma.[203] Reasoning along this line, it may be argued

Table 8.2 Genetic pathology of thyroid tumors of follicular cells[a]

[a]The main molecular alterations are reported; in parentheses the mutation prevalence percentage range, as estimated from the literature quoted in the text.
[b]Mutations in *N-, H, KRAS*; *NRAS* is the gene most frequently mutated.
[c]Hyperfunctioning follicular adenomas and adenomatous nodules have mutations of the TSH gene receptor (*TSHR*) (~50%–80% of cases), of the *GNAS* gene (~5% of cases), of the *EZH1* gene (~20%–30% of cases, nearly always in combination with *TSHR* or *GNAS* mutations, or with other presumed alterations in cAMP pathway genes).
[d]According to conventional cytogenetics, cytometric measurement of DNA content, comparative genomic hybridization, loss of heterozygosity and somatic copy-number alterations studies.
[e]The prevalence of *RET/PTC* is higher in children and much higher in radiation-associated papillary carcinomas (~50%–80%).
[f]The prevalence of *NTRK* rearrangements is variably reported between 0% and 5% for *NTRK1* and *NTRK3* in most series from nonradiation-associated papillary carcinoma in adult patients; the prevalence is higher in children and young patients, and in radiation-associated papillary carcinomas (up to ~15% for *NTRK3/ETV6*).
[g]*EIF1AX* mutations often co-exist with *RAS* mutations; they have been reported in follicular adenomas and rarely in hyperplastic nodules.
[h]The prevalence of *BRAF* p.V600E is approximately 40% in aggressive, radioiodine-refractory and FDG-PET positive tumors
[i]*CTNNB1* is the gene encoding β-catenin (effector of the *wnt* pathway); previous studies reported a higher prevalence of *CTNNB1* mutations in poorly and undifferentiated carcinomas.

that follicular adenomas with *PAX8/PPARG* are in fact noninvasive or preinvasive follicular carcinomas, or that the tumor has not been adequately sampled and that invasion of the capsule or blood vessel was missed. This is supported by the more common occurrence of the rearrangement in follicular carcinomas and also by the high cellularity and atypical features of some follicular adenomas with *PAX8/PPARG*.[204] A similar argument can be made for *RAS* mutations, since *RAS* mutated follicular adenomas may progress to *RAS* mutated follicular carcinomas and undergo further dedifferentiation.[203]

Follicular adenomas are typically (but not always) clonal according to X chromosome inactivation studies.[182,183] Conventional karyotyping identifies aberrations in 35%–65% of cases.[185,204,205] Numerical changes begin with an extra copy of chromosome 7, followed by the acquisition of additional copies of other chromosomes, a sequence that parallels the transition from hyperplastic to adenomatous nodules. Structural abnormalities overlap with those of follicular carcinomas.[185,205,206] Chromosomal translocations that involve 19q13, with the breakpoint corresponding to the *ZNF331* gene locus, and chromosome 2p21, with the breakpoint corresponding to the thyroid adenoma associated (*THADA*) gene locus, have been identified in approximately 10% of cases but are apparently rare in follicular carcinoma.[207,208] Fusion of *THADA* with the LOC389473 pseudo gene (at 7p15.3), leading to increased insulin-like growth factor receptor signaling, has been reported in approximately 5% of papillary carcinomas (follicular variant papillary carcinomas or NIFTP).[209] The PI3K/PTEN/AKT pathway is rarely altered in sporadic follicular adenomas, due to activating mutations of the *PIK3CA* gene that have been identified in a few cases (~5%); *PTEN* gene mutations are also uncommon.[210] This is somewhat surprising, considering that loss of function germline *PTEN* mutations are responsible for the Cowden syndrome (one of the PTEN-hamartoma tumor syndrome, PHTS) that is characterized by multicentric and bilateral thyroid follicular adenomas and hyperplastic/adenomatous nodules.[211] Follicular adenomas and adenomatous nodules also occur in the Carney complex type I[212] (*PRKARIA* germline mutations) and in the McCune–Albright syndrome (sporadic, postzygotic activating mutations of *GNAS*), in which case they are typically hyperfunctioning.[213]

Several variants of follicular adenoma have been described. *Oncocytic (Hürthle cell) adenoma* is discussed later and *hyalinizing trabecular adenoma* in the section that follows. The term *atypical adenoma* has been proposed for adenomas with pronounced cellular proliferation and less regular cytoarchitectural patterns but still lacking evidence of capsular or blood vessel invasion.[214,215]

Adenoma with bizarre nuclei is characterized by the presence of huge hyperchromatic nuclei, usually in clusters, unaccompanied by other features of malignancy (Fig. 8.31). This phenomenon is analogous to that seen in parathyroid adenomas and other endocrine neoplasms.

Other rare types of follicular adenoma are those with clear cell changes (including the signet ring, mucin-producing, and lipid-rich types), adenomas with adipose metaplasia of the stroma (so-called *lipoadenomas* or *adenolipomas*),[216] adenomas with cartilaginous metaplasia (so-called *adenochondromas*),[217] spindle cell adenomas (some vaguely resembling meningiomas),[218] and adenomas with massive deposition of cytoplasmic black pigment following minocycline therapy (so-called *black adenomas*).[219]

The differential diagnosis of follicular adenoma includes a dominant nodule of nodular hyperplasia, noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP), minimally invasive carcinomas (follicular carcinoma or follicular variant papillary carcinoma), medullary carcinoma, and intrathyroidal parathyroid adenoma. Some follicular adenomas may also be confused with vascular tumors because of their high vascularization.

The lack of immunoreactivity for galectin-3, HBME1, and CITED1 and the retention of CD56 helps to distinguish adenomas from NIFTP and follicular-variant papillary carcinoma (Table 8.3); immunoreactivity for thyroglobulin and lack of calcitonin and CEA distinguishes adenomas with solid/trabecular growth from medullary carcinoma; immunoreactivity for thyroglobulin and TTF-1 and lack of chromogranin and parathyroid hormone distinguishes follicular adenomas from intrathyroidal parathyroid adenomas.[202,220–224]

The standard therapy for follicular adenoma is removal by lobectomy. Enucleation of the adenoma should not be attempted. Suppression of the nodule with levothyroxine and treatment of the toxic adenoma with radioactive iodine have been used, but the results have generally been less than satisfactory.[197]

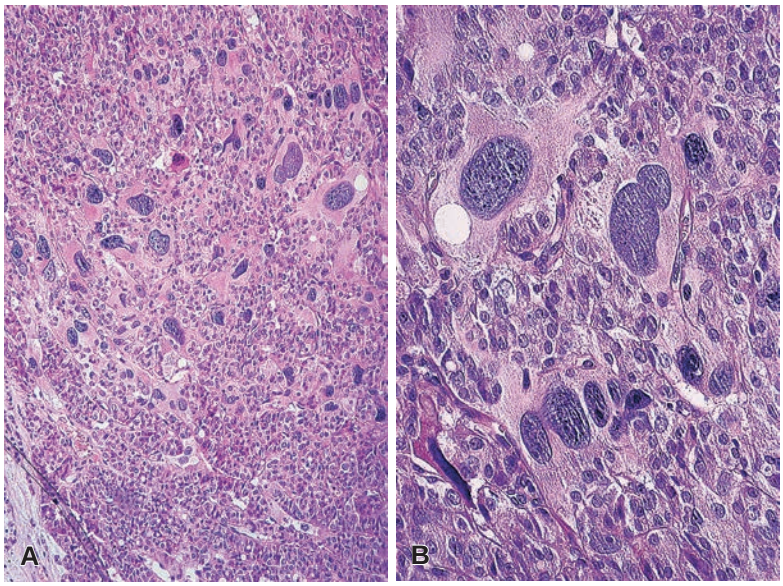

Figure 8.31 Low-power **(A)** and high-power **(B)** views of follicular adenoma with bizarre nuclei. This feature is not a sign of malignancy and is analogous to that seen in many other endocrine tumors.

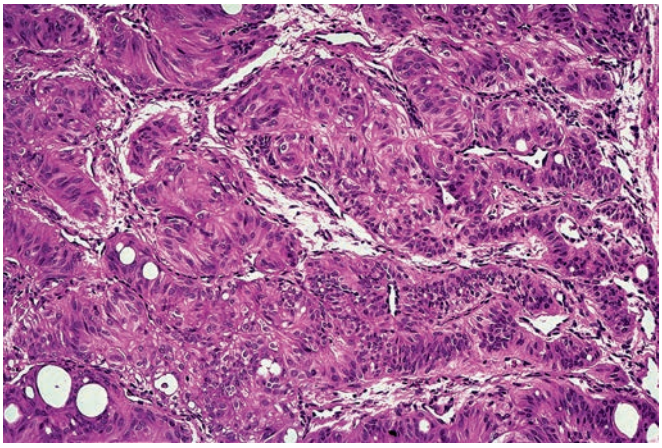

Figure 8.32 Low-power view of hyalinizing trabecular adenoma.

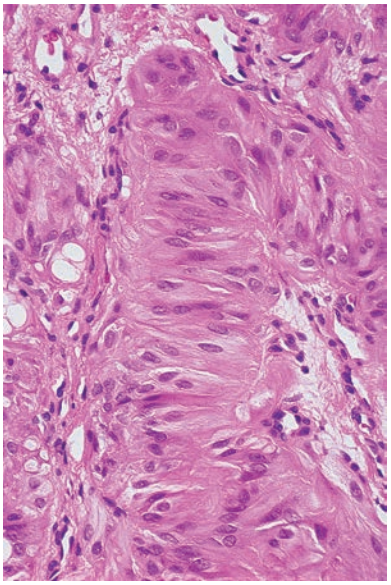

Figure 8.33 Hyalinizing trabecular adenoma. A wide trabecula is seen in the center of the picture, with the tumor cells arranged perpendicular to the longest axis.

Hyalinizing Trabecular Tumor and Related Lesions

Hyalinizing trabecular adenoma was the term given by Dr. J.A. Carney in 1987[226] to a peculiar type of follicular cell neoplasm (apparently first identified by Langhans).[227] Because of its unclear relationship with malignancy and because rare cases may show invasion (of the tumor capsule or vascular spaces) or metastases (see later) the term *hyalinizing trabecular tumor (HTT)* is currently preferred.[225,228,229] The lesion has a very distinctive histologic appearance, characterized by a prominent trabecular arrangement and an equally prominent hyaline appearance (Fig. 8.32). The latter is present both in the cytoplasm of the tumor cells (as the result of the accumulation of intermediate filaments) and in the extracellular space (as the result of heavy deposition of hyalinized collagen fibers and basement membrane material). The trabeculae can be straight or curved, resulting in curious organoid formations (Fig. 8.33). The pattern of growth may simulate that of paraganglioma and medullary carcinoma, whereas the presence of perinucleolar clearing, nuclear grooves, and psammoma bodies may suggest papillary carcinoma, particularly in material from fine-needle aspiration (FNA) (Fig. 8.34).[226] By ultrasound, HTT is typically hypoechoic with a pattern most similar to that of follicular adenoma and the follicular variant papillary carcinoma.[230] Another distinct (but not specific) morphologic feature of HTT is the so-called *cytoplasmic yellow body*, which is a round, 2–5 µm, pale yellow cytoplasmic inclusion body in a paranuclear

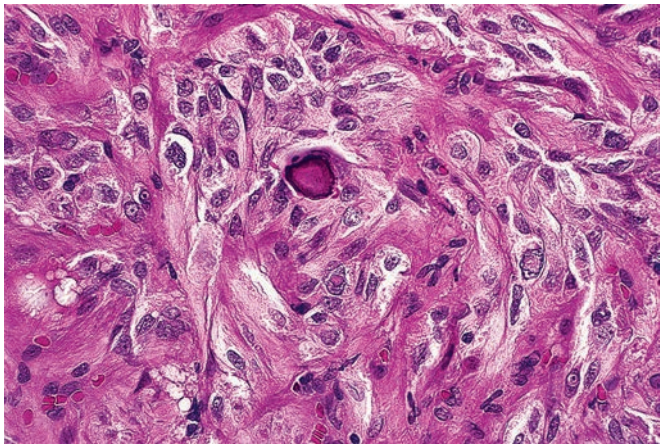

Figure 8.34 Psammoma body formation in hyalinizing trabecular adenoma.

location having a refractile quality and detectable both in tissue sections and in FNA smears.[231,232] These bodies correspond to giant secondary lysosomes[231] and can be found in other thyroid tumors (including papillary and follicular carcinoma), where they are however numerically rare.[232] Immunohistochemically, HTT is positive for thyroglobulin and TTF-1 but not for calcitonin.[226] HBME-1, galectin-3, and cytokeratin 19 are expressed inconsistently.[225,233,234] Focal and inconstant signs of neuroendocrine differentiation have been shown by immunohistochemistry (reactivity for NSE and chromogranin A) and confirmed by the finding of neurosecretory granules by electron microscopy.[227,235]

HTT also shows a peculiar cell membrane and cytoplasmic (instead of nuclear) immunostaining with the monoclonal antibody MIB1 to the proliferation marker Ki-67.[236] The peculiar pattern (likely due to epitope cross reactivity of the MIB1 antibody) is not seen with automated immunostainers which operate at 37°C but only when the reaction is performed at room temperature.[237] Immunostains for type IV collagen and laminin are consistent with heavy deposition of basement membrane material around the tumor cells (partially explaining their "hyaline" appearance) and—surprisingly—in the nuclear pseudoinclusions.[225,235,238]

Considerable controversy has arisen as to whether HTT is a distinct entity or an unusual pattern of growth that can be present in a variety of thyroid lesions.[239,240] It is generally accepted that the "HTT pattern" can be seen as a microscopic incidental finding in nodular hyperplasia,[241] and in rare neoplasms with HTT features accompanied by capsular and/or vascular invasion, which have therefore been designated as hyalinizing trabecular carcinomas.[228,229,242] Intriguing is the apparent link between HTT and papillary carcinoma, which manifests itself by the presence in HTT of morphologic features traditionally associated with papillary carcinoma, such as nuclear alterations (grooves and pseudoinclusions) and the finding of psammoma bodies; by the occurrence of papillary carcinoma merging with HTT (Fig. 8.35)[229,242]; by the association of both conditions with Hashimoto thyroiditis and possibly with radiation exposure.[225,235]

Regardless of this link, in the absence of capsular or vascular invasion there are no well-documented examples of HTT that have metastasized, and the only tumor that developed distant metastases (in the lung) out of a series of 119 cases had both.[225,227]

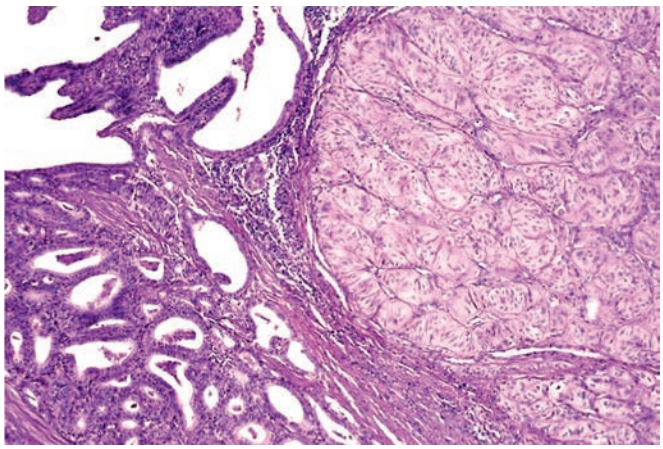

Figure 8.35 Typical hyalinizing trabecular adenoma pattern *(right)*, and a lesion with the features of a papillary carcinoma *(left)* are seen side by side, in a cervical lymph node metastasis. (From Rosai J, DeLellis RA, Carcangiu ML, Frabel WJ, Tallini G. *Tumors of the Thyroid and Parathyroid Glands. AFIP Atlas of Tumor Pathology*. Fourth series, Fascicle 21. Silver Spring, MD: American Registry of Pathology; 2014.)

A small number of cases are aneuploid by flow cytometric DNA analysis[226] or show simple karyotypic alterations.[240] Reports of *RET*/*PTC* rearrangements[243] are in all likelihood the result of subclonal events that are not diagnostically relevant.[128] *BRAF* p.V600E or *RAS* mutations do not occur, and the miRNA profile is different from that of papillary carcinoma.[243,244]

Papillary Carcinoma

General Features

Papillary carcinoma is defined by the presence of a distinctive set of alterations of nuclear morphology, the PTC-type nuclei (see later), although the presence of either papillae or invasion of the surrounding thyroid parenchyma is generally required for the diagnosis. It is the most common type of thyroid carcinoma and the most common endocrine malignancy.[245]

Females are more affected than males. It can present in any age group, the mean age at the time of initial diagnosis being approximately 40–50 years. Papillary carcinoma accounts for more than 90% of thyroid malignancies in children. In approximately 5% of cases, there is a history of irradiation exposure to the neck, and the non-neoplastic gland may show nuclear aberrations as a result. There is convincing evidence for an increase in the incidence of papillary carcinoma in Hashimoto thyroiditis, but the wide variation in the figures quoted suggests that the diagnostic criteria vary just as widely.[246] Whether the frequency of papillary carcinoma is increased in Graves disease remains a controversial subject.[156,247]

The prevalence of thyroid carcinoma has been increasing globally, mostly due to the increased detection of small papillary carcinomas through neck ultrasound.[245] By ultrasound, papillary carcinoma is usually solid, hypoechoic, with infiltrative or microlobulated margins, microcalcifications, and a "taller than wide" shape.[190] Before the widespread use of ultrasound screening the large majority of patients had clinically evident disease in the neck when they were first seen, localized to the thyroid gland in 67% of cases, thyroid and lymph nodes in 13%, and lymph nodes alone in 20%.[248]

Gross Features

The size of the primary tumor ranges from microscopic to very large. A very high proportion of thyroid cancers measuring less than 1 cm in diameter are of papillary type. Grossly, most cases are solid, whitish, firm, and clearly invasive; 10%–20% are surrounded by a complete capsule (Figs. 8.36 and 8.37).[248,249] Marked cystic changes are seen

Figure 8.36 Gross appearance of a papillary carcinoma.

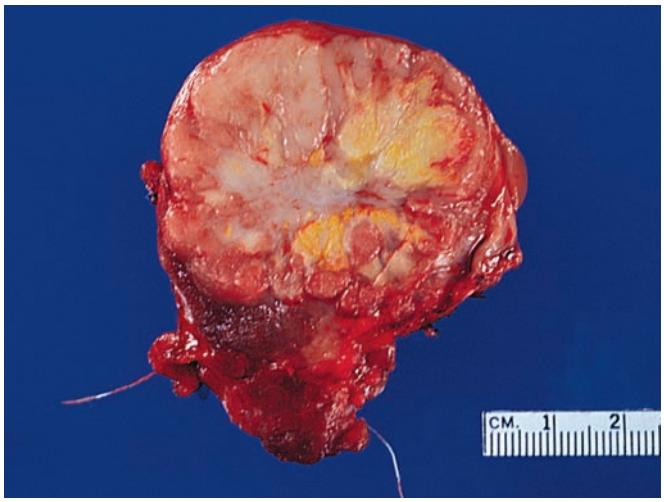

Figure 8.37 Gross appearance of a papillary carcinoma. The tumor shown exhibits a central area of fibrosis.

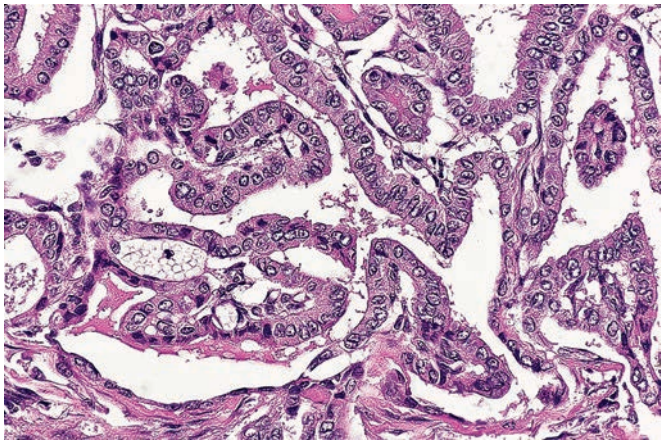

Figure 8.38 Complex branching papillae in classic papillary carcinoma.

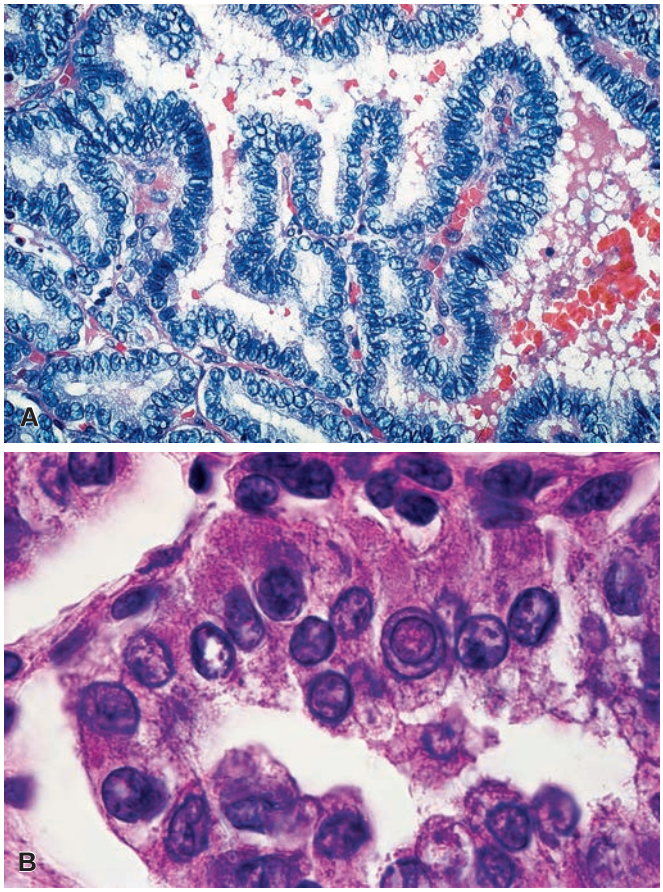

Figure 8.39 Nuclear features of papillary carcinoma: **A,** optically clear nuclei; **B,** nuclear pseudoinclusions.

in approximately 10% of cases. Sometimes the papillary formations are evident to the naked eye.

Microscopic Features

Microscopically, the typical papillary carcinoma contains numerous true papillae, an easily recognizable feature which—as one would have deduced—was the one originally chosen to name the tumor.[250] The papillae are usually complex, branching, and randomly oriented, with a central fibrovascular core and a single or stratified lining of cuboidal cells, some of which may have hobnail features (Fig. 8.38).[251] The stroma of the papillae may be edematous or hyaline and may contain lymphocytes, foamy macrophages, hemosiderin, or—exceptionally—adipose tissue. These papillae are nearly always associated with the formation of follicles, the ratio between the two components varying greatly from case to case. The follicles tend to be irregularly shaped, often tubular and branching. Tumors with a combination of papillary and follicular structures have the biologic behavior of papillary carcinoma and should therefore be classified as such instead of as mixed carcinomas.

The cells of papillary carcinoma have characteristic nuclear features. These have acquired so much relevance that currently the diagnosis of papillary carcinoma is more dependent upon their presence than on the papillary architecture, which may be minor or altogether absent (see under Variants).

These nuclear features (PTC-type nuclei) consist of:

1. Ground-glass (optically clear) nuclei, which often have a large size and an overlapping quality (Fig. 8.39A).[252] The nucleolus is usually inconspicuous and pushed against the nuclear membrane, which appears thickened. This change is present in sections obtained from paraffin-embedded material regardless of the fixative used, but is less apparent or altogether absent in frozen sections or cytology material, and is particularly prominent in tissue fixed in high concentrations of formalin.[253] The mechanism of its formation has not yet been ascertained.[254]
2. Nuclear pseudoinclusions. These represent invaginations of the cytoplasm and appear as sharply outlined (nuclear membrane–bound) round acidophilic vacuoles (see Fig. 8.39B).[255] In contrast to the ground-glass feature, the pseudoinclusions are also readily apparent in specimens from frozen section and aspirations. They should be distinguished from the nuclear "bubbles" that can be seen in a variety of lesions and organs and which are in all likelihood a processing artifact. These "bubbles," when present, tend to affect most nuclei and to be multiple within a single nucleus[177] and have been related to the process of histology section heating at 60°C in the oven before deparafinization (they are absent when sections are dried overnight or with a fan).[256]
3. Nuclear grooves. These tend to occur in oval or spindle nuclei, are usually arranged along the longest nuclear axis, and represent—like the pseudoinclusions—the morphologic expression of infoldings of a redundant nuclear membrane[257] as confirmed by confocal microscope analysis and tridimensional reconstruction.[258]

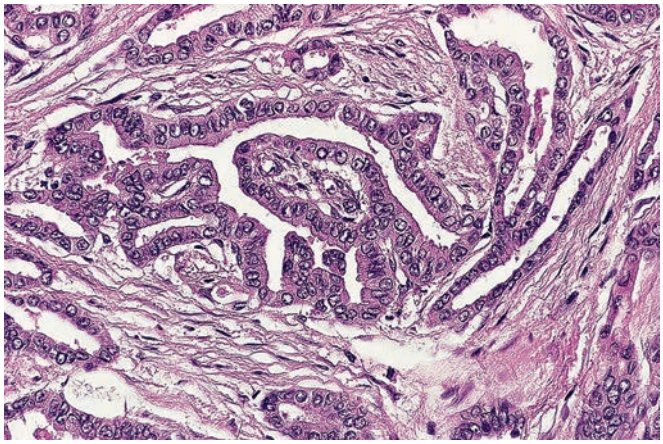

Figure 8.40 Desmoplastic stromal reaction in papillary carcinoma.

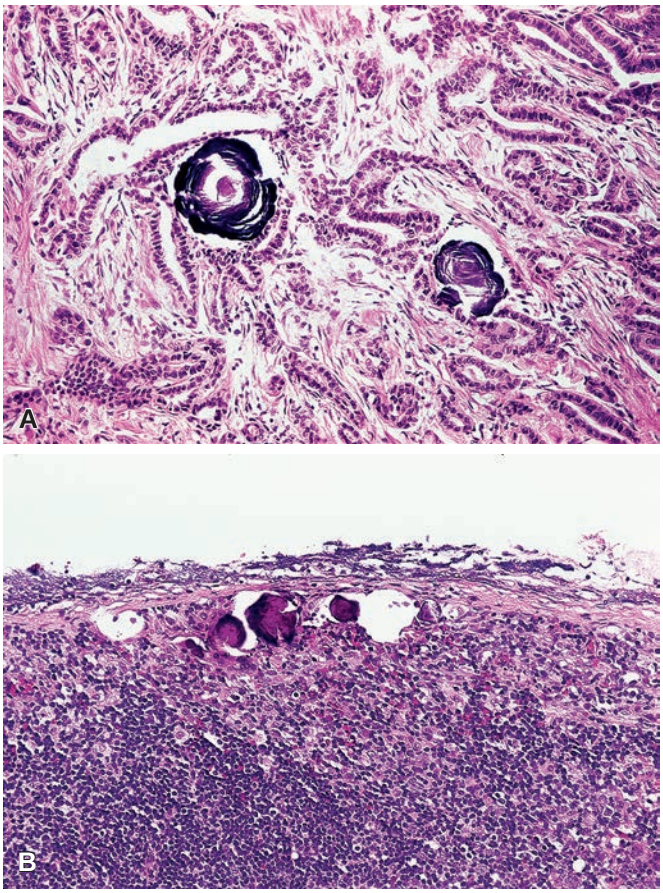

Figure 8.41 Psammoma body formation in papillary carcinoma: **A,** within the stroma of the primary tumor; **B,** beneath the capsule of a cervical lymph node, without identifiable tumor cells.

These nuclear membrane irregularities are seen to better advantage with markers specific for emerin, a nuclear membrane protein.[259]

4. Nuclear microfilaments. A few cases have been described in which the nuclear clearing is due to the accumulation of fine threadlike fibrils.[260]

Mitoses are usually very scanty or absent in papillary carcinoma.[261] Over half of the cases show extensive fibrosis, usually in the form of sharply outlined bands traversing the tumor; the appearance of this fibrosis may range from sclerohyaline to highly cellular (Fig. 8.40). Elastic tissue is often abundant in the tumor stroma.[262]

Psammoma bodies are seen in approximately half of the cases. These basophilic structures showing concentric laminations stain for mucin, calcium, and iron and appear to arise from necrosis of individual tumor cells, which occasionally may be seen at their very center, and which represent the nidus for their formation, very much the way a grain of sand acts as the nidus for the formation of a pearl in an oyster.[263] They may be located in the papillary stalk, in the fibrous stroma, or between tumor cells in solid foci (Fig. 8.41A). Their presence in a thyroid gland strongly suggests the diagnosis of papillary carcinoma, inasmuch as their occurrence in other thyroid lesions is exceptional[264]; Klinck and Winship[265] found them only once in a review of 2153 benign thyroids. Thus they represent a very important clue to the diagnosis not only in paraffin sections, but also in frozen sections and cytology preparations. If numerous enough they are visible on ultrasound scans.[190]

When psammoma bodies are found in otherwise normal thyroid tissue or lymph nodes from the neck, the chances are high that a papillary carcinoma is present in the immediate vicinity (see Fig. 8.41B).[265] Psammoma bodies should be distinguished from other forms of calcification and from the intraluminal foci of inspissated secretion often seen in oncocytic (Hürthle cell) tumors.[177,250]

Areas with a solid/trabecular pattern of growth are present in 20% of the cases and foci of squamous metaplasia in a similar number; these two patterns often merge and are probably related.[250] The presence of such foci is not per se an indication that the tumor is poorly differentiated unless accompanied by other alterations.

Occasionally, papillary carcinomas are seen to contain a bland-looking spindle cell component; this clinically insignificant metaplastic change (recognizable because of its blending with more typical epithelial cells and its immunoreactivity for thyroglobulin and TTF-1) should not be confused with a mesenchymal neoplasm or with the anaplastic transformation of a papillary carcinoma.[266]

Papillary carcinoma has a rich microvasculature, with high microvessel density. On the other hand, lymphatic vessels are very few inside the tumor, but their density is very high at the interface with the surrounding non-neoplastic thyroid.[267] Blood vessel invasion is found in only 5% of cases, a much lower proportion compared to follicular carcinoma.[248] Lymphocytic infiltration of the stroma is seen in a fourth of cases; it is not clear whether this represents a reaction to the tumor or the expression of preexisting thyroiditis.[268] Many tumors also exhibit a heavy infiltrate of S-100 protein–positive dendritic/Langerhans cells and macrophages.[269] Scattered multinucleated giant cells may be present, often in the lumen of the neoplastic follicles and probably representing a response to leakage of colloid.[270]

Multiple microscopic foci of tumor are found in approximately 20% of cases if a few random sections are taken and in over 75% if step sections of the entire gland are examined.[271] It is not entirely clear whether this represents *multicentricity* (multiple independent primary tumors) as opposed to intrathyroidal lymphatic permeation (*multifocality* due to spread of a single primary tumor). Both mechanisms likely operate: mutation analysis indicates the independent origin of these multiple foci in 30%–60% of cases.[272]

Electron Microscopic Features

Ultrastructurally, the most distinctive feature of the cells of papillary carcinoma is the highly indented nuclear membrane, with formation of pseudoinclusions and multilobation.[255,273] Changes in distribution of chromatin and ribonucleoprotein have been observed.[274] The cytoplasm is rich in mitochondria, lysosomes, and intermediate filaments. The apical surface exhibits microvillous differentiation.[255,273] The abnormal intracellular and extracellular deposition of basement

membrane material (of less degree but otherwise similar to that seen in hyalinizing trabecular carcinoma) is very evident at the ultrastructural level.[238]

Histochemical and Immunohistochemical Features

Papillary carcinoma retains immunoreactivity for pan-follicular cell markers, although these are generally downregulated compared with normal follicular cells.[5] Thus, TTF-1, and the other two transcription factors TTF-2 and PAX8 that are required to maintain the differentiated phenotype of follicular cells show consistent nuclear immunoreactivity in neoplastic cell nuclei.[18] Thyroglobulin is also consistently positive (although less than in well-differentiated follicular neoplasms), while TPO and NIS show reduced expression (in the case of NIS localization is redirected from the membrane to the cytoplasm).[13] Similar to normal follicular cells, those of papillary carcinoma are immunoreactive for keratins (detectable with pan-keratin, CAM 5.2, AE1/3 antibodies), with a CK7 positive/CK20 negative profile.[19,275–277] Unlike normal follicular cells, papillary carcinoma cells are often positive for the low-molecular-weight CK19,[19,275,278] and in keeping with their tendency to undergo squamous metaplasia they express high-molecular-weight keratins recognized by the antibody 34βE12.[277] Unlike normal follicular cells, that infrequently coexpress vimentin and keratin, papillary carcinoma cells are often vimentin positive,[21] although coexpression of both markers does not appear to be diagnostically relevant.[279]

The diagnosis of papillary carcinoma does not routinely require immunohistochemistry. When this is performed it is usually to establish the thyroid origin of a tumor at metastatic sites. Thyroglobulin and TTF-1 are very specific markers, and PAX8 can be used to differentiate papillary carcinoma (positive for both TTF-1 and PAX8) from lung adenocarcinoma and other tumors that are positive for TTF-1 but negative for PAX8.[18]

Another situation, considerably more complex, is the use of immunochemistry for the differential diagnosis of papillary carcinoma from other benign and malignant thyroid lesions. HBME-1 (membrane immunoreactivity), galectin-3 (both nuclear and cytoplasmic immunoreactivity), cytokeratin 19 (cytoplasmic immunoreactivity), and CITED1 (both nuclear and cytoplasmic immunoreactivity) are the markers more frequently overexpressed in papillary carcinoma (HBME-1 followed by galectin-3 are considered the most specific),[202,220–222] while CD56 is typically negative (see Table 8.3).[223,224] While the sensitivity of these markers is high, their specificity is relatively low, thus they are more effective when used in combination (usually HBME-1, galectin-3, cytokeratin 19).[202,220–224] Since results vary from one institution to another, in order to diagnose papillary carcinoma the performance characteristics of the panel need to be established in individual laboratories. Unfortunately, in problematic cases immunohistochemical results tend to be difficult to interpret, even if a panel is utilized, and this is particularly true for the abnormal follicular epithelium of Hashimoto thyroiditis.[177,281]

Traditional mucin stains are positive in many papillary carcinomas whether in the colloid, luminal border, or cytoplasm.[282] This correlates with the immunohistochemical demonstration of EMA (MUC1), mucins, simple mucin antigens, and histo-blood group antigens in papillary carcinoma cells (but also in those of follicular carcinoma).[20] EMA and alcian blue stain the apical membrane of the neoplastic cells lining the papillae but not those of the benign papillae of diffuse or nodular hyperplasia.[283]

A variety of other markers have been shown by immunohistochemistry in papillary carcinoma, including estrogen receptors,[22] S-100 protein,[280] S-100C,[284] HER2/neu,[285] cMet/hepatocyte growth factor receptor,[286] and involucrin,[277] while laminin and type IV collagen are demonstrable immunohistochemically at the interface of the tumor with the stroma.[238] Mutation-specific antibodies are available to detect BRAF p.V600E,[287] although molecular analysis is necessary in those cases with equivocal results.[288] Immunohistochemistry with the D5F3ALK antibody may be used as a surrogate marker to identify those rare papillary carcinomas with *ALK* rearrangement.[289]

Molecular Genetic Features

Activation of the mitogen-activated protein kinase (MAPK) pathway is the defining molecular genetic feature of papillary carcinoma.[203,290–292] This pathway regulates important cellular functions (e.g., proliferation, differentiation, and survival) and is frequently altered in human cancers.

Since the oncogenic events that cause MAPK signaling act sequentially in the same pathway, they are usually mutually exclusive.[203,290,291] One can be identified in the vast majority (~90%) of papillary carcinomas: in three out of four cases the MAPK pathway is activated by point mutations of *BRAF* (~60%) or of *RAS* (~15%), and in ~15% by chromosomal rearrangements that cause aberrant expression of receptor tyrosine kinases (RET, NTRK, and ALK) or of the kinase domain of BRAF.[292] Copy number gene variations likely play a tumorigenic role in approximately two-thirds of the remaining ~10% of cases, leaving less than 5% of papillary carcinoma without a known genetic defect.[292]

The prevalence of the main molecular alterations is shown in Table 8.2. The Cancer Genome Atlas (TCGA) Research Network has published in 2014 an integrated genomic characterization of 496 papillary carcinomas. The work, while confirming previous observations, has provided a clear picture of their molecular landscape.[292] The genome of papillary carcinoma is stable when compared to that of tumors from other organs, with approximately 0.4 non-synonymous somatic mutations per megabase of DNA.[292] Papillary carcinomas typically have a diploid karyotype with low rates of LOH,[292,293] although in ~7% of cases gene copy number variations likely play an important tumorigenic role.[292] They are a heterogeneous group that includes histopathologic variants defined on the basis of size (papillary microcarcinoma), growth pattern (follicular, macrofollicular, cribriform-morular, solid), or cellular characteristics (tall cell, hobnail/micropapillary, columnar cell, oncocytic), each with distinctive sets of molecular alterations (see later).

A general and schematic view that takes into account the four basic morphologic features used to diagnose differentiated thyroid carcinoma—that is, papillary growth pattern, follicular growth pattern, presence of a tumor capsule (with or without invasion, of the capsule itself or of vessels), PTC-type nuclei—identifies the following scenario of diagnostic categories[294]: classic PTC → follicular predominant classic PTC → infiltrative follicular variant PTC → encapsulated follicular variant papillary carcinoma (PTC-EFV, when invasion is present; noninvasive follicular thyroid neoplasm with papillary-like nuclear features, NIFTP, when there is no invasion) → follicular neoplasm (FTC, when invasion is present; FTA, when there is no invasion) (Fig. 8.42).[294] In this schematic scenario, a decrease in the extent of papillary growth and PTC-type nuclei is paralleled by increased follicular growth pattern, the appearance of a defined tumor capsule, and a shift from a *BRAF* p.V600E to a *RAS*-like molecular signature (see Fig. 8.42).[295–298] The unequivocal recognition of these two broad molecular families of papillary carcinoma has been one important result of the TCGA's study.[292] Tumors with a ***BRAF* p.V600E-like** signature have high levels of MAPK pathway signaling, a low thyroid differentiation score (based on the expression of 16 genes involved with follicular cell function and metabolism), a heterogeneous molecular profile (due to the molecular alterations specific to the different histopathologic papillary carcinoma variants), and represent the group of conventional papillary carcinoma.[292] Tumors with a ***RAS*-like** molecular signature have low levels of MAPK pathway signaling, a high thyroid differentiation score, a relatively homogeneous

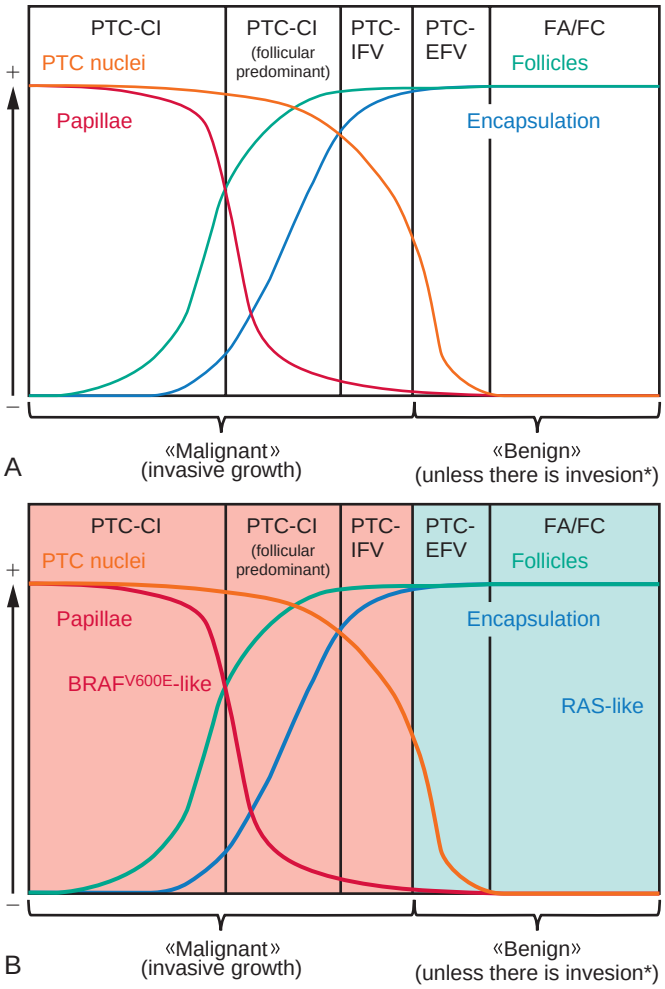

Figure 8.42 Correlation of diagnostic categories (**A**) and molecular alterations (**B**) with the four basic morphologic features used to diagnose tumors of follicular cell derivation: papillary growth pattern, follicular growth pattern, presence of a tumor capsule (with or without invasion, of the capsule itself or of vessels), alterations of nuclear morphology of papillary carcinoma. PTC-CI, classic papillary thyroid carcinoma; PTC-IFV, infiltrative follicular variant of papillary thyroid carcinoma (no tumor capsule); PTC-EFV, encapsulated follicular variant of papillary thyroid carcinoma (with or without invasion of capsule and vascular spaces); FA/FC, follicular adenoma/follicular carcinoma. (From Tallini G, Tuttle RM, Ghossein RA. The history of the follicular variant of papillary thyroid carcinoma. *J Clin Endocrinol Metab*. 2017;102;15–22.)

molecular profile, and are follicular variant papillary carcinomas,[292] reclassified as NIFTP when noninvasive (see "Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features," later).[295]

The genetic changes that characterize conventional papillary carcinoma are *BRAF* p.V600E,[288,290–292,299–301] and *RET/PTC* (Fig. 8.43),[128,292,302–312] *NTRK*,[292,309,313–317] or *ALK* rearrangements (fusion oncogene papillary carcinomas).[292,318–322]

***BRAF* p.V600E** is the most common alteration of papillary carcinoma and a very powerful diagnostic marker for those tumors characterized by papillary growth pattern (classic/conventional papillary carcinomas) that carry the mutation in ~40%–80% of cases.[290–292,301,306,323] The mutation is highly specific and has been identified in papillary carcinomas arising within struma ovarii.[324] The strongest association is with the tall cell variant that carries *BRAF* p.V600E in more than 90% of cases.[306,323] *BRAF* p.V600E is an early molecular alteration, in most cases clonally distributed in the majority of neoplastic cells.[288,292] Point mutations other than p.V600E (e.g., p.K601E) and other rare alterations are typically found in the follicular variant and have an oncogenic potential lower than the p.V600E mutation.[292,325] *BRAF* rearrangements, found in up to approximately 10% of radiation-associated papillary carcinomas are *AKAP9/BRAF*[326] and *AGK/BRAF*.[315] *BRAF* p.V600E–specific antibodies are available,[327] but sequencing is the gold standard for molecular diagnosis.[288] The mutation is detectable in the peripheral blood of papillary carcinoma patients, and its identification correlates with the status of disease.[300] The prognostic relevance of *BRAF* p.V600E is controversial. Several studies have associated the p.V600E mutation with poor outcome,[331–333] while other have not confirmed the association.[334–336] *BRAF* p.V600E has been linked to extrathyroid tumor extension and to an increased risk of recurrence (also in patients with low risk tumors),[333,337,338] but the overall prognostic relevance of the mutation appears limited when other factors (e.g., stage, papillary carcinoma variant) are considered.[303,334,339] Clinical response to kinase inhibitors that target the *BRAF* p.V600E mutation (such as dabrafenib[340] and vemurafenib[341]) has been demonstrated in patients with advanced papillary carcinoma.

RET/PTCs represent the prototypical fusion oncogenes of papillary carcinoma. Gene rearrangements occur in up to ~30% of papillary carcinomas, and the majority of them involve *RET*, a transmembrane tyrosine kinase receptor.[312] This oncogene is thus uniquely related to thyroid tumors, with activating *RET point mutations* in medullary carcinoma, and somatic *RET rearrangements* in papillary carcinoma. The latter, called *RET/PTC* (for *p*apillary *t*hyroid *c*arcinoma), are chimeric genes generated by the in-frame fusion of the entire RET tyrosine-kinase domain with other genes, that distinguish the different *RET/PTC* isoforms. The heterologous genes drive the expression of RET (not present at any significant level in normal follicular cells); by causing the chimeric proteins to dimerize, they also induce ligand independent, constitutive activation of the RET tyrosine kinase.[302,304,312]

Sixteen different oncogenic *RET* rearrangements have been identified so far: RET/PTC fusion proteins RET/PTC1 to PTC9, RET/PCM1, RFP/RET, HOOK3/RET, ELKS/RET,[312] DLG5-RET,[328] AFAP1L2/RET, and PPFIBP2/RET (the latter two found in carcinomas of young patients from the Fukushima area).[329] The most common are RET/PTC1 (*CCDC6/RET*), which accounts for approximately 60% of *RET*-rearranged tumors, RET/PTC3 *(NCOA4/RET)* representing approximately 30%, and RET/PTC2 *(PRKAR1A/RET)* representing approximately 5%; the other *RET* rearrangements have been described in a few papillary carcinomas that have characteristically arisen following radiation exposure.[312] *RET* rearrangements (as well as rearrangements of other tyrosine kinase genes e.g., *NTRK3*) typically occur in tumors that develop in children and young patients and in those related to radiation exposure (therapeutic or environmental).[309,312,314] In one large study *RET/PTC* was identified in 62.3% of 191 papillary carcinomas diagnosed after the 1986 Chernobyl nuclear disaster.[309] In the study, *RET/PTC3* was particularly common in tumors that developed after exposure to high radioactivity levels that were of short latency, more aggressive, and classified as solid variants of papillary carcinoma.[309] *RET*-rearranged carcinomas have in general classic papillary histology, with typical alterations of nuclear morphology and psammoma bodies.[306–308,313] The rearrangement is considered an early molecular alteration, and highly sensitive methods detect low-level *RET/PTC* recombination in a variable proportion of papillary [128] with or without other mutational events (e.g., *BRAF*) due to genetic heterogeneity.[310] Clonal *RET/PTC* expression is specific, but low-level *RET/PTC* recombination has been shown in hyperplastic thyroid nodules[311] and in Hashimoto thyroiditis.[128] While very sensitive methods can detect *RET/PTC* in the peripheral blood of patients with papillary carcinoma,[305] they must thus be avoided for routine molecular diagnosis. With appropriate methods, RET/PTC is now detected in ~5%–25% percent of papillary carcinomas, with a decreasing prevalence among non–radiation-associated tumors over the years.[342] Several studies[307,308,343,344] have failed to correlate *RET/PTC* with increased morbidity and mortality, although *RET* rearranged papillary carcinoma in young patients may present with lymph node metastases and aggressive clinicopathologic features.[313,317] The rearrangement, in particular *RET/PTC1* that largely predominates in papillary carcinomas not associated with radiation exposure, is often found in indolent tumors showing little propensity to progress to poorly differentiated and undifferentiated carcinomas.[307,308,343,344]

In addition to RET, other tyrosine kinases are rearranged in papillary carcinoma. These include the NTRK and ALK kinases. The ***NTRK1*** gene is rearranged with *TPM3*, *TPR* and *TFG*,[309,313,314] ***NTRK3*** with *ETV6*, or less frequently with other genes.[317,329] Some fusion partners of both *NTRK1* and *NTRK3* are still uncharacterized.[314,317] *NTRK* rearrangements have been reported in up to approximately 10% of unselected papillary carcinomas.[314] The general clinicopathologic features of papillary carcinomas with *NTRK* rearrangement are similar to those of *RET/PTC*-positive cases.[313] As in the case of *RET/PTC*, *NTRK* rearrangements have a higher prevalence in children and young adults[313,317,329] and in cases associated with radiation exposure.[315,316,329] *ETV6/NTRK3* has been identified in approximately 15% of radiation-induced papillary carcinomas and after *RET/PTC* is one of the most common forms of oncogenic alteration in radiation-associated tumors.[315,316]

ALK is rearranged in approximately 1%–5% of papillary carcinomas.[319,322] The most common *ALK* recombination is the *STRN/ALK* rearrangement,[319] *EML4/ALK*, typically found in non–small cell lung carcinoma, has been identified in a few cases,[319] including radiation-associated tumors from atomic bomb survivors.[345] *ALK*-rearranged carcinomas have a predominantly follicular, infiltrative pattern, often with areas of solid growth, or have the histologic features of diffuse sclerosing papillary carcinoma.[319,322] *ALK* rearrangement can be identified using the same fluorescent in situ hybridization probes and antibodies used to detect *ALK* rearrangement in non–small cell lung carcinoma.[319–322] *ALK*-rearranged tumors may have extrathyroidal extension and lymph node metastases[319,322] and may develop in papillary carcinomas undergoing dedifferentiation.[319,321] However, one large series has failed to demonstrate a statistical association with aggressive clinicopathologic features.[322]

Patients with *ALK*-rearranged tumors may respond to targeted therapies with ALK inhibitors (e.g., crizotinib).[320,321]

The encapsulated follicular variant of papillary carcinoma, regardless of whether the tumor has capsular or vascular invasion, or is noninvasive and now reclassified as NIFTP (see "Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features," later),[295] has a *RAS*-like molecular signature with a profile of genetic alterations overlapping that of follicular adenomas and carcinomas.[292,295–297] As in the case of follicular adenomas and carcinomas, the most common genetic alterations are point mutations in *NRAS*, followed by *HRAS*, with most mutations in codon 61.[187,298] Up to approximately 30% of follicular variant papillary carcinomas carry *PPARG* rearrangements (*PAX8/PPARG* or, much less frequently, *CREB3L2/PPARG)*.[298,346] Most of the *EIF1AX* mutations identified by the TCGA study in a small subset of papillary carcinoma were of the follicular variant.[292] Fusion of *THADA* (at 2p21) with the LOC389473 pseudo gene (at 7p15.3), 12 kb upstream of *IGF2BP3* leading to overexpression of the full-length IGF2BP3 mRNA and protein, and to increased insulin-like growth factor receptor signaling, has been reported in approximately 5% of papillary carcinomas. All *THADA*-rearranged cases were classified follicular-variant papillary carcinomas or NIFTP.[209]

TERT promoter mutations represent an important marker of poor prognosis in differentiated thyroid carcinoma.[328,347–351] They are identified with a prevalence of approximately 5%–15% in most series of papillary carcinomas,[347–350] and the association with aggressive behavior appears stronger in case of a coexisting *BRAF* p.V600E mutation.[328,347,349–351]

MED12-G44C substitutions, consistent with gain- or change-of-function and *RBM10* mutations (truncating and missense mutations), have been identified in fatal forms of papillary carcinomas (and in poorly differentiated thyroid carcinoma).[328]

MicroRNA expression is dysregulated in papillary carcinoma, with high levels of miRs-146b, -221, and -222.[292,352] A large meta-analysis has found that expression levels of miRs-21, −34b, −130b, −135b, −146b, −151, −181b, −199b-5p, −221, −222, −451, −623, −1271, −2861, and let-7e show a significant association with at least one aggressive feature (large tumor size, extrathyroidal extension, multifocality, lymphovascular invasion, lymph node metastases, distant metastasis, advanced stage, *BRAF* p.V600E).[353] Patients with DICER1 syndrome, a rare autosomal dominant cancer syndrome caused by inactivating germline mutations of *DICER1*, encoding the DICER1 ribonuclease (RNase) necessary to generate mature miRNA species, develop pleuropulmonary blastoma, ovarian Sertoli-Leydig cell tumors, cystic nephroma of the kidney and multinodular goiter with adenomatous nodules.[173] Patients with the syndrome have an increased risk of developing thyroid carcinoma, often follicular-variant papillary carcinoma.[173] Reduced *DICER1* expression has been associated with aggressive clinicopathologic features in non-familial papillary carcinomas.[354]

Variants

The following morphologic variants of papillary carcinoma have been described.[355]

Papillary Microcarcinoma. This is defined as a papillary carcinoma measuring 1 cm or less in diameter (Figs. 8.44 and 8.45). Most cases have a stellate configuration and correspond to the lesions

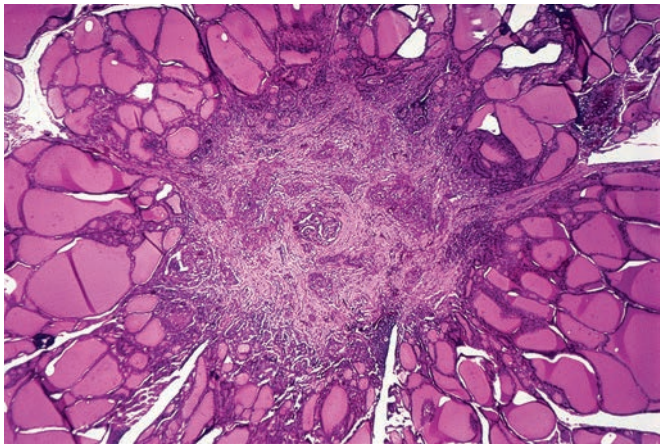

Figure 8.44 Typical stellate appearance of papillary microcarcinoma.

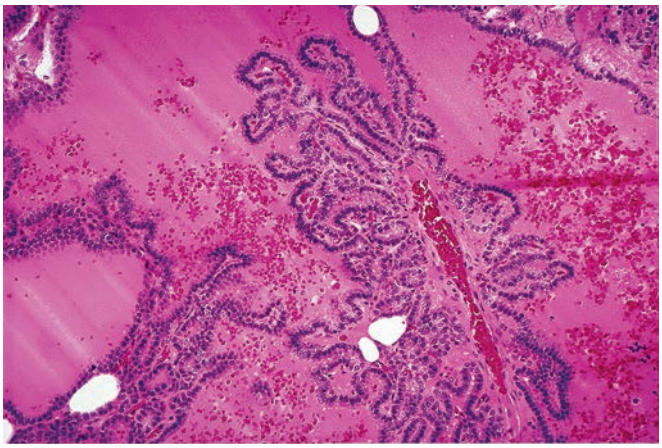

Figure 8.46 The benign papillary formations of nodular hyperplasia point toward the center of the cystically dilated follicles.

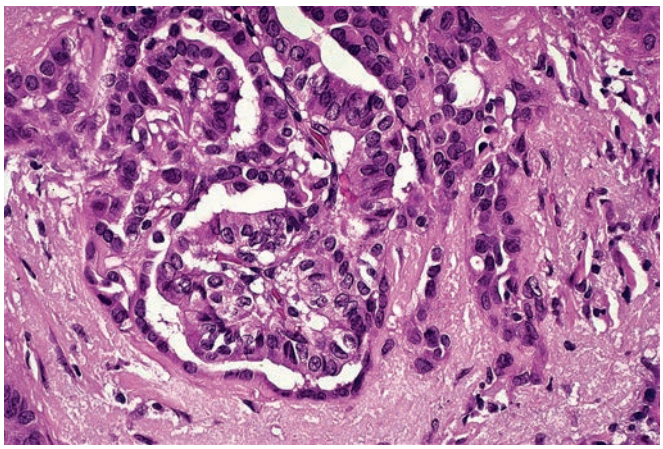

Figure 8.45 On high power, the appearance of papillary microcarcinoma is no different from that of its larger counterpart.

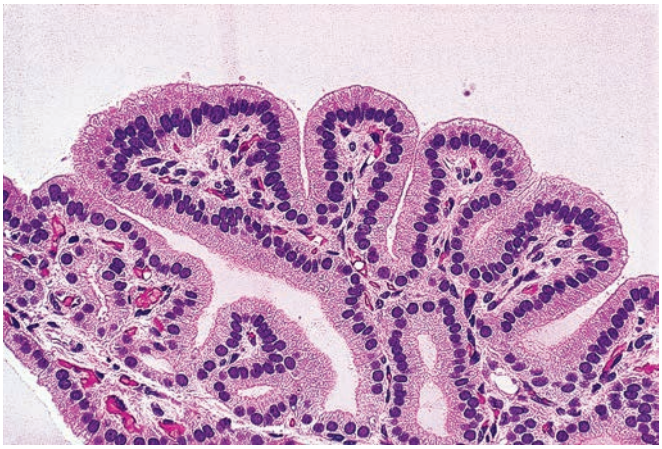

Figure 8.47 Benign papillary formations lined by columnar cells with basally located round normochromatic nuclei. The cytoplasm has a pale basophilic quality.

formerly known as occult sclerosing carcinoma or nonencapsulated sclerosing tumor,[356,357] whereas others show partial or near total encapsulation, with or without tumor outside the capsule. Sometimes the fibrous capsule is extremely thick and may be calcified. The microscopic features and the mutational profile are not different from those of their larger counterpart, and both *BRAF* p.V600E and *RET/PTC* have been identified.[306,308,323]

Papillary microcarcinoma is an extremely common incidental finding depending on the thoroughness of the examination,[358] with figures as high as 35.6% in one autopsy series.[359] A meta-analysis reviewing approximately 1000 microcarcinomas from 15 autopsy series from different parts of the world has found an overall prevalence of 11.5%,[360] compatible with the 12%–13% rate for microcarcinomas diagnosed incidentally in thyroid glands surgically removed for goiter or other reasons.[361] In contrast to its clinically evident counterpart, incidental papillary microcarcinoma seems to be relatively more common in males than females.[358] Despite its small size, the tumor can be identified in FNA specimens, and the increased detection of small papillary carcinomas is largely responsible for the considerable increase of thyroid carcinoma in developed countries.[362] It may be associated with cervical node metastases. However, distant metastases are exceptionally rare and the prognosis is generally excellent.[361] Thus a proposal has been made to replace microcarcinoma with the term *"papillary microtumor"* when occurring in adults and in its typical form.[363] Observational studies are showing that active surveillance is equally effective as immediate surgery to manage patients with low-risk microcarcinoma (no high-grade cytology, extrathyroidal extension, or metastases), while sparing the patients the side effects of surgery.[364] However, a few microcarcinomas can exhibit malignant behavior, particularly if the tumors carry the *BRAF* p.V600E mutation.[323] Rare, but well-documented fatal cases with evidence of tumor progression in cervical lymph node metastases have been reported.[365]

Encapsulated Variant. This is defined as a papillary carcinoma *totally* surrounded by a capsule. It may still be associated with nodal metastases, but the incidence of distant metastases or tumor death is nearly zero.[366,367] The cytoarchitectural (and particularly nuclear) features of this variant are the same as for the conventional invasive type. This lesion should be distinguished from the hyperplastic nodule with central cystic degeneration and papillary or pseudopapillary fronds in the wall (Figs. 8.46 and 8.47). In contrast to papillary carcinomas, these lesions are "hot" on thyroid scan and are characterized microscopically by a pale, vacuolated colloid. The papillary areas are largely limited to the area facing the cystic cavity. The follicular cells tend to be low columnar, with basally located normochromatic or hyperchromatic nuclei (instead of the centrally located, optically clear nuclei of papillary carcinoma).

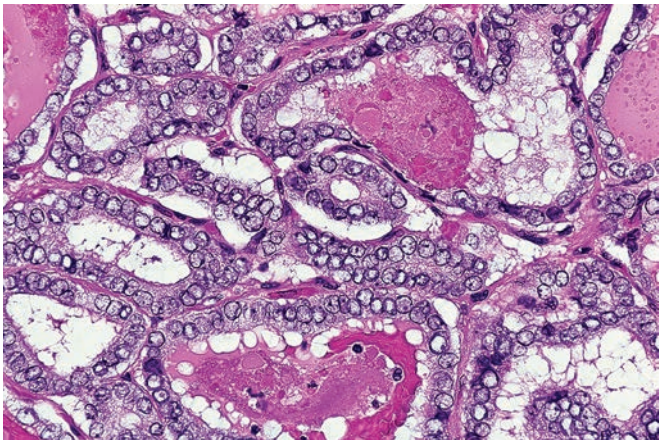

Figure 8.48 Follicular variant of papillary carcinoma. Note the clear overlapping nuclei.

Follicular Variant. This is a papillary carcinoma composed entirely or almost entirely of follicles (Fig. 8.48).[368,369] It is also referred to as *Lindsay tumor*.[370] The diagnosis is based on the presence of PTC-type nuclei. The behavior of these tumors, when infiltrative and not encapsulated, is analogous to that of conventional papillary carcinoma,[371] particularly in regard to the high incidence of nodal metastases.[248,370] Interestingly, these metastases sometimes exhibit well-developed papillary formations.[370]

Based on the outline of the tumor when it grows into the surrounding non-neoplastic tissue, two major groups of follicular variant papillary carcinoma with different histologic, clinical, and molecular features are recognized.

Infiltrative Follicular Variant Papillary Carcinoma. The tumor is characterized by infiltrative growth margins with neoplastic cells pervading the thyroid parenchyma with irregular strands and nests composed of neoplastic follicles. It corresponds to many of the cases originally described by Lindsay and to those reviewed by Chen and Rosai in 1977.[368] It is typically devoid of a fibrous capsule. Only partial remnants of a capsule can sometimes be identified. The tumor is very similar to follicular predominant classic papillary carcinoma, where well-developed papillae are found in the minority of the neoplastic mass that largely consists of follicular structures (see Fig. 8.42). If strict criteria are utilized (i.e., no papillary growth),[371] the infiltrative follicular variant papillary carcinoma is currently uncommon, representing less than 5% of all papillary carcinomas.[294] A rare *diffuse (or multinodular) variant* has been described, where most of a thyroid lobe—or sometimes both lobes—are diffusely infiltrated by the tumor, which is difficult to recognize because of its very diffuseness.[372] The infiltrative follicular-variant papillary carcinoma is characterized by a *BRAF* p.V600E–like molecular signature (see Fig. 8.42).[292,297,373]

Encapsulated Follicular Variant and Noninvasive Follicular Thyroid Neoplasm With Papillary-Like Nuclear Features. The tumor is entirely surrounded by a capsule (or well circumscribed, with a smooth contour facing the adjacent parenchyma),[373] has follicular growth pattern (with no papillae), but the nuclear alterations of papillary carcinoma. As in the case of follicular neoplasms, there may or may not be evidence of capsular and/or blood vessel invasion.

The encapsulated follicular variant has generated considerable controversy. To make a diagnosis, the nuclear alterations should be widespread and well developed, and some supportive features (such as intratumoral sharply defined fibrohyaline bands, elongated and branching follicles, abortive follicles, dense eosinophilic colloid) should be present[374,375]; sometimes minute follicles with the typical nuclear alteration are scattered in a background of normal-appearing follicles (the "sprinkling" sign of the follicular variant of papillary carcinoma).[376]

However, there has been excessive observer variation in the diagnostic weight given to these morphologic changes, with a progressive lowering over the years of the nuclear alteration threshold required to diagnose a tumor as papillary carcinoma.[377–380]

It is possible that noninvasive lesions in which the cytoarchitectural alterations are focal or "incomplete" represent the early development of papillary carcinoma in a preexisting benign nodule. This is suggested by the fact that the expression of galectin-3 and HBME-1 at the immunohistochemical level and the presence of molecular alterations in microdissection experiments may be restricted to these foci.[311,381,382] However, the word "carcinoma" should not be used for these lesions. The diagnostic term *"well-differentiated tumor of uncertain malignant potential (WDT-UMP)"* was proposed in the year 2000 for noninvasive nodules with questionable/incomplete nuclear changes that fall short of a diagnosis of papillary carcinoma, and that of *"well-differentiated carcinoma, not otherwise specified (WDC-NOS)"* for similar cases with invasive features, but neither has been widely utilized.[383]

Since then, two facts have become increasingly clear: that follicular-patterned nodules, when noninvasive and fully excised, are cured by conservative surgery in nearly every instance[380,384,385] and that the encapsulated follicular variant papillary carcinoma is characterized by a *RAS*-like molecular signature.[292,297,373]

To obviate cancer overdiagnosis and overtreatment, a working group of the Endocrine Pathology Society has critically reexamined the encapsulated follicular variant papillary carcinoma: Nikiforov et al. have introduced the diagnostic term *"noninvasive follicular thyroid neoplasm with papillary-like nuclear features"* (NIFTP) for noninvasive nodules previously diagnosed as follicular variant papillary carcinoma.[295] As a result of this effort the histologic features of the follicular variant papillary carcinoma have been redefined. Using molecular alterations as the reference standard, a 0–3 point scoring system based on conventional morphologic features has been shown to define with reasonable reproducibility the degree of nuclear alterations required to diagnose the follicular variant papillary carcinoma (Fig. 8.49).

The diagnostic criteria of NIFTP are:

1. Encapsulation or clear demarcation from the adjacent thyroid tissue
2. Follicular growth pattern with
   - <1% papillae
   - No psammoma bodies
   - <30% solid/trabecular/insular growth pattern
3. Nuclear alterations of papillary carcinoma (with a score of 2–3)
4. No vascular or capsular invasion (after thorough examination of the tumor interface with the surrounding tissues)
5. No tumor necrosis
6. No high mitotic activity (i.e., <3 mitoses per 10 high-power fields [×400])

If these criteria are met (Fig. 8.50) the likelihood of the tumor recurring or metastasizing is less than 1%. On the contrary, if there is invasion of the tumor capsule or of blood vessels, the study demonstrated adverse events (recurrence, metastases, tumor-related death) in 12% of patients after a median follow-up of 3.5 years.[295] In the latter case, to use the word "cancer" is fully justified, and such invasive tumors should be diagnosed as *encapsulated follicular variant of papillary carcinoma with capsular and/or vascular invasion*. If, after careful examination, the invasive features are still questionable the term "WDT-UMP" is appropriate to avoid overdiagnosis for those cases that show the nuclear alterations of papillary carcinoma, while the term "follicular tumor of uncertain malignant potential" (FT-UMP) is applied to those cases devoid of nuclear alterations (Table 8.4).[375]

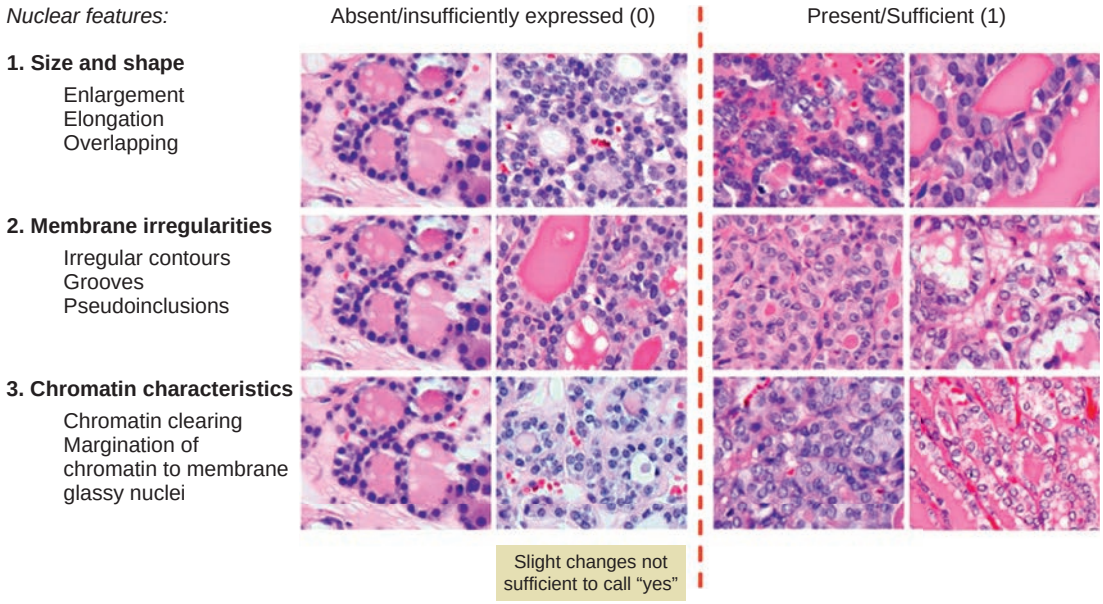

Figure 8.49 Visual guide for scoring the nuclear features of papillary carcinoma using the three-point scoring scale. (From Nikiforov YE, Seethala RR, Tallini G, et al. Nomenclature revision for encapsulated follicular variant of papillary thyroid carcinoma: a paradigm shift to reduce overtreatment of indolent tumors. *JAMA Oncol*. 2016;2(8);1023–1029.)

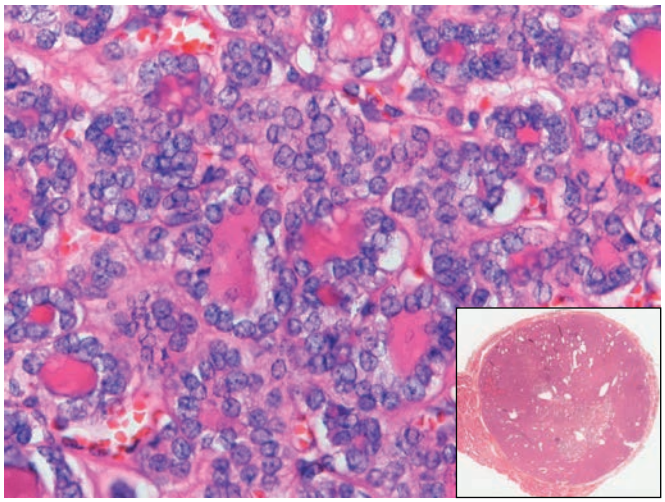

Figure 8.50 Noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP). This tumor has follicular growth pattern, the nuclear alterations of papillary carcinoma, and is well circumscribed and without invasion (inset).

On pure morphologic grounds, the follicular variant of papillary carcinoma can be viewed as the balanced result of two opposing biologic properties of the tumor cell: differentiation in the form of secretory activity (thereby making colloid-filled follicles), and proliferation. When one of these forces predominates over the other, two additional variants emerge:

Solid Variant. This variant, which is particularly common in children, develops when proliferation predominates over secretion. It is characterized by solid nests of generally round shape that can be viewed as filled-up follicles (Fig. 8.51). It is distinguished from insular carcinoma and other forms of poorly differentiated carcinoma because the nuclear features remain those of papillary carcinoma. This distinction is of great importance, because the behavior of this tumor is essentially that of papillary carcinoma (or perhaps only a little worse) but notably different from that of the truly poorly differentiated neoplasms.[386]

Macrofollicular Variant. This can be viewed as the opposite of the solid variant, in the sense that the secretory activity predominates over proliferation, resulting in large dilated follicles, so that the tumor resembles not so much a follicular neoplasm as a hyperplastic nodule (Fig. 8.52).[387–389]

Diffuse Sclerosing Variant. This uncommon variant is characterized by diffuse involvement of one or both thyroid lobes, dense

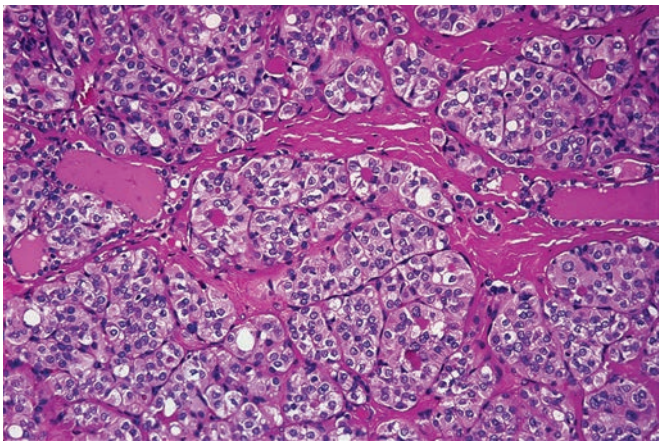

Figure 8.51 Solid variant of papillary carcinoma. The nests are separated by fibrohyaline strands.

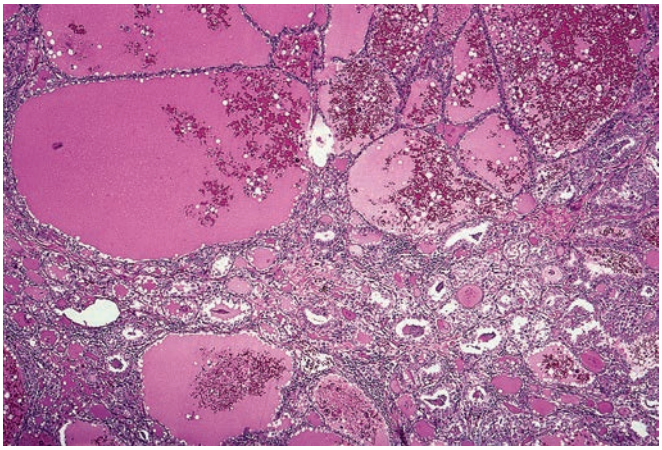

Figure 8.52 So-called macrofollicular variant of papillary carcinoma. This lesion simulates nodular hyperplasia. The nuclear features that allow the diagnosis cannot be seen at this magnification.

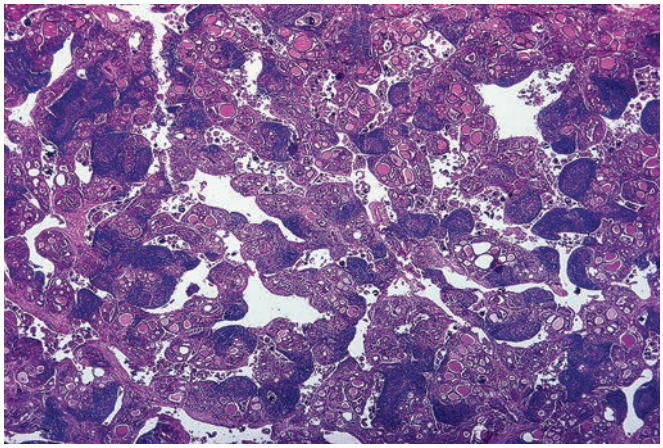

Figure 8.53 Diffuse sclerosing variant of papillary carcinoma. Note the diffuse pattern of growth, the heavy lymphocytic infiltrate, and the sclerosis.

sclerosis, abundant psammoma bodies, extensive solid foci, squamous metaplasia, heavy lymphocytic infiltration, and extensive lymph vessel permeation[390,391] (Figs. 8.53 and 8.54). Clinically, it may be misdiagnosed as Hashimoto thyroiditis. Nodal metastases are nearly always present, lung metastases are common, multiple brain metastases may supervene, and the disease-free survival rate is lower than for conventional papillary carcinoma.[391–395] However, in spite of a lower disease-free survival period, with appropriate treatment the mortality rate is the same of classic papillary carcinoma.[396] Both *RET/PTC1* and *RET/PTC3* have been identified, although *BRAF* mutations appear to be rare.[397]

Oncocytic (Oxyphilic, Warthin-Like) Variant. In this variant, the nuclear features remain those of papillary carcinoma, but the cytoplasm is abundant and has a granular oxyphilic quality.[398] The pattern of growth may be papillary or follicular, and the tumor may be encapsulated or invasive. A variation on the theme is the tumor having a papillary architecture, typical nuclear features, oncocytic cytoplasm, and a heavy lymphocytic infiltrate in the stroma of the papillae, resulting in an appearance reminiscent of Warthin tumor of salivary glands.[399,400] This *Warthin-like papillary carcinoma* may harbor the *BRAF* p.V600E mutation (although with a lower prevalence).[401] The prognosis of Warthin-like papillary carcinomas is generally very good, like that of conventional papillary carcinomas of similar size and stage.[400,402] Oncocytic papillary carcinomas, including Warthin-like papillary carcinoma must be distinguished from tall cell variant papillary carcinomas. It is also worth reminding the reader that a sine qua non for including a tumor in *any* of these subsets of papillary carcinoma is the presence of PTC-type nuclei as defined previously.

Tall Cell Carcinoma. This relatively common variant, originally described by Hawk and Hazard in 1976,[403] is characterized by papillae lined by a single layer of "tall" cells (the height being two to three times the width) and an abundant acidophilic (oncocytoid) cytoplasm (Fig. 8.55). The pattern of growth tends to be highly papillary, the papillae are overly elongated, cord-like, and running side-to-side in a regimented, "tram track" fashion. Nuclear pseudoinclusions are particularly prominent.[404] There may be an extensive lymphocytic infiltration of the stroma.[405] The variant tends to affect older patients more often than the conventional form, extrathyroidal extension is more common, and the clinical course is more aggressive when compared with classical papillary carcinoma,[406,407] even in the absence of extrathyroidal extension.[408] This aggressive behavior correlates with the presence of tall cell features in greater than 30% of the tumor, which may thus be considered a reasonable threshold for the diagnosis of tall cell papillary carcinoma.[409] A considerable proportion of radioactive iodine–refractory and of fatal forms of

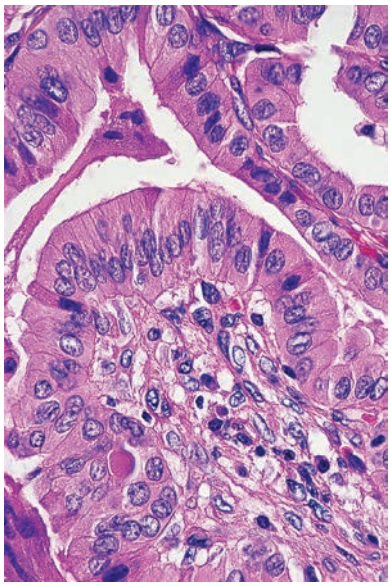

Figure 8.55 Tall cell variant of papillary carcinoma. Note the abundant granular acidophilic cytoplasm with oncocyte-like features.

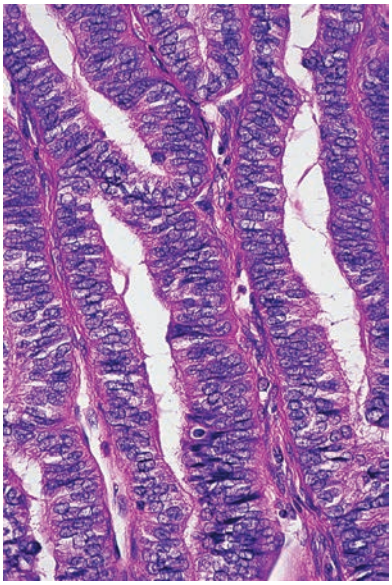

Figure 8.56 Columnar cell variant of papillary carcinoma. The papillae are lined by a pseudostratified layer of spindle tumor cells.

non-anaplastic thyroid carcinomas are tall cell papillary carcinoma variants.[410] Anaplastic transformation of tall cell papillary carcinoma typically occurs in the form of a spindle cell squamoid type of anaplastic carcinoma.[411]

Tall cell papillary carcinoma shows the strongest association with the *BRAF* p.V600E mutation, which is present in the vast majority of cases, including small papillary carcinomas.[306,323] Like other types of aggressive thyroid carcinoma, it often carries *TERT* promoter mutations, found in approximately 30% of cases.[412]

Columnar Cell Carcinoma. This rare variant was originally described by Dr. J.H. Evans in 1986.[413] It is characterized by thin papillae or glandular-like spaces lined by an epithelium with prominent nuclear stratification (Fig. 8.56); the cytoplasm is clear (sometimes with subnuclear vacuolization, reminiscent of early

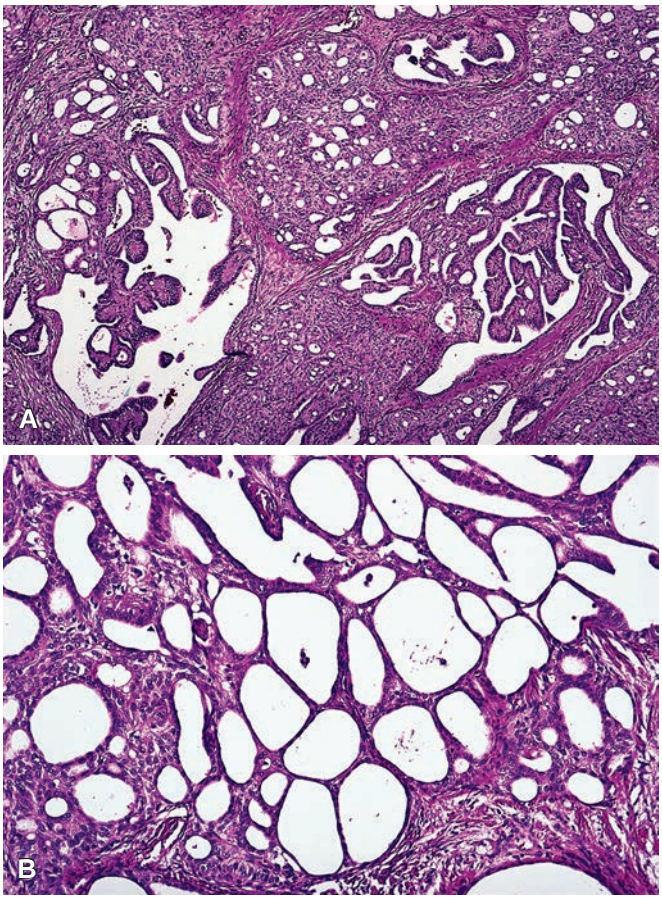

Figure 8.57 **A** and **B,** Cribriform–morular variant of papillary carcinoma. The cribriform quality of the tumor is particularly well appreciated in **B**.

secretory endometrium), rather than acidophilic as in the tall cell variant; squamoid whorls or morules may be present.[413–418] The nuclei usually lack the optically clear appearance, grooves, and pseudoinclusions seen in papillary carcinoma and all of its other variants,[413–418] and therefore it has been questioned whether columnar cell carcinoma is really a variant of papillary carcinoma, as opposed to a different tumor type despite its highly papillary architecture. However, while thyroglobulin may be variably expressed,[416,419] TTF1 is always positive.[419,420] Mitotic figures can be found, and the Ki-67/MIB1 proliferative index may be very high.[417,420] Immunoreactivity for the intestinal differentiation factor CDX2 is common, and the tumor must be differentiated from metastatic colonic adenocarcinoma.[419–421] There is no nuclear immunoreactivity for β-catenin, and that for p53 is weak or entirely lacking.[417,420] Hypercellularity with papillary structures, nuclear superposition, and a paucity of nuclear pseudoinclusions and grooves are the cytologic features in preoperative FNA samples.[419] The initial reports of this entity indicated a poor prognosis,[413–415] but more recent larger series have shown that—once again—the outcome is largely predicated by tumor stage; specifically, encapsulated columnar cell carcinomas are associated with a favorable course.[416–418] *BRAF* p.V600E is present in approximately 30% of cases.[417,420]

Cribriform–Morular Variant. As the name indicates, this variant is characterized by the presence of a cribriform pattern of growth and morular formations (Fig. 8.57). The tumor is very rare, representing 0.16% of 4194 papillary carcinomas in a large Japanese series.[422] It develops in a sporadic form,[423] or as an extraintestinal component of the familial adenomatous polyposis syndrome, of which it may

be the initial clinical manifestation; it is seen almost exclusively in females.[422–425] A few cases have been reported in children.[426] One case with focal neuroendocrine differentiation has been reported.[427] The cribriform–morular variant papillary carcinomas are often encapsulated with an intimate admixture of cribriform, follicular, papillary, trabecular, and solid patterns of growth; round squamoid morular structures are a characteristic finding; intraluminal colloid is scanty or absent altogether; invasion of the tumor capsule or of vessels is common; sporadic cases are usually solitary, while those associated with familial adenomatous polyposis are often multifocal.[422–425] The neoplastic cell nuclei are not particularly clear but exhibit variable amounts of grooves and pseudoinclusions. In the morules, however, neoplastic cells have optically clear nuclei. These are different from those of conventional papillary carcinoma and similar to the nuclei seen in morule-containing tumors at other sites, due to the accumulation of biotin.[428] Thyroglobulin is often weakly expressed, and TTF1 is variably positive within the tumor. Nuclear immunoreactivity for β-catenin, the hallmark of *wnt* pathway activation, is the rule.[423,424] *Wnt* signaling is activated in the familial tumors because of germline loss of function mutations of the *APC* gene, and in the sporadic ones because of somatic *APC* mutations or due to somatic mutations in exon 3 of the β-catenin gene *(CTNNB1)* that stabilize the β-catenin protein, preventing its degradation and promoting its accumulation in the nucleus.[424,429]

Hobnail Variant. This rare variant, as the name implies, is characterized by papillary, micropapillary, and follicular formations lined by neoplastic cells with eosinophilic cytoplasm, altered nuclear/cytoplasmatic ratio, and apically placed nuclei that produce a surface bulge responsible for the typical hobnail appearance (Fig. 8.58). Nucleoli are prominent, there is loss of cellular cohesion, mitoses are common, and necrosis may be present; angiolymphatic invasion and extrathyroidal extension are frequently observed.[251,430–434] The tumor is aggressive with metastases to lymph nodes and to distant organs and frequently recurs.[251,430–434] This aggressive behavior correlates with the presence of hobnail features in at least 30% of the tumor, which is considered the threshold for its diagnosis, although the prognosis may be unfavorable even in cases with a lower proportion of hobnail areas.[432,433] These areas may be present in association with poorly differentiated and even undifferentiated carcinomas, indicating that hobnail cells may be a morphologic marker for tumor progression.[434,435] Immunohistochemistry is positive for TTF1 and typically shows nuclear accumulation of p53 in a significant proportion of cells, the mean of the Ki-67/MIB1 proliferative index is approximately 10%.[251] *BRAF* p.V600E is present in a high proportion (~70%–80%) of cases, inactivating *TP53* mutations, and *TERT* promoter mutation are also very common.[434,436]

Papillary Carcinoma With Exuberant Fibromatosis/Fascitis-Like Stroma. In this variant, the prominence of the stromal reaction of the tumor may obscure the neoplastic epithelial component.[437,438] As a result, a biopsy may be misinterpreted as nodular fasciitis, fibromatosis, or some other proliferative stromal condition.[439,440] In some foci, the interplay of this stromal component with the tumor results in a fibroadenoma-like appearance.[437] Remarkably, exon 3 mutations of the β-catenin gene (*CTNNB1* p.S45P) with nuclear accumulation of β-catenin by immunohistochemistry—a characteristic finding of fibromatosis—has been shown in the mesenchymal (but not in the epithelial) component of some tumors. This indicates that they represent biphasic neoplasms and that papillary carcinoma with nodular fasciitis-like stroma and *CTNNB1* mutations should be renamed papillary carcinoma with desmoid-type fibromatosis.[441]

Spread and Metastases

Extrathyroidal extension into the soft tissues of the neck is found in approximately one-fourth of cases, with occasional spread into the parathyroid glands.[248,442,443] Involvement of cervical lymph nodes is very common (particularly in young patients), and it may be the first manifestation of the disease. The nodal metastases have a tendency to undergo cystic changes (Fig. 8.59). These metastases may not be clinically apparent because of their small size and also because their consistency may not differ from that of a normal node. In a study of 67 patients with clinically negative nodes, 41 (61%) had metastatic tumor on microscopic examination.[444] In rare but well-documented cases with lymph node metastases the primary tumor is not identified in spite of extensive microscopic examination of the thyroid gland.[445]

Blood-borne metastases are less frequent than with other thyroid carcinomas, but they also occur. Although the most common site is the lung, they can also develop in bones, soft tissues, central nervous system, pancreas, breast, and many other organs.[248,446–448] The lung metastases can have a miliary micronodular pattern detectable only on I scintiscans, or they can be rounded and macronodular.[449] *TERT* promoter mutations have been associated with the occurrence of distant metastases.[351]

Treatment

This is discussed together with the other epithelial tumors of the thyroid gland.

Prognosis

The overall survival of patients with papillary carcinoma is excellent, not significantly different from that of the general population.[450,451] Factors relating to prognosis are the following:

1. *Age*. The age of the patient at the time of diagnosis has long been known to be of great prognostic significance. Nearly all the deaths from papillary carcinomas occur when the tumor manifests itself after the age of 40 years.[248,452,453] Conversely, papillary carcinomas developing in children and adolescents are almost uniformly associated with a good outcome.[454]
2. *Sex*. Females are said to have a better prognosis than males, although in some series the difference has not been significant.[248]
3. *Extrathyroidal extension*. This feature adversely affects the prognosis in a very significant fashion.[248,455] Parenthetically, this feature and several others included in this listing have long been incorporated into the staging systems for thyroid carcinoma.[456–458]
4. *Microscopic variants* (see previous sections).
5. *History of previous irradiation*. Despite previous statements to the contrary, the prognosis of tumors in which this antecedent is present does not seem to differ significantly from the others.[459]
6. *Tumor size*. A rough inverse correlation is present between tumor size and prognosis.
7. *Capsule and margins*. Tumors that are encapsulated and/or have pushing margins have a better outcome than the others.[248,460,461]
8. *Multicentricity*. Patients in whom this is a prominent feature have a greater incidence of metastasis and less chance of disease-free survival.[248]
9. *Lymph node metastases*. The prognostic significance of nodal metastases from papillary carcinoma is limited when compared to that of carcinomas of other organs. It can, however, be stratified based on the size and number of metastatic lymph nodes[462,463]; extranodal tumor extension may be an indicator of a greater likelihood of distant metastases and poor prognosis,[462,464] even in patients with microcarcinomas,[465] although interobserver agreement for its identification is poor.[466]
10. *Distant metastases*. Metastases to lung have an adverse influence on prognosis; this influence is even greater for distant metastases in other sites, such as the skeletal system. Cases that present with distant metastases have poor prognosis.[248,467]
11. *Poorly differentiated, squamous, or anaplastic foci*. These features have a markedly detrimental effect on prognosis. Fortunately, they are present in fewer than 5% of the cases.[248,365,468]
12. *Grading*. This parameter, which is intertwined with the previous, bears a definite relationship with prognosis that we feel has been underestimated.[469,470] However, it needs to be clearly defined in terms of criteria (necrosis, mitotic activity, etc.) and properly standardized for it to reach its full potential.[471]
13. *TERT* promoter mutations have been associated with poor prognosis, and the association with aggressive behavior appears stronger in case of a coexisting *BRAF* p.V600E mutation.[328,347,349,350]
14. *BRAF* p.V600E. The prognostic relevance of this mutation is controversial. Several studies have associated the p.V600E mutation with poor outcome,[331–333] while other have not confirmed the association.[334–336] *BRAF* p.V600E has been linked to extrathyroid tumor extension and to an increased risk of recurrence (also in patients with low-risk tumors),[333,337,338] but the overall prognostic relevance of the mutation appears limited when other factors (e.g., stage, papillary carcinoma variant) are considered.[303,334,339]
15. Factors not generally found to correlate with prognosis are: relative proportion of papillae and follicles; presence or amount of fibrosis; presence or amount of squamous metaplasia or psammoma bodies; and microvessel density.[472] The effect of the type of therapy on prognosis remains controversial, with sometimes little correlation between the two parameters.[248]

Follicular Carcinoma

Generalities and Molecular Genetic Features

Follicular thyroid carcinoma (in a generic sense any malignant thyroid tumor with evidence of follicular cell differentiation) is usually defined as a form of thyroid malignancy arising from follicular cells in which the diagnostic nuclear features of papillary carcinoma are absent. We are not including in this category Hürthle (oncocytic) cell carcinoma, poorly differentiated carcinoma, or the exceptionally rare mixed medullary–follicular carcinoma.

Follicular carcinoma has become a relatively uncommon tumor whose diagnosis depends on the presence of invasion of the capsule, blood vessels, or adjacent thyroid.[203,303,473] It shares with papillary carcinoma the same predilection for females but occurs, on average, in patients who are a decade older.[203] Insufficient dietary iodine is regarded as an important factor for nodular goiter and follicular carcinoma.[203] Dietary iodide supplementation into iodine-insufficient regions has been associated with a decrease in the ratio of follicular to papillary carcinomas.[203]

Its microscopic appearance is extremely variable, ranging from well-formed follicles to a predominantly solid growth pattern. Poorly formed follicles, cribriform areas, or trabecular formations may be present, sometimes in combination. Exceptionally, the tumor may be entirely composed of spindle cells[474] or exhibit prominent glomeruloid formations.[475] Focal or extensive cytoplasmic clear changes can occur. Mitotic activity and nuclear atypia are usually seen but may be entirely lacking. Psammoma bodies are absent, and squamous metaplasia is exceptionally rare. Tumors showing a predominantly solid/trabecular/nesting pattern of growth should be carefully evaluated for mitoses and necrosis in order to rule out the diagnosis of poorly differentiated carcinoma, according to the Turin proposal.

Immunohistochemically, follicular carcinomas are reactive for thyroglobulin, TPO, low-molecular-weight keratins, EMA, basement membrane components such as laminin and type IV collagen, and the thyroid transcription factors TTF1, TTF2 (FOXE1), and PAX8.[202] Their reactivity for these and other markers, as well as their ultrastructural appearance, is not significantly different from that of follicular adenomas.[476] Follicular carcinomas have a higher proliferative index compared to adenomas (see Table 8.3), although this is of limited help in the diagnosis of individual cases. Immunohistochemical reactivity for HBME-1, Galectin-3, CK19, CITED1, and CD56 may be used to distinguish follicular carcinoma (and adenoma) from follicular-variant papillary carcinomas (and NIFTP) (see Table 8.3).

At a molecular genetic level, follicular carcinomas share a common tumorigenic pathway with follicular adenomas, and to date no molecular test can reliably distinguish between the two (see Table 8.2).[203,303] This pathway is different from that of papillary carcinoma and is characterized by aneuploidy and by the frequent occurrence of *RAS* mutations.[203,303] A subset of follicular carcinomas harbors the *PAX8/PPARG* rearrangement, which generates the PAX8/PPARG fusion protein, named PPFP.[477] Conventional karyotyping shows clonal aberrations in approximately 65% of follicular carcinomas, with both numerical changes and structural abnormalities.[205,478] Numerical changes are similar to those of follicular adenomas and include hyperdiploid karyotypes with extra copies of chromosome 7, but chromosomal losses tend to be more frequent in follicular carcinomas, and complex karyotypes are common.[185,205,206,478,479]

Cytometric measurements of DNA content and comparative genomic hybridization (CGH) also identify aneuploidy in both

follicular carcinomas and adenomas.[203] Two pathways have been postulated based on aneuploidy and the pattern of chromosomal DNA alterations in follicular tumors (adenomas and carcinomas): one followed by tumors with prominent aneuploidy, chromosomal gains, and microfollicular/trabecular/solid architecture; the second characterized by diploid/near diploid DNA content with common chromosomal losses and normofollicular architecture.[480] Consistent with the instability of their chromosomal DNA, follicular carcinomas typically have a high average rate of LOH, approximately 20% per chromosome arm, as opposed to the much lower rates of approximately 5% in follicular adenomas and of approximately 2.5% in papillary carcinoma.[481]

The most common oncogenic mutations are those that involve *RAS* and, as in the case of follicular adenomas, *K-*, *N-*, and *HRAS* can all be affected. Most of mutations in follicular carcinomas (and adenomas) are at codon 61 of *NRAS*.[187] *RAS* mutations are a marker of follicular-patterned tumors (follicular carcinoma, follicular variant papillary carcinoma/NIFTP, follicular adenoma), likely promote tumor progression through loss of differentiation, and have been linked to unfavorable clinical features.[203,303,482–485]

The *PAX8/PPARG* rearrangement,[477] caused by the t(2;3)(q13;p25) that fuses *PPARG* at 3p25 with *PAX8*, originally thought to be specific, is also found in a subset of follicular adenomas and in the follicular variant of papillary carcinoma.[204,346,486] *PAX8/PPARG* is not found in hyperplastic thyroid nodules or in aggressive tumors such as poorly differentiated or anaplastic thyroid cancer.[204] It seldom overlaps with *RAS* mutations and is uncommon in oncocytic tumors.[330] In follicular carcinomas, *PAX8/PPARG* has been associated with female gender, younger age, high cellularity, and invasive features.[330] However, the risk of distant metastases may be lower than in *PAX8/PPARG*-negative cases.[486] Thus, *PAX8/PPARG* may be a marker for a distinct subset of tumors characterized by follicular growth and invasive potential but not by overtly aggressive features. Immunohistochemistry with anti-PPARG antibodies shows upregulation of PPARG and can be used to infer the *PAX8/PPARG* rearrangement.[204]

The PI3K/PTEN/AKT pathway is aberrantly activated, due to germline loss of function *PTEN* mutations in patients with the Cowden syndrome, and follicular carcinoma is a manifestation of the disease.[211] The fact that follicular carcinoma develops in the background of benign nodular disease with adenomatous thyroid nodules is an important clue supporting a common tumorigenic pathway for follicular adenoma and carcinoma. In addition to Cowden syndrome, follicular carcinoma has also been reported in Carney complex type I and Werner syndrome (adult progeria).[487]

Inactivating *PTEN* mutations or gain-of-function mutations of the *PIK3CA* gene activate PI3K/PTEN/AKT signaling in a minority of sporadic follicular carcinomas. However, copy number gains of *PIK3CA* and receptor tyrosine kinase *(EGFR, VEGFR1)* genes are common.[210,488] *PTEN* and *PIK3CA* mutations, as well as oncogenic *RAS* activation, rarely coexist in follicular carcinomas (although they can overlap in aggressive tumors), suggesting that each alteration has an independent role.[210,488] *TSHR* mutations are uncommon, but they have been reported in hyperfunctioning follicular carcinomas.[489]

TERT promoter mutations have been reported in approximately 17% of FTC,[350] with a percentage range of approximately 10%–35%.[350,351,412,490,491] In a subset of follicular carcinomas they coexist with *RAS* mutations.[348] As in the case of papillary carcinoma, *TERT* promoter mutations have been linked to poor prognosis.[347,348,350,491]

Follicular Carcinoma Subtypes

Depending on its degree of invasiveness at the gross, macroscopic, level, follicular carcinoma has been traditionally subdivided into "minimally" invasive and "widely" invasive forms. A clinically more valid grouping that overcomes this traditional binary division should take into account the following considerations:

1. There are two major categories, of widely different prognostic import: the encapsulated tumors, in which one has to look for invasion; and the widely invasive tumors, in which one has a look for a capsule.
2. Among the former, there are marked prognostic differences among those that show invasion of *only* the capsule (very low likelihood of distant metastases) and those that show vascular invasion, with or without capsular invasion (greater potential for distant metastases).[492–498]
3. Among those with vascular invasion, there is a prognostic difference depending on the number of vessels involved (with 4 foci of vascular invasion as the cutoff).[497–501]

Accordingly, a prognostically relevant classification scheme is the following:

FOLLICULAR CARCINOMA	INVASION
Minimally invasive	Encapsulated, with capsular invasion only (no vascular invasion)
Encapsulated angioinvasive	With limited vascular invasion (1–3 vessels, with or without capsular invasion)
	With extensive vascular invasion (≥4 vessels, with or without capsular invasion)
Widely invasive	Extensive invasion (macro- and microscopically evident), multinodular growth, no obvious tumor capsule

Encapsulated Follicular Carcinoma (Minimally Invasive and Encapsulated Angioinvasive). The vast majority of follicular carcinoma diagnosed today in developed countries are encapsulated, round-oval thyroid nodules sharply separated from the surrounding normal parenchyma, with a macroscopic appearance virtually indistinguishable from that of follicular adenoma. Only microscopic identification of invasion of the tumor capsule or of blood vessels allows to differentiate between the two. The cut surface is typically solid and fleshy. The pattern of growth usually resembles that of an adenoma of embryonal or fetal type. Indeed, it has been suggested that some of the cases represent malignant transformation of an adenoma. The mean diameter of encapsulated follicular carcinoma is 3–4 cm, nearly double that of papillary carcinoma.[502] Unlike the case of papillary carcinoma, encapsulated follicular carcinomas are almost always solitary, and it is rare to find tumors smaller than 1 cm.[503] Occult follicular carcinomas (i.e., tumors that manifest their presence as a consequence of metastatic spread) are well documented, some of them may be relatively small (1–2 cm)[496]. Malignant behavior in the form of distant metastasis has been documented in follicular carcinomas as small as 0.7 cm.[494]

Since the diagnosis of malignancy depends entirely on the demonstration of blood vessel and/or capsular invasion, one should be very strict about these criteria (Fig. 8.60).[504] The blood vessel invasion is almost never evident grossly. Microscopically, the vessels (typically veins) should be located in or immediately outside the capsule (rather than within the tumor) and contain one or more clusters of tumor cells attached to the wall and protruding into the lumen. These intravascular tumor nests must be covered by endothelium or surrounded by fibrin in a fashion similar to that of an

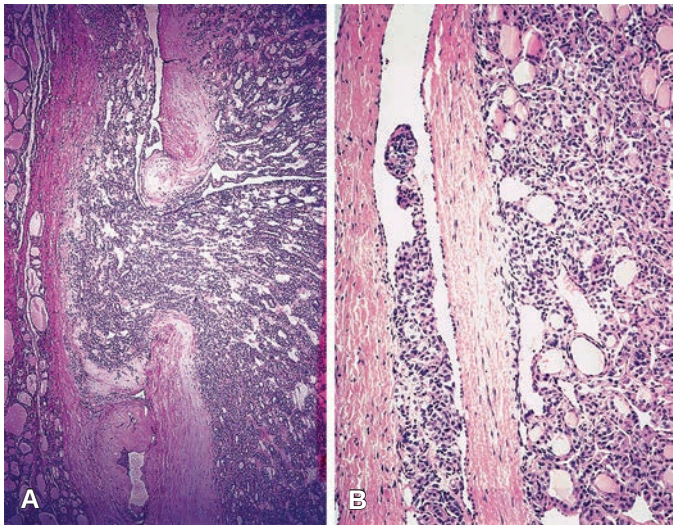

Figure 8.60 Capsular (**A**) and vascular (**B**) invasion in minimally invasive follicular carcinoma.

ordinary thrombus. Due to sectioning, sometimes nests of tumor cells with evidence of thrombus appear to be free-floating into the lumen. Elastic tissue stains of only limited use in identifying these vessels. Immunohistochemical stains for actin are more likely to be positive, but often these peculiar capsular vessels lack an elastic muscular layer altogether, despite their relatively large size. Endothelial markers—such as CD31, CD34, and Fli-1—can be useful, although their use can sometimes be disappointing due to improper fixation, technical reasons, or very low levels of expression. A mimic of vascular invasion is represented by the sometimes extremely florid proliferation of endothelial and smooth muscle cells of capsular vessels, which may look like a papillary endothelial hyperplasia (the "Masson lesion") or may even acquire a Kaposi-like appearance; this peculiar change can also be seen in follicular adenomas, but with a much lower frequency (Fig. 8.61).[177,505]

Interruption of the capsule must be full thickness for the process to qualify as capsular invasion.[506] After it has violated a narrow segment of the capsule, it is common for the tumor to expand in a mushroom-like fashion in the adjacent area. As a result, a tangential section might show a tumor nodule outside the main mass, separated from it by an intact capsule. Deeper sections may demonstrate the actual focus of capsular rupture. Another interesting phenomenon is the occasional formation of a second (or even a third) capsule in the advancing edge of the tumor that has already violated the original capsule. Evans[366] has made the interesting observation, confirmed by others,[507] that the capsule of follicular carcinoma tends to be thicker and more irregular than that of adenoma. Foci of capsular invasion should be distinguished from capsular rupture resulting from an FNA procedure. The latter should be suspected when the area in question has a fissure-like quality, contains foci of recent or old hemorrhage, and exhibits florid stromal reparative changes.[177] Another mimic is represented by the pseudoinvasion resulting from herniation of tumor tissue when the section for histology has been taken perpendicularly to a previous capsule cut made by the surgeon or pathologist on the fresh specimen; to avoid this trap, it is better to disregard the areas at the very edge of the section, in which the tumor appears to be coating an abrupt cross section of the capsule.[177]

There are prognostic differences among encapsulated follicular carcinomas that have vascular invasion and those in which invasion is only limited to the tumor capsule, the former having a greater potential for metastatic spread. Thus, thorough sampling of the

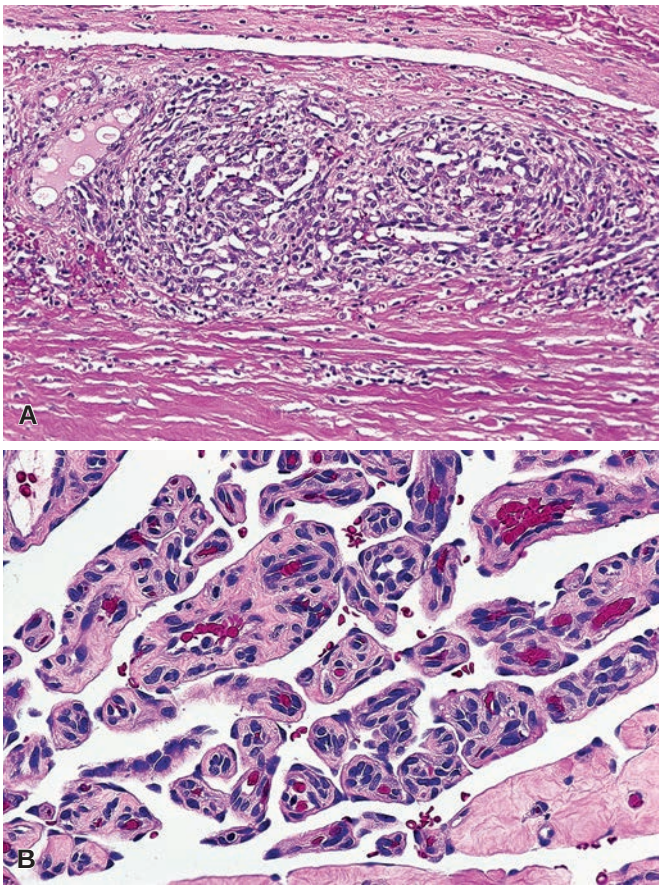

Figure 8.61 **A** and **B,** Reactive vascular proliferation in the capsule of a follicular neoplasm. On high power (**B**) the lesion has a papillary configuration.

interface of the nodule with the surrounding parenchyma is of paramount importance for encapsulated follicular-patterned lesions.[215] Sometimes even after accurate sampling and thorough examination there may still be doubts about true invasion of the tumor capsule or of vascular spaces. Vascular invasion may be questioned when nests of tumor cells abut into or are closely intermixed with vascular spaces, or when they appear inside them without endothelial lining or evidence of thrombus, and one cannot be sure that the findings are mere artifacts due to tumor dislodgement during sampling. Capsular invasion is questionable when tumor cells irregularly mushroom into but not completely through the capsule or when findings are limited to tumor nests in its outer portions. In these instances there can be considerable interobserver variability,[508] and the term "FT-UMP" may be appropriate. Similarly, that of "WDT-UMP" may be used for those cases where there are nuclear alterations of papillary carcinoma (see Table 8.4).[375,383] The "tumor of uncertain malignant potential" is not a "wastebasket" diagnostic category and should be used very sparingly as a pragmatic approach to address problematic cases.

Widely Invasive Follicular Carcinoma. Widely invasive follicular carcinomas used to be common, particularly in iodine-deficient areas, but have now become very rare in developed countries because of the improved diagnostic methods and health care standards. Invasion of the thyroid gland is widespread and immediately apparent on sectioning of the specimen, with multiple, irregular fronts of infiltration and frequent extension into the extrathyroidal soft tissues. Gross (and sometimes even microscopic) evidence of preexisting tumor encapsulation may be missing altogether. Cases with numerous

invasive nodules, the result of intravascular dissemination, may be mistaken for multinodular goiter.[177] Microscopically, vascular invasion is obvious. Many cases show high-grade morphology, at least in part of the tumor, with mitoses, foci of necrosis, and poorly differentiated cytoarchitectural features. Thus, many cases are more appropriately labeled poorly differentiated thyroid carcinomas. Some tumors have mixed histologic appearance, with combined follicular, solid, insular, and even papillary or oncocytic features.

Spread, Metastases, and Prognosis

In contrast to papillary carcinomas, follicular carcinomas of any subtype are almost always solitary and rarely occult. Metastases are blood-borne rather than to regional nodes.[509] The report of true lymph node metastases in a patient with follicular carcinoma should always be questioned, and, particularly if the tumor is not oncocytic, the possibility of a follicular variant of papillary carcinoma or a poorly differentiated carcinoma should be seriously considered.

In keeping with the tendency of follicular carcinoma to diffuse through blood vessels, even early-stage tumors have a small, but definite potential to give rise to distant metastases that can be the first manifestation of the disease. These are found at the time of the initial diagnosis in approximately 5%–10% of patients with encapsulated follicular carcinomas (a much higher proportion compared with papillary carcinoma)[496,499,510] and in a greater percentage (~20%–30%) of those with widely invasive carcinomas.[499,511] In an additional 5%–15% of patients with encapsulated tumors, distant metastases are discovered afterwards, not infrequently more than 10 years after the original diagnosis, underlying the need for a prolonged follow-up.[499,510] It is important to remember that even small tumors can metastasize. In one series five of eight minimally invasive carcinomas with distant metastases measured 2 cm or less.[496]

The most common sites of distant metastases are lungs and bone, but they can be seen in many other places, including kidney and skin.[512] The skeletal metastases are usually multicentric but have a predilection for the shoulder girdle, sternum, skull, and iliac bone.[513] Sometimes they pulsate because of their vascularity, a feature they share with metastatic renal cell carcinoma. These metastases have a strong affinity for radioiodine and—curiously—may exhibit a better differentiated appearance than the primary tumor, to the point of looking like normal thyroid as an expression of terminal differentiation (so-called metastasizing adenoma, malignant adenoma, or metastasizing goiter). The majority, however, have poorly differentiated features, at least at the architectural level.[509] Thyroglobulin and/or TTF-1 staining is essential in confirming the thyroid origin of a metastatic tumor.

Distant metastases are common in the widely invasive type or in encapsulated tumors with extensive angioinvasion, occur in fewer than 5% of the encapsulated tumors *with focal* blood vessel invasion (1–3 foci), and develop in fewer than 1% of the tumors diagnosed as carcinoma *only on the basis of minimal capsular invasion*.[492,494,495,499,501] While the prognosis of patients with follicular carcinoma is directly related to the degree of encapsulation and invasion of vascular spaces,[499,514] encapsulated follicular carcinomas with focal capsular and vascular invasion, without poorly differentiated features and without distant metastases at presentation, are rarely fatal.[384,410]

The prognosis for patients with follicular carcinoma that present with distant metastases is poor.[497,498,511,514,515] In one large series of encapsulated follicular carcinoma the cause-specific survival at 10 years was 55% compared with 97.8% for patients that did not have distant metastases at presentation.[510]

Rare follicular neoplasms show marked cytoarchitectural abnormalities (in the form of solid/trabecular pattern of growth, mitotic activity, necrosis, etc.) in the absence of capsular or blood vessel invasion. Considerations should be given to consider these tumors *noninvasive follicular carcinoma* with high-grade features.[516]

Hürthle Cell (Oncocytic) Tumors

The Oncocyte

Since the presence of oncocytes is the common denominator for all the tumors included in this section, it seems appropriate to begin with a description of these cells, which in the thyroid are usually but inaccurately designated as Hürthle cells (a misnomer, since the oncocytic cells were originally recognized in the thyroid gland by Askanazy in 1898).[517] Oncocyte, oncocytic cell ("swollen" cell, that we consider the more accurate descriptive term), and oxyphilic cell ("acidophilic" or "eosinophilic" cell) are terms, more popular in the European literature, used interchangeably for Hürthle cell.[518] The characteristic cytoplasmic granularity of these cells is due to the accumulation of mitochondria, many of which show a variety of morphologic abnormalities both on transmission and scanning electron microscopy (Fig. 8.62).[519,520] Due to the striking mitochondrial accumulation there is complete loss of cell polarity.[518] It is important, to avoid confusion in diagnostic terminology, to distinguish oncocytic cells from other "mitochondria-rich" cells that do not have total loss of cell polarity and have fewer mitochondria at the ultrastructural level (e.g., the tall cells of tall cell papillary carcinoma that have an eosinophilic "oncocytoid" cytoplasm).[518] It is also good to remember that the granularity of the neoplastic cell cytoplasm should have a deeply eosinophilic quality in H&E-stained sections; otherwise, alternative possibilities such as (oncocytic) medullary carcinoma should be considered. Secondary cytoplasmic clearing is not uncommon in oncocytic cells, usually due to mitochondrial swelling. Immunohistochemically, oncocytes show reactivity many mitochondrial antigens, glucose transporter 4 (GLUT-4), and keratin.[7,521] Marked reduction or loss of expression of complex I subunit genes (e.g., *NDUFS4*) and of complex I enzyme activity is a common feature in oncocytic cells both in the thyroid and in the kidney.[522,523] It is important to remember that the endogenous biotin of mitochondria may result in spurious immunohistochemical staining of oncocytic cells.[524]

The obvious cellular derangement of oncocytic cells causing the accumulation of mitochondria has long been suspected to be due to some form of abnormality in mitochondria biogenesis. Oncocytic tumors have a higher prevalence of mitochondrial DNA mutations than non-oncocytic tumors, ranging from point substitutions, to small insertions or deletions that can lead to frameshifts or premature stop codons, and large-scale deletions, like the "common" 4977-base pairs deletion.[525–529] We now know that the biochemical, metabolic, and phenotypic (i.e., accumulation of mitochondria) alterations of oncocytic tumors are caused by mutations in the genes coding for some of the subunits of the five multimeric complexes of the inner mitochondrial membrane that constitute the oxidative phosphorylation (OXPHOS) system. If these subunits are missing or defective due to the mutation, the entire multimeric complex does not assemble properly, OXPHOS is impaired, and there is a compensatory accumulation of mitochondria.[530,531] In oncocytic thyroid tumors, as well as in those from other organs, greater than 50% of the mutations occur at homoplasmic levels in mitochondrial genes, in more than 70% of cases in the *MT-ND* genes encoding Complex I (NADH coenzyme Q reductase) subunits.[522,523,527,532] Mutations of the Complex I subunit encoded by the *NDUFA13 (GRIM-19)* nuclear gene are the only nuclear gene mutations specific to oncocytic tumors reported to date. They have been found in a few carcinomas, including one patient with a germline mutation who developed an oncocytic variant of papillary carcinoma and multiple benign oncocytic thyroid nodules.[533] While mutations in mitochondrial and nuclear genes affecting OXPHOS function are the cause of the oncocytic phenotype, their relationship with tumor development is complex and there is no definitive proof that the mutations have a direct tumorigenic role.[530,531,534] However, the accumulation of defective mitochondria

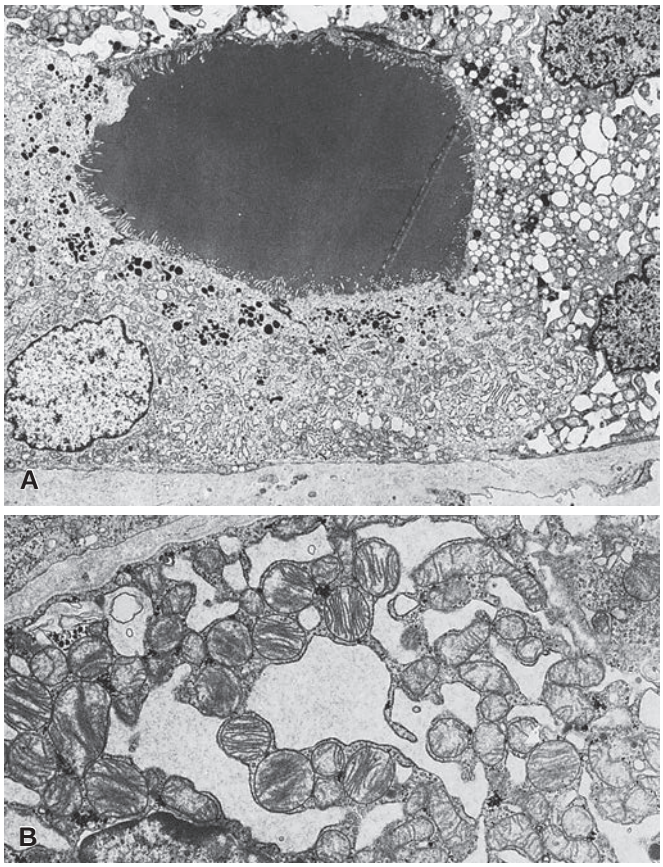

Figure 8.62 Ultrastructural appearance of Hürthle cell (oncocytic) tumor of thyroid gland. **A,** The cytoplasm is packed with mitochondria. Secretory product is located toward the lumen, which is filled with colloid. **B,** Variably sized mitochondria with prominent cristae. (**A**, ×3840; **B**, ×11,230.)

Figure 8.63 Gross appearance of Hürthle cell (oncocytic) carcinoma. The cut surface shows a tan color and a necrotic hemorrhagic center.

explains well one of the distinctive pathologic features of oncocytic tumors, that is their exquisite sensitivity to hypoxia.[530]

Clinicopathologic Features

Hürthle cell (oncocytic) tumors represent approximately 3%–4% of all thyroid carcinomas.[535] Tumors included in this category are those composed exclusively or predominantly (over 75%) of follicular cells exhibiting oncocytic features.[518] In a traditional view Hürthle cell tumors composed of follicular cells have not been regarded as a distinct type and have been placed in one of the existing tumor categories (i.e., follicular or papillary), depending on their pattern of growth. However, their biologic characteristics, morphologic features, and natural history are distinctive enough for them to be regarded as a special group.

Most patients with Hürthle cell thyroid tumors are adults, and there is a predominance of females.[536–538] Grossly, the tumors are characteristically solid, tan, and well vascularized (Fig. 8.63). Most are well encapsulated throughout; the invasive tumors tend to grow into the parenchyma in a multinodular fashion that can be very deceptive in that it can be underinterpreted as nodular hyperplasia. Microscopically, the pattern of growth may be follicular, trabecular/solid, or papillary. The former is the most common. The follicles, when large, are separated by long and thin fibrovascular septa that simulate papillae when cut tangentially. Hürthle cell tumors usually contain little stroma, and discohesive cells in areas of solid growth may also simulate papillary structures. Another diagnostic trap is the presence of inspissated intraluminal colloid with concentric laminations, having an appearance similar to that of the psammoma bodies associated with papillary carcinoma, from which they are distinguished because of their intraluminal location. The nuclei typically show pleomorphism and prominent nucleoli, sometimes with isolated bizarre forms, these not being features of malignancy by themselves.

Immunohistochemically, there is reactivity for thyroglobulin, although in lesser degree than in conventional follicular lesions.

Hürthle cell (oncocytic) tumors with follicular or solid/trabecular patterns—which constitute the large majority—should be evaluated and diagnosed using criteria analogous to those used for follicular neoplasms of non-oncocytic types; that is, capsular and/or blood vessel invasion should be used as the main criterion for malignancy.[536–538] In the past all Hürthle cell (oncocytic) neoplasms were regarded as malignant or potentially malignant.[539] In fact, the majority of them behave in a benign fashion and are properly designated as *Hürthle cell (oncocytic) adenoma* (Fig. 8.64).[536,537] Tumors with clear-cut capsular and/or blood vessel invasion are designated as *Hürthle cell (oncocytic) carcinoma*.[536,537]

As a group, the carcinomas occur in an older age group, show less degree of female predominance, are larger (tumors measuring 3.5 cm or more are carcinomas in approximately two thirds of the

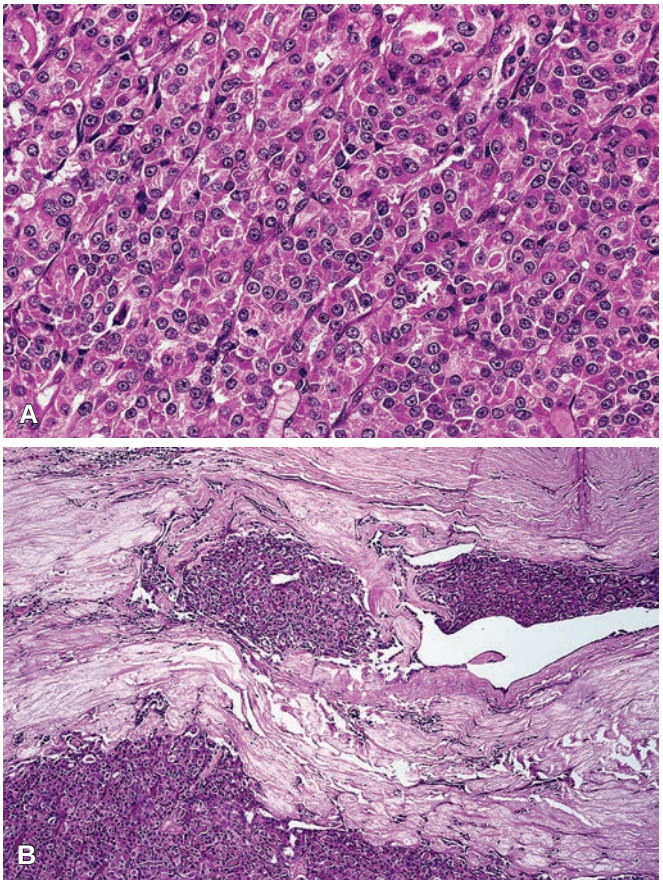

Figure 8.65 Hürthle cell (oncocytic) carcinoma. **A,** The tumor has a predominantly solid pattern of growth. **B,** Extensive vascular invasion.

cases),[540] and tend to have a solid/trabecular rather than a follicular pattern of growth (Fig. 8.65).[536–538] The cells of carcinoma are often smaller than those of adenoma and have a higher nucleocytoplasmic ratio, a feature also noticeable on cytologic examination. In the presence of any of these features, the search for capsular and/or vascular invasion should be particularly thorough (Fig. 8.65).[536–538] However, even small oncocytic nodules should be carefully sampled, as they can show invasive growth and malignant clinical behavior.[541] If no vascular invasion but only equivocal capsular invasion is found in an oncocytic tumor the behavior is usually benign.[538]

At the other end of the spectrum are the Hürthle cell (oncocytic) carcinomas that are highly invasive, with a predominantly or exclusively solid/trabecular pattern of growth, mitotically active, with foci of tumor necrosis; these are to be placed in the poorly differentiated category and regarded as high-risk tumors.[542–544]

One problem of Hürthle cell tumors is their tendency to undergo massive infarct-type necrosis, often following FNA.[545] This phenomenon, which is analogous to that seen in oncocytic tumors at other sites and which the consequence of the great sensitivity of oncocytes to ischemia due to impaired mitochondrial function, can render the identification of the tumor difficult or impossible. However, the shadows of the tumor cells can sometimes still be discerned by simply lowering the microscope condenser, and there can be a surprising retention of immunohistochemical markers, particularly keratin.[546] It is important to realize that under these circumstances the capsule can become very irregular and entrap within its substance thyroid follicles with "regenerative" or "reactive" atypia, including some nuclear clearing and overlapping; these changes should not be overinterpreted as carcinoma.

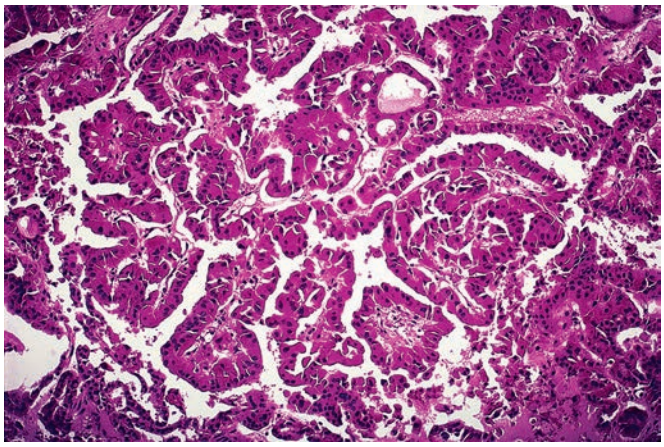

Figure 8.66 Hürthle cell (oncocytic) neoplasm with a papillary pattern of growth. The nuclear features of the papillary family of neoplasms are absent, and therefore this tumor should not be classified as a papillary carcinoma.

A difficult diagnostic problem is represented by the rare Hürthle cell (oncocytic) tumors composed entirely of papillae (as opposed to the more common pseudopapillary formations previously mentioned).[547] Those that have the nuclear features of papillary carcinoma should be placed in the latter category, as already indicated; those that do not should be handled as follicular tumors (Fig. 8.66).[548] In other words, malignancy should be largely based on the presence of capsular and/or vascular invasion. Tumors that are encapsulated behave in a benign fashion,[549] whereas those that are invasive behave in a malignant fashion,[549] perhaps more so than conventional papillary carcinomas.[550]

Hürthle cell (oncocytic) carcinomas have a marked propensity for vascular invasion. True lymph node metastases can occur but are (contrary to past opinion) uncommon.[551] In the large majority of cases locoregional disease in the neck occurs in the form of rounded nodules of carcinoma within the soft tissues. These are the result of endovascular tumor dissemination, and wide excision of the nodules alone, as opposed to formal lymph node dissection, may provide adequate local control.[551] Distant metastases are identified at presentation in approximately 10% of cases, although they may also appear years after the initial diagnosis.[552] Bone is a common metastatic site, but metastases may develop at unusual sites and be misdiagnosed as primary tumors.[509,512]

Hürthle cell (oncocytic) adenomas are cured by lobectomy, if fully excised. The carcinomas are rather aggressive neoplasms. When compared with conventional non-oncocytic carcinomas of follicular cell derivation, Hürthle cell (oncocytic) carcinomas are relatively more common among men and among older patients, have larger tumors, and present with higher disease stage.[553] Importantly, they have lower overall and disease-specific survival,[553] a reflection of their poor iodide uptake (that also limits the efficacy of radioactive iodine scans to identify metastatic disease).[552] Compared to patients with conventional non-oncocytic carcinoma, those with oncocytic carcinomas also have a significantly higher rate of secondary primary malignancies.[553] In a large series, survival of at 5 year was 85%, although for patients with stage III–IV disease the 5-year cumulative probability of clinical recurrence or death was 74% for female and 91% for male patients.[552] Older patient age, large tumor size, extrathyroidal extension, extensive vascular invasion, and metastases represent unfavorable prognostic factors.[552] The extent of vascular invasion (1–3 vs. 4 or more foci) greatly influences prognosis of patients with encapsulated carcinomas.[500,552]

No specific chromosomal abnormalities have been reported in Hürthle cell (oncocytic) tumors. However, aneuploidy is a characteristic feature of both adenomas and carcinomas and typically involves whole chromosomes or large chromosome sections, as if the increased mitochondrial mass were to hinder correct chromosomal segregation.[554–558] Gains at chromosome 12q, 19q, and 20p have been associated with tumor recurrence,[557] while chromosome 22 loss has been associated with patient mortality.[555] Cytometric DNA content analysis has linked aneuploid tumors to invasion, metastases, and poor outcome.[559,560]

The main molecular alterations that characterize non-oncocytic tumors can also be found in Hürthle cell (oncocytic) tumors. Thus, *RAS* mutations occur in tumors with follicular growth (although they are detected much less frequently),[330,486,558] and *BRAF* mutations in the rare oncocytic papillary carcinomas.[291,334] Intriguingly, *TP53* mutations have been reported in 10%–20% of Hürthle cell (oncocytic) tumors lacking high-grade/poorly differentiated features,[561,562] sometimes in association with *PTEN* mutations.[563]

A comprehensive high-throughput molecular study of tumorigenic mutations, DNA copy number changes, and expression profiling of Hürthle cell (oncocytic) tumors has shown that they have a genetic profile different from that of their conventional non-oncocytic counterparts. Carcinomas with extensive vascular invasion (4 foci or more) and aggressive features, unlike tumors with no or limited invasion, have molecular signatures consistent with activation of wnt/β-catenin and PI3K/PTEN/AKT pathways.[558]

Clear Cell Tumors

Clear cell changes can occur in thyroid neoplasms of various microscopic types and as a consequence of a variety of mechanisms, which include cytoplasmic vesicles (of mitochondrial, reticulum endoplasmic, or Golgi origin[564,565]) and accumulation of glycogen, lipid, thyroglobulin, or "mucin" (Fig. 8.67). The natural history of these tumors is determined by their basic nature rather than the presence of, degree of, or mechanism for cytoplasmic clearing in them. Therefore *clear cell carcinoma* should not be viewed as a specific tumor type.[564,566]

The neoplasm most prone to undergo secondary clear cell changes are Hürthle cell (oncocytic) tumors, this being the result of vesicular swelling of mitochondria (Fig. 8.68).[564] The oxyphilic and clear cell changes may be seen in cells facing each other or even in different regions of the same cell (Fig. 8.69).[567] Clear cell changes can also occur in follicular adenomas and carcinomas (usually because of vesicles of either mitochondrial or granular endoplasmic reticulum derivation),[568] papillary carcinoma (usually because of glycogen accumulation),[569] undifferentiated carcinoma (also the result of glycogen overload), and—exceptionally—medullary carcinoma.[570] Except for the latter, thyroglobulin stain is usually positive in these neoplasms, although sometimes in a focal and faint fashion.[564,571] Positive TTF1 immunoreactivity can confirm the thyroidal origin of the clear cells. Although the presence of clear cell change in a follicular neoplasm per se is not an indication of malignancy, it occurs more frequently in carcinomas than in adenomas and should therefore be viewed with suspicion when encountered.

A peculiar variant of thyroid tumor with clear cell changes is the *signet ring type*, in which the formation of variously sized cytoplasmic vacuoles results in a configuration reminiscent of signet ring cells or lipoblasts (Fig. 8.70). Most of these signet ring neoplasms are adenomas, but carcinomas with this appearance also occur.[572–574] Immunohistochemically, the vacuoles contain intracellular thyroglobulin.[564,572–574] The stroma is usually heavily hyalinized and with punctate calcification, suggesting that the signet ring change may be of degenerative nature and the expression of an arrest of folliculogenesis.[572,573] Some of this material has been found to react positively with mucin stains.[574]

Another rare form of clear cell change is that seen in the *lipid-rich cell adenoma*, in which the cytoplasmic vacuolization is due to the accumulation of neutral fat.[575,576]

The main differential diagnosis of primary thyroid tumors with clear cells is with parathyroid neoplasms and metastatic renal cell carcinoma.[564,566] When struggling with this problem, the pathologist should keep in mind the fact that both of these lesions can be intrathyroidal, whereas thyroid clear cell tumors can occur in ectopic locations.[577] Immunohistochemistry will be of great help in the differential diagnosis.

It should also be noted that cytoplasmic clear cell changes can also occur in non-neoplastic thyroid disorders, including Hashimoto thyroiditis and dyshormonogenetic goiter.[564]

Squamous Cell, Mucinous, and Related Tumors

Squamous cells can be found in the thyroid as a result of persistence of thyroglossal duct or structures derived from the branchial pouch (such as thymic epithelium), or as an expression of squamous metaplasia in Hashimoto thyroiditis, papillary carcinoma, and other conditions. Pure **squamous cell carcinomas** are exceptional.[578,579] Some have been associated with leukocytosis and hypercalcemia[580] (as have anaplastic carcinomas).[581,582] Most high-grade thyroid tumors with squamous foci blend with areas of undifferentiated (anaplastic) carcinoma and are generally placed in the latter category because of their similar natural history.[583] Indeed, many of them are seen to develop from papillary carcinoma in a fashion analogous to that of undifferentiated carcinoma.[468,584] The tall cell variant of papillary carcinoma has a particular tendency to evolve into a spindle cell squamoid type of anaplastic carcinoma.[411] In the presence of an obvious squamous cell carcinoma involving the thyroid, the possibility should also be considered of secondary direct involvement from a tumor of larynx or trachea or a metastasis from lung or other sites. The thyroid differentiation factors TTF1 and TTF2 are usually negative in primary squamous (and anaplastic squamoid) carcinomas of the thyroid gland, but PAX8 immunoreactivity is frequently retained in these primary thyroid tumors, while it is invariably negative in squamous cancers of the head and neck and of the lung.[18,585]

Mucoepidermoid carcinoma (Fig. 8.71) is a rare thyroid neoplasm composed of squamous areas arranged in solid sheets, sometimes with keratin pearl formation, and of mucinous (goblet) cells lining duct-like structures or glandular spaces; mucinous cells may contain intracytoplasmic PAS-positive droplets resembling colloid and are exceptionally ciliated. The squamous and mucinous components are closely intermingled, and the stroma is fibrotic. Accumulation of extracellular mucin with cystic spaces containing mucin and keratin material and a cribriform growth pattern may occur. The mucinous material is positive with Mayer mucicarmine and alcian blue stains.[586–592]

Although an origin from solid cell nests has been suggested,[593] the fact that psammoma bodies, nuclear grooves, and pseudoinclusions can all be sometimes observed in mucoepidermoid carcinoma suggests that it may in fact represent a type of papillary carcinomas with an extreme degree of squamous and mucinous metaplasia.[590–592] Indeed, cases of papillary carcinoma with prominent mucoepidermoid features have been described,[594] and the tumor may be associated with papillary carcinoma.[590–592] Mucoepidermoid carcinoma commonly develops in the background of Hashimoto thyroiditis.[590–592]

Immunohistochemically the tumor is usually positive for thyroglobulin, CEA (polyclonal), TTF1, and PAX8.[590–592]

The behavior is that of a low-grade malignant neoplasm that may metastasize to cervical nodes but rarely spreads to distant sites. Rare fatal cases have been reported, typically in tumors with poorly differentiated or anaplastic components.[590,592,595]

The t(11;19) translocation (*CRTC1/MAML2* fusion) typical of salivary and bronchial gland mucoepidermoid carcinomas has been identified in some cases.[596] Mutations of *BRAF* or of *RAS* genes have not been identified, but *RET/PTC* rearrangements have been found in a combined papillary/mucoepidermoid carcinoma.[597]

Sclerosing mucoepidermoid carcinoma with eosinophilia (SMECE) is a distinctive variant of mucoepidermoid carcinoma arising in thyroid glands affected by Hashimoto thyroiditis, often of the fibrous type (Fig. 8.72).[598] The tumor is believed to originate from the benign squamous nests found in Hashimoto thyroiditis.[598] Microscopically, strands and nests of squamous tumor cells with mild to moderate pleomorphism are seen infiltrating a dense fibrohyaline stroma. Foci of definite squamous differentiation and mucin secretion are often present, sometimes admixed with mucin secretion. There is a constant and often striking infiltration by eosinophils, which tend to congregate around the more atypical tumor cells, thus helping to locate them on low-power examination (Fig. 8.73). In some cases there are prominent glycogen-rich clear squamous cells.[590,598–600] Some of these features can be appreciated in FNA material.[601] Immunohistochemically, there is strong reactivity for cytokeratins and p63, but only limited reactivity for TTF-1, and often none for thyroglobulin.[591,599] The clinical course is generally indolent, but cases with distant metastases and aggressive behavior have been reported.[600] The lymph node metastases may simulate microscopically Hodgkin lymphoma.[602]

A few cases of **mucinous carcinoma** lacking a squamous component and exhibiting varying degrees of differentiation (including poorly differentiated types) have been described.[603–605] In this regard, it is pertinent to note that the thyroglobulin molecule contains variable amounts of carbohydrates that may result in some degree of alcianophilia.[10]

A rare entity occurring in or around the thyroid that may exhibit squamous differentiation is *intrathyroid thymic carcinoma* or *carcinoma showing thymus-like differentiation (CASTLE)*.[40] This tumor is described in more detail in Chapter 12, together with other tumors showing thymic or related branchial pouch differentiation that can occur in the neck, often in close anatomic relationship with the thyroid gland.[40,606,607]

Poorly Differentiated Carcinoma

Malignant tumors of follicular cells are divided into a conventional well-differentiated type, composed of papillary and follicular carcinoma, and an undifferentiated or anaplastic type. There is, however, a group of tumors that shows limited evidence of structural follicular cell differentiation and falls in between these two extremes, in terms of both morphologic appearance and clinical behavior.[608–614] "Insular carcinoma," the prototype of this class of tumors, was originally reported in 1984 by Carcangiu, Zampi, and Rosai.[608] The generally accepted diagnostic criteria for this tumor were outlined in the 2007 report of the international Turin consensus conference (Fig. 8.74).[615]

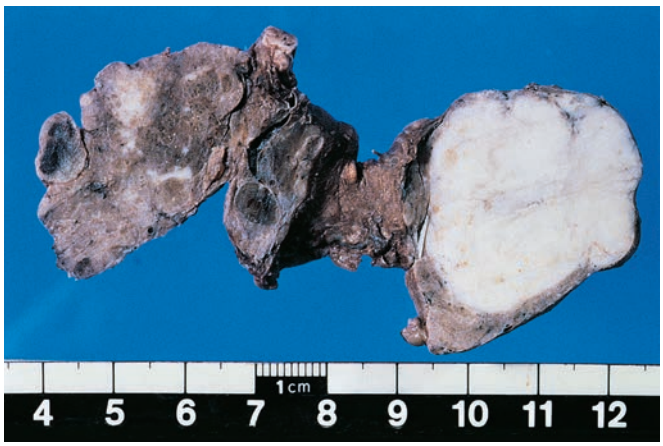

Figure 8.72 Sclerosing mucoepidermoid carcinoma with eosinophilia occurring in a thyroid gland affected by Hashimoto thyroiditis. The neoplasm, which almost entirely replaces a lobe, has a well-circumscribed quality. (Courtesy of Dr. Josie Zaroway, Edmonton, Canada.)

Poorly differentiated carcinomas are uncommon. If the Turin consensus criteria are utilized they represent a small fraction of thyroid carcinomas, less than 2% in the United States and less than 1% in Japan, although a prevalence of approximately 5% has been reported in the area of Turin in Italy and in some regions of France.[616,617] Iodine deficiency likely represents a risk factor based on the association of poorly differentiated carcinoma with longstanding goiter.[612]

Compared to the well-differentiated tumors, poorly differentiated carcinoma occur in an older group, with a mean age at presentation of 55–65 years (although they have also been reported in children and adolescent,[619] and show a lower predominance of female patients.[608,615,617,620]

On gross examination the tumors are large (in one series 5 cm was the median diameter),[617] with pushing margins and satellite nodules. They may be partially encapsulated but are often indistinguishable from widely invasive follicular carcinoma. Because of multinodular growth, they may simulate thyroid goiter.

Microscopically, the features of insular carcinoma are very characteristic (to the point of instant pattern recognition): a nesting—"insular"—pattern of growth (Fig. 8.75), solid to microfollicular arrangement, small uniform tumor cells (Fig. 8.76), variable mitotic activity, and fresh tumor necrosis, sometimes resulting in a peritheliomatous pattern (Fig. 8.77). "Insular" nests are surrounded by thin fibrovascular septa, which are often separated from tumor cell nests by artefactual clefts. The tumor cells have round hyperchromatic nuclei, indistinct nucleoli, and minimal pleomorphism. Sometimes the nuclei may show irregular, "raisin-like," convoluted features reminiscent of papillary carcinoma, but the chromatin is dark and there are no pseudoinclusions.[608]

Some poorly differentiated cases do not show the classical features of "insular" carcinoma: a trabecular pattern predominates (Fig. 8.78), neoplastic cells have larger more pleomorphic nuclei, and necrosis

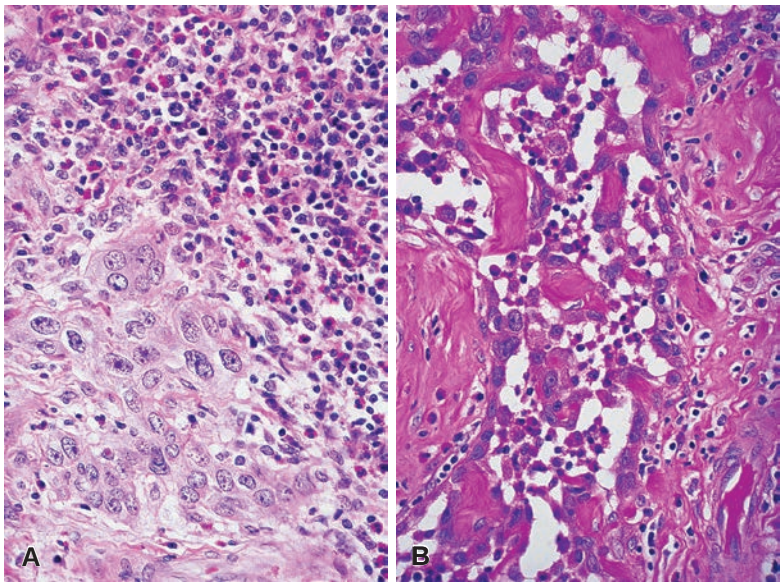

Figure 8.73 Sclerosing mucoepidermoid carcinoma with eosinophilia. **A,** The pattern of growth is solid and squamoid and is associated with a massive eosinophilic infiltration. **B,** The formation of tissue spaces results in a pseudovascular appearance.

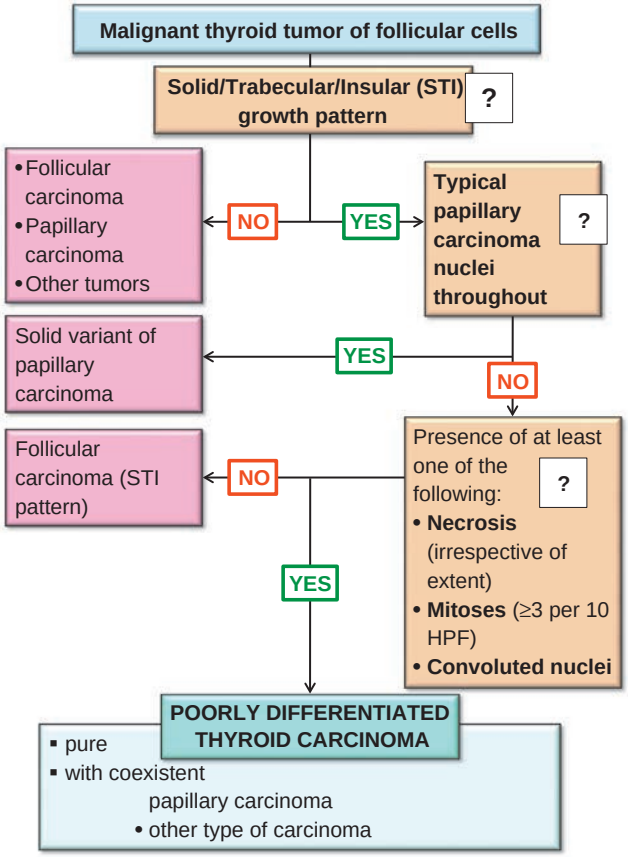

Figure 8.74 Diagnostic criteria for poorly differentiated thyroid carcinoma. HPF: high power field; random mitotic counts in areas with solid/trabecular/insular (STI) growth pattern (From Volante M, Collini P, Nikiforov YE, et al. Poorly differentiated thyroid carcinoma: the Turin proposal for the use of uniform diagnostic criteria and an algorithmic diagnostic approach. *Am J Surg Pathol*. 2007;31(8):1256–1264.)

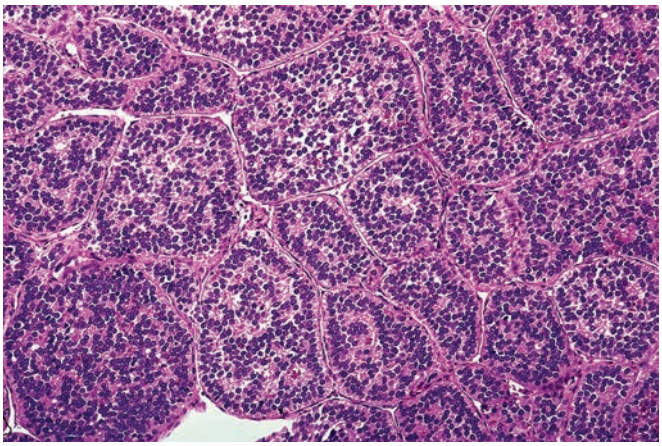

Figure 8.75 Low-power view of poorly differentiated thyroid carcinoma, showing a well-developed insular pattern.

is comedo-like. Vascular invasion is identified in the majority of cases. Extrathyroidal infiltration is common, but it is less pervasive than in anaplastic carcinoma.[608,615,617,618] The Turin consensus criteria,[615] which currently define poorly differentiated carcinoma, represent a generalization of the original concept of insular carcinoma put in the form of a diagnostic algorithm. They are based on (see Fig. 8.74):

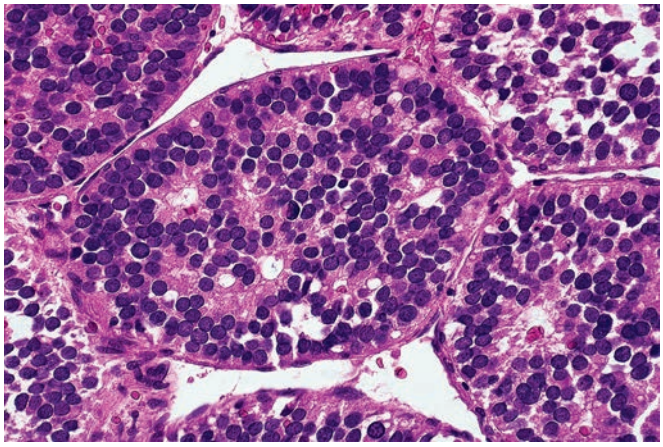

Figure 8.76 On high power, the cells of insular carcinoma show round, medium-sized nuclei with a smooth contour and hyperchromasia.

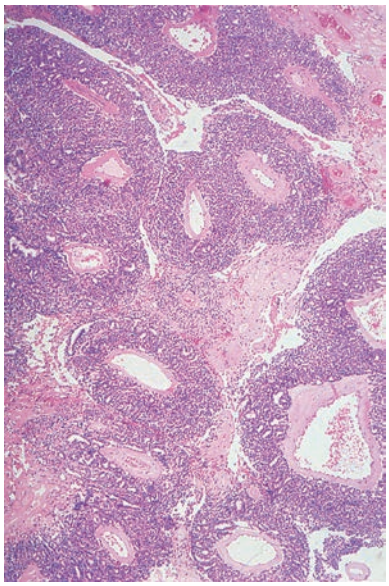

Figure 8.77 Poorly differentiated (insular) carcinoma. The peritheliomatous pattern of growth results from necrosis associated with preservation of the tumor cells that are closer to nutrient vessels.

- Pattern of growth that is nested ("insular")/solid/trabecular.
- Absence of the conventional nuclear features of papillary carcinoma
- Presence of at least one of the following features:
  - mitotic activity (≥3 mitoses per 10 high-power fields)
  - tumor necrosis
  - convoluted nuclei

Some poorly differentiated carcinomas are composed of Hürthle (oncocytic) cells.[542–544]

Clear cells foci,[542] mucinous differentiation,[603] and signet ring[621] or rhabdoid[622] features have been reported. In many cases poorly differentiated tumors exhibit a complex pattern, and poorly differentiated areas can be intermixed with a variety of growth patterns, including areas of well-differentiated papillary or follicular carcinoma. This complexity and the non-standardized use of the term "poorly differentiated" to designate thyroid carcinomas with unfavorable prognosis can produce diagnostic problems.[616] It has been shown that the focal presence (as low as 10%) of poorly differentiated areas in an otherwise well-differentiated papillary or follicular carcinoma may be associated with unfavorable outcome and should therefore

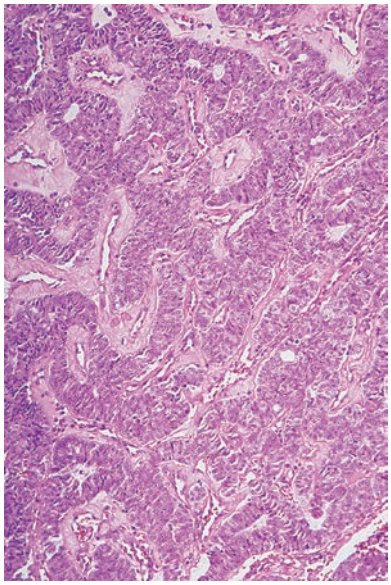

Figure 8.78 Poorly differentiated carcinoma showing trabecular pattern of growth rather than insular formations.

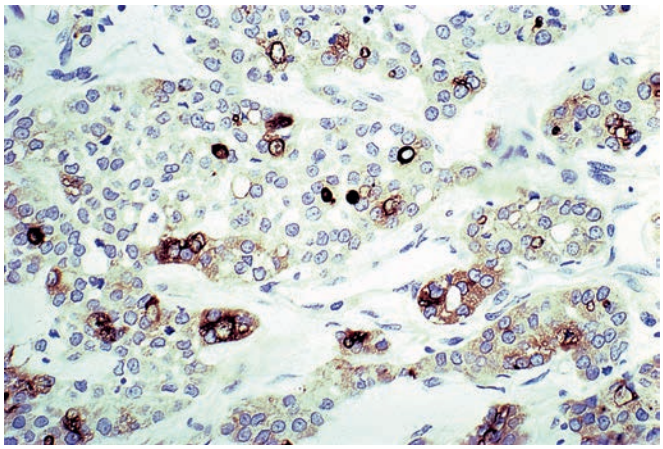

Figure 8.79 Poorly differentiated carcinoma of thyroid of insular type showing immunoreactivity for thyroglobulin.

be reported.[616] Areas of poorly differentiated carcinoma are also encountered in association with tumor histotypes that are characterized by aggressive behavior such as the hobnail variant.[435] Cellular anaplasia and nuclear pleomorphisms mark the transition to anaplastic carcinoma.[623] One fatal case of poorly differentiated carcinoma arising within struma ovarii has been reported.[624]

Immunohistochemically, poorly differentiated carcinoma, like other differentiated thyroid tumors, shows a cytokeratin7+/cytokeratin20– profile.[276] Thyroglobulin expression is reduced and characteristically limited to microfollicular structures and to the paranuclear portion of some of the neoplastic cells (see Fig. 8.79).[611] TTF1 is positive, although with weaker immunoreactivity.[18] Immunoreactivity for p53 may be restricted to areas of infiltrative growth and is not as widespread as in anaplastic carcinoma.[625] The Ki-67/MIB1 labeling index is often 10%–30%.[626]

The differential diagnosis of poorly differentiated carcinoma includes primarily medullary thyroid carcinoma, parathyroid carcinoma, and carcinoma metastatic to the thyroid gland and immunohistochemistry is useful in resolving difficult cases.

Poorly differentiated carcinoma presents as thyroid mass, sometimes as a recent growth in a longstanding goiter. In preoperative FNA samples, cytologic features suggestive of poorly differentiated carcinoma are marked cellular crowding, clusters with insular/solid/trabecular morphology, single cells, and cells with high nuclear/cytoplasmic ratio, but a definitive diagnosis can only be made after histologic examination.[627]

At the time of the initial diagnosis there are distant metastases in approximately 15% of patients, and lymph node metastases are common.[471,608]

Although some tumors may concentrate radioactive iodine, poorly differentiated carcinomas are typically FDG-PET positive[620] and represent approximately 50% of thyroid tumors that are FDG-PET positive and refractory to radioactive iodine treatment.[628] Because of the poor radioactive iodine uptake the survival at 5 years varies between 40% and 70% in most series.[608,615,617,618]

A high density of tumor-associated macrophages (a common finding in advanced thyroid cancers) has been reported as a poor prognostic factor.[629] A favorable prognostic factor is full encapsulation. In one report, completely encapsulated high-grade tumors with mitotic activity or necrosis, and with the features of poorly differentiated carcinoma according to the Turin consensus criteria—but for the lack of invasion—have not recurred or metastasized after a median follow-up greater than 10 years.[516]

It is important to remember that poorly differentiated carcinomas are not the only tumors with a prognosis intermediate between well- and undifferentiated (anaplastic) thyroid malignancies. Follicular tumors with extensive angioinvasion, aggressive papillary carcinoma variants (tall cell, hobnail), and well-differentiated carcinomas that present with distant metastases also have an intermediate prognosis.[616] A simple grading scheme based on the identification of necrosis or high mitotic activity (≥5 mitoses per 10 high-power field) successfully captures thyroid carcinomas with such an intermediate prognosis, irrespective of architectural features or tumor subtype, with good overlap with the Turin consensus criteria for poorly differentiated carcinoma.[471] Other schemes based on the Ki-67/MIB1 labeling index may successfully be applied for the same purpose.[626] Poorly differentiated tumors, defined only on the basis of mitotic activity and necrosis,[471] represent over half of the fatal forms of non-anaplastic thyroid carcinoma.[328]

The molecular alterations are summarized in Table 8.2. Somatic genetic changes that characterize poorly differentiated carcinoma are *TERT* promoter mutations, *TP53* mutation, and dysregulation of the PI3K/PTEN/AKT pathway, although all these alterations are less common than in anaplastic carcinoma. In addition to these "late" molecular events, "early" changes such as *RAS*[630] and *BRAF* p.V600E[301] mutations are also common. The high prevalence of *RAS*-activating mutations (20%–50%) suggests that many poorly differentiated carcinoma develop from follicular carcinomas or from the follicular variant of papillary carcinoma.[482,485,618,630]

Compared to well-differentiated carcinomas, poorly differentiated tumors have a higher mutational load[344] and frequently carry multiple molecular alterations (typically one early change together with a late alteration).[344] In combined tumors with a well-differentiated component, areas with early molecular alterations are found both in the well-differentiated and in the dedifferentiated areas, while the late molecular alterations appear restricted to the dedifferentiated parts of the tumor,[625,631,632] *CTNNB1* mutations,[633] and *ALK* rearrangements,[319,321,344] as well as *EIF1AX* in combination with *RAS* mutations[344] have been reported in poorly differentiated carcinoma subsets (and in anaplastic carcinoma). In one study disruption of the SWI/SNF chromatin remodeling complex, mutation of histone methyltransferases (HMTs) and inactivation of the DNA mismatch repair system have been

reported in 6%, 7%, and 2% of poorly differentiated tumors, respectively, (and in a considerably higher proportion of anaplastic carcinomas).[344]

The tumors are aneuploid with frequent copy number variations,[344] and many of the follicular carcinomas with complex karyotypes reported in the past were poorly differentiated tumors.[478] The microRNA profile of poorly differentiated carcinoma is different from that of well-differentiated tumors and anaplastic carcinomas.[353]

Anaplastic (Undifferentiated) Carcinoma

Anaplastic (undifferentiated) carcinoma typically presents in elderly patients as a rapidly growing firm mass, fixed to the surrounding structures, associated with hoarseness, dysphagia, and dyspnea.[582,634] Extrathyroidal extension is encountered at the time of initial presentation in most of the cases.[583,634] Grossly, a highly necrotic and hemorrhagic solid tumor mass is seen replacing large portions of the organ (Fig. 8.80).

Microscopically, the term anaplastic or undifferentiated carcinoma is used in the thyroid gland in connection with two major categories that sometimes coexist. The first is undifferentiated in the sense that it does not make follicles, papillae, or even trabeculae or nests, but the tumor still retains an unmistakable *epithelial appearance* on morphologic and immunohistochemical grounds. This pattern, which is referred to as **squamoid**, may blend with clear-cut foci of keratinization.[583] A very unusual subset of this tumor type has a lymphoepithelioma-like appearance but does not seem to be related to the Epstein–Barr virus.[635,636]

The second category is actually composed of two patterns which are often seen together and which can be grouped under the qualifier of *sarcomatoid*: **spindle cell** and **giant cell** (the latter showing a degree of pleomorphism substantially greater than that seen in the spindle and squamoid types) (Figs. 8.81 and 8.82). They may exhibit a fascicular or storiform pattern of growth, heavy neutrophilic infiltration, prominent vascularization, and divergent differentiation into bone, cartilage, and skeletal muscle.[637,638] As a result, their appearance may closely simulate a large variety of soft tissue sarcomas, particularly so-called malignant fibrous histiocytoma (including its inflammatory and myxoid variants), angiosarcoma, malignant hemangiopericytoma, rhabdomyosarcoma, and fibrosarcoma.[583,639] Osteoclast-like multinucleated giant cells may be present, giving the tumor an appearance reminiscent of giant cell tumor of bone or soft tissues.[640] As in similar tumors in other organs, these osteoclast-like giant cells are not neoplastic but rather reactive cells of monocytic/histiocytic lineage derived from mononuclear cells through the mechanism of cell fusion.[641,642] In fact, a high density of tumor-associated macrophages, a common finding in advanced thyroid cancer in general, is found in virtually every anaplastic carcinoma.[629]

One variation on the theme of the spindle cell form of undifferentiated carcinoma is the *paucicellular variant*, which mimics Riedel thyroiditis because of the extreme degree of fibrosis and hyalinization, and which is recognized because of the scattered atypia, areas of necrosis, vascular invasion, vascular permeation, and positivity for epithelial markers.[643,644]

The rare *rhabdoid variant* may be considered a variation on the theme of the giant cell form of undifferentiated carcinoma.[645]

It should be kept in mind that the majority of sarcoma-like tumors of the thyroid are, histogenetically speaking, undifferentiated carcinomas. Common and diagnostically useful features are palisading at the necrotic edges and tendency for the tumor cells to invade the wall of veins, replacing the normal smooth muscle. Ultrastructural examination will reveal markers suggestive of epithelial differentiation in approximately half of the cases.[255,583,646]

Immunohistochemically, the most useful marker for confirming the epithelial nature of the tumor (although obviously not for determining its thyroid origin) is keratin, which will be found to

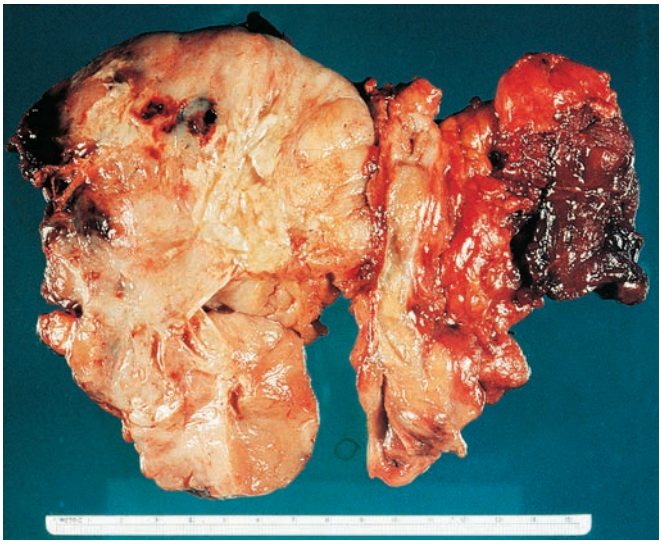

Figure 8.80 Undifferentiated carcinoma of the thyroid entirely replacing the gland and extending into the surrounding skeletal muscle.

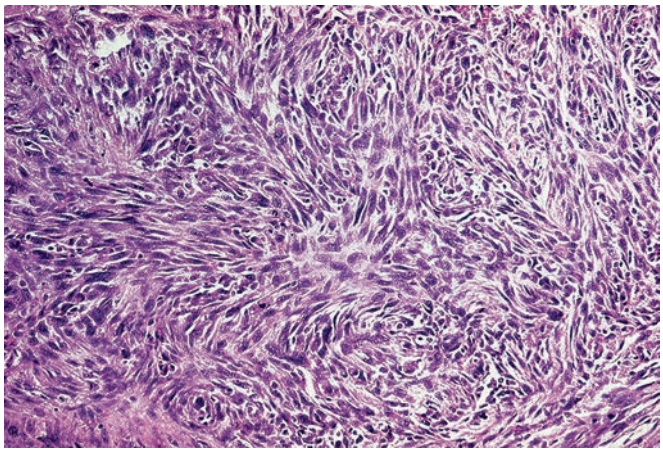

Figure 8.81 Undifferentiated carcinoma of the spindle cell type.

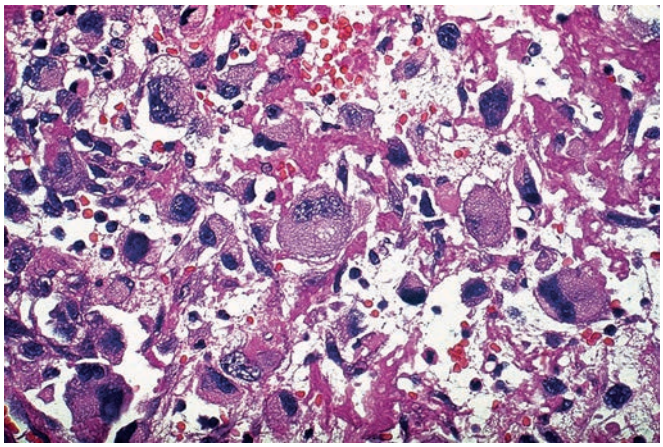

Figure 8.82 Undifferentiated carcinoma of giant cell type.

be expressed in 50%–100% of cases, according to the different series.[583,647,648] However, since cytokeratins are not always positive, negative immunoreactivity does not necessarily rule out a diagnosis of anaplastic carcinoma. Vimentin is consistently present (particularly in the neoplastic spindle cells), there is scattered stromal (basement membrane–related) reactivity for laminin,[26] and focal EMA and CEA positivity may be found, especially in the squamoid type.[583,647,648] Immunoreactivity of thyroglobulin in anaplastic carcinoma is nearly always absent, particularly in those cases that are totally undifferentiated.[583,647,648] False-positive results may be due to entrapment of normal thyroid, residual foci of better differentiated tumor (Fig. 8.83), or diffusion of thyroglobulin from destroyed normal follicles into the tumor cells. Among the thyroid differentiation factors, TTF1 and TTF-2 (FoxE1) are positive only in a minority of anaplastic carcinomas[18,648]; however, positivity for PAX8 is retained in 70%–80% of the cases.[18,585] PAX8 is expressed in carcinomas of the female genital tract and of the kidney (including sarcomatoid renal cell carcinoma), and its positivity in anaplastic carcinoma may be limited to a minority of the tumor cells. In spite of these caveats, it is can be very useful: it is frequently positive in anaplastic carcinomas lacking a well-differentiated component and in the squamoid variant, while it is invariably negative in squamous cancers of the head and neck and of the lung.[18,585] Anaplastic carcinoma (unlike poorly differentiated thyroid carcinomas) is diffusely positive for p53, correlating in part with the frequent occurrence of inactivating *TP53* mutation,[625,649] and has very high proliferative activity (Ki-67/MIB1 labeling index ~35%) (see Table 8.3). Immunohistochemistry is essential in the differential diagnosis of anaplastic carcinoma, which includes a long list of tumors, depending on the pattern of growth they may exhibit. In general, the diagnosis of anaplastic carcinoma should be favored in the presence of any pleomorphic malignant tumor that seems to arise in the thyroid gland, even if no clear-cut evidence of epithelial differentiation is found by any method. This is especially true if the patient is elderly and if there is evidence of a residual better-differentiated epithelial neoplasm in the gland.

Most (if not all) undifferentiated thyroid carcinomas arise as a result of anaplastic transformation ("dedifferentiation") of a preexisting, well-differentiated tumor, as confirmed by molecular studies.[631,632,650] This "dedifferentiation" is fortunately rare, probably less than 1% of cases. In most instances, the anaplastic transformation takes place in the primary tumor, but it may also occur in a recurrence or in a metastasis.[411,582,651] Thorough sampling may be necessary to detect the residual well-differentiated component. It is likely that the sharply outlined sclerohyaline nodules sometimes present within undifferentiated carcinoma represent the burnt-out residue of such components.[583,652] The better-differentiated tumor is usually a papillary carcinoma (Fig. 8.84) or one of its variants (such as the tall cell variant),[411] but it may also be a follicular carcinoma, a Hürthle cell (oncocytic) carcinoma, or a poorly differentiated carcinoma.[484]

There is no clear-cut relationship between the type of well-differentiated carcinoma and the pattern of anaplastic carcinoma that it may give rise to. Exceptions are the link between the tall cell variant of papillary carcinoma and a spindle cell squamoid type of anaplastic carcinoma[411] and between papillary carcinoma with squamous metaplasia and the squamoid type of anaplastic carcinoma.[653]

The evolution of all types of undifferentiated thyroid carcinoma is very rapid, with massive growth in the neck and infiltration of the ribbon muscles, esophagus, trachea, skin, and even contiguous bones. Tracheal extension may simulate a primary tracheal tumor.[411,654]

Preoperative FNA cytology typically shows highly cellular smears, dominated by large, often bizarre cells, with background necrosis and inflammation.[655] Nodal metastases are common and distant metastases are found in 40%–50% of cases at presentation.[634,656] The prognosis is notoriously poor, with only 10%–20% of the patients surviving 12 months after the initial diagnosis, the immediate cause of death usually being the involvement of vital structures in the neck.[582,583,634,656] Favorable prognostic factors on multivariate analysis are younger age and tumor limited to the thyroid, while unfavorable ones are acute symptoms at presentation (sudden appearance of dysphonia, dysphagia, dyspnea, and rapid growth of the tumor),

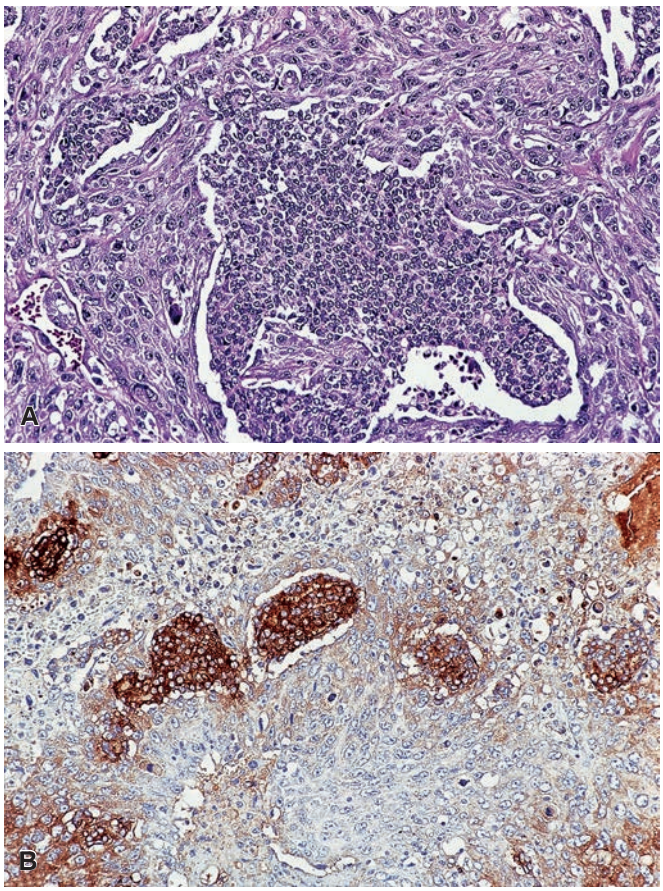

Figure 8.83 **A** and **B,** Combined poorly differentiated and undifferentiated thyroid carcinoma. Immunoreactivity for thyroglobulin is restricted to the poorly differentiated areas (**B**).

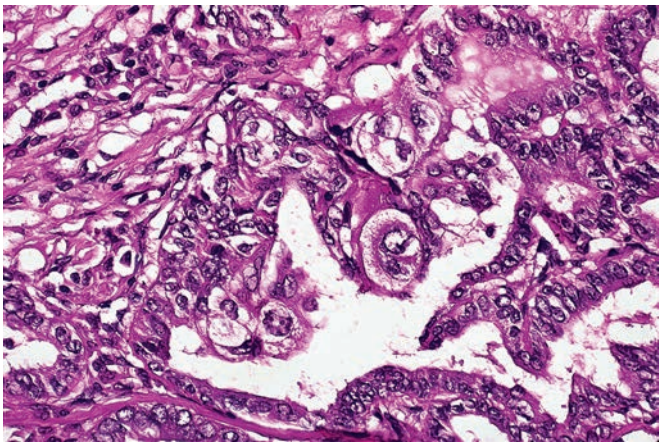

Figure 8.84 Undifferentiated thyroid carcinoma showing residual papillary carcinoma.

leukocytosis (due to the release of leucocyte colony-stimulating factors by the tumor),[581] large tumor size, and distant metastases.[581,656,657] Most anaplastic carcinomas are unresectable, but selected patients may benefit from radical surgery often associated with adjuvant chemotherapy and external beam radiation therapy.[658,659] Those intrathyroidal anaplastic carcinomas discovered incidentally as a focal change in an otherwise well-differentiated tumor are virtually the only cases that can really be cured.[660]

The main molecular genetic alterations of anaplastic carcinoma are shown in Table 8.2. Consistent with the endpoint for thyroid tumor progression, anaplastic carcinomas are characterized by the simultaneous dysregulation of multiple pathways, with a large variety of molecular alterations.[344,661] Even compared to poorly differentiated thyroid carcinoma, anaplastic carcinoma has a very high mutational load, with an average of 121 somatic mutations per sample.[661] They have long been known to be aneuploid,[662] and to show complex karyotypes by conventional cytogenetics.[293]

The alteration most consistently associated with anaplastic carcinoma is *TP53* inactivation.[344,485,632,661,663] The fact that *TP53* mutations are not usually present in residual differentiated components but segregate with the anaplastic one, indicates that they occur *after* the initial development of the tumor and that they have an important role in the progression to anaplastic cancer.[631,632]

TERT promoter mutation[344] and alterations of the PI3K/PTEN/AKT pathway are commonly identified. The PI3K/PTEN/AKT signaling is altered by loss of function *PTEN* mutations or by activating mutations of the *PIK3CA* gene.[210,344,488,661,664] A high prevalence of copy number gains of *PIK3Ca* and *PIK3Cb* (and of receptor tyrosine kinase genes like *EGFR*, *VEGFR1*, *PDGFR-alpha* and *-beta*, *KIT*) has been reported.[210,488] While *PTEN* and *PIK3CA* gene alterations rarely coexist in well-differentiated follicular carcinomas, they can overlap with each other and with either *BRAF* or *RAS* mutations in anaplastic carcinoma.[210,344,488,661,664]

In addition to mutations of *TP53*, *TERT* promoter, and of PI3K/PTEN/AKT pathway effector genes, gene mutations of SWI/SNF subunits and of HMTs appear to be an important feature of anaplastic carcinoma.[344]

Mutations found in conventional papillary and follicular carcinomas are also found in anaplastic carcinomas, a clue to their evolution from preexisting well-differentiated tumors. *RAS* mutations are common,[344,482,484,485,661] as are *BRAF* mutations, particularly in those cases with a papillary carcinoma component.[301,344,661] *RET/PTC* and *PAX8/PPARG* are not usually identified,[344] suggesting that these rearrangements, unlike *RAS* and *BRAF* mutations, do not promote dedifferentiation.

Inactivation of the DNA mismatch repair enzymes has been identified in approximately 10%–20% of cases.[344,661] *EIF1AX* mutations, typically in combination with mutated *RAS*, occur in approximately 5%–15% of anaplastic carcinomas.[344,661] Subsets of anaplastic carcinoma are characterized by *ALK* rearrangements [319,321] or *CTNNB1* mutations.[661,665]

The miRNAs expression profile of anaplastic carcinoma is different from that of other less aggressive thyroid tumor types. Downregulation of miR-30d, -125b, -26a, -30a-5p has been reported,[666] and dysregulated miRNAs expression may influence the epithelial to mesenchymal transition process in anaplastic carcinoma.[667]

Medullary Carcinoma and Related Neuroendocrine Lesions

Medullary Carcinoma

Morphologic Features. Medullary carcinoma is the original and preferred term for a distinctive type of malignant thyroid neoplasm composed of C (parafollicular) cells; prior synonyms include solid carcinoma with amyloid stroma, hyaline carcinoma, and C-cell carcinoma.[668] A benign counterpart of medullary carcinoma is not recognized, although the term medullary microcarcinoma has been used for small tumors (<1 cm) with a low risk of recurrence and metastasis.[669,670] Grossly, the typical tumor is solid, firm, and nonencapsulated but relatively well circumscribed and has a gray to yellowish cut surface (Fig. 8.85). A continuous fibrous capsule envelops an occasional tumor. Most tumors are located in the midportion or upper half of the gland, corresponding to a greater concentration of C cells in these regions.

Microscopically, the classic medullary carcinoma cytoarchitecture is represented by a solid proliferation of round to polygonal cells of granular amphophilic cytoplasm and medium-sized nucleus, separated by a highly vascular stroma, hyalinized collagen, and amyloid (Fig. 8.86).[671] The number of morphologic variations on

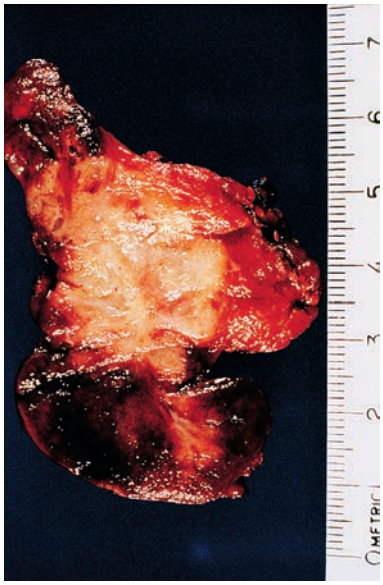

Figure 8.85 Gross appearance of medullary carcinoma. Note its unencapsulated quality, solid appearance, and yellowish tan color.

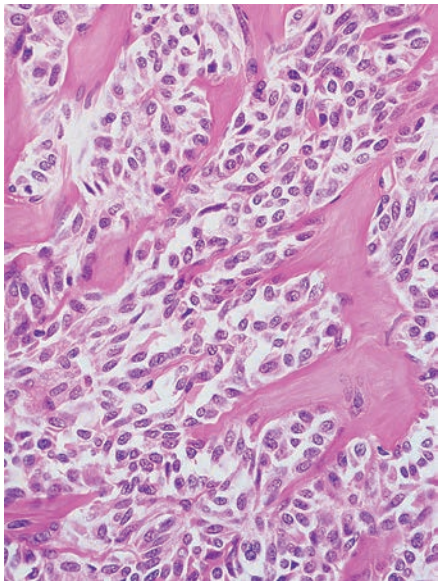

Figure 8.86 Medullary carcinoma. Low-power microscopic view showing solid pattern of growth and deposition of amyloid.

this theme is very large. The pattern of growth can be carcinoid-like, paraganglioma-like, trabecular, glandular (tubular and follicular), or pseudopapillary (Fig. 8.87).[672–675] Therefore, it is prudent to consider medullary carcinoma in the differential diagnosis of any thyroid neoplasm with an unusual morphology. The stroma may be scanty, hemorrhagic, ossified, or edematous. The amyloid deposition may be widespread, limited to small psammomatoid concretions, or altogether absent. Sometimes this amyloid elicits a florid foreign body–type giant cell reaction. True psammoma bodies may be present. A heavy neutrophilic infiltrate is occasionally seen (so-called inflammatory type). The tumor cells may be plasmacytoid (because of nuclear peripheralization), spindle shaped, oncocytic, squamoid, or squamous, or exhibit bizarre features (so-called anaplastic or giant cell type, not to be equated with bona fide undifferentiated carcinoma).[676,677] The oncocytic variety is particularly treacherous because of its uncanny resemblance to Hürthle cell (oncocytic) neoplasms of follicular cell derivation (Fig. 8.88).[678] The diagnosis of oncocytic medullary carcinoma should be suspected if the oncocytic cells are amphophilic rather than brightly eosinophilic and/or if the tumor is divided into nests by sharply outlined fibrous bands. Other unusual varieties of medullary carcinoma include a true papillary form,[679] a type exhibiting luminal differentiation and/or mucinous features (mucinous or amphicrine medullary carcinoma),[680,681] a clear cell variant,[570] a small cell type resembling the homonymous lung tumor, another small cell type with features resembling neuroblastoma,[682] and a pigmented (melanin-producing) variant.[683,684]

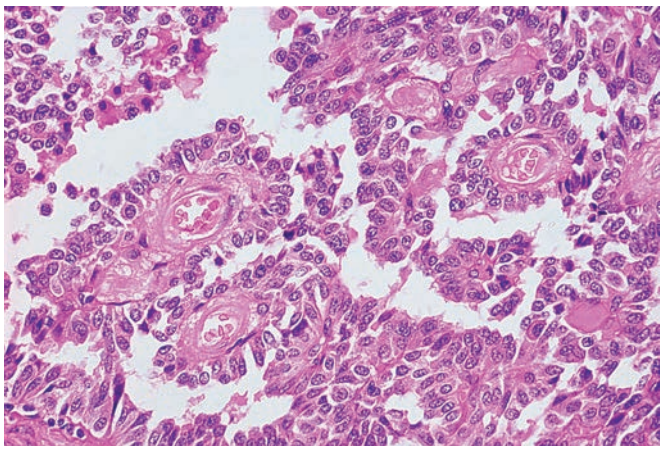

Figure 8.87 Medullary carcinoma with pseudopapillary pattern of growth resulting from lack of cohesiveness of tumor cells.

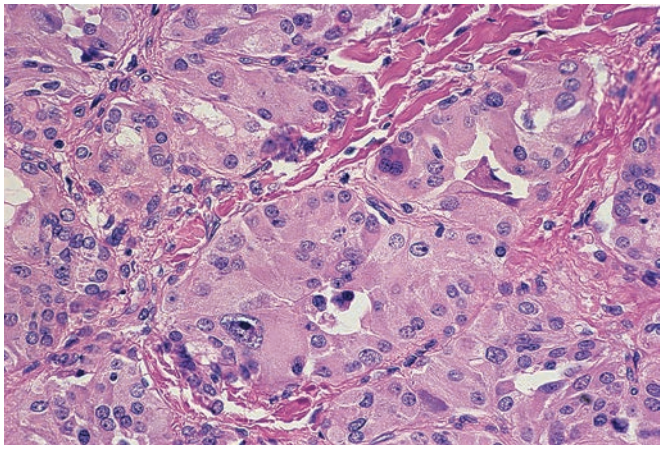

Figure 8.88 Medullary carcinoma of oncocytic type. The appearance closely simulates that of Hürthle cell carcinoma. Clues to the diagnosis are represented by the amphophilic (rather than eosinophilic) staining quality of the cytoplasm and the prominent fibrous septation. This tumor was strongly immunoreactive for calcitonin.

Cytologic Features. In FNA preparations, medullary carcinoma is characterized by eccentric nuclei, salt and pepper (neuroendocrine-type) chromatin, inconspicuous nucleoli, binucleated and multinucleated cells, ill-defined cell borders, and a clean background.[685,686] Amyloid material can be identified in some cases (Fig. 8.89).

Electron Microscopic, Histochemical, and Immunohistochemical Features. Ultrastructurally, cytoplasmic dense-core secretory granules are invariably present. A variability in their sizes has been detected, suggesting the existence of multiple endocrine cell types in this tumor.[687] These granules are usually argyrophilic with the Grimelius stain, especially if the tissue has been fixed in Bouin fluid.[688] Mucin stains are often positive.[689]

Immunohistochemically, the tumor cells are reactive for epithelial markers such as keratin; general thyroid markers such as TTF-1 (although PAX8 is variably expressed and may be negative in medullary carcinoma[690]); panendocrine markers such chromogranin A, B, and C (the latter also known as secretogranin II); synaptophysin; CD56; opioid peptides; and—most important—the specific product of C cells, i.e., calcitonin (Fig. 8.90).[691–694] However, occasional medullary carcinomas display either focal or complete loss of calcitonin expression, a diagnostic pitfall. They are also consistently positive for CEA and negative for thyroglobulin.[695–697] Similar to other neuroendocrine neoplasms, medullary carcinomas have also been reported to express a wide variety of markers, including numerous small peptide products: somatostatin, adrenocorticotropic hormone (ACTH), calcitonin gene–related peptide, serotonin, melanocyte-stimulating hormone (MSH), prostaglandins, bombesin, gastrin-releasing peptide, substance P, L-dopa decarboxylase, histaminase, glucagon, insulin, hCG, the polysialic acid of the neural cell adhesion molecule, galectin-3, hepatocyte growth factor and its receptor, matrix metalloproteinases, prohormone convertases, and progesterone receptors (but virtually no estrogen receptors).[698–715] Accordingly, medullary carcinoma can be associated with various paraneoplastic syndromes, such as Cushing syndrome, depending on the specific hormones produced.[716]

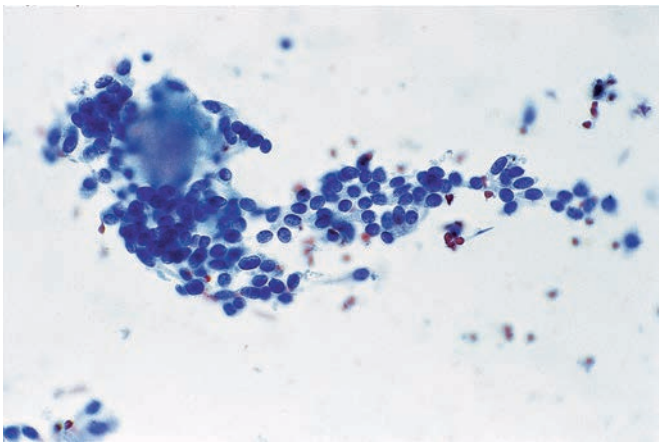

Figure 8.89 Cytologic appearance of medullary carcinoma. The nuclei have clumped chromatin. An amorphous material compatible with amyloid is present.

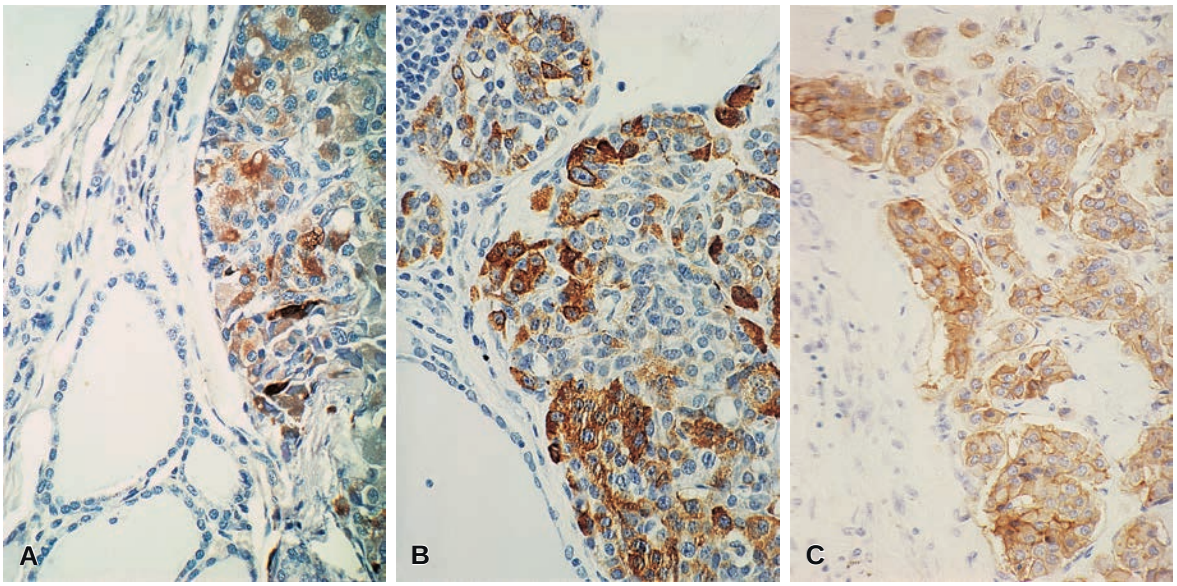

Figure 8.90 Medullary carcinoma showing immunocytochemical positivity for calcitonin (**A**), chromogranin (**B**), and CEA (**C**).

The amyloid of medullary carcinoma reacts with the generic stains for this substance and has a typical microfibrillary appearance ultrastructurally (Fig. 8.91). It also shows reactivity for calcitonin, suggesting that its production may be related to the secretion or degradation of this hormone.[717] Mass spectrometry of medullary carcinoma-related amyloid demonstrates the presence of calcitonin in all cases and secretogranin-1 and calcitonin gene–related peptide in a subset of cases.[718]

Genetics, Hereditary Medullary Carcinoma, and C-cell Hyperplasia. Medullary carcinoma occurs in sporadic and heritable forms. Sporadic medullary carcinoma comprises approximately 70% of the cases, affects adult individuals in their fifth and sixth decades of life (mean age, 45 years), and is almost always solitary.[719] It presents as a thyroid mass that is cold on thyroid scan: in some cases, it is accompanied by intractable diarrhea or Cushing syndrome.[720,721] Only rarely is it clinically occult.[722] Genetically, nonhereditary sporadic medullary carcinoma is characterized by mutations of *RET* in 40%–60% of cases,[723–725] with the *M981T* variant being most common.[723–725] In addition to *RET*, mutations of the *RAS* gene family also occur in a substantial number of cases.[726,727] *RET* and *RAS* family mutations tend to be mutually exclusive, suggesting that these mutations represent alternative drivers for the development of medullary carcinoma.[726] Rare gene fusions involving *RET*[728] and *ALK*[729] have been identified in medullary carcinoma.

Hereditary medullary carcinoma occurs in 30% of patients and follows an autosomal dominant pattern of inheritance with high penetrance, related to germline *RET* mutations. This form of medullary carcinoma becomes clinically apparent in a younger age group (mean age, 35 years), is often multiple and bilateral, and is invariably accompanied by multifocal C-cell hyperplasia in the residual gland. An increasing number of cases are diagnosed when measuring 1 cm or less, i.e., at the stage of medullary microcarcinomas.[730,731] Almost all cases of medullary carcinomas occurring in children belong to this type. Hereditary medullary carcinoma occurs in one of three settings: (1) multiple endocrine neoplasia type 2a (MEN 2A); (2) type 2b (MEN 2B); or (3) familial medullary thyroid carcinoma (FMTC) syndrome.[732–734] In MEN patients, medullary carcinoma is usually the first manifestation of the syndrome.

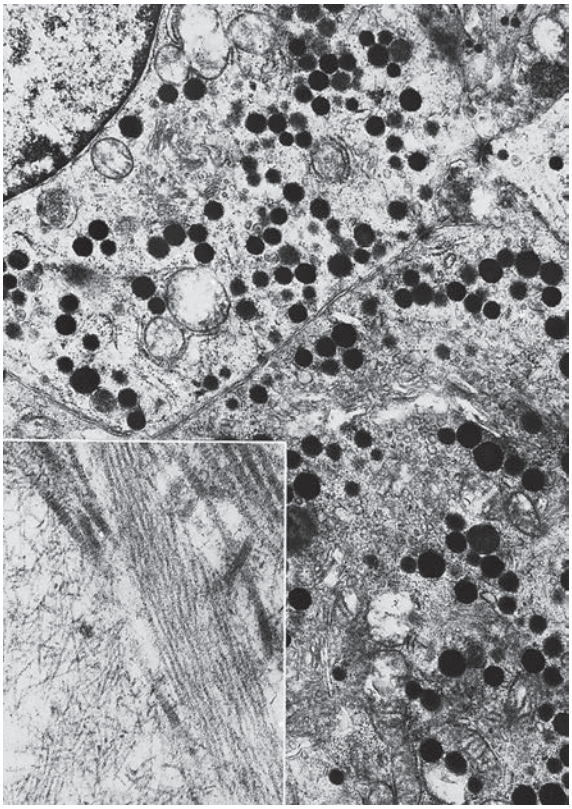

Figure 8.91 Ultrastructural appearance of medullary carcinoma. Portions of two tumor cells show multiple dense secretory granules in the cytoplasm. Each granule is surrounded by a single membrane, and the dense central portion is separated from it by a clear zone. Inset shows both oriented and randomly placed amyloid filaments and may be contrasted with larger banded collagen fibers. (Courtesy of Dr. J.S. Meyer, St Louis.)

The understanding of the genetics of medullary carcinoma has advanced substantially.[735] The gene involved in the development of all forms of inherited medullary carcinoma is *RET*, located on chromosome 10q11.2, which is affected in the form of various activating germline mutations (Table 8.5).[733,736–738] In MEN 2A and FMTC, mutations affect the extracellular cysteine-rich domain of *RET* and are nearly always located on either exons 10 or 11, involving codons 609, 611, 618, 620, 630, 631, or 634 and nearly always involve cysteine residues that are replaced by other amino acids.[733,735] These cysteine residues are normally engaged in intramolecular disulfide bonds in wild-type *RET*. The mutation allows the unpaired cysteine residue in a *RET* monomer to form an aberrant intermolecular disulfide bond with another mutated monomer, causing ligand-independent dimerization and constitutive activation of *RET*.[733,735] In MEN 2A the majority (80% or more) of the mutations are at codon 634, usually in the form of a C634R substitution, not found in FMTC; rare patients with MEN 2A may have mutations in the intracellular tyrosine kinase domain.[733,735] In FMTC the mutations are fairly evenly distributed throughout the various codons of the extracellular domain and in a minority of cases can also be located in the intracellular tyrosine kinase domain (exons 13 and 14).[733,735] In MEN 2B, the *RET* mutations occur in the intracellular tyrosine kinase domain, virtually all of them (>90%) at codon 918 (exon 16) in the form of an *M918T* substitution, the remaining mutations being located at codon 883 (exon 15).[733,735] Mutations in the intracellular tyrosine kinase domain induce structural changes of the catalytic core, causing constitutive activation of the monomeric form of *RET*.[733,735] Given the location of the known clinically relevant mutations, exons 10, 11, 13, 14, 15, and 16 have to be screened in patients with suspected hereditary medullary carcinoma using DNA obtained from peripheral blood samples.[733,739,740]

An important consequence of a heritable medullary carcinoma diagnosis is the need to perform a prophylactic total thyroidectomy in asymptomatic kindreds of patients with hereditary medullary carcinoma that carry germline *RET* mutations, including children.[733] The development of medullary carcinoma is clearly age related, a fact that guides the decision concerning the timing of prophylactic thyroidectomy. Since specific *RET* mutations are related not only to the type of syndrome, but also to the aggressiveness of the medullary carcinoma, *RET* mutations have been stratified into risk levels to guide patient management: level HST, the highest risk category, exemplified by the codon 918 mutation of MEN 2B; level H, the high risk category, exemplified by the codon 634 mutation of MEN 2A; level MOD, the moderate risk category that includes the large majority of mutations.[733,741]

C-cell hyperplasia is the precursor lesion of all these familial syndromes.[742] Its typical location is in the central part of the lateral lobes. It may be diffuse or nodular, and the C cells may be seen in an interfollicular or intrafollicular location. The arbitrary figures of more than six cells per thyroid follicle and/or of greater than 50 intrafollicular calcitonin positive cells in at least one low power field (X100) have been suggested as an indicator of C-cell hyperplasia.[732,743] Because of the extreme difficulty in establishing a clear definition of minimal C-cell hyperplasia based on cell count, it is probably wise to regard the *nodular* form as the only definite precursor for the hereditary type of medullary carcinoma.

As a rule, the hyperplastic C cells exhibit greater CEA immunoreactivity than normal C cells and greater calcitonin immunoreactivity than the cells of medullary carcinoma. The differential diagnosis of this preneoplastic disorder includes on one hand early medullary carcinoma (microcarcinoma) and on the other the reactive or physiologic C-cell hyperplasias that can be seen in a variety of conditions. Medullary carcinoma is recognized because of the nesting expansile pattern with the acquisition of a fibrous stroma, the destruction of the follicular basement membrane, and the diminished intensity of calcitonin immunostaining.[743] Reactive or physiologic C-cell hyperplasias have been described in the immediate periphery of thyroid neoplasms of various microscopic types[744] and in association with lymphocytic thyroiditis[745,746] and secondary hyperparathyroidism.[747] All of these conditions should be distinguished from the normal clusters of C cells seen in relation to solid cell nests.[748]

Patients with thyroid C hyperplasia have elevated serum levels of calcitonin and CEA[741,742]; in addition, patients with medullary carcinoma also have elevated levels of chromogranin A.[749]

Spread and Metastases. Medullary carcinoma invades locally and gives rise to metastases in cervical and mediastinal lymph nodes and also in distant organs, particularly lung, liver, and skeletal system.[750] They are more common in sporadic and MEN 2B-associated tumors than in MEN 2A-associated neoplasms and have been associated with the *M918T* mutation.[733,739,740,751] These metastases may be the first manifestation of the disease and a source of confusion to the pathologist.[752] Microscopically, they tend to resemble the primary tumor and—as a result—usually contain amyloid. The resemblance also applies to their immunohistochemical reactivity, although notable discrepancies occur.[753]

Table 8.5 *RET* point mutations in medullary thyroid carcinoma[a]

RET DOMAIN	*RET* EXON	CODON	MOLECULAR MECHANISM	DISEASE	MEDULLARY CARCINOMA RISK LEVEL[b]
Extracellular cysteine rich	10	609, 611, 618, 620	*RET* dimerization	MEN 2A, FMTC	MOD
Extracellular cysteine rich	11	634	*RET* dimerization	MEN 2A	H
Intracellular tyrosine kinase 1	13	768	Altered substrate specificity	FMTC	MOD
Intracellular tyrosine kinase 1	14	804	Altered substrate specificity	FMTC	MOD
Intracellular tyrosine kinase 2	15	883	Altered substrate specificity	MEN 2B	H
Intracellular tyrosine kinase 2	16	918	Altered substrate specificity	MEN 2B, sporadic medullary carcinoma	HST

[a]The most frequently mutated *RET* codons are reported.
[b]Risk of aggressive medullary carcinoma: MOD, moderate risk; H, high risk; HST, highest risk.
Modified from de Groot JW, Links TP, Plukker JT, Lips CJ, Hofstra RM. RET as a diagnostic and therapeutic target in sporadic and hereditary endocrine tumors. *Endocr Rev*. 2006;27:535–560.

Treatment and Prognosis. The primary treatment of medullary carcinoma is surgical, in the form of total thyroidectomy (particularly important for the familial form because of the multicentricity and C-cell hyperplasia) and cervical lymphadenectomy.[741] Local recurrence supervenes in approximately 35% of patients, and the 5-year survival rate varies between 70% and 80%.[671,754,755] The tumor is not particularly responsive to radioactive iodine, external radiation therapy, or chemotherapy. Several tyrosine kinase inhibitors have recently been approved[756–758] with some success.

Stage of disease and age at diagnosis are the strongest predictors of survival of all medullary carcinoma patients.[719,741,759,760] Indeed, small medullary carcinomas found in prophylactic thyroidectomies are associated with an excellent prognosis.[761] Good prognostic factors are young age, female sex, occurrence in a familial setting, tumor size, and tumor confinement to the gland.[671,741,755,762,763] Microscopically, a greater degree of aggressiveness should be expected of tumors with high mitotic activity, necrosis, squamous pattern, associated with desmoplastic reaction,[764] and/or of the small cell type.[765] It has been claimed that poor immunohistochemical reactivity for calcitonin can serve as a marker of the degree of tumor differentiation and is an indicator of poor prognosis, particularly if coupled with increased reactivity for CEA.[741,765–768]

Other Neuroendocrine Tumors

Medullary (C-cell) adenoma has been suggested as a diagnosis for the rare totally encapsulated forms of C-cell tumors, but they should be regarded as encapsulated variants of medullary carcinomas.[769] The differential diagnosis includes hyalinizing trabecular carcinoma.[770]

Mixed medullary–follicular carcinoma is an extremely rare tumor in which the morphologic features of medullary carcinoma (together with immunoreactivity for calcitonin) coexist with those of a follicular neoplasm (together with immunoreactivity for thyroglobulin).[771,772] Some of the reported cases have been familial.[773] Initial skepticism notwithstanding, sufficient evidence has been advanced to validate the existence of this entity,[774–776] with the added perplexing observation that the two components do not seem to be derived from a single progenitor cell.[777] In any event, it should be kept in mind that most cases in which the diagnosis of mixed medullary–follicular carcinoma has been entertained represent either medullary carcinomas with entrapped follicles and/or secondary incorporation of thyroglobulin by the medullary carcinoma cells or medullary carcinomas with a glandular (tubular and follicular) pattern of growth.

Mixed medullary–papillary carcinoma represents the even more unusual combination of calcitonin-positive medullary carcinoma and thyroglobulin-positive papillary carcinoma, the latter areas having typical ground-glass nuclei.[778–780] This should be distinguished from the more common event of separate medullary and papillary carcinomas in the same gland, which may collide with each other,[781] and the even more bizarre phenomenon of a mixed medullary–follicular carcinoma colliding with a papillary carcinoma.[782]

Paraganglioma can occur adjacent to or within the thyroid, sometimes in association with carotid body tumors.[783–786] The differential diagnosis with medullary carcinoma and follicular adenoma can be very difficult, particularly with the former (Fig. 8.92). Paraganglioma reacts immunohistochemically for panendocrine markers such as chromogranin and opioid peptides but is negative for calcitonin, thyroglobulin, TTF-1, PAX8, and keratin. A particularly useful (although neither constant nor pathognomonic) feature is the presence of S-100 protein–positive sustentacular cells at the periphery of the "Zellballen" (Fig. 8.93).[787] Practically all of the reported cases have been cured by surgical excision.[788,789]

Small cell (neuroendocrine) carcinoma morphologically identical to the homonymous lung tumor has been described in the thyroid. Some of these tumors are calcitonin positive and are therefore regarded as small cell variants of medullary carcinoma. Those that are calcitonin negative probably represent the most undifferentiated members of the spectrum[790]; their behavior is extremely aggressive.[791]

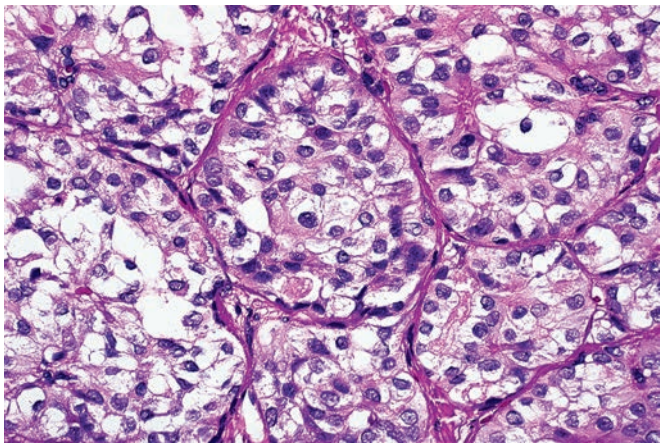

Figure 8.92 Thyroid paraganglioma showing well-formed "Zellballen."

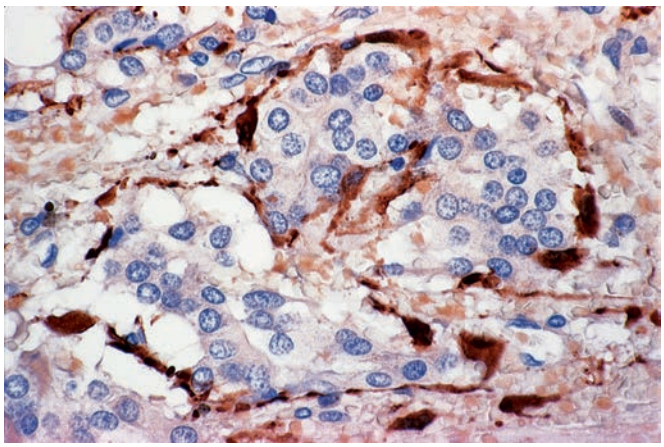

Figure 8.93 S-100 protein–positive sustentacular cells at the periphery of the "Zellballen" in paraganglioma of thyroid.

Neuroendocrine tumors of various types (such as carcinoid tumors of larynx and lung) can invade or metastasize to the thyroid gland and simulate a medullary carcinoma.[792,793] Immunohistochemistry will be of great diagnostic help in the differential diagnosis, with the caveat of TTF-1 immunoreactivity in pulmonary neuroendocrine tumors (and in some cases of extra-pulmonary neuroendocrine carcinomas).[792,793]

Epithelial Tumors—General Features

Geographic Distribution

Most series have shown a statistical correlation between iodine deficiency and an increased incidence of thyroid carcinoma of both follicular and undifferentiated types.[794–800] Because of difficulties in clinical detection related to the background disease, the tumors tend to be more advanced at the time of diagnosis than in nonendemic areas.[801,802] Introduction of iodized salt in iodine-deficient areas can reduce the incidence of some types of thyroid cancer, especially follicular and anaplastic.[803,804]

Papillary carcinoma is the predominant type in areas without iodine deficiency,[802,804] and its frequency is said to be increased in regions with high iodine uptake.[804,805] Developed countries in the

Western and the Eastern Hemispheres appear to have a similar incidence of the major histologic types of thyroid carcinoma.[806]

Thyroid Neoplasia in Childhood

Most thyroid tumors developing in childhood are benign and are examples of either follicular adenoma or nodular hyperplasia. However, the proportion of carcinomas is much higher than that seen in adults, to the point of surpassing the benign processes in some series. Among the malignancies, papillary carcinoma comprises the overwhelming majority of the cases, followed by the hereditary form of medullary carcinoma and Hürthle cell neoplasms.[454,807] In older series there is also an important representation of follicular carcinomas, but most of those would probably be regarded at present as follicular variants of papillary carcinomas.[808,809] *RET/PTC*, NTRK1, and NTRK3 rearrangements are common in papillary carcinoma arising in children and young adults, while activating *BRAF* mutations are relatively uncommon.[306,317,810] Poorly differentiated carcinomas are very rare in this age group, and undifferentiated carcinomas are practically nonexistent.

The papillary carcinomas occurring in children tend to have extensive solid and/or squamous areas and are associated with a high frequency of cervical node metastases.[317,454,811,812] The overall prognosis is excellent, but occasional aggressive and even lethal cases are on record.[317,454,813] Some of these children have a history of previous radiation exposure to the neck (see next section).[814]

Thyroid Neoplasia and Radiation Exposure

Exposure of the thyroid gland to low-dose therapeutic radiation (administered for thymic enlargement, tonsillar hypertrophy, or acne to approximately one million patients in the United States during the early part of the twentieth century) can result in a number of abnormalities later in life.[815] The most common of them are of a benign nature—a fact to remember—and consist of nodular hyperplasia, lymphocytic thyroiditis, and fibrosis.[155,816,817] However, there is also an unquestionable increase in the incidence of carcinoma in this population, the large majority of the tumors being of the papillary type.[818,819] Of patients in this population who have thyroid operations, the incidence of carcinoma ranges from 20% to over 50%.[820,821]

Parenthetically, tumors from other structures of the neck can also develop in individuals with radiation exposure to the area; these include salivary gland, parathyroid, osseous, and neural neoplasms.[822,823] This obviously indicates the need for a continuous surveillance of this population.

High-dose radiation to the neck region, such as that administered for Hodgkin lymphoma, can also result in thyroid carcinoma and other abnormalities of the gland.[459,824,825] There is also conclusive evidence that thyroid carcinoma, dominated by the papillary type,[826] occurs with a much increased incidence in populations accidentally exposed to high radiation doses, such as that resulting from the nuclear accident of Chernobyl in 1986.[309,827–829] The Chernobyl accident exposed residents to high doses of internal radiation due to radioactive iodine, and the health effects related to this exposure have been extensively studied.[309,830,831] Regarding the thyroid gland, it is very clear that there is substantial increased risk of developing thyroid cancer in the Chernobyl population, with children under 15 being especially susceptible.[832–834] A very interesting pattern has emerged from the analysis of these cases.[826,835] Short latent period tumors have a significantly higher proportion of *architecturally less differentiated components* (solid and trabecular) and are more aggressive than long latent period tumors,[309] suggesting that successive waves of carcinoma have occurred in the exposed population. On the other hand, the *type* of differentiation is linked to age at exposure rather than to the latent period, in the sense that a follicular pattern is more common in children exposed at a young age, and a papillary pattern is more frequent in children exposed at a later age.[836] Fortunately, the outcome of children and adolescents in Belarus with post-Chernobyl papillary carcinoma has been favorable.[837]

The Chernobyl nuclear accident has provided insights into the pathogenesis of radiation-induced thyroid cancer. Consistent with a molecular model in which ionizing radiation induces double-stranded DNA breaks, which then leads to chromosomal rearrangements and translocations,[838] these thyroid cancers are highly enriched for oncogenic gene fusions, especially *RET/PTC* and *ETV6/NTRK3* rearrangements.[203,315] *RET/PTC* has been identified in up to 60%–80% of papillary carcinoma from patients exposed to radiation.[203,309,839] The frequency with which *RET* fusion partners (e.g., *CCDC6*) juxtapose in interphase thyrocyte nuclei is likely to predispose the DNA to the rearrangement.[840] In fact, rearrangements other than *RET/PTC1*, *RET/PTC2*, or *RET/PTC3* are enriched in radiation-induced tumors, although the TCGA study identified a variety of gene fusions in papillary carcinoma without a radiation history.[292] In papillary carcinomas that developed after radiation exposure following the Chernobyl accident, *RET/PTC3* has been associated with tumors that arose with shorter latency, in the most heavily contaminated regions and that were more aggressive (larger tumor size, higher stage, solid architecture).[309] Point mutations of *BRAF* and *RAS* are relatively uncommon among radiation associated tumors.[203,315]

The Fukushima nuclear accident in Japan in 2011 has sadly provided another opportunity to learn about radiation-induced thyroid cancer.[320,841,842] Similar to Chernobyl tumors, novel gene fusions involving *RET* and *NTRK3* have been identified.[329] More time and study will be needed to fully evaluate the health impact of this accident on the exposed residents of this region, although there is hope that lower doses of radioactive iodine, compared to Chernobyl, will prevent an excess risk for the development of thyroid cancer.[843,844]

Familial Incidence and Association With Other Conditions

Approximately 3%–9% of thyroid carcinomas of *nonmedullary* type (particularly of the papillary variety) develop in a familial setting.[845–848] Familial nonmedullary thyroid cancer (FNMTC) has been divided into two groups. **Syndromic FNMTC**, in which there is a predominance of nonthyroid tumors and well-defined germline driver mutations, includes familial adenomatous polyposis (including Gardner syndrome), Cowden/PTEN hamartoma tumor syndrome, Carney complex type I, McCune–Albright syndrome, Werner syndrome (adult progeria), MEN type 1, and DICER1 syndrome.[849–855] As already indicated, the thyroid tumors developing in patients with colonic polyposis/Gardner syndrome have a distinctive cribriform-morular appearance.[425,856] **Non-syndromic FNMTC**, in which there is a predominance of thyroid tumors, includes pure familial papillary carcinoma (fPTC) with or without oncocytic features, fPTC with papillary renal cell carcinoma, and fPTC with nodular hyperplasia.[487,848,857] The genetics of non-syndromic FNMTC is less clear. Studies of families with FNMTC have identified numerous associated chromosomal loci, as well as 4 distinct susceptibility genes (*SRGAP1*, *TITF-1/NKX2.1*, *FOXE1*, and *HABP2*).[487,848] None of these genetic susceptibility markers have been implemented in routine clinical practice. Papillary carcinoma has also been reported in patients with ataxia–telangiectasia[858] and acromegaly[859] and in association with parathyroid tumors[860] and paragangliomas of the carotid body.

Evaluation of the Solitary Thyroid Nodule

The most common thyroid problem facing the surgeon and the pathologist is the evaluation of the patient with an apparently single

thyroid mass.[197,861–863] The magnitude of the problem is obvious from the fact that approximately 4% of the population of the United States between the ages of 30 and 60 years have one or more palpable nodules. Using ultrasound examination, this number approaches 50% of adults. These are four times more common in females than in males. Because the majority of these nodules are benign and most are hyperplastic, the goal is to be selective in the cases taken to surgery while at the same time including most of the carcinomas in this group. Factors to consider when making this difficult selection process are the following[863]:

1. Age. The incidence of malignancy is higher in children and the elderly than in young or middle-aged adults.[864,865]
2. Sex. The incidence of malignancy is higher in males.[864]
3. History of familial thyroid cancer (see earlier).
4. Hashimoto thyroiditis. The likelihood of malignancy for a nodule present in Hashimoto thyroiditis is roughly the same as for that occurring in a normal gland.
5. History of radiation. The likelihood of malignancy is higher if there is a history of irradiation to the neck in infancy[865] or total body radiation flowing bone marrow transplantation.[866]
6. Presence of hoarseness and/or vocal cord paralysis.
7. Number. Solitary nodules are more likely to be malignant than multiple ones. It should be kept in mind, however, that approximately one-third of the nodules thought to be solitary on palpation are shown to be multiple on scan and an even higher number on pathologic examination.
8. Rate of nodule growth. Rapid nodule growth is concerning for carcinoma. Most adenomas are very slow growing, but this is also true for most papillary or minimally invasive follicular carcinomas. Rapid enlargement of a longstanding nodule may signify an undifferentiated (anaplastic) transformation or simply the development of hemorrhage within the nodule. Assessment of growth in follow-up of benign nodules has limited ability to predict malignant transformation.[862,867]
9. Cervical lymphadenopathy. This is the strongest clinical indicator of malignancy if present.
10. Thyroid function, including measurement of serum TSH. Nodules that are hyperfunctioning ("toxic") at the clinical level and/or hot on thyroid scintiscan are much less likely to be malignant than the others.
11. Ultrasonography. Cystic and spongiform nodules are less likely to be malignant than solid ones.[868,869]
12. Needle biopsy. In experienced hands, this technique provides the best means of determining the likelihood of malignancy of a thyroid nodule short of surgical excision and pathologic examination (see later section).[870–872]
13. Molecular testing (see later section).

To put these various criteria in perspective, it should be mentioned that even when the nodule is solitary, solid, and cold on scintiscan, it will prove malignant in no more than 10%–20% of the cases and that as many as one-third of the thyroid nodules disappear spontaneously if left untreated.[862,873]

Core Needle Biopsy and Fine-Needle Aspiration (FNA)

Core needle biopsy has been used extensively in a few institutions in the United States and abroad but has failed to gain widespread acceptance.[874] It is particularly helpful in diffuse diseases such as Hashimoto thyroiditis and in confirming the diagnosis of an advanced malignant neoplasm.[875] Most authors have been reluctant to use this technique in the evaluation of the single thyroid nodule not only because of the small but definite risk of complications (bleeding, nerve injury, tracheal perforation, tumor implantation),[876] but also because of the fact that the differential diagnosis between a benign and malignant follicular neoplasm is usually impossible due to the inability of to assess the presence of capsular and lymphovascular invasion on biopsy.[863]

FNA has become instead the gold standard technique for the evaluation of solitary thyroid nodules. Its appeal is obvious: it is quick and inexpensive, it can be carried out in the physician's office, and the risk of complications (including tumor implantation) is minimal.[863,877–880] Furthermore, FNA-derived material is suitable for immunohistochemical and molecular evaluation.[881–883] Published results claim a sensitivity and specificity of over 90%, leading some authors to recommend FNA as the initial test in the evaluation of any thyroid nodule.[863,884–887] Most papillary carcinomas and other types of malignancy other than follicular carcinoma can be identified with ease.[888–891] The same is true for the various types of thyroiditis.[892] The main difficulty, as in the case of core needle biopsy, resides in the identification of follicular carcinoma.[863,893,894]

To standardize the approach and terminology of thyroid FNA procedure, the National Cancer Institute hosted in 2007 the NCI Thyroid FNA State of the Science Conference, which led to the Bethesda Thyroid Atlas Project and constituted the framework for the Bethesda System for Reporting Thyroid Cytopathology.[895] This document recommends that each FNA report begin with one of six diagnostic categories. The categories imply an estimated risk of malignancy and a recommended clinical management. Over the past decade the diagnostic value of the Bethesda system has been clearly demonstrated.[896,897]

The performance of FNA may result in partial or complete infarction of the tumor, with only a thin rim of tissue preserved at the periphery[898]; this complication is particularly common with Hürthle cell tumors and may result in transient elevation of the serum levels of thyroglobulin.[899] Hemorrhage and thrombosis can also develop, with the secondary organization and recanalization sometimes leading to pseudoangiosarcomatous papillary endothelial hyperplastic changes.[898,900] Another complication of the procedure when carried out in cystic lesions has been the development of transient thyrotoxicosis.[901]

Molecular Testing of Fine-Needle Aspiration Specimens

The last decade has witnessed the development of various molecular tests for the diagnostic evaluation of thyroid nodules using cells derived from FNA. The primary goal of such testing is to identify benign nodules that do not require surgical resection, or alternatively, to identify those nodules that are indeed cancerous and do require surgery. According to current American Thyroid Association (ATA) Guidelines, molecular testing of thyroid nodules should be performed in a Clinical Laboratory Improvement Amendments (CLIA)/College of American Pathologists (CLIA/CAP)-certified laboratory and may be considered for nodules with indeterminate FNA results.[863] The implementation of molecular testing currently varies substantially between treatment centers.

A gene expression classifier (GEC) based on the expression of 167 genes has been demonstrated to preoperatively identify benign thyroid nodules[902] and has reduced surgery for benign disease,[903,904] although the clinical utility and performance of the GEC varies across different centers.[867,905,906]

An alternative approach to molecular testing of thyroid nodules is to directly identify the driving mutations present in a given nodule. Recent advances in molecular diagnostics and next-generation DNA sequencing have made this approach feasible and robust. The ThyroSeq assay developed at the University of Pittsburgh represents the prototypical assay of this type,[562,907,908] although several commercial forms are also available. This approach has also been applied to sporadic pediatric nodules, with increased sensitivity compared to

routine molecular diagnostic testing.[909] Evaluations of ThryoSeq performance to date are encouraging,[910] although one of the issues that impacts the performance of all of these molecular tests is the diagnostic threshold of the surgical pathologist, specifically in regard to the diagnosis of the follicular variant of papillary carcinoma. As these tumors are enriched for *RAS* family mutations, the performance of molecular testing is negatively impacted by pathologists who favor benign diagnoses when faced with a follicular-patterned tumor with equivocal diagnostic features.

Frozen Section

The pathologist is often asked to perform a frozen section at the time of exploration of a thyroid mass,[911,912] although with decreasing frequency due to a combination of factors. The specimen may be from an area of extrathyroidal invasion by carcinoma or from a metastatic cervical node. In these instances, the diagnosis is usually obvious, although Riedel thyroiditis, extrathyroidal growth in diffuse hyperplasia, and sequestered thyroid nodule (see next section) represent important diagnostic pitfalls.[913] The most common specimen received for frozen section is a lobectomy carried out because of a nodule. A few of these will be found to be examples of granulomatous thyroiditis, Hashimoto thyroiditis, or malignant lymphoma, each of which may manifest as an apparently single nodule on physical examination. However, in the majority of cases the differential diagnosis will be between a dominant nodule of nodular hyperplasia, adenoma, and carcinoma.[914] An experienced pathologist should have no problem in identifying most cases of undifferentiated carcinomas, poorly differentiated carcinomas, widely invasive follicular carcinomas, conventional papillary carcinomas, or medullary carcinomas. The most difficult problem resides in the distinction between a dominant nodule of nodular hyperplasia, follicular adenoma, minimally invasive follicular carcinoma, and the variant of papillary carcinoma that is both follicular and encapsulated. These considerations also apply to the encapsulated Hürthle cell neoplasms. Capsular and/or blood vessel invasion is typically not evident in the samples chosen for frozen sections but become apparent later in the more thorough sampling of permanent sections.[915–917] The ground-glass nuclear feature that is one of the most distinctive features of papillary carcinoma may not show up at all in the frozen section. For these reasons, the surgeon should accept the fact that a large percentage of well-differentiated carcinomas will not be identifiable on frozen section examination regardless of the experience and diagnostic acumen of the pathologist. Accordingly, many frozen sections are "deferred to permanent sections." This apparent deficiency does not create serious therapeutic problems because, in our opinion, most if not all of the lesions listed in this paragraph are effectively treated by lobectomy or—at the most—subtotal thyroidectomy.

With the increase in popularity in the performance of FNAs, the number of cases in which the surgical planning depends on frozen section results has diminished considerably.[246,918–921] LiVolsi and Baloch have pointed out that frozen sections are most useful in lesions interpreted by FNA as "suspicious for papillary carcinoma" rather than for those diagnosed as "diagnostic of papillary carcinoma," "follicular neoplasm," or Hürthle cell neoplasm."[922] Some centers have instituted expedited routine pathology in lieu of frozen section.[923] Other centers use frozen section to assess extrathyroidal extension.[924] Parenthetically, the performance of a cytologic preparation at the time of the frozen section has proven to be a very useful diagnostic adjunct.[925]

Presence of Thyroid Tissue Outside Gland

There are several circumstances in which normal or abnormal thyroid tissue may be found in the neck outside the confines of the thyroid gland:

1. Ectopic thyroid tissue resulting from faulty embryogenesis. Thyroglossal duct cyst and lingual thyroid are the most common examples.
2. Hyperplastic thyroid tissue outside the gland in Graves disease.
3. Mechanical implantation of thyroid tissue in the neck as a result of surgical intervention or accidental trauma. In the former instance, suture material may be seen adjacent to the thyroid tissue.
4. So-called sequestered thyroid nodule. This phenomenon, also known as parasitic or accessory nodule, refers to the occurrence of a peripherally located thyroid nodule in which either the anatomic connection with the main gland is lost or this connection is missed by the surgeon,[926] the process being probably analogous to that of parasitic uterine leiomyoma.[927,928] The nodule is usually an expression of nodular hyperplasia or nodular Hashimoto thyroiditis, less commonly of diffuse hyperplasia (Graves disease).[929] The diagnosis requires that the tissue reside in the same fascial plane as the thyroid gland, that it be unassociated with lymph nodes, and that it exhibit the same or similar histologic appearance as the main gland, whenever the latter is available. Sequestration also occurs (and may actually be more common) in thyroid nodular hyperplasia located in the mediastinum. The fact that the sequestered nodule is subject to the same morphologic alterations as the main gland may lead to significant interpretive problems in Hashimoto thyroiditis, in which the combination of nuclear atypia (as part of the oncocytic alteration) and heavy lymphoid infiltration (as part of the thyroiditis) may result in an appearance closely simulating a lymph nodal structure containing metastatic tumor (Fig. 8.94).
5. Thyroid tissue within cervical lymph nodes. The determination of the significance of this finding in the presence of an apparently normal thyroid gland can be a very difficult exercise. This phenomenon accounts for most cases of the condition formerly called lateral aberrant thyroid.[930] It is now generally accepted that this may be the result of two unrelated processes and that microscopic examination permits their separation in the majority of the instances.[931]

   The majority of cases represent metastases of clinically undetected thyroid carcinomas, nearly always of the papillary variety. It should be emphasized that detection of the primary neoplasm may require extremely careful microscopic study with embedding of the entire thyroid gland and cutting of the blocks at various levels.[932] The metastatic deposits may replace most of the node, although a peripheral rim of residual lymphoid tissue can usually be found. Secondary cystic changes can be so prominent as to simulate the appearance of a branchial cleft cyst (see Fig. 8.58). The smaller foci of metastatic tumor are frequently located within sinuses. The pattern of growth may be so well differentiated as to simulate normal thyroid tissue. However, close inspection will usually reveal the presence of one or more of the cytoarchitectural features of papillary carcinoma, such as small papillae, psammoma bodies, follicles with darkly staining colloid, and the characteristic nuclear changes of this tumor type. The second situation is the occurrence of normal follicles within nodes, a concept that was originally proposed by Frantz et al.[930] and that some authors still have difficulty in accepting. The best evidence in its favor is the study performed by Meyer and Steinberg.[933] These authors serially sectioned cervical lymph nodes from 106 autopsies and found thyroid tissue in five of them. Serial section of the whole thyroid gland in these cases failed to reveal carcinoma, except for a probably unrelated microscopic papillary carcinoma in the contralateral lobe of one case. In these instances, the ectopic thyroid tissue typically presents as a small conglomerate of follicles lacking all the attributes

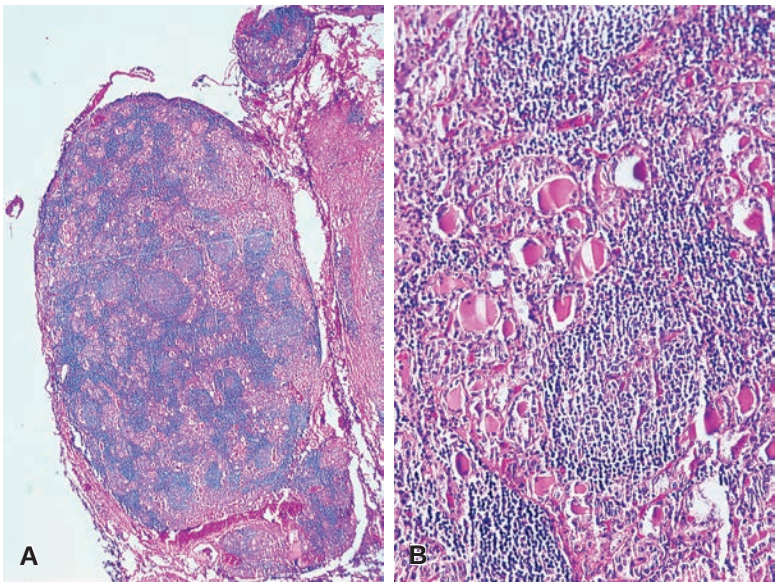

Figure 8.94 **A** and **B,** So-called sequestered (parasitic) thyroid nodule occurring in association with a gland involved by Hashimoto thyroiditis. The combination of oxyphilic change and germinal center formation in the sequestered nodule results in an appearance that can be confused with thyroid carcinoma metastatic to a lymph node.

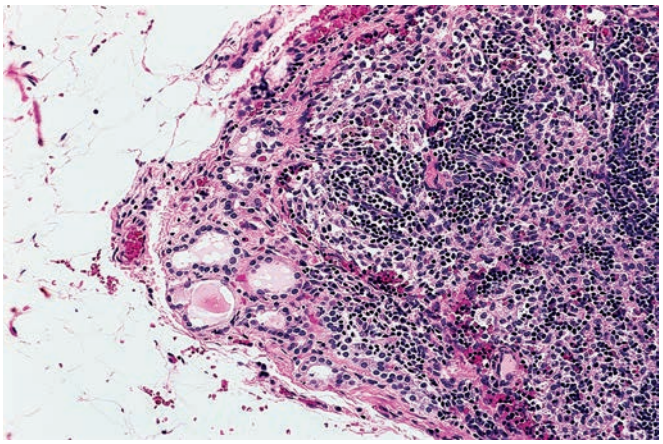

Figure 8.95 Ectopic thyroid follicles in lymph node. The follicles are scanty, centered in the lymph node capsule, and devoid of structural and cytologic abnormalities.

of papillary carcinoma and limited to the periphery of one or two nodes (Fig. 8.95). Any thyroid tissue replacing most of the node and/or involving several nodes is most likely metastatic carcinoma.

A point worth making, despite its apparent obviousness, is that not all metastatic papillary carcinomas with psammoma bodies in a cervical lymph node originate in the thyroid. Cases are on record in which a thoroughly studied specimen of total thyroidectomy failed to reveal tumor in the gland.[934] The possibility of the carcinoma being extrathyroidal (e.g., salivary gland, lung, ovary, and even thymus) should be particularly considered for those tumors lacking the classic nuclear features of papillary carcinoma and devoid of thyroglobulin immunoreactivity.

6. Thyroid as a component of teratoma. Thyroid tissue may be seen as one of the many components of teratoma, particularly those located in the ovary. This thyroid tissue may appear normal, hyperplastic, or—exceptionally—neoplastic. Ovarian teratomas composed predominantly or exclusively of thyroid tissue are referred to as *struma ovarii*. Before accepting any tissue located in an unusual place as representing thyroid, one should keep in mind that a thyroid-like appearance can result from cystically dilated glands of one type or another whenever their epithelium flattens and the intraluminal secretion inspissates.[935] Struma ovarii should also be distinguished from the exceptional thyroid carcinoma that metastasizes to the ovary.[936]

Treatment

The management of thyroid cancer is constantly evolving and thus can be highly variable and controversial.[937,938] The mainstay of treatment of most types of thyroid tumors is primarily surgical. In cases in which the nodule is limited to one lobe, lobectomy (with or without isthmusectomy) is usually done as the first approach, with subsequent therapy depending on the nature of the nodule. Nodulectomy is not an accepted form of therapy for these lesions. Lobectomy or total thyroidectomy is standard of care, depending on the specifics of the pathology, overall assessment of the risk for structural disease recurrence and the desire for treatment with radioiodine.[863] It should be noted that some centers of excellence use active surveillance for select patients with small papillary carcinomas.[939]

The use of radioactive iodine varies considerably across institutions based on a variety of factors.[940] Patient selection and the overall efficacy of radioactive iodine continues to be debated topics.[941] Several targeted therapies for differentiated thyroid cancer have been recently approved.[942,943]

Prognosis

Most of the clinical and pathologic factors that relate to prognosis have been discussed with the specific tumor types. In general terms, the most important are the patient's age (very significant), patient's sex (less so), tumor microscopic type, tumor microscopic grade (to a large extent already included in the microscopic typing), and tumor stage.[944–948] These and other factors have been sometimes combined in rather complex prognostic indices.[492,949,950] Cady et al.[492] grouped

their patients with well-differentiated (papillary or follicular) carcinomas into two categories having strikingly different survival rates: low risk (comprising men under 40 years of age and women under 50 years) and high risk (the others). These findings have been confirmed. For papillary carcinomas Carcangiu et al. found that the prognostic difference is even more striking if the low-risk group includes women 60 years and under.[248] The large majority of deaths from thyroid carcinomas result from undifferentiated, poorly differentiated, Hürthle cell, and medullary tumors. It should be realized that, in many series, several of these tumor types are included among the follicular carcinomas.[951] Conversely, encapsulated well-differentiated follicular-patterned thyroid carcinomas do not play a significant role in the fatality rates from thyroid carcinoma (or, for that matter, their morbidity).[384]

AJCC/UICC TNM staging and diagnostic algorithms (e.g. AGES, patient age, presence of distant metastases, extent and size of the primary tumor; MACIS, metastasis, patient age, completeness of resection, local invasion, and tumor size) adequately predict the risk of tumor related death, but are not designed to predict that of recurrence.[863] The American Thyroid Association (ATA) has developed a three-tiered risk stratification system that groups patients into *low*, *intermediate*, or *high risk* of recurrence based on a series of clinicopathologic parameters that include aggressive histologic types or subtypes of thyroid carcinoma (e.g., tall cell papillary carcinoma), extent of vascular invasion, of extrathyroidal extension, of metastatic disease to the cervical lymph nodes.[863] According to ATA thyroid cancer guidelines initial recurrence risk estimates should be modified during follow-up (dynamic risk stratification), since the risk of recurrence and disease-specific mortality may change over time as a function of the clinical course and the response to therapy. A uniform set of criteria has been proposed to assess response to therapy that groups patients as having: *Excellent response* (no clinical, biochemical, or structural evidence of disease); *Biochemical incomplete response* (abnormal thyroglobulin values or rising anti-thyroglobulin antibodies in the absence of localizable disease); *Structural incomplete response* (persistent or newly identified loco-regional or distant metastases); and *Indeterminate response* (nonspecific biochemical or structural findings that cannot be confidently classified as either benign or malignant).[863]

The tumor mutational profile may add useful prognostic information.[303,339] *TERT* promoter mutations have been associated with aggressive features and unfavorable outcome in differentiated thyroid carcinoma, independent of other clinicopathologic parameters.[348,350,351,412] Inactivating *TP53* mutations have long been known to be a marker for poorly and undifferentiated thyroid carcinomas.[339,632] *BRAF* p.V600E has been associated with decreased iodide uptake, increased risk of recurrence, and poor outcome in papillary carcinoma,[331,332,338,952,953] but the overall prognostic relevance of the mutation may be relatively limited when other factors (e.g. stage, papillary carcinoma variant) are taken into account.[303,334,339] The probability of aggressive behavior is higher in cases that harbor more than one of the mutations known to be relevant for thyroid carcinoma: for instance, the co-occurrence of *BRAF* p.V600E with *TERT* promoter, *PIK3CA* or *TP53* mutations may be an important sign of poor prognosis.[210,347,349,664,952]

Lymphoid Tumors and Tumorlike Conditions

Most cases of primary **malignant lymphoma** of the thyroid are seen in adult or elderly females.[954,955] The thyroid enlargement is often rapid and can lead to symptoms of tracheal or laryngeal compression.[956,957] Most patients are euthyroid, and the tumor presents as one or more cold nodules on thyroid scan.[958] Grossly, the tumor shows a solid white cut surface with a fish-flesh appearance.

Microscopically, the majority of the cases are of *diffuse large B-cell* type (Fig. 8.96).[955,956,959] Sclerosis may be focally prominent. The second largest category is that of the low-grade lymphomas composed of small or "intermediate" lymphocytes, having either a diffuse or a nodular (follicular) pattern of growth.[960,961] Many of these tumors exhibit focal plasmacytoid features,[962] and a few are composed of signet ring cells.[963] It has been proposed that both of these major thyroid lymphoma types belong to the *MALT-type* category ("marginal zone B-cell lymphomas"), despite a follicular architecture in approximately one-fourth of the cases. This architecture is thought to be the result of colonization of the follicles by the tumor cells.[955,960,961,964] This is supported by the fact that large cell lymphomas often show an associated low-grade MALT-type component,[955,965] and that some show a marginal zone

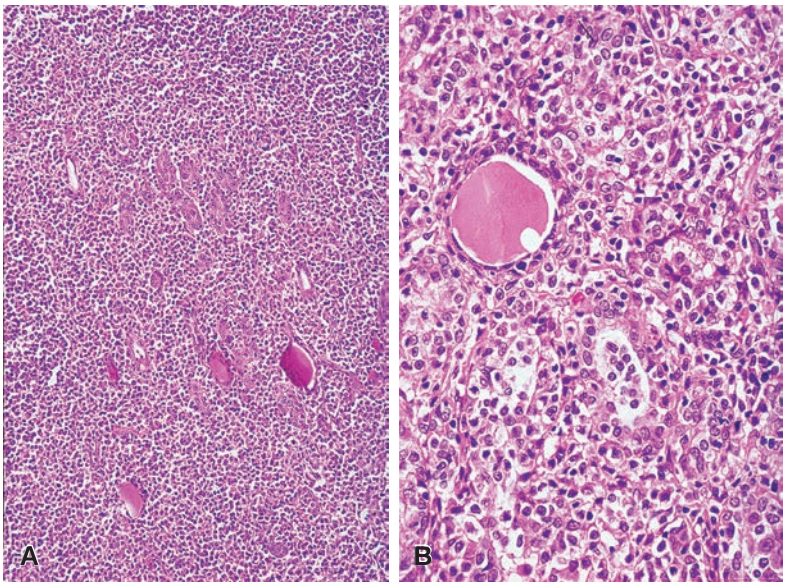

Figure 8.96 Malignant lymphoma of thyroid. **A,** Low-power view showing a diffuse pattern of growth. **B,** Medium-power view showing tumor cells surrounding lymphoid follicles. One of the follicles shows "packing' of the lumen by lymphoid cells, a feature of diagnostic significance.

distribution of the tumor cells.[966] An important diagnostic finding is the packing of follicular lumina by lymphoid cells ("lymphoepithelial lesions"), a feature usually not present in thyroiditis.[955,962]

True *follicular lymphomas* of the thyroid are very rare; interestingly, most of them contain lymphoepithelial lesions similar to those seen in MALT-type lymphomas. Two distinct types have been described, the most common being almost always associated with extrathyroidal disease.[961,967]

Immunohistochemically, all types of thyroid lymphomas exhibit consistent positivity for CD45, and nearly all of them show markers indicative of B-cell derivation,[955,968,969] whereas primary thyroid T-cell lymphomas are vanishingly rare.[970] The differential diagnosis includes the small cell variant of medullary carcinoma and insular carcinoma and may require the use of immunohistochemistry.[971]

A very high proportion of primary thyroid lymphomas arise in a background of lymphocytic or Hashimoto thyroiditis, this association representing one of the better documented examples of the pathogenetic link between immunoproliferation and autoimmune disease.[955,972,973] Accordingly, most of the patients have positive serum tests for antithyroid antibodies.[960] The Epstein–Barr virus does not seem to play a major pathogenetic role.[974]

The tumor may be restricted to the thyroid, may spread to the soft tissues by direct extension, or may involve the regional nodes. The prognosis is better for marginal zone B-cell lymphomas than for diffuse large B-cell lymphomas.[961] Most treatment failures result from distant recurrences.[975] It is not uncommon for this recurrence to be located in the gastrointestinal tract.[976]

The treatment of thyroid lymphoma usually includes thyroidectomy followed by adjuvant therapy that varies depending on the lymphoma subtype[977]; in cases with extrathyroidal involvement, surgical debulking does not seem to be necessary before the administration of adjuvant therapy.[978]

Primary thyroid lymphoma should be distinguished from systemic lymphoma with thyroid involvement, a rather unusual event.

Plasmacytoma of thyroid can be seen as a component of widespread myeloma or as the only manifestation of the disease.[979,980] Immunoglobulin abnormalities may be present in the serum.[981] The term should be restricted to tumors entirely composed of plasma cells of various degrees of maturity; tumors with a lymphoid component should be placed in the malignant lymphoma category.[982] Plasmacytoma should also be distinguished from *plasma cell granuloma*, a non-neoplastic condition in which a polyclonal infiltrate of mature plasma cells is seen admixed with other inflammatory cells in a fibrotic background.[983]

Hodgkin lymphoma involving primarily the thyroid is extremely rare, but its occurrence has been documented.[955,984] Most of the cases have been of the classic type (nodular sclerosis subtype), and some have shown concomitant involvement of cervical lymph nodes (Fig. 8.97).[985,986]

Langerhans cell histiocytosis (histiocytosis X, eosinophilic granuloma) can involve the thyroid gland as an isolated event (Fig. 8.98)[987,988] or associated with papillary carcinoma.[989] Practically all reported cases have occurred against a background of lymphocytic/Hashimoto thyroiditis, and some have also involved the adjacent parathyroid glands.[990]

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) can also involve the thyroid gland, either as an isolated event or as a component of multisystem disease.[991,992]

Extramedullary hematopoiesis has been observed within the substance of thyroid nodules in patients with myelofibrosis (agnogenic myeloid metaplasia).[179,993,994]

Mesenchymal Tumors

Benign mesenchymal tumors of thyroid are exceptional. Isolated cases of *lipoma*,[995,996] *hemangioma*,[997,998] *angiolipoma*,[999] *lymphangioma*,[1000,1001] *leiomyoma*,[1000,1002] *schwannoma*,[1003,1004] *granular cell tumor*,[1005] *hemangiopericytoma*, and *solitary fibrous tumor* have been reported, the latter with an increasing frequency.[1006–1009] While on the subject of hemangioma, we thought of mentioning here the strange phenomenon by which severe hypothyroidism can accompany infantile hemangioma of liver and other sites as a result of degradation of thyroid hormone in the tumor tissue by type 3 iodothyronine deiodinase activity.[1010]

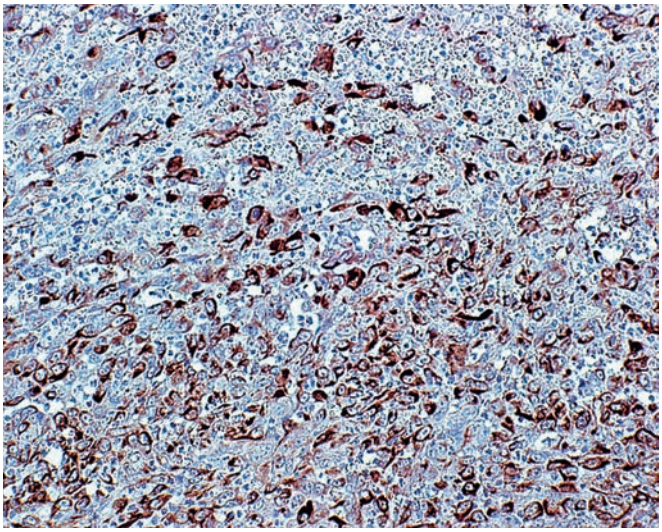

Figure 8.101 Keratin immunoreactivity in thyroid angiosarcoma. There was also positivity for endothelial markers.

Sarcomas of various microscopic types have been reported in the thyroid, usually in the form of individual case reports. These include *fibrosarcoma*,[1011] *liposarcoma*,[1012] *leiomyosarcoma*,[1001,1013,1014] *chondrosarcoma*,[1015] *osteosarcoma*,[1016] and *malignant peripheral nerve sheath tumor* (including triton tumor).[1002,1017,1018] Some of the leiomyosarcomas have occurred in a setting of immunodeficiency in association with the Epstein–Barr virus.[1014] It should be remembered that most sarcoma-like thyroid tumors are examples of the spindle or giant cell types of undifferentiated carcinoma.[1011]

Controversy still exists about the frequency and very existence of thyroid *angiosarcoma*, most early examples of which have been reported from Switzerland and other mountainous regions. There is no question that some of these neoplasms exhibit all the attributes of angiosarcoma, such as anastomosing vascular channels, Weibel–Palade bodies on ultrastructural examination, immunoreactivity for endothelial cell markers, and tendency to produce hemorrhagic pleuropulmonary metastases (Fig. 8.99).[1019–1022] Some of them show, together with a typical angiosarcomatous architecture and immunoreactivity for endothelial markers, an epithelioid morphology, accompanied by marked nucleolar prominence and immunoreactivity for keratin (Figs. 8.100 and 8.101).[1023,1024] These tumors (some of which have occurred in non-Alpine areas)[1025] are keratin-positive *epithelioid angiosarcomas*, in analogy to similar cases reported in other sites, such as skin, bone, and uterine corpus.[1026–1028] They have been regarded, together with related tumors, as anaplastic carcinomas, due to the perennial issue of presumed histogenesis versus phenotype.[1029–1031] Most malignant tumors showing vascular

differentiation have arisen in glands with nodular hyperplasia, and the evolution has usually been fatal.

Low-grade malignant examples of endothelial vascular tumor in the category of *epithelioid hemangioendothelioma* have been reported.[1032]

Other Primary Tumors and Tumorlike Conditions

Teratomas of thyroid usually occur in neonates, infants, or children.[1033] The large majority of the cases have been cystic and benign. Neural tissue is usually the predominant component; the fact that it is often immature is not a sign of clinical malignancy.[1034] However, these teratomas can lead to obstruction of the airway, necessitating emergency surgery because of their location in the mid neck and the huge size that they can attain.[1035]

The few thyroid teratomas that have been described in adults have been malignant[1036]; some of the reported cases have a very primitive neuroepithelial component with rosette formations associated with islands of well-differentiated cartilage.[1033,1037] Another group of reported cases of teratomas[1038] has been reinterpreted as neoplasms showing thymic or related branchial pouch differentiation (see later and Chapter 12).[40]

Neuroblastomas of the thyroid have been reported.[1039] They should be distinguished from the much more common teratomas with immature neural elements.

Parathyroid tumors can occur within the thyroid gland and create problems of differential diagnosis with follicular neoplasms. Unlike follicular neoplasms they are positive for chromogranins and parathyroid hormone, and lack TTF-1 immunoreactivity.[5] Parathyroid tumors are further described in Chapter 9.

Amyloidosis can involve the thyroid as part of a systemic disease or as a localized primary *amyloid tumor* ("amyloid goiter").[1040,1041] The lesion may be unilateral or bilateral and is commonly associated with a foreign body–type reaction. The amyloid deposits are often accompanied by mature adipose tissue.

Malakoplakia and **Wegener granulomatosis** have been described involving the thyroid and mimicking a primary neoplasm clinically.[1042–1044]

Thymic and branchial pouch–derived tumors can involve the thyroid gland and simulate primary thyroid neoplasms.

Metastatic Tumors

Direct extension into the thyroid may occur in carcinomas of pharynx, larynx, trachea, or esophagus, as well as from metastatic lesions from adjacent cervical lymph nodes.[1045] The majority of these tumors are of squamous cell type; therefore the possibility of secondary invasion should be considered when such a tumor type is encountered in a thyroid specimen, especially if the tumor is relatively well differentiated.

Blood-borne metastases represent 0.2% of thyroid malignancies.[1046] Metastases are found in the thyroid at autopsy in approximately 10% of patients dying of malignant tumors; the most common sites for the primary tumor are skin (melanoma) (39%), breast (21%), kidney (12%), and lung (11%) (Fig. 8.102).[1047] These metastases can be solitary (most commonly), multiple, or diffuse.[1048] A fair number of these metastases are found within preexisting thyroid lesions, such as follicular adenoma (the most common), follicular carcinoma, or papillary carcinoma of either the classic or follicular variant type.[1049–1051]

It is rare for metastases to the thyroid to simulate clinically a primary thyroid neoplasm.[1052,1053] The outstanding exception is renal cell carcinoma, which can present as a thyroid mass in the absence of renal symptoms years or decades after the removal of the primary tumor.[250,1054,1055] The differential diagnosis is with primary thyroid tumors with clear cell features. Features favoring the diagnosis of metastatic renal cell carcinoma are multiplicity of the nodules, optically clear (as opposed to finely granular) cytoplasm, sinusoidal-type blood vessels, intraluminal fresh hemorrhage ("bloody glands"), and a large amount of cytoplasmic glycogen and fat (Fig. 8.103).[250,1056] Immunohistochemical stains for thyroglobulin, TTF-1, and PAX8 are also helpful, but one should be aware of the fact that diffusion of the former marker from entrapped follicles may occur, with subsequent nonspecific absorption by neighboring tumor cells.[250] If material from the primary renal tumor is available, a molecular comparison with the thyroid clear cell neoplasm can also be helpful.[1057]

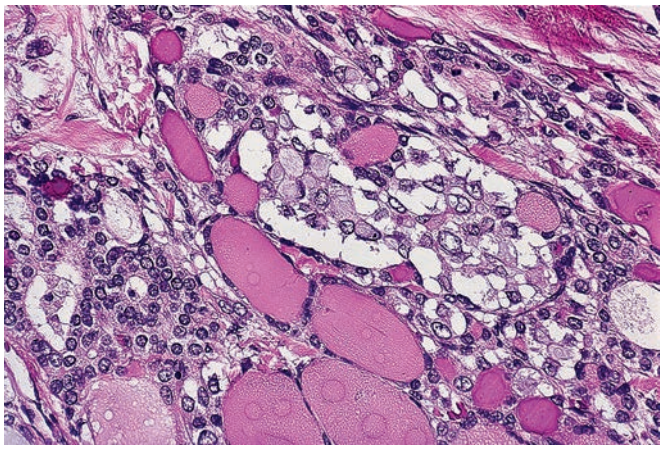

Figure 8.102 Lobular carcinoma of the breast with signet ring features metastatic to thyroid.

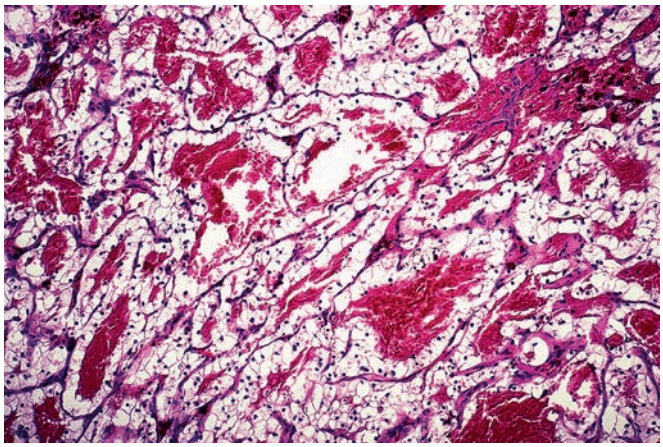

Figure 8.103 Renal cell carcinoma of clear cell type metastatic to thyroid. Note the blood-filled glands.

For adenocarcinomas of other types, mucin stains are also of some use. Although exceptions certainly occur, the presence of intracytoplasmic mucin of an epithelial type in a malignant tumor located within the thyroid gland points toward a metastatic origin. Similarly, the presence of mucin in a metastatic tumor of unknown source makes very unlikely the possibility that the primary is in the thyroid gland. This traditional approach has been largely superseded by immunohistochemical evaluation for markers such as thyroglobulin, TTF-1, PAX8, CEA, and the various keratins.

The fact that neuroendocrine carcinomas can exceptionally metastasize to the thyroid and simulate a primary thyroid neoplasm (particularly medullary carcinoma)[792,793] is discussed under "Other Neuroendocrine Tumors."
