Some patients with endometrioid carcinoma of the ovary have either endometrial hyperplasia or a synchronous endometrial adenocarcinoma, which is often well differentiated and superficial.[272] There is a wide disparity in the reported incidence of the latter occurrence (largely because of different diagnostic criteria used for diagnosis

Figure 35.44 **Gross Appearance of Clear Cell Carcinoma of Ovary.** The tumor is predominantly cystic, but it contains several mural nodules.

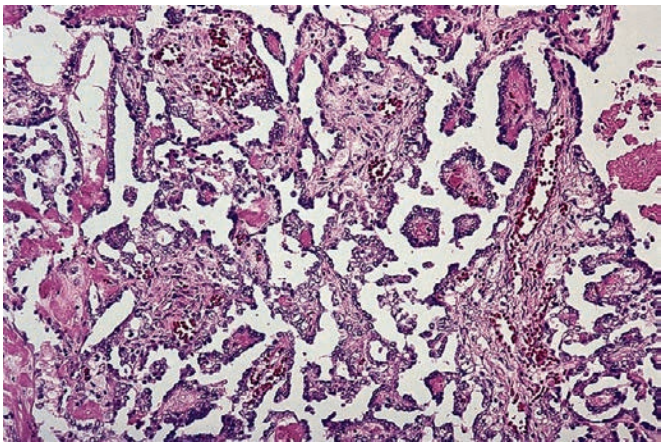

Figure 35.45 A highly papillary configuration is seen in this low-power view of ovarian clear cell carcinoma.

of endometrioid carcinoma in the past), with most series ranging from 15% to 45%. This incidence is higher in recent years due to more accurate diagnosis of endometrioid histotype in the ovary (i.e. there are fewer HGSCs misdiagnosed as endometrioid).[239,272,119] It is frequent enough, in our opinion, that if an endometrial biopsy has not been done previously, it would be warranted to obtain one in any patient with an ovarian endometrioid carcinoma.

The differential diagnosis of endometrioid carcinoma includes serous carcinoma (WT1 positive), mucinous carcinoma of intestinal type (negative or only weakly ER positive), and, in rare instances, sex cord–stromal tumors (negative for EMA and positive for inhibin).

Clear Cell Tumors

Clear cell carcinoma accounts for 10% of ovarian carcinomas (see Table 35.2) and is a distinctive ovarian tumor with a grossly spongy, often cystic appearance (Fig. 35.44), which microscopically can grow in tubulo–cystic, papillary, and solid-sheet patterns (Fig. 35.45).[273,274] Stroma-rich variants of clear cell carcinoma, with a prominent adenofibromatous component, are also common. In contrast to serous carcinomas, the papillae of clear cell carcinoma have a nonhierarchically branched pattern and lack epithelial stratification.[275]

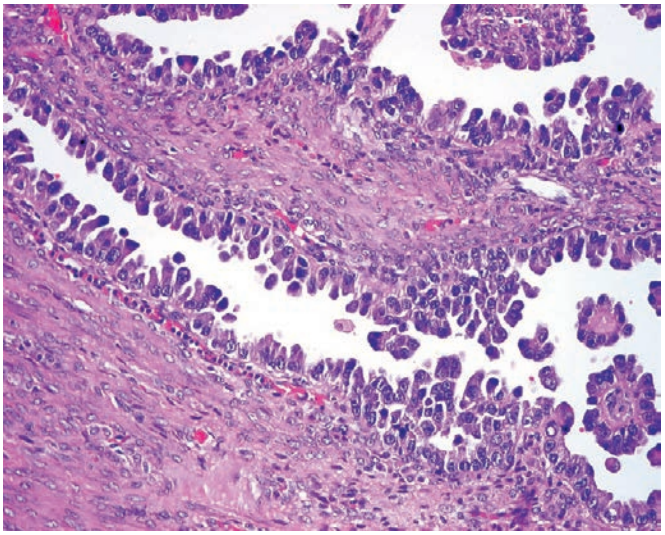

Figure 35.46 Clear Cell Carcinoma of Ovary. Note the high nuclear grade and the hobnail configuration.

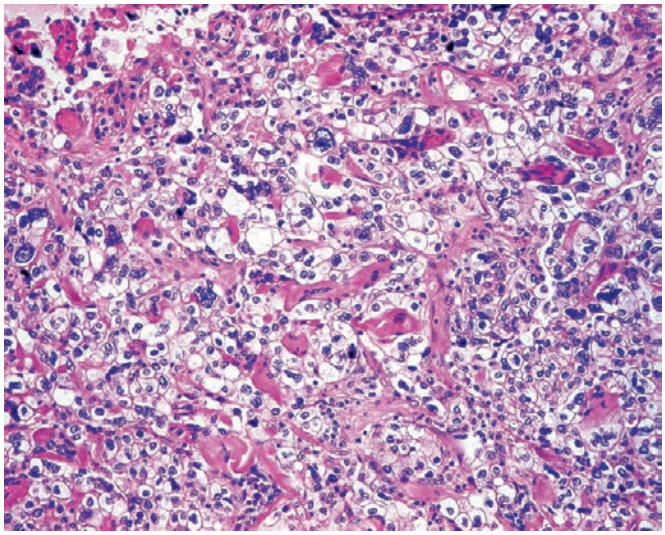

Figure 35.48 Clear cell carcinoma of ovary showing short papillae with hyalinized cores lined by highly atypical cells.

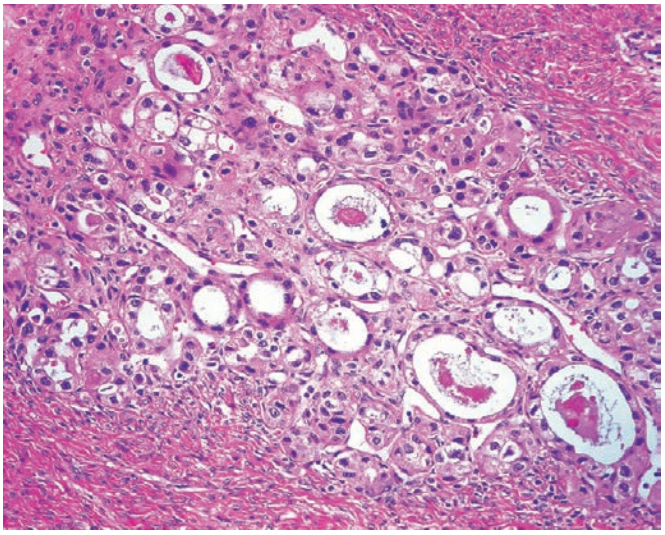

Figure 35.47 Oxyphilic variant of clear cell carcinoma.

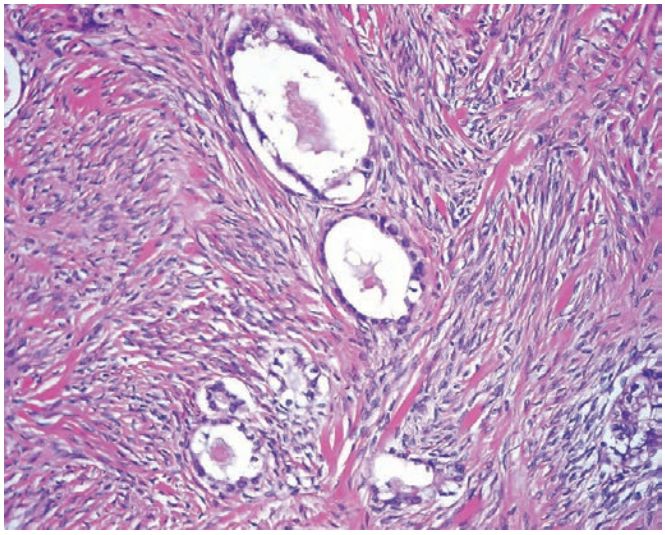

Figure 35.49 Clear cell borderline tumor; the epithelial cells of this adenofibroma show mild to moderate nuclear atypia.

The tumor cells are large and some of the nuclei protrude into the lumina, resulting in a "hobnail" configuration (Fig. 35.46). Their cytoplasm is clear; it often contains glycogen, mucin, and fat, and it may exhibit periodic acid–Schiff (PAS)-positive, diastase-resistant hyaline globules, which are negative for alpha-fetoprotein. In some of the tumor cells, the cytoplasm may appear oxyphilic rather than clear (Fig. 35.47).[268,276] Stromal hyalinization is a common and distinctive feature of clear cell carcinoma, with the stroma of papillae distended by basement membrane material (Fig. 35.48). Immunohistochemically, the tumor cells are always reactive for keratin (CK7, CK5/6, CAM 5.2, 34βE12), EMA, CD15 (Leu-M1), Ber-EP4, vimentin, and PAX8. ER and PR are usually negative or, at most, only focally positive, while p53 shows wild-type staining. Napsin A and hepatocyte nuclear factor-1β (HNF-1β, a transcription factor involved with liver differentiation), are usually expressed.[249,277]

Clear cell carcinoma is frequently associated with pelvic endometriosis, arising in some cases from endometriotic cysts.[278,279] The lining cells of endometriotic cysts may show marked cytological atypia, a finding designated "atypical endometriosis," which is thought to be the precursor of clear cell carcinoma.[98] At the electron microscopic level, the cytoplasmic clearing is seen to be largely due to the accumulation of glycogen.[280]

Benign and **borderline** ovarian clear cell tumors are rare. They can be "pure" or be associated with obviously malignant clear cell carcinomas.[281] Their growth pattern is most commonly that of an adenofibroma.[248] The borderline tumors are identified because of moderate to marked degrees of epithelial proliferation and atypia in the absence of recognizable stromal invasion (Fig. 35.49).[282]

The differential diagnosis of ovarian clear cell carcinoma includes:

- *Metastatic renal cell carcinoma*, which is negative for keratin 34βE12 and positive for CD10, whereas primary clear cell ovarian carcinoma usually (but not always) shows the opposite results.[283]
- *Ovarian yolk sac tumor*, which is characteristically positive for SALL4.[284] It is also positive for glypican-3,[285] but this is also true for about 40% of clear cell carcinomas.[286]

- *Ovarian serous carcinoma*, as a result of the fact that clear cell carcinomas can have a highly papillary pattern of growth,[287] and that serous carcinomas can contain clear cells.[178] An immunohistochemical panel consisting of WT1, estrogen receptor, and HNF-1β is useful in making the distinction.[288]

Brenner Tumor

Brenner tumors constitute between 1% and 2% of all ovarian neoplasms.[289] The average age at presentation is approximately 50 years, about 70% of the patients being over 40 years of age. Some cases are accompanied by signs of hyperestrinism, such as uterine bleeding from endometrial hyperplasia in a postmenopausal woman. The rate of growth is slow, and ascites is rare. Grossly, these tumors vary greatly in size; they are usually unilateral, firm, and white or yellowish white (Fig. 35.50). They closely resemble fibromas or thecomas, except for the frequent presence of small cystic areas filled with opaque, viscous, yellowish-brown fluid. Microscopically, they consist of solid and cystic nests of epithelial cells resembling transitional epithelium (urothelium) surrounded by an abundant stromal component of dense, fibroblastic nature (Fig. 35.51). The epithelial cells have sharply defined outlines; those lining the cysts may be flattened, cuboidal, or columnar. The nuclei of the tumor cells are oval, with a small but distinct nucleolus and longitudinal grooves similar to those seen in granulosa cell tumors (Fig. 35.52). The cytoplasm is clear and immunoreactive for keratin, EMA, and CEA (the latter also present in the lumen of the cysts); nuclear GATA3 reactivity is also common.[290] Scattered argyrophilic cells are present in about one-third of cases; they are positive for chromogranin and 5-HT, have dense-core granules at the ultrastructural level, and are similar to those seen in normal urothelium.[250,291] Steroidogenic enzymes as detected immunohistochemically are usually absent.[292]

Sometimes the cystic formations within the tumor are unduly prominent and accompanied by florid mucinous change.[293] If there is architectural complexity (crowding, stratification of the epithelium) and nuclear atypia but no evidence of invasion, a diagnosis of borderline Brenner tumor is indicated; all such tumors have followed a benign course (Figs. 35.53 and 35.54). *Malignant Brenner tumors* are rare. Some of these have been bilateral.[294,295] They are recognized through the association of the malignant epithelial component with

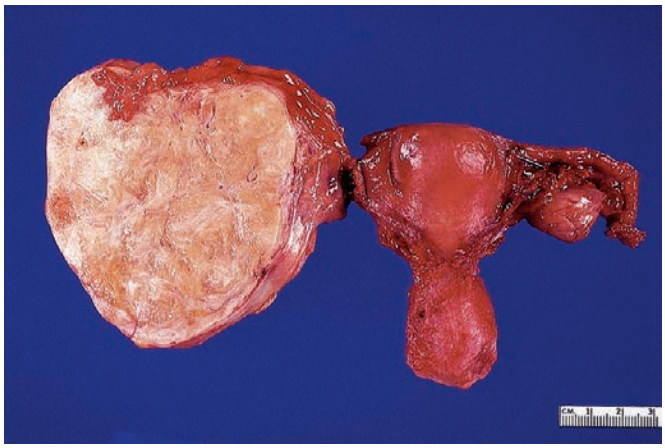

Figure 35.50 Large Brenner Tumor Involving the Right Ovary. The gross appearance of this neoplasm is very similar to that of fibroma or thecoma.

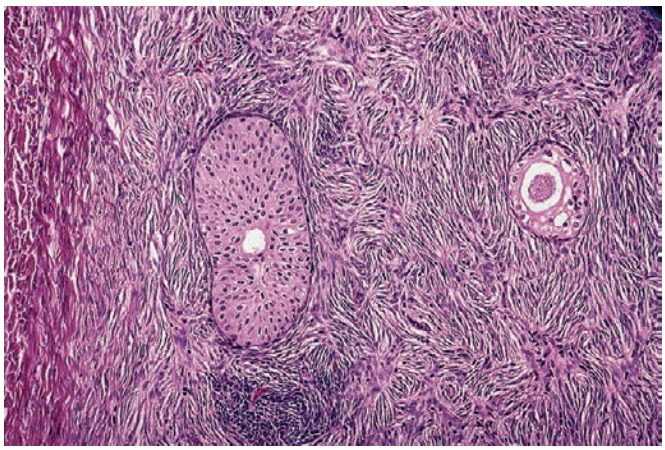

Figure 35.51 Brenner tumor of ovary showing solid and cystic epithelial cell nests embedded within fibrous tissue.

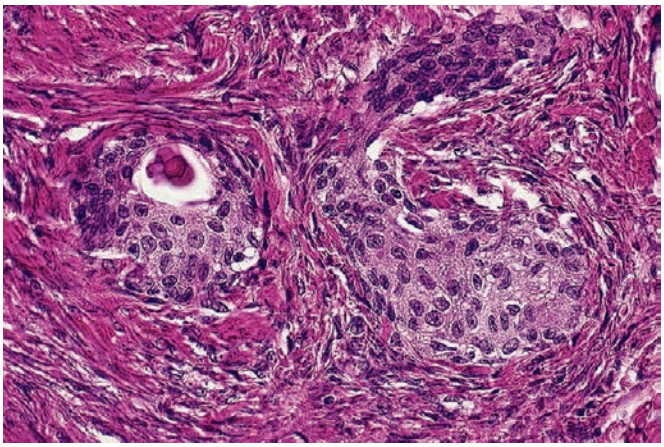

Figure 35.52 The epithelial nests of Brenner tumor are composed of cells with oval nuclei, many of which exhibit longitudinal grooves.

Figure 35.53 Borderline Brenner Tumor.

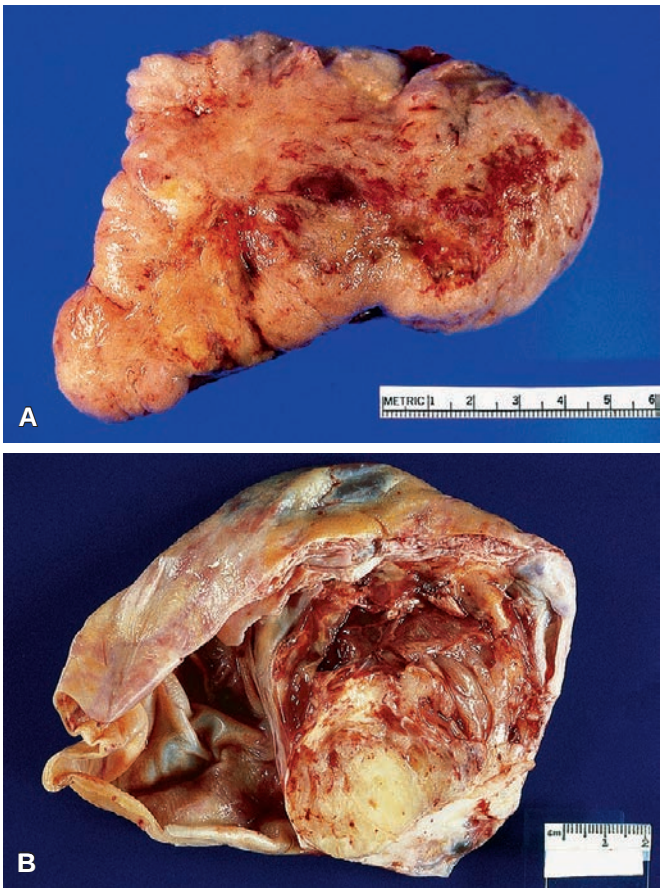

Figure 35.56 **A** and **B,** Gross appearances of carcinosarcoma of ovary. The neoplasms are large, variegated, solid and cystic, with hemorrhagic and necrotic areas.

a typical benign or borderline component.[296] The appearance of the malignant epithelium may be that of a transitional cell, squamous, glandular, or undifferentiated carcinoma, or an admixture of these.[296]

The tumors formerly referred to as **transitional cell carcinomas** (non-Brenner type),[292,297] unassociated with a benign or borderline Brenner tumor (see Fig. 35.32), are now recognized to be variants of HGSC (i.e. they are not related to Brenner tumors). Their immunophenotype is typical of HGSC (WT1 and ER expression).[298]

Brenner tumors show a strong association with mucinous tumors (Fig. 35.55)[299] and are sometimes seen together with struma ovarii.[300] Brenner tumors have exceptionally been seen to occur in accessory ovaries[301] or in other female genital tract sites, including vagina.

Carcinosarcoma and Adenosarcoma

Carcinosarcoma (malignant mixed müllerian tumor or MMMT) of the ovary resembles grossly and microscopically in every respect its more common uterine counterpart (Fig. 35.56). Thus a *homologous* variety (with nonspecific malignant stroma) and a *heterologous* variety (with malignant heterologous elements) occur.[302] The carcinomatous component may be of serous, endometrioid, squamous, or clear cell type. The sarcoma-like elements may have the appearance of chondrosarcoma (the most common), osteosarcoma, rhabdomyosarcoma, or angiosarcoma (Fig. 35.57). Hyaline droplets containing α1-antitrypsin are often present in the cytoplasm of the tumor cells.[303] Although some response to chemotherapy has been noted,[161] the overall prognosis is extremely poor,[304] with some outstanding exceptions.[305] The most reliable prognostic criterion is the initial tumor stage.[208,306–308] Unfortunately, most tumors have already extended outside the ovary at the time of surgery.[309] The most important differential diagnosis is with immature teratoma and adenosarcoma with heterologous elements. Almost all carcinosarcomas are seen in postmenopausal patients, whereas immature teratomas are typically tumors of children and adolescents. Furthermore, the former usually lack the neural and other germ cell elements of teratomas. However, cases of carcinosarcoma featuring prominent neuroectodermal differentiation have been described.[247,310,311]

Müllerian adenosarcoma, more commonly seen in the endometrium and cervix, also can occur in the ovary.[306,312–314] The morphologic appearance and behavior are again similar to those of its uterine counterpart, including the occurrence of sex cordlike elements, sarcomatous overgrowth, and heterologous elements.[313] The subject was discussed previously (see Chapter 33).

Mixed and Other Epithelial Tumors

Carcinomas composed of an admixture of two or more of the five common histotypes of ovarian carcinoma account for fewer than 1% of cases and most commonly consist of an admixture of those histotypes that are associated with endometriosis (e.g. clear cell and

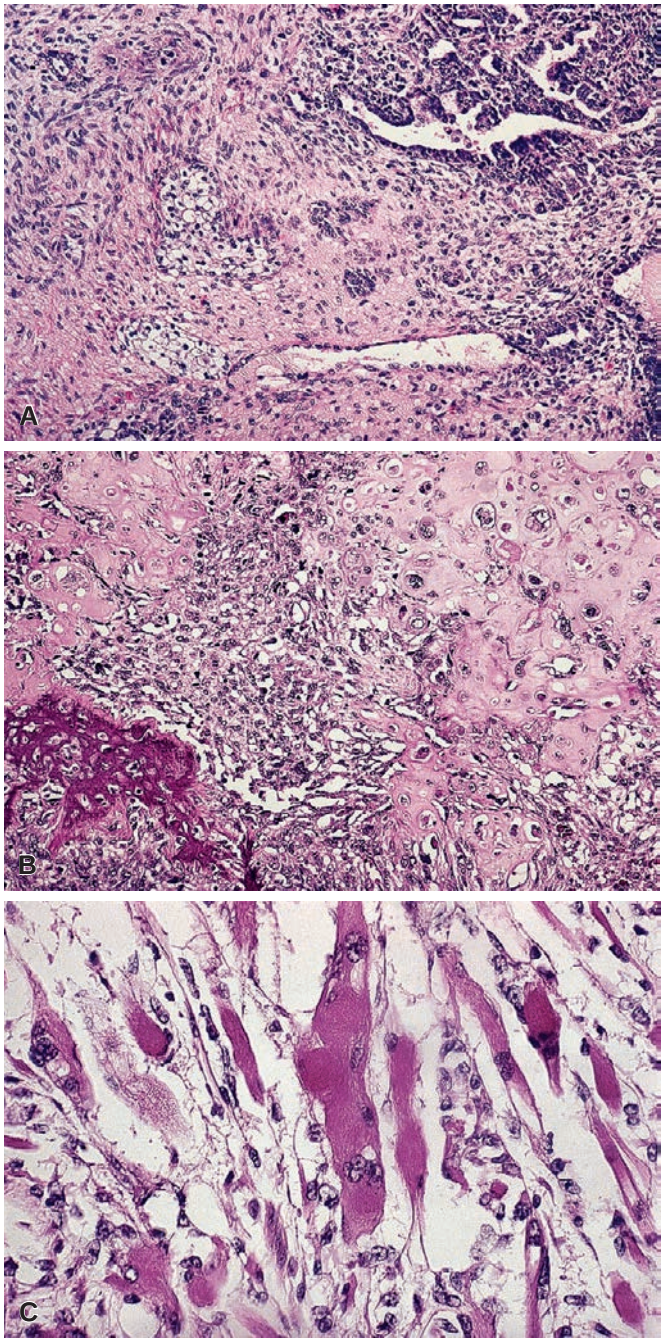

Figure 35.57 Carcinosarcoma of Ovary. The tumor shown in **A** is of the so-called homologous type, whereas the others exhibit heterologous foci in the form of bone and cartilage **(B)** or skeletal muscle **(C)**.

endometrioid carcinoma).[179] A diagnosis of mixed carcinoma should only be made when there is clear evidence of more than one histotype present, preferably supported by the appropriate immunostains (although they need not be done in an unequivocal case).

There are also approximately 1% of ovarian carcinomas that defy histotype classification; we refer to these as "adenocarcinoma NOS." Undifferentiated carcinoma is a diagnosis reserved for tumors that are undifferentiated throughout. Any component of HGSC, or even expression of the serous marker WT1, is sufficient to classify such a tumor as high-grade serous. Undifferentiated carcinoma, when seen in association with low-grade endometrioid carcinoma, is a de-differentiated carcinoma, following the practice for endometrial tumors.[265] Exceptionally, carcinomas of the ovary show a pattern resembling that of salivary gland carcinomas of adenoid cystic type or that of cutaneous basal cell carcinomas.[284,315,316] These may be seen in pure form or in association with conventional serous, endometrioid, or clear cell patterns. The tumors with an adenoid cystic carcinoma-like appearance are more aggressive than the basaloid neoplasms.[284]

Ovarian Carcinoma

Ovarian Tumors in Children

Germ cell tumors are the most common tumors in children, accounting for 60%–70% of all ovarian tumors in this age group.[317–319] Whereas mature cystic teratomas predominate, the proportion of malignant germ cell tumors (especially immature teratomas, yolk sac tumors, and dysgerminomas) is much greater than in adults.[320–324]

Sex cord–stromal tumors constitute 10%–25% of cases and are largely represented by juvenile granulosa cell tumor and fibrothecomas.[325] Epithelial tumors represent only 15%–20% of ovarian tumors in children, and the vast majority are benign.[326] Indisputable cases of carcinoma occur, particularly of the mucinous type; however, some cases reported as serous carcinomas actually represent yolk sac tumors or retiform Sertoli–Leydig cell tumors with a prominent papillary component, and when one encounters a malignant ovarian neoplasm in the first two decades of life, it is most probably NOT an ovarian carcinoma.

As in adults, primary malignant ovarian tumors in children need to be distinguished from metastatic neoplasms. The latter include neuroblastoma, adrenal cortical carcinoma, rhabdomyosarcoma, Ewing sarcoma, and intra-abdominal desmoplastic small cell tumor.[327]

Coexistence of Ovarian and Endometrial Carcinoma

The simultaneous presence of carcinoma in the ovary and uterus is an uncommon but well-recognized event.[328–330] The two tumors may have a similar appearance (usually endometrioid but sometimes serous or clear cell) or may be of different histologic types.[328] Theoretically, this phenomenon could be the result of: (1) metastasis from an endometrial carcinoma into the ovary; (2) two independent primary tumors; or (3) metastasis from an ovarian carcinoma to the endometrium.[329] Historically, ovarian metastasis from an endometrial tumor was favored in the presence of high-grade (especially serous), advanced stage, bilaterality, and/or very small size of the ovarian tumor, involvement of the tubal lumen, and presence of deep myometrial invasion and/or vascular invasion in the uterine tumor.[328] It was thought that most neoplasms with a low-grade endometrioid appearance in both sites were probably independent neoplasms, as they are associated with little or no myometrial invasion in the uterus, extrauterine disease confined to the ovary (without ovarian surface involvement or trans-coelomic spread), and often endometriosis. These patients have an excellent prognosis, even without adjuvant therapy, as would be expected for synchronous stage Ia tumors. It was surprising, then, to find that based on sequencing of tumor DNA, the endometrial and ovarian tumors in a large majority of such cases are derived from a single clone.[331,332] The compelling molecular evidence that these tumors are clonally related does not, of course, change the excellent prognosis and it is therefore reasonable to continue with the previous practice of staging such low-grade organ-confined tumors as independent primary tumors, as that reflects their behavior. A further interesting point is that patients with synchronous endometrial and ovarian carcinoma have Lynch syndrome in only 7% of cases.[333]

Cytology

The main role of diagnostic cytology in ovarian carcinoma is the identification of malignant cells in the peritoneal cavity. The value of peritoneal washing cytology to detect the microscopic spread of ovarian carcinoma has been acknowledged by the fact that the FIGO staging system incorporates the results of cytological examination of the washings in its scheme. Serous carcinomas are more often positive than carcinomas of other types, and high-grade tumors more than low-grade tumors.[334] Specifically, a high positive rate is related to advanced stage of disease, involvement of the ovarian surface, a moderate to large amount of fluid, and nonbloody serous ascites.[335]

The interpretation of peritoneal washings can be made difficult by the admixture of reactive mesothelial cells as well as the differential diagnosis with peritoneal malignant mesothelioma. Calretinin is a good positive marker of mesothelioma, while BerEP4 is consistently positive in carcinomas, but also stains occasional mesotheliomas.[336,337] It should be noted that the "epithelial/carcinoma" markers such as BerEP4 and MOC31 do not allow distinction between carcinoma and benign epithelium (e.g. derived from endometriosis) as both can stain positively. Heterozygous loss of 9p21 is specific for mesothelioma, but not completely sensitive.[336]

Therapy

The primary form of therapy of epithelial tumors is surgical.[338–340] Benign tumors are cured by a conservative operation in the form of unilateral salpingo-oophorectomy. Although the uninvolved portion of the ovary can be preserved for some small benign tumors, the majority require the excision of the entire gonad. Most borderline tumors in young females can also be treated conservatively with safety, the results following salpingo-oophorectomy being equivalent to those seen following more extensive procedures.[341,342] As a matter of fact, some cases have been treated with cystectomy only, the overall outcome being excellent; however, recurrences in the ipsilateral ovary are relatively common and close follow-up is necessary.[343]

Carcinomas were traditionally treated initially by bilateral salpingo-oophorectomy with total abdominal hysterectomy and omentectomy, peritoneal washings, peritoneal biopsies, and lymph node dissection (so-called complete surgical staging), irrespective of histotype. There has been some move away this more extensive surgical staging as it is clear that patients with "apparently" low stage (stage Ia) mucinous and endometrioid carcinomas do exceptionally well, even without extensive staging or adjuvant therapy. Avoiding the morbidity of more extensive surgery and chemotherapy for these two subtypes does not significantly impact on their excellent prognosis (>95% disease-free survival at 5 years).[344] On the other hand, patients with HGSC have such a guarded prognosis that, to date, it has not been possible to identify a group where chemotherapy would not be offered, in the absence of medical contraindications. Thus, more extensive surgery, including node dissection, is not needed to guide treatment for these patients as all will receive platinum/taxane chemotherapy (with intraperitoneal delivery in some patients)[338] irrespective of nodal status. At the present time, most patients with ovarian carcinoma have something less than complete surgical staging.

A recent trend is towards neoadjuvant chemotherapy for patients with advanced stage ovarian carcinoma. As noted previously, most such tumors are HGSC. A large international randomized clinical trial found that neoadjuvant chemotherapy followed by surgery, rather than surgery first, resulted in comparable survival rates and less morbidity.[345] This approach is becoming more widely accepted; only those patients who experience a response to chemotherapy go on to surgery, and in this interval debulking specimen there is the opportunity to assign a chemotherapy response score (CRS), as an indication of response to neoadjuvant chemotherapy.[346] CRS is assigned based on examination of the omentum, as follows: CRS1: mainly viable tumor with no or minimal regression-associated fibroinflammatory changes limited to a few foci, CRS2: appreciable tumor response amidst viable tumor, CRS3: no residual tumor OR minimal irregularly scattered tumor foci seen as individual cells, cell groups or nodules up to 2 mm in maximum size. Only CRS3 is prognostically significant, and these patients, as one would expect, are more likely to be long-term survivors.[346]

Prognosis

The overall prognosis of ovarian carcinoma remains poor. HGSC accounts for most cases, most of which are advanced stage at presentation, and a large majority of these patients will die of disease. Stage and histotype are of independent prognostic significance (even though they co-vary, as noted in Table 35.2). Assignment of grade in ovarian carcinoma is done in a histotype-specific way.[347] Grade is not assigned in HGSC, low-grade serous carcinoma or clear cell carcinoma. Grading systems for the latter have been proposed but have not been independently validated to be of prognostic significance independent of stage. Endometrioid carcinomas are typically graded using the FIGO system in use for endometrial carcinomas of endometrioid type, while mucinous carcinomas are most commonly graded using the WHO system, which does not provide specific criteria for grading.

Germ Cell Tumors

Germ cell tumors constitute approximately 20% of all ovarian neoplasms. Most of them are seen in children and young adults, and approximately 95% are benign cystic teratomas; the younger the patient, the more likely the germ cell tumor will be malignant.[328,348]

Significant advances have been made in the understanding of these tumors,[349,350] many of them fueled by the description of new immunohistochemical markers having a high degree of specificity for germ cell tumors in general and for some of the individual types.[351–353]

In the sections that follow, the tumors are discussed as individual types; however, it should be recognized that a combination of various elements occurs in approximately 8% of cases. These are referred to as *mixed germ cell tumors*[354,355]; the most common combination is that of dysgerminoma with yolk sac tumor, but many others occur,[356] including some with a predominance of the polyembryoma component.[348]

One of the greatest achievements in oncology is represented by the therapy of malignant germ cell tumors. Chemotherapeutic regimens consisting of a combination of bleomycin, etoposide, and cisplatin have resulted in overall disease-free survival rates greater than 95%.[357,358]

Dysgerminoma

Dysgerminoma constitutes less than 1% of all ovarian tumors.[359] Most patients are young. In Santesson's series of nearly 300 cases, 81% were under 30 years of age and 44% were under 20 years of age.[360] Dysgerminoma made up 6% of 188 childhood ovarian neoplasms collected by Abell et al.[361] Approximately 5% of dysgerminomas arise in abnormal gonads: pure or mixed gonadal dysgenesis (from a gonadoblastoma) or testicular feminization (androgen insensitivity) syndrome. Exceptionally, the tumor is associated with hypercalcemia.[362]

Dysgerminoma is somewhat more common on the right side and is bilateral in 15% of cases.[360] It is often large (it may reach

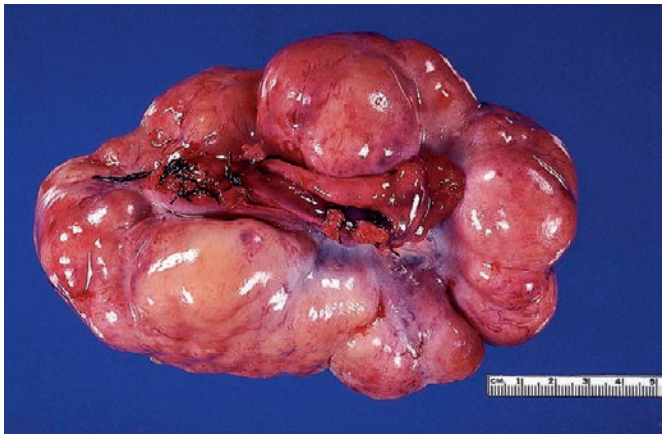

Figure 35.58 Typical lobulated outer aspect of ovarian dysgerminoma.

Figure 35.59 Cut Surface of Ovarian Dysgerminoma. The multinodular solid quality and the tan color are characteristic features.

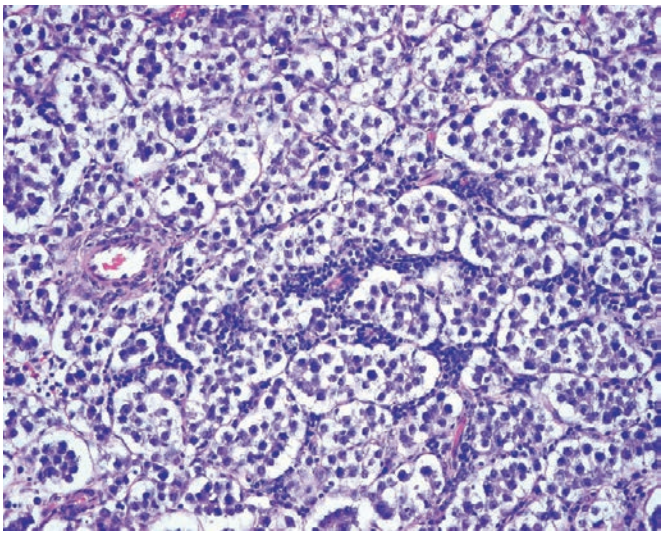

Figure 35.60 Typical nesting appearance of ovarian dysgerminoma. The septa contain numerous inflammatory cells.

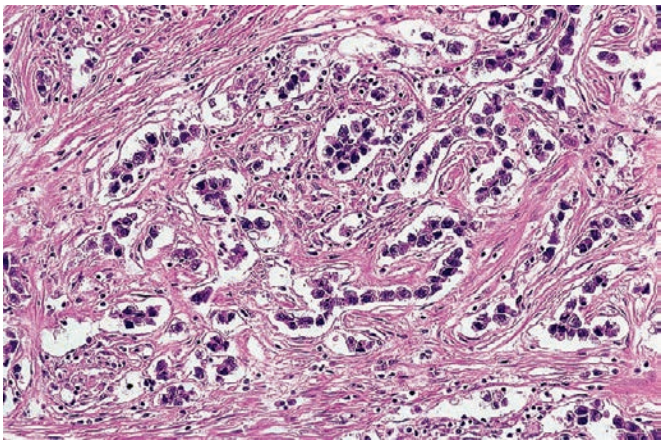

Figure 35.61 The thin trabecular pattern that dysgerminomas sometimes exhibit may be the source of diagnostic errors.

over 1000 g) and encapsulated, with a smooth, often bosselated surface (Fig. 35.58). The cut surface is solid and gray; foci of hemorrhage and necrosis can occur, but they are not as common or prominent as in other malignant germ cell tumors (Fig. 35.59). Microscopically, the tumor cells usually group themselves in well-defined nests separated by fibrous strands infiltrated by lymphocytes (most of which are T cells[363]; Fig. 35.60). Occasionally, a pseudotubular, alveolar, or cordlike arrangement may be seen (the latter particularly at the tumor periphery), which may be quite confusing (Fig. 35.61).[364] Focal necrosis, hyaline changes in vessels, germinal centers, and granulomatous foci may be present. The individual tumor cells are uniform and have large "squared-off" nuclei, *one or more prominent elongated purple nucleoli*, and abundant clear to finely granular cytoplasm that contains glycogen and sometimes fine droplets of fat. The cell membrane is prominent.

Immunohistochemically, the tumor cells are consistently reactive for PLAP and CD117, variably for keratin (erratically and focally), and sometimes for GFAP and desmin but not for CD30.[365–368] OCT4, a transcription factor involved in the regulation of pluripotency during embryonic development, stains the cells of dysgerminoma, the germ cell component of gonadoblastoma, and embryonal carcinoma, but not yolk sac tumor.[369] SALL4 is typically positive.[370]

The microscopic pattern, ultrastructural appearance, immunohistochemical and cytogenetic profiles, clinical behavior, and probable histogenesis (from indifferent or primordial germ cells) of ovarian dysgerminoma are the same as for classic seminoma of the testis.[371–373] It also commonly shows cytogenetic abnormalities involving chromosome 12p. Like testicular seminoma, ovarian dysgerminoma may exhibit signs of early differentiation toward other types of germ cell elements. These include:

1. Scattered hCG-positive syncytiotrophoblastic cells, often in close proximity to blood vessels or to hemorrhagic foci (Fig. 35.62).[374] This change, seen in approximately 3% of all dysgerminomas, may be accompanied by serum elevation of hCG and tissue immunoreactivity for this marker.
2. Abortive yolk sac elements, accompanied by serum elevation of alpha-fetoprotein and tissue immunoreactivity for this marker (Fig. 35.63).[375]

As with the equivalent testicular examples, it is not clear whether these changes alter the prognosis of dysgerminoma, and it is, therefore, important to distinguish them from dysgerminoma admixed with choriocarcinoma, embryonal carcinoma, or yolk sac tumor, a phenomenon that occurs in approximately 8% of cases and that affects prognosis significantly.

Metastases of dysgerminoma occur more commonly in the contralateral ovary, retroperitoneal nodes, and peritoneal cavity.

The survival rate of pure dysgerminoma is 95%. The initial treatment of unilateral dysgerminoma is oophorectomy. Chemotherapy is the treatment of choice for this tumor when it has spread beyond the ovary.

Yolk Sac Tumor and Embryonal Carcinoma

The history of these two germ cell neoplasms of the ovary is replete with confusing, contradictory, and sometimes erroneous statements as to their origin, relationship, and natural history. Yolk sac tumor was included in Schiller's original description of mesonephroma,[376] together with the ovarian tumor presently designated as clear cell carcinoma.[377] Once it was realized that the latter has a different histogenesis, morphologic appearance, and natural history, the analogy became no longer tenable. The next generation of articles on the subject clearly separated these two neoplasms but used more or less interchangeably the terms *yolk sac tumor* and *embryonal carcinoma*. Since both of these neoplasms are of germ cell derivation, share many morphologic features, and are closely related histogenetically, this is not entirely inappropriate.[378] However, enough differences exist between the two to justify their separation.

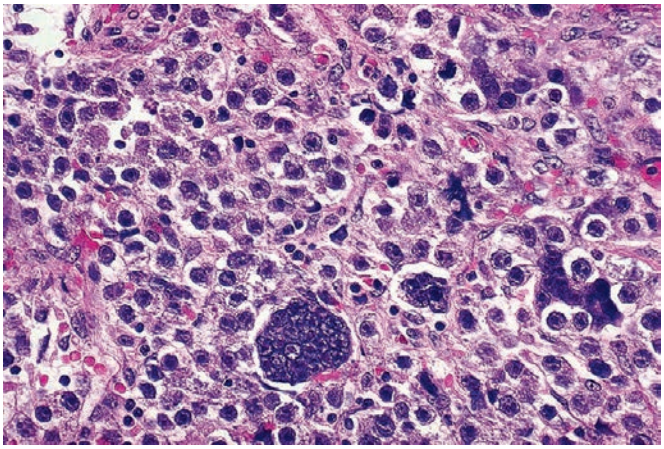

Figure 35.62 Isolated multinucleated cells of trophoblastic type in ovarian dysgerminoma.

Yolk sac tumor (endodermal sinus tumor) is generally a neoplasm of children and young adults (median age, 19 years).[379] In the series of Kurman and Norris,[380] 23% of the patients were prepubertal at the time of diagnosis. None of the patients presented with precocious puberty, amenorrhea, or hirsutism. Vaginal bleeding occurred in only 1%. The serum alpha-fetoprotein level was invariably elevated, whereas the chorionic gonadotropin levels were normal, resulting in consistently negative pregnancy tests. Grossly, the tumors had an average diameter of 15 cm, a smooth and glistening external surface, and a variegated cut surface, partially cystic and often containing large foci of hemorrhage and necrosis (Fig. 35.64). A component of benign cystic teratoma was identified in 10 of the 71 cases.

Exceptionally, a yolk sac tumor will be found in the pelvis (in close proximity to the uterus), omentum, or mesentery, unattached to the ovary.[381–383]

Microscopically, the appearance of yolk sac tumors is extremely variable.[384] There are reticular or microcystic areas formed by a loose meshwork lined by flat or cuboidal cells (Fig. 35.65), rounded or festooning pseudopapillary processes with central vessels (Schiller–Duval bodies), and solid areas. The mesenchyme-like component of these tumors has pluripotential properties; it usually presents in the form of spindle cells in a well-vascularized myxoid background, but it exhibits keratin immunoreactivity as a sign of early epithelial differentiation and may contain heterologous elements such as skeletal muscle.[385]

Intracytoplasmic and extracellular PAS-positive hyaline droplets are nearly always present. Their chemical composition is heterogeneous; they usually stain for alpha-fetoprotein, but they may also

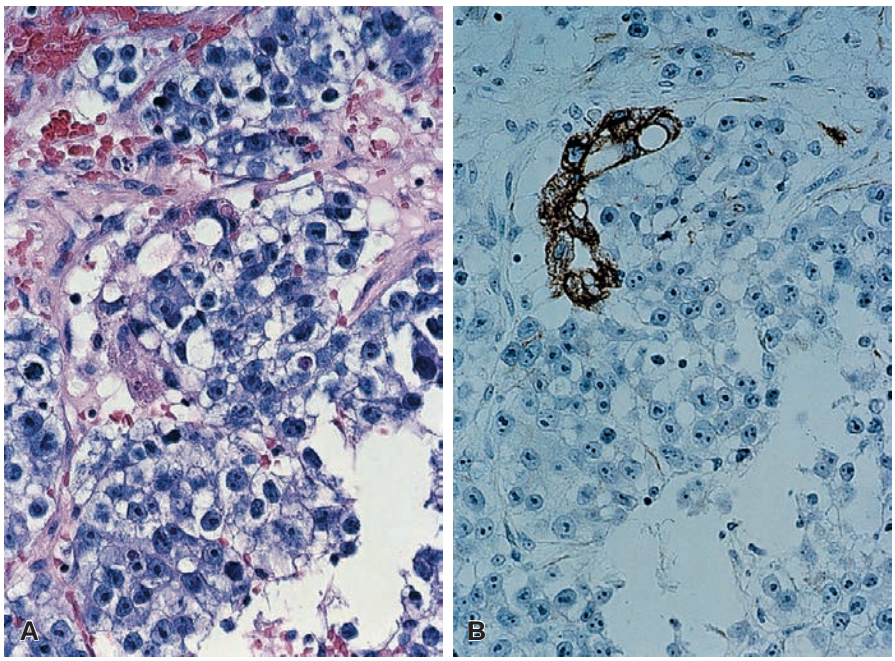

Figure 35.63 Ovarian Dysgerminoma With Early Yolk Sac Differentiation. A, H&E appearance. The foci of early yolk sac differentiation are represented by the small gland-like structures near the center. **B,** This formation is strongly immunoreactive for keratin, in contrast with the rest of the neoplasm. (Courtesy of Dr. Vinita Parash, New Haven, CT.)

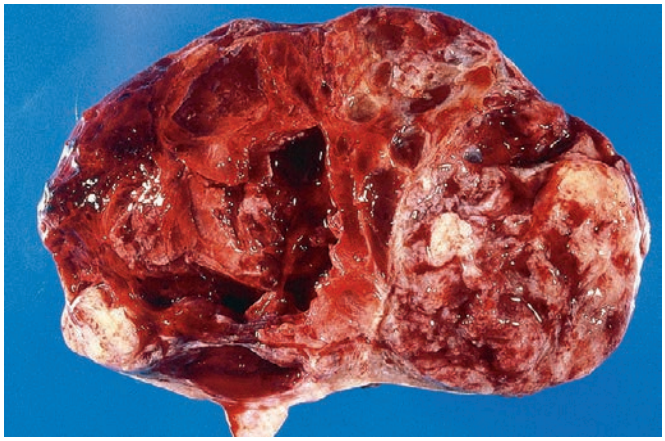

Figure 35.64 Gross appearance of yolk sac tumor. The cut surface is remarkably heterogeneous due to extensive hemorrhage, necrosis, and cystic degeneration.

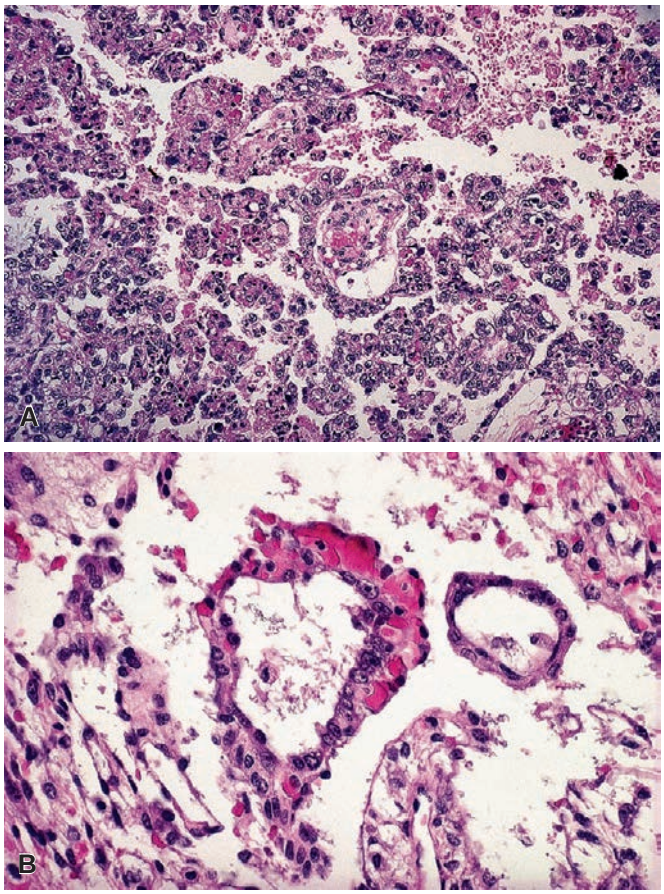

Figure 35.65 **A** and **B,** Low- and high-power views of ovarian yolk sac tumor. Numerous hyaline globules are seen in the cytoplasm of the tumor cells lining the papillae.

contain α1-antitrypsin and basement membrane components (type IV collagen and laminin).[386] Yolk sac tumor also stains for pankeratin but not for keratin 7 or EMA (in contrast with endometrioid and clear cell ovarian carcinoma), or for WT1 (in contrast with serous ovarian carcinoma).[387] They also exhibit positivity for SALL4 and glypican 3,[388] a property they share with testicular and extragonadal yolk sac tumors.[389] However, OCT4 is typically negative. DNA ploidy studies have shown that yolk sac tumors are almost invariably aneuploid.[390]

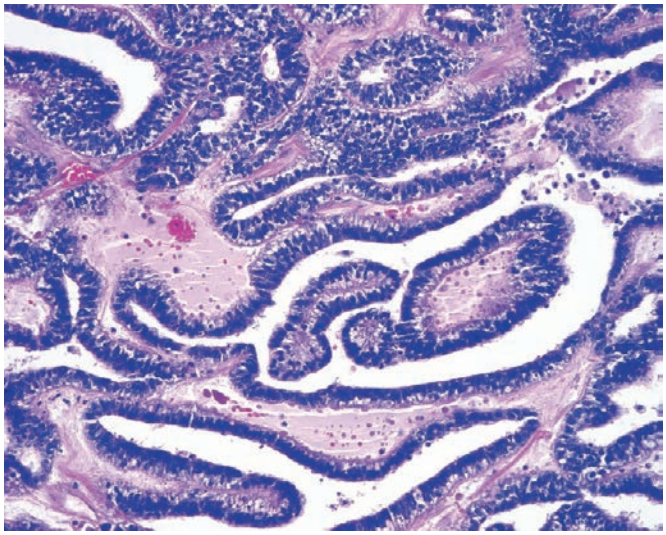

Figure 35.66 Yolk sac tumor with endometrioid features.

A fourth of the yolk sac tumors have vesicular structures with eccentric constrictions surrounded by a dense spindle cell stroma; this has been referred to as a *polyvesicular vitelline pattern* and is said to be associated with a good prognosis when present in a pure form.[391] Others show a scattered hCG-positive syncytiotrophoblast component. Still others exhibit evidence of differentiation toward hepatic, intestinal, and parietal yolk sac structures.[392] The latter are recognized by the presence of thick layers of intercellular basement membrane.[393] The *hepatoid* component, which can predominate almost to the exclusion of the others, is composed of masses, nests, and broad bands of large polyhedral cells with occasional glandular formations and numerous hyaline bodies. Their immunohistochemical profile is similar to that of hepatocellular carcinoma, including reactivity for α1-antitrypsin and a canalicular staining pattern with polyclonal CEA.[394,395] These hepatoid yolk sac tumors are to be distinguished from *hepatoid ovarian carcinomas*, rare tumors of epithelial origin.[396] In some yolk sac tumors, the presence of *glandular* formations may simulate the appearance of endometrioid carcinoma (Fig. 35.66).[397] An exceptional event in ovarian yolk sac tumor is the presence of mucinous carcinoid tumor as a manifestation of endodermal differentiation.[398]

Areas of luteinized stromal cells may be present and may sometimes be responsible for virilization.

An important phenomenon in the differential diagnosis of yolk sac tumor of germ cell origin is the occurrence of typical yolk sac tumor in older women, sometimes in association with an epithelial malignancy such as clear cell carcinoma.[399] These yolk sac tumors of presumed somatic cell origin are analogous to the well-known phenomenon of choriocarcinomatous differentiation in poorly differentiated carcinomas from a number of different primary sites[400] and should be distinguished from yolk sac tumors of germ cell origin. The patient's age can usually serve to make this distinction as those of somatic cell origin arise in the elderly.

Teilum's brilliant hypothesis that this tumor recapitulates normal yolk sac elements[377] has been amply confirmed by histochemical and ultrastructural studies,[401–403] including the detection of GATA4, a transcription factor that regulates the differentiation and function of murine yolk sac endoderm.[404]

In the series of Kurman and Norris,[380] from more than 40 years ago, the actuarial survival at 3 years was only 13%; although 71%

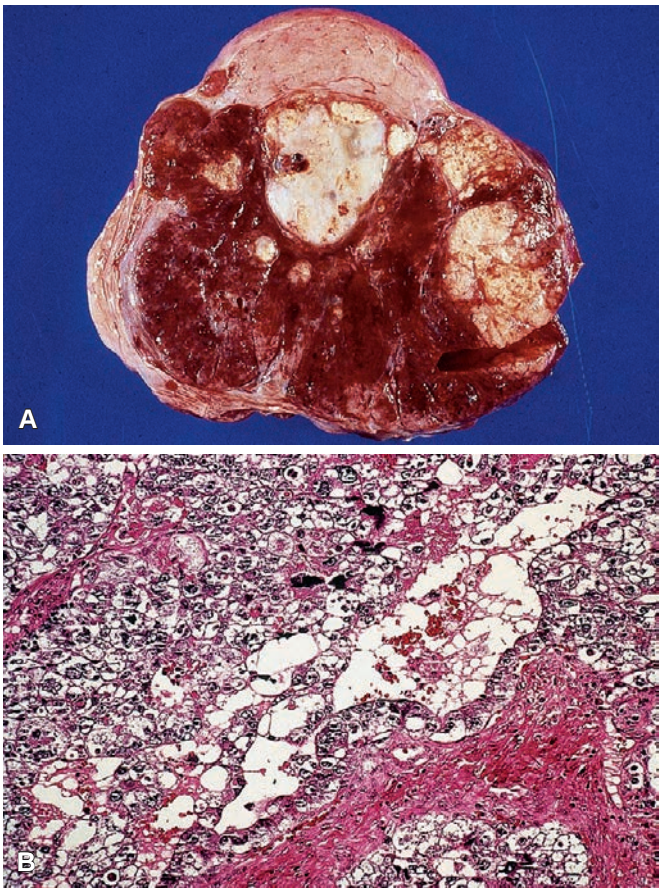

Figure 35.67 **A** and **B**, Gross and microscopic appearance of embryonal carcinoma of ovary.

of the patients were thought to have stage I tumors, subclinical metastases were present in 84%. The introduction of multidrug chemotherapy has dramatically improved survival rates.[405] As usual, clinical stage is the most important prognostic indicator.[385,406] Serial determinations of serum alpha-fetoprotein are useful in monitoring the tumor course.[407,408]

Embryonal carcinoma also occurs in a young age group (median age, 15 years). In one series, 47% of the patients were prepubertal at the time of diagnosis, and 43% of them presented with precocious puberty.[409] Vaginal bleeding was recorded in 33%, amenorrhea in 7%, and hirsutism in 7%. Serum chorionic gonadotropin levels are invariably high, to a level that may result in consistently positive pregnancy tests.

Grossly, the median diameter of these neoplasms is 17 cm, on average. Their external surface is smooth and glistening, and their cut surface is predominantly solid and variegated, with extensive areas of necrosis and hemorrhage (Fig. 35.67). Microscopically, this tumor has a similar appearance to the embryonal carcinoma of the adult testis. As such, it is composed of solid sheets and nests of large primitive cells, occasionally forming papillae and abortive glandular structures (see Fig. 35.67). Syncytiotrophoblast-like tumor cells are frequently seen scattered among the smaller cells; these are immunoreactive for hCG. Embryonal carcinoma shows immunoreactivity for pan-keratin, CD30, OCT4, and SALL4.[410] In the Kurman and Norris series,[421] the prognosis was somewhat better than for yolk sac tumor, but current multidrug chemotherapeutic regimens have erased these differences.[380,411]

Embryonal carcinomas largely composed of embryoid bodies are referred to as *polyembryomas*.[360]

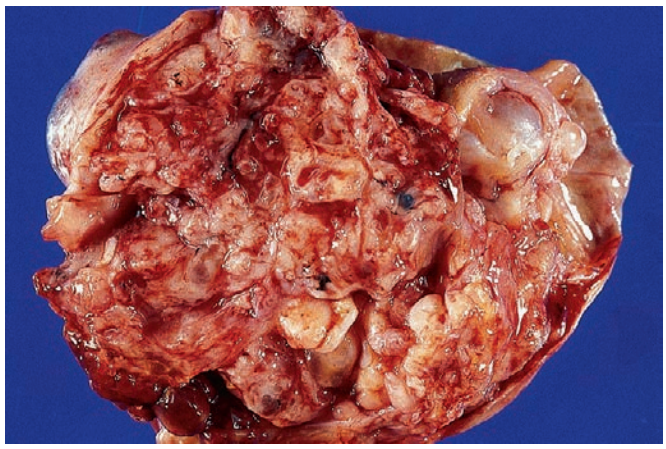

Figure 35.68 Gross appearance of ovarian immature teratoma.

Choriocarcinoma

Most choriocarcinomas involving the ovary represent metastases from uterine tumors. The exceedingly rare primary ovarian choriocarcinomas can develop from an ovarian pregnancy (gestational type, which is the most common) or as a form of germ cell neoplasm (nongestational).[412] The latter can be pure or, more frequently, a component of a mixed germ cell tumor. If pure, DNA typing may be required to distinguish between a gestational choriocarcinoma, containing paternal DNA, and nongestational choriocarcinoma of maternal germ cell origin. Microscopically, they show the typical admixture solid cytotrophoblastic elements enveloped by a rim of syncytiotrophoblast, often in a necrotic and hemorrhagic background. This should be distinguished from aggregates of syncytiotrophoblasts admixed with other germ cell elements (e.g. yolk sac tumor or embryonal carcinoma), which should not alter the diagnosis. Immunohistochemical reactivity for hCG is the rule.

Ovarian choriocarcinomas of either gestational or nongestational type should be distinguished from the exceptionally rare ovarian carcinomas of epithelial origin exhibiting choriocarcinomatous differentiation, a phenomenon analogous to that sometimes seen in carcinomas of the lung, breast, endometrium, gallbladder, and other sites.[413] Patients with choriocarcinomatous differentiation arising in an epithelial malignancy are typically considerably older than those with ovarian choriocarcinoma of either germ cell or gestational origin.

Ovarian gestational choriocarcinomas have a better prognosis than their nongestational counterparts.[400]

Immature Teratoma

Immature teratoma is the currently preferred term for the malignant ovarian teratoma usually seen in children and adolescents and composed of a mixture of embryonal and adult tissues derived from all three germ layers, regardless of its gross appearance (Fig. 35.68). Any type of tissue may be represented. The main component is usually neuroepithelial, but mesodermal elements are also common (Fig. 35.69).[414] Some tumors are predominantly composed of endodermal derivatives, including esophagus, liver, and intestinal structures.[415]

Staining for GFAP is helpful in the identification of mature and immature glial tissue.[416] It should be noted, however, that GFAP is also detectable in chondrocytes.[417]

Grossly, immature teratoma may be solid throughout, solid with multiple minute cysts, or predominantly cystic. Grading of immature

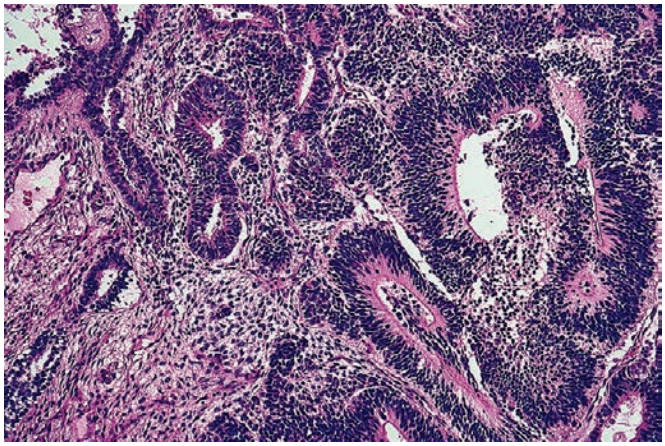

Figure 35.69 Ovarian immature teratoma with predominance of primitive neuroepithelial elements.

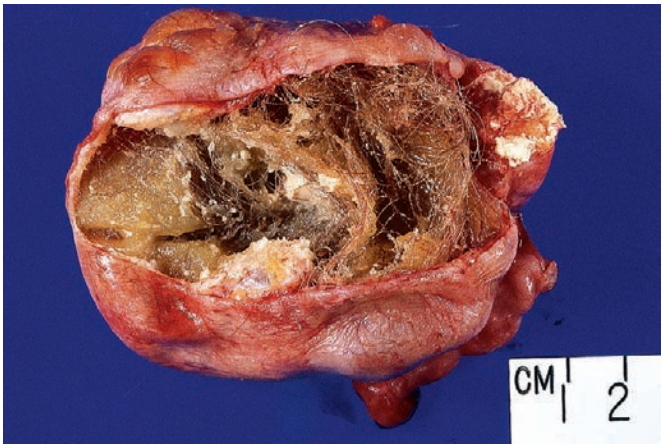

Figure 35.70 Admixture of sebum and hair within the cavity of an ovarian mature cystic teratoma.

teratomas is done based on the WHO 2014 recommendations; grade 1 immature teratomas behave in a benign fashion, while grade 2 and 3 immature teratomas are malignant and can be referred to collectively as "high-grade" immature teratoma. The grading system is as follows:

Grade I, Rare foci of immature neuroepithelial tissue (<1 low power field in any slide)
Grade II, Occasional foci of immature neuroepithelium with mitoses, *not exceeding* three low power fields in any one slide
Grade III, Few or no mature tissues; numerous neuroepithelial elements, merging with a cellular stroma *occupying* four or more low power fields per slide.

Obviously, a thorough tumor sampling is necessary for this grading system to be accurate.

It is important to separate from this group the teratomas that also have yolk sac or embryonal carcinoma patterns.[418] On occasion, an ovarian immature teratoma can be predominantly or exclusively composed of one type of tissue. Neoplasms with an exclusive or almost exclusive malignant neuroectodermal composition are designated **malignant neuroectodermal tumor** and are generally regarded as a form of monodermal teratoma.[419,420] A variation on the theme is the ovarian **ependymoma**, in which this neuroectodermal component is made up entirely of primitive ependymal structures.[420–422] Other teratomas have a prominent component of renal (metanephrogenic),[423] retinal anlage,[424] or skeletal muscle (rhabdomyosarcomatous) nature.[425]

A sometimes confusing pattern seen in teratomas, usually in connection with the neuroectodermal component, is the presence of florid vascular proliferation,[426] a phenomenon possibly due to the secretion of angiogenic factors by the tumor cells and which has also been recorded at other sites.[427]

Another peculiar morphologic change sometimes encountered in these tumors is membranous fat necrosis, perhaps secondary to torsion and ischemia.[428]

The treatment of immature teratoma consists of surgery plus multidrug chemotherapy for grade 2 or grade 3 tumors[429–431]; sometimes, only mature tissue is found in metastatic sites following chemotherapy, a sign of excellent prognosis.[416] It is interesting, however, that the abnormal karyotype of the original immature teratoma is maintained in the area of chemotherapy-induced maturation.[432] This mature tissue may continue to grow (the growing teratoma syndrome, more commonly observed with testicular germ cell tumors), but the growth is self-limited if all tissues are mature and masses formed can be observed, without further treatment.[433]

Mature Solid Teratoma

Mature solid teratoma has a predominantly solid gross appearance, but multiple small cystic areas also are present. By definition, the tumor should be *composed entirely of adult tissues* derived from all three germ layers.[434,435]

Clearly, extensive sampling is needed to separate this tumor from a grade 1 immature teratoma. The two tumors are closely related, and the distinction is somewhat subjective; as a matter of fact, some authors refer to mature solid teratoma as "grade 0" immature teratoma.

This rare neoplasm occurs in young women, predominantly in the second decade. The prognosis is excellent, even if peritoneal implants (also mature and for the most part glial in composition) are present.[436]

Mature Cystic Teratoma

Mature cystic teratomas make up almost 20% of all ovarian neoplasms. They constitute the most common ovarian tumor in childhood.[332] They are unilateral in 88% of cases and typically provoke only symptoms relating to the mass. Occasionally, however, they are accompanied by hemolytic anemia,[437,438] virilization,[439,440] or paraneoplastic encephalitis.[441] The latter is often associated with autoantibodies against N-methyl-D-aspartate (NMDA) receptor; teratoma (mature or immature) is the most common neoplasm found in association with this particular paraneoplastic syndrome, and resolution of symptoms, consisting of psychiatric manifestations and/or neurological deficits, occurs in most patients after removal of the teratoma. A moving account of this condition, from the patient's perspective, is provided in the memoir "Brain on Fire" by Susannah Cahalan. Grossly, they are usually multiloculated. The cystic content is greasy, largely composed of keratin, sebum, and hairs (Fig. 35.70). Teeth are often present (Fig. 35.71).[442] Sometimes the tumor contains an imperfectly formed mandible or even a partial human body-like structure (homunculus); the latter are referred to as *fetiform teratomas*.[443] The teeth tend to be located in a well-defined nipple-like structure covered with hair, known as *Rokitansky's protuberance*. This structure should be selected for microscopic examination (even if

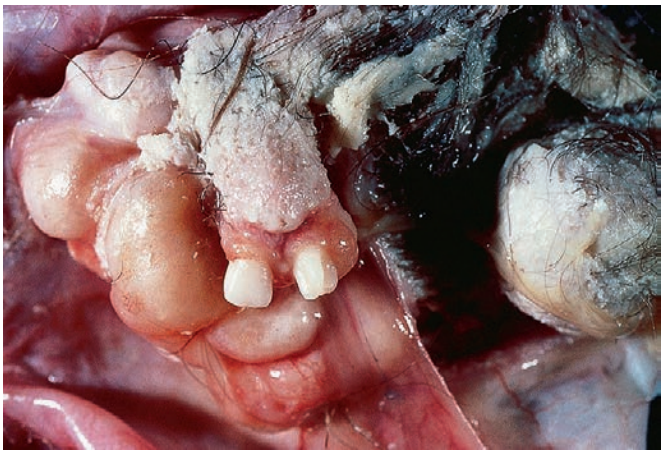

Figure 35.71 Well-developed teeth in ovarian mature cystic teratoma.

decalcification may be required) because it will exhibit the greatest variety of tissue types.

In a classic microscopic study, Blackwell et al.[444] found ectodermal derivatives in 100% of the tumors, mesodermal structures in 93%, and endodermal derivatives in 71%. The cystic cavities are lined by mature epidermis. Skin appendages and neural (particularly glial) tissue are extremely common. The latter may feature meningothelial proliferations and Wagner–Meissner corpuscles and be accompanied by florid vascular proliferation.[445,446] Other common tissue types present are cartilage, respiratory tissue, and gastrointestinal tract tissue (Fig. 35.72). The gastric mucosa can be very well developed anatomically, to the point of containing interstitial cells of Cajal[447]; sometimes it is complicated by peptic ulcer formation.[448] Other tissues include thyroid (10% of cases), various types of melanin-containing tissue (particularly patients with dark skin),[449] anterior pituitary,[450] various types of neuroendocrine cells,[451] prostate,[452,453] pancreas, and cavernous blood vessels. Prominent lymphoid infiltration of glial elements, with germinal center formation, is a feature of teratomas associated with NMDA receptor paraneoplastic syndrome; occasionally the syndrome becomes manifest after removal of the teratoma.[441]

Because of the usual predominance of skin and skin adnexal structures, and also on historical grounds, some authors still prefer the old term dermoid cyst for ovarian mature cystic teratoma. Time-honored considerations aside, we feel that this term is pathogenetically not very informative and that it does not do justice to the plethora of other tissue types that can be present in these tumors.

By definition, all of the components present in mature cystic teratomas should appear histologically mature. However, on occasions one sees microscopic foci of immature (to be distinguished from malignant, see later) tissue in them. The behavior of these tumors, which can be considered to be grade 1 immature teratomas, is usually benign, with no further treatment required beyond surgical removal.[454]

Mature cystic teratomas may coexist with Brenner tumor and thecoma.[455,456]

On occasion, teratomas rupture into the abdominal cavity; when this occurs, the keratin and sebum present in the lumen may provoke a prominent foreign body reaction that can look like metastatic cancer to the surgeon, who may be incredulous when the surgical pathologist goes back to him or her with a benign diagnosis (but not incredulous enough to accept a risky bet about it; Fig. 35.73).[457,458]

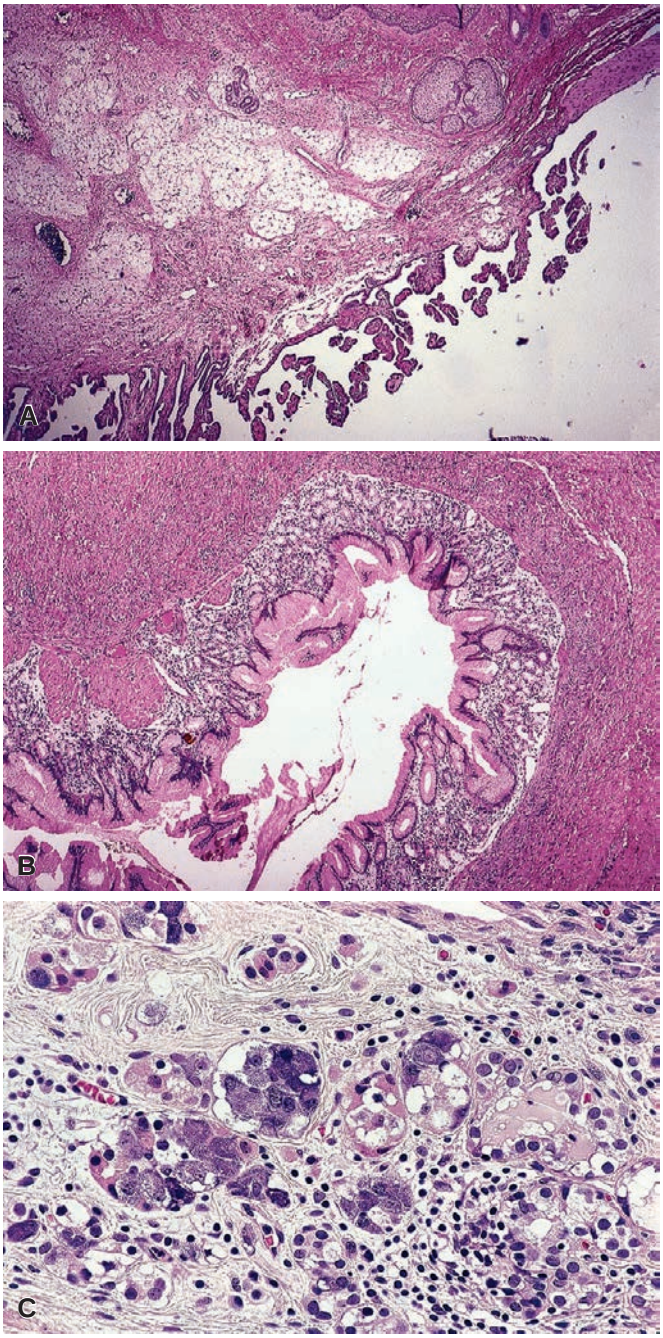

Figure 35.72 Various Tissue Components of Mature Cystic Teratoma of Ovary. A, Skin adnexa, glial tissue, and choroid plexus; **B,** gastric mucosa of pyloric type; **C,** anterior pituitary gland.

In other instances, mature ovarian teratomas of either the cystic or solid variety—as well as immature teratomas—may be accompanied by peritoneal nodules exclusively composed of mature glial and neuronal tissue, a condition known as *gliomatosis peritonei* (Fig. 35.74).[459–462] These nodules appear grossly as miliary grayish-white nodules in the peritoneal surface or omentum and may be accompanied by fibrosis and chronic inflammation. This is a benign process, as long as the glial tissue is entirely mature and unaccompanied by other teratomatous elements (Fig. 35.75).[463–465] Another teratoma-related process is peritoneal "melanosis," which can also follow the rupture of a cystic teratoma.[466]

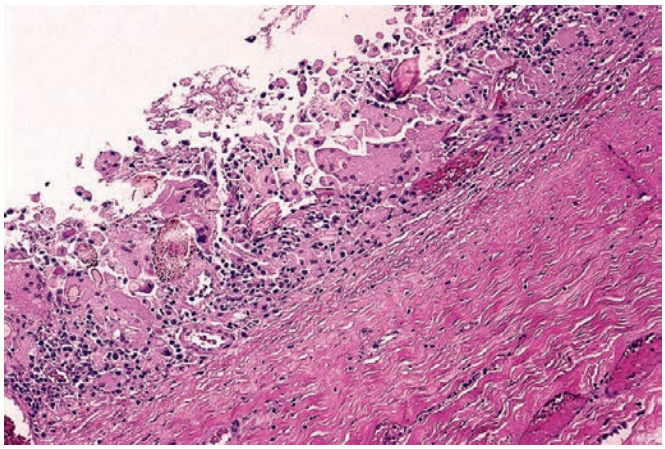

Figure 35.73 Exuberant foreign body-type giant cell response to contents of ruptured ovarian mature cystic teratoma. These changes may simulate grossly the appearance of tuberculous peritonitis or metastatic carcinoma.

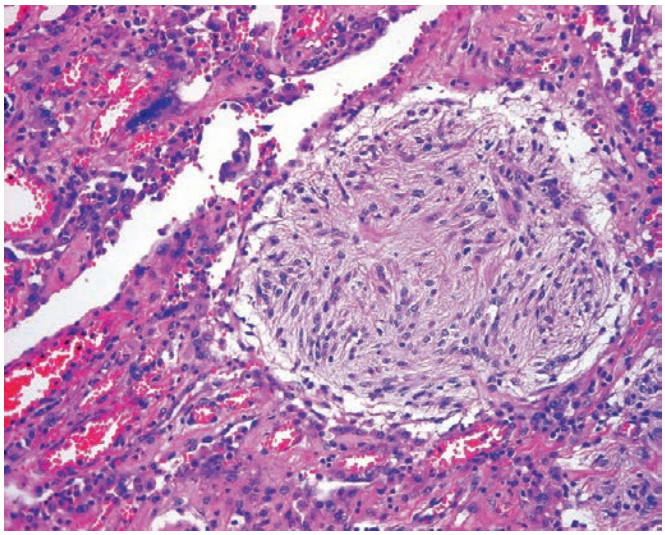

Figure 35.74 Peritoneal implant of mature glial tissue associated with an ovarian teratoma (so-called gliomatosis peritonei).

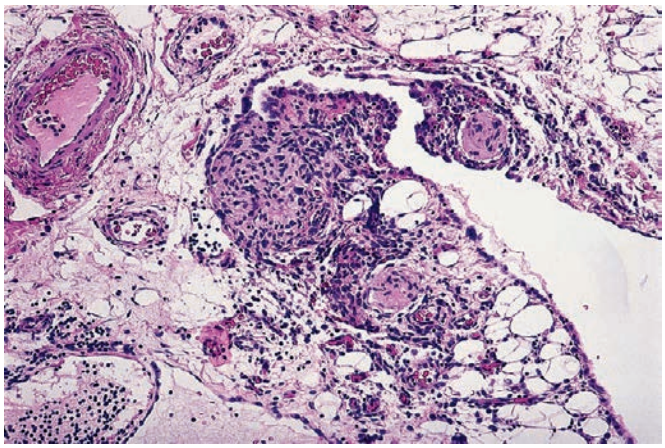

Figure 35.75 Peritoneal implants secondary to immature ovarian teratoma. When the appearance of the implants is immature, as shown here, the prognosis is more guarded than in gliomatosis peritonei (compare with Fig. 35.74).

"Somatic-type" Tumors Developing in Mature Cystic Teratoma

Emergence of a benign or a malignant neoplasm with somatic-type features is an uncommon event in mature cystic teratoma, occurring in approximately 2% of all cases.

The most common malignant change in cystic teratoma is squamous cell carcinoma (possibly arising from metaplastic columnar epithelium),[467] followed by carcinoid tumor and adenocarcinoma.[468–471] These ovarian squamous cell carcinomas typically present in the 5th or 6th decade, suggesting that transformation requires prolonged contact between the epithelium and the cyst contents. The prognosis of squamous cell carcinoma arising from a teratoma is guarded and these tumors are characterized by aggressive locally invasive growth.[469] Other types include malignant melanoma,[472,473] Paget disease,[474]sarcomas of various types, carcinosarcoma, glioblastoma multiforme,[475] central-type neurocytoma,[476] and neuroblastoma/PNET.[477,478] This malignant transformation is accompanied by complex chromosomal aberrations.[479] An interesting twist is the occurrence of mucinous borderline tumors and adenocarcinomas similar to appendiceal neoplasms and resulting in pseudomyxoma peritonei.[480–482] These mucinous tumors arising in association with teratoma have a complete intestinal immunophenotype, indistinguishable from that of colorectal neoplasms. In an elegant study by Kerr et al., they were able to demonstrate, by DNA typing, that these mucinous neoplasms associated with a teratoma are of germ cell origin, while those without a teratomatous component are of somatic origin.[201] The teratoma component may be inconspicuous or consist of a monodermal component such as a carcinoid tumor.

Benign tumors have also been described, such as blue nevus,[483,484] sebaceous adenoma,[485] sweat gland tumors,[486] glomus tumor,[487] epithelioid (histiocytoid) hemangioma,[488] and various types of pituitary adenoma.[489,490]

Epidermoid Cyst

The rare **epidermoid cyst** of the ovary possibly arises from epithelial cell nests, of the type encountered in Brenner tumors.[65] It is distinguished from mature cystic teratoma on thorough sampling by the absence of skin adnexa and other tissues. It is discussed here not only in the light of this differential diagnosis but also because of the distinct possibility that some of these lesions were mature cystic teratomas in which the skin adnexal components were either missed or absent.

Struma Ovarii

Struma ovarii is the expression of the dominant growth of thyroid tissue in a teratoma, sometimes to the exclusion of other components (Fig. 35.76).[491] Grossly, the mass has the color and consistency of thyroid tissue, but it is often cystic (Fig. 35.77). These cystic changes can be very prominent and obscure the diagnosis, and result in a misdiagnosis of serous cystadenoma.[492,493] The thyroid nature of the lesion has been fully documented with biologic and immunohistochemical studies for TTF-1 and thyroid hormones.[494] The tissue may show any of the pathologic changes seen in a normally placed gland, including diffuse or nodular hyperplasia (which may lead to hyperthyroidism[495]), thyroiditis, papillary carcinoma (including the follicular or microcarcinoma variants[496] and featuring either *RAS* or *BRAF* mutation),[497,498] follicular carcinoma (sometimes resulting in peritoneal spread, so-called peritoneal strumosis),[499,500] and malignant lymphoma.[494,501] Some of the carcinomas are extremely well differentiated,[498,499,502] whereas others have a predominantly solid or trabecular pattern.[493]

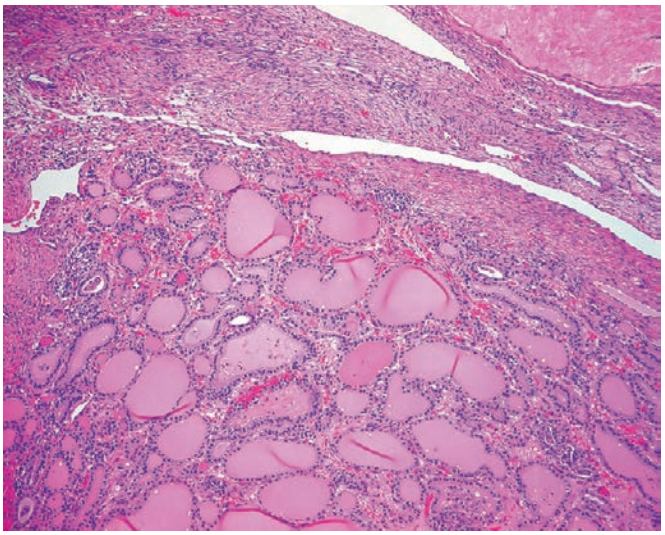

Figure 35.76 Struma Ovarii. The thyroid tissue, which has a microscopically unremarkable appearance, is sharply delimited from the ovarian stroma.

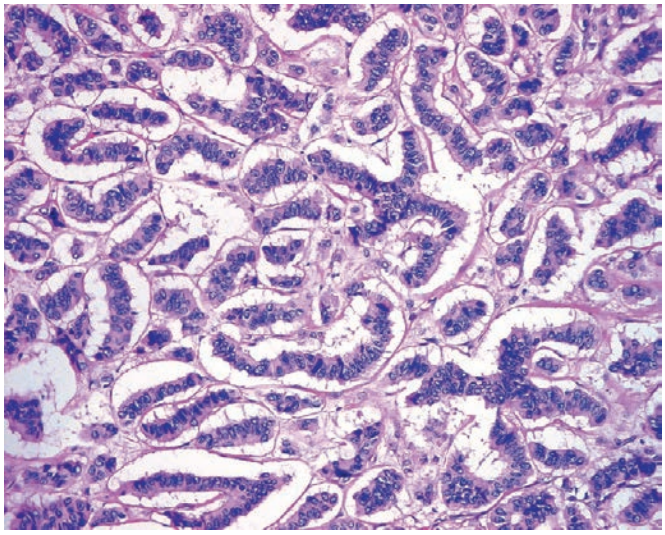

Figure 35.79 Primary Ovarian Carcinoid Tumor With a Trabecular Pattern of Growth. There is a close resemblance to carcinoid tumors of lung and rectum.

Struma ovarii can be seen combined with mucinous cystadenoma, Brenner tumor, or carcinoid tumor. The latter combination, known as strumal carcinoid, is discussed in the following section.

Carcinoid Tumor and Strumal Carcinoid

Carcinoid tumor can be seen in the ovary as a metastasis of a primary tumor located in the gastrointestinal tract or elsewhere,[503] as a component of adult cystic teratoma, or as a primary pure neoplasm of this organ. Approximately one-third of the latter are associated with the carcinoid syndrome, even in the absence of liver metastases[504]; the larger the tumor, the more likely that the carcinoid syndrome will develop. Some cases present with severe constipation, presumably because of secretion of peptide YY.[505] Small tumors arising in cystic teratomas are nearly always asymptomatic. The large majority of primary ovarian carcinoid tumors are unilateral, but in 16% of cases the contralateral ovary is involved by a cystic teratoma or a mucinous neoplasm.[506] In contrast, most metastatic carcinoid tumors to the ovary are bilateral and associated with peritoneal metastases. The prognosis in primary ovarian carcinoid tumors (whether pure or as a component of cystic teratoma) is very good, whereas metastatic carcinoids have a poor outcome.

Grossly, pure primary carcinoid tumors have a mean diameter of 10 cm; their external surface is smooth or bosselated, and the cut surface is predominantly solid, firm, tan to yellow, and homogeneous (Fig. 35.78). Microscopically, the appearance is similar to that of carcinoid tumors elsewhere, in that they recapitulate the various patterns of this well-differentiated neuroendocrine tumor as seen in various sites. Thus, there are tumors with an *insular* pattern of growth similar to those seen in the appendix and small bowel, tumors with a *trabecular* appearance similar to those seen in the rectum (Fig. 35.79), and tumors with a *mucinous* (goblet cell) appearance similar to those seen primarily in the appendix.[507–509] The similarities also apply to the occasional presence of pleomorphic forms,[510] to their histochemical features (argentaffinity or argyrophilia depending on the type), and to the consistent presence of neurosecretory granules at the electron microscopic level.[511]

Neuron-specific enolase (NSE), chromogranin, 5-HT, and a large variety of peptide hormones (including peptide YY) have been

demonstrated immunohistochemically, particularly in tumors of the trabecular type.[505,512]

It is not possible to separate primary from metastatic carcinoid tumors on morphologic grounds; however, if the ovarian carcinoid is admixed with areas of teratoma, the chances are overwhelming that it is of primary origin. Conversely, tumors with goblet cell carcinoid-like features and signet ring patterns (traditionally known as goblet cell carcinoid tumors, see Chapter 16) are likely to be metastases from the appendix.[513] A potential pitfall should be mentioned here: primary ovarian carcinoid tumors and those metastatic from the gastrointestinal tract show identical immunoprofiles (e.g. expression of CDX2),[514] so immunohistochemistry is not helpful in distinguishing primary from metastatic carcinoid tumor.

Excision of a primary ovarian carcinoid of insular or trabecular type is usually curative. As in the appendix, the behavior of the mucinous type is more aggressive, particularly if the tumor contains a clear-cut carcinomatous component.[507]

Strumal carcinoid is an ovarian neoplasm combining the features of carcinoid tumor and struma ovarii (Fig. 35.80).[515] There was some question about the thyroidal nature of the latter element on the basis of ultrastructural studies, but the immunohistochemical demonstration of thyroglobulin and TTF-1,[516,517] and the occasional occurrence of thyroid-type papillary microcarcinomas[518] have settled the issue. The interesting suggestion has been made that the carcinoid-like component represents a medullary carcinoma arising from thyroid C cells,[519] but the morphologic appearance and immunohistochemical profile of the tumor are more akin to those of a trabecular carcinoid of hindgut derivation[520,521]; specifically, calcitonin and amyloid are only rarely demonstrable.[522] It is of interest that these tumors also exhibit immunoreactivity for prostatic acid phosphatase in the carcinoid component, as further evidence of their similarity to rectal (hindgut-type) carcinoids.[523] The occasional occurrence of severe constipation, presumably due to secretion of peptide YY,[511] and of carcinoid heart disease[524] also link it with pure ovarian carcinoid tumor. Exceptionally, the carcinoid component is of mucinous type.[525]

Other teratomatous elements are found in over 50% of the cases of strumal carcinoid.[504] This lesion has also been observed in association with multiple endocrine neoplasia type 2a.[526]

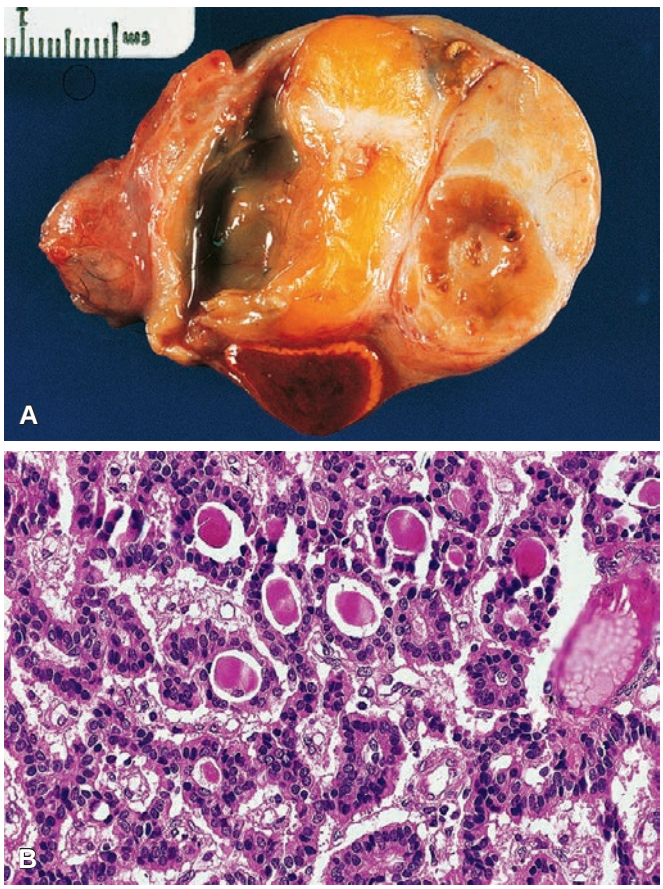

Figure 35.80 **A**, Gross appearance of strumal carcinoid showing a variegated appearance resulting from the admixture of carcinoid tumor and struma ovarii. **B**, Microscopic appearance, showing intimate admixture of thyroid follicles and carcinoid trabecula.

Sex Cord–Stromal Tumors

Sex cord–stromal tumors, which comprise approximately 5% of all ovarian neoplasms, are tumors that differentiate in the direction of sex cords and/or the specialized ovarian stroma.[527] This includes female-type cells (granulosa and theca cells), male-type cells (Sertoli and Leydig cells), and indifferent elements.[528,529] These various elements can occur in combination[530] and exhibit a wide range of differentiation, which often seems to recapitulate the patterns produced during embryogenesis of both the ovary and testis, as proposed many years ago by Gunnar Teilum.[531] Secondary changes, such as luteinization, may also develop. As a result, a wide array of tumor types may be seen, some of which do not fit easily into a rigid classification system. In general, a relationship exists between the morphologic appearance of the tumor and the presence and type of clinically evident hormonal activity.[532–534] However, there may be no demonstrable endocrine effects, and rare examples of hormonal effects opposite to those expected from the morphologic features also occur.[535,536]

Recently, a number of immunohistochemical markers have become available that are of considerable assistance in the identification of these tumors.[537,538] *Inhibin* has emerged as one of the most useful.[539] The α-subunit of the molecule seems to have a greater degree of specificity than the β-subunit.[540,541] It stains all types of sex cord–stromal tumors, the sex-cordlike elements of other gynecologic neoplasms, and most trophoblastic tumors.[542,543] It is also useful for the identification of steroid hormone-secreting cells in the non-neoplastic stroma component of epithelial, germ cell, and other types of ovarian tumor.[544] It has been reported to stain some carcinomas at other sites,[545] but this seems to be due at least in part to endogenous biotin, in older studies where avidin-biotin detection systems were used.[546] It should be also pointed out that negativity for inhibin does not rule out a diagnosis of sex cord–stromal tumor (following the general rule that a negative stain never rules out anything).

Molecules functionally related to inhibin that also stain sex cord–stromal tumors are activin (a molecule biochemically similar to inhibin but with an opposite function, and composed of two βA-subunits), müllerian inhibiting substance (anti-müllerian hormone), and relaxin-like factor.[537,547,548]

Calretinin is more sensitive but less specific than inhibin, in the sense that it often stains sex cord–stromal tumors that are inhibin negative, such as fibromas.[549–551] However, it also stains a good number of surface epithelial neoplasms.

Melan-A is consistently expressed in sex cord–stromal tumors and other types of steroid-producing cells, such as those of ovarian steroid cell tumor and adrenal cortical neoplasms.[552] Like calretinin, however, it lacks specificity as a marker of sex-cord stromal differentiation.

FOXL2 is a transcription factor, expressed in the nuclei of tumor cells; this can be an advantage in staining cells with scant cytoplasm

(e.g. adult granulosa cell tumors and fibromas), where cytoplasmic stains such as inhibin may not be positive.[549] It is a very sensitive marker of sex cord-stromal tumors with the exception of Sertoli–Leydig cell tumors (only 50% stain) and steroid cell tumors (most are negative).

SF-1 (steroidogenic factor 1) is a sensitive sex cord–stromal marker.[553]

WT1, present in normal granulosa cells, is also expressed by a majority of ovarian sex cord–stromal tumors.[542]

Sex cord–stromal tumors of ovarian type are exceptionally encountered in extraovarian locations, such as the broad ligament.[554]

Granulosa Cell Tumor

Granulosa cell tumor is a sex cord–stromal ovarian neoplasm showing differentiation toward follicular granulosa cells. Two distinct types exist, known respectively as adult and juvenile.

Adult granulosa cell tumor is usually diagnosed during childbearing age, but it can occur after menopause and sometimes (despite its name) before puberty. Three-fourths of cases are associated with hyperestrinism; the excessive production of estrogens can lead to isosexual precocious puberty in children[555] and to metrorrhagia in adults, including postmenopausal patients.[556] Some of the cases are hormonally inactive at the clinical level, and a very few are androgenic.[557,558]

Grossly, adult granulosa cell tumors have a smooth, lobulated outline and a predominantly solid cut surface (Fig. 35.81). The color is usually gray, but it may be yellow in areas of luteinization (Fig. 35.82). Cysts filled with straw-colored or mucoid fluid may be present (Fig. 35.83). Sometimes the cysts are so prominent as to simulate grossly the appearance of a cystadenoma (Fig. 35.84). Interestingly, a disproportionate number of androgenic granulosa cell tumors are large and cystic, either unilocular or multilocular.[558,559] The microscopic appearance of granulosa cell tumors is extremely variable, even within the same neoplasm. Patterns of growth include microfollicular (with Call–Exner bodies), macrofollicular, trabecular, insular, watered-silk, solid, pseudopapillary, and diffuse (sarcomatoid) (Fig. 35.85).[560,561] A theca cell component may also be present. Focal luteinization of either the granulosa or the theca cell component may occur[562]; it is particularly prominent in those tumors associated with pregnancy, together with edema and disorderly arrangement.[563] An important diagnostic feature is the presence of folds or grooves in the nuclei, resulting in a "coffee-bean" appearance (Fig. 35.86). Occasionally, bizarre nuclei and multinucleated giant cells (some of the "floret" type) are seen; this change is not a sign of malignancy, but rather of a degenerative nature.[564] Rare cases of granulosa cell tumor have been reported exhibiting hepatocytic differentiation[565,566] and others are associated with mucinous cystadenoma.[567]

Consistent immunohistochemical markers of granulosa cell tumors include vimentin, FOXL2, and SF-1 (see preceding section; Fig. 35.87).[549,556,568–571] Inhibin expression may be weak or absent in

tumors where the cells have very scant cytoplasm, and this is a frequent source of diagnostic confusion. Keratin expression is present in one-third to one-half of cases; it has a typical dot-like distribution and consists mainly of CK8 and CK18 types.[572] Approximately 50% of cases are reactive for S-100 protein, whereas none are immunoreactive for EMA.[573] Estrogen and progesterone receptors are usually expressed.[574] The peptide hormone inhibin and follicle regulatory proteins, two substances normally produced by ovarian granulosa cells, have been found to be elevated in the serum of patients with granulosa cell tumor.[575] Curiously, granulosa cell tumors have also been found to be often immunoreactive for CD99, a marker associated with Ewing sarcoma.[568]

Recently, it has been shown that almost all cases of adult granulosa cell tumor show somatic mutation in the *FOXL2* gene (402C→G),[567,576,577] and this has emerged as a useful diagnostic marker. Except for occasional well- or moderately differentiated Sertoli–Leydig cell tumors, *FOXL2* mutation is specific for adult granulosa cell tumor. Mutational status need not be assessed in a typical adult granulosa cell tumor, but in diagnostically challenging cases, *FOXL2* mutation testing can be invaluable in confirming/excluding adult granulosa cell tumor.[577]

Juvenile granulosa cell tumor is diagnosed in nearly 80% of cases during the first two decades of life, most patients presenting with isosexual precocity (Fig. 35.88). A few cases have been associated with enchondromatosis (Ollier disease)[578] or Maffucci syndrome.[579] Typical morphologic features of this subtype include diffuse or macrofollicular patterns of growth (the former predominating), mucin-positive intrafollicular secretion, larger tumor cells with extensive luteinization, paucity of nuclear grooves, presence of a thecal component, nuclear atypia, and variable but often high mitotic activity (Fig. 35.89).[580,581] Like their adult counterpart, they may exhibit pseudopapillary features.[560] They also show consistent trisomy for chromosome 12.[582]

The differential diagnosis of granulosa cell tumor (particularly of the adult variety) includes poorly differentiated (predominantly

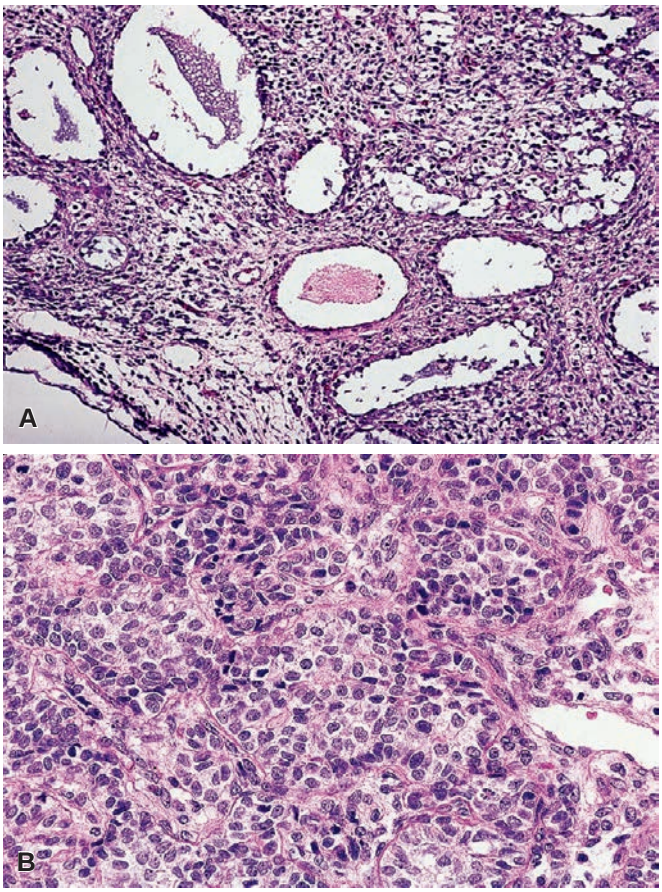

Figure 35.89 Juvenile Granulosa Cell Tumor. The follicle-like spaces seen on low-power examination **(A)** are a common feature of this neoplasm. On high power **(B)** the tumor cells are seen to lack the coffee bean nuclei seen in the adult type.

Figure 35.90 Cut surface of thecoma showing a predominance of yellow areas alternating with whitish foci.

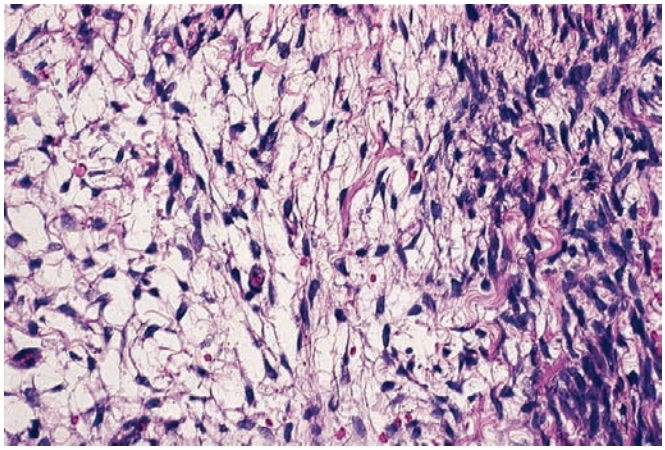

Figure 35.91 Bland microscopic appearance of thecoma, with some variability in cellularity.

solid) carcinoma of surface epithelial origin, carcinoid tumor, and the rare tumors of endometrial stromal type.[542] The nuclear features are of crucial importance in this regard. Some early series describing a poor prognosis for granulosa cell tumors are contaminated with solid-pattern ovarian carcinomas (i.e. tumors of epithelial rather than sex-cord origin).[583] Strong and widespread positivity for keratin should point toward the direction of carcinoma in a controversial case, especially if this positivity is diffuse cytoplasmic rather than dot-like. The differential diagnosis also includes the *ovarian granulosa cell proliferations of pregnancy*; this change is usually microscopic, multiple, and associated with atretic follicles.[584]

The prognosis of granulosa cell tumors is largely dependent on the clinical stage and resectability of the tumor. Adult granulosa cell tumors are indolent, and the prognosis is little different from age matched controls[583]; however, pelvic or upper abdominal metastases do occur, especially in cases with intraoperative tumor rupture. Importantly, these clinical relapses may occur 10 or even 20 years after initial surgery. Juvenile granulosa cell tumors are also associated with a favorable prognosis, especially when confined to the ovary at diagnosis, as is true in most patients.

Thecoma, Fibroma, and Related Tumors

Fibroma and thecoma are closely related tumors, but distinction between them is possible in most cases (although some recommend a diagnosis of *fibrothecoma* for all tumors in this category).

Thecoma presents after menopause in 65% of patients. It is usually unilateral and varies considerably in size. It has a well-defined capsule and a firm consistency. The cut surface is largely or entirely solid, but cysts may be present. It has a yellow color, an important feature in the differential diagnosis with fibroma (Fig. 35.90). Microscopically, it is composed of fascicles of spindle cells with ill-defined borders, centrally placed nuclei, and a moderate amount of pale grayish-pink cytoplasm (Fig. 35.91). The intervening tissue may show considerable collagen deposition and focal hyaline plaque formation. The degree of cellularity varies considerably. Some tumors in young women are heavily calcified.[585]

With oil red O, the cells of thecoma show abundant intracytoplasmic neutral fat, and silver stains usually demonstrate reticulin fibers surrounding individual cells (as opposed to granulosa cell tumor, in which the reticulin surrounds clusters of cells). The differential diagnosis with a luteinized adult granulosa cell tumor can be challenging; *FOXL2* mutational analysis can be of use in such cases, with the presence of a mutation supporting the diagnosis of adult granulosa cell tumor.[577]

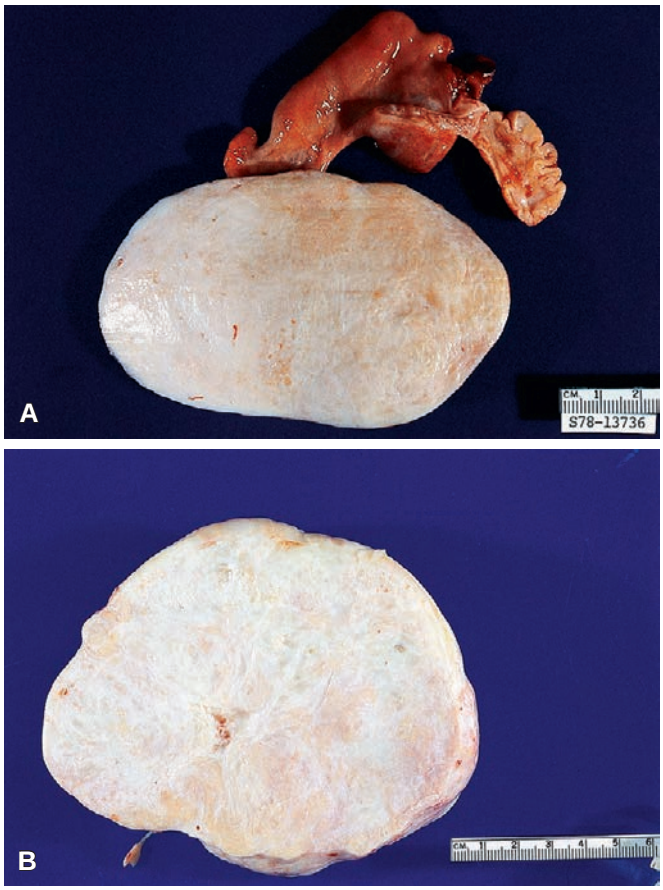

Figure 35.92 **A** and **B,** Outer aspect and cut surface of ovarian fibroma. The white color contrasts with the yellow hue of thecoma (compare with Fig. 35.90).

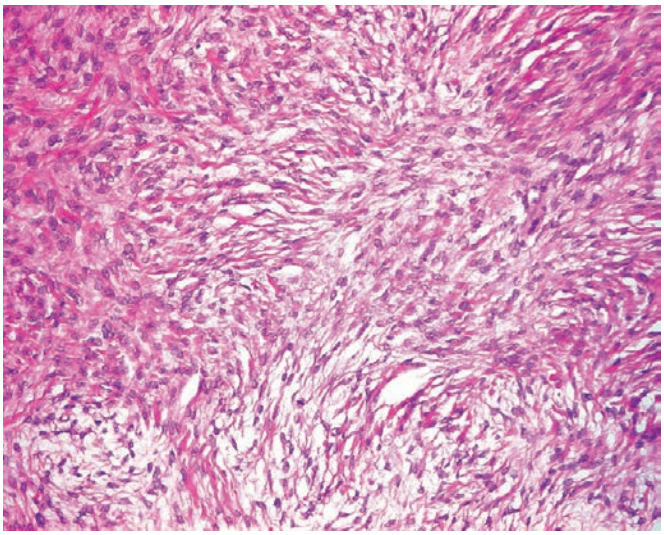

Figure 35.93 Ovarian fibroma showing, bland nuclear features, and a suggestion of a storiform pattern of growth.

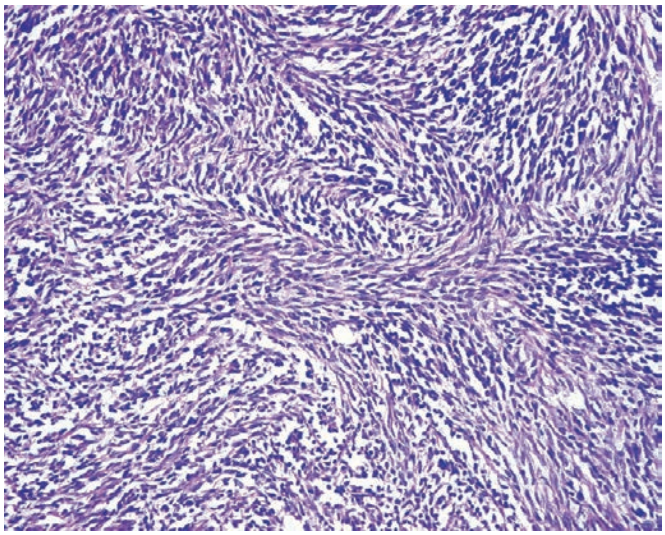

Figure 35.94 Cellular fibroma. The tumor is hypercellular, but pleomorphism and mitotic activity are minimal.

Thecomas may be associated with prominent stromal hyperplasia, particularly in postmenopausal patients. Thecomas are typically associated with estrogenic manifestations, although some (particularly those containing steroid cells, as just indicated) may be androgenic. They are nearly always benign, but a few malignant examples have been documented.[586] Some ovarian tumors with the overall appearance of thecoma with luteinized stromal cells have been found to be associated with a peculiar form of *sclerosing peritonitis;* in this context they have been referred to as stromal luteomas.[587–589]

Fibromas are common ovarian tumors, usually unilateral, which occur almost invariably after puberty.[590] They are solid, lobulated, firm, uniformly white, and usually not accompanied by adhesions (Fig. 35.92). The average diameter is 6 cm. Myxoid or edematous changes may be seen, sometimes resulting in cystic degeneration. Grossly, fibromas may have an appearance similar to thecoma, Brenner tumor, and Krukenberg tumor.

Microscopically, fibromas are composed of closely packed spindle stromal cells arranged in a "feather-stitched" or storiform pattern (Fig. 35.93). Hyaline bands, edema, and hyaline globules may be present.[591] Some fibromas occur in young women with the basal cell nevus (Gorlin) syndrome; these are calcified, usually bilateral, and often multinodular.[592] Fibromas exhibiting a high degree of cellularity can be referred to as *cellular fibromas* (Fig. 35.94). Some cellular fibromas can have conspicuous mitotic activity, and these may be diagnosed as *mitotically active cellular fibroma*, but the diagnosis of *fibrosarcoma*[593] should be reserved for tumors with moderate to severe atypia, with or without necrosis (Fig. 35.95).[594] Differences between ovarian fibroma and fibrosarcoma have also been described at the DNA ploidy, genetic, and cell proliferation levels.[595]

Some otherwise typical fibromas have a minor component of sex cord elements.[596]

Cytogenetically, both thecomas and fibromas have been found to exhibit trisomy of chromosome 12 in a minority of the tumor cells.[597,598] Loss of heterozygosity at both the *PTCH* gene (implicated in Gorlin syndrome) and the *STK11* gene (implicated in Peutz–Jeghers syndrome) is relatively frequent in cellular fibromas.[599]

Fibromas are distinguished from thecoma by their gross appearance (white rather than yellow), the absence of significant cytoplasm in the tumor cells, and the lack of evidence of hormone production (e.g. endometrial hyperplasia or carcinoma).

Ovarian fibroma (especially if large) can be associated with ascites, sometimes in combination with right-sided pleural effusion (Meigs syndrome).[600,601] This may lead to a mistaken impression of inoperable ovarian neoplasm, but removal of the tumor leads to the disappearance of these manifestations. The mechanism for the pleural effusion

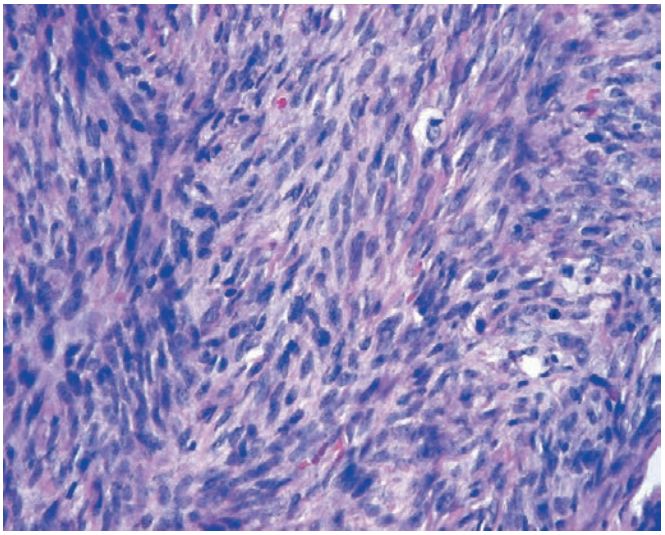

Figure 35.95 Fibrosarcoma of Ovary. Hypercellularity, nuclear hyperchromasia, and brisk mitotic activity are present. The latter is the most important feature in the differential diagnosis with cellular fibroma.

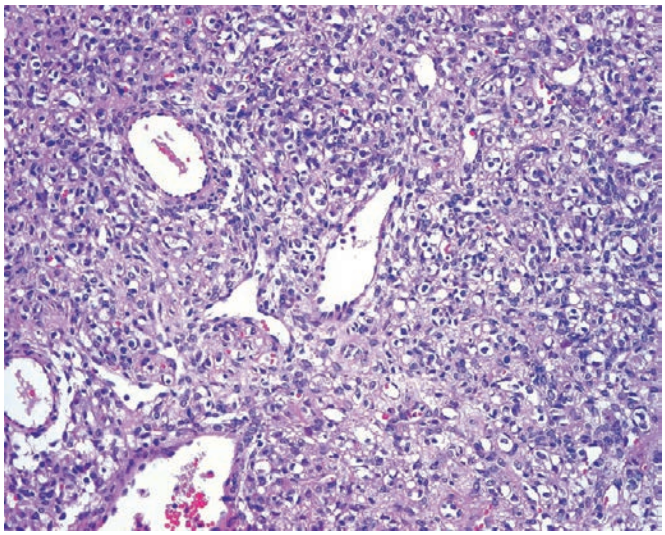

Figure 35.97 Sclerosing Stromal Tumor of Ovary. The hemangiopericytoma-like foci and the alternation of hypocellular and hypercellular areas are important diagnostic clues.

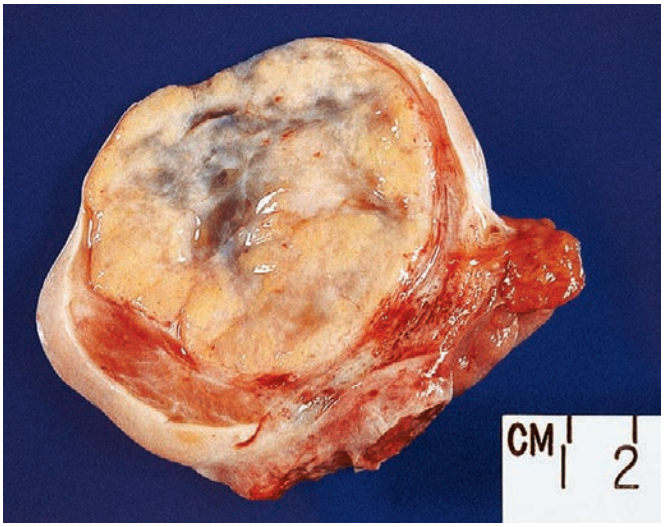

Figure 35.96 Multinodular quality of cut surface of sclerosing stromal tumor.

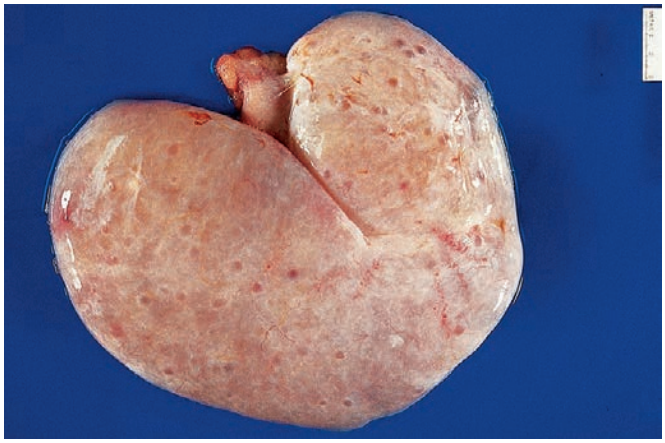

Figure 35.98 Bulging cut surface of ovary involved by massive edema.

is said to be related to intrathoracic negative pressure and transdiaphragmatic passage of fluid through peritoneal "pores" or lymphatics. Meigs syndrome can also occur in association with other ovarian tumors.[602]

Fibromas are benign, and oophorectomy is curative. However, cellular fibromas may recur or be associated with peritoneal implants.[593]

Sclerosing stromal tumor is a benign ovarian neoplasm that shares many features with fibroma and thecoma. However, it occurs in a younger age group, has a less homogeneous gross appearance (Fig. 35.96), and is characterized microscopically by a lobular pattern of growth, interlobular fibrosis, marked vascularity, and the presence of a dual cell population: collagen-producing spindle cells and lipid-containing round or oval cells (Fig. 35.97). Some of the latter may have a signet ring appearance and thus simulate a Krukenberg tumor.[603] Endocrine manifestations are rarely present.[604] The tumor cells are immunoreactive for smooth muscle actin and sometimes for desmin.[605,606] Cytogenetically, this tumor shares the tendency for trisomy 12 that is also a feature of fibromas and thecomas.[607]

Massive edema of the ovary is probably not a neoplasm but is a tumorlike condition discussed here because of its gross similarities with fibroma. Most patients present with pain, abdominal mass, and/or menstrual irregularities; virilization, precocious puberty, and Meigs syndrome have also been described.[608,609] Partial torsion of the meso-ovarium with interference in the venous and lymphatic drainage has been suggested as the pathogenetic mechanism.[609] The cut surface has been described as watery (Fig. 35.98). Microscopically, there is marked edema of the stroma surrounding follicles and other structures (Fig. 35.99).[610] Clusters of luteinized cells are often present.[611] The presence of follicles and other normal ovarian structures distinguishes massive edema and fibromatosis from fibroma.

Fibromatosis is the term proposed by Young and Scully[612] for a disorder that they proposed to be related to massive edema. The patients usually present because of menstrual irregularities. Grossly, the ovaries show a firm, white, cut surface. Microscopically, a diffuse proliferation of spindle cells separated by dense collagen is seen surrounding normal follicular structures. Luteinized cells may be

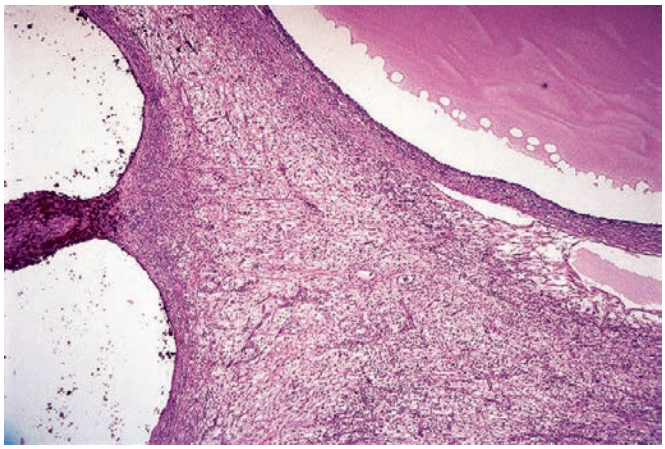

Figure 35.99 Massive edema of ovary typically surrounding dilated follicles.

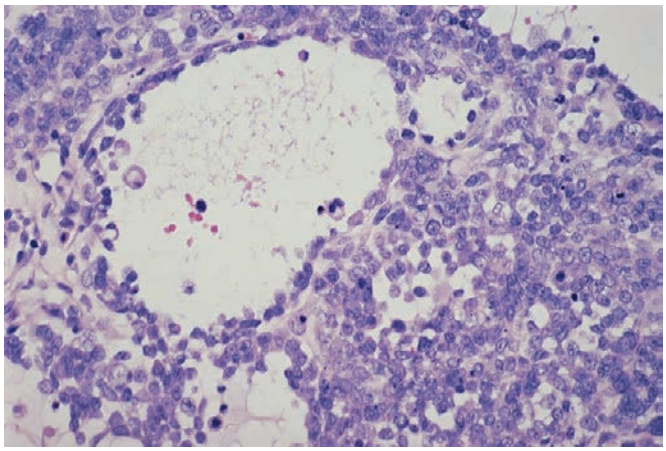

Figure 35.101 Small Cell Carcinoma, Hypercalcemic Type. The presence of follicle-like formations is an important diagnostic feature.

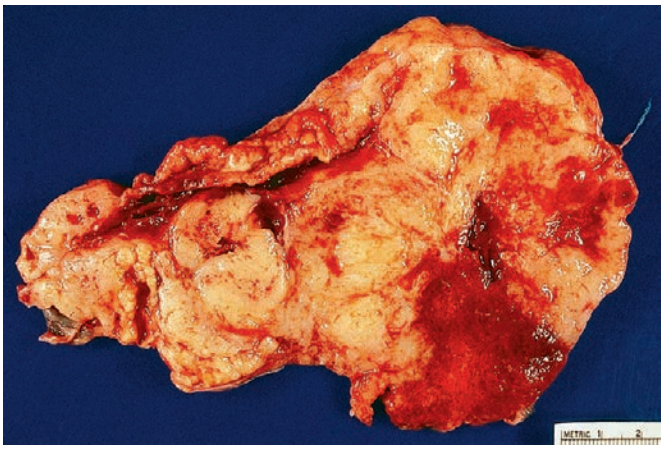

Figure 35.100 Solid cut surface with hemorrhagic foci in ovarian small cell carcinoma of hypercalcemic type.

present. The fact that some cases of massive ovarian edema are accompanied by small cellular foci of fibromatosis lends support to their interpretation. The term *fibromatosis*, although descriptively correct, should not be equated with the similarly named lesion of soft tissues (i.e. desmoid tumor), which under exceptional circumstances can involve the ovary.[613]

Myxoma of ovary presents as a solid and cystic mass, some of the cysts being occasionally filled with blood. Microscopically, scattered cells with fibroblastic/myofibroblastic features are seen in a well-vascularized myxoid background.[614,615] Some authors regard this as a distinct type of ovarian neoplasm, whereas others view it as part of the spectrum of differentiation in the fibrothecoma group.[616,617]

Small Cell Carcinoma of Hypercalcemic Type

Small cell carcinoma of hypercalcemic type is a high-grade ovarian malignancy that may be confused with granulosa cell tumor.[618–620] It occurs in young females (average age, 23 years) and is often bilateral. Familial cases have been reported.[621] The tumor is associated with hypercalcemia in up to two-thirds of cases, which disappears following removal of the tumor.[622] Grossly, the tumor is large and solid, with areas of necrosis and hemorrhage (Fig. 35.100). Microscopically, a diffuse proliferation of small, closely packed cells of carcinomatous appearance with scant cytoplasm and small nuclei is seen (Fig. 35.101). Clusters of larger and more pleomorphic rhabdoid cells are present in approximately half of cases. Cytoplasmic hyaline globules may also be seen. Tumors containing a large number of these larger cells have been referred to, tongue-in-cheek, as the "large cell variant" of small cell carcinoma. There may also be islands, cords, trabeculae, mucinous glands, and *follicle-like structures*. The latter are an important clue to the diagnosis.

The tumor cells usually express keratin, vimentin, EMA, and WT1 but not S-100 protein, chromogranin, inhibin, CD117, or OCT4.[623,624] The genetic basis of these tumors, whether sporadic or familial, has recently been elucidated[625–628]; most have mutations in the *SMARCA4* gene, which encodes the BRG1 protein, a component of the SWI/SNF chromatin remodeling complex. Loss of expression of both BRG1 and BRM (another SWI/SNF protein encoded by the *SMARCA2* gene) in an ovarian tumor appears to be completely specific for small cell carcinoma of hypercalcemic type.[629] The prognosis is very poor. The histogenesis remains obscure, but the occasional association with a germ cell tumor (mature or immature teratoma, or yolk sac tumor) has led to suggestions that it is a primitive germ cell tumor. The differential diagnosis of small cell carcinoma of hypercalcemic type includes **pulmonary-type small cell carcinoma,** which resembles the homonymous lung tumor (Fig. 35.102).[630] It may be pure or associated with endometrioid carcinoma or other patterns. Immunohistochemically, there is reactivity for keratin, EMA, NSE, and (rarely) for chromogranin and Leu7 (CD57). The prognosis is poor. They occur in older patients than small cell carcinoma of hypercalcemic type and are thought to represent dedifferentiation in an epithelial malignancy.

Sertoli–Leydig Cell Tumor

As the name indicates, Sertoli–Leydig cell tumors are composed of a mixture in variable proportions of cells morphologically resembling male Sertoli and Leydig cells; the Sertoli cell elements predominate with a variable, often inconspicuous Leydig cell component. This term replaces the old designations arrhenoblastoma and androblastoma and should be regarded as synonymous with Sertoli–stromal cell tumor. Pure Sertoli cell tumors are also included in this group, but pure Leydig cell tumors are included with the steroid cell tumors.[631] The interesting point has been made that the only neoplastic component of this tumor may be represented by the Sertoli cells, as the Leydig cell component has been shown to be polyclonal, in at least some cases.[632,633]

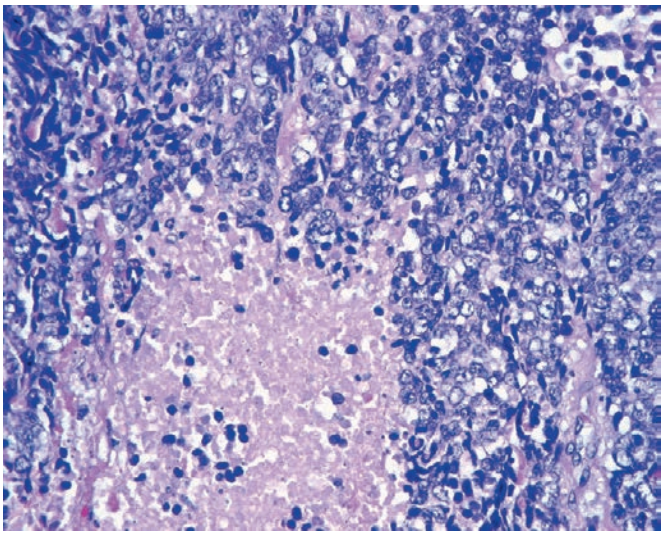

Figure 35.102 Small Cell Carcinoma of Pulmonary Type. The sharply outlined foci of necrosis are a common feature of this tumor, which has a microscopic appearance very similar to its pulmonary counterpart.

Figure 35.103 Variegated appearance of cut surface of ovarian Sertoli–Leydig cell tumor.

Sertoli–Leydig cell tumors are rare, comprising less than 0.1% of ovarian neoplasms. Grossly they are predominantly solid, but cystic areas may also be present (Fig. 35.103).

The microscopic pattern is extremely variable. Several major patterns have been described, which may coexist in the same tumor:

1. *Well differentiated* (11%). Composed of tubules lined by Sertoli-like cells separated by variable numbers of Leydig-like cells (Fig. 35.104).[634] Sometimes those tubules have a hollow "pseudoendometrioid" appearance, the tumor thus simulating a borderline or malignant endometrioid neoplasm.[635] The opposite phenomenon, endometrioid adenocarcinoma simulating Sertoli–Leydig cell tumor, also occurs (and is more common), immunohistochemical evaluation being sometimes necessary to arrive at a correct diagnosis.[636]
2. *Moderately differentiated (intermediate grade)* (54%). Characterized by the formation of cords, sheets, and aggregates of Sertoli-like cells, separated by spindle stromal cells and recognizable Leydig cells (Fig. 35.105).
3. *Poorly differentiated (sarcomatoid; undifferentiated)* (13%). Composed of masses of spindle-shaped cells arranged in a "sarcomatoid" pattern (Fig. 35.106).

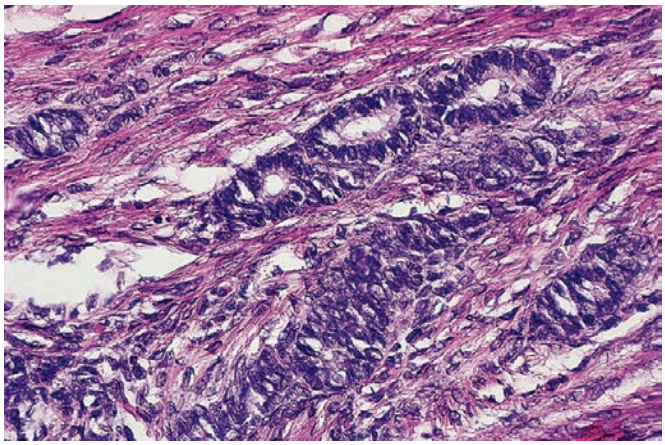

Figure 35.104 Well-differentiated Sertoli–Leydig cell tumor.

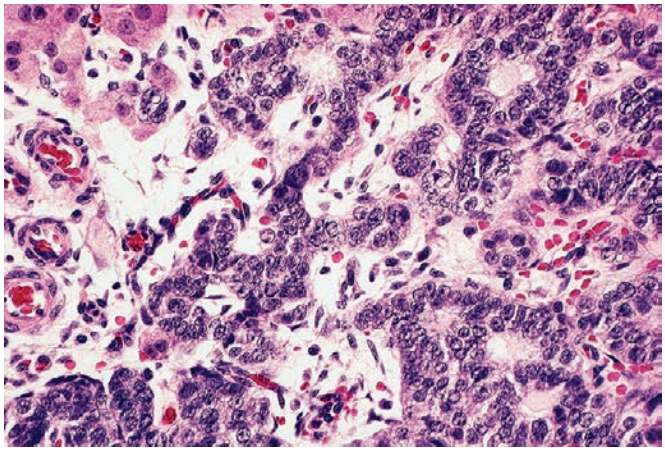

Figure 35.105 Moderately differentiated Sertoli–Leydig cell tumor.

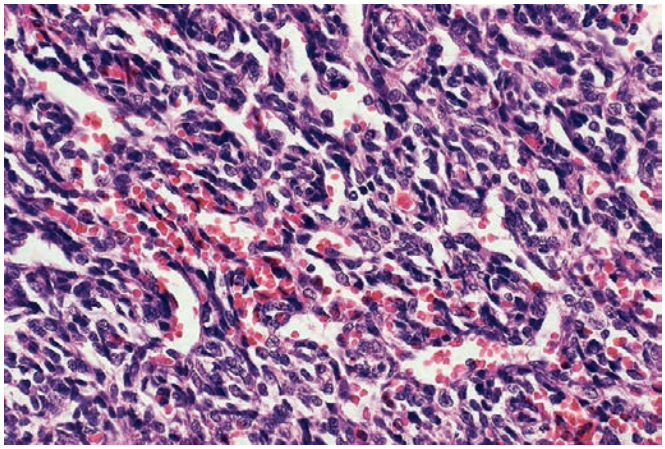

Figure 35.106 Poorly differentiated Sertoli–Leydig cell tumor.

4. *Pure Sertoli cell tumors.* Essentially identical to well-differentiated Sertoli–Leydig cell tumors but lacking Leydig cells and primitive stromal elements.[637,638] Abundant lipid may be present in the cytoplasm. The microscopic pattern can be tubular or follicle-like.[639] Amyloid-like material can be present, and cytoplasmic crystalline structures have been found by electron microscopy.[640] Some Sertoli cell tumors are composed of cells with oxyphilic cytoplasm.[641]

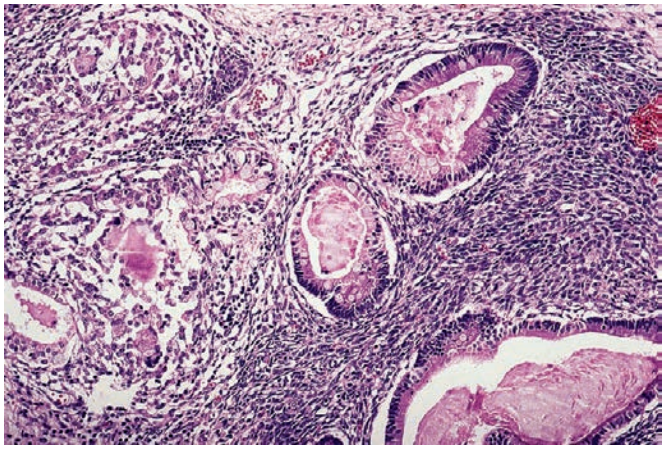

Figure 35.107 Sertoli–Leydig cell tumor with heterologous elements represented by well-differentiated mucin-secreting glands.

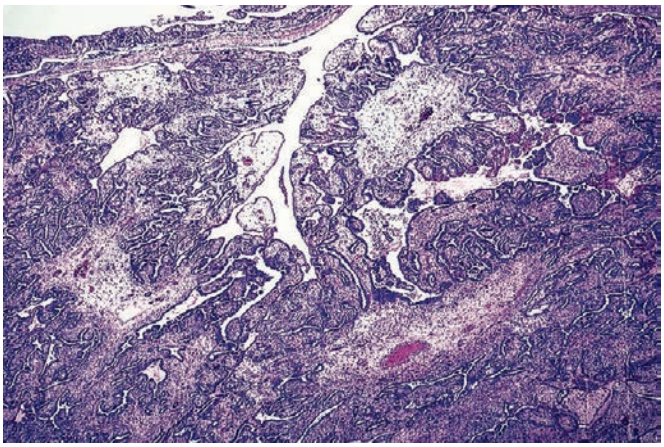

Figure 35.109 Retiform variant of Sertoli–Leydig cell tumor as seen on low-power examination. The retiform areas are represented by the micropapillary foci.

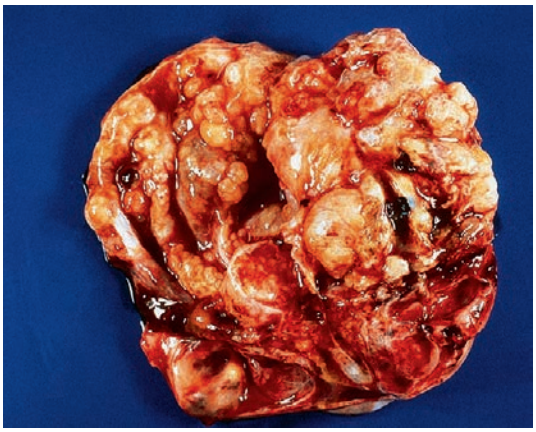

Figure 35.108 Gross appearance of Sertoli–Leydig cell tumor of the retiform variant.

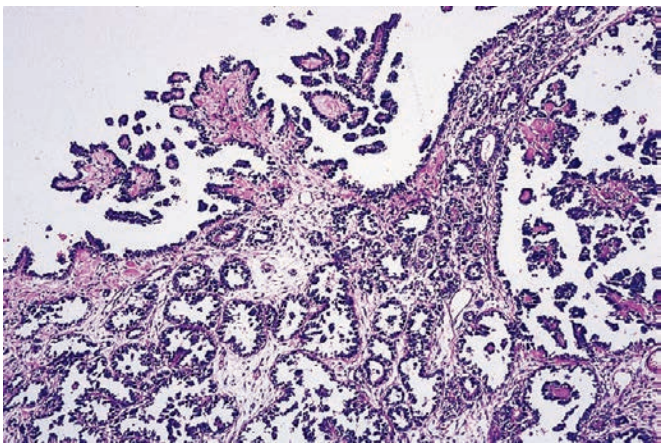

Figure 35.110 When the retiform type of Sertoli–Leydig cell tumor is made up predominantly or exclusively of retiform elements without conventional foci of Sertoli–Leydig cells, as seen here, the diagnosis can be easily missed.

5. *With heterologous elements* (22%). Rare cases are associated with tissues such as mucinous epithelium of gastrointestinal type, liver,[642] skeletal muscle, or cartilage (Fig. 35.107).[643,644] The epithelial component of this neoplasm contains a variety of endocrine cells[645] and can give rise to microscopic carcinoid tumors.[576,646]
6. *Retiform* (15%). In this category, typical elements of Sertoli–Leydig cell tumors coexist with formations resembling the rete of the ovary or testis (Figs. 35.108 and 35.109). These appear as irregular cleft-like spaces lined by low cuboidal cells; blunt papillae with hyalinized or edematous cores are often present. Sometimes the retiform formations predominate almost to the exclusion of the Sertoli–Leydig cell component (Fig. 35.110).[647,648] In other instances there is a hepatocytic component in the tumor, which may be difficult to distinguish from Leydig cells without immunostains.[649]

As in the case of granulosa cell tumor, the cells of a few Sertoli–Leydig cell tumors may contain bizarre and/or multiple nuclei, a change of no apparent prognostic significance.[579]

Immunohistochemically, testosterone and estradiol are found in both Sertoli and Leydig cells and less frequently in primitive stromal cells.[650] The areas of Sertoli cell differentiation stain for keratin and Sox-9 (but not for EMA, PLAP, CEA, or S-100 protein).[651] Positivity for inhibin, calretinin, and WT1 is seen in most tumors.[652,653]

Mutations in *DICER1*, which encodes an endoribonuclease involved in miRNA processing, are found in most Sertoli–Leydig cell tumors[654]; mutations are associated with young age at diagnosis, as well as higher-grade, heterologous elements, or retiform pattern. The *DICER1* mutations may be germline, in which case there is a hereditary predisposition not just to Sertoli–Leydig cell tumor but also pleuropulmonary blastoma and embryonal rhabdomyosarcoma.[655] A small number of low-grade Sertoli cell or Sertoli–Leydig cell tumors harbor a somatic FOXL2 mutation identical to that seen in 95% of adult granulosa cell tumors; these tumors are typically in patients who are older than the usual age of patients with Sertoli–Leydig cell tumor (i.e. postmenopausal), and their relationship to adult granulosa cell tumor remains to be determined.

Most Sertoli–Leydig cell tumors are seen in young patients (average age, 25 years) and they are relatively rare after menopause. Some are diagnosed during pregnancy.[578] These tend to exhibit prominent intercellular edema. Bilateral involvement is seen in less than 2% of cases. Cases have been reported in association with mature cystic teratoma.[656] Nearly half are accompanied by signs of androgen excess. This is manifested first by *defeminization* (amenorrhea, breast atrophy, loss of subcutaneous tissue deposits) and later by *masculinization*

(clitoral hypertrophy, deepening of the voice, hirsutism). Usually prompt return of feminine characteristics follows excision of the tumor, but the manifestations of masculinization disappear more slowly.

Some Sertoli–Leydig cell tumors do not have demonstrable endocrine effect, whereas others are accompanied by secretion of estrogen or progesterone. The latter is often the case for pure Sertoli cell tumors.[657] It is opportune to mention again that the diagnosis of these neoplasms should be based on their morphologic appearance rather than on the nature of their hormonal manifestations. Curiously, some cases of Sertoli–Leydig cell tumor have been associated with serum elevation of alpha-fetoprotein[658–660]; this marker has been detected immunohistochemically in areas of hepatocytic differentiation[642] and in the more conventional Leydig and Sertoli cell-like component.

The prognosis of Sertoli–Leydig cell tumor, which is usually good, correlates with the stage and degree of differentiation of the tumor.[661,662] The overall incidence of clinical malignancy in one large series was 18%; all the well-differentiated tumors were benign, but 11% of those with intermediate differentiation, 59% of those with poor differentiation, and 19% of those with heterologous elements were malignant.[642] In one series of 28 cases of pure Sertoli cell tumor, there were two recurrences.[640] Conservative surgery is indicated in young women for Sertoli–Leydig cell tumors grossly confined to the ovary.[639,662]

Steroid Cell Tumor

A small group of ovarian tumors is composed entirely of cells with morphologic features indicative of steroid hormone secretion. These are manifested by an abundant eosinophilic or vacuolated cytoplasm that is often positive for fat stains and that, at the ultrastructural level, is shown to contain well-developed smooth endoplasmic reticulum and mitochondria with tubulovesicular cristae.[663] Normal steroid hormone-secreting cells can be of lutein (thecal or stromal), Leydig (hilus), and adrenal cortical type.[664] Theoretically, these tumors could arise from any of these sources. In the few cases in which Reinke crystalloids are found, the tumor can be categorized as **Leydig cell tumor**.[664–666] The exact origin of this tumor remains undecided; the descriptive terms **lipid, lipoid**, and—more recently—**steroid cell tumor** have therefore been proposed for the entire group, with the subcategory of Leydig cell tumor recognized for those tumors with Reinke crystalloids or arising in the hilus, with associated hilus cell hyperplasia.

Steroid cell tumors are usually unilateral and are composed of yellow or yellowish-brown nodules separated by fibrous trabeculae (Fig. 35.111). Microscopically, they are characterized by masses of large rounded or polyhedral cells with the morphologic and ultrastructural features previously described for their normal counterparts (Fig. 35.112). Immunohistochemically, there is reactivity for vimentin in three-fourths of cases, for keratin in one-half, and for actin in about one-third.[667] There is also consistent reactivity for inhibin and Melan-A.[668]

This neoplasm can occur at any age. Most are associated with a virilizing syndrome (with defeminization and amenorrhea), and a few cases meet the criteria for Cushing syndrome. Some of the tumors are biologically inactive, at least at the clinical level, and others are associated with estrogenic or progestogenic manifestations. A few cases have been associated with endometrioid carcinoma.[669] The incidence of clinical malignancy is approximately 25%.[670] Malignant tumors tend to be larger (7 cm in diameter or greater), with foci of necrosis and hemorrhage, and often exhibit nuclear atypia and mitotic activity.[670] Tumors containing Reinke crystalloids are almost invariably benign.[665]

Figure 35.111 Cut Surface of Ovarian Steroid Cell Tumor. The deep brown color is reminiscent of a renal or thyroid oncocytoma.

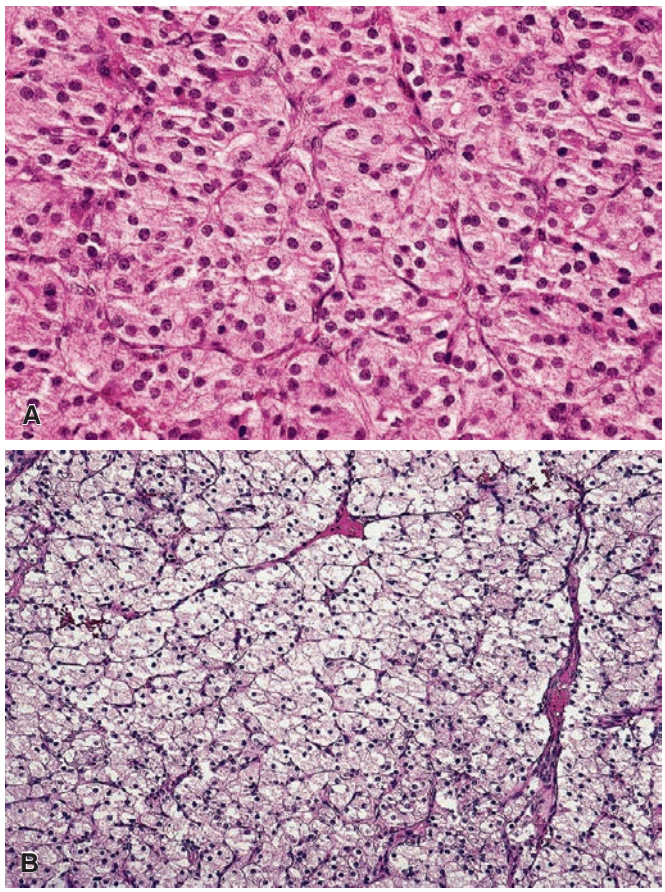

Figure 35.112 Two cases of steroid cell tumor showing acidophilic **(A)** and clear **(B)** appearances of the cytoplasm of the tumor cells.

Steroid cell tumors should be distinguished from lesions in which acquisition of cells with features of steroid hormone–producing cells occurs as a secondary event. These include luteinized granulosa cell tumor (particularly the juvenile type), fibrothecoma, and the relatively common finding of proliferation of non-neoplastic steroid cells that may be seen at the periphery of other tumors, such as struma ovarii, strumal carcinoid, epithelial tumors, and metastatic carcinoma.[671]

Other Types

Gynandroblastoma is the term used for the sex cord–stromal tumor composed of a mixture *in similar amounts* of clearly identifiable granulosa cell and Sertoli–Leydig cell elements.[672] When thus defined, this entity is extremely rare. On occasion the granulosa cell component is of the juvenile rather than the adult type.[673,674] Reported cases of this entity have been accompanied by androgenic, estrogenic, or no hormonal effects.[675,676] Examples of late recurrence following excision are on record.[677] Mutations in *DICER1* can be found in gynandroblastomas, in particular those where the granulosa cell component is of juvenile type.[678]

Sex cord tumor with annular tubules is a distinctive ovarian tumor that is associated in one-third of the cases with the Peutz–Jeghers syndrome.[679,680] This lesion combines features suggestive of a granulosa cell tumor with a pattern of growth reminiscent of Sertoli cells.[681] Its morphologic hallmark is the presence of simple and complex annular tubules containing eosinophilic hyaline bodies, often calcified (Fig. 35.113). The appearance is similar to that of gonadoblastoma, from which it differs because of the clinical/genetic background and the presence of a germ cell component in the latter.

The ambiguous or biphasic nature of the tumor cells is also apparent on ultrastructural examination: features consistent with granulosa cell or nonspecialized ovarian stroma[682,683] alternate with features indicative of Sertoli cell differentiation, notably the presence of Charcot–Bottcher filaments.[684] Symptoms suggestive of hyperestrinism have been described in approximately 50% of cases. Tumors associated with the Peutz–Jeghers syndrome are typically multifocal, bilateral, small (or even microscopic), calcified, and usually benign, although exceptions occur.[685] Those unassociated with the syndrome are unilateral, often large, and clinically malignant in approximately 22% of cases.[686,687]

It should be mentioned here that Peutz–Jeghers syndrome can be associated with other neoplasms of the female genital tract, such as other sex cord–stromal ovarian tumors,[688] mucinous ovarian tumors, and HPV-independent well-differentiated adenocarcinoma of the cervix of gastric type (adenoma malignum).

Wolffian tumor is the designation for the tumor entity first named *ovarian tumor of probable wolffian origin or female adnexal tumor of probable wolffian origin* (the latter designation reflecting its more frequent occurrence in the broad ligament, compared to the ovary).[689–691] It is thought to be of wolffian (mesonephric) derivation. Although it is not thought to be sex cord–stromal in nature, they are discussed here because of their resemblance to them and the fact that their immunophenotype overlaps with that of tumors in the sex cord-stromal category. Grossly, they may be either solid or solid and cystic. Microscopically, epithelial cells are seen growing in the form of cystic structures, solid or hollow tubules, and diffuse sheets (Fig. 35.114). The sieve-like appearance on low-power examination is a useful diagnostic feature. Conversely, the presence of a predominant spindle cell component can be confusing.[692] PAS-positive basement membranes are prominent around the epithelial aggregates. These tumors lack stromal cells of steroid hormone–secreting type and are unaccompanied by hormonal manifestations. Mucin stains are negative. Immunohistochemically, the tumor is positive for keratin (CK7 but not CK20), androgen receptor (three-fourths of cases), estrogen and progesterone receptors (one-fourth), inhibin (over half), FOXL2, calretinin (almost all), and vimentin (always). Surprisingly, given its putative wolffian origin, most cases are negative for GATA3.[693] It is negative for CEA. The behavior is generally benign, but a few have recurred or metastasized.[691,694,695]

Signet ring stromal tumor of the ovary is a very rare type but of great practical importance because of the fact that it can be easily mistaken for Krukenberg tumor. Some of the examples may be variants of sclerosing stromal tumor. The tumor cells are negative for keratin, PAS, and mucin. Their behavior is benign.[696]

Microcystic stromal tumor is the latest addition to the group of sex cord–stromal ovarian neoplasms.[697] It is usually unilateral and nonfunctioning. Microscopically, its most distinctive feature is the presence of small round to oval cystic spaces, in areas coalescing to form larger irregular channels, combined with lobulated cellular masses with intervening fibrous or fibrohyaline stroma. Mutations in β-catenin, with associated nuclear immunoreactivity, are a feature of this tumor.[698,699]

Sex cord–stromal tumor NOS (indeterminate or unclassified type) is a justifiable designation for ovarian tumors in which the cytologic and/or architectural features are consistent with a sex cord–stromal origin but which cannot be assigned to any specific category. These tumors are decidedly uncommon. Their behavior is similar to that of granulosa cell tumor and Sertoli–Leydig cell tumor, with a generally favorable prognosis when confined to the ovaries at presentation.[699,700]

Germ Cell–Sex Cord–Stromal Tumors

The most distinctive member of the group of tumors composed of a combination of germ cells and sex cord–stromal cells is **gonadoblastoma**.[701] This tumor occurs practically always in sexually abnormal

individuals, most commonly affected by gonadal dysgenesis and carrying all or part of the Y chromosome (i.e. XY gonadal dysgenesis and XO-XY mosaicism but not XX gonadal dysgenesis). The testis-specific protein Y-encoded gene is the putative gene for the gonadoblastoma locus on the Y chromosome.[702]

The risk of neoplasia in these dysgenetic gonads is estimated to be 25%. However, gonadoblastomas have also been documented in phenotypically and chromosomally normal females, even during pregnancy.[703,704] They have also been seen in association with ataxia–telangiectasia.[705] It is often impossible to determine the nature of the gonad bearing the tumor. In some cases it has been identified as a streak and in others as a cryptorchid testis, but never as a normal ovary.

Approximately 36% of the tumors are bilateral. They are usually small, and many become apparent only on microscopic examination (Fig. 35.115).[706] The key microscopic feature is the admixture of primitive germ cells (resembling those of dysgerminoma) with sex cord–stromal cells resembling morphologically and immunohistochemically immature Sertoli and granulosa cells (Fig. 35.116).[707–709] Steroid hormone–producing cells may also be present, especially after puberty; their capacity for steroidogenesis has been demonstrated by their in vitro production of androgens and estrogens.[710] Hyalinization and calcification are common. The hyaline material reacts strongly with anti-laminin antibodies, indicating basement membrane deposition.[711]

An interesting analogy has been made between gonadoblastoma and intratubular germ cell neoplasia of the testis on the basis of the morphology and the immunohistochemical profile, the implication being that gonadoblastoma is an in situ germ cell malignancy arising in a dysgenetic gonad.[709]

The germ cell component of gonadoblastoma may overgrow the stromal elements and result in the formation of a germinoma (i.e. a tumor that would be diagnosed as a seminoma if arising in the testis or dysgerminoma if arising in the ovary) or, exceptionally, another type of germ cell tumor.[712,713] Only under these circumstances is the tumor endowed with a malignant potential. Much more unusual is the overgrowth of the sex cord–stromal component, which may acquire the features of a Sertoli cell tumor.[714]

Microscopic structures resembling gonadoblastoma and sex cord tumor with annular tubules are sometimes found incidentally in the ovaries of *normal* infants and children in association with follicular cysts; it has been suggested that they represent the precursor of these tumors.[715]

Rare *germ cell–sex cord–stromal tumors* not fulfilling the diagnostic criteria for gonadoblastoma have been described in genetically normal females,[716,506] some of them containing retiform structures.[717] The germ cell component of these tumors—like that of gonadoblastomas—is positive for PLAP, OCT4, and CD117.[718] These tumors can be hormonally active and clinically malignant.[719] Like gonadoblastoma, they can be accompanied by dysgerminoma or other germ cell tumors.

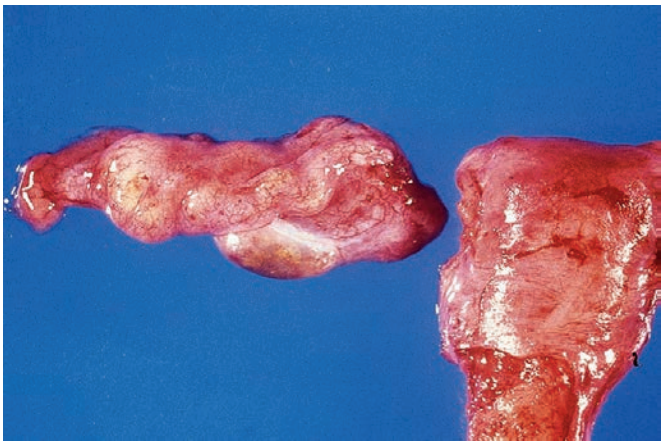

Figure 35.115 Streak gonad microscopically shown to contain gonadoblastoma. The tumor was barely apparent grossly.

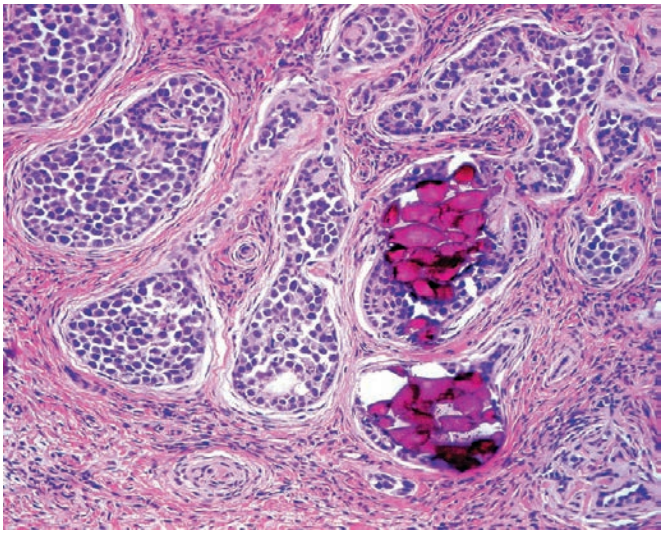

Figure 35.116 Ovarian Gonadoblastoma. Note the sharply outlined tumor nests and the heavy calcification.

Tumors Not Specific to Ovary

Malignant Lymphoma and Leukemia

Secondary ovarian involvement by generalized lymphoma or leukemia is well recognized.[720,721] Much more rarely, malignant lymphoma involves the ovaries as the primary manifestation of the disease (Fig. 35.117).[721–725] This is also true for *granulocytic sarcoma*.[726,727]

Nearly all ovarian lymphomas are of non-Hodgkin type.[728] In children, Burkitt lymphomas predominate; in adults, most are diffuse large B-cell lymphomas.[728,729] Immunophenotypically, practically all cases are of B-cell nature.[728,730] In the series of Osborne and Robboy,[731]

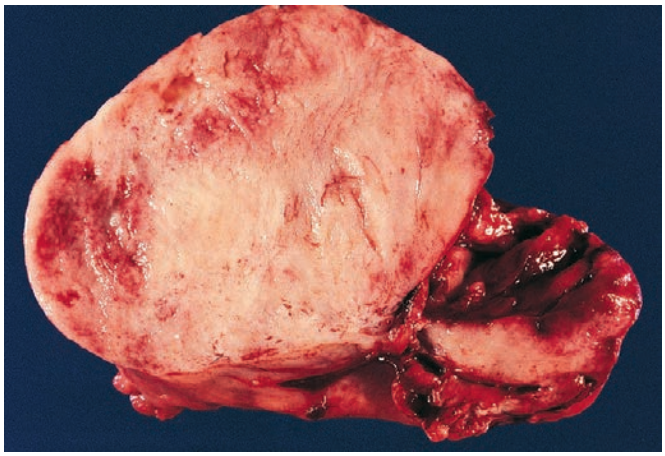

Figure 35.117 Malignant lymphoma of Burkitt type with massive ovarian involvement.

55% were bilateral, and 64% also involved extragonadal sites (usually the omentum, fallopian tubes, or lymph nodes); only 9 of their 42 patients survived more than 5 years, and 2 subsequently died of lymphoma.

Exceptionally, ovarian lymphoma has been found to coexist with a borderline serous tumor.[732]

Sarcoma

Primary sarcomas of the ovary are extremely rare. They need to be distinguished from undifferentiated carcinomas, carcinosarcomas/MMMTs, "sarcomatoid" forms of sex cord–stromal tumors, Krukenberg tumors associated with brisk stromal reaction, and cellular fibromas.

Fibrosarcomas are separated from cellular fibromas mainly on the basis of their mitotic activity (4 or more per 10 high-power fields) plus moderate to severe cytologic atypia; hemorrhage and necrosis are also common (see Figs. 35.94 and 35.95). They tend to be large, solid, and accompanied by adhesions. The clinical course is aggressive.[610] One case has been diagnosed in the context of the nevoid basal cell carcinoma syndrome.[733]

Endometrial (endometrioid) stromal sarcomas can present as primary ovarian neoplasms; they can closely simulate the pattern of growth of the diffuse type of granulosa tumor[734] but are recognized because of the presence of plump oval cells arranged around vessels of the spiral arteriole type.[735] Immunohistochemically, they are reactive for CD10 but negative for inhibin and FOXL2.

Müllerian adenosarcoma is discussed elsewhere, although it is probably more closely related to endometrial stromal sarcoma than to MMMT.

Other sarcomas of the adult ovary, all exceptionally rare, are *leiomyosarcoma*[736,737] (some of the myxoid type and some in patients with the nevoid basal cell carcinoma syndrome),[738,739] *chondrosarcoma*,[740] *osteosarcoma*,[741–743] *malignant peripheral nerve sheath tumor*,[744] *angiosarcoma*,[745] *rhabdomyosarcoma*,[746] *low-grade fibromyxoid sarcoma*,[747] and *Ewing sarcoma*.[748,749] The rhabdomyosarcomas are usually of the embryonal type, but they can also be of the alveolar variety[750]; a case has been reported in association with clear cell carcinoma.[751] The angiosarcomas show a wide morphologic spectrum and can be associated with mature cystic teratoma.[752,753]

The treatment of ovarian sarcoma is surgical excision ("cytoreduction") followed by chemotherapy.[754]

Other Primary Tumors

Hemangiomas of the ovary are usually small, found incidentally, unilateral, and cavernous in type.[755] Rarely, they are bilateral and/or associated with hemangiomas elsewhere in the body. Ovarian hemangiomas should be distinguished from the normal prominent hilar vasculature, lipid cell tumors having a prominent vascular component, and from the florid non-neoplastic vascular proliferation that sometimes accompanies the primitive neuroectodermal component of ovarian germ cell tumors.[439] Other types of vascular tumors that have been reported in the ovary are *infantile hemangioendothelioma*,[756] *lymphangioma* (which can be bilateral),[757] and *glomus tumor*.[758,759] *Leiomyomas* can exceptionally develop in the ovary, usually in association with uterine leiomyomas[760]; some are mitotically active and need to be distinguished from leiomyosarcomas.[761–763] The criteria for making this distinction are similar to those employed for their infinitely more common uterine counterparts (and just as frustrating).[758]

Isolated examples of ovarian myofibroblastoma,[764] epithelioid angiomyolipoma/PEComa,[765] nephroblastoma (Wilms tumor),[766] desmoplastic small cell tumor,[767] pheochromocytoma/paraganglioma,[768,769] and hydatidiform mole[770] have also been described. Adenomatoid tumor can occur in an intra- or juxta-ovarian location; it can simulate the appearance of yolk sac tumor,[771] and it can be predominantly composed of oxyphilic cells.[772]

The great majority of cases of *melanoma* involving the ovary are metastatic, but cases thought to be primary in the ovary have been described, the most convincing examples being those arising within a mature cystic teratoma or a struma ovarii.[773] Pancreatic-type solid and pseudopapillary neoplasm can also occur in the ovary.[774]

Metastatic Tumors

The ovary is a common site of involvement for metastases.[775–778] Approximately 7% of lesions presenting clinically as primary ovarian tumors are of metastatic origin. Over half are bilateral. The most common sources are stomach, large bowel, appendix, breast, uterus (corpus and cervix),[779] lung,[780,781] and skin (melanoma).[782–785] The difficult situation resulting from the simultaneous presence of carcinoma in ovary and uterus is discussed elsewhere. At the time when therapeutic oophorectomies were done in patients with breast carcinoma, it was not unusual to find small and sometimes microscopic (occult) metastases. Their pattern of growth could be either diffuse (with single file formations, suggestive of a lobular nature) or glandular, more in keeping with a ductal type. Immunoreactivity for GCDFP-15 and GATA3 is the rule, a fact of importance in the differential diagnosis with primary ovarian carcinoma, which is generally negative.[786,787] The reverse is true for WT1 and PAX8, which tend to be positive in ovarian carcinomas but negative in breast carcinoma.[161,788]

Adenocarcinomas of the large bowel are particularly important because of their relatively high frequency and their ability to simulate primary ovarian carcinomas, mainly of the mucinous and endometrioid types but sometimes also of the clear cell type (Fig. 35.118).[784,789–791] The primary tumors are usually advanced but sometimes are small and clinically occult.[792] The ovarian metastases tend to be cystic, well differentiated, mucin-producing, and associated with necrosis and hemorrhage. In some cases (particularly those of cecal origin), the ovarian metastases are associated with luteinization of the surrounding stroma, which may lead to masculinization and other endocrine changes.[793]

Features favoring metastasis from large bowel are bilaterality, surface involvement by tumor cells, infiltrative or nodular pattern of invasion, ovarian hilar involvement, single cell invasion, signet ring cells, garland and cribriform growth pattern, "dirty" necrosis, segmental destruction of glands, lack of squamous metaplasia, and vascular invasion (Fig. 35.119).[789,794–796] Features favoring a primary ovarian tumor are an expansile (pushing) pattern of invasion, a complex papillary architecture, size over 13 cm, a smooth external surface, and the presence of benign- and borderline-appearing foci.[795] This combination of primarily architectural features should allow the differential diagnosis to be made in the large majority of cases with the H&E sections. Unfortunately, exceptions to each and every one of these criteria exist.[797] Immunohistochemical stains can be of great assistance, although they also fall short of being pathognomonic. Metastatic large bowel carcinoma is characteristically CK7–/CK20+, CDX2+, and SATB2+. By contrast, primary ovarian mucinous carcinomas are nearly always CK7+ and variably CK20+, SATB2+, and CDX2+.[798–800] Hormone receptors are of no help, being negative in both metastatic carcinoma from the colon and the usual type of primary ovarian mucinous carcinoma.[801]

It should be realized that these distinctions apply specifically to the large bowel. Ovarian metastases from gastric, biliary, or pancreatic primaries have different phenotypic features (Fig. 35.120).[225,802–804] Of note, pancreaticobiliary adenocarcinomas often have bland foci

Figure 35.118 **A** and **B,** Colonic carcinoma metastatic to ovary. This may be misdiagnosed as a primary ovarian tumor both grossly and microscopically.

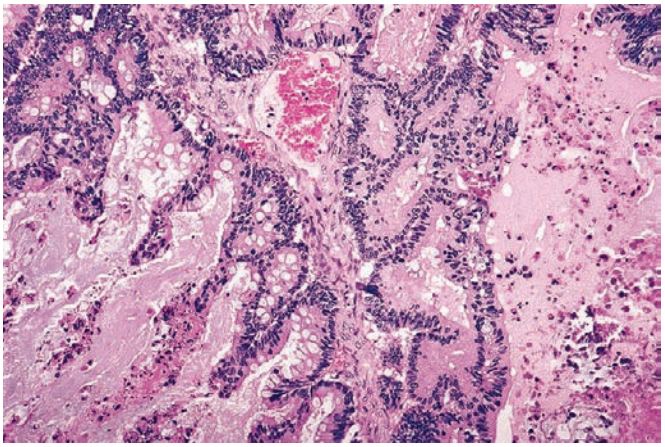

Figure 35.119 Colonic carcinoma metastatic to ovary.

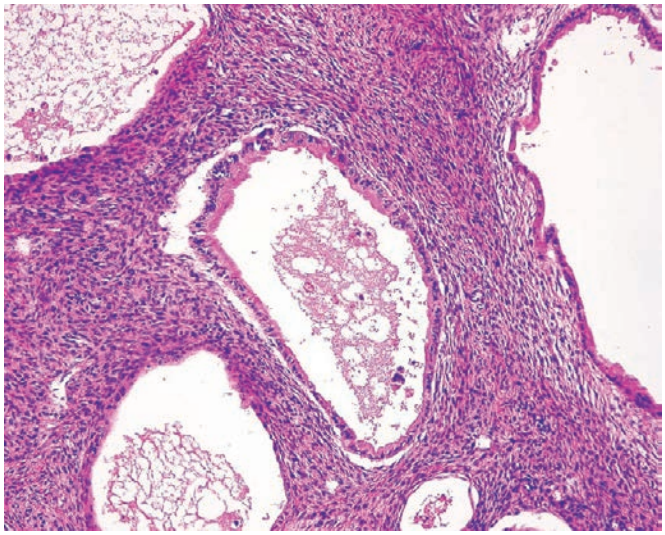

Figure 35.120 **Ovarian Metastasis From Pancreatic Adenocarcinoma.** As in the primary tumor, this ovarian metastasis shows the disparity between the extremely well-differentiated architecture and the high degree of nuclear atypia that is characteristic of pancreatobiliary neoplasms.

that simulate a benign or borderline ovarian mucinous tumor. The peculiar situation concerning the relationship of ovarian mucinous tumors and pseudomyxoma peritonei has been mentioned earlier in this chapter. Briefly, the current consensus—based on a combination of clinical, morphologic, immunohistochemical, and molecular observations—is that the overwhelming majority of these tumors are primary appendiceal neoplasms that have implanted on the peritoneal surface and on the ovaries.[805,806] However, that may not be true for all cases (e.g. the rare appendiceal-type ovarian mucinous adenocarcinomas arising from benign cystic teratomas).[482]

Metastatic carcinoid tumors to the ovary are discussed elsewhere. Small cell (neuroendocrine) carcinomas from the lung, gastrointestinal tract, thymus, and other sites can metastasize to the ovary; these should be distinguished from both the hypercalcemic and the pulmonary type of primary ovarian small cell carcinoma,[807] the latter being a more difficult task.

The eponym **Krukenberg tumor** is used to designate an ovarian neoplasm, usually bilateral and nearly always of metastatic origin, characterized grossly by moderate solid multinodular enlargement of the ovaries and microscopically by a diffuse infiltration by signet ring cells containing abundant neutral and acidic (sialo) mucins[808–811] (Figs. 35.121 and 35.122). Tumor emboli are found in over half of the cases.[812] Marked stromal proliferation with a storiform pattern of growth and a variable degree of luteinization are common and may obscure the diagnosis.[811] Another difficult problem is represented by the variant of this tumor referred to as *tubular*, in which a prominent tubular pattern, stromal luteinization, and

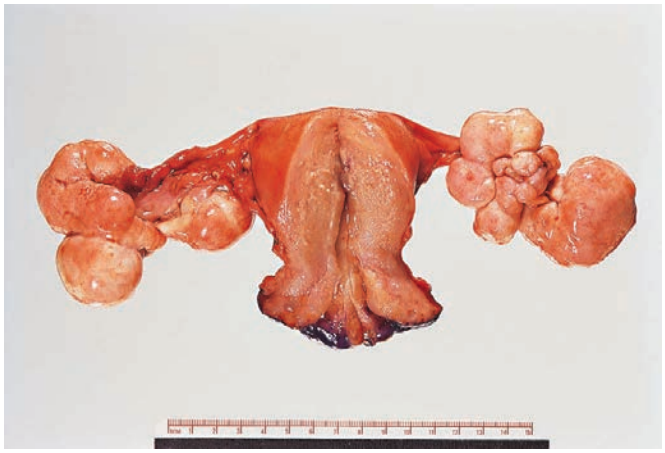

Figure 35.121 Typical Gross Appearance of Krukenberg Tumors of Ovary. The involvement is bilateral and the tumors are characterized by a multinodular outer appearance. Figure 35.122 Krukenberg Tumor of Ovary. A, Microscopic appearance. Numerous signet ring cells are present in a highly fibrous stroma, either individually or in small nests. **B,** Presence of intracellular mucin evidenced by Meyer mucicarmine stain.

occasional associated virilization may lead to a mistaken diagnosis of Sertoli–Leydig cell tumor (Fig. 35.123)[812]; the presence of typical mucin-positive signet ring cells should point toward the correct diagnosis.

Most examples of Krukenberg tumors occur after the age of 40 years, but younger patients can also be affected. In the latter instance, a mistaken diagnosis of granulosa cell tumor or steroid cell tumor may be made.

The usual primary sources of Krukenberg tumor are stomach, large bowel, appendix, and breast (Fig. 35.124).[812–815] Of these, diffuse gastric carcinoma ("linitis plastic") used to be the most common, but at present there is a preponderance of cases originating from the breast, at least in the United States. The ovarian deposits can be accompanied by retroperitoneal lymph node metastases and peritoneal implants. A rarer phenomenon is ovarian metastasis from gastric carcinoma of intestinal type.[816]

Exceptionally, an extra-ovarian primary tumor is not found at autopsy in a patient harboring a Krukenberg tumor. In such an instance, the lesion is assumed to be primary in the ovary.[817] Before such an occurrence is accepted, a meticulous study of the gastrointestinal tract, breast, and other organs should be carried out.[812] It should be emphasized here that the diagnosis of Krukenberg tumor requires the histochemical identification of intracytoplasmic mucin, and the immunohistochemical detection of epithelial markers, inasmuch as mucin negative signet ring cells are occasionally seen in other ovarian conditions.[818]

Other tumors that can metastasize to the ovary and give rise to difficult diagnostic problems are pancreatobiliary ductal adenocarcinoma (which can simulate primary ovarian mucinous tumors and which can arise in the pancreas, gallbladder or extrahepatic or intrahepatic bile ducts),[819–822] pancreatic acinar cell carcinoma,[823] renal cell carcinoma (which mimics ovarian clear cell adenocarcinoma),[824,825] carcinoma of the renal pelvis,[826] thyroid carcinoma (which can be confused with struma ovarii),[827] hepatocellular carcinoma and hepatoblastoma (not to be mistaken for hepatoid yolk sac tumor or hepatoid carcinoma, all of which are Hep Par1 positive[828]),[829,830] intra-abdominal desmoplastic small cell tumor (of which the ovary can be the only manifestation),[831,832] and a variety of sarcomas, including rhabdomyosarcoma,[777] leiomyosarcoma, osteosarcoma,[833] gastrointestinal stromal tumor (GIST),[834] soft tissue–type clear cell sarcoma,[835] and chordoma.[778,836,837] We have also seen ovarian metastases from malignant thymoma.

Malignant melanomas are usually easy to recognize because of their pigmentation, nodular pattern of growth, and cytologic features; however, some can be confused with primary ovarian tumors (particularly juvenile granulosa cell tumor and the hypercalcemic type of small cell carcinoma) because of their tendency to form follicle-like spaces (Figs. 35.125 and 35.126).[785] Positivity for S-100 protein, SOX-10, Melan-A, and HMB-45 should remove whatever doubts may remain after examination of H&E-stained sections.[838] Metastatic melanoma should be distinguished from the much rarer primary ovarian melanoma.

Not surprisingly, carcinoma metastatic to the ovary is generally associated with a very poor prognosis.

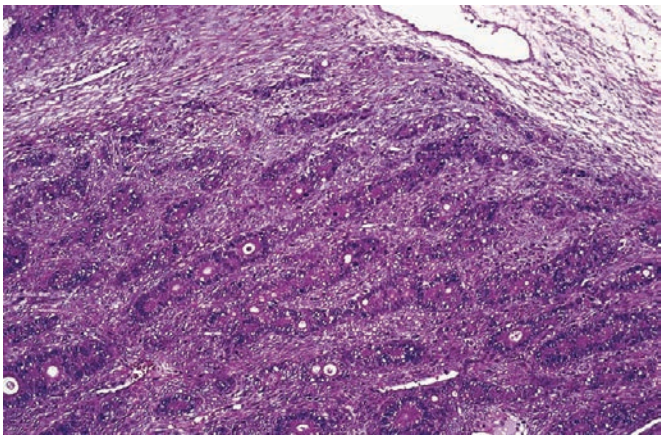

Figure 35.123 Tubular variant of Krukenberg cell tumor.

Normal Anatomy

The breast or mammary gland is covered by skin and subcutaneous tissue and rests on the pectoralis muscle, from which it is separated by a fascial layer. The morphofunctional unit of the breast is a complex branching structure that is topographically arranged into *lobes* and which is made up of two major components: the *terminal duct–lobular unit (TDLU)* and the *large duct system*.[1] The TDLU is formed by the *lobule*, which in turn is made up of acini, and the *terminal ductule* and represents the secretory portion of the gland. It connects with the *subsegmental duct*, which in turn leads to the *segmental duct*, and this to the *collecting* (*lactiferous*) *duct*, which empties into the nipple. A fusiform dilation located beneath the nipple between the collecting and segmental ducts is known as the *lactiferous sinus* (Fig. 36.1).

The TDLU is recognized by its distinctly lobular architecture, the presence of a mantle of specialized, myxoid-appearing hormone-responsive connective tissue, and the absence of elastic fibers. The development of the breast is dependent on the close interaction of these specialized epithelial and mesenchymal tissues.[2] The large ducts have less specialized stroma and are enveloped by a continuous and well-developed layer of elastic tissue. The entire ductal–lobular system of the breast is lined by a specialized *inner epithelial cell layer* with secretory and absorptive functions (often simply called epithelium)

Abstract

Breast pathology encompasses a wide range of benign, atypical, and malignant lesions. This chapter reviews both neoplastic and non-neoplastic lesions of the breast with discussion of differential diagnoses and appropriate adjunctive studies. Consideration is given to challenges that may be encountered with particular specimen types, such as core needle biopsies. Risk factors and molecular alterations are discussed as they pertain to the entities described.

Keywords

Breast,
carcinoma,
benign breast disease,
fibroepithelial lesions,
papillary lesions,
adenosis,
nipple lesions

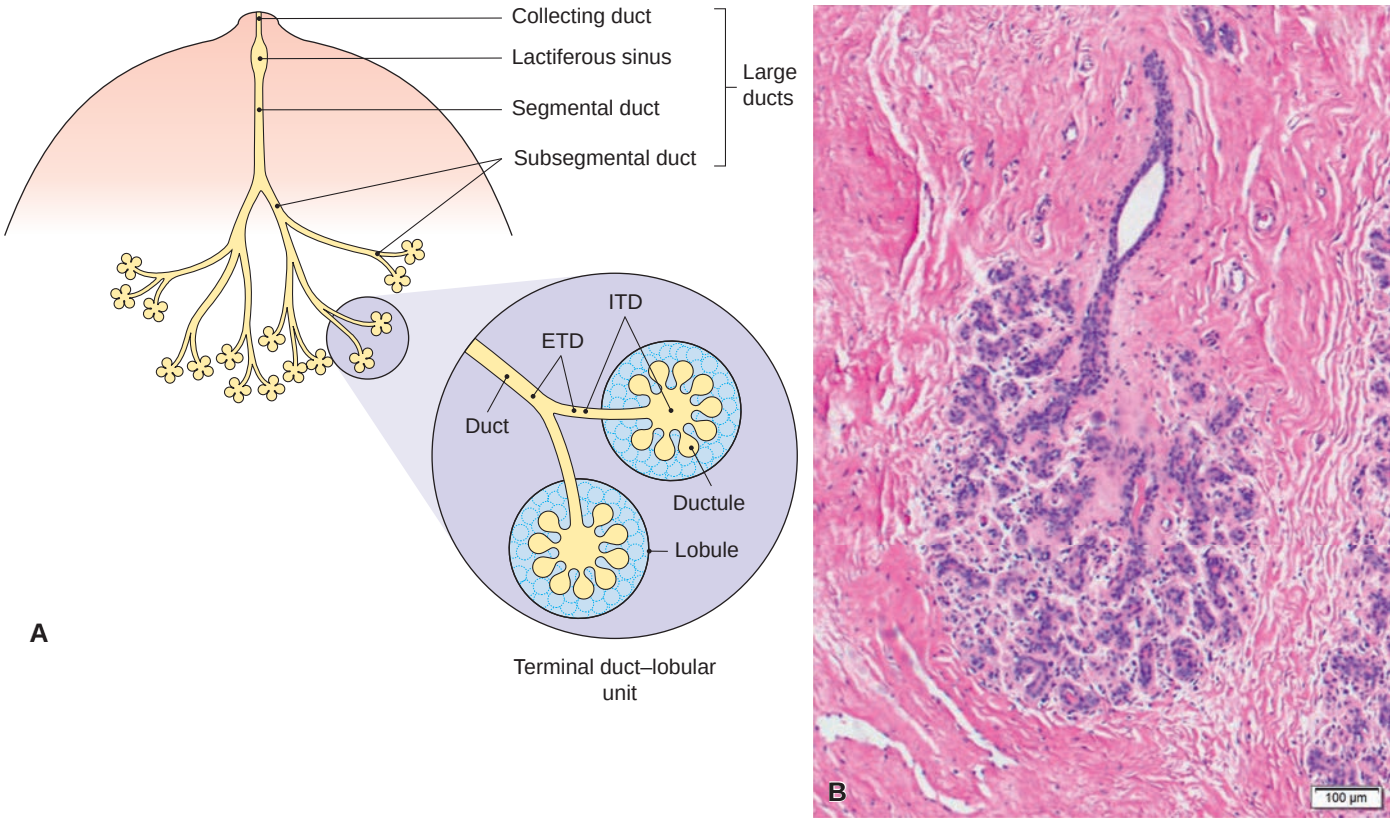

Figure 36.1 Terminal Duct–Lobular Unit. A, Diagrammatic representation of this structure. **B,** Photomicrograph of this unit as seen in a normal adult female. *ETD*, Extralobular terminal duct; *ITD*, intralobular terminal duct.

and is surrounded by an outer *myoepithelial cell layer*. These two cell types have distinctive immunohistochemical features. The most reliable markers for the epithelial cells are the various cytokeratins (see later), epithelial membrane antigen (EMA), mammaglobin (Fig. 36.2A), GCDFP-15, and GATA3. Myoepithelial cells react with high-molecular-weight (HMW) cytokeratins, smooth muscle actin (SMA), calponin, smooth muscle myosin heavy chain (see Fig. 36.2B), maspin, and caldesmon (the latter only in the ductal portion). They also show nuclear reactivity for p63 (a member of the *TP53* gene family) and p75 neurotrophin receptor (p75NTR).

EMA reacts strongly with the apical region of active secretory cells but may be faint or negative in other epithelial cells. Pankeratin antibodies react with both epithelial and myoepithelial cells. Cytokeratins (CK) 8, 18, and 19 react with the epithelial cells throughout the TDLU but not with the myoepithelial cells, whereas the converse is true for CK14. Other immunohistochemical features of mammary epithelial cells are discussed in the section on invasive carcinoma. A sparse population of endocrine cells has been demonstrated in the normal breast with the use of chromogranin stain.[3]

It has been proposed that the two basic cell lineages of the breast—epithelial and myoepithelial—derive from a common cell that displays the phenotypic features of a committed stem cell (progenitor cell). This cell expresses CK5 in the absence of CK8, 18, and 19 and SMA. These progenitor cells are postulated to differentiate through an intermediary cell type that is CK5+ and either CK8/18+ or SMA+.[4,5]

The entire glandular system rests on a continuous basement membrane. This can be demonstrated with reticulin stains or with immunohistochemical reactions for laminin or type IV collagen.

The nipple has a very characteristic microscopic appearance. In addition to the large collecting ducts, which open onto the surface through five to nine orifices arranged as a central and a peripheral group,[6] it contains numerous sebaceous glands that open independently of hair follicles, and a dense fibrous stroma in which erectile smooth muscle tissue is embedded. *Montgomery tubercles* are areolar protuberances, usually between 10 and 20 in number, which become prominent during pregnancy; microscopically, they are formed by the association of a collecting (lactiferous) duct with sebaceous glands. The epidermis of the nipple and areola resembles that of the skin elsewhere, except for an increase in melanin content in the basal layer and the occasional presence of clear cells known as *Toker cells*, which can be mistaken for the cells of Paget disease.[7,8] The irregular corrugated appearance of the lactiferous sinus should not be confused with a pathologic condition. In approximately 15% of individuals, normal breast lobules are present in the nipple region.[9]

Breast tissue responds to hormonal and other influences throughout life, and, as a result, it may display a wide range of "normal" appearances: the immature and largely resting breast before puberty; the developed breast of reproductive life, which exhibits changes depending on the point in the menstrual cycle[10]; the actively secreting breast of lactation (Fig. 36.3); and the involuted postmenopausal breast. In the resting breast, cellular proliferation is largely confined to epithelial cells[11]; during pregnancy and lactation, all cell types show a high level of proliferative activity.[12] Nodularity and leakage of milk into the stroma can occur; exaggerated expressions of these phenomena have been designated *lactating adenoma* and *milk granuloma*, respectively.[13,14]

Mild, transient changes may be seen with initiation of contraceptive therapy. Microscopically, the only definite mammary change that can be ascribed to the medication is the development of true acini resembling those seen in the lactating breast.[15]

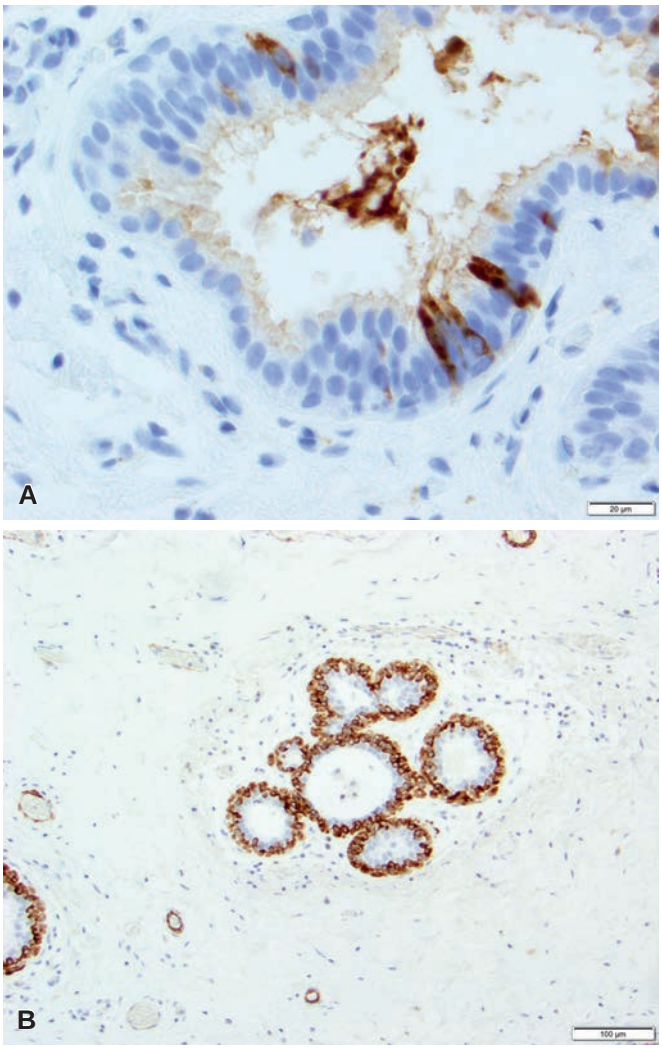

Figure 36.2 Immunohistochemical Markers of Mammary Lobule. **A,** Mammaglobin, showing positivity in scattered secretory epithelial cells and material in the glandular lumen. **B,** Smooth muscle myosin heavy chain, showing positivity in the outer myoepithelial cell component. Smooth muscle cells present in adjacent vessel walls serve as internal controls.

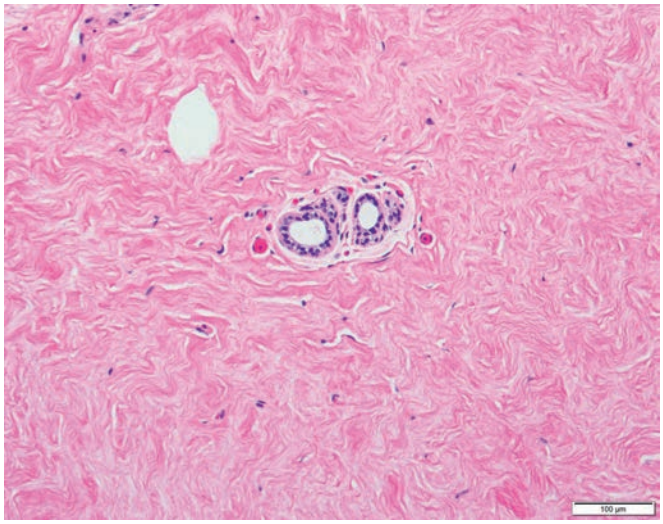

Figure 36.4 Postmenopausal Breast Tissue. The TDLU undergoes involution leaving few atrophic acini.

The process of normal *postmenopausal involution* is most apparent in the TDLU and involves both epithelium and specialized stroma (Fig. 36.4); it may acquire a microcystic quality. Deposits of elastic tissue around the ducts *(elastosis)* have been reported in nearly half of all women over 50 years of age.[16]

There are two morphologic curiosities of the breast worth knowing about, not because of their clinical significance, but because they can simulate other conditions of greater consequence. One is the *pregnancy-like change* seen in one or several lobules in the absence of pregnancy or hormonal manipulation.[17,18] The cells have abundant vacuolated cytoplasm, the nuclei are large and sometimes apically located (giving the lesion an appearance that resembles the Arias-Stella reaction), and the lumina are dilated (Fig. 36.5). Pregnancy-like change may be seen in association with *cystic hypersecretory hyperplasia (CHH)*, though the exact relationship of these two lesions is unknown at present.[19] The other process is *clear cell change* of the ductal or lobular epithelium, in which the cytoplasm acquires a finely granular, finely vacuolated, or totally clear appearance (Fig. 36.6).[17,20] The mechanism of these two changes is unknown.

The main importance of the division of the mammary gland unit into two major portions (ducts and lobules) resides in its relation to diseases of this organ. As Wellings et al.[21] convincingly showed and Azzopardi[22] strongly emphasized, the site of origin of benign breast disease, and most carcinomas (including those of so-called ductal type) is the TDLU and not the large duct system. The latter is instead the primary site of most single solitary papillomas and of duct ectasia.

Ectopia

The mammary gland is not a sharply demarcated organ; as a result, isolated mammary lobules can sometimes be seen outside the standard anatomic confines of the breast parenchyma, such as in the nipple or axilla.[9,23] The latter may explain the occurrence of some seemingly primary breast carcinomas in the axilla. Ectopic breast tissue has also been reported within axillary lymph nodes[24,25] and along the

"milk line" that runs from the axilla to the inguinal region, the most common sites being the chest wall and the vulva.[26]

Ectopic breast parenchyma is subject to changes similar to those of the orthotopic organ, including lactational changes, benign neoplasms, and carcinomas.[26,27] There is considerable overlap between ectopic breast tissue and breast-like metaplasias of sweat glands, a fact that renders precise histogenetic identification of some of these lesions almost impossible.[28]

Inflammatory and Related Lesions

Mammary Duct Ectasia

Mammary duct ectasia has also been referred to as periductal mastitis and mastitis obliterans (Fig. 36.7).[29] Most cases are seen in premenopausal women and may represent a localized response to stagnant secretions. While the pathogenesis remains unknown, some studies have shown an association with smoking.[30] As beautifully described and illustrated in the classic article by Haagensen,[31] the disease may produce retraction or inversion of the nipple and thus clinically and radiologically may simulate invasive carcinoma.

Calcification is common, producing tubular, annular, and linear shadowing on mammographic examination. Nipple discharge is present in 20% of cases. Microscopically, there is dilation of large ducts, with accumulation of lipid-rich detritus in the lumen and fibrous thickening of the wall, which contains an increased amount of elastic fibers. There is usually no accompanying epithelial hyperplasia or apocrine metaplasia. If the luminal material escapes from the duct, a florid inflammatory reaction rich in macrophages and plasma cells may ensue. In advanced stages, fibrous obliteration of the ducts can occur. Some authors have suggested that the inflammatory stage ("periductal mastitis") and the later fibrotic stage ("duct ectasia") represent two different disease processes, given the younger age and greater association with smoking in the former.[30,32]

Fat Necrosis

A process with the microscopic features of fat necrosis (i.e., foamy macrophages infiltrating partially necrotic adipose tissue) can be seen in the breast under two disparate circumstances. One is as a secondary and relatively minor event in mammary duct ectasia and—to lesser extent—with large cyst formation. In these cases, rupture of the dilated duct or cystic structures leads to extravasation of luminal contents, some degree of tissue necrosis, and a secondary inflammatory reaction in which foamy macrophages can be numerous. In particularly florid examples of this phenomenon, the term *xanthogranulomatous mastitis* has been used.[33] Parenthetically, small collections of foamy cells are seen not infrequently within duct lumina or in cohesive masses along duct walls; their immunohistochemical profile is that of histiocytes rather than epithelial cells.[34]

The other circumstance, which perhaps is the one that deserves to be called fat necrosis, is the traumatic (either accidental or surgical) type. This usually involves the superficial subcutaneous tissue rather than the breast parenchyma itself in accidental trauma (Fig. 36.8). A history of trauma, usually 1 to 2 weeks before diagnosis, can be elicited in about half the cases. The process can simulate carcinoma clinically because of skin retraction (Fig. 36.9), and also on imaging studies.[35] In long-standing cases, the nodule is harder and more fibrotic and has an orange–brown color because of the deposition of hemoglobin-derived pigments. The microscopic diagnosis is usually straightforward on core needle or excisional biopsy.

Cases of mammary fat necrosis have also been reported following radiation therapy for breast carcinoma[36] and as a local manifestation of Weber–Christian disease. Exceptionally, the fat necrosis acquires the morphologic features of the so-called membranous type, which is of variably sized cystic spaces with eosinophilic membranes, particularly in postradiation therapy cases.[37]

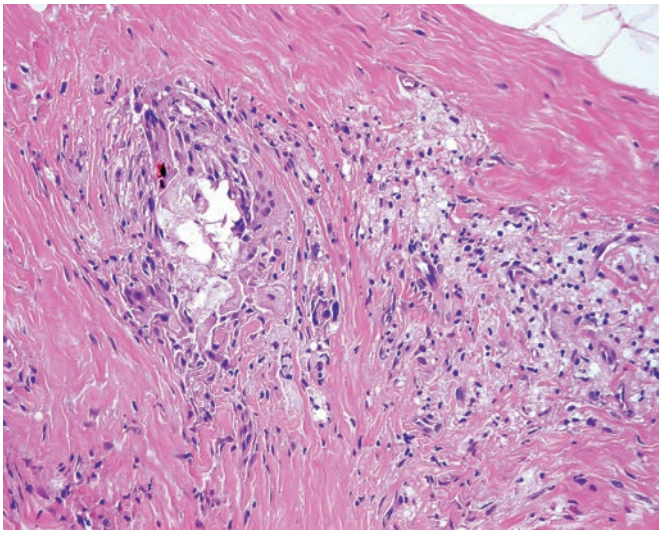

Figure 36.8 Post-traumatic fat necrosis involving breast.

Lymphocytic Mastopathy

Lymphocytic mastopathy is an unusual breast lesion of probable immune-mediated pathogenesis consisting microscopically of dense perilobular, and perivascular lymphocytic infiltrates associated with lobular atrophy and keloid-like fibrosis (Fig. 36.10).[41,42] The lymphocytes are mainly of the B-cell type. Often, the lymphocytic infiltrate is accompanied by stromal epithelioid myofibroblasts that can lead to a mistaken diagnosis of invasive carcinoma, granular cell tumor, or Rosai–Dorfman disease.[43,44] Lymphocytic mastopathy can result clinically in a palpable mass; cases can be seen in association with diabetes (hence the synonym *diabetic mastopathy*[45–47]) but may also occur in the absence of this disease or in the presence of other

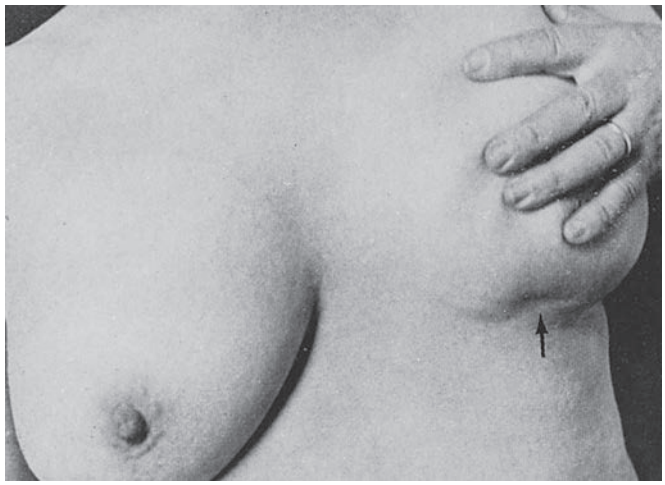

Figure 36.9 Retraction of skin in a patient with fat necrosis *(arrow)*, as seen in a photograph taken from a well-seasoned paper. (From Lee BJ, Adair F. Traumatic fat necrosis of the female breast and its differentiation from carcinoma. *Ann Surg.* 1924;80:670–691.)

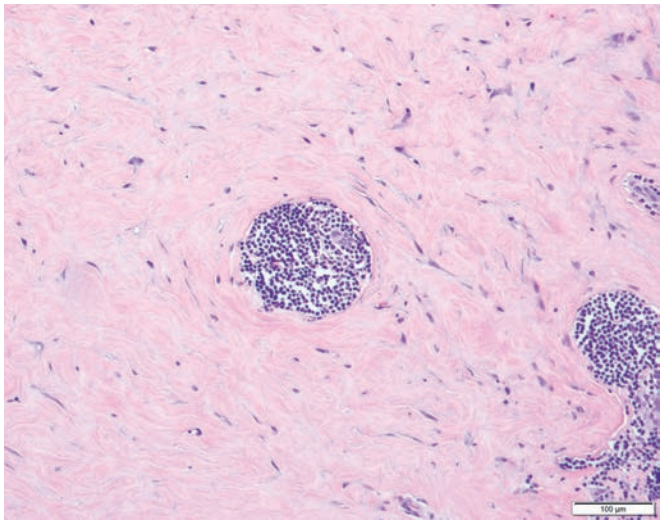

Figure 36.10 Lymphocytic Mastopathy. This process is characterized by periductal and perivascular lymphocytic infiltrates, fibrosis, and epithelioid myofibroblasts present in the stroma.

autoimmune diseases.[48] There is no increased risk for malignancy associated with a diagnosis of lymphocytic mastopathy though coexistent carcinoma has been reported.[49]

Core needle biopsy specimens of lymphocytic mastopathy may go underrecognized due to the subtle stromal changes and a tendency to overlook benign inflammatory cells. In an apparently nondiagnostic core needle biopsy of a targeted mass, the constellation of perilobular and perivascular lymphocytic infiltrates, keloidal collagen and epithelioid myofibroblasts should be examined for, before rendering a diagnosis of normal or unremarkable breast tissue.

Idiopathic granulomatous mastitis

Idiopathic granulomatous mastitis is a term applied to a granulomatous inflammatory process of the breast characterized by the presence of non-necrotizing granulomas confined to breast lobules, in which no microorganisms are identified. The suggestion has been made that the disease may be immunologically mediated and, therefore, analogous to granulomatous thyroiditis or granulomatous orchitis.[50,51] It can simulate malignancy clinically and on imaging studies.[52] Microscopically, lobulocentric granulomatous inflammation is present, usually with admixed neutrophils. It has been postulated that some cases of granulomatous mastitis may belong to the family of IgG4-related diseases[53,54] or be cases of cystic neutrophilic granulomatous mastitis (CNGM) (see next). Idiopathic granulomatous mastitis is a diagnosis of exclusion.

Cystic Neutrophilic Granulomatous Mastitis

CNGM is a relatively newly recognized entity that presents as mastitis in parous or lactating women.[55–58] It has also been described in nulliparous women with hyperprolactinemia.[59] Patients are often febrile and have a leukocytosis. Nipple inversion or retraction is common and fistulas can occur.

Histologically, this lesion is characterized by lobulocentric granulomas that often contain neutrophils or areas of microabscess formation similar to that described for idiopathic granulomatous mastitis. The feature distinguishing CNGM from idiopathic granulomatous mastitis is the presence of empty "cystic" spaces consistent with dissolved lipid (Fig. 36.11). These spaces are surrounded by neutrophils; giant cells may also be present. With careful searching, faint rod-like structures may be identified within some of these "cystic" spaces. The bacteria are more easily identified on a Gram stain as gram-positive rods morphologically consistent with *Corynebacteria*. Microbiologic identification has shown that the lipophilic bacteria *Corynebacterium kroppenstedtii* is the species most commonly present.[55,56,58] It is hypothesized that women who have been unable to breastfeed from one breast (due to nipple inversion, for example) may have stasis of lipid-rich milk secretions predisposing to the development of CNGM in that breast. It is possible that some (if not all) cases of idiopathic granulomatous mastitis represent CNGM in which the bacteria have not been recognized/identified. Note that these organisms are difficult to grow in the laboratory, requiring special culture media and prolonged incubation times. Treatment often includes antibiotic therapy (though to date this likely has not been specific to *Corynebacterium* spp.), excision and sometimes steroids. As this is an underrecognized entity, the most appropriate therapeutic algorithm has not yet been established.[55,56,60,61]

Other Inflammatory Diseases

Abscess of the breast usually results from rupture of mammary ducts, occurring most often during lactation but also independently of it.[38] It may be located deep within the parenchyma or in the periareolar region.[39] Microscopically, a central cavity filled with neutrophils and secretion is surrounded by mixed inflammatory cells and, eventually, fibrosis, with obliteration of the lobular pattern. Clinically, a localized abscess may simulate carcinoma. Periareolar abscess associated with squamous metaplasia of lactiferous ducts (SMOLD) is referred to as such or as *Zuska disease* (see later).[39,40]

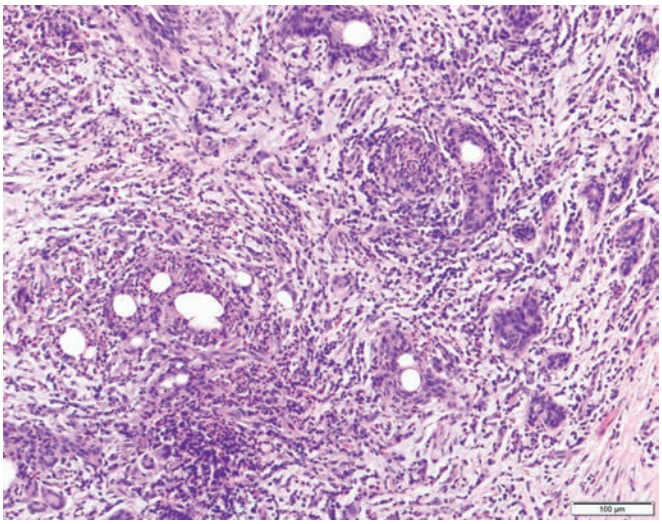

Figure 36.11 Cystic Neutrophilic Granulomatous Mastitis. In this field note the presence of "cystic" spaces cuffed by neutrophils and a background of lymphocytes, histiocytes, and giant cells (bottom left of field).

Tuberculosis of the breast may be secondary either to bloodstream dissemination or direct extension from an adjacent tuberculous process.[62] Grossly, multiple sinuses and areas of caseous necrosis occur. Microscopically, typical necrotizing granulomas are identified in most cases. The lesion may be mistaken clinically for advanced breast carcinoma. Regional nodes are often involved; occasionally, these tuberculous nodes are in an intramammary location.[63]

Actinomycosis, coccidiomycosis, and **histoplasmosis** of the breast can cause necrotizing granulomatous masses and multiple sinus tracts.[64,65]

Sarcoidosis can begin in the breast and remain localized in this organ for long periods.[66,67] Alternatively, breast involvement may be seen as a component of systemic disease.[68] The morphologic features are the same as those described for sarcoidosis elsewhere in the body.

Foreign body reaction to the polyvinyl plastic or silicone used for mammoplasty in the past or that is occasionally injected directly into the breast by unorthodox practitioners sometimes resulted in tumorlike masses and sinus tracts (Fig. 36.12) (see later for discussion of malignancy associated with implants).[69]

Breast infarct can complicate a large variety of conditions, including intraductal papilloma, fibroadenoma, phyllodes tumor, hyperplastic lobules during pregnancy, syphilis, and granulomatosis with polyangiitis.[70,71] It also has been reported in association with anticoagulant therapy, postpartum abscess, thrombophlebitis migrans disseminata, and mitral stenosis with heart failure.[72]

Mondor disease is the eponymous term given to a peculiar thrombophlebitis involving the breast and contiguous thoracoabdominal wall.[73] The condition, which may simulate clinically a malignant neoplasm, often has a sudden onset and appears as a firm, slightly nodular cord beneath the skin. Ecchymosis may or may not be present. Microscopically, the process is one of phlebitis with thrombosis. With time, the thrombus recanalizes completely. The condition is self-limited and practically never recurs. It may be related to mechanical injury, as suggested by the fact that in 8 of

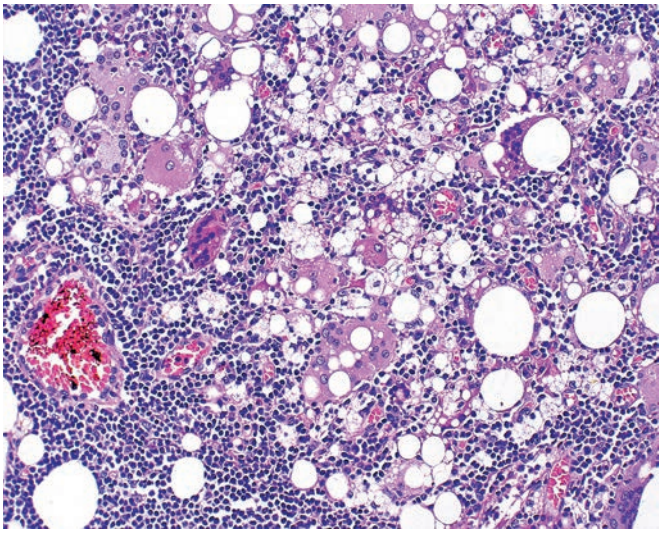

Figure 36.12 Florid Granulomatous Reaction to Silicone. Foamy macrophages, foreign body–type multinucleated giant cells, and lymphocytes are present.

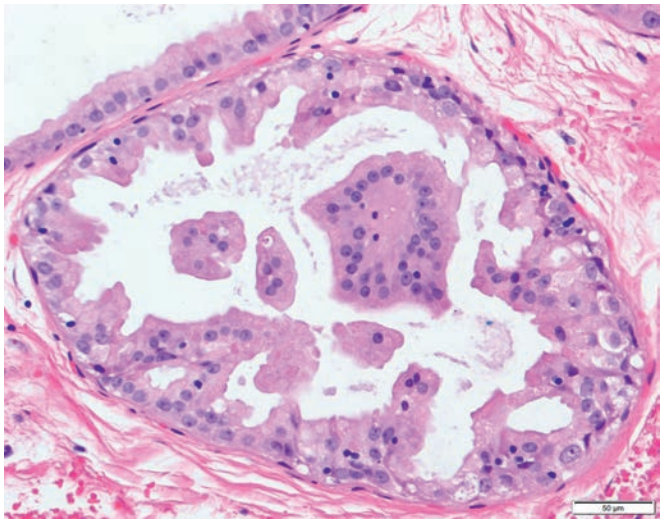

Figure 36.13 Apocrine Metaplasia. The cells have abundant granular eosinophilic cytoplasm, often with an apical "apocrine snout." The nuclei are round, of medium size and have prominent nucleoli.

the 15 cases reported by Herrmann[74] the disease appeared a few months after radical mastectomy. A few cases have been found to be associated with untreated breast carcinoma.[75]

Rheumatoid nodules, periarteritis nodosa, lupus profundus, and **granulomatosis with polyangiitis (Wegener granulomatosis)** may present as single or multiple breast masses.[70,76–82]

Benign Breast Disease

Benign breast disease is the term used to describe collectively an interrelated group of proliferative disorders of the breast parenchyma, many of which are not true neoplasms but, rather, hormone-induced hyperplastic processes.[83]

Intraductal Proliferative Lesions and Nonproliferative Changes

Fibrocystic change was the term introduced by the College of American Pathologists (CAP) for the collective description of nonproliferative and proliferative changes of the breast.[84] It was the term preferred over "fibrocystic disease," and was to be followed by specification of the component lesions in the body of the pathology report or in the diagnosis, but neither of these terms is widely used in reports today, rather the component lesions are listed a priori. Benign breast lesions form an extremely important group because of their high frequency, the ability of some of the lesions to simulate the clinical, radiographic, gross, and microscopic appearance of carcinoma, and the relationship of some of the lesions to carcinoma.[85]

Nonproliferative and intraductal proliferative lesions are most frequently seen, at least at the clinical level, between the ages of 25 and 45 years. Proliferative lesions of the breast are more common in Anglo-Saxon than in Latin American, Native American, or Japanese women.[86] The real incidence is difficult to estimate because the diagnosis depends a great deal on definitions used by the individual clinician, radiologist, or pathologist.[87] The cumulative incidence of biopsy-proven benign breast disease is approximately 9% among women below the age of 65 years, which compares with a rate of between 50% and 60% from autopsy series.[87,88] Hormones play a role in the development of proliferative lesions of the breast, but the exact pathogenesis remains obscure.[89] There is no definitive evidence that administration of oral contraceptives increases the degree of epithelial proliferation.[90] Epidemiologic evidence suggests a modest relationship between alcohol consumption and the development of benign breast disease and ultimately to subsequent breast cancer risk, with an inverse relationship being found for coffee consumers.[91,92]

It is important to realize that nonproliferative and proliferative breast lesions primarily affect the TDLU, although epithelial hyperplasia can also extend to larger ducts. The basic morphologic changes are the following:

Nonproliferative Changes

1. **Cysts.** These can be microscopic or grossly visible and sometimes reach large proportions. They usually contain a cloudy yellow or clear fluid. Some of these cysts have a bluish cast ("blue dome cysts" of Bloodgood). Occasionally, numerous small thin-walled cysts are seen in the breast parenchyma surrounding a large cyst. Microscopically, the epithelial lining of most cysts, especially the larger ones, is flattened or absent, the cyst having only a thick fibrous wall. Frequently cysts rupture and elicit an inflammatory response in the stroma, with abundant foamy macrophages and cholesterol clefts. Azzopardi has observed that cysts—no matter how large—arise from the TDLU rather than from ducts.[22]
2. **Apocrine metaplasia.** This is a very common change. It is most often seen in dilated and cystic structures, but it may appear in normal-sized lobules as well. The individual cells have abundant granular eosinophilic cytoplasm, often with supranuclear vacuoles and yellow–brown pigment, some of which contains iron. The apical portion of the cytoplasm shows the typical "apocrine snout." The nucleus is round and medium sized, and the nucleolus can be very prominent (Fig. 36.13). Periodic acid–Schiff (PAS) stain shows a crescent of coarse glycolipid granules on the luminal side. Immunohistochemical stain for GCDFP-15 shows strong cytoplasmic reactivity, and there is strong nuclear reactivity for androgen receptor.[93] Clusters of apocrine cysts may be detected on imaging studies as a "mass lesion" or as an area of calcifications, prompting core needle biopsy. Typically the calcifications take the form of calcium oxalate crystals, which may be overlooked on routine histologic examination. Viewing the cysts through polarized light will reveal the translucent crystals.

3. **Fibrosis.** "Fibrosis" is often present, but its degree varies markedly and thus deciding when it is pathologic can be a challenge. It is probably most often seen as an event secondary to cyst rupture, and it may proceed to hyalinization. The terms *fibrous disease* of the breast and *fibrous mastopathy* have been used by some authors to designate a breast condition in which the main change seems to be a more or less localized stromal fibrosis; however, it is not clear that this represents a distinct clinicopathologic entity, and since it is difficult to determine an individual woman's degree of "fibrosis," particularly on a core needle biopsy, use of the term is discouraged.
4. **Calcification.** Chemically, calcification may be composed of calcium phosphate or calcium oxalate. On mammography, calcium oxalate is amorphous, of low-to-medium density and is nearly always associated with benign disease. The crystals can be easily missed on routine sections; they are better seen with polarized lenses (because of their birefringent quality). As mentioned previously, calcium oxalate is frequently associated with apocrine cysts, and searching for the crystals with that knowledge in mind can be fruitful. Calcium phosphate is of medium-to-high density on imaging studies and is readily detectable on hematoxylin–eosin (H&E) stained sections.
5. **Chronic inflammation.** This is another common but secondary feature present in benign breast biopsies. It is usually related to cyst rupture, with release of secretion into the stroma. Lymphocytes, plasma cells, and foamy histiocytes are the predominant elements. Cysts with associated intense chronic inflammation should not be confused with mammary duct ectasia.

Intraductal Proliferative Lesions

Usual Ductal Hyperplasia

Usual ductal hyperplasia (UDH) is the preferred term of the WHO Working Group. The degree of proliferation may be commented upon if desired: *mild* (when made up of three or four epithelial cells in thickness) or *moderate to florid* (when more pronounced). In florid UDH, the entire lumen is filled by the epithelial proliferation. The features most helpful in recognizing the benign nature of the proliferation are the following:

1. Nuclei that are oval (rather than round, except when cut transversely), normochromatic (rather than hyperchromatic), with nuclear grooves, and with slight overlap; small, single, indistinct nucleoli; occasional intranuclear inclusions; scant or no mitotic activity (Fig. 36.14).
2. Cytoplasm that is eosinophilic rather than pale and homogeneous.
3. Indistinct cytoplasmic borders, so that the nuclei seem to lie in a syncytial mass rather than within sharply outlined cell membranes.
4. Streaming effect, induced by the oval cells being vaguely arranged in parallel bundles (Fig. 36.15).
5. "Tufts" and "mounds" projecting into the lumen.
6. Presence of peripheral elongated clefts, bound on one side by a single layer of basally located cells and on the other by a solid intraluminal formation; sometimes this cleft spans almost the entirety of the circumference, with the retracted solid ball of epithelial cells hanging from the wall like the vascular tuft of a renal glomerulus. The intercellular lumina of UDH tend to be irregular in size, shape (elongated rather than round), and location (predominating at the periphery) rather than regular in all three parameters as seen in the cribriform pattern of ductal carcinoma in situ (DCIS). Notably, there is an absence of cellular polarization around the clefts.

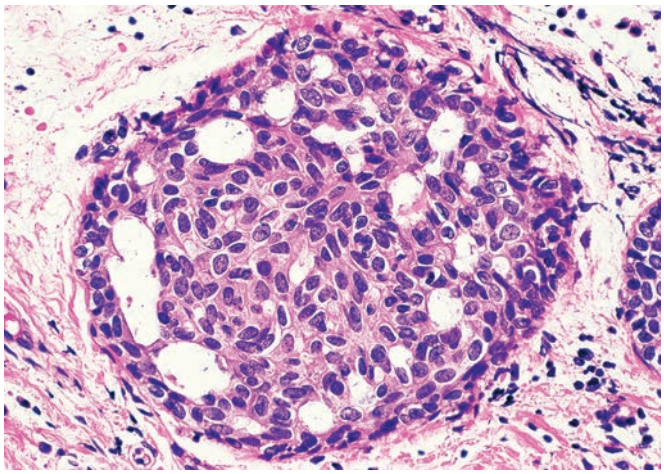

Figure 36.14 Usual Ductal Hyperplasia. In this proliferation note the presence of oval nuclei that are normochromatic, with slight overlap giving the cells a streaming appearance. The clefts are preferentially located at the periphery of the duct and there is a lack polarization of cells around the spaces.

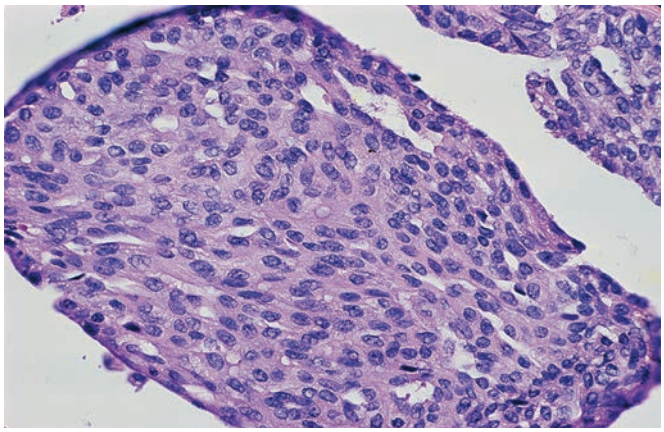

Figure 36.15 Usual Ductal Hyperplasia. Note the oval shape of the nuclei and the parallel arrangement, resulting in a "streaming" effect.

7. Presence of irregularly shaped bridges connecting opposite portions of the wall. The cells in these bridges have oval nuclei arranged parallel to the long axis of the bridge. Their appearance is very different from that seen in the rigid trabecular bars and Roman bridges of low nuclear grade DCIS.
8. Complete or incomplete apocrine metaplasia.
9. Presence of a peripheral layer of myoepithelial cells, with clear or eosinophilic cytoplasm, or elongated and smooth muscle-like ("myoid").
10. Presence of foamy macrophages, both in the lumen and intimately admixed with the proliferating epithelial cells.[94]
11. Occasional intraluminal or stromal calcifications.
12. Absence of necrosis (though see below).

As important as these features are, none of them is diagnostic by itself. They need to be weighed against each other, sometimes modified depending on the nature of the case, and occasionally ignored altogether. For instance, focal necrosis may be found in UDH, particularly in the setting of UDH in a nipple adenoma. Furthermore, proliferative benign breast disease and carcinoma can coexist, which means that an area may be diagnostic of DCIS even

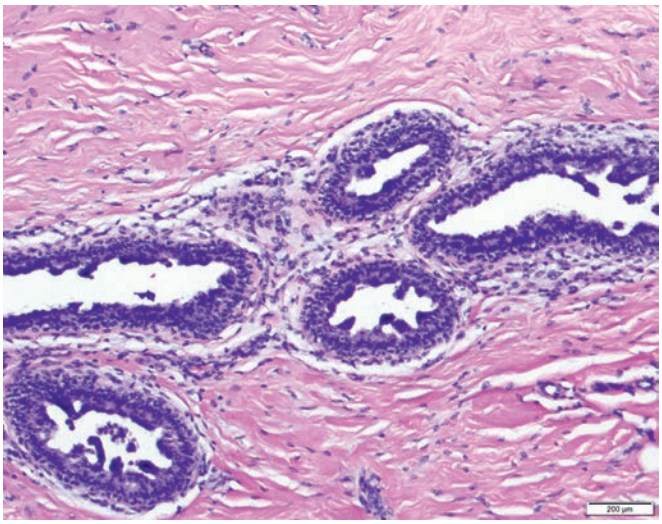

Figure 36.16 Gynecomastoid Hyperplasia. A form of UDH characterized by micropapillary tufting of the lining epithelium; the micropapillae have broader bases and narrow pinched tips. The nuclei are also smaller and more hyperchromatic at the tips than at the bases of the micropapillae.

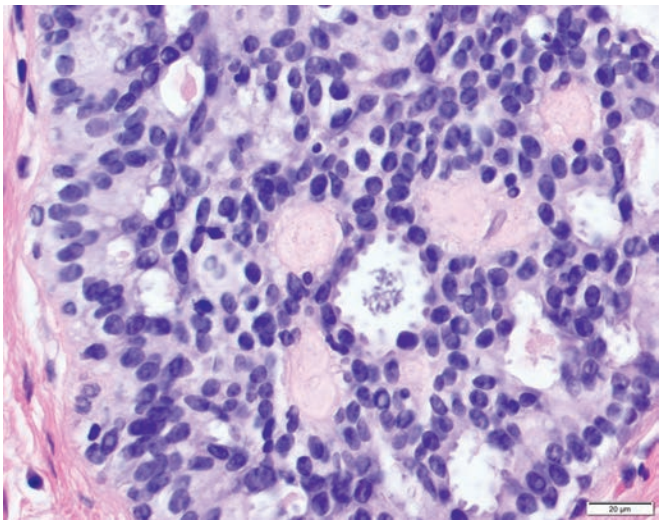

Figure 36.17 Collagenous Spherulosis. The round spaces contain eosinophilic or sometimes basophilic collagen-rich spherules composed of basement membrane material. Note the more spindled nuclei of the myoepithelial cells surrounding the spaces containing the eosinophilic basement membrane material.

if the immediately surrounding glands show features indicative of benign disease.

Immunohistochemically, UDH is characterized by a heterogeneous or "mosaic" pattern of immunoreactivity for HMW cytokeratin antibodies, in particular for CK 5/6 (which is preferred over 34βE12).[95] This is of importance in the differential diagnosis with atypical ductal hyperplasia (ADH) and low and intermediate nuclear grade DCIS, which lack reactivity for HMW cytokeratins. The combination of CK 5/6 with estrogen receptor (ER), which also shows a heterogeneous pattern of staining in UDH whereas strong, diffuse nuclear staining is seen in ADH and DCIS, can be particularly helpful in this differential diagnosis.

Other benign intraductal proliferations, or variants of UDH, of note include the following:

Gynecomastoid hyperplasia is a form of UDH of the female breast that resembles gynecomastia of the male breast and is characterized by micropapillary tufting of the lining epithelium. The micropapillae have broad bases and narrow pinched tips with nuclei that are larger at the base than at the tip of the micropapillae (Fig. 36.16).

The special variant of ductal hyperplasia known as *juvenile papillomatosis* or "Swiss cheese" disease is discussed later in this chapter.

Collagenous spherulosis is characterized by the presence of intraluminal eosinophilic but sometimes basophilic, collagen-rich spherules that arise within spaces surrounded by myoepithelial cells (Fig. 36.17).[96] Ultrastructurally, the spherules show a variable composition of basement membrane material, banded collagen, and mineral deposition.[97] This curious entity can be confused with adenoid cystic carcinoma, signet ring carcinoma, and cribriform pattern DCIS. It should be noted that collagenous spherulosis can be seen in association with intraductal papilloma, sclerosing adenosis and lobular carcinoma in situ (LCIS).[98] The latter can be a particular pitfall in the distinction with cribriform pattern DCIS due to the monomorphic appearance of the LCIS cells in combination with the cribriform appearance of collagenous spherulosis (Fig. 36.18).[99]

Cystic hypersecretory hyperplasia is characterized by the presence of cystically dilated ducts containing a bright pink colloid-like material lined by cells that have relatively abundant vacuolated or secretory cytoplasm (Fig. 36.19A); this lesion needs to be distinguished from cystic hypersecretory carcinoma, not always an easy task.[100] CHH can become atypical (CHH with atypia or DCIS), which is recognized by an increase in architectural and nuclear atypia (see Fig. 36.19B).[101]

Having discussed benign *ductal* proliferations, specifically UDH, it should be noted that the term lobular hyperplasia should never be used unless qualified as atypical lobular hyperplasia (ALH) (see next).

Atypical Ductal Hyperplasia and Atypical Lobular Hyperplasia

As already mentioned, there is a wide range in the degree of epithelial proliferation in benign breast disease. It has been demonstrated that there is a correlation between proliferative breast disease and the risk of development of invasive carcinoma.[102–105] Dupont and Page[103] proposed the terms *ADH* and *ALH* for proliferative lesions in which some but not all of the features of DCIS or LCIS, respectively, are present. Using these criteria in a retrospective study of women with benign breast disease, they diagnosed atypical hyperplasia (ADH and/or ALH) in 3.6% of the cases and demonstrated that these patients had a relative risk for the subsequent development of invasive breast carcinoma that was 4 to 5 times that of the general population (i.e. about half of that of DCIS or LCIS). Largely on the basis of that study, the recommended grouping of patients with benign breast disease (previously "fibrocystic change") is into the following three categories[106]:

1. No or mild UDH (**nonproliferative changes**): no increased risk for subsequent invasive carcinoma.
2. Moderate or florid UDH (**proliferative disease without atypia**): 1.5–2 times the risk.
3. ADH or ALH (**atypical hyperplasia**): 4–5 times the risk.

For completeness and comparison purposes, Page[107] added to this list the following category:

4. DCIS or LCIS: 8–10 times the risk.

The Page–Dupont studies represent an extremely important contribution to the study of benign breast disease vis-à-vis breast carcinoma, as well as the standardization of nomenclature and criteria in the diagnosis of benign breast disease, which in turn have had a

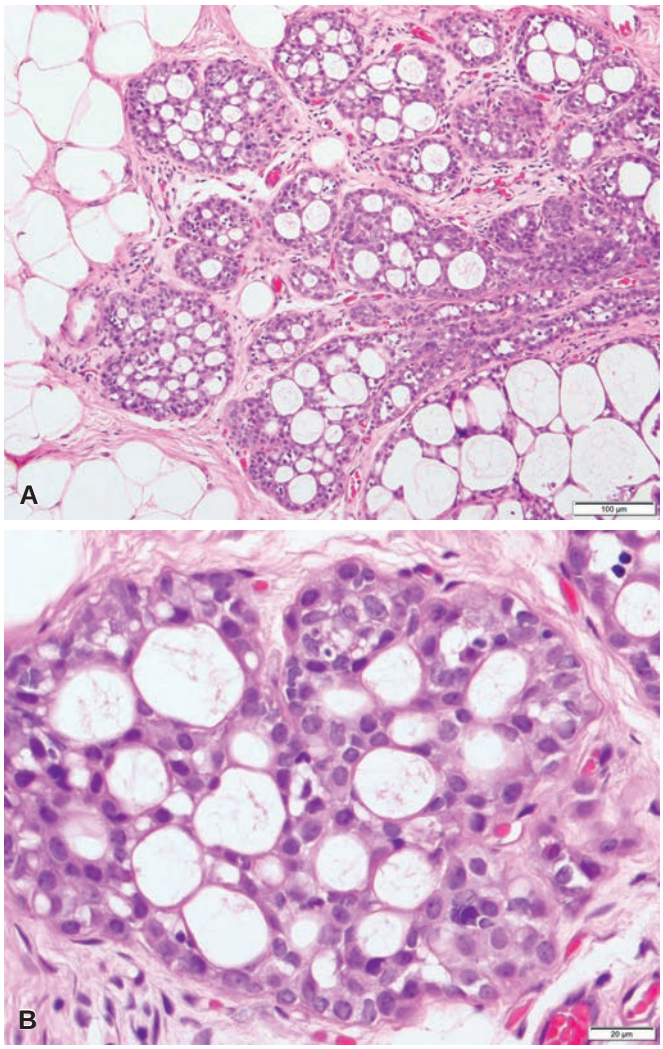

Figure 36.18 Lobular Carcinoma In Situ Involving Collagenous Spherulosis. The monomorphic appearance of the LCIS cells in combination with the cribriform appearance of the collagenous spherulosis can be a mimic for ductal carcinoma in situ at low power **(A)**. At high power **(B)**, the cytologic atypia and cellular dyshesion of the LCIS is better appreciated. Again, note the presence of myoepithelial cells surrounding the spaces containing the eosinophilic basement membrane material.

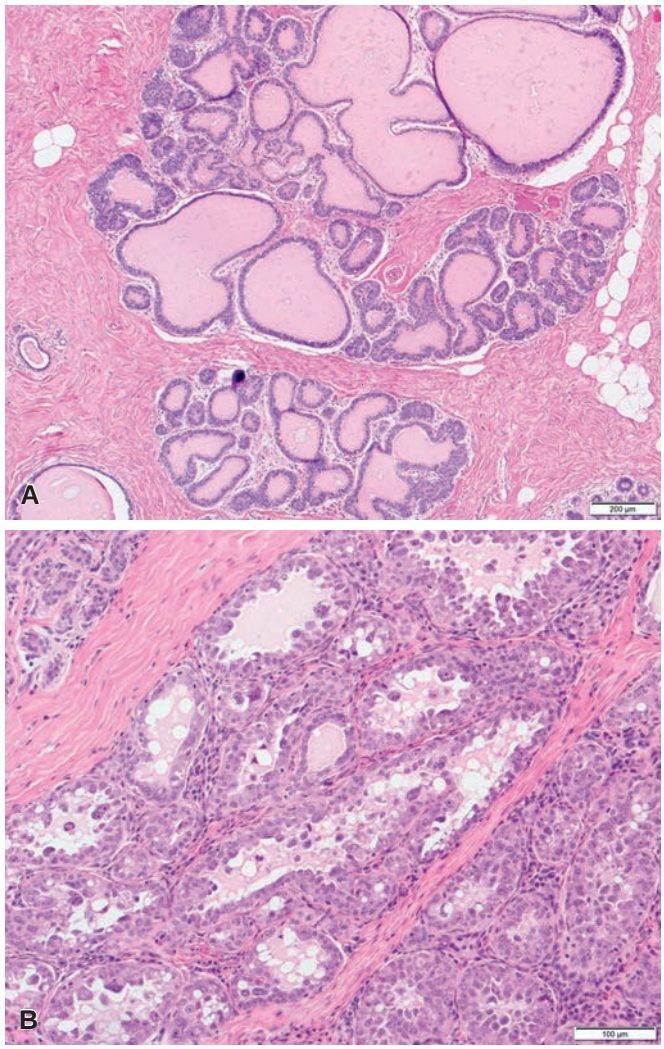

Figure 36.19 A and **B,** Cystic hypersecretory hyperplasia (CHH) is characterized by the presence of cystically dilated spaces containing a bright pink colloid-like material lined by cells that have relatively abundant vacuolated or secretory cytoplasm **(A)**. The lesion can demonstrate areas of architectural and cytologic atypia **(B)**, in this case sufficient for a diagnosis of ductal carcinoma in situ.

great impact on patients, clinicians, and pathologists. The currently accepted definition of *ADH* is that of a lesion with cytologic and architectural features indistinguishable from those of low-grade DCIS, that is, monomorphic cells with ovoid to rounded nuclei and the formation of micropapillae, tufts, fronds, bridges, solid, and/or cribriform patterns within the involved space (Figs. 36.20–36.22), *but* either (1) intimately admixed with UDH or (2) showing only partial involvement of the TDLU. Quantitative requirements have been proposed for when there is complete involvement of the space(s) involved (namely to be ≤2 mm or to be present in fewer than two adjacent spaces; the corollary being that a diagnosis of low-grade DCIS would be rendered if these same cells involved two or more spaces or measured >2 mm); the most recent WHO Working Group did not recommend one size/extent approach over another.[108]

ALH is defined as a monomorphic proliferation of atypical epithelial cells with round nuclei and indistinct nucleoli. The cells are dyshesive and often have intracytoplasmic lumina (Figs. 36.23 and 36.24). ALH is said to be present when less than 50% of the TDLU is expanded by the atypical proliferation, with LCIS being defined as greater than 50% of the TDLU expanded by the atypical proliferation. Pagetoid extension along the ducts may also be seen in ALH.

There are no special techniques (e.g., morphometry, DNA ploidy studies, immunohistochemical stains, or genetic molecular tests) that are able to separate ADH and ALH from low nuclear grade DCIS and LCIS, respectively.[109,110]

Columnar Cell Lesions and Flat Epithelial Atypia

A further variation on the theme of mammary ductal hyperplasia, the identification of which has increased through screening mammography because of the association with microcalcifications, is the group of lesions collectively referred to as columnar cell lesions. The lesions that make up this group are columnar cell change, columnar cell hyperplasia, and flat epithelial atypia (FEA), which is the terminology preferred by the WHO Working Group.[111]

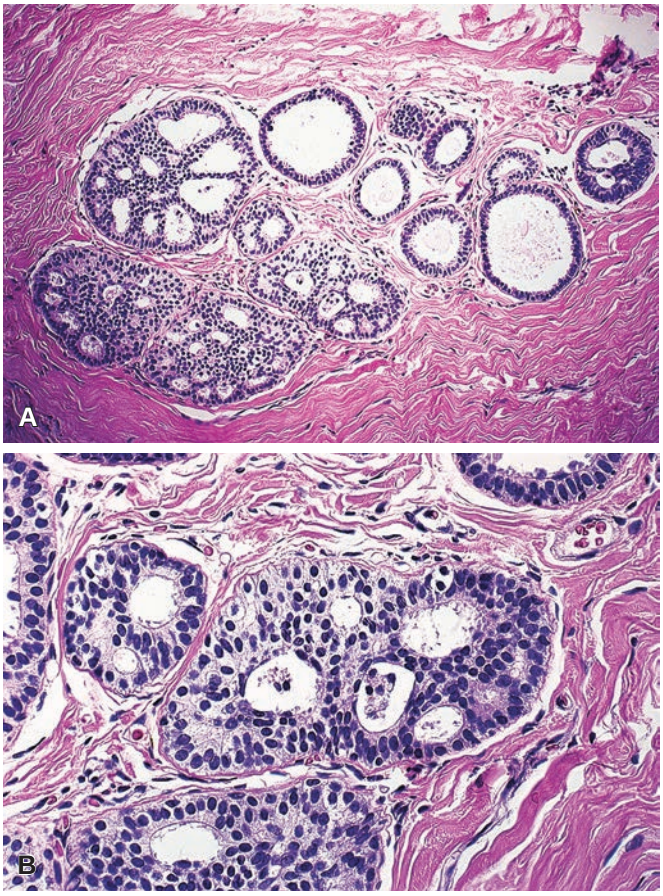

Figure 36.20 **A** and **B,** Atypical ductal hyperplasia. Proliferative ductal lesion with monomorphic cells and cribriform architectural pattern diagnosed as atypical ductal hyperplasia on account of these cytoarchitectural features and small lesion size.

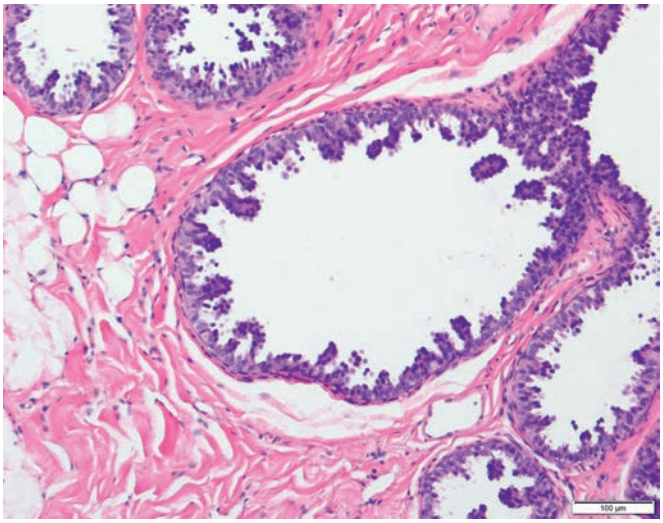

Figure 36.21 **Atypical Ductal Hyperplasia.** This micropapillary proliferation demonstrates bulbous micropapillations with enlarged atypical nuclei present both at the base and the tip of the micropapillations.

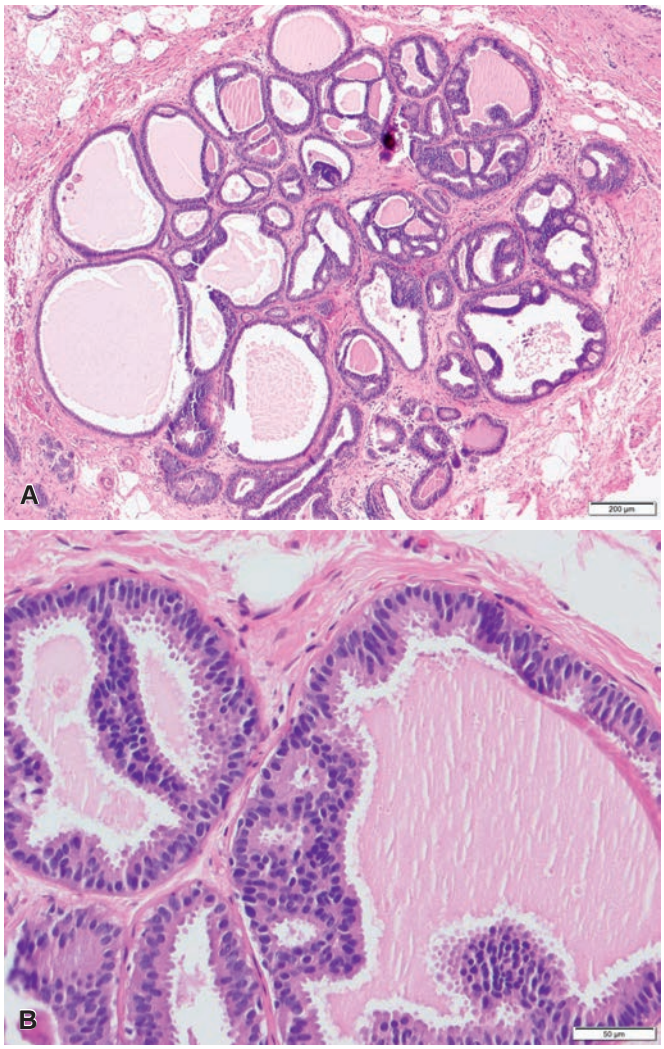

Figure 36.22 **Atypical Ductal Hyperplasia. A,** A TDLU with a predominantly cribriform proliferation of monomorphic epithelial cells; some rigid bridges and bars are also present. **B,** At high power note the low-grade nuclear atypia and the polarization around the cribriform spaces.

Unfortunately, the literature is awash with other names for these lesions. For example, early terms for FEA included low-grade (monomorphic) clinging carcinoma, atypical cystic lobules, atypical columnar change, columnar cell hyperplasia and columnar cell change with atypia.

FEA is characterized by a single or stratified layer of columnar to cuboidal cells with low nuclear grade cytologic atypia and loss of polarization with respect to the basement membrane. There is variable dilatation of the acini of the affected TDLUs, with smooth, rather than irregular, contours (Figs. 36.25 and 36.26). Apical snouts can be prominent. The lumens of the acini contain granular secretions and/or calcifications.[112] It may seem paradoxical that a lesion can be flat and columnar at the same time; the explanation is that "flat" refers to the "architectural" appearance of the involved acini, whereas "columnar" refers to the shape of the lining epithelial cells.

In contrast to FEA, *columnar cell change* and *columnar cell hyperplasia* refer to these same architecturally "flat" lesions but without the cytologic atypia. It is these two lesions in which the lining epithelial cells are most recognizably columnar with elongated nuclei oriented perpendicular to the basement membrane, whereas in FEA the lining epithelial cells tend to have a more cuboidal appearance. In columnar

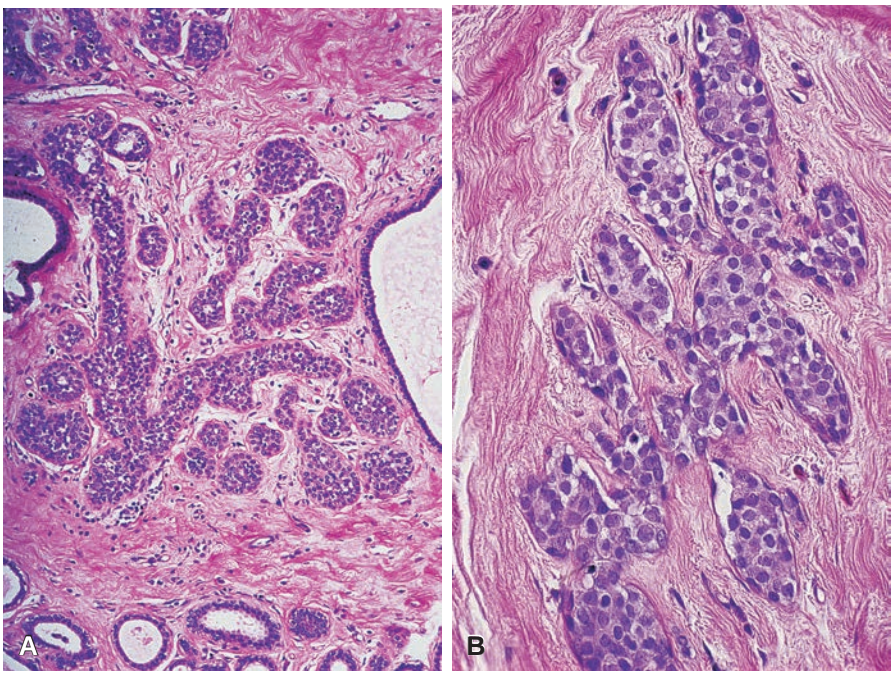

Figure 36.23 Atypical Lobular Hyperplasia. A, There is expansion of the lobules by a monomorphic proliferation of atypical epithelial cells with round nuclei and indistinct nucleoli. **B,** The cells are dyshesive and often have intracytoplasmic lumina, which can be appreciated at higher power.

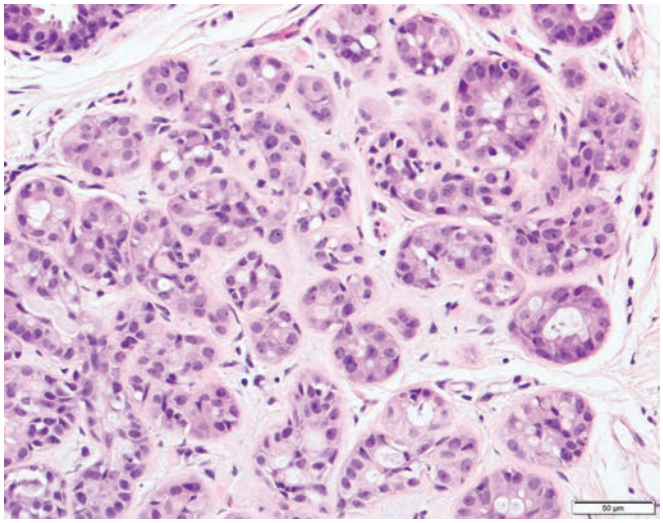

Figure 36.24 Atypical Lobular Hyperplasia. There is expansion of the lobules by a monomorphic proliferation of atypical epithelial cells with enlarged nuclei and small nucleoli. The cells are dyshesive and many have intracytoplasmic vacuoles.

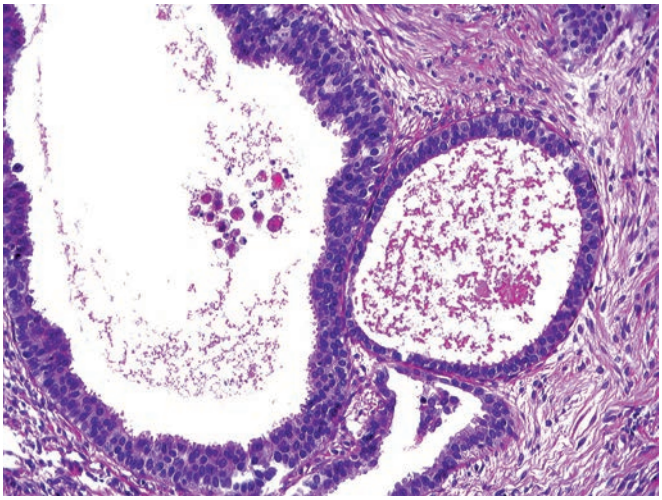

Figure 36.25 Flat Epithelial Atypia. The spaces are dilated and lined by a stratified layer of cuboidal cells with low-grade cytologic atypia.

cell hyperplasia, there is stratification of the lining epithelial cells with some tufting but no true micropapillations. Other features of these lesions include variably dilated acini with irregular acinar contours, prominent apical snouts, luminal secretions, and calcifications (Figs. 36.27 and 36.28).[111] ER is strongly positive, CK5/6 is negative, and there is an increased expression of MIB-1 in all columnar cell lesions.[113]

The biologic significance of FEA is still being elucidated, but it is generally thought to be the earliest step in the low-grade breast neoplasia pathway (perhaps the precursor to ADH),[114] with a subsequent breast cancer risk similar to proliferative lesions without atypia (i.e., 1.5- to 2-fold risk), though it may be that there is no increase in risk over and above that of any associated proliferative lesion present.[115–117] In several studies, columnar cell lesions have been found to be frequently associated with low-grade DCIS, LCIS, and pure and/or mixed forms of tubular carcinoma.[118–121]

Nomenclature of Proliferative Ductal and Lobular Lesions

While the nomenclature first suggested by Page et al. and endorsed by the CAP is the preferred term of the WHO Working Group,[122] other terminology has been suggested, such as mammary intraepithelial neoplasia (MIN) of either ductal or lobular type, followed

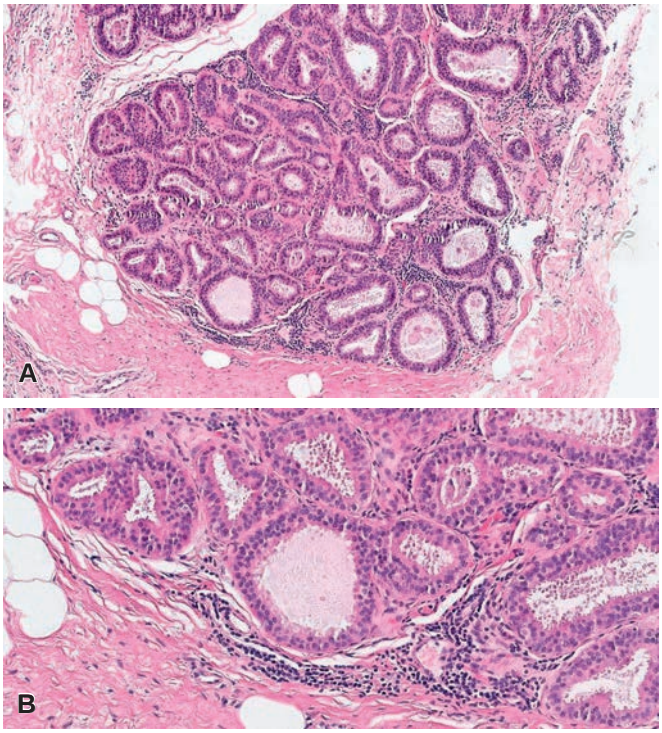

Figure 36.26 Flat Epithelial Atypia. A, The acini of the terminal duct lobular unit are variably dilated and the spaces lined by a stratified layer of monomorphic cuboidal cells. **B,** At higher power the low-grade cytologic atypia is appreciated as well as the apical snouts and secretions.

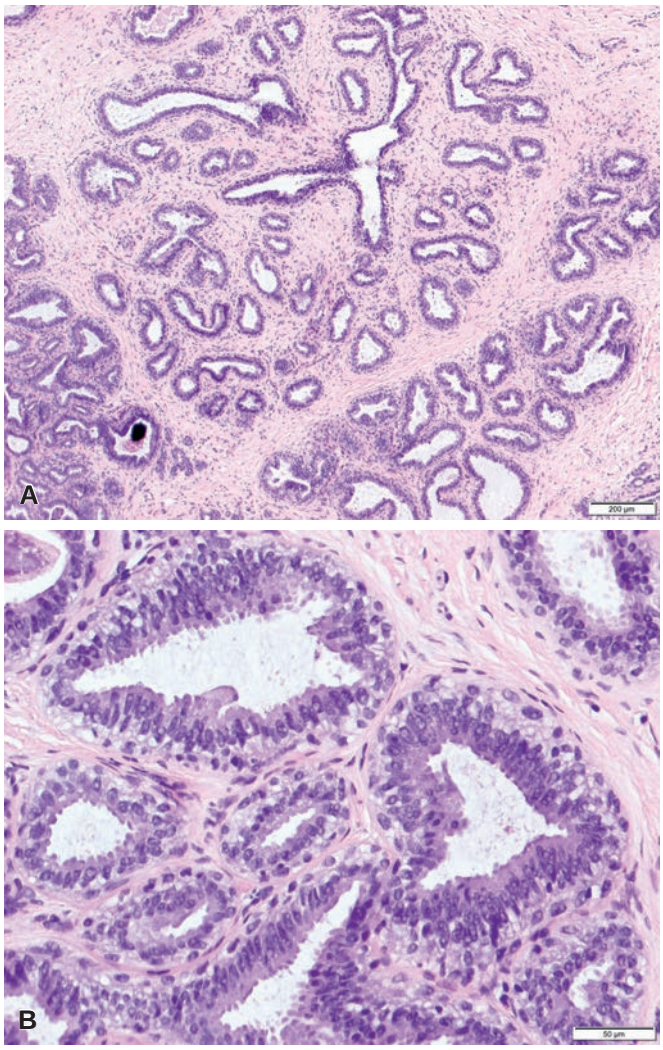

Figure 36.27 Columnar Cell Change. A, The acini of the terminal duct lobular unit are variably dilated and the spaces lined by a layer of columnar epithelial cells; a calcification is present in the lower left of the field. **B,** At higher power the columnar cells are seen to be arrayed perpendicular to the basement membrane; apical snouts are present.

by a grading system[123] in accordance with the trend at many other sites, such as cervix (CIN), prostate (PIN), and gastrointestinal tract. Tavassoli and her group have further developed this nomenclature, according to the scheme shown in Table 36.1.[124–126]

The proposal has some merit; in point of fact, many of the arguments that have been raised against its adoption apply to other organ sites just as well, yet they have not prevented a terminology change taking place in those sites. There is one issue, however, that deserves comment. The ductal intraepithelial neoplasia (DIN) numerical terminology implies a continuum of changes, which may or may not exist. The alternative view, masterfully articulated by Azzopardi[22] and currently supported by many experts, is that proliferative breast disease can be divided into distinct categories: the "usual" hyperplasia category and the intraductal carcinoma category, which may be further subdivided into a low-grade and a high-grade pathway.[127] In this scheme, ADH and likely FEA are the nonobligate precursors to low nuclear grade DCIS. Given this, linking these conditions (i.e., low- and high-grade DCIS) in a grading system that presupposes a nosologic unity might be misleading. In practice, the MIN schema has not been widely adopted in the United States, and this terminology was not included in the 2012 edition of the WHO publication on Tumors of the Breast.[128]

Relationship With Carcinoma and Management

A relationship between benign breast disease and breast carcinoma has been suggested over the years on the basis of the following evidence:

1. The observation that breast tissue excised for carcinoma usually also exhibits changes of benign breast disease[129] and that there is a greater degree of epithelial proliferation than is found in a population without carcinoma.[130]
2. The fact that retrospectively studied breast biopsies in patients who subsequently developed invasive carcinoma often show proliferative disease without atypia or atypical hyperplasia rather than nonproliferative changes.[131,132]
3. The parallelism in incidence of breast carcinoma and benign proliferative breast lesions in various populations,[133] including the fact that kindreds susceptible to breast carcinoma also inherit a predisposition to proliferative breast disease.[134]
4. The presence of molecular alterations in atypical hyperplasias that parallel those of breast carcinoma.[114,135–138]
5. The observation that patients with benign breast disease are found to develop invasive carcinoma at a higher rate than a control population.[139–141] Parenthetically, the breast carcinomas that develop in patients with a previous diagnosis of benign breast disease do not differ depending on the histologic category of the latter.[142]

A quantitative leap was made once it was demonstrated that it is not benign breast disease per se but rather the presence and type of epithelial proliferation that determines the risk for subsequent carcinoma and that this risk seems to range from one to five times

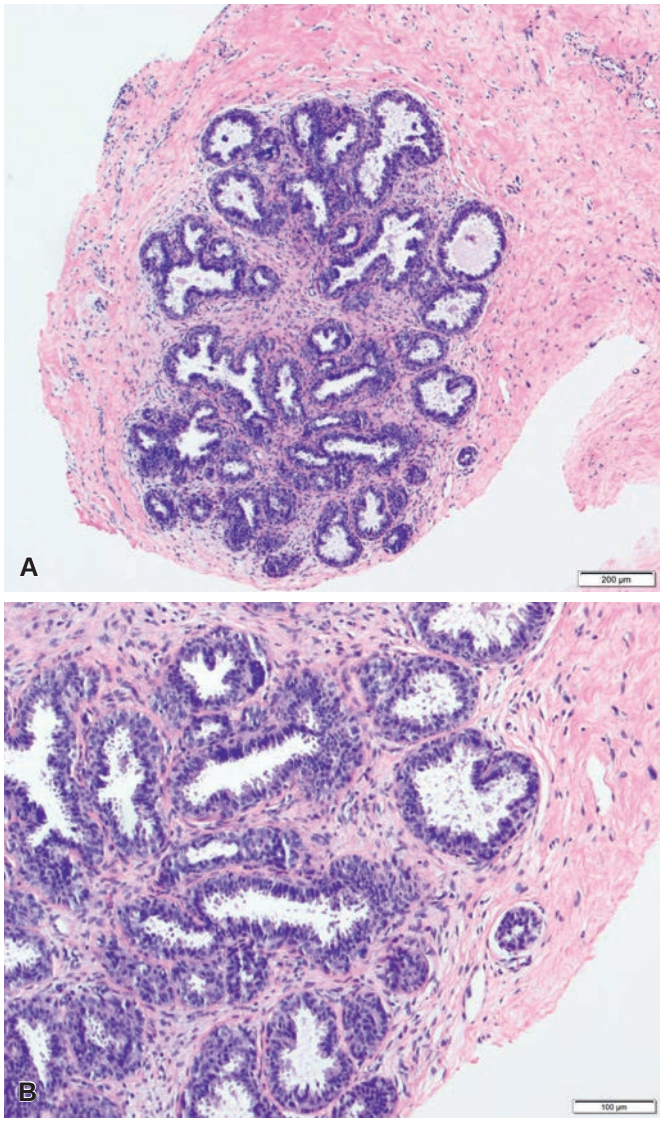

Figure 36.28 Columnar Cell Hyperplasia. A, The acini of the terminal duct lobular unit are variably dilated and the spaces lined by a layer of columnar epithelial cells with some multilayering and tufting; calcifications are present in some acini (*upper part* of field). **B,** At higher power the columnar nature of the cells is appreciated as well as the apical snouts.

Table 36.1 Alternate nomenclature of proliferative ductal and lobular lesions

TRADITIONAL TERMINOLOGY	MIN TERMINOLOGY
Usual ductal hyperplasia	(No DIN equivalent)
Flat epithelial atypia	DIN1A
Atypical ductal hyperplasia	DIN1B
DCIS low nuclear grade	DIN1C
DCIS intermediate nuclear grade	DIN2
DCIS high nuclear grade	DIN3
Lesions in the ALH/lobular CIS spectrum	LIN 1, 2, and 3
Proliferative epithelial lesions not easily placed into either a ductal or a lobular category	MIN

ALH, Atypical lobular hyperplasia; *CIS*, carcinoma in situ; *DCIS*, ductal carcinoma in situ; *DIN*, ductal intraepithelial neoplasia; *LIN*, lobular intraepithelial neoplasia; *MIN*, mammary intraepithelial neoplasia.

that of the control population, as indicated in the section on atypical hyperplasia.[107,143] This fact, which has been confirmed in independent studies,[139,140] indicates that evaluation of epithelial hyperplasia is an important gauge in deciding on the best approach to ongoing management for these patients. Naturally, several other factors need to be taken into consideration, such as the length of time since the diagnosis of atypical hyperplasia was made and the type of atypical hyperplasia (ADH vs. ALH).[144–147] In general, a conservative approach to benign breast disease is amply justified.[148]

Fibroepithelial Lesions

Fibroadenoma

Fibroadenoma is a very common benign neoplasm typically occurring in patients between the ages of 20 and 35 years. It increases in size during pregnancy and tends to regress with age. It is usually single, but in 20% of cases there are multiple lesions in the same breast or bilaterally.

Grossly, the typical fibroadenoma is a sharply demarcated, firm mass, usually no more than 3 cm in diameter. The cut surface is solid, grayish white, and bulging, with a whorled pattern and slit-like spaces (Fig. 36.29). Necrosis is absent.

Microscopically, fibroadenomas vary in appearance from case to case, depending on the relative amounts of glandular and fibrous tissue and the configuration of the former (Fig. 36.30). They are labeled *intracanalicular* when the connective tissue invaginates into the glandular spaces so that it appears to be within them, and *pericanalicular* when the regular round or oval configuration of the glands is preserved. Often, both growth patterns are seen in the same lesion and the distinction has no clinical connotations. The glands are composed of cuboidal or low columnar cells with round, regular nuclei resting on a myoepithelial cell layer. The stroma is usually made up of loose connective tissue rich in acid mucopolysaccharides, but it may be partially or completely composed of a dense

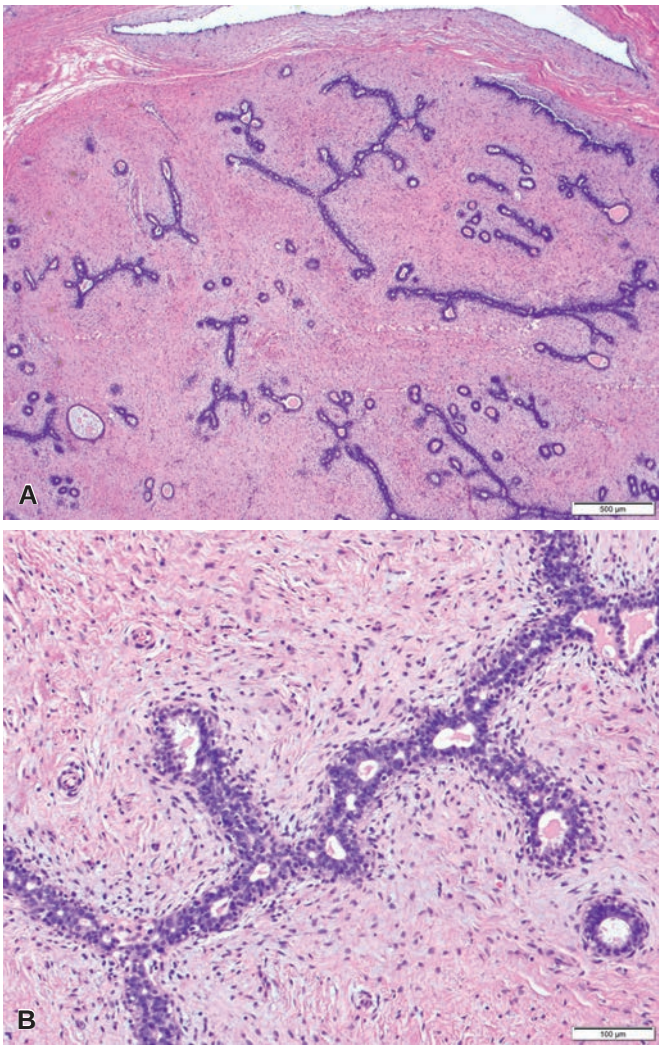

Figure 36.30 Microscopic Appearance of Fibroadenoma. A, Low-power image showing the circumscribed border, mixed glandular and stromal growth. **B,** On higher power, the bland nature of the stromal spindle cells is appreciated as well as the presence of mild epithelial hyperplasia.

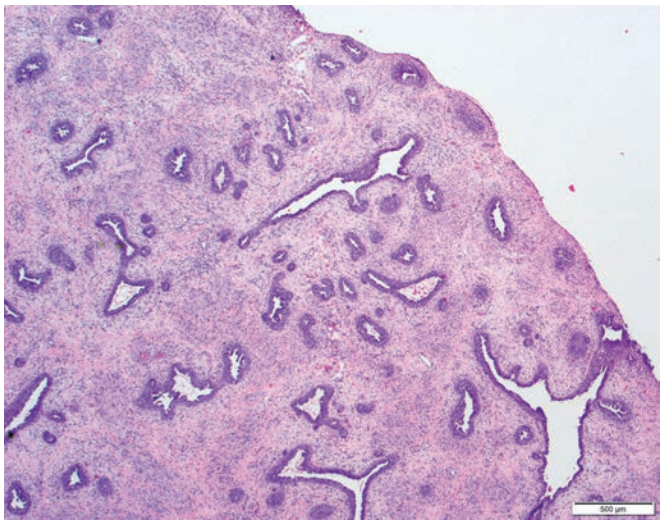

Figure 36.31 Juvenile Fibroadenoma. In this particular lesion the pericanalicular growth pattern predominates; florid hyperplasia is often seen as part of the epithelial component.

fibrous-type stroma. The spindle cells are predominantly CD34-positive fibroblasts.[149] Elastic tissue is absent, in keeping with the presumed TDLU origin of the lesion. The cellularity of the stroma varies from case to case, but in any unduly hypercellular lesion the alternative diagnosis of phyllodes tumor should be considered (see later).

Morphologic variations in fibroadenoma are plentiful, some of greater significance than others:

1. Hyalinization, calcification, and/or ossification of the stroma. These changes are more commonly seen in older patients and can be appreciated radiographically.
2. Presence in the stroma of multinucleated giant cells of reactive nature, similar to those seen in polypoid lesions of nasal cavity and other sites.[150,151]
3. Presence in the stroma of mature adipose tissue, smooth muscle, or metaplastic cartilage.[152] Some of the lesions described as hamartoma or choristoma of the breast probably belong to this category.[153]
4. Prominent myxoid changes. Most of these fibroadenomas are not otherwise different from the others. However, whenever multiple, highly myxoid fibroadenomas are found, the possibility that they are a component of Carney complex, which also includes endocrine hyperactivity, cardiac myxoma, cutaneous hyperpigmentation, and other abnormalities should be investigated. Parenthetically, other breast abnormalities that can be seen in this syndrome are myxoma and ductal adenoma with tubular features.[154]
5. Hypercellular stroma. On occasion, fibroadenomas will have an increase in stromal cellularity raising the differential diagnostic consideration of *cellular fibroadenoma* versus benign phyllodes tumor.
6. Hemorrhagic infarct. Fibroadenomas with this complication show a bulging, red appearance grossly that can be quite perplexing. This complication is more likely to occur during pregnancy.
7. Ill-defined edge blending with the surrounding breast parenchyma. This appearance is usually referred to as *fibroadenomatous change*.
8. Sclerosing adenosis. This occurs in less than 10% of cases.[22] Fibroadenomas with cysts larger than 3 mm, sclerosing adenosis, calcifications, or papillary apocrine change are referred to as "complex fibroadenomas."[155]
9. Squamous metaplasia. This is a rare finding; its presence in abundance should suggest the alternative possibility of phyllodes tumor.
10. Lactational changes. These are manifested by an increase in the amount of cytoplasm in the epithelial cells, which appear vacuolated, and by dilation of the glandular lumina by secretion.[26] It has been suggested that lactation adenomas in actuality represent this phenomenon rather than a distinct entity.
11. Young patients, large tumor size, and hypercellularity. There is a reasonably distinct type of fibroadenoma that tends to occur in adolescents (often in African-Americans and sometimes involving both breasts), reach a large size (over 10 cm), and show hypercellularity of glands and/or stroma.[156] A plethora of names exists to designate these lesions, depending on which feature predominates or which has impressed the writer the most. There are age-related terms, such as *juvenile fibroadenoma*;[157,158] size-related terms, such as giant or massive fibroadenoma; and cellularity-related terms, such *cellular fibroadenoma*.[158] In juvenile fibroadenoma the cellularity is mainly florid UDH and a pericanalicular growth pattern predominates (Fig. 36.31).[157] What

matters most is to recognize the lesion as a fibroadenoma and not to confuse it with virginal hypertrophy or, more importantly, phyllodes tumor. The epithelial hypercellularity can be dismissed as clinically inconsequential (unless it has the cytoarchitectural features of DCIS). Stromal hypercellularity and stromal cell atypia should be evaluated more carefully in terms of degree; it is good to remember, however, that it is rare for phyllodes tumors to occur in young patients (although they certainly can).

Fibroadenomas removed from patients taking oral contraceptives occasionally demonstrate formation of acini.[159]

Fibroadenomas express progesterone receptor (PR) almost universally and ER in approximately a quarter of cases.[160] Interestingly, the stromal cells of fibroadenomas express ER beta rather than ER alpha, this expression being related to the expression of smooth muscle markers.[161]

Cytogenetically, approximately 20% of fibroadenomas have been found to have clonal chromosome aberrations.[162] A lineage-restricted analysis has shown that these clonal aberrations are present in the stromal component, suggesting that fibroadenoma is a benign neoplasm of the specialized stroma of the breast with an accompanying epithelial component.[163] A recent large-scale epidemiologic study has confirmed that fibroadenoma represents a low, long-term risk for the development of breast carcinoma (1.5–2-fold; i.e., similar to proliferative lesions without atypia) and that there is no further increase in risk in women with complex fibroadenomas[164] nor is the risk further increased if the fibroadenoma contains foci of atypical hyperplasia.[165]

Malignant Changes

Malignant changes in fibroadenomas are found in only 0.1% of cases.[166,167] The malignant change usually involves the epithelial component, and the large majority are in situ lesions (Fig. 36.32).[168] In some cases the malignant tumor is entirely within the confines of the fibroadenoma, but in others it involves the surrounding breast parenchyma as well. The latter may simply represent extension into the fibroadenoma by a carcinoma originating elsewhere in the breast.[168]

Phyllodes Tumor

Phyllodes tumor is the term for the biphasic neoplasm originally named cystosarcoma phyllodes by Johannes Müller in 1838, a term that is to be avoided because of its malignant connotations. Phyllodes tumor occurs in middle-aged and older women. Very few patients are younger than 25 years of age, which is in striking contrast with the age distribution of fibroadenoma. However, phyllodes tumor can certainly occur in young adults and even in adolescents,[169] and, therefore, the diagnosis cannot be excluded on the basis of age. Of note, in Asian populations the average age is 41 years.[170] The interesting observation has been made that phyllodes tumors are more common in Hispanics than in other ethnic groups and that this risk is higher among Hispanics born in Latin America than those born in the United States.[171]

Figure 36.32 Fibroadenoma with focal involvement by low-grade ductal carcinoma in situ.

Grossly, the typical phyllodes tumor is round, relatively well circumscribed, and firm. The nipple may be flattened, but the overlying skin is almost never attached. The cut surface is solid and gray–white and shows the cleft-like spaces that give the tumor its name (Fig. 36.33A). Areas of necrosis, cystic degeneration, and hemorrhage may be present (see Fig. 36.33B). Rarely, the entire tumor undergoes hemorrhagic infarction. Many phyllodes tumors are large, and some reach huge dimensions, but others measure less than 5 cm in diameter. It follows, then, that the diagnosis of phyllodes tumor can be neither made nor ruled out by size alone. A lesion with the microscopic appearance of fibroadenoma should still be diagnosed as such, after appropriate sampling, even if large.

Microscopically, the two key features of phyllodes tumor are stromal hypercellularity and the presence of benign glandular elements as an integral component of the neoplasm (Fig. 36.34). It is the amount and appearance of the stromal component that determine whether a breast neoplasm should be called a fibroadenoma or a phyllodes tumor and, in the latter instance, what the chances are of the tumor behaving clinically in an aggressive fashion. Three histologic categories of phyllodes tumor have been defined, although there is considerable overlap in the features such that a sharp distinction between benign and borderline and to lesser extent between borderline and malignant forms of phyllodes tumor is not always possible.[172] Furthermore, at the benign end of the spectrum it can be difficult to reliably distinguish cellular fibroadenoma from benign phyllodes tumor.

Tumors with the configuration of fibroadenomas but with a hypercellular stroma and some imbalance of the gland to stroma ratio are on the "benign" end of the spectrum; the stromal component has a fibroblastic appearance with little or mild stromal cell atypia and few mitoses (<5 per 10 high-power fields). Malignant phyllodes tumors have a high degree of stromal cellularity, marked stromal cell nuclear atypia, numerous mitoses (≥10 per 10 high-power fields), and a greater imbalance in the distribution of glands in the stroma. An important diagnostic criterion of malignancy is overgrowth of the glands by the malignant stroma such that low-power views (4× microscopic field) of the tumor show stroma only, without epithelial elements ("stromal overgrowth").[172] The neoplastic stromal component may be monomorphic or highly pleomorphic, and its appearance is most often reminiscent of fibrosarcoma, but liposarcomatous differentiation (Fig. 36.35) may also be seen; heterologous elements such as metaplastic cartilage, bone, or, exceptionally, skeletal muscle may be encountered. Phyllodes tumors with heterologous stromal elements are more aggressive. Tumor necrosis is also associated with poor prognosis.[173] It goes without saying that borderline tumors have features intermediate between benign and malignant phyllodes tumors with moderately cellular stroma, mild to moderate stromal cell atypia, 5–9 mitoses per 10 high-power fields and no (or very focal) stromal overgrowth. The border of the tumor is another feature used to help categorize phyllodes tumors: benign phyllodes tumor has a well-defined border, and malignant phyllodes tumor has an infiltrative or permeative tumor border. Borderline phyllodes tumor usually has a well-defined border, but it may be focally permeative. The epithelial component, although not neoplastic, can have a

Figure 36.33 Gross Appearance of Phyllodes Tumor. The tumor shown in **(A)** exhibits the typical appearance of the cut surface. The tumor illustrated in **(B)** has undergone extensive infarction.

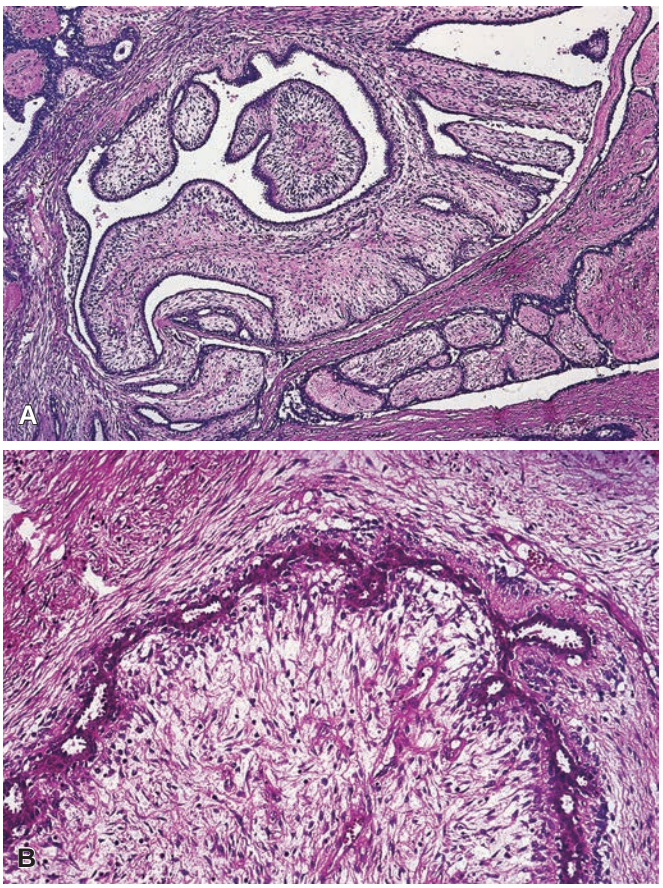

Figure 36.34 A and **B,** Two views of benign phyllodes tumor, showing cleft-like spaces and condensation of stromal cells under the epithelium.

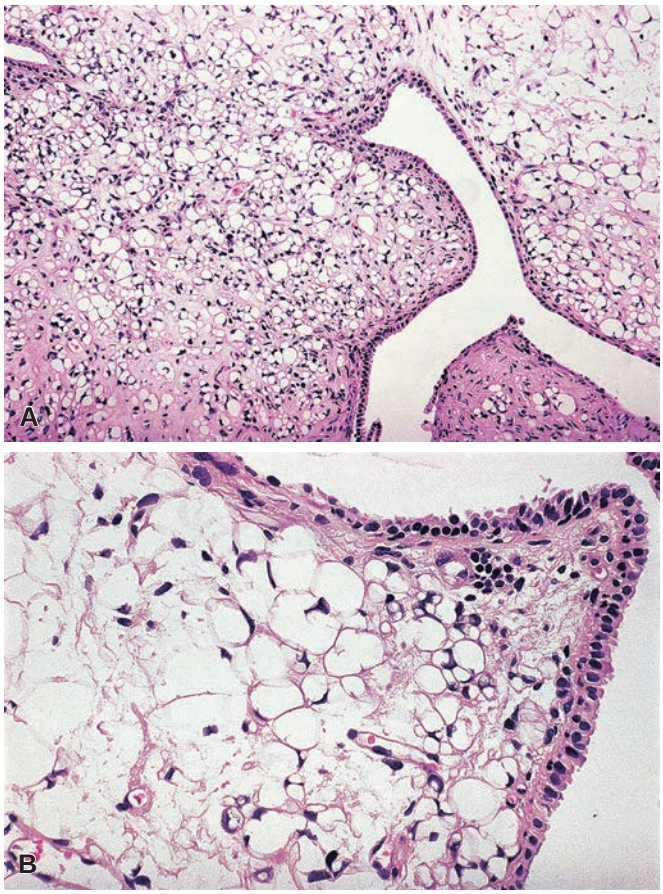

Figure 36.35 A and **B,** Malignant phyllodes tumor with liposarcomatous differentiation of the neoplastic stromal component.

markedly proliferative appearance, as it sometimes does in fibroadenoma, a finding of no clinical significance. On rare occasions, the features of carcinoma in situ of either ductal or lobular type may be present.[174–176]

Immunohistochemically, there is frequent expression of CD34 and bcl2, similar to other stromal tumors of the breast and in contrast to spindle cell metaplastic carcinomas, a feature of significance in the differential diagnosis.[161,177] Of note, recent reports have demonstrated staining with both p63 and cytokeratin in the stromal cells of phyllodes tumors,[178,179] albeit focal and weak in the majority of cases, a finding that may be problematic when working up a core needle biopsy of an apparently pure spindle cell lesion. Whenever the diagnosis of a spindle cell metaplastic carcinoma is being considered on a core needle biopsy, bear in mind that such specimens may represent sampling of the stromal component of a malignant phyllodes tumor. CD117 is expressed in about a third of all phyllodes tumors and over half of malignant ones.[180] ER beta and PR are expressed in the stromal cells of nearly all cases.[160] There is overexpression of p53 in a variable number of histologically malignant and borderline cases but very rarely in those with bland microscopic features; however, there is insufficient discrimination for this marker to prove clinically useful.

Fibroepithelial lesions have been shown to harbor *MED12* mutations with slightly greater prevalence in phyllodes tumor compared with fibroadenoma (62.5% vs. 59%).[181] Phyllodes tumors on the malignant end of the spectrum have a higher complexity of alterations, with recent array-based comparative genomic hybridization (CGH) data demonstrating interstitial deletion of 9p21 involving the *CDKN2A* locus.[182,183]

The behavior of benign phyllodes tumors is characterized by a potential for local recurrence but an extreme rarity of distant metastases.[172] If an enucleation has been performed under the clinical impression of fibroadenoma, the patient can be safely followed for the possibility of recurrence. If the latter develops or if this type of phyllodes tumor is recognized at the time of initial surgery, local excision with a wide margin of normal tissue is the treatment of choice.[184] Recurrent phyllodes tumor may still be managed with wide local excision.

The cytologically malignant tumors have the potential for metastasis, with the incidence of metastases ranging from 3% to 12% in various series, though local recurrence is still the more common event. Axillary lymph node metastases are exceptional. The most common sites of distant involvement are lung and bone.[185,186] The metastases are of the stromal component, although entrapment of normal structures in the lung may simulate a biphasic composition.

Wide local excision with an adequate margin of normal breast tissue is sufficient therapy for most cytologically malignant phyllodes tumors,[184] but if there is any question of invasion of the fascia, the tumor should be removed together with the underlying muscle. There is no need for removal of the axillary nodes, except for the exceptional instances in which they are clinically involved.

If both the benign epithelial component and the stromal component are sampled, the diagnosis of phyllodes tumor is generally straightforward (tumor grading notwithstanding). The main differential diagnosis of malignant phyllodes tumors is with spindle cell metaplastic carcinoma (as discussed previously) and far less likely with other types of sarcoma (again largely depending on the presence or absence of a non-neoplastic epithelial component). Benign phyllodes tumors need to be distinguished mainly from cellular fibroadenomas, both of which will have increased stromal cellularity, but the latter is more likely to have a pericanalicular growth pattern and will have an even balance in the gland distribution within the stroma. It should be acknowledged that in some instances this may not be possible at a practical level or justified at a conceptual level, in which case the term "benign fibroepithelial neoplasm" has been proposed by the WHO.[172]

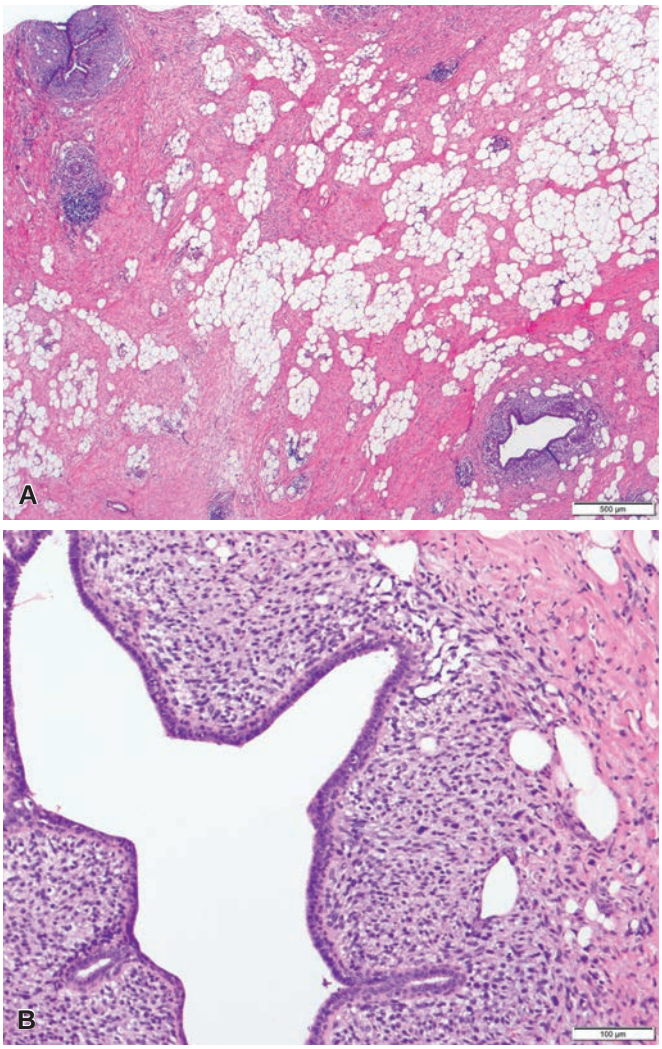

Figure 36.36 Periductal Stromal Tumor. A, This fibroepithelial tumor lacks the circumscription of fibroadenoma or phyllodes tumor and instead is seen as dispersed nodules. **B,** Higher power view reveals the hypercellular stroma surrounding a benign epithelial element.

The neoplasm described as *periductal stromal tumor*[187] contains epithelial structures like those of fibroepithelial lesions, but the stromal component lacks the phyllodes architecture and tumor circumscription and instead is seen as dispersed nodules (Fig. 36.36). Stromal cell cytologic atypia and mitoses may be present.

Adenosis and Sclerosing Lesions

Adenosis

The term adenosis can be applied to any hyperplastic process that primarily involves the glandular component of the breast; it should, therefore, be used with a qualifier in order to acquire a specific clinicopathologic connotation.

Blunt Duct Adenosis

This is a term that has been applied variably in the literature and as such its use is no longer recommended. The WHO Classification

of Tumors of the Breast refers to this term as a synonym of columnar cell change.[122]

Sclerosing Adenosis

Sclerosing adenosis is the best known form of adenosis because of its relative frequency and the potential for misdiagnosis as carcinoma. Most often, sclerosing adenosis is an incidental microscopic finding; however, in some instances it may present as an image-detected breast mass or as mammographically detected microcalcifications. The gross appearance can be of a small mass with a disk-like, somewhat multinodular configuration that cuts with increased resistance. In some cases, the overall gross appearance may be quite reminiscent of invasive carcinoma.

Microscopically, the most important diagnostic feature of the lesion is its architecture, as seen at low magnification. Sclerosing adenosis retains a rounded, lobulocentric configuration and is more cellular centrally than peripherally (Figs. 36.37 and 36.38). The elongated and compressed proliferating tubules are lined by epithelial cells and have a peripheral myoepithelial cell layer. The myoepithelial component predominates in some lesions and may even acquire spindle-shaped "myoid" features. Atypia in the form of cribriform areas, nuclear pleomorphism, and necrosis is absent. The stroma is dense and may show foci of elastosis, although not as commonly as in radial scar or invasive carcinoma. Microcalcifications may be present.

The involvement of myoepithelial cells in the process can be demonstrated with various immunohistochemical stains (see Figs. 36.37C and 36.38C) (smooth muscle myosin heavy chain, calponin, p63, or, less commonly now, actin), and the presence of basement membrane around the tubules with stains for laminin or type IV collagen, although the latter are not commonly used in clinical practice.

Morphologic variations of sclerosing adenosis that further complicate interpretation are the florid changes that may accompany pregnancy, the presence of apocrine metaplasia (which is accompanied by nuclear and nucleolar enlargement), the occasional occurrence of perineural invasion (Fig. 36.39),[188] and permeation of the walls of veins.[189]

The risk of subsequent invasive carcinoma in patients with sclerosing adenosis is the same as for proliferative disease without atypia.[190]

On occasion, foci of sclerosing adenosis may be secondarily involved by LCIS or even DCIS (Fig. 36.40).[191] In these cases, the distortion already present because of the sclerosing adenosis may result in a mistaken diagnosis of invasive carcinoma. The low-power impression is critical to arriving at the correct diagnosis; foci of sclerosing adenosis (with or without CIS) have dilated ductules peripherally and narrow ones centrally, whereas invasive lobular carcinoma has no overall organization.[192] Immunohistochemical evaluation demonstrating the presence of myoepithelial cells can be of assistance in recognizing the underlying benign lesion.

Nodular adenosis and **adenosis tumor** refer to sclerosing adenosis lesions that form a palpable or mammographic mass. The proliferating glands are better circumscribed forming a more discrete mass than in sclerosing adenosis.

Microglandular Adenosis

Microglandular adenosis is a rare form of adenosis in which small, uniform glands with open lumina containing eosinophilic secretions are distributed in a haphazard fashion within the fibrous tissue or fat (Fig. 36.41).[193–195] The glands are composed of a single layer of small, uniform cuboidal cells with vacuolated or granular cytoplasm, lacking apocrine-type "snouts." In contrast to other forms of adenosis,

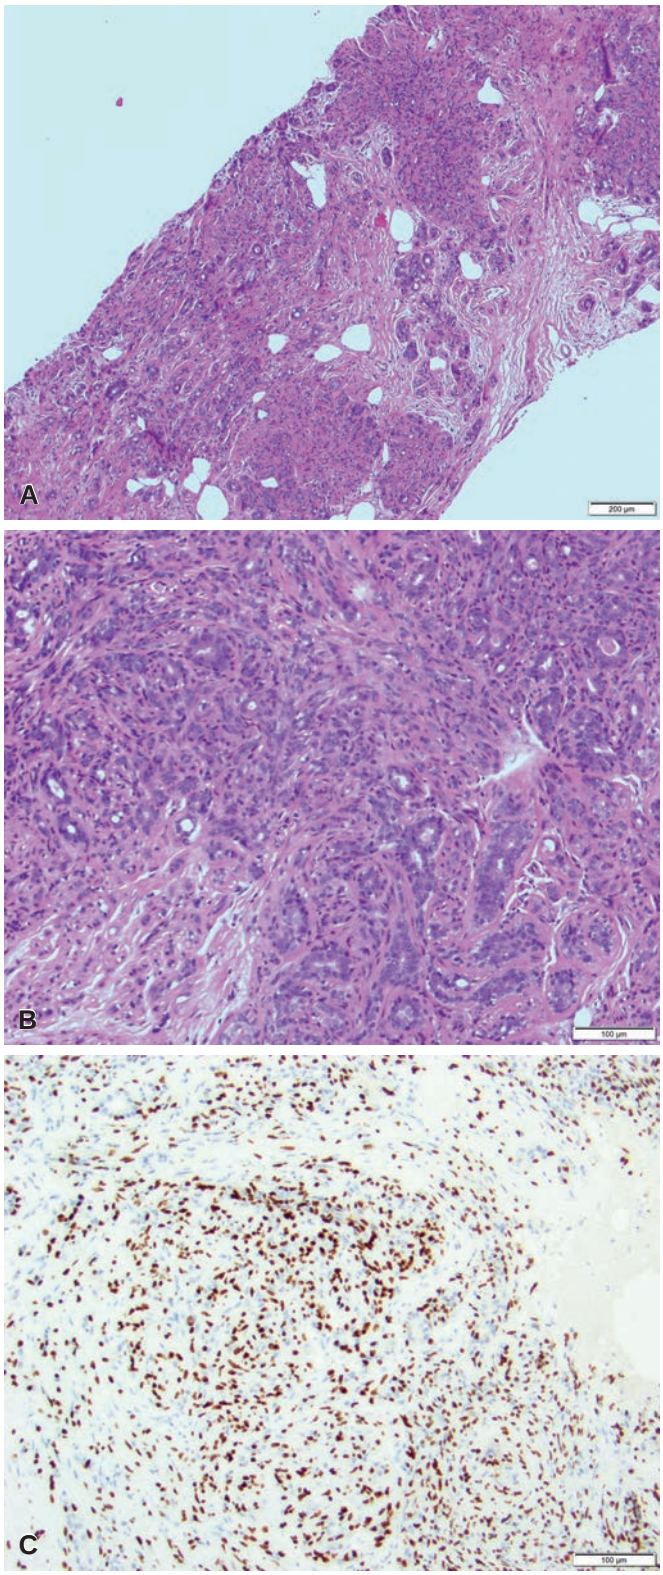

Figure 36.37 Sclerosing Adenosis. A, Low-power view. The lobular configuration of the small glandular proliferation is readily apparent even on this core needle biopsy specimen. **B,** Medium-power view. Note the spindle shape of the myoepithelial cells present. **C,** Immunohistochemical stain for p63 showing strong immunoreactivity in the myoepithelial cell component.

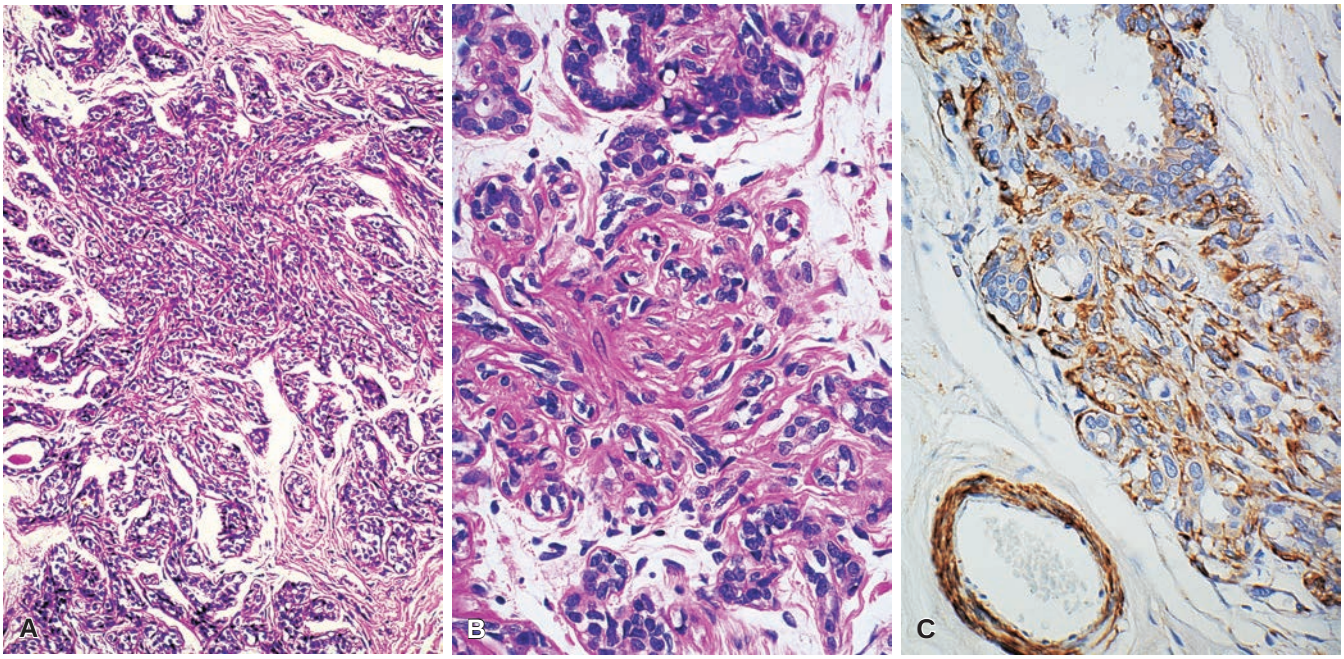

Figure 36.38 Sclerosing Adenosis. A, Low-power view. The lobular configuration of the lesion is obvious. **B,** Medium-power view of the myoepithelial cells in the center of the TDLU. **C,** Actin immunostain showing strong reactivity in the myoepithelial cell component.

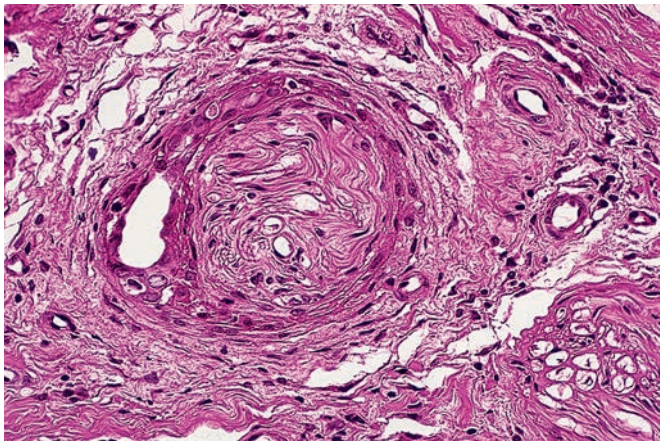

Figure 36.39 Benign "perineural invasion" in a breast lesion that had elsewhere the typical features of sclerosing adenosis.

the myoepithelial layer is absent.[193,196] However, there is a basement membrane that can be appreciated immunohistochemically and ultrastructurally.[195] The stroma may be hyalinized but is not cellular or elastotic. Microglandular adenosis is ER, PR, and HER2 negative and strongly and diffusely positive for S-100 protein. The main differential diagnosis of this lesion is with tubular carcinoma, which also lacks a myoepithelial cell layer but is uniformly ER positive.[193]

Atypical microglandular adenosis should be diagnosed when the glands begin to coalesce, forming small nests either solid or cribriform in architecture, often with cytologic atypia (Fig. 36.42). Luminal secretions are less prominent in atypical microglandular adenosis.

It is unclear whether microglandular adenosis is a benign process or whether it may be a precursor lesion[197]; enough cases have been reported in continuity with carcinoma to suggest that the lesion may evolve into malignancy in some patients.[197–199] Interestingly, a high percentage of these carcinomas in one series have been of the adenoid cystic type.[198] Actually, this frequently occurring spatial relationship with an easily recognizable carcinoma, and the fact that microglandular adenosis is the only "benign" epithelial breast lesion devoid of myoepithelial cells, makes one wonder whether it represents an indolent form of invasive ductal carcinoma. Indeed recurrent losses of chromosome 5q and gains of 8q as well as mutations in *TP53* have been reported in microglandular adenosis, particularly in cases with coexistent atypical microglandular adenosis and invasive carcinoma, specifically triple negative breast carcinomas.[200–202] Given the uncertainty about the role of microglandular adenosis as a precursor lesion, the need for excision to clear margins is controversial; diagnosis on a core needle biopsy should prompt an excision.

Apocrine Adenosis

Apocrine adenosis is a form of adenosis in which the glands are larger, the lining epithelium is apocrine in nature, and myoepithelial cells are present (Fig. 36.43).[203,204] Occasionally nuclear atypia and nucleolar prominence are noted; when at least threefold variation in nuclear and nucleolar size is seen, *atypical apocrine adenosis* is said to be present. The subsequent breast cancer risk associated with apocrine adenosis and atypical apocrine adenosis is uncertain.[205,206]

Tubular Adenosis

Tubular adenosis is an unusual form of adenosis, which is characterized by elongated, tubular, and branching glands arranged in a somewhat haphazard pattern. A myoepithelial cell layer is present, which is of value in distinguishing this lesion from invasive carcinoma, of which it can be a mimic (Fig. 36.44).[207]

Radial Scar and Complex Sclerosing Lesions

This is a group of breast lesions characterized by a generally small size, stellate shape, and a central fibroelastotic core, with variable degree of epithelial proliferation and distortion.[208,209] They have been variously designated as radial scar, complex sclerosing lesion,

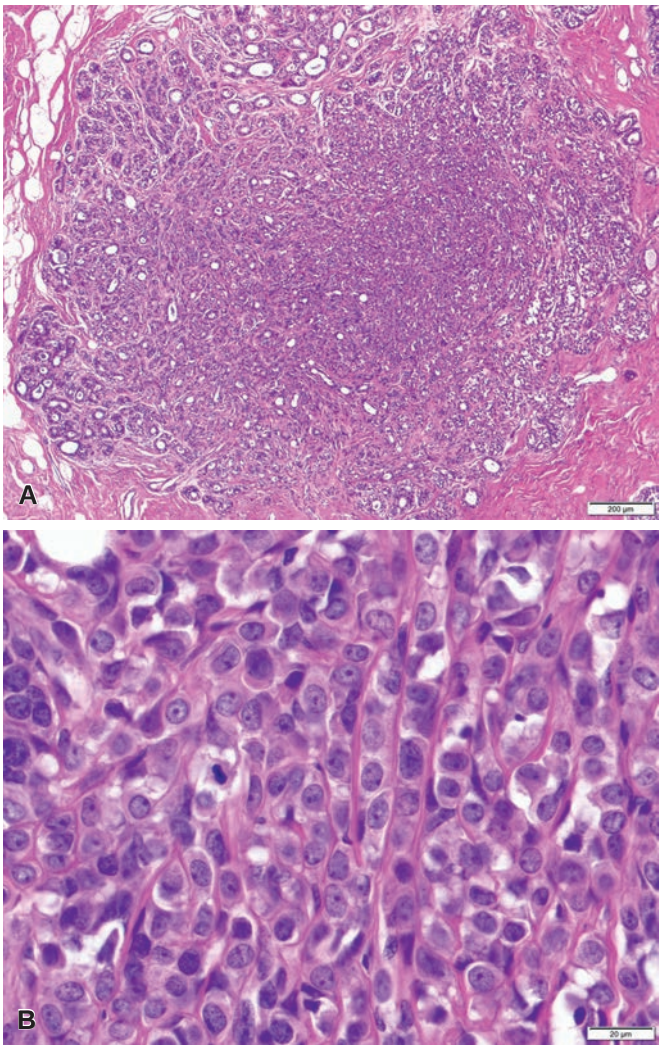

Figure 36.40 Sclerosing Adenosis With Lobular Carcinoma In Situ. A, Note the absence of infiltrative features at the border of the proliferation on low power. **B,** High power confirming the presence of LCIS in adenosis.

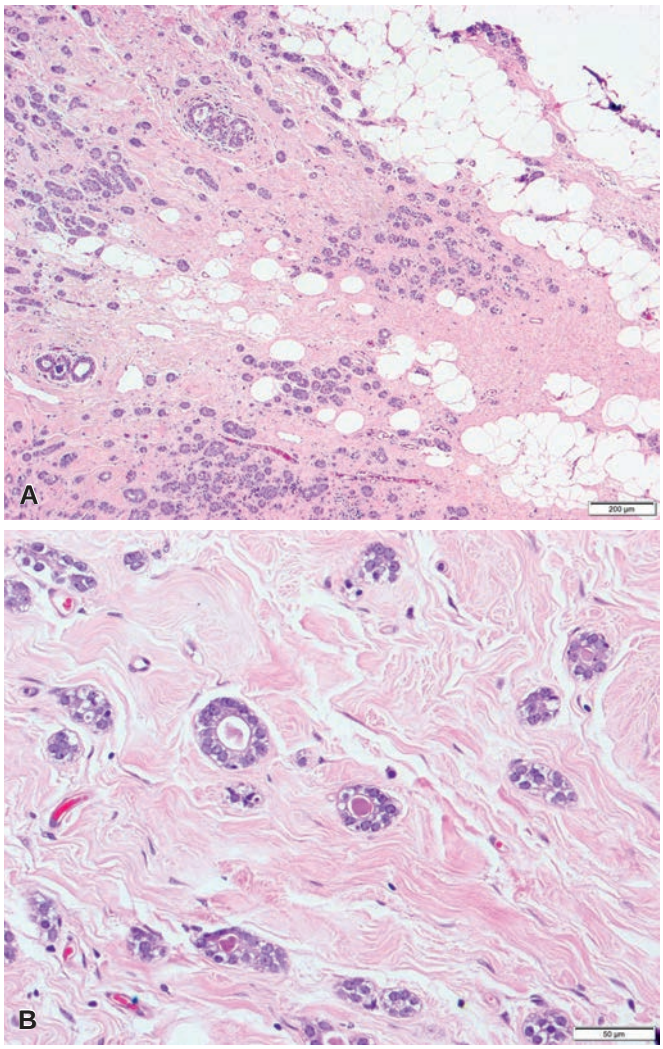

Figure 36.41 Microglandular Adenosis. A, Low-power appearance, showing haphazardly scattered small round glands. **B,** On high power, the glands are open and contain bright eosinophilic luminal secretion. There is no myoepithelial cell layer.

and infiltrating epitheliosis.[210] On mammography and gross examination, the irregular, stellate shape confers a resemblance to invasive ductal carcinoma (Fig. 36.45). Microscopically, the connective tissue center is densely fibrotic or fibroelastotic (Fig. 36.46). Basophilic elastic tissue may be seen in the walls of obliterated ducts and the stroma, sometimes in abundance. Embedded within the stroma are small ducts and glands that appear disorganized due to the distortion caused by the fibrosis, but which are still composed of both epithelial and myoepithelial cells; at the periphery of the "radial spokes" are larger duct-like structures that may be dilated and/or may exhibit UDH.

The terms radial scar and complex sclerosing lesion are used somewhat interchangeably, with some authors making the distinction on size (<1 cm for the former vs. >1 cm for the latter) and others making the distinction based on the degree to which the lesion is organized around a central scar. The most important aspect of radial scars/complex sclerosing lesions is the differential diagnosis with invasive ductal carcinoma, a problem that may be compounded if the radial scar is involved by DCIS or LCIS (Fig. 36.47). The diagnostic criteria for the identification of carcinoma should be the same whether a central scar is present or not. They include the cytoarchitectural criteria as seen in H&E-stained sections, as well as evaluation for the presence of a myoepithelial cell layer, using immunohistochemistry if necessary. Note that reduction in staining has been reported with some myoepithelial cell markers in this setting, thus a panel of immunohistochemical stains is recommended.[211]

There is no evidence to suggest radial scars are a direct precursor lesion to invasive breast carcinoma; any risk associated with this lesion is related to the presence of proliferative disease within the lesion.[208] Studies have demonstrated that women with radial scars have a risk for breast cancer that is almost twice that of women without radial scars, regardless of the histologic type of benign breast disease present[212,213]; however others contend that there is no increase in breast cancer risk above and beyond that conferred by the histologic type of benign breast disease present in the background breast tissue.[214,215] The management of mammographically detected radial scar is usually core needle biopsy with follow-up conservative excision to exclude a worse lesion, though with greater sampling by large gauge and vacuum-assisted core biopsy needles, excision may not be necessary in every case.[216]

Tubular adenoma presents in young adults as a solitary, well-circumscribed, firm, tan–yellow mass composed microscopically of closely packed uniform small tubules lined by a single layer of epithelial cells and an attenuated layer of myoepithelial cells; the

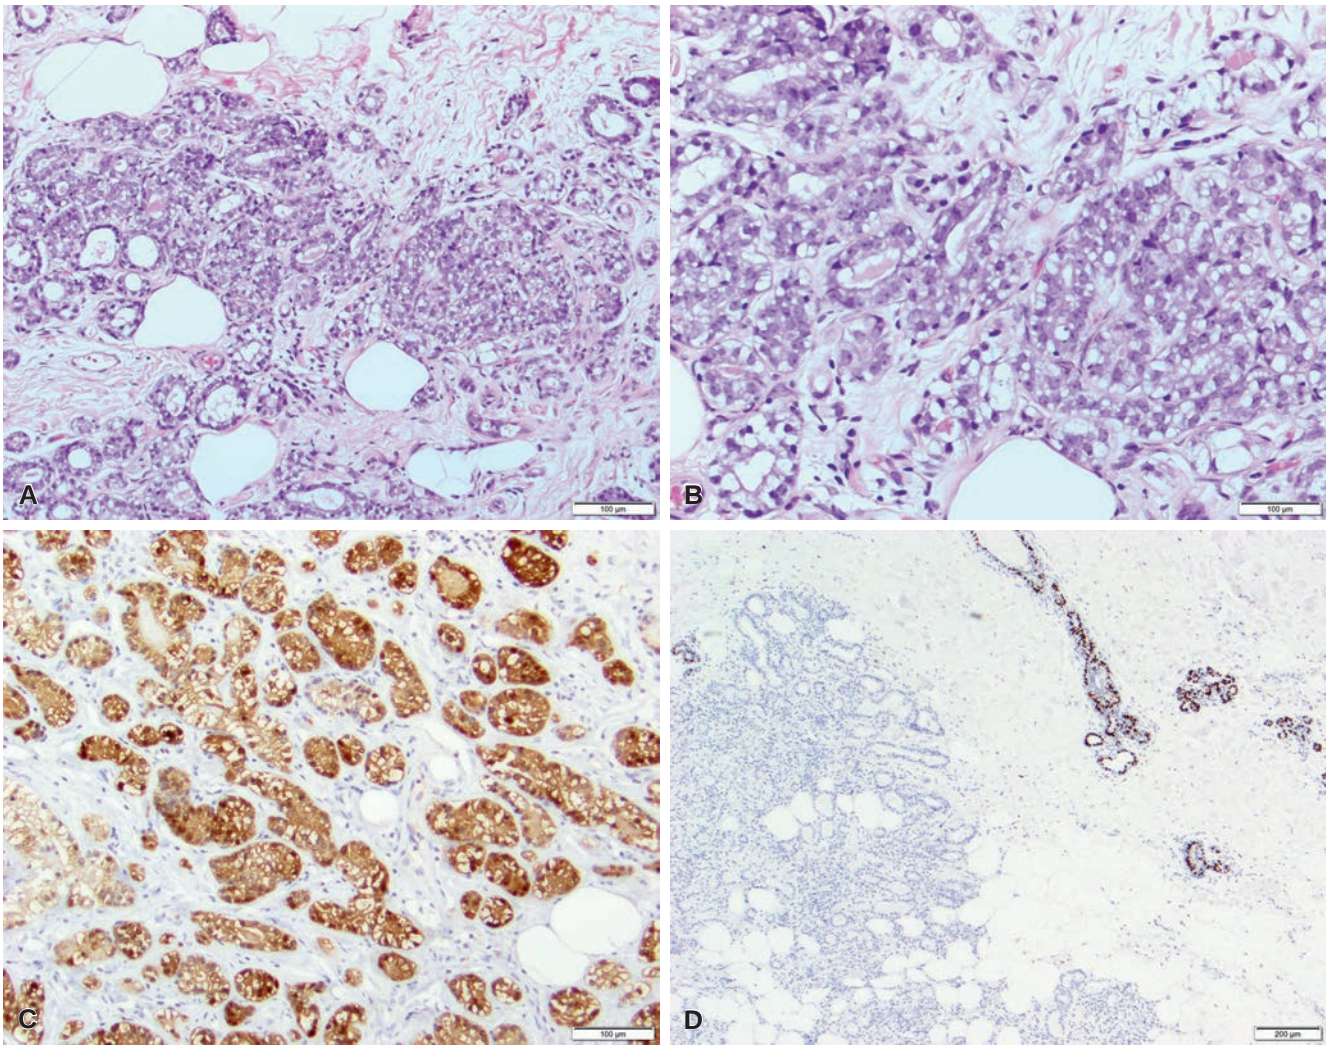

Figure 36.42 Atypical Microglandular Adenosis. A, Intermediate-power appearance, showing haphazardly arranged small round glands peripherally, with solid nests centrally. **B,** On high power, the cytologic atypia is appreciated; some luminal secretions are retained (*top right* of field). **C,** An S-100 protein immunostain is strongly positive. **D,** Estrogen receptor immunostain is negative in microglandular adenosis with good internal control in an adjacent normal duct.

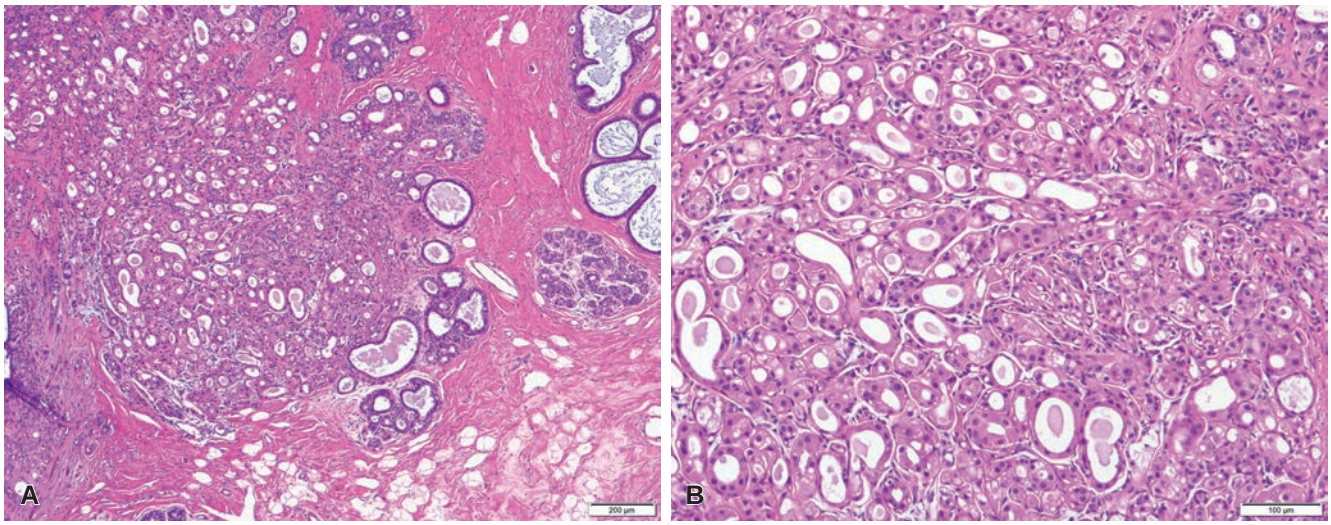

Figure 36.43 Apocrine Adenosis. A, This low-power image shows the lobulocentric architecture of adenosis; apocrine features are present. **B,** At higher power, the apocrine cells can be evaluated. The nuclei are round with large nucleoli, but there is no significant nuclear enlargement or variability.

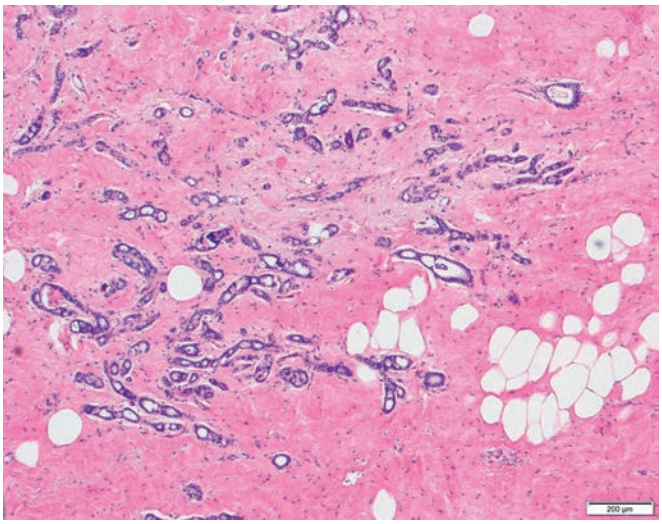

Figure 36.44 Tubular Adenosis. This low-power image shows the characteristic elongated, tubular, and branching glands of tubular adenosis arranged in a somewhat haphazard pattern.

Figure 36.45 Gross appearance of radial scar.

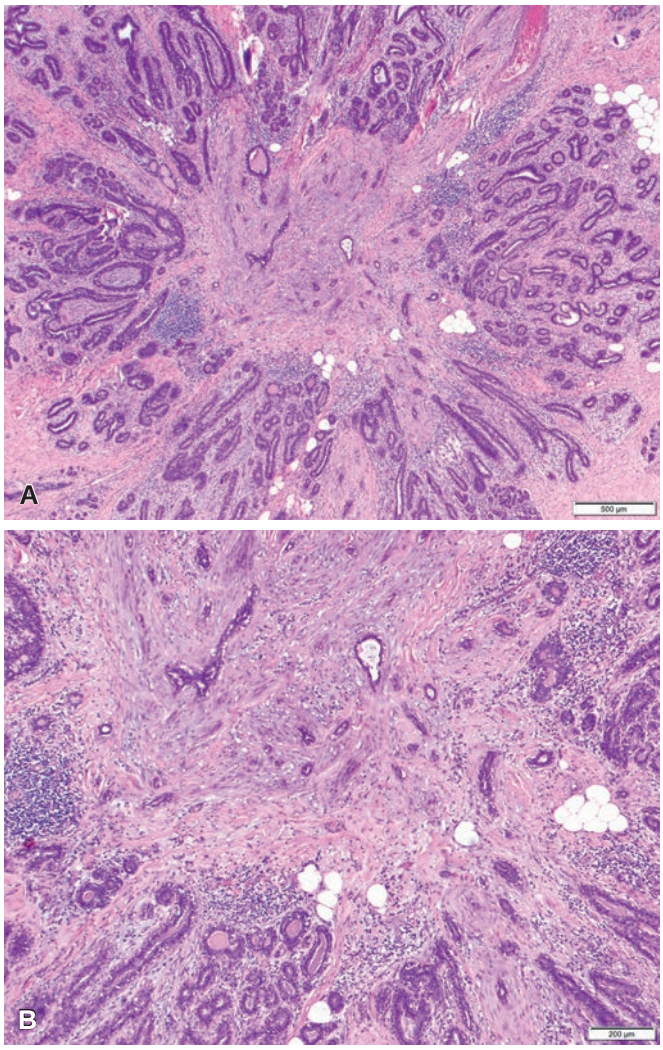

Figure 36.46 Radial Scar. A, Typical stellate shape of radial scar as seen on low power. **B,** Benign ductular structures are entrapped in the central fibroelastotic stroma.

stroma is sparse. It is not clear whether this is a separate entity or a pattern of fibroadenoma.[217]

Lactating adenoma presents as a solitary or multiple freely mobile breast masses during pregnancy or the puerperium. The lesion is more likely a localized focus of hyperplasia in the lactating breast, which may also develop in ectopic locations such as the axilla, chest wall, or vulva.[26,217] Grossly, the lesion is well circumscribed and lobulated. The cut surface is gray or tan, in contrast to the white color of fibroadenoma (Fig. 36.48). Areas of infarction may be seen. Microscopically, hyperplastic lobules are present lined by actively secreting cuboidal cells (Fig. 36.49). This lesion may be confused with the proliferative and secretory changes brought on by pregnancy in a preexisting fibroadenoma, a distinction that is likely of no clinical consequence.[26]

Papillary Lesions

Intraductal Papilloma

Intraductal papilloma of the breast occurs most commonly between the ages of 30 and 50 years. It can arise in large or small ducts; consequently, it can be identified grossly as a polypoid intraductal mass or be found only on microscopic examination. Intraductal papilloma can give rise to bloody nipple discharge and may be palpable in the subareolar location, but its diameter rarely exceeds 3 cm. The lesion is soft and friable and may have areas of hemorrhage. The duct that contains the papilloma may be dilated (Fig. 36.50). Approximately 90% of cases are solitary. Multiple papillomas are seen in slightly younger patients, arise in smaller, more peripherally located ducts, are usually not associated with nipple discharge, and are bilateral in one-quarter of cases.

Microscopically, papillomas are complex, cellular, and often intricately arborescent (Fig. 36.51A). Features favoring benignity in a papillary breast lesion are a hyalinized stroma in broad papillary

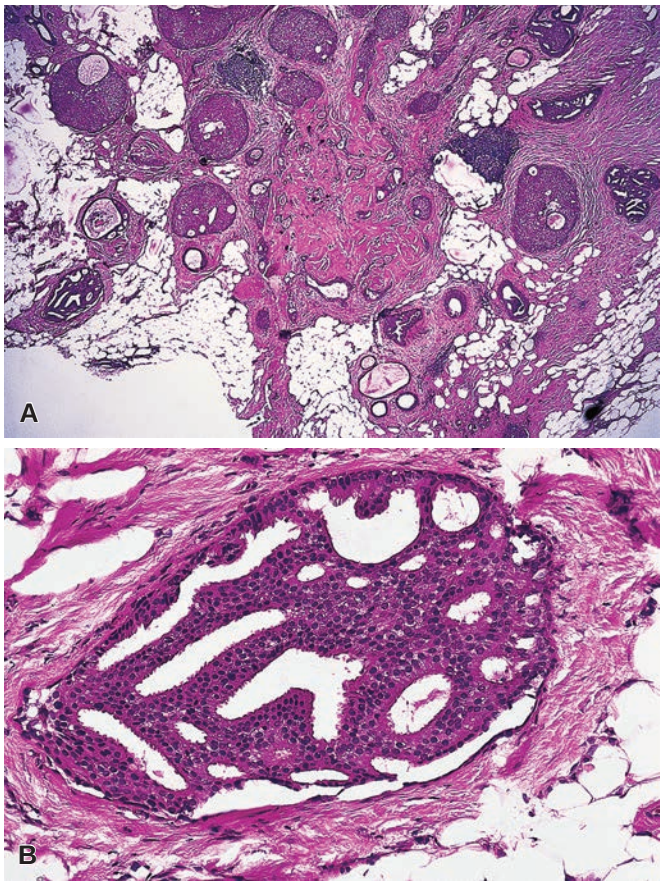

Figure 36.47 **A** and **B,** Radial scar with associated low-grade ductal carcinoma in situ.

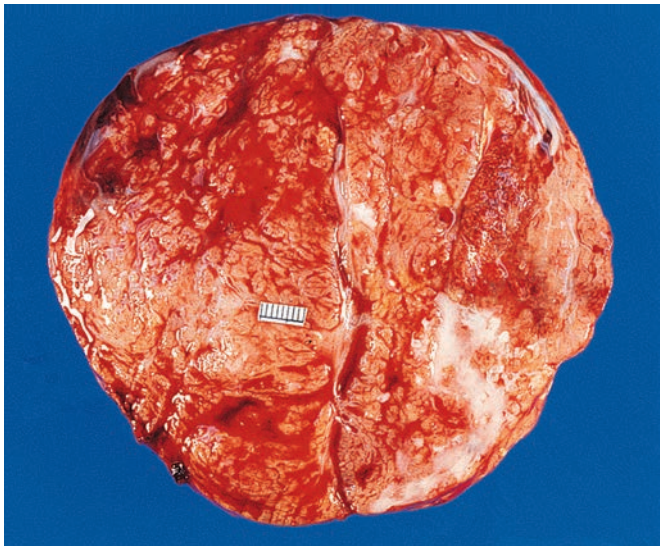

Figure 36.48 **Gross Appearance of a Lactating Adenoma.** The mass has a distinct lobular configuration, yellowish color, and marked vascularization.

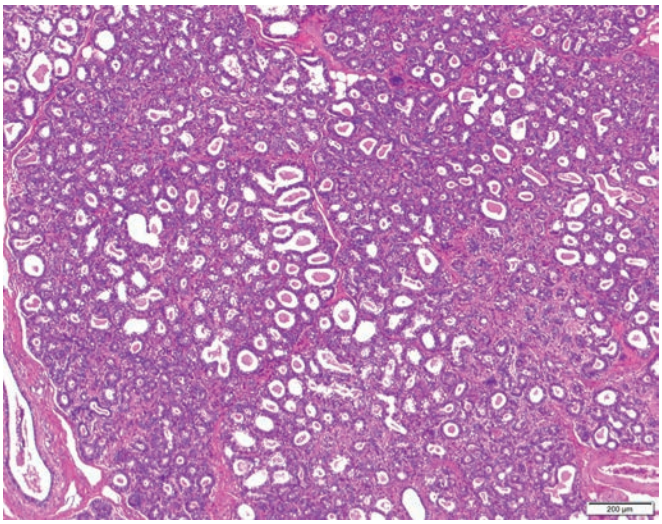

Figure 36.49 **So-called Lactating Adenoma.** The hyperplastic lobules show secretory change.

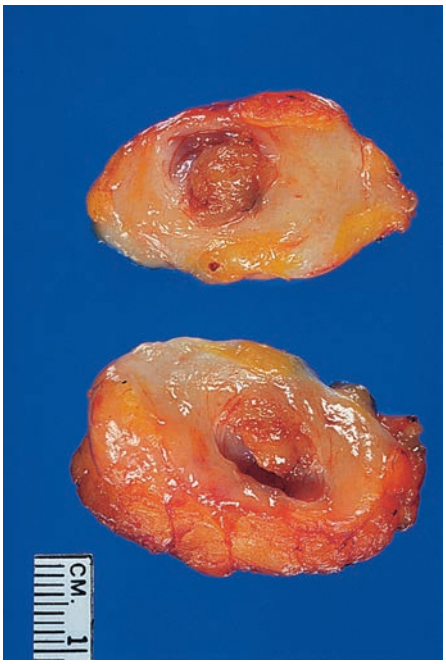

Figure 36.50 **Gross Appearance of an Intraductal Papilloma.** A polypoid mass is seen protruding within the lumen of a markedly dilated duct.

fibrovascular cores, the presence of two cell types (epithelial and myoepithelial) (see Fig. 36.51B), normochromatic often oval epithelial cell nuclei, scanty mitotic activity, the presence of foci of apocrine metaplasia, and lack of a cribriform pattern.[218] Necrosis is nearly always absent (but see later). The presence of a myoepithelial cell component can be highlighted with various immunostains, such as p63, calponin, and smooth muscle myosin heavy chain. Clonal analysis has shown that intraductal papilloma is a clonal lesion, a finding that supports its neoplastic nature.[219]

Morphologic variations sometimes encountered in intraductal papilloma include:

1. Partial or total hemorrhagic infarct. This change, which is probably caused by interruption of the blood supply, is entirely different from the tumor necrosis seen in carcinoma, and is most commonly seen following a fine-needle aspiration (FNA) or core needle biopsy procedure.
2. Necrosis. Necrosis has been described in papillomas involved by florid UDH; its presence should not lead to a misdiagnosis of DCIS.[220] The necrosis is most often focal in nature.

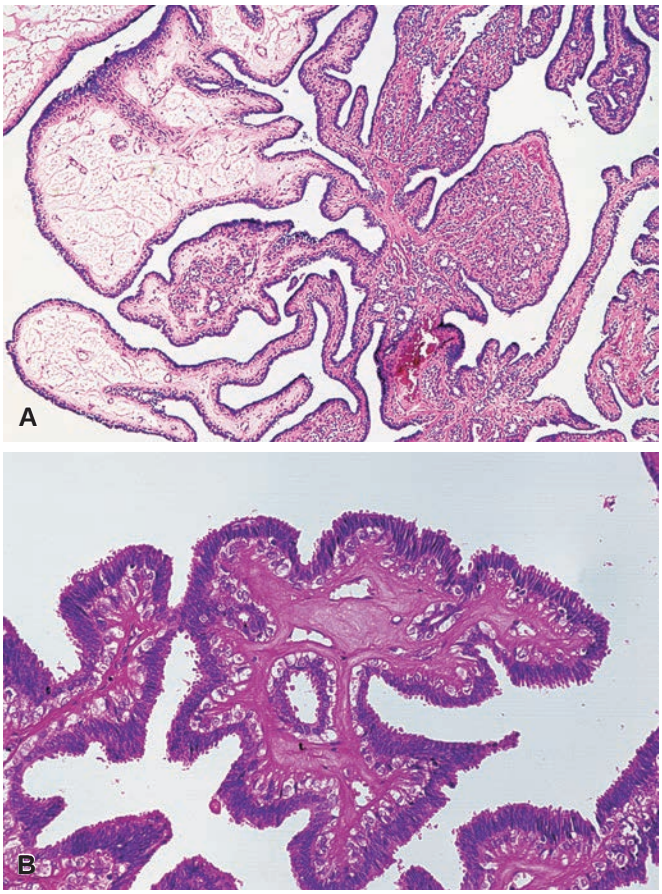

Figure 36.51 Intraductal Papilloma. A, Low-power appearance showing complex arborizing architecture. **B,** High-power view showing dual cell composition, with a well-defined row of myoepithelial cells.

3. Squamous metaplasia. This change is probably secondary to focal necrosis and is uncommon.
4. Entrapped glands within or adjacent to the papilloma. This is the most problematic change in terms of possible overinterpretation. It is the result of sclerosis (perhaps sometimes secondary to infarction), which leads to marked distortion of the glandular component and sometimes to the presence of isolated tubules embedded in dense fibrous tissue. When pronounced throughout the lesion, use of the diagnosis "sclerosed papilloma" is appropriate (Fig. 36.52). Preservation of the two-cell layer, as well as accompanying hemosiderin deposits and cholesterol clefts, are supportive diagnostic features. Immunohistochemical stains for myoepithelial cells, such as p63 or smooth muscle myosin heavy chain, are often helpful in cases where the two-cell layer is difficult to appreciate on H&E stained sections.
5. Superimposed florid UDH. In cases in which distinction between usual (florid) ductal hyperplasia and carcinoma in situ is problematic, the combination of ER and HMW cytokeratin stains (e.g., CK5/6) can be very useful. The former will demonstrate a heterogeneous pattern of staining with both ER and CK5/6; atypical ductal proliferations and DCIS will show strong, diffuse staining with ER and an absence of staining with CK5/6.
6. ***Ductal adenoma***. This lesion lacks the arborescent papillary quality of the typical papilloma, but its intraductal location with a dense fibrotic capsule and the distorted epithelial proliferation composed of two cell types (as confirmed immunohistochemically) embedded in a sclerotic stroma suggest that these lesions likely represent highly sclerotic variants of intraductal papilloma.[221,222] Ductal adenoma with tubular features can be seen as a component of Carney syndrome.[223]
7. Sebaceous metaplasia. This is an exceptionally rare but well-documented event.[224]
8. ***ADH and DCIS*** arising in an intraductal papilloma. The cytologic criteria for the recognition of these alterations are no different from those employed when a papilloma is not present (see later).[225, 226] The absence of myoepithelial cells in the areas of atypia may be confirmed with immunohistochemical stains (e.g. p63, SMMHC); of greater utility is the combined use of ER and CK5/6 (see previous discussion for use of these immunostains in the differential diagnosis with UDH). The recommendation of the WHO Classification of Tumors of the Breast Working Group is that foci of low nuclear grade atypia measuring less than 3 mm in extent arising in a papilloma be classified as intraductal papilloma with ADH; those with ≥3 mm of atypia merit a diagnosis of DCIS involving an intraductal papilloma (Fig. 36.53).[122]
9. Post-biopsy or FNA with benign epithelial displacement/implantation. Excision specimens of benign intraductal papilloma that have had a prior needling procedure can have small irregular nests and single epithelial cells with degenerative features distributed haphazardly within the biopsy site, which can be a mimic for invasive carcinoma. (Fig. 36.54).[227]

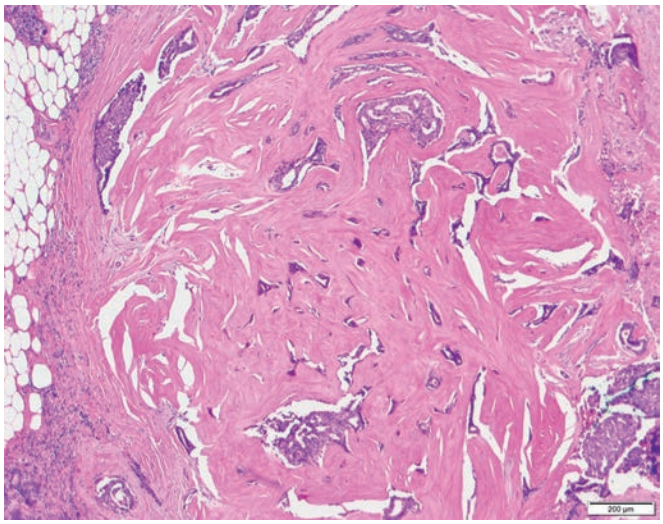

Figure 36.52 Sclerosed papilloma of breast showing entrapment of epithelial structures by fibrotic stroma, resulting in a pseudoinvasive appearance.

Solitary intraductal papilloma is a benign lesion that is curable by local excision. Management following core biopsy is evolving; however, most patients are still referred for surgical consultation. The subsequent breast cancer risk is similar to that of other proliferative lesions without atypia (1.5–2 fold).[228,229] Multiple papillomas have been found to be associated with a higher risk.[229–231] Some authors have reported that papillomas with foci of atypical hyperplasia ("atypical papillomas") are associated with a substantially increased risk for carcinoma largely restricted to the anatomic region of the original papilloma,[232] whereas others report that the risk is the same as when the atypical hyperplasia is unrelated to a papilloma and furthermore that the risk is conferred equally on both breasts.[229]

Papillary Ductal Carcinoma In Situ

A lesion considered to be distinct from papilloma with DCIS, as explained later, is papillary DCIS.[233] In contrast to the dual population of epithelial and myoepithelial cells seen in intraductal papilloma,

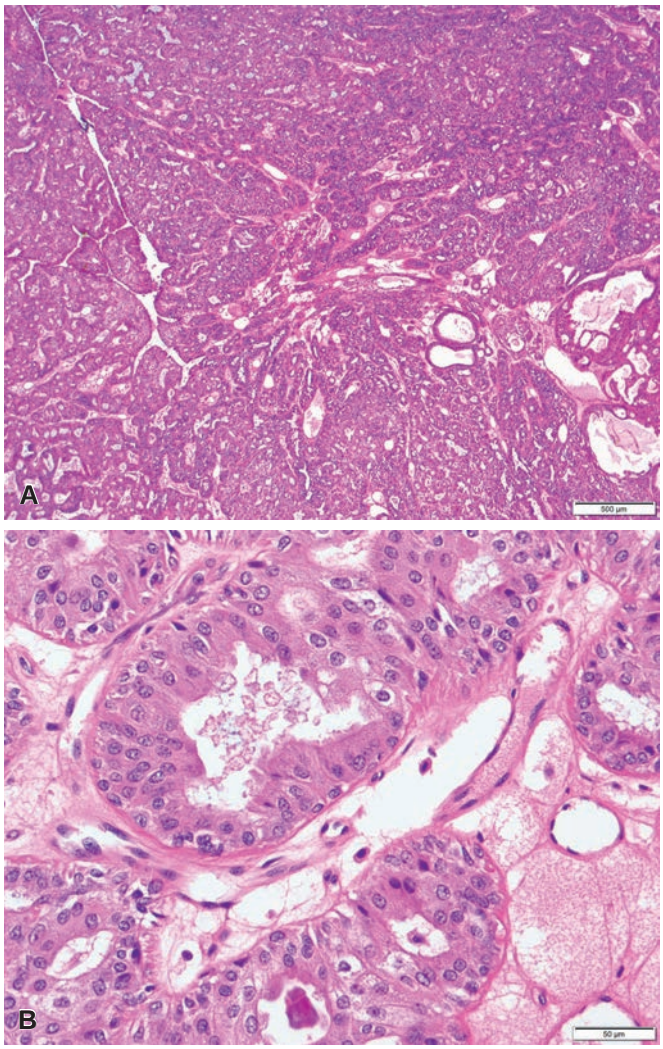

Figure 36.53 Intraductal Papilloma Involved by Ductal Carcinoma In Situ. A, Low-power appearance showing complex arborizing architecture with fibrovascular cores (particularly prominent in the *lower left* of field) and epithelial proliferation. **B,** High-power view showing monomorphic epithelial cells with areas of cribriforming; note the presence of scattered myoepithelial cells juxtaposed to the fibrovascular cores.

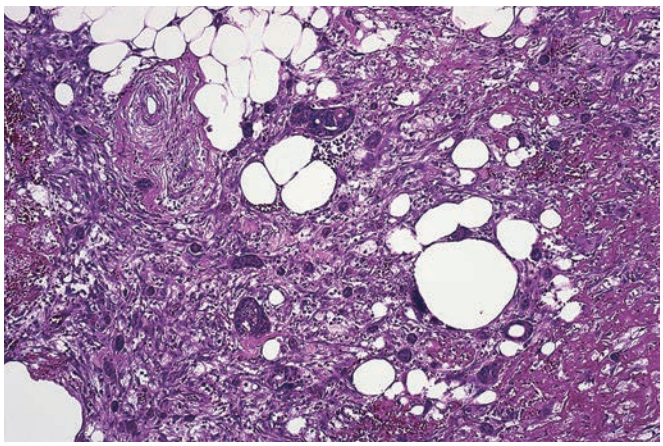

Figure 36.54 Displaced epithelium following core needle biopsy of a benign intraductal papilloma. The presence of nests and single squamoid-appearing cells embedded in a reactive stroma are characteristic of displaced epithelium.

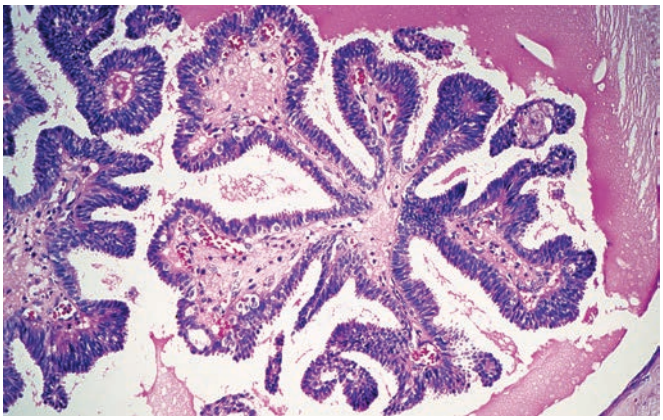

Figure 36.55 Papillary Ductal Carcinoma In Situ. The arborizing nature of this tumor and the prominent fibrovascular core in this example are not too different from those of a benign papilloma. The absence of a myoepithelial cell layer along the fibrovascular core along with the nuclear atypia clinch the diagnosis.

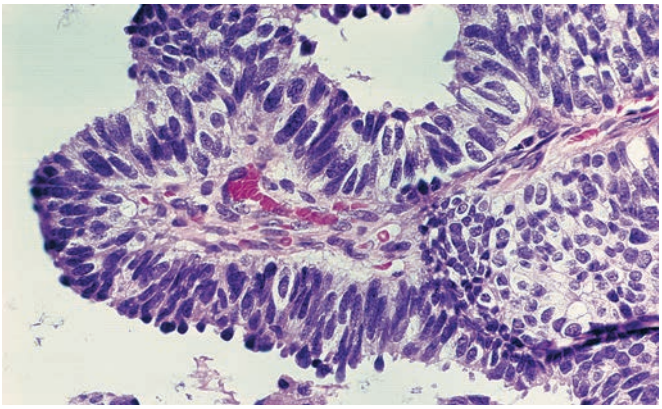

Figure 36.56 High-Power View of Papillary Ductal Carcinoma In Situ. Note the multi layering of cells, loss of nuclear polarity, marked hyperchromasia, and lack of a myoepithelial cell layer along the fibrovascular cores.

papillary DCIS is characterized by a single, uniform population of atypical epithelial cells, usually of low or intermediate nuclear grade (Figs. 36.55 and 36.56). The cells are arranged perpendicular to the delicate fibrovascular cores that typify papillary carcinomas (see following sections).[218] Notably, there are no myoepithelial cells lining the fibrovascular cores, supporting the premise that the papillae arise de novo as part of the neoplastic process,[233] whereas in DCIS involving a papilloma, the identification of a myoepithelial cell layer along the fibrovascular cores indicates the presence of an underlying benign papilloma. A myoepithelial cell layer is present at the periphery of spaces involved by papillary DCIS, consistent with the in situ nature of the disease. Helpful clues to the diagnosis of papillary DCIS are the presence of other patterns of DCIS in adjacent ducts and the absence of apocrine metaplasia within the papillary proliferation. A potential diagnostic trap is the occasional presence of scattered large pale eosinophilic cells, known as globoid cells, concentrated along the basal layer, which can be mistaken for myoepithelial cells (Fig. 36.57).[218]

Encapsulated Papillary Carcinoma

Encapsulated papillary carcinoma is a well-circumscribed papillary tumor surrounded by a thick fibrous capsule (Fig. 36.58). This tumor

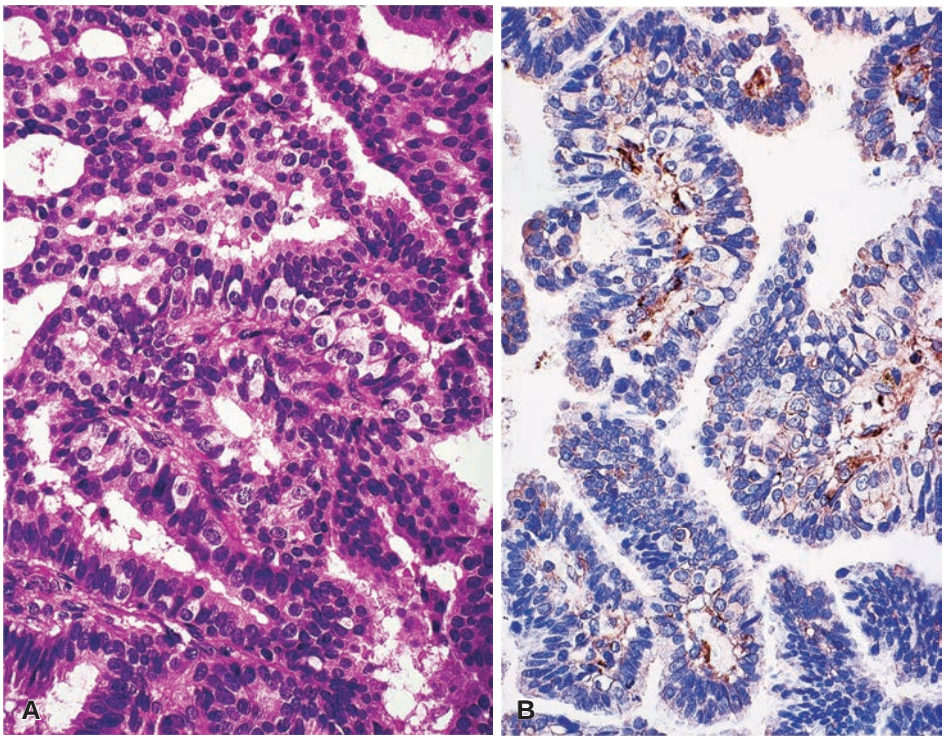

Figure 36.57 **A** and **B,** Papillary ductal carcinoma in situ with "globoid" cells. These cells, which are immunoreactive for GCDFP-15 and cytokeratin, should not be confused with myoepithelial cells. **B,** The globoid cells are negative for myoepithelial cell markers, as is demonstrated with this smooth muscle actin immunostain.

Figure 36.58 **Encapsulated Papillary Carcinoma of the Breast.** The papillary configuration of the tumor is grossly evident.

arises in older women, is centrally located, and often presents as a breast mass with or without bloody nipple discharge. On microscopic examination, the tumor gives the appearance of arising within a duct or "cyst" and had traditionally been considered to be an in situ or "intracystic" lesion. The fibrovascular cores are delicate and are surmounted by a monotonous proliferation of atypical epithelial cells that may, in addition to the papillary pattern, have areas of solid or cribriform architecture (Fig. 36.59). As with papillary DCIS, there is an absence of myoepithelial cells along the fibrovascular cores, but in contradistinction to the aforementioned DCIS, there is also an absence of myoepithelial cells at the periphery of most encapsulated papillary carcinomas,[234–236] raising the possibility that these tumors may be low-grade invasive carcinomas rather than in situ lesions.[237,238] Further evidence of the potential invasive nature of encapsulated papillary carcinoma is the rare occurrence of axillary lymph node metastases, even in the absence of conventional invasive carcinoma.[239] It is important to evaluate for areas of unequivocal conventional invasive carcinoma, as this will influence how the patient is staged and treated. This can be more challenging than might be imagined as the majority of patients have undergone a core needle biopsy procedure with the consequent displacement of epithelial nests into the biopsy site and fibrous capsule. Therefore, it is prudent to restrict diagnosis of associated invasive carcinoma to foci clearly away from the biopsy site. As far as tumor staging, it is the recommendation of the WHO Working Group that encapsulated papillary carcinomas be staged and managed as in situ lesions (Tis); any associated microinvasive or invasive carcinoma should be reported and staged according to the size of the largest focus of conventional invasive carcinoma.[237] Encapsulated papillary carcinomas are typically ER and PR positive and HER2 negative. The vast majority of encapsulated papillary carcinomas have low- or intermediate-grade nuclei and behave in an indolent manner; however, there are rare cases of encapsulated papillary carcinoma that have high-grade nuclei and a brisk mitotic rate.[240] Recent data indicate that these particular tumors, which represent approximately 3% of encapsulated papillary carcinomas, behave in a more aggressive manner and as such should be staged and managed as conventional invasive carcinoma of similar size.[240]

Solid Papillary Carcinoma

Solid papillary carcinoma presents in older women, often as an image-detected breast mass. Microscopically the tumor is composed of multiple, solid nests of neoplastic epithelial cells, within which is a fine fibrovascular network conferring the papillary architecture (Fig. 36.60). The epithelial cells may be spindled and have a streaming

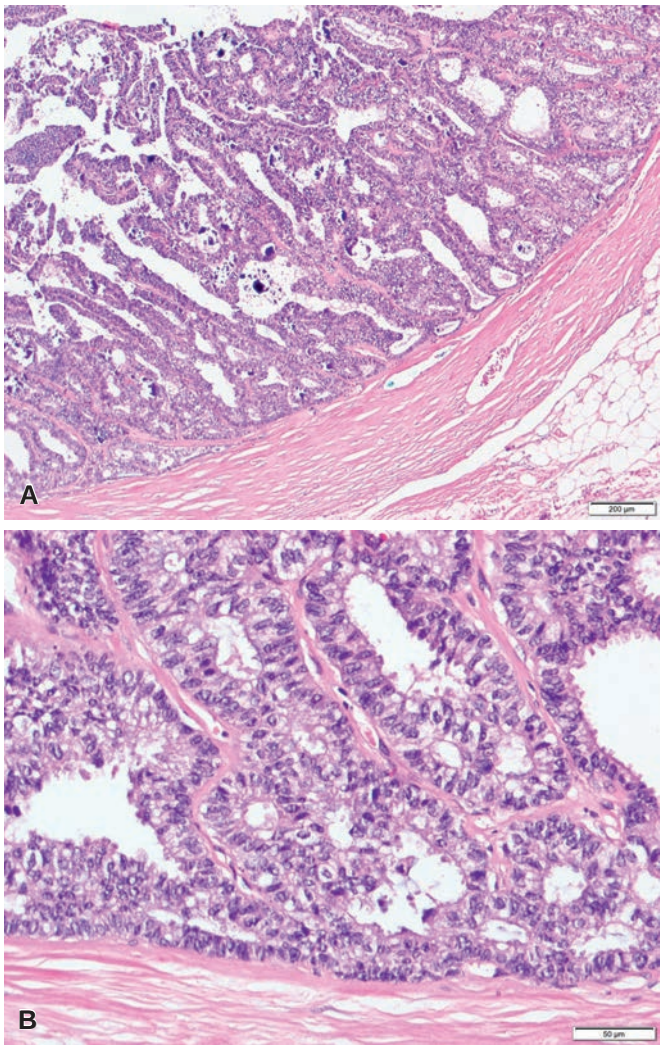

Figure 36.59 Encapsulated Papillary Carcinoma. A, Low-power view showing the fibrous capsule surrounding an encapsulated papillary carcinoma. At this power, the papillary architecture is apparent. **B,** At higher power the monotonous neoplastic epithelial cell population is better appreciated; in addition, note the cribriform architecture, the absence of myoepithelial cells at the periphery of the EPC (*lower left* of field), and the absence of myoepithelial cells running along the fibrovascular cores.

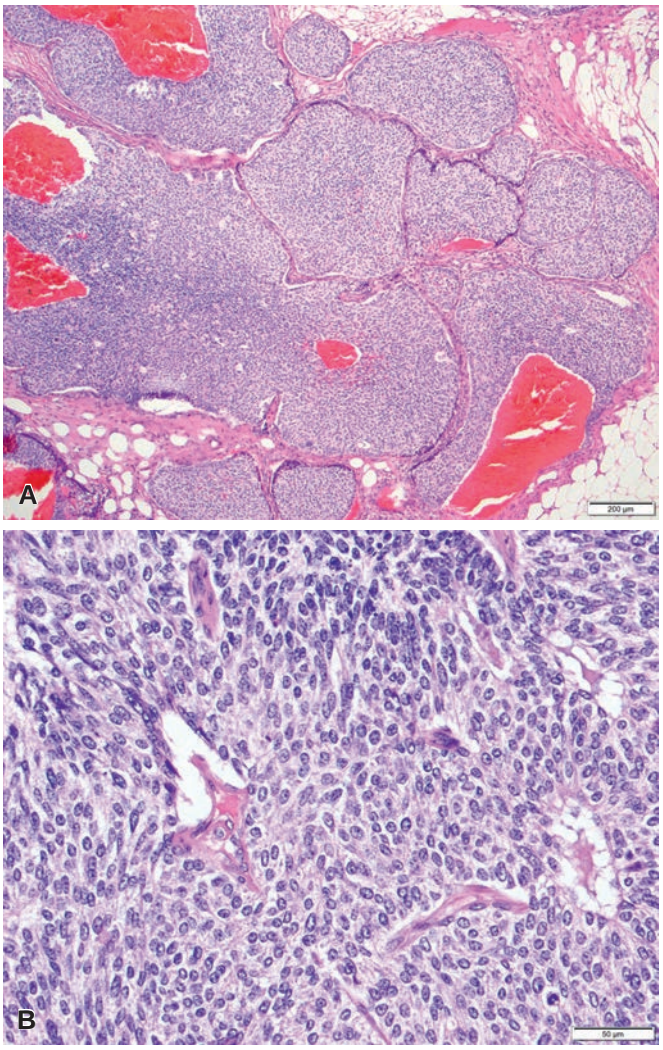

Figure 36.60 Solid Papillary Carcinoma. A, Low-power view showing multiple solid nests of neoplastic epithelial cells. **B,** High-power view reveals the fibrovascular network not readily appreciated at low power. The cells have a streaming appearance in areas but are monotonous with cytologic atypia.

appearance mimicking usual ductal hyperplasia. They may also have granular eosinophilic cytoplasm and fine nuclear chromatin consistent with endocrine differentiation. Mucin production is commonly seen in solid papillary carcinoma. As with papillary DCIS and encapsulated papillary carcinoma, there is an absence of myoepithelial cells within the neoplastic nodules. Studies have reported an absence of myoepithelial cells at the periphery of at least some cases of solid papillary carcinoma.[241] Thus, like encapsulated papillary carcinoma, this tumor may be an indolent, invasive carcinoma rather than an in situ lesion.[242] The WHO Working Group provides recommendations to aid in categorization of solid papillary carcinoma as in situ or invasive disease:[242]

Tumors with rounded nests and a complete or partial myoepithelial cell layer should be classified as DCIS, solid papillary pattern.

Tumors composed of nests with irregular borders and a geographic, jigsaw growth pattern and an absent myoepithelial cell layer may be considered invasive disease.

Tumors in which some but not all nests lack a myoepithelial cell layer are more difficult to classify. The recommendation is that if there is uncertainty about invasion, the lesion should be reported as in situ carcinoma for staging and management purposes.

The major differential diagnostic consideration is with UDH. Recognition of the fine fibrovascular network is the first step to separating these two entities. Other features favoring solid papillary carcinoma over UDH include a very monotonous appearance to the epithelial cells, cellular polarization around the fibrovascular cores, mucin production, and mitotic activity. In problematic cases, the combination of ER and CK5/6 can aid in diagnosis. ER is strongly and diffusely positive and CK5/6 is negative in solid papillary carcinoma.[243]

Solid Papillary Carcinoma With Reverse Polarity

Solid papillary carcinoma with reverse polarity (SPCRP) is a relatively recently described entity that is characterized by, as the name implies, solid papillary nests of bland columnar epithelial cells in which

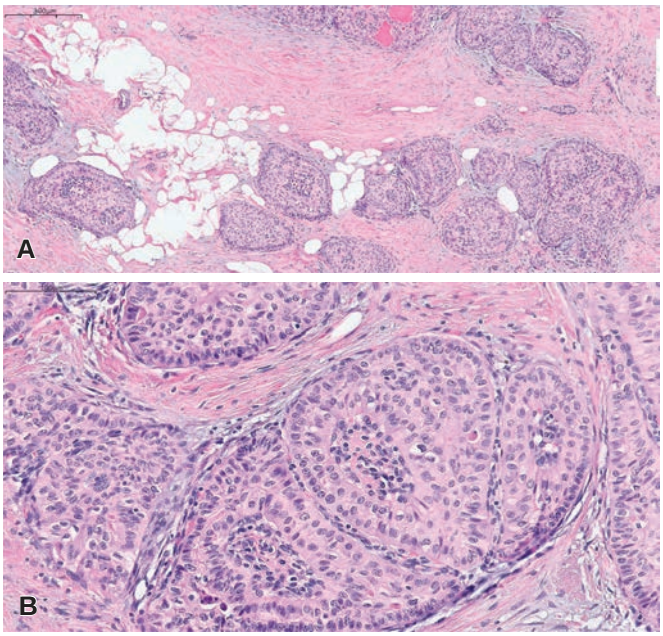

Figure 36.61 Solid Papillary Carcinoma with Reverse Polarity. **A,** Low-power view showing solid papillary nests of neoplastic epithelial cells infiltrating through the breast parenchyma. **B,** Higher-power demonstrating the fibrovascular core and the characteristic reverse polarization of the tumor cells.

nuclei of low or intermediate grade are apically rather than basally located ("reverse polarity"). Foamy histocytes are often present in the papillary cores.[243a] The tumor cell nests infiltrate through the breast parenchyma and adiopose tissue in a haphazard pattern, and lack a surrounding myoepithelial cell layer (Fig. 36.61). The morphology of these tumors is so striking, that once encountered, subsequent cases are readily recognized. The tumor cells are typically ER, PR and HER2 negative (though ER and/or PR positivity is reported); interestingly both low and high molecular weight cytokeratins are expressed by the epithelial cells.[243a] Earlier reports describing a "breast tumor resembling tall cell variant of papillary thyroid carcinoma"[243b,243c] bear some similarities to SPCRP, but because SPCRPs express breast markers (GCDFP-15, mammaglobin) and lack expression of thyroid markers (TTF-1 and thyroglobulin) this term better describes the lesions. Molecular analysis of these tumors has demonstrated recurrent *IDH2* as well as *PIK3CA* and *PIK3R1* mutations.[243a,243d] While little clinical follow-up is available for these rare tumors, they appear to behave in an indolent manner.

Invasive Papillary Carcinoma

Invasive papillary carcinoma is a very rare entity.[244] Papillary DCIS, encapsulated papillary carcinoma, and/or solid papillary carcinoma with associated invasive ductal or mucinous carcinoma should be categorized as such and not as invasive papillary carcinoma. Metastasis to the breast, such as from the ovary or lung, should be considered in cases of apparent invasive papillary carcinoma before rendering a diagnosis of primary papillary carcinoma of the breast.

Nipple Lesions

Nipple Adenoma

Nipple adenoma, also known as florid papillomatosis of the nipple ducts and erosive adenomatosis, is a benign proliferation of glands embedded in a fibrotic stroma (Fig. 36.62). It usually occurs in the fourth or fifth decade, is nearly always unilateral, and is often accompanied by serous or bloody discharge from the nipple. Clinically, the nipple may appear eroded, and the disease may be confused with Paget disease.

Microscopically, the most common pattern seen is of marked papillomatous changes, often associated with distortion induced by the dense stroma present. The latter is referred to by Rosen and Caicco[245] as the sclerosing papillomatosis pattern, the other patterns being papillomatosis (without sclerosis) and adenosis (the least common of the three). The features used to identify this lesion as benign are to a large extent analogous to those seen in intraductal papilloma and UDH. They include the presence of a dual population of epithelial and myoepithelial cells (confirmed if needed by immunohistochemical evaluation), an oval nuclear shape, lack of atypia, "streaming," the formation of peripheral clefts, and the absence of a cribriform pattern. Features of which to be aware in this lesion relate to the close interaction of the glandular epithelium of the mammary ducts with the squamous epithelium from the epidermis (Fig. 36.62), resulting in formation of adenosquamous nests that may be overinterpreted. Otherwise typical nipple adenomas can exhibit small foci of necrosis in the center of the proliferating ducts (Fig. 36.63).[245]

A note of warning is in order; just because an intraductal papillary lesion is located in or close to the nipple, it does not necessarily mean that it is a nipple adenoma and, therefore, benign. Papillary DCIS and invasive ductal carcinomas can also occur in this location, some occasionally even arising within a nipple adenoma.[245,246]

The treatment of uncomplicated nipple adenoma is local excision.[245,247]

Squamous Metaplasia of Lactiferous Ducts

SMOLD presents clinically as recurrent abscess with or without fistula formation.[248] As the name implies, the lesion is characterized by extension of the squamous epithelium of the nipple further than the usual 1–2 mm down the lactiferous ducts. The resulting accumulation of keratinaceous debris leads to duct rupture with consequent inflammatory response (Fig. 36.64). Patients are often managed with incision and drainage on the presumption of mastitis with abscess formation. By the time tissue samples reach the pathology department, the inflammatory response is often quite severe and specimens are sent piecemeal, making recognition of the underlying squamous metaplasia of the lactiferous ducts difficult. The diagnosis should be considered in this clinicopathologic scenario so that the patient may be directed to appropriate management, namely wide excision of the involved duct often with a wedge resection of the nipple to facilitate eradication of the process.

Paget Disease

Paget disease is the name given to a crusted lesion of the nipple caused by breast carcinoma in the nipple epithelium, as originally described by Sir James Paget in 1874. It is accompanied in nearly all instances (>95%) by an underlying breast carcinoma, typically high-grade DCIS, with or without associated stromal invasion. In this regard, the presence of Paget disease is a secondary, albeit dramatic, feature of the tumor. The management and prognosis depend largely on the in situ versus invasive nature of the underlying carcinoma, and on the presence or absence of axillary lymph node involvement, rather than on the presence or appearance of the intraepidermal component in the nipple.

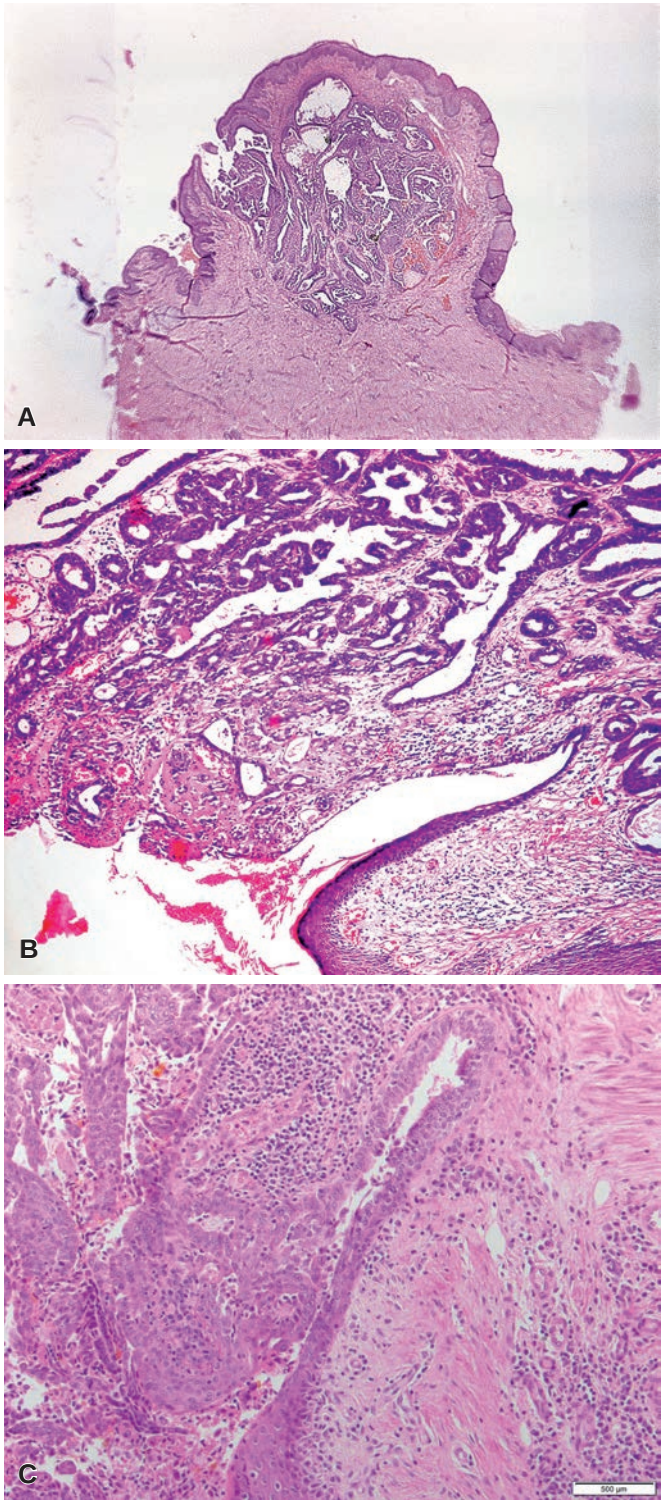

Figure 36.62 **A,** Typical polypoid shape of nipple adenoma, as seen in a whole mount section. **B,** The complex architectural arrangement can lead to overdiagnosis. **C,** The continuity with the squamous epithelium of the skin is a characteristic feature of this entity.

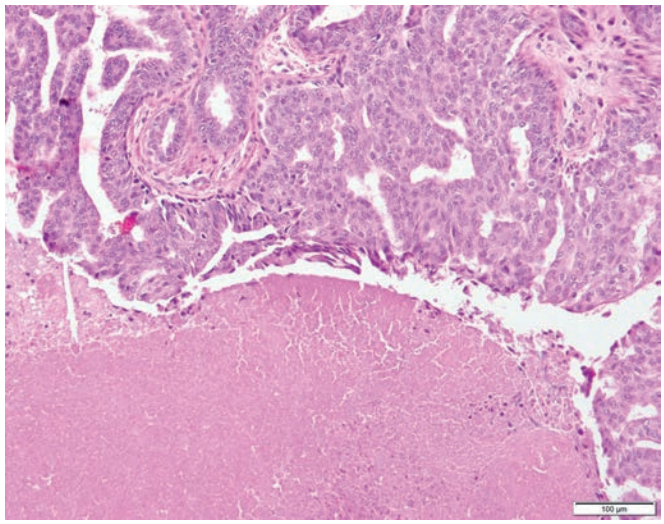

Figure 36.63 **Nipple Adenoma.** High-power view showing usual ductal hyperplasia and necrosis present in a nipple adenoma.

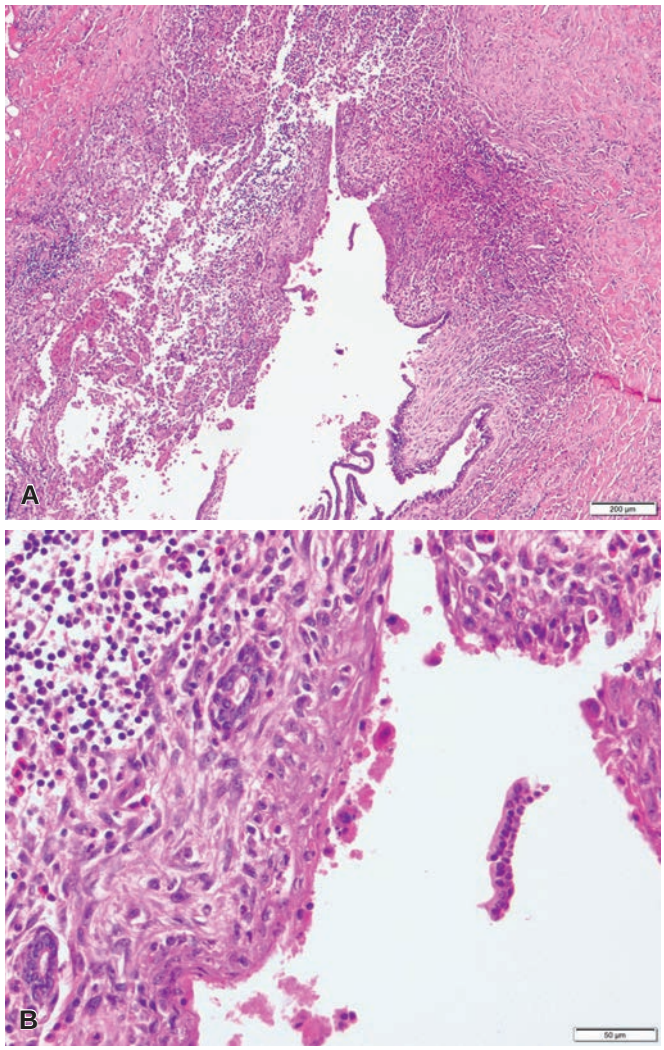

Figure 36.64 **Squamous Metaplasia of Lactiferous Ducts. A,** Low-power view of a dilated nipple duct partially lined by squamous epithelium, with surrounding inflammation. **B,** High-power view of the squamous epithelial lining.

Figure 36.65 Eczematous hyperemic and eroded clinical appearance of Paget disease. (Courtesy of Dr RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

Clinically, these weeping, eczematous lesions are centered on the nipple (Fig. 36.65). Later the areola and surrounding skin may become involved over an area of a few centimeters. Microscopically, large clear cells with highly atypical nuclei are seen within the epidermis, usually concentrated along the basal layer but also spreading up through the epidermal layers (pagetoid growth pattern) (Fig. 36.66). The cells can be isolated or present in clusters, and sometimes they form small glandular structures.[249] Occasionally, intracytoplasmic melanin granules are present, a feature that may result in a mistaken diagnosis of malignant melanoma.[250]

The underlying breast carcinoma is practically always of high-grade ductal type and is composed of cells similar to those present within the epidermis. Mucin stains are usually positive. Immunohistochemically, Paget cells show reactivity for EMA, polyclonal CEA, low-molecular-weight cytokeratin (including CK7), HER2 and, in some cases, GCDFP-15 (Fig. 36.67). In general, they are negative for HMW cytokeratins and S-100 protein. ER may be positive or negative.

The main differential diagnostic considerations are Bowen disease, malignant melanoma, and Toker cells. Immunohistochemical stains are often necessary to help differentiate these entities in the absence of a readily identifiable breast carcinoma or in a small biopsy of the nipple (Table 36.2).

It is thought that Paget cells in the nipple epidermis have migrated there from a carcinoma present in deeper ductal structures. The similarities in immunohistochemical profile between Paget cells and any underlying high-grade carcinoma present (such as HER2 positivity, ER negativity) support this hypothesis. On the other hand, the existence of rare cases of Paget disease without underlying ductal carcinoma have led to the suggestion that in some cases the cell of origin is the Toker cell or keratinocytes at the squamocolumnar junction.[251,252] In this regard, the observation made by Toker[8] about the presence of clear cells in nipples without clinical evidence of Paget disease and without microscopic evidence of breast carcinoma is of great interest. These cells have some immunohistochemical similarities with Paget cells (positivity for CK7 and EMA, and negativity for p63)[7,253] and may exhibit mild nuclear atypia, suggesting the possibility of a dysplastic or "pre-Paget" change.[254,255] From a practical standpoint, Toker cells are distinguished from the cells of Paget disease because of the lack of clinical changes, the absence of cytologic features of malignancy (Fig. 36.68), and some histochemical and immunohistochemical differences, such as negativity for mucin and GCDFP-15.

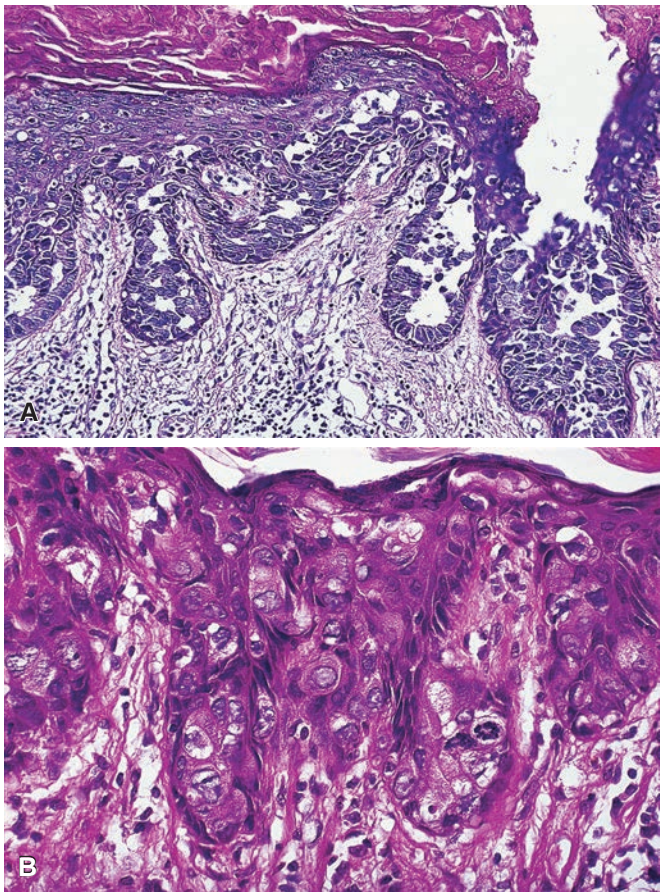

Figure 36.66 **A** and **B,** Low- and high-power views of Paget disease. **A,** The cleft-like separation between the tumor cells and the overlying squamous epithelium is characteristic. **B,** At high power, striking cytologic atypia in the tumor cells is readily apparent.

Carcinoma

General Features

Age

The large majority of breast cancers are detected during the postmenopausal years. However, breast cancer can develop at any age, from childhood to old age.

Incidence

Breast carcinoma is the most common malignant tumor and the second most common cause of carcinoma death in women, with more than 1.7 million cases occurring worldwide annually.[256] In the United States, approximately 230,000 new cases are diagnosed annually and approximately 40,000 patients die from the disease each year.[257] The incidence is high in North America and northern Europe (92 new cases per 100,000 women/year), intermediate in southern European and Latin American countries, and low in most Asian and African countries (but rising rapidly in recent years in some of these countries). In the United States, there has been a sharp increase in the detection of breast carcinoma, largely due

to the widespread use of mammography.[258] Most of these cases have been early stage, measuring less than 2 cm in diameter and/or DCIS.[259] Initially, this increase in the number of smaller tumors did not translate into an improved survival rate. As a matter of fact, the mortality rate for breast carcinoma changed very little from the 1930s to the early 1990s.[259] However, in some regions of the world (North America, Western Europe, and Australia) breast cancer mortality is now declining, which has been attributed to the combined effects of earlier diagnosis and improved therapy.[260,261]

The incidence of clinically occult carcinoma can be inferred to a degree from examination of reduction mammoplasty specimens. In a study of 2498 cases, Desouki et al. found invasive carcinoma and DCIS to be extraordinarily rarely present (0.2%); by comparison, atypical proliferative lesions were identified in 4.3% of cases; the most common lesion being lobular neoplasia (2.2%).[262]

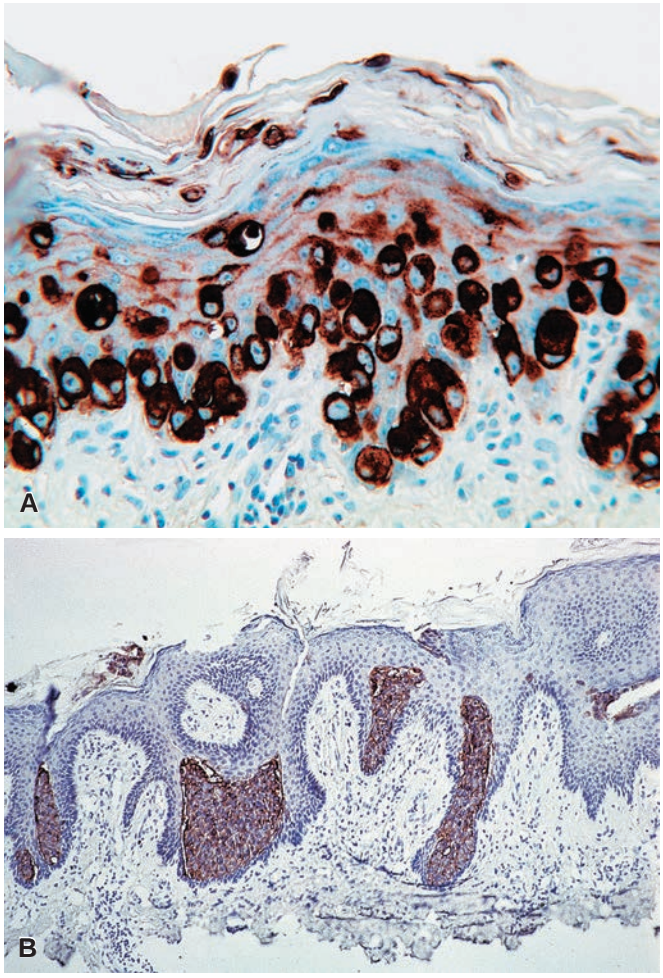

Figure 36.67 Immunohistochemical demonstration of malignant intraepidermal cells in Paget disease. **A,** EMA immunostain. **B,** HER2 immunostain.

Risk Factors

Several risk factors for the development of breast carcinoma have been established, whereas many others remain questionable. It has been hypothesized that the common denominator for most of these factors is strong and/or prolonged estrogen stimulation operating on a genetically susceptible background.

1. *Country of birth*. This has already been touched upon above.
2. *Family history*. Women who have a first-degree relative with breast carcinoma have a risk 2 or 3 times that of the general population, a risk further increased if the relative was affected at an early age and/or had bilateral disease.[263] The aspects related to discovery

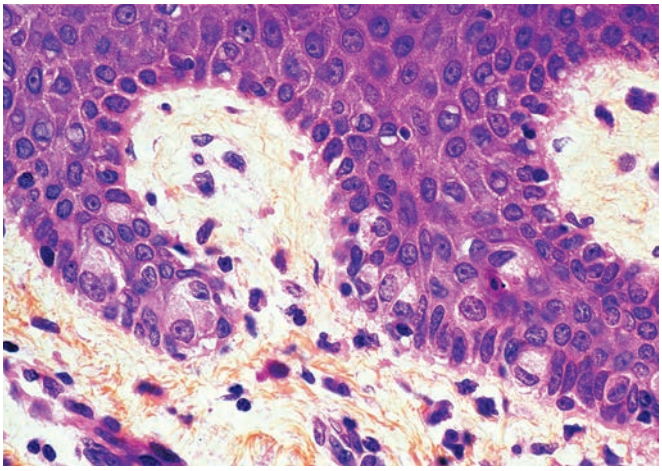

Figure 36.68 Biopsy of nipple showing scattered clear cells without nuclear atypia in the basal layer ("Toker cells").

Table 36.2 Differential histochemical and immunohistochemical staining patterns of epidermal lesions of the nipple (reported as proportion of cases expressing marker)

	PAGET DISEASE	MALIGNANT MELANOMA	SQUAMOUS CELL CARCINOMA IN SITU	TOKER CELLS
Mucin	High	Negative	Negative	Negative
Cytokeratin 7	Positive	Low	Low	Positive
HER2	High	Negative	Low	Negative
ER/PR	Low	Negative	Negative	High
GCDFP	Moderate	Negative	Negative	Low
S100	Low	Positive	Low	Negative
HMB45	Negative	Positive	Negative	Negative

Key: Positive >90% of cases, high 60%–90% of cases, moderate 40%–60% of cases, low 10%–30% of cases, negative <10% of cases express the marker.
From Dillon D, Lester S. Lesions of the nipple. In: Collins LC ed. *Current Concepts in Breast Pathology*. Philadelphia PA: Saunders; 2009:391–412.

of the genes responsible for predisposition to breast carcinoma are discussed in the next section.

3. *Menstrual and reproductive history.* Increased risk is correlated with early menarche, nulliparity, late age at first birth, and late menopause.[264] Breast carcinoma is rare in women who have undergone bilateral oophorectomy; risk-reducing salpingo-oophorectomy before 35 years of age reduces the risk by about one half.[265,266] Younger age at first pregnancy is associated with a lower lifetime risk of breast cancer. Note though, that there is a dual effect associated with pregnancy: an early transient increase in breast cancer risk followed by a prolonged protective effect.[267] A reduction in the risk of breast carcinoma among parous women who have breastfed for at least 4 months has been documented.[268] Breast carcinoma risk is increased in postmenopausal women with a hyperandrogenic plasma hormone profile.[269,270]
4. *Intraductal proliferative lesions*. The relationship between intraductal proliferative lesions without atypia and breast carcinoma has been discussed in earlier sections.
5. *Exogenous estrogens.* The influence of exogenous hormones on breast cancer risk is complex and varies with duration of therapy and combination of agents used. In brief, the risk appears greater with longer duration of use/current use and with use of estrogen combined with progestins compared with use of estrogen alone.[264]
6. *Contraceptive agents*. The various epidemiologic studies that have been conducted have shown no increased risk, or at most a very low increase among young long-term users.[271]
7. *Ionizing radiation*. An increased risk of breast carcinoma has been documented with exposure to ionizing radiation, particularly if this exposure occurred at the time of breast development, such as in young women receiving mantle irradiation for Hodgkin disease or atomic bomb survivors who were younger than 10 years of age at exposure.[272–274]
8. *Breast augmentation*. Breast implants do not result in an increase in breast cancer risk. Re-analysis of a previously published linkage study that had reported an elevated risk has shown that the incidence of breast carcinoma in that cohort was neither higher nor lower than that among the general population (see later section for discussion of other malignancies related to breast implants).[275,276]
9. *Others*. A peculiar association between breast carcinoma and meningioma has been repeatedly noted, with the even more peculiar observation that sometimes the breast carcinoma is found to metastasize to the meningioma. However, a recent study evaluating over 12,000 patients with breast cancer found no increased risk of meningioma, with a 10-year cumulative incidence of just 0.37%.[277]

Genetic Predisposition

Approximately 5%–10% of all breast cancers are familial.[278,279] An epochal event in the study of breast carcinoma was the discovery of two high-penetrance susceptibility genes which, when affected by germline mutations, are associated with a high lifetime risk for development of breast cancer, as well as some other cancers, in particular ovarian cancer.[278] Originally, mutations in these genes were thought to be responsible for a high proportion of familial breast carcinomas, but they are now found to be responsible for only about 16% of them.[279–281] These are *BRCA1*, located on chromosome 17q21, and *BRCA2*, located on chromosome 13q12.3 (Table 36.3).[282–284] Mutations of these genes are present in approximately 2% of the Ashkenazi Jewish population; it has been estimated that the risk for breast carcinoma among carriers is up to 70%–80% by the age of 70 years.[285–287] The finding of a positive test for the mutation can lead to an agonizing decision on the part of the affected individual, the main choices being close follow-up or bilateral prophylactic mastectomy.[288]

The *BRCA1*-encoded protein has many functions, including repair of DNA damage through homologous recombination, cell cycle checkpoint control, ubiquitylation, chromatin remodeling, and DNA decatenation.[279] The protein encoded by *BRCA2* is involved in DNA repair, cytokinesis, and meiosis.[279] That is, both *BRCA1* and *BRCA2* are essential for accurate repair of DNA double-strand breaks through homologous recombination.[279] Loss of such function in the associated cancers has been exploited to develop novel therapies—for example, poly-adenosine diphosphate (ADP)-ribose polymerase (PARP) inhibitors which block repair of DNA damage via alternate pathways in tumor cells deficient in DNA repair through homologous recombination—a process that has been referred to as "synthetic lethality".[289,290]

Analysis of breast carcinomas developing in carriers of *BRCA1* mutations has shown a higher percentage of tumors with the basal-like gene expression profile (see later discussion) and that tend to be high grade, mitotically very active, with a syncytial growth pattern, pushing margins, confluent necrosis, negativity for hormone receptors and HER2 ("triple negative"), and associated with *TP53* mutation.[279,291–293] On the other hand, *BRCA2*-associated cancers are a heterogeneous group without specific morphology or phenotype and are commonly positive for hormone receptors.[291,293]

In addition to *BRCA1* and *BRCA2*, several other genes (e.g., *CHEK2*, *CDH1*, *RAD50*, and *PALB2*) confer a low to moderate increased risk for the development of breast cancer.[294] Hereditary breast cancer can also occur in the setting of multiple cancer syndromes,[279] such as Lynch syndrome (e.g., *MLH1*), Li–Fraumeni syndrome *(TP53)*, ataxia–telangiectasia syndrome *(ATM)*, and Cowden syndrome *(PTEN)*, as summarized in Table 36.3.[279,295]

Location

The location of breast carcinoma is usually indicated in relation to the breast quadrants. Approximately 33% are in the upper outer quadrant, 9% in the upper inner quadrant, 6% in the lower outer quadrant, 5% in the lower inner quadrant, 7% in the central region (within 1 cm of the areola), and 40% occur in overlapping quadrants (or location not specified).[296] Several studies have also documented the peculiar fact that breast carcinoma is slightly more frequent in the left breast than in the right ("laterality ratio"). In one recent series, the excess for the left side varied by age, quadrant, and place of birth.[296] Preliminary studies in mouse models indicate that there may be baseline differences in gene expression that are left-right independently regulated during pubertal development, which may play a role in this observation.[297]

Multicentricity and Multifocality

Multicentricity, defined as the presence of carcinoma in a breast quadrant other than the one containing the dominant mass, was described as early as 1920 and later reported by others.[298,299] Multifocality is defined as the presence of additional foci of carcinoma in the same quadrant as the index carcinoma. Among a contemporary population of 1495 patients with invasive carcinoma, 82.3% of tumors were unifocal, 11.3% were multifocal, and 6.4% were multicentric. Multicentricity was more common in lobular than in ductal carcinomas; patients were more likely to be younger with larger tumors, to have lymphovascular space invasion and positive lymph nodes. Multifocality was more commonly seen with invasive ductal carcinomas that had an extensive intraductal component and were

Table 36.3 Summary of the syndromes associated with hereditary breast cancer

SYNDROME (OMIM)	GENE INVOLVED AND CYTOBAND	CLINICAL FEATURES
Hereditary breast cancer and ovarian cancer syndrome (113705)	*BRCA1* (17q21)	Breast cancer, high risk (50%–80%) Ovarian cancer, high risk (40%–50%)
Hereditary breast cancer and ovarian cancer syndrome (600185)	*BRCA2* (13q12.3)	Breast cancer, high risk (50%–70%) Ovarian cancer, intermediate risk (10%) Prostate cancer Pancreatic cancer Melanoma
CHEK2 mutations (Li–Fraumeni 2 syndrome?)	*CHEK2* (22q 12.1)	Breast cancer, intermediate risk (~twofold) Sarcomas Brain tumors
Other FANC genes (114480, 610355, 607139, 600901, 605882)	*PALB2/FANCN* (16p12)*FANCA* (16q24.3)*FANCE* (6p22–p21)*BRIP1/FANCJ* (17q22)	*PALB2/FANCN* and *BRIP1/FANCJ*: moderate risk of breast cancer development Other FANC genes: low risk of breast cancer development
Familial linitis plastica type gastric cancer and lobular breast carcinoma syndrome (192090)	*CDH1* (16q22.1)	Gastric cancer Lobular breast cancer
Louis–Bar syndrome (208900)	*ATM* (11q22.3)	Lymphoma Cerebellar ataxia Immune deficiency Glioma Medulloblastoma Breast cancer
Li–Fraumeni syndrome (151623)	*TP53* (17p13.1)	High penetrance for breast cancers at young age Risk of soft tissue sarcomas and osteosarcomas, brain tumors, leukemia, and adrenocortical carcinoma
Cowden syndrome (158350)	*PTEN* (10q23.31)	Increased risk of developing neoplasms (breast cancer, thyroid carcinoma, endometrial carcinoma and others) Hamartomatous polyps of the gastrointestinal tract Mucocutaneous lesions
Bannayan–Riley–Ruvalcaba syndrome (153480)	*PTEN* (10q23.31)	Breast cancer Meningioma Follicular cell tumors of the thyroid
Peutz–Jeghers syndrome (175200)	*STK11* (19p13.3)	Melanocytic macules of the lips, buccal mucosa, and digits Multiple gastrointestinal hamartomatous polyps Increased risk of various neoplasms (breast, testis, pancreas, and cervix)
Lynch cancer family syndrome II (114400)	*MSH2* (2p22–p21), *MSH3* (5q11–q12), *MSH6* (2p16), *MLH1* (3p21.3), *PMS1* (2q31–q33), *PMS2* (7p22)	Increased risk of endometrial carcinoma and colorectal carcinoma High risk of multiple primary malignant neoplasms, including breast, ovarian, gastrointestinal, and genitourinary carcinomas, sarcomas, glioblastoma, and leukemia

ER, PR, and HER2 positive.[299] Not surprisingly, a higher incidence of multicentricity and multifocality is reported in patients undergoing preoperative MRI and mastectomy.[299] Theoretically, multiple breast carcinomas can result from either intramammary spread of a single lesion or from independent events.[300] Clonal studies suggest that both mechanisms play a role.[301,302] If aggregate diameters are used, unifocal and multifocal carcinomas are similar with respect to the frequency of regional lymph node involvement,[303] but other studies have shown that the single largest tumor diameter, as is recommended by the AJCC TNM staging system, even in patients with multiple tumor foci, is an accurate method for staging patients.[299,304]

Bilaterality

The chance that a patient with invasive breast carcinoma will develop a carcinoma in the contralateral breast is estimated to be about 1% per year and is even higher if there is a family history of breast carcinoma and in cases of invasive lobular carcinoma.[305] The use of adjuvant estrogen blockade with or without chemotherapy significantly decreases the risk of metachronous contralateral breast carcinoma.[305,306] Annual screening mammography is the current surveillance practice for these patients, unless the lifetime risk is greater than 20%–25%, in which case adjunctive screening with MRI is recommended.[307]

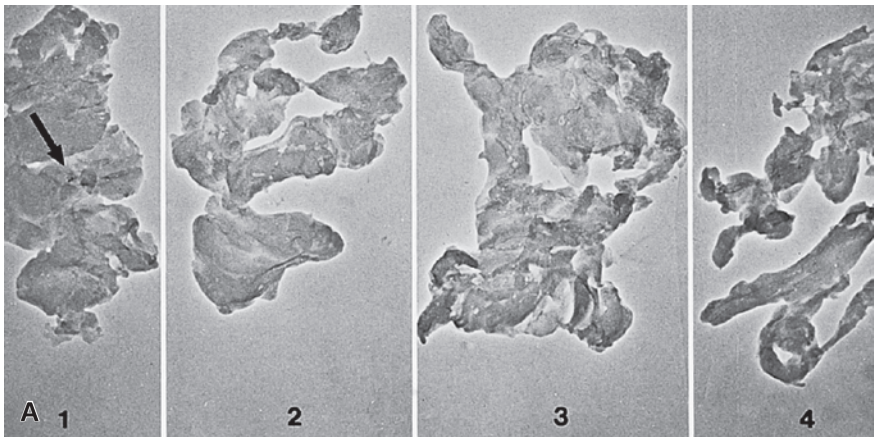
Synchronous bilateral invasive breast carcinomas are being detected more frequently because of the use of MRI in the work-up of patients with a confirmed diagnosis of breast cancer, ostensibly for surgical planning purposes. An unfortunate corollary of this practice is the rising number of contralateral mastectomies being performed in patients found to have benign or atypical (nonmalignant) pathology on core needle biopsies of areas of radiologic concern in the contralateral breast.[308,309] No significant difference in overall survival has been reported for patients with bilateral breast carcinoma when appropriately matched to women with unilateral breast cancer.[310]

Diagnosis

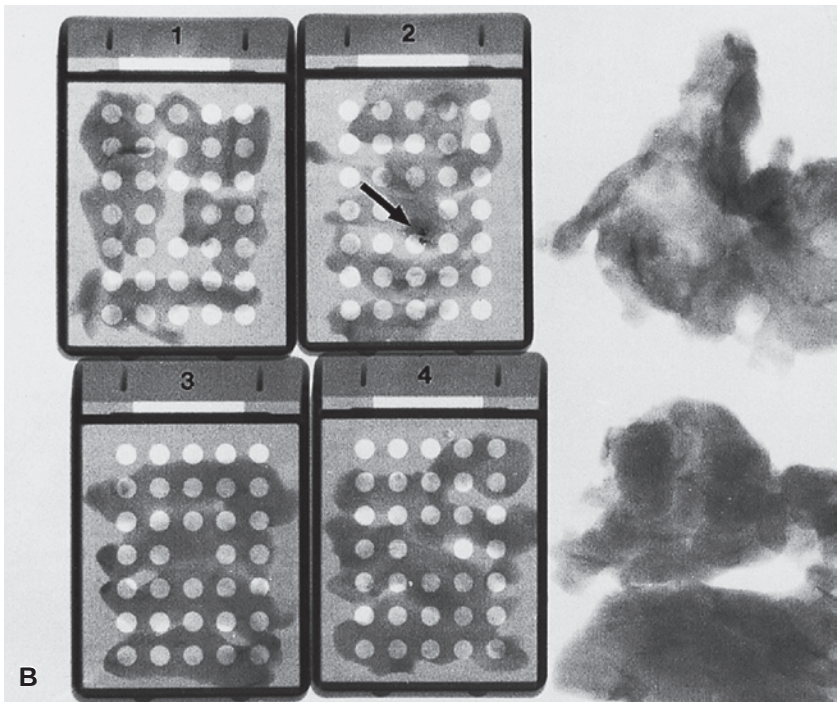
Clinical Examination

Clinical examination is the time-honored method for the detection and evaluation of breast disease. It remains an extremely useful and practical technique, whether carried out by the physician or by the patient herself. However, both its sensitivity and discriminatory power are limited. Today, the majority of breast cancers are detected through imaging studies, with only 10% of the tumors being detected solely by palpation.[311] The clinical impression is incorrect in approximately 15% of the cases thought to be benign and approximately 10% of those thought to be malignant. The clinical evaluation of axillary lymph nodes is also fraught with error; determination of lymph node status requires microscopic examination.[312]

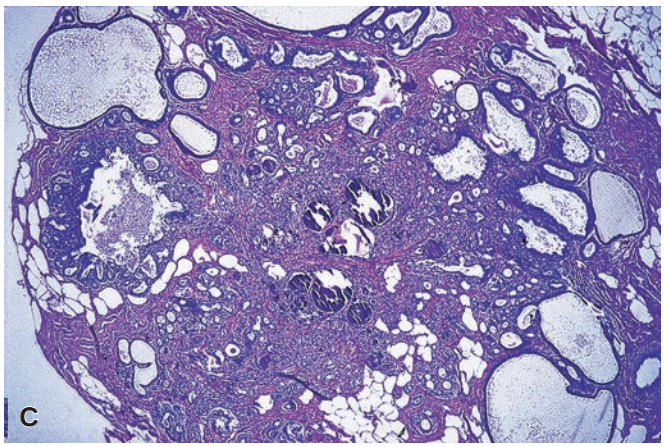
Mammography



The widespread use of screening mammography has led to an increase in the detection of breast cancers at an earlier stage and of smaller size, primarily based on the presence of microcalcifications, nonpalpable masses, or architectural distortion.[313] The incidence of calcification in breast carcinoma is approximately 50%–60%, and the incidence in benign breast disease is 20%.[314] There are also important qualitative differences in the appearance of the microcalcifications, with pleomorphic or heterogeneous calcifications that are fine, linear, branching, or casting (conforming to the pattern of a duct) being more frequently predictive of malignant disease on histology. In a study of 2545 women enrolled in a breast screening program found to have microcalcifications alone on imaging, 47.9% were subsequently shown to be associated with malignancy (31.8% DCIS and 16.1% invasive carcinoma, mostly with associated DCIS) and 52.1% of cases were associated with nonmalignant lesions.[315] In the United States, mammographic findings are universally reported using the Breast Imaging Reporting and Data System (BI-RADS), which allows the radiologist to convey the degree of suspicion, with 1 being negative and 5 being highly suspicious for malignancy.[316] The majority of core biopsy samples will be from patients with BI-RADS category 4 lesions. This category is very broad, with the likelihood of cancer being diagnosed on biopsy ranging from 2% to 94%. Consequently, subcategories were created to better convey the level of concern: BIRADS 4A (2%–9% chance of malignancy), 4B (10%–49% chance of malignancy), and 4C (50%–94% chance of malignancy).



It should be kept in mind that a negative mammogram does not rule out the possibility of the presence of carcinoma, since approximately 15% of palpable tumors are not detectable with this technique.[317] Ultrasound may be the better modality for palpable masses. The proper management of breast lesions detected by mammography requires close cooperation between radiologist, surgeon, and pathologist. Mammographically detected nonpalpable lesions usually require preoperative wire localization, if excision is necessary, to guide the surgeon to the suspicious area within the breast. Today, most patients have undergone a core needle biopsy procedure prior to excision with placement of a radio-opaque clip, and it is this clip, along with tissue landmarks, that is used to guide wire-localization by the radiologist. Once the appropriate area is excised, the margins should be marked by the surgeon with sutures (typically superior and lateral margins, short and long sutures, respectively by convention) and an x-ray study of the specimen performed to confirm removal of the target area and biopsy clip. If no lesion/calcification or clip is seen, the surgeon should obtain additional tissue, if feasible. If the abnormal area is present in the specimen, the specimen should be inked with six different colored inks according to the orientation given by the surgeon and the specimen sliced and processed in the pathology laboratory. As mentioned above, the vast majority of patients have undergone a core needle biopsy procedure prior to definitive surgery; therefore the pathologic diagnosis from that earlier procedure can be used to guide tissue processing. The highest yield is obtained from histologic examination of the areas with radiographic calcification and fibrous parenchyma.[318]



X-ray studies can be taken of the paraffin blocks to document the fact that the microcalcifications seen in the mammogram have been embedded (Fig. 36.69). An important source of discrepancy between mammographic targeting of calcifications and microscopic findings are calcium oxalate crystals, which can be easily identified radiographically but may be missed on histologic examination.[319] Every attempt should be made to identify, in the microscopic sections, the imaging target regarded by the radiologist as "suspicious" for carcinoma.

Breast ultrasonography is a valuable examination tool, particularly for determining whether a mass lesion is cystic or solid, and whether it is circumscribed and "wider than tall," which are features of benignity, or conversely whether it is hypoechoic with irregular borders, "taller than wide" and has posterior shadowing, which are features favoring a malignant diagnosis.[320]

MRI is unlikely to replace mammography as the imaging modality of choice, although contrast-enhanced techniques have rendered it more informative and potentially more useful. It is more sensitive but has lower specificity, resulting in greater numbers of false-positive call backs and unnecessary biopsies. There is greater application for

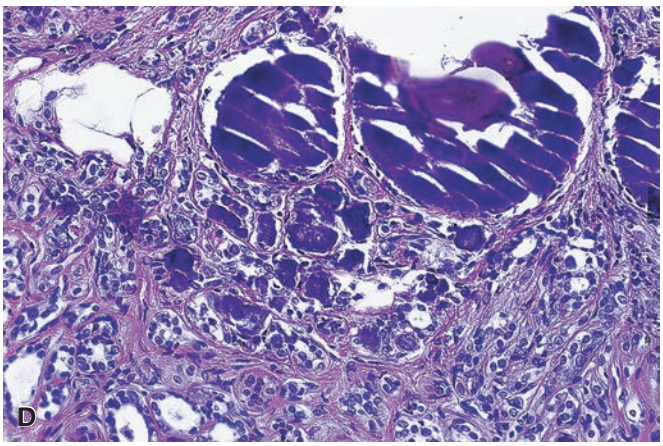


Figure 36.69 Demonstration of the Use of Specimen Radiography. A mammographically detected breast lesion was excised. **A,** The specimen was sliced into four portions and a radiograph taken. A pattern of calcification identical to that seen in original mammogram was detected in slice 1 *(arrow)*. **B,** The portion corresponding to this area of calcification was further divided into four fragments, and all four were embedded in paraffin. A radiograph of the cassettes shows that the suspicious area is in cassette 2 *(arrow)*. The remainder of the slice (two fragments at right) shows no calcification. **C** and **D,** Low- and high-power views of the corresponding microscopic specimen demonstrating the microcalcifications.

use of MRI in patients at high risk (>20% lifetime risk) for the development of breast cancer.[321]

Where adopted for screening purposes, the National Cancer Institute has traditionally recommended mammography be done on an annual basis from the age of 40 years onwards. Great controversy has recently arisen following the revised recommendations from the US Preventive Services Task Force, which calls for mammograms to be done biennially from the ages of 50 to 74, with the decision to begin screening at 40 years being an individual one depending on a woman's risk factors.[322]

Cytology

The two methods that have been used to obtain cytologic material from breast lesions are collection of nipple discharge (often directly onto a glass slide) and aspiration of a palpable lesion using a fine needle.

Nipple secretion cytology is of limited use, whether for the diagnosis of a clinically or mammographically detectable breast lesion or for screening purposes. Some carcinomas may be found, but the ability to provide a definitive interpretation from these often bloody, degenerated specimens is limited, rendering this technique of only marginal value. The situation with FNA is different, as shown in the pioneer attempts at Memorial Sloan Kettering Cancer Center in the 1930s. In experienced hands the technique is highly reliable (Fig. 36.70).[323,324] The average sensitivity is approximately 87%, the specificity close to 100%, the predictive value of a positive diagnosis nearly 100%, and the predictive value of a negative diagnosis between 60% and 90%.[323,325] Most benign lesions misinterpreted cytologically as possibly malignant are usually fibroadenomas or intraductal papillomas with marked epithelial proliferation.[326] At the malignant end of the spectrum however, it is not possible to distinguish between in situ and invasive carcinoma on FNA cytology,[327] for these reasons core needle biopsy has largely superseded FNA cytology as the diagnostic procedure of choice in the United States. There remains a role in the evaluation of clinically positive axillary lymph nodes, particularly in the neoadjuvant setting to document lymph node metastasis prior to initiation of chemotherapy.

Core Needle Biopsy

In recent years, core needle biopsy (image-guided and with or without vacuum assistance) has become the gold standard for the diagnosis of image-detected nonpalpable and palpable breast lesions. Core needle biopsy is favored over FNA for the preoperative diagnosis of breast carcinoma. As mentioned previously, core needle biopsy allows for evaluation of both cytologic *and* architectural features, thereby permitting definitive diagnosis of invasive carcinoma when present. Conversely a benign lesion, such as fibroadenoma, can be readily recognized, and core needle biopsy allows for easier sampling and identification of microcalcifications. Furthermore, it reduces the number of inadequate samples and does not require cytopathology expertise. In order to obtain maximum information from the procedure, the pathologist should be provided with complete a clinical history, including radiographic signs and the site of the biopsies. In cases with microcalcifications, the core biopsy specimens should be x-rayed and the cores with calcifications submitted separately from those without, in the event additional levels are needed.[328] The use of site-marking devices at the time of the core biopsy is helpful for the radiologist, to guide placement of a localization wire should an excision be required, and in determining whether the subsequent surgical specimen includes the radiographically abnormal area.

Per American Society of Clinical Oncology (ASCO)/ College of American Pathologists (CAP) published guidelines, breast specimens should be fixed for a minimum of 6 hours and a maximum of 72 hours to permit accurate biomarker testing, should that be required[329]; a minimum of three levels should be obtained initially on all core needle biopsy specimens, with additional levels and immunostains performed when necessary.[330] A definitive diagnosis on the basis of a core biopsy and triage for patient management is possible in the majority of cases.[331] However, there are some diagnoses that are not malignant that have warranted surgical excision because of the frequency with which a worse lesion has been found upon excision of the area of concern (i.e., the "upgrade" or "underestimation" rate). Unfortunately, many of these recommendations for excision were based on data from small studies, often with radiologic-pathologic discordance and selection bias with regard to which patients underwent excision. Newer studies have taken care to address the imaging findings, ensure radiologic-pathologic correlation, and provide data on upgrade rates for incidental cases of atypia.[216] The following is a standard management algorithm:

1. All cases showing DCIS or invasive carcinoma should undergo excision.
2. Cases showing ADH or atypical ductal proliferations with features bordering on DCIS should undergo excision.[216]
3. The management of LCIS and ALH is evolving. In the past, most authors recommended surgical excision,[332,333] but more recent studies, in which there is good radiologic-pathologic correlation and the lobular neoplasia is determined to be incidental to the targeted lesion, are recommending observation over excision (if the targeted lesion is benign and does not itself require excision), with the exception of cases of nonclassical or pleomorphic LCIS.[334,335]
4. Columnar cell lesions without atypia (i.e., columnar cell change and columnar cell hyperplasia) do not require excision. The management of FEA identified on core needle biopsy remains controversial. The WHO recommendation is for radiologic-pathologic correlation with consideration of excision in patients in whom there are residual calcifications on a post-biopsy mammogram or for whom there is radiologic-pathologic discordance.[112]
5. In most cases, papillomas can be distinguished from papillary carcinomas on core needle biopsies.[336] A diagnosis of papillary carcinoma or papilloma with atypia warrants excisional biopsy, whereas a diagnosis of papilloma may be managed with clinical follow-up if imaging findings are concordant, though many centers still excise radiologically targeted papillomas.[216]
6. The presence of stromal pools of mucin associated with mucocele-like lesion had been an indication for surgical excision because of the concern for undersampled mucinous carcinoma, but in patients in whom there is no atypia and no imaging findings of concern, observation may be acceptable.[216]

Complications of the core needle biopsy procedure include hemorrhage, reactive spindle cell nodules, and epidermal inclusion cysts.[337,338] A different type of complication, also seen in connection with the FNA procedure but more likely with the core biopsy technique, is the mechanical displacement of epithelial cells into the stroma or even inside vessel lumina (see Fig. 36.54).[339,340] This phenomenon is more common with both benign and malignant papillary lesions, presumably because of their greater friability.[341] It is doubtful whether this finding is of any clinical significance. The greater importance lies in recognition of this phenomenon as a procedural artifact and not as a focus of invasive carcinoma for which it may be mistaken. The displaced epithelial cells may appear as small nests or single cells with atypical, "squamoid," or degenerated features. Identification of

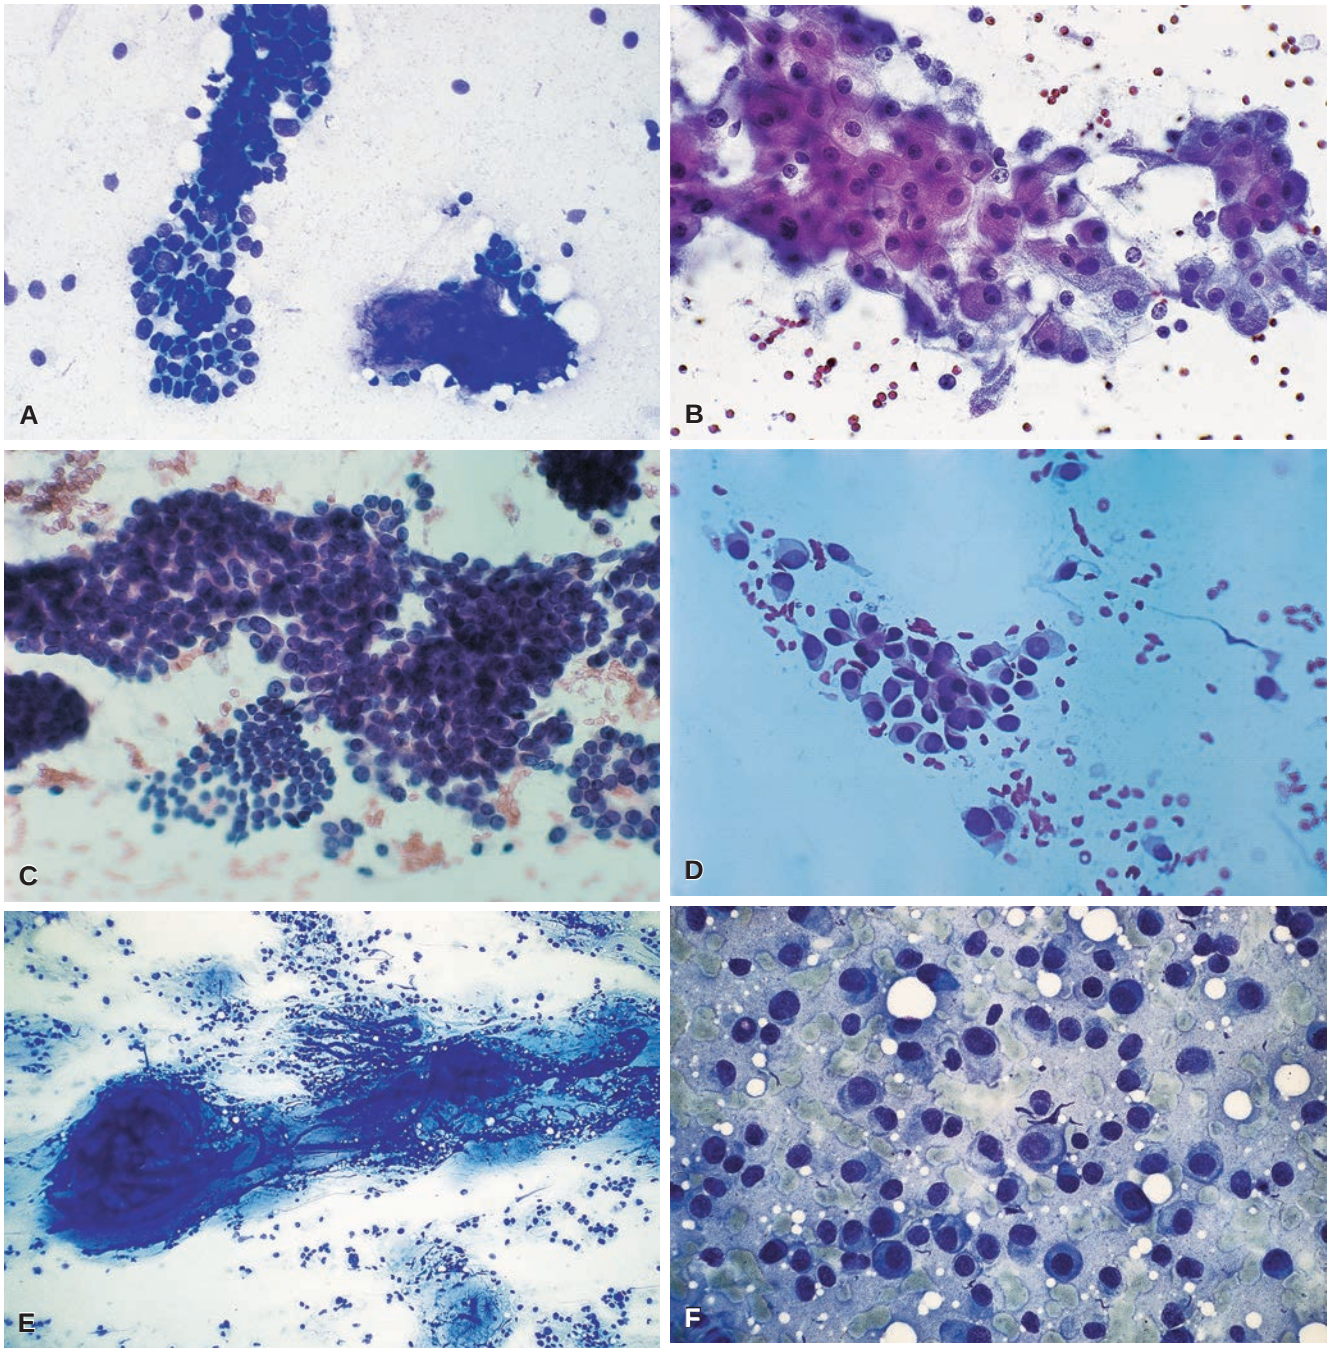

Figure 36.70 Cytologic features of various types of breast lesion as seen in FNA specimens: **(A)** fibroadenoma; **(B)** apocrine metaplasia; **(C** and **D)** invasive ductal carcinoma; **(E)** mucinous carcinoma; **(F)** invasive lobular carcinoma.

biopsy site changes such as granulation tissue and hemosiderin-laden macrophages will help prevent an erroneous diagnosis. Note that myoepithelial cells are often absent, as such IHC is not helpful.

Frozen Section

Intraoperative evaluation by frozen section has limited applicability in current practice. Some centers perform intraoperative evaluation of the specimen margins with a view to immediate reexcision of involved margins. These can be technically challenging specimens to freeze because they are often composed entirely of adipose tissue, and they can be challenging to interpret, resulting in well-documented false-positive and false-negative rates.[342]

A few centers still perform intraoperative frozen section evaluation of sentinel lymph nodes. The need for this is largely obsolete[343] given the results of the American College of Surgeons Oncology Group (ACSOG) Z0011 randomized clinical trial demonstrating an absence of clinical benefit for completion axillary dissection even in patients with 1–3 positive sentinel lymph nodes.[344] On occasion, request is made for frozen section in the setting of mastectomy, where completion dissection may be performed if the sentinel lymph node is positive.

Histologic Types

Two key determinations to make in the morphologic study of breast carcinoma are: (1) whether the tumor is confined to the ductolobular system (carcinoma in situ) or has invaded the stroma (invasive carcinoma), and (2) whether it is of ductal or lobular type. The first criterion, the prognostic significance of which far outweighs that of the second, is self-explanatory, but it may be appropriate to elaborate on the second. The term "ductal carcinoma" may be taken to imply that the tumor is either arising from or involving a duct, and an analogous assumption could be made about lobular carcinoma in relation to the lobule. The evidence obtained from the classic study of Wellings et al.[21] and several others indicates instead that both tumor types (and, for that matter, most benign proliferative breast diseases) arise from the same segment of the mammary gland, that is, the TDLU. As far as location is concerned, it is certainly true that many ductal carcinomas in situ preferentially involve structures with the appearance of ducts and that most lobular carcinomas in situ preferentially involve lobules. However, numerous exceptions in both directions exist. It has been hypothesized that these cases represent—respectively—ductal carcinomas in situ with secondary extension into lobules ("lobular cancerization"—an obsolete term), or lobular carcinomas in situ with secondary extension into ducts.[345] Be that as it may, it should be made clear that it is the type of tumor as defined by cytoarchitectural features that establishes its placement into one of these two diagnostic categories rather than its precise location within the breast. Therefore, it may be more accurate and less confusing to refer to these tumors as *ductal type* and *lobular type*, respectively. For the sake of brevity and tradition however, the conventional nomenclature of ductal and lobular will be used in this chapter.

Carcinoma In Situ

Ductal Carcinoma In Situ

DCIS is defined by the presence of neoplastic epithelial cells confined to the ductolobular system. Many architectural variants of DCIS exist, such as papillary, solid, cribriform, and micropapillary; in addition, there is nuclear variability ranging from low- to high-grade types. DCIS is believed to originate in the TDLU (although often extending into larger ducts) and had been historically divided into high-grade comedocarcinoma (characterized by large pleomorphic cells associated with necrosis) and a low-grade solid/cribriform/micropapillary group (composed of smaller uniform cells unassociated with necrosis). Contemporary classification schemes divide DCIS into a three-grade system largely on the basis of *nuclear pleomorphism* with or without the inclusion of *comedo necrosis*. These criteria apply irrespective of the architectural pattern. They may also apply independently of the presence or absence of necrosis, depending on the classification scheme employed.[346–348] Unfortunately, there is still no international consensus on a classification scheme for DCIS, but if nuclear grade, the presence or absence of comedo necrosis, architectural pattern, and some estimate of size is reported, any of the myriad classification schemes can be used to categorize a given DCIS lesion.[349,350]

Nowadays, the vast majority of DCIS is detected through screening mammography as clustered microcalcifications. Linear, branching calcifications raise the most concern for DCIS, but other patterns exist and are indeterminate with regard to the degree of certainty with which they can be distinguished from benign lesions associated with microcalcifications on radiologic studies. When sufficient concern exists, a core needle biopsy is performed to allow for pathologic diagnosis.

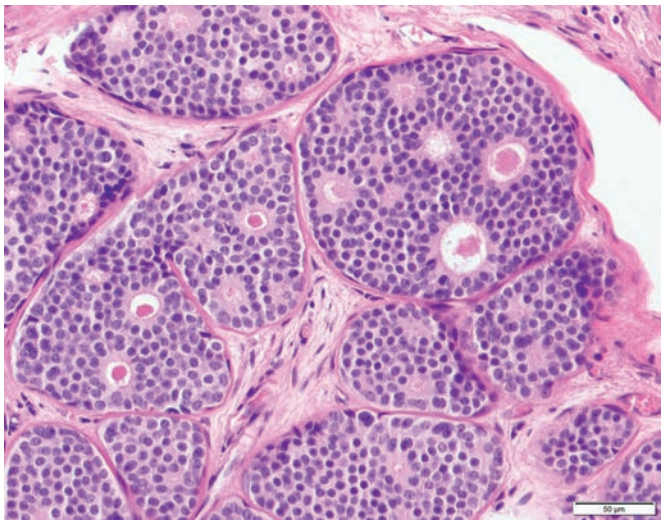

Figure 36.71 Ductal carcinoma in situ, low nuclear grade, cribriform pattern.

A small minority of DCIS lesions present as a palpable mass or with nipple discharge. It has been shown that DCIS occurring in younger women is more often symptomatic, more extensive, and more often accompanied by involvement of lobules than DCIS in older women.[351]

Low Nuclear Grade Ductal Carcinoma In Situ

Low nuclear grade DCIS is characterized by a neoplastic proliferation of monomorphic epithelial cells growing in solid, cribriform, papillary, or micropapillary patterns (Fig. 36.71). Microacini and/or areas of cellular polarization may be apparent in the solid pattern; a feature that aids in the distinction from LCIS. The cells have round, regular nuclei with even chromatin and inconspicuous nucleoli. Mitoses are rare. Punctate or even comedo necrosis may be seen but is unusual. Microcalcifications are often present.

Intermediate Nuclear Grade Ductal Carcinoma In Situ

Intermediate nuclear grade DCIS is characterized by cells with slightly more nuclear variability than low nuclear grade DCIS. The cells are larger and less evenly spaced within the involved TDLU. Polarization is still observed, though is less pronounced (Fig. 36.72). Calcification, mitoses, and necrosis may be present.

High Nuclear Grade Ductal Carcinoma In Situ

High nuclear grade DCIS is characterized by a neoplastic proliferation of highly atypical epithelial cells with large pleomorphic nuclei, coarse clumped chromatin, and prominent nucleoli. The proliferation may be solid, cribriform, or micropapillary in architectural pattern, but the cells are poorly organized and polarization is not usually evident (Fig. 36.73). Mitoses are abundant, and necrosis is a common, though not a required, feature. Comedo necrosis is said to be present when approximately half of the involved space has abundant necrotic material and is surrounded by DCIS cells. A less common pattern of high nuclear grade DCIS is the clinging pattern, in which a single layer of highly atypical cells lines the involved space (see later).

DCIS is not usually detectable on gross examination, with the possible exception of large areas of high-grade DCIS with comedo necrosis that induce a desmoplastic stroma. In this scenario, a mass may be palpable and on cut surface clusters of thick-walled ducts may be seen. When these ducts are compressed, plugs of necrotic

Figure 36.72 Ductal carcinoma in situ, intermediate nuclear grade, cribriform pattern with necrosis. There is greater nuclear variability compared with that seen in low-grade DCIS.

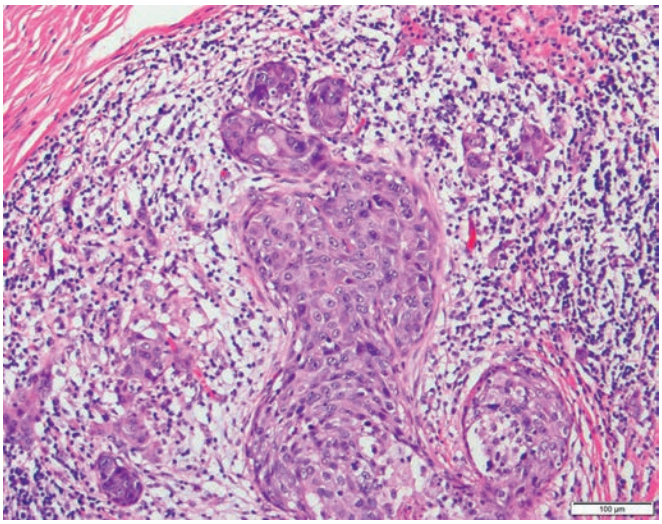

Figure 36.74 Microinvasive carcinoma associated with high-grade ductal carcinoma in situ. Notice the clusters and single highly atypical epithelial cells present in the stroma surrounding the high-grade DCIS. A dense lymphocytic infiltrate is often present.

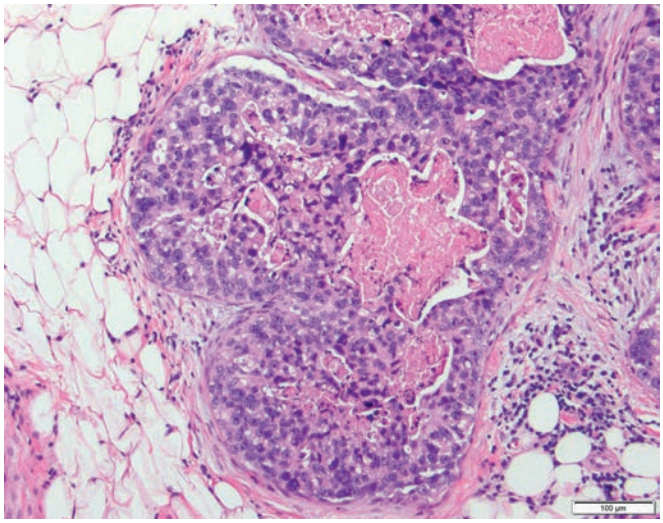

Figure 36.73 Ductal carcinoma in situ, high nuclear grade, solid pattern with necrosis.

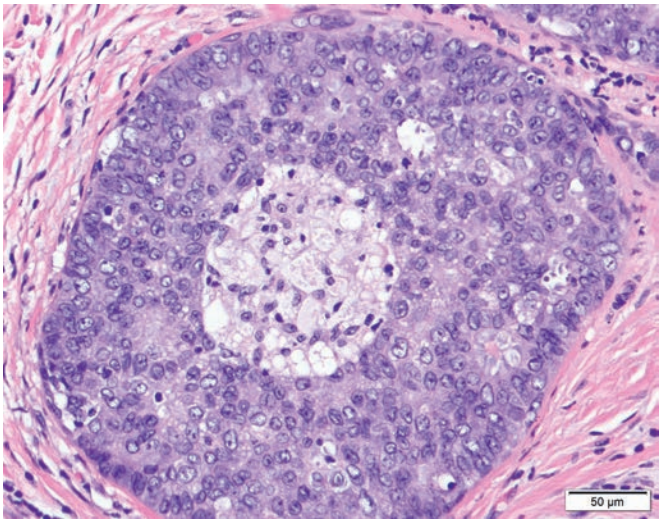

Figure 36.75 Ductal Carcinoma In Situ, Intermediate Nuclear Grade. Note how even in the absence of well-formed cribriform spaces, the cells are arranged in rosettes or microacinar structures.

tumor extrude from them, reminiscent of comedones, hence the historic appellation "comedocarcinoma."

Once the diagnosis of DCIS has been established, two additional important determinations need to be made. The first is the extent of the lesion, which in some cases may be very extensive and even reach the nipple, resulting in Paget disease. The other is to search for areas of definite stromal invasion and, if these are present, to report the size of the largest focus of invasion. Even if no definite invasion is detected in the sections examined, the possibility always exists, especially with extensive high nuclear grade DCIS, that a minute focus of invasion is present somewhere in the specimen (Fig. 36.74).[352] This accounts for the observation that up to 15% of patients have tumor cells present in the axillary lymph nodes (especially with cytokeratin immunohistochemical examination) in the absence of an identifiable invasive component in the breast.[353–355]

Architectural Patterns of Ductal Carcinoma In Situ

In the *solid* form of DCIS, the acini of the TDLU are filled by a proliferation of medium-sized cells, which are larger than those of LCIS, often with low-grade monomorphic nuclei, though any nuclear grade may be seen. Azzopardi[22] pointed out the sharp cell edges (as opposed to a "syncytial" quality) and the pallor of the cytoplasm (as opposed to prominent eosinophilia) often exhibited by these cells compared with the cells of UDH. Even in the absence of true lumen formation, the cells in solid pattern DCIS attempt to polarize, creating a rosette or microacinar pattern within the solid proliferation (Fig. 36.75). It is this feature that is most helpful in distinguishing low nuclear grade, solid pattern DCIS from LCIS.

In the *cribriform* pattern, round regular spaces are formed within the involved acini of the TDLU (see Figs. 36.71 and 36.72); in DCIS

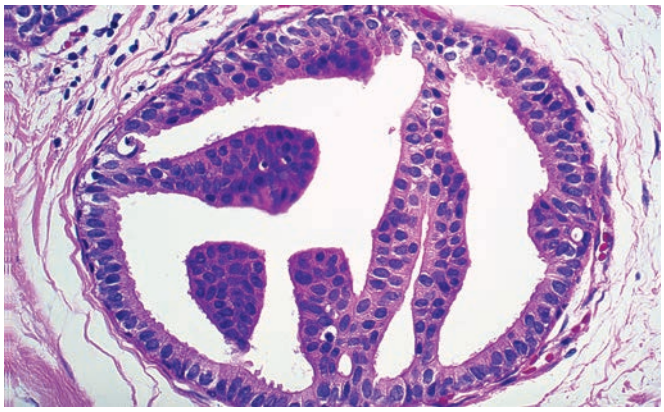

Figure 36.76 Trabecular Bars in Atypical Ductal Hyperplasia. Note the perpendicular arrangement of the nuclei in relation to the long axis of the bars.

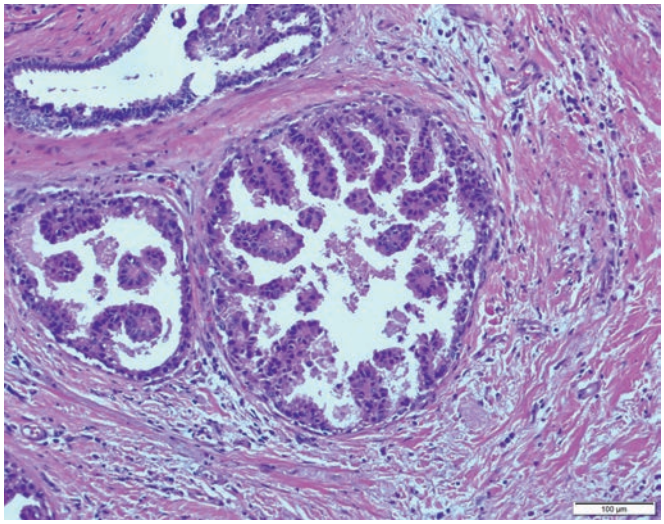

Figure 36.77 Ductal carcinoma in situ, micropapillary pattern.

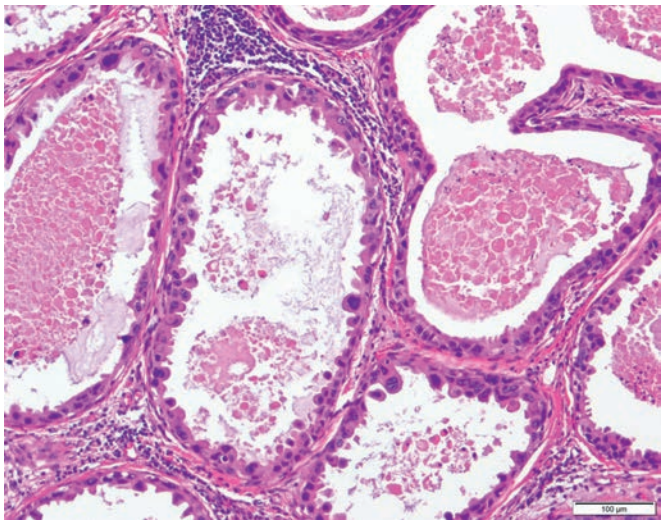

Figure 36.78 Ductal Carcinoma In Situ, Clinging Pattern. One or two layers of highly atypical cells line dilated glandular structures containing necrosis.

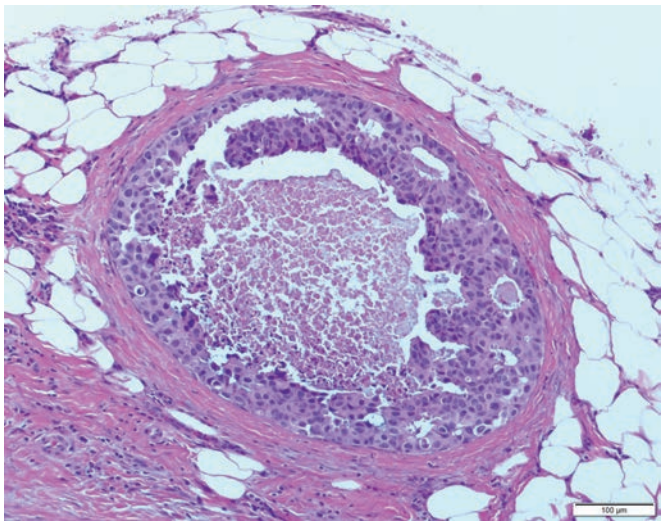

Figure 36.79 Ductal carcinoma in situ, with comedo necrosis.

the spaces are more regular in terms of distribution, size, and shape, as opposed to UDH in which the spaces are irregular and slit-like (see Figs. 36.36 and 36.37). Cribriform DCIS is often seen in association with two formations of similar pathogenesis, designated by Azzopardi[22] as trabecular bars and Roman bridges, respectively. Trabecular bars are rigid rows of cells with their long axes arranged more or less perpendicular (or at least not parallel) to the long axis of the bar, features that are more readily appreciated in examples of ADH (Fig. 36.76). Roman bridges are curvilinear trabecular bars connecting two portions of the epithelial lining. Collagenous spherulosis and adenoid cystic carcinoma can be mimics for the cribriform pattern of DCIS.

The *micropapillary* pattern shows epithelial micropapillations projecting into the ductular lumen; these lack connective tissue support and often show a bulbous expansion at the tip (Fig. 36.77). This variant is more likely than others to involve multiple quadrants of the breast.[356]

Papillary DCIS is another architectural pattern characterized by papillary projections with fibrovascular cores (see previous discussion).

Clinging pattern DCIS shows one or two layers of neoplastic epithelial cells lining a space often with an empty lumen, though necrosis may be seen.[22,357] The lining cells are large, highly atypical, and associated with apoptosis (Fig. 36.78). In the United States the term clinging carcinoma is restricted to the aforementioned high nuclear grade lesion. In Europe, reference is made to a pattern of DCIS referred to as clinging carcinoma of the monomorphic type,[22] but this lesion is now classified as FEA.

Comedo DCIS really refers to a pattern of necrosis, rather than an architectural pattern of DCIS, in which the involved space is lined by several layers of neoplastic epithelial cells with approximately half the space involved by necrosis (Fig. 36.79).

There are occasions when the acini or lobules involved by DCIS remain small, a phenomenon formerly known as lobular cancerization; nowadays the term "lobular involvement" or "involvement of lobules" by DCIS is preferred. (Fig. 36.80). Available evidence suggests that this phenomenon represents instead a variation in the growth pattern of DCIS in which the structure involved is still easily recognizable as belonging to a lobule.[345]

Rare additional morphologic variations of DCIS include cases with *signet ring cells* (see Fig. 36.62),[358] with *apocrine cytology* (Fig. 36.81),[359] with *squamous features,*[360] and with evidence of *(neuro)*

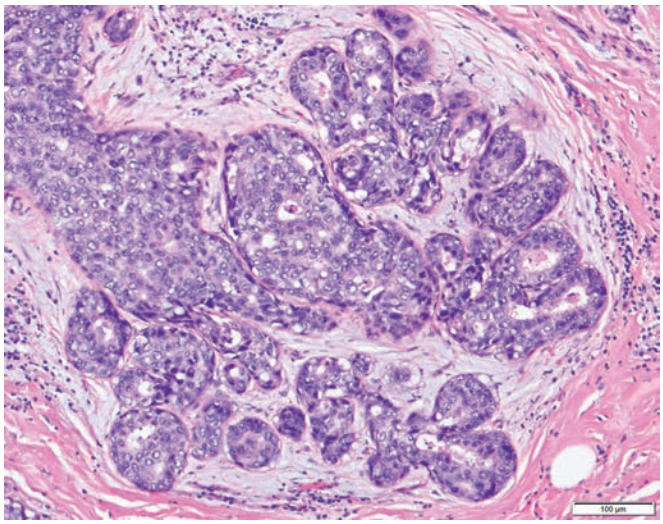

Figure 36.80 Ductal Carcinoma In Situ Involving Lobules. The terminal duct lobular unit is markedly expanded and composed of relatively large DCIS cells.

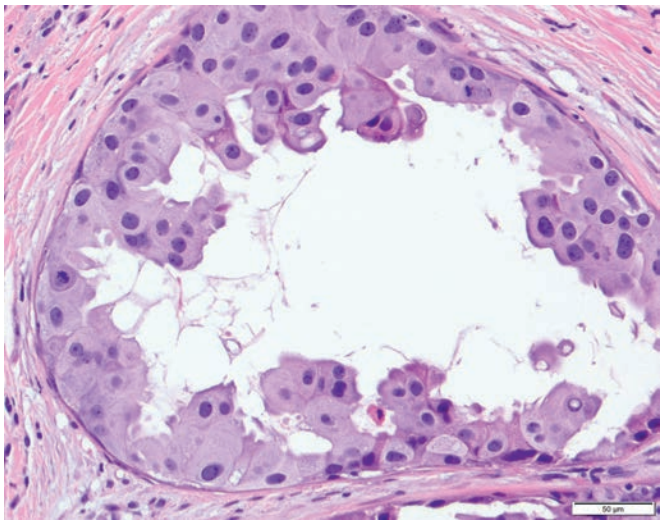

Figure 36.81 Ductal carcinoma in situ with apocrine features.

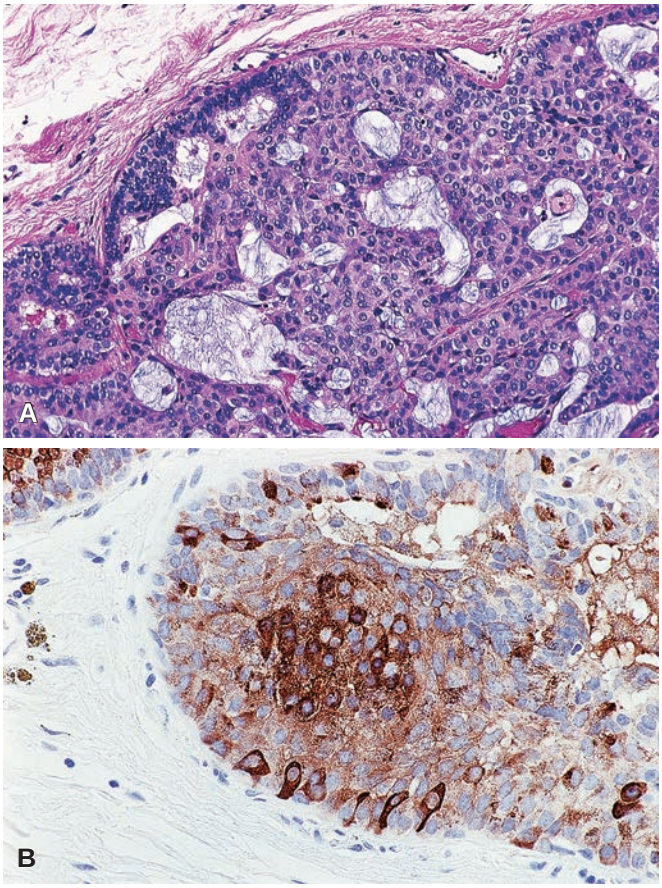

Figure 36.82 Ductal Carcinoma In Situ With Endocrine Features. A, Hematoxylin–eosin stain. **B,** Chromogranin immunostain.

endocrine differentiation (Fig. 36.82).[361] The latter tumor, known as *(neuro)endocrine DCIS (E-DCIS)*, is often seen in association with solid papillary carcinoma.[362] Sometimes these tumors are accompanied by an invasive component, which is also of neuroendocrine type. This tumor is probably closely related to the lesion that has been described as *spindle cell DCIS*.[363]

The two major differential diagnostic considerations of DCIS are LCIS (with low nuclear grade DCIS) and UDH (with intermediate nuclear grade DCIS), both of which can be separated on morphologic grounds supplemented by immunohistochemistry where needed.

Solid pattern, low nuclear grade DCIS is composed of cells that are cohesive and attempt to polarize (microacinar or rosette formation). In contrast, LCIS cells are dyshesive, often have intracytoplasmic vacuoles, and lack polarization. Immunostains for E-cadherin, β-catenin, and p120 catenin will show a strong membranous pattern of staining in DCIS. In general, LCIS cells have an absence of staining with E-cadherin and β-catenin and show a cytoplasmic pattern of staining with p120 catenin (but see discussion under LCIS for aberrant expression patterns).

Intermediate nuclear grade DCIS can be separated from UDH by recognizing the monotony of the atypical cells, even if showing a streaming pattern mimicking UDH. Some areas of polarization may be apparent even in intermediate nuclear grade DCIS. The cells of UDH are more variable in size, shape, and quality of chromatin. Immunohistochemically, DCIS will show an absence of staining with CK5/6 and strong, diffuse staining with ER, whereas UDH will have a heterogeneous pattern of expression with both markers.

Molecular genetic analyses in DCIS and ADH indicate that there is a low-grade pathway of neoplasia in which loss of 16q is identified in lesions as early in the progression pathway as FEA. These same genetic aberrations are present in ADH and low-grade DCIS, as well as in the lobular neoplasia pathway, suggesting that lobular lesions and low-grade ductal lesions are closely related.[118] High-grade DCIS has a different and greater set of molecular genetic alterations, which includes 17q loss, compared with low-grade lesions.[364] Needless to say intermediate-grade lesions are heterogeneous with regard to their molecular genetic alterations.[365]

Evolution

The implication of the diagnosis of DCIS is that, if left untreated, the lesion may progress to an invasive carcinoma of similar morphologic features. Evidence that DCIS is a nonobligate precursor lesion is as follows:

1. The transformation to an invasive phenotype does not occur in all cases, at least during the normal life span of an individual.[366]
2. When such a transformation occurs, the process usually evolves over a period of years if not decades.[366]

3. There is a substantial difference in the frequency with which this phenomenon occurs depending on the type of DCIS, with more rapid progression occurring in high nuclear grade DCIS and a more protracted course with low and intermediate nuclear grade DCIS.[367–370]
4. There is a relationship between the grade (and to some extent, microscopic type) of DCIS and the concurrent invasive component; however, numerous exceptions occur.[371]
5. The molecular alterations present in DCIS are more similar to invasive carcinomas of the same grade than they are to DCIS of a differing grade (e.g., low nuclear grade DCIS has a gene expression pattern more similar to low-grade invasive carcinoma than it does to high nuclear grade DCIS and vice versa).[372]

Not all invasive breast carcinomas go through the sequence just described; some have a very short intraductal stage and become invasive before being detectable by any imaging modality. It is this very fact that takes some of the value away from screening techniques such as mammography, which are much more likely to detect slow-growing carcinomas with a prolonged in situ stage. The goal of treatment is complete eradication of DCIS, through local (breast-conserving) surgery with or without irradiation, followed by anti-estrogen therapy in those with ER-positive DCIS.[373,374] There are some patients for whom mastectomy is indicated because of the extent of DCIS.

Lobular Carcinoma In Situ

LCIS has no distinguishing features on gross examination and is usually found incidentally in breast biopsies or excisions performed for other reasons. On occasion the term "lobular neoplasia" is used, particularly when referring to both ALH and LCIS. LCIS is multicentric in 60%–80% of cases and bilateral in approximately 30%–40%.[375]

Microscopically, the lobules are distended and completely filled by relatively uniform, round, small-to-medium-sized neoplastic epithelial cells with round and normochromatic or only mildly hyperchromatic nuclei.[376] In the typical case, there is a lack of cohesiveness among the tumor cells; intracytoplasmic vacuoles may be seen; and pleomorphism, mitotic activity, and necrosis are minimal or absent (Figs. 36.83 and 36.84).[375] LCIS cells may form a continuous row beneath the ductal epithelium, a pattern referred to as *pagetoid* (Fig. 36.85). Any of the following minor morphologic variations can occur, singly or in combination: moderate nuclear pleomorphism, larger nuclear size, appreciable mitotic activity, scattered signet ring cells (relatively common), apocrine changes (exceptional), and focal necrosis.[377] When the tumor cells are of medium-to-large size, with more marked nuclear pleomorphism, often prominent nucleoli, and moderate-to-abundant cytoplasm, the lesion is referred to as *pleomorphic LCIS* (Fig. 36.86).[378] Another variant form of LCIS is *florid LCIS with comedo necrosis* (Fig. 36.87), in which the involved TDLU is greatly expanded by a proliferation of LCIS cells, usually with classical cytologic features but accompanied by comedo necrosis and calcifications.[379]

LCIS can also involve fibroepithelial lesions (Fig. 36.88), sclerosing adenosis (see Fig. 36.40), a pattern that can be a mimic for invasive lobular carcinoma, or collagenous spherulosis (Fig. 36.89 and see Fig. 36.18), a pattern that can be a mimic for cribriform DCIS. The diagnosis of LCIS should be made only in those cases in which the cellular proliferation has resulted in the formation of solid nests that have expanded the lobules by greater than 50%, whereas the designation of ALH is to be given to those lesions in which the expansion of the lobules is of a lesser degree. LCIS also needs to be distinguished from solid pattern DCIS.

The cells are large with abundant eosinophilic cytoplasm and have pleomorphic nuclei with prominent nucleoli. **B,** E-cadherin immunostain. There is absence of staining in the LCIS cells. Myoepithelial cells and adjacent normal ductal epithelium show a membranous staining pattern. **C,** p120 catenin immunostain. There is cytoplasmic staining in the LCIS cells. Myoepithelial cells and adjacent normal ductal epithelium show a membranous staining pattern. **D,** β-Catenin immunostain. Like E-cadherin, there is absence of staining in the LCIS cells with myoepithelial cells and adjacent normal ductal epithelium showing a membranous staining pattern.

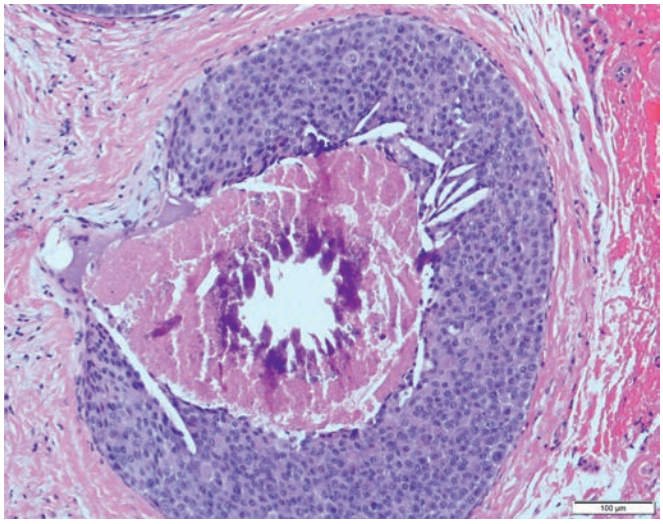

Figure 36.87 **Lobular Carcinoma In Situ With Comedo Necrosis.** The space is expanded by a monotonous proliferation of dyshesive epithelial cells (most pronounced in the lower right of the field); there is an absence of polarization of the cells. Comedo necrosis and calcifications are present in the center of the space.

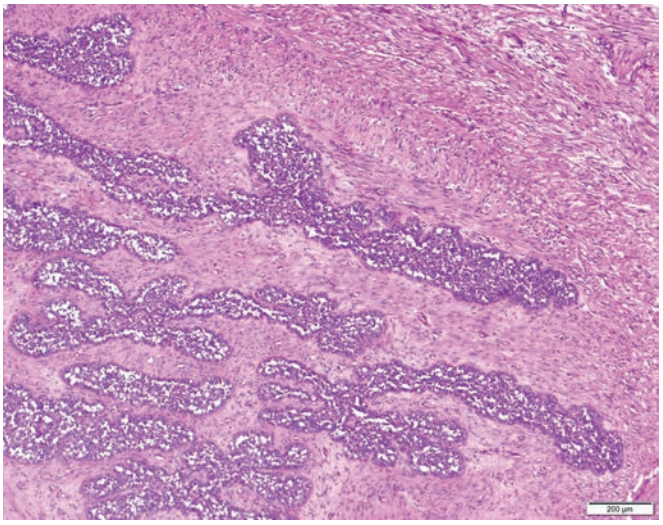

Figure 36.88 **Lobular Carcinoma In Situ Involving a Benign Phyllodes Tumor.** The ducts are expanded by a monotonous proliferation of dyshesive LCIS cells.

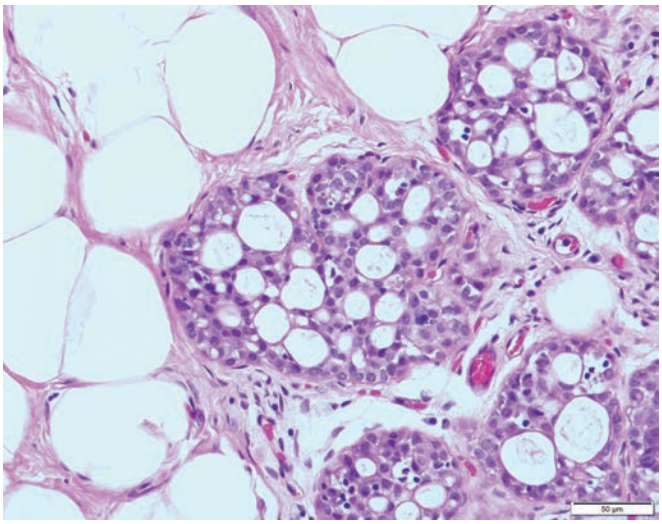

Figure 36.89 Lobular Carcinoma In Situ Involving Collagenous Spherulosis. The cribriform pattern conferred by this process can be a mimic for ductal carcinoma in situ.

From the point of view of the differential diagnosis with DCIS, morphologic features favoring a diagnosis of LCIS are cellular dyshesion, the presence of intracytoplasmic vacuoles, and an absence of polarization around the periphery of the involved space or of any attempt at microacinar formation; pagetoid involvement of ducts is also more characteristic of LCIS. Important immunohistochemical features of LCIS are an absence of expression with E-cadherin (see Fig. 36.86B and D) and β-catenin, and cytoplasmic positivity for p120 catenin (see Fig. 36.86C). By contrast, DCIS is consistently positive for all three markers, with a membranous pattern of expression.[380,381] As might be expected, some cases of LCIS show hybrid immunohistochemical features, manifested as aberrant, weak expression with E-cadherin; helpfully, p120 catenin tends to maintain the characteristic cytoplasmic staining pattern in lesions with a lobular phenotype.[381] The molecular correlate for loss of E-cadherin expression in LCIS is alteration of the *CDH1* gene; it is speculated that aberrant expression may be a function of the type of inactivation present.[382–384]

Evolution

One of the most controversial aspects of breast pathology is the nature of LCIS, specifically in regard to the probability of development of invasive carcinoma following a biopsy diagnosis of LCIS without additional therapy. Although the figures obtained in the various reported series[385–389] are not exactly superimposable, it is reasonable to conclude from them that: (1) approximately 20%–30% of patients will develop invasive carcinoma, a risk about 8–10 times higher than for a control population; (2) the risk seems greater in well-developed LCIS than in ALH; (3) the risk is about the same regardless of the amount of LCIS; (4) this increased risk applies to both breasts, although it is slightly greater on the side of the biopsy; (5) the invasive carcinoma may be of either lobular or ductal type, though there is a preponderance of invasive lobular carcinoma; and (6) if a patient with a biopsy diagnosis of LCIS is examined periodically, the chances of death from breast carcinoma are minimal. There are very limited data on the subsequent breast cancer risk associated with the nonclassical or variant forms of LCIS.

Most investigators agree that careful lifelong follow-up appears to be a safe and rational option for patients with LCIS.[387,390,391] Greater risk reduction is achieved with ER blockade with selective ER modulators (SERMs; such as with tamoxifen) or an aromatase inhibitor (e.g., anastrozole).[392,393] While an uncommon strategy today, the performance of simple mastectomy may be considered in the presence of a strong family history of carcinoma or if prolonged follow-up evaluation cannot be ensured, though given the bilateral nature of the risk conferred by LCIS, bilateral mastectomy would be the more appropriate surgical management.

Invasive Carcinoma

Tumors included in this category are all those in which stromal invasion is detectable, whether an in situ component is identifiable or not, and regardless of the relative proportion of the two components; in other words, it also includes "microinvasive carcinoma." Like in situ lesions, most invasive tumors can be divided into two major categories—ductal type and lobular type—acknowledging the existence of mixed forms. It should be mentioned that the type of invasive carcinoma ought to be determined from its own appearance, rather than deduced from the type of in situ component present, if any, since the two do not always correspond.

The classification of invasive breast carcinoma has evolved over a long period of time and, as a result, has had incorporated into it a wide range of criteria, such as cell type (as in apocrine carcinoma), type and amount of secretion (as in mucinous carcinoma), architectural features (as in papillary carcinoma), and pattern of spread (as in inflammatory carcinoma, which strictly speaking is a clinical and not a pathologic definition).

Microinvasive Breast Carcinoma

Once the concept of "microinvasive carcinoma" was entrenched in the gynecologic literature, it was only natural that it would be proposed at other sites, including the breast. Alas, its application at this site was not as straightforward, one of the reasons being that the mammary epithelium is not separated from the stroma by a sharp, straight line as it is in the cervix.[394] Be that as it may, microinvasive carcinoma is defined as any breast carcinoma showing stromal invasion not exceeding 1 mm in extent.[395] The term is applicable to both ductal and lobular lesions, but the former is more frequent. There may be a single focus of microinvasion or multifocal microinvasion may be identified. The mean number of foci reported is two.[396] Features of DCIS associated with microinvasion include greater extent, high nuclear grade, solid pattern, comedo necrosis, and periductal lymphoid infiltrates (see Fig. 36.74).[393] Note though that microinvasion may be seen with other grades and patterns of DCIS and with LCIS. Immunohistochemical evaluation with myoepithelial cell markers, in combination with cytokeratin if possible to highlight the microinvasive epithelial component, may be needed to confirm the diagnosis.[395,397] Patients with microinvasive carcinoma are at risk for nodal metastases,[398] but their survival rate is better than for patients with T1 invasive carcinoma[399] and the extent of microinvasive carcinoma does not appear to be correlated with likelihood of lymph node metastases.[400,401]

Invasive Ductal Carcinoma

This lesion represents the prototypic expression of breast carcinoma and is the tumor type usually implied when the terms "breast carcinoma" or "breast cancer" are used without further qualification. The size, shape, and tumor border are highly variable. Grossly, the typical case is firm and poorly circumscribed, cuts with a resistant gritty sensation, and shows a yellowish–gray cut surface, with trabeculae radiating through the surrounding parenchyma into the fat, resulting in the notorious stellate or crab-like configuration, from which the word "cancer" originated (Fig. 36.90). Areas of necrosis,

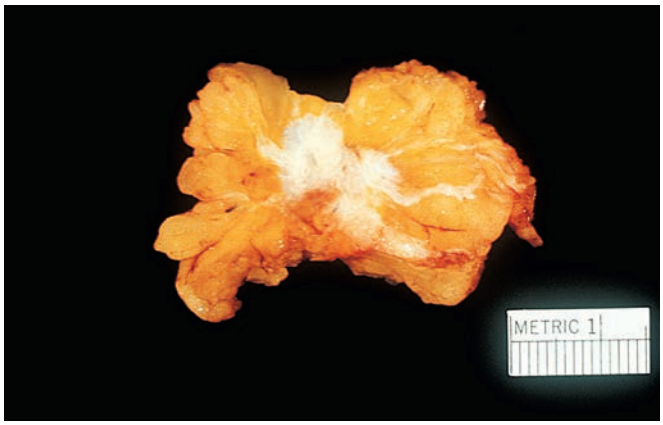

Figure 36.90 Typical Gross Appearance of Invasive Ductal Carcinoma. Note the irregular (crab-like) shape of the tumor, white fibrous appearance, and chalky streaks.

hemorrhage, and cystic degeneration are unusual but may be present, particularly in larger neoplasms. The tumor may invade the overlying skin or the underlying fascia and pectoralis muscle. Tumors that are particularly hard because of the large amounts of desmoplastic stroma were traditionally referred to as "scirrhous carcinomas." It is common for these neoplasms to exhibit "chalky streaks" on the cut surface, a feature caused by duct elastosis.[402] When this occurs, the appearance of the lesion has an uncanny resemblance to an unripe pear, further accentuated by the consistency felt while cutting it.

Microscopically, the variations are also legion. The tumor can grow in diffuse sheets, well-defined nests, cords, or as individual cells. Glandular/tubular differentiation may be well developed (Fig. 36.91), barely detectable, or altogether absent. The tumor cells vary in size and shape, the nuclei are large with varying degrees of pleomorphism, and nucleoli may be prominent. Mitotic figures vary from infrequent to more numerous. Areas of necrosis are unusual but may be identified in some cases. The amount of stroma ranges from none to abundant, and its appearance from densely fibrotic to cellular ("desmoplastic"). In cases with abundant stroma, it may be difficult to identify the tumor cells. Areas of "elastosis" may be present, which can involve the wall of the ducts and the vessels (mainly veins).[402] Calcification has been reported in approximately 60% of cases, either as coarse or fine deposits or, rarely, as psammoma bodies; most often the calcifications are identified within the associated in situ component.[315,403] A mononuclear inflammatory infiltrate of variable intensity may be present at the interface between tumor and stroma. Granulomatous inflammation is rarely seen.

Definite invasion of the perineural spaces, lymphatic vessels, and blood vessels was reported by Fisher et al.[403] in 28%, 33%, and 5% of cases, respectively. Lymphatic vessel invasion may be difficult to distinguish from artifactual tissue retraction. Features used to document the presence of lymphatic tumor emboli are the following: (1) the occurrence of the area in question outside the margin of the carcinoma, (2) the fact that the tumor emboli do not conform exactly to the space in which they lie, (3) the presence of an endothelial cell lining, and (4) the presence of blood vessels in the immediate vicinity.[404] If doubts persist, a stain with D2-40 or other endothelial cell markers might prove helpful (Fig. 36.92). Note that D2-40 crossreacts with myoepithelial cells;[405] thus it is prudent to include a myoepithelial cell marker in the panel also. These reactions can be carried out in the H&E-stained preparations after removing the coverslip and decolorizing the slide, if necessary.[406]

The term "extensive intraductal carcinoma" (EIC) applies to tumors in which the intraductal component comprises 25% or more of the

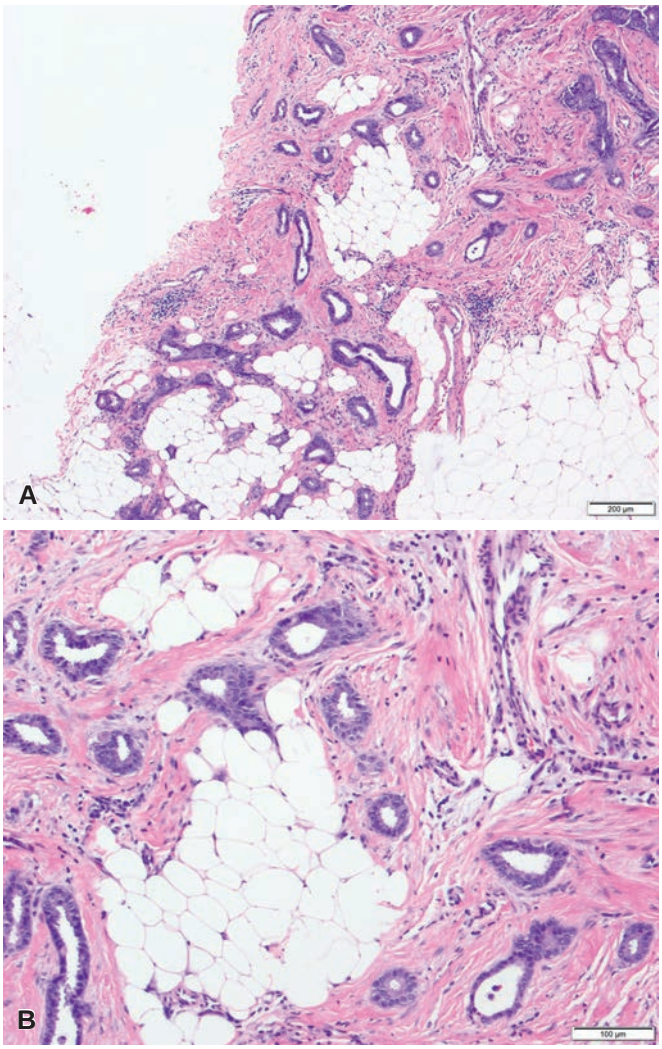

Figure 36.91 Prototypical Invasive Ductal Carcinoma. A, Irregularly shaped glands infiltrate through the stroma in a haphazard pattern. **B,** There is cytologic atypia present and myoepithelials cell are absent.

area encompassed by the infiltrating tumor and is also present in the surrounding breast tissue.[407] The identification of EIC was of importance in predicting the likelihood of residual carcinoma in women undergoing reexcision; however, in contemporary practice, where greater attention is given to margin evaluation, this pathologic feature has become less critical.

Immunohistochemically, breast carcinoma cells show reactivity for low-molecular-weight cytokeratins (particularly types 8, 18, and 19) and EMA.[408] Some tumors (particularly high-grade tumors with a solid growth pattern and those with foci of squamous metaplasia) are also immunoreactive for HMW cytokeratin (CK5/6).[409] Three useful breast-related markers are mammaglobin, GCDFP-15, and GATA3. Each has varying degrees of sensitivity and specificity that can be improved by using them in combination where determination of breast origin is needed.[410–412]

Breast carcinomas can be immunoreactive for S-100 protein, the proportion ranging from 10% to 45% in the various reported series.[413,414] This is a fact to remember in the differential diagnosis of metastatic tumors to axillary nodes, lest a breast carcinoma be mislabeled as metastatic melanoma. Even more treacherous is the fact that some breast carcinomas may show positivity for HMB-45.[415]

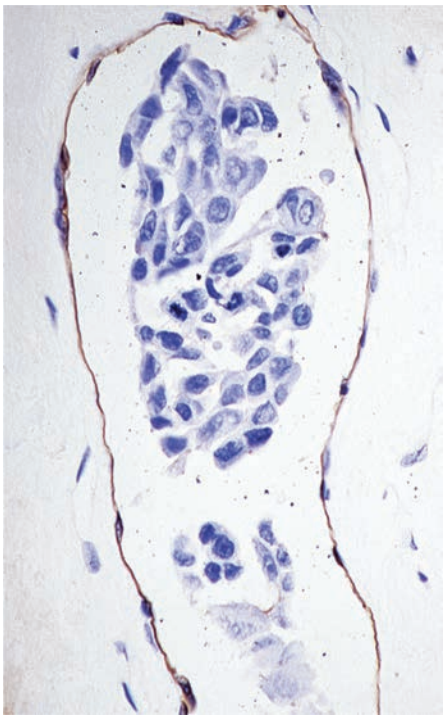

Figure 36.92 Vascular invasion by breast carcinoma demonstrated by positivity of endothelial cells for Ulex europaeus lectin I.

TTF-1 positivity has also been documented, a point to be remembered in the evaluation of core needle biopsies of a lung mass in a patient with a history of breast carcinoma.[416] While not often used in clinical practice, increased expression of the bone matrix proteins osteonectin and osteopontin has been documented, with the added suggestion that this may play a role in the bone homing of breast carcinoma metastases.[417,418] The basement membrane components laminin and collagen IV show a discontinuous linear pattern or are altogether absent, in contrast to the continuous pattern exhibited in intraductal lesions.[419,420] Smooth muscle myosin heavy chain, calponin, p63, and other myoepithelial cell markers are negative in invasive carcinomas, confirming the absence of myoepithelial cells around the tumor nests.

Ultrastructurally, breast carcinoma cells exhibit, in greater or lesser degree, features of glandular differentiation such as microvilli and terminal bars on their luminal side.[421] A particularly characteristic feature, although not as specific for breast carcinoma as originally suggested, is the presence of intracytoplasmic lumina bordered by microvilli.[422,423] These formations, when sufficiently large, appear as "bulls eyes" at the light microscopic level and are different from the formations seen in signet ring cells, which are intracytoplasmic vacuoles. The desmoplastic stroma accompanying breast carcinomas is formed by cells having the ultrastructural features of fibroblasts and myofibroblasts.[424]

Invasive Lobular Carcinoma

Classic type. In its most typical form, invasive lobular carcinoma is characterized by the presence of small and relatively uniform tumor cells growing in single file and in a targetoid fashion around ducts (Figs. 36.93–36.95). Gland formation is not a feature of invasive lobular carcinoma. The stroma is usually abundant, of dense fibrous type, with areas of periductal and perivenous elastosis. Rarely, a lymphocytic infiltrate may be present.

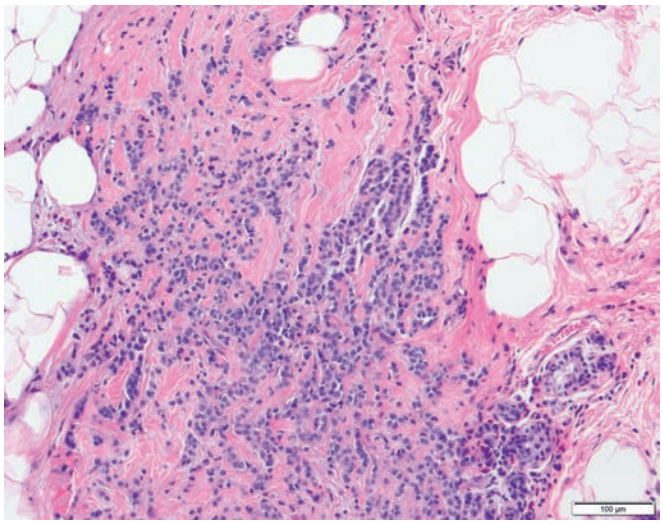

Figure 36.93 **Invasive Lobular Carcinoma.** The tumor cells are small and uniform with round nuclei and grow in single file fashion.

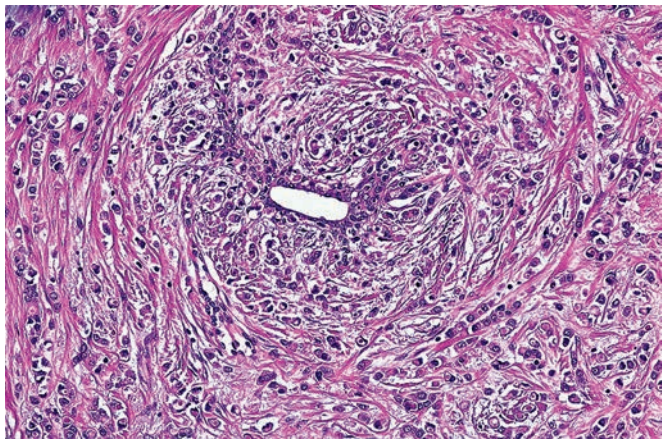

Figure 36.94 Typical target-like growth of tumor cells around an uninvolved duct in invasive lobular carcinoma.

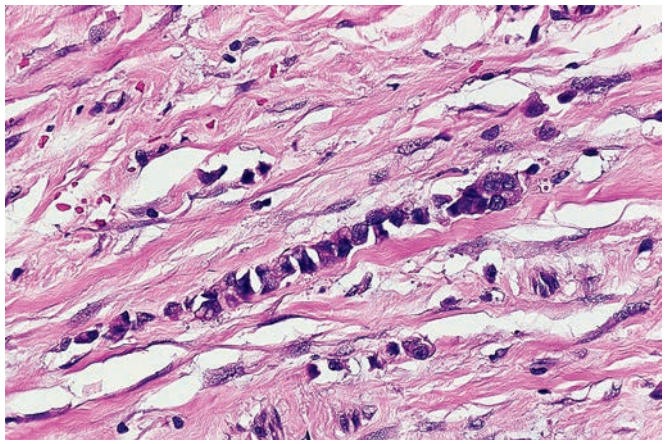

Figure 36.95 Single file pattern of growth of invasive lobular carcinoma.

The immunohistochemical features of invasive lobular carcinoma are analogous to those described for its in situ counterpart. This includes the presence of low-molecular-weight cytokeratins, an absence of E-cadherin expression, and a cytoplasmic staining pattern with p120 catenin.[380] While loss of E-cadherin expression is the hallmark of lobular carcinoma, positive immunostaining for E-cadherin does not preclude this diagnosis when the morphologic features are compatible. As a matter of fact, up to 16% of cases of invasive lobular carcinomas show immunoreactivity for E-cadherin, but these cases typically exhibit abnormal expression of one or more of the catenin complex members, most commonly diffuse cytoplasmic expression of p120 catenin.[382,426] That said, the diagnosis of invasive lobular carcinoma should be made on morphologic grounds; use of E-cadherin is not indicated in histologic typing of invasive carcinomas.[381]

The genetic basis for the loss of E-cadherin expression in lobular carcinoma includes: (1) inactivating mutation of the E-cadherin gene *CDH1*, usually attributable to loss of heterozygosity on chromosome 16q or homozygous deletions of *CDH1*; (2) *CDH1* promoter hypermethylation; (3) truncating mutation in *CDH1*; and (4) transcriptional inactivation.[426]

The main differential diagnosis of invasive lobular carcinoma is with invasive carcinoma with ductal and lobular features. The small size and uniformity of the cells and their lack of cohesiveness are the most important distinguishing features. It should be remarked, however, that in some cases the distinction is difficult and to a large extent subjective, as borne out by the fact that the incidence of invasive lobular carcinoma ranges from 0.7% to 20% in the published series.[427] As discussed earlier, LCIS involving adenosis can be a mimic of invasive lobular carcinoma. Myoepithelial cell markers are helpful in such cases. Other entities that can be confused with invasive lobular carcinoma are carcinoma with neuroendocrine features and malignant lymphoma. The latter possibility arises more often when invasive lobular carcinoma metastasizes to axillary nodes and other sites, particularly the orbit.[428] In those situations cases may be misdiagnosed as large cell lymphoma or malignant histiocytosis because of the diffuse pattern of growth and the histiocyte-like appearance of the tumor cells. Immunoreactivity for cytokeratins and histochemical positivity with mucicarmine should eliminate any problems not resolved by the examination of the routinely stained slides.

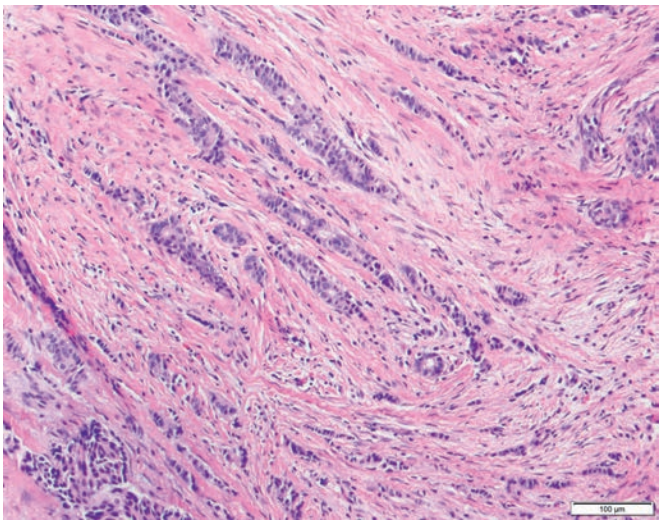

Figure 36.96 Invasive carcinoma with ductal and lobular features; in some areas there is gland formation, while in others, the tumor cells align in a single file (*lower portion* of field).

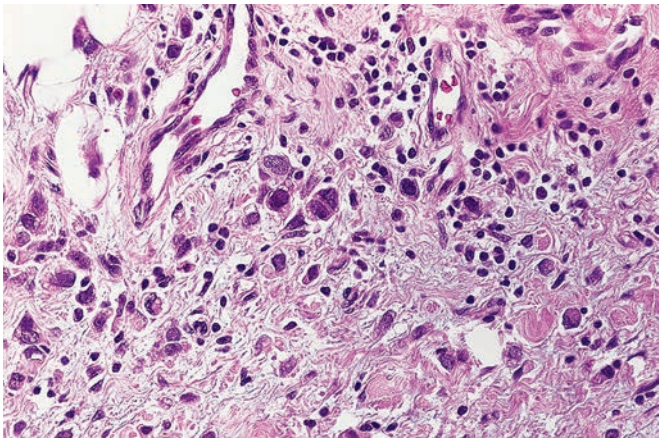

Figure 36.97 Pleomorphic variant of invasive lobular carcinoma.

Invasive Carcinoma With Ductal and Lobular Features

Carcinomas composed in part of a component with definite features of invasive ductal carcinoma and in part of a component with definite features of invasive lobular carcinoma do occur; more commonly seen are tumors with features neither definitively lobular nor definitively ductal (Fig. 36.96). It is acceptable to classify these tumors as invasive carcinoma with ductal and lobular features. They should be distinguished from cases in which two separate neoplasms of different microscopic appearances are present in the same breast. They should also be distinguished from so-called tubulo-lobular carcinoma, which has a reasonably distinct morphologic appearance (see next section).

Variants of Invasive Lobular Carcinoma

Pleomorphic invasive lobular carcinoma. This form of invasive breast carcinoma has the growth pattern of a classic breast carcinoma but exhibits a marked degree of nuclear pleomorphism (Fig. 36.97).[429] Apocrine differentiation and focal signet ring morphology may also be seen. Pleomorphic invasive lobular carcinoma more frequently demonstrates a lack of hormone receptors and shows expression of HER2 and p53, while still demonstrating an absence of E-cadherin staining, as well as loss of the long arm of chromosome 16, in keeping with the lobular phenotype.[383,384,430]

Signet ring carcinoma. Signet ring carcinoma is a type of breast carcinoma in which a significant number of tumor cells show intracytoplasmic mucin accumulation, resulting in the typical signet ring appearance (Fig. 36.98). It is important to separate this tumor from mucinous carcinoma (in which the mucin is extracellular) because of their differing prognoses.

Most cases of signet ring carcinoma show cytoarchitectural features (such as small cell size, uniformity, and cellular dyshesion) similar to those of classic invasive lobular carcinoma and sometimes coexist with it. Furthermore, it is not rare for LCIS or invasive lobular carcinoma to contain scattered signet ring cells. For these reasons, most cases of signet ring carcinoma are regarded as variants of invasive lobular carcinoma.[431]

Immunohistochemically, signet ring carcinoma is positive for CK7 and MUC1 and usually negative for E-cadherin.[432]

Care must be taken with the challenging differential diagnosis of gastric signet ring adenocarcinoma, as invasive lobular carcinomas with signet ring cell features are known to metastasize to the stomach.

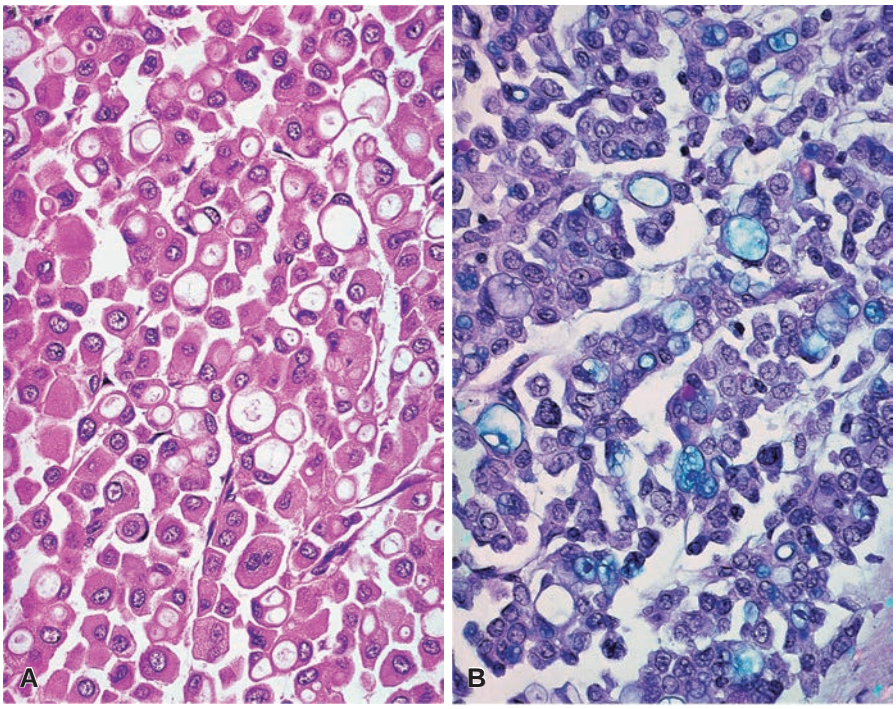

Figure 36.98 A, and B, Signet Ring Carcinoma of the Breast. This is regarded as a variant of lobular carcinoma. **B,** Alcian blue-PAS stain.

Rarely the converse of gastric metastasis to the breast has been reported.[433,434]

Histiocytoid carcinoma. Histiocytoid carcinoma is characterized by a diffuse pattern of growth of bland tumor cells displaying abundant granular, foamy cytoplasm.[435] It may simulate the appearance of an inflammatory process or of granular cell tumor.[436,437] Histiocytoid carcinoma is viewed as a variant of invasive lobular carcinoma exhibiting apocrine differentiation, as evidenced by immunohistochemical reactivity for GCDFP-15 and absence of E-cadherin expression.[436–438]

Histiocytoid carcinoma should also be distinguished from *lipid-rich carcinoma*. The latter is simply a form of breast carcinoma showing lipid accumulation in the cytoplasm of greater than 90% of the tumor cells (Fig. 36.99).[439–441]

Other types. As long as the relatively bland and homogeneous cytologic appearance is maintained, cases having closely aggregated cells, solid pattern, trabecular pattern, and loose alveolar pattern have been accepted as invasive lobular carcinoma. Perhaps the most distinctive of these forms is the *alveolar variant*, in which the tumor cells are arranged in sharply outlined groups separated by fibrous tissue sometimes containing osteoclast-like giant cells.[442] The cytologic and/or architectural similarities between these various forms and classic invasive lobular carcinoma are undeniable. The problem, however, is that the more the concept of invasive lobular carcinoma is widened, and to some extent diluted, the less distinct the entity becomes and the less significant (or at least the less uniform) its clinical connotations.[443]

Tubular Carcinoma

Tubular carcinoma is a well-differentiated tumor more common among older women. Grossly, tubular carcinoma suggests malignancy by virtue of its poorly circumscribed margins and hard consistency similar to invasive ductal carcinomas of no special type. It is

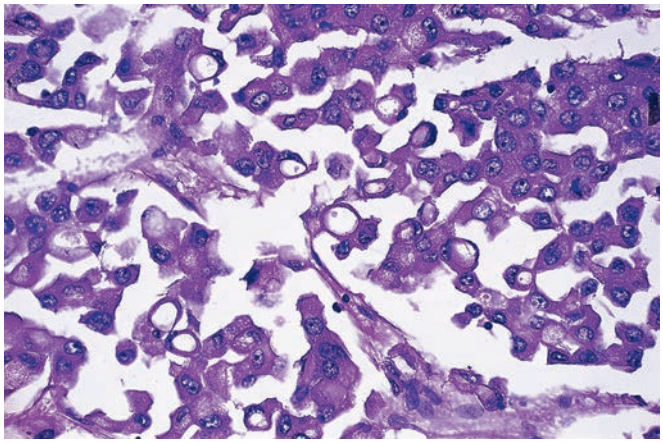

Figure 36.99 Lipid-Rich Carcinoma of the Breast. The cells show cytoplasmic vacuolation with nuclear displacement due to lipid accumulation. **A,** Intermediate power. **B,** High power.

characteristically small, with a mean diameter of about 1 cm.[444,445] Microscopically, it simulates a benign condition (particularly radial scar but also microglandular adenosis) because of the well-differentiated nature of the glands, absence of necrosis or mitoses, and scanty pleomorphism. Clues to the diagnosis are the haphazard arrangement of the glands in the stroma with absence of any lobular configuration; frequent invasion of fat at the periphery of the lesion; cellular (but often also elastotic[446]) nature of the stroma; irregular and often angulated contours of the glands (Fig. 36.100); open lumina sometimes with basophilic secretion; apical "snouts" in the cytoplasm; lack of a myoepithelial cell component (well appreciated in immunostained preparations with myoepithelial cell antibodies such as p63 and SMMHC); lack of basement membrane; and occurrence

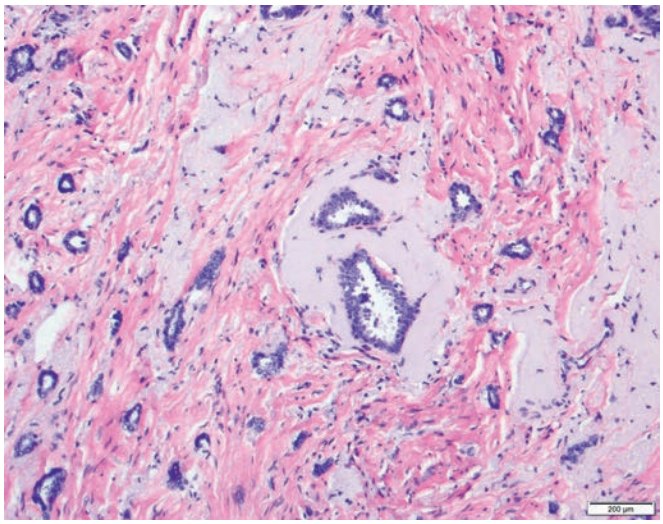

Figure 36.100 Tubular Carcinoma of Breast. The angulated shape of the glands percolating haphazardly through the cellular stroma are characteristic of this lesion. In this particular case, there is prominent stromal elastosis.

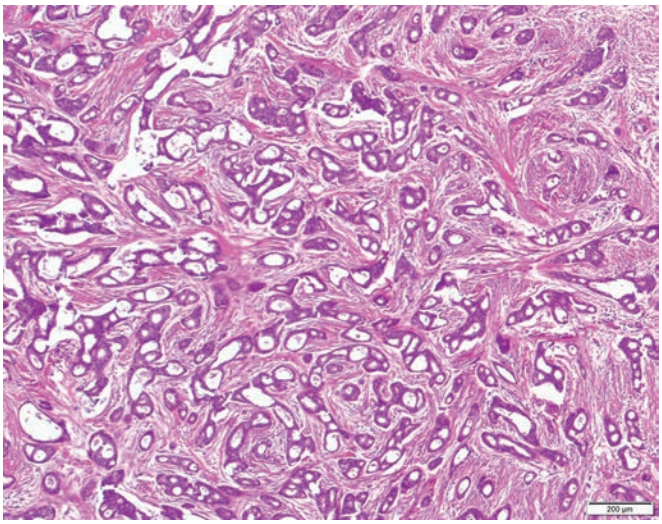

Figure 36.101 Invasive Cribriform Carcinoma. In this example, all the nests have a cribriform pattern. The irregular contour of the nests and the infiltrative growth pattern help distinguish this lesion from cribriform pattern DCIS.

in two-thirds of cases or more of low nuclear grade DCIS, often micropapillary or cribriform pattern.[444] FEA also is frequently found in cases of tubular carcinoma. In fact, low-grade DCIS, ADH, and FEA are considered to be nonobligate precursor lesions of low-grade invasive carcinomas and tubular carcinomas in particular.[118,447,448]

Because of the marked degree of cellular differentiation, it is not unusual for these tumors to be underdiagnosed as fibroadenoma or some other benign process on FNA material.[449] They are more readily recognized in core needle biopsy specimens.

Metastases to axillary lymph nodes occur in approximately 10% of cases,[444] but this does not appear to affect outcome, even in the absence of systemic chemotherapy.[450–452] In a series by Rakha et al.,[452] only 7% of their 102 patients developed recurrent or metastatic disease during a median follow-up period of 127 months and these events were all found to be associated with an intervening recurrence of breast carcinoma of different histologic type and/or grade. Thus tubular carcinoma can be considered a special-type breast cancer with an exceptionally favorable prognosis.[452]

Sometimes, a tubular carcinoma pattern is seen in association with an ordinary invasive ductal carcinoma; however, the diagnosis of tubular carcinoma should be reserved for those tumors in which the tubular component makes up more than 90% of the tumor.

Tubulolobular carcinoma. This variant is characterized by the admixture of small tubular formations with cords of tumor cells growing in a lobular configuration.[453] The in situ component, if present, may be of either lobular, ductal or both types.[454] The immunohistochemical profile is intermediate between those of ductal and lobular carcinoma, in that it may show positivity for E-cadherin.[454] This tumor is associated with a higher incidence of multifocality and positive axillary nodes than pure tubular carcinoma.[455,456]

Invasive Cribriform Carcinoma

Invasive cribriform carcinoma is another special-type breast carcinoma, which, similar to tubular carcinoma, has an excellent prognosis.[457,458] As the name indicates, the tumor has a cribriform appearance similar to that seen in the more common in situ counterpart, but it exhibits stromal invasion and lacks a myoepithelial cell layer (Fig. 36.101). This pattern is often seen in association with tubular carcinoma, the relative proportion of the two elements determining the term used.[458] The most important aspect of this particular tumor is the recognition that a cribriform lesion can be invasive, a potential diagnostic pitfall. In many cases, cribriform pattern DCIS is also present, but it is the size of the invasive component that should be reported for staging purposes. The invasive component can be recognized by the more infiltrative growth pattern extending between and around ducts and lobules, the irregular contour of some of the tumor cell nests and the presence of a desmoplastic-appearing stroma. DCIS, in contrast, has a growth pattern that conforms to the normal ductolobular architecture and more rounded contours to the nests; stromal changes are usually absent. If necessary, immunohistochemistry for myoepithelial cells can be used to separate the relative proportions of DCIS versus invasive cribriform carcinoma.

Mucinous Carcinoma

Mucinous carcinoma occurs over a wide age range (25–85 years), but the median age of 71 years is greater than that for invasive ductal carcinoma of no special type.[459] Grossly, it is well circumscribed, fluctuant to palpation, and formed by a gelatinous mass held together by delicate septa (Fig. 36.102). Foci of hemorrhage may be seen. Microscopically, the classic and often quoted description is that of small clusters of tumor cells "floating in pools of mucin" (Fig. 36.103). These clusters may be solid, exhibit acinar formations, or form micropapillary structures.[460] The mucin is almost entirely extracellular, and it may be of acid or neutral type.[461] Occasionally, mucinous carcinoma will consist almost entirely of mucin, and thorough sampling will be necessary to detect the neoplastic epithelium. An easily recognizable in situ component may be absent or inconspicuous (but see later section). Immunohistochemically, there is strong MUC2 cytoplasmic immunoreactivity and decreased MUC1 immunoreactivity compared with invasive ductal carcinoma of no special type.[462,463] Both pure and mixed mucinous carcinomas of the breast often express WT1, a potential diagnostic trap with ovarian carcinoma.[464] Hormone receptors are invariably positive, while HER2 is almost always negative.[465]

Interestingly, about a quarter to nearly one-half of mucinous carcinomas show features consistent with endocrine differentiation,

Figure 36.102 Typical Gelatinous Gross Appearance of Pure Mucinous Carcinoma. Note the sharply circumscribed quality of the tumor. (Courtesy of Dr RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

such as synaptophysin and chromogranin immunoreactivity, and the presence of dense-core secretory granules by ultrastructural examination.[466,467] This unexpected finding has raised the possibility of a link between mucinous carcinoma and neuroendocrine carcinoma.[468] Some authors have suggested the existence of two types of mucinous carcinoma on the basis of being paucicellular or hypercellular and the absence or presence of endocrine differentiation, designated as type A and B, respectively (Fig. 36.103A, B and C, D respectively).[466] There appears to be no influence of this separation on survival.[469]

On analysis of array-based CGH assays, pure mucinous carcinomas are a homogeneous group and cluster together, separately from invasive ductal carcinoma of no special type.[465,468] They less frequently harbor gains of 1q and 16p and losses of 16q and 22q than grade- and ER-matched invasive ductal carcinomas of no special type. Gene expression profiling has shown that type B mucinous carcinomas and neuroendocrine carcinomas are part of a spectrum of lesions, whereas type A mucinous carcinoma is a discrete entity.[468]

It is important for prognostic reasons, and perhaps useful histogenetically, to restrict the term mucinous carcinoma to breast neoplasms exhibiting this feature throughout the tumor ("pure" mucinous carcinomas) and to exclude: (1) "mixed" tumors in which the mucinous pattern is admixed with an invasive ductal carcinoma (these having a prognosis analogous to the latter)[465]; and (2) signet ring carcinomas, even if technically speaking these are also "mucinous" tumors. The distinctiveness of signet ring carcinoma resides in the fact that the mucin remains within the cell, and the uniqueness of mucinous carcinoma is that most of the mucin is extracellular.

Pure mucinous carcinoma is associated with a very low incidence (2%–4%) of nodal metastases.[451,459,470] The higher incidence reported in some series is probably attributable to the inclusion of "mixed" mucinous tumors. Consequently, the pure form of mucinous carcinoma carries an excellent short-term prognosis. However, it has been shown that deaths from this tumor can occur greater than 25 years after therapy, indicating the need for long-term follow-up.[451,471] As already indicated, several groups found no prognostic difference between mucinous carcinomas with endocrine-like features and those without,[470] although others claim that the former are associated with favorable histologic and immunohistochemical parameters.[472]

A diagnostic challenge of which to be aware when encountering a mucinous lesion is the occurrence of extravasated mucin in association with benign or atypical lesions. "**Mucocele-like lesion**"[473] is the occurrence of a cystically dilated duct filled with mucin that may rupture, resulting in extravasation of mucin into the stroma (Fig. 36.104). In many cases, the lining epithelium is attenuated, but in some mucocele-like lesions the lining epithelium is proliferative, with morphologic changes including UDH, ADH, and even DCIS. On occasion, this proliferative epithelium may become detached and "float" in the stromal mucin pools, mimicking mucinous carcinoma. The distinction can be challenging, particularly if the detached epithelium is from DCIS. Features favoring a mucocele-like lesion with detached epithelium over mucinous carcinoma are the linear arrangement of the epithelial fragments that have detached from the duct wall and the presence of myoepithelial cells.

On core needle biopsy specimens, mucinous lesions can be particularly difficult to categorize, given the knowledge that some mucinous carcinomas are hypocellular with abundant mucin. Most practitioners have recommended excision for mucinous lesions on core needle biopsy regardless of the identification of atypia[474]; however, more recent publications have moved toward recommending a more conservative approach to management for mucocele-like lesions without epithelial atypia that are radiologically concordant.[475,476]

A further variation on the theme is represented by *mucinous cystadenocarcinoma*, an exceptionally rare tumor composed predominantly of tall columnar cells with abundant intracytoplasmic mucin and a multicystic gross quality similar to that of its ovarian counterpart.[477]

Carcinoma with Medullary Features

It is the recommendation of the WHO consensus panel convened in 2011 for the Classification of Tumors of the Breast that medullary carcinoma and atypical medullary carcinoma be included together under the descriptor "carcinoma with medullary features."[478] These tumors tend to occur in younger women, with the average age reported to range from 42 to 52 years. It has also been reported that patients with *BRCA1* mutations are particularly likely to have carcinomas with medullary features.[479] Grossly, carcinoma with medullary features is well circumscribed and may become large; as such it can be mistaken clinically, radiologically, and grossly for a fibroadenoma, but it lacks the trabeculation or whorling of the latter. Rather, the cut surface is solid, homogeneous, and gray, sometimes exhibiting small foci of necrosis (Fig. 36.105). Rare examples are partially or predominantly cystic.[480] Microscopically, the borders are of the "pushing" type. The pattern of growth is diffuse, with minimal or no glandular differentiation. The tumor cells are large, with enlarged, pleomorphic nuclei, prominent nucleoli, and abundant mitoses (some of them atypical). The cell borders are indistinct, giving the tumor a syncytial or sheet-like appearance somewhat reminiscent of a germ cell tumor of the embryonal carcinoma type. This is accentuated by the observation that the tumor cells located at the periphery are more elongated and have a denser, more acidophilic cytoplasm, acquiring a vague resemblance to syncytiotrophoblast. Spindle cell morphology, bizarre tumor giant cells, extensive necrosis, and the absence of calcification

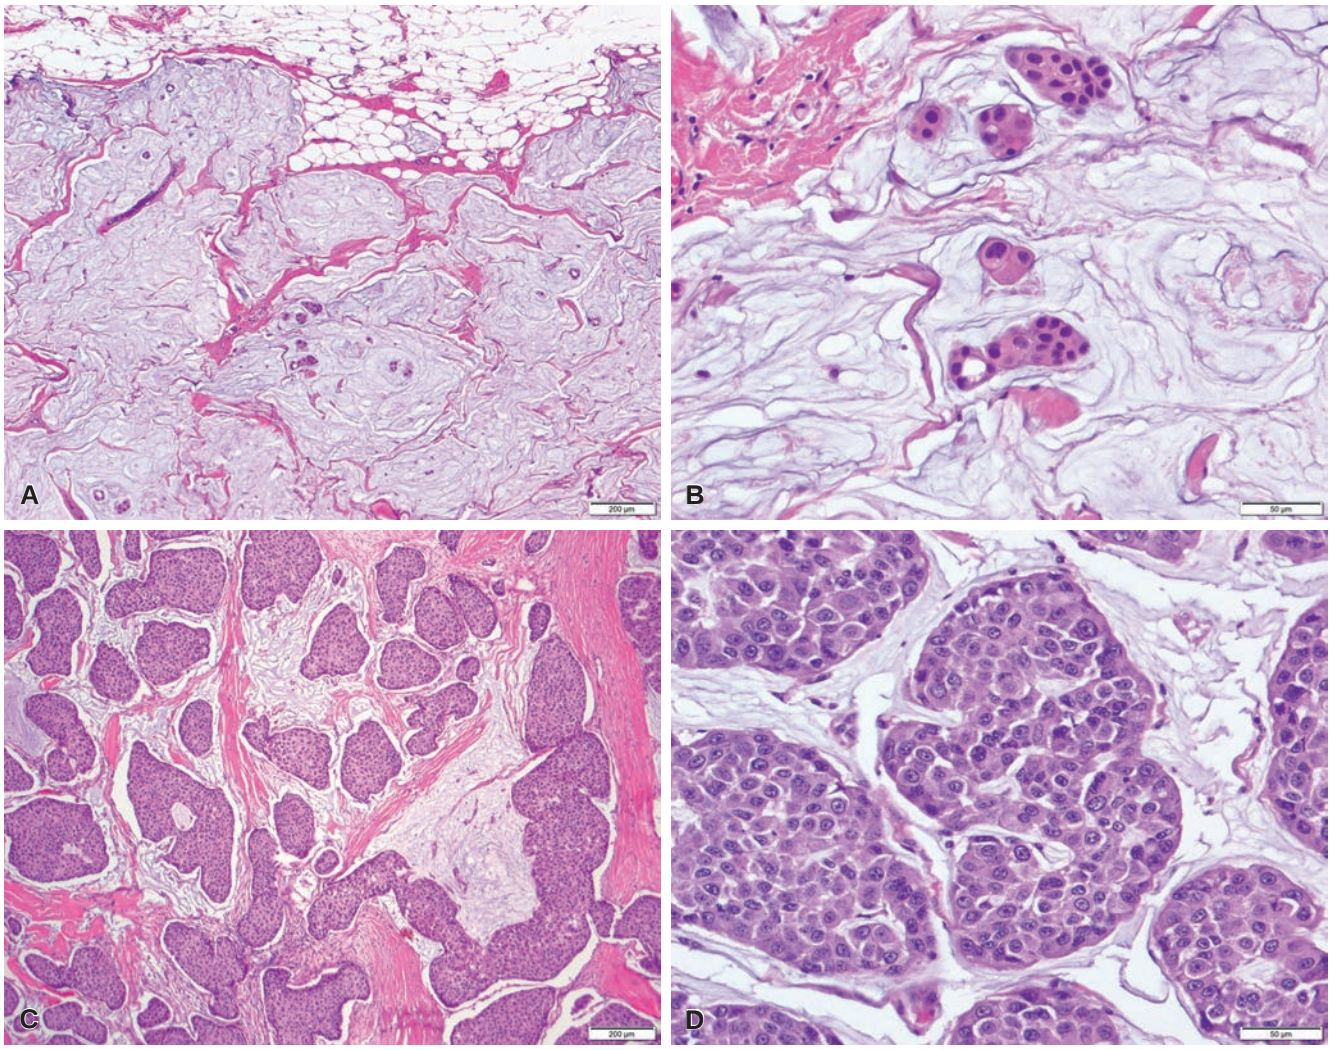

Figure 36.103 Mucinous Carcinoma of the Breast. Clusters of well-differentiated tumor cells are seen floating in a sea of mucin. Hypocellular variant, at low power **(A)** and high power **(B)**. Hypercellular variant, at low power **(C)** and high power **(D)**.

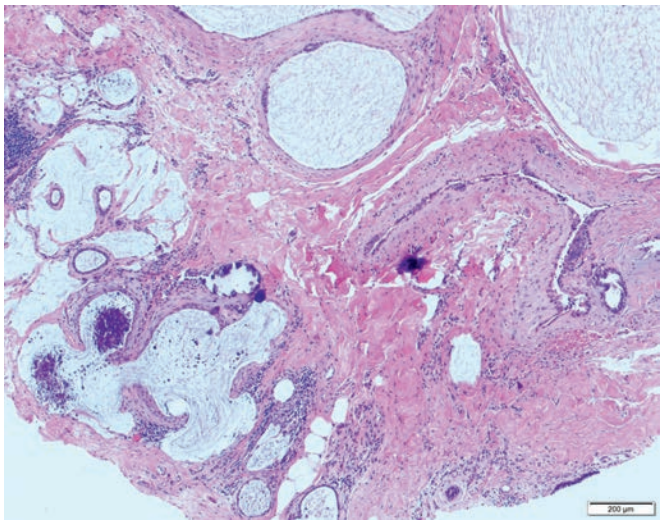

Figure 36.104 Mucocele-Like Lesion. Cystically dilated ducts are lined by an attenuated epithelium which are filled with mucin. Focally there is rupture with extravasation of mucin into the stroma. Note the association with calcifications in this case.

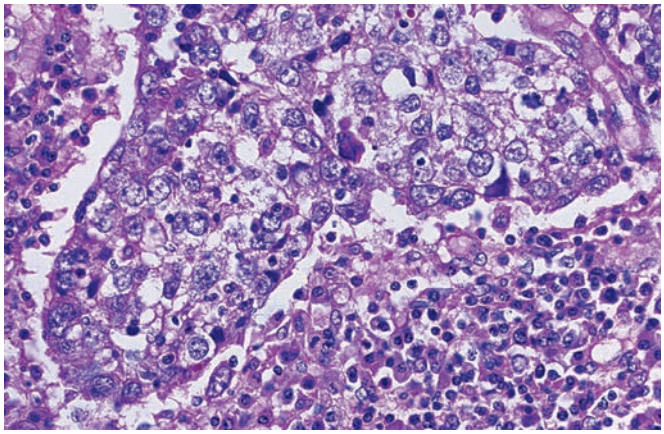

Figure 36.105 Carcinoma With Medullary Features. The large tumor cells grow in a "syncytial" fashion and are sharply separated from the surrounding stroma, which is heavily infiltrated by lymphocytes and plasma cells.

are other common features. A constant component is a prominent lymphoplasmacytic infiltrate, which is thought to represent a reaction of the host to the neoplasm. DCIS is usually minimal or absent.

Immunohistochemically, carcinomas with medullary features share the markers of ordinary invasive ductal carcinoma. They typically express CK7, often vimentin, S-100 protein, and p53, as well as HMW (basal) cytokeratins, and caveolin-1.[478] They are almost invariably negative for hormone receptors, as well as HER2 ("triple negative" phenotype).[478]

Genetically, carcinomas with medullary features commonly show *TP53* gene mutation.[481] Although the gene expression profile of carcinoma with medullary features is considered to represent part of the basal-like carcinoma spectrum (see later)[482] and it shares genetic changes such as 1q and 8q gains and X losses with basal-like carcinomas not otherwise specified, it does show distinct molecular features, including higher numbers of gains and losses on array CGH analysis, as well as recurrent 10p, 9p, and 16q gains, 4p losses, and 1q, 8p, 10p, and 12p amplicons.[481]

Axillary lymph node metastases are common, but they are usually few and limited to the low axillary group. The prognosis for "medullary carcinoma" is reported to be better than for the ordinary invasive ductal carcinoma, but given the low level of interobserver reproducibility for the diagnosis and the use of more descriptive terms for tumors with the aforementioned features, clinicians are increasingly treating these patients with the aggressive therapies used for patients with triple negative breast carcinoma.[478] Newer gene expression profiling studies reveal immune signatures that appear to correlate with a better outcome in patients with triple negative breast carcinomas that have a prominent lymphoplasmacytic infiltrate.[483]

Invasive Micropapillary Carcinoma

Invasive micropapillary carcinoma is a distinct variant of invasive ductal carcinoma with important prognostic correlates.[484,485] Microscopically, it bears close similarity to micropapillary carcinoma of other organs, most notably ovary, and bladder.[486] It is characterized by the formation of pseudopapillary structures lacking a fibrovascular core and by tubular structures free-floating in clear empty spaces (Fig. 36.106). Some of these spaces have been demonstrated to be lymphatic vessels, but the majority are newly formed clefts resulting from the inversion of polarity of the tumor cells (as evidenced by MUC1 and EMA staining).[487,488] The nuclear grade is often high.[489] Psammoma bodies are present in about one-half of the cases.[484] Immunohistochemically, invasive micropapillary carcinoma is usually positive for ER and breast markers (mammaglobin, GCDFP-15, and GATA3) and negative for PAX8 and WT1, a panel that will facilitate distinction from metastatic serous carcinoma from the ovary.[490,491] HER2 positivity is unusual, with fewer than 10% of cases showing overexpression/amplification.[485] Lymph node metastases are the rule (their frequency being directly related to the presence of lymphatic vessel invasion[492]), local recurrence is high, but the survival rate is no different than that for stage- and grade-matched conventional invasive ductal carcinoma.[493,494]

Carcinomas with Apocrine Differentiation

Carcinoma with apocrine differentiation is a rare form of breast malignancy (ranging from 1% to 4% of all cases), at least when defined as composed entirely or predominantly of apocrine-type epithelium.[495,496] The large tumor cells have abundant eosinophilic, somewhat granular cytoplasm, which may contain eosinophilic or golden brown granules that are strongly PAS positive. The nuclei are vesicular, and nucleoli are prominent. Glandular differentiation is usually found, and the luminal aspect of the epithelial cells often

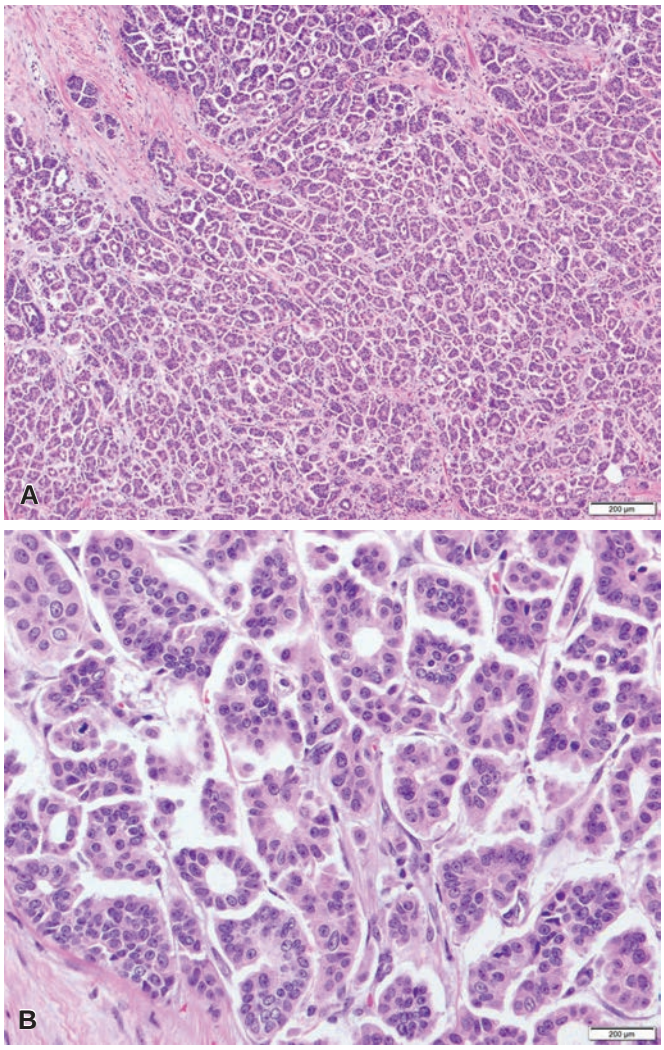

Figure 36.106 Invasive Micropapillary Carcinoma. A, At low power the tumor is characterized by the formation of micropapillary structures lacking a fibrovascular core and by tubular structures free-floating in clear empty spaces. **B,** At higher power the reverse polarity of the tumor cells can be appreciated.

have a characteristic bulbous expansion ("apocrine snout") (Fig. 36.107). Ultrastructurally, the cells of carcinoma with apocrine differentiation show prominent mitochondria (some with abnormal cristae).[497] Immunohistochemically, there is diffuse reactivity for GCDFP-15 and androgen receptor.[498] The gene coding for GCDFP-15 is located on chromosome 7q and is identical to the gene of prolactin-inducible protein (PIP); the expression of this gene in carcinomas with apocrine differentiation has been demonstrated with in situ hybridization techniques.[499] Carcinoma with apocrine differentiation is usually ER negative; HER2 overexpression is common.

Since apocrine changes in the breast are usually indicative of benignity, even when the cells exhibit prominent nucleolar enlargement, the diagnosis of carcinoma with apocrine differentiation should be made only when the architectural features are clearly those of a carcinoma; a distinction more problematic for in situ than invasive apocrine lesions. It is also important to limit the diagnosis to malignant tumors in which the apocrine change is widespread, in view of the fact that focal apocrine differentiation can be detected in close to 10% of ordinary carcinomas.[498] Finally, it should be noted that although carcinoma with apocrine differentiation is usually a

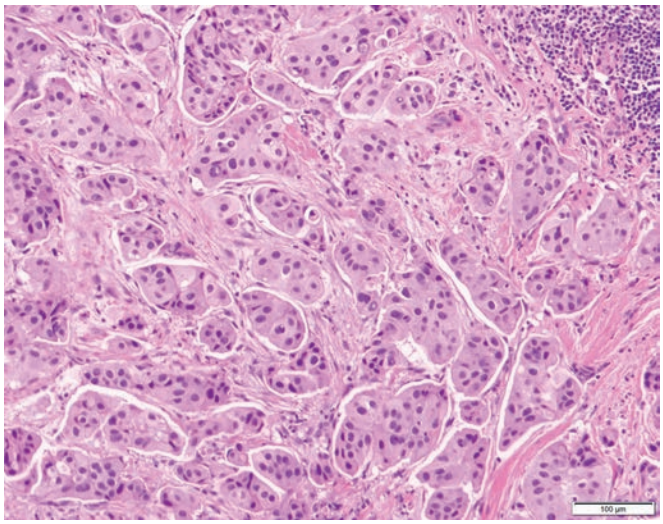

Figure 36.107 Carcinoma With Apocrine Differentiation. The large tumor cells have abundant eosinophilic, somewhat granular cytoplasm, which may contain eosinophilic or golden brown granules that are strongly PAS positive. The nuclei are vesicular and nucleoli are readily seen.

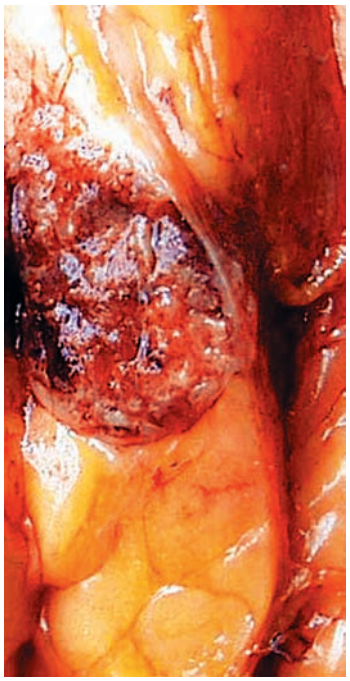

Figure 36.108 Gross Appearance of Secretory Carcinoma. The tumor is well circumscribed and shows a variegated cut surface.

variant of either DCIS or invasive ductal carcinoma, apocrine differentiation has also been described in LCIS and invasive lobular carcinoma.[500]

Secretory Carcinoma

This rare form of breast carcinoma is seen primarily in children, but it can also occur in adults.[501,502] Grossly, it is well circumscribed, with an average reported size of 3 cm (Fig. 36.108).[503] The margins of the tumor are of the "pushing" type, and prominent hyalinization is often present in the central portion. The microscopic appearance

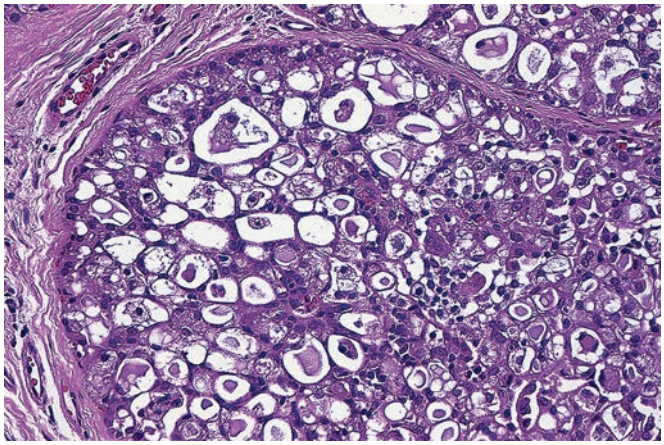

Figure 36.109 Secretory Carcinoma. The small uniform glands are filled by a secretory material.

is distinctive (Fig. 36.109). Tubular, microcystic and solid patterns are variably present forming lumina filled with an eosinophilic, PAS-positive secretion surrounded by cells with vacuolated (sometimes "hypernephroid"), granular cytoplasm.[502–504] Nucleoli may be prominent, but mitoses are scanty. Ultrastructurally, the tumor cells contain numerous membrane-bound intracytoplasmic secretory vacuoles.[505]

Immunohistochemically, there is strong reactivity for α-lactalbumin and S-100 protein, accompanied by variable expression of GCDFP-15 and CEA.[506] Secretory carcinoma is typically triple negative (ER, PR, and HER2 negative). It has been hypothesized that there may be a histogenetic link between secretory carcinoma and a type of salivary gland tumor historically placed among the acinic cell carcinomas, a subset of which have more recently been recategorized as a mammary analogue secretory carcinoma due to the identification of a similar molecular genetic abnormality,[507] namely a recurrent balanced chromosomal translocation, t(12;15)(p13;q25), which leads to fusion of the *ETV6* and *NTRK3* genes as is found in secretory carcinoma of the breast.[508,509] In fact, it is the identification of this gene fusion product that allows distinction of secretory carcinoma from acinic cell carcinoma of the breast.[509]

The overall prognosis is excellent, especially in younger patients, with most series quoting a 5-year survival rate close to 100%.[502–504] Local recurrences and nodal metastases can develop, sometimes very late in the course of the disease.[502–504] Death resulting from disseminated tumor has been recorded only exceptionally.[502] Secretory carcinoma has also been reported to occur in the axillary skin in the absence of a breast primary.[510]

Carcinomas with Neuroendocrine Features

(including so-called carcinoid tumor). The clinical presentation of carcinoma with neuroendocrine features is no different from that of ordinary breast carcinoma. Specifically, none of the patients has had carcinoid syndrome, even in the presence of widespread disease. There are no distinctive gross features. Carcinomas with neuroendocrine features occur in older women and constitute less than 1% of all breast carcinomas.

Microscopically, the tumor cells are small, arranged in solid nests separated by delicate bands of fibrous tissue (Fig. 36.110). Ribbons and rosette-like formations are not typically seen in carcinoma with neuroendocrine features arising in the breast. Mitoses are generally rare. Mucin secretion may be present. The microscopic differential diagnosis includes the alveolar variant of invasive lobular carcinoma

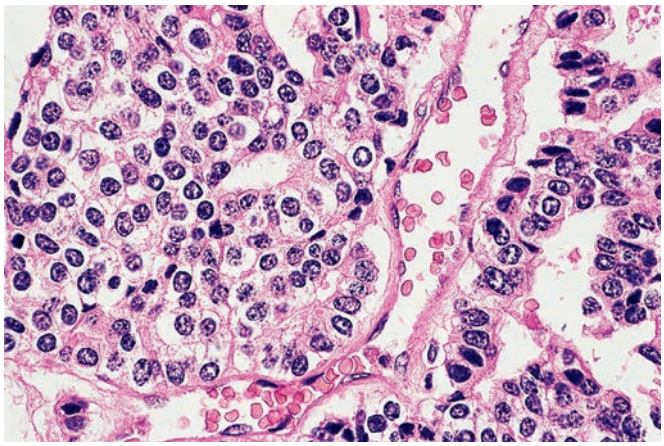

Figure 36.110 Breast carcinoma with neuroendocrine features.

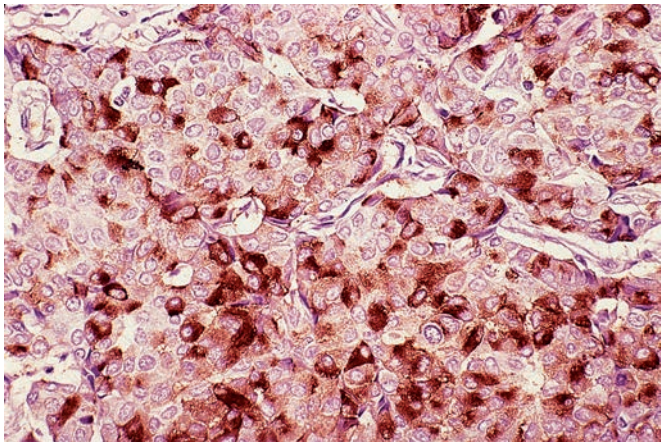

Figure 36.111 Strong reactivity for chromogranin in breast carcinoma with neuroendocrine differentiation.

and a metastasis to the breast of a neuroendocrine tumor located elsewhere. Identification of an intraductal component aids in establishing breast origin.

Of historical interest the tumor cells of neuroendocrine carcinoma of the breast are argyrophilic but not argentaffin positive and are found to contain dense-core secretory granules of various types ultrastructurally.[511,512] The tumor cells demonstrate immunohistochemical positivity for chromogranin, synaptophysin, NSE, and CD56[513–515] and in some instances for specific hormone peptides,[516] indicative of endocrine differentiation (Fig. 36.111).

It should be mentioned here that there are breast carcinomas of other morphologic patterns in which neuroendocrine features have been found.[517] Since markers of neuroendocrine differentiation are not routinely performed in breast pathology, the true incidence of this tumor is not known,[513,518] though a recent report found between 10% and 30% of invasive ductal carcinomas of no special type expressed neuroendocrine markers.[519]

Metaplastic Carcinoma

Metaplastic carcinoma is a generic term for breast carcinoma in which there is differentiation of the epithelial component into non-glandular elements. These include squamous differentiation and/or differentiation into mesenchymal elements.[520,521] Given that the designation is so broad, the diagnosis is best used with a qualifier.

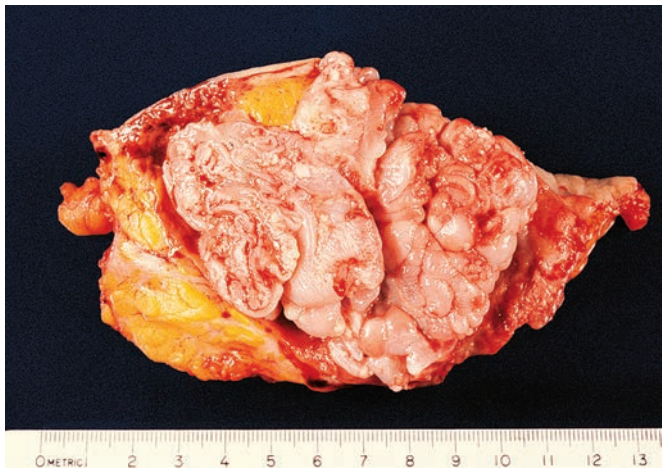

Figure 36.112 Gross Appearance of Metaplastic Carcinoma. A large, fleshy mass is seen protruding inside a cavity. Microscopically, this tumor showed an admixture of squamous and spindle cell elements.

The following categories, which overlap considerably with each other, are included:

1. *Metaplastic carcinoma with mesenchymal differentiation*. Grossly, this tumor tends to be well circumscribed (Fig. 36.112). Microscopically, the mesenchymal component may appear relatively well differentiated with minimal spindle cell atypia or may resemble its sarcomatous counterpart with areas of a chondrosarcoma, osteosarcoma, rhabdomyosarcoma, angiosarcoma, or a combination thereof.[522] There may be a gradual transition from carcinomatous to mesenchymal elements, or the separation between them can be abrupt. Tumors having overt carcinoma with abrupt transition to a cartilaginous and/or osseous matrix without an intervening spindle cell zone or osteoclastic giant cells have been referred to as *matrix-producing carcinomas*.[522–524]

   Immunohistochemically, the mesenchymal elements of these tumors have usually acquired vimentin positivity and other features of a mesenchymal nature ("phenotypic switch") but still retain epithelial markers, albeit focal and variable, a fact best demonstrated by employing several wide-spectrum cytokeratin antibodies.[525]

   As in other sites, molecular studies support the interpretation that the recognizable epithelial and the mesenchymal components originate from the same stem cell.[526,527]
2. *Spindle cell carcinoma*. The overt carcinomatous component of these tumors, when present, may be invasive ductal carcinoma or DCIS or it may be entirely squamous.[528] The spindle cell component is composed of atypical spindle cells within a fibrocollagenous stroma with feathered, myxoid, angioid, and storiform patterns (Fig. 36.113).[529,530] Merging of areas between the epithelial and the spindle components is common. The spindle cells are immunoreactive for cytokeratins and p63, albeit focal and variable in some cases.[531, 532]
3. *Fibromatosis-like metaplastic carcinoma*. These tumors are characterized by bland spindle cells with little to no cytologic atypia, resembling, as the name suggests, fibromatosis (Fig. 36.114). The spindle cells are arranged in fascicles that infiltrate into the surrounding fat and between ducts and lobules. On occasion, a central scar-like area may be present. Some of these tumors arise in connection with complex sclerosing lesions, sclerosing papillary lesions, or adenomyoepitheliomas.[522,533]
4. *Metaplastic carcinoma with osteoclast-like giant cells*.[534] When these cells appear in conjunction with mesenchymal elements, the

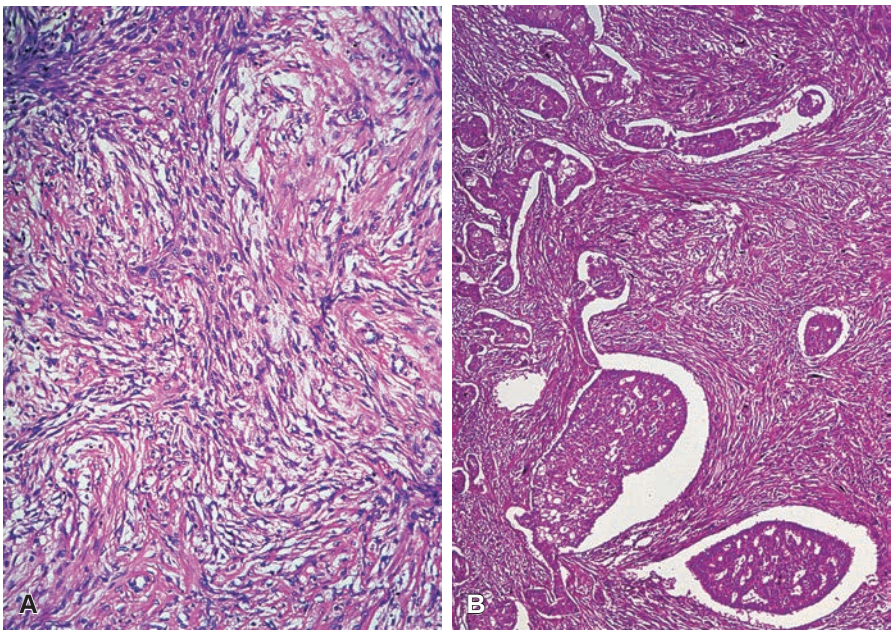

Figure 36.113 Metaplastic Carcinoma. The tumor shown in **(A)** exhibits a blending of the epithelial and spindle cell components making it more difficult to recognize this as a carcinoma, whereas that depicted in **(B)** has more readily recognizable epithelial elements admixed with the malignant spindle cell component.

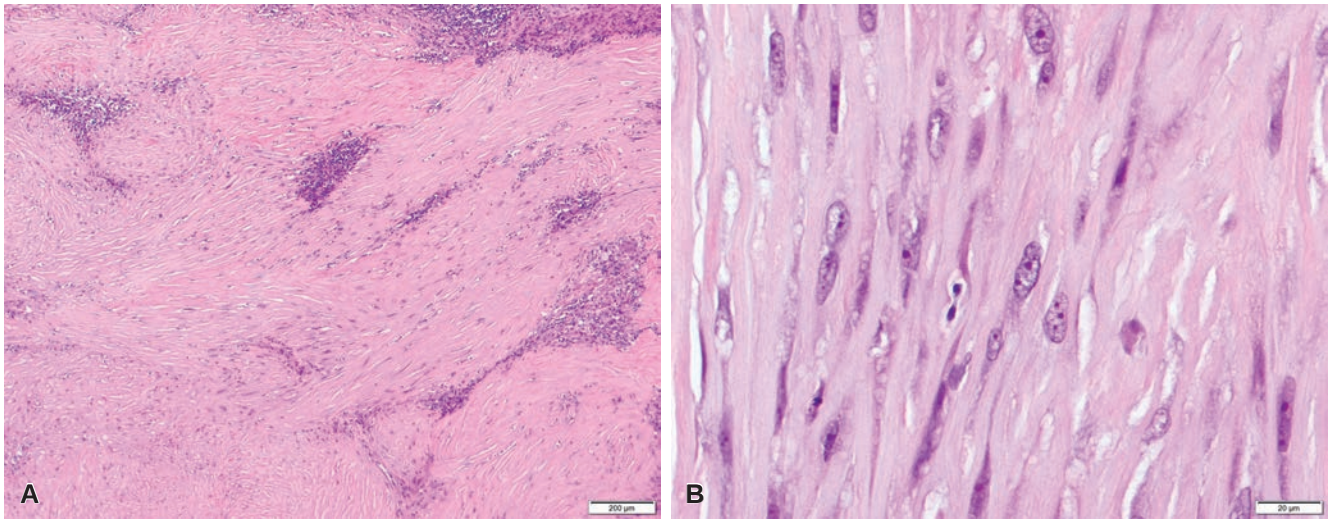

Figure 36.114 Low-grade Fibromatosis-like Metaplastic Carcinoma. A, At low power the tumor appears to be composed of bland spindle cells embedded in dense collagen resembling a scar. **B,** At high power the cytologic atypia of the spindle cells can be appreciated. The tumor cells were positive for cytokeratin (MNF116).

tumor should be regarded as a variant of metaplastic carcinoma. When osteoclast-like giant cells are seen in the stroma of what is otherwise a typical carcinoma lacking mesenchymal differentiation, the tumor is better classified as *invasive ductal carcinoma with osteoclast-like giant cells*. Interestingly, this particular tumor tends to have a reddish-brown appearance grossly and extravasated red blood cells on microscopic examination. All available evidence suggests that the osteoclast-like elements are of a non-neoplastic histiocytic nature and that they form from fusion of mononuclear precursors.[535,536]

5. *Squamous cell carcinoma*. Squamous cell carcinoma is a rare variant of metaplastic carcinoma.[522,537] Tumors of cutaneous origin and those in which the squamous component is a portion of an otherwise typical phyllodes tumor should be excluded. It is also important not to misinterpret the syncytial areas of carcinoma with medullary features or the partial apocrine changes sometimes seen in other tumors as representing squamous change. The gross appearance of squamous cell carcinoma differs little from that of conventional breast carcinomas, although sometimes a large central cyst filled with keratin can be identified. Microscopically, most cases seem to represent instances of squamous metaplasia in invasive ductal carcinoma, indicating that squamous cell carcinoma is a special type of metaplastic carcinoma (Fig. 36.115).[538] Occasionally, the tumor is accompanied by a prominent myxoid stroma.[539]

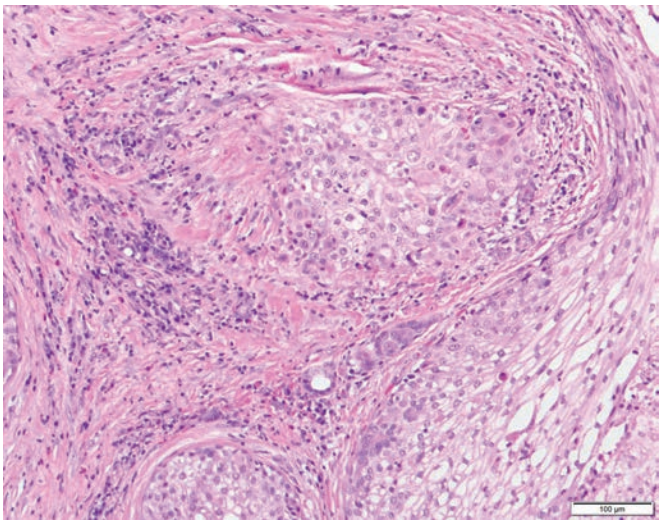

Figure 36.115 Metaplastic carcinoma, squamous cell type.

Two further variants are *acantholytic squamous cell carcinoma*, in which the lack of tumor cell cohesiveness results in a pseudovascular or pseudoglandular appearance (Fig. 36.116),[540] and *low-grade adenosquamous carcinoma* (see next).

6. *Low-grade adenosquamous carcinoma.* Low-grade adenosquamous carcinoma is a well-differentiated tumor with dual glandular and squamous differentiation with squamous pearl or cyst formation infiltrating through a cellular stroma (Fig. 36.117). Local recurrence is common following conservative surgery, but nodal and distant metastases are exceptional.[541] Like fibromatosis-like metaplastic carcinoma, low-grade adenosquamous carcinoma may arise in association with adenomyoepithelioma and benign sclerosing lesions.[533,541–544]

The differential diagnosis of metaplastic carcinoma includes phyllodes tumor, fibromatosis or scar, and less likely primary breast sarcoma. A broad panel of cytokeratin stains along with p63 is often necessary to aid in diagnosis of these challenging cases. As mentioned previously, metaplastic carcinomas vary with regard to which cytokeratin will be expressed and with regard to the extent of tumor cell positivity. In a well-sampled pure spindle cell lesion, unequivocal staining with cytokeratin or p63 is considered sufficient for the diagnosis of metaplastic carcinoma,[522] though it should be noted that it has been recently demonstrated that the stromal component of phyllodes tumor, particularly malignant phyllodes tumor may show focal staining with p63 (and/or p40) and/or cytokeratin immunostains.[178,179] As such, caution should be exercised in rendering a definitive diagnosis based on the interpretation of these immunostains on core needle biopsy specimens of pure spindle cell lesions.

The behavior of metaplastic carcinoma compared with that of invasive ductal-type carcinoma of no special type is not well defined, though fibromatosis-like metaplastic carcinoma and low-grade adenosquamous carcinoma do appear to have a more indolent course.[530] Metastases tend to occur via hematogenous spread rather than to lymph nodes.[530]

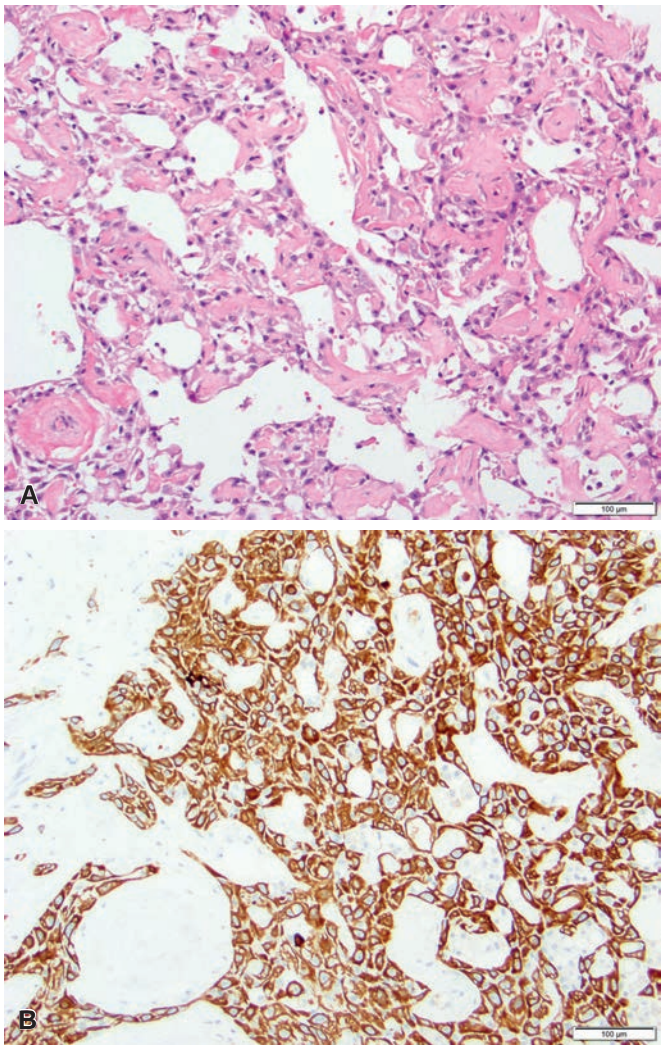

Figure 36.116 **A,** Metaplastic carcinoma, squamous cell type with acantholytic pattern mimicking angiosarcoma. **B,** Cytokeratin 903 immunostain.

Inflammatory Carcinoma

The term "inflammatory carcinoma" is used in a clinical context for a type of breast carcinoma in which the breast is reddened and warm, with widespread edema of the skin, simulating the appearance of mastitis.[545] A discrete breast mass is not always palpable. The clinical appearance is due to widespread carcinomatous emboli involving the dermal lymphatic vessels (Fig. 36.118). However, patients may have inflammatory carcinoma clinically in the absence of pathologically identifiable dermal lymphatic involvement, at least on small punch biopsies of the skin; conversely, widespread permeation of dermal lymphatics can be seen in the absence of the clinical features of inflammatory carcinoma (so-called occult inflammatory carcinoma[546]). The underlying carcinoma is usually a high-grade invasive ductal carcinoma of no special type. Inflammatory carcinoma is staged as T4d. From a prognostic standpoint, the presence of dermal lymphatic permeation on microscopic examination is an ominous sign, whether the clinical appearance is that of an inflammatory carcinoma or not, though there is some improvement in survival outcome with the use of neoadjuvant chemotherapy.[546,547]

Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is similar to tumors of the same name occurring in the salivary gland and lung. It is important not to confuse this uncommon neoplasm with the much more common DCIS with cribriform pattern, with invasive cribriform carcinoma, or with collagenous spherulosis.[548,549] Adenoid cystic carcinoma of

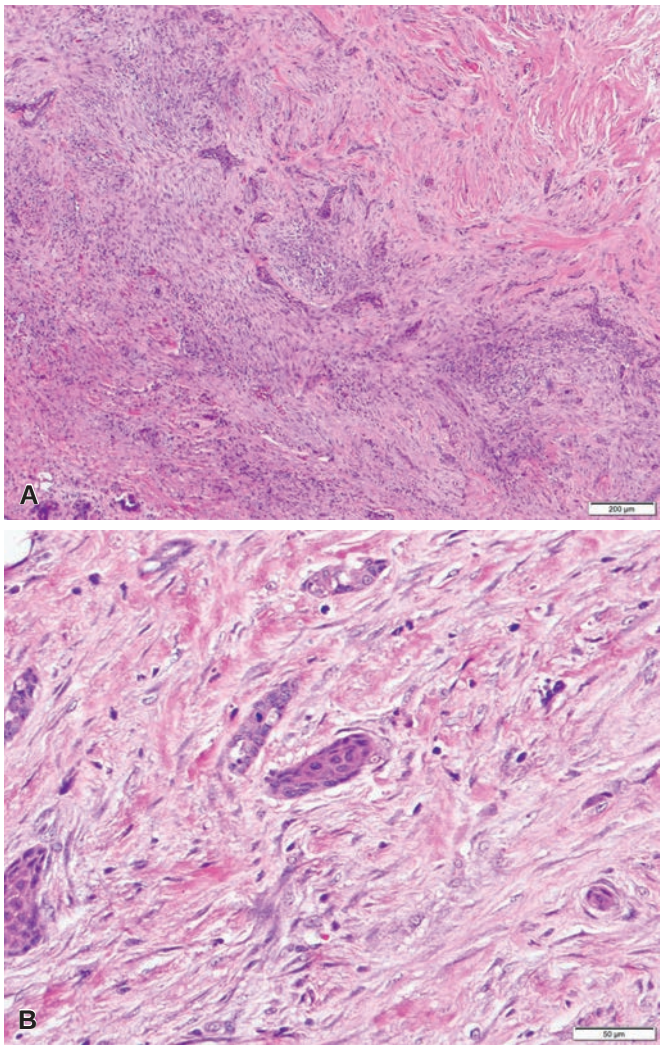

Figure 36.117 **Low-grade Adenosquamous Carcinoma. A,** At low power glands and squamous nests can be seen infiltrating haphazardly in a variably cellular and dense collagenous stroma. **B,** At high power the cytologic atypia and mitotic activity of the tumor cells is readily apparent.

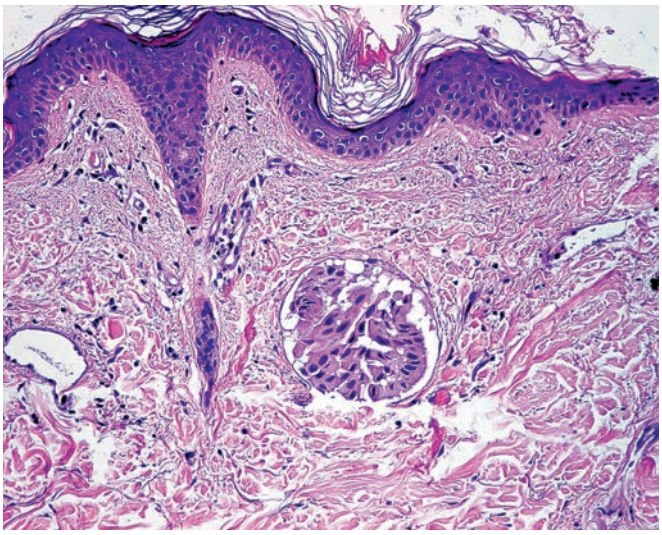

Figure 36.118 Large tumor embolus in a dermal lymph vessel in a case with the clinical appearance of inflammatory carcinoma.

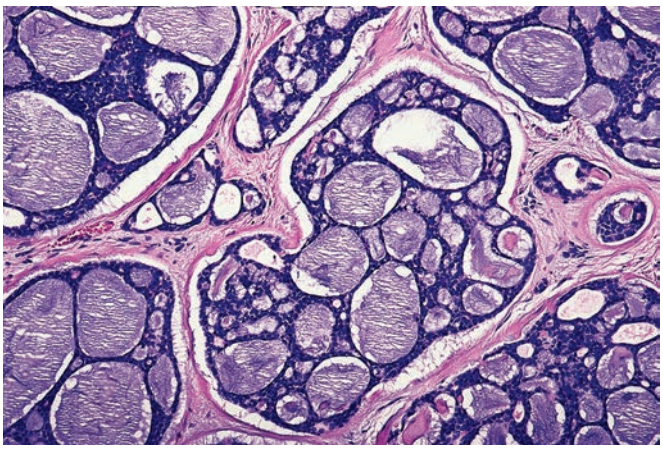

Figure 36.119 **Adenoid Cystic Carcinoma.** The appearance is similar to that of its more common homologue in salivary glands. The tumor is characterized by two types of cavity formation; true glandular lumina and pseudolumens containing basement membrane material surrounded by basal-myoepithelial cells, a feature that is more pronounced in this image.

the breast shows, as in the salivary glands, two types of lumen formation: true glandular lumina lined by cells which are positive for CK7 and 8/18, and pseudolumens containing eosinophilic basement membrane material and/or basophilic mucin surrounded by basal-myoepithelial cells which may express myoepithelial markers and basal cytokeratins (Fig. 36.119).[550] Foci of sebaceous differentiation may also be seen.[551] Perineural involvement may be present. Adenoid cystic carcinomas are typically ER, PR, and HER2 negative (i.e., they are "triple negative" tumors,[552] although they should not be equated with mammary carcinomas now bearing that catchy designation).[553] CD117 is usually expressed, mirroring the pattern of salivary gland adenoid cystic carcinoma; CD117 staining is not present in the previously mentioned simulators.[554,555] Like the homologous tumor occurring in the salivary gland, a distinctive chromosomal translocation, t(6;9) resulting in *MYB–NFIB* gene fusion is commonly found and the presence of nuclear MYB staining with IHC can be used to confirm the diagnosis in histologically ambiguous cases.[556,556a] Axillary lymph node metastases are extremely rare.[557,558] Some patients have developed local recurrence or pulmonary metastases many years after initial therapy,[557,559] but the prognosis for this tumor as a group is remarkably good.[560] The relationship between microscopic grading and prognosis is controversial.[557,561,562]

A solid variant of adenoid cystic carcinoma with basaloid features has been described in which the glandular lumens and pseudolumens with basement membrane material are more subtle. The tumor cell nuclei are usually higher grade, and mitoses and necrosis may be present (Fig. 36.120). The prognosis for these tumors appears to be less favorable, albeit with limited data.[561,562] As already mentioned, some cases of adenoid cystic carcinoma are seen in association with microglandular adenosis.[198]

Acinic Cell Carcinoma

As the name indicates, acinic cell carcinoma is highly reminiscent of the homologous tumor of the salivary gland with variable growth patterns, which include microcystic, microglandular, and solid, occasionally with comedo necrosis. The cells have abundant granular eosinophilic or clear cytoplasm with round nuclei and prominent

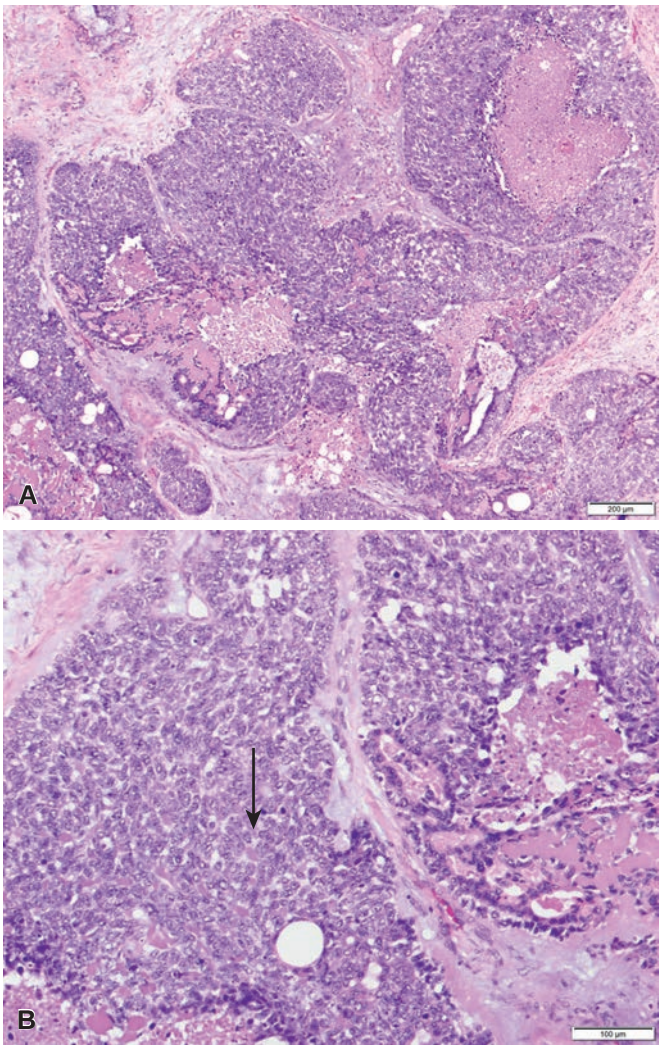

Figure 36.120 Solid Variant of Adenoid Cystic Carcinoma With Basaloid Features. A, At low power, solid nests of high-grade tumor cells with basaloid features and abundant necrosis are appreciated. Basement membrane material is also present at the lower left portion of the field. **B,** At higher power, pseudolumens with basement membrane material are confirmed to be present. The identification of true glandular lumens can be more challenging *(arrow).*

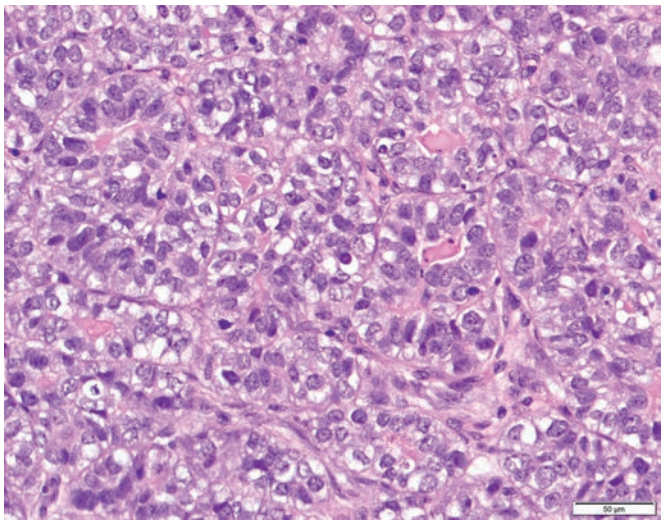

Figure 36.121 Acinic Cell Carcinoma of Breast. The cells have abundant eosinophilic or clear cytoplasm with round nuclei and prominent nucleoli. Coarse eosinophilic cytoplasmic granules can usually be identified.

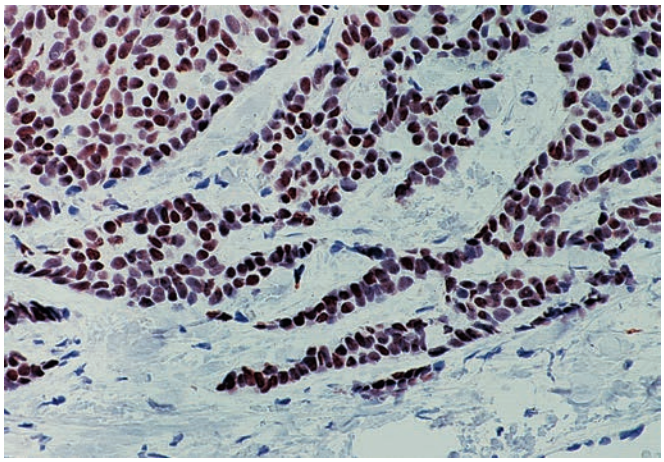

Figure 36.122 Immunostain for Estrogen Receptor in Invasive Ductal Carcinoma. Strong nuclear positivity of the tumor cells is shown.

nucleoli (Fig. 36.121). The cytoplasmic granules are coarse and bright pink. The similarities extend to the ultrastructural and immunohistochemical features, which include positivity with α1-antichymotrypsin, salivary gland amylase, and lysozyme.[563,564] Like secretory carcinomas, for which they can be a mimic, acinic cell carcinomas are triple negative and positive for S-100 protein. Notably acinic cell carcinomas do not show the t(12:15) *ETV6-NTRK3* rearrangement characteristic of secretory carcinoma.[565,566]

Other rare malignant breast tumors with similar counterparts in the salivary gland are **mucoepidermoid carcinoma,**[567] **polymorphous (low-grade) adenocarcinoma,**[568] **sebaceous carcinoma,**[569] **oncocytic carcinoma,**[570] and **basaloid carcinoma.**[571]

Glycogen-rich (clear cell) carcinoma is composed of large clear cells, which are found to contain abundant glycogen.[572–576] The differential diagnosis includes other breast tumors with clear cytoplasm, including adenomyoepithelioma, lipid-rich carcinoma, histiocytoid carcinoma, metastatic renal cell carcinoma, and the exceptionally rare tumors of perivascular epithelioid cells (PEComa).[572]

Hormone Receptors

A crucial development in the treatment of breast carcinoma was the recognition that the presence of hormone (estrogen and progesterone) receptors in the tumor tissue correlates well with response to hormone therapy and chemotherapy.[577] As a matter of fact, ER status is regarded as one of the most powerful predictive markers in breast cancer management.[578] ER and PR are codependent variables, PR being a weaker predictor of response to endocrine therapy than ER.[579] Initially, these hormone receptors were measured by the dextran-coated charcoal and sucrose gradient assay, but this has been replaced by the immunohistochemical method, on the grounds that it offers several important advantages (it does not require fresh tissue, it can be done with minute amounts of tumor, the location of the hormone receptor positivity can be visualized, etc.) (Fig. 36.122), correlation between the two methods is very good,[580,581] and technical ease of the immunohistochemical assay. Efforts have been made to semiquantitate the immunohistochemical method by standardizing the technical procedure and reporting and by using appropriate controls.[329,582,583] Delay in fixation has been reported to affect the results, whereas fixation time within reasonable boundaries

appears not to.[584] The ASCO and CAP have published guideline recommendations for immunohistochemical testing of ER and PR in breast specimens.[329,585] The guidelines have facilitated standardization of assay performance and reporting across laboratories in North America. Some of the more salient points of this document are the following:

- The pathologist must report the percentage of invasive tumor cells that are immunoreactive.
- Tumors having 1% or more invasive cancer cells staining are regarded as positive.
- The average intensity of the stain must be included (weak, moderate or strong).
- The pathologist must give an interpretation as to whether the sample is positive or negative.
- The use of a composite score based on percentage plus intensity (Allred, H, or Quick scores) is optional.
- Specimens should be placed in 10% neutral buffered formalin no later than 1 hour (but ideally much sooner) after being removed from the patient (cold ischemic time).
- Fixation time should be at least 6 hours and not longer than 72 hours.
- Normal breast cells in the sample should be used as internal positive controls and a comment about the adequacy of staining in the internal control provided.

Hormone receptors can also be evaluated in paraffin-embedded breast tissue by the in situ hybridization technique and by PCR.[586,587]

About 80% of breast cancers are ER positive, so that an ER-negative rate of greater than 30% suggests that some problems exist with the assay which need to be investigated and resolved.

ER-positive breast carcinomas tend to be better differentiated tumors; conversely ER-negative breast carcinomas tend to have grade 3 histology, the exception being some special type tumors, such as adenoid cystic carcinoma and secretory carcinoma. Most carcinomas with medullary features, metaplastic, and apocrine carcinomas are ER negative, whereas mucinous, tubular, and lobular carcinomas have a high rate of ER positivity. In DCIS, high nuclear grade is the best morphologic predictor of ER-negative status.[588,589] The positivity in LCIS is particularly strong, although this is not tested or reported in clinical practice.[590] It is very unusual for an ER-negative cancer to become ER-positive at the time of recurrence or metastasis, whereas the reverse is more common, especially if there has been intervening tamoxifen therapy.

Hormone receptor positivity also correlates with bcl2 immunoreactivity[591] and absence of *TP53* mutations[592] and correlates inversely with the presence of epidermal growth factor receptors (such as HER2).[593]

It should be pointed out that most breast carcinoma cells also have receptors for androgens, and that these may be found in the absence of estrogen and PR, a finding that is being exploited as a therapeutic option for patients with triple negative breast cancers.[594]

HER2

HER2 (c-*erb*B-2) is an oncogene that encodes a transmembrane glycoprotein with tyrosine kinase activity known as p185, which belongs to the family of epidermal growth factor receptors.[595] Approximately 15% of invasive breast cancers show HER2 gene amplification and protein overexpression.[596] Identification of HER2+ tumors is critically important in selecting patients for HER2-targeted therapies, such as trastuzumab. HER2 overexpression and amplification can be measured by immunohistochemistry or fluorescent in situ hybridization (FISH) (or its chromogenic equivalent), respectively,[597] and a good correlation exists between these methods (Fig. 36.123).[598]

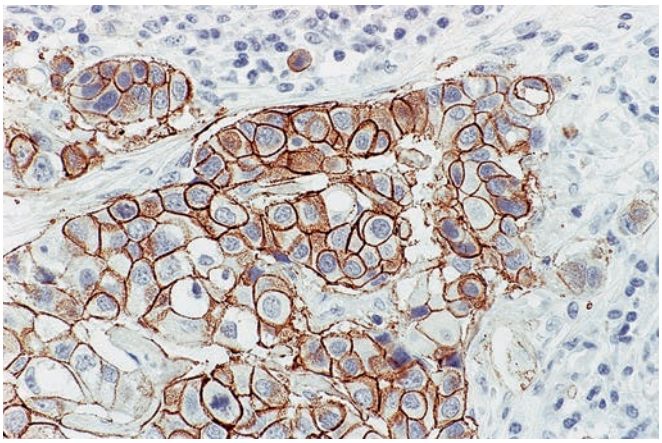

Figure 36.123 HER2-positive (3+) immunostain in high-grade invasive ductal carcinoma showing the required strong, complete, membranous pattern of staining in >10% of tumor cells.

The ASCO/CAP has published and updated guideline recommendations for HER2 testing in breast cancer.[599,600] According to this joint document, a *positive* HER2 result is:

- immunohistochemical staining of 3+ (uniform, intense membrane staining of greater than 10% of invasive tumor cells), or
- a FISH result of more than six *HER2* gene copies, or
- a FISH ratio (*HER2* gene signals to chromosome 17 signals) of greater than 2.0.

A *negative* HER2 result is:

- immunohistochemical staining of 0 or 1+, or
- a FISH result of less than 4.0 HER2 copies per nucleus, or
- a FISH ratio of less than 2.0.

An *equivocal* HER2 result is:

- immunohistochemical staining of 2+ (weak and moderate membrane staining in greater than 10% of tumor cells), or
- a FISH ratio of less than 2.0 *and* a FISH result of ≥4.0 and less than 6.0 copies per nucleus.

In the event of an equivocal IHC result, reflex testing to FISH is recommended. If the FISH test is equivocal, either reflex test to IHC using the same specimen, test with an alternative ISH chromosome 17 probe, or order a new test (new specimen if available, ISH or IHC).

Many laboratory directors have concluded that the best approach to HER2 testing from the point of view of cost effectiveness is to start with the immunohistochemical procedure, which is scored according to the ASCO/CAP guideline summarized in Table 36.4.[599] If the results are either 3+ or 0/1+, the determination can safely stop there, since the correlation with gene amplification or lack of it, respectively, as measured by FISH, is nearly 100%. If the IHC is 2+ (equivocal), the performance of FISH is recommended, and the result obtained tends to be regarded as the definitive result. Other laboratories perform both IHC and FISH on all cases because of the small possibility of a patient being HER2 positive by one or other of the tests.[601]

HER2 positivity by either technique is a very good predictor of response to trastuzumab. HER2-positive tumors are typically high-grade tumors. *HER2* amplification correlates inversely with estrogen and progesterone expression, though some hormone receptor positive tumors are also HER2 positive (~10% of all invasive breast carcinomas).[596]

HER2 heterogeneity is of sufficient importance that a CAP Expert Panel developed criteria to define it.[602] In 2009, this Expert

Table 36.4 Scoring of the immunohistochemical staining for HER2 overexpression

STAINING PATTERN	SCORE	HER2 PROTEIN OVEREXPRESSION ASSESSMENT
No staining is observed or faint, incomplete membrane staining is observed in ≤ 10% of tumor cells	0	Negative
Incomplete membrane staining that is faint/barely perceptible and within > 10% of tumor cells	1+	Negative
Weak and moderate complete membrane staining in >10% of tumor cells	2+	Equivocal
Circumferential membrane staining that is complete, intense, and within >10% of tumor cells	3+	Positive

Data from Wolff AC, Hammond ME, Hicks DG, et al. Recommendations for human epidermal growth factor receptor 2 testing in breast cancer: American Society of Clinical Oncology/College of American Pathologists clinical practice guideline update. *J Clin Oncol*. 2013;31(31):3997–4013.

Panel defined HER2 genetic heterogeneity as greater than 5% but less than 50% of invasive tumor cells, with an elevated ratio (then >2.2, now >2.0) in a dual probe ISH assay.[602] Approximately 20%–30% of cases are reported to be heterogeneous for HER2 amplification.[603,604]

Before leaving the topic of ER, PR, and HER2 in breast carcinoma, a few words need to be said about tumors that are negative for all three markers which are referred to as **triple negative tumors**.[605,606] Triple negative cancers overlap considerably with basal-like cancer (a tumor defined through gene-expression profiling studies, more fully discussed in the next section) and breast carcinomas arising in *BRCA1* mutation carriers. However, triple negative cancers are not synonymous with basal-like cancers—only 70%–80% of cases classified by gene expression profiling as basal-like show a triple negative phenotype, and conversely a similar, though not necessarily the same, proportion of triple negative cancers exhibit a basal-like gene expression profile.[607] Triple negative breast cancers represent a heterogeneous group of tumors, which most characteristically exhibit the following features: morphologically usually high-grade invasive ductal carcinoma of no special type, high degree of aneuploidy, and greater tendency to metastasize to lungs and brain.[605,606]

Molecular Genetics and Molecular Classification of Breast Cancer

Molecular Genetics

The development of invasive breast carcinoma involves multiple genetic alterations, as with other carcinomas of various anatomic sites. The genes most commonly affected, and consistently identified in breast cancer include: *PIK3CA*, *PTEN*, *AKT1*, *TP53*, *GATA3*, *CDH1*, *RB1*, *MLL3*, *MAP3K1*, and *CDKN1B*.[608] In addition, some types of breast carcinoma, such as secretory carcinoma, lobular carcinoma, and adenoid cystic carcinoma, exhibit distinctive genetic changes, as described in the respective sections.

Molecular Classification

The pioneering efforts of Perou and colleagues in 2000 to segregate breast cancers into distinct subgroups based on similarities in the gene expression profiles using a microarray platform has been enthusiastically embraced by the medical and scientific community, with the hope that this approach will provide new insights into the biology of breast cancers and impact therapeutic strategies.[609,610] The subtyping reported by this group has evolved into a molecular classification of breast cancer.

The subtypes of breast cancers most widely recognized by their gene expression signature include: luminal (type A and B), HER2 enriched, basal-like, and normal breast-like. The last subtype may represent an artifact rather than a genuine subtype of breast cancer, resulting from lack or paucity of tumor in the tissue samples used for the microarray analysis. The main features of the four molecular subtypes are summarized in Table 36.5. Among the various subtypes, the basal-like subtype is associated with the worst prognosis.[610] Since the different molecular subtypes of breast cancers exhibit specific characteristics, it is thought that more specific and targeted forms of therapy could be developed. Efforts have been made to use immunohistochemistry as a surrogate (such as a panel including antibodies to ER, PR, HER2, cytokeratin 5/6, EGFR, Ki-67) to assign tumors to the various molecular subtypes (Table 36.6),[611–614] but discordance is not uncommon, and there are currently no widely agreed upon criteria to define immunostain positivity for this purpose (particularly for Ki-67).

The current molecular classification of breast cancers still has drawbacks. The molecular subtypes were defined based on a relatively small number of cases, and some of the less common distinctive types of breast cancer (such as secretory carcinoma) were not included as part of the original analyses.[468,615] The basal-like subtype is highly heterogeneous and encompasses some tumors with a favorable prognosis, such as secretory carcinoma and adenoid cystic carcinoma, necessitating the creation of a "low-grade" category of basal-like carcinoma.[615] It is too simplistic to try to subsume the many different types of breast carcinoma into a few molecular categories, ignoring the known distinctive types with characteristic morphology and biologic features (such as invasive lobular carcinoma and secretory carcinoma).[616] In fact, additional molecular subtypes have since been identified, such as molecular apocrine, or luminal androgen receptor and claudin-low.[617–619]

Issues with standardization of analytic approaches, replication, attaining adequate sample size, and the evaluation of the clinical utility in heterogeneous populations apply to gene expression profiling studies as much as to any clinical trial with a component of pathologic testing and classification. In addition, how gene expression profiling can be applied to routine diagnosis and prognostication has yet to be fully determined. Further, although nearly every published microarray-based system can recognize molecular subtypes with similar survival and can also identify the basal-like subtype fairly consistently, the systems do not reliably assign the same patients to the same molecular groups for nonbasal-like tumors.[620]

Despite all the interest surrounding the molecular classification of breast cancers, currently the clinical value of characterizing invasive breast cancers beyond routine histologic type, histologic grade, and ER/PR/HER2 status has not been established; in fact it is these very characteristics that determine therapy.[614] Thus assignment of breast cancer cases to a molecular subtype is not a requirement at present,

Table 36.5 Major molecular subtypes of breast cancer determined by gene expression profiling

	MOLECULAR SUBTYPE			
	LUMINAL A-LIKE	**LUMINAL B-LIKE**	**HER2-ENRICHED**	**BASAL-LIKE[a]**
Gene expression pattern	Expression of luminal (low-molecular-weight) cytokeratins, and high expression of hormone receptors and associated genes	Expression of luminal (low-molecular-weight) cytokeratins and moderate to weak expression of progesterone receptor and associated genes	High expression of *HER2* and other genes in amplicon on 17q12 Low expression of ER and associated genes	High expression of basal epithelial genes, basal cytokeratins Low expression of ER and associated genes Low expression of HER2 related genes
Clinical and biologic features	~60% of invasive breast cancers ER/PR positive HER2 negative Low proliferation rate	~10% of invasive breast cancers ER positive, PR low positive HER2 expression variable (positive or negative) Intermediate or high proliferation rate (Ki-67 high) Luminal B tends to be higher histologic grade than luminal A	~15% of invasive breast cancers ER/PR negative HER2 positive (though not all HER2 enriched by molecular subtype are HER2+ by clinical definition) High proliferation rate *TP53* mutation common More likely to be high grade and node positive	~15% of invasive breast cancers Most ER/PR and HER2 negative ("triple negative") High proliferation rate *TP53* mutation common; *BRCA1* dysfunction (germline, sporadic) Particularly common in African–American women
Histologic correlation	Tubular carcinoma Cribriform carcinoma Low grade invasive ductal carcinoma NST[b] Classic lobular carcinoma	Invasive ductal carcinoma NST Micropapillary carcinoma	High-grade invasive ductal carcinoma NST	High-grade invasive ductal carcinoma NST Metaplastic carcinoma Carcinoma with medullary features
Treatment response and outcome	Respond to endocrine therapy Chemotherapy generally not indicated Good prognosis	Respond to endocrine therapy (tamoxifen and aromatase inhibitors) Response may not be as good as for luminal A Response to chemotherapy variable (greater than luminal A) Prognosis not as good as for luminal A	Respond to trastuzumab (Herceptin) Respond to anthracycline-based chemotherapy Generally poor prognosis, but better with HER2-targeted therapies	No response to endocrine therapy or trastuzumab (Herceptin) Appear to be sensitive to platinum-based chemotherapy and PARP inhibitors Generally poor prognosis (but not uniformly poor)

ER, Estrogen receptor; *PARP*, poly-adenosine diphosphate-ribose polymerase; *PR*, progesterone receptor; *NST*, no special type.
[a]There is a low-grade group of basal-like tumors that similarly express basal-type (high-molecular-weight) cytokeratin and have a triple negative phenotype, but with low proliferation (e.g., adenoid cystic carcinoma, secretory carcinoma).
[b]While classic lobular carcinoma usually exhibits luminal A features, pleomorphic lobular carcinoma often exhibits features of other molecular subtypes.

Table 36.6 Use of immunohistochemistry as surrogate marker for the molecular subtypes of breast cancer

	MOLECULAR SUBTYPE			
IMMUNOPROFILE	**LUMINAL A**	**LUMINAL B**	**HER2 ENRICHED**	**BASAL-LIKE**
ER, PR	ER+ and PR high+	ER+ and PR low or intermediate+	ER–, PR–	ER–, PR–
HER2	HER2–	HER2+ or HER2–	HER2+	HER2–
Others	Low Ki-67 (<14%)	Ki-67 ≥14%		CK5/6 and/or EGFR+

EGFR, Epidermal growth factor receptor; *ER*, estrogen receptor; *PR*, progesterone receptor.
Modified from Coates AS, Winer EP, Goldhirsch A, et al. Tailoring therapies—improving the management of early breast cancer: St Gallen International Expert Consensus on the Primary Therapy of Early Breast Cancer 2015. *Ann Oncol*. 2015;26(8):1533–1546.

though oncologists likely use the information provided in the pathology report to categorize tumors into their surrogate molecular subtypes.[621]

Oncologists treating patients with luminal-type breast cancers, that is, those with hormone receptor positive tumors, may opt for one of the genomic prognostic tests (e.g., Oncotype Dx, MammaPrint, PAM50, see later) to determine the need for adjuvant chemotherapy. Despite the relatively high cost of these tests, the human and economic benefits derived from a decision to avoid chemotherapy when the test result indicates a low risk of recurrence are enormous.[613,622–624]

Extent, Local Recurrence, and Metastases

Breast carcinoma spreads by direct invasion, by the lymphatic route, and by the hematogenous route. Some of these metastases are already present at the time of diagnosis, and others become manifest clinically months, years, or decades after initial diagnosis and treatment. Local invasion can occur into the nipple, skin, pectoralis fascia and muscle, or other structures of the chest wall.

The frequency of microscopic extension beyond the gross confines of the tumor was evaluated by Rosen et al. by performing a simulated "local excision" with a 2-cm gross margin in mastectomy specimens. Of 18 mastectomies performed for carcinoma measuring less than 1 cm, residual invasive carcinoma was found in 11% and residual DCIS in an additional 22%; this is particularly so for invasive lobular carcinoma.[625,626] The importance of a thorough pathologic evaluation of extent of breast carcinoma and the status of the margins is paramount because of the large number of conservative surgical procedures being performed.[627,628]

A somewhat related problem is that of microscopic involvement of the nipple by DCIS, since this structure is left in place when a local excision is carried out. Nipple involvement has been found in about 12% of all clinically detectable invasive carcinomas,[629] which is increasingly relevant in an era of nipple-sparing mastectomy. Evaluation of the shaved resection margin below the nipple is indicated in this procedure.[630]

Local recurrence following mastectomy appears as superficial nodules in or near the surgical scar or as subcutaneous parasternal nodules. Their malignant nature should always be documented by biopsy because the condition can be closely simulated by foreign body granulomas and infectious processes.

Tumor recurrence following local excision usually develops in the same breast quadrant, a fact that led some authors to recommend a primary excision technique that removes en bloc the tumor mass and the associated duct system.[631] However, contemporary excisions are more conservative because of the frequent use of adjuvant radiation therapy.

The two lymph node stations typically involved by metastatic breast carcinoma are the axilla and the internal mammary chain, with the supraclavicular area representing an extension of the former. It should be remembered that it is not too unusual also to find lymph nodes within the substance of the mammary gland ("intramammary lymph nodes"). Axillary lymph node metastases are present in approximately 30% of cases [632] and are divided into levels according to their topographic relation with the insertion of the pectoralis minor muscle: low or proximal, medium, and high or distal. When extensively involved by metastatic carcinoma, the axillary lymph nodes are palpable, but the margin of error with clinical examination is high. Careful dissection and microscopic examination of the submitted lymph nodes by the pathologist is important for accurate staging of the patient. Supraclavicular lymph node involvement is reported to be present in close to 20% of patients with axillary lymph node involvement but is almost zero in cases with negative axillae.[633]

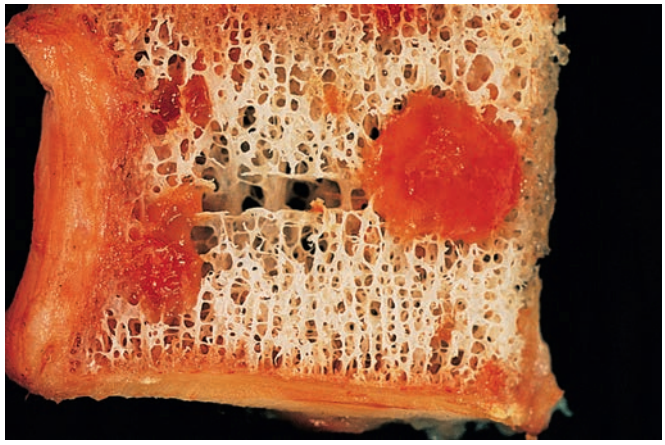

Figure 36.124 Breast Carcinoma Metastatic to Vertebra. The normal bone marrow has been flushed out by placing a thin slice of tissue under a strong jet of water.

The second major lymph node drainage area is to the internal mammary chain, which lies at the anterior ends of the intercostal spaces by the side of the internal thoracic artery. The overall incidence of metastatic involvement of this chain in patients with clinically detectable axillary lymph node metastases is approximately 20%.[634] Rarely, a metastatic lymph node will appear entirely necrotic and may simulate an infectious process; immunostains for keratin may be useful in aiding detection of necrotic tumor cells.

Distant metastases are seen most commonly in the skeletal system (Fig. 36.124), lung and pleura, liver, ovary, adrenal gland, and central nervous system (including leptomeninges and eyes)[635, 636] and vary according to breast cancer subtype, with the hormone receptor–positive, HER2-negative subtype having a higher rate of lymph node metastasis at diagnosis than the triple negative subtype.[637] Invasive lobular carcinoma (including the signet ring variant) has a propensity to metastasize to the abdominal cavity, particularly to the gastrointestinal tract (Fig. 36.125), ovaries, and serosal surfaces.[638,639]

In the presence of metastatic deposits of unknown source to lung and other sites, immunoreactivity for breast markers GCDFP-15, mammaglobin, GATA3, as well as hormone receptors, strongly suggests a breast primary.[412,640–642] Metastases of breast carcinoma to the ovary are likely to be positive for the aforementioned breast markers and negative for WT1, CA125, and PAX8, whereas the reverse is true, with the exception of ER, for primary ovarian carcinoma.[412,643,644]

The pattern of metastatic spread of breast carcinoma as evaluated by Fisher et al.[645] in a large randomized series of patients treated with various modalities brought them to the following conclusions: there is no orderly pattern of tumor dissemination; regional nodes are ineffective as barriers to tumor spread and, when positive, are more an indicator of a particular host–tumor relationship than the instigator of distant metastases; hematogenous spread is of considerable importance in tumor dissemination; complex host–tumor interrelationships affect every facet of the disease; operable breast carcinoma is a systemic disease; and variations in local–regional therapy are unlikely to substantially affect survival.[646]

Occult Breast Carcinoma

Sometimes a single enlarged axillary lymph node in an adult female is found to be involved by metastatic nonlymphoid tumor in the presence of a clinically and radiographically normal breast, with no evidence of tumor elsewhere. When this situation arises, the diagnosis will be metastatic breast carcinoma or metastatic malignant melanoma

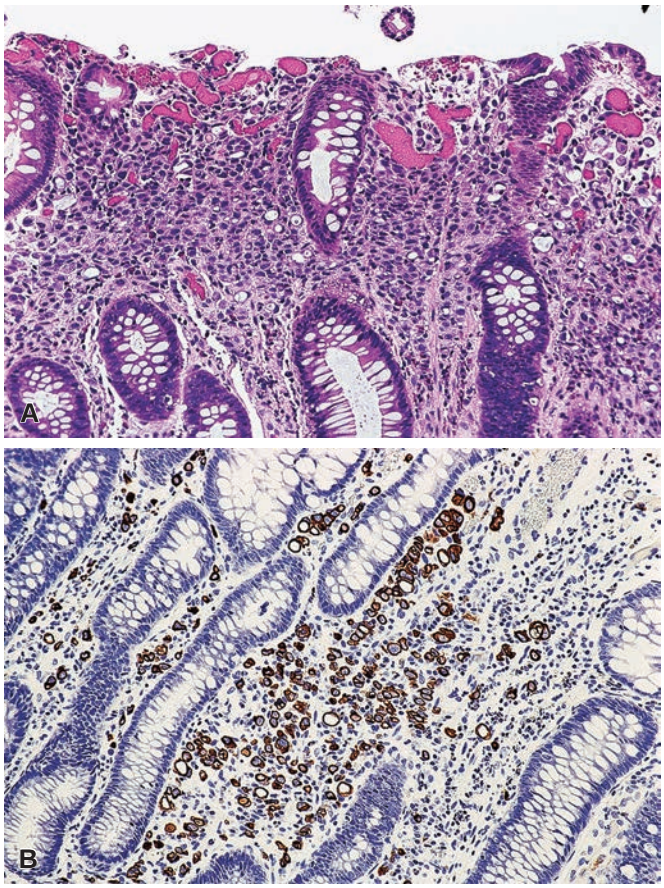

Figure 36.125 **A** and **B,** Metastasis of mammary lobular carcinoma to lamina propria of large bowel mucosa. **B,** Cytokeratin 7 immunostain.

in over 90% of cases. Making the distinction between carcinoma and melanoma should be possible in nearly every case from the combination of morphologic features and immunohistochemical stains, including cytokeratins, GCDFP-15, mammaglobin, GATA3, S-100 protein, HMB-45, and other markers. A note of caution is in order regarding the interpretation of the immunostains, since S-100 protein (originally thought to be very distinctive of melanoma in this situation) is now known to stain a high number of breast carcinomas and, some melanomas may show aberrant expression of cytokeratin. MRI is indicated to attempt to establish the location of the tumor. If the combined approach has shown that: (1) the tumor is a carcinoma rather than a melanoma; (2) the appearance of this carcinoma is compatible with breast origin; and (3) there is no clinicoradiographic evidence of tumor elsewhere, treatment options include ipsilateral mastectomy, whole breast irradiation, and even chemotherapy.[647–649] A primary tumor, which can be extremely small, will be found in most cases.[647–649] It appears from the limited data available that those women who undergo mastectomy fare better than those who elect to have breast irradiation.[647,649]

Occasionally, occult carcinomas are found on routine microscopic examination of a reduction mammoplasty specimen.[262] As already pointed out, these are almost always in situ rather than invasive tumors.

Sentinel Lymph Node

First pioneered in the early 1990s, the technique of sentinel lymph node biopsy for the evaluation and management of breast carcinoma has gained enormous popularity and has become the standard of care.[650] The procedure is based on the concept that if the sentinel node is negative, the other nodes of that group will also be negative in nearly all instances, whereas if it is positive, the chance that there will be additional metastases in that nodal group is about one-third.[344,651,652] In most substantial series the size of the primary tumor and the presence of lymphovascular invasion have been found to be significant predictors of positive sentinel lymph nodes.[653,654] The goal of sentinel lymph node examination is to identify macrometastases (>2 mm), which can be achieved by sectioning the lymph nodes at 2-mm intervals and examining one H&E section.[655] The use of enhanced techniques, such as step-sectioning or performing immunostains for cytokeratin to identify occult metastases, are not routinely indicated, as their identification does not translate into additional clinical benefit.[656,657] Molecular evaluation with RT-PCR (searching for the mammaglobin genes *MGB1* and *MGB2* or CK19 mRNA) offers an alternate method for identifying lymph node metastases[658]; however, these techniques have not been widely adopted in the United States, for the reasons stated previously.

Pitfalls in the interpretation of lymph nodes include keratin-positive reticulum cells indigenous in the lymph node (which may become quite hyperplastic and which have a typical dendritic morphology; use of AE1/AE3 and avoiding CAM5.2 will prevent this error), benign glandular inclusions, endosalpingiosis and other epithelial tissue, as well as traumatic displacement of breast epithelium.[27,659,660] Of these various traps, the one that presents the greatest challenge is that of *mechanical transport*, that is, the possibility that the biopsy procedure may push either normal or neoplastic epithelial cells into mammary lymphatic spaces, from which they could find their way into the sentinel lymph node.[659,660] This phenomenon likely does occur, as supported by the fact that it is seen more commonly in those patients in whom such instrumentation procedures were carried out.[661] It is also credible that it may involve both tumor and normal cells. Alas, it is also too evident that the distinction between normal and neoplastic epithelial cells for these isolated nodal-based epithelial cells is anything but easy.[662,663] Suffice it to say that, for practical purposes, it has been recommended that the term *micrometastases* be applied to a cluster of tumor cells greater than 0.2 mm (>200 cells) but ≤2 mm and that the term *isolated tumor cells* be used for the presence of single cells interpreted as malignant totaling fewer than 200 cells or ≤0.2 mm in greatest dimension. Cells that appear degenerated and that are associated with hemosiderin-laden macrophages are favored to be displaced.

As mentioned previously, the identification of isolated tumor cells and even micrometastases has little impact on patient management; further, the management of the axilla in patients with 1–3 lymph nodes with macrometastases and no extranodal extension has evolved to become less invasive. The ACSOG Z0011 trial demonstrated no significant differences in outcome for patients with the aforementioned findings undergoing completion axillary dissection versus those managed with wide local excision, whole breast irradiation, and sentinel lymph node biopsy alone.[344] This has translated into fewer intraoperative sentinel lymph node evaluations and fewer completion axillary dissections.[664,665]

Staging of Breast Carcinoma

The most widely used clinical staging system for breast carcinoma is the one adopted by both the International Union for Cancer Control (UICC) and the American Joint Commission on Cancer (AJCC). It is based on the TNM system (T, tumor; N, nodes; M, metastases) and is shown in (Table 36.7).[666] There are two stage group tables: the anatomic stage group table and the prognostic

Table 36.7 Definitions of AJCC TNM for breast carcinoma

Definition of Primary Tumor (T) — Clinical and Pathological

T CATEGORY	T CRITERIA
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis (DCIS)*	Ductal carcinoma in situ
Tis (Paget)	Paget disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget disease should still be noted.
T1	Tumor ≤ 20 mm in greatest dimension
T1mi	Tumor ≤ 1 mm in greatest dimension
T1a	Tumor > 1 mm but ≤ 5 mm in greatest dimension (round any measurement 1.0-1.9 mm to 2 mm)
T1b	Tumor > 5 mm but ≤ 10 mm in greatest dimension
T1c	Tumor > 10 mm but ≤ 20 mm in greatest dimension
T2	Tumor > 20 mm but ≤ 50 mm in greatest dimension
T3	Tumor > 50 mm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall and/or to the skin (ulceration or macroscopic nodules); invasion of the dermis alone does not qualify as T4
T4a	Extension to the chest wall; invasion or adherence to pectoralis muscle in the absence of invasion of chest wall structures does not qualify as T4
T4b	Ulceration and/or ipsilateral macroscopic satellite nodules and/or edema (including peau d'orange) of the skin that does not meet the criterial for inflammatory carcinoma
T4c	Both T4a and T4b are present
T4d	Inflammatory carcinoma

Definition of Regional Lymph Nodes — Clinical (cN)†

cN CATEGORY	cN CRITERIA
cNX‡	Regional lymph nodes cannot be assessed (e.g., previously removed)
cN0	No regional lymph node metastases (by imaging or clinical examination)
cN1	Metastases to movable ipsilateral Level I, II, axillary lymph node(s)
cN1mi§	Micrometastases (approximately 200 cells, larger than 0.2 mm, but none larger than 2.0 mm)

Definition of Regional Lymph Nodes — Clinical (cN)†

CN CATEGORY	CN CRITERIA
cN2	Metastases in ipsilateral Level I, II axillary lymph nodes that are clinically fixed or matted; *or* in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN2a	Metastases in ipsilateral Level I, II axillary lymph nodes fixed to one another (matted) or to other structures
cN2b	Metastases only in ipsilateral internal mammary nodes in the absence of axillary lymph node metastases
cN3	Metastases in ipsilateral infraclavicular (Level III axillary) lymph node(s) with or without Level I, II axillary lymph node involvement; *or* in ipsilateral internal mammary lymph node(s) with Level I, II axillary lymph node metastases; *or* metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
cN3a	Metastases in ipsilateral infraclavicular lymph node(s)
cN3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
cN3c	Metastases in ipsilateral supraclavicular lymph node(s)

Definition of Regional Lymph Nodes — Pathological (pN)¶

pN CATEGORY	pN CRITERIA
pNX	Regional lymph nodes cannot be assessed (e.g., not removed for pathological study or previously removed)
pN0	No regional lymph node metastasis identified or ITCs only
pN0(i+)	ITCs only (malignant cell clusters no larger than 0.2 mm) in regional lymph node(s)
pN0(mol+)	Positive molecular findings by reverse transcriptase polymerase chain reaction (RT-PCR); no ITCs detected
pN1	Micrometastases; or metastases in 1-3 axillary lymph nodes; and/or clinically negative internal mammary nodes with micrometastases by sentinel node biopsy
pN1mi	Micrometastases (approximately 200 cells, larger than 0.2 mm, but none larger than 2.0 mm)
pN1a	Metastases in 1-3 axillary lymph nodes, at least one metastasis larger than 2.0 mm
pN1b	Metastases in ipsilateral internal mammary sentinel nodes, excluding ITCs
pN1c	pN1a and pN1b combined

Table 36.7 Definitions of AJCC TNM for breast carcinoma—cont'd

Definition of Regional Lymph Nodes — Pathological (pN)¶	
pN CATEGORY	**pN CRITERIA**
pN2	Metastases in 4-9 axillary lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the absence of axillary lymph node metastases
pN2a	Metastases in 4-9 axillary lymph nodes (at least one tumor deposit larger than 2.0 mm)
pN2b	Metastases in clinically detected internal mammary lymph nodes with or without microscopic confirmation; with pathologically negative axillary nodes
pN3	Metastases in 10 or more axillary lymph nodes; *or* in infraclavicular (Level III axillary) lymph nodes; or positive ipsilateral internal mammary lymph nodes by imaging in the presence of one or more positive Level I, II axillary lymph nodes; *or* in more than three axillary lymph nodes and micrometastases or macrometastases by sentinel lymph node biopsy in clinically negative ipsilateral internal mammary lymph nodes; *or* in ipsilateral supraclavicular lymph nodes
pN3a	Metastases in 10 or more axillary lymph nodes (at least one tumor deposit larger than 2.0 mm); *or* metastases to the infraclavicular (Level III axillary lymph) nodes
pN3b	pN1a or pN2a in the presence of cN2b (positive internal mammary nodes by imaging); *or* pN2a in the presence of pN1b
pN3c	Metastases in ipsilateral supraclavicular lymph nodes

Definition of Distant Metastasis (M)	
M CATEGORY	**M CRITERIA**
M0	No clinical or radiographic evidence of distant metastases**
cM0(i+)	No clinical or radiographic evidence of distant metastases in the presence of tumor cells or deposits no larger than 0.2 mm detected microscopically or by molecular techniques in circulating blood, bone marrow, or other nonregional nodal tissue in a patient without symptoms or signs of metastases
M1	Distant metastases detected by clinical and radiographic means (cM) and/or histologically proven metastases larger than 0.2 mm (pM)

From Amin M, Edge S, Greene F, et al. (Eds.). AJCC Cancer Staging Manual. Ed. 8. New York: Springer; 2017.
*Note: Lobular carcinoma in situ (LCIS) is a benign entity and is removed from TNM staging in the AJCC Cancer Staging Manual, 8th edition.
†Note: (sn) and (f) suffixes should be added to the N category to denote confirmation of metastasis by sentinel node biopsy or fine needle aspiration/core needle biopsy respectively.
‡The cNX category is used sparingly in cases where regional lymph nodes have previously been surgically removed or where there is no documentation of physical examination of the axilla.
§cN1mi is rarely used but may be appropriate in cases where sentinel node biopsy is performed before tumor resection, most likely to occur in cases treated with neoadjuvant therapy.
¶Note: (sn) and (f) suffixes should be added to the N category to denote confirmation of metastasis by sentinel node biopsy or FNA/core needle biopsy respectively; with NO further resection.
**Note that imaging studies are not required to assign the cM0 category.

stage group table. Cancer registries and U.S. physicians must use the prognostic stage group table for reporting. Pathology synoptic reports need only report the biomarker status so that the prognostic stage group table may be appropriately assigned.

Therapy for Breast Carcinoma

Therapy for breast carcinoma includes surgery, radiation therapy, hormonal therapy, chemotherapy, and targeted therapy, depending on the type and extent of the disease.[667]

Surgical therapy, historically synonymous with Halsted's radical mastectomy, now includes a wide variety of options, such as partial mastectomy (lumpectomy, segmentectomy, or quadrantectomy, i.e., breast-conserving surgeries) and total (simple) mastectomy. The procedure selected is influenced by many factors, including tumor stage, patient preference and breast size, the surgeon's practice, whether or not reconstructive surgery is available, and geographic region.[668–670]

Radiation therapy is often employed as a postoperative adjunct (especially in more limited operations), as well as for control of locally recurrent disease.[671,672]

Microscopic evaluation of all surgical margins in breast-conserving surgery and of the deep margin in mastectomy is critical to determining the need for additional surgery and/or radiation therapy. A recent meta-analysis has endorsed the definition of ink on tumor (either invasive or DCIS) as being required for a positive margin in patients with invasive carcinoma being treated with breast-conserving surgery and whole breast irradiation. Anything less should be reported as a negative margin and the distance in millimeters reported.[673] Several studies have shown that patients with positive margins are more likely to develop local recurrence, as well as distant failure.[674–676] For margin-negative cases, the likelihood of ipsilateral breast failure and distant metastases is related to the amount of carcinoma near the margins.[677] Margin width is also a factor influencing recurrence among women with DCIS, particularly among those who forgo radiation

therapy.[678] A recent meta-analysis indicates that a 2-mm margin is desirable for patients with DCIS.[679] There is no requirement to report the margin status for classical LCIS, though reporting of margin status is recommended for the variant forms of LCIS, such as pleomorphic LCIS.

Endocrine therapy is the standard of care for all patients with ER-positive breast cancer.[680] At present, administration of a selective estrogen receptor modulator (SERM, e.g., tamoxifen) or an aromatase inhibitor in postmenopausal women (e.g., anastrazole) is the standard of care for early-stage, hormone receptor–positive breast carcinoma, usually combined with irradiation, with or without adjuvant chemotherapy, depending on the patient's age and other parameters.[680] Hormonal therapy, which had historically included the options of bilateral oophorectomy, adrenalectomy, and hypophysectomy, is now largely dependent on the aforementioned antiestrogen drugs.

Trastuzumab (Herceptin), a humanized monoclonal antibody against the HER2 receptor, is a form of targeted therapy that is effective for breast cancers that are HER2 positive (score 3+ by immunohistochemistry or *HER2* amplified by FISH studies). Although originally used only for patients with metastatic disease, the drug is now standard of care as an adjuvant agent for early-stage breast cancer as well.[681] Furthermore, newer agents against HER2 and its related receptors are becoming increasingly available either as alternate therapeutic options or as second-line therapy at the time of recurrence or metastasis.

Chemotherapy has had a significant impact on the survival of patients with metastatic breast carcinoma, the best results having been obtained with combination regimens. In addition, chemotherapy is currently used as an adjunct following local treatment, with curative intent, in patients with positive axillary nodes. The interested reader should refer to clinical texts for further information.[682] The value of platinum-based chemotherapeutic agents and of PARP inhibitors for treatment of breast cancers with specific DNA repair defects, including those arising in carriers of *BRCA1* or *BRCA2* mutation and basal-type breast cancers, have also shown promise.[683]

Effects of Therapy on the Tumor and on Normal Breast

Radiation therapy of breast carcinoma may result in bizarre nuclear changes, formation of giant tumor cells, naked nuclei, and abnormal mitotic figures. Extensive tumor necrosis may develop, which can become surrounded by a thick fibrous wall. It is important to remember that morphologic viability is not necessarily equivalent to biologic viability (i.e., the capacity of the tumor cell to replicate). In the non-neoplastic breast, the most characteristic irradiation effect is atypia of epithelial cells in the terminal ductules, associated with lobular sclerosis and atrophy (Fig. 36.126).[684] These postradiation changes can persist for years.[685]

Treatment of ER-positive tumors with endocrine therapy leads to prominent stromal fibrosis and hyalinization, an increase in the amount of elastic tissue, and degenerative changes in the tumor cells. The latter are manifested by cytoplasmic vacuolization, rupture of cell membranes, nuclear aberrations, and eventual necrosis. These changes may occur both in the primary tumor and in the metastases, and can be very patchy, in the sense of showing morphologically unaffected cells lying side by side with highly altered cells.

Chemotherapy can also induce striking morphologic changes in the tumor cells (Fig. 36.127), including such a degree of vacuolization as to simulate histiocytes. It also results in atrophy of the TDLU, with occasional atypia of the normal epithelial cells.[686] In most instances, treatment with neoadjuvant chemotherapy does not affect the histologic grading of the carcinoma; however, in some cases the tumor may appear to be higher grade (due to greater nuclear pleomorphism) or even lower grade (due to the identification of fewer mitoses).[687] The microscopic features of the treated tumor correlate poorly with patient outcome.[687] In some cases the residual tumor is present exclusively or predominantly as lymphatic emboli, a prognostically unfavorable feature.[688]

Guidelines have been published detailing appropriate gross examination, sampling, and reporting of breast carcinomas after neoadjuvant therapy.[687] In such patients, careful examination of the tumor bed, which is characterized by a hyalinized vascular stroma with fibroelastosis and edema infiltrated by histiocytes (Fig. 36.128), is critical to confirming the degree of pathologic response, particularly in the absence of any residual foci of invasive carcinoma. There are a variety of classification schemes in use to score the degree of tumor response with the two best known being the Residual Cancer Burden score and the Miller-Payne grade (Table 36.8).[689,690]

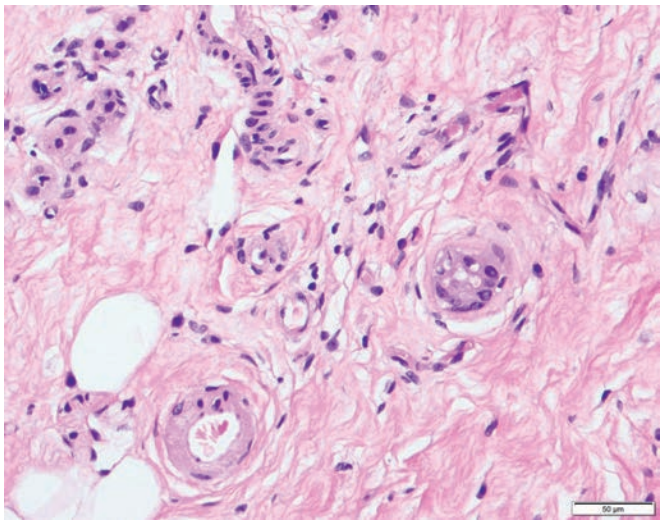

Figure 36.126 Radiation Effect in Non-Neoplastic Breast. The epithelial cells of the lobules show cytomegaly with smudgy nuclear features and cytoplasmic vacuolation associated with lobular sclerosis and atrophy. Note the absence of any epithelial proliferation.

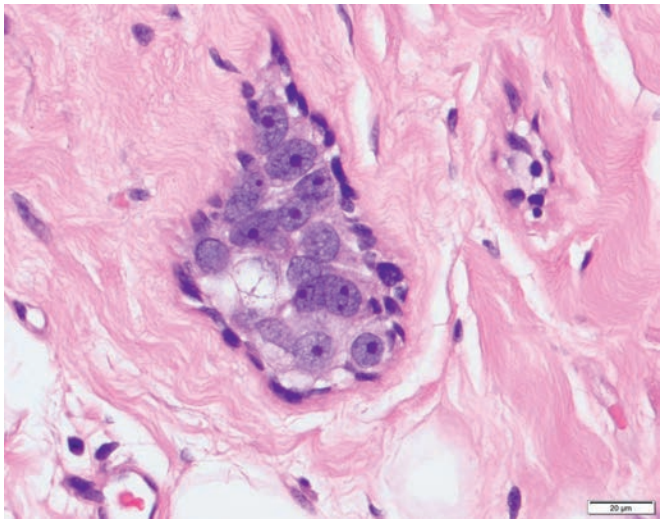

Figure 36.127 Chemotherapy Effect. Residual ductal carcinoma showing the effects of chemotherapy: nuclear enlargement, prominent nucleoli, and cellular vacuolization.

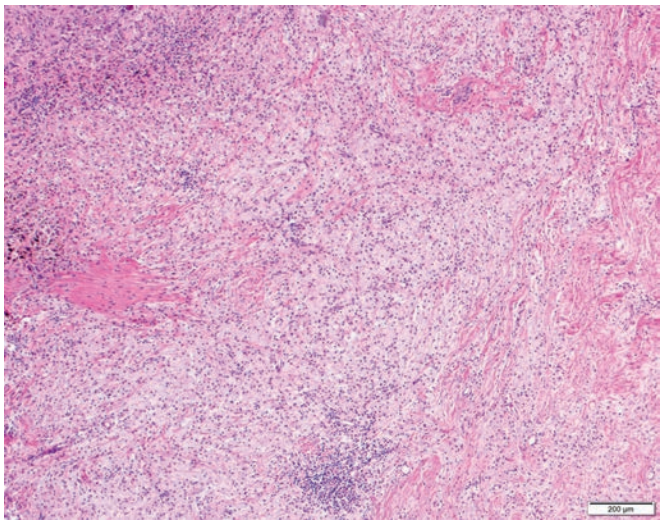

Figure 36.128 Tumor bed which is characterized by a hyalinized vascular stroma with fibroelastosis and edema infiltrated by histiocytes. Lymphocytes and hemosiderin are also noted in this field.

Table 36.8 Classification of neoadjuvant-treated breast cancers

Residual Cancer Burden (RCB)[689] Used in conjunction with MD Anderson Website Calculator (http://www3.mdanderson.org/app/medcalc/index.cfm?pagename=jsconvert3)

CATEGORY	DEFINITION
RCB-0 (pCR)	No carcinoma in breast or lymph nodes
RCB-I	Partial response
RCB-II	Partial response
RCB-III	Chemoresistant

Miller-Payne System

GRADE	DESCRIPTION OF RESPONSE
Grade 1	No change or some alteration to individual malignant cells, but no reduction in overall cellularity
Grade 2	A minor loss of tumor cells but overall cellularity remains high; up to 30% loss
Grade 3	Between an estimated 30% and 90% reduction in tumor cell volume
Grade 4	A marked disappearance of tumor cells (>90% reduction); only small clusters or widely dispersed individual cells remain
Grade 5	No malignant cells identifiable; only tumor bed present. May have DCIS or LVI present

DCIS, Ductal carcinoma in situ; *LVI*, lymphovascular space invasion.
Data from Symmans WF, Peintinger F, Hatzis C, et al. Measurement of residual breast cancer burden to predict survival after neoadjuvant chemotherapy. *J Clin Oncol*. 2007;25(28):4414–4422; and Ogston KN, Miller ID, Payne S, et al. A new histological grading system to assess response of breast cancers to primary chemotherapy: prognostic significance and survival. *Breast*. 2003;12(5):320–327.

Another "treatment-related" effect worthy of comment relates to the use of breast implants for reconstructive purposes. The implants frequently develop a fibrous capsule around them, and the inside surface of this capsule has a tendency to undergo *synovial metaplasia*, which on occasion may become quite hyperplastic. Sometimes, the capsule is surrounded by benign squamous epithelium,[691] and, very rarely, implant-associated anaplastic lymphoma may occur (see later).[692,693]

Prognosis

The prognosis of breast carcinoma is related to a huge number of clinical and pathologic features, some of which are discussed later, often with conflicting reports as to the level of risk associated with any particular putative prognostic factor.

Patient age. Older, postmenopausal women have the best prognosis as these patients tend to have the better differentiated, ER-positive, screen-detected tumors presenting at a lower stage, though, of course, this age group will have competing morbidities that will affect survival data. As far as tumors occurring in young women (≤35 or <40 years of age), studies have shown young age to be an independent risk factor associated with a propensity for recurrence and distant metastases despite more aggressive therapies, related to the fact that these patients tend to have adverse histologic features, often have had delays in diagnosis, and thus present at a later/higher stage.[694–697]

BRCA. Early studies suggested that breast carcinomas developing in *BRCA1* mutation carriers were associated with worse overall survival if adjuvant therapy was not given, but a large study of Israeli women carriers of *BRCA1* and *BRCA2* mutations showed that their breast cancer–specific death rates were similar to those of noncarriers.[698] At this time, mutation status is not considered to be an independent predictor of clinical outcome.[666]

Pregnancy and oral contraceptives. There is general agreement that carcinoma of the breast manifesting during pregnancy or lactation is generally an aggressive tumor with low expression of hormone receptors and high expression of HER2 and that it is associated with an overall poorer prognosis.[699,700] However, it has been found that this difference does not reach statistical significance when evaluated stage for stage.[701,702]

No convincing evidence has been found that prior use of oral contraceptive agents has an effect on the evolution or survival of patients with breast carcinoma.[703]

Early diagnosis. The relative 5-, 10-, and 20-year survival rates for asymptomatic breast carcinomas detected in a large screening project (Breast Cancer Demonstration Detection Project) were 87%, 79%, and 78.2%, respectively.[311,704] These figures are much higher than those for clinically detectable carcinoma and relate to the fact that the tumors were small in most cases, were usually devoid of axillary metastases, and included a high percentage of microscopically favorable types.

Size. The diameter of the primary tumor shows a good correlation with the incidence of nodal metastases and with survival rate, with the notable exception of basal-like carcinomas which do not follow the "size–node rule," that is, small triple negative cancers may be lymph node positive and vice versa.[605,611,705,706] As a matter of fact, this easily, quickly, and cheaply determined parameter has been found to be one of the strongest predictors of dissemination and rate of relapse in node-negative breast carcinomas.[707] It should be noted that in tumors having both DCIS and an invasive component, the size of the latter, as measured microscopically, is a better predictor than is the total tumor size, hence the staging guideline for reporting microscopic size of the invasive component as the T-stage.[666,706,708]

Site. No relationship has been found in most studies between prognosis and the quadrant location of the primary tumor. However, in one large study, it was found that medial location of the tumor was associated with a risk of tumor-related death when compared with lateral location but not with local tumor control.[709–711]

Histologic type. There is no significant prognostic difference between ordinary invasive ductal and invasive lobular carcinoma.[712] Morphologic variants of invasive ductal carcinoma with a more favorable prognosis are tubular carcinoma, invasive cribriform carcinoma, pure mucinous carcinoma, adenoid cystic carcinoma, and secretory carcinoma.[210,713] A variant of invasive lobular (and sometimes ductal) carcinoma associated with a poor prognosis is signet ring carcinoma and the prognosis of inflammatory carcinoma (as defined microscopically, see next) is also particularly ominous. Metaplastic carcinomas show similar survival rates to invasive carcinomas of no special type.[210]

Microscopic grade. Since both architecture and cytology have been found to correlate with prognosis, Elston and Ellis championed a modification of the original Bloom and Richardson[714] and Black et al.[715] grading schemes, which were based on tubule formation and degree of nuclear atypia, respectively. This has come to be known as the Nottingham modification of the Bloom–Richardson system; it also incorporates evaluation of mitotic activity.[716] In this scheme, the grade is obtained by adding up the scores for tubule formation, nuclear pleomorphism, and mitotic count, each of which is given 1, 2, or 3 points. This is translated into the final grade by formulae outlined in Box 36.1 and Tables 36.9 and 36.10. The utility of this and related grading systems has been convincingly and repeatedly proven[717,718] to the point that incorporation of this information into the routine pathology report has become a requirement.[666] Further, an acceptable degree of interobserver reproducibility has been achieved when the criteria are applied.[719,720] The system was largely conceived for invasive ductal carcinoma NST, but it can also be applied to the special types of ductal carcinoma and to invasive lobular carcinoma.[721]

Box 36.1 Microscopic grading of breast carcinoma: Nottingham modification of the Bloom–Richardson system

Tubule formation

1 point: Tubule formation in >75% of the tumor
2 points: Tubule formation in 10%–75% of the tumor
3 points: Tubule formation in <10% of the tumor

Nuclear pleomorphism

1 point: Nuclei with minimal variation in size and shape
2 points: Nuclei with moderate variation in size and shape
3 points: Nuclei with marked variation in size and shape

Mitotic count

1, 2, or 3 points, according to Table 36.9.

Table 36.9 Assignment of points for mitotic counts according to the field diameter

Field diameter (mm)	0.44	0.59	0.63
Mitotic count			
1 point	0–5	0–9	0–11
2 points	6–10	10–19	12–22
3 points	>11	>20	>23

Tumor-infiltrating lymphocytes (TILs). Emerging data indicate that patients with breast carcinomas demonstrating a prominent lymphocytic reaction, particularly triple negative and HER2-positive tumors, have a better response to neoadjuvant chemotherapy than those tumors without.[722] Similarly, patients with triple negative or HER2-positive tumors and a prominent lymphocytic reaction receiving adjuvant chemotherapy appear to have a survival advantage over those without TILs.[722,723] No significant differences are noted for patients with hormone receptor–positive, HER2-negative disease according to TIL status.[722] At this point in time, however, there are no agreed-upon criteria for counting TILs or on how to report an "immune-score."

HER2. As already stated, overexpression or amplification of HER2 as determined either by immunohistochemistry or by FISH is an excellent predictor of response to trastuzumab (or other HER2-targeted therapies). Although it identifies a subset of patients with poor prognosis, HER2 status correlates closely with tumor grade and as such loses much of its independent prognostic significance in multivariate analysis.[724,725]

Skin invasion. Breast carcinomas in which invasion of the overlying skin has occurred are associated with a decreased survival rate.[726] Invasion of dermal lymphatic vessels as a determinant of the "inflammatory carcinoma" picture is a particularly ominous prognostic sign.

Lymphatic tumor emboli. The presence of tumor emboli in lymphatic vessels within the breast is associated with an increased risk of distant recurrence; an association made stronger with immunohistochemical confirmation of the lymphatic nature of the involved spaces (e.g. with D2-40).[727,728]

Blood vessel emboli. This finding shows a high correlation with tumor size, histologic grade, tumor type, lymph node status, development of distant metastases, and poor prognosis.[729]

Paget disease. The presence or absence of Paget disease in invasive ductal carcinoma is of no prognostic relevance.[730]

ER. Patients with ER-positive tumors have a longer disease-free survival than others.

DNA ploidy. Despite numerous studies evaluating DNA ploidy with flow cytometry, it is yet unclear whether this parameter adds *independent* information of therapeutic or prognostic value once the size of the tumor, microscopic grading, lymph node status, and hormone-receptor status have been taken into account; this ancillary information is not provided in routine clinical practice.[731–733]

Cell proliferation. This parameter, whether measured by the old-fashioned mitotic count, by MIB-1 (Ki-67) or analogous immunostain, by determination of S-phase fraction by flow cytometry, or by molecular-based testing such as PCR or gene expression profiling, has emerged as a very important prognostic determinant, particularly for ER-positive cases, hence its inclusion in the combined grading scheme espoused by Elston.[716] Many view it as the most important component of that system, which is being supported by evidence from innumerable gene expression profiling panels which all

Table 36.10 Final grading score

SUM OF POINTS	FINAL GRADE
3–5	1
6–7	2
8–9	3

demonstrate that proliferation-related genes are the main drivers in each of the gene signatures.[734,735]

Axillary lymph node metastases. This is one of the most important prognostic parameters. Not only is there a sharp difference in survival rates between patients with positive and negative nodes, but the survival rate also depends on the level of axillary node involved (low, medium, or high), the absolute number (fewer than four versus four or more), the amount of metastatic tumor and the presence or absence of extranodal extension.[655] There is no clinical significance to the presence of "micrometastases" (>0.2 to ≤2 mm) or "isolated tumor cells" (≤0.2 mm) as demonstrated in the NSABP (National Surgical Adjuvant Breast and Bowel Project) B32 trial.[736] For prognostic purposes, the best grouping seems to be the following: negative nodes, one to three positive nodes, and four or more positive nodes.

Internal mammary lymph node metastases. Survival in patients with involvement of this lymph node group is lower than in those without such involvement, especially if only patients with one to three positive axillary nodes are evaluated.[737]

Circulating tumor cells. There is increasing evidence that the presence and number of tumor cells in the bloodstream provide independent prognostic information on progression-free and overall survival in patients with early-stage and metastatic breast cancer.[738]

Local recurrence. Early studies showed this to be a sign of ominous prognosis. However, more recent data on larger series indicate that risk of death after local recurrence is related to the stage at initial breast cancer diagnosis.[739]

Type of therapy. This is too complex and multifactorial an issue to be adequately addressed here. Available evidence suggests that the outcome in breast carcinoma depends on both the nature of the individual tumor and on the type of therapy given, in addition to those factors discussed previously. A complicating factor in evaluating therapeutic results is the marked variation in the natural history of the disease among individuals, which renders imperative the use of carefully randomized studies.[740,741] The results of six large prospective randomized clinical trials have clearly demonstrated that the combination of breast-conserving surgery and radiation therapy provides survival rates equivalent to those following mastectomy.[742]

Surgical margins. Microscopically positive surgical margins in specimens from conservative breast excisions are associated with a higher risk of ipsilateral tumor recurrence.[628,673,743] Definitions of "positive" and "close" margins have varied in the literature, but a recent guideline statement by a multidisciplinary group of experts recommends use of "ink on tumor" as the definition of a positive margin in patients with invasive breast carcinoma. All else should be reported as a negative margin, with the distance to the margin reported in millimeters.[673] It is anticipated that standardizing the definition of a positive margin will result in less arbitrary decision-making regarding the need for reexcision. Early indications are that there has been a change in surgical practice with a reduction in reexcision rates reported.[744] Some surgeons excise multiple separate "cavity margins" (from the wall of the residual cavity during the same surgical procedure) and regard them as the "final margins" that supersede the initial margins from the excised specimen.[745]

Gene expression profiling. There are many studies reporting the use of microarray analysis to select tumor gene signatures for separating patients into meaningful prognostic/predictive groups that will potentially help with selection of therapy.[609,746–749] Two popular commercially available tests are: (1) MammaPrint (70-gene expression analysis by microarray); and (2) Oncotype DX (analysis of expression of 16 cancer-related genes and 5 reference genes by reverse transcription quantitative PCR). Both may be performed on formalin-fixed paraffin-embedded tissue.[750] A third test, PAM50 Prosigna assay, has recently come to market; it utilizes nanostring technology, as well as providing prognostic and predictive information, the test also classifies the tumor according to its intrinsic molecular subtype. This test will be available for laboratories to perform themselves, in contrast to the Onocotype Dx and MammaPrint assays, which are performed in single, commercial laboratories. It should be noted that almost all the gene signatures are applicable to hormone receptor–positive tumors with the decision point being whether or not to give the patient chemotherapy in addition to antiestrogen therapy.[623,749,751] Recent data from two prospective clinical trials indicate that chemotherapy may be safely omitted in patients with a low recurrence score on Oncotype Dx or a good prognosis signature on testing by MammaPrint.[623] Results guiding management of patients in the intermediate risk group have not yet been reported.

Salivary Gland and Skin Adnexal-Type Tumors (Including Myoepithelial Tumors)

A small proportion of benign and malignant tumors of the breast have an appearance analogous to, or at least reminiscent of, that more commonly seen in salivary glands or skin adnexa, particularly sweat glands.[752] This should not be too surprising, since the breast is a modified sweat gland and a close analogy exists between sweat gland tumors and salivary gland neoplasms. Some of the malignant tumors in this category share many of the features of ordinary breast carcinoma and therefore have been discussed in the preceding section. However, they could have been included here because of the histogenetic link they seem to have (at least at the conceptual level) with benign tumors of salivary gland and/or their skin adnexal-type morphology.

The benign tumors in this category include **eccrine spiradenoma** (which, as in the skin, may undergo malignant transformation), **syringomatous squamous tumors** (to be distinguished from low-grade adenosquamous carcinoma), **papillary syringocystadenoma**, dermal-type **cylindroma** (not to be equated with adenoid cystic carcinoma), **eccrine acrospiroma** (including nodular, solid–cystic, and clear cell hidradenoma), and **pleomorphic adenoma.** The latter, which is very rare in humans but relatively common in female dogs, has been interpreted by some as a variant of intraductal papilloma, but its appearance is quite similar to that of pleomorphic adenoma of salivary glands (benign mixed tumor) or of cutaneous sweat glands (chondroid syringoma) (Fig. 36.129). This tumor can arise as single or multiple nodules sometimes in a background of usual ductal hyperplasia, or in association (possibly coincidental) with breast carcinoma. An association with metaplastic carcinoma has not been well defined.[753,754]

A more complicated issue is represented by breast tumors of probable myoepithelial nature. First, it should be recognized that myoepithelial participation is an integral component of benign proliferative breast diseases (such as sclerosing adenosis, UDH, intraductal papilloma, and nipple adenoma) and that, in some instances, it dominates the histologic picture. Second, myoepithelial cells are a normal constituent of ducts and lobules, and therefore one might question whether these neoplasms should even be regarded as of salivary or sweat gland type. They are discussed here because the morphologic variations they exhibit and classification problems they elicit are very similar to those they pose in the salivary glands (see Chapter 12). **Adenomyoepithelioma** is a small (average diameter 1 cm), firm, well-circumscribed, often multilobulated tumor composed microscopically of cells of polygonal shape and optically clear to eosinophilic cytoplasm, arranged in nests within which

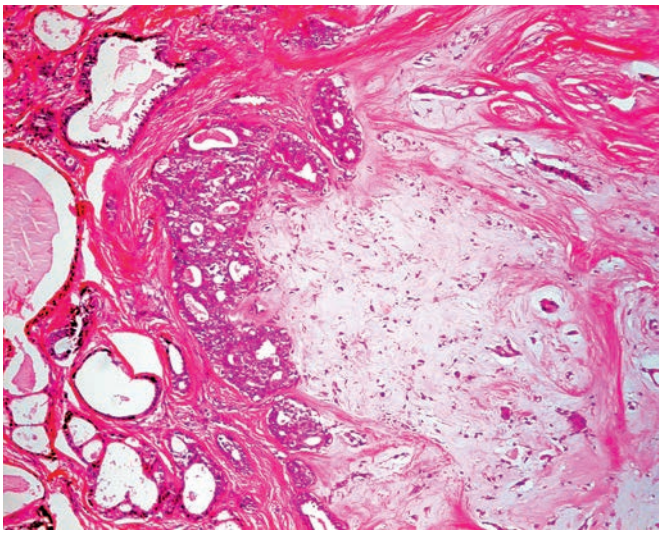

Figure 36.129 Pleomorphic Adenoma/Benign Mixed Tumor of the Breast. A prominent myxochondroid stroma is interspersed among the glandular structures.

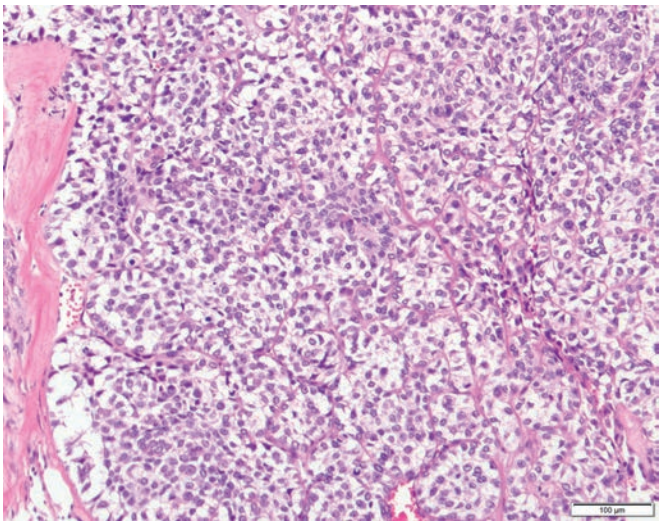

Figure 36.130 Adenomyoepithelioma. This well-circumscribed, multilobulated tumor is composed of polygonal cells with optically clear cytoplasm, arranged in nests. The gland-forming epithelial cells, with more eosinophilic cytoplasm, are harder to appreciate.

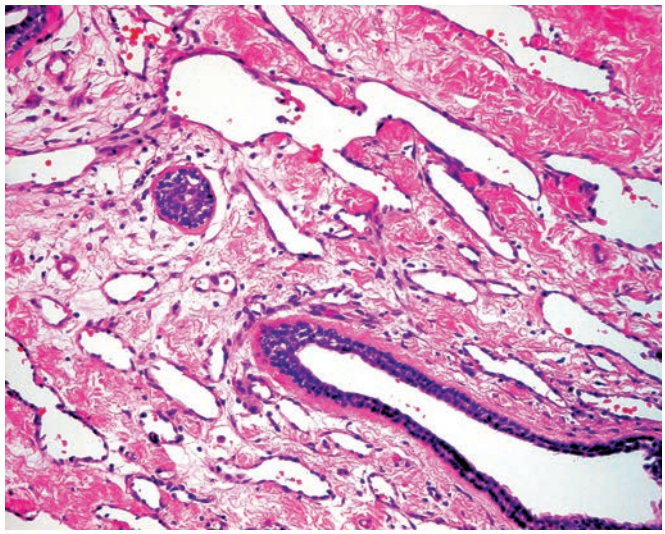

Figure 36.132 Well-Differentiated Angiosarcoma of Breast.

gland-forming epithelial cells may be appreciated.[755] The patterns of growth may be spindle cell (myoid), tubular, or lobulated (Fig. 36.130).[755–757] The behavior is generally benign, with local recurrence reported but no instances of metastatic spread.[756,758] Fully malignant myoepithelial tumors arising in association with adenomyoepithelioma (malignant myoepithelioma and/or myoepithelial carcinoma) are better classified as metaplastic carcinomas given the considerable overlap in expression of myoepithelial and epithelial markers in these tumors; a classification change that is largely semantic.[210]

Stromal and Vascular Tumors and Tumorlike Conditions

Primary angiosarcoma of the breast is an extremely rare tumor of young to middle-aged women.[759] Mammographically, it presents as a solitary mass without associated calcifications.[760] Grossly, the tumor is soft, spongy, and hemorrhagic (Fig. 36.131). Microscopically, the diagnostic areas are characterized by anastomosing vascular channels lined by atypical endothelial cells infiltrating through the breast parenchyma (Fig. 36.132). The appearance may vary, even in the same tumor, from that of a highly undifferentiated solid neoplasm to one that is extremely bland cytologically. However, close examination will usually reveal that even the better differentiated areas exhibit the telltale sign of angiosarcoma (i.e., inter-anastomosing vascular channels and endothelial cell atypia) (Figs. 36.133 and 36.134; see also Fig. 36.132). The tumor is thought to be of blood vessel rather than lymphatic vessel nature. Occasionally, the tumor is more epithelioid appearing and may mimic a high-grade invasive ductal carcinoma; a pitfall that may be compounded by aberrant keratin expression.[761] Curiously, some cases of breast angiosarcoma have been found to express ER.[762] The differential diagnosis of angiosarcoma includes metaplastic carcinoma, in particular, the acantholytic variant of squamous cell carcinoma (see Fig. 36.116), hemangioma (see following discussion), and pseudoangiomatous stromal

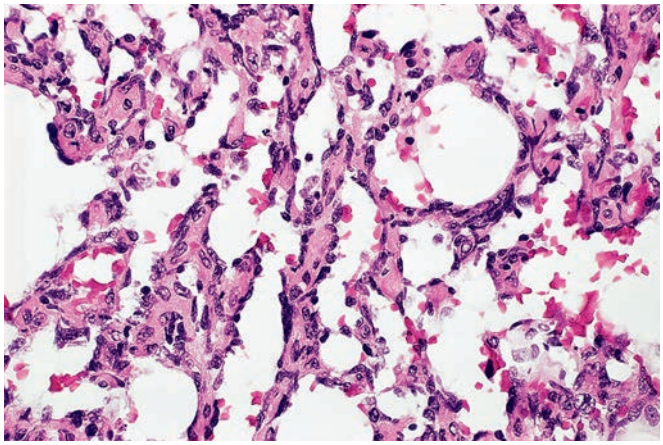

Figure 36.133 Complex anastomosing vascular pattern in angiosarcoma of breast.

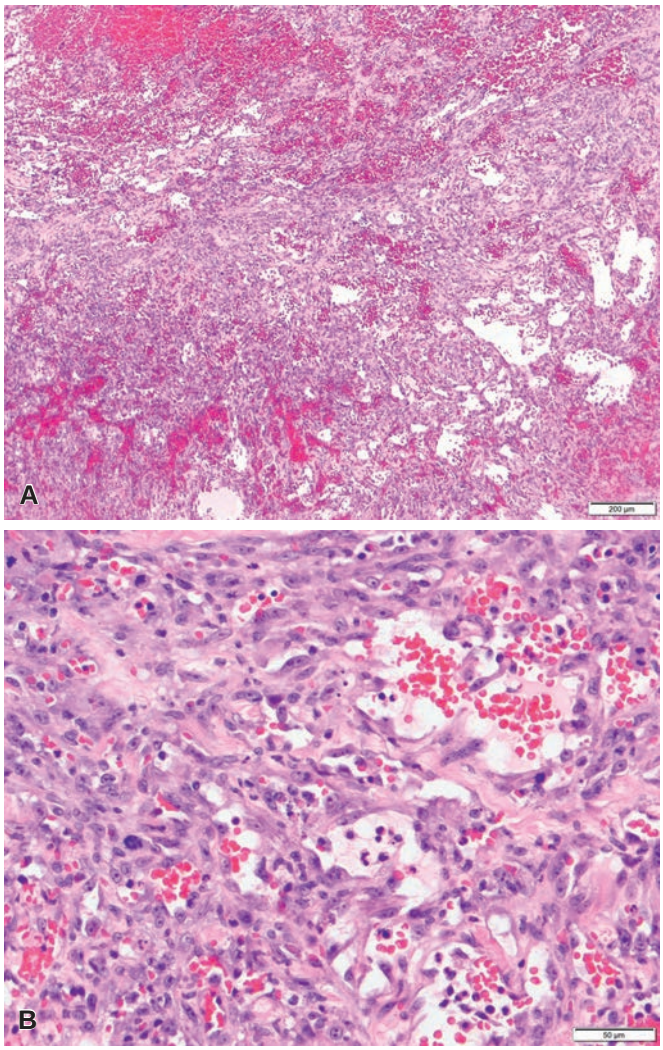

Figure 36.134 **Poorly Differentiated Angiosarcoma of Breast. A,** At low power, the interanastomosing vascular channels are apparent, as well as areas of solid growth and "blood lakes." **B,** High power, showing the significant endothelial cell atypia and brisk mitotic activity.

hyperplasia (PASH). Immunostaining for MIB-1 (Ki-67) is said to be of utility in distinguishing the better differentiated angiosarcomas from hemangiomas.[763]

A useful immunohistochemical panel for angiosarcoma should include vascular markers, such as ERG, CD34, and CD31, as well as cytokeratins and, on occasion p63, if the differential diagnosis includes metaplastic carcinoma and/or high-grade invasive ductal carcinoma. Note that some angiosarcomas, particularly the epithelioid variant, may show aberrant cytokeratin expression.

The overall prognosis of angiosarcoma is poor, with most patients developing metastases via hematogenous dissemination.[764] Donnell et al.[765] demonstrated that good correlation exists between microscopic grade and outcome. In their series, the 5-year disease-free survival was 33%; 10 of their 13 patients with grade I lesions were alive and well. The relationship of grading with prognosis has been confirmed in some, but not all, series.[766–768]

Post-mastectomy; post-lymphedema lymphangiosarcoma was a rare dreadful complication developing in the soft tissues of the upper extremity as a result of longstanding lymphedema following radical mastectomy or, exceptionally, segmental mastectomy[769] (Stewart–Treves syndrome). This is hardly seen now, though it has been replaced by another type of iatrogenic process, this time following radiation therapy for carcinoma of the breast, as described in the following paragraph.

Post-radiation vascular proliferations. Following the administration of radiation therapy to patients with breast carcinoma who have been treated with conservative surgery, the overlying skin can develop a variety of vascular proliferative lesions, which range from lymphangioma-like nodules to angiosarcoma,[770] with intermediate forms that have been descriptively named *atypical vascular lesions*.[771–777] Atypical vascular lesions are characterized by a proliferation of vascular channels located in the dermis and arrayed in a wedge-like manner. There is little if any endothelial cell atypia and they tend to run a benign clinical course, at least on a short-term basis. Some reports indicate that these lesions may evolve into angiosarcomas.[778]

Recent work has demonstrated that *post-radiation angiosarcomas* frequently show *MYC* amplification which potentially could be used to distinguish these lesions from primary angiosarcomas and atypical vascular lesions, which do not demonstrate amplification of this oncogene.[779–782] Post-radiation angiosarcomas, too, are preferentially located in the skin rather than the breast parenchyma itself.[783] The histologic features are as described for primary angiosarcomas, and the prognosis is poor. In contrast to angiosarcoma of the Stewart–Treves type, the interval between the radiation and the development of this tumor is short and lymphedema is minimal or absent.[784]

Benign vascular tumors can also develop within the breast parenchyma, contradicting the old adage that virtually all vascular tumors of the breast are malignant. Although the bland microscopic appearance of some angiosarcomas of the breast cannot be overemphasized, it is also true that a number of perfectly benign vascular tumors can occur in the breast. To begin with, hemangiomas of various types that share the features of those seen elsewhere in the body can develop in the overlying skin and subcutaneous fat. The most likely to be overdiagnosed is *angiolipoma* because sometimes it can be very cellular and the adipose tissue component can be inconspicuous.[785,786] The presence of fibrin thrombi in the vessels and absence of breast parenchyma indicating location in the subcutaneous tissue are important diagnostic clues on core needle biopsy[787]; encapsulation is often subtle in these specimens.

Perilobular hemangioma is usually an incidental microscopic finding; it is characterized by dilated capillary-sized vessels in a perilobular location, without anastomoses or cellular atypia.[788] Autopsy studies have shown that it is a relatively common lesion, having been found in 11% of all breasts.[789] Other *hemangiomas* are not perilobular in

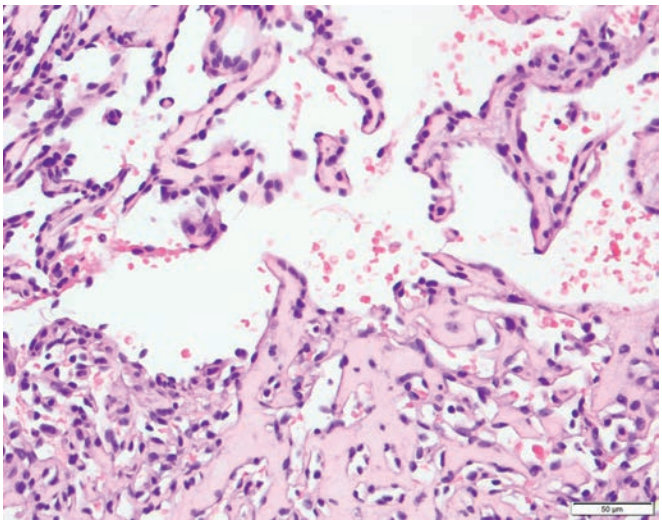

Figure 36.135 Papillary Endothelial Hyperplasia. High-power view showing a pattern of vascular anastomosis and prominent endothelial cells, which may be a mimic for low-grade angiosarcoma.

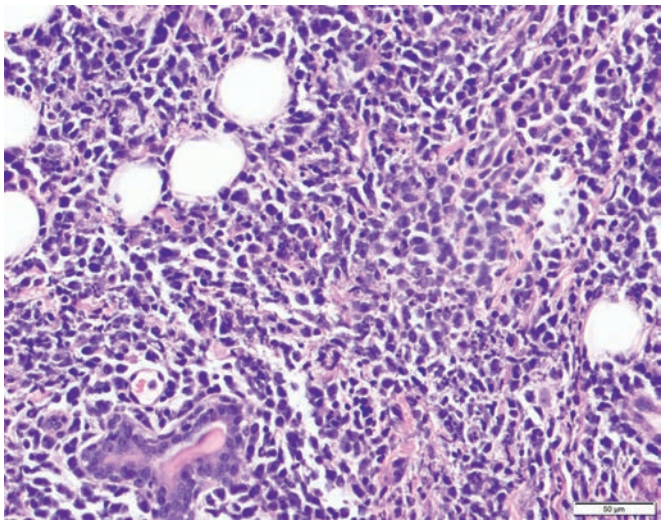

Figure 36.136 Diffuse Large B-cell Lymphoma of Breast. The breast parenchyma is infiltrated by a population of abnormal lymphoid cells which are medium and large in size, with irregular nuclear contours. Numerous apoptotic cells are seen.

location; they also tend to be small but can reach a diameter of 2 cm.[790] There are also *venous hemangiomas*.[791] Hemangiomas having a diffuse quality (although without anastomosing channels) have been referred to as *angiomatosis*.[792] *Epithelioid hemangioma* and *intravascular papillary endothelial hyperplasia (Masson tumor)* can also be located within the breast parenchyma (Fig. 36.135); the latter can be a mimic for low-grade angiosarcoma.

Other Malignant Stromal Tumors

Primary breast sarcoma is an extremely rare tumor. In fact, with the exception of angiosarcoma, any sarcomatous appearing tumor of the breast should be thoroughly worked up to exclude metaplastic carcinoma or the stromal component of a malignant phyllodes tumor before the diagnosis is rendered. Grossly, primary breast sarcomas appear solid, grayish white, and homogeneous. Necrosis may be present. Microscopically, most of them have the features of fibrosarcoma; focal osseous metaplasia can occur. Infiltrative margins and severe atypia indicate a greater tendency for local recurrence and distant metastases.[793] Many of these sarcomas do not match precisely the appearance of those arising in the usual soft tissue locations, probably owing to the fact that they are composed of a specialized type of stroma. Reported cases of CD10-positive mammary sarcomas are examples of this phenomenon.[794] Having said that, it ought to be acknowledged that tumors with an appearance equivalent to that of various types of sarcomas of somatic soft tissues do exist.[795] They include but are not limited to *liposarcoma*, *leiomyosarcoma*, *rhabdomyosarcoma* (though most such tumors are metastatic), *fibrosarcoma*, *chondrosarcoma*, and *osteosarcoma*.

Lymphoid Tumors and Tumorlike Conditions

Malignant lymphoma can present as a primary mammary neoplasm or involve the breast as part of a systemic process.[796] Lymphoma can also occur in association with breast implants (see below).[692,693] Grossly, lymphoma of the breast is fleshy and tan–white in color. It is not accompanied by skin retraction or nipple discharge. Multiple nodules are sometimes encountered. The involvement is bilateral in 10% of patients. In adult patients, primary lymphomas of the breast

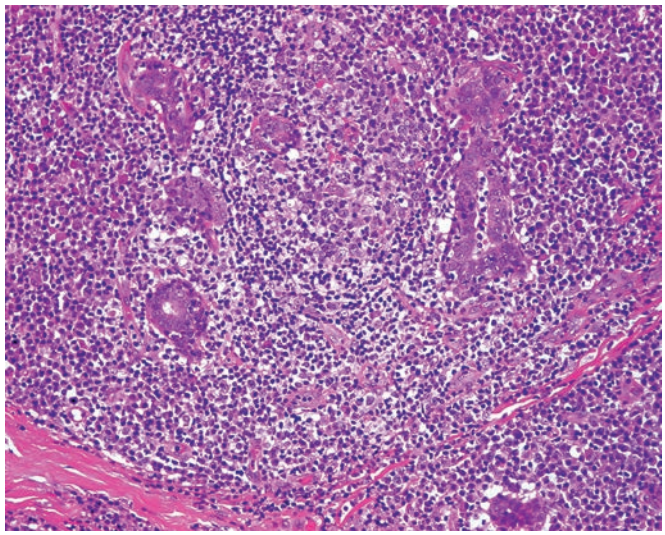

Figure 36.137 Extranodal Marginal Zone Lymphoma of Mucosa-Associated Lymphoid Tissue (MALT Lymphoma) of Breast. Some of the neoplastic lymphocytes infiltrate the glandular structures.

are nearly always of non-Hodgkin type and are usually composed of B cells,[796] although examples of T-cell lymphoma are also on record.[797,798] The B-cell lymphomas can be composed of either large or small cells[799,800] and usually show a nongerminal center phenotype.[801] Most primary breast lymphomas are of the diffuse large B-cell type (Fig. 36.136); other types include extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) and follicular lymphoma (Fig. 36.137).[796] Rare types of lymphoma include Burkitt lymphoma, lymphoblastic lymphoma, and implant-associated anaplastic large cell lymphoma (see later). Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT lymphoma) shows the typical tendency to surround and invade the wall and lumina of the epithelial structures, resulting in the so-called "lymphoepithelial lesion." Immunohistochemical studies demonstrate the characteristic profile of the lymphoma as found at other sites.[800] Be aware that the targetoid pattern sometimes seen around the ducts in extranodal

marginal zone lymphoma of mucosa-associated lymphoid tissue may simulate the appearance of invasive lobular carcinoma; in such cases, stains for CD45, CD20, and cytokeratin should solve the diagnostic dilemma. The survival of patients with breast lymphoma is related to stage and microscopic type.[796,799]

"Pseudolymphoma" has been described in the breast. As in other organs, its position in relation to extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue has become fuzzy. Some cases seem clearly reactive on morphologic and immunohistochemical grounds, perhaps representing an exuberant local reaction to injury.[802–804] Some cases may represent part of the spectrum of IgG4-related disease.[53,54] Other cases, instead, are composed of a monotonous small lymphocytic population and not easily separable from low-grade lymphomas. In some instances, the noncommittal diagnosis of *small lymphocytic proliferation* may be the best approach, followed by a recommendation for no further therapy if no systemic evidence of lymphoma is encountered. As far as the term pseudolymphoma is concerned, it is probably better to avoid it altogether.

Involvement of the breast by **Burkitt lymphoma** in African children has resulted in the formation of huge bilateral masses. Bilateral Burkitt-type lymphoma has also been seen in young women during pregnancy.[805]

Hodgkin lymphoma primary in the breast is exceptional. Most cases of Hodgkin lymphoma involving the breast represent secondary involvement in stage IV disease.

Plasmacytoma has been seen presenting as a primary breast mass, sometimes associated with a serum monoclonal protein.[806]

Intravascular lymphoma can involve the breast and bear an uncanny resemblance to high-grade DCIS, as Dr. Rosai admitted learning the hard way at a seminar in which he participated many years ago.[807,808]

Anaplastic large cell lymphoma can also involve the breast.[809] Notably, the majority of the reported cases have developed around a breast prosthesis ("implant-associated"). **Implant-associated anaplastic large cell lymphoma** is a recently reported distinct entity, very different from systemic ALK-negative anaplastic large cell lymphoma. There appears to be no relation to the indication for the implant, or the duration since the implant was placed; recent data indicate a significant association with textured implants. Limited data indicate a relatively indolent course, managed with implant removal and observation, unless associated with a mass-forming lesion, in which case a more aggressive course may ensue.[692,693,809]

Myelocytic leukemia of either acute or chronic type can present as a localized mass (granulocytic or myeloid sarcoma) in the breast and be microscopically confused with large cell lymphoma (Fig. 36.138).[810] The most important clue to the diagnosis in H&E sections is the presence of eosinophilic myelocytes and metamyelocytes, identified by their round or slightly indented nucleus and bright eosinophilic cytoplasmic granules. The diagnosis can be confirmed with immunostains for myeloperoxidase or CD117.[811]

Extramedullary hematopoiesis can exceptionally present in the form of a mass lesion in the breast in patients with idiopathic myelofibrosis or following neoadjuvant chemotherapy.[812,813]

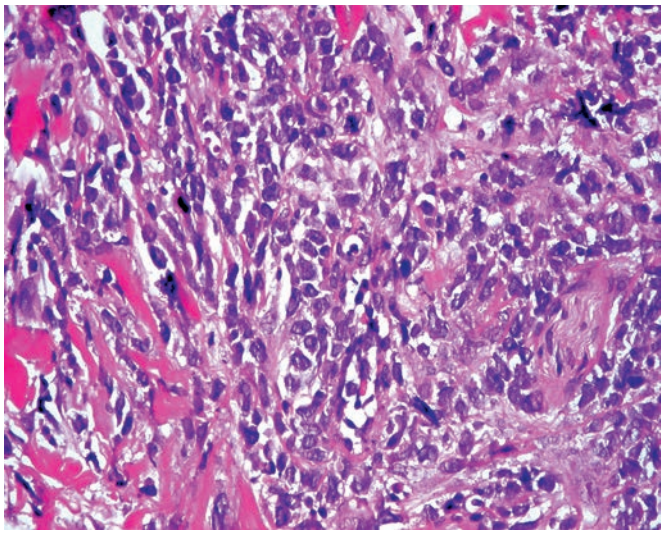

Figure 36.138 Granulocytic Sarcoma of Breast. It is easy to misdiagnose this lesion as a large cell lymphoma.

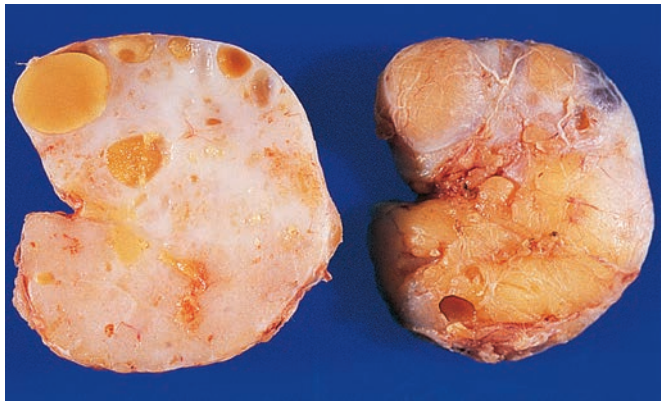

Figure 36.139 Gross Appearance of So-Called Hamartoma. There is a combination of cystic dilation of ducts, fibrosis, and entrapment of adipose tissue. This lesion is more distinctive and impressive grossly than microscopically.

Other Primary Tumors and Tumorlike Conditions

Basal cell carcinomas, squamous cell carcinomas, keratinous cysts, and **sweat gland tumors** may arise in the skin of the nipple or other sites in the breast, but they are not considered primary breast tumors.

Mammary hamartoma is defined as combination of ducts, lobules, collagenous stroma, and adipose tissue present as a relatively circumscribed lesion. Its identification is said to depend on the combination of clinical, radiologic, and pathologic criteria.[814,815] Morphologically, lesions that have been thought to be hamartomas on mammography may exhibit a wide diversity of appearances, the common denominator, by definition, being the admixture of epithelial and stromal elements, the latter including fat (Figs. 36.139 and 36.140).[816–818] A reproducible immunohistochemical profile has not been reported.[819] *Myoid hamartoma*[817,820] (which can contain epithelioid smooth muscle cells[821]) and *chondrolipoma* (a benign lesion composed of an admixture of fat, cartilage, and sometimes bone) are two other processes straddling the fence between malformation and benign neoplasia.

Granular cell tumor is important because of its ability to simulate grossly the appearance of invasive carcinoma.[822–824] It is usually small, but it may reach a size of 10 cm or more. On cut section, it is firm, homogeneous, and white or grayish yellow. As a rule, it is not attached to the overlying skin, but it may be fixed to the underlying fascia. The behavior is benign, and the treatment is local excision.[822,825]

Myofibroblastoma is a benign mesenchymal tumor originally described in the male breast but also occurring in the female organ.[826,827] Grossly, it is well circumscribed and usually small,

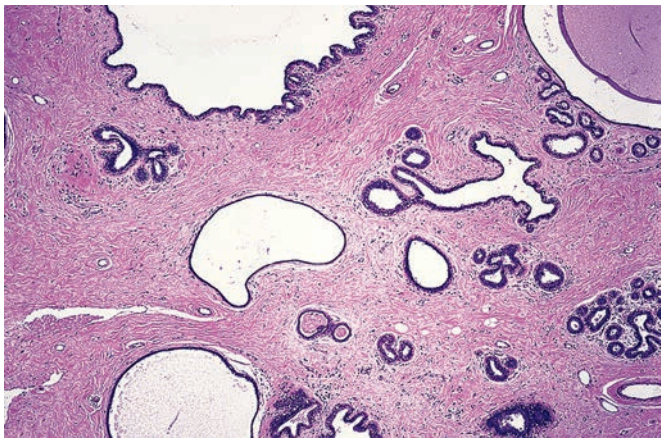

Figure 36.140 Glandular epithelium and fibrous stroma with distorted arrangement in hamartoma of breast.

although on occasion it can reach a large size. Microscopically, uniform, bland-looking spindle cells are arranged in short fascicles separated by broad bands of hyalinized collagen (Fig. 36.141).[826–828] Focally, there may be smooth muscle, cartilaginous, or adipose metaplasia. The appearance is very reminiscent of both solitary fibrous tumor and spindle cell lipoma, the suggestion having been made that there is a close histogenetic link between these neoplasms.[828–830] This hypothesis is further supported by the finding of genetic rearrangement or deletion of 13q14 and loss of Rb expression by immunohistochemistry in this group of lesions.[828,831,832] Immunoreactivity for desmin and CD34 is reported in the majority of cases.[828] ER and bcl-2 are also strongly expressed.[826]

There are several variants described, for example, *epithelioid* and the *deciduoid* myofibroblastoma. The former may be a mimic for invasive lobular carcinoma, particularly on core needle biopsy; an error that may be compounded by ER expression of the lesional cells.

Solitary fibrous tumor has been reported in the breast. Its morphologic and immunohistochemical features are the same as those reported for solitary fibrous tumor occurring at other sites and blend with those of spindle cell lipoma and myofibroblastoma.[833] Immunoreactivity for CD34, bcl-2, and especially STAT6 are helpful in confirming the diagnosis.[833]

Leiomyoma usually involves the nipple and is often painful[834]; occasionally, it is seen within the breast substance.[835] Some have been reported as having epithelioid features and granular changes.[836]

Benign peripheral nerve tumors of both *schwannoma* and *perineurioma* types have been described. *Traumatic neuromas with granular cell changes* have been observed in mastectomy scars.[837]

Perivascular epithelioid cell neoplasm (PEComa; clear cell ["sugar"] tumor) has been reported in the breast.[838] This a neoplasm characterized by HMB45-positive epithelioid smooth muscle cells.

Nodular fasciitis is rarely seen within the breast, its appearance and behavior being similar to those of its more common soft tissue counterpart. It should be included in the differential diagnostic consideration of spindle cell lesions of the breast.

Fibromatosis (extra-abdominal desmoid tumor) can also be found within the substance of the breast (Fig. 36.142). Morphologically it is composed of long, sweeping fascicles of bland spindle cells that entrap the native ducts and lobules. Lymphoid infiltrates are commonly seen at the periphery of the lesion (Fig. 36.143). It shares with its homologue in the somatic soft tissue a tendency for infiltration, local aggressiveness, and local recurrence.[839] This is also true at the molecular level, in that they have a similar spectrum of

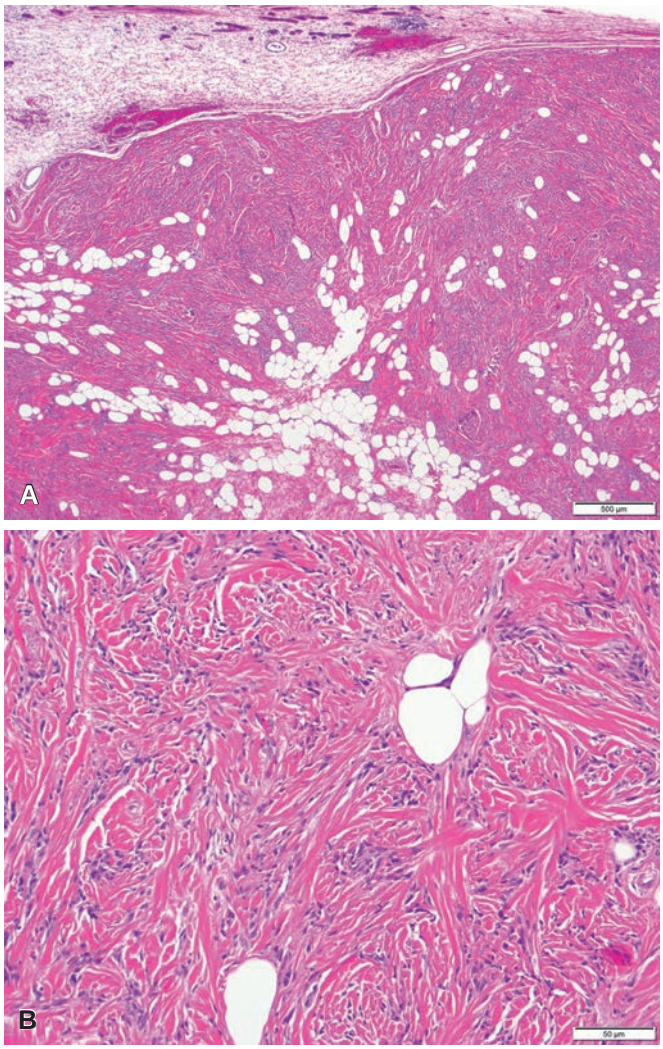

Figure 36.141 **Myofibroblastoma. A,** At low power, the well-circumscribed margin of this bland spindle cell tumor is appreciated. **B,** At high power, the spindle cells are bland, arranged in short fascicles separated by broad bands of collagen.

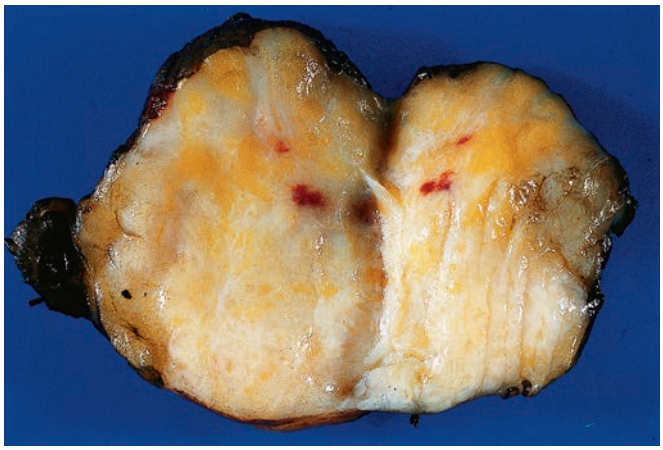

Figure 36.142 Gross appearance of fibromatosis involving breast. The mass is solid and ill defined.

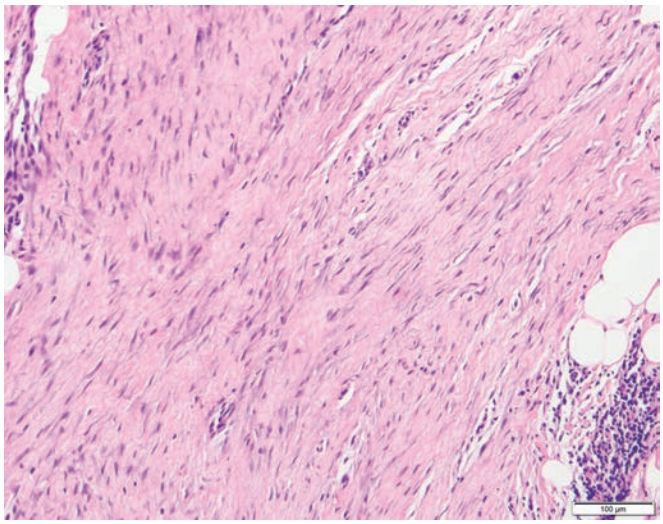

Figure 36.143 Fibromatosis. The lesion is composed of long, sweeping fascicles of bland spindle cells that entrap the native ducts and lobules. Lymphoid infiltrates are commonly seen at the periphery of the lesion.

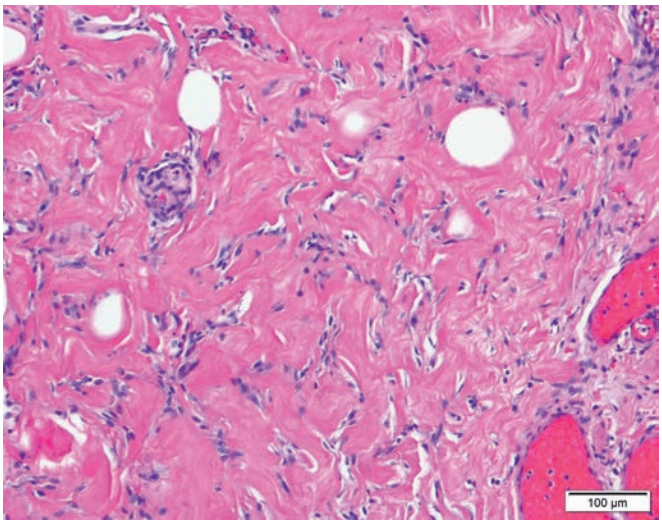

Figure 36.144 Pseudoangiomatous Stromal Hyperplasia. Thin channels lined by spindle cells are seen scattered within a hyalinized stroma.

CTNNB1 (β-catenin) and *APC* gene alterations.[840] Reports of mammary fibromatosis occurring in or around the capsule of a grossly intact implant have not been able to establish a significant pathogenetic relationship.[841]

Cases of mammary fibromatosis occurring during childbearing age are, in general, more cellular than those seen after menopause,[842] being infiltrative, aggressive, and prone to local recurrence.[839] Fibromatosis should be distinguished from low-grade fibromatosis-like metaplastic carcinoma and scarring secondary to (surgical) trauma. Nuclear staining with β-catenin may be useful in confirming the diagnosis of fibromatosis, though it should be noted that this is not specific for the lesion as phyllodes tumor and metaplastic carcinoma may also stain with β-catenin.

Pseudoangiomatous stromal hyperplasia (PASH) is characterized by a proliferation of stromal spindle cells of fibroblastic/myofibroblastic nature associated with the formation of clefts that simulate vascular channels (Fig. 36.144).[843,844] It is a common finding identified in nearly one-third of breast biopsies. PASH may present as a mass on mammographic and ultrasound studies; on MRI it is more likely to present as an area of non-mass-like enhancement. It is prudent to rule out other possible pathologies before diagnosing PASH as the imaging correlate for a targeted mass. Occasionally, the myofibroblasts may aggregate into fascicles; this appearance has been referred to as fascicular PASH. The spindle cells are immunoreactive for vimentin and CD34 and negative for vascular markers, such as ERG and CD31. In addition, they show intense positivity for PR. The latter finding suggests that PASH represents a localized form of stromal overgrowth with a hormonal (primarily progestogenic) pathogenesis.[845]

Multinucleated giant cells of reactive appearance are sometimes found incidentally in the normal mammary stroma or in the stroma of fibroadenomas[150,846]; they are of no clinical significance and are probably analogous to those seen in non-neoplastic polypoid stromal lesions located beneath mucosal membranes, such as the nasal cavity, oral cavity, anus, and lower female genital tract (Fig. 36.145).[846] Recognition of these cells for what they are and not mistaking them for a malignant process is the reason for mentioning them here.

Inflammatory myofibroblastic tumor may involve the breast, its microscopic features being analogous to those seen in other, more common sites.[847,848]

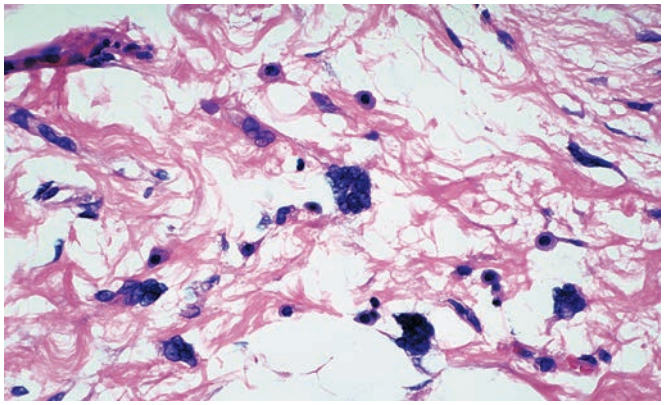

Figure 36.145 Bizarre Multinucleated Cells in Mammary Stroma. This non-neoplastic change is analogous to that more often seen in the stroma of the upper aerodigestive tract and in the genital tract.

Amyloidosis can appear as a solitary nodule within the breast parenchyma (so-called amyloid tumor).[849,850]

Rosai–Dorfman disease and **Erdheim–Chester disease** can also present under exceptional circumstances as breast masses, the former either as an isolated event or as a component of systemic disease.[851,852]

Juvenile xanthogranuloma can affect the breast of children and, exceptionally, of adult patients.[853]

Nodular mucinosis presents as a circumscribed area of myxoid stromal change near the nipple.[854] It should be distinguished from mucinous carcinoma and mucocele-like lesion.

Metastatic Tumors

Metastatic malignant tumors rarely affect the breast except when widely disseminated.[855] They typically appear as superficial, well-defined multinodular masses. Malignant melanoma and carcinoma of the lung, ovary, kidney, and stomach are the most common sources.[856,857] Most of the lung tumors are of the small cell neuroendocrine type. Breast metastases have also been documented from better differentiated neuroendocrine tumors, such as from the bronchus or small bowel, pancreatic (neuro)endocrine tumor, thyroid

medullary carcinoma, and even carcinoid tumor arising from a tailgut cyst.[858–862]

One should not forget in this listing the metastases from contralateral breast carcinoma, which is not an infrequent finding in autopsy series.[855] Azzopardi has made the interesting observation that the presence of elastosis has not been documented in association with metastatic disease of the breast.[22]

Metastatic carcinomas to the breast can simulate primary malignant tumors of this organ; exceptionally, they greatly mimic the appearance of DCIS.[863] In an era of increasing use of neoadjuvant chemotherapy, it is important to consider metastasis when encountering a tumor of the breast with unusual morphology, extensive lymphovascular invasion in the presence of a small "invasive" component, an absence of an in situ component and/or a triple negative immunophenotype. If doubt exists as to whether the tumor represents a breast primary, a panel of breast markers (GCDFP-15, mammaglobin, GATA3) may be appropriate. Of course, eliciting a history of prior malignancy at another site and comparing the morphology may be the most helpful tool.

In children, the most common malignant tumor to metastasize to the breast (hematolymphoid malignancies excluded) is rhabdomyosarcoma, particularly of the alveolar type.[864–866]

Breast Diseases in Children and Adolescents

The most common breast "mass" for which clinical consultation is sought in this age group is actually not a pathologic condition at all but rather precocious, sometimes predominantly unilateral, breast development.[867] Should such a "mass" be inadvertently removed, no development of the breast will occur.

Fibroadenoma is the most common pathologic condition of the breast between puberty and 20 years of age but is exceptional before puberty.[867]

Virginal hypertrophy (gigantomastia; macromastia) may result in massive unilateral or bilateral enlargement.[867] Microscopically, it is characterized by a combined proliferation of ducts and stroma with little, if any, lobular participation (Fig. 36.146).[866]

Pseudoangiomatous stromal hyperplasia is generally a disorder of adult life, but cases have been documented in adolescents and children (including a 3-year-old boy).[868]

So called fibrocystic change is practically never seen in this age group. However, highly proliferative epithelial lesions can develop, such as papillomas and usual duct hyperplasia, similar to those seen in the adult breast, with or without associated sclerosis and ductular distortion.[869] Wilson et al.[870] studied 74 patients with a process they termed *papillary duct hyperplasia*, which they distinguish from the juvenile papillomatosis described later. They found that 28% of the patients had a family history of breast carcinoma but that none of the patients had developed carcinoma at the time of the last follow-up.

Juvenile papillomatosis ("Swiss cheese" disease) is usually seen in young individuals (average age 19 years) but occurring in a wide age range (10–44 years). Clinically, the localized, multinodular masses simulate the appearance of fibroadenoma. Grossly, the clustering of cysts results in a cut surface appearance reminiscent of Swiss cheese—hence the alternative designation for this entity (Fig. 36.147). Microscopically, there is florid epithelial hyperplasia (sometimes with atypia and/or focal necrosis), cysts with or without apocrine metaplasia, duct stasis, and sclerosing adenosis (Fig. 36.148).[871,872] A family history of breast carcinoma is reported in 58% of cases, and 10% of the patients subsequently develop breast carcinoma.[872,873]

Figure 36.147 Juvenile Papillomatosis (Swiss Cheese Disease). The gross appearance is that of clustered cystic formations.

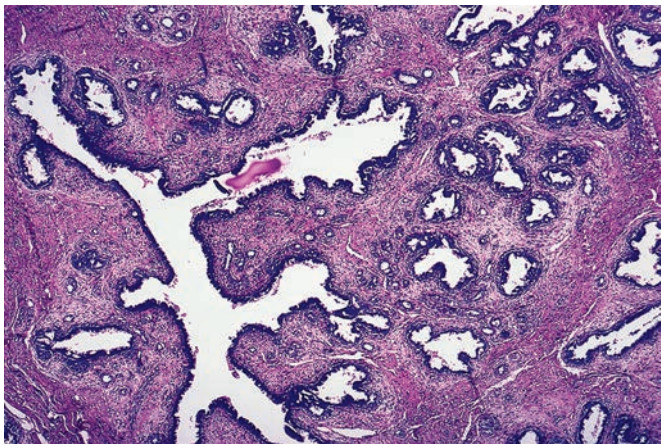

Figure 36.146 So-called "virginal hypertrophy" of breast, showing proliferative changes in epithelium and stroma.

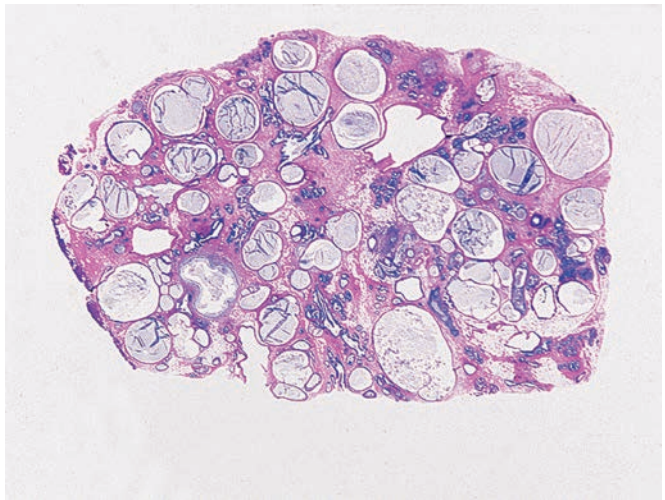

Figure 36.148 Juvenile Papillomatosis (Swiss Cheese Disease). Whole-mount view showing variously sized cystic formations, alternating with solid epithelial proliferations.

Carcinoma of the pre-pubertal breast is very rare; most cases are of the so-called secretory type (see earlier description). A few tumors have the appearance of ordinary invasive ductal carcinomas.

In the presence of a high-grade malignant round cell tumor of the breast in a child or adolescent, the possibility should be considered that it may be a solid variant of alveolar rhabdomyosarcoma, whether primary or metastatic.[156]

Breast Diseases in Males

Gynecomastia

Gynecomastia is defined as the enlargement of the male breast resulting from hypertrophy and hyperplasia of both glandular and stromal components. It may result from numerous causes, which share a background of relative increase in estrogenic activity (whether endogenous or exogenous), decrease in androgenic activity, or both.[874,875] Development of gynecomastia before 25 years of age is usually related to hormonal pubertal changes, whereas development in later years may be caused by hormonally active tumors (Leydig cell tumor of testis, hCG-secreting germ cell tumors, lung carcinoma, or others), cirrhosis, or medications (digitalis, reserpine, phenytoin, and others).[876] Cases have also been reported in type 1 neurofibromatosis.[877] Clinical gynecomastia developing in diabetic patients may have the features of diabetic or lymphocytic mastopathy, as seen in females.[878] Many cases are idiopathic.

Clinically, gynecomastia is usually centered behind the nipple, an important point in the differential diagnosis with carcinoma, which tends to be located eccentrically.[874] It may be unilateral (at least at the clinical level, the left breast being more commonly involved than the right) or bilateral. Pubertal and hormone-induced gynecomastias tend to be bilateral, whereas idiopathic and nonhormonal drug-induced gynecomastias are usually unilateral.

On ultrasound examination, gynecomastia may appear as a hypoechoic or hyperechoic mass or be of mixed echogenicity.[879] Mammographic examination reveals a round, retroareolar density with stranded extensions into the deeper adipose tissue.[879] The gross appearance is characteristic. The mass is oval, disk shaped, of elastic consistency, and with well-circumscribed borders. Microscopically, the ducts show a variable and sometimes very prominent degree of epithelial hyperplasia and are surrounded by a prominent edematous stroma, which results in a typical "halo" effect (Fig. 36.149). This stroma contains large amounts of acid mucopolysaccharides (mainly hyaluronic acid) of a type similar to that seen in fibroadenoma of the female breast.[880] The immunophenotype parallels that of normal breast stroma.[881] There may be PASH and focal squamous metaplasia; formation of lobules may be observed.[874,882] Exceptionally, a population of clear or globoid cells immunoreactive for GCDFP-15 may be present within the ducts.[883]

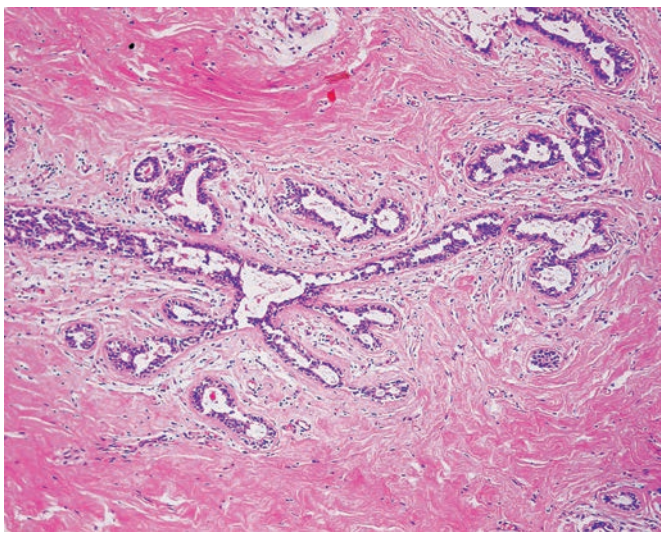

Figure 36.149 Epithelial proliferation surrounded by a hypocellular myxoid halo in gynecomastia.

The microscopic changes are related to the duration of the gynecomastia. Cases of short duration tend to have a prominent hyperplastic epithelial component, often with micropapillary ("gynecomastoid") architecture, and stromal edema, whereas those of long duration have prominent stromal fibrosis.[884] Occasionally ADH may be present; however, the clinical significance of the diagnosis in this setting is unknown.[885] The possible relationship between gynecomastia and carcinoma is discussed later. Changes morphologically similar to those of gynecomastia can be seen in the female breast ("gynecomastoid hyperplasia").

Myofibroblastoma

Myofibroblastoma is the term used for a benign stromal neoplasm composed of myofibroblasts and collagen first described by Toker et al.[886] Originally thought to involve primarily the male breast, it is now known to occur in the female breast with a higher frequency.[887]

Carcinoma

In the United States, only 1% of all breast carcinomas occur in males, but in some Arab countries the incidence rises to nearly 10%.[888–891] An increased incidence of breast carcinoma is seen in patients with Klinefelter syndrome.[892] Familial cases have also been recorded, particularly among *BRCA2* mutation carriers.[893,894] Cases of primary breast carcinoma have occurred in patients with prostatic carcinoma treated with estrogens.[875,895] A definitive relationship between gynecomastia and breast carcinoma has not been demonstrated.

Clinically, most breast carcinomas present in elderly men as breast masses, with or without associated nipple abnormalities.[896] Nipple discharge in an adult male, especially if bloody, should arouse a strong suspicion of carcinoma. Skin involvement by direct extension and Paget disease are much more common in males.

Imaging studies demonstrate findings as described earlier for the radiographic identification of breast cancer in female patients; namely a spiculated mass on mammography and a hypoechoic mass, taller-than-wide, with posterior shadowing on ultrasound examination.[879] Similarly, grossly, microscopically, and immunohistochemically, carcinomas of the male breast are like those seen in females. As such, they can be in situ or invasive, low grade, or high grade. All of the microscopic types and molecular subtypes identified in the female breast have been encountered in males. The incidence of papillary carcinoma is higher than in females.[889,897] The least common of the major categories is invasive lobular carcinoma, only a few cases having been described.[897,898]

Breast carcinoma is diagnosed on core needle biopsy in most patients, with the most important differential diagnosis for a breast mass in a male patient being gynecomastia. The incidence of positivity for ER is higher than in females.[899]

The overall survival rate is lower than for breast carcinoma occurring in females but, as is often the case, the differences tend to disappear when the tumors are compared stage by stage.[888,889] Indeed, the prognosis of breast cancer in males, like that in females, is heavily influenced by clinical stage, histologic grade, and receptor status. It also correlates with mitotic activity, DNA ploidy, and p53 status.[900,901]

Other Lesions

Mammary duct ectasia and **sclerosing adenosis** can occur in the male breast. Fibroadenoma (sometimes bilateral), phyllodes tumor, PASH, and nodular fasciitis have also been reported.[902,903] **Nipple adenoma** and **intraductal papilloma** have been seen on several occasions. There are also reports of **leiomyoma** and **leiomyosarcoma** of the nipple[904] and **neurofibromatosis** in a child whose condition simulated gynecomastia.[905]

Metastatic carcinoma to the male breast commonly originates from the prostate, is often bilateral, and is almost always seen following estrogen therapy.[895] As such, it occurs against a background of gynecomastia. Some of these cases have been confused with primary breast carcinoma. Immunohistochemical stains for PSA and prostatic acid phosphatase are helpful in the differential diagnosis. The matter is complicated by the fact that the normal mammary duct epithelium of males and the hyperplastic epithelium of gynecomastia are often immunoreactive for PSA (but not for prostatic acid phosphatase). Male breast carcinoma is typically negative for both markers; though PSA positivity has been reported in an FNA specimen from a primary breast carcinoma.[906,907]

The most common type of nonepithelial tumor to metastasize to the male breast is malignant melanoma.[897]

Normal Anatomy

The lymph node is one of the major anatomic components of the immune system.[1,2]

The three major regions of a lymph node are the *cortex, paracortex,* and *medulla* (Fig. 37.1A). The cortex is situated beneath the capsule and represents the compartment where most lymphoid follicles reside and is composed of primarily B lymphocytes and follicular dendritic cells. The medulla, close to the hilum, grows in the form of cords. It is rich in lymph sinuses, arteries, and veins but contains only a minor lymphocytic component that is a mix of B and T lymphocytes. The appearance of the follicles varies according to their state of activity. Primary follicles appear as round aggregates of small lymphocytes with little cytoplasm; secondary follicles appear following antigenic stimulation and are characterized by the presence of germinal centers surrounded by mantle zones.[3] The germinal center cells are predominantly B lymphocytes known as follicular center cells (centroblasts and centrocytes or small and large cleaved and noncleaved cells), macrophages, and follicular dendritic cells, but a population of T follicular–helper cells also reside normally in this compartment. The germinal center contains pale-staining large cells on hematoxylin and eosin (H&E) sections that are normally highly proliferative and shows polarization toward the side of antigen stimulation. The surrounding mantle zone B lymphocytes are small

Abstract

The disorders that may present in lymph nodes are diverse and include infectious diseases, neoplasms, and reactive responses to injury elsewhere. This chapter reviews the histologic patterns of various reactive conditions that involve lymph nodes, as well as the hematologic neoplasms that may primarily involve lymph nodes. The approach to the immunophenotypic evaluation as well as the role of molecular genetic studies, particularly in the hematopoietic neoplasms, are reviewed. In addition, unusual inclusions and disorders that may mimic malignancy in lymph nodes are discussed.

Keywords

Malignant lymphoma,
Hodgkin lymphoma,
Reactive follicular hyperplasia

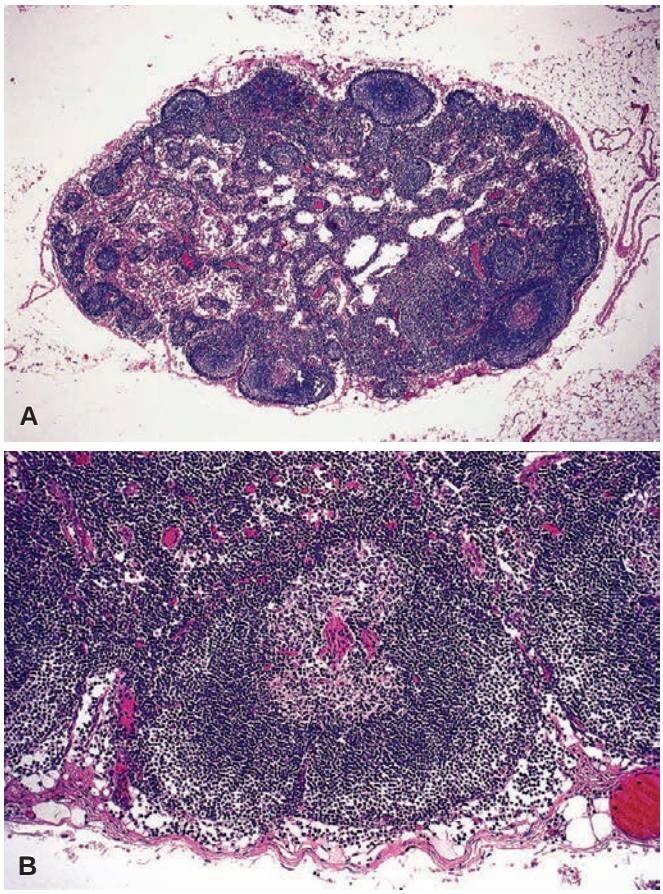

Figure 37.1 Normal Lymph Node. A, The morphologic differences among the various nodal compartments are particularly evident in mesenteric lymph nodes, of which this is an example. **B**, Secondary lymphoid follicle with obvious polarity of the germinal center.

and stain dark blue and contain little cytoplasm (see Fig. 37.1B).[1] Proliferated germinal centers are always indicative of humoral antibody production. Under conditions of intense antigenic stimulation, they also can appear within the medullary cords.[4]

The paracortex is the zone situated between the cortex and the medulla, which contains the mobile pool of T lymphocytes responsible for cell-mediated immune responses.[1] A characteristic feature is the presence of postcapillary venules, which are identifiable by their lining of high endothelial cells and the presence of lymphocytes migrating through their cytoplasm. Another cell type present in the paracortex is the interdigitating dendritic cell, a member of the accessory immune system. Expansion of the paracortex is indicative of a cell-mediated immunologic reaction. The number of lymphocytes within the lumen and wall of postcapillary venules gives a rough indication of the degree of lymphocyte recirculation.[5]

Afferent lymph vessels penetrate the nodal capsule to open into the marginal sinus; this communicates with an intricate intranodal sinus network that merges into efferent lymph vessels exiting the node at the hilum. The endothelial lining of the outer (subcapsular) side of the marginal sinus is nonphagocytic and similar to that of the afferent and efferent vessels; the lining of the intranodal sinuses has strong phagocytic properties. The main arteries and veins pass through the hilum and radiate to the medulla, paracortex, and inner part of the cortex; other blood vessels penetrate the capsule to supply the superficial cortex and a small area surrounding the trabeculae.

The morphologic and phenotypic features of the various populations of lymphoid cells and cells of the accessory immune system are discussed in the next sections and in connection with the respective proliferative pathologic changes affecting these populations.

Lymph Node Evaluation

The proper examination of a lymph node is a complicated task that may require the performance of a variety of specialized procedures depending on the nature of the case.

Biopsy

Selection of the lymph node to be biopsied is of great importance. In cases of generalized lymphadenopathy, inguinal nodes are to be avoided whenever possible because of a high frequency of nonspecific chronic inflammatory and fibrotic changes. Axillary or cervical nodes are more likely to be informative. Whenever possible, the largest lymph node in the region should be excised. Small superficial nodes may show only nonspecific hyperplasia, whereas a deeper node of the same group may show diagnostic features.

The surgeon biopsying intra-abdominal nodes or large cervical or axillary masses should have a frozen section or touch preparations performed to be certain that the tissue is representative—*not* necessarily to obtain a specific diagnosis at this point. This may save a second biopsy.

Adherence to a strict technique for the preparation of lymph nodes in the pathology laboratory is of paramount importance (see later).[6] The specimen should be received fresh in the laboratory immediately after excision, bisected as soon as it is received, and sampled for the appropriate studies. The portion to be embedded in paraffin (which should not exceed 3 mm in thickness) can be placed in 10% buffered formalin and/or a mercury-containing fixative such as B5. As a routine procedure, initial examination of a preparation stained with H&E is perfectly adequate, followed by whatever additional stains and special techniques the nature of the case may require (which may range from very many to none).

A technique that complements the study of tissue sections and that is too often neglected is the examination of touch preparations from the cut surface of the fresh lymph node stained with Giemsa or Wright solution. This is particularly useful in the evaluation of lymphoma and leukemia, and in the initial triage of the specimen (such as sending tissue for culture if granulomas are seen). For instance, granulocytic leukemia can closely simulate large cell lymphoma in a hematoxylin–eosin-stained section, but an imprint may readily distinguish the two conditions.

Needle Biopsy

Core needle biopsy is adequate for the diagnosis of metastatic carcinoma. Although not preferred for the evaluation of primary lymphoid disorders, core biopsies are increasingly used nowadays, putting pressure on the pathologist to render a diagnosis based on limited amounts of tissue. Compression artifact is very common in core biopsies, with the cells appearing smaller and the nuclei appearing darker compared with those seen in excisional biopsies. Very often, flow cytometry immunophenotyping and more extensive immunohistochemical evaluation are required to maximize the information obtainable from the biopsies.

Fine-needle aspiration of lymph nodes is particularly useful for the documentation of metastatic carcinoma (Fig. 37.2). It is used most often in cervical lymph nodes[7] but also in other locations, including intra-abdominal and retroperitoneal regions.[8] The cytologic diagnosis of malignant lymphoma can be made in 50%–75% of the cases, the accuracy being greatest in the high-grade lesions (see Fig. 37.2).[9] A primary diagnosis of malignant lymphoma based on

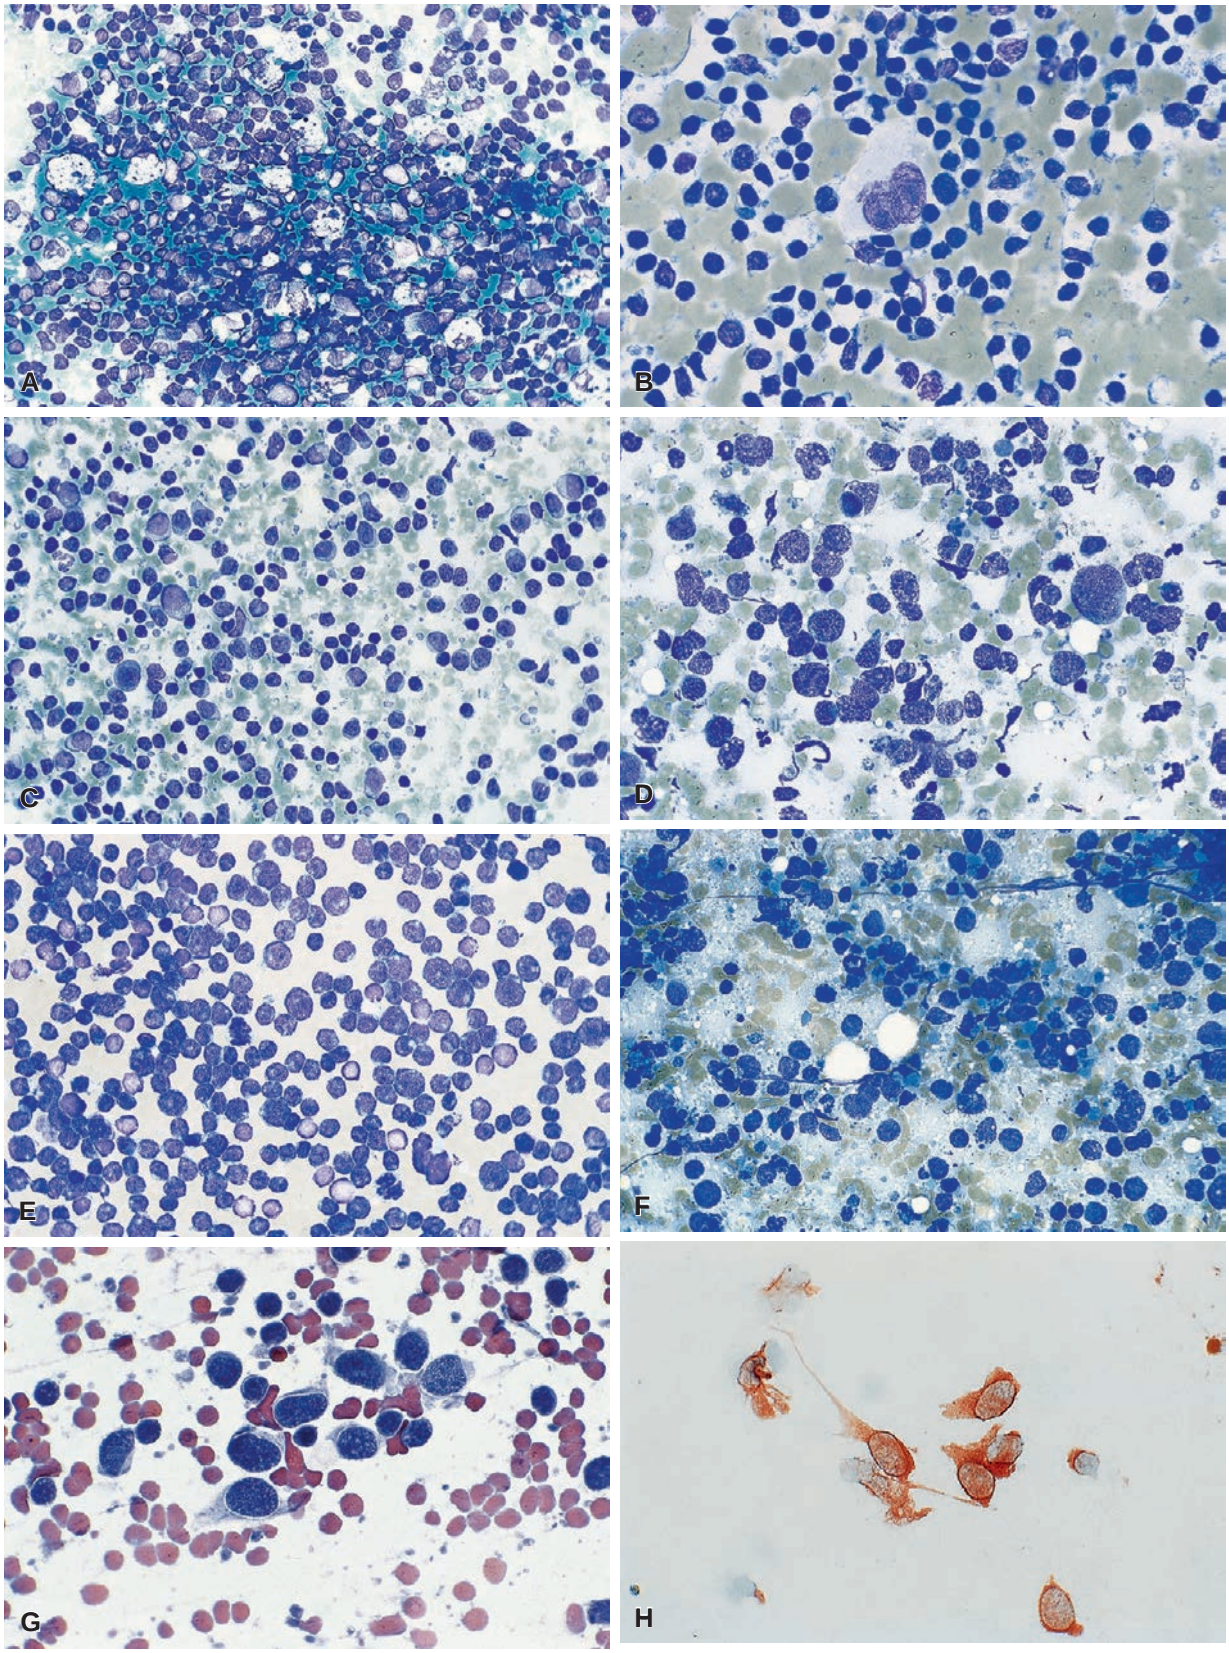

Figure 37.2 Appearance of Various Lymph Node Diseases as Seen in Fine Needle Aspiration Specimens. A, follicular hyperplasia; **B**, Hodgkin lymphoma (Reed–Sternberg cell); **C**, small lymphocytic lymphoma/chronic lymphocytic leukemia; **D**, follicular lymphoma, grade 3; **E**, lymphoblastic lymphoma; **F**, metastatic pulmonary small cell carcinoma; **G**, metastatic alveolar rhabdomyosarcoma; **H**, same case as **G** immunostained for desmin. (Courtesy of L. Alasio, Milan, Italy.)

cytology morphology, however, is not adequate, and all cases undergoing fine-needle aspiration for possible lymphoma should have an aspirate sample submitted for flow cytometry immunophenotyping, and preferably, be accompanied by a core biopsy for architectural evaluation. Even with this combination, complete lymphoma classification may not be possible in up to 35% of cases, requiring an excisional biopsy. The fine-needle aspiration technique has been found most useful for the selection of a representative node for biopsy, for the diagnosis of recurrent lymphoma, for staging the extent of the disease, for monitoring treatment and to collect material for ancillary testing. Hemorrhage, necrosis, and myofibroblastic proliferation may develop along the needle tract; the latter should not be confused with Kaposi sarcoma or other neoplasms.

Infectious Disease Examination

If there is a possibility that the node contains an infectious process, an adequate, sterilely collected sample of the biopsied lymph node must be sent directly for bacteriologic, fungal, and viral studies or at least be placed in a sterile Petri dish in the refrigerator. If permanent sections show an inflammatory process, the material can then be retrieved and studied for infectious diseases. For some reason, this technically trivial step is the one most commonly forgotten; but molecular assays to identify infectious agents may now be performed on formalin-fixed, paraffin-embedded tissues[10–13] and should be considered if the histologic changes suggest an infectious etiology, even if cultures are negative.

Immunophenotyping

Phenotyping of lymphoid disorders has evolved into a highly complex field, as a result of the enormous cellular diversity within the immune system and the huge number (over 1000) of markers that have become available for this purpose.

Rosetting tests with coated or uncoated red blood cells and polyclonal antibodies, which were so useful for the early characterization of lymphomas, have been all but replaced by the use of monoclonal antibodies. These have received a multitude of designations, which are more dependent on the manufacturer's source than the features of the antibody. Fortunately, an internationally agreed-upon nomenclature (the CD system, which stands for *cluster designation* or *cluster of differentiation*) has evolved, and this has allowed for better communication among the various laboratories. Over 300 CD antigens have been identified. Many of these monoclonal antibodies are now applicable to paraffin sections (Table 37.1). A detailed discussion of these tests and their optimal use in the differential diagnosis of hematolymphoid disorders is outside the scope of this book.

Immunophenotyping can be performed by flow cytometry (requiring fresh tissue) or on paraffin-embedded materials.[14,15] Two major advantages of the former are rapid availability of results, and excellent assessment of surface immunoglobulin and hence B-cell clonality. The disadvantages are the need for immediate handling of fresh tissue, and suboptimal architectural–morphologic correlation.

Molecular Genetic and Cytogenetic Studies

Gene Rearrangement Analysis

Individual T and B lymphocytes normally undergo rearrangements of antigen receptor genes as part of normal maturation, resulting in the development of unique immunoglobulin or T-cell receptor molecules. The vast majority of mature B cells have undergone rearrangement of the immunoglobulin heavy chain (IGH) gene and the immunoglobulin kappa light chain (IGK) gene, and approximately one-third of B cells have also undergone rearrangement of the immunoglobulin lambda (IGL) gene. Maturing T cells normally rearrange the T-cell receptor gamma and delta genes (TRG and TRD, respectively), and most cells then undergo rearrangement of the T-cell receptor alpha and beta genes (TRA and TRB, respectively). These mature T cells express the alpha and beta proteins and are termed α/β T cells. A small percentage of normal T cells fail to undergo TRA and TRB rearrangements, resulting in expression of surface gamma and delta proteins and these cells are termed δ/γ T cells. The gene rearrangement process results in editing of the original germline DNA to move one variable or V-region of the gene in contact with a single joining or J-region, sometimes with an individual diversity or D-region in between the two (Fig. 37.3). Varying numbers of small nucleotides are added between these regions. This shuffling of V-, D-, and J-regions results in variation in size of an individual reactive lymphocyte's antigen receptor gene, while clonal populations will have large numbers of cells with identically sized gene rearrangements. Molecular genetic assays attempt to capitalize on this difference between reactive and clonal populations, but some normal antigen responses may result in oligoclonal proliferations that can result in false positive results.

Mature B-cell lymphomas almost always show clonal rearrangements of the immunoglobulin genes, although rare cases may show simultaneous rearrangements of T-cell receptor genes.[16] Mature T-cell lymphomas almost always show clonal rearrangements of the T-cell receptor genes, but rare cases may show simultaneous rearrangements of the immunoglobulin genes, an occurrence which is particularly common in angioimmunoblastic T-cell lymphoma (AITL) (20%–30%), probably due to the presence of an associated B-cell proliferation.[17] However, precursor lymphoblastic lymphomas frequently show cross-lineage antigen receptor gene rearrangements.[18]

Analysis of the immunoglobulin and T-cell receptor gene status in lymphoid proliferations may help in determining clonality, which generally but not invariably indicates a neoplastic process,[19] and in determining lineage in mature lymphoid proliferations, with the caveats of possible cross-lineage gene rearrangements.[16,20] Demonstration of clonal immunoglobulin or T-cell receptor gene rearrangements is most commonly achieved by methods using the polymerase chain reaction (PCR) technique, which has superseded the much more laborious and demanding Southern blot technique.[21] Although PCR is a highly sensitive technique, being able to demonstrate even minor clonal populations, there can be significant false-negative results due to imperfect annealing of the consensus primers with the target DNA sequences which can be particularly difficult when fragmented DNA from formalin-fixed, paraffin-embedded tissue is used.[16,22,23] However, false-negative results can be significantly reduced by using multiple primer pairs against the antigen receptor gene target, such as using the BIOMED-2 primers.[18,24] False-positive results also occur with these assays, often related to oligoclonal proliferations or small numbers of lymphocytes in the specimens.[25] Newly developed next-generation sequencing assays appear to be useful in overcoming some of these obstacles.[26]

Chromosomal Translocation

In addition to clonal rearrangements of antigen receptor genes, a subset of non-Hodgkin lymphomas are associated with nonrandom chromosomal translocations, the more common of which are summarized in Table 37.2. Although most are not entirely specific for a single lymphoma type, their detection may be useful in the proper clinical setting which is discussed in more detail with the various lymphoma types.

Text continued on p. 1538

Table 37.1 Principal antibodies applicable on paraffin tissue sections for lymphoid proliferations

CD ANTIGEN AND/ OR ANTIBODY	PREDOMINANT NORMAL CELL REACTIVITY	REACTIVITY IN NEOPLASMS	COMMENT/CAUTION
Leukocytes			
CD45RB Leukocyte common antigen	B cells and most T cells, macrophages, myeloid cells	Most lymphomas and leukemias	Plasma cell neoplasms and Reed–Sternberg cells usually unreactive; some lymphoblastic and anaplastic large cell lymphomas unreactive
B Lymphocytes			
C20 (L26)	B cells, except plasma cells	Most B-cell lymphomas; L&H cells in NLPHL; some Reed–Sternberg cells in ~20% of classic Hodgkin lymphomas; rare T-cell lymphomas	Plasmablastic and plasma cell neoplasms usually unreactive; epithelium of some thymomas may stain
Immunoglobulin light chains	B cells and plasma cells	B-cell and plasma cell neoplasms	Cytoplasmic Ig often detectable in paraffin sections; surface Ig often requires flow cytometry or frozen tissue
CD79A	B cells, including most plasma cells	Most B-cell lymphomas; B-lymphoblastic leukemias	CD79A is associated with antigen receptor (Ig) on B cells in a similar manner as CD3 on T cells
PAX5	B cells, except most plasma cells	B-cell neoplasms, including B-lymphoblastic neoplasms; L&H cells in NLPHL; Reed–Sternberg cells in classic Hodgkin lymphoma show moderate to weak staining	Plasma cell neoplasms are usually unreactive
OCT2	B cells, including plasma cells	B-cell neoplasms, including plasma cell and plasmablastic neoplasms; strong nuclear expression in L&H cells of NLPHL; weak or absent staining in classical Hodgkin lymphoma	
BOB.1	B cells, including plasma cells	B-cell neoplasms, including plasma cell and plasmablastic neoplasms; weak or absent staining in classical Hodgkin lymphoma	Some T-cell lymphomas can be BOB.1 positive
B Lymphocyte Differentiation Stage			
CD10 (CALLA)	Precursor B cells, follicular center B cells; follicular center T helper cells; granulocytes	Many B-cell and some T-cell lymphoblastic lymphomas/leukemias; follicular lymphoma; Burkitt lymphoma; some large B-cell lymphomas; angioimmunoblastic T-cell lymphoma	Useful in separating follicular from other low-grade B-cell lymphomas; expressed by subset of myeloma; reactive with a variety of nonhematolymphoid neoplasms
BCL6	Follicular center B cells; follicular center T-helper cells; rare subpopulations of T cells	Follicular lymphoma; Burkitt lymphomas; some large B-cell lymphomas; angioimmunoblastic T-cell lymphoma; anaplastic large cell lymphoma	
MUM1	Plasma cells and plasmablasts; subpopulation of BCL6 follicular center B cells; small percentage of activated T cells	Plasma cell and plasmablastic neoplasms; lymphoplasmacytic lymphoma; diffuse large B-cell lymphoma (75% of cases); other B-cell lymphomas (variable); some T-cell lymphomas (variable)	MUM1 may be positive in nonhematolymphoid neoplasms, such as malignant melanoma
CD138	Plasma cells and plasmablasts; some immunoblasts	Plasma cell and plasmablastic neoplasms; some large B-cell lymphomas	CD138 is positive in normal epithelial cells and many nonhematolymphoid neoplasms

Table 37.1 Principal antibodies applicable on paraffin tissue sections for lymphoid proliferations—cont'd

CD ANTIGEN AND/ OR ANTIBODY	PREDOMINANT NORMAL CELL REACTIVITY	REACTIVITY IN NEOPLASMS	COMMENT/CAUTION
CD23	Mantle zone B cells, subset of follicular dendritic cells	CLL/small lymphocytic lymphomas usually reactive; follicular lymphoma (some cases); mediastinal large B-cell lymphoma; follicular dendritic cell tumor	Low-affinity Fc receptor for IgE; upregulated by EBV infection
T and NK Lymphocytes			
Cytoplasmic CD3 (detected by polyclonal or monoclonal antibody)	T cells and NK cells	Most T-cell and NK-cell lymphomas; exceptional cases of B-cell lymphoma can be CD3+	CD3 demonstrable in paraffin sections represents cytoplasmic CD3; this is present in T cells as well as NK cells. Surface CD3, which is typically positive in T cells but negative in NK cells (and their neoplasms), requires fresh or frozen tissue for demonstration.
CD2	T cells, NK cells	Most T-cell and NK-cell lymphomas and leukemias; few myeloid leukemias; systemic mastocytosis	CD2 is the sheep erythrocyte receptor
CD5	T cells, weak expression by small B-cell subset	Most T-cell lymphomas and leukemia; chronic lymphocytic leukemia/small lymphocytic lymphoma; mantle cell lymphoma; rare subset of diffuse large B-cell lymphoma	CD5-reactive B cells may be elevated in autoimmune disorders; expression of CD5 by diffuse small B-cell neoplasms useful in diagnosis; CD5 typically negative in NK cells and their neoplasms; CD5 can be expressed in nonhematolymphoid neoplasms, such as thymic carcinoma
CD7	Most T cells, NK cells	Most T-cell and some NK-cell lymphomas and leukemias; some myeloid leukemias	Earliest expressed antigen in T-cell ontogeny and one of the best T-cell markers for lymphoblastic neoplasms; most commonly deleted antigen in peripheral T-cell malignancy, particularly mycosis fungoides
TCRβ	Expressed by over 95% of mature T cells	Many T-cell lymphomas	NK cells and their neoplasms are unreactive
TCRγ	Expressed by a small population of mature T cells, often in extranodal sites	T-cell lymphomas of gamma/delta type, usually extranodal	NK cells and their neoplasms are unreactive
CD56	NK cells, minor subpopulation of T cells, neural tissues	NK-cell lymphomas; some peripheral T-cell lymphomas; some plasma cell neoplasms	Also reacts with neural and neuroendocrine cells and their neoplasms
CD43	T cells, macrophages, Langerhans cells, myeloid cells, minor subset of B cells	Most T-cell lymphomas; some B-cell lymphomas (CLL/small lymphocytic lymphoma, mantle cell lymphoma some marginal zone lymphomas); myeloid leukemias; histiocytic neoplasms; Langerhans cell histiocytosis; some plasma cell neoplasms	Coexpression on B cells is helpful for diagnosis, but caution should be used in interpreting partial coexpression due to heterogeneity of cell types that react with CD43

Table 37.1 Principal antibodies applicable on paraffin tissue sections for lymphoid proliferations—cont'd

CD ANTIGEN AND/ OR ANTIBODY	PREDOMINANT NORMAL CELL REACTIVITY	REACTIVITY IN NEOPLASMS	COMMENT/CAUTION
T- or NK-Cell Subset or Differentiation Stage			
CD57	Some NK cells; subset of germinal center T cells	T-cell large granular lymphocyte leukemia; rare cases of T-lymphoblastic neoplasm	CD57+ cells often rosette around L&H cells in NLPHL
PD1	Follicle helper T cells	Angioimmunoblastic T-cell lymphoma	PD1+ cells frequently rosette around L&H cells in NLPHL
CD4	Most helper/inducer T cells, many macrophages, many dendritic cells	Many peripheral T-cell lymphomas; histiocytic neoplasms; Langerhans cell histiocytosis	
CD8	Most cytotoxic/suppressor T cells, subset of NK cells, splenic sinus lining cells	Minority of peripheral T-cell lymphomas	
Precursor Cell Marker			
Terminal deoxynucleotidyl transferase (TdT)	Precursor cells in marrow B-cell precursors, cortical thymocytes	Most lymphoblastic lymphomas and leukemias of a T or B lymphoblastic lineage; some myeloid leukemias	Useful as marker of precursor cell
CD34	Various cell types, including endothelial cells and immature hematopoietic cells	Vascular tumors, gastrointestinal stromal tumors, many lymphoblasts and myeloblasts	May confirm immaturity in rare TdT negative lymphoblastic proliferations
Hodgkin Lymphoma-Associated			
CD30	Some activated B and T cells, some plasma cells	Reed–Sternberg cells in most cases of classic Hodgkin lymphoma; anaplastic large cell lymphomas; some B- and T-cell lymphomas	Embryonal carcinomas and few other nonhematolymphoid neoplasms reactive
CD15 (Leu-M1)	Granulocytes, some macrophages	Reed–Sternberg cells in most cases of classic Hodgkin lymphoma; large cells in some B- and T-cell lymphomas; histiocytic neoplasms; some myeloid leukemias	Many carcinomas reactive; CMV-infected cells reactive; antibody of IgM isotype and thus may benefit from isotype-specific detection; L&H cells usually unreactive
Accessory Cells			
CD68	Macrophages and monocytes; myeloid cells positive with KP1 but not PGM1 antibody	True histiocytic neoplasms; monocytic leukemias; myeloid leukemias positive with KP1	Reactive in granular cell tumors, some melanomas, malignant fibrous histiocytomas, and renal cell carcinomas
CD163	Macrophages except those of germinal centers and splenic white pulp	Histiocytic neoplasms; acute monocytic leukemia	Dendritic cells and their tumors are unreactive
Lysozyme	Macrophages, myeloid cells	Histiocytic neoplasms; many myeloid leukemias	Reactive with many nonhematolymphoid neoplasms
S100 protein	Langerhans cells, interdigitating (IDRC) and sometimes follicular dendritic cells	Langerhans cell histiocytosis; IDRC tumors; rare T-cell lymphomas; histiocytic neoplasms; Rosai–Dorfman disease	Reactive with many nonhematolymphoid neoplasms
CD1a	Cortical thymocytes, Langerhans cells	Some T-lymphoblastic lymphomas/ leukemias; Langerhans cell histiocytosis	
CD207 (langerin)	Langerhans cells	Langerhans cell histiocytosis	

Table 37.1 Principal antibodies applicable on paraffin tissue sections for lymphoid proliferations—cont'd

CD ANTIGEN AND/ OR ANTIBODY	PREDOMINANT NORMAL CELL REACTIVITY	REACTIVITY IN NEOPLASMS	COMMENT/CAUTION
CD21	Mantle and marginal zone B cells, follicular dendritic cells	Some B-cell lymphomas; follicular dendritic cell tumors	C3d (CR2) complement receptor; receptor for EBV; expanded CD21-positive follicular dendritic cell networks characteristic of angioimmunoblastic T-cell lymphoma
CD35	Mantle and marginal zone B cells, follicular dendritic cells, some macrophages	Some B-cell lymphomas; follicular dendritic cell tumors; some myeloid leukemias	C3b (CR1) complement receptor
Miscellaneous			
BCL2	Nongerminal center B cells, most T cells, plasma cells	Overexpressed in most follicular lymphomas and some diffuse large B-cell lymphomas; also expressed in many other lymphomas and leukemias	Most useful in differentiating follicular lymphoma from reactive follicular hyperplasia
Cyclin D1	Some histiocytes; normal lymphoid cells are negative	Mantle cell lymphoma; proliferation centers of some cases of CLL/small lymphocytic lymphoma; some plasma cell neoplasms; hairy cell leukemia	Cyclin D1 is expressed in many nonhematolymphoid neoplasms but is useful in confirming mantle cell lymphoma in a CD5 positive small B-cell proliferation
ALK	None	ALK+ anaplastic large cell lymphoma; ALK+ large B-cell lymphoma	ALK also positive in some cases of inflammatory myofibroblastic tumor
Myeloperoxidase	Myeloid cells	Myeloid leukemias	Most sensitive and specific marker for myeloid neoplasms

ALK, Anaplastic lymphoma kinase; *CLL,* chronic lymphocytic leukemia; *CMV,* cytomegalovirus; *EBV,* Epstein–Barr virus; *NLPHL,* nodular lymphocyte predominant Hodgkin lymphoma.

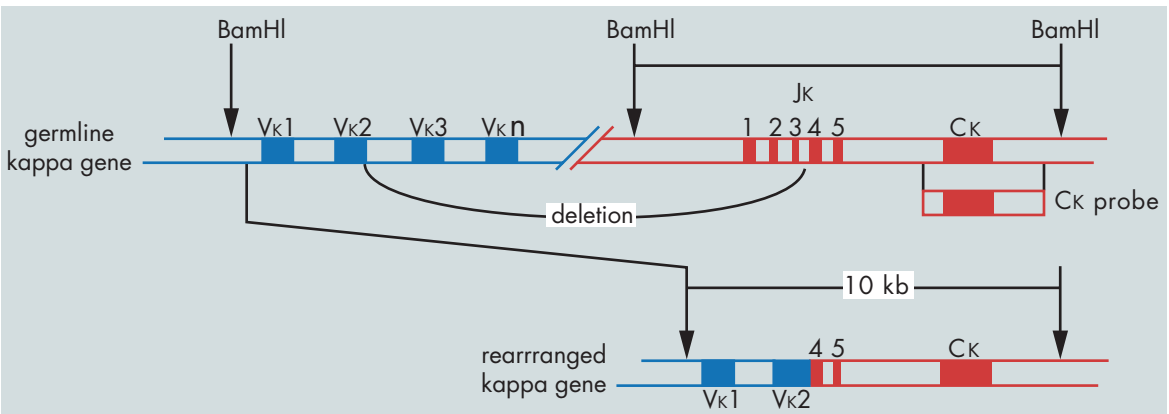

Figure 37.3 Schematic representation of an immunoglobulin gene rearrangement, in this case the kappa (IGK) gene. The germline configuration of the kappa light chain gene (upper line) consists of numerous variable gene segments (V-kappa, 1–*n*), five joining gene segments (J-kappa, 1–5), and a single constant region gene segment (C-kappa). To assemble a functional light chain gene (lower line), select V and J segments are juxtaposed with each other by deletion of the intervening DNA. The deletion reconfigures restriction enzyme cutting sites upstream of J-kappa, changing the size of the *BamH1* fragment detected with a C-kappa hybridization probe (12 kb germline vs. 10 kb rearranged in figure) when examined by Southern blot analysis. Current polymerase chain reaction method target detection of the rearranged product (lower line). (From Warnke RA, Weiss LM, Chan JKC, et al. *Tumors of the Lymph Nodes and Spleen. Atlas of Tumor Pathology*, series 3, fascicle 14. Washington, DC: Armed Forces Institute of Pathology; 1995.)

Table 37.2 Recurrent chromosomal abnormalities in lymphomas

CHROMOSOMAL ABNORMALITY	MOST FREQUENT TYPES OF LYMPHOMA	ANTIGEN RECEPTOR GENE	ONCOGENE

[a]Variable.
NA, Not applicable.

Chromosomal translocations are most often detected by conventional cytogenetics, direct or reverse transcriptase PCR, and fluorescence in situ hybridization (FISH). Each of these techniques has its own advantages and limitations. However, the FISH technique, either using break-apart probe or dual-fusion probes, generally offers the highest sensitivity and can often be performed in formalin-fixed, paraffin-embedded tissue.[27,28]

Chromosome Copy Change and Chromosomal Gain or Deletion

Increase in copies of entire chromosomes is common in certain lymphoma types, such as trisomy 3 or trisomy 18 in extranodal marginal zone lymphoma, and trisomy 12 in chronic lymphocytic leukemia (CLL)/small lymphocytic lymphoma (SLL).[29,30] Lymphomas can also exhibit deletions or gains of specific regions of chromosome, such as del 6q21–25 in extranodal NK/T-cell lymphoma, del 6q23.3 in marginal zone lymphoma, and gain of 3q26 in mantle cell lymphoma.[31] These chromosomal changes can be demonstrated by conventional cytogenetics, FISH, or single nucleotide polymorphism (SNP) microarrays but are usually less helpful diagnostically when compared to gene rearrangement studies or detection of chromosomal translocations.

Gene Mutation, Amplification, and Hypermethylation

Point mutations in specific genes are characteristic of some lymphoma types, including activating mutations of proto-oncogenes, such as point mutations in genes involved in regulation of the nuclear factor kappa B (NFκB) in some cases of diffuse large B-cell lymphoma (DLBCL), and inactivating mutations of tumor suppressor genes, such as *A20* in various lymphoma types.[32–35] An inactivating mutation in a tumor suppressor gene is often accompanied by chromosomal/gene deletion in the remaining allele, resulting in complete loss of function of the gene.[33,35] Tumor suppressors genes are alternatively inactivated in some lymphomas through hypermethylation of the gene promoters, such as p16 in mantle cell lymphoma.[36] Gene amplifications are found in some lymphomas, such as *REL* in DLBCL.[37]

Gene Expression Profiling

Some highly publicized studies have demonstrated the use of molecular profiling with the microarray technology to segregate DLBCLs into subtypes[38] and to predict survival after chemotherapy.[39] Although microarray-based gene expression profiling has provided tremendous information on various lymphoma types, this technology has not been reproducibly applied in the diagnostic setting[38] Instead, immunohistochemical algorithms[40] predictive of gene expression profiling results have become routine while new methods of detecting complex molecular lymphoma subtypes are being developed.

Primary Immunodeficiencies

Primary immunodeficiency syndromes are congenital abnormalities of the immune system that most often result in an increased risk of infection but are now also known to be associated with an increased risk for developing malignant lymphoma.[41,42] Over 250 genetic abnormalities have identified in associated with primary immunodeficiency, and the range of these defects and disorders is beyond the scope of this textbook. However, the genetic defects result in a decrease in number and/or function of normal B, T, and/or NK cells or their subsets. While loss of T cells, a feature of some types of severe combined immunodeficiency, is most striking in the

thymus, lymph nodes also often demonstrate loss of the normal immunoarchitecture. This may also include complete loss of B-cell follicles or the presence of "naked" germinal centers without normal mantle zones. Some disorders, such as Omenn's syndrome,[43] have normal or elevated numbers of T cells despite genetic mutations that impact T-cell function. Rare X-linked disorders associated with mutations of *SH2D1A* and *BIRC4* are associated with an Epstein–Barr virus (EBV) positive, fatal infectious mononucleosis-like proliferation that affects young males.[44]

Autoimmune lymphoproliferative syndrome (ALPS; Canale–Smith disease) occurs in young males with lymphadenopathy and hepatosplenomegaly and an average age of onset of 3 years.[45,46] It is an inherited disorder due to defects in FAS-mediated apoptosis and characterized in most instances by lymphadenopathy, splenomegaly, hypergammaglobulinemia, and autoimmune phenomena.[45,47] Most patients present in childhood, but cases of adult onset are on record.[48] Most patients with ALPS have germline, and less commonly somatic, mutations of *FAS* (*TNFRSF6*), *FASL*, or *CASP10* genes.[49] Four subtypes of this condition have been described.[49]

Microscopically, the main change in the affected lymph nodes is a marked paracortical expansion by a mixed population of small- and intermediate-sized lymphocytes and numerous large immunoblasts.[50,51] The interfollicular areas are expanded by a proliferation of T cells that lack both CD4 and CD8 ("double negative") with increased S100 positive dendritic cells.[52] This expansion can be so extensive as to simulate a lymphoma. In addition, there is often florid follicular hyperplasia, frequently accompanied by focal progressive transformation of germinal centers. A polyclonal plasmacytosis is also common.[51]

An increased incidence of malignant lymphoma has been detected in this population.[53] Interestingly, as many as 41% of patients with type Ia ALPS have Rosai–Dorfman disease (RDD)-like changes in their lymph nodes, raising the possibility that RDD may be related to ALPS and possibly represent a forme fruste of it.[52]

While the morphologic features of most primary immunodeficiency syndromes are nonspecific, the findings of recurrent atypical hyperplasia or persistent infectious mononucleosis-like changes in a young person should warrant further clinical and genetic evaluation for an underlying immune defect.[54]

Patterns of Hyperplasia

The various components of the lymph node react to various known and unknown stimuli by undergoing reactive changes, some being the expression of an inflammatory reaction and some being indicative of an immune response. The two are often present together. A similar microscopic picture may result from a variety of causes, but some agents produce a characteristic microscopic picture. When the hyperplastic change is very intense, the differential diagnosis with malignant lymphoma may become difficult[5,55,56] and may require the application of immunophenotyping and molecular genetic methods.[57]

Although most lymph node reactions involve several compartments, it is useful to evaluate these compartments individually, not only because their presence and relative intensity correlate with various specific disorders (thus providing important etiologic clues), but also because each of them raises differential diagnostic problems with different types of malignant processes. From a topographic and functional standpoint, the major patterns of reactive lymphoid proliferations are *follicular/nodular*, *interfollicular/paracortical*, *diffuse*, *sinus*, and *mixed*. These patterns also apply to the various types of malignant lymphoma (Table 37.3).

Follicular Hyperplasia

The criteria laid down in the classic article by Hicks et al.[58] and further elaborated by Nathwani et al.[59] remain extremely useful and reliable to distinguish reactive follicular hyperplasia from follicular lymphoma (Table 37.4). In general, reactive follicles vary considerably in size and shape; their margins are sharply defined and surrounded by a mantle of small lymphocytes often arranged circumferentially with an onion-skin pattern and sometimes concentrating on one pole of the follicle (corresponding to the side of the antigenic stimulation); the follicles are composed of an admixture of small and large lymphoid cells with irregular (elongated and cleaved) nuclei; mitoses are numerous; and phagocytosis of nuclear debris by histiocytes is prominent, resulting in a starry sky pattern. The lymphoid tissue present between the follicles is distinctly different from that of the follicles themselves (although this also may be true

Table 37.3 Differential diagnosis of reactive proliferations based upon recognition of predominant pattern in lymph node at low magnification

FOLLICULAR/ NODULAR	INTERFOLLICULAR/ PARACORTICAL	DIFFUSE	SINUS	MIXED/OTHER
Non-Neoplastic				
Reactive follicular hyperplasia Explosive follicular hyperplasia (HIV) Progressive transformation of germinal centers Castleman disease Rheumatoid lymphadenopathy Luetic lymphadenitis Kimura disease	Immunoblastic proliferations Viral lymphadenitis (EBV, CMV, herpes) Post-vaccination lymphadenitis Drug sensitivity, e.g., diphenylhydantoin (Dilantin)	Immunoblastic proliferations Viral lymphadenitis (EBV, CMV, herpes) Post-vaccination lymphadenitis Drug sensitivity, e.g., diphenylhydantoin	Sinus hyperplasia Rosai–Dorfman disease Lymphangiogram effect Whipple disease Vascular transformation of sinuses Hemophagocytic syndrome	Mixed hyperplasia Dermatopathic lymphadenopathy Toxoplasmosis Cat-scratch disease Systemic lupus erythematosus Kawasaki disease Kikuchi lymphadenitis Granulomatous lymphadenitis Inflammatory pseudotumor

Table 37.4 Architectural and cytologic features of follicular lymphoma and of reactive follicular hyperplasia

FOLLICULAR LYMPHOMA	REACTIVE FOLLICULAR HYPERPLASIA
Architectural Features	
Complete effacement of normal architecture	Preservation of nodal architecture
Even distribution of follicles throughout cortex and medulla	Follicles more prominent in cortical portion of lymph node
Slight or moderate variations in size and shape of follicles	Marked variations in size and shape of follicles with presence of elongated, angulated, and dumbbell-shaped forms
Fading of follicles	Sharply demarcated reaction centers
Massive infiltration of capsule and pericapsular fat with or without formation of neoplastic follicles outside capsule	No, or only moderate, infiltration of capsule and pericapsular fat tissue with inflammatory cells that may be arranged in perivascular focal aggregates (when associated with lymphadenitis)
Condensation of reticulin fibers at periphery of follicles	Little or no alteration of reticular framework
Cytologic Features	
Follicles composed of neoplastic cells exhibiting cellular pleomorphism with nuclear irregularities	Centers of follicles (germinal centers) composed of lymphoid cells, histiocytes, and "reticulum cells," with few or no cellular and nuclear irregularities
Lack of phagocytosis	Active phagocytosis in germinal centers
Relative paucity of mitotic figures usually without significant difference in their number inside and outside the follicles; occurrence of atypical mitoses	Moderate to pronounced mitotic activity in germinal centers; rare or no mitoses outside germinal centers; no atypical mitoses
Similarity of cell type inside and outside follicles	Infiltration of tissue between germinal centers with inflammatory cells (when associated with lymphadenitis)

Slightly modified from Rappaport H, Winter WJ, Hicks EB. Follicular lymphoma. A re-evaluation of its position in the scheme of malignant lymphoma, based on a survey of 253 cases. *Cancer.* 1956;9:792–821.

for follicular lymphoma); it is composed of a mixture of small lymphocytes, large lymphoid cells, prominent postcapillary venules, and sometimes a prominent component of mature plasma cells (Fig. 37.4).

Follicular hyperplasia can accompany a large number of inflammatory and noninfectious conditions. When the reactive follicles are particularly large ("giant"), particularly if there is associated zonal or single cell necrosis and a polymorphous, plasmacytoid paracortical expansion, infection by EBV should be suspected.

It should be kept in mind that follicular hyperplasia may coexist in the same node with follicular lymphoma or other types of malignant lymphoma.

The immunophenotypic differences between follicular hyperplasia and follicular lymphoma are discussed later, but the B-cells reactive follicles should not express BCL2 and should not harbor the *IGH/BCL2* fusion. However, immunoglobulin gene rearrangement studies may detect clonal or oligoclonal populations in reactive follicular hyperplasia, especially in association with EBV infection, and this test alone should not be used to diagnose lymphoma.

Progressively and Regressively Transformed Germinal Centers

Progressively transformed germinal centers are the morphologic expression of a distinct type of follicular hyperplasia. They usually are seen in conjunction with more typical reactive germinal centers and are often located more centrally within the node (Fig. 37.5).[60] They are large and contain numerous small lymphocytes, the borders are indistinct, and the interphase between the germinal center and the cuff of small lymphocytes is blurred. However, residual starry sky macrophages are present, together with scattered large lymphoid cells (cleaved and noncleaved) and occasional collections of epithelioid cells at the periphery.[61] There is an increased network of follicular dendritic cells, a larger number of mantle zone lymphocytes, and a relatively large number of T lymphocytes.[62] While multiple transformed germinal centers may be present, they do not form a distinct mass within the lymph node and are admixed with the more typical, small reactive follicles. Remnants of residual, BCL2-negative germinal center B cells remain within the transformed follicles and the surrounding mantle zones retain IgD-positive cells. Evaluation of these features should allow the differential diagnosis between progressively transformed germinal centers and follicular lymphoma to be made with ease in most instances; however, cases exist in which this is extremely difficult on the basis of routinely stained sections,[63] and immunohistochemical studies are warranted in most cases.

Progressively transformed germinal centers can occur as an isolated self-limited reactive process, particularly in young men.[63,64] However, they also show an interesting and still poorly understood relation with nodular lymphocyte predominant Hodgkin lymphoma (NLPHL), which may manifest itself in three ways: they may precede the development of NLPHL, they may accompany NLPHL in involved nodes, or they may appear in the absence of NLPHL in recurrent post-therapy adenopathy done for the latter.[65–67] Indeed, the main differential diagnosis of progressively transformed germinal centers is with NLPHL, which should be suspected if T-cell rosettes are prominent, if large B cells extend beyond the transformed germinal center or if the expanded nodules form tumor masses that displace

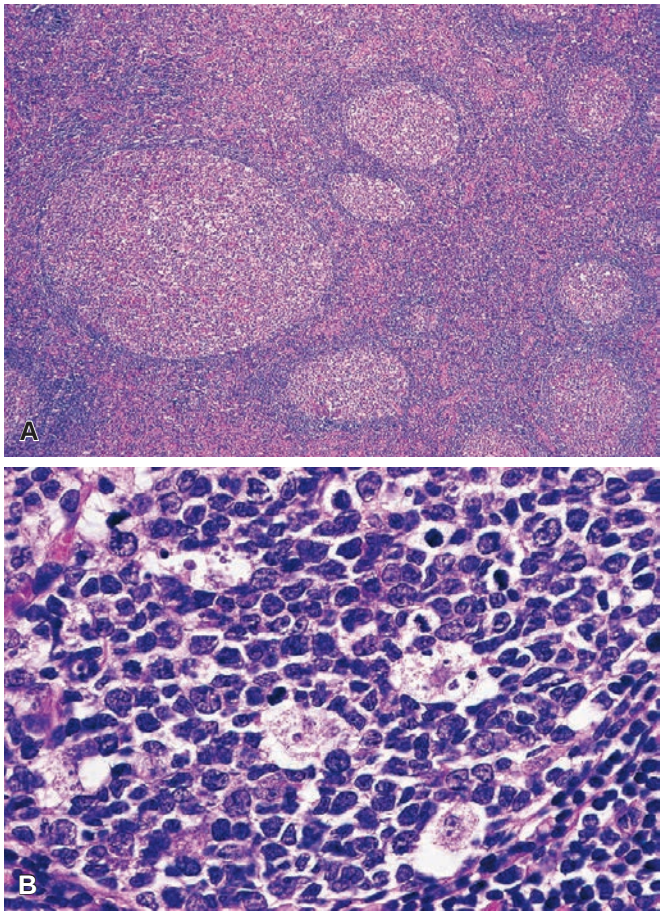

Figure 37.4 Follicular Hyperplasia. A, Low-power view showing marked differences in size of germinal centers, their well-circumscribed character, and the fact that they are surrounded by a well-defined mantle. **B**, High-power view showing numerous "tingible body" macrophages.

adjacent reactive or normal lymph node tissue. A thorough search for the atypical cells seen in NLPHL (see later) should then be undertaken.[68]

Regressively transformed germinal centers are small, practically devoid of lymphoid cells, and composed of follicular dendritic cells, vascular endothelial cells, and hyalinized periodic acid–Schiff (PAS)-positive intercellular material. These abnormal centers have an onion-skin appearance on low-power examination. Regressively transformed germinal centers are particularly prominent and numerous in Castleman disease (see later) but may also be seen with HIV infection or in association with AITL. A peculiar form of regressive germinal centers with "follicular dendritic cells only" has been described in organ transplant recipients.[69]

Mantle/Marginal Zone Hyperplasia

This pattern of hyperplasia, which blends with the lymphoid subtype of hyaline vascular Castleman disease, is characterized by a monomorphic proliferation of small lymphoid cells with round nuclei and clear cytoplasm which may be arranged in a nodular, inverse follicular, and/or marginal zone pattern. The main differential diagnosis is with the rare mantle zone pattern of mantle cell lymphoma and the monocytoid B-cell pattern of some cases of nodal marginal zone lymphoma. Features in favor of benignancy at the H&E level are the lack of pericapsular infiltration, preservation of sinuses, scattered reactive follicles, and paracortical nodular hyperplasia.[70] In addition, reactive "monocytoid B cells" are frequently BCL2 negative and contain admixed neutrophils. In contrast, the cells of marginal zone lymphoma are usually BCL2 positive and show aberrant coexpression of CD43 in approximately 40% of cases.[71,72] Mantle cell lymphoma shows aberrant coexpression of CD5 and CD43 on the B cells in the vast majority of cases as well as nuclear expression of cyclin D1, all features that are absent in reactive proliferations.

Paracortical Hyperplasia

Expansion of the paracortical (interfollicular) region can be nodular or diffuse. The nodular form is characteristic of dermatopathic lymphadenitis, while viral lymphadenitis, drug reactions, postvaccinial proliferations, and immunoblastic proliferations in general tend to be more diffuse (Fig. 37.6). The differential diagnosis of the diffuse form is often with peripheral T-cell lymphoma. These specific types of hyperplasia are discussed in more detail later.

Sinus Hyperplasia

The sinuses appear dilated and prominent in various disorders. The most common and least significant is *sinus hyperplasia* (sinus histiocytosis, sinus "catarrh") seen in nodes draining infectious or neoplastic processes and characterized by an increased number of macrophages in the lumen (Fig. 37.7). Other reactive disorders involving primarily the sinuses are RDD/sinus histiocytosis with massive lymphadenopathy (SHML), Langerhans cell histiocytosis (LCH), Whipple disease, vascular transformation of sinuses, and hemophagocytic syndromes.

Granulomatous Inflammation

There are a large number of diseases that can result in granulomatous formations in lymph nodes. They include various types of infection, foreign body reactions, aberrant immune reactions, sarcoidosis, and secondary responses in lymph nodes draining carcinoma[73,74] or in patients with Hodgkin lymphoma and other lymphomas, whether the node is involved by the malignancy or not,[75–77] and associated with metastatic seminoma. Sometimes the appearance of the granulomas is such that a specific diagnosis can be strongly suggested on the basis of the hematoxylin–eosin-stained slide.[78] Features of importance in this regard are the presence and type of necrosis; presence, number, and size of Langhans giant cells; size, shape, and distribution of the granulomas; and type of associated changes in the intervening tissue. In most cases, however, a combination of clinical, morphologic, and culture data is necessary to determine the etiology of the granulomas. It is therefore important that any node suspected of harboring a granulomatous process be sampled for culture analysis in addition to being subjected to the standard microscopic examination.

Other Cell Types Involved in Nodal Hyperplasia

Monocytoid B Cells

Monocytoid B-cell hyperplasia, a variation on marginal zone hyperplasia mentioned previously, is characterized by the filling of the sinuses by small lymphoid cells with round or angulated nuclei and clear cytoplasm, sometimes admixed with neutrophils (Fig. 37.8). It was originally described as *immature sinus histiocytosis*, but marker studies have shown that these monocytoid clear cells are of

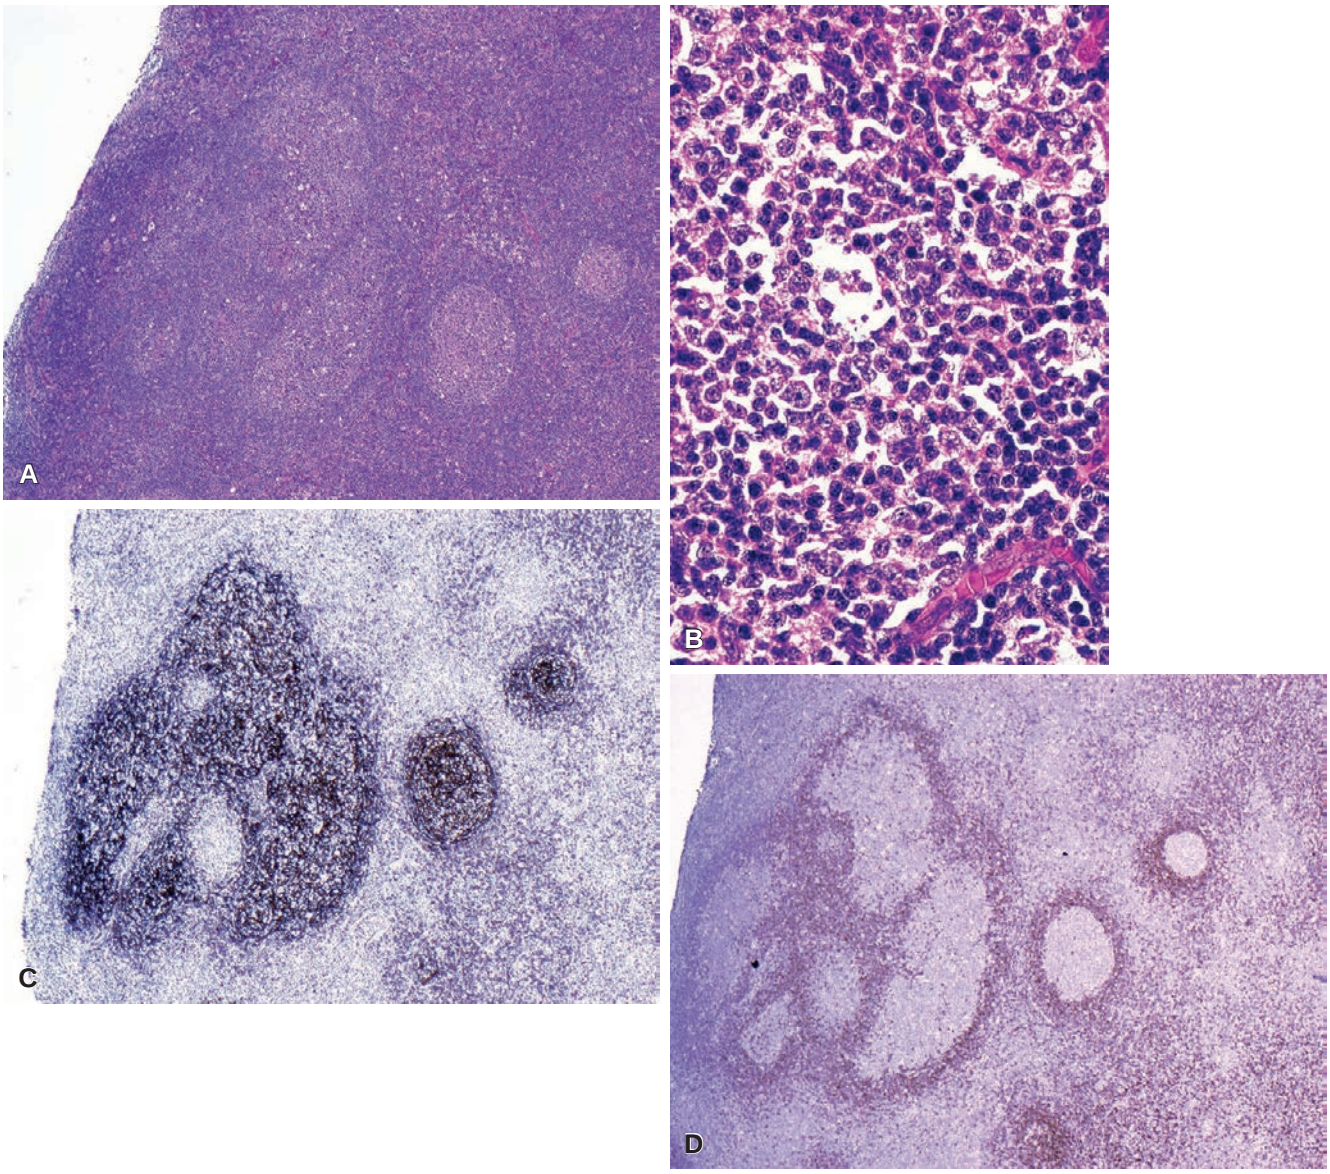

Figure 37.5 Progressively Transformed Germinal Centers. A, Low-power view showing that this formation is larger and less well defined than the adjacent hyperplastic follicles. **B**, High-power view showing cytologic composition not too dissimilar from that of ordinary hyperplastic follicles. **C**, CD21 staining highlights the expanded and disrupted follicular dendritic cell network of follicle. **D**, IgD staining shows preserved mantle zones with infiltration into the transformed germinal center.

B-cell type.[79,80] This alteration occurs most frequently in toxoplasmosis, but it has also been seen in many other reactive disorders, including cat-scratch disease,[81] infectious mononucleosis, AIDS, and autoimmune disorders[82]; it may also accompany malignant lymphomas, including Hodgkin lymphoma.[83] It should be distinguished from other nodal lesions featuring cells with clear cytoplasm (such as peripheral T-cell lymphomas, hairy cell leukemia, and mastocytosis) and also from a type of malignant lymphoma composed of cells with features of monocytoid B cells (nodal marginal zone B-cell lymphoma).[84]

Plasmacytoid Dendritic Cells

Clusters of cells with plasmacytoid cytoplasm, fine nuclear chromatin pattern, and small nucleoli are sometimes seen in a variety of reactive nodal lesions (Fig. 37.9). Pyknosis and starry sky pattern may be present.[85] These cells were originally interpreted as T-associated plasma cells and later as a subtype of T cells, but then as macrophages/monocytes (plasmacytoid monocytes), and more recently as a special form of dendritic cells.[86–88] They are particularly common in Kikuchi necrotizing lymphadenitis and Castleman disease,[89,90] but they can also be seen in other lymphadenitides[91] and in association with chronic myelomonocytic leukemia. Neoplasms of blastic plasmacytoid dendritic cells also occur.

Polykaryocytes

The term *polykaryocyte* is used for a type of multinucleated giant cell found in lymphoid tissues, of which the Warthin–Finkeldey giant cell of measles is the paradigm. These cells can be found in lymph nodes in association with a variety of reactive and neoplastic disorders.

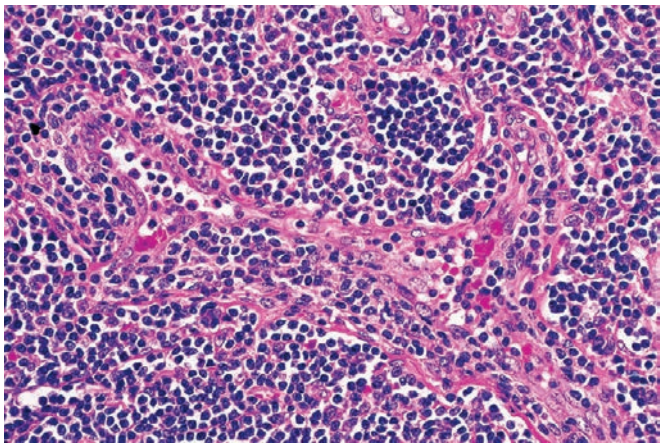

Figure 37.6 Paracortical hyperplasia, identified by the prominence of postcapillary venules.

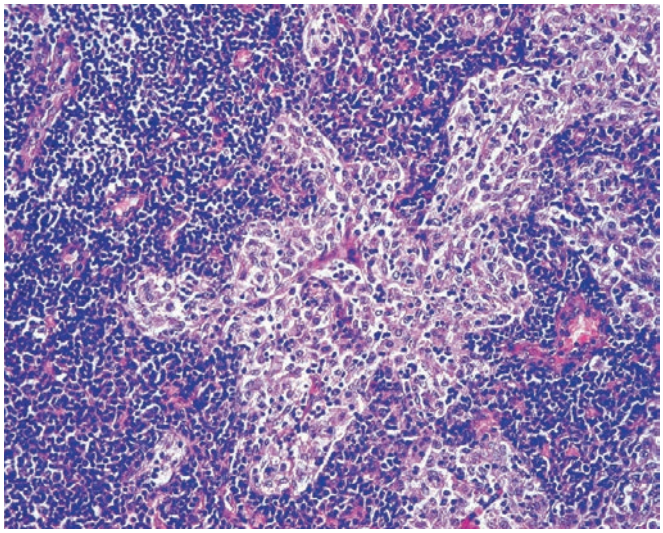

Figure 37.7 Sinus Hyperplasia. The cells present in the sinus represent an admixture of histiocytes and sinus lining cells.

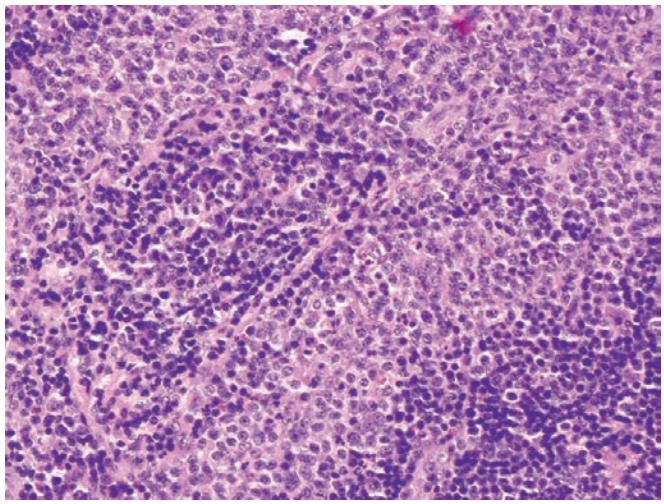
They measure 25–150 μm in diameter and have as many as 60 nuclei arranged in grapevine clusters.[92] Their cytoplasm is very scanty (Fig. 37.10). Although some early studies suggested a T-cell phenotype, more recent evaluations are in keeping with the hypothesis that these cells are multinucleated forms of follicular dendritic cells, a possibility that fits much better their morphologic appearance.[93]

Inflammatory/Hyperplastic Diseases

Acute Nonspecific Lymphadenitis

The typical case of acute nonspecific lymphadenitis is rarely biopsied. Microscopically, the earliest change is sinus dilation resulting from increased flow of lymph, followed by accumulation of neutrophils, vascular dilation, and edema of the capsule. *Suppurative lymphadenitis* is a feature of staphylococcal infection, mesenteric lymphadenitis, lymphogranuloma venereum, and cat-scratch disease. *Necrotizing features* may be seen in bubonic plague, tularemia, anthrax, typhoid fever, melioidosis, and the entity known as Kikuchi necrotizing lymphadenitis (see next section).



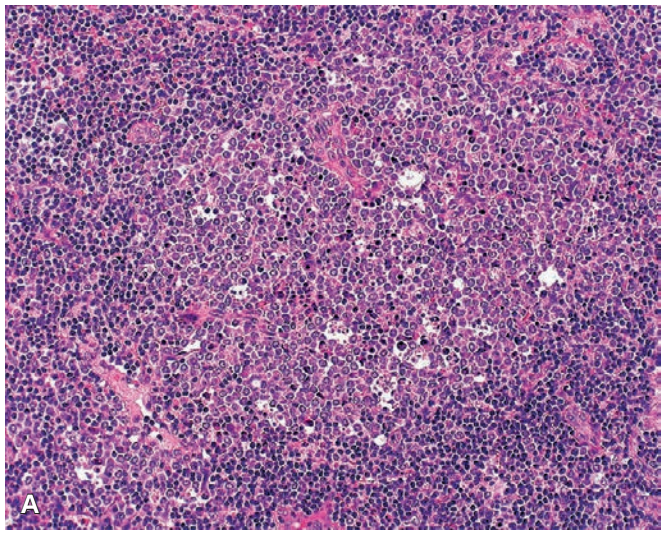


Figure 37.8 Monocytoid B-Cell Hyperplasia in a Case of Toxoplasmic Lymphadenitis. Clusters of small to medium-sized cells are present with clear cytoplasm. Note the presence of admixed neutrophils and nuclear remnants, a feature of reactive monocytoid B-cells.

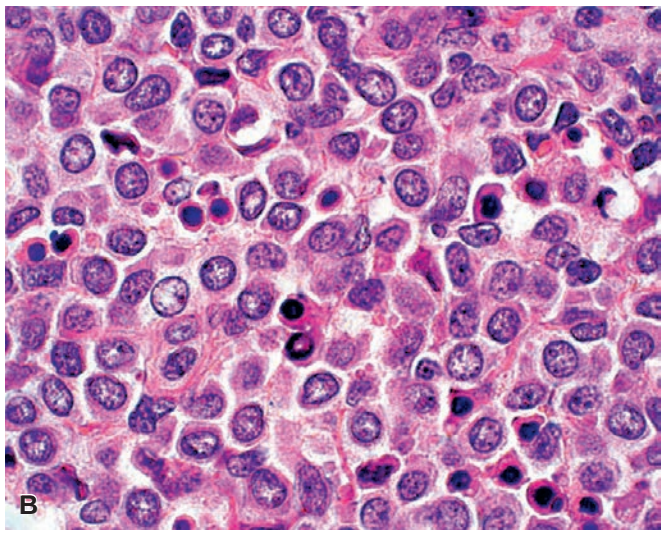

Figure 37.9 Plasmacytoid monocytes as seen on low (**A**) and high power (**B**).

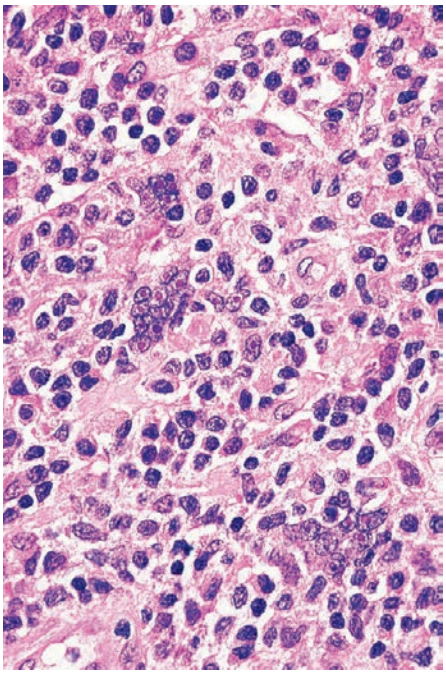

Figure 37.10 So-Called Polykaryocytes. These cells are characterized by numerous clustered nuclei.

Kikuchi Necrotizing Lymphadenitis

Kikuchi necrotizing lymphadenitis (Kikuchi lymphadenitis; Kikuchi–Fujimoto disease) is seen most commonly in Japan and other Asian countries,[94] but it also occurs elsewhere, including the United States and Western Europe. Most patients are young women with persistent, painless cervical lymphadenopathy of modest dimensions that may be accompanied by fever.[95] Microscopically, the affected nodes show focal, well-circumscribed, paracortical necrotizing lesions. There are abundant karyorrhectic debris, scattered fibrin deposits, and collections of mononuclear cells[96] with cellular debris but an absence of intact neutrophils (Fig. 37.11). Special studies have shown that the necrosis is the expression of cytotoxic lymphocyte-mediated apoptotic cell death.[97,98] Plasma cells are very scanty, and intact neutrophils are absent, a feature of diagnostic importance.[99,100] Instead, plasmacytoid dendritic cells, macrophages, and activated T cells are often numerous.[89,101] When these cells are abundant, the appearance may simulate that of malignant lymphoma.[102–104] The main lesional cells include histiocytes (CD68 and CD163+) that contain cytoplasmic myeloperoxidase and are associated with aggregates of plasmacytoid dendritic cells (TCL1 and CD123+).[87,105] On occasion, a prominent secondary xanthomatous reaction is seen and may be prominent.[106] Such cases may lack areas of necrosis, but the apoptotic debris without neutrophils remains in association with the xanthomatous change. Ultrastructurally, tubuloreticular structures and intracytoplasmic rodlets similar to those described in lupus erythematosus are often found.[107]

The diagnosis can be made or at least suspected in material from fine-needle aspiration because of the prominence of phagocytic histiocytes with peripherally placed ("crescentic") nuclei and medium-sized cells with eccentrically placed nuclei consistent with plasmacytoid dendritic cells.[108]

The evolution is generally benign and self-limited. However, cases have been described with recurrent lymphadenopathy or accompanied by skin lesions.[109,110] Isolated fatal cases are also on record.[111] The etiology is unknown. The most important differential diagnosis is with malignant lymphoma with secondary necrosis and the admixed T-cell component with large crescentic histiocytes may be overinterpreted as a peripheral T-cell lymphoma. Lupus lymphadenitis may demonstrate features identical to Kikuchi lymphadenitis, and the possibility of lupus should be investigated in all cases.[112] The hematoxylin bodies of lupus, which are not always present, should not be seen with Kikuchi disease.

Chronic Nonspecific Lymphadenitis

The morphologic features and the very concept of chronic lymphadenitis merge with those of hyperplasia. The general features of chronic lymphadenitis are follicular hyperplasia; prominence of postcapillary venules; increased number of immunoblasts, plasma cells, and histiocytes; and fibrosis. The capsule may appear inflamed and/or fibrotic, and the process may extend into the immediate perinodal tissues. In some cases, one may find an undue predominance in the number of eosinophils, foamy macrophages, and/or mast cells. Terms such as *eosinophilic* or *xanthogranulomatous lymphadenitis* have been sometimes used, depending on the type of the infiltrate.[113] The presence of numerous eosinophils in a lymph node should raise the possibility of Langerhans cell histiocytosis, parasitic infections, Hodgkin lymphoma, autoimmune disorders, and Kimura disease. Eosinophils can also be numerous in epithelioid hemangioma/angiolymphoid hyperplasia with eosinophilia (which may rarely involve lymph nodes), Churg–Strauss disease, T-cell lymphomas, and various chronic eosinophilic neoplasms.

Tuberculosis

Lymph nodes involved by tuberculosis may become adherent to each other and form a large multinodular mass that can be confused clinically with metastatic carcinoma (Fig. 37.12). The most common location of clinically apparent lymphadenopathy is the cervical region ("scrofula"), where a draining sinus that communicates with the skin ("scrofuloderma") may form.[114] Microscopically, the appearance ranges from multiple small epithelioid granulomas reminiscent of sarcoidosis to huge caseous masses surrounded by Langhans giant cells, epithelioid cells, and lymphocytes. Demonstration of the organisms by special stains, cultures, or PCR is necessary to establish the diagnosis.[115]

Atypical Mycobacteriosis

Atypical mycobacteria are a common cause of granulomatous lymphadenitis. In the United States, caseating granulomatous disease in a cervical lymph node of a child unaccompanied by pulmonary involvement is more likely to be caused by an atypical mycobacterium. The process typically involves lateral nodes in the midportion of the neck. Drainage may continue for months or years in the absence of specific therapy, and healing may result in scarring and contractures. Microscopically, the host reaction may be indistinguishable from that of tuberculosis, but often the granulomatous response is overshadowed by suppurative changes.[116–118] A nontuberculous mycobacterial etiology should also be suspected if the granulomas are ill-defined (nonpalisading), irregularly shaped, or serpiginous.[50,117] An acid-fast stain should be performed in every granulomatous and suppurative lymphadenitis of unknown etiology, especially if the patient is a child or an HIV-infected individual.[119] The final identification of the organism rests on the culture or molecular characteristics.

In immunosuppressed patients, mycobacterial infections may result in a florid spindle cell proliferation that can simulate a neoplastic process *(mycobacterial spindle cell pseudotumor)*.[120]

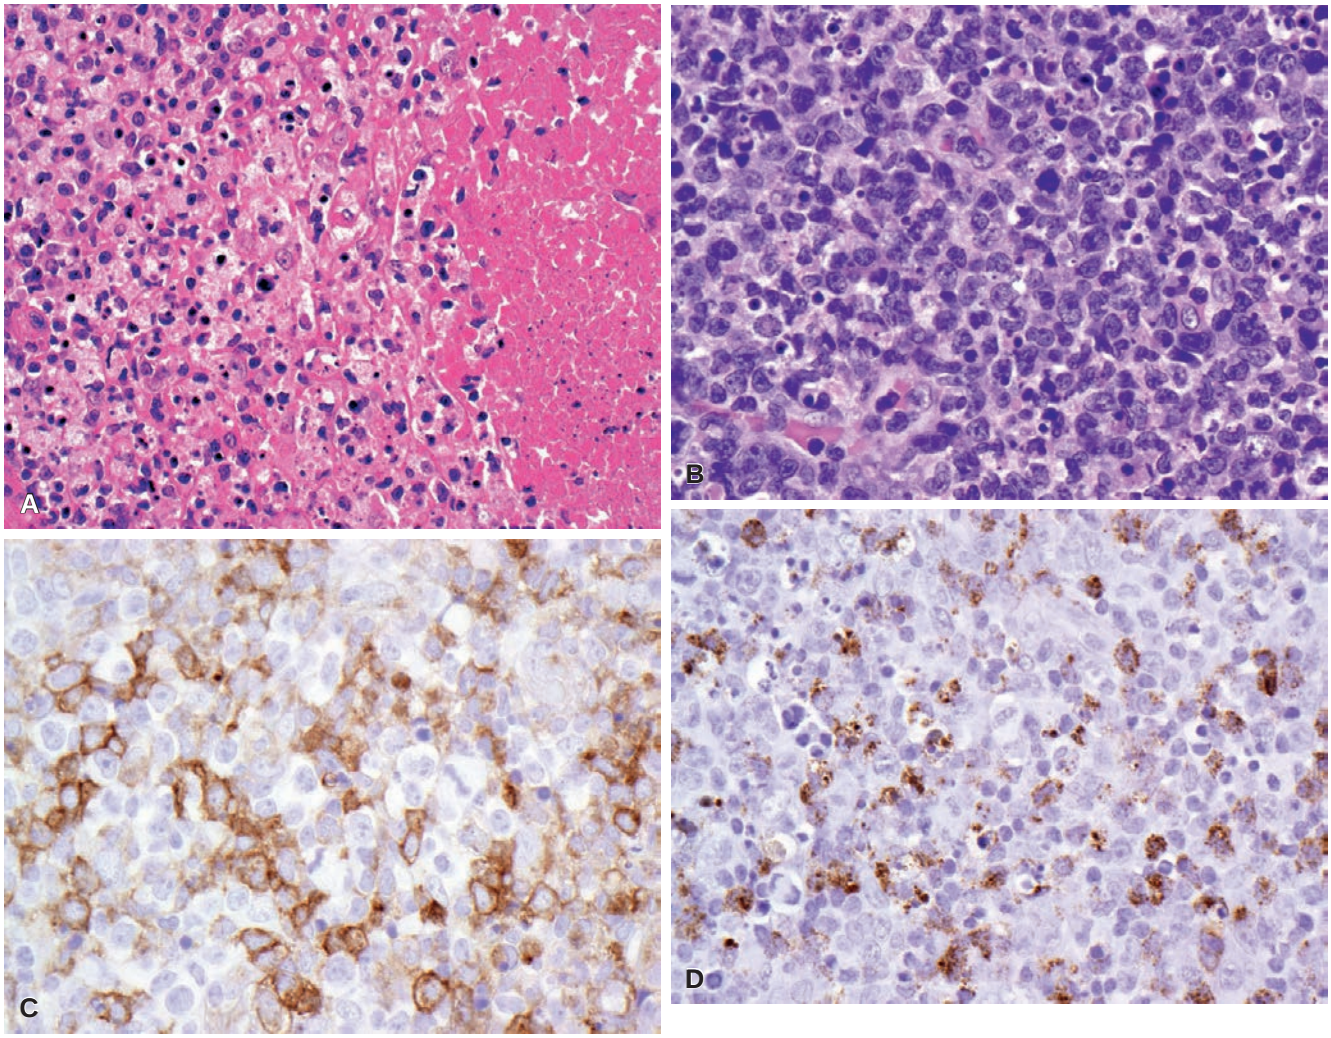

Figure 37.11 Necrotizing Lymphadenitis (Kikuchi-Fujimoto Disease). A, The most common pattern shows necrosis with karyorrhexis/pyknosis with nuclear debris but no neutrophils. **B**, Other cases show a more mononuclear infiltrate with debris without zonal necrosis. **C**, Increased numbers of CD123-positive cells, and **D,** myeloperoxidase positive histiocytes, support the diagnosis.

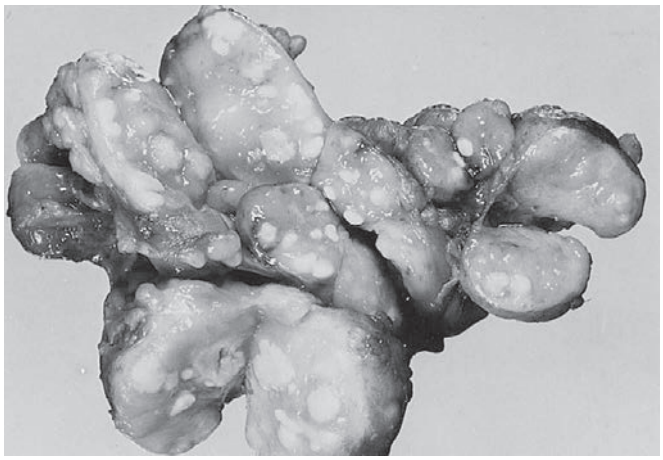

Figure 37.12 Large adherent tuberculous lymph nodes containing extensive foci of caseation necrosis.

Sarcoidosis

The enigmatic clinicopathologic entity known as sarcoidosis has a worldwide distribution.[121] Scandinavian countries are particularly affected.[122] In the United States, the disease is 10–15 times more common in blacks than in whites. Practically every organ can be involved, but the ones most commonly affected are lung, lymph nodes, eyes, skin, and liver.[123–125] Erythema nodosum often precedes or accompanies the disease. Functional hypoparathyroidism is the rule, although a few cases of sarcoidosis coexisting with primary hyperparathyroidism have also been reported.[126,127] This seems to be due to the secretion of a parathyroid hormone (PTH)-related protein by the cells in the granuloma.[128]

Microscopically, the basic lesion is a small granuloma mainly composed of epithelioid cells, with scattered Langhans giant cells and lymphocytes (Fig. 37.13).[129] As a general rule, the Langhans giant cells are smaller and have fewer nuclei than those typically seen in tuberculosis. Necrosis is either absent or limited to a small central fibrinoid focus ("hard" granulomas); a "necrotizing" variant of sarcoidosis exists, but this is usually extranodal. Schaumann bodies, asteroid bodies, and calcium oxalate crystals are sometimes found

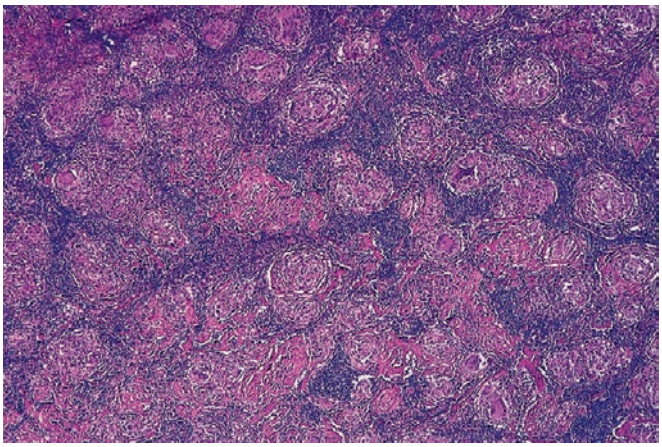

Figure 37.13 Numerous confluent non-necrotizing granulomas mainly composed of epithelioid cells in a lymph node affected by sarcoidosis.

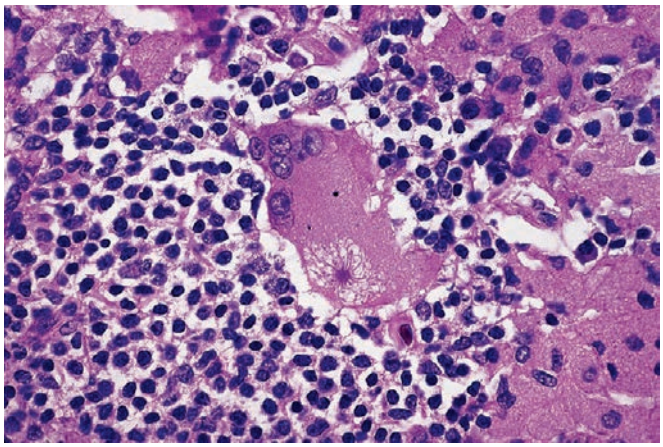

Figure 37.14 Asteroid body in the cytoplasm of a multinucleated giant cell in sarcoidosis.

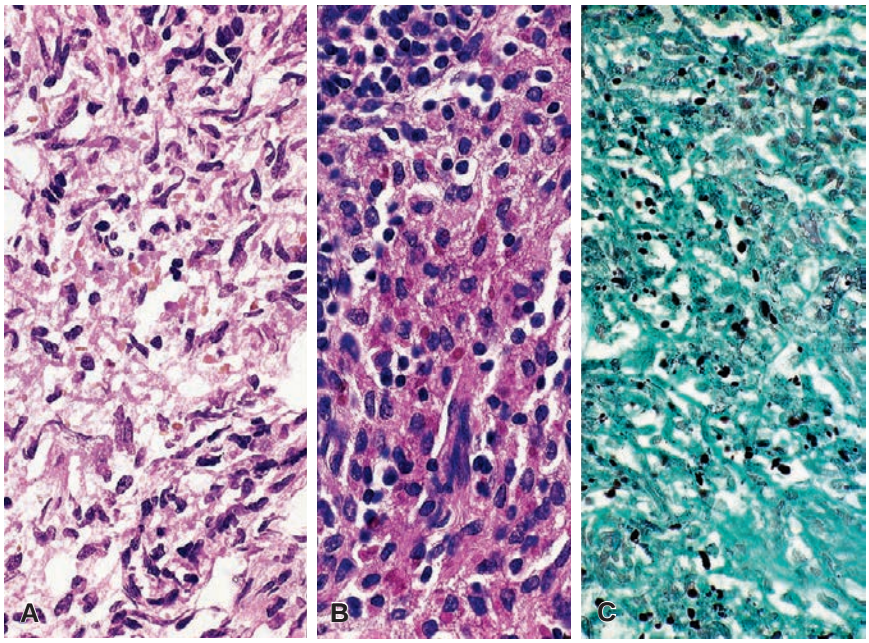

Figure 37.15 Hamazaki–Wesenberg bodies in a lymph node with sarcoidosis, as shown in (**A**) hematoxylin–eosin, (**B**) periodic acid–Schiff, and (**C**) Gomori methenamine-silver stains.

in the cytoplasm of the giant cells (Figs. 37.14 and 37.15).[130] Schaumann bodies are round, have concentric laminations, and contain iron and calcium. Ultrastructurally, asteroid bodies are composed of radiating filamentous arms enveloped by "myelonoid" membranes.[131] Elemental analysis has shown calcium, phosphorus, silicon, and aluminum in these formations.[129,131] Peculiar PAS-positive inclusions known as Hamazaki–Wesenberg, yellow, or ovoid bodies were claimed to be specific for sarcoidosis, but subsequent histochemical and ultrastructural studies[132] have shown that they have no etiologic or pathogenetic significance. They probably represent large lysosomes containing hemolipofuscin material and are found in a large variety of conditions.[130,133] None of these inclusions is specific for sarcoidosis. From a pathologic standpoint the diagnosis of sarcoidosis is always one of exclusion. A noncaseating granulomatous inflammation in the lymph nodes or skin microscopically indistinguishable from sarcoidosis can be seen in tuberculosis, atypical mycobacteriosis (including swimming pool granuloma), fungus diseases, leprosy, syphilis, leishmaniasis, brucellosis, tularemia, chalazion, zirconium granuloma, berylliosis, Crohn disease, and Hodgkin lymphoma; in nodes draining a carcinoma; and in several other conditions.[134] Only when all these possibilities have been excluded and the clinical picture is characteristic is there justification in labeling a case as consistent with sarcoidosis.

Most of the lymphocytes present in the sarcoidal granulomas are CD4-positive T cells; both these cells and the epithelioid histiocytes exhibit features of proliferation and/or activation, as shown by their immunocytochemical positivity with the Ki-67 antibody and for interleukin-1, respectively.[135,136] Pathogenetically, sarcoidosis is thought to represent a dysfunction of circulating T cells with overactivity of B cells.[137] The association of particular human leukocyte antigens (HLAs) with sarcoidosis suggests a role for HLA-linked immune response genes and disease susceptibility.[138] Specifically, it has been shown that certain types of genetic polymorphism are associated with increased risk of disease or affect disease presentation.[139]

The Kveim test for sarcoidosis is an intradermal reaction that occurs following inoculation with an extract of human spleen involved with the disease. It is positive in 60%–85% of patients with sarcoidosis, and the number of false-positive results is small. The test is regarded as positive when a biopsy of the area taken 4–6 weeks after inoculation shows microscopically sarcoid-type granuloma. A trial employing a single test suspension among 2400 subjects in 37 countries on six continents showed a similar level of reactivity and microscopic appearance from country to country, supporting the concept that sarcoidosis is the same disease the world over. The Kveim test is rarely practiced today because of lack of availability of the antigen. The etiology and pathogenesis of sarcoidosis remain elusive.[140]

Fungal Infections

Fungal infections of lymph nodes may present as chronic suppurative lesions, as granulomatous processes, or as a combination of the two. The most important fungal lymphadenitis is *histoplasmosis*, which in addition to the previously mentioned patterns can also result in widespread nodal necrosis and in marked diffuse hyperplasia of sinus histiocytes (Fig. 37.16). Other fungal diseases known to result in lymphadenitis are blastomycosis, paracoccidioidomycosis, coccidioidomycosis, and sporotrichosis.[141] To these, one should add opportunistic infections such as cryptococcosis, aspergillosis, mucormycosis, and candidiasis.

The fungal organisms can usually be demonstrated with Gomori methenamine silver (GMS) or PAS–Gridley stains, but sometimes their number is so small that they can be detected only in cultures or by molecular testing.[10]

Toxoplasmosis

Toxoplasmosis, one of the most common parasitic infections of humans and other warm-blooded animals, is caused by the protozoan parasite *Toxoplasma gondii*.[142] Toxoplasmic lymphadenitis (formerly known as Piringer–Kuchinka lymphadenitis), in its most typical form, involves the posterior cervical nodes of young women.[143] On palpation, the nodes are firm and only moderately enlarged. Microscopically, the nodal architecture is rather well preserved. The typical triad of the disease, which is not present in all cases, is constituted by: (1) marked follicular hyperplasia, associated with intense mitotic activity and phagocytosis of nuclear debris; (2) small, loose collections of epithelioid histiocytes, located within the hyperplastic follicles and at the periphery, encroaching on and blurring their margins; and (3) distention of marginal and cortical sinuses by monocytoid B cells (Fig. 37.17). An additional feature is the presence of immunoblasts and plasma cells in the medullary cords.[144] Variations on the theme include presence in

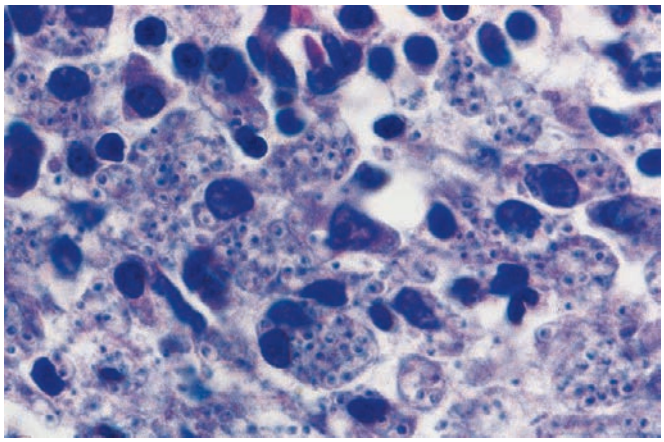

Figure 37.16 Numerous *Histoplasma* organisms in the cytoplasm of histiocytes.

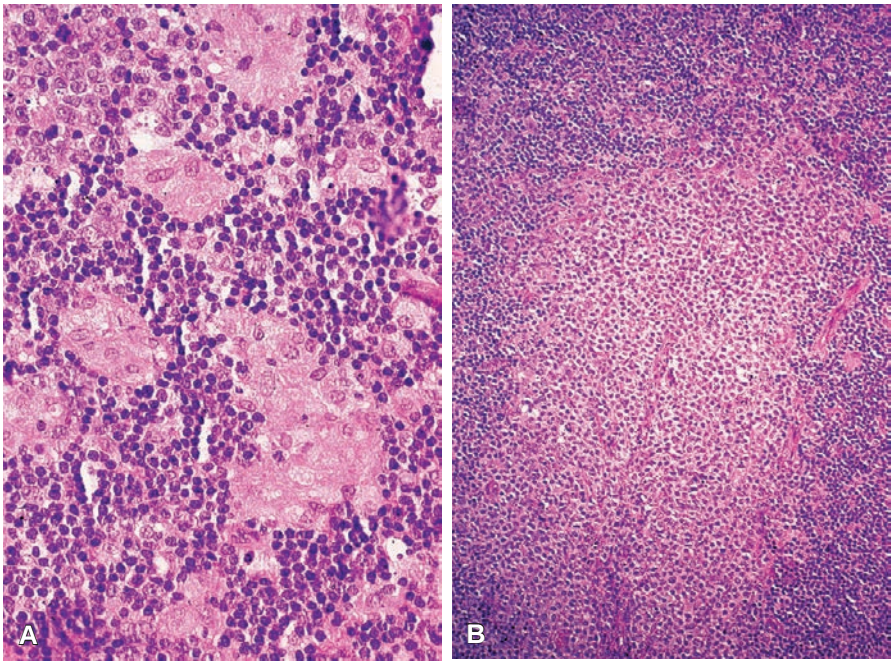

Figure 37.17 Toxoplasmosis of Lymph Node. A, Small noncaseating granulomas composed of epithelioid cells are located at the periphery of a hyperplastic follicle. This picture is almost pathognomonic of this disease. **B**, An area of massive monocytoid B-cell hyperplasia.

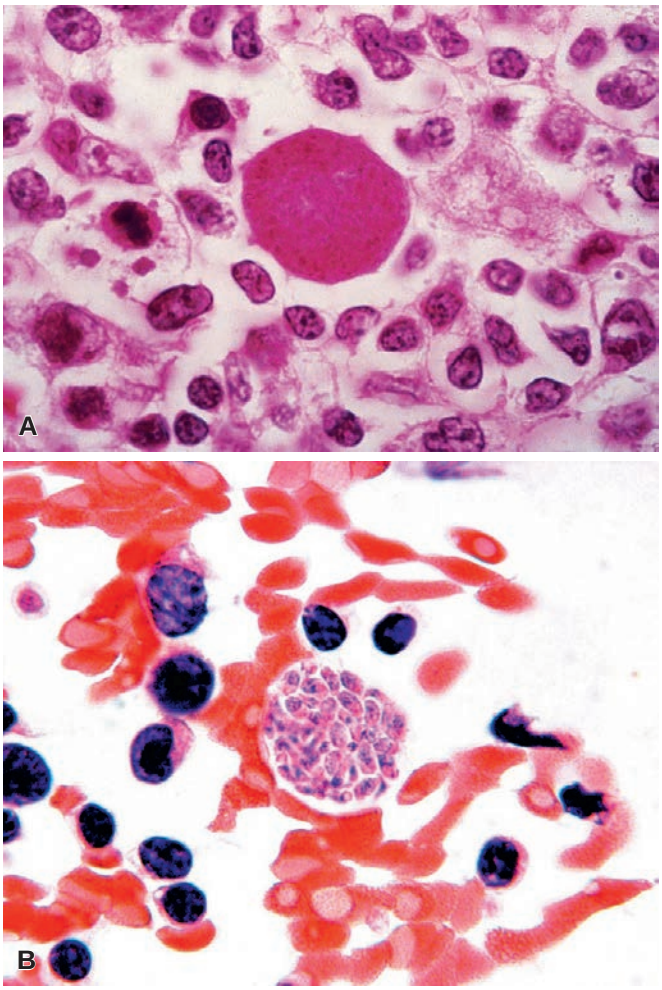

Figure 37.18 *Toxoplasma* cyst as seen in a microscopic section, (**A**) and a touch preparation (**B**). This is a very unusual finding in lymph nodes affected by the disease.

the granulomas of necrosis or more than an occasional Langhans giant cell.

It is extremely rare to find *Toxoplasma* organisms in the lymph node by morphologic examination, immunohistochemistry, or PCR (Fig. 37.18).[145,146] This finding contrasts sharply with the results obtained in toxoplasmic encephalitis and myocarditis[146] and suggest that the lymph node findings may be an immunologic response to infection at other sites. The combination of microscopic features described correlates remarkably well with serologic studies. Of 31 cases studied by Dorfman and Remington[147] the Sabin–Feldman dye test was positive in all and the IgM immunofluorescent antibody test was positive in 97% of the cases.

If the diagnosis of toxoplasmic lymphadenitis is suspected from the microscopic pattern, it should be confirmed serologically, keeping in mind that these tests may be normal in the early stages of the disease.[148]

The differential diagnosis of toxoplasmosis includes other infectious diseases and the lymphocyte predominant form of Hodgkin lymphoma. In this regard, Miettinen and Franssila[149] have made the interesting point that occurrence of collections of epithelioid cells *within* germinal centers seems to be a nearly specific feature for toxoplasmosis.

Syphilis

Generalized lymphadenopathy is a common finding in secondary syphilis, whereas localized node enlargement can be seen in the primary and tertiary stages of the disease. In secondary syphilis, the changes are those of a florid follicular hyperplasia. In primary syphilis, the combination of changes may result in a mistaken diagnosis of malignant lymphoma. Most of the cases have presented as solitary inguinal lymphadenopathy.[150] There are capsular and pericapsular inflammation and extensive fibrosis, diffuse plasma cell infiltration with extension often into or beyond the capsule, proliferation of blood vessels with endothelium swelling and inflammatory infiltration of vessel walls (phlebitis and endarteritis), and follicular hyperplasia (Fig. 37.19).[150] Rarely, noncaseating granulomas and abscesses are present. Exceptionally, the appearance is that of a nodal inflammatory pseudotumor, the message being that spirochetes should be searched for whenever making that diagnosis in a nodal biopsy, by histochemical or immunohistochemical stain.[151]

The morphologic features of syphilitic infection are not substantially different when occurring in HIV-infected patients[152] and can be identified in most cases by the Warthin–Starry or Levaditi stains, by immunofluorescence techniques applied to imprint preparations, or immunohistochemical staining on paraffin section.[153] The organisms are most frequently found in the wall of blood vessels. Detection of *Treponema pallidum* is now also feasible in lymph node biopsies and fine needle aspirations by PCR.[154]

Leprosy

Lymph nodes involved by the lepromatous type of leprosy have a very characteristic microscopic appearance. The main change is the progressive accumulation of large, pale, rounded histiocytes ("lepra" or "Virchow" cells), without granuloma formation and with minimal or no necrosis (Fig. 37.20). Wade–Fite and Fite–Faraco stains (which are modified Ziehl–Neelsen reactions) demonstrate packing of the cytoplasm by acid-fast organisms, which can also be demonstrated by a fluorescent method,[155] and by PCR.[156]

Mesenteric Lymphadenitis

Mesenteric (Masshoff) lymphadenitis is produced by *Yersinia pseudotuberculosis* or *Yersinia enterocolitica*, two gram-negative polymorphic coccoid or ovoid motile organisms.[157–160] It is a benign, self-limited disease that can clinically simulate acute appendicitis. Microscopically, there are capsular thickening and edema, increase of immunoblasts and plasma cells in the cortical and paracortical region, dilation of sinuses with accumulation of large lymphocytes within, and germinal center hyperplasia.[161,162] In the lymphadenitis produced by *Y. pseudotuberculosis*, small granulomas and abscesses are commonly present, whereas this is unusual in infection caused by *Y. enterocolitica*.[162] These nodal changes are accompanied by inflammatory changes of the terminal ileum and cecum. Ideally, the diagnosis should be confirmed with cultures. Too often, the diagnosis of mesenteric lymphadenitis is made on normal or mildly hyperplastic nodes in an attempt to explain why a patient with the clinical picture of acute appendicitis has a normal appendix.

The organism can be identified by PCR. Interestingly, *Yersinia* DNA has been detected in mesenteric lymph nodes in patients with Crohn disease.[163]

Cat-Scratch Disease

Cat-scratch disease is characterized by a primary cutaneous lesion and enlargement of regional lymph nodes, usually axillary or cervical

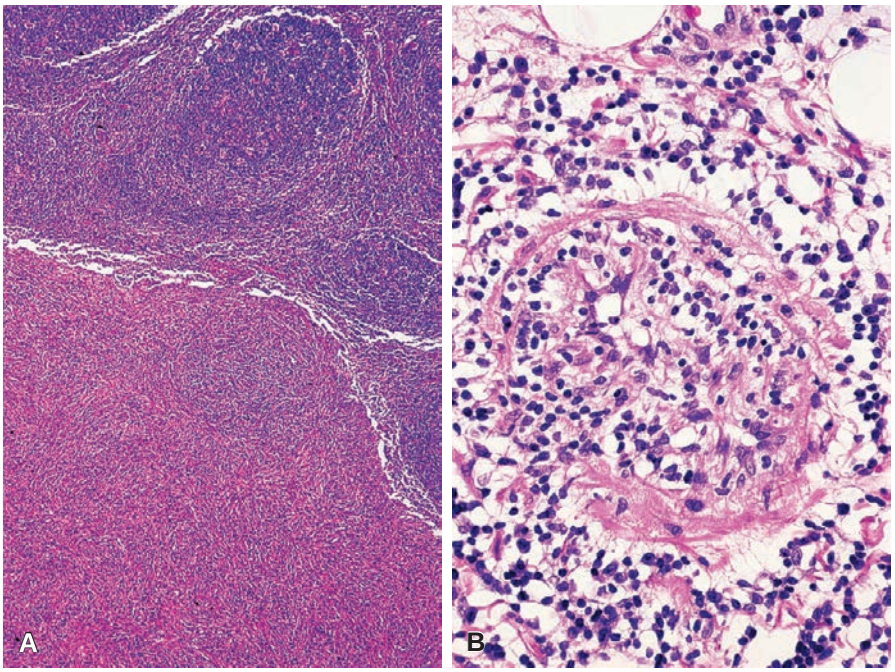

Figure 37.19 Syphilis of Lymph Node. A, Follicular hyperplasia associated with striking pericapsular inflammation and fibrosis. **B**, The prominent vasculitis seen in this field is an important clue to the diagnosis.

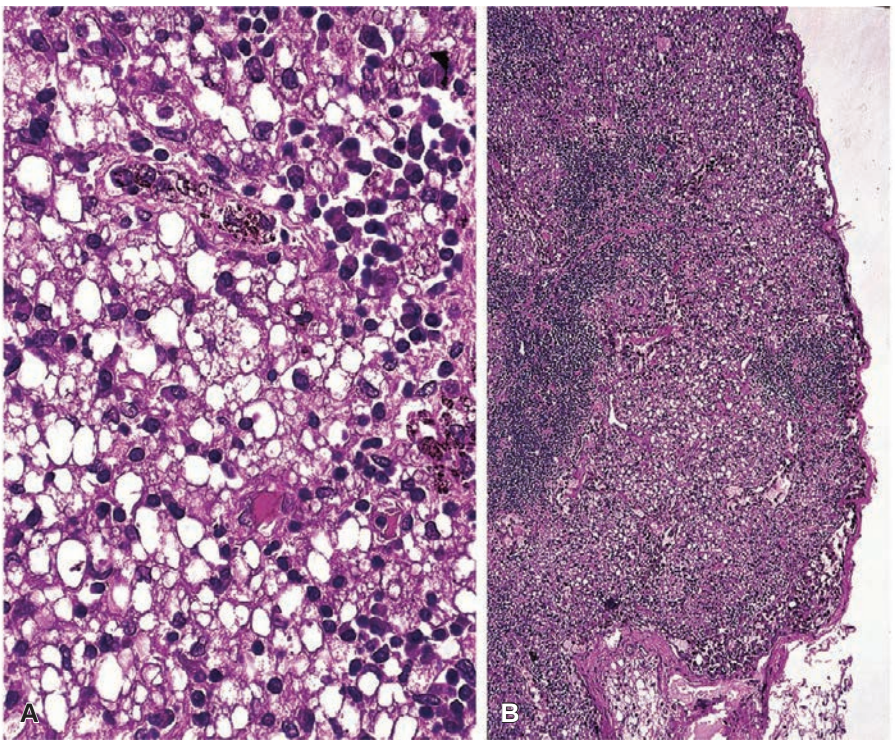

Figure 37.20 A and **B**, Lymph node involvement by lepromatous leprosy. The sinuses are massively dilated as a result of the accumulation of foamy histiocytes.

(Fig. 37.21).[164] The changes in the nodes vary with time. Early lesions have histiocytic proliferation and follicular hyperplasia, intermediate lesions have granulomatous changes, and late lesions have abscesses of various sizes (Fig. 37.22).[165] These abscesses are very suggestive of the diagnosis because of their pattern of central, sometimes stellate necrosis with abundant neutrophils, surrounded by a palisading of histiocytes.[166] However, similar abscesses can be seen in lymphogranuloma venereum. Another common feature of lymph nodes with cat-scratch disease is the packing of sinuses by monocytoid B cells, which, together with the follicular hyperplasia, may simulate

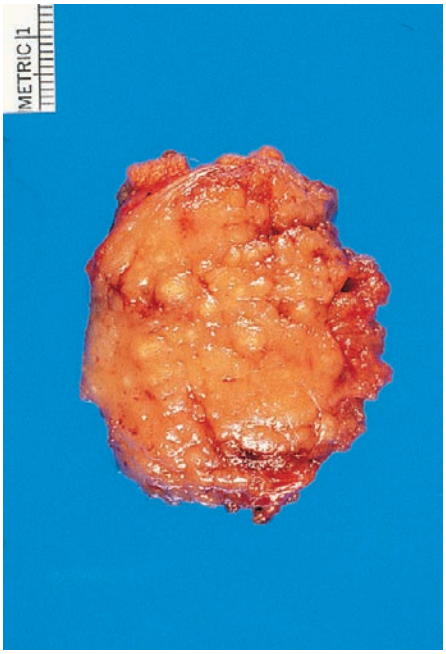

Figure 37.21 Lymph Node Involved by Cat-Scratch Disease.

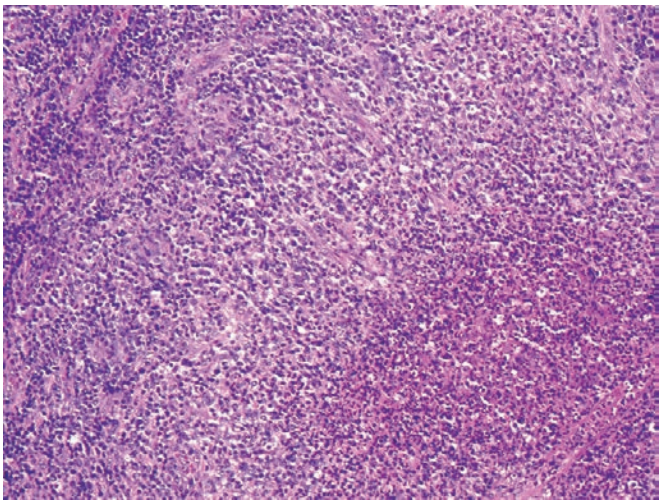

Figure 37.22 Cat-scratch disease with an area of stellate necrosis with neutrophils surrounded by histiocytes.

toxoplasmosis.[81] However, clusters of perifollicular and intrafollicular epithelioid cells are absent.[55]

The primary lesion is a red papule in the skin at the site of inoculation, usually appearing between 7 and 12 days following contact. It may become pustular or crusted. Microscopically, there are foci of necrosis in the dermis surrounded by a mantle of histiocytes. Multinucleated giant cells, lymphocytes, and eosinophils are also present.[167]

The agent of cat-scratch disease is a coccobacillary pleomorphic extracellular bacterium that can be identified with the Warthin–Starry silver stain or by immunohistochemistry, particularly in those cases exhibiting extensive necrosis.[168–170] This organism, which has also been detected ultrastructurally,[171] was originally designated *Rochalimaea henselae* and has been renamed *Bartonella henselae*. The diagnosis can be confirmed by serology, immunohistochemistry, or PCR.[172–175]

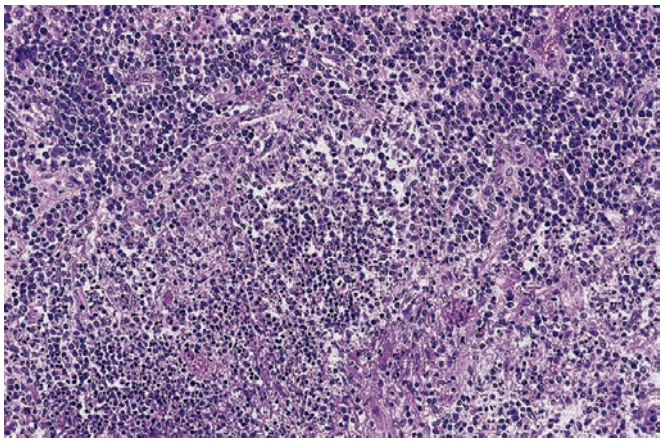

Figure 37.23 Necrotizing granuloma in a lymph node affected by lymphogranuloma venereum, showing features similar, if not identical, to cat-scratch disease.

Rare complications of the disease include granulomatous conjunctivitis ("oculoglandular syndrome of Parinaud"), thrombocytopenic purpura, and central nervous system manifestations.[176]

Lymphogranuloma Venereum

This sexually transmitted disease (not to be confused with granuloma inguinale) is caused by *Chlamydia trachomatis* organisms corresponding to serotypes L1, L2, and L3.[177] The initial lesion is a small (2–3 mm), painless genital vesicle or ulcer that often goes unnoticed and heals in a few days. This is followed by inguinal adenopathy, which can be very prominent. As mentioned, the morphologic features are similar to cat-scratch disease, although the site of disease is a helpful clue to the diagnosis. The earliest microscopic change in an affected node is represented by tiny necrotic foci infiltrated by neutrophils. These enlarge and coalesce to form the stellate abscess that represents the most characteristic feature of this disease (Fig. 37.23). In later stages, epithelioid cells, scattered Langhans giant cells, and fibroblasts are seen to line the abscess walls. Confluence of these abscesses is common, and cutaneous sinus tracts may develop. The healing stage is represented by nodules with dense fibrous walls surrounding amorphous material.[178]

The microscopic picture just described is not pathognomonic of this disease. Similar changes can occur in cat-scratch disease, atypical mycobacteriosis, and tularemia. Therefore a presumptive diagnosis of lymphogranuloma venereum should be confirmed with the Frei test (a delayed hypersensitivity skin test using purified "lygranum" chlamydial antigen), complement fixation, immunofluorescence, or molecular testing.[177,179–181]

Tularemia

Tularemia is a bacterial disease produced by *Francisella tularensis*, an extremely virulent pathogen,[182–184] which has recently gained notoriety as a potential biowarfare agent.[185,186] In the ulcero-glandular form of the disease, prominent lymphadenopathy occurs; this predominates in the axillary region when mammalian vectors are involved and in cervical or inguinal regions with arthropod vectors.[187] A history of handling rabbits suggests the diagnosis in the first instance. The diagnosis is supported by a rise in hemagglutinin titers.[183,188]

Microscopically, the picture in the acute phase is that of an intense lymphadenitis with widespread necrosis, sometimes associated with

irregularly shaped microabscesses and granulomas.[185] In the more chronic forms, there is a granulomatous reaction that in some cases may have a frankly tuberculosis-like appearance.[189] Although the histologic and cytologic features are not specific, fine-needle aspiration specimens may be useful to obtain material for molecular identification of the organism.[190]

Brucellosis

Brucellosis is caused by *Brucella abortus*, *melitensis*, or *suis*.[191] In the United States it has evolved from an occupational to a food-borne illness related to consumption of milk and cheese.[192] The most common clinical manifestations are fever, hepatomegaly, and splenomegaly.[193] Lymphadenopathy is uncommon and, when present, usually of modest dimensions. Microscopically, there may be nonspecific follicular hyperplasia and clusters of epithelioid histiocytes sometimes forming large noncaseating granulomas. This is accompanied by a polymorphic infiltrate containing eosinophils, plasma cells, and immunoblasts. When the latter are numerous, the microscopic picture may show a vague resemblance to Hodgkin lymphoma.

A definitive diagnosis can only be made by recovery of the organism with bacteriologic or PCR techniques[194] or the detection of a high agglutination titer.[195]

Acquired Immunodeficiency Syndrome–Related Lymphadenopathy

The lymph node abnormalities in AIDS patients can be of various types. They include mycobacterial and other opportunistic infections (some resulting in spindle cell pseudotumors),[120,196] Kaposi sarcoma, malignant lymphomas of either Hodgkin or non-Hodgkin type, and *florid reactive hyperplasia*.[197–199] The lymphomas, discussed later, and reactive hyperplasia are the most common (Fig. 37.24). Hyperplasia may be accompanied by collections of monocytoid B cells in the sinuses, neutrophils, and features of dermatopathic lymphadenopathy. In many of the cases, the reactive germinal centers show a feature termed *follicle lysis*, characterized by invagination of mantle lymphocytes into the germinal centers, and this feature is often associated with interfollicular hemorrhage. Follicle lysis is associated with disruption of these centers ("moth-eaten appearance") and a distinctive clustering of large follicular center cells,[200,201] resulting in an appearance that has been termed *explosive follicular hyperplasia*. Ultrastructurally, a prominence of follicular dendritic cells exhibiting alterations of their fine processes has been described;[202] it has been suggested also on the basis of immunohistochemically (fascin stain) that the AIDS virus preferentially infects these cells.[203,204] It has been suggested that the polykaryocytes (Warthin–Finkeldey cells) that are sometimes seen in HIV-infected nodes are a multinucleated form of follicular dendritic cell.[93] Immunohistochemically, positive stain for the HIV core protein P24 has been documented within the abnormal germinal centers.[205,206]

This combination of follicular changes is not pathognomonic of AIDS, but the possibility of this disease should be considered and investigated whenever they are found, such as by immunostaining for P24 or by serologic study.[205]

Some lymph nodes in untreated AIDS patients may also show advanced lymphocyte depletion, with or without abnormal (regressively transformed) germinal centers.[200,202]

The interfollicular tissue may show prominent vascular proliferation, the resulting picture acquiring a vague resemblance to Castleman disease. It is important to search in these areas and in the subcapsular region for the earliest signs of development of Kaposi sarcoma.[207] These changes should be distinguished from those of vascular transformation of the sinuses.

A rough relationship has been found among the pattern of nodal reaction, the cell suspension immunophenotypic data, and the patient's HIV status.[208,209]

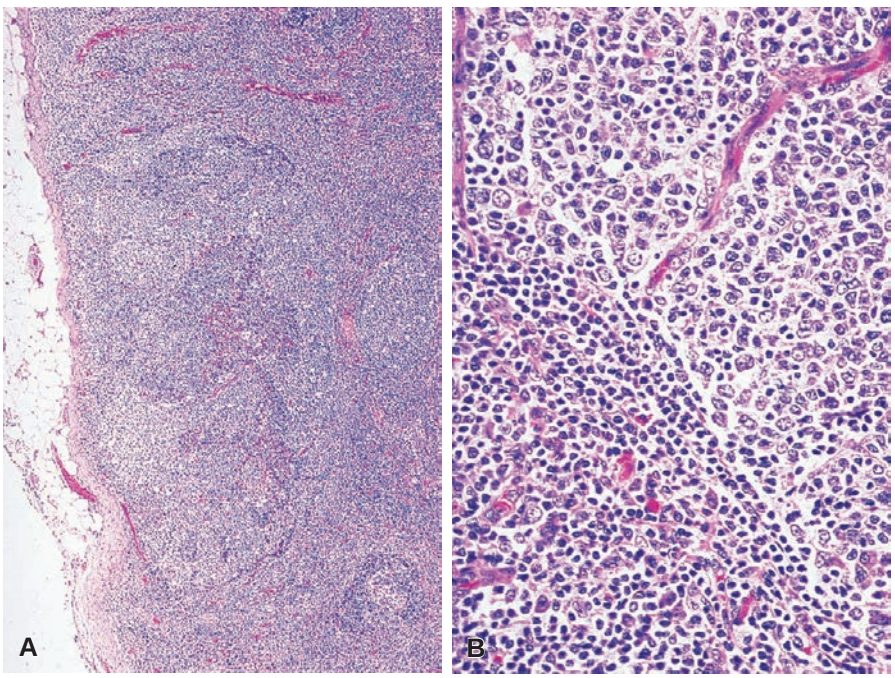

Figure 37.24 Low-power (**A**) and high-power (**B**) microscopic views of AIDS-related lymphadenopathy. The depicted germinal center shows disruption of its architecture by intrusion of small lymphocytes from the mantle zone. This is a common but not pathognomonic feature of this disease.

The term *chronic lymphadenopathy syndrome* has been defined as an unexplained enlargement of nodes of at least 3 months' duration at two or more extrainguinal sites in an individual at risk for AIDS.[210] The microscopic picture is similar to that described previously.[211] Overall, up to a fourth of the patients have developed AIDS on follow-up, cachexia and weight loss being the clinical signs of this progression.[212,213]

The HIV-associated lymphoproliferative diseases of lymph nodes are discussed later in this chapter.

Infectious Mononucleosis

The etiologic agent of classic infectious mononucleosis is EBV,[214] but other agents may be involved in atypical cases.[215] It is rare for the pathologist to see a lymph node from a patient with a typical clinical picture because in most instances the presumptive clinical diagnosis is confirmed by examination of the peripheral blood and serologic evaluation without need of a lymph node biopsy.[216] It is in the atypical case, presenting with lymphadenopathy without fever, sore throat, or splenomegaly, that the clinician will perform a lymph node biopsy to rule out the possibility of malignant lymphoma.

Microscopically, nodes and other lymphoid organs affected by infectious mononucleosis can be confused with malignant lymphoma because of the effacement of the architecture; infiltration of the trabecular, capsule, and perinodal fat; and the marked proliferation of immunoblasts, immature plasma cells, and mature plasma cells ("polymorphic B-cell hyperplasia") (Figs. 37.25 and 37.26). These features are particularly prominent when the disease develops in transplant recipients or other immunosuppressed patients.[217] Necrosis may also be present; this is usually only focal, but in immunodeficient children it may be massive.

Features of importance in the differential diagnosis with lymphoma include the predominantly sinus distribution of the large lymphoid cells, follicular hyperplasia with marked mitotic activity and phagocytosis (these follicles being usually small), increase in the number of plasma cells, often polymorphic in appearance, and vascular proliferation.[218] Another important feature is the fact that, although the nodal architecture may appear effaced, the sinus pattern remains intact or even focally accentuated. Another characteristic feature of this disease is the presence in the sinuses of clusters or "colonies" of lymphocytes in graduated sizes, from the small lymphocyte to the large lymphoid cell or immunoblast, often with plasmacytoid features.[219] The immunoblasts usually have only one large vesicular nucleus with a thin nuclear membrane and one or two prominent amphophilic or basophilic nucleoli. A paranuclear "hof" is often seen. When binucleated, this cell may closely resemble a Reed–Sternberg cell and result in a mistaken diagnosis of Hodgkin lymphoma (see Fig. 37.26).[220,221] A combination of immunophenotyping and in situ hybridization for EBV should resolve the issue in most cases (Fig. 37.27),[222–224] but it should be recognized that many enlarged, EBV-infected cells that may morphologically mimic Hodgkin cells will also express CD30[225] and the neoplastic cells of approximately 40% of cases of classical Hodgkin lymphoma will be EBV positive. The EBV infection in Hodgkin disease, however, is largely restricted to the neoplastic cells, while in infectious mononucleosis the EBV positive cells are more variable in size and include small cells. Because of the morphologic overlap between infectious mononucleosis and Hodgkin lymphoma and even DLBCL, extreme caution should be used before diagnosing either malignancy in immunocompetent adolescent or young adults in the head and neck region, especially on a tonsil biopsy.

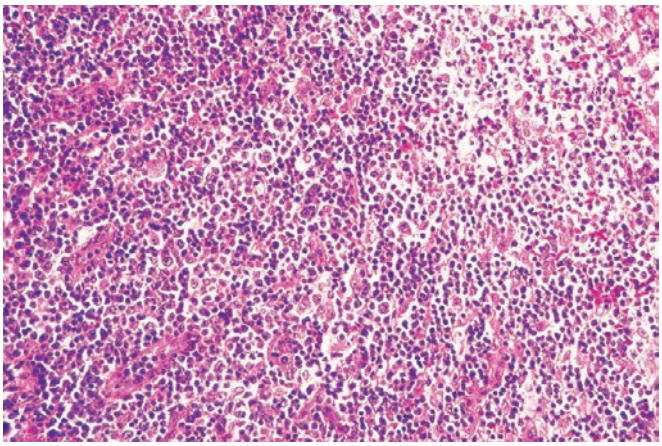

Figure 37.25 Lymph Node Involved by Infectious Mononucleosis. There is a marked effacement of the architecture by a polymorphic lymphoid infiltrate.

Other Viral (Including Postvaccinial) Lymphadenitides

Lymph nodes draining an area of the skin subjected to smallpox vaccination can enlarge and become painful. If removed and examined microscopically, they can be easily confused with lymphoma, especially if the history of vaccination is overlooked. Of 20 cases of postvaccinial lymphadenitis reported by Hartsock,[226] 13 were located in the supraclavicular region on the side of the vaccination. The largest node measured 6 cm in diameter. The interval between the vaccination and the biopsy varied between 1 week and 3 months.

Microscopically, the changes are those of a diffuse or nodular paracortical expansion, with mixed cellular proliferation, consisting of eosinophils, plasma cells, and a large number of immunoblasts. The alterations are accompanied by vascular and sinus changes and focal discrete necrosis. The most important histologic feature of postvaccinial hyperplasia is the presence of numerous immunoblasts scattered among the lymphocytes and imparting to the lymphoid tissue a mottled appearance (Fig. 37.28). Hartsock[226] noted that follicular hyperplasia was present only in those nodes removed more than 15 days after vaccination. These changes have been reproduced experimentally.[226]

Viral lymphadenitis resulting from *herpes simplex infection* may be localized[227] or generalized.[228] The morphologic features are similar to those of postvaccinial lymphadenitis, particularly in reference to the marked immunoblastic proliferation.[229,230] Intranuclear viral inclusions may be found, especially at the edge of necrotic areas.[231–233] The nodal changes seen in herpes zoster lymphadenitis and infectious mononucleosis are of similar nature; the latter are discussed under a separate heading (see preceding section). It is likely that analogous morphologic changes occurring in the absence of these clinical conditions are, in most cases, the result of some unidentified viral infection.

Prominent regional lymphadenopathy also may follow the administration of live attenuated measles virus vaccine. Microscopically, the typical multinucleated giant cell of Warthin–Finkeldey (polykaryocytes) may be found (see Fig. 37.10).[234]

Mucocutaneous Lymph Node Syndrome

Mucocutaneous lymph node syndrome, also known as Kawasaki syndrome, is a febrile disorder of unknown etiology usually affecting children, originally described in the Japanese literature but having a worldwide distribution.[235] Fever, cervical lymphadenopathy, pharyngeal and conjunctival inflammation, and erythematous skin

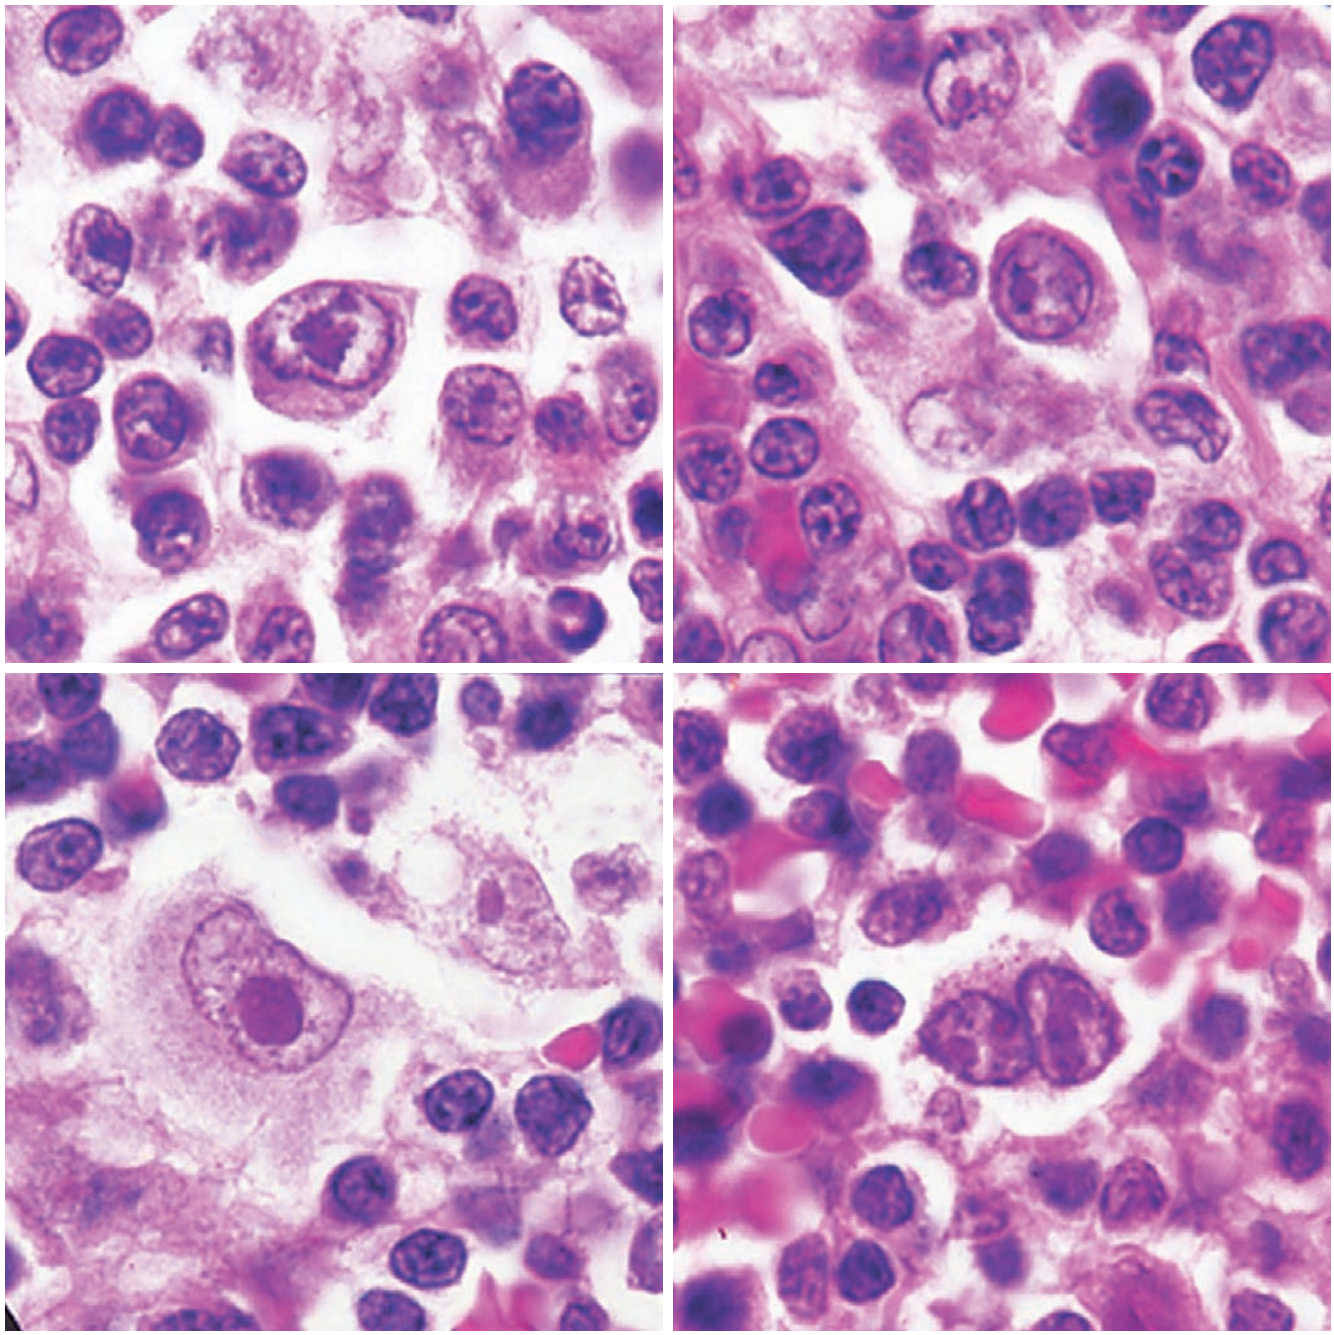

Figure 37.26 Various types of immunoblast seen in a lymph node involved by infectious mononucleosis. The binucleated form (shown in the fourth image) can simulate Reed–Sternberg cells. Note the basophilic character of the nucleus and the presence of a paranuclear hof. Also note the variability in size of background lymphocytes that also demonstrate a plasmacytoid appearance. This variability is characteristic of infectious mononucleosis.

rashes are the most common clinical symptoms. Sometimes lymphadenopathy represents the dominant manifestation of the disease.[236] Arthritis is present in approximately 40% of the cases. Coronary arteritis may lead to fatal complications. The etiology is unknown, but an infectious agent is suspected.

Microscopically, the affected lymph nodes often show fibrin thrombi in the smaller vessels accompanied by patchy infarcts/areas of nongranulomatous necrosis with or without neutrophils.[237,238] These changes have been interpreted as the expression of an acute vasculitis. The main differential diagnosis is Kikuchi necrotizing lymphadenitis, but the presence of thrombi would favor Kawasaki disease. Persistent damage to the coronary arteries occurs in approximately one-fourth of untreated children.[239]

Lupus Erythematosus

The lymph node changes in lupus erythematosus are generally of a nonspecific nature and consist of moderate follicular hyperplasia

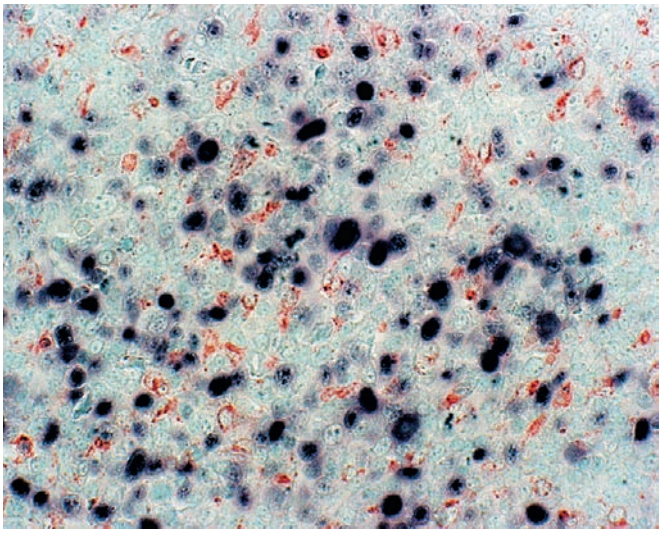

Figure 37.27 Demonstration of EBV EBER by in situ hybridization in a case of infectious mononucleosis. Note that both large and small cells are positive, in contrast to EBV+ Hodgkin lymphoma in which the EBV is primarily in large cells.

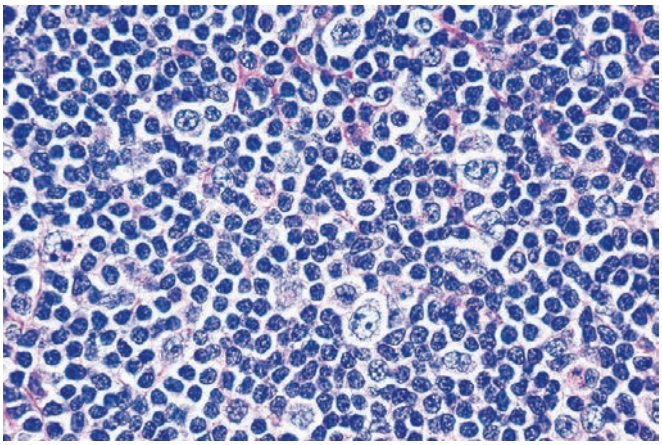

Figure 37.28 Viral lymphadenitis showing scattered immunoblasts resulting in a "salt-and-pepper" appearance.

associated with increased vascularization and scattered immunoblasts and plasma cells; some of the latter contain PAS-positive cytoplasmic bodies that represent sites of immunoglobulin production.[240] Occasionally, one encounters a peculiar form of necrosis characterized by the deposition of hematoxyphilic material in the stroma, in the sinuses, and on the wall of blood vessels (Fig. 37.29).[241] These have been found to be composed of DNA derived from karyorrhectic nuclear material, presumably from lymphocytes. As mentioned previously, the microscopic appearance of lupus lymphadenitis may be indistinguishable from that of Kikuchi disease,[242] and some patients originally diagnosed with Kikuchi disease may actually represent an early presentation of systemic lupus erythematosus.[112] The presence of hematoxylin bodies is considered relatively specific for lupus over Kikuchi disease. On occasion the changes of lupus are morphologically similar to those of either the hyaline vascular or intermediate types of Castleman disease.[243,240] In other instances, Warthin–Finkeldey-like polykaryocytes have been numerous.[244] The immunophenotype of lupus lymphadenitis is nonspecific.[241]

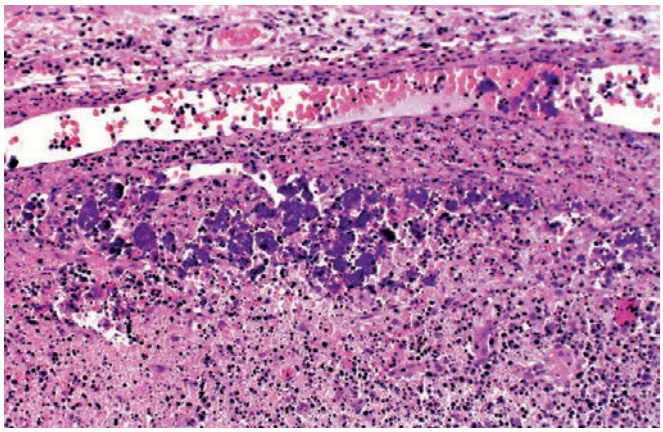

Figure 37.29 Large accumulations of DNA-containing basophilic material in the subcapsular region of a lymph node in a patient with systemic lupus erythematosus.

Rheumatoid Arthritis

Most patients with rheumatoid arthritis have generalized lymphadenopathy at some time during their illness.[245] The lymph node enlargement may precede the arthritis and raise the clinical suspicion of lymphoma.

Microscopically, the most important changes are follicular hyperplasia and plasma cell proliferation, with formation of Russell bodies.[246] Vascular proliferation is also a consistent finding. The appearance may be quite similar to that of the plasma cell type of Castleman disease. Small foci of necrosis and clumps of neutrophils are seen in some instances. The capsule is often infiltrated by lymphocytes. Immunohistochemically, the plasma cell proliferation is polytypic.[247] Adult-onset **Still disease** can also result in an intense hyperplastic change that can vaguely resemble peripheral T-cell lymphoma.[248] Other immune-mediated diseases, such as lupus erythematosus, polyarteritis nodosa, and scleroderma, are usually not associated with this type of lymph node abnormality.

Patients with rheumatoid arthritis treated with gold compounds can develop **gold-associated lymphadenopathy**.[249] They are also said to have a slightly increased incidence of malignant lymphomas.[250,251]

Castleman Disease

Castleman disease (giant lymph node hyperplasia) represents a morphologically distinct lymph node proliferation that in most cases is of unknown etiology. It occurs most commonly in adults, but it can also affect children.[252] Two major clinical and microscopic categories have been described that do not always correlate with each other[253,254] The first microscopic category, designated as *hyaline-vascular type* or angiofollicular, shows large follicles scattered in a mass of lymphoid tissue. The follicles show marked vascular proliferation and hyalinization of their abnormal germinal centers; they have been confused with Hassall corpuscles and with splenic white pulp, prompting in the first case a mistaken diagnosis of thymoma and in the second of ectopic spleen (Fig. 37.30). Their appearance corresponds to that of regressively transformed germinal centers. Many of the large cells with vesicular nuclei present in the hyaline center are follicular dendritic cells, as evidenced by their strong immunoreactivity for CD21 and CD35.[255] There is a tight concentric layering of lymphocytes at the periphery of the follicles (corresponding to the mantle zone), resulting in an onion-skin appearance. The interfollicular stroma is also prominent, with

numerous hyperplastic vessels of the postcapillary venule type and an admixture of plasma cells, eosinophils, and immunoblasts, as well as tight collections of CD123-positive plasmacytoid dendritic cells and frequently admixed TdT-positive T cells.[256–259] Sinuses are characteristically absent. In the variant of the hyaline-vascular type described as the *lymphoid subtype*, the follicles have a marked expansion of the mantle zone and small, relatively inconspicuous germinal centers. This variant of Castleman disease merges with the process known as *mantle zone hyperplasia*, and it is the one more likely to be confused with malignant lymphoma of either follicular or mantle cell type. Immunohistochemically, there is polyclonal immunoglobulin production by plasma cells, and large numbers of suppressor T cells are found in the interfollicular areas. An aberrant phenotype of Ki-B3–negative B lymphocytes has been detected in the mantle zone cells.[260]

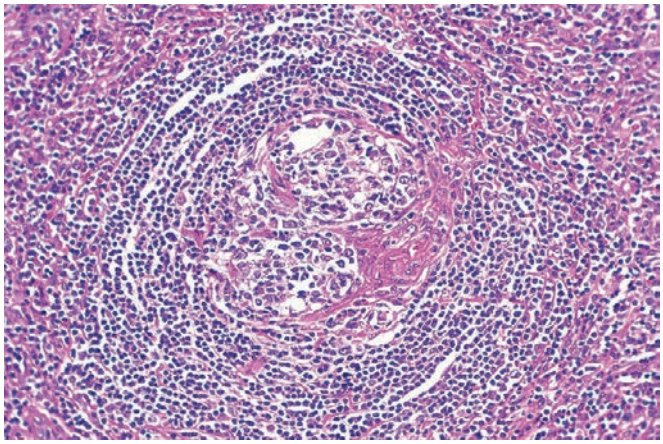

Figure 37.30 Castleman Disease of Hyaline Vascular Type. There is a prominent germinal center showing well-developed changes.

The second major morphologic category of Castleman disease is known as the *plasma cell type.*[254] It is characterized by a diffuse plasma cell proliferation in the interfollicular tissue, sometimes accompanied by numerous Russell bodies. The hyaline-vascular changes in the follicles are inconspicuous or absent; instead, one often encounters in the center of these follicles a deposition of an amorphous acidophilic material that probably contains fibrin and immune complexes. The overall appearance is reminiscent of that seen in the lymph nodes from patients with rheumatoid arthritis (Fig. 37.31). The abundant expression of interleukin-6 that has been detected in this condition is thought to be responsible for the marked plasma cell infiltration.[261]

Based on clinical presentation, Castleman disease has been divided into a solitary and a multicentric form. The *solitary form* presents as a mass located most commonly in the mediastinum but also described in the neck, lung, axilla, mesentery, broad ligament, retroperitoneum, soft tissues of the extremities (including subcutis and skeletal muscle),[262] nasopharynx, meninges, and several other sites.[263] Grossly, it is round, well circumscribed, with a solid gray cut surface and can measure 15 cm or more in diameter (Fig. 37.32). Although this form by definition presents as a single mass, microscopic changes suggesting an early stage of the same process are sometimes seen in adjacent nodes. Microscopically, over 90% of the cases are of the hyaline-vascular type (including the lymphoid subtype), and the remainder are of the plasma cell type. The former is usually asymptomatic, whereas the plasma cell type is often associated with fever, anemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, and hypoalbuminemia. The disease reported in Asia as *idiopathic plasmacytic lymphadenopathy with polyclonal hypergammaglobulinemia* is probably different from the plasma cell type of Castleman disease but may represent IgG4-related lymphadenopathy in a significant proportion of cases.[264,265] The treatment of solitary Castleman disease is surgical excision, which has been found to result in rapid regression of the associated abnormalities whenever present.[266]

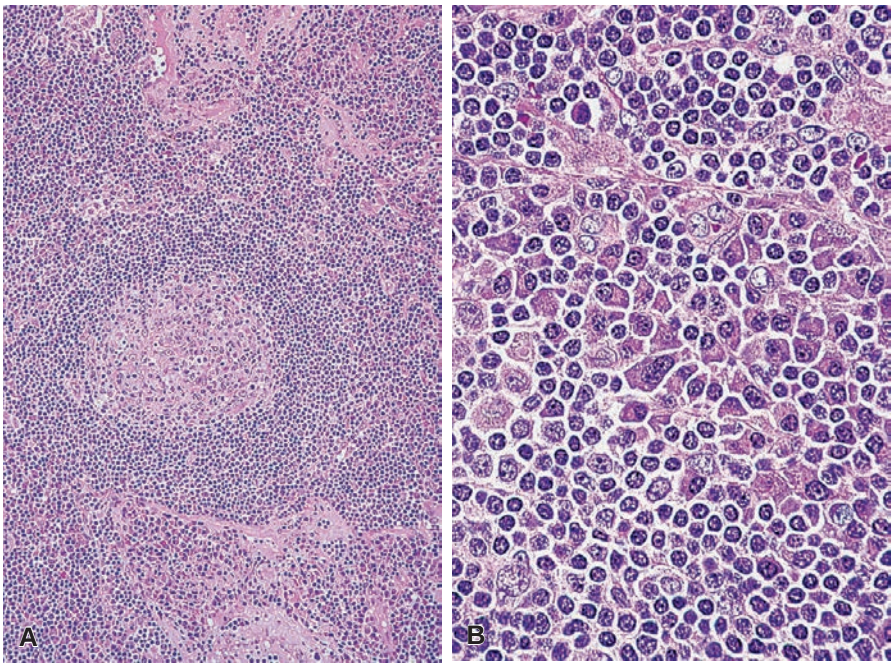

Figure 37.31 Castleman Disease of Plasma Cell Type. A, Low-power view showing follicular hyperplasia without hyaline vascular changes. **B**, High-power view of the interfollicular region showing a massive infiltration by plasma cells. Some of these plasma cells show multinucleation and mild nuclear atypia.

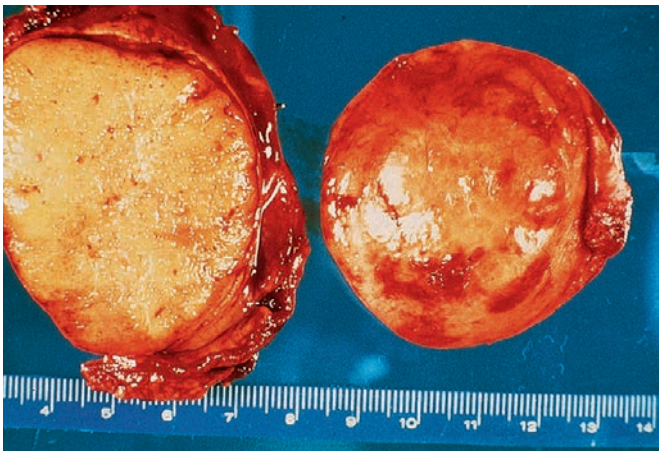

Figure 37.32 Gross appearance of Castleman disease of the hyaline vascular type.

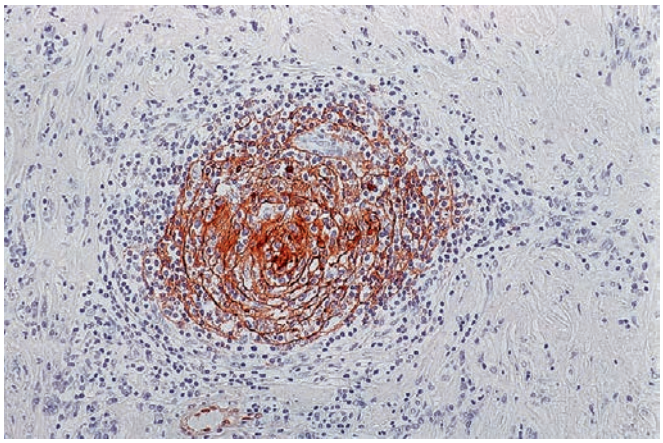

Figure 37.33 Prominent network of CD21-positive dendritic follicular cells in the abnormal germinal center of Castleman disease.

The *multicentric* or *systemic form* is nearly always of the plasma cell type,[267] although occasional examples of the hyaline-vascular type (involving even the skin) are on record.[268] It presents with generalized lymphadenopathy and may also involve the spleen.[269–271] The etiology is unknown, the two main hypotheses (not mutually exclusive) being abnormal immune response and viral infection.[272] Regarding the latter, a definite link has been documented between HHV8 and multicentric Castleman disease (this virus being also linked to Kaposi sarcoma and primary effusion sarcoma and can be identified by immunohistochemistry).[273–275] Cases of HHV8+ Castleman disease are said to be characterized morphologically by dissolution of the lymphoid follicles.[276] It has been hypothesized that HHV8 induces the changes of Castleman disease through the production of interleukin-6.[277,278]

Sometimes multicentric Castleman disease is seen in association with the POEMS syndrome, an acronymic designation for polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes.[279,280] The latter include a distinctive vascular lesion known as glomeruloid hemangioma.[281] In other instances, Castleman disease has been reported in association with amyloid deposits.[282,283]

The long-term prognosis of systemic Castleman disease is poor; the disease tends to persist for months or years and to result sometimes in renal or pulmonary complications.[284] Furthermore, some of the patients have been found to have Kaposi sarcoma. Indeed, the coexistence of multicentric Castleman disease and Kaposi sarcoma in the same tissue sample is not an uncommon phenomenon.[285] Other cases have developed large cell lymphomas with plasmablastic features, most of which are associated with HHV8 infection. Evidence of clonal rearrangement for immunoglobulin and T-cell receptor genes has been found in cases of systemic Castleman disease together with copies of the EBV genome; no such features having been detected in the solitary form of the disease.[286–289] This suggests that multicentric Castleman disease is a disorder different from the classic localized type and one that may evolve into a clonal lymphoproliferation. Some authors actually regard it as a lymphoproliferative process rather than a reactive/inflammatory condition.

An important theme of the hyaline-vascular type of Castleman disease is the active participation of a variety of nonlymphoid cellular components. One such component is the follicular dendritic cell, which is prominently present in the hyalinized nodules that characterize the disease and which is thought by some authors to be at the core of the pathogenesis of this disorder (Fig. 37.33).[290,291] These cells can become atypical ("dysplastic") both in the abnormal germinal centers and in the intervening tissue[291] and can manifest cytogenetic and molecular evidence of clonality (Fig. 37.34).[292–294] Furthermore, they may result in the formation of full-blown follicular dendritic cell tumors.[295,296] Another type of proliferation involves the vascular and related contractile (myoid) elements that are present in the interfollicular tissue. Cases of Castleman disease in which these elements are unduly prominent have been referred to as *stroma rich* (Fig. 37.35).[256] Further proliferation of this component results in the formation of *angiomyoid proliferative lesions*,[296] and of lesions that have been referred to as *angiomatous hamartomas* (Fig. 37.36)[297] or *vascular neoplasms*, the latter sometimes having hemangiopericytoma-like features.[298] Finally, cases have been described of high-grade spindle cell sarcomas arising in Castleman disease, which have been originally interpreted as of probable vascular nature because of the presence of myoid tumor cells adjacent to vascular structures (Fig. 37.37).[299] Whether these myoid cells are truly vessel related or whether they originate from yet another member of the reticulum/dendritic cell family (so-called fibroblastic reticulum cells, myoid reticulum cells, or dychthyocytes) is not clear.

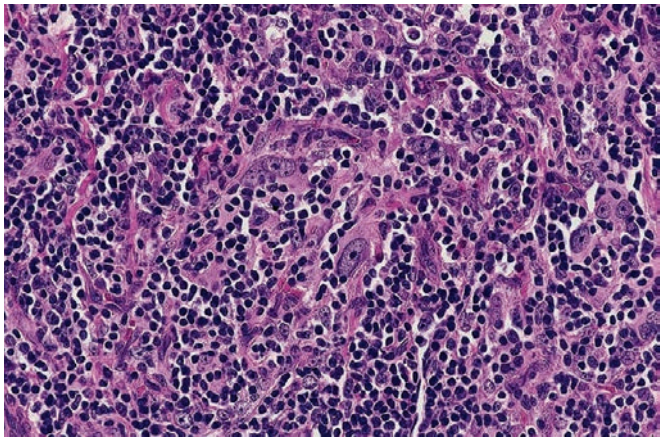

Figure 37.34 "Dysplasia" of Reticular/Dendritic Cells in Castleman Disease. These cells were immunoreactive for desmin.

In the light of the above information, one might conclude that the neoplastic potentialities of Castleman disease tend to manifest themselves mainly through the development of lymphoid tumors in the plasma cell type and of dendritic/stromal tumors in the hyaline-vascular type. However exceptions occur, in the sense that isolated cases of the latter have been accompanied or preceded by

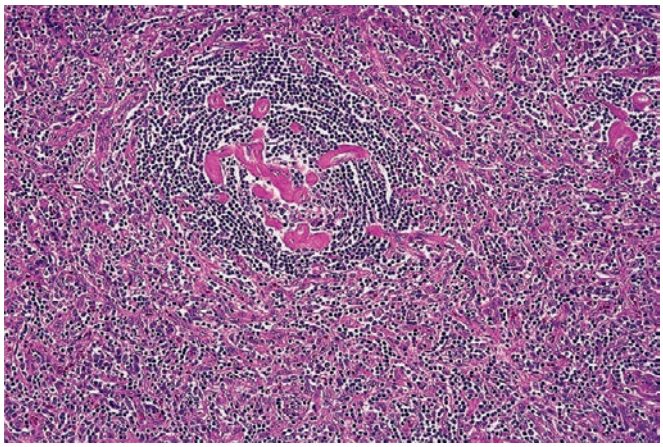

Figure 37.35 Castleman disease of hyaline vascular type with a prominent stromal component which is richly vascularized ("stroma-rich" variant).

plasmacytoma,[300,301] follicular lymphoma,[302,303] and particularly Hodgkin lymphoma.[304–306]

Drug Hypersensitivity

Antiepileptic drugs derived from hydantoin, such as diphenylhydantoin (Dilantin) and mephenytoin (Mesantoin), can result in a hypersensitivity reaction manifested by skin rash, fever, generalized lymphadenopathy (mainly cervical), and peripheral eosinophilia. The reaction, which is quite uncommon, tends to occur within the first few months of therapy. The changes disappear if the drug is discontinued. The nodal enlargement can occur in the absence of some of the other manifestations of the drug reaction.

Microscopically, partial effacement of the architecture by a polymorphic cellular infiltration is seen.[307] Histiocytes, immunoblasts, eosinophils, neutrophils, and plasma cells are all present. Some of the immunoblasts have atypical nuclear features, including rare cases with Reed–Sternberg-like cells. Foci of necrosis were noted in the classic article by Salzstein and Ackerman in which this condition was first described.[308] In some of the cases, the microscopic appearance may mimic viral infections, postvaccinial lymphadenopathy and even angioimmunoblastic T-cell lymphoma and classical Hodgkin lymphoma. Detailed medication history and clinical information is needed to diagnose appropriately and the diagnosis might only be confirmed with clinical resolution after discontinuation of the drug.

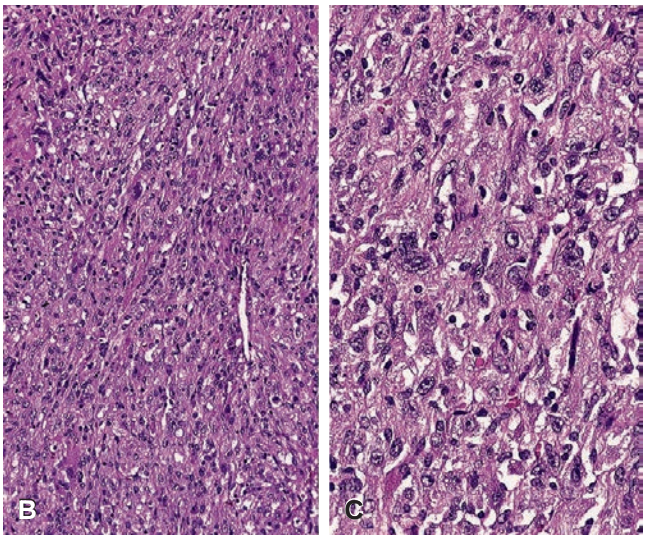

Figure 37.37 Castleman Disease Complicated by the Development of Sarcoma. A, Gross appearance of a case located in the perirenal region. **B**, Microscopic appearance of another case. The tumor has a vaguely hemangiopericytomatous quality. **C**, High-power view.

Dermatopathic Lymphadenitis

Dermatopathic lymphadenitis (lipomelanosis reticularis of Pautrier) is a form of nodal hyperplasia usually secondary to a generalized dermatitis, particularly those with exfoliative features. Pathogenetically, it represents a T-cell response to skin antigens processed and presented by interdigitating dendritic cells. It may occur in any skin disorder in which itching and scratching are prominent; this includes inflammatory dermatoses such as psoriasis and neoplastic diseases such as mycosis fungoides. Rarely, the morphologic changes of dermatopathic lymphadenitis are seen in the absence of clinical skin disease.[309]

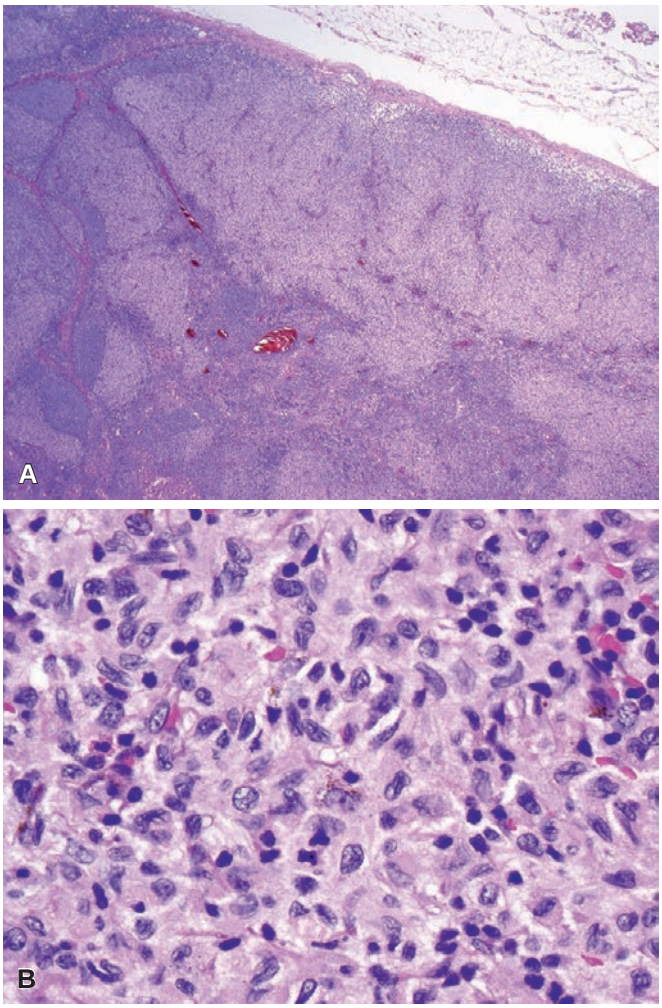

Figure 37.38 Dermatopathic Lymphadenitis. A, Massive expansion of the paracortical region, resulting in a wide, pale area between the capsule and the lymphoid follicles. **B**, High-power view of the paracortical region showing numerous cells with oval vesicular nuclei, which correspond to an admixture of interdigitating dendritic cells and Langerhans cells with nuclear grooves. Scattered cells containing pigment are also present.

Grossly, the lymph node is enlarged, the cut surface bulging, and the color pale yellow. In florid cases, black linear areas are seen in the periphery, representing clumps of melanin pigment and simulating the appearance of malignant melanoma.

Microscopically, the nodal architecture is preserved. The main change is represented by a marked pale widening of the paracortical zone, which stands out prominently on low-power examination (Fig. 37.38).[310] Most of the large nonlymphoid cells occupying this area are thought to be of three types: histiocytes, Langerhans cells, and interdigitating dendritic cells marking with a mix of CD163, CD1a, langerin, and S100 positivity.[311,312] Many of the histiocytes contain phagocytosed melanin and neutral fat in their cytoplasm. Plasma cell infiltration and follicular hyperplasia are often present. A scattering of eosinophils also may be seen.

Nodes affected by dermatopathic lymphadenitis may be confused with Hodgkin lymphoma, mycosis fungoides, monocytic leukemia, or LCH. The differential diagnosis with mycosis fungoides is of particular concern because of the fact that mycosis fungoides is one of the cutaneous disorders that can be associated with dermatopathic lymphadenitis.[313,314] Diagnostic assistance can be obtained from immunohistochemistry and molecular pathology. Dermatopathic lymph nodes *that are also involved by mycosis fungoides* may show loss of CD7 and CD62L expression, and sometimes also loss of the pan–T-cell markers CD5, CD3, and CD2.[315] At the molecular level, clonal rearrangements of T-cell receptor genes may be demonstrated in cases involved by mycosis fungoides.[316] The presence of dermatopathic lymphadenitis in a patient with known mycosis fungoides, even in the absence of involvement by mycosis fungoides, is considered an abnormal finding and results in an N1 staging status and the need for molecular studies for T-cell receptor gene rearrangements.[317,318]

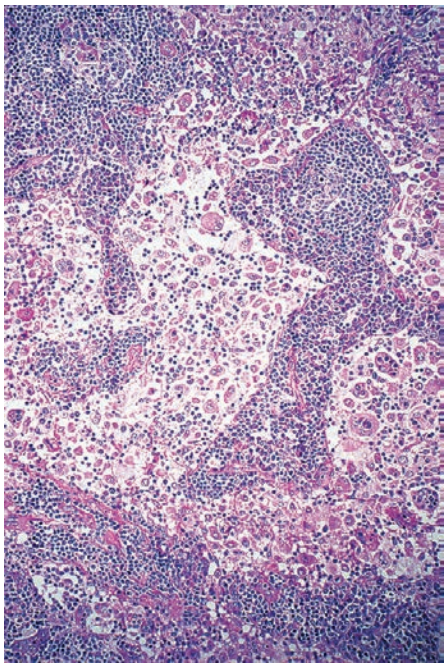

Figure 37.39 Rosai–Dorfman Disease. Low-power view showing massive distension of the sinuses by the histiocytic infiltrate.

Rosai–Dorfman Disease

Rosai-Dorfman disease (RDD), also known as sinus histiocytosis with massive lymphadenopathy (SHML), presents in its most typical form as massive, painless, bilateral lymph node enlargement in the neck, associated with fever, leukocytosis, elevated erythrocyte sedimentation rate, and polyclonal hypergammaglobulinemia.[319,320] Most cases occur during the first or second decade of life, but any age group can be affected. A few cases have affected two members of the same family.[321] There is a predisposition for the condition in blacks. Although the disease has a widespread geographic distribution and most of the reported cases have been from the United States and Western Europe, there is a disproportionally high number of cases from Africa and the Caribbean region.[319] The cervical region is by far the most common and most prominent site of involvement, but other peripheral or central lymph node groups can be affected, with or without cervical disease.

Grossly, the nodes are matted together by prominent perinodal fibrosis. Their cut surface varies from gray to golden yellow, depending on the amount of fat present.

Microscopically, there is a pronounced dilation of the lymph sinuses, resulting in partial or complete architectural effacement (Fig. 37.39). These sinuses are occupied by lymphocytes, plasma cells, and—most notably—by numerous cells of histiocytic appearance

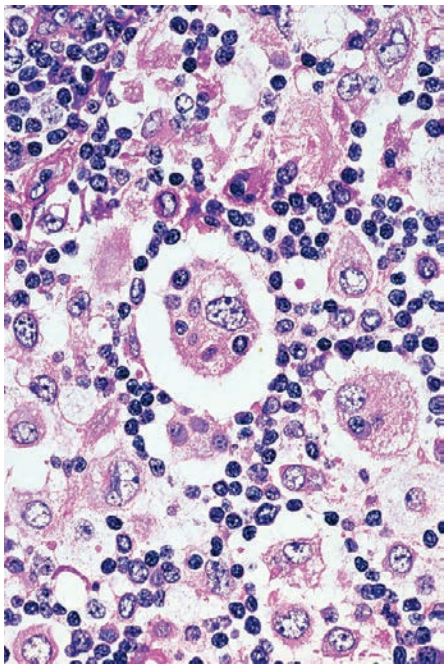

Figure 37.40 Rosai–Dorfman Disease. High-power view showing lymphocytophagocytosis by the sinus histiocytes.

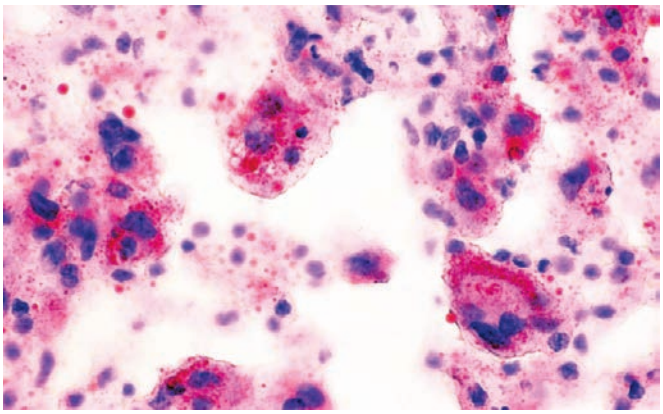

Figure 37.41 Rosai–Dorfman Disease. Oil red O stain showing abundant neutral lipid in the cytoplasm of the histiocytes.

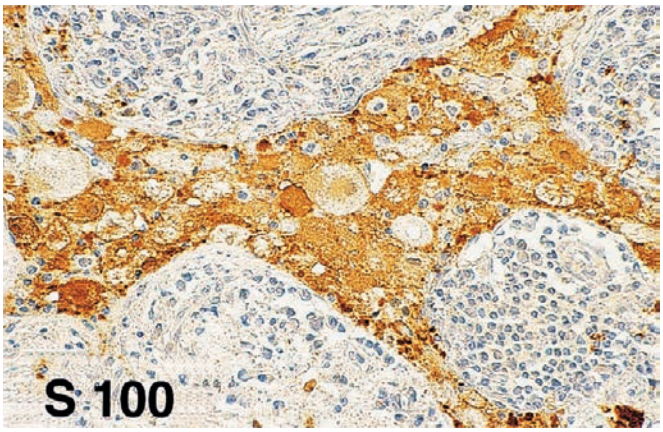

Figure 37.42 Strong immunoreactivity of the sinus histiocytes for S100 protein in Rosai–Dorfman disease.

with a large vesicular nucleus and abundant clear or lightly eosinophilic cytoplasm that may contain large amounts of neutral lipids. Many of these histiocytes have within their cytoplasm numerous intact lymphocytes, a feature that has been designated as emperipolesis or lymphocytophagocytosis. Although not specific, this is a constant feature of RDD (as least in the lymph node location) and is therefore of great diagnostic significance (Fig. 37.40). Sometimes other cell types are present within the cytoplasm of the histiocytes, such as plasma cells and red blood cells.

The intersinusal tissue exhibits a variable but sometimes impressive number of mature plasma cells, some of which may contain Russell bodies. Capsular and pericapsular inflammation and fibrosis are common, but intranodal fibrosis is minimal or absent. In a minority of cases, small microabscesses or foci of necrosis are found within the dilated sinuses. Ultrastructurally, the histiocytes located in the sinuses have extensive pseudopodia and lack Birbeck granules; viral particles or other evidence of infection is consistently lacking. The sinus histiocytes contain cytoplasmic fat (Fig. 37.41) and are strongly reactive for S100 protein[322] and CD68 (Fig. 37.42) but negative for CD1a; some of them are also positive for immunoglobulin, presumably phagocytosed from the surroundings. Their immunohistochemical profile (including the adhesion molecules pattern) suggests that they are monocytes that have been recently recruited from the circulation.[323–326] The plasma cells show a polyclonal pattern of immunoglobulin expression. Some cases show an increase in IgG4-positive plasma cells and the relationship between RDD and IgG4-related disease requires clarification.[327–329] The lymphocytes present are an admixture of B and T cells.

In over one-fourth of the cases, RDD involves extranodal sites.[319] This usually occurs in the presence of massive lymphadenopathy, and the disease is therefore easily recognized. However, in some cases these extranodal manifestations represent the predominant or even exclusive manifestation of the disease. Practically all organ systems have been recorded as being the site of the disease. The most common are eyes and ocular adnexa (especially orbit),[330] head and neck region,[331] upper respiratory tract,[332,333] skin and subcutaneous tissue (perhaps more commonly in Asia),[334–339] skeletal system,[340] and central nervous system.[341–343] However, the disease has been reported in many other sites, including gastrointestinal tract,[344–346] pancreas,[347] salivary glands,[348] genitourinary tract, thyroid,[349] mediastinum,[350] breast,[351,352] uterine cervix,[353] and bone marrow.[354] In some instances, widespread nodal and extranodal dissemination is found.[355] Organs that stand out because of their almost universal sparing by the disorder are lung, and spleen, and bone marrow (the latter exclusive of the focal bone lesions mentioned previously). The histopathologic features of RDD in extranodal sites are similar to the nodal disease except for the fact that fibrosis tends to be more pronounced and emperipolesis less conspicuous.

The etiology of RDD remains unknown, the two most likely possibilities (not mutually exclusive) being infection by a virus or some other microorganism and the manifestation of a subtle undefined immunologic defect. It has been suggested that stimulation of monocytes/macrophages via macrophage colony-stimulating factor (M-CSF) leading to immune suppressive macrophages may be the main pathogenetic mechanism.[356] Despite some suggestive early data derived from serologic tests, most studies fail to demonstrate an infectious etiology.[357,358] Molecular studies done on involved tissue have failed to show evidence of clonality, in keeping with their presumed reactive nature. This contrasts with the findings in at least some studies of LCH, a disease that it otherwise resembles in many clinical, morphologic, and phenotypic aspects,[325,359,360] and with which it can coexist.[361,362]

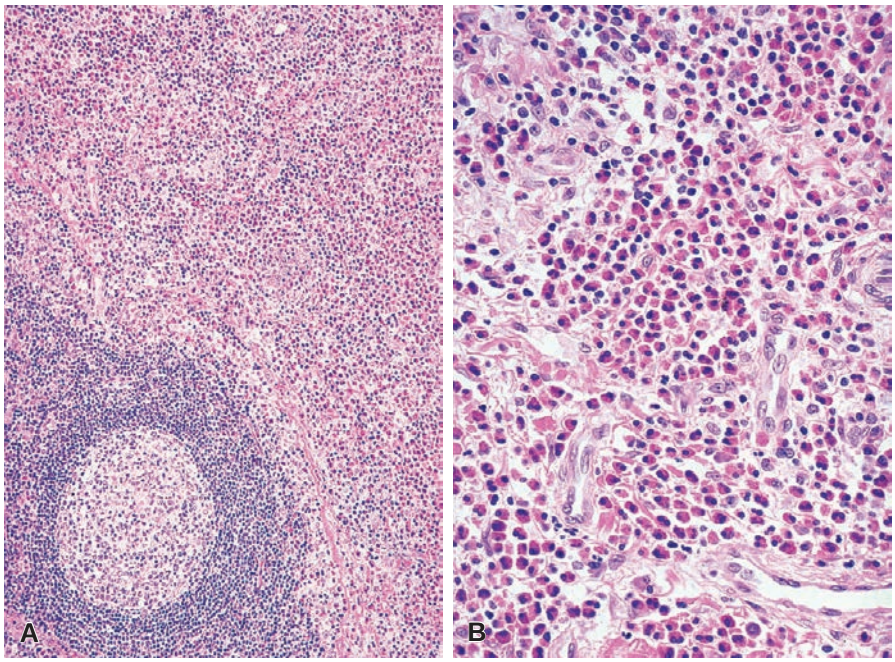

Figure 37.43 **A** and **B,** Lymph node involvement by Kimura disease. There is follicular hyperplasia and massive perinodal inflammation, which is predominantly composed of eosinophils. (Courtesy of Dr. T.-T. Kuo, Taipei, Taiwan.)

RDD is relatively unaffected by therapy, although chemotherapy has proved effective in some cases,[363–365] occasionally with allegedly complete and permanent results.[366] In many cases, RDD undergoes quick and complete spontaneous resolution. In others, it follows a protracted clinical course for years or decades. The latter is particularly true in cases with widespread extranodal involvement. In some instances the disease disappears, only to come back years later at another site. Some patients have died as a result of RDD, either because of extensive disease affecting vital organs or because of complications related to the immunologic abnormalities that may be present,[367,368] such as amyloidosis.[369]

The differential diagnosis of RDD includes nonspecific sinus hyperplasia (in which the cells lack emperipolesis and are S100 protein-negative), LCH (in which the cells are positive for S100 protein, langerin, and CD1a), leprosy, rhinoscleroma (with which it can apparently coexist[370]), and metastatic malignant melanoma. Perhaps the condition that resembles it most is the sinus histiocytosis induced by cobalt-chromium and titanium that can occur in pelvic lymph nodes after hip replacement.[344]

It should also be noted that focal RDD-like changes can sometimes be seen in lymph nodes involved by other processes, such as Hodgkin[371] or non-Hodgkin lymphoma, a phenomenon analogous to that sometimes seen in LCH.[372] Similar changes can also occur in lymph nodes involved by ALPS.[52]

Kimura Disease

Kimura disease is an inflammatory disorder of unknown etiology seen in an endemic form in Asia[373] but also in other parts of the world, including the United States and Europe.[374] It usually presents as a mass lesion in the subcutaneous tissue of the head and neck region or the major salivary glands, often associated with regional lymphadenopathy. Sometimes lymph node enlargement is the only manifestation of the disease.

Microscopically, the involved nodes show marked hyperplasia of germinal centers, a few of which may be of the progressively transformed type. These germinal centers are often well vascularized and contain polykaryocytes, interstitial fibrosis, and deposition of a proteinaceous material. There is also extensive infiltration by mature eosinophils, with occasional formation of eosinophilic abscesses (Fig. 37.43). Hyalinized vessels are often seen in the paracortical region, and there is a variable degree of sinus and paracortical sclerosis. An increase in the number of plasma cells and mast cells has been noted in the paracortex,[375] together with proliferation of postcapillary venules.[374] Some cases are associated with increases in IgG4-positive plasma cells, a feature of unclear significance.[376]

Despite early statements to the contrary, current evidence strongly suggests that Kimura disease and the disease known to dermatologists as angiolymphoid hyperplasia with eosinophilia are different entities (see Chapter 3); specifically, the former disorder lacks the epithelioid (histiocytoid) endothelial cells that are the morphologic hallmark of the latter.[377–380] The differential diagnosis of Kimura disease includes parasitic infections as well as tissue manifestations of chronic eosinophilic leukemia and the related clonal eosinophilic disorders reviewed in Chapter 39.

Chronic Granulomatous Disease

Chronic granulomatous disease is the result of a genetically determined enzymatic defect of granulocytes and monocytes.[381–383] These cells ingest microorganisms but are unable to destroy them because of their inability to generate superoxide anion (O_2^-). This is due to a defect in any one of five components of NADPH oxidases, the enzyme responsible for the generation of the antimicrobial oxidants.[382] A pattern of X-linked inheritance is seen in approximately 65% of the patients and results from mutations in the gene that encodes the g91-phox subunit of the cytochrome b558 component of the oxidase. The remaining 35% of patients inherit the disease in an autosomal recessive manner resulting from mutations in the genes that encode the other three oxidase components.[384–386]

The traditional laboratory technique for the detection of the disease is the nitro blue tetrazolium test although detection of dihydrorhodamine oxidation can be performed by flow cytometry.[383,387]

The main clinical features are recurrent lymphadenitis, hepatosplenomegaly, skin rash, pulmonary infiltrates, anemia, leukocytosis, and hypergammaglobulinemia.[388–390] Microscopically, granulomas with necrotic purulent centers are seen in lymph nodes and other organs. They closely simulate the appearance of cat-scratch disease and lymphogranuloma venereum. Collections of histiocytes containing a lipofuscin-like pigment are also commonly observed and represent an important clue to the diagnosis.[391]

Lipophagic Reactions

Accumulation of neutral lipid with formation of foamy macrophages (xanthoma cells) can be seen as an inconsequential secondary event in a variety of inflammatory and neoplastic conditions of lymph nodes, including LCH, RDD, Erdheim–Chester disease, and Hodgkin lymphoma. There are, in addition, conditions in which the **lipophagic granuloma** is the primary alteration. The lipophagic granuloma is defined as a collection of mononuclear and multinucleated giant cells, both of them exhibiting a cytoplasmic foamy appearance and lacking a significant participation of other cell types. By far the most common situation in which this occurs (so common as to be nearly universal, at least in Western countries) is represented by the incidental microscopic finding in periportal and mesenteric nodes in asymptomatic individuals, probably the result of mineral oil ingestion (Fig. 37.44).[392] Boitnott and Margolis[393] found this change in 78% of a series of 49 autopsied adults. Their chemical and histochemical studies showed that the oil droplets represent deposits of liquid-saturated hydrocarbons. Mineral oil is extensively used in the food processing industry, as a release agent and lubricant in capsules, tablets, bakery products, and dehydrated fruits and vegetables. Lipophagic granulomas of an extensive degree have been reported in association with long-term total parenteral nutrition therapy for short bowel syndrome.[394]

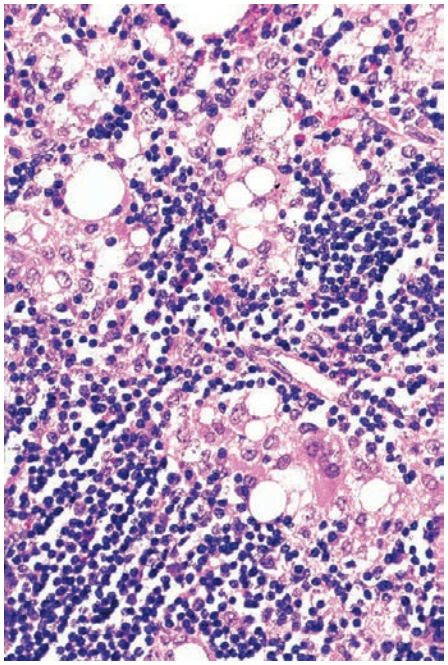

Figure 37.44 Lymph Node Containing Lipophagic Granulomas. The change is manifested by the presence of mononuclear and multinucleated histiocytes located in the sinuses and containing large cytoplasmic vacuoles.

Whipple disease can result in marked enlargement of mesenteric lymph nodes, with formation of numerous lipophagic granulomas.[395] Collections of histiocytes containing a PAS-positive glycoprotein are also present.[396] Under oil immersion and with electron microscopy, the characteristic bacillary bodies can be identified. Collections of PAS-positive histiocytes can also develop in peripheral nodes and may be the first clue to the diagnosis in a patient with gradual weight loss, weakness, and polyarthritis. Steatorrhea, the other classic symptom of the disease, may appear only in a later stage. In the presence of suggestive findings in routinely stained sections, confirmation of the diagnosis can now be obtained by the demonstration of the responsible organism *(Tropheryma whipplei)* by immunohistochemistry or PCR.[397–399]

Lymphangiography, a procedure now largely abandoned, induces a lipophagic granulomatous reaction that may persist for several months. The sinuses are markedly distended and lined by histiocytes, many of which are multinucleated. Eosinophils may be present in appreciable numbers in the medullary cords. This is preceded by a predominantly neutrophilic infiltration.[400]

Malignant Lymphoma

Malignant lymphoma is the generic term given to tumors of the lymphoid system and specifically of lymphocytes and their precursor cells, whether of T, B, or null phenotypes. Tumors now known to be composed of histiocytes, and other cells of the accessory immune system were previously included in the category of malignant lymphoma but are now regarded separately for both conceptual and practical reasons. Many tumors that were designated in the past as histiocytic lymphomas or reticulum cell sarcomas, however, are in reality of lymphocytic nature and therefore true malignant lymphomas and an interrelationship between some true histiocytic tumors and malignant lymphomas is becoming clear.[401]

Although some overlapping exists, the term *malignant lymphoma* is reserved for those neoplastic processes that initially present as localized lesions and are characterized by the formation of gross tumor nodules. Conversely, neoplastic lymphoid proliferations that are systemic and diffuse from their inception are usually termed leukemias (see Chapter 39).

The malignant lymphomas can be divided into two major categories: Hodgkin lymphoma and all the others, which, for lack of a better term, are known collectively as non-Hodgkin lymphomas.[402–406] Both groups are further subdivided into several more or less distinct subcategories, with the most currently and widely accepted classification being the 2016 WHO revision.[407] This classification has incorporated a wealth of information gathered from the fields of immunophenotyping, molecular genetics, genomics, and proteomics but also relies on clinical information and morphology. While other classification systems, including those of Rappaport, Kiel, and the so-called Working Formulation,[408–410] have historic significance, they should no longer be used.

Hodgkin Lymphoma

The disease originally described by Thomas Hodgkin in 1832 and which Samuel Wilks first proposed to be called Hodgkin's disease makes one of the richest chapters of history of oncologic pathology.[411–414] The original color illustrations have become icons,[415] and the original cases, still housed at the pathology museum of Guy's Hospital in London, have been "exhumed" and studied microscopically and immunohistochemically, and the diagnosis has been confirmed (at least in some of the cases) after well over a

century of fixation.[416] The interest in this enigmatic disease remains unabated, having been quoted as the paradigm for the emerging science of "molecular morphology."[414]

The conventional definition of Hodgkin's disease, now termed Hodgkin lymphoma, is that of a type of malignant lymphoma in which Reed–Sternberg cells are present in a "characteristic background" of reactive inflammatory cells of various types, accompanied by fibrosis of a variable degree. This definition still applies, at least in part, for cases of so-called classical Hodgkin lymphoma, but it is now recognized that cases of nodular lymphocyte predominance Hodgkin lymphoma (NLPHL) are distinct from this group. While identification of typical Reed–Sternberg cells is useful for the initial diagnosis of classical Hodgkin lymphoma, cells with similar features may be seen in other neoplasms, including some non-Hodgkin lymphomas and a diagnosis of Hodgkin lymphoma, in some cases, can be made without identification of cells with the classic binucleated Reed-Sternberg appearance. As far as the "characteristic background" or "appropriate milieu" is concerned, it is highly variable, but in classical Hodgkin lymphoma, it lacks the monomorphic appearance of most other malignant lymphomas. Mature lymphocytes, eosinophils, plasma cells, and histiocytes may all be present in greater or lesser amount, depending on the microscopic type. Many of the Reed–Sternberg cells are surrounded by T lymphocytes arranged in a rosettelike fashion.

Most cases of classical Hodgkin lymphoma and all cases of NLPHL are derived from B cells,[417–420] and approximately 40% of cases of classical Hodgkin lymphoma cases are associated with EBV infection.[421] Individuals with a history of infectious mononucleosis have an increased incidence of Hodgkin lymphoma;[422,423] patients with Hodgkin lymphoma have an altered antibody pattern to EBV prior to diagnosis;[424] marked phenotypic similarities exist between infectious mononucleosis and Hodgkin lymphoma;[425] and EBV genomes have been identified in Reed–Sternberg cells at least 40% of the cases (particularly in the mixed cellularity subtype, in young patients, and/or in developing countries) (Fig. 37.45).[426–430] There is also evidence for a genetic susceptibility factor.[431]

Gross Features

Except for the very early stages, lymph nodes involved by Hodgkin lymphoma are enlarged, sometimes massively so. The gross appearance is somewhat dependent on the microscopic subtypes (see later section). The consistency varies from soft to hard depending on the amount of fibrosis. Some degree of nodularity is often appreciated, particularly in the nodular sclerosis form (Fig. 37.46). Foci of necrosis may be present. Except for NLPHL, the cut surface of the node has a more heterogeneous appearance than most non-Hodgkin lymphomas. In advanced cases, several nodes from the same group become matted together, a feature spectacularly demonstrated in the drawing that accompanied Hodgkin's classic article.

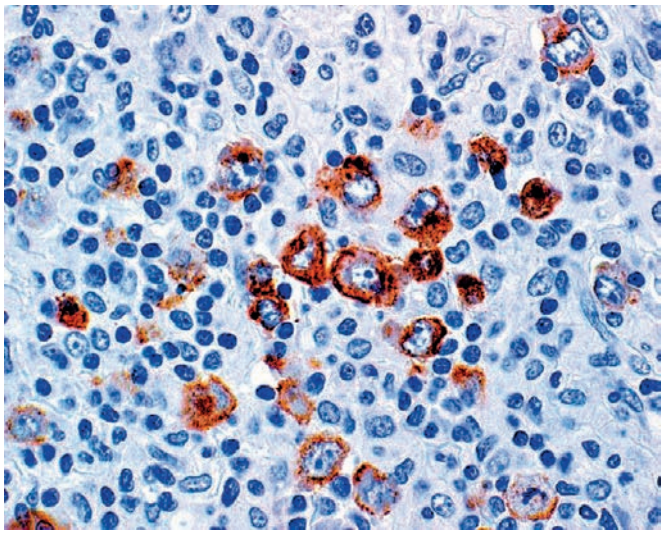

Figure 37.45 Presence of the EBV in a the neoplastic cells of Hodgkin lymphoma as demonstrated immunohistochemically by the detection of LMP1 antigen.

Classical Hodgkin Lymphoma

Reed–Sternberg Cell

The classic Reed–Sternberg cell, as seen in all subtypes of classic Hodgkin lymphoma (but not in NLPHL, see later), is a large cell (20–50 μm in diameter or more) with abundant weakly acidophilic or amphophilic cytoplasm, which may appear homogeneous or granular and which lacks a pale zone in the Golgi area (Fig. 37.47). The nucleus is bilobed or polylobed so that the cell appears binucleated or multinucleated; it is possible that in some cases bona fide

Figure 37.46 **A** and **B,** Gross appearance of lymph nodes involved by Hodgkin lymphoma. Note nodularity and sclerosis.

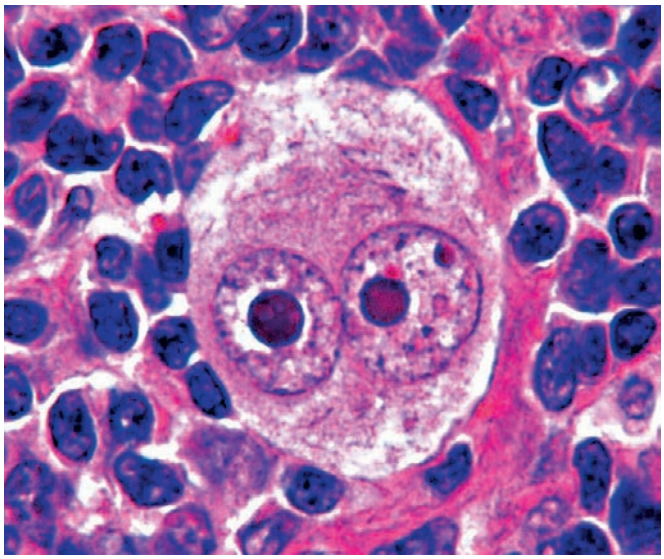

Figure 37.47 Spectacular example of a Reed–Sternberg cell. (Courtesy of Dr. Fabio Facchetti, Brescia, Italy.)

binucleation or multinucleation actually occurs (Fig. 37.48). The nuclear membrane is thick and sharply defined. The nuclear pattern is usually vesicular but with some coarse chromatin clumps scattered throughout. There is a very large, variously shaped, but usually rounded, highly acidophilic central nucleolus surrounded by a clear halo. In the most typical example of the Reed–Sternberg cell, the two nuclear lobes face each other ("mirror image"), resulting in the oft-cited "owl eye" appearance. When multilobation occurs, the appearance has been likened to that of an "egg basket." Cells with this set of features but lacking nuclear lobation have been referred to as mononuclear variants of Reed–Sternberg cells or Hodgkin cells. It has been stated that the minimal requirement for a diagnostic Reed–Sternberg cell is a bilobed nucleus in which at least one of the lobes has a prominent acidophilic nucleolus. At the other end of this spectrum is the Reed–Sternberg cell of giant size and highly pleomorphic hyperchromatic nuclei, having an appearance such as to simulate the cells of anaplastic carcinoma or one of the pleomorphic sarcomas. Another type of Reed–Sternberg cell, characterized by a darkly staining and retracted quality, is referred to as the mummified or necrobiotic variant and appears to be the morphologic expression of apoptosis (Fig. 37.49). Additional morphologic variations of Reed–Sternberg cells exist, and these will be discussed with the various types of Hodgkin lymphoma.

The Reed–Sternberg cell of Hodgkin lymphoma needs to be distinguished from other multinucleated cells that may be present in lymph nodes. Megakaryocytes can simulate it closely in hematoxylin–eosin-stained sections, but they can be identified by the presence of a strongly PAS-positive substance in their cytoplasm and their different immunophenotype, which includes positivity for Factor VIII–related antigen and CD61. Cells morphologically very similar to Reed–Sternberg cells, representing pleomorphic immunoblasts, can be seen in infectious mononucleosis and other viral diseases.[221] Neoplastic cells from a variety of epithelial and mesenchymal tumors also can resemble Reed–Sternberg cells.[432] Finally, some malignant lymphomas of non-Hodgkin type may be accompanied by cells with the appearance of Reed–Sternberg cells. In all of these disorders—and especially in the lymphomas—it is of the utmost importance to examine not only the putative Reed–Sternberg cells but also the background in which they are situated. The more cytologically atypical the lymphoid population, the less likely is the diagnosis of Hodgkin lymphoma. Despite these fairly distinctive morphologic features, a diagnosis of Hodgkin lymphoma is no longer made based on morphology alone and should be confirmed by demonstration of the characteristic immunophenotype of the neoplastic cells (see later).

The immunohistochemical profile of the Reed–Sternberg cell and mononuclear variants in classic Hodgkin lymphoma have been summarized in numerous studies.[433–447] While variability in antigen expression exists, immunohistochemical studies, usually by paraffin section immunohistochemistry, are essential for proper diagnosis and to exclude disorders that may morphologically mimic classical Hodgkin lymphoma. The vast majority of cases are CD30 positive (Fig. 37.50), and caution should be taken if there is not fairly strong expression of CD30 in most if not all atypical large cells. CD15 expression, in membrane, Golgi, or cytoplasmic patterns, is reported in up to 80% of cases but appears to be slightly less common in the author's experience. The neoplastic cells of classical Hodgkin lymphoma are CD45 negative, but interpretation of CD45 staining is often difficult unless large numbers of back-to-back neoplastic cells are present in the specimen. Although classical Hodgkin lymphoma is usually derived from a B cell, expression of B-cell antigens is inconsistent and typically variable. CD20 expression is reported in approximately 20% of cases, but even those cases show variable expression with some neoplastic cells usually negative. A finding of strong and uniform CD20 expression should raise consideration for an alternative diagnosis. The B-cell transcription factor PAX5 demonstrates weak nuclear positivity in at least 90% of cases, but expression of other transcription factors, specifically OCT2 and BOB1, is usually not present or minimal. Individual pan–T cell markers may rarely be expressed, but strong expression of multiple T-cell antigens should suggest a T-cell neoplasm.

Molecular studies are usually of limited utility in the diagnosis of classical Hodgkin lymphoma. Most cases yield a germline configuration for immunoglobulin heavy and light chain genes and the T-cell receptor genes, but this simply results from a dilution factor by the non-neoplastic cells; indeed, studies of cases with an increased number of Reed–Sternberg cells and their variants show clonal rearrangements, usually of the IGH,[448–452] while cases studied after microdissection also reveal evidence of B-cell clonality.[417,420]

General and Clinical Features

Classical Hodgkin lymphoma accounts for 20%–30% of all malignant lymphomas in the United States and Western Europe but a much lower percentage in Japan and other Asian countries.[453] There is a wide range in age incidence, which varies according to geographic location. In the United States, there is a bimodal distribution, with a peak at 15–40 years and a second, smaller peak in the seventh decade. In Japan, the peak in young adulthood is absent. In poorly developed countries, there is a high incidence in children, a relatively low incidence in the 15- to 40-year age group, and a third peak later in life.[454,455] There is a male preponderance (approximately 1.5 : 1) in all microscopic types except nodular sclerosis. The disease may present in a variety of ways, the most common (approximately 90% of the cases) being painless enlargement of superficial (usually cervical) lymph nodes. Fever, night sweats, and loss of weight (so-called B symptoms) occur in approximately 25% of the cases; their presence influences the clinical staging. Pruritus is also frequent.

Nodular sclerosis is by far the most common type of Hodgkin lymphoma in the United States. It characteristically presents in the neck and/or mediastinum of young females.[456] Lymphocyte depletion Hodgkin lymphoma may present in adults or elderly patients as a febrile illness with pancytopenia or lymphocytopenia, hepatomegaly, abnormal liver function tests, and no peripheral lymphadenopathy,[457] or it may manifest the usual clinical presentation of Hodgkin

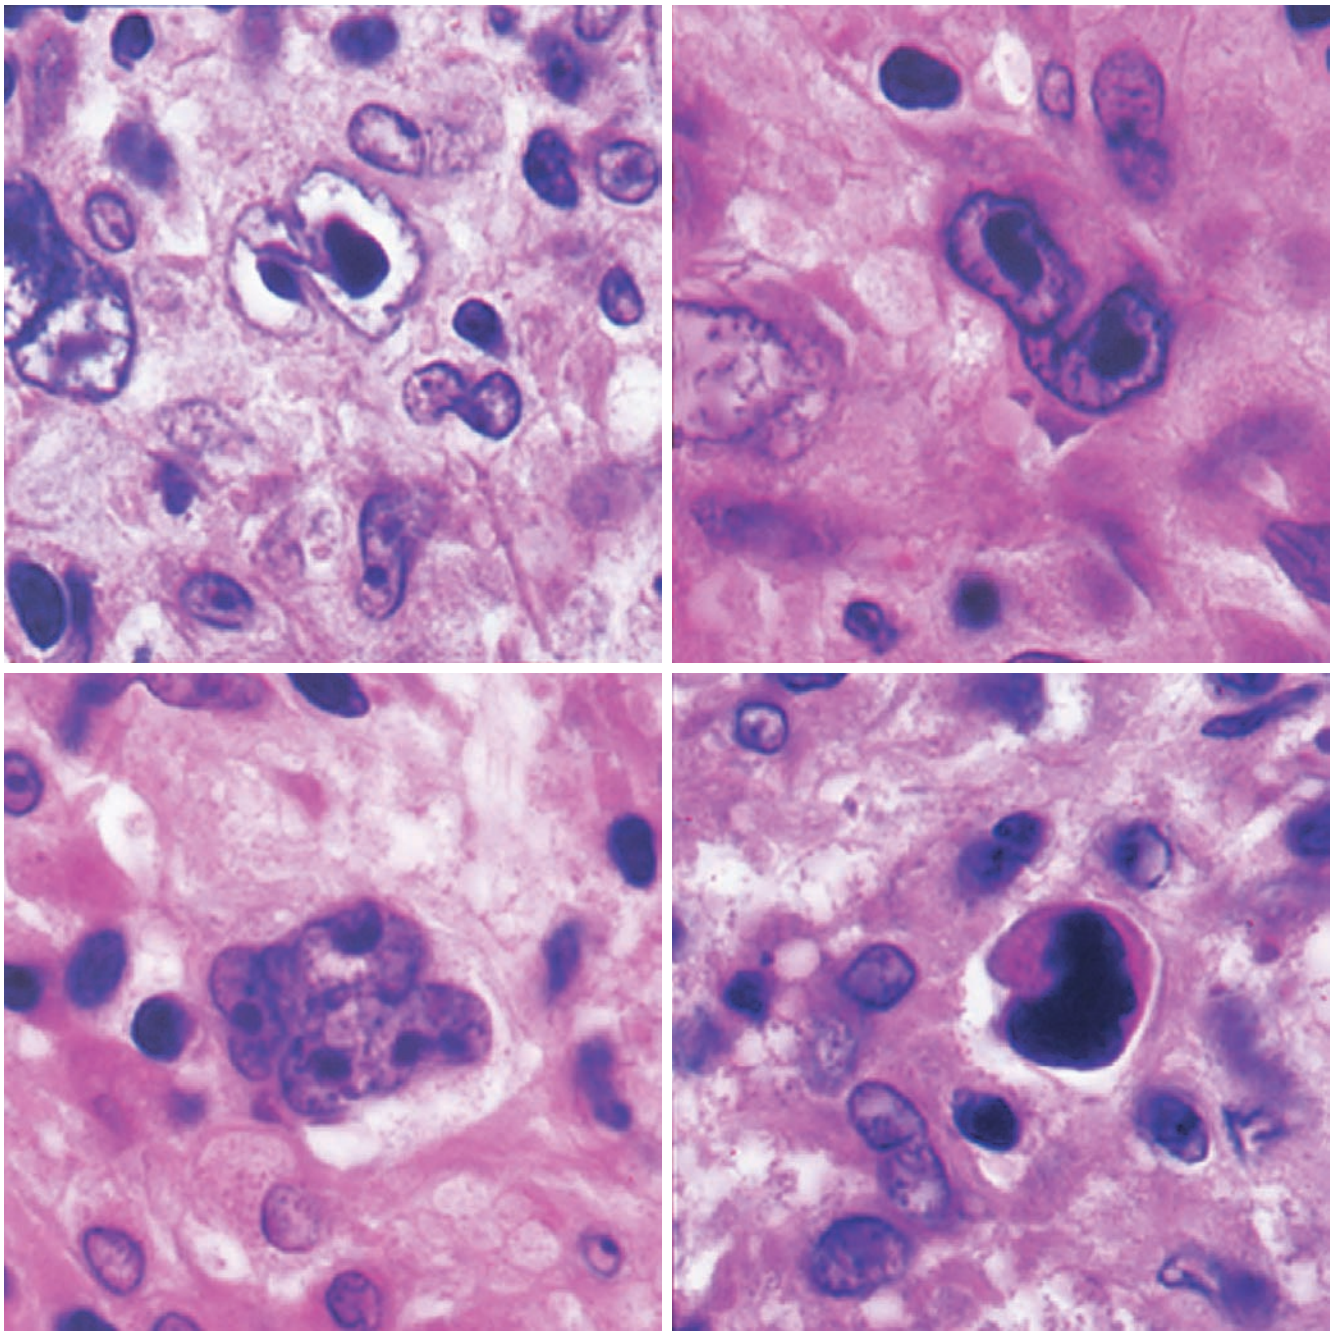

Figure 37.48 Various Appearances of Reed–Sternberg Cells. The cell located at the bottom right has a "mummified" appearance.

lymphoma.[458] This form is extremely rare in children, in whom nodular sclerosis and lymphocyte predominance predominate greatly.[459,460]

Mediastinal involvement is the rule in nodular sclerosis and is inconstant in mixed cellularity and lymphocyte depletion.[461] The risk of abdominal involvement is greater in patients with B symptoms and in lymphocyte depletion or mixed cellularity types; the lowest risk is for asymptomatic females with nodular sclerosis histology (6%).[462]

The diagnosis of Hodgkin lymphoma should be questioned for any lymphoma initially involving Waldeyer's ring, the skin, and the gastrointestinal tract or presenting below the diaphragm. Most of these cases are examples of non-Hodgkin lymphomas with Hodgkin-like cells.

Patients with Hodgkin lymphoma often have defects in cellular immunity, which leads to an increased susceptibility to some infections.[463] However, a diagnosis of Hodgkin lymphoma should be viewed with suspicion if it presents as a complication of a natural immune deficiency, immunosuppression, or other immune diseases. Although clear cases of this association exist (particularly in patients with ataxia–telangiectasia and with HIV infection),[464,465] most of these cases actually represent other neoplasms. HIV-associated Hodgkin lymphoma tends to present at a high stage and to run an aggressive clinical course.[466]

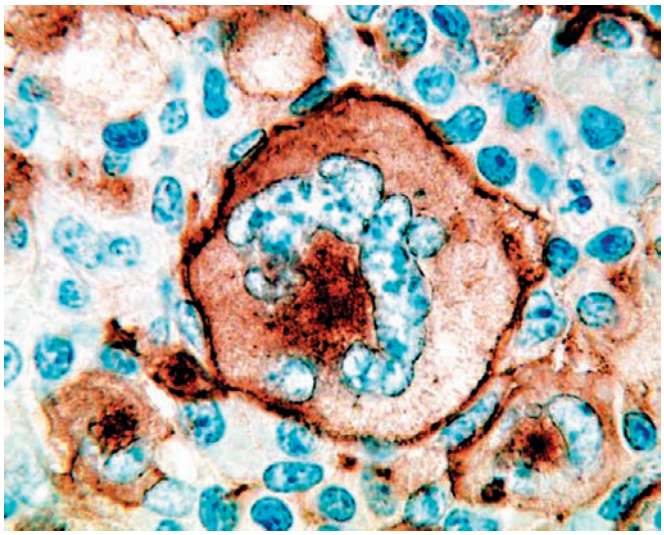

Figure 37.50 Membrane and Golgi-type immunoreactivity for CD30 in a Reed–Sternberg cell. (Courtesy of Dr. Fabio Facchetti, Brescia, Italy.)

Spread

Most cases of classical Hodgkin lymphoma begin in lymph nodes above the diaphragm and spread from there to other lymph node groups and to extranodal sites. Important information has been acquired in regard to the frequency and significance of this spread as a result of an aggressive diagnostic approach, particularly with the use of laparotomy as a routine staging procedure.[467,468]

1. *Direct extension*. The disease may spread to the perinodal tissues, sometimes extensively, and result in a fusion of the involved nodes. In advanced cases, direct invasion of skin, skeletal muscle, and other sites can occur. Mediastinal Hodgkin lymphoma can extend by continuity into the large vessels, lung, and chest wall.[469]
2. *Other lymph node groups*. Most cases of classical Hodgkin lymphoma spread by involvement of adjacent lymph node groups.[470] This contiguous manner of spread is particularly common in the nodular sclerosis type.[469] Nodal spread has been evaluated with lymphangiogram, CT scan, and staging laparotomy. When it was carried out with some frequency, lymphangiography had an overall diagnostic accuracy in excess of 90%; it was more effective in detecting involvement below the level of the second lumbar vertebra but inconsistent for nodes situated higher in the periaortic area. Approximately 30% of patients with negative lymphangiograms in whom the para-aortic nodes were left untreated later demonstrated disease below the diaphragm.[471] Of the nodes biopsied at laparotomy during the course of a staging procedure, the most likely to be involved were those located in the splenic hilum and retroperitoneum. Mesenteric nodes are almost always spared.
3. *Spleen*. A spleen weighing 400 g or more is practically always histologically positive. The converse is not true: spleens below this weight are involved in a high proportion of cases. The focal nature of the disease calls for a careful gross examination of this organ. The specimens should be sectioned throughout in thin slices, and every suspicious area should be examined microscopically. If no nodules are detected on gross inspection, the chances of finding Hodgkin lymphoma in random microscopic sections are negligible. Splenic involvement is thought to represent a critical stage in the spread of Hodgkin lymphoma and is an early manifestation of blood vessel dissemination. The approximate number of tumor nodules present in the spleen should be indicated because of their relation to prognosis; specifically, it should be stated whether there are five or more.
4. *Liver*. Hepatic disease is almost invariably associated with splenic and retroperitoneal lymph node involvement and with so-called B symptoms. Clinical assessment of liver involvement is quite unreliable. Care should be exercised in distinguishing involvement by Hodgkin lymphoma from benign lymphoid aggregates, some of which may show mild atypia.[472]
5. *Bone marrow*. This is discussed in Chapter 39.
6. *Others*. Practically any other organ can show secondary involvement by Hodgkin lymphoma, such as the lung, skin, gastrointestinal tract, and central nervous system (see respective chapters).

Microscopic Types

A variety of classification systems for Hodgkin lymphoma have been proposed and historically accepted,[473–475] with numerous histologic subtypes described. The 2016 WHO classification, however, is the currently accepted nomenclature system for this disease and should be used for all cases.[407] NLPHL is now recognized to be morphologically, biologically, and clinically distinct from more traditional types of Hodgkin lymphoma, termed classical Hodgkin lymphoma, and it is described separately later. With current therapy, the histologic subtypes of classical Hodgkin lymphoma have no clinical or prognostic significance and, especially on small needle biopsies, a simple diagnosis of "classical Hodgkin lymphoma" is appropriate for patient care.

As mentioned, the category of classical Hodgkin lymphoma subsumes all types of Hodgkin lymphoma except for NLPHL. It is regarded as a nosologic entity because of the similar immunophenotype of the tumor cells. The differences consist in sites of involvement, clinical features, growth pattern, presence of fibrosis, composition of cellular background, number and degree of atypia of the tumor cells, and prevalence of EBV infection. These subtypes are nodular sclerosis, mixed cellularity, lymphocyte rich, and lymphocyte depleted.

Nodular sclerosis Hodgkin lymphoma is characterized in its fully developed stage by broad bands of birefringent collagen separating the lymphoid tissue in well-defined nodules (Fig. 37.51). These fibrous bands, which have a birefringent quality when examined under polarized light, often center around blood vessels. In addition to the classic Reed–Sternberg cell, nodular sclerosis Hodgkin lymphoma also displays a variant known as *lacunar* cells (Fig. 37.52). This cell type is quite large (40–50 µm in diameter), with an abundant clear cytoplasm and multilobulated nuclei having complicated infoldings and nucleoli of smaller size than those of the classic Reed–Sternberg cell. The "frail" cytoplasm of these cells is retracted close to the nuclear membrane so that the cell appears to be floating in a "lacuna." This is the result of an artifact induced by formalin fixation, inasmuch as it is absent in tissues fixed in B5 or Zenker. In some cases, there is clustering of these lacunar cells, particularly around areas of necrosis. They form sheets and cohesive nests, to the point that a mistaken diagnosis of large cell non-Hodgkin lymphoma, carcinoma, germ cell tumor, or thymoma can be made. Cases of nodular sclerosis Hodgkin lymphoma showing prominence of this feature have been referred to as the *syncytial*, *sarcomatoid*, or *sarcomatous* variant.[476]

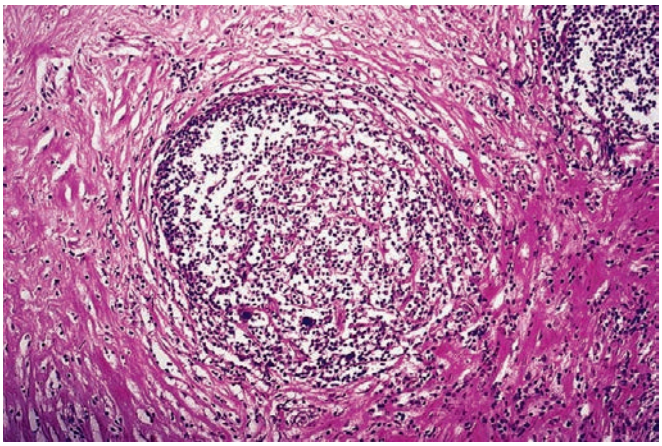

Figure 37.51 A Typical Case of Nodular Sclerosis Hodgkin Lymphoma. The lymphoid nodule is encased in dense fibrohyaline tissue.

The composition of the non-neoplastic infiltrate varies widely, to the point that some authors have proposed to subdivide nodular sclerosis Hodgkin lymphoma into lymphocyte predominant, mixed cellularity, and lymphocyte depletion categories, and this subdivision carried some prognostic implications in the past. Along similar lines, the British National Lymphoma Investigation group proposed to divide cases of nodular sclerosis Hodgkin lymphoma into two grades. In their scheme, cases were assigned to the allegedly more aggressive grade II if any of these features are present: (1) a "reticular" or "pleomorphic" pattern of lymphocytic depletion in over 25% of the cellular nodules; (2) a "fibrohistiocytic" pattern of lymphocyte depletion in over 80% of the cellular nodules; and (3) the presence of numerous bizarre and highly anaplastic Reed–Sternberg and Hodgkin cells without lymphocyte depletion in over 25% of the nodules.[477] Grade II lesions include the already mentioned "syncytial" variant of other authors. With current therapy, these subtypes of nodular sclerosis Hodgkin lymphoma have no prognostic significance and such subtyping is not necessary.[478]

By electron microscopy, nodular sclerosis Hodgkin lymphoma shows abundant collagen fibers together with myofibroblasts;[479] it has been suggested that the latter contribute to the retraction seen in this condition. In regard to the fibrosis, it should be kept in mind that practically all types of Hodgkin lymphoma can exhibit some degree of this change, particularly after therapy and recurrent cases of classical Hodgkin lymphoma should not be further subtyped.

In **mixed cellularity** Hodgkin lymphoma, a large number of eosinophils, plasma cells, and atypical mononuclear cells are admixed with classic Reed–Sternberg cells, which tend to be numerous. Focal necrosis may be present, but fibrosis should be minimal or absent (Fig. 37.53). This type tends to occur more frequently in the head and neck region and be associated with EBV infection of the Hodgkin cells.

The **lymphocyte-rich** type is characterized by the presence of Reed–Sternberg cells scattered against a nodular (most commonly) or diffuse background, largely composed of small B lymphocytes (in contrast to the striking T-cell background of other classical Hodgkin lymphoma types) and practically devoid of eosinophils and neutrophils.[480] The main differential diagnosis is with NLPHL, and is primarily based on the presence of cells with the typical morphologic and immunohistochemical features of classic Hodgkin cells.

The **lymphocyte-depletion** group, which comprises less than 5% of all cases of Hodgkin lymphoma, includes two morphologically different subtypes, designated as "diffuse fibrosis" and "reticular" in the original Lukes classification. In the diffuse fibrosis subtype, the number of lymphocytes and other cells progressively decreases as the result of heavy deposition of collagen fibers. The reticular subtype is characterized by a very large number of diagnostic Reed–Sternberg cells (many of them of bizarre configuration) among atypical mononuclear cells and other elements (Fig. 37.54). Areas of necrosis are more common than in other types. The "reticular" subtype of lymphocyte depletion Hodgkin lymphoma needs to be distinguished from non-Hodgkin lymphoma of large cell type (including anaplastic large cell lymphoma [ALCL]) and from the variant of nodular sclerosis Hodgkin lymphoma with aggregates of lacunar cells.[481]

The immunophenotypic profile of the neoplastic cells in classic Hodgkin lymphoma is described in a preceding section on "Reed–Sternberg cells." The background lymphocytes are predominantly T cells with the exception of lymphocyte-rich classical Hodgkin lymphoma.

While relapsed Hodgkin lymphoma often retains the same immunophenotypic and morphologic features as the primary disease, radiation and chemotherapy may result in morphologic

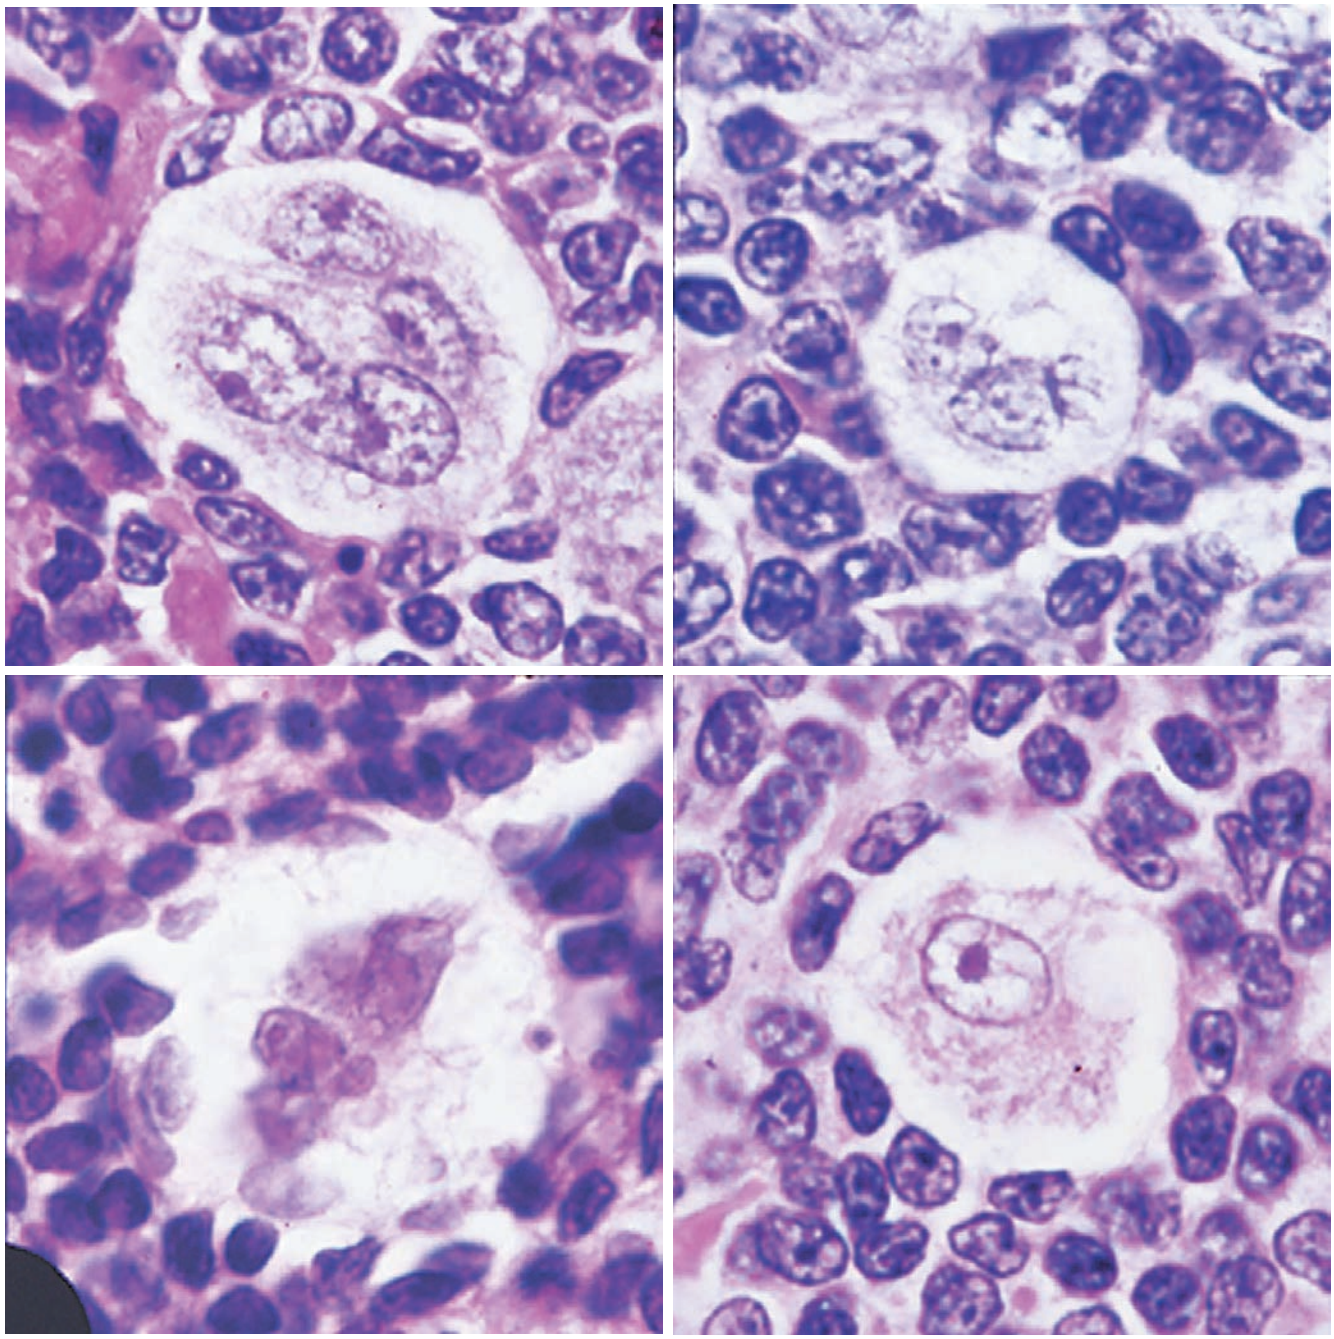

Figure 37.52 Various appearances of lacunar cells in nodular sclerosis Hodgkin lymphoma.

changes that differ from the untreated disease.[482–484] Additionally, some cases relapse with higher numbers of neoplastic cells, more typical of lymphocyte-depleted Hodgkin disease, but an attempt to reclassify relapsed disease is confusing and not advised. Such cases should be studied by immunohistochemistry to confirm that they represent recurrent disease rather than a new neoplasm but are probably best diagnosed simply as recurrent classical Hodgkin lymphoma.

Other Microscopic Features

There are some microscopic variations on the theme of classical Hodgkin lymphoma worth mentioning, mainly because lack of knowledge of their occurrence may result in mistaken diagnoses.

1. *Foamy macrophages*. Clumps of foamy macrophages resulting in a xanthogranulomatous appearance may be found, particularly in the nodular sclerosis form.[485]
2. *Eosinophils*. In some instances, the intensity of eosinophilic infiltration is massive and accompanied by so-called eosinophilic microabscesses. Such cases may be confused with LCH, hypersensitivity reaction, or "allergic granulomatosis."
3. *Other inflammatory cells*. S100 protein–positive dendritic cells,[486] mast cells,[487] and monocytoid B cells[488] may be very numerous.
4. *Focal interfollicular involvement*. In the early stages of the disease, only focal involvement of a lymph node may be encountered,[489] often restricted to the paracortical region between florid

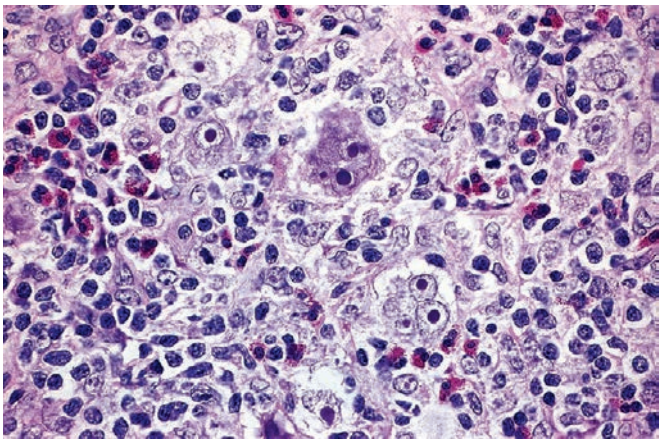

Figure 37.53 Mixed Cellularity Hodgkin Lymphoma. Several diagnostic Reed–Sternberg cells are seen admixed with a polymorphic lymphoid infiltrate rich in eosinophils.

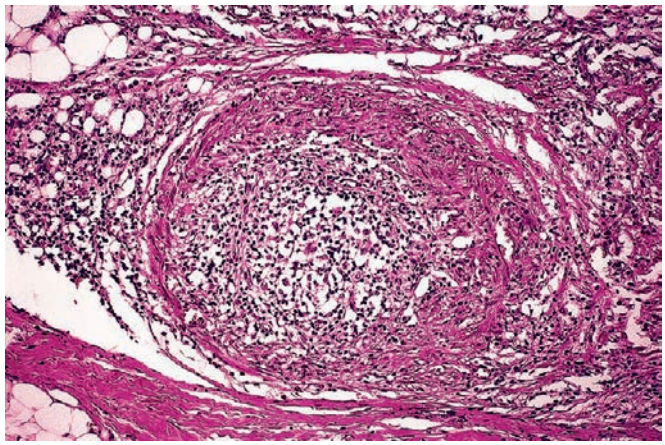

Figure 37.56 Blood Vessel Invasion in Hodgkin Lymphoma.

hyperplastic follicles; this pattern has been referred to as *interfollicular Hodgkin lymphoma*.[490]

5. *Follicular involvement*. Sometimes the nodal involvement by Hodgkin lymphoma is mainly in the germinal centers, the appearance being reminiscent of NLPHL.[491]
6. *Castleman disease–like features*. Cases of Hodgkin lymphoma may be accompanied or preceded by a plasmacytic infiltrate and abnormalities of germinal centers closely resembling those seen in plasma cell type Castleman disease, probably attributable to interleukin-6 secretion by Reed–Sternberg cells.
7. *Fibrosis*. In cases of nodular sclerosis Hodgkin lymphoma but sometimes also in other types, the amount of fibrosis can be such as to simulate the appearance of one of the inflammatory fibroscleroses (such as sclerosing mediastinitis or retroperitoneal fibrosis).
8. *Spindle cell proliferation*. In rare cases of Hodgkin lymphoma, there is a proliferation of oval to spindle cells of such a degree as to simulate fibrosarcoma, malignant fibrous histiocytoma, or a follicular dendritic cell tumor; such lesions have been referred to as **fibrosarcomatous or fibroblastic Hodgkin lymphoma**. Some of these spindle cells have a degree of nuclear atypia such as to indicate their neoplastic nature and relationship with Reed–Sternberg and Hodgkin cells; indeed, most of these lesions would be included in the grade II category of nodular sclerosis Hodgkin lymphoma proposed by the British National Lymphoma Investigation Group. Others are of a reactive nature and stromal derivation (i.e. made up of fibroblasts and myofibroblasts).[492]
9. *Noncaseating granulomas*. These formations are sometimes present in nodes and other organs involved by Hodgkin lymphoma. Occasionally they are so numerous as to obscure the diagnostic features of the disease (Fig. 37.55). In other instances, these granulomas may be seen within otherwise uninvolved organs of patients with Hodgkin lymphoma.[77] Their significance is unknown. Perhaps they represent an expression of delayed hypersensitivity. Some seen in the past were reactions to the contrast material used in lymphangiography.[493] Their presence does not indicate involvement of that organ by Hodgkin lymphoma and should therefore not influence the staging criteria. Actually, it has been suggested that, within a given stage, the presence of these granulomas is associated with a better prognosis.[494]
10. *Vascular invasion*. Blood vessel infiltration has been detected microscopically in 6%–14% of the cases of Hodgkin lymphoma by the use of elastic tissue stains (Fig. 37.56).[495] This finding is said to be associated with an increased incidence of extranodal organ involvement,[496] but the statement and the very validity of the observation have been questioned.

Molecular Genetics

In almost all cases of classical Hodgkin lymphoma, clonal immunoglobulin gene rearrangements can be demonstrated in microdissected neoplastic (Reed–Sternberg) cells or tissue samples rich in neoplastic cells; only exceptionally are clonal T-cell receptor gene rearrangements present instead.[417,497–499] The variable regions of the immunoglobulin genes frequently show hypermutation but not ongoing mutations. Remarkably, immunoglobulin mRNA transcripts are usually absent, which may result from functional defects in immunoglobulin gene regulatory elements or crippling mutations in the immunoglobulin genes.[500,498] That is, the neoplastic cells are compatible with germinal center B cells that have lost the capacity to express a functional antigen receptor, but which differ from their normal counterpart in having been rescued from apoptosis by various mechanisms, such as presence of EBV or aberrant activation of the NFκB pathway.[501–503]

Cytogenetic studies of classic Hodgkin lymphoma reveal complex karyotypes, commonly featuring hyperdiploidy or hypertetraploidy.[504,505] Recent FISH studies have shown rearrangements of the immunoglobulin genes in approximately 20% of cases, involving variable partners genes which may include *BCL2*, *BCL3*, *BCL6*, *REL*, *MYC*, *MHCT2A*, and unidentified genes,[506–508] and mutations of other genes, including NFκB.[509,510]

About 40% of cases of classic Hodgkin lymphoma are associated with EBV, which can be demonstrated by EBV-LMP1 immunohistochemistry or EBV-encoded early RNA (EBER) in situ hybridization.[511] The association with EBV is stronger at the extremes of age, that is children/young adults and elderly adults, and in the mixed cellularity subtype. Of note, the overall frequency of EBV association is much higher in individuals with immunodeficiency (approximately 100%) or from developing countries (80%–100%).[512–515]

Nodular Lymphocyte Predominant Hodgkin Lymphoma

In NLPHL, the predominant cell is an irregular, medium-sized B lymphocyte (L&H or popcorn cell), with or without an accompanying population of benign-appearing histiocytes.[516,517] Postcapillary venules with high endothelium may be prominent.[518,519] The lymph node architecture is partially or totally effaced, and the infiltrate has a variously well-developed nodular pattern of growth.[520] The nodularity may be so pronounced as to simulate on low power the appearance of follicular lymphoma; however, the nodules of NLPHL are more irregular in size and staining quality, and the admixture of lymphocytes and epithelioid cells gives them a mottled appearance (Fig. 37.57). A rim of uninvolved or hyperplastic lymphoid tissue which may include progressively transformed germinal centers may be present but reactive follicles are not admixed with the large tumor nodules. Eosinophils, plasma cells, and foci of fibrosis are scanty or absent. Classic Reed–Sternberg cells are usually absent. One sees instead a variable but usually large number of a type of Reed–Sternberg cell (the L&H cell, LP cell, or "popcorn" cell) characterized by a folded, multilobed nucleus with smaller nucleoli. These cells are most commonly found within the nodules but tend to also spill into the internodular areas. If numerous typical Reed–Sternberg cells are found in a node with a lymphocyte predominant background, the case probably belongs in the classical Hodgkin lymphoma category (lymphocyte-rich subtype). Occasionally, the L&H cells predominate at the margins of the nodules, creating a "wreath" around them. In others, they may cluster in large confluent sheets resembling diffuse large cell lymphoma.[521]

Poppema et al.[61,522,523] first proposed that cases of NLPHL arise from B-cell regions of the node and specifically from progressively transformed germinal centers. They supported their theory by showing

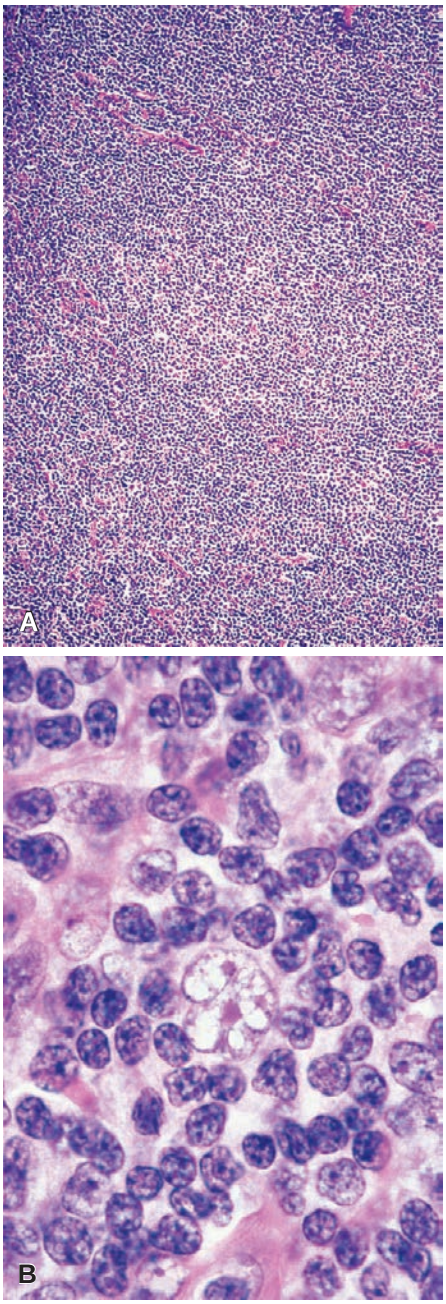

Figure 37.57 Lymphocyte Predominant Hodgkin Lymphoma. **A**, Low-power view showing a mottled appearance of the node. **B**, High-power view showing the lymphocytic and/or histiocytic (L&H) type of cell ("popcorn" cell) that is characteristic of this condition.

that the L&H cell that is characteristic of this condition is of B-cell lineage, and this has been confirmed by many others.[524–526] L&H cells express the pan–B-cell markers CD19, CD20, CD22, CD79A, PAX5, and OCT2.[525,527,528] They are also positive for CD45RB (LCA) but consistently negative for T-cell markers. They commonly express epithelial membrane antigen (EMA) and generally lack CD30 and CD15 expression. The neoplastic cells characteristically occur within nodules of small B cells (CD20+) with expanded follicular dendritic cell networks and spill out into the T-cell zones. OCT2 nuclear staining is usually strong in the tumor cells and highlights their expansion beyond the B-cell nodules. These "popcorn" cells are

typically rosetted by follicular helper T (TFH) cells which express CD3, PD1, BCL6, and CD57.[529,530]

NLPHL should be sharply separated (also on epidemiologic and clinical grounds) from classical Hodgkin lymphoma, even if occasionally the two are seen to coexist.[531,532] Although usually a rather indolent tumor, some cases will transform to DLBCL and such cases have been demonstrated to be clonally related.[533]

The differential diagnosis between NLPHL and T-cell/histiocyte-rich B-cell lymphoma, which is discussed in more detail later, may not be resolvable on small biopsies. A nodular pattern with background small B cells and associated follicular dendritic cells networks support NLPHL when this differential diagnosis arises.

Molecular Genetics

Microdissected neoplastic (L&H/LP) cells exhibit clonal rearrangements of the immunoglobulin genes, which show hypermutation and ongoing mutations, compatible with transformed antigen-selected germinal center B cells.[418,502,534,535] The rearranged immunoglobulin genes are functional, and can be transcribed into immunoglobulin mRNA, and further translated to immunoglobulin.[535,536]

Cytogenetic studies reveal complex karyotypes, often in the diploid range, with the commonest abnormalities being gain or partial gain of 1q, loss of chromosome 4q28–q32, and rearrangement involving 3q27 (shown to implicate *BCL6*, which is fused with a variety of partner genes, including the *IGH* gene at 14q32).[537–539] Array comparative genomic hybridization (CGH) studies have demonstrated gains in 2p16.1, the site of *REL*, and loses at 2p11.2 and 9p11.2, features similar to T-cell/histiocyte-rich large B-cell lymphoma.[540]

Although the vast majority of cases of NLPHL are not associated with EBV, a few rare cases have been recently reported.[541,542]

Non-Hodgkin Lymphoma

The 2016 WHO classification contains numerous categories of non-Hodgkin lymphomas that are listed in Box 37.1. While most of these involve lymph nodes, some are primarily extranodal diseases and those are discussed in more detail in other chapters. As mentioned, the WHO classification is based on a combination of clinical features, morphology, immunophenotyping, and genetics to define disease entities; morphology alone is no longer sufficient to make a lymphoma diagnosis.

The non-Hodgkin lymphomas are grouped into general categories of B-cell lineage or T/NK-cell lineage diseases and these are further grouped into mature and precursor neoplasms. The precursor neoplasms represent lymphoblastic leukemias/lymphomas and are grouped together because of similarities in the disease despite variations in their clinical presentation (leukemic, tissue based, or both).

Precursor Lymphoid Neoplasms

Lymphoblastic lymphomas represent the tissue-based presentation of either T- or B-lymphoblastic leukemia/lymphoma. The leukemic presentations are discussed in more detail in Chapter 39. Most lymphoblastic leukemias are of precursor T-cell lineage.

Lymphoblastic lymphoma is seen primarily in children and adolescents, but it also occurs in adults.[543,544] T-lymphoblastic lymphoma has a distinctive clinical presentation. In approximately half of the cases there is a mediastinal mass in the thymic region (the old Sternberg sarcoma). The clinical course of the untreated disease is extremely aggressive, with rapid multisystem dissemination and development of a leukemic blood picture,[545] and death after a few months.[546] Grossly, the tumor is whitish and soft and often exhibits foci of hemorrhage and necrosis. Microscopically, there is a diffuse and relatively monomorphic pattern of proliferation, broken only by a focal starry sky appearance in some of the cases. The tumor often extends outside the node or thymus to invade the adipose tissue in a diffuse fashion. Permeation of the wall of blood vessels in a targetoid fashion is another characteristic feature. The neoplastic cells have scanty cytoplasm and a nucleus that has a round contour (instead of the angulated shape typical of follicular lymphoma) that, on close examination, shows in some cases the presence of delicate convolutions resulting from multiple small invaginations of the nuclear membrane. Oil-immersion examination of well-prepared, very thin sections is necessary to demonstrate this feature, which may be present in only a small percentage of the tumor cells or sometimes practically absent (Fig. 37.58).[546] The chromatin is finely stippled, and nucleoli are inconspicuous. Mitotic activity is extremely high. These convoluted cells are similar to the cerebroid cells of mycosis fungoides–Sézary syndrome (as one might assume from their similar names) but differ from the latter because the nuclear membrane is thinner, the chromatin more dispersed, and the invaginations more delicate. Actually, the need for distinction between these two cell types is more theoretical than real because of the fact that the two diseases are vastly different in their clinical presentation.

Remnants of thymus often are found in the mediastinal mass, and this may lead to a mistaken diagnosis of thymoma; in this regard, it should be remembered that thymoma is very infrequent in children and that, when it occurs, it is characterized by a population of small or activated lymphocytes but not convoluted ones. When lymphoblastic lymphoma spreads to lymph nodes, it preferentially involves the paracortical (thymic-dependent) zone.

The immunohistochemical hallmark of lymphoblastic lymphoma is TdT, a marker for precursor lymphoid cells. The precursor T-cell cases express pan–T antigens, such as CD1, CD2, CD7, cytoplasmic CD3, and CD43, but usually do not express surface CD3.[547] The latter feature is of importance if flow cytometry immunophenotyping is performed without study of cytoplasmic markers but is not a major concern by immunohistochemistry, with routinely detects cytoplasmic CD3. Approximately one-third of cases of T-lymphoblastic leukemia/lymphoma will express CD10, which may cause confusion with a B-cell lymphoma. CD34 expression may also be present and is useful for rare cases that demonstrate weak or negative TdT expression. Positivity is also consistently encountered for CD99.

Translocations involving the alpha and delta T-cell receptor loci at 14q11.2, the beta locus at 7q35, and the gamma locus at 7p14–15 with a variety of partner genes (such as *MYC*, *TAL1*, *RBTN1*, *RBTN2*, and *HOX11*), leading to a dysregulation of transcription of the latter, are relatively common in T-lymphoblastic leukemia/lymphoma. *NOTCH1* and/or NOTCH1 pathway mutations are identified in the majority of cases.[548] Rare cases may be associated with eosinophilia and translocations involving *FGFR1*, particularly t(8;13)(p11;q12). Such cases are considered a distinct entity in the WHO classification (myeloid/lymphoid neoplasms with *FGFR1* rearrangement) and may relapse with a significantly different immunophenotype.[549] While cases presenting as leukemia or as lymphoma are similar in most regards, one study has found upregulation of *BCL2*, *S1PR1*, and *ICAM1* in cases with a tissue-based presentation, suggesting a role in homing of tumor cells to tissue rather than marrow in these patients.[550]

In 15%–20% of the cases of lymphoblastic lymphoma, the tumor cells are precursor B cells expressing CD19 and CD79A and most are CD10 positive.[551] They also usually express TdT but not surface immunoglobulin, and many are CD20 negative. These cases usually do not present in the mediastinum. These are predominantly extranodal tumors with low propensity for leukemic involvement.[552] The genetic changes of B-lymphoblastic lymphoma are similar to

Box 37.1 2016 World Health Organization classification of mature lymphoid neoplasms

Provisional entities are in italics. Only entities that primarily involve lymph nodes are discussed in this chapter.

Mature B-cell neoplasms

Chronic lymphocytic leukemia/small lymphocytic lymphoma
Monoclonal B-cell lymphocytosis
B-cell prolymphocytic leukemia
Splenic marginal zone lymphoma
Hairy cell leukemia
Splenic B-cell lymphoma/leukemia, unclassifiable
Splenic diffuse red pulp small B-cell lymphoma
Hairy cell leukemia variant
Lymphoplasmacytic lymphoma
Waldenström macroglobulinemia
Monoclonal gammopathy of undetermined significance (MGUS), IgM+
μ heavy chain disease
γ heavy chain disease
α heavy chain disease
MGUS, IgG/A+
Plasma cell neoplasms
Solitary plasmacytoma of bone
Extraosseous plasmacytoma
Monoclonal immunoglobulin deposition diseases
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
Nodal marginal zone lymphoma
Pediatric nodal marginal zone lymphoma
Follicular lymphoma
In situ follicular neoplasia
Duodenal-type follicular lymphoma
Pediatric-type follicular lymphoma
Large B-cell lymphoma with IRF4 rearrangement
Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
In situ mantle cell neoplasia
Diffuse large B-cell lymphoma (DLBCL), not otherwise specified
Germinal center B-cell type
Activated B-cell type
T-cell/histiocyte-rich large B-cell lymphoma
Primary DLBCL of the central nervous system
Primary cutaneous DLBCL, leg-type
Epstein–Barr virus (EBV) + DLBCL, NOS
EBV+ mucocutaneous ulcer
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
ALK+ large B-cell lymphoma
Plasmablastic lymphoma
Primary effusion lymphoma
HHV8+ DLBCL, NOS
Burkitt lymphoma
Burkitt-like lymphoma with 11q aberration
High-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements
High-grade B-cell lymphoma, NOS
B-cell lymphoma, unclassifiable, with features intermediate between diffuse large B-cell lymphoma and classical Hodgkin lymphoma

Mature T-cell and NK cell neoplasms

T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
Chronic lymphoproliferative disorder of NK cells
Aggressive NK cell leukemia
Systemic EBV+ T-cell lymphoma of childhood
Hydroa vacciniforme-like lymphoproliferative disorder
Adult T-cell leukemia/lymphoma
Extranodal NK-/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Monomorphic epitheliotropic intestinal T-cell lymphoma
Indolent T-cell lymphoproliferative disorder of the GI tract
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary syndrome
Primary cutaneous CD30+ T-cell lymphoproliferative disorders
Primary cutaneous γδT-cell lymphoma
Primary cutaneous CD8+ aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous acral CD8+ T-cell lymphoma
Primary cutaneous CD4+ small/medium T-cell lymphoproliferative disorder
Peripheral T-cell lymphoma, NOS
Angioimmunoblastic T-cell lymphoma
Follicular T-cell lymphoma
Nodal peripheral T-cell lymphoma with TFH phenotype
Anaplastic large cell lymphoma, ALK+
Anaplastic large cell lymphoma, ALK–
Breast-implant associated anaplastic large-cell lymphoma

Data from Swerdlow SH, Campo E, Pileri SA, Harris NL, Stein H, Siebert R, et al. The 2016 revision of the World Health Organization classification of lymphoid neoplasms. *Blood.* 2016;127(20):2375-2390.

B-lymphoblastic leukemia and are discussed in more detail in Chapter 39.

The differential diagnosis of lymphoblastic lymphoma includes the already mentioned thymoma when in a mediastinal location, as well as Ewing sarcoma/ peripheral neuroectodermal tumor (PNET), Burkitt lymphoma, and the blastoid variant of mantle cell lymphoma.[553–556] Other than thymoma, the detection of TdT should exclude the other possibilities. Non–mass-forming TdT-positive proliferations, however, may occur in lymph nodes and tonsils, often in association with other disorders, and are not by themselves evidence of lymphoblastic lymphoma.[557] Similarly, some more diffuse lymphoblastic proliferations, especially in extranodal sites, have been identified as having an indolent clinical course and correlation with clinical findings is essential for proper classification of these rare cases.[558]

Mature Lymphoid Neoplasms of B Lineage

Chronic Lymphocytic Leukemia/Small Lymphocytic Lymphoma and Related Disorders

Similar to the lymphoblastic neoplasms, CLL and SLL are considered to represent different manifestations of the same disease. CLL is discussed in more detail in Chapter 39 but now requires a presence of $\geq 5 \times 10^9$/L neoplastic cells in the blood[407] and is also usually accompanied by bone marrow involvement, with our without other tissue involvement. The term SLL is reserved for rare cases that present with only tissue involvement and such a diagnosis should trigger an evaluation of the peripheral blood for evidence of CLL. SLL preferentially occurs in middle-aged and elderly individuals.[559,560] The patients often have few or no symptoms, the evolution is

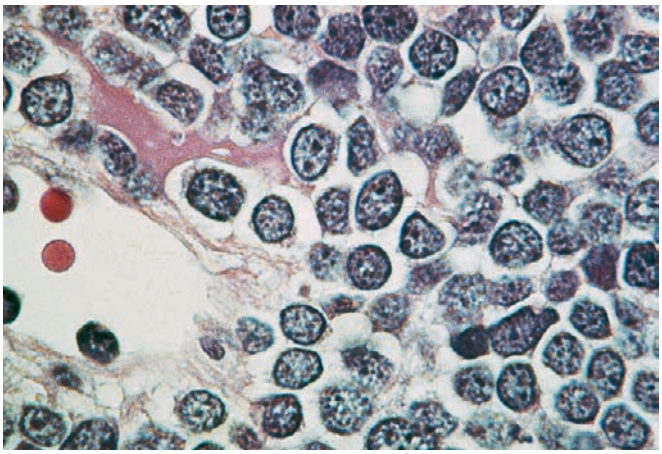

Figure 37.58 Lymphoblastic Lymphoma. The immature lymphoma cells have fine nuclear chromatin more characteristic of blasts over large mature B cells.

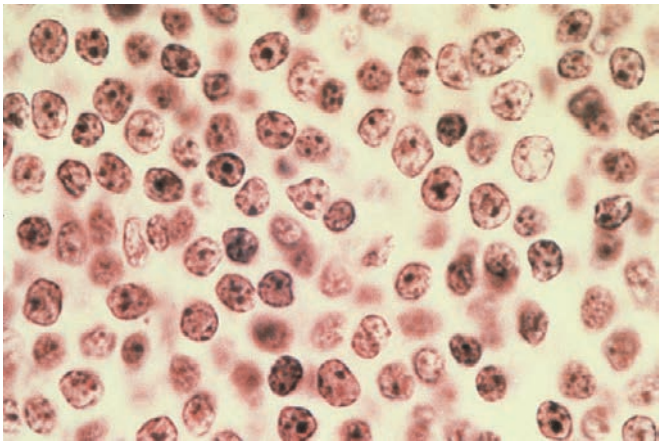

Figure 37.60 High-Power View of Small Lymphocytic Lymphoma. There is some variability in cell size. The nuclear contours are regular, the chromatin is clumped, and nucleoli are inconspicuous.

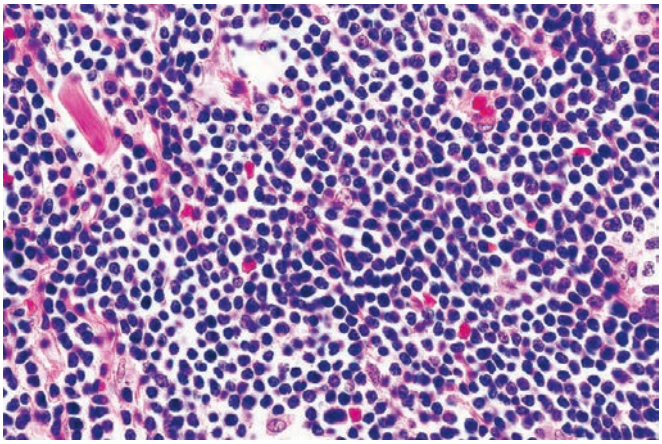

Figure 37.59 Low-Power View of Small Lymphocytic Lymphoma. A proliferation of small lymphocytes effaces the architecture of the node.

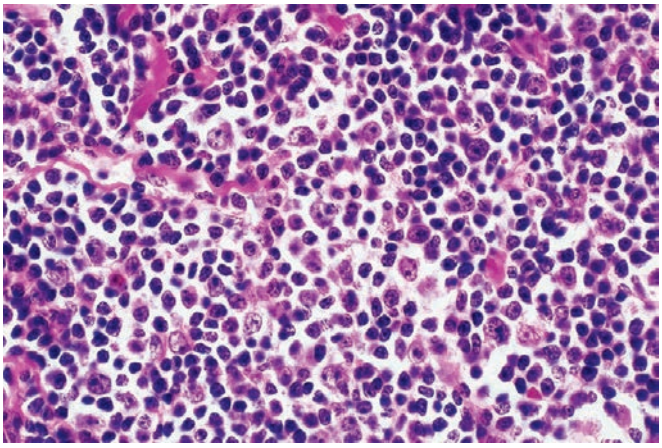

Figure 37.61 So-called proliferation center in a lymph node involved by small lymphocytic lymphoma.

prolonged, and the survival is very good. It is not unusual to find the disease incidentally in lymph node dissections done for carcinoma of one type or another.[561]

The architecture of the node in most cases of SLL is massively effaced by a population of predominantly small round lymphocytes with clumped chromatin, inconspicuous nucleoli, barely visible cytoplasm, and scanty mitotic activity (Figs. 37.59 and 37.60). There are also variable numbers of larger cells (prolymphocytes and paraimmunoblasts) with vesicular nuclei and distinct nucleoli, singly or in small aggregates, termed proliferation centers (Fig. 37.61).[562–565] The presence of proliferations centers and of a heterogeneous mixture of small lymphocytes with prolymphocytes/paraimmunoblasts is characteristic of SLL as opposed to mantle cell lymphoma.

Lymph node infiltration is usually diffuse, but on occasion a similar infiltrate is confined to the marginal zone, the perifollicular regions, or the interfollicular regions surrounding benign lymphoid follicles, the latter pattern being referred to as *interfollicular SLL*.[566–568] Such cases might be considered partial lymph node involvement by monoclonal B-cell lymphocytosis (MBL) (see later). Extranodal extension of SLL is seen in approximately one-third of the cases.[569]

By definition, SLLs are always of mature B-cell lineage.[570] Monoclonal immunoglobulins, including both IgM and IgD types, are consistently found on their surface, but both surface heavy and light chain expression is characteristically dim compared to normal B lymphocytes and most other B-cell lymphomas. They are usually weakly CD20+ with aberrant expression of CD5+ and CD43+. They also usually express CD23, as well as CD200, BCL2, and LEF1, but are negative for CD10, cyclin D1, and SOX11.[571–576] At the molecular level, Ig heavy and light chain genes are rearranged. While most tumors are slow growing and demonstrate a negative karyotype on routine analysis, cytogenetic abnormalities are detectable in approximately 80% of cases by FISH analysis and these findings have prognostic significance.[577] The presence of somatic hypermutations in IGH is also a good prognostic indicator[578,579] (often correlating with the absence of ZAP70 expression), and a variety of gene mutations and array CGH findings with potentially prognostic importance have been identified, including mutations of *NOTCH1* and *SF3B1*.[580–584] These prognostic markers are discussed in more detail with CLL in Chapter 39. On occasion one sees cases of SLL with admixed typical Reed–Sternberg cells. Such cases may relapse as classical Hodgkin lymphoma but should not be diagnosed as a composite lymphoma unless there are discrete areas of typical classical Hodgkin lymphoma.[585] A development of even greater clinical significance is the transformation of a SLL into another lymphoma, usually DLBCL (Figs. 37.62 and 37.63).[586] This occurrence has been

traditionally known as *Richter syndrome*[587,588] and is accompanied by a precipitous decline in the clinical course.

Monoclonal B-cell lymphocytosis (MBL) is generally defined by peripheral blood findings of less than 5×10^9/L monotypic B-cells[589] but may also infiltrate tissues. Most cases have an immunophenotype similar to CLL/SLL, and similar infiltrates found in lymph nodes without nodal enlargement are probably best classified as MBL rather than partial involvement by SLL unless more extensive disease is identified in the blood or elsewhere.[590]

B-prolymphocytic leukemia is a rare disorder that is defined by peripheral blood findings with 55% or more circulating B-lineage prolymphocytes[591] but can involve lymph nodes in a diffuse or vaguely nodular pattern. Prolymphocytes are small- to medium-sized cells with a central, prominent nucleolus and usually also show an increased proliferation rate. Most cases differ from CLL/SLL by demonstrating bright immunoglobulin heavy and light chains, bright CD20 expression, and lack of CD5 and CD23 expression. Some cases of mantle cell lymphoma in a leukemic phase may mimic these features but will demonstrate nuclear expression of cyclin D1,[592] which should not be seen in B-cell prolymphocytic leukemia.

Figure 37.62 Gross appearance of lymph nodes involved by chronic lymphocytic leukemia/small lymphocytic lymphoma with anaplastic transformation (so-called Richter syndrome).

Lymphoplasmacytic Lymphoma

Lymphoplasmacytic lymphoma is an indolent neoplasm of small B-lymphocytes with admixed plasmacytoid lymphocytes and plasma cells.[593,594] By definition, other lymphomas of small B cells, which may also have a plasmacytoid component, must be excluded before the diagnosis can be made. The bone marrow and spleen are frequently involved, with lymph node involvement in a smaller percentage of cases. Most patients have elevations of monotypic IgM, which may cause hyperviscosity, and meet clinical criteria for Waldenström's macroglobulinemia. Two patterns of lymph node involvement by lymphoplasmacytic lymphoma have been described, but the first is probably more specific. This generally diffuse infiltration of mostly small cells with admixed plasmacytoid cells often includes small plasma cells with intranuclear inclusions or Dutcher bodies (Fig. 37.64). Reactive mast cells are commonly admixed with the lymphoplasmacytic cells. The extent of the plasma cell proliferation can be quite variable, ranging to very little to sheets of small plasma cells. These cases may show a prominent interfollicular component with residual germinal centers. A more polymorphous type has also been described with epithelioid histiocytes and more variably sized plasmacytoid cells. This latter group appears to include cases of so-called polymorphous immunocytoma (Fig. 37.65), which has subsequently been shown to be a nonspecific pattern that includes a variety of lymphoma types of both T- and B-cell lineage.

The neoplastic cells in lymphoplasmacytic lymphoma show CD20 expression on at least the more mature lymphocyte component and

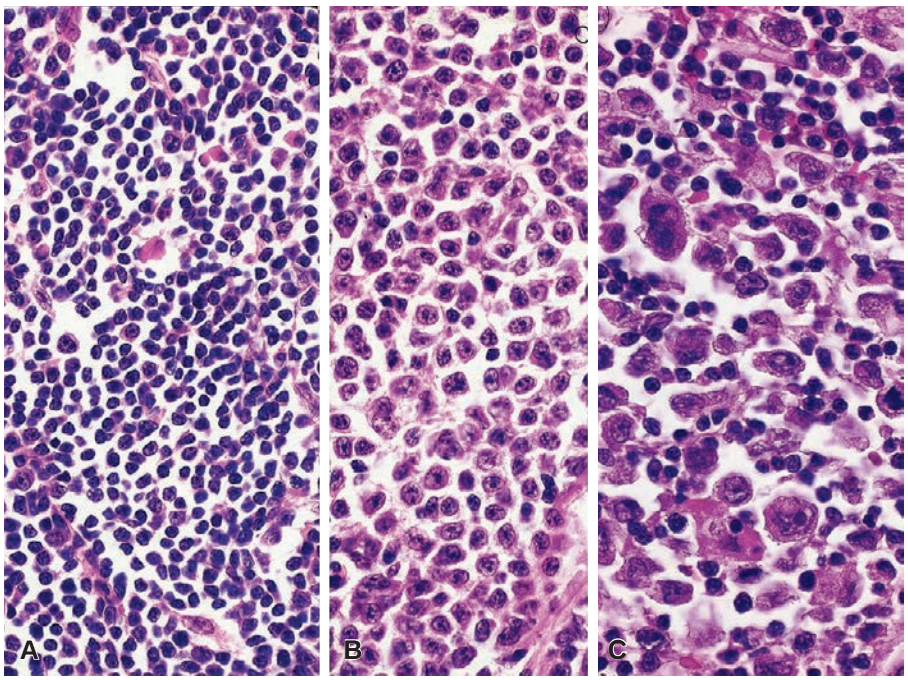

Figure 37.63 Various morphologic types of lymph node involvement by chronic lymphocytic leukemia/small lymphocytic lymphoma: **A**, monotonous infiltrate of small mature lymphocytes; **B**, increased prolymphocytes, with slightly larger nuclei and more open chromatin; **C**, large pleomorphic tumor cells (so-called Richter syndrome).

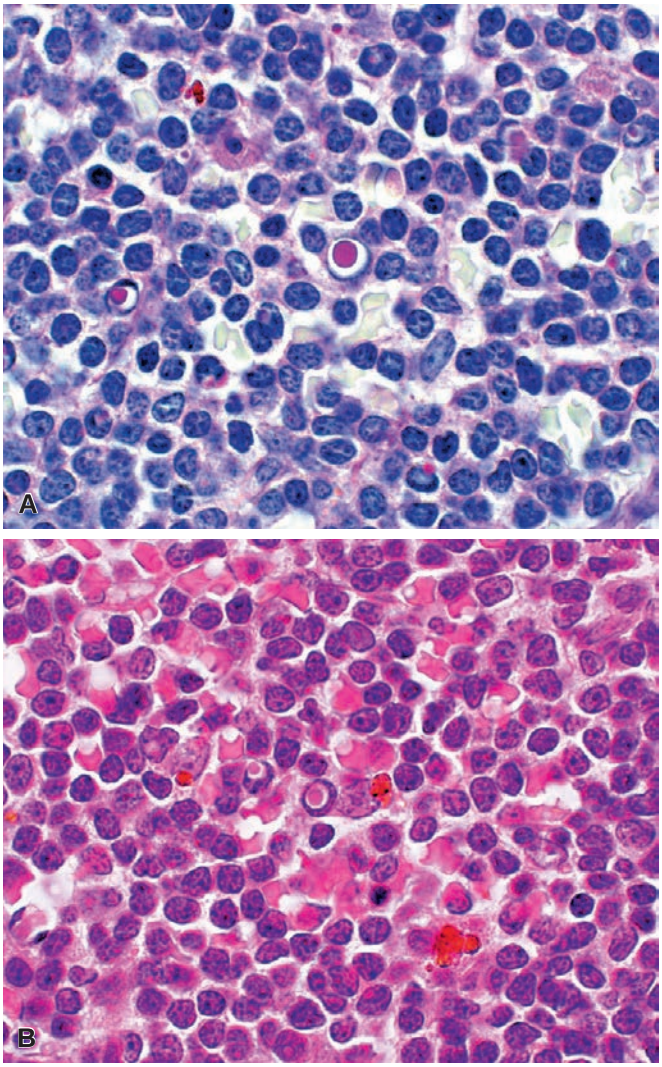

Figure 37.64 Intranuclear immunoglobulin inclusions (Dutcher bodies) in a lymph node affected by lymphoplasmacytoid lymphoma as seen after hematoxylin–eosin (**A**) and PAS stains (**B**).

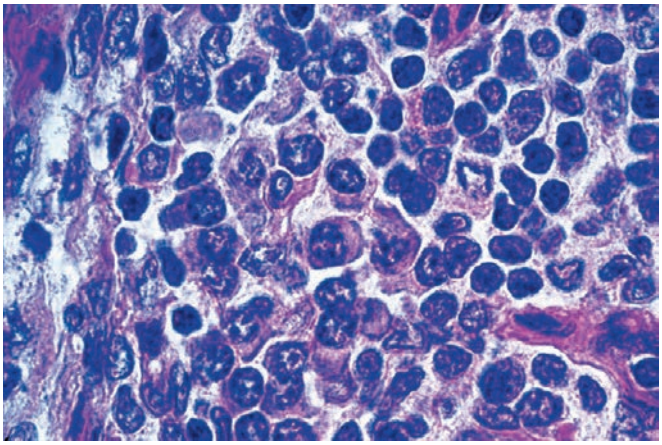

Figure 37.65 Malignant lymphoma composed of lymphocytes and immature plasmacytoid forms (so-called pleomorphic immunocytoma).

monotypic light chain expression in the plasmacytoid cell component. The B cells generally lack CD5 and CD10 expression and are cyclin D1 and CD103 negative. This immunophenotype, however, is nonspecific and can be seen in a variety of B-cell lymphomas, most notably marginal zone lymphoma.

Mutations in *MYD88* have been recently described in over 90% of cases of lymphoplasmacytic lymphoma[595,596] with features described previously for the diffuse type (but not the polymorphous type). While a small percentage of other lymphomas of small B cells will have this mutation, its detection in the proper clinical and morphologic setting is helpful in confirming a diagnosis of lymphoplasmacytic lymphoma.

The differential diagnosis of lymphoplasmacytic lymphoma ranges from marginal zone lymphoma to plasma cell myeloma. As mentioned, detection of a mutation in *MYD88* would favor lymphoplasmacytic lymphoma or marginal zone lymphoma; this finding is not entirely sensitive or specific, and it may not be possible to resolve this differential diagnosis on small biopsies. Some cases of plasma cell myeloma may have a prominent lymphoid component and even express IgM (in contrast to most myeloma cases that are IgG or IgA producing).[597] These lymphoid predominant myeloma cases may have cyclin D1 translocations and express the cyclin D1 protein, which is not a feature of lymphoplasmacytic lymphoma. Recognition of clinical features of plasma cell myeloma, including lytic bone lesions, may be the only means of differentiating these unusual types of myeloma from lymphoplasmacytic lymphoma.

Heavy Chain Diseases

The so-called heavy chain diseases are monoclonal plasma cell and B-lymphocyte proliferations that do not typically express immunoglobulin light chains and only express heavy chains.[598] While rare, they can mimic other lymphoma types and may involve lymph nodes. *Mu heavy chain disease* resembles CLL/SLL but usually lacks light chains. *Gamma heavy chain disease* may show a variety of tissue presentations, including mimicking lymphoplasmacytic lymphoma, marginal zone lymphoma, and even T-cell lymphomas and Hodgkin lymphoma.[599] It does not, however, show mutations of *MYD88*.[600] *Alpha heavy chain disease* is a subtype of extranodal marginal zone lymphoma, usually involving the gastrointestinal tract, but may involve regional lymph nodes as well.[601]

Nodal Marginal Zone B-Cell Lymphoma

Marginal zone B-cell lymphoma is the general term used to designate a group of low-grade B-cell lymphomas composed of a heterogeneous population of small B cells. The concept represents a grouping of entities that had been described separately, most of them at extranodal sites.[602] There appears to be considerable clinical, morphologic, and immunohistochemical overlap among the three entities (extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue [MALT lymphoma], nodal marginal zone lymphoma, and splenic marginal zone lymphoma).[603] Consequently, the proposal has been made that they represent a related family of neoplasms showing morphologic evidence of differentiation into cells of marginal zone type.[604,605] These cells are thought to have the capacity to mature into both monocytoid B cells and plasma cells and to display tissue-specific homing patterns. A corollary of this proposal is that the various clinical syndromes may be the result of the homing pattern of the specific neoplastic clone.[602] The three main categories of marginal zone lymphoma, however, are distinct and differ, especially on the genetic level. Extranodal and splenic marginal zone lymphomas are discussed elsewhere in association with their anatomic sites, but nodal marginal zone lymphoma is covered here.

Nodal marginal zone lymphoma, previously termed monocytoid B-cell lymphoma, is a tumor of small to medium-sized postgerminal

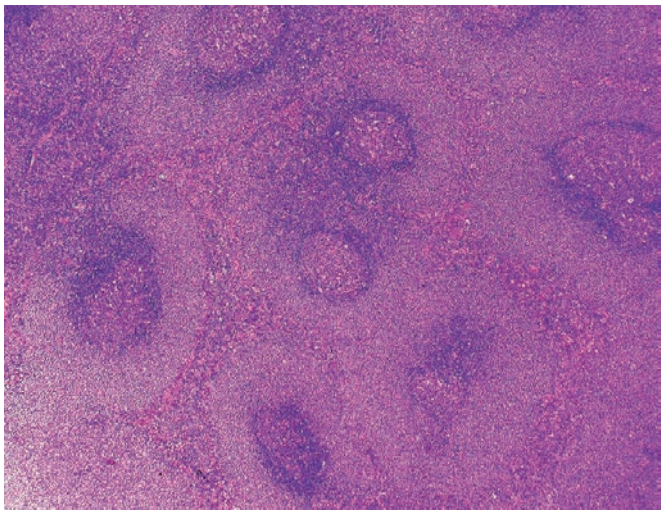

Figure 37.66 Lymph node involvement by marginal zone B-cell lymphoma with a prominent perifollicular or marginal zone pattern. There are numerous residual, non-neoplastic germinal centers.

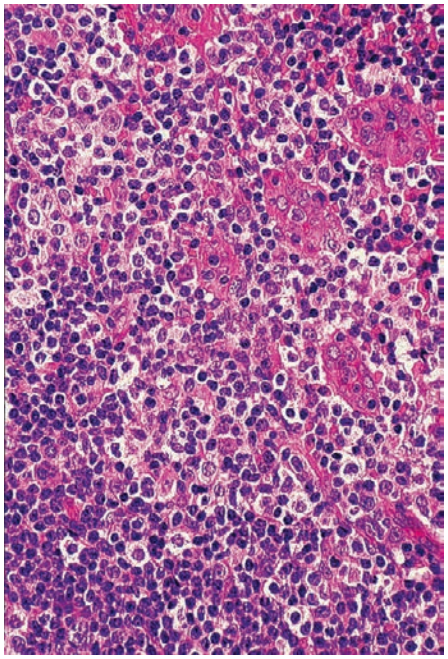

Figure 37.67 Lymph node involvement by marginal zone B-cell lymphoma with small lymphoma cells with clear cytoplasm. This tumor also affected the thymus gland. (Courtesy of Dr. John Chan, Hong Kong.)

center B lymphocytes with round or slightly indented nuclei and relatively abundant clear cytoplasm, usually located in lymph nodes, hence its designation as nodal (Figs. 37.66 and 37.67).[606] The tumor cells have been regarded as the neoplastic counterpart of the monocytoid B lymphocytes found in lymph node sinuses in toxoplasmosis and other reactive disorders.[607] Plasmacytoid features are prominent in some cases. The pattern of involvement is predominantly perifollicular or interfollicular,[608] but cases have been seen with "follicular colonization" and with "floral" features.[609] Clinically, the disease is more common in women and can be localized or generalized at presentation.[610] Some patients have suffered from autoimmune disorders such as Sjögren disease. In all cases, the possibility of nodal spread from an extranodal marginal zone lymphoma has to be excluded by clinical work-up. Histologic transformation to large cell lymphoma has been documented in some cases.

The neoplastic cells of nodal marginal zone lymphoma are monotypic, mature B-cells that express CD19, CD20, CD79A, and PAX5 and are weakly positive for BCL2.[611–613] They usually lack CD5 and are negative for CD10, CD23, and cyclin D1. Approximately 40% of cases show aberrant coexpression of CD43 on the B-cells.[72] CD21 or CD23, while negative on the neoplastic cells, may highlight expanded follicular dendritic cell networks that are infiltrated by the lymphoma cells (follicular colonization). Plasma cells are monotypic in some but not all cases.

There are no specific genetic markers for nodal marginal zone lymphomas.[614] They demonstrate clonal immunoglobulin gene rearrangements, similar to other B-cell neoplasms but do not usually demonstrate the recurring cytogenetic abnormalities associated with extranodal marginal zone lymphoma. Abnormalities of chromosome 3, including trisomy 3, are common but nonspecific in nodal marginal zone lymphoma. Mutations of *MYD88* are uncommon in this disease.

Pediatric nodal marginal zone lymphoma is a provisional entity in the 2016 WHO classification that occurs as localized disease, usually in cervical lymph nodes.[407,615] Patients have a median age of 16 years with a marked male predominance. Because of the very indolent and localized nature of such proliferations in contrast to the more systemic presentation of usual type nodal marginal zone lymphoma, this provisional designation has been proposed.

Follicular Lymphoma

Follicular (nodular) lymphoma is a B-cell neoplasm that recapitulates the architectural and cytologic features of the normal germinal center.[616] This tumor comprises up to 40% of all adult non-Hodgkin lymphomas in the United States, but in other countries the relative incidence is much lower. Most cases occur in elderly individuals. It is very unusual under 20 years of age and relatively uncommon in patients of African descent.[617]

Grossly and at low-power examination, the most distinctive feature of these tumors is the nodular pattern of growth (Figs. 37.68 and 37.69). The morphologic features that are useful in the differential diagnosis of follicular lymphoma and reactive follicular hyperplasia were described earlier in this chapter. With progression of the disease, this distinct nodularity becomes blurred, and eventually most of the proliferation acquires a diffuse pattern. The cytologic composition of the neoplastic nodules is characterized by a mixture in different proportions of small and large lymphoid cells, both of which resemble their normal follicular counterparts.[618] The small cells have scanty cytoplasm and an irregular, elongated cleaved nucleus with prominent indentations and infoldings; the size is similar to or slightly larger than that of normal lymphocytes, the chromatin is coarse, and the nucleolus is inconspicuous (Figs. 37.70–37.72). These cells have been variously referred to as centrocytes, poorly differentiated lymphocytes, and small cleaved follicular center cells. The large cells are 2 or 3 times the size of normal lymphocytes; they have a distinct rim of cytoplasm and a vesicular nucleus with one or three nucleoli often adjacent to the nuclear membrane. These cells, which have a rapid turnover rate and probably represent the proliferating component of the tumor, have been designated over the years as germinoblasts, centroblasts, histiocytes, large (cleaved or noncleaved) follicular center cells, large lymphoid cells, and lymphoblasts. Some may be binucleated and simulate Reed–Sternberg cells.[619] Another type of large cell seen in follicular lymphoma is the non-neoplastic follicular dendritic cell. It is recognized because of its finely dispersed chromatin, the lack of identifiable cell boundaries, and the inconspicuousness of the nucleolus.

Immunohistochemically, the follicles of follicular lymphoma (including all its variants) are composed of a monoclonal population

of mature B cells admixed with variable numbers of non-neoplastic small T cells, macrophages, and follicular dendritic cells, corresponding to the cellular composition of a normal germinal center (Fig. 37.73).[620,621] The tumor cells express pan–B antigens, such as CD19, CD20, CD22, PAX5, and CD79A, in addition to HLA-DR. They also express surface and/or cytoplasmic immunoglobulins (usually of the IgM type) with light chain restriction. CD10, a germinal center cell marker that is also present in lymphoblastic proliferations, Burkitt lymphoma, and some large B-cell lymphomas, is detected in approximately 60%–70% of the cases.[622] This marker can aid in distinction from reactive follicular hyperplasia when significant numbers of CD10+ cells are found in the interfollicular zone as an indication of interfollicular invasion. Other germinal center cell markers, such as BCL6, HGAL, and LMO2, are expressed in most cases. CD5 and CD43 are usually negative.

Figure 37.68 Gross Appearance of a Lymph Node Affected by Follicular Lymphoma. The neoplastic nodules bulge onto the surface. (Courtesy of Dr. R. A. Cooke, Brisbane, Australia; from Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

The BCL2 protein can be identified immunohistochemically in approximately 85% of cases[71] and is thus one of the most useful markers for the differential diagnosis with reactive follicular hyperplasia (BCL2 negative), although it is important to realize that BCL2 negativity does not totally rule out follicular lymphoma.[621,623,624] Immunostaining for BCL2 cannot be used for distinction of follicular lymphoma from other low-grade B-cell lymphomas, because the latter are commonly BCL2 positive; to deal with such a diagnostic problem, immunostaining for follicular center cell markers such as CD10 and BCL6 is more helpful.[625,626]

Follicular lymphoma shows clonal rearrangements of the immunoglobulin genes, which also feature hypermutations and ongoing somatic mutations, as characteristic of follicle center B cells.[627]

The hallmark genetic alteration of follicular lymphoma is t(14;18)(q32;q21), found in 90% of cases.[628] The chromosomal translocation juxtaposes IGH with the *BCL2* gene, driving overexpression of BCL2 protein, an anti-apoptotic molecule located in the inner mitochondrial membrane whose expression is typically switched off in normal follicle center B cells.[629–631] As a result of aberrant BCL2 expression, the neoplastic follicle center cells do not undergo apoptosis. Thus follicular lymphoma results more from cell accumulation than cell proliferation. Although *BCL2* rearrangement is also seen in some cases of DLBCL, demonstration of this molecular alteration provides a good support for a diagnosis of follicular lymphoma in the appropriate context, such as distinction from atypical follicular hyperplasia, marginal zone lymphoma with follicular growth pattern

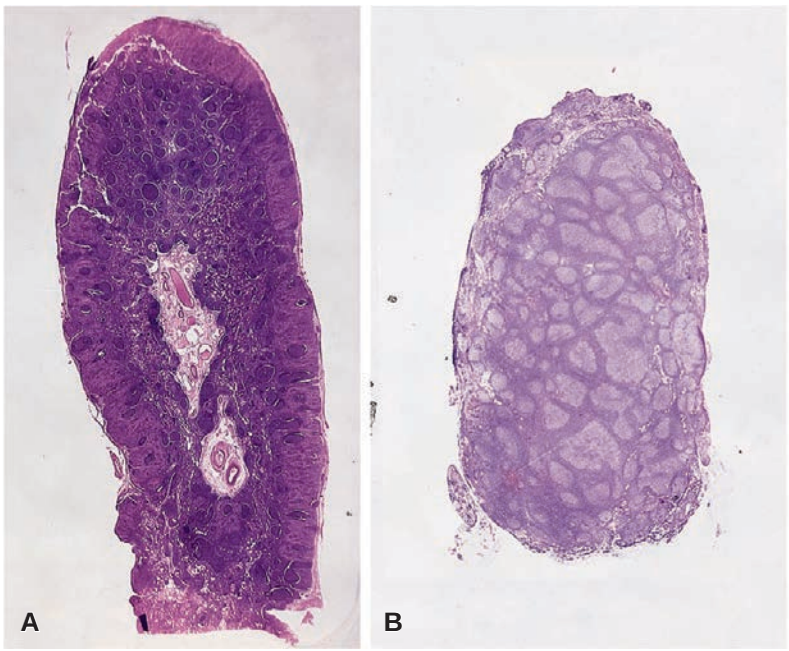

Figure 37.69 Even distribution of neoplastic follicles in follicular lymphoma (**B**), as opposed to the predominantly cortical distribution typical of follicular hyperplasia (**A**).

and mantle cell lymphoma. For this purpose, FISH is more sensitive than PCR.[628,632] Certain types of follicular lymphoma uncommonly or do not exhibit *BCL2* rearrangement, including pediatric follicular lymphoma, primary cutaneous follicle center lymphoma, and grade 3b follicular lymphoma (see later).[633–638]

The presence of t(14;18) alone appears to be insufficient for the development of follicular lymphoma, because this is rarely the sole genetic aberration and even healthy subjects commonly harbor low numbers of B lymphocytes with t(14;18).[639–643] Common additional genetic changes include −1p36, +2p15, +6q, +7p, +7q, −9p, +12q, −17p, +18q, and +X, with some of them, such as −1p36, −6q, −9p, and +18q, being associated with a worse prognosis.[643–646]

BCL6 translocation occurs in approximately 10% of the cases, usually mutually exclusive to *BCL2* translocation.[637,647] This is correlated with grade 3b histology, high proliferative index, and infrequent expression of CD10 and BCL2.[635,648,649] Follicular

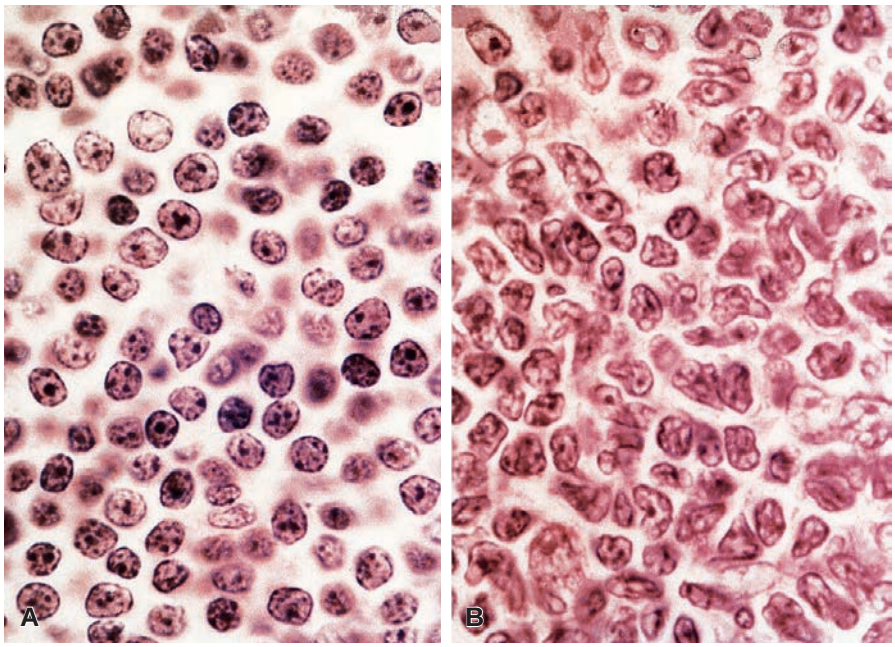

Figure 37.72 Marked contrast between the cleaved cells of follicular lymphoma (**B**) and the regular mature lymphocytes of small lymphocytic lymphoma (**A**).

lymphomas with del6q23–26 or del17p at presentation are at increased risk of transformation to high-grade B-cell lymphoma.[631] Genetic changes that mediate such a transformation may include *MYC* translocation, *TP53* mutation, *BCL2* mutation, deletions of 9p21 involving P16 and P15, and mutation of the 5′ noncoding region of *BCL6*.[650–652]

The gene expression profile of follicular lymphoma recapitulates that of normal germinal center B cells and furthermore clusters close to resting B cell samples, in keeping with its indolent nature.[38] On microarray analysis, the immune response-1 signature, reflecting presence of a complex infiltrate of T cells and other immune cells, predicts long survival, while immune response-2 signature, reflecting a significant infiltrate of monocytes and dendritic cells, predicts short survival.[653]

Depending on the relative proportion of small and large cells, typical follicular lymphomas are subdivided into two categories. Because of reproducibility issues in grading and a lack of prognostic significance, low-grade cases are now designated as grade 1/2 and are defined by the presence of 15 or fewer centroblasts (large B cells) per high-power field. Grade 3 is defined as more than 15 centroblasts per high-power field and are further subdivided into grades 3a and 3b. Cases with admixed centrocytes (small cleaved B cells) are referred to as grade 3a, which is most common, while cases with solid sheets of centroblasts are referred to as grade 3b.

Several important clinical differences exist between these groups.[654,655] Patients with grade 1/2 follicular lymphoma are often asymptomatic, usually have generalized disease (often involving extranodal sites, such as the liver and bone marrow), and have a good prognosis,[656] to the point that some authors advise against aggressive treatment for them.[657–662] Grade 3 tumors are more commonly localized at the time of presentation but run a more aggressive clinical course[617,663] and are more likely to lose their nodular pattern of growth and become diffuse.

The extranodal spread of follicular lymphoma is quite predictable. In the spleen, it tends to affect the B-derived lymphoid follicles located eccentrically in the white pulp. In the liver, the infiltrate is predominantly periportal. The bone marrow infiltrates tend to have a paratrabecular location. In the skin, there is an extensive dermal infiltrate without particular relation to vessels or adnexa.

In some cases of follicular lymphoma (particularly grade 1/2), malignant cells are found in the peripheral blood; hematologists refer to them by the inelegant term "buttock" cells because of their prominent nuclear cleft (Fig. 37.74). No prognostic significance has been assigned to this finding.

Specimens from subsequent biopsies or autopsy from patients with grade 1/2 follicular lymphomas may show a similar microscopic appearance or a progression to grade 3 or to DLBCL.[664,665] A more ominous development is represented by the occasional "blastic" or "blastoid" transformation of follicular lymphoma, in which the tumor cells resemble those of Burkitt or lymphoblastic lymphoma; this is accompanied by a highly aggressive clinical course.[666,] The resulting high-grade malignant tumor may also express CD30 but remains a mature B-cell neoplasm and not true ALCL.[667]

Several morphologic variations on the theme of follicular lymphoma have been described. They include the following:

1. Presence of fine or coarse bands of fibrosis that accentuate even more the nodular character of the lesion but, in so doing, may induce confusion with carcinoma. This feature is more commonly seen in grade 3 tumors;[668] it is particularly frequent in the retroperitoneum, but it also occurs in the cervical region, mediastinum, and other locations.
2. Presence of monocytoid B cell/marginal zone differentiation. In about 10% of follicular lymphomas, discrete foci of monocytoid B cells are seen, typically appearing on low-power examination as a pale rim around the neoplastic follicles.[669,670] Molecular studies have shown a common clonal origin of the monocytoid B cells from follicle center cells.[671,672] Clinically, this feature is said to be associated with a shorter survival time.[673]
3. Deposition of proteinaceous material in the center of the nodules, similar to that seen in some reactive conditions, particularly the plasma cell variant of Castleman disease (Fig. 37.75). The material is amorphous, acellular, brightly eosinophilic, and PAS

positive.[654,674] Ultrastructurally, it is composed of membranous structures, membrane-bound vesicles, and electron-dense bodies.[654] It is described in grade 1/2 follicular lymphomas.[675]

4. Presence of large cytoplasmic eosinophilic globules—presumably immunoglobulins—or a single vacuole that push the nucleus laterally and result in a signet ring effect (Fig. 37.76).[676]
5. Clear-cut plasmacytic differentiation in some or many of the neoplastic follicular center cells.[669,677]
6. Presence of cells with cerebriform nuclei (similar to those of T-cell lymphoma)[678] or multilobated nuclei.[679]
7. Permeation of the tumor follicles by small round lymphocytes of presumably mantle zone origin, the appearance simulating that of progressively transformed germinal centers ("floral" variant) (Fig. 37.77).[63,680]
8. Presence of rosettes made up of cytoplasm and cytoplasmic processes of the lymphoid tumor cells and simulating the appearance of a neuroendocrine neoplasm (Fig. 37.78).[270]
9. Presence of hyaline vascular follicles similar to those seen in the hyaline-vascular type of Castleman disease.
10. Inversion of the usual staining pattern as seen on low-power examination so that the neoplastic follicles appear darker than

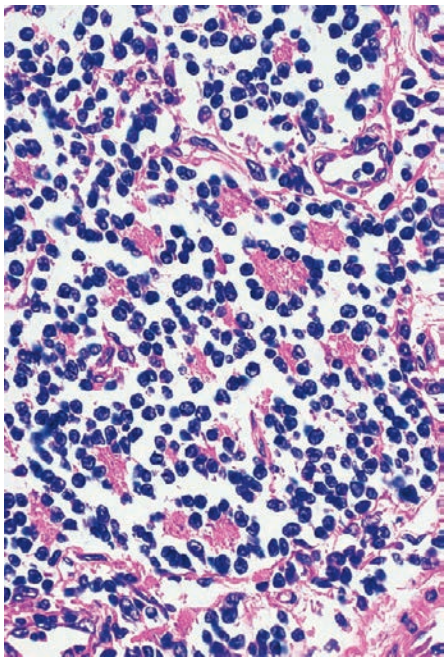

Figure 37.78 Follicular lymphoma showing rosette formation by some of the lymphoid cells.

the surrounding lymphoid tissue. This pattern, which is referred to as the "reverse" or "inverse" variant of follicular lymphoma, carries no prognostic significance.[681]

11. Prominent epithelioid granulomatous response.[682]
12. Preserved reactive germinal centers in some foci of the involved lymph node. This feature is said to be a strong indicator of limited disease stage,[683] and such reported cases may have represented in situ follicular neoplasia (see later).

In some reactive lymph nodes, BCL2-positive germinal centers can be detected in the absence of infiltration beyond the germinal center or other evidence of follicular lymphoma. Such cases may occur in patient with follicular lymphoma or another lymphoma type elsewhere but may also occur in otherwise healthy individuals. Their presence does not consistently predict development of frank lymphoma and such lesions should diagnosed *in situ follicular neoplasia* rather than follicular lymphoma.[407,684,685]

Pediatric-type follicular lymphoma is a distinct entity in the 2016 WHO classification.[407,686,687] It is a localized disease that usually occurs in children but is reported in adults. It usually shows grade 3b features with a blastoid, large cell predominance. These cases often do not express BCL2 and should not demonstrate a t(14;18). They have an indolent course and should only be diagnosed in the setting of localized disease and in the absence of diffuse areas.

Large B-cell lymphoma with *IRF4* rearrangement is a provisional entity in the 2016 WHO classification that also tends to occur in children and young adults, is negative for t(14;18), and is usually localized to cervical lymph nodes or Waldeyer's ring.[686,688] These may have a follicular or diffuse pattern, show strong expression of BCL6 and IRF4 (MUM1), and usually demonstrate a translocation involving *IRF4*. Although more aggressive than pediatric-type follicular lymphoma, these patients usually respond well to lymphoma therapy.

Finally, duodenal-type follicular lymphoma is a distinct category in the WHO classification that tends to present at a low stage with a more indolent course when compared to traditional follicular lymphoma or even follicular lymphoma involving other gastrointestinal sites.[689]

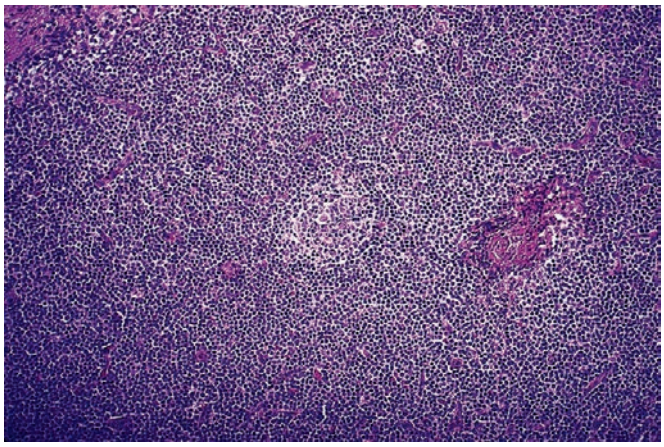

Figure 37.79 Mantle cell lymphoma surrounding a small residual germinal center.

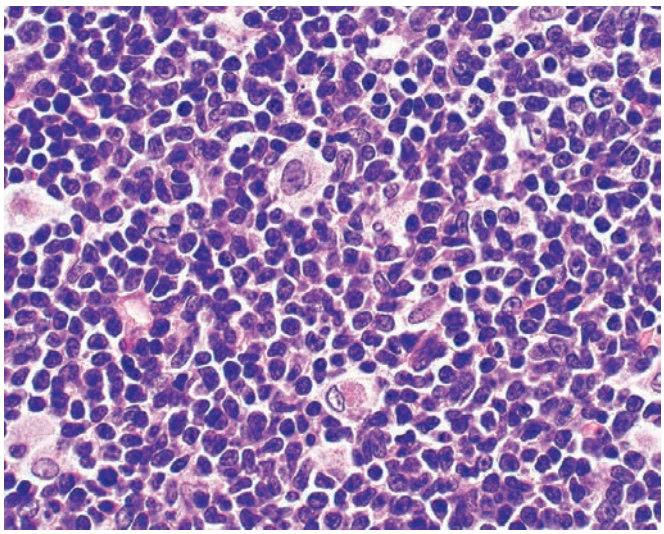

Figure 37.80 High-Power View of Mantle Cell Lymphoma. There are subtle abnormalities of the nuclear contours, the appearance being intermediate between that seen in small cleaved follicular lymphoma and that of small lymphocytic lymphoma. Note the individual epithelioid histiocytes that are characteristically associated with this disorder.

Mantle Cell Lymphoma

Mantle cell lymphoma is a relatively aggressive neoplasm of small B-lymphocytes that includes cases previously known as intermediate lymphocytic, mantle zone, centrocytic, and diffuse small cleaved cell lymphoma.[690–692] It comprises from 3% to 10% of all cases of non-Hodgkin lymphoma. Like follicular lymphoma, it usually occurs in middle-aged and elderly individuals.[693,694] The low-power appearance is largely that of a diffuse lymphoma, although nodular and mantle zone patterns also occur (Fig. 37.79).[695] The neoplastic cells are small and often show irregular and indented nuclear contours similar to those seen in small cleaved cell follicular lymphoma without an admixed large cell component (Fig. 37.80).[696] On occasion, some of the tumor cells show plasma cell differentiation.[697] In some cases, the tumor cells have larger nuclei with more dispersed chromatin and a higher proliferative fraction ("blastoid" or "pleomorphic" variant)[698] (Fig. 37.81), but the lymphoma cells retain a homogeneous pattern of cell size in contrast to CLL/SLL and follicular lymphoma. Admixed epithelioid histiocytes are common but do not form clusters

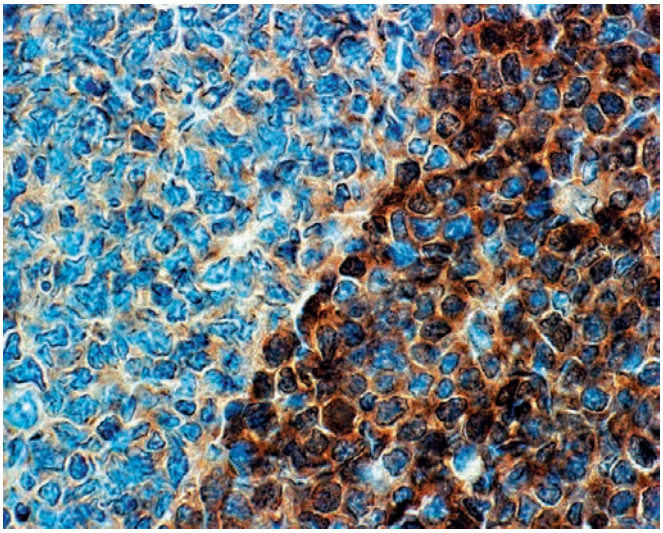

Figure 37.82 Immunoreactivity for cyclin D1 in mantle zone lymphoma.

or granulomas and do not contain cellular debris. The blastoid form of mantle cell lymphoma (and sometimes also the classic form) may be accompanied by blood, bone marrow, and spleen involvement ("mantle cell leukemia").[699–702]

The tumor cells are mature B cells, positive for immunoglobulins (IgM and often also IgD), and immunoglobulin light chain restricted; express B cell–associated antigens such as CD19, CD20, CD79A, and PAX5; and demonstrate aberrant expression of CD43 and CD5.[703,704] The general absence of CD23 is useful in distinguishing mantle cell lymphoma from SLL,[572,705] and the presence of CD5 is useful in the differential diagnosis with follicular and marginal zone lymphomas. It should be remarked, however, that CD5 expression is not always present in mantle cell lymphoma[706] and can be present in some DLBCLs apparently unrelated to mantle cell lymphoma.[707] Most cases demonstrate nuclear expression of cyclin D1, correlating with the presence of a t(11;14)(q13;q32) (Fig. 37.82).[708,709] Rare cases are cyclin D1 negative, and SOX11 is usually expressed in such cases.[575]

The immunoglobulin genes are clonally rearranged, and the variable regions are usually nonmutated, suggesting a naive B-cell stage of differentiation.[710,711] Nearly all cases show fusion of *CCND1* (cyclin D1) with the IGH gene, which results from t(11;14)(q13;q32) (in approximately 70% of cases by karyotype and almost 100% with molecular methods).[692,712] As a consequence, cyclin D1, a cell cycle protein, is overexpressed, promoting cell proliferation. *CCND1* translocation is practically specific for mantle cell lymphoma, except that it also occurs in some cases of plasma cell myeloma, and thus its demonstration may help confirm a diagnosis of mantle cell lymphoma.[713,714] FISH gives the highest sensitivity (>95%) and is superior to conventional cytogenetics, Southern blot, or PCR.[712,715] Additional genetic changes are common in mantle cell lymphoma, such as inactivating mutation of *ATM* (11q22–23), homozygous deletions of *INK4a/ARF* (p16), and *TP53* mutation.[710,716,717] The blastoid/pleomorphic variant is correlated with presence of *TP53* mutation, *MYC* abnormalities, and tetraploidy.[718–721]

Microarray studies have shown that mantle cell lymphoma exhibits a unique gene expression signature distinct from other lymphoma types, and furthermore confirm the existence of a cyclin D1-negative subset of mantle cell lymphoma (up to 7% of cases).[722,723] At least some cases of the latter subset express cyclin D2 or cyclin D3 instead of cyclin D1,[723–725] and most express SOX11.[575] Mantle cell lymphoma may be difficult to distinguish from follicular hyperplasia with a prominence of mantle zone cells ("mantle zone hyperplasia") and Castleman disease.[70] Determination of clonality of the infiltrate by immunohistochemical techniques is of importance in this regard as is demonstration of cyclin D1 in mantle cell lymphoma. The differential diagnosis also includes grade 1 follicular lymphoma. The fact that centroblasts and immunoblast-like cells are totally absent in mantle cell lymphoma is an important differential feature. Expression of cyclin D1, while very useful in the diagnosis, is not specific for mantle cell lymphoma and may also occur in hairy cell leukemia, multiple myeloma, and proliferation centers of CLL/SLL.

Finally, the blastoid form of mantle cell lymphoma needs to be distinguished from either T- or B-cell lineage lymphoblastic lymphoma.[556]

The median survival of mantle cell lymphoma is approximately 3–5 years. As a group, it is characterized by more widespread disease and a much lower response rate to chemotherapy than follicular lymphoma.[709,726] The blastic variant has a more aggressive clinical course.[690,727] A rare indolent type of mantle cell lymphoma has also

been described.[728] Proliferation rate is a strong predictor of survival for all types of mantle cell lymphoma, with rates of 30% or higher associated with a worse prognosis.[729] For this reason, Ki-67 staining should be performed on all new diagnosis specimens.

Some clonal mantle cell proliferations have a more indolent clinical course. *Leukemic nonnodal mantle cell lymphoma* is one such example.[730] In addition to lack of lymph node involvement, it tends to involve the spleen and be negative for SOX11. Cases with cyclin D1–positive cells restricted to the mantle zones without infiltration to surrounding structures or diffuse nodal involvement are now termed *in situ mantle cell neoplasia* to reflect the low rate of progression of such lesions.[731]

Diffuse Large B-Cell Lymphoma and Related Disorders

DLBCL encompasses a heterogeneous group of disorders. The term replaces the old histiocytic lymphoma, which in turn replaced the older reticulum cell sarcoma. It is characterized morphologically by large size of the cells, vesicular nuclei with prominent nucleoli, and relatively abundant cytoplasm, and immunophenotypically by expression of B-lineage markers. In general, DLBCLs can be diagnosed based on a limited panel of markers that confirm that the diffuse, large cell proliferation is of B-cell lineage, but there are now numerous subtypes of DLBCL that require additional studies and there are numerous prognostic markers that must now be performed on individual cases.

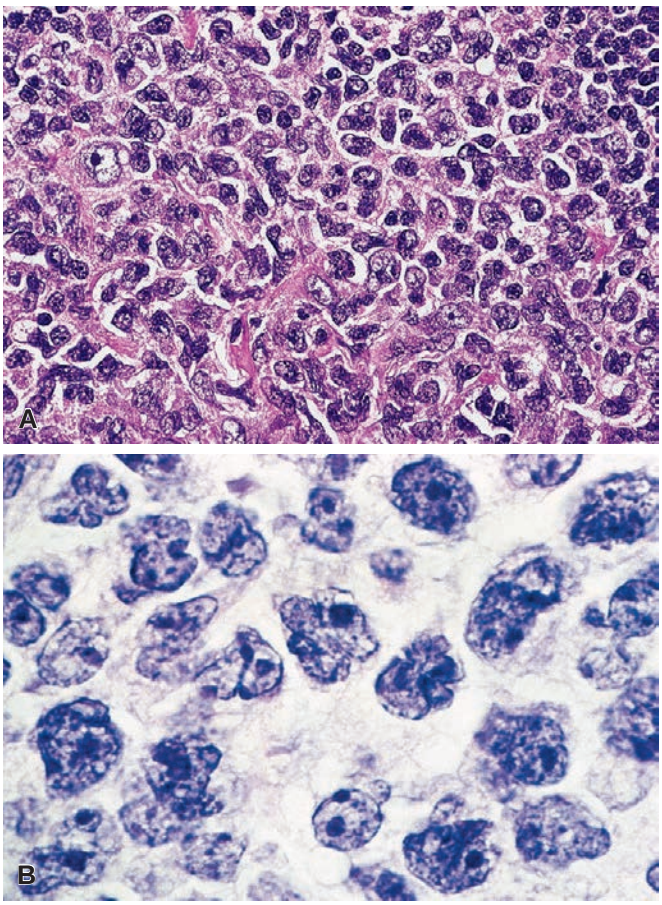
As a group, DLBCL occurs in both children and adults but mostly in the latter.[732] In comparison with most other types of lymphoma, it has a greater tendency for extranodal presentation and for being localized at the time of presentation. The progression is rapid, and the prognosis is poor if untreated. Indeed, it constitutes a high percentage of so-called aggressive lymphomas.[733,734] However, excellent responses have been obtained with multidrug chemotherapy, in particular in combination with rituximab (anti-CD20 therapy),[735–737] and new therapies are being developed for some subtypes.[738] In many cases, the tumor is limited to one side of the diaphragm (40%, as opposed to 90% for follicular lymphoma).[739] Involvement of the bone marrow or liver is less common than in follicular or SLLs.[740] Approximately 40% of the cases present in extranodal sites, such as the digestive system, skin, and skeletal system.[739] When the liver or spleen is involved, it is usually in the form of scattered large tumor masses instead of the multiple smaller nodules or miliary type seen with the group of lymphomas composed of small lymphocytes. The involved nodes are usually markedly enlarged, homogeneous, individualized, and with little or no necrosis (Fig. 37.83).

Microscopically, the pattern of nodal involvement is by definition diffuse. However, it may be complete or partial, and on occasion it may be interfollicular or show a sinus pattern (see later). There is commonly extranodal extension, sometimes with accompanying sclerosis. Mitoses are numerous, and a starry sky pattern may be present.

In the past, a separation based on cytologic features was made between tumors composed of germinal center (large cleaved and noncleaved; centroblastic) cells (Fig. 37.84) and immunoblastic cells with a large vesicular nucleus with prominent central nucleolus and thick nuclear membrane, and a deeply staining amphophilic and pyroninophilic cytoplasm with a distinct nuclear hof (Fig. 37.85). Such distinctions, however, have shown poor intraobserver and interobserver reproducibility and are no longer recommended.

The majority of cases of DLBCL fall into the "not otherwise specified", or NOS group, but even within this group there is great morphologic variability. Most of these variations do not have an impact on therapy or prognosis and for this reason are not formally

Figure 37.83 Gross appearance of lymph nodes involved by non-Hodgkin lymphoma of diffuse large B-cell type. The nodes are enlarged and show a homogeneous tan cut surface.



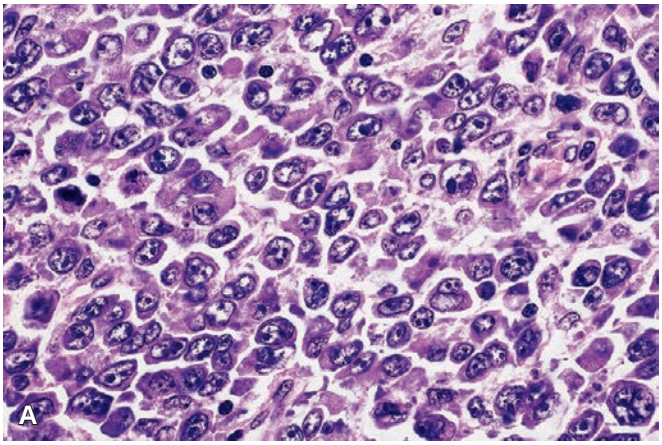


Figure 37.84 Medium- (**A**) and high-power (**B**) views of diffuse large B-cell lymphoma with large cleaved cells.

subclassified, but they are important because they may result in a mistaken diagnosis. They include the following:

1. *Sclerosis*. Diffuse large cell lymphomas can undergo marked sclerosing changes, similar to those seen in follicular lymphomas (Fig. 37.86).[668,674,741,742] This material is mainly composed of types I, III, and V collagen and fibronectin.[743] Sclerosis is a

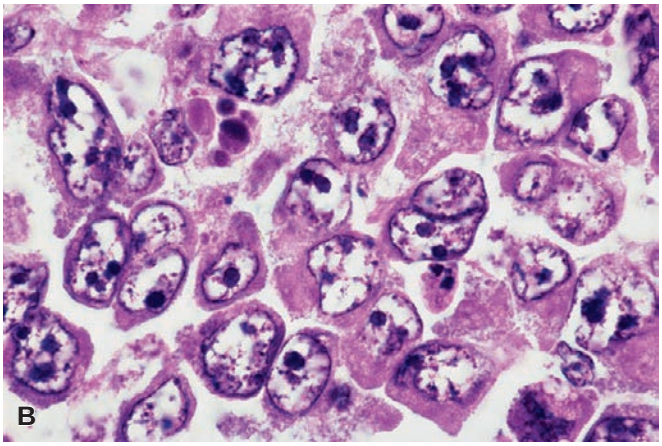

Figure 37.85 Medium- (**A**) and high-power (**B**) views of diffuse large B-cell lymphoma with immunoblastic features.

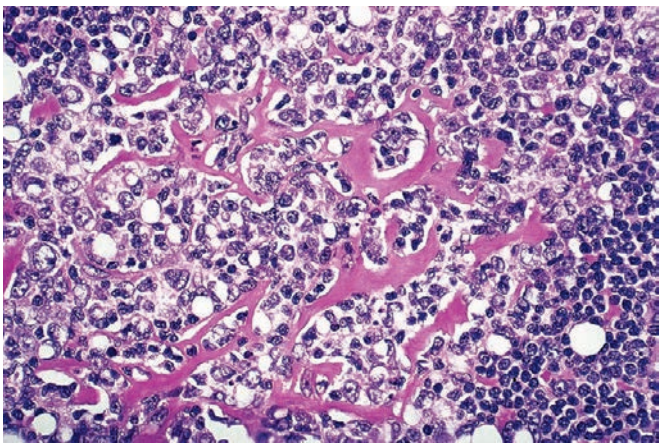

Figure 37.86 Marked sclerosis and hyalinization in diffuse large B-cell lymphoma.

particularly common feature in mediastinal (thymic) large B-cell lymphomas.

2. *Spindling of tumor cells*. This phenomenon, which is probably related to the aforementioned fibrosis, seems to be more common in large cell lymphomas of mediastinum and bone but it can be seen in any location, including lymph nodes.[744] It is thought to be related to the presence of markers characteristic of a germinal center B-cell origin.[745]

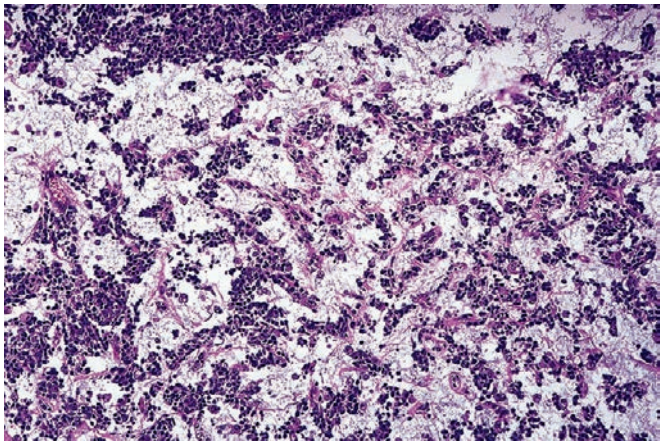

Figure 37.87 Myxoid stromal change in diffuse large B-cell lymphoma. This is an exceptional occurrence.

3. Presence of a *myxoid stroma* that can simulate the appearance of myxoid malignant fibrous histiocytoma or myxoid chondrosarcoma (Fig. 37.87).[746,747]
4. *Rosette formation*. This peculiar change, originally described in follicular lymphoma, has also been seen in large cell lymphoma. Ultrastructural studies have shown that the material in the center of the rosettes is made up of complex cell prolongations.[748]
5. *Filiform cell prolongations*. This phenomenon, which is probably related to that described in the previous paragraph, is appreciable in ultrastructural preparations and is similar to that sometimes seen in carcinomas, mesotheliomas, and other neoplasms. Large cell lymphomas exhibiting this spectacular feature have been designated anemone cell, microvillous, filiform cell, villiform cell, and porcupine lymphomas.[749,750]
6. *Signet ring features*. This alteration, which is more common in follicular lymphoma, is rarely seen in large cell lymphoma and may simulate metastatic adenocarcinoma.[751]
7. *Sinus pattern of spread*, in which the tumor cells are predominantly or entirely confined to the lymph node sinuses, resulting in an appearance closely simulating that of metastatic carcinoma, malignant melanoma, or ALCL (Fig. 37.88).[737,752] Such cases may also demonstrate anaplastic morphology and even expression of CD30, but should not be diagnosed as ALCLs, which is a distinct entity of T- or null-cell lineage.
8. *Interfollicular pattern of growth*. This is more common in T-cell tumors but has also been described in B-cell neoplasms.
9. *Nuclear multilobation*. Although originally thought to be a feature of T-cell tumors, this alteration is now known to occur in B-cell neoplasms.[753,754]

Immunophenotypically, DLBCL is by definition a monotypic B-cell neoplasm positive for B-lineage markers (most importantly CD20 but also CD19, CD79A, and PAX5) and variably immunoglobulin (surface or cytoplasmic).[755] The follicle center cell markers CD10 and BCL6 are expressed in 40% and 60% of cases, respectively. A proportion of cases express postgerminal center cell or plasma cell–associated markers such as CD38, VS38, and MUM1. About 50% of cases express BCL2 protein. A minority of DLBCLs express CD30, usually in a heterogeneous pattern. CD5 is expressed in 10% of cases and a pleomorphic variant of mantle cell lymphoma must be excluded in such cases. Ki-67 staining usually shows a variable, but usually high proliferation index, with some cases showing an index approaching 100%. An exceptionally rare occurrence is immunoreactivity for cytokeratin, which may lead the unwary to a misdiagnosis of carcinoma.[756]

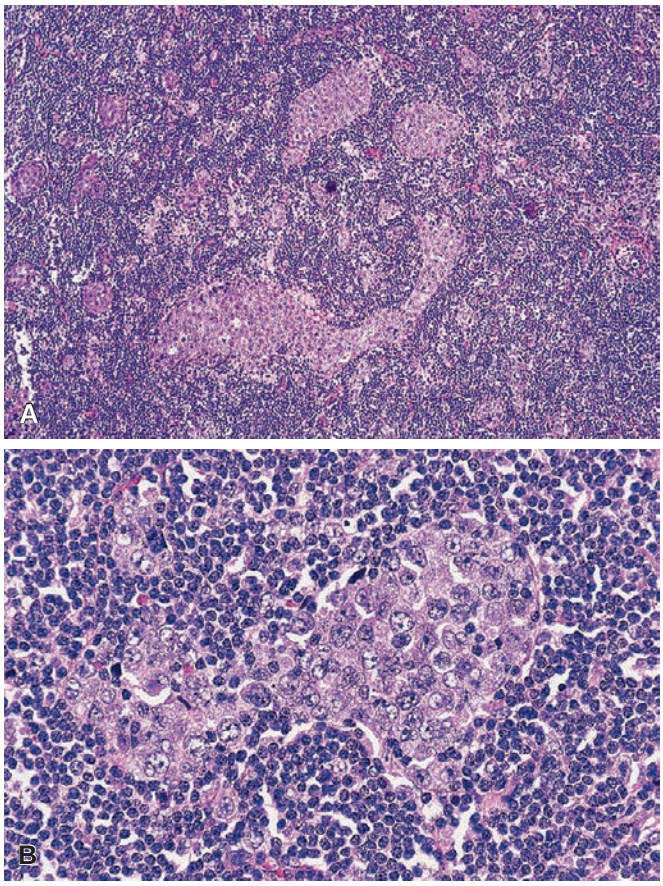

Figure 37.88 **A** and **B**, Large B-cell lymphoma with a sinus pattern of growth that simulates a metastatic tumor.

DLBCLs show rearrangements of the immunoglobulin genes as expected for a B-lineage neoplasm. The variable region of the IGH is usually hypermutated, with some cases also showing ongoing somatic mutations, indicating a germinal center or postgerminal center stage of B-cell differentiation.[757]

Approximately 20% of cases of DLBCLs show *BCL2* rearrangement due to t(14;18)(q32;q21), a hallmark of follicular lymphoma.[758–760] Such cases may have transformed from a known or occult follicular lymphoma, or may have even directly evolved to DLBCL without a precursor phase of follicular lymphoma. However, additional genetic alterations are required for the development of DLBCL, such as *TP53* mutation. The *BCL6* gene encodes a transcription factor essential for formation of secondary lymphoid follicles and T-cell-dependent antibody responses, and its aberrant expression plays an important role in the *de novo* pathway of DLBCL formation. In about 35% of cases of DLBCLs, translocation of *BCL6* (3q27) with a variety of partner genes (with IGH gene located on 14q32 being the commonest) results in constitutive overexpression of BCL6 protein, causing a sustained proliferative setting in which additional mutations can occur.[761–764] This translocation is not specific for DLBCL but is also found in a subset of follicular lymphomas.[648,765] In addition, about 75% of cases of DLBCLs show somatic mutations in the 5′ noncoding regions of the *BCL6* gene, a phenomenon also commonly observed in other germinal center and postgerminal center B-cell lymphomas.[766,767] At least some of the mutations result in deregulation of *BCL6* expression.[768] These mutations, occurring independent of *BCL6* translocation, are generated by the same somatic hypermutation mechanism that targets the variable regions of immunoglobulin genes.[769,770] *MYC* (8q24) translocation is found in up to 10% of DLBCLs.[771–774] In contrast to Burkitt lymphoma, the *MYC* gene may be fused with a non-immunoglobulin gene, and the karyotype is complex. *MYC* translocation is associated with a highly aggressive behavior.[775] *MYC* translocations in DLBCL are often associated with translocations of *BCL2* or *BCL6* and these "double-hit" lymphomas have a particularly aggressive clinical behavior.[776] A *MYC* translocation alone in a case with morphologic features of DLBCL does not alter the diagnosis of DLBCL, NOS; however, the finding of double hit would now change the diagnosis to *high-grade B-cell lymphoma with* MYC *and* BCL2 *and/or* BCL6 *rearrangements* (see later). For this reason, routine testing for translocations of these three genes by FISH is recommended for many patients with DLBCL, NOS. Expression of MYC, BCL2, and/or BCL6, detected by immunohistochemistry, does not directly correlate with translocations detected by FISH, but so-called double expressors are also associated with a worse prognosis,[777] and some centers routinely perform immunohistochemistry for MYC to identify this group.

Gene expression profiling studies can identify three major groups of DLBCLs[33,34,38,778,779]: (1) germinal center B cell–like (GCB) DLBCL that expresses genes characteristic of germinal center B cells, and is correlated with presence of t(14;18) and *C-REL* amplification; (2) activated B cell–like (ABC) DLBCL that expresses genes normally induced during in vitro activation of peripheral blood B cells, and is correlated with presence of *BCL6* translocation, *PRDM1/BLIMP1* inactivation, and constitutive activation of NFκB due to somatic mutations in genes encoding the NFκB pathway components, such as *A20/TNFAIP3* and *CARD11*; and (3) a type 3 that did not correlate with either of the first two groups.[34] The GCB group is associated with a better prognosis than the ABC group, with 5-year overall survival of 60% versus 35% with CHOP or CHOP-like therapy.[39] Although gene expression profiling for these subtypes is not available in most diagnostic laboratories, several immunohistochemical algorithms have been proposed to distinguish the GCB group from the non-GCB lymphomas. The Hans algorithm is most commonly used and is now recommended for all cases of DLBCL, NOS.[40] This approach uses three immunohistochemical markers: CD10, BCL6, and MUM1. Cases are defined as GCB if CD10 positive (without regard to BCL6 or MUM1 status) or if CD10−/BCL6+/MUM1−. All others (CD10-/BCL6+/MUM1+ or CD10−/BCL6−/MUM1+/−) are considered as non-GCB type. While this approach does not perfectly match CGH studies, it still identifies prognostically significant disease groups and some novel DLBCL therapies are recommended for the non-GCB type.[738,780] The WHO classification now includes *germinal center B-cell type* and *activated B-cell type* as subgroups of DLBCL, NOS.[407]

Although most cases of DLBCL fall into the NOS category of the 2016 WHO classification, this classification also defines a number of specific types of DLBCL.[407] Some do not primarily involve the lymph node and are discussed elsewhere in this text, including *primary mediastinal (thymic) large B-cell lymphoma*, *primary cutaneous DLBCL, leg type*, *primary DLBCL of the central nervous system*, *EBV+ mucocutaneous ulcer*, and *lymphomatoid granulomatosis*. **Intravascular large B-cell lymphoma** (angiotropic lymphoma)[781] is a systemic malignant disease that may present in lymph nodes or any organ. It was originally regarded as a multicentric malignant transformation of endothelial cells and designated as malignant angioendotheliomatosis but is now known to be a type of large B-cell lymphoma with a remarkable tropism for blood vessels.[782]

T-cell/histiocyte-rich large B-cell lymphoma is a large B cell overshadowed by a reactive population of T cells (Fig. 37.89).[783,784] The tumor cells may represent less than 10% of the entire cell population. The pattern of growth is diffuse, and there may be a fine interstitial fibrosis. The main differential diagnosis is with NLPHL,

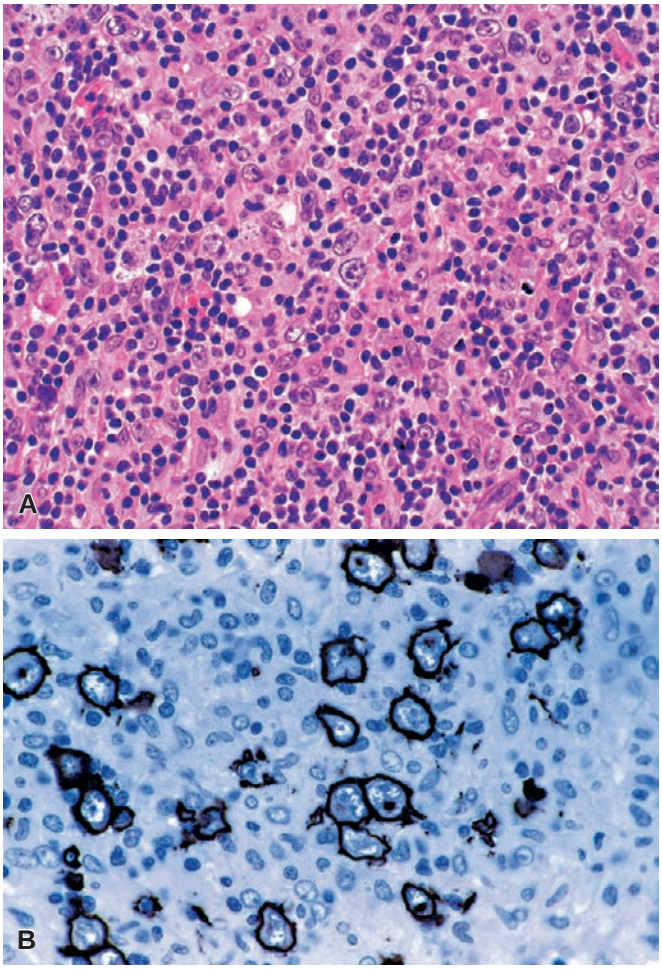

Figure 37.89 **T-Cell/Histiocyte-Rich Large B-Cell Lymphoma. A**, hematoxylin–eosin; **B**, membrane and Golgi-type immunoreactivity for CD20 in the large tumor cells.

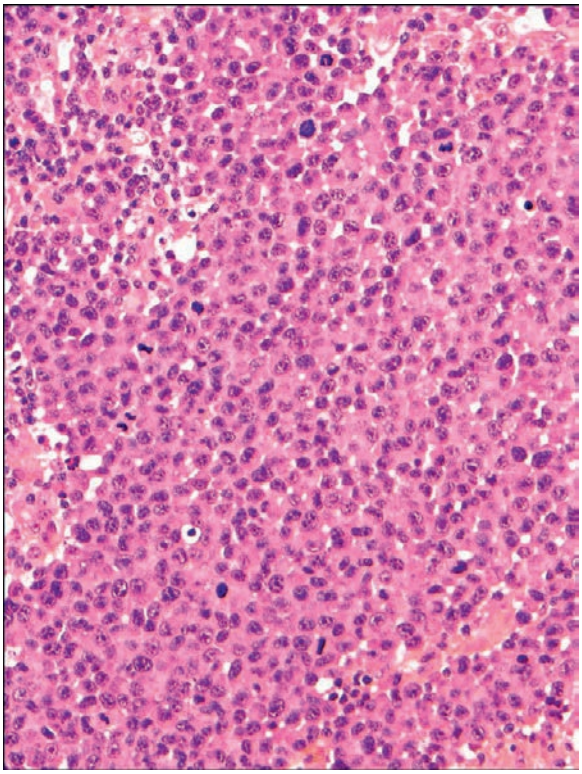

Figure 37.90 The neoplastic cells of this case of plasmablastic lymphoma have fairly fine nuclear chromatin with abundant eosinophilic cytoplasm and a high mitotic rate.

with which it shares many phenotypic features,[785] but NLPHL should demonstrate a nodular growth pattern, usually with admixed small B lymphocytes. Some authors have questioned the validity of separating the two entities.[786] It would seem, though, that there are enough clinical, morphologic, and molecular genetic differences to keep them distinct. T-cell/histiocyte-rich large B-cell lymphoma is clinically more aggressive,[787] has a different pattern of follicular dendritic cell staining,[788] and has a different genetic pattern on comparative genomic hybridization.[789]

DLBCL associated with chronic inflammation. This variant occurs in the context of long-standing chronic inflammation, and shows consistent association with EBV.[755] Most cases involve body cavities or narrow spaces, with the prototype being pyothorax-associated lymphoma, which involves the pleural cavity of patients with longstanding pyothorax.[790] Occasional cases are discovered incidentally in surgical specimens, such as splenic cyst, hydrocele sac, and atrial myxoma.[791]

EBV-positive DLBCL, NOS was previously termed EBV-positive DLBCL of the elderly or senile EBV-positive lymphoproliferative disorder.[792] This is a type of DLBCL that may occur at any age but is most common in adults aged over 50 years, without overt underlying immunodeficiency.[793–796] It is, by definition, EBV positive by in situ hybridization. It frequently shows associated necrosis but has no specific or distinctive morphologic features. This is a diagnosis of exclusion, in the sense that a case will not be classified as such if it fits other defined DLBCL entities (such as DLBCL associated with chronic inflammation, EBV+ mucocutaneous ulcer, or plasmablastic lymphoma).

Plasmablastic lymphoma was originally described as neoplastic proliferation of the oral cavity associated with HIV infection, but it may occur in any site, including lymph nodes, and in association with other causes of immunodeficiency or with aging.[797–799] Two morphologic types of plasmablastic lymphoma have been described. The monomorphic variant has features more typical of DLBCL, with large cells with vesicular nuclei, a single centrally located prominent nucleolus, or multiple peripheral nucleoli and abundant basophilic cytoplasm (Fig. 37.90), while the plasmacytic variant may mimic an anaplastic plasmacytoma with multinucleation and paranuclear hofs. The immunophenotype usually mirrors that of plasma cells, being CD45–, CD20–, CD79a+/–, PAX5–, CD38+, VS38c+, CD138+, and MUM1+. There is variable expression of cytoplasmic immunoglobulin. EBV is positive in 60%–75% of cases, and HHV8 is, by definition, negative. B lineage can be confirmed by demonstrating rearrangement of IGH, and translocations of *MYC* are present in approximately half of cases.[800,801]

The diagnosis of plasmablastic lymphoma should be considered in cases with morphologic features of DLBCL that lack the common B cell markers, such as CD20, CD79A, or PAX5, and for cases with features of anaplastic myeloma but are EBV positive. Other disorders have morphologic features similar to plasmablastic lymphoma. These include ALK+ large B-cell lymphoma, tissue infiltrates of primary effusion lymphoma, and HHV8+ DLBCL that may be associated with Castleman disease (see later). These are all distinct entities that take diagnostic precedence over plasmablastic lymphoma.

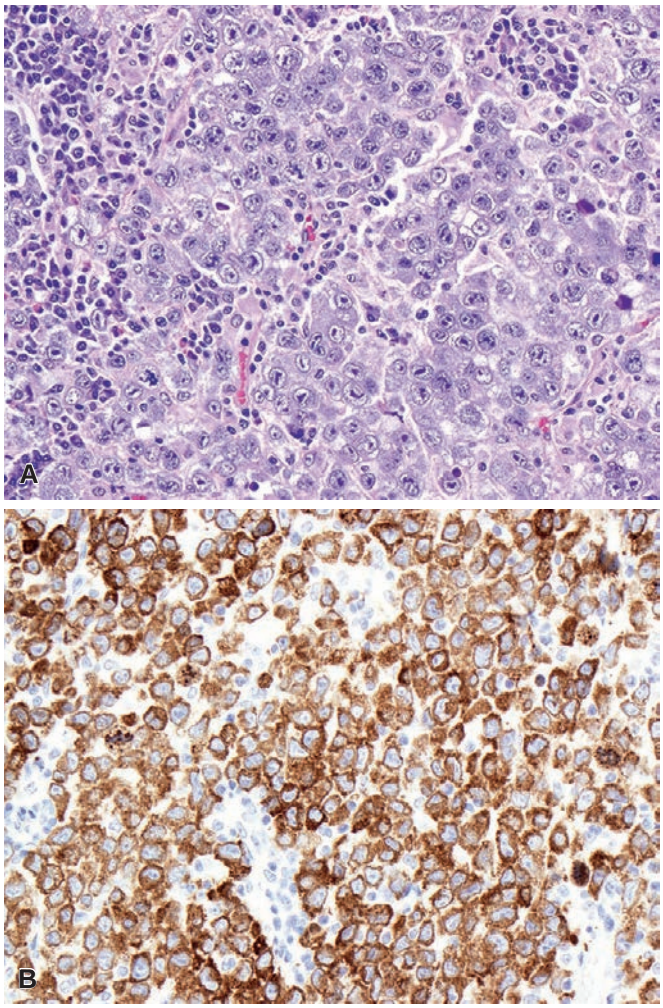

Figure 37.91 ALK-Positive Large B Cell Lymphoma. A, The large atypical cells cluster and may mimic metastatic carcinoma. **B**, the neoplastic cells demonstrate ALK expression.

ALK+ large B-cell lymphoma is an uncommon form of DLBCL with plasmablastic differentiation and a poor prognosis. The tumor cells have an immunoblastic or plasmablastic appearance, and sinusoidal infiltration is common.[802,803] Since they can appear deceptively cohesive, they may be misinterpreted as carcinoma cells (Fig. 37.91). The immunophenotype is similar to plasmablastic lymphoma, CD30 is negative and IgA is commonly positive. The commonest molecular alteration is t(2;17)(p23;q23), which fuses the *ALK* gene with the *CLTC* gene.[804,805] Since *CLTC* encodes a granule-associated protein, immunostaining for ALK is typically in the form of cytoplasmic granules. These tumors are negative for EBV and HHV8 and lack *MYC* translocations.[806]

Primary effusion lymphoma does not usually involve lymph nodes but is briefly mentioned here due to its potential overlap with plasmablastic lymphoma. This is a large B-cell lymphoma with plasmablastic differentiation, occurring predominantly as a pleural or pericardial effusion in patients with AIDS.[807] These effusions contain markedly pleomorphic cells that may suggest carcinoma or mesothelioma. Similar to plasmablastic lymphoma, the cells tend to lack B-cell antigen expression and are associated with both HIV and EBV. The also show a strong association with HHV8, which does not occur with plasmablastic lymphoma. A solid tissue counterpart also exists.[808] The tumor differs from plasmablastic lymphoma by the presence of HHV8, its clinical presentation in body fluids, and by the absence of MYC translocations.

HHV8-positive DLBCL, NOS is an aggressive lymphoma type that was previously termed *large B-cell lymphoma arising in HHV8-associated multicentric Castleman disease*.[809,810] While the association with Castleman disease remains, cases arising outside of this disorder may occur. These lymphomas have plasmablastic morphologic features (Fig. 37.92), similar to plasmablastic lymphoma, but are more likely to express CD20, are EBV-negative, and are positive for HHV8, which can be detected with LANA-1 antibodies by immunohistochemistry; all features that do not occur in plasmablastic lymphoma. The neoplastic cells only express lambda light chains, a feature of HHV8 infection even in non-neoplastic settings. In contrast to individual atypical lambda positive plasmablastic cells in multicentric Castleman disease, these lymphomas form sheets of neoplastic cells. Some cases are associated with Kaposi sarcoma in the same lymph node.

Current Testing in Diffuse Large B-Cell Lymphoma

While demonstrating sheets of large B-cells with a CD20 stain may be sufficient for an overall diagnosis of DLBCL, the above discussion highlights the need for a variety of other tests to be performed currently in the routine evaluation of these cases. As mentioned, testing for CD10, BCL6, and MUM1 are now necessary to subclassify cases of DLBCL, NOS into germinal center versus non-germinal center types. FISH testing for translocations involving *MYC*, *BCL2*, and *BCL6* are also now routinely done to identify the high-risk "double-hit" group. Most centers also perform Ki-67 staining for prognosis and CD30 staining may be performed since new anti-CD30 antibodies make this is a potential therapeutic target. In situ hybridization is necessary to identify the EBV-associated NOS group. CD5 staining, which when present would warrant further evaluation (cyclin D1 staining, etc) to exclude a pleomorphic mantle cell lymphoma, may also be useful. MYC and BCL2 immunohistochemistry to identify so-called high risk "double expressors" is not currently routine but will probably be more commonly performed in the near future.

Burkitt Lymphoma

Burkitt lymphoma is a high-grade malignant lymphoma composed of germinal center B cells, which can present in three clinical settings:

1. *Endemic*. This occurs in the equatorial strip of Africa and is the most common form of childhood malignancy in that area. The patients characteristically present with jaw and orbital lesions. Involvement of the gastrointestinal tract, ovaries, kidney, and breast are also common.
2. *Sporadic*. This is seen throughout the world. It affects mainly children and adolescents and has a greater tendency for involvement of the abdominal cavity than the endemic form.[811]
3. *Immunodeficiency associated*. This is seen primarily in association with HIV infection and often occurs as the initial manifestation of the disease.[812,813]

In all three forms peripheral lymphadenopathy is rare and, when present, usually limited to a single group.[814,815] Bone marrow involvement is common in the late stage of the disease, but leukemic manifestations are less common.[811,816]

Microscopically, the pattern of growth of Burkitt lymphoma is usually diffuse, although early cases may show preferential involvement of germinal centers.[817] The tumor cells are medium sized (10–25 μm) and round. The nuclei are round or oval and have *several* prominent basophilic nucleoli. The chromatin is coarse and the nuclear membrane is rather thick. The cytoplasm is easily identifiable; it is amphophilic in hematoxylin–eosin-stained preparations

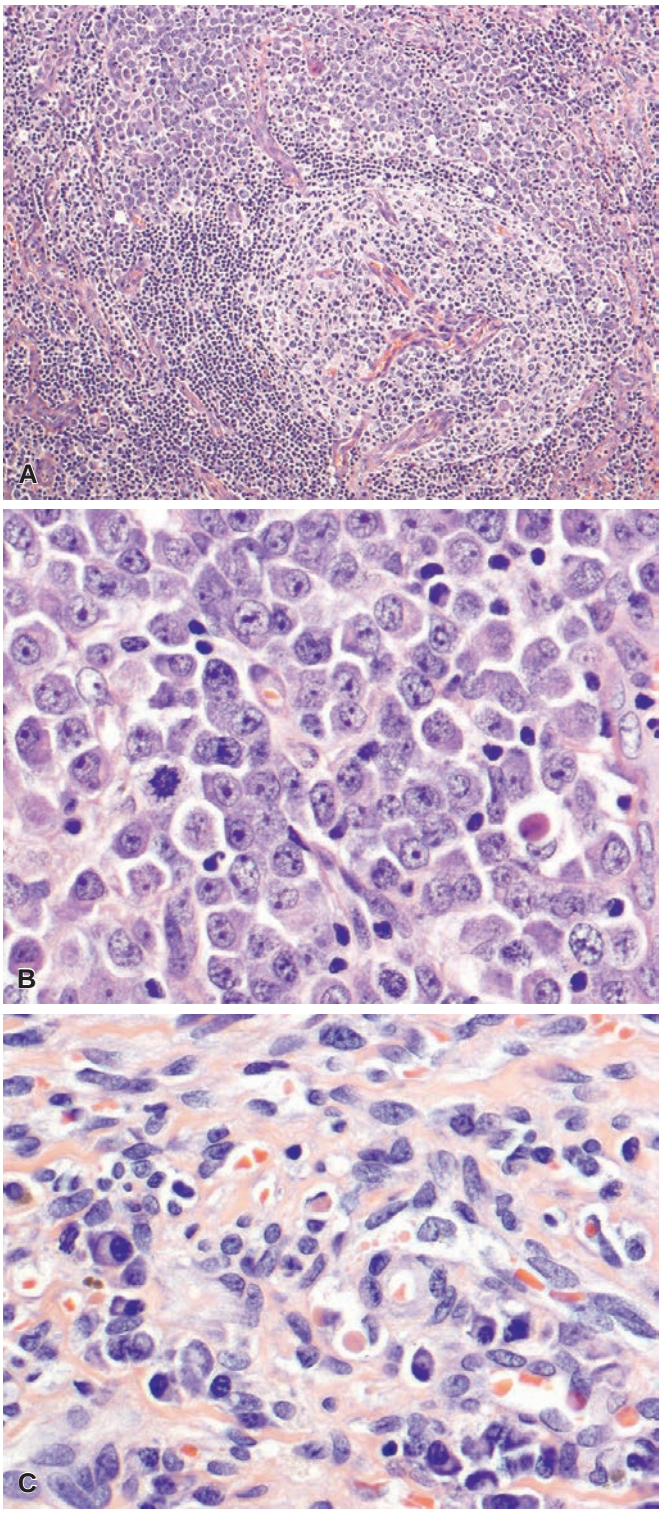

Figure 37.92 HHV+ DLBCL, NOS Arising in a Patient With Castleman Disease. A, The lymphoma cells surround the upper left portion of the typical Castleman germinal center. **B**, The cells have morphologic features similar to plasmablastic lymphoma but were HHV8 positive and EBV negative. **C**, The lymph node capsule also showed a focus of Kaposi sarcoma.

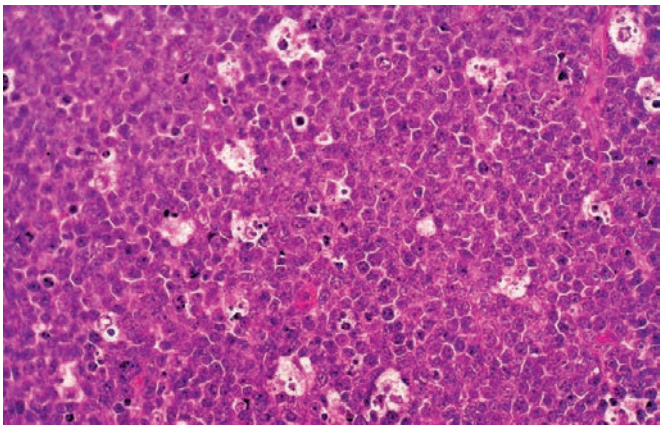

Figure 37.93 Burkitt lymphoma with characteristic starry sky appearance.

and strongly pyroninophilic. Fat-containing small vacuoles are present; these are particularly well appreciated in touch preparations. Mitoses are numerous, and a prominent starry sky pattern is the rule, although by no means pathognomonic (Fig. 37.93).[818] There are also many admixed apoptotic bodies. In well-fixed material, the cytoplasm of individual cells "squares off," forming acute angles in which the membranes of adjacent cells abut on each other. Occasionally, the tumor is accompanied by a florid granulomatous reaction.[819] Ultrastructurally, the main features are abundant ribosomes, frequent lipid inclusions, lack of glycogen particles, and presence of nuclear pockets or projections.[820]

Burkitt lymphomas are of mature B-cell lineage. They express immunoglobulins (predominantly IgM), invariably associated with heavy and light chain restriction.[821] B cell–specific antigens (such as CD19, CD20, and CD22) as well as the germinal center cell markers CD10 and BCL6 are expressed.[822] They are negative for the activation markers CD25 and CD30 and are BCL2 negative. In contrast to lymphoblastic lymphoma, they do not express TdT. The most helpful immunohistochemical profile to aid in diagnosis of Burkitt lymphoma includes CD20+, CD10+, BCL2–, and a Ki-67 index over 95%.

As expected of a B-lineage neoplasm, Burkitt lymphoma shows clonal rearrangements of the immunoglobulin genes. The hallmark genetic change is t(8;14), t(2;8), or t(8;22), which fuses the *MYC* gene with an IGH, kappa light chain, or lambda light chain gene.[823] As a result, the *MYC* gene is overexpressed, promoting cell cycle progression and inhibiting differentiation.[824] However, *MYC* translocation is not entirely specific for Burkitt lymphoma; it can also be observed in transformed follicular lymphomas, rare cases of DLBCL, and the highly lethal "double-hit" lymphomas (with presence of both *MYC* and *BCL2* translocation).[775,825–828] In Burkitt lymphoma, as currently defined, the *MYC* translocation should be the sole abnormality.[775]

FISH studies are now necessary to support a diagnosis of Burkitt lymphoma by demonstrating the presence of a *MYC* translocation together with absence of *BCL2* and *BCL6* translocations.[819]

There is an association of Burkitt lymphoma with EBV, with frequencies of approximately 100% for the endemic type, 20%–30% for the sporadic type, and 25%–40% for the immunodeficiency-associated type (Fig. 37.94).[823] The EBV shows type I latency, that is EBER and EBNA1 are expressed, while LMP1 and EBNA2 are negative.

In the past, some cases resembling Burkitt lymphoma but having atypical morphologic and/or immunophenotypic features were diagnosed as *atypical Burkitt lymphoma*, *Burkitt-like lymphoma*, *small non-cleaved, non-Burkitt lymphoma*, *gray-zone lymphoma*, or *B-cell*

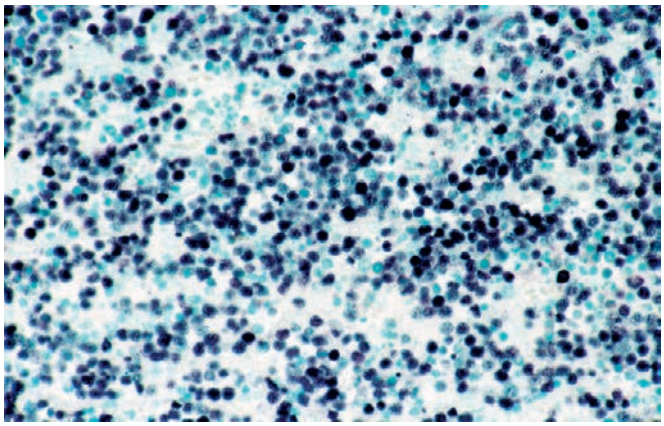

Figure 37.94 Presence of EBV genome in Burkitt lymphoma, as demonstrated with in situ hybridization for EBER.

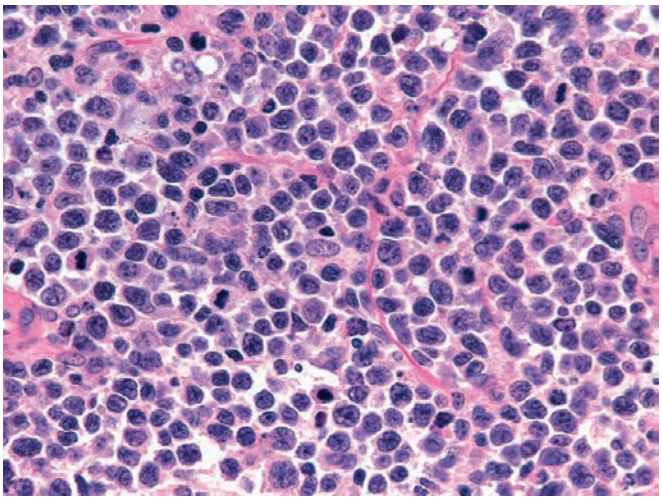

Figure 37.95 High-Grade B-Cell Lymphoma With *MYC* and *BCL2* Rearrangements. The morphologic features are intermediate between diffuse large B-cell lymphoma and Burkitt lymphoma. The presence of a so-called double hit of the two translocations confirms this diagnosis.

lymphoma, unclassifiable with features intermediate between DLBCL and Burkitt lymphoma. These terms are no longer used and have been replaced with several new categories/names in the 2016 WHO classification.[407]

Burkitt-like lymphoma with 11q aberration is a provisional entity in the 2016 WHO classification. It has morphologic and immunophenotypic features similar to Burkitt lymphoma described previously except it may have more nuclear pleomorphism than usual type Burkitt lymphoma.[829,830] In contrast to Burkitt lymphoma, which has *MYC* translocations without other complex cytogenetic abnormalities, Burkitt-like lymphoma with 11q aberration has gains or losses at 11q and may have an associated complex karyotype. Some cases of this type are reported post-transplantation or in association with immunodeficiency. Since testing for these 11q aberrations is not routinely available, most cases currently would be classified as high-grade B-cell lymphoma, NOS (described next).

High-Grade B-Cell Lymphomas

Some lymphomas, particularly those with features similar to Burkitt lymphoma, either lack *MYC* translocations or have *MYC* translocations as well as additional cytogenetic abnormalities, particularly translocations of *BCL2* or *BCL6*.[776,831] Cases with a *MYC* translocation with either a *BCL2* or *BCL6* translocation are now termed **high-grade B-cell lymphoma with *MYC* and *BCL2* and/or *BCL6* rearrangements**. These cases may have morphologic features of DLBCL or Burkitt lymphoma and often express CD10 and BCL2 and demonstrate a very high proliferation rate (Fig. 37.95). No single finding, however, is predictive of these combined cytogenetic abnormalities. Many cases also have other cytogenetic abnormalities. Some prognostic variation is reported based on the second "hit" and for "triple-hit" cases that have all three translocations,[832–834] but any combination of two or more translocations would qualify a case for this category. Cases with a morphologic appearance similar to Burkitt lymphoma or intermediate between DLBCL and Burkitt lymphoma, but lack a *MYC* translocation or an 11q aberration are now termed **high-grade B-cell lymphoma, NOS**.

Lymphoma in Immunodeficiency States

An increase in the incidence of malignant lymphoma has been documented in most types of congenital and acquired immunodeficiency.[835–837] Chronic antigenic stimulation—possibly by oncogenic viruses—and perhaps loss of antibody feedback inhibition of the lymphoid proliferation may account for the high rate of lymphoid malignancies.[838] EBV in particular has been repeatedly implicated.[839]

1. *Primary immunodeficiencies*. Patients with genetically determined immune deficiencies have an increased incidence of malignant tumors, especially lymphomas.[835,840,841] This includes ataxia–telangiectasia, Wiskott–Aldrich syndrome, X-linked lymphoproliferative syndrome, common variable immunodeficiency, and severe combined immunodeficiency syndrome.[842]
2. *Post-transplant lymphoproliferative disorders (PTLDs)*. The incidence of lymphoma is increased in recipients of all types of solid organ transplant as a direct or indirect result of the induced immunosuppression.[843–847] In renal transplant recipients, this incidence is in the order of 4%–6%.[848] Skin tumors, malignant lymphomas, Kaposi sarcoma, and cervical carcinoma are the most common neoplasms. The frequency of lymphoma has been estimated to be 350 times higher than in the age-matched general population.[848–850] The incidence has been found to be particularly high in adult cardiac transplant patients treated with OKT-3–containing regimens.[851,852] In approximately half of the reported cases, the central nervous system is involved, compared with less than 1% in lymphoma patients in general. In 30% of the cases, the allograft is also involved.

   A number of microscopic patterns of PTLD occur. More indolent cases involve lymph nodes or tonsils without a destructive architectural pattern. These include *plasmacytic hyperplasia, infectious mononucleosis,* and *florid follicular hyperplasia* types of PTLD. While these may progress to destructive and frankly neoplastic proliferations, many do not, and it is controversial whether these types all actually represent PTLDs or are unrelated hyperplastic lesions. This is particularly true for plasmacytic hyperplasia and florid follicular hyperplasia types that may have only rare EBV-positive cells and are similar to reactive lesions seen in patients with no transplant history. The infectious mononucleosis type of PTLDs is morphologically identical to what is seen in infectious mononucleosis in immunocompetent individuals but may at times be difficult to differentiate from polymorphic PTLDs (see later). Reactive-appearing proliferations without EBV should probably not be considered as a PTLD.

   There is better agreement that destructive lesions, often similar to other lymphoma types, represent true PTLDs. These include

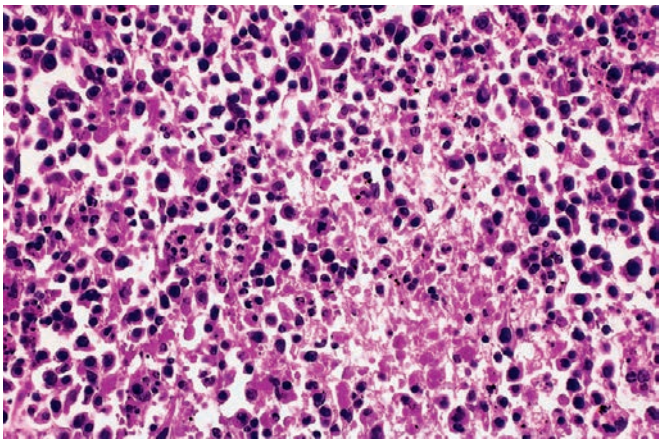

Figure 37.96 Polymorphic lymphoproliferative process associated with necrosis in lymph node of a renal transplant patient. There was evidence of active EBV infection.

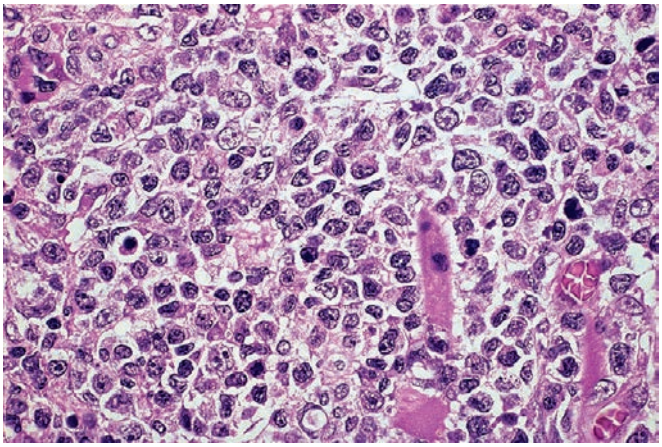

Figure 37.97 Monomorphic posttransplant lymphoproliferative disorder (diffuse large B-cell lymphoma) in a recipient of a renal transplant.

polymorphic, *monomorphic*, and *classical Hodgkin lymphoma types.* **Polymorphic PTLD** distorts the normal lymph node architecture with a heterogeneous mix of B cells and plasma cells (Fig. 37.96).[853] Large, admixed immunoblasts and cells with Hodgkin-like features are often present. The B-cell and plasma cell component may be monotypic or polytypic in these proliferations. The large atypical cells are frequently CD30 positive and EBV is present in most cells of the majority of cases. **Monomorphic PTLD** has histologic features similar to well-established non-Hodgkin lymphoma types of non-immunocompromised patients (Fig. 37.97). These most commonly are DLBCL, Burkitt lymphoma, or plasmacytoma and are usually EBV positive.[854] T- or NK-cell lineage cases of monomorphic PTLD are also described.[855] Rare cases of monomorphic PTLD of marginal zone lymphoma type are reported and are EBV positive,[856] a feature that is otherwise uncommon in marginal zone lymphoma. In general, however, most lymphomas of small B cells arising in the post-transplant setting are not considered to be PTLD. The **classical Hodgkin lymphoma PTLDs** have morphologic and immunophenotypic features of classical Hodgkin and are usually EBV positive. Cases with Hodgkin-like cells admixed with a polymorphous background, not typical of classical Hodgkin lymphoma, are considered polymorphic PTLD and not the classical Hodgkin lymphoma type.

Molecular studies have confirmed the recipient origin of the lymphoma following solid organ transplantation, with donor origin more common after hematopoietic cell transplantation.[857–859]

The clinical course of post-transplant lymphoma/lymphoproliferative disease is usually very rapid.[860,861] Treatment of PTLDs consists of a combination of immunosuppression reduction and standard lymphoma therapy (chemotherapy and radiation).[862]

3. *HIV*. Patients with HIV infection are at a high risk for developing malignant tumors, principally Kaposi sarcoma and malignant lymphoma,[863–869] sometimes in combination.[809] It has been estimated that approximately 3% of AIDS patients develop non-Hodgkin lymphoma, and that the risk of developing a lymphoma in this population is 60-fold greater than in the normal population. The majority of the cases present with multiple sites of extranodal involvement, with a high incidence of involvement of the gastrointestinal tract, central nervous system, bone marrow, liver, oral cavity, body cavities, and heart.[866,870] Practically all cases are of B-cell lineage and—as such—show clonal immunoglobulin gene rearrangements.[864,871,872] Distinct morphologic subtypes of lymphoma associated with HIV have already been described, but many patients have DLBCL or Burkitt lymphoma, with similarities to non-HIV cases.[812,813,873,874] Cases have also been reported of peripheral T-cell lymphomas with a peculiar component of Touton-like giant cells,[875] and others having the features of the polymorphic lymphoproliferative disorders seen more often in solid organ transplant recipients.[876] HIV-associated lymphomas, especially the unique types of plasmablastic lymphoma, primary effusion lymphoma, and HHV8+ DLBCL (see earlier), have an increased association with HHV8 and/or EBV infection.[877–880]
4. *Others*. Acquired diseases of the immune system in which an increased incidence of lymphoma has been recorded include rheumatoid arthritis,[881,882] Sjögren syndrome,[883] Hashimoto thyroiditis, and other autoimmune diseases.[884]

Peripheral (Post-Thymic) T-Cell and Natural Killer–Cell Lymphomas

Peripheral (post-thymic) T-cell and NK-cell lymphoma is the generic term given to a family of tumors composed of neoplastic lymphocytes with phenotypic and genotypic features of mature T cells or NK cells.[885,886] This is an extremely heterogeneous group of lesions, many of them occurring primarily at extranodal sites, and which have received a myriad of designations. Most of them were identified as entities long before their peripheral T-cell or NK-cell nature was ascertained.

Peripheral T-cell and NK-cell lymphomas in general are highly aggressive. Their morphologic features are variable depending on the type, but immunohistochemical studies are always required to confirm their T-cell or NK-cell nature. They commonly express CD3, CD45RO, CD2, CD5, and CD7, although expression of one or more of these pan–T-cell markers may be lost (so-called aberrant immunophenotype, which is sometimes utilized to support the neoplastic nature of a T-cell proliferation). NK-cell lymphomas are commonly CD2+, cytoplasmic CD3+, surface CD3–, CD5–, and CD56+ and are EBV-positive by in situ hybridization. Most cases of peripheral T-cell lymphoma express a CD4+/CD8– mature helper phenotype; approximately 20% express a CD4–/CD8+ cytotoxic/suppressor phenotype, with rare cases having CD4–/CD8– or CD4+/CD8+ phenotypes.

At the molecular level, peripheral T-cell lymphomas exhibit clonal rearrangements of the γ and β T-cell receptor genes, although about 10% of cases may show simultaneous clonal rearrangements of IGH.[887]

The T/NK neoplasms of the 2016 WHO classification are listed in Box 37.1. Many do not primarily involve lymph nodes and are discussed in other chapters. The major lymph node disease categories are AITL, ALCL, and peripheral T-cell lymphoma, NOS.

Angioimmunoblastic T-Cell Lymphoma

AITL includes cases originally described as angioimmunoblastic lymphadenopathy (AILD) and immunoblastic lymphadenopathy. AILD was originally considered a premalignant proliferation with a high risk for transformation to T-cell lymphoma but is not considered neoplastic from its origin.[888] AILD was originally described as occurring almost exclusively in adults and elderly individuals and is characterized clinically by fever, anemia (usually hemolytic), polyclonal hypergammaglobulinemia, and generalized lymphadenopathy.[889–891] Other common manifestations include hepatomegaly, splenomegaly, constitutional symptoms, and skin rash.[892–894] In 27% of the patients studied in the classic series by Lukes and Tindle[891] the disease occurred abruptly after administration of drugs, particularly penicillin. Some of these cases, however, might now be considered as mimics of AITL rather than lymphoma based on more extensive testing now performed.

Microscopically, the disease is systemic, with lesions in the lymph nodes, spleen, liver, bone marrow, and skin. The lymph node changes are characterized by obliteration of the nodal architecture (with focal preservation of sinuses) by a polymorphic cellular infiltrate and by an extensive proliferation of finely arborizing vessels of the caliber of postcapillary venules (Fig. 37.98). The cellular infiltrate is composed of small lymphocytes, plasma cells, numerous immunoblasts, frequent and sometimes abundant eosinophils, and, occasionally, multinucleated giant cells. Normal germinal centers are usually absent; what one may find instead are germinal centers composed of loose aggregates of pale histiocytes, rare immunoblasts, or large epithelioid cells; these are referred to as "burnt-out germinal centers" and can closely resemble the appearance of granulomas. Only occasionally one finds hyperplastic germinal centers.[895] There is also a component of proliferating cells of dendritic/reticulum nature[896] that extends beyond the residual germinal centers and is highlighted by CD21 or CD23 staining. An amorphous, eosinophilic PAS-positive intercellular material may be found scattered throughout the node. Extension of the infiltrate in the capsule and pericapsular tissue is common. Although subtle in many cases, some cases demonstrate clusters of large, often clear cells that represent the clonal T-cell proliferation in most cases (Fig. 37.99). These T cells are now believed to arise from the germinal center and are termed TFH cells. Immunohistochemical studies for CD21 or CD23 are useful to identify the expanded follicular dendritic cell networks characteristic of this disorder. The identification of TFH cells outside of follicles is also a helpful feature. These T cells express CD10, CXCL13, BCL6, and PD1. Lymphoid cells positive for EBV are found in over 75% of the cases, but these cells may be infrequent and do not correlate with the neoplastic T cell population.[897] Additionally, admixed atypical large B cells and/or increased plasma cells may be present, and these may be monotypic. Hodgkin-like cells may also occur in AITL. The increase in large B cells may create diagnostic difficulties,[898] with the T-cell component missed in some cases at presentation or the lymphoma correctly identified as AITL relapsing with features of DLBCL.

While AITL expectedly shows clonal rearrangements of the T-cell receptor genes in most cases, up to 40% of cases show simultaneous clonal rearrangements of the immunoglobulin genes supportive of an underlying B cell clone. This finding has been attributed to EBV infection of B cells in the past but is also seen in EBV-negative cases.[17,899,900] Chromosomal alterations in AITL are common but nondistinctive, such as +3, +5, +18, +19, +21, +X, −6q, and −7.[505,899,901,902] The gene expression profile shows a strong contribution by the admixed follicular dendritic cells, B cells, and stromal components, as well as overexpression of genes characteristic of normal TFH cells.[903–905] A variety of mutations have now been described in AITL, including mutations in myeloid-associated genes *TET2*, *DNMT3A*, and *IDH2*.[906–908] Mutations in *RHOA*, however, appear to be most common reported in approximately 60% of cases.[909] A subset of cases demonstrate t(5;9)(q33;q22) involving *ITK* and *SYK*.

Two rare lymphoma types are now considered provisional entities in the 2016 WHO classification and both are closely related to AITL.[407,910] Both are neoplasms of TFH cells with expression of CD10, BCL6, CXCL13, and/or PD1 on the neoplastic T cells. **Follicular T-cell lymphoma** shows a prominent follicular pattern with extensive follicular dendritic cell networks. **Nodal peripheral T-cell lymphoma with TFH phenotype** does not show all typical features of AITL but has a similar lymphoma cell immunophenotype.

Anaplastic Large Cell Lymphoma

ALCL in its most typical form is characterized by highly atypical and pleomorphic neoplastic cells with expression of the activation marker CD30.[911–914] ALCL is distinguished from CD30-positive transformation of other lymphomas, especially mycosis fungoides, and only includes cases of T-cell or null lineage. Primary cutaneous ALCL is also a distinct entity that is part of the spectrum of primary cutaneous CD30+ T-cell lymphoproliferative disorders and is not discussed here.

The systemic form of ALCL can involve lymph nodes or extranodal sites, such as the bone marrow, bone, respiratory tract, skin, and gastrointestinal tract.[915–917] It can occur in children or adults.[918–921] Exceptionally, it is accompanied by leukemic manifestations.[922] Systemic symptoms such as fever can be present. Currently two types are segregated based on ALK expression, owing to differences in clinical features and prognosis. ALK+ ALCL tends to occur in children and young adults, and the outcome is good if appropriate treatment is given. ALK– ALCL tends to occur over a wider age range, especially older adults, and is associated with a poor outcome similar to peripheral T-cell lymphoma, NOS.

Microscopically, the infiltrate has a polymorphic appearance, often with a variable admixture of neutrophils, lymphocytes, and histiocytes, with the highly atypical large lymphoma cells showing marked pleomorphism.[923] The nuclei of these cells are often horseshoe shaped or multilobed, and nucleoli are prominent. Cells indistinguishable from Reed–Sternberg cells may be seen. The cytoplasm is abundant and eosinophilic. Cohesive growth and preferential sinus involvement are common (Fig. 37.100). The undue prominence of the latter feature in some cases was one of the reasons for this lesion to be mistakenly placed in the category of malignant histiocytosis. ALCL can also simulate malignant melanoma, undifferentiated carcinoma, and various types of soft tissue sarcoma.[924]

Several morphologic variants of ALCL (usually ALK+) have been described.

1. *Small cell*. As the name indicates, this shows a predominant population of small- to medium-sized cells. A very important clue is the presence of the characteristic large anaplastic cells around blood vessels.[923,925] Cases of the small cell variant have been seen to transform into the classic anaplastic large cell form.[926]
2. *Lymphohistiocytic*. The distinctiveness of this variant results from the presence of a large number of admixed reactive (nonepithelioid) histiocytes (Fig. 37.101).[927–929] As for the previous variant, an important diagnostic clue is the clustering of anaplastic tumor cells around vessels.

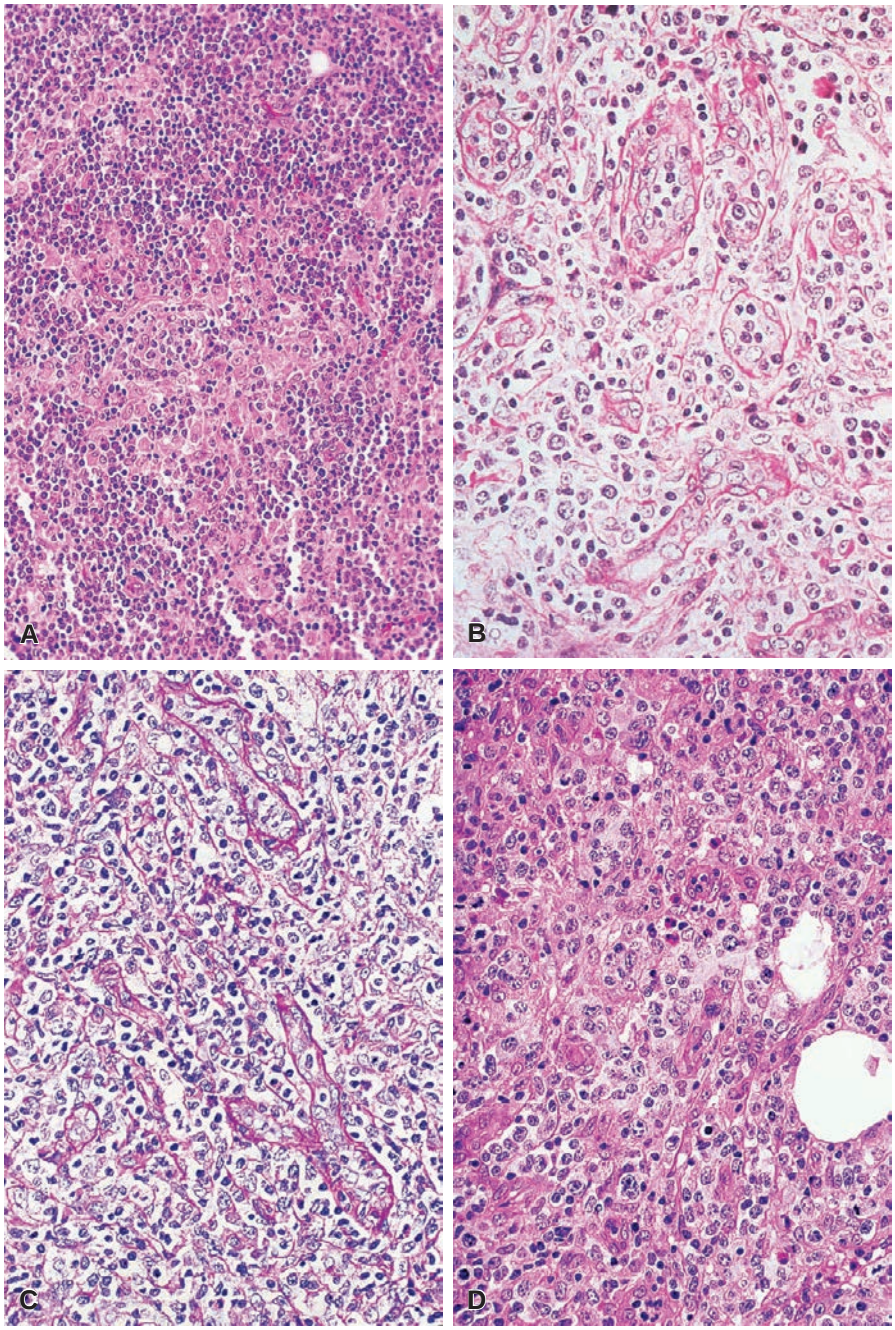

Figure 37.98 Lymph Node Involvement by Angioimmunoblastic T-Cell Lymphoma. A, Low-power view showing a moderate effacement of the architecture by a polymorphic infiltrate composed of lymphocytes, plasma cells, and histiocytes. There is also marked vascular proliferation. **B** and **C**, The PAS stain highlights the prominence of the postcapillary venules. **D**, Atypical lymphoid cells are present in this polymorphic infiltrate, often with clusters of cells with clear cytoplasm. There are also scattered eosinophils.

3. Other morphologic variations of ALCL that do not qualify as bona fide tumor variants are the neutrophil—and/or eosinophil—rich,[930,931] sarcomatoid,[924] giant cell,[932] signet ring-like,[933] and hypocellular.[934]

Immunohistochemically, the tumor cells of ALCL are by definition CD30+ (Ki-1) positive (Fig. 37.102).[935] There is also consistent positivity for EMA, interleukin-2 receptor,[936] clusterin (in a Golgi pattern),[937] cadherins,[938,937] and galectin-3 (a β-galactoside-binding animal lectin).[939,940] There is occasional reactivity for keratin.[940]

There is variable expression of T-lineage markers, and application of a wide panel may be required to have one or two markers staining. In the so-called null-cell cases, T-lineage markers cannot be demonstrated. B-cell markers are, by definition, absent. The B-cell transcription factor PAX5 is usually not expressed, and this marker is extremely helpful for distinction of ALCL from classic Hodgkin lymphoma (PAX5+). ALK, by definition, is expressed in ALK+ ALCL, but not in ALK– ALCL (Fig. 37.103). EBV is generally negative.[941]

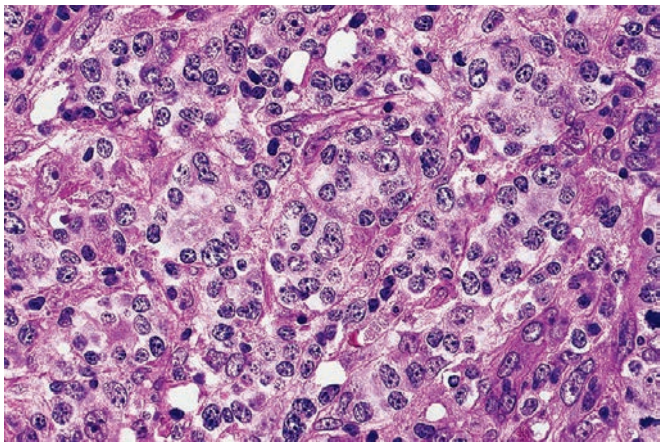

Figure 37.99 Angioimmunoblastic T-cell lymphoma with a uniform proliferation of large neoplastic lymphoid cells.

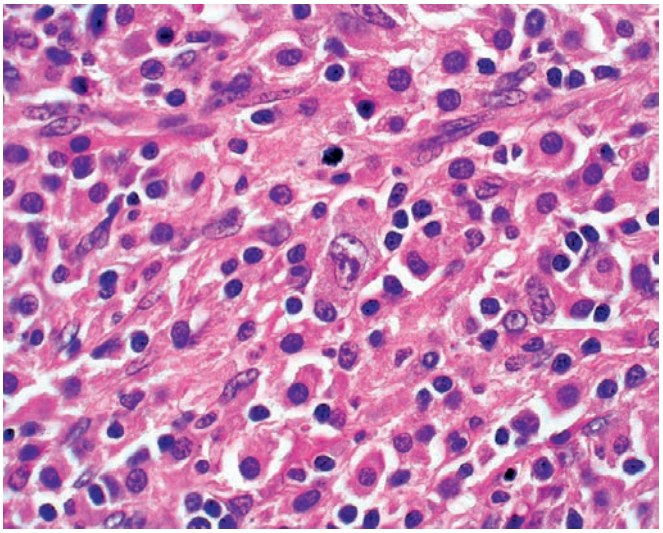

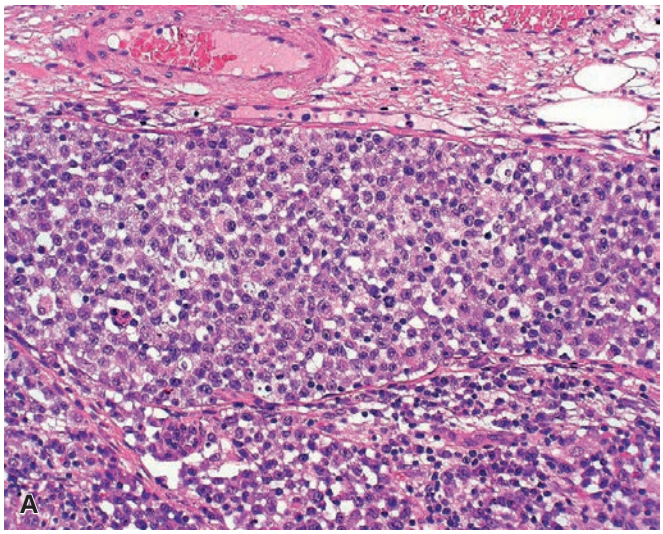

Figure 37.101 So-called lymphohistiocytic variant of anaplastic large cell lymphoma with only scattered, large neoplastic cells.

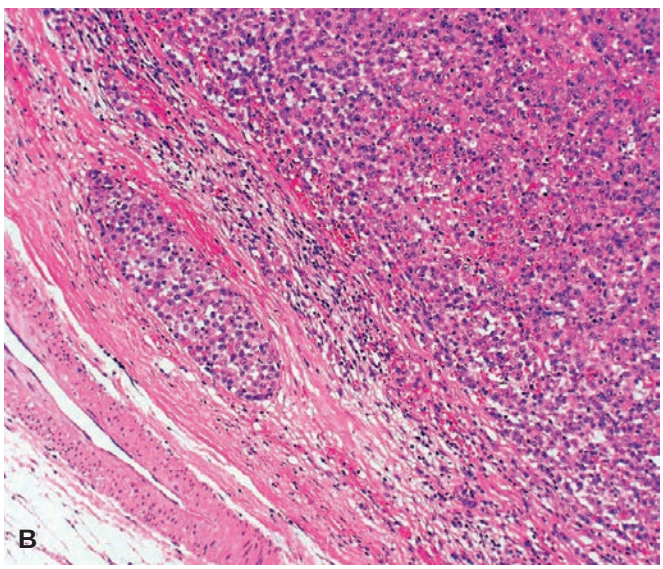

Figure 37.100 Anaplastic Large Cell Lymphoma. A, Packing of the peripheral sinus. **B**, Vascular involvement.

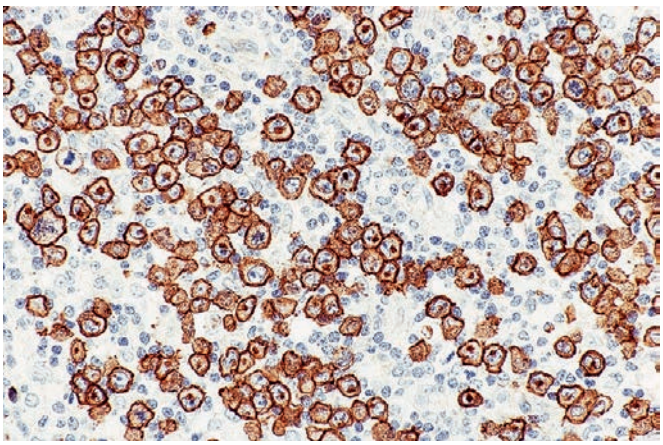

Figure 37.102 Strong membranous and Golgi-type immunoreactivity for CD30 in anaplastic large cell lymphoma.

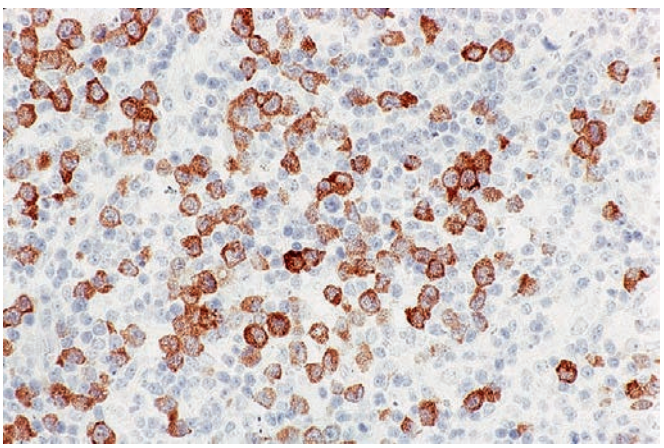

Figure 37.103 ALK immunoreactivity in anaplastic large cell lymphoma.

The T-cell receptor genes are clonally rearranged in approximately 90% of cases of ALK+ ALCL, including cases lacking expression of T-lineage markers.[936,941] The hallmark of this lymphoma type is translocation of anaplastic lymphoma kinase gene (*ALK* on 2p23), although this molecular alteration is also found in an uncommon subtype of DLBCL (ALK+ large B-cell lymphoma), ALK+ histiocytosis, inflammatory myofibroblastic tumor and an uncommon subset of pulmonary adenocarcinoma.[802,942–947] The *ALK* gene can be fused with a variety of partner genes, most of which are housekeeping genes.[948] The translocation results in production of a chimeric protein, in which the ALK domain (a tyrosine kinase receptor) is constitutively activated due to presence of an oligomerization domain at the N-terminus. The commonest partner gene is *NPM* (nucleophosmin gene on 5q35), accounting for 80% of cases. Other partner genes include *TPM3* (tropomyosin-III), *TPM4* (tropomyosin-IV), *TFG* (*TRK* fused gene), *ATIC*, *CLTL* (clathrin), *MSN* (moesin), *CARS*, and *MYH9*. Interestingly, the subcellular localization of ALK on immunostaining correlates well with the normal distribution of the protein encoded by the partner gene, for example, nuclear-cytoplasmic staining for nucleophosmin, cytoplasmic staining with subplasmalemmal accentuation for tropomyosin, cell membrane staining for moesin, and cytoplasmic granular staining for clathrin. The partner gene fused with the *ALK* gene does not influence the prognosis of ALK+ ALCL.[949]

ALCLs with *ALK* translocation have a much more favorable prognosis than ALK– ALCLs.[949–952] Gene expression profiling studies have also confirmed that these two types of ALCL represent distinct entities.[953] Recent studies, however, have identified two additional recurring genetic abnormalities in ALCL that are exclusive of *ALK* translocations.[954,955] Translocations involving *DUSP22*, usually as a t(6;7)(p25.3;q32.3), are found in approximately 30% of cases and abnormalities of *TP63*, usually as in inv(3)(q26q28), occur in approximately 8% of cases. *DUSP22* translocations appear to be associated with a more favorable prognosis, similar to ALK+ ALCL, while *TP63* abnormalities are associated with a worse prognosis, possibly worse than peripheral T-cell lymphoma, NOS. Patients with ALCL lacking *ALK*, *DUSP22*, and *TP63* abnormalities have an intermediate prognosis.

The differential diagnosis for ALCL is broad due to the large number of CD30-positive tumors now known. Classical Hodgkin lymphoma with high numbers of Hodgkin cells usually lacks T-cell antigen expression and is PAX5 positive. CD30 positive lymphoma cells are relatively common in peripheral T-cell lymphoma, NOS, but the expression is not strong and uniform in most cases. Cases of DLBCL with pleomorphic, CD30 positive lymphoma cells are excluded by the expression of B-lineage markers. Primary cutaneous ALCL is biologically distinct from systemic ALCL and should be ALK negative and localized to skin. Identification of ALK-positive cutaneous disease should result in a thorough systemic evaluation. Finally, an ALK-negative ALCL is now recognized in association with serous fluid accumulations in women with breast implants. Such cases are considered biologically distinct from systemic ALCL, do not infiltrate the breast stroma, and are often clinically indolent.[956]

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphoma, NOS is a fairly common "waste basket" group of peripheral T-cell neoplasms that do not meet criteria for other T- or NK-cell lymphoma types. They show a gene expression profile distinct from that of AITL and ALCL with diverse profiles, indicating that it represents a heterogeneous category.[904,905,957] Morphologic features are quite variable with infiltration by virtually any combination of cell sizes. A proportion of cases (5%–11%) show association with EBV[958,959]; they may show variable expression of CD30 and may have an associated B-cell proliferations similar to AITL. Similar to DLBCL, NOS, this category will continue to shrink over time as specific biologic entities are identified.

Current Testing in Peripheral T- and Natural Killer–Cell Lymphomas

Because of the large number of disease categories associated with these rare disorders, a fairly extensive work-up is needed to diagnose peripheral T- and NK-cell neoplasms. Multiple T-cell associated antigens, such as CD2, CD3, CD5, CD7, CD4, and CD8, should be performed on each case due to the high frequency of loss of one or more antigen as well as the lack of specificity of some markers (such as CD5 on some B-cell neoplasms). Markers such as CD10, CXCL13, BCL6, and PD1 are useful to evaluate TFH cells and CD21 and/or CD23 are useful to evaluate follicular dendritic cell networks that are characteristically disrupted in AILT. Additionally, in situ hybridization for EBV and CD56 immunohistochemistry are necessary to identify the nasal-type NK/T cell lymphoma (discussed elsewhere) and CD30 staining (with ALK staining when positive) should be performed to evaluate for ALCL. T-cell receptor gene rearrangement studies are helpful when the differential diagnosis is with reactive conditions, but care must be taken to not overinterpret such studies since oligoclonal reactive proliferations may result in false positive clonality results in some cases.

Tumors of the Accessory Immune System

The accessory immune system includes two major categories of cells: antigen-presenting cells (dendritic cells) and antigen-processing cells (macrophages).[960–965] The dendritic cells belong to the group of nonlymphoid elements traditionally designated by histologists and pathologists as reticulum cells, which have been divided into more or less well-defined subtypes on the basis of location, enzyme histochemical, ultrastructural, and immunohistochemical features. Tumors of most, if not all, of these cell types are now described, and both the WHO and the Histiocyte Society offer recently revised classifications of these neoplasms.[407,966]

Follicular dendritic cell tumor (follicular dendritic cell sarcoma; dendritic reticulum cell sarcoma) often presents as a solitary mass in a cervical lymph node (Fig. 37.104)[967] but can involve other lymph node groups and a large variety of extranodal sites,[968] including stomach,[969] small bowel,[970] large bowel,[971] omentum,[972] mesentery,[973] liver,[974] nasopharynx,[975] oral cavity,[295] tonsil,[976] soft tissues of head and neck region,[977] mediastinum,[978] spleen,[979] lung,[980] and breast.[981,982] Some cases of follicular dendritic cell tumor have occurred as a complication of the hyaline vascular type of Castleman disease,[983,984] and others in connection with inflammatory pseudotumor of the liver and spleen,[985] although the latter instance has been a constant association with EBV that is not seen in other sites.[974,986,987]

Microscopically, follicular dendritic cell tumor is characterized by a proliferation of oval to spindle cells that form fascicles and whorls (Fig. 37.105).[988] Sometimes there is a suggestion of a storiform or palisading pattern.[967,989] In other instances the stroma has a myxoid quality.[981] The appearance at low power may simulate that of meningioma. The nuclei are generally oval, with a vesicular chromatin pattern, small nucleoli, and scanty mitotic activity. Pseudonuclear inclusions and multinucleated giant cells may be present. A characteristic feature is the presence of small lymphocytes scattered throughout the tumor cells, resulting in a thymoma-like appearance.[990] The ultrastructural and immunohistochemical features correspond

to those of follicular dendritic cells (Fig. 37.106). Markers that are particularly useful for their identification are CD21, CD35, clusterin, Ki-M4P, and Ki-FDRC1p.[991,992]

The tumor cells are negative or equivocal for CD45RB and erratically positive for S100 protein. Although it was thought previously that these tumors do not exhibit clonal rearrangements of the immunoglobulin or the T-cell receptor genes, it has been shown recently that a proportion of cases indeed exhibit clonal rearrangements of immunoglobulin genes.[993]

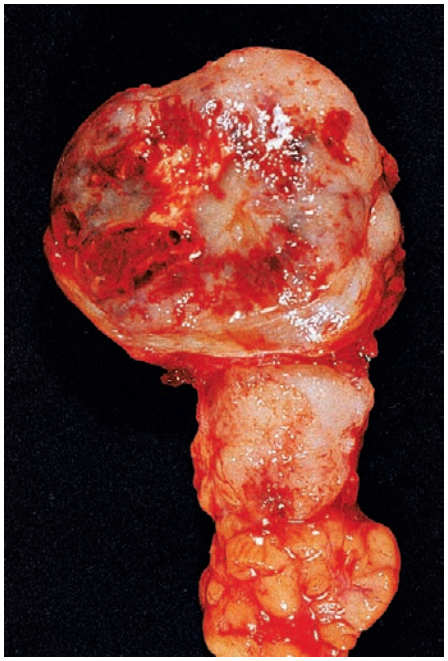

Figure 37.104 Gross appearance of follicular dendritic cell tumor.

The behavior is that of a malignant tumor, with local recurrence and distant metastases to sites such as the liver and lung.[994,992] The pattern of spread resembles that of a soft tissue sarcoma more than that of a malignant lymphoma. Intra-abdominal neoplasms tend to be particularly aggressive.[995] Recurrent and metastatic lesions may show increased atypia and pleomorphism.[992]

Interdigitating dendritic cell tumor (interdigitating reticulum cell sarcoma) is even more uncommon or perhaps not as easily recognized.[996] Most patients are adults, but it can also occur in the pediatric population.[997] Most of the reported cases have arisen in lymph nodes,[998,999] but instances of extranodal involvement in sites such as skin, bowel, spleen, and testis have been recorded.[979,1000–1002] The microscopic appearance can be indistinguishable from that of follicular dendritic cell tumor, but there is more tendency to spindling

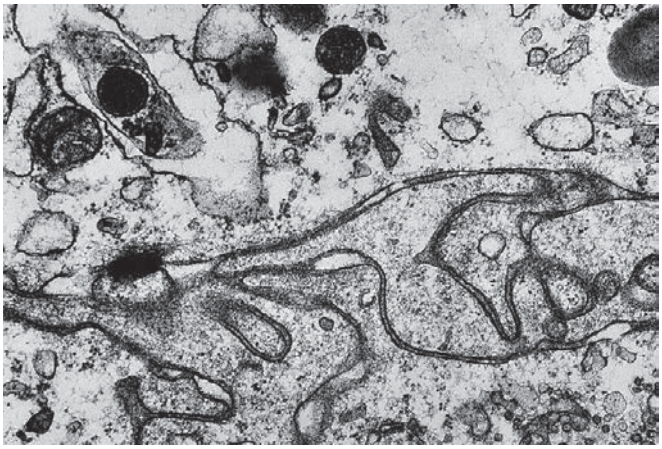

Figure 37.106 Electron Microscopic Appearance of Follicular Dendritic Cell Tumor. A characteristic feature is the presence of well-developed cytoplasmic prolongations joined by desmosomes.

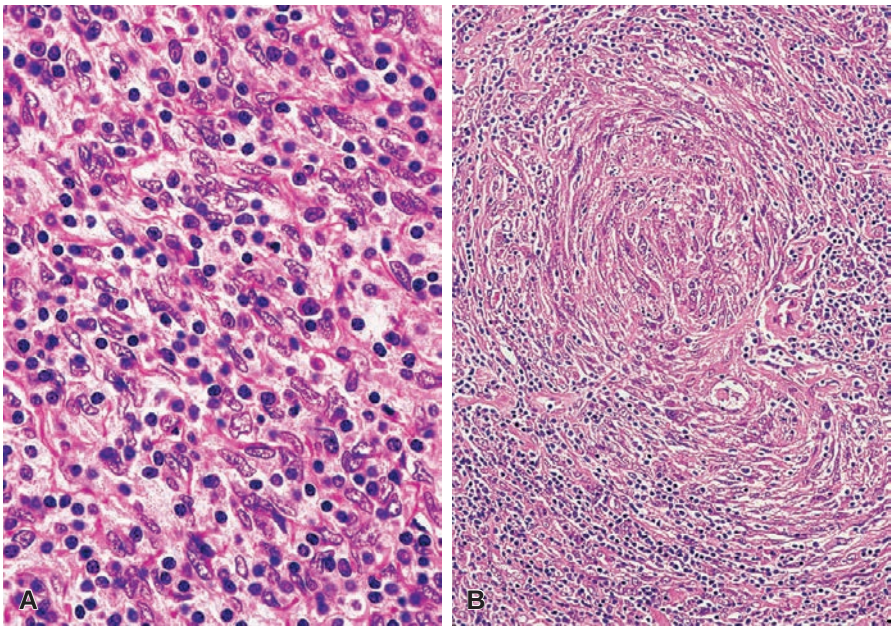

Figure 37.105 Follicular Dendritic Cell Tumor of Lymph Node. A, The admixture of neoplastic cells with predominantly oval vesicular nuclei and non-neoplastic small lymphocytes results in an appearance reminiscent of thymoma. **B**, Prominent whorling in a case of follicular dendritic cell tumor, engrafted upon Castleman disease.

and pleomorphism.[1003,1004] The diagnosis is dependent on the immunohistochemical profile, which unfortunately is not entirely specific. The tumor cells are positive for S100 protein but are negative for CD21 and CD35. The behavior seems more aggressive than for follicular dendritic cell tumor. Contrary to earlier belief, a proportion of cases are shown to exhibit clonal rearrangements of the immunoglobulin genes.[993,400]

Langerhans cell histiocytosis (LCH), also known as Langerhans cell granulomatosis, histiocytosis X, differentiated histiocytosis, and eosinophilic granuloma, is applied to a specific, although remarkably variable, clinicopathologic entity characterized and defined by the proliferation of Langerhans cells.[1005–1007] These cells are regarded as a distinct type of immune "accessory" cells that are involved in the capturing of some antigens and their presentation to the lymphoid cells. Contrary to a formerly held belief, these cells are not primarily phagocytic in nature. Their nuclei are highly characteristic: irregular, usually elongated, with prominent grooves and folds that traverse them in all directions. The cytoplasm is abundant and acidophilic, sometimes to the point that an embryonal rhabdomyosarcoma or ALCL is simulated. Most Langerhans cells are mononuclear, but occasional ones contain several nuclei while still maintaining the aforementioned nuclear and cytoplasmic features. An extensive eosinophil infiltrate usually accompanies LCH. Histochemically, they show weak acid phosphatase and nonspecific esterase activity but considerable leucyl-β-naphthylamidase activity and membrane-bound ATPase activity.[1008] They are believed to develop from a lymphoid-committed precursor,[1009] a hypothesis supported by the presence of an identical rearrangement of the IGH in cases with B-cell lymphoma and in cases without an associated lymphoma.[1010,1011]

In paraffin sections, both Langerhans cells and the cells of LCH are reactive for S100 protein, vimentin, langerin (CD207), fascin (a dendritic cell marker), CD1a, CD74, and HLA-DR in most cases (Fig. 37.107).[1012–1014] They also tend to be positive for peanut agglutinin lectin and the macrophage-associated antigens CD68, cathepsin D, and cathepsin E.[1015–1017] They generally do not express CD45RA, CD45RB, CDw75, α1-antitrypsin, EMA, or CD15. The most useful of these formalin-resistant epitopes are S100, CD1a,[1018] and langerin, the latter having a great degree of specificity and sensitivity.[1019,1020]

By electron microscopy, they contain a highly characteristic and apparently diagnostic organelle: the Birbeck or Langerhans granule, which correlates with langerin immunohistochemistry. This is an elongated, zipperlike cytoplasmic structure of unknown function, sometimes continuous with the cell membrane.[1021]

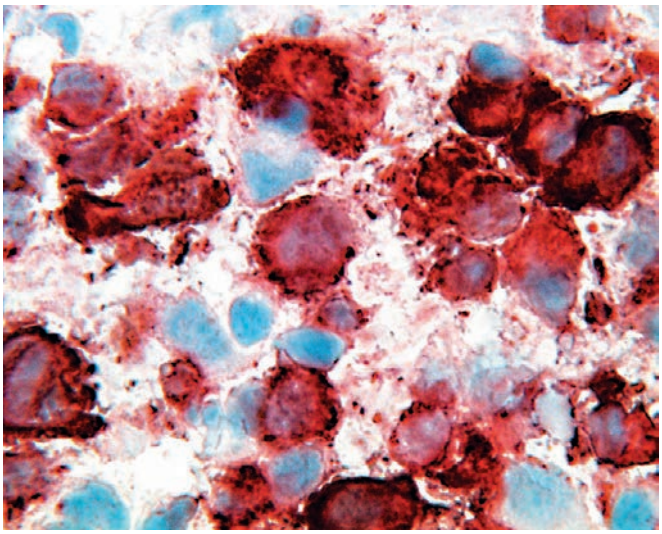

Figure 37.107 Immunoreactivity of the cells of Langerhans cell histiocytosis for langerin.

Scattered Langerhans cells are present in the skin, lymph node, thymus, and other organs in normal conditions and may be slightly increased in some disorders, such as interstitial lung diseases and dermatopathic lymphadenitis. Therefore the identification of a few cells with these features in one of these sites is not necessarily indicative that the patient has LCH.[1022] Rather, the infiltrate should have a sizable number of these cells before such a diagnosis is entertained.[1020] Conversely, the identification of Langerhans cells is necessary for the diagnosis of LCH. There is already too much confusion in the literature stemming from the fact that cases have been given this label only because a widespread proliferation of histiocytes was associated with a compatible clinical picture.

LCH can present as solitary or multiple lesions in one organ system (bone being the most common) or as a disseminated disease.[1023] Most patients are children or adolescents, but the disease can affect any age group, including the elderly.[1024] The treatment, prognosis, and terminology used largely depend on the extent (staging) of the disease rather than the microscopic features or the pattern of DNA ploidy.[1025–1028] The term **Letterer–Siwe disease** was used in the past for the systemic form occurring in infants, and **Hand–Schüller–Christian disease** for the less widespread and more indolent type seen in older children and adults.[1029] A self-healing, congenital form is known as **Hashimoto–Pritzker disease**.[1030]

Lymph node involvement can be seen as a component of the systemic form, or it may represent the initial and sometimes exclusive manifestation of the disease.[1031–1033] The microscopic appearance is characteristic. There is distention of the sinuses by an infiltrate of mononuclear and multinuclear Langerhans cells, admixed with a variable number of eosinophils (Fig. 37.108); foci of necrosis are common, often surrounded by a rim of eosinophils (so-called "eosinophilic microabscesses"), and always confined to the sinuses. The nodal architecture may be preserved or variably effaced.[1034]

Sometimes, incidental foci of LCH are seen in lymph nodes involved by non-Hodgkin lymphoma or Hodgkin lymphoma, a sharp segregation existing between the two processes.[1035,1036] In most of these cases, the Langerhans cell proliferation is limited to the node and may represent a reaction to the lymphoma,[1037] but in others it is an expression of generalized LCH.[1038] Follow-up studies have shown a broad spectrum of involvement, embracing all those syndromes that have been associated with LCH. However, the prognosis is usually excellent.

In addition to bone and lymph nodes, solitary LCH has been described in the lung, thymus, skin, central nervous system, and many other sites, including stomach, liver, anus, female genital tract, and thyroid[1039–1044] (see respective chapters). Changes morphologically consistent with LCH have been seen in coexistence with RDD, with Erdheim–Chester disease, and in lymph nodes draining malignant melanoma or papillary thyroid carcinoma.[1045,1046]

The differential diagnosis of LCH is wide and to some extent influenced by the site of involvement. It includes RDD, parasitic infections, Kimura disease, hypersensibility reactions, cat-scratch disease, Erdheim–Chester disease, and some types of malignant lymphoma, such as Hodgkin lymphoma and peripheral T-cell lymphoma.[1047]

The etiology of LCH remains unknown. A viral cause has been suggested but not substantiated.[1048,1049] Molecular studies have shown evidence of clonality in most cases, but some cases of localized pulmonary belch may be nonclonal.[359,1050,1051] Approximately 60% of cases have mutations of *BRAF* or associated pathways[1052–1054] and most *BRAF* V600E mutations can be identified by immunohistochemistry.[1051] The Langerhans cells are affected by recurrent cytogenetic

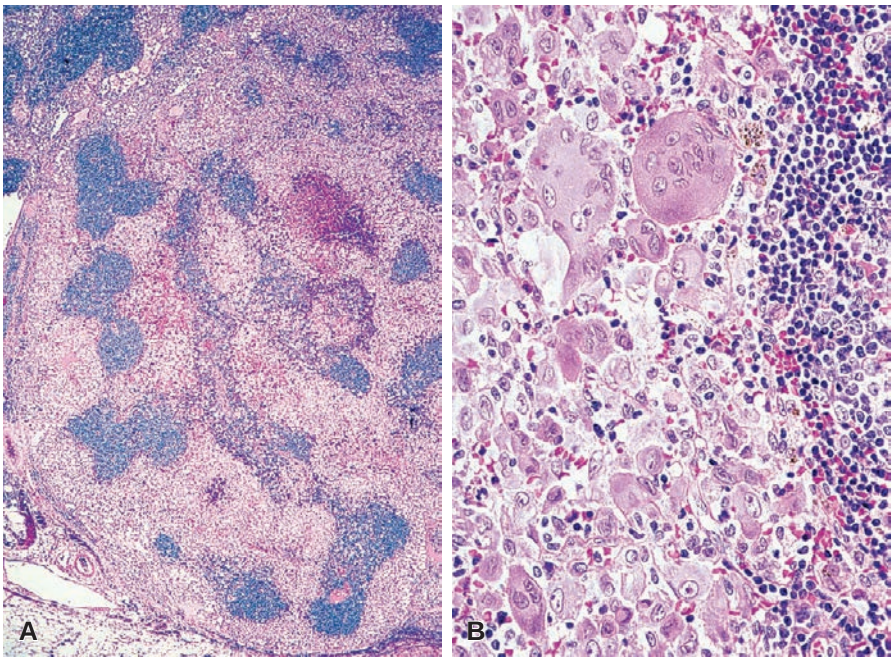

Figure 37.108 Lymph Node Involvement by Langerhans Cell Histiocytosis. A, The infiltrate has a predominantly sinus distribution. **B**, High-power view showing mononuclear and multinucleated Langerhans cells. There are also numerous eosinophils.

alterations[1055] and do not appear to be a particularly proliferative cell population.[1056]

Exceptionally, a morphologically malignant process is seen in which the tumor cells have the ultrastructural and immunohistochemical features of Langerhans cells.[1057–1059] This is to be regarded as **Langerhans cell sarcoma**.[1060]

Indeterminate dendritic cell tumor is a rare neoplasm that more commonly involves skin but has been reported in lymph nodes.[1061,1062] It has features of LCH, with expression of S100 and CD1A, but lacks Birbeck granules by electron microscopy and langerin by immunohistochemistry. Recently, a fusion of *ETV3-NCOA2* has been reported as unique to this tumor.[1063]

Erdheim–Chester disease is another "histiocytosis" of unknown etiology involving mainly the central nervous system, bones, and lung. The histiocytes in this condition are only focally S100 positive, are negative for CD1a and langerin, and lack Birbeck granules.[1064]

Histiocytic sarcomas (malignant histiocytosis) are malignant neoplasms of histiocytic lineage that do not meet criteria for other accessory cell neoplasms. Their presentation is highly variable, with a high proportion of extranodal involvement in sites such as the spleen, skin, bone, and particularly the gastrointestinal tract.[1065–1069] As in the case of the dendritic cell tumors, some "true histiocytic sarcomas" have been seen in combination with bona fide malignant lymphoma,[1070] and some subdivide these tumors into primary and secondary disease.[966] Microscopically, the tumor cells are large, with irregularly shaped nuclei and abundant, generally acidophilic cytoplasm. Immunohistochemically, the tumor cells lack by definition B cell– and T cell–related markers and show reactivity for histiocytic markers, such as CD68, CD163, lysozyme, and CD4.[1071–1073]

Although the presence of immunoglobulin or T-cell receptor gene rearrangement was previously considered to be incompatible with a diagnosis of histiocytic sarcoma, recent studies have shown that clonal immunoglobulin gene rearrangement, and rarely T-cell receptor gene rearrangement, can occur in up to 50% of cases.[401,993] This phenomenon is observed in sporadic cases as well as cases that occur subsequent to or concurrent with B- or T-lymphoblastic leukemia/lymphoma or low-grade B-cell lymphoma (especially follicular lymphoma).[401,993,1074–1076] In the latter scenario, the histiocytic sarcoma often shares the clonal markers of the previous leukemia/lymphoma, such as immunoglobulin gene rearrangement, *BCL2* rearrangement, and clonal cytogenetic aberrations.[401,1074]

Vascular Tumors and Tumorlike Conditions

Hemangioma and **lymphangioma** involving nodes usually represent extension by contiguity of primary soft tissue lesions. However, rare cases of primary nodal hemangioma and lymphangioma have been described (Fig. 37.109).[1077,1078]

Epithelioid vascular neoplasms of lymph nodes include epithelioid hemangioma, epithelioid hemangioendothelioma, spindle and epithelioid hemangioendothelioma, and polymorphous hemangioendothelioma, which are discussed in more detail elsewhere.[1079–1082]

Bacillary angiomatosis, which occurs almost exclusively in the setting of immunodeficiency (especially in patients with HIV infection), presents as multiple coalescent intranodal clusters of proliferating vessels. These vessels are lined by plump, somewhat epithelioid endothelial cells (hence the original term epithelioid angiomatosis for this condition). A feature of great diagnostic importance is the presence of abundant eosinophilic to amphophilic, amorphous, or granular material in the interstitium. Another helpful feature is the presence of neutrophils, sometimes forming microabscesses.[1083–1085] When stained with the Warthin–Starry technique, this material is shown to be composed of aggregated bacillary organisms, now known to represent *Bartonella henselae* and *Bartonella quintana*, that are indistinguishable from those of cat-scratch disease (also

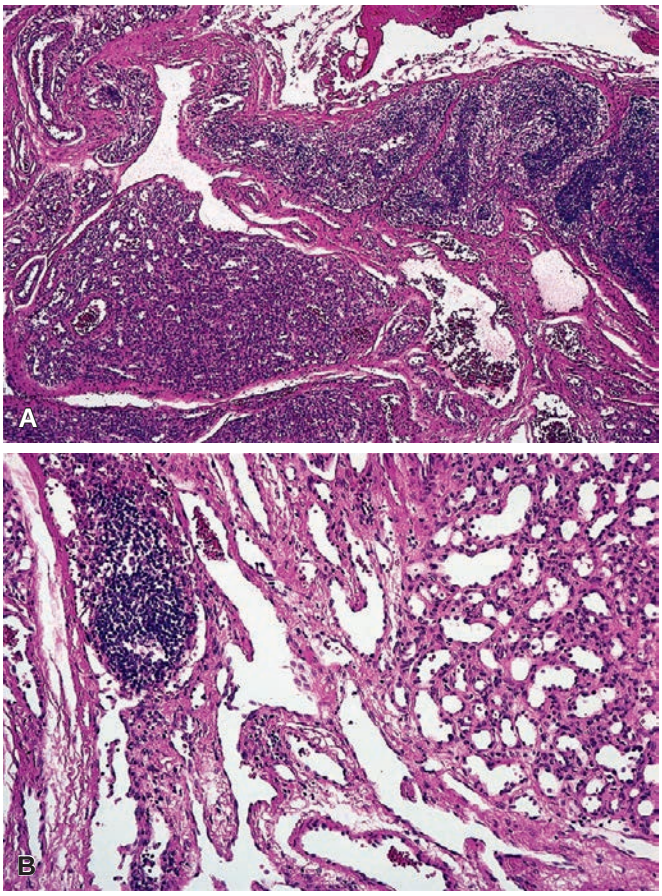

Figure 37.109 Low-power (**A**) and medium-power (**B**) views of nodal hemangioma.

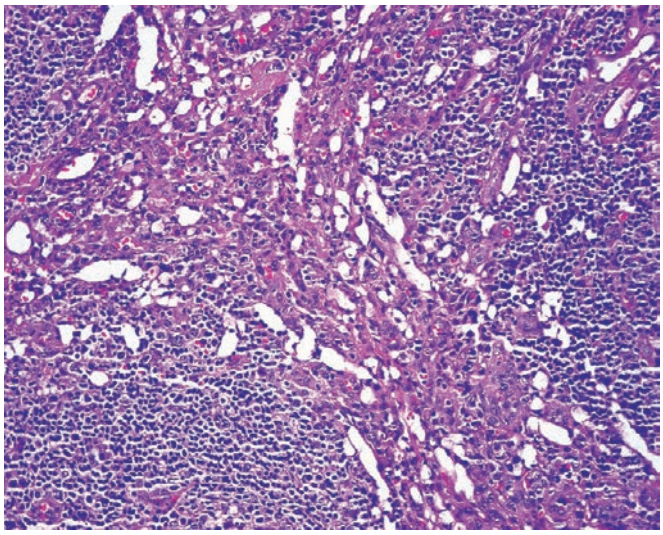

Figure 37.110 Lymph Node Involvement by Bacillary Angiomatosis. An intense vascular proliferation featuring epithelioid endothelial cells is seen in the interfollicular region, accompanied by neutrophils and other inflammatory cells.

caused by *B. henselae*). These organisms may be more precisely detected by immunohistochemistry or PCR. A recent study of the lymph nodes changes associated with *B. henselae*, however, found that infection was usually not associated with features of bacillary angiomatosis.[1086]

Vascular transformation of sinuses is characterized by a conversion of lymph node sinuses into a complex network of anastomosing endothelial-lined channels (Fig. 37.110).[1087] Fibrosis and reactive stromal changes are commonly present.[1088] *Nodal angiomatosis* probably refers to a more cellular form of the same condition (Fig. 37.111).[1089,1090] In the *nodular spindle-cell variant*, spindle-cell nodules composed of interlacing fascicles alternate with the vascular clefts.[1091] This variant is particularly likely to be misdiagnosed as Kaposi sarcoma. It is distinguished from the latter because it is HHV8-negative, is confined to the sinuses (with sparing of the capsule and parenchyma), shows no cellular atypia, contains fascicles that blend with well-formed vascular channels, commonly is associated with fibrosis, and almost invariably lacks the PAS-positive hyaline globules of Kaposi sarcoma (Fig. 37.112).[1092,1093] Other cases of vascular transformation may result from proximal obstruction of the efferent vessels; indeed, the process has been reproduced experimentally by complete occlusion of these vessels.[1094]

Angiolipoma (including its cellular variant) is usually located in the soft tissue, but exceptionally it may be centered in a lymph node.[1095]

Kaposi sarcoma of the lymph nodes may be associated with typical skin lesions or develop in their absence.[1096] The latter occurrence is seen mainly in African children, but it also occurs in adults (usually but not always HIV infected). Microscopically, the involved nodes show proliferation of spindle cells separated by slitlike spaces containing red blood cells (Fig. 37.113).[1097] The earliest changes are seen in the nodal capsule, but eventually there is involvement of the entire node and extension into the perinodal tissues. Cytoplasmic and extracellular hyaline globules that are positive for PAS and PTAH are almost always present.[1098] Recognition of early nodal involvement by Kaposi sarcoma is an extremely difficult task; although a definitive diagnosis can be made if immunostaining for HHV8 is positive in the proliferating spindle cells. In well-developed cases, the tumor may grow in a diffuse fashion or as discrete deposits. The spindle-cell lesion is often accompanied by a lymphoid proliferation with a prominent component of plasma cells and immunoblasts. Kaposi sarcoma is also associated with HHV8+ multicentric Castleman disease, usually of the plasma cell type.[269] In other instances, nodal Kaposi sarcoma coexists with malignant lymphoma or leukemia.[1099]

If a lymph node is involved by a malignant tumor with the morphologic features of **angiosarcoma**, there is a high probability that the tumor is metastatic (Fig. 37.114).

Other Primary Tumors and Tumorlike Conditions

Systemic mastocytosis often involves lymph nodes, resulting in partial (usually interfollicular) or complete effacement of the architecture by a monotonous proliferation of round, spindled or polygonal cells (Fig. 37.115).[1100,1101] Clues as to the nature of the proliferation include the regular contours of the round or oval nucleus, the clear or granular cytoplasm, the well-defined cell outlines, admixture of eosinophils, and accompanying sclerosis. Special techniques that confirm mast cell lineage, especially immunohistochemical stains for CD117 and tryptase, are required for diagnosis[1102–1108].

Acute myeloid leukemia can first be seen in a lymph node biopsy and misdiagnosed as malignant lymphoma.[1109] Traditionally, the disease has been referred to as granulocytic sarcoma, myeloid sarcoma, or chloroma when appearing as a tumor mass in a lymph node or

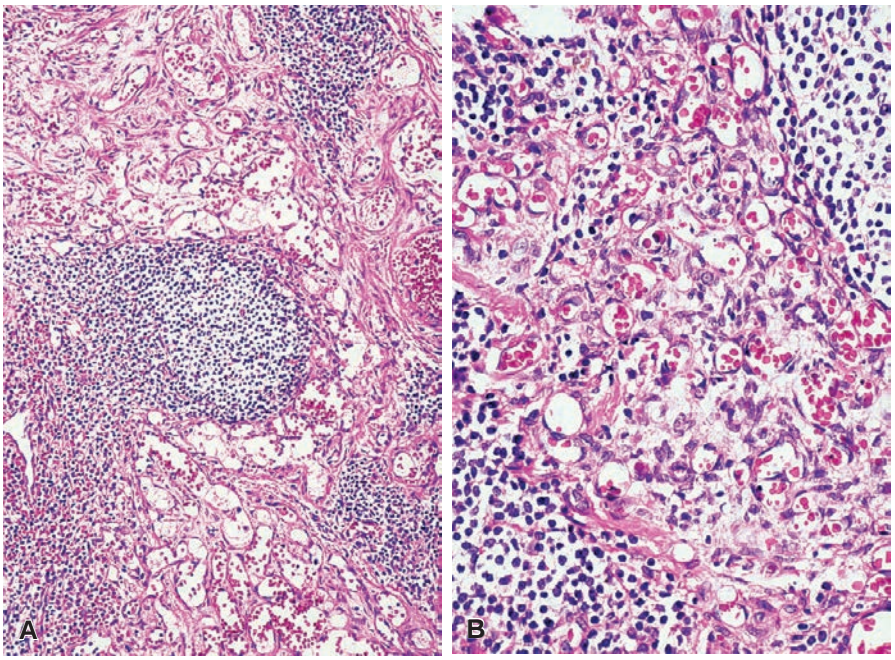

Figure 37.111 **A** and **B**, Vascular transformation of lymph nodes. The process involves the sinuses, and it has a reactive appearance.

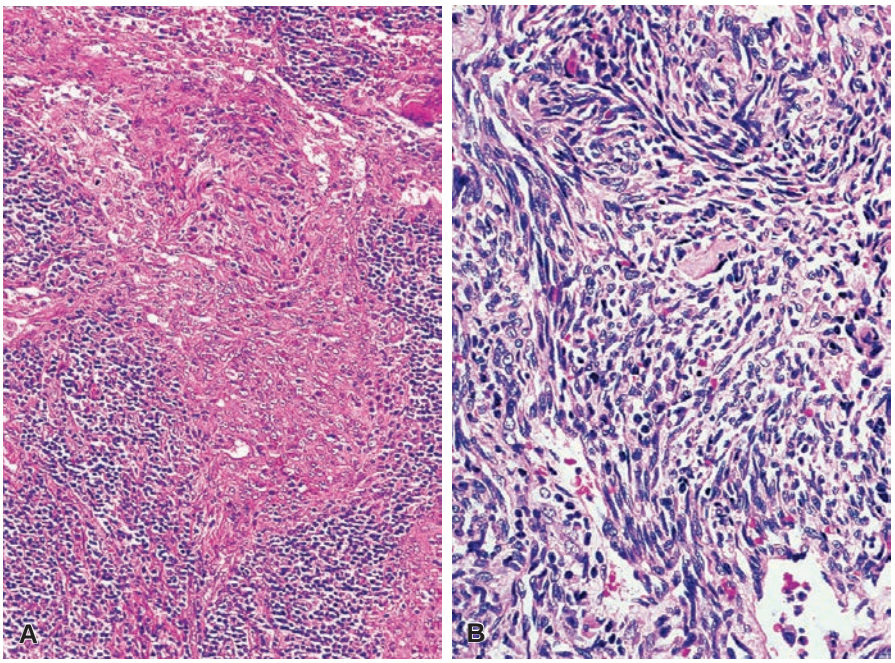

Figure 37.112 **Solid Form of Vascular Transformation of Lymph Nodes.** This process has also been designated as nodal angiomatosis. **A,** Predominantly sinus distribution of the lesions. **B,** Example in a retroperitoneal lymph node in a patient with renal cell carcinoma.

some other location outside the bone marrow (Fig. 37.116). Clues to the diagnosis include a patchy or sinus type of nodal involvement, sometimes associated with a single-file pattern of infiltration in the capsule; fine granularity of the cytoplasm; fine nuclear chromatin without the typical chromatin clearing of DLBCL, and presence of eosinophilic myelocytes. Immunohistochemically, there is reactivity for CD43, lysozyme, myeloperoxidase, CD99, and CD117.[1110,1111] Identification of a myeloid sarcoma should trigger a bone marrow evaluation. If negative, additional material from lymph nodes, even if by fine-needle aspiration, should be obtained to preform complete immunophenotyping, karyotype analysis, and molecular studies necessary to complete classify the acute myeloid leukemia (see Chapter 39) *Extramedullary hematopoiesis,* either reactive or secondary to a myeloproliferative neoplasm, accompanied by megakaryocytes can

be confused with Hodgkin lymphoma and other malignancies (Fig. 37.117). A Leder chloroacetate or myeloperoxidase stain will reveal the maturing myeloid forms.

Smooth muscle proliferations of a primary nature can be seen within lymph nodes in the following situations:

1. *Smooth muscle proliferation in the hilum*. This is often accompanied by fibrosis and prominent vascularity.[1112] It is most common in the inguinal region and is of no clinical significance.
2. *Angiomyolipoma*. The most common location is the retroperitoneal region, usually in conjunction with a renal tumor of the same type.[1113] Immunoreactivity for HMB45 and other melanocyte-related markers is a constant feature of this entity.
3. *Lymphangiomyomatosis*. This is seen exclusively in women, often in association with pulmonary involvement, but sometimes showing pelvic lymph node involvement alone as an incidental

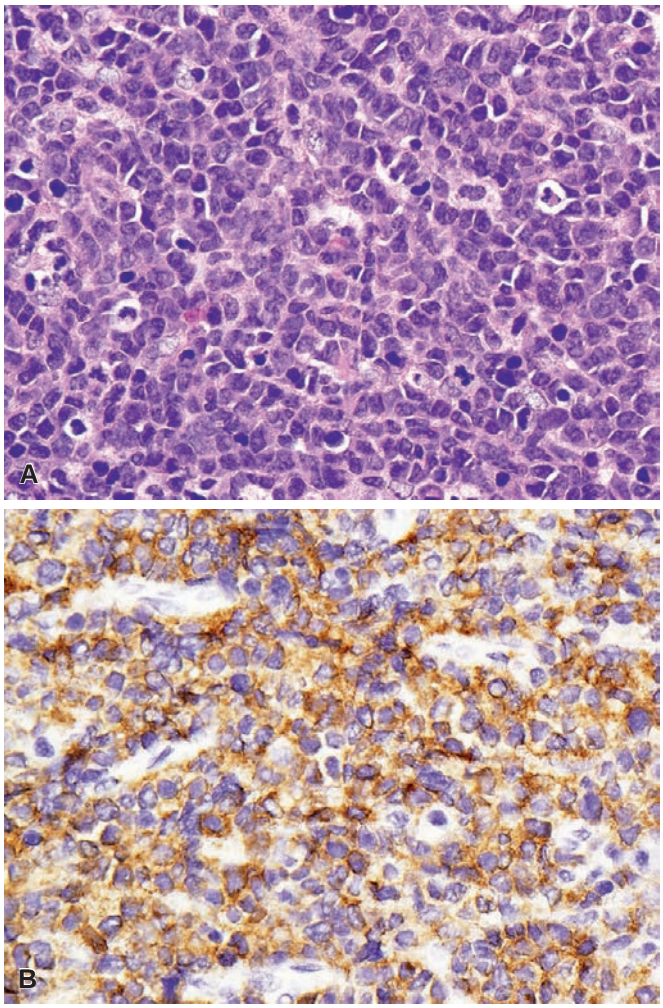

Figure 37.116 Lymph Node Involved by Acute Myeloid Leukemia (Myeloid Sarcoma). A, The infiltrate is medium in size with irregular nuclear contours but fine nuclear chromatin. **B**, The cells express the myeloid-associated antigen CD33.

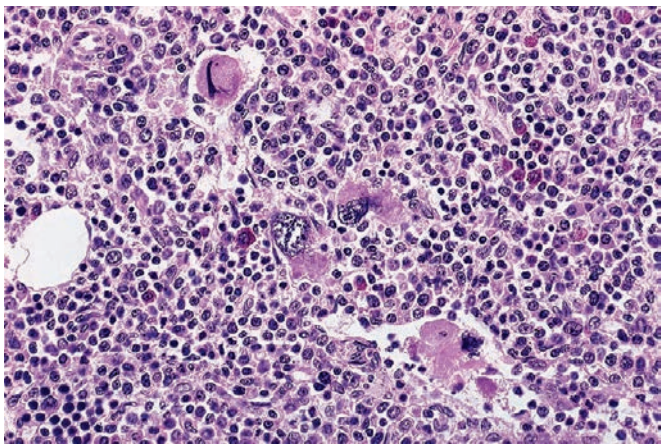

Figure 37.117 Scattered Megakaryocytes in Lymph Node Involved by Extramedullary Hematopoiesis. These elements should not be confused with Reed–Sternberg cells or carcinoma cells.

finding.[1114] Like the previous entity, to which it is histogenetically related, it exhibits immunoreactivity for HMB45.

4. *Leiomyomatosis*. This has been reported mainly in intra-abdominal nodes, sometimes in association with uterine leiomyomas or leiomyomatosis peritonealis disseminata.[1115,1116]
5. *Angiomatous hamartoma*. This is a distinctive form of smooth muscle proliferation that seems to occur only in the inguinal region. It is characterized by a proliferation of thick-walled hilar blood vessels that sometimes extends into the nodal parenchyma.[1079]
6. *Intranodal leiomyoma*. Some of the reported cases have occurred in the setting of HIV infection.[1117]

Hemorrhagic spindle-cell tumor with amianthoid fibers (also known as palisaded myofibroblastoma) is a distinctive benign neoplasm that occurs preferentially in inguinal lymph nodes but that can involve nodes of other sites, such as the neck and mediastinum.[1117–1123] The main microscopic features are the proliferation of bland-looking spindle cells, sometimes in a palisading fashion; extensive foci of recent and old hemorrhage; and giant rosettelike collections of collagen fibers (so-called "amianthoid fibers") (Fig. 37.118).[1124–1126] The differential diagnosis includes Kaposi sarcoma and intranodal schwannoma. Immunohistochemically, the spindle cells are reactive for vimentin and actin, particularly around the rosettelike formations, and are negative for LANA-1 (HHV8) and S100 protein. The staining qualities and ultrastructural features are more in favor of a smooth muscle than a myofibroblastic derivation.[1127] The behavior has been benign in all reported cases, but there has been an isolated instance of recurrence.[1128]

Inflammatory pseudotumor-like change of lymph nodes may be localized or affect several lymph node groups and may be accompanied by fever, anemia, elevated erythrocyte sedimentation rate, and hypergammaglobulinemia.[1129–1133] Microscopically, the process involves primarily the fibrous stroma of the node, with secondary spread into the lymphoid tissue and perinodal tissues. It is characterized by a storiform pattern of growth, vascular proliferation, and a polymorphic infiltrate composed of fibroblasts, plasma cells, immunoblasts, small lymphocytes, histiocytes, dendritic cells, and neutrophils (Fig. 37.119). Morphologic variations on this basic theme exist, which have been attributed to the stage of the disease at which the biopsy has been taken.[1134] In contrast to morphologically similar, but neoplastic, lesions in the spleen and liver, EBV is not usually present in lymph node cases.[1135] A diagnosis of inflammatory pseudotumor in lymph nodes is not a specific diagnosis and often represents a chronic response to infection or other damage. The cause is unknown in most patients, but some are responses to infectious organisms, including syphilitic infection[151] and *Mycobacterium avium-intracellulare* infection.[120] The latter occurs in immunocompromised individuals (mycobacterial spindle cell pseudotumor) (Fig. 37.120).

Anthracosis and **anthracosilicosis** can result in a pseudoneoplastic appearance because of the presence of a sometimes intense histiocytic proliferation with a focally storiform pattern of growth (Fig. 37.121).[1136]

Solar elastotic material can be found in the subcapsular sinus and parenchyma of lymph nodes, presumably as a result of mechanical transport from the skin.[1137]

Lymph Node Inclusions

Inclusions of various types of benign tissue can occur within lymph nodes.[1138] Lack of awareness of this phenomenon can lead to a mistaken diagnosis of metastatic carcinoma. These include the following:

1. *Salivary gland tissue*. This is an extremely common finding in high cervical nodes, to be regarded as a normal event related to

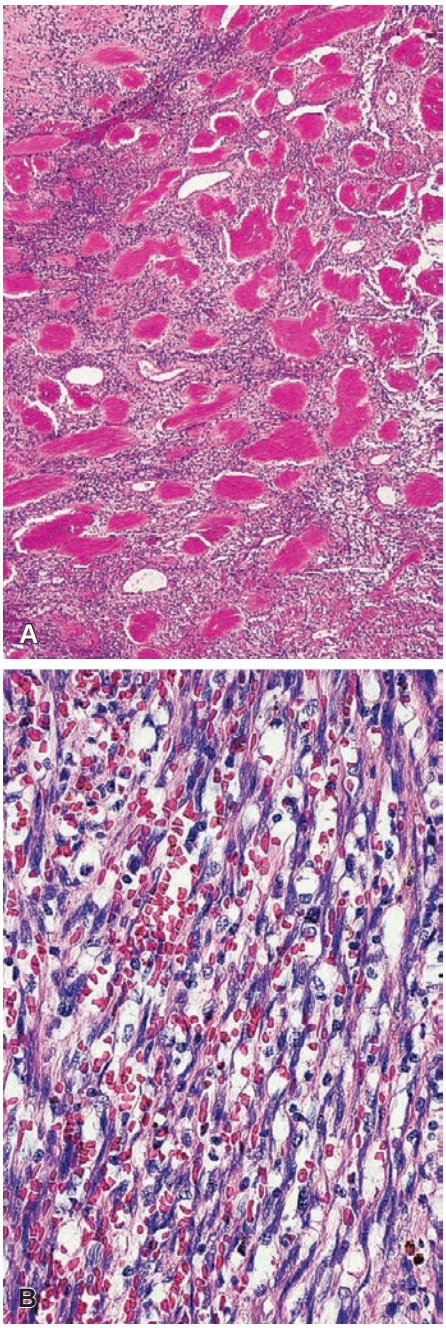

Figure 37.118 Hemorrhagic Spindle Cell Tumor With Amianthoid Fibers. A, Prominent deposition of "amianthoid" collagen throughout the tumor. **B**, The admixture of neoplastic spindle cells and extravasated red blood cells results in a Kaposi sarcoma-like appearance.

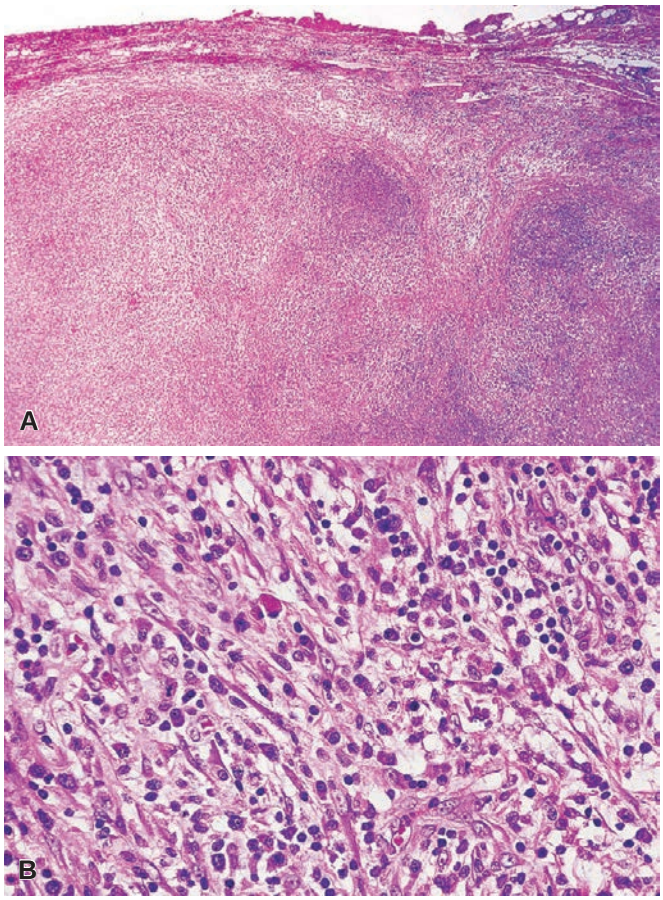

Figure 37.119 Inflammatory Pseudotumor of Lymph Node. A, Low-power appearance showing partial effacement of architecture and expansion of the sinusal and perinodal regions by a reactive proliferation. **B**, High-power view showing a polymorphic infiltrate composed of lymphocytes, plasma cells, and myofibroblasts.

the embryology of the region (Fig. 37.122).[1139] Both ducts and acini are usually present. These inclusions may undergo neoplastic changes. Warthin tumor is the most common type, but many other types have been reported, including benign mixed tumor, monomorphic adenoma, mucoepidermoid carcinoma, and acinic cell carcinoma.

2. *Squamous epithelium*. Microscopic cystic structures lined by well-differentiated squamous epithelium are sometimes seen in the upper cervical lesion. They are thought to represent an anomaly related to the aforementioned one, in the sense of being composed of branchial pouch derivatives. The term "benign lymphoepithelial cyst" is sometimes applied to them. We have hypothesized that these formations result from cystic dilation of preexisting epithelial inclusions as the result of their stimulation by the lymphoid component that surrounds them, a pathogenesis that also applies to multilocular thymic cysts, other cystic structures of the head and neck region, and possibly to Warthin tumor itself (see Chapter 6). Similar formations have been described in peripancreatic lymph nodes.[1140] The obvious differential diagnosis is metastatic well-differentiated squamous cell carcinoma, which in the cervical region is notorious for its tendency to undergo marked cystic changes.[1141]
3. *Thyroid follicles*. These can be found in the capsular or subcapsular region of midcervical nodes in the absence of pathologic changes of the thyroid gland. The differential diagnosis with metastatic thyroid carcinoma can be very difficult.
4. *Decidual reaction*. During pregnancy, decidual reaction may occur within pelvic nodes and mimic metastatic carcinoma.[1142] The decidual reaction can occur in the stromal cells of endometriosis or in hormonally receptive cells of the region, in a fashion similar to that seen in peritoneal decidual reaction.
5. *Müllerian-type epithelium*. Glandular inclusions lined by cuboidal cells with a müllerian or coelomic appearance are commonly found in the capsule of the pelvic lymph nodes of females and sometimes within the node itself.[1143,1144] Their appearance and pathogenesis are similar to those of the peritoneal lesions generally known as endosalpingiosis (Fig. 37.123). Like the latter, these

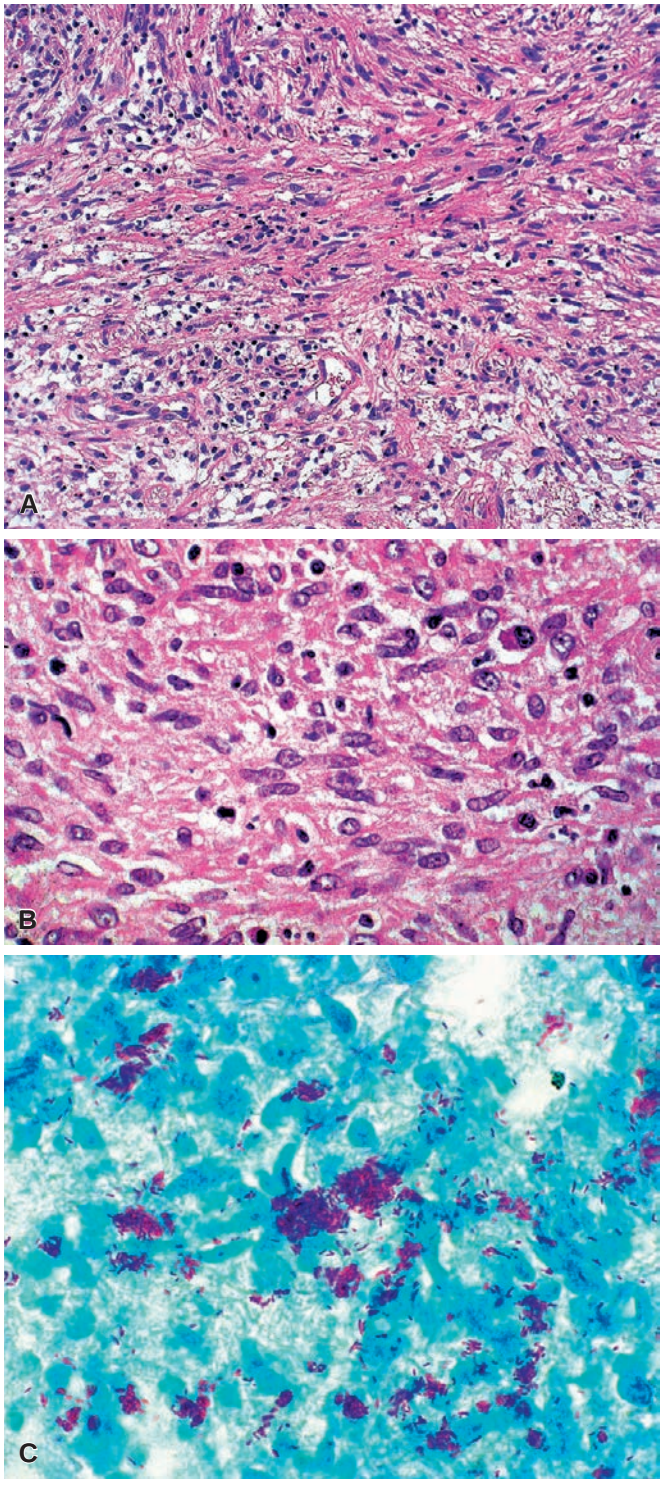

Figure 37.120 Inflammatory Pseudotumor of Lymph Node Due to *Mycobacterium avium-Intracellulare* Infection in an HIV-Infected Patient. A, Low-power view, showing spindle cell admixed with lymphocytes. **B**, High-power view. **C**, Acid-fast stain.

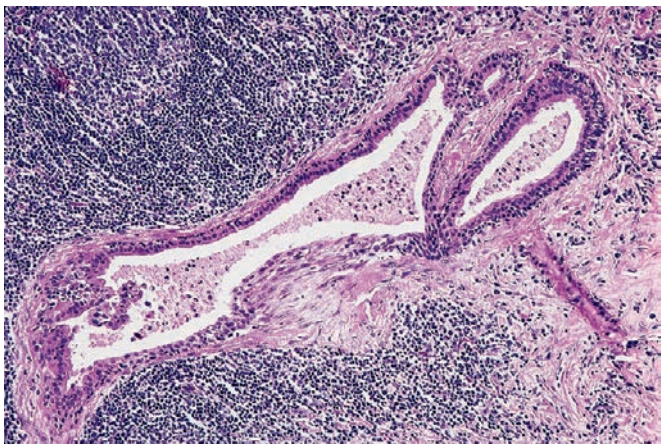

Figure 37.122 Salivary Gland Inclusion Composed of Ductal Structures in a High Cervical Lymph Node. This is a very common occurrence.

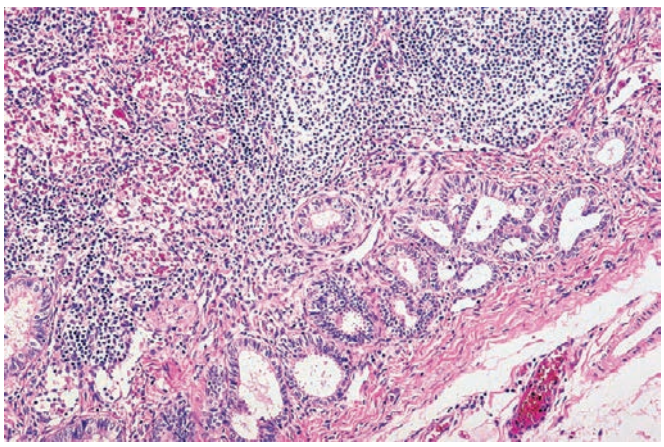

Figure 37.123 Pelvic Lymph Node Involved by Endosalpingiosis. Glands lined by cuboidal cells with a müllerian appearance and lacking atypical figures are present in the capsule of the node.

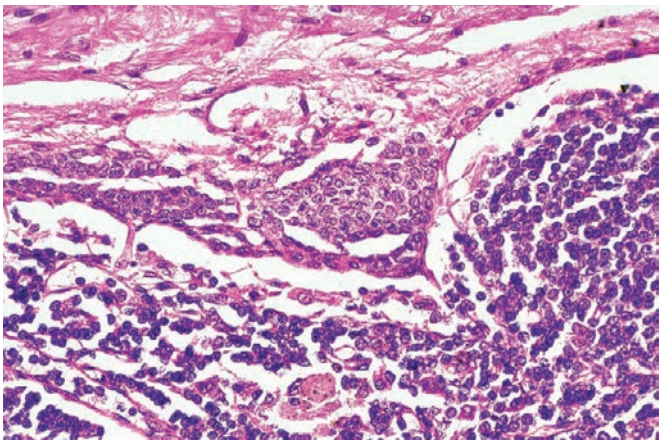

Figure 37.124 Nevus Cells in the Capsule of an Axillary Lymph Node. These inconsequential formations should not be mistaken for metastatic melanoma or metastatic carcinoma.

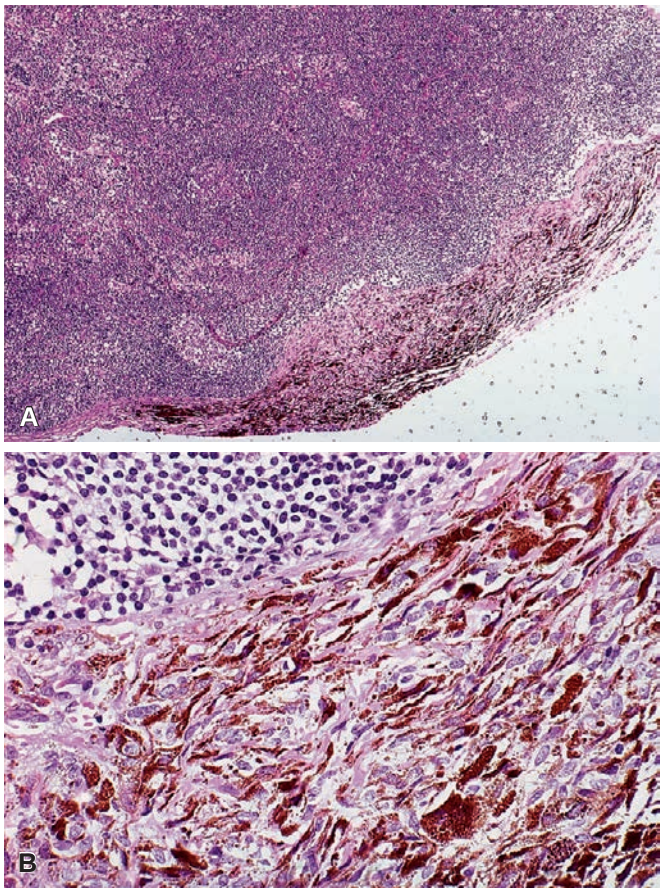

Figure 37.125 A and **B**, Blue nevus involving lymph node capsule.

lymph node inclusions may be difficult to distinguish from metastases originating in low-grade ovarian neoplasms, since they may grow into the peripheral sinuses, form papillae, be accompanied by psammoma bodies, and even proliferate as small sheets of cells.[1145] Some authors have suggested that some of these "inclusions" are actually metastases from ovarian serous borderline tumors.[1146] Morphologically similar inclusions have been seen in the mediastinal nodes of males[1138] and axillary nodes of females. Nodal glandular inclusions of similar appearance but surrounded by endometrial-type stroma occur less frequently and represent *nodal endometriosis*.

6. *Nevus cells*. Clusters of normal-appearing nevus cells are occasionally found in the capsule of lymph nodes, without involvement of the nodal parenchyma (Fig. 37.124). Most of the reported cases have occurred in axillary lymph nodes.[1147] A related lesion is the *blue nevus* that has been reported in the lymph node capsule (Fig. 37.125).[1148] The morphologic features of these formations and their differential diagnosis with metastatic malignant melanoma are discussed in Chapter 3.
7. *Mesothelial cells*. Occasionally, mesothelial cells are found within lymph nodes in the apparent absence of a malignant mesothelioma.[1149–1151] The obvious differential diagnosis is with metastatic malignant mesothelioma from an occult primary in the peritoneal cavity or pleura.[1152]
8. *Breast tissue*. One of the most unusual forms of ectopia is represented by normal mammary lobules within axillary lymph nodes.[1153–1155] A slightly more common occurrence is the presence in axillary nodes of tubules lined by a single layer of cuboidal cells (sometimes with a hobnail appearance), located in the nodal capsule or immediately beneath. These formations are similar to the müllerian-type epithelial inclusions in pelvic lymph nodes previously described. Since some of these cases occur in patients with breast carcinoma, the distinct possibility exists of mistaking them for metastatic tumor.[1156,1157] Epithelial inclusions in axillary lymph nodes of females can be classified into three major groups: those composed exclusively of glandular structures, those made up only of squamous cysts, and those containing both glandular and squamous epithelium.[1158]

Other Non-Neoplastic Lesions

Adipose metaplasia of lymph nodes is very common. When extensive, it may lead to the formation of large masses, up to 10 cm or more in diameter. These nodes are sometimes referred to as *lipolymph nodes*; the external iliac and obturator groups are the sites most commonly involved.[1159]

Ectopic thymus sometimes seen in supraclavicular lymph node biopsies should be mentioned here for the sake of differential diagnosis even if it is not a lymph node lesion. The pathologist unaware of this occurrence might easily misinterpret the Hassall corpuscles as islands of metastatic squamous cell carcinoma.

Vasculitis involving lymph nodes may be seen in a large number of disorders: polyarteritis nodosa (having necrotizing qualities and only rarely biopsied), Henoch–Schönlein purpura (leukocytoclastic, also rarely biopsied), Wegener granulomatosis (sometimes accompanied by extensive infarct), systemic lupus erythematosus, drug hypersensitivity, and mucocutaneous lymph node syndrome. One should also mention the obliterative vasculitis often seen in syphilitic lymphadenitis.

Infarction of the lymph nodes presents with painful swelling, usually located in a superficial lymph node chain. Microscopically, there is extensive necrosis of medullary and cortical lymphoid cells, with marked reactive perinodal inflammation and a layer of granulation tissue. A thin rim of viable subcapsular lymphoid tissue may be present.[1160] Thrombosis of veins within the substance and the hilum of the nodes has been suggested as the pathogenesis.[1160] Similar changes can be seen in mesenteric lymph nodes in patients with intestinal volvulus.[1161] Other cases are the result of embolism, arterial occlusion in cases of polyarteritis nodosa and related disorders, or fine-needle aspiration;[1162,1163] in these instances, the nodal infarct tends to have a segmental quality. The differential diagnosis of lymph node infarction includes necrotizing lymphadenitis, mucocutaneous

lymph node syndrome, infectious mononucleosis,[1164] necrotizing granulomatous inflammation, and necrotic malignant tumors. Two types of malignancy that have been occasionally found to undergo extensive and sometimes massive infarct-type necrosis when involving lymph nodes are malignant lymphoma[1165,1166] and metastatic malignant melanoma. Therefore thorough examination of the infarcted node, the extranodal region, and other nodes submitted is mandatory in order to exclude a concomitant or underlying malignancy (Fig. 37.126A and B).[1166] A thorough immunohistochemical study is also in order. Tumor cells reactivity for CD20 in the face of extensive necrotic changes is retained (see Fig. 37.126C).[1167,1168] As a general rule, the possibility of an underlying malignancy should be suspected if the infarcted node is markedly enlarged.

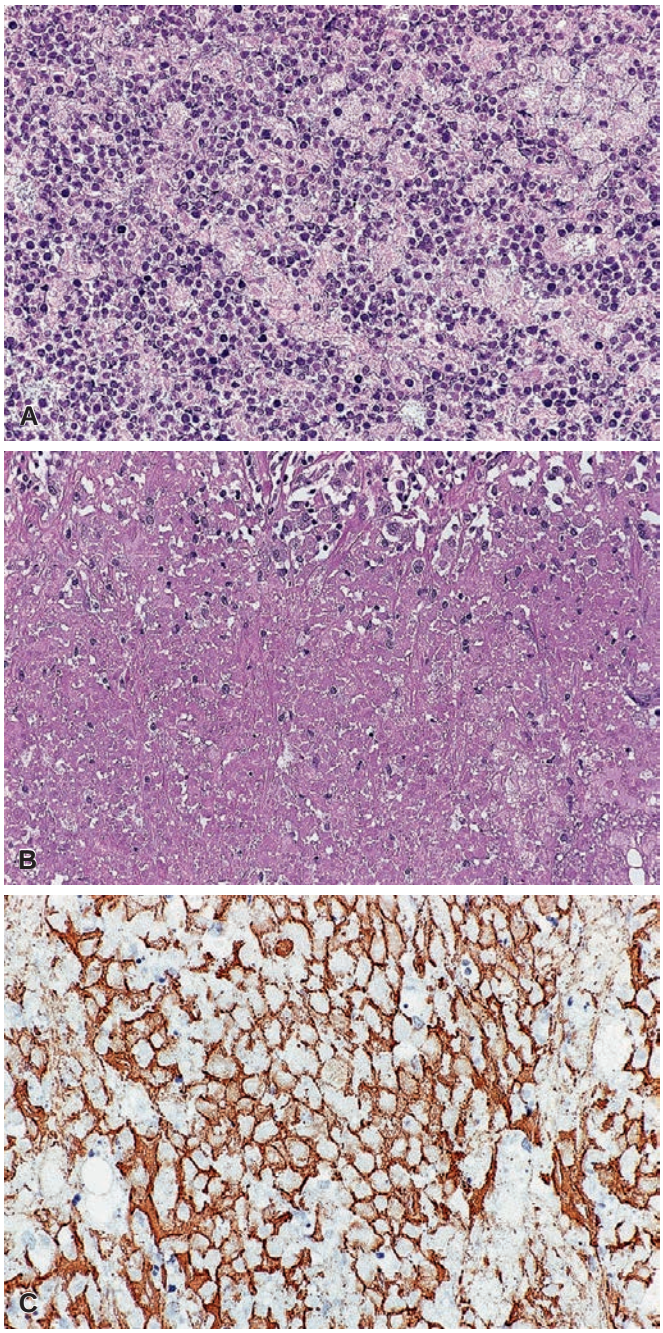

Figure 37.126 **A–C**, Large B-cell lymphoma that has undergone massive infarct-type necrosis. **A**, The outlines of the tumor cells can still be discerned. **B**, A totally necrotic area, indistinguishable from that of a "benign" infarct. **C**, There is a remarkable degree of retained immunoreactivity for CD20 in the necrotic area.

Hyaline material sometimes accumulates in the stroma of lymph nodes. This finding is very frequent in those situated in the aorto-iliac region (Fig. 37.127). The material can undergo secondary calcification. Because of its homogeneous eosinophilic appearance, it can be confused with amyloid and has been referred to in the past as *paraamyloid*. It should also be distinguished from the hyaline material deposited in nodes in cases of hemorrhagic spindle cell tumor with amianthoid fibers. The presence of this hyaline material, which is probably an abnormal type of collagen, has no clinical significance.

Proteinaceous lymphadenopathy is the name given to a lymph node abnormality in which an eosinophilic extracellular material of proteinaceous nature is deposited in lymph nodes. This material simulates the appearance of amyloid but is histochemically and ultrastructurally distinct from it. The few patients who have been described with this obscure abnormality had hypergammaglobulinemia, and the hyaline material itself has been shown to contain precipitated immunoglobulin.[1169]

Foreign material of various types can accumulate in lymph nodes. One example is the *silicone lymphadenopathy* developing as a side effect of mammary augmentation produced by injection of liquid silicone or by placement of a bag-gel prosthesis. Microscopically, a nonbirefringent refractive material is present in the sinuses, together with variously sized vacuoles and multinucleated giant cells (Fig. 37.128).[1170]

Another example is the already mentioned sinus histiocytosis of pelvic lymph nodes, which is induced by the cobalt-chromium and titanium contained in hip prostheses (Fig. 37.129).[1171]

Metastatic Tumors

Lymph nodes are the most common site of metastatic malignancy and sometimes constitute the first clinical manifestation of the disease.[1172–1174] The task of the pathologist is to identify the presence of a malignant process in the node, to establish whether it is metastatic or not, and—if metastatic—to provide an estimate of its amount, microscopic type, and possible source. If malignant cells are identified within the efferent lymph vessels and/or extranodal adipose tissue, this should also be noted in the report because of the possible prognostic significance of these findings.

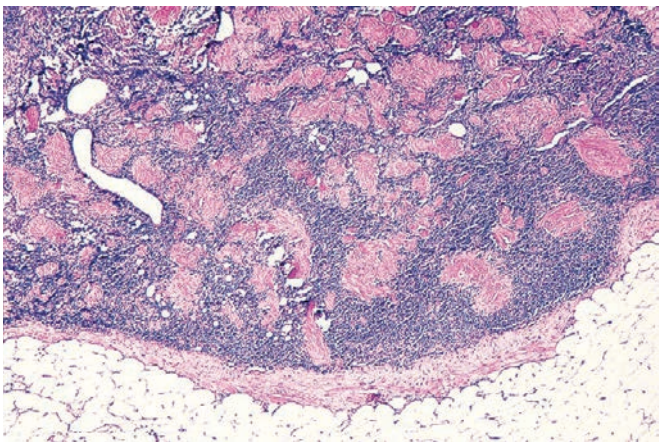

Figure 37.127 **Hyaline Deposits in Pelvic Lymph Node.** This change is of no clinical significance.

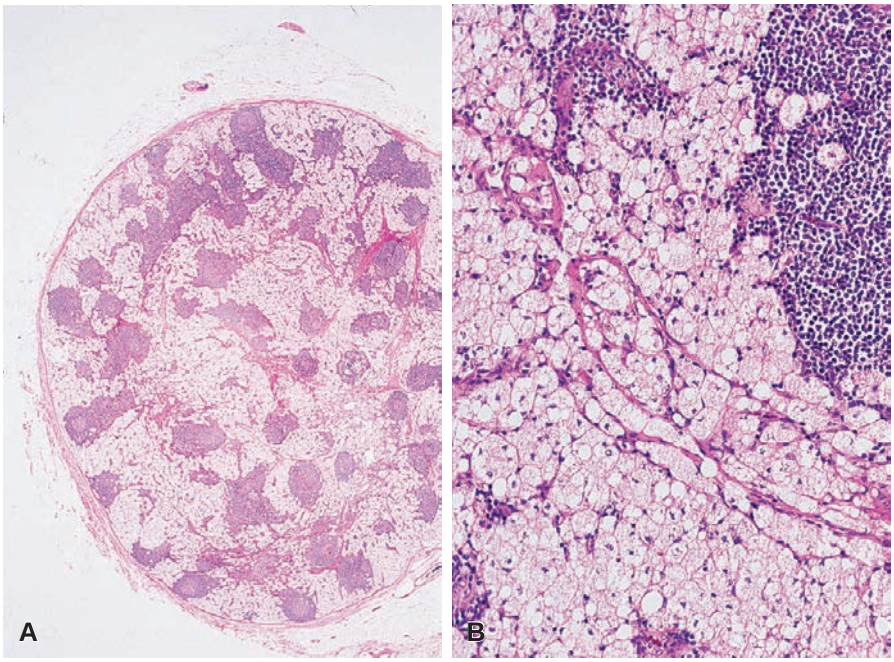

Figure 37.128 Low-power (**A**) and medium-power (**B**) appearances of silicone lymphadenitis. The sinuses are massively expanded by a histiocytic infiltrate, which simulates the appearance of Rosai–Dorfman disease.

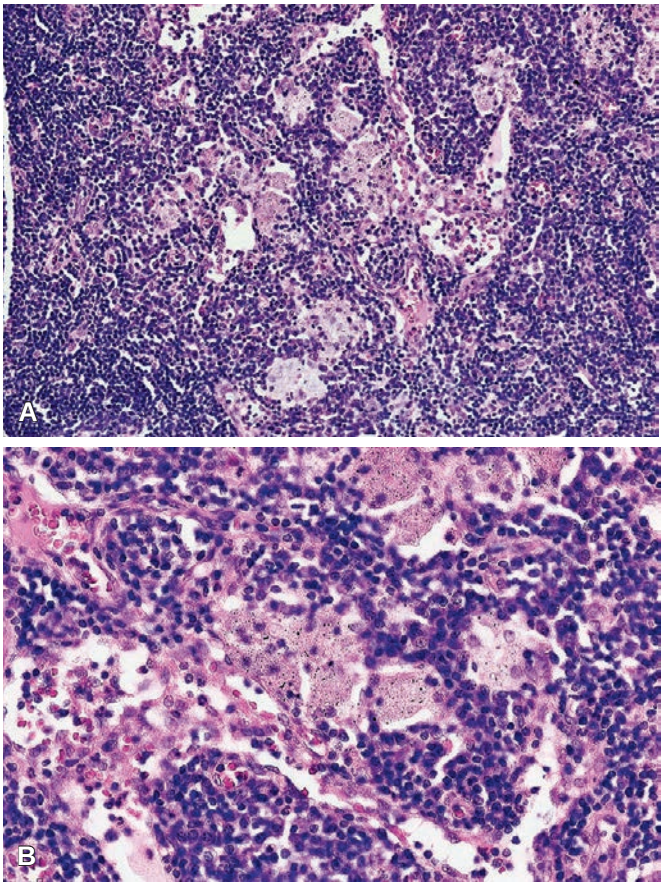

Figure 37.129 **A** and **B**, Lymph node changes in a patient who had a prosthesis implanted in the joint drained by this node. A fine particulate black material can be appreciated in the high-power view. It is easy to dismiss this material as "dirt."

Any malignant tumor can give rise to lymph node metastases, but the incidence varies greatly depending on the tumor type. It is common with carcinomas, malignant melanomas, and germ cell tumors, and rare with sarcomas and central nervous system tumors. It should also be noted that large cell lymphomas primary in an organ (such as stomach or thyroid) sometimes involve the regional nodes in a pattern consistent with metastatic spread and the pattern of lymph node infiltration of ALCL may mimic a metastasis.

An additional diagnosis to consider in a lymph node involvement by metastatic tumor is that of malignant mesothelioma (Fig. 37.130). Examples of this tumor type presenting initially with lymphadenopathy in the cervical or inguinal region are reported; most of the primary tumors were located in the peritoneum rather than the pleura, regardless of the location of the nodes.[1152] The differential diagnosis includes reactive benign mesothelial cells in lymph nodes (see later) (Fig. 37.131).

It is very rare for soft tissue sarcomas to present initially as a lymph node metastasis. The outstanding exception is alveolar rhabdomyosarcoma (particularly the solid variant), which can be confused with malignant lymphoma not only on morphologic grounds but also because it may involve several lymph node groups (so-called "lymphadenopathic form") (Fig. 37.132). Other sarcomas that have a greater than average tendency to metastasize to regional nodes are embryonal rhabdomyosarcoma, angiosarcoma, epithelioid sarcoma, and synovial sarcoma.

The differential diagnosis between metastatic undifferentiated carcinoma and diffuse large cell lymphoma in routine sections may be difficult or even impossible without ancillary studies in some cases. Features favoring lymphoma are presence of focal nodularity within the tumor not induced by fibrosis, and diffuse permeation of walls of veins (as opposed to tumor thrombi) and adipose tissue if an extranodal component is present. Features favoring metastatic tumor are focal nodal involvement, definite nesting, extensive necrosis, predominantly sinus distribution, and solid tumor plugs in lymphatic vessels. The types of malignant lymphoma most likely to be misdiagnosed as metastatic carcinoma are ALCL, large B-cell lymphoma

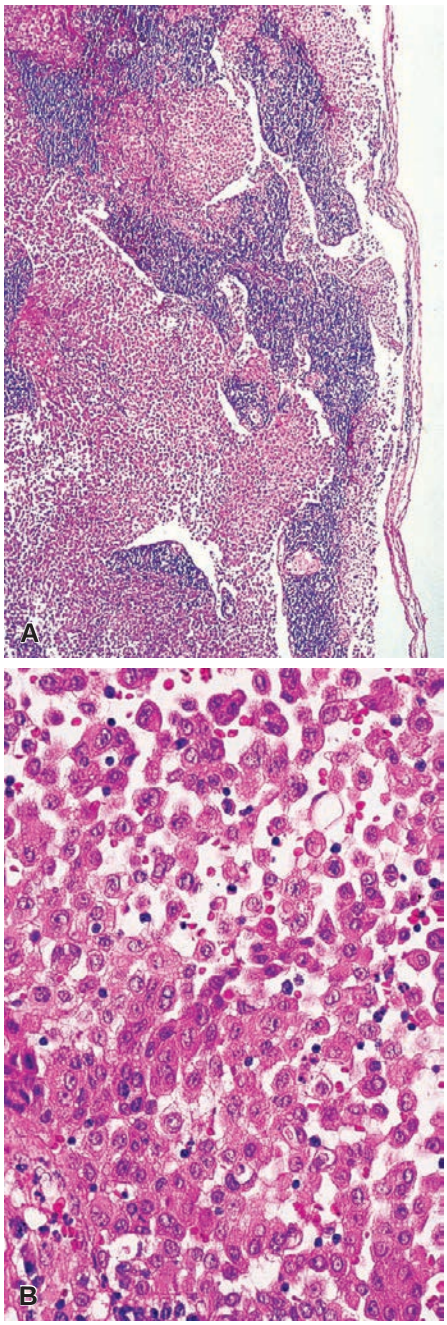

Figure 37.130 **A** and **B**, Lymph node involved by metastatic mesothelioma. The tumor massively expands the sinuses and is composed of cuboidal cells with a central nucleus and acidophilic cytoplasm. The primary tumor was located in the peritoneal cavity.

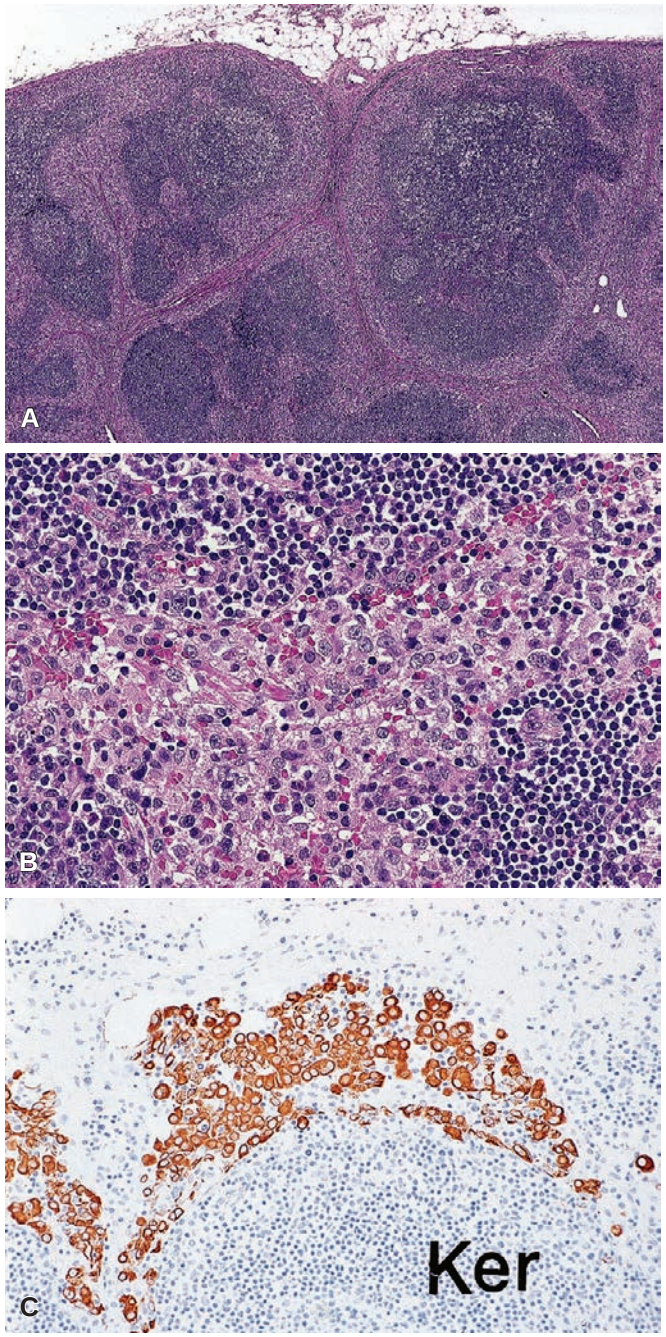

Figure 37.131 **Hyperplastic Mesothelial Cells in Lymph Node.** **A**, Sinusal distribution. **B**, Bland cytologic appearance. **C**, Strong immunoreactivity for keratin. *Ker,* Keratin.

with sclerosis resulting in prominent nesting, large B-cell lymphoma with a predominantly sinus pattern of growth, nodular sclerosis Hodgkin lymphoma with concentration of large mononuclear variants of Reed–Sternberg cells around areas of necrosis, and signet ring cell lymphoma. Yet another type is the composite lymphoma made up of follicular small cleaved and diffuse large cell components, the double error consisting in diagnosing the latter component as metastatic carcinoma and the former as follicular hyperplasia.

The metastatic carcinomas that most closely simulate a malignant lymphoid process are nasopharyngeal lymphoepithelial carcinoma and lobular carcinoma of the breast (Figs. 37.133 and 37.134). The first may masquerade clinically and pathologically as Hodgkin lymphoma because of its common presentation in a young adult with painless unilateral cervical lymphadenopathy, EBV positivity, and the presence of a polymorphic population (including eosinophils) on microscopic examination.[1175] The second may be confused with malignant lymphomas of one type or another, including signet ring lymphoma (Fig. 37.135), or the carcinoma cells may be mistaken for histiocytes. Metastatic small cell neuroendocrine carcinoma from the lung or other sites can be difficult to distinguish from lymphoma;

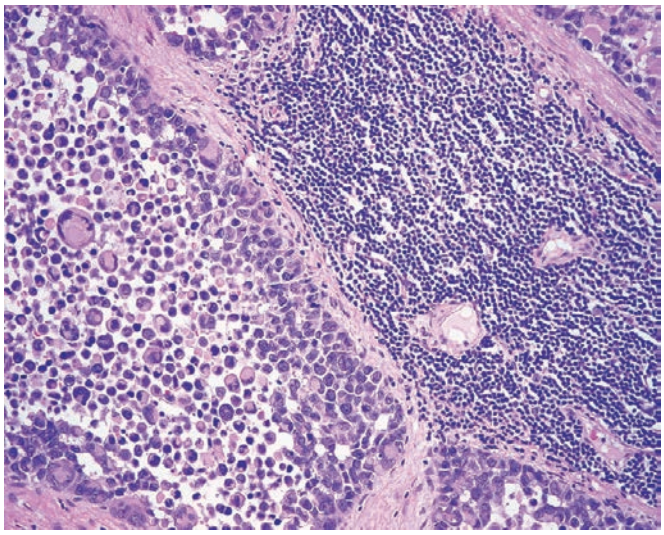

Figure 37.132 Alveolar Rhabdomyosarcoma Metastatic to a Lymph Node. This is a relatively common occurrence in this tumor type, and it may be the first clinical manifestation of the disease.

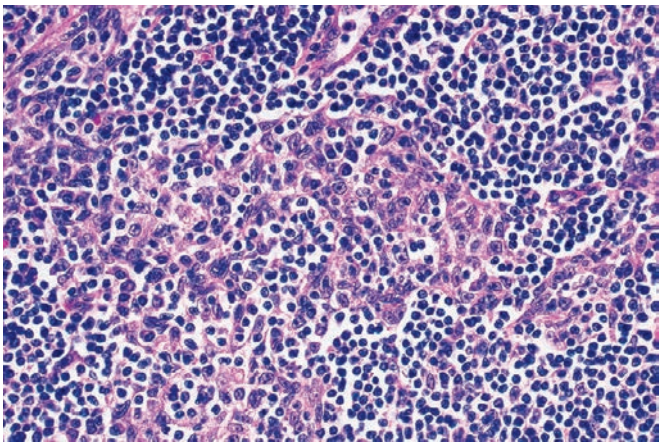

Figure 37.133 Lymph Node Involved by Metastatic Lymphoepithelioma From the Nasopharynx. The relatively diffuse pattern of the proliferation may result in a mistaken diagnosis of malignant lymphoma.

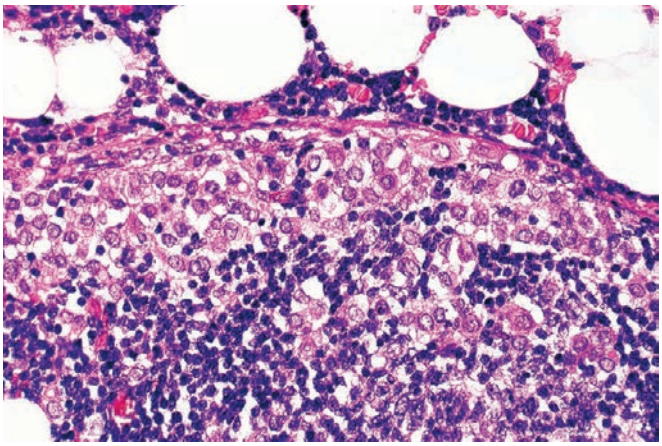

Figure 37.134 Breast Carcinoma of Lobular Type Metastatic to the Sinuses of a Lymph Node. The cytologic appearance may be confused with that of a malignant lymphoma or a benign histiocytic proliferation.

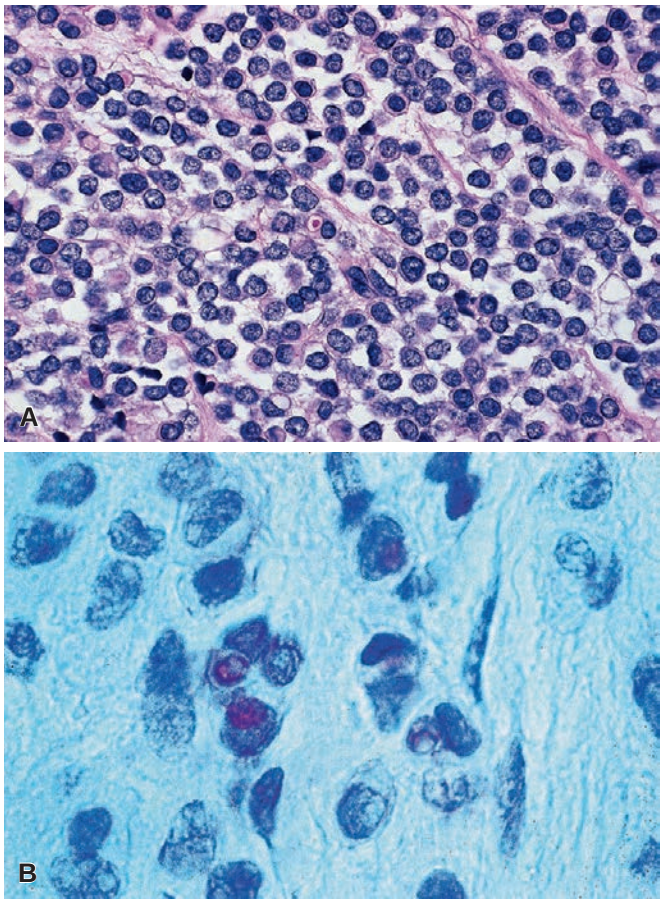

Figure 37.135 Poorly Differentiated Adenocarcinoma With Signet Ring Features Initially Misinterpreted as a Malignant Lymphoma. The mistake may have been partially induced by the fact that the tumor developed in a renal transplant recipient. **A**, Hematoxylin–eosin. **B**, Mucicarmine stain, showing a few droplets of intracytoplasmic mucin.

dense nuclear chromatin pattern, nuclear molding, focal areas of necrosis, and hematoxyphilic staining of vessel walls favor a diagnosis of small cell carcinoma. Somewhat similar considerations pertain to the diagnosis of metastatic Merkel cell carcinoma. Metastatic melanoma can closely simulate on cytologic grounds the appearance of large cell lymphoma and plasmacytoma. The balloon cell variety can closely mimic RDD (Fig. 37.136). One should also not forget that metastases can develop in a node already involved by lymphoma or leukemia.

Nodal metastases of squamous cell carcinoma have a particular tendency to undergo cystic changes. When these are prominent in a node located in the neck, a mistaken diagnosis of branchial cleft cyst may ensue (Figs. 37.137 and 37.138).

The location of a node involved by metastatic carcinoma gives important clues about the possible site of the primary. The large majority of tumors metastatic to *upper cervical* lymph nodes originate from the upper aerodigestive tract. Sites well known for harboring small, clinically undetectable primaries in the presence of cervical adenopathy are the nasopharynx and retrotonsillar pillar.[1176–1178] *Midcervical* nodes containing papillary carcinoma are usually examples of metastatic thyroid carcinoma, a possibility that becomes a virtual certainty in the presence of psammoma bodies. However, these papillary tumors may also originate from salivary gland, female genital tract, or thymus (see respective chapters). Squamous cell

Figure 37.137 Squamous Cell Carcinoma Metastatic to Lymph Node. The tumor has undergone partial cystic transformation.

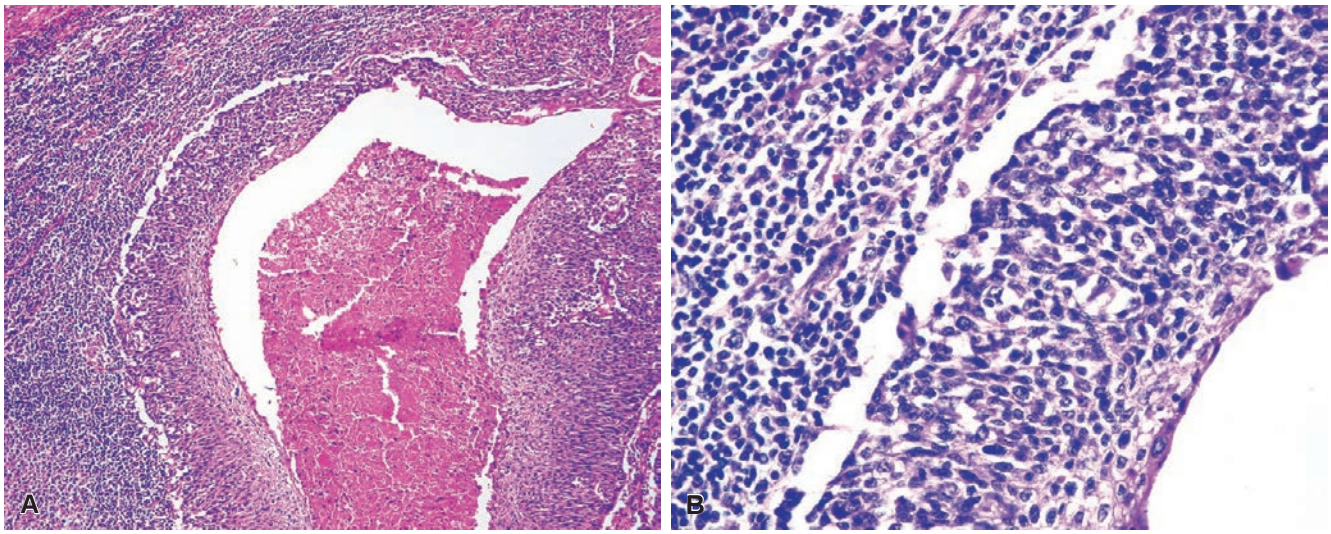

Figure 37.138 Squamous Cell Carcinoma Metastatic to Cervical Lymph Node. A, Medium-power view, showing marked cystic change that may result in a mistaken diagnosis of branchial cleft cyst. **B**, High-power view showing malignant cytologic features involving the entire thickness of the epithelial strip.

carcinomas in lymph nodes of this region usually arise in the upper aerodigestive tract, particularly pharynx and larynx.[1179] Most carcinomas metastatic to *supraclavicular* lymph nodes originate in the lung or breast. Other sources of metastases to this nodal group, particularly if located on the left side, are carcinoma of stomach, pancreas, prostate, and testis.[1177,1180] These reach the node through the terminal collecting lymphatic trunks. Supraclavicular nodes involved by intra-abdominal carcinomas are sometimes referred to as Virchow or Troisier nodes.[1181] The large majority of metastatic tumors in *axillary* nodes of adult females are breast carcinoma and malignant melanoma.[1182,1183] Lung carcinoma should also be considered, especially in older patients with a smoking history.[1184] *Inguinal* nodes are often the recipients of carcinomas from the external genital organs (usually evident on clinical examination) or malignant melanomas of the lower extremities, but only rarely from the internal abdominal organs (ovary, uterine cervix, anal canal) and even less commonly from the testis, unless direct extension to the scrotal skin has occurred.[1185]

The immunohistochemical approach to an obviously malignant tumor involving a lymph node is CD45, keratin, and S100 protein, as markers for lymphoid, epithelial, and melanocytic cells, respectively. A second line of reagents could include EMA, CEA, CD20, CD3, CD30, and—depending on the circumstances—GCDFP-15 and lactalbumin (for breast), chromogranin (for endocrine tumors), PSA/PAP (for prostate), and keratin subsets. The specific immunoprofiles of various tumor types are discussed in more detail in other chapters. When properly applied and interpreted, the performance of these studies should solve all but a very small minority of cases.

It is just as important to mention some of the benign conditions of lymph nodes that can mistakenly be interpreted as metastatic carcinoma. They include hyperplastic mesothelial cells,[1149] megakaryocytes,[1186] signet ring sinus histiocytosis,[1187] the related nodal muciphages and mucicarminophilic histiocytosis,[1188,1189] florid anthracosis/anthracosilicosis,[1136] and the various lymph node epithelial inclusions listed above, without forgetting the banal germinal centers of hyperplastic follicles cut tangentially.

Normal Anatomy

The normal spleen serves as a lymphoid organ as well as a filtering organ.[1–3] While fetal hematopoiesis occurs in the spleen, the spleen is not normally a hematopoietic organ after birth but may contain evidence of extramedullary hematopoiesis in a variety of settings. The splenic architecture largely reflects its functions. The splenic white pulp (or malpighian corpuscles) and the periarterial lymphoid sheaths constitute the primary lymphoid component, and the splenic red pulp with its associated cords and sinuses provides the filtering component, but the white pulp is closely associated with the splenic arterial circulation. The white pulp in infants and children, as well as antigenically stimulated adults, normally contains germinal centers composed predominantly of B cells, surrounded by a dark staining mantle zone and a more pale-staining outer marginal zone. In healthy adults, the germinal centers disappear, but normal B cell–rich mantle zones remain, similar to inactive lymph node follicles. In contrast to most other lymphoid organs, however, the white pulp B-cell compartment is also surrounded by an outer marginal zone of medium-sized lymphocytes with moderately abundant cytoplasm that is an admixture of B and T lymphocytes. This marginal zone tends to expand in reactive conditions that induce germinal center formation in the spleen, but B lymphocytes tend to remain localized to the white pulp areas and do not normally form aggregates in the red pulp. The periarterial lymphoid sheath contains primarily T lymphocytes in a less organized architecture and scattered T lymphocytes also circulate normally in the red pulp component. The splenic red pulp is composed of the splenic vascular sinuses with lining cells often termed littoral cells, and the cords of Billroth. These are made up of a matrix of splenic macrophages, capillaries, venules, and stromal cells and provide the filtering function of the spleen.

Biopsy and Fine-Needle Aspiration

Historically, biopsy of the spleen was rarely attempted because of the possibility of hemorrhage and the preconceived notion that the biopsy will not be of diagnostic help. Obviously, the procedure should not be performed on patients with a bleeding tendency. More recently, such procedures have become more routine, either with the Vim–Silverman-type needle to obtain a core of tissue or with a fine needle to obtain an aspirate.[4] These procedures are often performed with ultrasound or computed tomography guidance.[5] This approach has demonstrated limited complications, and the technique frequently results in a definitive diagnosis that is not easily obtainable by other means. A multicenter study in Italy on ultrasound-guided fine-needle aspiration (FNA) of the spleen documented the high yield and low risk of the procedure.[6] The overall accuracy was 91%, and the incidence of major complications was less than 1%. Aspiration cytology and core needle biopsy gave similar diagnostic yields, except for malignant lymphoma, in which core needle biopsy proved superior.

The material obtained by FNA is suitable for flow cytometry immunophenotyping,[7] as well as molecular genetic studies.

Rupture and Splenectomy

Blunt trauma to the abdomen and surgical intervention within the abdominal cavity are the two most common factors responsible for rupture of the normal spleen.[8] In most instances, hemoperitoneum is an immediate consequence, leading to an emergency splenectomy. In about 15% of the cases, the rupture is "delayed" anywhere from 48 hours to several months.[9] Examination of the excised spleen will reveal the ruptured area, which, in many cases, is limited to a deceptively small capsular tear, often in the superior pole and/or hilum. A neutrophilic infiltrate may be seen subcapsularly and along the edges of the tear. Foci of intraparenchymal hemorrhage are often present. Germinal centers with an expanded marginal zone and other signs of lymphoid hyperplasia were found more commonly by Farhi and Ashfaq[10] in ruptured spleens than in control cases, leading them to conclude that immunologically stimulated organs may be more prone to traumatic rupture. If the marginal zone expansion is prominent, the possibility of a splenic marginal zone lymphoma (SMZL) needs to be considered; however, it has been shown that the large majority of ruptured spleens with expanded marginal zones do not contain a clonal B-cell population.[11]

Following traumatic rupture, splenic tissue may implant in the form of encapsulated nodules on the peritoneal surface, abdominal wall (including surgical scars), and even within the pleural cavity, lung parenchyma, and brain, a process known as **splenosis**.[12–17] Although some are poorly developed architecturally,[18] others show a full complement of red and white pulp, resulting in an appearance similar to that of accessory spleen.[19] In most cases, the pathogenesis is probably through mechanical implant on the surface, but in the single instance of cerebral splenosis, a hematogenous spread of splenic tissue has to be assumed.[16]

The diseases most commonly associated with spontaneous rupture of the spleen are infectious mononucleosis,[20] malaria, typhoid fever, subacute bacterial endocarditis, peliosis lienis (see later),[21,22] malignant lymphomas (including those occurring in HIV-infected patients),[23] leukemias, and primary nonlymphoid splenic neoplasms.[24] In every case of ruptured spleen without a history of trauma or in which the trauma seems insignificant, a careful microscopic study should be performed in order to rule out these possibilities. Rupture of the spleen with resulting hemoperitoneum is the most frequent cause of death in infectious mononucleosis. This complication usually occurs from 10 to 21 days after the onset of the disease.[25] In rare cases, "spontaneous" rupture may occur in an apparently normal spleen, particularly during pregnancy.[26]

Splenectomy performed in adults for traumatic rupture of the spleen, including intraoperative trauma, often does not result in any sequelae of significance.[27] Asplenic patients, however, are at risk for sepsis due to encapsulated bacteria.[28] While the sepsis risk is highest in children and immunocompromised patients, sepsis may occur years after splenectomy and pneumococcal, meningococcal, and *Haemophilus influenzae* vaccines are recommended in all patients.[29] Other complications of splenectomy include bleeding and pelvic vein thrombosis, and a recent large study suggests that asplenic patients have a slightly higher long-term risk of malignancy.[28,30]

Splenectomy performed in the presence of diffuse splenomegaly or a discrete splenic mass for the purpose of obtaining a diagnosis almost always achieves that purpose. About 75% of the cases proved to be malignant tumors in one study,[31] but improved detection methods appear to currently identify a higher percentage of incidental, nonmalignant proliferations than reflected in that report. Whenever splenectomy is performed for hematologic disorders, a thorough search should be made for accessory spleens in order to excise them if present. A similar precept applies if the operation is done laparoscopically, a procedure that is now commonly performed and has proved safe and effective for a variety of splenic diseases.[32]

Congenital Anomalies

Accessory (supernumerary) spleen is found in about 10% of individuals. It may be solitary or multiple, usually measures no more than 4 cm in diameter, and has a gross and microscopic appearance similar to that of the parent organ. Its most common location is the hilum of the spleen, and it is sometimes seen in contiguity with the tail of the pancreas. It should be distinguished from lymph nodes (especially when the latter are involved by Castleman disease) and splenosis (see previous section). Accessory spleens may contain epithelial cysts within them (see later).

Congenital absence of the spleen (asplenia) is associated in more than 80% of the cases with malformations of the heart, nearly always involving the atrioventricular endocardial cushion and the ventricular outflow tracts.[33] Anomalies of the blood vessels, lung, and abdominal viscera also are frequent.[34] In polysplenia, the cardiac anomalies are less severe and the prognosis is therefore more favorable.[35] A hereditary form of splenic hypoplasia has been reported.[36] Similarly, rare cases of isolated congenital asplenia, without other organ abnormalities, occur.[37] Most appear to be familial with a probable autosomal dominant inheritance pattern. Recently, mutations of the *RPSA* gene have been found in the majority of cases of isolated congenital asplenia.[38] Not surprisingly, these patients have increase pneumococcal infections in childhood and a high mortality rate due to fulminant infections.

Splenic–gonadal fusion occurs in two forms. One is continuous, in which the main spleen is connected by a cord of splenic and fibrous tissue to the gonadal (usually testicular) mesonephric structures; the other is discontinuous, in which discrete masses of splenic tissue are found fused to these same structures (Fig. 38.1).[39–41] Of the 52 cases reviewed by Watson,[42] only four were in females. Eleven were associated with other congenital defects, such as peromelus and micrognathia. Various degrees of testicular ectopia and inguinal hernias are common. All of the reported cases have been on the left side.[43]

Cases of splenohepatic and splenorenal fusion have also been recorded, as a well as an isolated case of ectopic prostatic tissue in the spleen.[44–46]

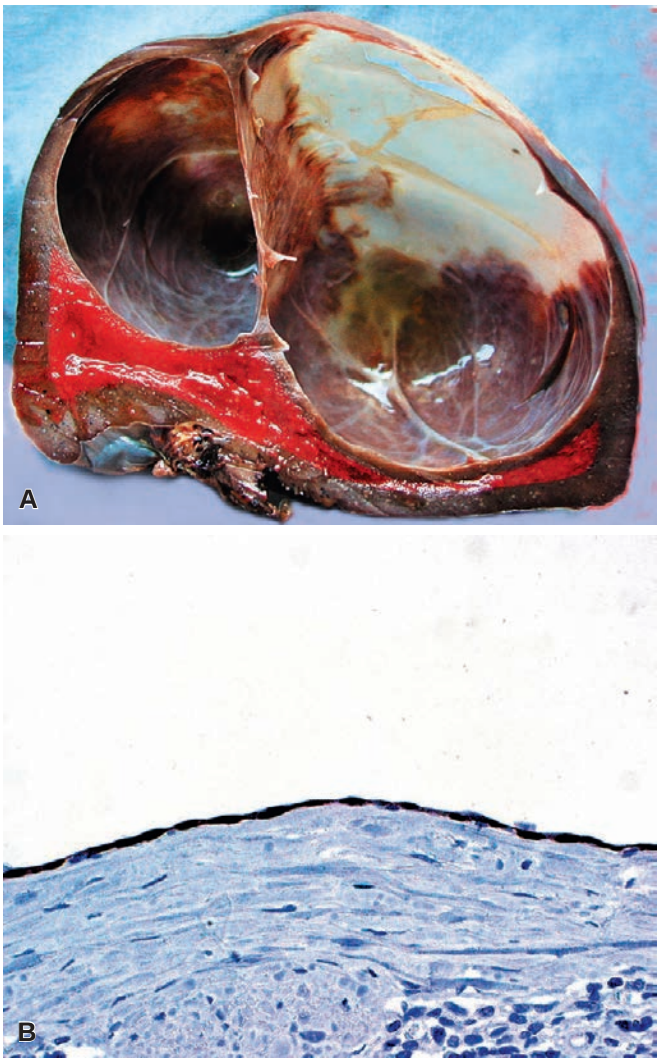

Figure 38.3 **Primary Splenic Cyst Lined by Mesothelial Cells.** **A,** Gross appearance. **B,** Immunoreactivity of the lining cells for calretinin.

Cysts

Cysts of the spleen are now categorized as primary (or true) and secondary (or false) cysts based on the detection of an epithelial lining, even focally, as definitional of a primary cysts. **Primary (epithelial) cysts** are mainly seen in children or young adults[47–49] but may be an incidental finding at any age. They are usually solitary but can be multiple. Cases have also been described in accessory spleens.[50,51] Grossly, a glistening inner surface with marked trabeculation is often seen (Fig. 38.2A). Microscopically, the wall is lined by columnar, cuboidal (mesothelial-like), or squamous epithelium (see Fig. 38.2B). When the latter is the case, the term *epidermoid cyst* has been employed in the past,[52] but because mixed epithelium is often frequent such designations are not necessary. Curiously, the stratified epithelium lining these cysts is immunoreactive for carcinoembryonic antigen (CEA) and CA 19-9, and these markers can be elevated in the serum.[53] Skin adnexa are absent. The histogenesis is unknown; embryonic inclusions of epithelial cells from adjacent structures, invagination of capsular surface mesothelium, and a monodermal teratomatous nature have been proposed,[54,55] and a subset of cysts may be small and subcapsular in location mimicking lymphangiomas.[47] The immunohistochemical profile of some is in keeping with a teratomatous derivation or origin from fetal squamous epithelium,[56] though most have the profile of mesothelial cells (mesothelial cyst) (Fig. 38.3).[47] A case occurring in an intrapancreatic accessory spleen that has the appearance of a lymphoepithelial cyst has been reported by Tateyama.[51] While some are incidental findings, large splenic cysts may require splenectomy. If enough parenchyma is preserved, the performance of a partial splenectomy should be attempted, particularly in children. Parasitic cysts of the spleen, usually secondary to *Echinococcus* infestation, are a subtype of primary cyst (Fig. 38.4).

Mucinous epithelial cysts of the spleen are usually associated with pseudomyxoma peritonei; rarely, splenomegaly due to this change is the presenting manifestation of the disease or an indicator of recurrence.[57]

Secondary (false or pseudocysts) cysts constitute approximately 75% of the nonparasitic cysts of the spleen (Fig. 38.5).[58] Their wall is composed of dense fibrous tissue, often calcified, with no epithelial lining. The content is a mixture of blood and necrotic debris. If the cyst ruptures, massive hemoperitoneum may result. The majority of these cysts are solitary and asymptomatic. Trauma and resolving abscess are the most likely etiologic factors, although it is possible that some are epithelial cysts of the type described below in which the lining has been destroyed.

Inflammation

Reactive follicular hyperplasia of the spleen can be seen as an acute phenomenon in response to a systemic infection or immune stimulation. Morphologically, infectious causes are often associated with variable degrees of congestion, diffuse immunoblastic and plasmacytic proliferation, and outpouring of neutrophils in the red pulp (so-called **septic spleen** or **acute septic splenitis**); measles and typhoid fever are the two better known etiologies. It also occurs in a chronic form in a large number of infectious diseases—including AIDS[59,60]—and in immune-mediated diseases, such as idiopathic thrombocytopenic purpura, acquired hemolytic anemia, rheumatoid arthritis (including Felty syndrome),[61] and the systemic form of Castleman disease,[62,63] as well as in hemodialyzed patients.[64]

Figure 38.4 Primary cysts due to hydatidosis of spleen.

Diffuse lymphoid hyperplasia with production of immunoblasts and plasma cells can be the result of infection (particularly viral) and graft rejection. In infectious mononucleosis, the splenic involvement is mainly in the red pulp with a spectrum of plasmacytoid lymphocytes present, often with capsular infiltration, but reactive white pulp hyperplasia may also be present.

Bagshawe[65] compared the clinical and laboratory features of hypersplenism (see next section) among 46 patients with congestive splenomegaly and 29 with reactive splenomegaly and found no significant differences between them. Massive splenomegaly of a reactive nature is commonly seen in inhabitants of several tropical countries, such as Madagascar, the Democratic Republic of Congo, Nigeria, and New Guinea.[66] Spleens removed for this tropical splenomegaly syndrome are often extremely heavy (mean, 3270 g) and exhibit a uniform dark red, cut surface. Microscopically, there is marked dilation of the sinuses and foci of extramedullary hematopoiesis but no significant fibrosis or hemosiderin deposition.[67] Signs of hypersplenism are the rule. Epidemiologic and therapeutic studies suggest a causal relationship with malaria,[67,68] and such cases often meet criteria for the so-called hyperactive malarial splenomegaly syndrome (HMSS).[69] In this regard, it is interesting that the cases of idiopathic splenomegaly reported by Banti in 1883[70] were from an area of central Italy that at the time was endemic for malaria. The criteria for HMSS require persistent gross splenomegaly, elevated anti-malarial antibodies (an IgM titer more than 2 standard deviations above the local mean) and a response to long-term malaria prophylaxis. Molecular assessment for chronic malaria infection may

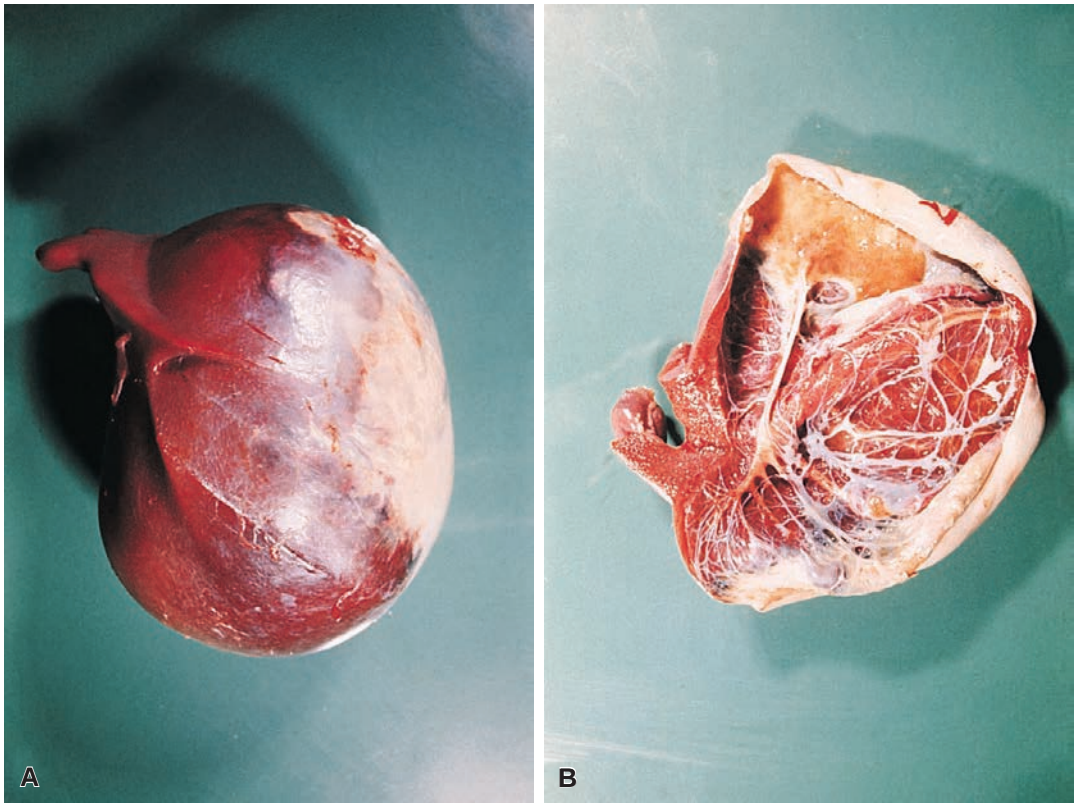

Figure 38.5 Splenic Secondary Cyst (False or Pseudocyst). A, Outer aspect. **B,** Inner surface. Notice the white trabeculation.

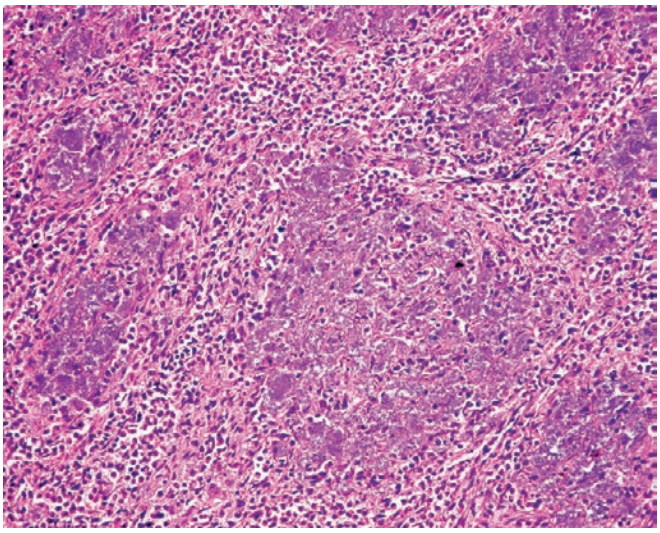

Figure 38.7 Granulomas of spleen due to *Mycobacterium avium* in an immunosuppressed patient.

be useful in patients suspected of having HMSS, because a lack of such molecular evidence correlates with lack of a response to therapy,[71] which could be a sign of splenic lymphoma rather than infection.

Abscess of the spleen, a rare condition, can be the result of trauma, functional asplenia secondary to sickle cell disease, or systemic infection (Fig. 38.6).[72,73] Septic abscesses of the spleen secondary to subacute bacterial endocarditis may necessitate surgical intervention.[74] As mentioned, after resolution of the abscess the remaining capsule may form a lesion identical to a secondary splenic cyst.

Granulomatous inflammation is a relatively common finding in splenectomy specimens. The granulomas can be roughly divided into three major types: (1) large active granulomas containing epithelioid and Langhans-type giant cells, with or without central necrosis; (2) small, widespread, sarcoid-like epithelioid granulomas with scanty giant cells and no necrosis (not to be equated with "epithelioid" germinal centers)[75]; and (3) old inactive granulomas, with fibrosis and calcification. A variant of the first type, characterized by extensive necrotizing changes, has been seen as a complication of leukemia in childhood.[76]

The third type of granuloma, which can be solitary or found scattered throughout the spleen, is particularly common in areas of endemic histoplasmosis.[77] Kuo and Rosai evaluated 20 cases of splenectomy done for splenomegaly and/or hypersplenism in which the only major pathologic finding was the presence of active granulomas of either the first or second type.[78] All of the patients were adults. Fever, weight loss, hepatosplenomegaly, and the various manifestations of hypersplenism were the most common symptoms, and these were markedly ameliorated with splenectomy. The splenic granulomas were nearly always the expression of a generalized disease, which also often involved lymph nodes, liver, and bone marrow. Despite the performance of special stains and cultures, the etiology remained unknown in all but three cases. In these, the organisms identified were *Histoplasma capsulatum*, an atypical *Mycobacterium*, and *Sporotrichum schenckii*, respectively (Fig. 38.7). None of the patients developed malignant lymphoma on follow-up.

Sarcoid-like granulomas can be seen in the spleen of patients with Hodgkin lymphoma[79] and, less commonly, non-Hodgkin lymphoma and hairy cell leukemia,[80] with or without involvement of the spleen by tumor. In some cases of non-Hodgkin lymphoma, the numerous granulomas may obscure the underlying lymphoma.[81] It should be emphasized that the presence of splenic granulomas in patients with lymphoma is not an indication per se that the spleen is involved by tumor. Actually, some authors have suggested that in patients with Hodgkin lymphoma, this finding is associated with an improved prognosis.[82] Neiman[83] found sarcoid-like granulomas in 24 of 412 splenectomy specimens; in addition to the conditions previously listed, he found them in chronic uremia and in a single case of IgA deficiency. He pointed out that in all cases the granulomas appeared to arise in the periarteriolar lymphoid sheath, suggesting that they are the result of abnormal or defective processing of antigen presented to the spleen. Granulomas have also been described in spleens affected by infectious mononucleosis.[84] Lipogranulomas are reported in approximately half of autopsy spleens in North America and may be related to dietary intake.[85,86]

Perisplenitis presents as thick white fibrous plaques coating the surface. It is a common incidental finding at autopsy (Fig. 38.8).

Hypersplenism

Hypersplenism (dysplenism) is the generic term used for the group of disorders in which the removal of hematopoietic elements by the spleen increases to a pathologic degree.[87,88] Any of the cellular elements of the blood may be affected, singly or in combination. Thus neutropenia, thrombocytopenia, hemolytic anemia, or pancytopenia may all be present. In some conditions, such as spherocytic hemolytic anemia or idiopathic thrombocytopenic purpura, the basic abnormality resides in the blood elements themselves. In others, the hypersplenism results from widening of the splenic cords with an increase in macrophages and/or connective tissue fibers and premature destruction of the normal elements of the blood. Hypersplenism resulting from this mechanism can be seen with congestive splenomegaly, Gaucher disease (Fig. 38.9), malignant lymphoma, leukemia, Langerhans cell histiocytosis, hemangioma, hamartoma, angiosarcoma, and practically any condition involving more or less diffusely the splenic parenchyma and particularly in the red pulp.[2]

A syndrome of hypersplenism developing in uremic hemodialyzed patients has also been recognized.[64] Splenectomy results in a marked improvement; a striking degree of lymphoid hyperplasia is found in the excised spleens.

Thrombocytopenic Purpuras

Immune thrombocytopenic purpura (traditionally known as idiopathic thrombocytopenic purpura) is caused by an antiplatelet

Figure 38.8 Typical gross appearance of perisplenitis ("sugar-coated" or "snow-covered" spleen). (Courtesy of Dr. RA Cooke, Brisbane, Australia. From Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004)

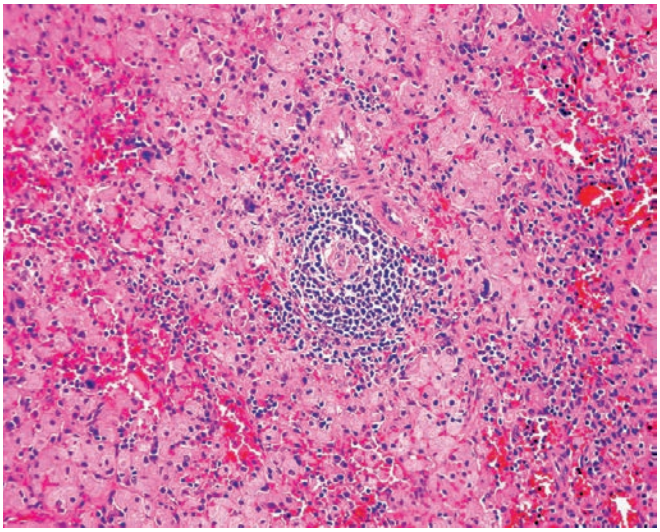

Figure 38.9 Gaucher Disease of Spleen. Macrophages with abundant pale acidophilic cytoplasm pack the red pulp.

IgG, which is produced largely in the spleen.[89,90] Occasionally, thrombocytopenic purpura is seen as a manifestation of lupus erythematosus, viral infection, drug hypersensitivity,[91] chronic lymphocytic leukemia,[92] or Hodgkin lymphoma.[93] The antibody-coated platelets have a short life span because they are rapidly removed by the cells of the reticuloendothelial system, particularly in the spleen and liver. There is some evidence that the number of antibody molecules bound to the platelets may determine the main site of removal. Heavily coated platelets are removed by the liver phagocytes, whereas lightly coated platelets pass through the liver but are sequestered in the spleen.

While immune-mediated disorders were a common indication for splenectomy in the past, the effective use of immune-modulatory mediations, including monoclonal antibodies such as rituximab and thrombopoietin receptor agonists, have significantly reduced the need for splenectomy in these patients.[94] When removed, however, the spleen in immune thrombocytopenic purpura is of normal size or only mildly enlarged[95]; white pulp may be grossly prominent, imparting a miliary pattern to the cut splenic surface. Microscopically, there is expansion of the white pulp due to formation of secondary follicles with well-developed germinal centers,[96] prominence of histiocytes in the red pulp, dilation of sinuses, variable numbers of perivascular plasma cells in the marginal zone, and infiltration with neutrophils of the red pulp.[97] Mild extramedullary hematopoiesis in the red pulp, usually in the form of megakaryocytes, is present in most cases.[98,97,95] The germinal centers, which usually show phagocytosis of nuclear debris and periarterial fibrosis,[99] are no longer prominent in cases previously treated with steroids.[100]

Collections of foamy macrophages containing phospholipid deposits are present in the red pulp in some of the cases.[101,102] They are the result of phagocytosis of platelets and of incompletely degraded membrane-derived phospholipids,[103,104] as supported by the fact that the platelet antigen CD41 has been detected immunohistochemically in them.[96] The phagocytosis of platelets by splenic histiocytes can be better appreciated in touch preparations. It should be noted that the presence of foamy macrophages in the spleen is not pathognomonic of this disorder.

Splenectomy in idiopathic thrombocytopenic purpura is reserved for patients unresponsive to steroid or immunosuppressive therapy.[105] It achieves sustained remission in 50%–80% of the cases.[106] It is difficult to predict its effectiveness in an individual case. However, Chang et al.[97] have shown that patients with prominent secondary follicles have a higher rate of antiplatelet antibody production and exhibit a better initial response, with a great increase in platelets postoperatively.

Thrombotic thrombocytopenic purpura may be accompanied by splenic enlargement.[107] The most important pathologic change is the presence of thrombi in arteries and arterioles without associated inflammation. PAS-positive hyaline subendothelial deposits are present. Other changes include expanded white pulp with germinal center formation, periarteriolar concentric fibrosis, hemosiderin-laden macrophages, hemophagocytosis, and extramedullary hematopoiesis.[108]

Hemolytic Anemia

Hereditary spherocytosis (congenital hemolytic anemia) is a genetically determined disease in which the red blood cells become rigid spheres (spherocytes) without the usual central pallor.[109] The abnormality lies in the cell membrane of the red blood cell. Consistent molecular alterations of spectrin and ankyrin have been detected, resulting in defects in the horizontal interactions that hold the membrane skeleton together, particularly the critical spectrin self-association reaction.[110–113] As a result, the erythrocytes lack the plasticity

of normal red blood cells and become trapped in the interstices of the spleen.[114] The splenic function itself is normal.

Acquired hemolytic anemia can be caused by toxins (bacterial hemolysins), plasma lipid abnormalities, parasites that invade red blood cells, and—most important—immune reactions that result in deposition of immune complexes on red blood cell membranes.[115] About half of the cases of immune hemolytic anemias are unassociated with other significant pathologic abnormalities. The remaining cases are seen as a manifestation of a large variety of disease, such as various forms of acute and chronic leukemia, Hodgkin lymphoma, sarcoidosis, lupus erythematosus, tuberculosis, and brucellosis. The Coombs test is the classic method to distinguish between the acquired (positive) and congenital (negative) types of hemolytic anemia. A positive Coombs test consists of agglutination of the patient's washed red blood cells following mixture with antihuman globulin rabbit serum.

Grossly, the spleen of both congenital and acquired hemolytic anemia is fairly firm and deep red, has a thin capsule and no grossly discernible white pulp, and ranges in weight from 100 to 1000 g. In congenital hemolytic anemia, the splenic cords are congested, whereas the sinusoids appear relatively empty because of the presence of ghost red blood cells.[116] The lining cells of the sinuses are prominent, sometimes resulting in a gland-like appearance. Hemosiderin deposition and erythrophagocytosis are present in both conditions but are usually more pronounced in the acquired variety. Ultrastructural studies have shown that the splenic cords are not empty but rather contain red blood cells that have lost their electron density, thus corresponding to the red cell ghosts of light microscopy.[117]

In acquired hemolytic anemia, the congestion may predominate in the cords or sinuses or be equally prominent in both. A high correlation exists between spherocytosis and increased osmotic fragility on one hand and the degree of cord congestion on the other. Foci of extramedullary hematopoiesis may be present. Splenic infarcts are found in one-fourth of the cases.[2]

Hereditary spherocytosis is the hematologic disease that most benefits from splenectomy.[118] The clinical cure rate is almost 100%, although the intrinsic red cell abnormality persists.[119] In acquired hemolytic anemia, splenectomy is usually reserved for cases that cannot be controlled by steroid or immunosuppressive therapy. A sustained remission rate is obtained in about 50% of the cases, and an objective improvement is obtained in an additional 25% of the cases. Studies of splenic sequestration using Cr^{35}-tagged red cells give a rough estimation of the benefit to be expected from splenectomy.[120]

Congestive Splenomegaly

Congestive splenomegaly is a direct consequence of portal hypertension. It may be caused by cirrhosis (by far the most common pathogenesis); thrombosis of hepatic veins (Budd–Chiari syndrome); thrombosis of the splenic veins; or occlusive thrombosis, cavernous transformation (recanalized thrombosis), sclerosis, or stenosis of the portal vein. Portal vein thrombosis may be the result of inflammation, trauma, or extrinsic pressure by inflammatory or neoplastic tissue.[87] Stenotic or sclerotic changes may be the result of extension into the main portal vein of the physiologic obliterative process that takes place at birth in the umbilical vein and the ductus venosum as they empty into the left portal vein. Cases of portal hypertension accompanied by congestive splenomegaly in which no apparent cause is discernible either in the liver or in the hepatic or portal veins are referred to as **idiopathic portal hypertension** (also known as *Banti syndrome*). It has been regarded by many with skepticism, but cases with similar features are still being seen today, particularly in Japan and India.[121,122]

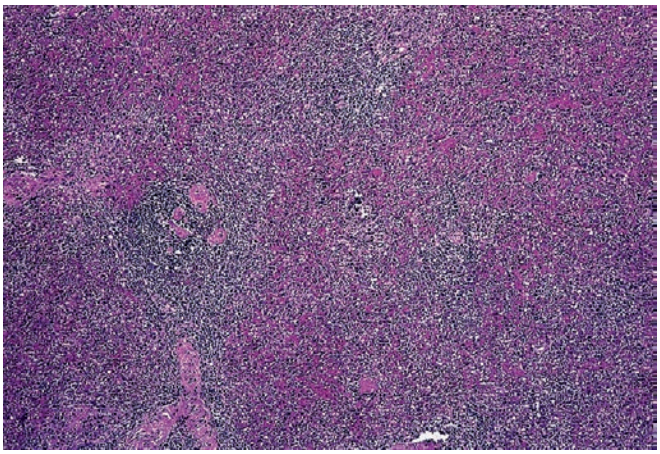

Figure 38.10 Passive Congestion of Spleen. The red pulp is massively expanded due to increased content of red blood cells.

Congestive splenomegaly may be accompanied by signs of hypersplenism, such as anemia, leukopenia, and/or thrombocytopenia. Grossly, the spleen is large, firm, and dark. Fibrous thickening of the capsule is frequent.[123] Microscopically, there is marked dilation of the veins and sinuses, fibrosis of the red pulp, and accumulation of hemosiderin-containing macrophages (Fig. 38.10). Lymphoid follicles are inconspicuous. Iron incrustation of the connective tissue and sclerosiderotic nodules, often with an associated foreign body reaction, ("Gamna–Gandy bodies") develop as a result of focal hemorrhages. Because fibrosis is commonly present in advanced cases, the condition is also known as fibrocongestive splenomegaly.

Splenectomy without shunt is successful when the coronary vein joins the portal system central to the point of obstruction. Otherwise, shunt is indicated. Various types have been done, including anastomosis of the splenic vein to the renal vein and anastomosis of the portal vein to the vena cava. These operations have been successful as a means of controlling repetitive hemorrhage from esophageal varices but do not seem to prolong life.[124]

Other Non-Neoplastic Disorders

Foamy macrophages can be found in the spleens of patients with idiopathic thrombocytopenic purpura, as already indicated. They also occur, as an incidental finding without clinical significance, in the malpighian follicles of normal individuals (so-called follicular or mineral oil lipidosis mentioned previously) in association with similar changes in the liver and intra-abdominal lymph nodes.[125] They are much more common in North American than in Latin American or African populations.[85,86] Biochemical studies have demonstrated the presence of saturated hydrocarbons, which imply the ingestion of exogenous mineral oil. The most common source seems to be material related to the packaging and display of foodstuff.[85,126]

Foamy histiocytes have also been described in Gaucher disease, Niemann–Pick disease,[127] Tay–Sachs disease, chronic granulomatous disease, thalassemia,[128] and hyperlipemic stages.[129] Histochemical techniques usually may be useful for a distinction among these various conditions,[130] but biochemical genetic studies are now recommended to fully assess individuals for the specific storage diseases. It is now accepted that the process originally designated as sea-blue histiocyte syndrome[131] is not a specific entity and that histiocytes with a sea-blue appearance can be present in any of the disorders previously mentioned[132] and also in chronic myeloid leukemia and other hematologic disorders with high cell turnover.

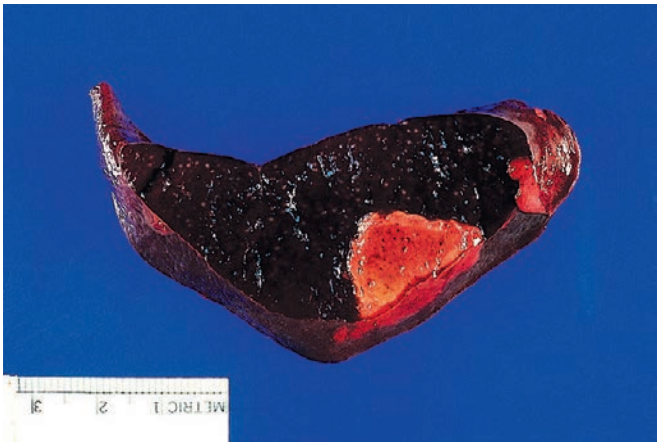

Figure 38.11 Typical wedge-shaped appearance and "anemic" quality of splenic infarct. A second smaller infarct is also present.

Infarction of the spleen may result from thrombosis of the splenic vein, a phenomenon not always associated with a detectable etiology. Infarct of the spleen is one of the complications of Wegener granulomatosis and may result in rupture of the organ.[133–135] Splenic infarcts are also common in cases of massive splenomegaly, regardless of its cause (Fig. 38.11).

Peliosis of the spleen (peliosis lienis) is characterized by widespread, blood-filled cystic spaces. Most reported cases have been associated with peliosis hepatis,[136] but it may occur independently from it.[137] The most common location for the lesions is the parafollicular region.[137] Cases have been reported in which this condition led to splenic rupture[138] and death.[137] Most cases have occurred in patients with wasting diseases, such as tuberculosis and carcinomatosis, or in patients who have received anabolic–androgenic steroids.[139] They have also been seen in association with chronic leukemia[138] and following liver transplantation.[140]

Radiation injury to the spleen, usually produced in the course of therapy for lymphoma, results in an organ with a wrinkled, thick capsule and parenchymal collapse, with diffuse fibrosis of the red pulp and lymphocyte depletion.[141]

Amyloidosis of the spleen is nearly always an expression of the "secondary" form of the disease and has been associated with spontaneous splenic rupture in several reports.[142–145] "Sago spleen" and "lardaceous spleen" are the classic descriptions, depending respectively on the follicular versus diffuse locations of the deposits. Exceptional cases of localized splenic amyloid nodules ("amyloid tumor") have also been described.[146] Amyloidosis of the spleen should be distinguished from the common hyaline adventitial thickening of splenic vessels, a change sometimes referred to as para-amyloid and said to be accentuated in AIDS patients.[147]

Hematolymphoid Tumors and Tumorlike Conditions

Non-Hodgkin Lymphoma

Malignant lymphoma is by far the most common malignant tumor involving the spleen. Although usually affected as part of a generalized process, in some cases the spleen represents the first or only detectable site of disease. In either case, splenic involvement by malignant lymphoma may present as an asymptomatic splenomegaly or result in a picture of hypersplenism. Ahmann et al.[148] described four gross patterns of involvement: homogeneous, miliary, multiple masses, and solitary masses, which show some correspondence to the various microscopic types (Fig. 38.12).

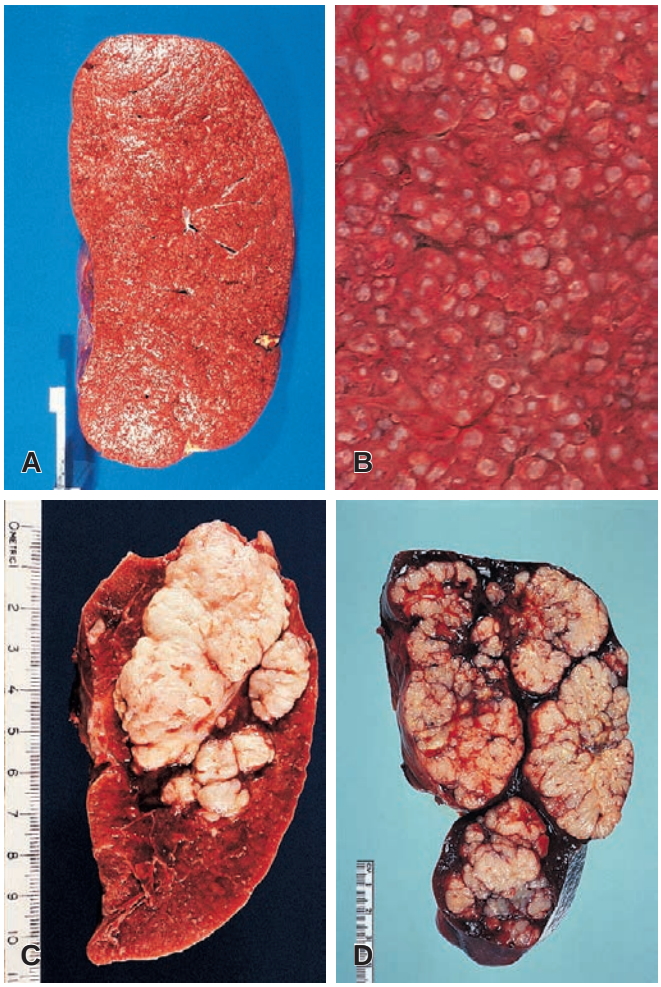

Figure 38.12 Gross Appearances of Various Types of Malignant Lymphoma Involving the Spleen. A, Miliary pattern in small lymphocytic lymphoma/chronic lymphocytic leukemia. **B,** Miliary pattern with follicular lymphoma. **C** and **D,** Nodular pattern due to involvement by large B-cell lymphoma.

Primary splenic lymphoma (defined as restricted to the spleen and hilar lymph nodes) is rare, accounting for less than 1% of all lymphomas. Although a few types of primary splenic lymphoma, discussed later, are unique to the spleen, most other lymphoma types, described in more detail in Chapter 37, may rarely present as a primary splenic disorder.[149] **Diffuse large B-cell lymphoma**, the most common disseminated lymphoma, most often involves the spleen in a macronodular pattern, as either primary or secondary disease. Two other primary patterns of splenic large B-cell lymphoma have also been described: a micronodular pattern in which the tumor nodules, although smaller, show a diffuse proliferation of mixed cells that include small T cells, large B cell and histiocytes similar to *T-cell/histiocyte-rich large B-cell lymphoma* of other sites, and a diffuse infiltration of the red pulp that mimics splenic involvement by acute leukemia.[150–152] The diffuse red pulp pattern is the least common of the three.

Patients with splenic large B-cell lymphoma often present with left upper quadrant pain, fever, weight loss, and an elevated erythrocyte sedimentation rate.[153] Some of the cases have been seen in association with HIV infection,[154] and others (particularly in Japan) have occurred

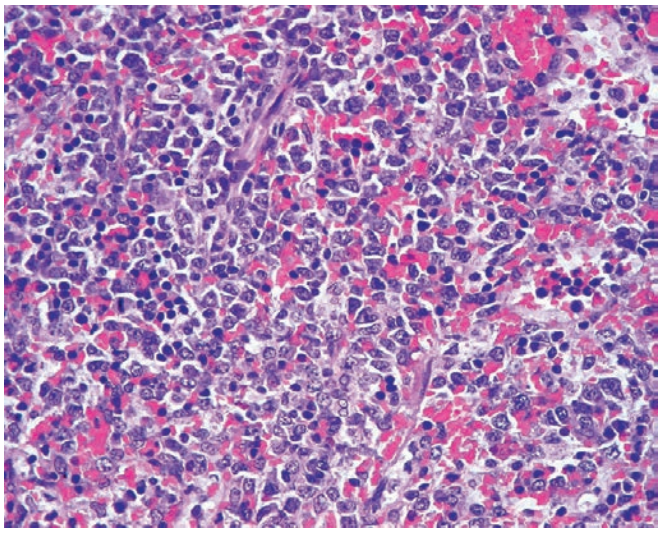

Figure 38.13 Large B-cell lymphoma of spleen causing diffuse infiltration of the tumor nodule.

in patients with hepatitis C virus infection.[155] Grossly, transgression of the splenic capsule is common, sometimes accompanied by invasion of adjacent structures. Hilar and retroperitoneal lymph nodes are often involved. Immunophenotypically, these neoplasms express B cell–associated antigens such as CD20, CD79A, and PAX5; most are BCL6 positive.[156,150] Morphologically, they most often form multiple discrete nodules in the white pulp or large coalescing nodules (Fig. 38.13). Some peripheral T-cell lymphomas may also show a predominance of large cells in nodules, mimicking diffuse large B-cell lymphoma, but these cases are easily excluded by routine immunohistochemical studies. Morphologic features that are common in T-cell lymphoma include an epithelioid histiocytic reaction, tumor confinement to the periarteriolar lymphoid sheath and marginal zone, and clear cell or polymorphous cytologic features (Fig. 38.14),[157–159] but none of these are sufficient to assign lineage without immunophenotyping studies. Along these lines, it should be mentioned that the cases originally interpreted as a chronic form of malignant histiocytosis with predominant splenic involvement on the basis of phagocytic activity, lysozyme positivity, and clinical evolution probably represent instead variants of large T-cell lymphoma.[160]

Secondary splenic involvement by tumor is particularly common in low-grade lymphomas, most of which are of B-cell type.[161] This includes small lymphocytic lymphoma/chronic lymphocytic leukemia (Fig. 38.15), lymphoplasmacytic lymphoma, mantle cell lymphoma, and follicular lymphoma. While the characteristics of these various systemic lymphoma types are discussed in more detail in Chapter 37, some characteristic features in the spleen are discussed here.

Small lymphocytic lymphoma/chronic lymphocytic leukemia in the spleen usually presents grossly as nodules measuring a few millimeters in diameter (miliary pattern) scattered throughout the organ (Fig. 38.16). The low-power appearance is also distinctly nodular because of the preferential involvement of the white pulp.[162] In this regard, it is important to point out that this miliary pattern of growth is common to several types of lymphoproliferative disease of the spleen (including small lymphocytic lymphoma/chronic lymphocytic leukemia, mantle cell lymphoma, and SMZL). In these disorders, the "nodular" pattern is due to expansion of the normal splenic white pulp by the lymphoma and not an expansion of true follicles and that its presence should not be equated with a diagnosis of follicular lymphoma.[160]

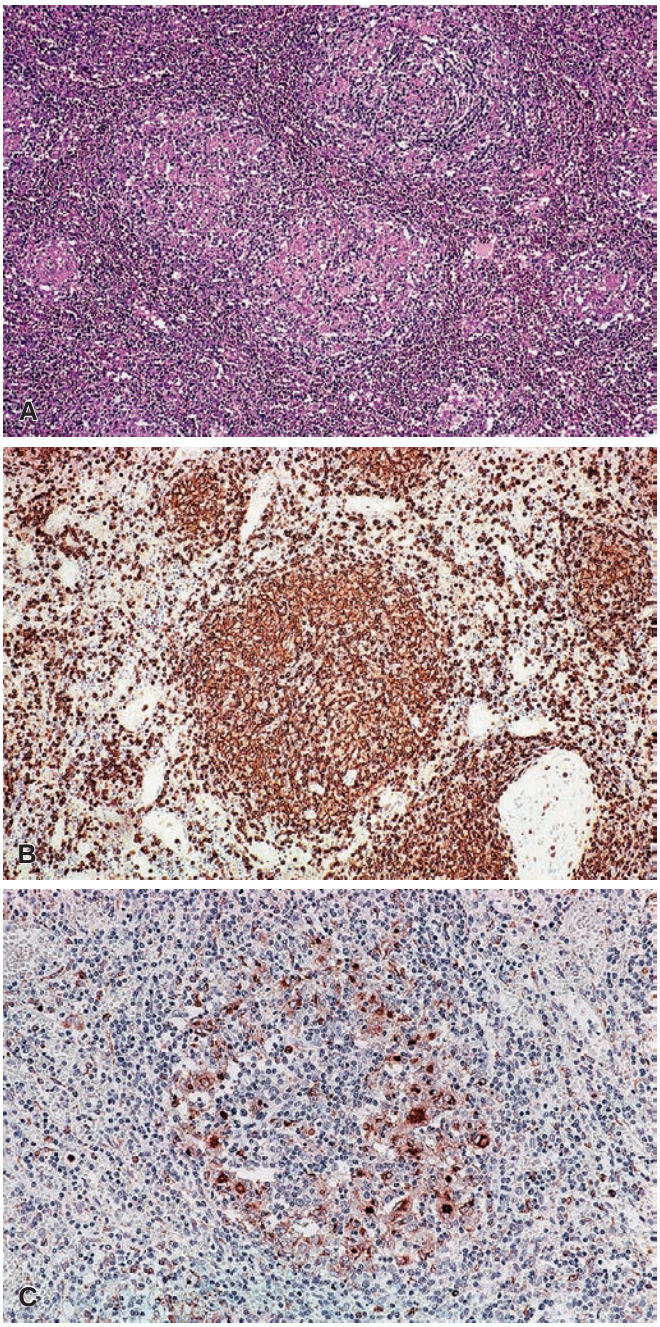

Figure 38.14 **Peripheral T-Cell Lymphoma of Spleen Rich in Reactive Histiocytes. A,** Low-power appearance. **B,** CD43 immunoreactivity of neoplastic T cells. **C,** Lysozyme positivity of reactive histiocytes.

In the early stages, the diagnosis of small lymphocytic lymphoma/chronic lymphocytic leukemia can be easily missed. Clues to the diagnosis in these cases include prominent enlargement and coalescence of follicles; marked expansion of the mantle zone; germinal centers that are absent, inconspicuous, or overrun by small cells; presence of B cells in the red pulp; and presence of clusters of small lymphoid cells protruding beneath the endothelium of trabecular veins.[163] Infiltration of endothelium and trabecular veins by small lymphocytes may also be seen in infectious mononucleosis, but the infiltrate in infectious mononucleosis is predominantly T cells compared to the monotypic B cells in small lymphocytic lymphoma/

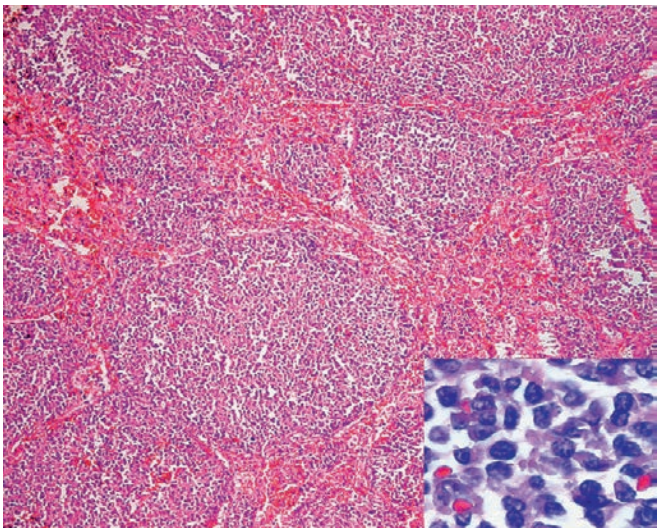

Figure 38.15 Small lymphocytic lymphoma/chronic lymphocytic leukemia of spleen, replacing normal white pulp with fusion of white pulp nodules and extension of small lymphocytes into the red pulp.

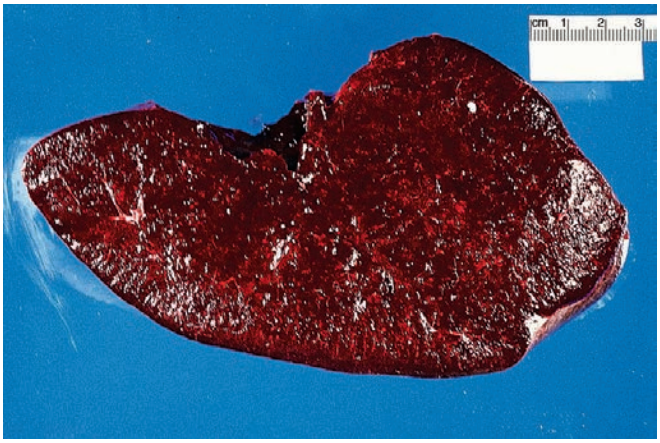

Figure 38.16 The splenic involvement by small lymphocytic lymphoma/chronic lymphocytic leukemia results in marked diffuse enlargement of the organ.

chronic lymphocytic leukemia. Infiltration of the subendothelial space by red cell precursors in infants with erythroblastosis fetalis and (together with granulocyte precursors) in adults with myelofibrosis may also mimic this process. A helpful hint for the diagnosis of lymphoma is to carefully dissect and examine the lymph nodes in the splenic hilum, since they may show obvious lymphoma when the changes in the spleen are only equivocal. Additionally, immunohistochemical studies to assess the immunoarchitecture of the splenic lymphocytes are extremely helpful in identifying abnormal B-cell populations infiltrating the red pulp in B-cell lymphoma.

An "entity" that exemplifies the difficulties sometimes encountered in the recognition of splenic small lymphocytic lymphoma is so-called *idiopathic nontropical splenomegaly* (see earlier). Although originally regarded as a benign and probably reactive form of splenomegaly,[164] a follow-up study by the same group showed that half of these cases actually represented malignant lymphoma.[165]

Such cases now can be diagnosed on biopsies or primary splenic lymphoma can at least be strongly suggested by pattern and immunophenotype of disease in the bone marrow, and many

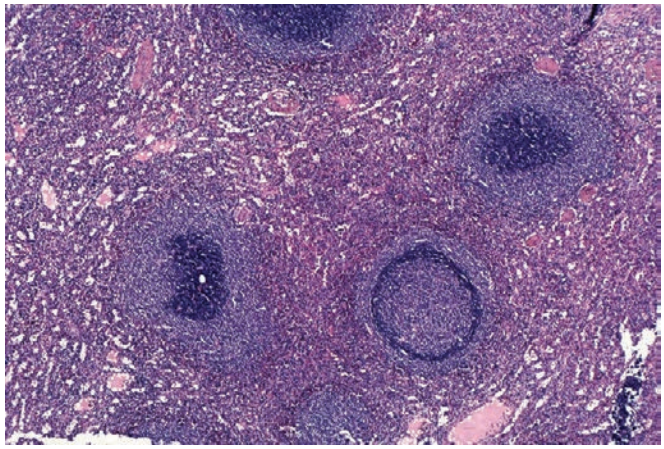

Figure 38.17 Follicular Lymphoma Involving the Spleen. The lower right nodule contains follicular lymphoma, mimicking a germinal center, surrounded by a thin mantle zone. Note the expanded outer marginal zones that may cause confusion with splenic marginal zone lymphoma.

patients are now treated with chemotherapy and without undergoing splenectomy.

Splenic involvement by follicular lymphoma can cause prominent architectural abnormalities, creating gross tumor nodules, or result in preservation of the splenic architecture with expansion of what appear to be germinal centers in the white pulp (Fig. 38.17). Most cases demonstrate a consistent CD10+/BCL2+ phenotype,[166] which aids in excluding reactive follicles, but similar to follicular lymphoma in other sites, some cases will be negative for these markers.[167] Most, if not all, patients with follicular lymphoma involving the spleen, however, have disseminated disease with involvement of hilar lymph nodes and disseminated adenopathy.

Two types of primary malignant lymphoma of the spleen that need to be singled out because their distinctive features are splenic marginal zone B-cell lymphoma and hepatosplenic T-cell lymphoma.

SMZL tends to occur in older adults, with no sex predilection, and usually presents with splenomegaly, anemia, and weight loss.[168–170] The bone marrow is involved with an intrasinusoidal component in nearly all cases, and liver involvement is also common,[171] but nonsplenic hilar lymph node involvement is rare. Grossly, the spleen usually weighs 1000 g or more, and splenic involvement manifests itself through miliary expansion of the white pulp.

Histologically, the white pulp is expanded by a proliferation of small- to medium-sized lymphocytes with clusters of similar lymphocytes in the red pulp.[172] Classically, the lymphoid component has been described as biphasic with an inner zone of dark staining small lymphocytes with scant cytoplasm surrounded by a ring of medium-sized lymphocytes with more abundant, clear cytoplasm mimicking the normal splenic marginal zone (Fig. 38.18). Both white pulp lymphocyte components in such cases represent lymphoma cells. Some cases with this pattern will have central areas of reactive germinal centers, especially if the patient has associated immune disorders with the neoplastic white pulp elements mimicking both the mantle and marginal zones of the reactive spleen. Red pulp lymphocytes, however, are also increased and occur in clusters and often have moderately abundant cytoplasm, similar to the outer white pulp zone of the neoplastic infiltrate. In contrast to this classic pattern of splenic infiltration, many cases of SMZL will expand the white pulp with a more monotonous cell population without a distinct outer and inner zone. Immunohistochemically, the neoplastic

cells express CD20 and other B cell–associated antigens such as CD79A and PAX5, surface immunoglobulin (usually IgM ± IgD), and BCL2 but not CD10, BCL6, CD23, CD11c, or CD43.[173] There is no cyclin D1 protein,[174] Annexin A1 or LEF1 expression, features typical of mantle cell lymphoma, hairy cell leukemia, and chronic lymphocytic leukemia, respectively, although a subset of cases express CD103, which is common in hairy cell leukemia. A subset of cases also shows aberrant expression of CD5, which is associated with higher white blood cell counts and more frequent bone marrow involvement.[175] Such cases are otherwise similar to SMZL and do not have other immunophenotypic, molecular genetic, or clinical features to suggest chronic lymphocytic leukemia. SMZL lacks the common translocations seen in the other small B-cell lymphomas, including those of extranodal marginal zone lymphoma. Various chromosomal abnormalities have been reported, with complete or partial trisomy 3q being the commonest but not specific.[176–178] On the other hand, deletion or translocation involving 7q32, found in 40% of cases, is a characteristic chromosomal aberration in SMZL.[176,179,178] Although SMZL is reported to have a unique gene expression profile, such testing is not routinely necessary for diagnosis.[180] Various gene mutations, including mutations of *TP53*, *NOTCH1*, and *KLF2*, are reported to be frequent in SMZL, but none do date are unique to this lymphoma type.[181]

The differential diagnosis of SMZL includes mantle cell lymphoma (Fig. 38.19),[182,183] follicular lymphoma with marginal zone differentiation,[184] hairy cell leukemia, chronic lymphocytic leukemia/small lymphocytic lymphoma, and the diffuse red pulp small B-cell lymphomas, including hairy cell leukemia variant. As mentioned, the immunophenotype of the neoplastic cells is very helpful in this differential diagnosis, and in the case of splenic diffuse red pulp small B-cell lymphoma, the pattern of splenic infiltration is essential. Several lymphoma types, but especially follicular lymphoma,[149,184] involving the spleen may be associated with an expanded outer marginal zone that may mimic SMZL and histologic identification of small cleaved cells, as well as detection of CD10 expression are useful to exclude SMZL in these cases (see Fig. 38.17).

Ten to 15% of cases of SMZL will transform to diffuse large B-cell lymphoma, usually with late lymph node involvement at a distant site.[185]

Hepatosplenic T-cell lymphoma, previously known as hepatosplenic γ/δT-cell and erythrophagocytic Tγ lymphoma, is a distinct

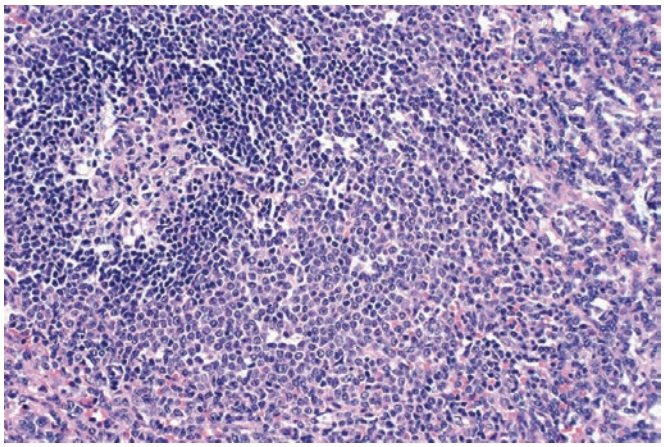

Figure 38.20 Hepatosplenic T-Cell Lymphoma. Medium-sized atypical lymphocytes infiltrate the red pulp, surround a white pulp nodule on the left.

clinical entity within the spectrum of peripheral T-cell lymphomas.[186,187–189] It typically presents with massive hepatosplenomegaly, fever, and weight loss in young males and carries a poor prognosis. Cases have been described in immunocompromised patients, in association with Epstein–Barr virus (EBV) and in patients with inflammatory bowel disease.[190–193] In the latter group, the increased risk of hepatosplenic T-cell lymphoma is controversial but appears to be increase in patients that are treated with a combination of tumor necrosis factor alpha (TNF-α) and thiopurines.[193] Grossly, the spleen is usually 1000 g or larger, with a uniform, beefy red cut surface without malpighian follicles. Microscopically, the neoplastic infiltration involves the cords and sinuses and is composed of variably sized lymphoid cells with oval or folded nuclei, moderately condensed chromatin, and pale cytoplasm (Fig. 38.20). Tumor involvement of the liver and bone marrow is characterized by an intrasinusoidal distribution and marrow involvement may be subtle on H&E sections alone.[194]

The neoplastic cells are mature T cells that usually express CD2, CD3, CD56, perforin, TIA-1, and TCRG but usually lack CD5, CD4,

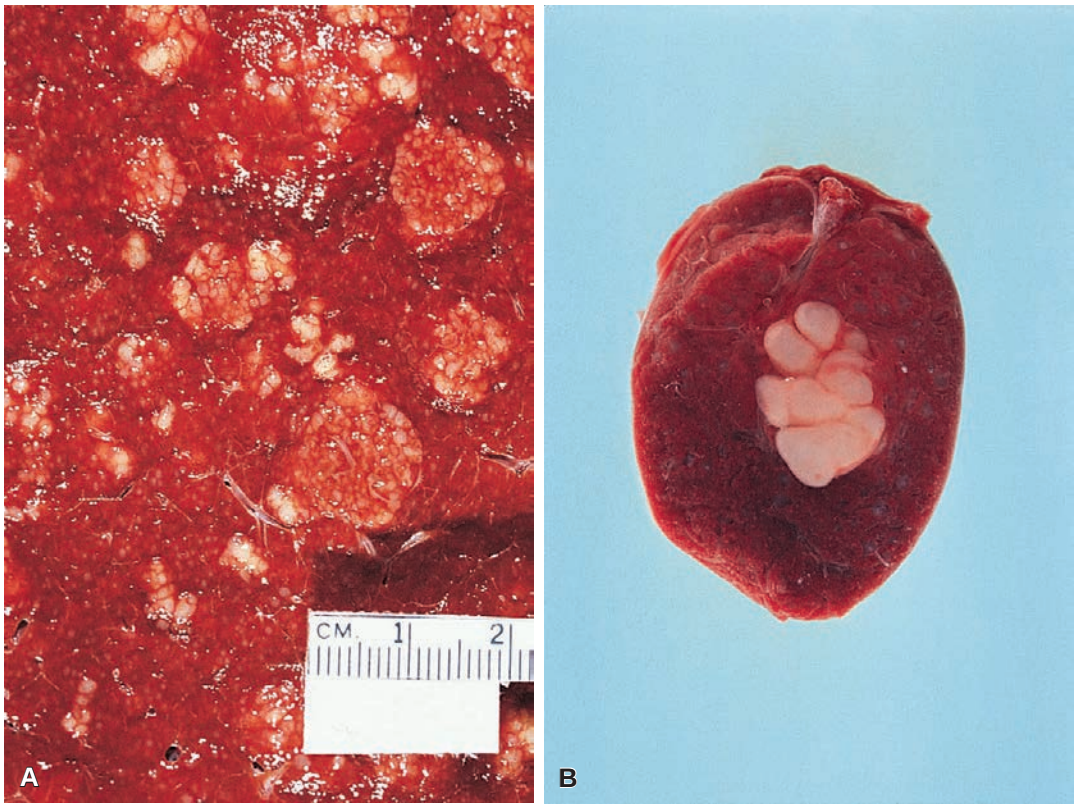

Figure 38.21 **A** and **B,** Gross appearance of Hodgkin lymphoma involving the spleen.

CD8, granzyme B, and TCRB.[195] Cases, however, may be of the α/β type and express TCRB without TCRG.[196] Based on histologic sections, the primary differential diagnosis is with hairy cell leukemia, from which it is distinguished by the absence of blood lakes and its different immunophenotype.

At the molecular level, there is usually clonal rearrangement of the gamma of the T-cell receptor gene, but this assay cannot be used to distinguish the α/β from the γ/δ type. Both immunophenotypic types are associated with isochromosome 7q and trisomy 8. Mutations of *STAT5B* are also common.[195]

The treatment of primary malignant lymphoma of the spleen has historically involved splenectomy, followed by chemotherapy,[197] but patients are now treated commonly without splenectomy. Some of these patients have presumptive splenic lymphoma, based on the presence of splenomegaly with evidence of blood involvement or sinusoidal disease in the bone marrow if no evidence of adenopathy. The prognosis is directly related to the microscopic type and the clinical stage, in the sense that it is distinctly better for low-grade tumors and for stage I and II disease.[148,198] Patients with localized splenic non-Hodgkin lymphoma seem to have the same rate of survival as other stage I non-Hodgkin lymphoma patients.[199]

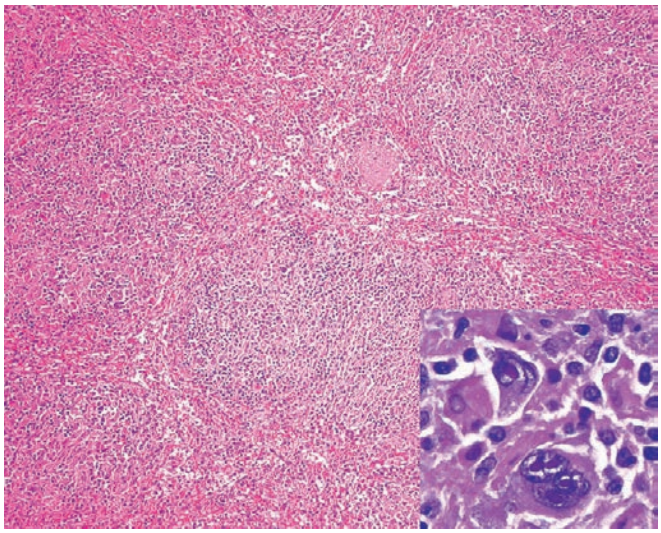

Figure 38.22 Classic Hodgkin lymphoma of spleen. The inset shows typical Reed–Sternberg cells.

Hodgkin Lymphoma

The spleen is the most common site of extranodal organ involvement by Hodgkin lymphoma, but primary Hodgkin lymphoma of the spleen is extremely rare. The morphologic features of Hodgkin lymphoma are discussed in Chapter 37. Grossly the involvement is in the form of one or multiple nodules, grossly indistinguishable from those of large cell lymphoma (Fig. 38.21). Foci of involvement can be only a few millimeters in size, a fact which calls for a very meticulous gross inspection of the organ. The earliest lesions are located in the periarterial lymphoid sheath or marginal zones of the follicles. By far the most common type is the nodular sclerosis subtype of classic Hodgkin lymphoma, but others may be seen as well, including lymphocyte predominance (Fig. 38.22).[200,201] Some cases have initially presented with spontaneous splenic rupture.[202] As already mentioned, sarcoid-type granulomas can be seen in spleens of patients with Hodgkin lymphoma and should not be construed by themselves as evidence of splenic involvement by the lymphoma.

Leukemias

Any type of leukemia can involve the spleen, the location being predominantly the red pulp except in chronic lymphocytic leukemia (see earlier for small lymphocytic lymphoma/chronic lymphocytic leukemia),[160,203] but the spleen is rarely removed or sampled for such a diagnosis. The earliest involvement is in the cords, with secondary spillage into the sinuses.

Hairy cell leukemia is a specific indolent B-cell malignancy that must be distinguished from other lymphomas of small B cells[204,205]; it is further discussed in Chapter 39. Grossly the spleen shows diffuse and usually marked enlargement without formation of nodules (Fig. 38.23).[206] Microscopically, hairy cell leukemia is a disease of the red pulp, which shows diffuse infiltration by a monotonous population of small mononuclear cells with very scanty mitotic activity and practically no phagocytosis (Fig. 38.24).[207,208] The initial involvement occurs around the fibrous trabeculae. The nuclei of the hairy cells are small, round, or oval, with irregular contours, occasional deep indentations ("coffee beans"), and inconspicuous nucleoli. Rarely, the nuclei have a multilobular appearance.[209] The cytoplasm is usually moderate to abundant and lightly stained. Ultrastructurally, prominent cytoplasmic villous projections are evident.[210] The distinctive enzyme histochemical feature of the disease is the presence of tartrate-resistant acid phosphatase (isoenzyme 5),[211] but this assay is no longer performed in most laboratories and immunophenotyping is required for diagnosis. The hairy cell leukemia cells are monotypic B cells that express CD20 and other B-lineage antigens, as well as CD103, annexin A1, and CD123. They are negative for CD5 and CD43, but a subset of cases express CD10. The cells are also positive for TRAP and DBA.44, but these markers are less specific for hairy cell leukemia.[212–216] The splenic vasculature is abnormal in the sense of showing an absolute increase in the volume, surface, and length of pulp arterial vessels, as well as enlargement of pulp cords and sinuses.[217] Pools of blood in the red pulp, lined by hairy cells and simulating dilated sinuses or even hemangiomas, are commonly seen and constitute an important diagnostic feature termed "red blood cell lakes."[218] It has been suggested that this results from the hairy cells adhering to the sinus surface, producing endothelial cell injury and impeding the venous blood flow.[219] In what is perhaps the preceding stage of this process, some of the tumor cells are seen to aggregate in the subendothelial spaces of trabecular veins; sometimes this is the only recognizable site of involvement.[220] The lymph nodes in the splenic hilum are often involved, the pattern of permeation being interfollicular.

Figure 38.23 Gross Appearance of Hairy Cell Leukemia. Note the diffuse involvement, lack of nodularity, and dark red color.

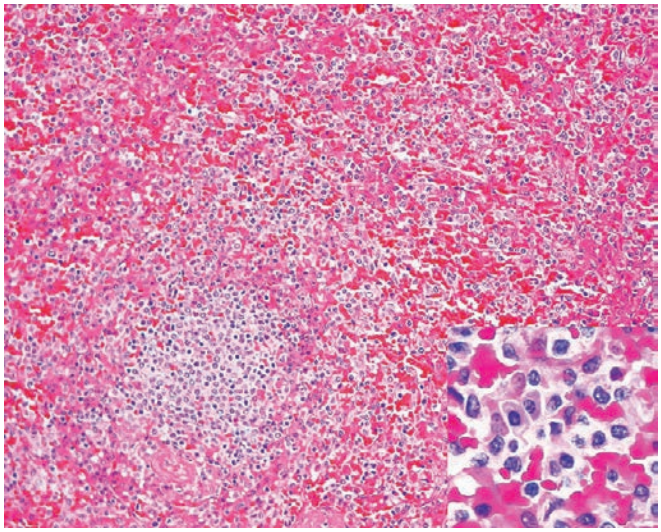

Figure 38.24 Splenic Involvement by Hairy Cell Leukemia. The inset shows the bland monotonous appearance of the red pulp infiltrate.

Myeloproliferative Neoplasms

Chronic myeloid leukemia, *BCR-ABL1* positive results grossly in a large, dark red, diffusely involved organ in which malpighian follicles are inconspicuous or absent. The red pulp is infiltrated by granulocytic precursors as well as scattered abnormal megakaryocytes. Infarcts are common. In rare cases, blastic transformation is first seen in a splenectomy specimen, and immunohistochemistry for CD34 expression on blast cells is useful when such transformation is suspected.

Primary myelofibrosis is discussed in detail in Chapter 39 but is characteristically associated with splenomegaly and splenectomy is often performed due to an associated wasting syndrome. The average spleen weight is 2 kg.[221] Grossly, the spleen is diffusely dark red and moderately firm, with frequent areas of hemorrhage (Fig. 38.25) and frequently associated with infarcts. Microscopically, the diagnostic feature is the presence in the red pulp of abnormal hematopoietic cell lines: megakaryocytes, erythroid precursors, and granulocyte precursors. The latter are made evident with Leder chloroacetate esterase stain or myeloperoxidase (Fig. 38.26). The

Figure 38.25 Diffuse involvement of the spleen by primary myelofibrosis.

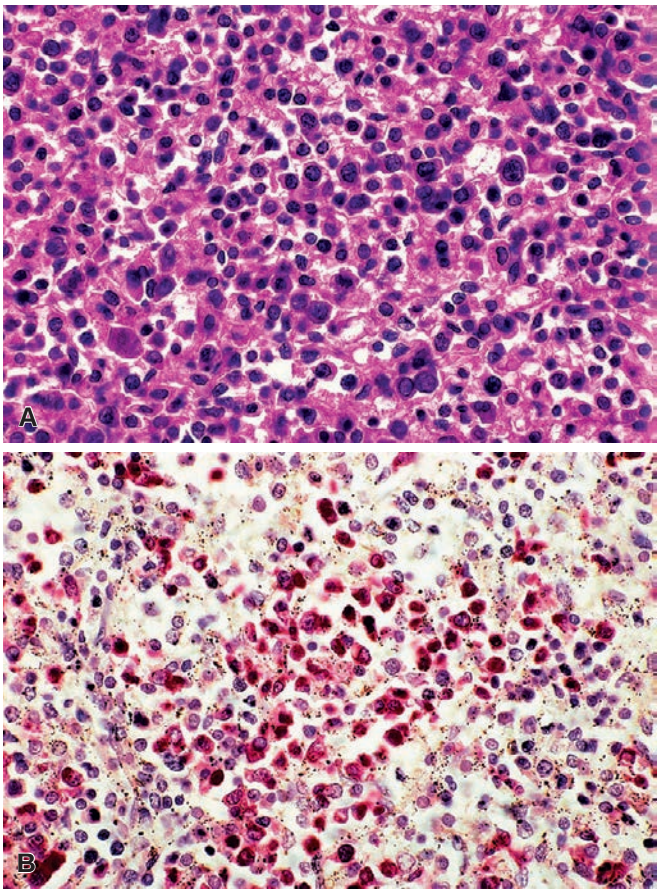

Figure 38.26 Abnormal hematopoiesis in splenic red pulp due to involvement by primary myelofibrosis, as seen in H&E section **(A)** and with Leder chloroacetate esterase stain **(B)**.

megakaryocytes often have atypical nuclear features and can be confused with Reed–Sternberg cells, but Hodgkin lymphoma of the spleen forms tumor nodules in contrast to the diffuse red pulp infiltration of primary myelofibrosis.[222] It is believed that the hematopoietic cells present in the spleen result from filtration of circulating cells from the peripheral blood rather than arising de novo from splenic stem cells.[223,224] Other splenic changes in myelofibrosis include congestion, hemosiderosis, and paucity of lymphoid follicles.[225,226]

Splenic changes similar to primary myelofibrosis are seen in the so-called spent phase of polycythemia vera. Splenomegaly in early polycythemia vera and essential thrombocythemia is less common and is often due to congestion of the red pulp and increases in red pulp macrophages containing platelets. Splenic enlargement in chronic myelomonocytic leukemia may also occur, due to increases in red pulp monocytes, and may demonstrate red blood cell lakes similar to those seen in hairy cell leukemia.[138,227]

Mastocytosis

The general features of systemic mastocytosis are discussed in Chapter 39. The spleen is frequently involved, and the morphologic changes in it can be very deceptive.[228] Grossly, the spleen is typically enlarged, with ill-defined nodules having a fibrotic appearance scattered throughout the organ. Microscopically, these highly fibrotic foci are often centered on a vessel or surround the white pulp, an important diagnostic clue.[228,229] The diagnosis depends on the identification of mast cells, which usually appear as pale-staining small clusters embedded in fibrous tissue, accompanied by a variable number of eosinophils, lymphocytes, or histiocytes (Fig. 38.27). The nucleus is centrally located and of regular outline; the cytoplasm is light staining, with a variable degree of granularity; the cell borders tend to be sharply outlined. Confirmation of the diagnosis is obtained by the immunohistochemical demonstration of mast cell tryptase and CD117 (KIT).[149,228,230,231] The mast cells also express CD68 and CD43 and often show aberrant expression of CD2, CD25, and CD30.[232]

Most patients with systemic mastocytosis exhibit the D816V point mutation in the *KIT* gene, involving the tyrosine kinase domain of the transmembrane receptor.[233]

The lymph nodes in the splenic hilum are often involved; the diagnosis may be easier on them than on the spleen. The foci of involvement in the lymph nodes are usually perifollicular and may also show a perivascular distribution. The gastrointestinal tract is also commonly affected.[234] Approximately one-third of patients with systemic mastocytosis have another hematologic disorder that may be life-threatening, such as chronic myelomonocytic leukemia and acute myeloid leukemia, and the red pulp cords and sinuses may be filled by this second neoplasm. Identification of the associated hematologic neoplasm is critical for management of the patient.

Other Hematolymphoid Conditions

Focal lymphoid hyperplasia can present in the spleen as a solitary nodule that may be confused grossly with lymphoma, especially if the patient is known to suffer from that condition. Microscopically, the nodule is formed either by aggregates of reactive germinal centers or by a localized proliferation of lymphocytes, immunoblasts, and plasma cells.[235,236] Focal lymphoid hyperplasia, however, is rare and care must be taken to exclude lymphoma, especially in patients with a history of Hodgkin lymphoma.

Castleman disease can involve the spleen, although it rarely results in prominent splenomegaly. Most of the reported types have been of the multicentric and plasma cell type,[63] but a few instances of the hyaline vascular type are also on record (Fig. 38.28).[62] As an aside, it could be mentioned here that the hyaline vascular form of Castleman disease shows a close resemblance to spleen on low-power examination, to the point that it is sometimes misdiagnosed as ectopic or supernumerary spleen when located in places such as mediastinum or retroperitoneum.

Wiskott–Aldrich syndrome, an X-linked hematologic disorder characterized by thrombocytopenia, eczema, and immunodeficiency, is accompanied by a general depletion of the splenic white pulp, with significant reduction of the marginal zone thickness.[237]

Vascular Tumors

Hemangioma is the most common primary tumor of the spleen.[238,58,239] They may be of the cavernous or capillary variety with morphologic features similar to hemangiomas at other sites. Most are less than 2 cm in diameter and present as incidental findings. Rarely, they are large and/or multiple, and they may involve the entire spleen (Fig. 38.29). They may be associated with hemangiomas of other sites *(angiomatosis)*. The most common complication is rupture and bleeding.[240] Cases associated with anemia, thrombocytopenia, and consumption coagulopathy (Kasabach–Merritt syndrome) have been reported.[241,242]

Littoral cell angioma is a vascular tumor unique to the spleen, originally thought to arise from normal splenic lining (littoral) cells.[243] It varies in size from minute foci to large nodules almost completely replacing the splenic tissue (Fig. 38.30). Microscopically, it is composed of anastomosing vascular channels resembling

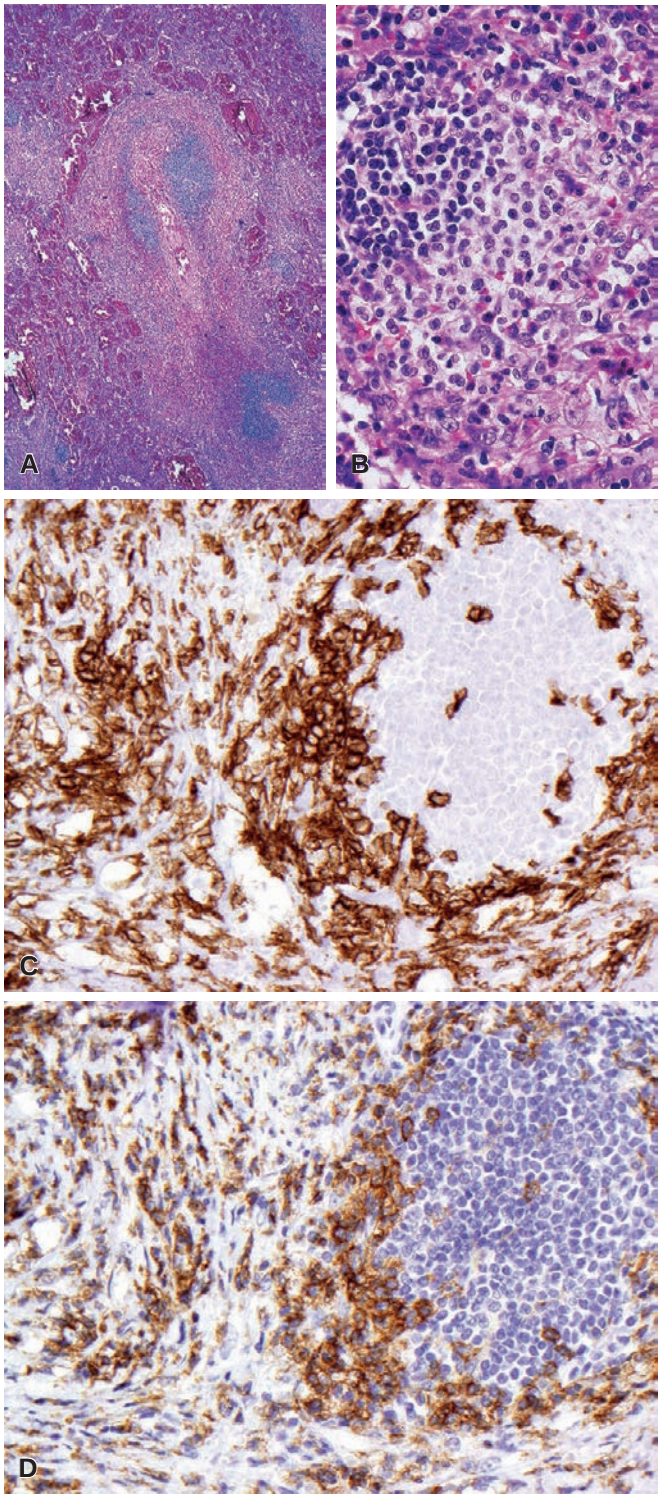

Figure 38.27 Involvement of the Spleen by Systemic Mastocytosis. **A,** Low-power view showing the perimalpighian and perivascular arrangement of the infiltrate. **B,** High-power view showing clusters of mast cells. **C,** The mast cells are strongly positive for CD117 and, **D,** show aberrant expression of CD25.

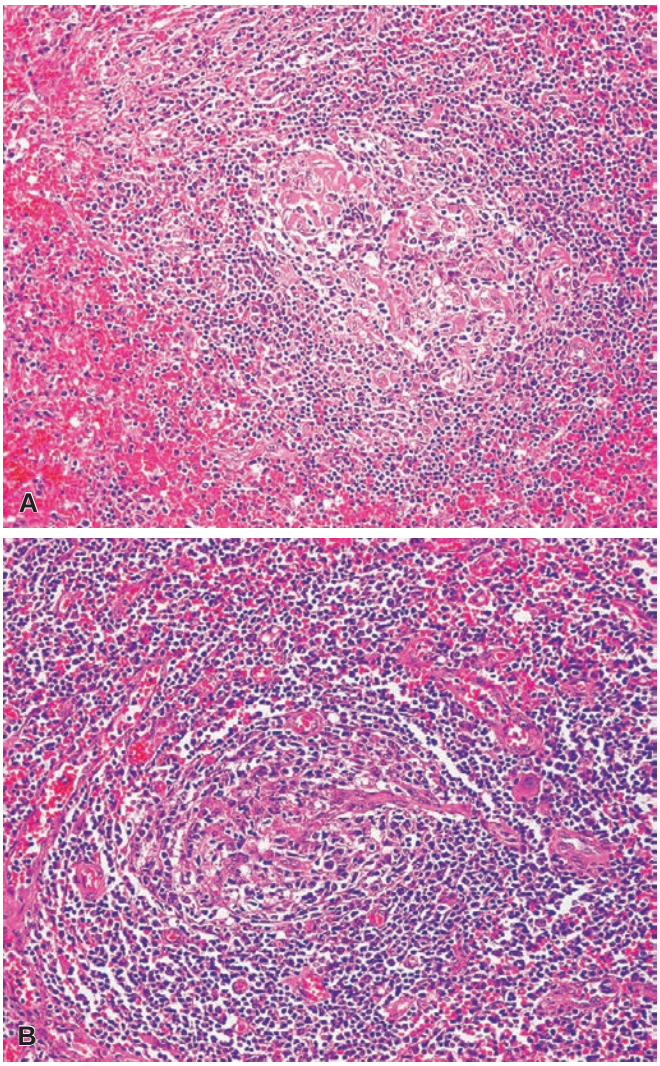

Figure 38.28 Castleman Disease of Hyaline-Vascular Type. A, Splenic involvement. **B,** Lymph node involvement in the same case.

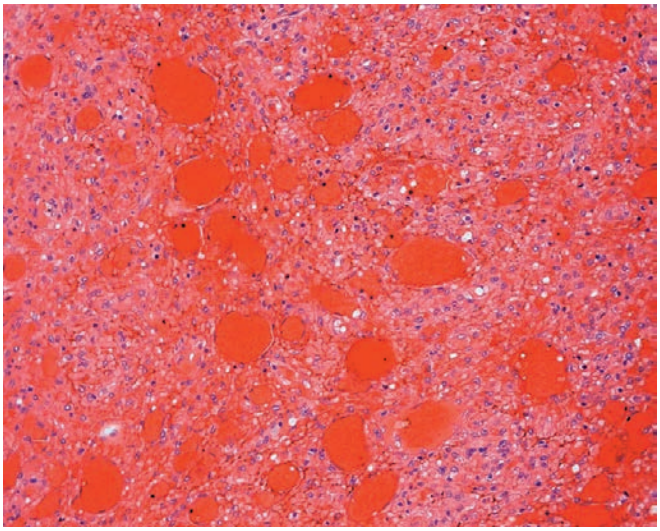

Figure 38.29 Diffuse involvement of spleen by benign vascular tumor ("angiomatosis").

splenic sinuses (Fig. 38.31). These channels have irregular lumina often featuring papillary projections and cyst-like spaces, often containing individual lining cells or histiocytes. They are lined by tall endothelial-like cells, some of which show hemophagocytosis. The lining cells show nuclear enlargement, but a low mitotic rate and no evidence of necrosis. Immunohistochemically, the neoplastic cells express some endothelial (factor VIII–related antigen) and histiocytic (KP1/CD68, lysozyme) markers, which suggested a littoral cell origin (Table 38.1). The lining cells also express CD31, but not CD34, and do not express CD8, typical of normal splenic sinus lining cells. Interestingly, most cases demonstrate at least focal expression of CD21 on the lining cells (Fig. 38.32).[238] Typical cases of littoral cell angioma are indolent and adequately treated with splenectomy. However, two cases, both with foci of clear cells in sheets, have developed late abdominal metastases of only the clear cell component and were diagnosed in retrospect as littoral cell hemangioendotheliomas.[244,245] Reported cases of so-called littoral cell angiosarcoma are usually based solely on expression CD8, which is a nonspecific finding in angiosarcoma and is not normally expressed in littoral cell angioma. No such cases have documented evidence of typical littoral cell angioma prior to development of angiosarcoma.

Figure 38.30 Gross Appearance of Littoral Cell Angioma. Numerous hemorrhagic lesions with a lobular configuration are seen.

Lymphangioma of the spleen is historically described as being located in the subcapsular region but may involve the entire organ *(diffuse lymphangiomatosis)* (Fig. 38.33).[246] Most of the subcapsular lesions diagnosed as splenic lymphangioma actually represent mesothelial cysts.[47] Most larger or diffuse cases have been reported in children, sometimes in association with lymphangiomas in other organs.[247] **Hemangioendothelioma** is the term that has been applied in the spleen (as in many other sites) in a somewhat loose fashion to vascular endothelial neoplasms that are either more cellular and/or are thought to be potentially more aggressive than conventional hemangiomas but are not full-fledged angiosarcomas. Some of these tumors have been described as *epithelioid* (sometimes associated with functional hyposplenism),[248] some as *epithelioid and spindle cell,*[249] and some as combining endothelial and myoid features *(myoid angioendothelioma)*.[250] Other than the very rare littoral cell hemangioendothelioma described previously, some tumors called hemangioendotheliomas in the past may represent other proliferations,

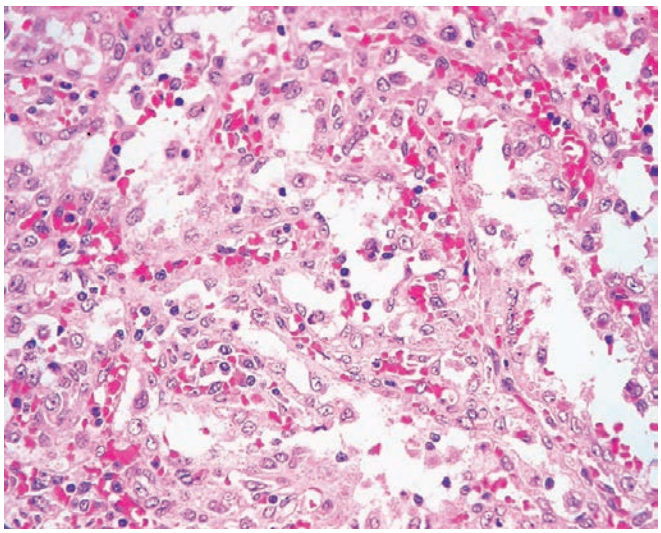

Figure 38.31 Littoral Cell Angioma of Spleen. The vascular spaces are lined by plump cells with the appearance of sinus lining ("littoral") cells.

Table 38.1 Useful markers in the differential diagnosis of non-hematopoietic primary splenic proliferations

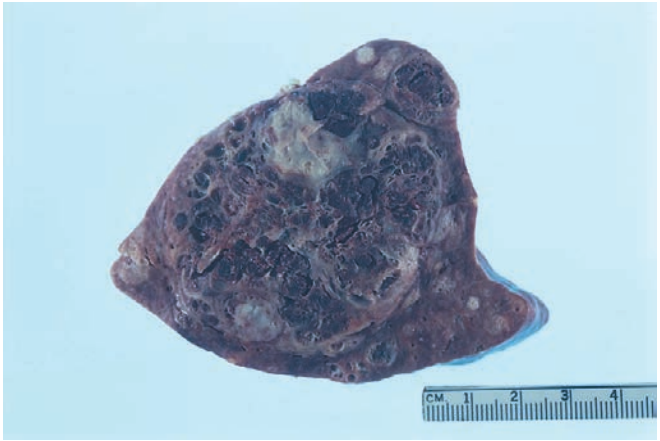

Figure 38.34 **Angiosarcoma of Spleen.** The tumor is markedly hemorrhagic and necrotic.

such as sclerosing angiomatoid nodular transformation (SANT; see later).

Angiosarcoma (malignant hemangioendothelioma) is considered the most common malignant primary nonlymphoid tumor of the spleen,[251] but the tumor is often disseminated at diagnosis and proving splenic origin is often difficult or impossible in those cases. In the spleen, it may present as a well-defined hemorrhagic nodule or involve the spleen diffusely and may lead to spontaneous rupture of the organ (Fig. 38.34).[252,253] It may also be accompanied by microangiopathic anemia, thrombocytopenia, and consumption coagulopathy.[254] As in other sites, there are cases of angiosarcoma of spleen that have developed many years following the insertion of a foreign body (gauze sponge).[255] Microscopically, the pattern of

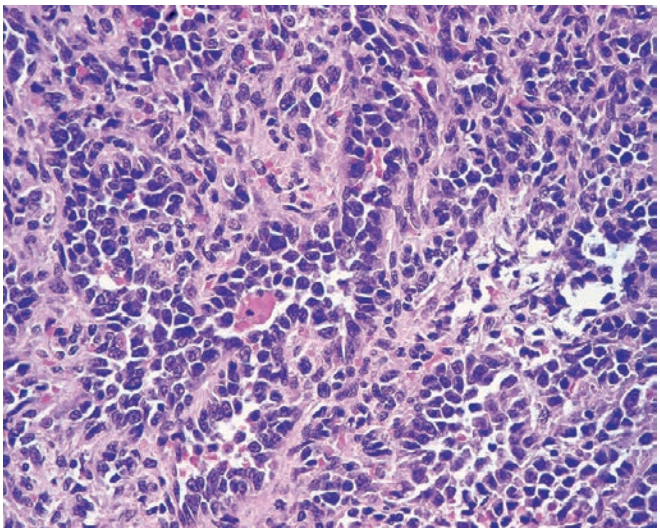

Figure 38.35 Angiosarcoma of Spleen. The tumor cells have markedly hyperchromatic nuclei that protrude into the vascular lumina.

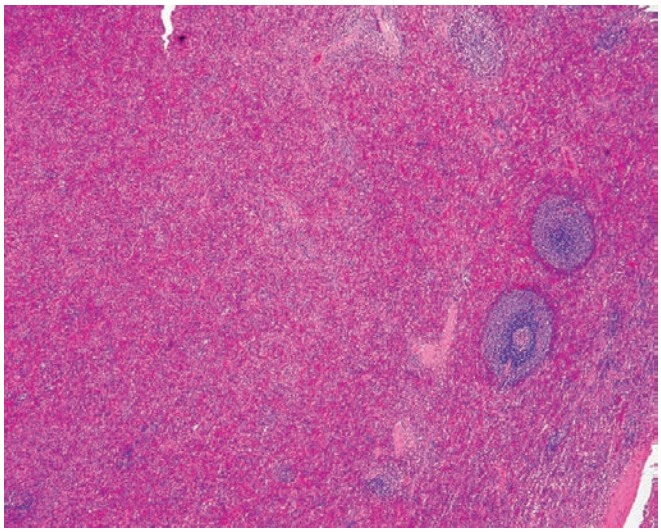

Figure 38.36 Low-Power Appearance of Splenic Hamartoma. The lesion is formed by disorganized red pulp without white pulp. Residual normal spleen is seen on the right.

growth of angiosarcoma may be solid, papillary, or characterized by the classic freely anastomosing vascular channels (Fig. 38.35).[256] Intracytoplasmic hyaline globules are common. Sometimes the tumor cells have an epithelioid appearance *(epithelioid angiosarcoma)*.[257] Immunohistochemically, the tumor cells exhibit endothelial markers, though some may show focal antigen loss, and often express CD68 and other less lineage-specific markers.[238,256] The clinical course of splenic angiosarcoma is rapid and almost invariably fatal, with widespread metastases occurring frequently.[256]

Hemangiopericytoma is mentioned last in this listing of vascular splenic tumor because of its exceptional rarity[257] and the controversies that exist about its real nature.

Other Primary Tumors and Tumorlike Conditions

Hamartoma (splenadenoma or splenoma) is the term used for a nodular lesion of the spleen composed exclusively of red pulp elements, without intervening white pulp (Fig. 38.36).[2,258–260] It does not contain follicles or follicular dendritic cells, fibrous trabeculae are scanty, and foci of extramedullary hematopoiesis may be present.[261] Occasionally, it may contain a population of bizarre stromal cells of probable dendritic/reticulum or myoid cell nature, which should not be overdiagnosed as malignant.[262,263] Immunohistochemically, a reverse pattern of factor VIII and CD31 staining when compared with the adjacent normal spleen has been described in splenic hamartoma.[264] Otherwise, predominant cell type is CD8 positive, similar to normal splenic sinus lining cells.[238] This lesion may attain a large size and be accompanied by thrombocytopenia and other signs of hypersplenism.[265]

Sclerosing angiomatoid nodular transformation (SANT) of the spleen is a distinctive splenic process that forms a distinct gross tumor nodule (Fig. 38.37) and has a striking multinodular quality that can simulate the appearance of granulomas on low-power histologic examination (Fig. 38.38A).[266–268] The individual nodules, which have a vaguely lobular architecture, are surrounded by a hyaline shell (see Fig. 38.38B). The vessels within the nodules are markedly cellular, to the point that they were initially interpreted as neoplastic and were named in a previous edition of his book as multinodular hemangioma. Immunostaining reveals three distinct types of vessel: CD34+/CD8–/CD31+ capillaries, CD34–/CD8+/

Figure 38.37 Gross Appearance of Sclerosing Angiomatoid Nodular Transformation. The bisected spleen shows a firm, stellate, tan-white lesion with foci of hemorrhage,

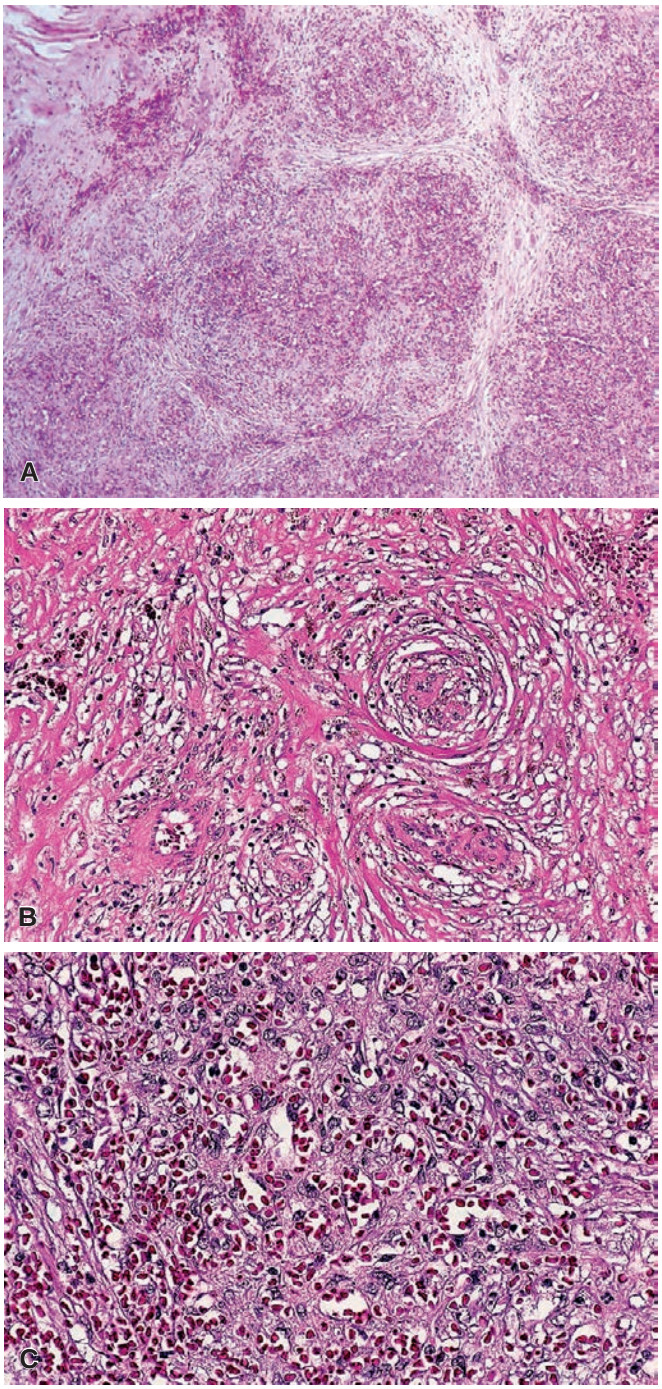

Figure 38.38 Sclerosing Angiomatoid Nodular Transformation of Spleen (SANT). A, Low-power appearance showing a distinctly nodular architecture. **B,** Highly hyalinized area simulating an ancient granuloma. **C,** Cellular area of clearly angiomatous nature.

CD31+ sinusoids, and CD34–/CD8–/CD31+ small veins (see Fig. 38.38C). The internodular stroma consists of variably myxoid to dense fibrous tissue with scattered plump myofibroblasts, plasma cells, lymphocytes, and siderophages. The lesion is almost always solitary and the evolution is benign. Its pathogenesis remains controversial. It shares a number of features with inflammatory pseudotumor,[269] a nonspecific diagnosis in the spleen; it may contain numerous IgG4-positive plasma cells,[270] and it was reported in one instance to be positive for EBV.[271]

Figure 38.39 Gross appearance of inflammatory pseudotumor-like fibroblastic/follicular dendritic cell sarcoma of the spleen. The cut surface has a variegated color resulting from a combination of necrosis, hemorrhage, and cellular infiltration.

The term **inflammatory pseudotumor** has been used in the past to describe a supposedly reactive tumorlike condition that may be encountered as an incidental finding at laparotomy or that may present as an asymptomatic splenic mass.[258,272] This term, however, is nonspecific and represents a variety of proliferations that range from inflammatory responses to malignant neoplasms. Infectious causes include the *splenic spindle cell pseudoneoplastic lesions* that can result from mycobacterial infection in immunocompromised patients.[273] Also, as mentioned, sclerosing angiomatoid nodular transformation of the spleen can have features of so-called inflammatory pseudotumor. Most cases with this presentation, however, represent what is now termed **inflammatory pseudotumor-like follicular/fibroblastic dendritic cell sarcoma**. These proliferations are unique to the liver and spleen and were originally described as EBV-positive inflammatory pseudotumors and subsequently as inflammatory pseudotumor-like follicular dendritic cell tumors.[274,275] They differ from traditional follicular dendritic cell tumors, and although it is remains as a subtype of follicular dendritic cell tumor, the name has been modified again in 2016 World Health Organization classification of hematopoietic neoplasms.[276] These tumors usually present with fever and abdominal pain. Grossly, the spleen demonstrates a discrete, firm tan lesion, sometimes with focal hemorrhage, without capsular extension (Fig. 38.39). Histologically,

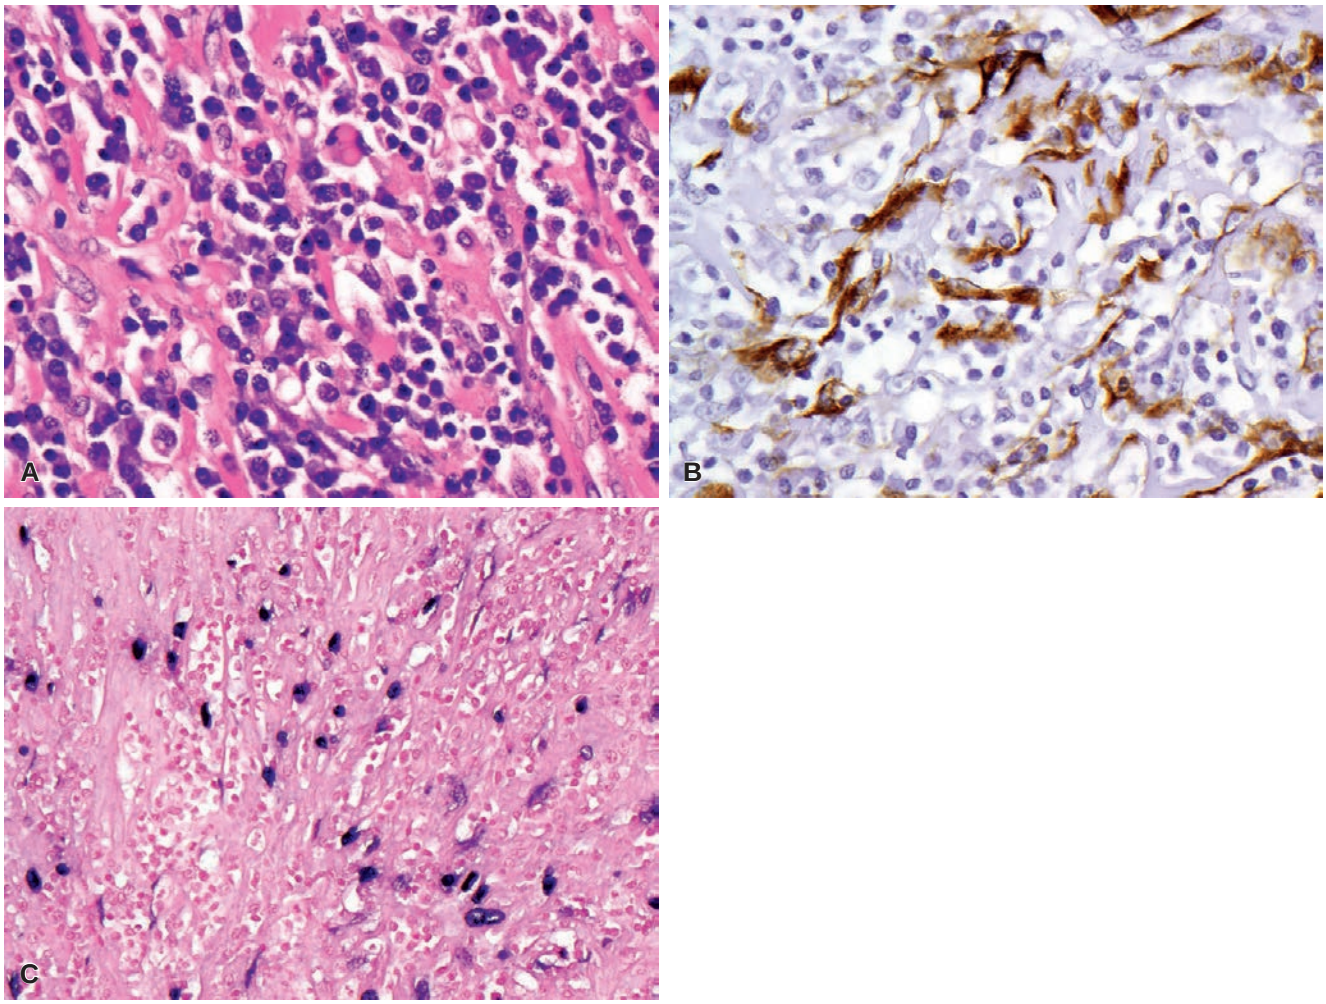

Figure 38.40 Inflammatory Pseudotumor-Like Fibroblastic/Follicular Dendritic Cell Sarcoma of Spleen. Spindle cells of myofibroblastic appearance are admixed with various types of inflammatory cell **(A)**. The spindle cells are focally positive for smooth muscle actin **(B)** and are EBV positive **(C)**.

the tumor is composed of a mixture of inflammatory cells as well as a spindle cell proliferation with interspersed variable amounts of collagenous stroma (Fig. 38.40). The inflammatory component is usually extensive, including lymphocytes, plasma cells, histiocytes, and eosinophils, and foci of necrosis are common. Unlike inflammatory pseudotumors in other organs, the spindled cells in the spleen are positive for EBV and may express smooth muscle actin (SMA), and vimentin. Spindle cells in many, but not all, tumors express CD21, CD23, or CD35. All cases of inflammatory pseudotumor-like follicular/fibroblastic dendritic cell sarcoma are negative for ALK1 in contrast to inflammatory myofibroblastic tumor of soft tissue which is generally positive for ALK1. Because of the presence of EBV in essentially all cases, and the lack of follicular dendritic cell markers in some, this tumor is biologically (as well as clinically) distinct from traditional follicular dendritic cell sarcoma. Splenectomy is curative for symptomatic cases, but cases that are partially resected may recur or metastasize.

Other primary neoplasms of the spleen are rare. Rare reported mesenchymal tumors of the spleen include the *EBV-related smooth muscle neoplasms* seen in the context of AIDS (often occurring in children) and following renal transplantation,[277,278] as well as other rare primary sarcomas.[58,279–281] Rare primary lipomas, carcinosarcomas, low-grade mucinous cystadenocarcinoma, and transitional cell carcinoma have all also been reported in the spleen.[282–285]

Metastatic Tumors

Metastatic malignancy of the spleen is a very uncommon clinical problem[286] but is not an unusual finding at autopsy if a thorough examination of the organ is carried out.[287] Malignant melanoma and carcinoma of lung, breast, stomach, large bowel, pancreas, and liver are the most common types.[288] Many others have been encountered, including ileal carcinoid.[289,290] There appears to be an unusual tendency for gynecologic cancers to develop delayed solitary metastasis in the spleen (Fig. 38.41).[291–295] Grossly, splenic metastases can appear as solitary or diffuse nodules, involve the organ diffusely, or be limited to the splenic capsule.[290] Breast carcinoma diffusely metastatic to the spleen may present as idiopathic thrombocytopenic purpura.[296] Occasionally, metastases in the spleen may be accompanied by nodular transformation of the red pulp, simulating follicular lymphoma on low-power examination.[297] The metastases can be superimposed on preexistent diseases of the spleen, such as hairy cell leukemia.[298]

Biopsy Procedure and Processing of Specimen

Trephine biopsy of the bone marrow has wide application in clinical medicine; its greatest utility is in the evaluation of patients with malignant lymphoma, acute leukemias, myeloproliferative neoplasms (MPNs), myelodysplastic syndromes (MDSs), metastatic tumor, granulomatous disorders, myelofibrosis, aplastic anemia, and plasma cell dyscrasias.[1–8] It also serves as the most reliable method for assessing marrow cellularity following the administration of antineoplastic drugs and in assessing the status of engraftment following hematopoietic cell transplantation. Marrow biopsy is also utilized in the investigation of patients with infectious disease and metabolic disorders.

The trephine biopsy should be viewed as one component of the bone marrow specimen that should also include smears and particle crush preparations from aspirated marrow and touch imprint preparations of the core biopsy specimen. In some instances, because of marrow fibrosis, the trephine biopsy specimen will be the only marrow tissue available for examination. Marrow biopsy can usually

Abstract

Bone marrow examination is performed for both staging and primary diagnosis. This chapter reviews the features of reactive conditions as well as primary bone marrow neoplasms, including leukemias, myelodysplastic syndromes, and myeloproliferative neoplasms. It also reviews the features of marrow involvement by various types of malignant lymphoma and metastatic tumors.

Keywords

Bone marrow,
leukemia,
lymphoma,
reactive lesions

be done with relatively little discomfort to the patient and is accompanied by very low morbidity when performed by experienced individuals with the biopsy needles presently available.[9] The posterior superior iliac spines are the preferred sites. Bilateral trephine biopsies may be useful in the staging of patients with some types of lymphoma, granulomatous disorders, and metastatic tumor, although improved imaging studies have replaced bilateral staging marrow biopsies in some institutions. This approach should be decided on an individual basis, considering both the reason for the procedure and the impact of positive findings for therapy.[3,10,11] In general, severe thrombocytopenia is not a contraindication to marrow biopsy. Whenever a marrow biopsy is performed, careful attention should be directed to preventing hematoma formation by applying an adequate pressure bandage to the biopsy site following the procedure. Prior to performing a biopsy on a patient with a bleeding disorder or on anticoagulants, consultation should be obtained from a physician expert in coagulation disorders.

Considerable discussion has occurred about the relative merits of trephine biopsy of the bone marrow as opposed to sections of particles obtained by aspiration biopsy.[5,6,12,13] Particle sections are of limited value in marrow disorders that are accompanied by fibrosis; these frequently result in inadequately aspirated specimens.[1,2] In addition, assessment of cellularity, determination of the extent of marrow involvement by neoplastic processes, and the relationship of lesions to marrow structures such as bone trabeculae and vasculature can be accurately assessed only in trephine biopsies. Nevertheless, any particles obtained in a marrow aspirate should be processed for histologic examination, as this material provides additional sampling that may be important when disease involvement is focal.

Paraffin embedding is the preferred method for the routine processing of bone marrow biopsies, and the observations described in this chapter are based primarily on examination of specimens prepared in this manner.[10,14] Plastic embedding offers some advantages over the paraffin method, such as excellent cytology and the ability to perform numerous histochemical reactions.[15] However, plastic embedding techniques are more time consuming than the processing of paraffin-embedded tissue, and with careful attention to technical detail, excellent results can be obtained with specimens processed in paraffin. Additionally, immunohistochemistry with a wide range of antibodies can now be performed with excellent results on most paraffin-embedded specimens.[16] For these reasons, plastic embedding is not routinely performed in most laboratories at this time.

Myelofibrosis is one of the more vexing problems in bone marrow histopathology because of the wide range of disorders that may cause marrow fibrosis and the usual difficulty in obtaining satisfactory aspirates for cytologic studies.[17] Although marrow fibrosis occurs as a primary disorder, it is usually a secondary phenomenon; the most common causes are metastatic tumor and malignant lymphoma. Fibrosis also occurs relatively frequently in the evolution of chronic MPNs, such as chronic myeloid leukemia (CML) and polycythemia vera (PV). In general, fibrosis that occurs as a component of hematopoietic proliferations is characterized initially by the deposition of increased reticulin fibers; metastatic tumors such as breast and prostate are usually characterized by a severe desmoplastic reaction with collagenous fibrosis and possibly osteosclerosis.

In those instances in which the etiology for the marrow fibrosis is not apparent, several techniques may be used in an attempt to determine the cause. Immunohistochemistry, using paraffin-embedded specimens and the several antibodies described in the section on immunohistochemistry, may be particularly helpful in identifying lymphoma or metastatic tumor; antibodies to myeloperoxidase, lysozyme, CD14, CD68, and CD117 are particularly useful for identifying cells of granulocytic or monocytic origin.[18] An additional procedure that may be useful in hematopoietic disorders associated with marrow fibrosis is the preparation of particle crush preparations from trephine biopsy specimens. This approach may necessitate a second biopsy unless the problem of fibrosis is anticipated before the initial procedure. As soon as possible after the trephine specimen is obtained and before it is placed in a fixative, small portions of the biopsy are cut away with a sharp scalpel blade and used for particle crush preparations in the same manner as particles from aspirated specimens. These crush preparations can be used for routine stains, cytochemistry, and immunocytochemistry. Portions of the biopsy specimen obtained in this manner may also be used for cytogenetics, molecular genetics, flow cytometry studies, routine electron microscopy, and ultrastructural cytochemistry. However, electron microscopy is generally no longer performed because of the availability of immunohistochemistry.

The use of special stains in bone marrow pathology should be determined following review of the routinely stained aspirate smears and biopsy and the patient's clinical history.

Several instruments are available for the bone marrow trephine biopsy procedure. The most satisfactory from the standpoint of safety, ease of performance, and overall quality of specimen obtained is the Jamshidi-type biopsy needle; several such instruments, both reusable and disposable, are commercially available.[9] These instruments are produced in several sizes for both adult and pediatric patients. The 11-gauge needle is the most commonly used for routine procedures in adults and older children. The 8-gauge instruments are preferred by some for lymphoma staging procedures; this size may result in more postbiopsy discomfort. If difficulty is encountered with the 11-gauge needle in obtaining adequate specimens from patients with severe osteoporosis, an 8- or 9-gauge instrument should be used. Numerous modifications of the original instruments are available.

The importance of proper technique in performing the biopsy procedure cannot be overemphasized. Instructions for the use of the biopsy needles are included with the instruments, and some manufacturers provide audiovisual aids that illustrate proper technique. Accurate identification of body landmarks is crucial in obtaining satisfactory specimens; an improperly positioned needle may cause considerable discomfort to the patient and frequently yields an inadequate biopsy specimen. Individuals not acquainted with the biopsy technique are advised to familiarize themselves with the procedure on cadavers.

Optimally, the biopsy specimen should be at least 1.5 cm in length and should be free of distortion caused by crushing or other damage. Crush artifact and the deposition of fibrin in torn biopsies may render accurate interpretation difficult or impossible. In such instances the biopsy should be repeated. Aspiration through the biopsy needle prior to obtaining the trephine biopsy specimen should be discouraged because of the possibility of introducing hemorrhage or other artifact in the biopsy specimen.

Occasionally, in patients undergoing frequent repeat biopsies, a specimen may be obtained from a recently biopsied site. In these instances, the changes will reflect the stage of healing. The presence of granulation tissue in the biopsy may result in misinterpretation of cellularity. The appearance of the marrow biopsy may be inconsistent with the marrow smears, which show recovering or normal hematopoiesis (Fig. 39.1).

Imprint preparations should be routinely made from the biopsy specimen immediately after it is removed from the biopsy needle and prior to being placed in a fixative. These can be used for Romanowsky stains and special cytochemical and immunocytochemical procedures. Following the preparation of imprints, the specimen is placed in an appropriate fixative; the most satisfactory are B5, 10% buffered neutral formalin, and acetic acid–zinc-formalin (AZF).[18,19] Zenker acetic acid gives excellent cytology but ablates several antigens that may be useful in evaluating neoplastic processes;

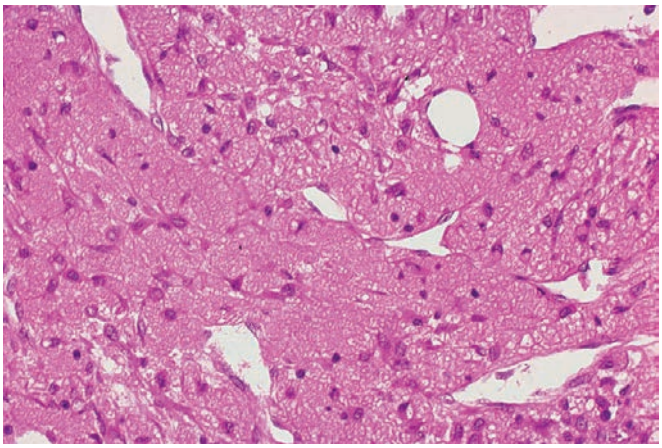

Figure 39.1 Marrow biopsy obtained at site of a biopsy performed 14 days previously. The marrow space is replaced by granulation tissue.

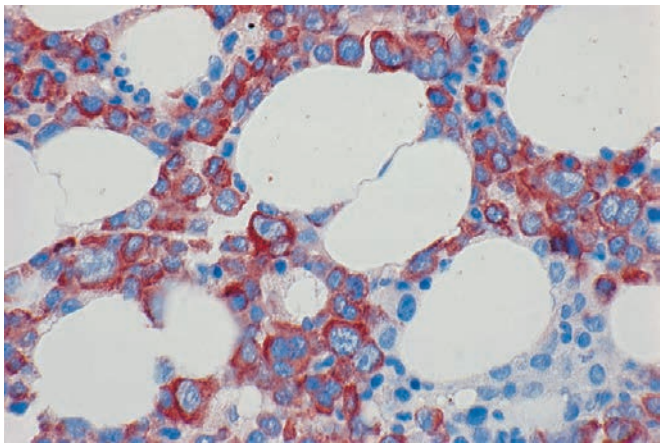

Figure 39.2 Marrow biopsy from patient with multiple myeloma reacted with polyclonal antibody to lambda light chain; the blastic appearing plasma cells show intense cytoplasmic reaction. (Immunoperoxidase.)

importantly it and B5 contain mercury, which is environmentally hazardous. In laboratories where bone marrow specimens are processed with other tissues, buffered neutral formalin may be the preferred fixative. Because of the environmental concerns and disposal problems, some institutions prohibit the use of mercury-based fixatives. As noted in the section on immunohistochemistry, reactivity with some antibodies may be ablated by some fixatives, and the choice of fixative may be determined by the reason for the biopsy. Following fixation for an appropriate period of time, the biopsy is decalcified. Several decalcification solutions are commercially available. Most biopsy specimens will be adequately decalcified following 45–60 minutes in a rapid decalcifying solution. Most rapid decalcification methods, however, destroy nucleic acids making the samples unsuitable for molecular genetic studies. Formalin-fixed clot sections that do not undergo decalcification are commonly collected to overcome this limitation. Alternatively, slower decalcification with ethylenediaminetetraacetic acid (EDTA) allows for preservation of nucleic acids.[20] A discussion of the relative merits and disadvantages of several fixatives and decalcifying agents used for bone marrow biopsies has been published.[18]

The biopsies should be sectioned at 3–4 µm with a sharp knife that is checked frequently for the presence of defects. In those patients being evaluated for the extent of lymphomatous involvement, metastatic tumor, or granulomatous disease, the specimens should be completely sectioned and stepwise serial sections mounted for hematoxylin and eosin staining.[3,11] The remaining ribbons should be numbered and retained in a manner that will facilitate the ready and accurate mounting of additional sections for special stains, immunohistochemical studies, and molecular studies.[8,18] Most of the stains used for other fixed tissues are also applicable to bone marrow sections. However, tissue processed with acid fixatives, such as B5 and Zenker, or with acid decalcifiers will yield unsatisfactory results with the chloroacetate esterase stain.

Optimally, when interpreting the trephine biopsy, the pathologist should examine the trephine imprints, bone marrow aspirate, blood smears, and other pathology specimens. Knowledge of the patient's clinical history, hematology profile, immunoelectrophoretic studies, and radiographic findings may be of considerable importance and may greatly facilitate the interpretation of the biopsy specimen.

Immunohistochemistry

As in other areas of pathology, immunohistochemistry is an important resource in the evaluation of proliferative processes involving the

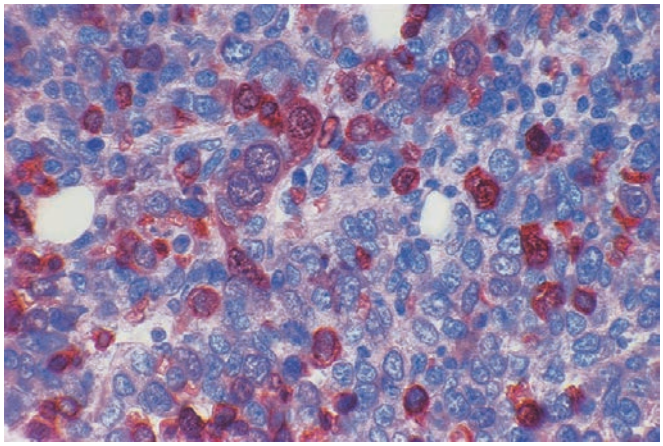

Figure 39.3 Marrow from patient with pure erythroleukemia reacted with antibody to hemoglobin A; many of the erythroblasts show a positive cytoplasmic reaction. Intensity of reaction varies from very slight to marked. (Immunoperoxidase.)

marrow.[21] The availability of antibodies reactive in paraffin-embedded tissue and the use of antigen retrieval have been of considerable importance in the application of immunohistochemistry in bone marrow pathology. Although cryostat sections of marrow may be used for immunohistochemistry, the procedure is difficult and is not routinely performed.[22] In addition, cytologic preservation in cryostat sections is frequently of marginal quality.

Although decalcification with rapid acid decalcifiers may result in ablation of some antigens, an increasing number of antibodies to membrane antigens and cytoplasmic constituents are reactive in paraffin-embedded decalcified marrow biopsies and can be of considerable aid in identifying the lineage of immature cell populations in the marrow; these include antibodies to kappa and lambda light chains, leukocyte common antigen (CD45), myeloperoxidase, CD33, CD117, glycophorin, hemoglobin A, E-cadherin, von Willebrand factor (factor VIII–related antigen), CD61, CD14, CD68, CD163, CD20 (L26), CD79a, PAX5, CD3, CD5, CD30, CD15, CD34, terminal deoxynucleotidyl transferase (TdT), and tumor-related antigens, and proliferation antigens (Figs. 39.2–39.10).[22–32] Antibodies to kappa and lambda immunoglobulin light chains are particularly useful

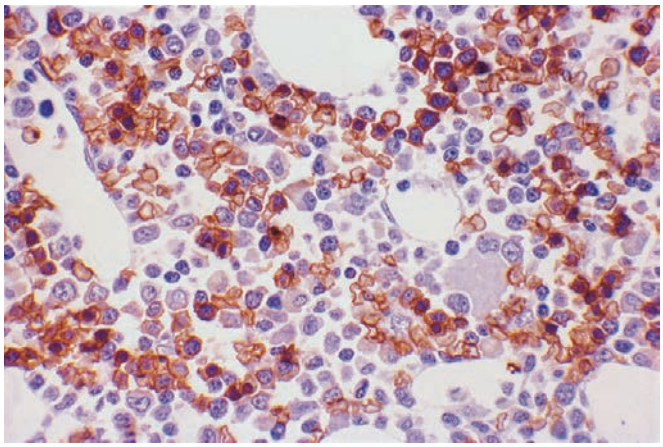

Figure 39.4 Marrow biopsy from a 2-year-old child with congenital neutropenia reacted with antibody to glycophorin A. There are numerous positive erythroid precursors at all stages of maturation. (Immunoperoxidase.)

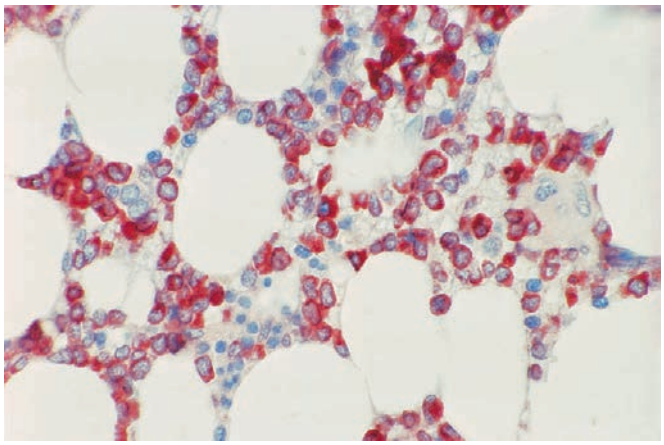

Figure 39.5 Bone marrow biopsy from a patient with hypocellular acute myeloid leukemia reacted with polyclonal antibody to myeloperoxidase. The predominant myeloblasts and promyelocytes show intense cytoplasmic reactivity. (Immunoperoxidase.)

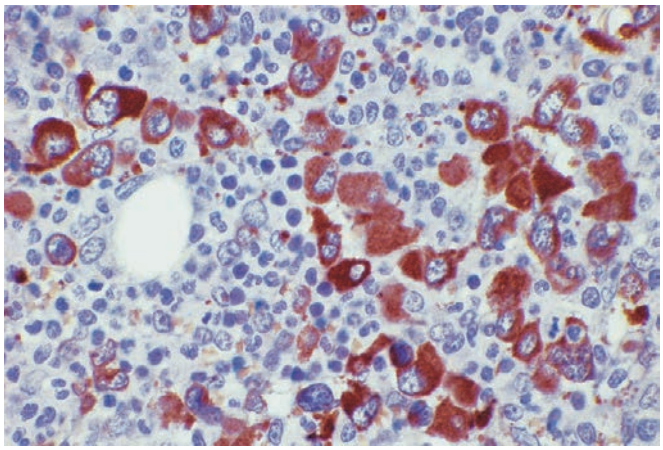

Figure 39.6 Bone marrow biopsy from a patient with chronic myeloid leukemia in accelerated phase reacted with polyclonal antibody to factor VIII–related antigen (von Willebrand factor). There are numerous dysplastic megakaryocytes with hypolobulated nuclei which show intense cytoplasmic reactivity. (Immunoperoxidase.)

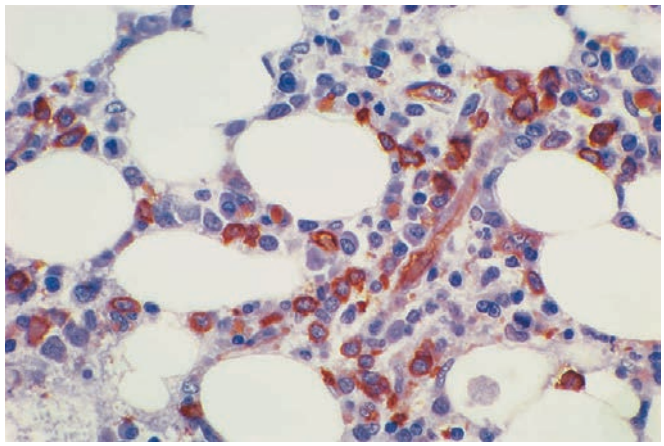

Figure 39.7 Bone marrow biopsy from an adult man with therapy-related myelodysplastic syndrome and hypocellular marrow reacted with antibody to CD34. The number of positive cells approximates the 18.5% blasts in the marrow smear. (Immunoperoxidase.)

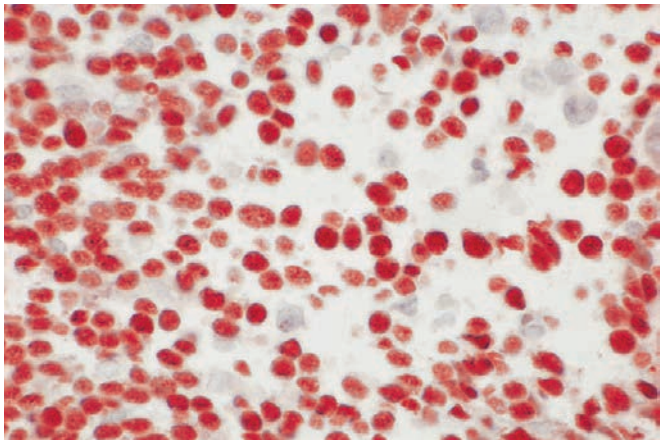

Figure 39.8 Marrow biopsy from a child with precursor B acute lymphoblastic leukemia reacted with polyclonal antibody to TdT; the lymphoblasts show intense nuclear reactivity. (Immunoperoxidase.)

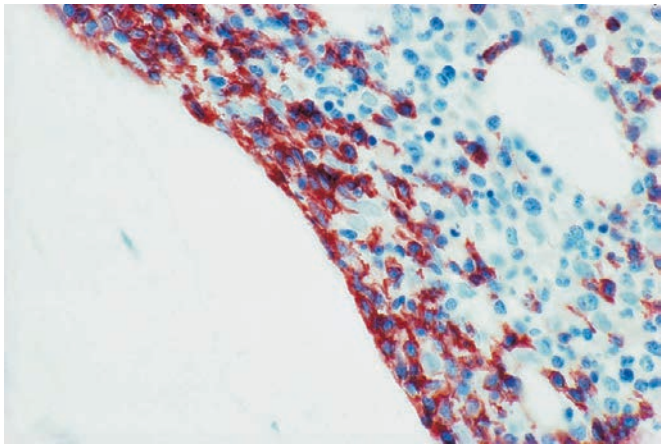

Figure 39.9 Marrow biopsy from an adult man with recurrent follicular lymphoma positive for CD20. Numerous positive lymphocytes are present in a paratrabecular location. (Immunoperoxidase.)

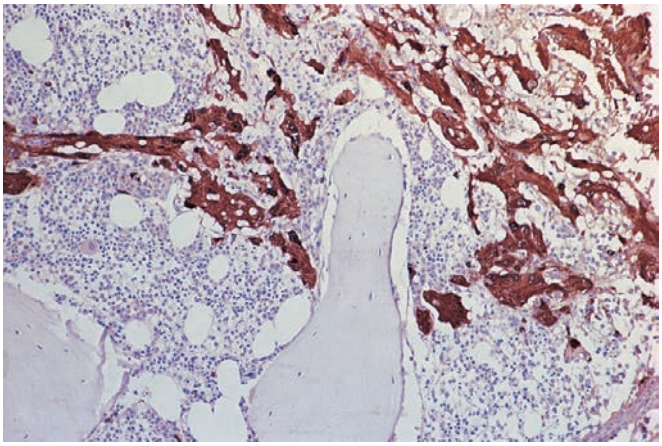

Figure 39.10 Marrow biopsy from a child with neuroblastoma with ganglion differentiation reacted with antibody to neuron-specific enolase. The tumor cells are intensely reactive. (Immunoperoxidase.)

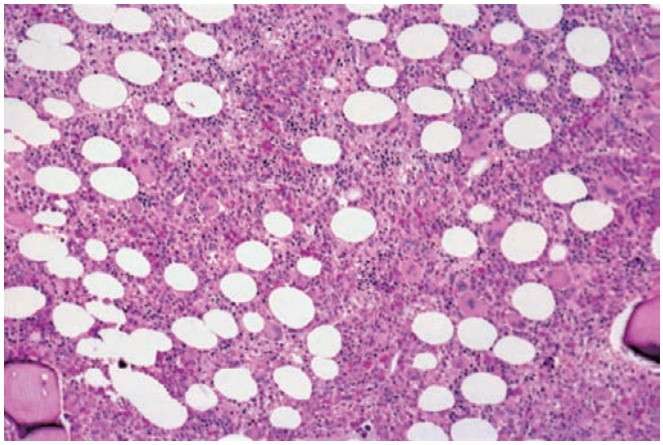

Figure 39.11 Normocellular bone marrow from 42-year-old man obtained as part of evaluation as potential donor for bone marrow transplantation. Hematopoietic cells and adipose tissue are present in approximately equal quantities.

for determining the relative proportions of kappa- and lambda-containing cells in immunoproliferative disorders such as multiple myeloma.[33] Reactivity with these antibodies is generally restricted to processes in which the cells contain cytoplasmic immunoglobulin. The technique is not sufficiently sensitive to detect surface immunoglobulin on the lymphocytes in most B lymphoproliferative diseases. Occasionally the lymphocytes in a B-cell lymphocytic lymphoma contain cytoplasmic immunoglobulin that may be detected by this method. With some fixatives, in situ hybridization methods for immunoglobulin light chains work well in marrow specimens, often with less background staining than immunohistochemical methods.[34] The antibodies to lymphocyte antigens are useful in determining the B- or T-cell origin of the lymphoproliferative processes and the extent of marrow involvement (see Fig. 39.9). These antibodies are not determinants of clonality. Polyclonal antibody to myeloperoxidase is a specific and sensitive antibody for cells of neutrophil origin that reacts with the myeloblasts in most cases of acute myeloid leukemia (AML; see Fig. 39.5).[24,35,36] Some studies, however, have shown that in paraffin-embedded tissue, monoclonal antibodies to myeloperoxidase are more specific. Several panels for the immunohistochemical characterization of acute leukemia have been described.[18,24,25,35,37,38] These generally include antibodies to CD68 (both PGM1 and KP1), myeloperoxidase, CD34, lysozyme, lymphocyte antibodies, and TdT, with addition of other antibodies as needed.

It is important that the reactivity pattern of all antibodies be determined by each laboratory. The range of reactivity attributed to an antibody by the manufacturer should be confirmed with lesions of known antigenicity. The pattern of reactivity of the antibodies to lymphoid cells is generally based on studies of lymph nodes fixed in B5 or buffered neutral formalin. The same reactivity results may not be applicable to marrow biopsies decalcified with a rapid acid decalcifier; L26, an excellent antibody to CD20, a pan B-cell antigen, works well in bone marrow biopsies decalcified with a rapid acid decalcifier but may not react in Zenker-fixed tissue decalcified in the same manner. The effects of decalcification on antibody reactivity should be determined by subjecting lymph node tissue to the same decalcification procedure employed for bone marrow biopsies as part of the antibody validation procedure.

Most large histopathology laboratories use automated instruments for immunohistochemistry; with careful attention to detail, generally very good results are obtained.

In addition to routine histopathologic studies, the bone marrow specimen is being increasingly utilized for molecular and cytogenetic studies.[8,39] These special techniques should, if possible, be anticipated prior to obtaining the biopsy in order for the specimen to be processed in an appropriate manner. However, not infrequently, the need for these studies is not determined until a biopsy specimen is examined with routine stains. In these instances, it would be appropriate to repeat the biopsy for the necessary specimens. Fixed specimens embedded in paraffin may have been used for some of these studies. This may suffice if the reliability of the technique is ensured from quality control studies. Decalcified specimens may yield distinctly different, often inferior, results from nondecalcified fixed specimens.

This section is not intended to serve as a complete description of all of the antibodies available for bone marrow immunohistochemistry; the individual antibodies that may be useful will be noted in the discussion of the various disease conditions.

Normocellular Bone Marrow

Assessment of marrow cellularity must take into account the age of the patient because the amount of hematopoietic tissue in bone marrow from normal individuals varies with age, as demonstrated in both histologic and radiologic imaging studies.[40–42] The simplistic formula "100 minus the patient age" to estimate normal cellularity for age is relatively inaccurate and may overestimate or underestimate the normal cellularity of many patients because the decrease in cellularity is not constant throughout human life. In the first decade, the mean marrow cellularity is 79%; the mean cellularity in the eighth decade is 29%. In the first three decades of life more than half of the marrow is composed of hematopoietic cells. During this period, there is a gradual decrease in the amount of hematopoietic tissue with an increase in fat cells. From the fourth to the seventh decade, there is relative stabilization of the number of hematopoietic cells (Figs. 39.11 and 39.12); beginning in the eighth decade, there is a renewed decrease. The increase in adipose tissue results from a decrease in both hematopoietic and bone tissue.[42]

The immediate subcortical area of the bone marrow may normally be more hypocellular than the deeper medullary areas. As a result, specimens that contain a substantial amount of subcortical marrow may be inadequate for estimating cellularity. In addition, the immediate paratrabecular areas may be preferentially hypocellular.

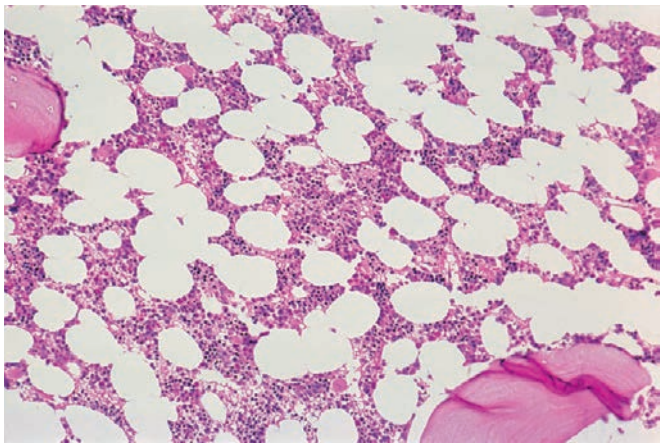

Figure 39.12 Marrow biopsy from a 70-year-old man being evaluated for metastatic tumor. The marrow is approximately 30%–35% cellular, normal for age. There was no evidence of tumor.

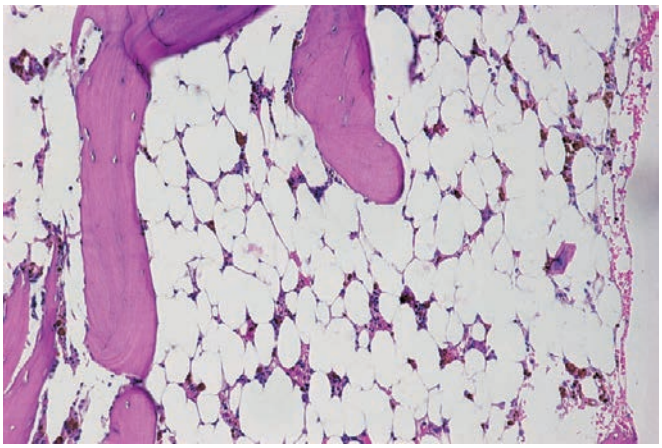

Figure 39.13 Bone Marrow Section From a 7-Year-Old Girl With Idiopathic Acquired Aplastic Anemia. Hematopoietic cells are almost totally absent. Sinuses and capillaries are prominent. Iron-laden macrophages reflecting increased iron stores from repeated red blood cell transfusions are present.

Alterations in Cellularity

Aplastic Anemia

Acquired aplastic anemia has historically been classified as idiopathic or secondary, the latter cases allegedly resulting from exposure to drugs, chemicals, viral infections, or ionizing radiation.[43–48] Contemporary theories have focused on immunologic mechanisms as the causative factor in the majority of cases.[49,50] These mechanisms involve activation of T-cell subsets that attack marrow stem cells and progenitor cells. In some instances, apparently acquired aplastic anemia is related to inherited genetic mutations and telomere shortening.[51] Severe aplastic anemia is defined by a markedly hypocellular bone marrow (<25% of normal for age or 25%–50% of normal with <30% hematopoietic cells) accompanied by two of the following: granulocytes less than 0.5×10^9/L; platelets less than 20×10^9/L; or a corrected reticulocyte count less than 1%.[52]

The biologic mechanisms underlying the occasional evolution of aplastic anemia to paroxysmal nocturnal hemoglobinuria (PNH) is not presently known,[53] but the presence of small PNH clones in aplastic anemia may be associated with in improved response to immunosuppressive therapy.[54]

The term "constitutional aplastic anemia" has been used collectively for all congenital aplastic anemias, familial and nonfamilial, with and without associated abnormalities of body structures. There are several inherited bone marrow failure syndromes that may manifest marrow aplasia or hypoplasia, including Fanconi anemia, Shwachman–Diamond syndrome, dyskeratosis congenita, and Diamond–Blackfan anemia.[55–63]

Fanconi anemia is a syndrome of familial hypoplastic anemia occurring primarily in the first decade of life that is associated with multiple organ malformations, including hypoplasia of the kidneys and absent or hypoplastic thumbs or radii.[56,58–60] It is associated with numerous gene mutations and is the most common cause of aplasia in the first decade of life.[64,65] An association of hypoplastic bone marrow and pancreatic dysfunction (Shwachman–Diamond syndrome) is a rare disorder occurring in children.[61] Diamond–Blackfan anemia is characterized by erythroid aplasia or hypoplasia related to mutations of genes encoding ribosomal structural proteins, manifesting usually in the first year of life.[66]

Selective aplasia or hypoplasia of the megakaryocytes associated with missing radii (TAR syndrome) is a rare disorder. An inherited autosomal dominant hematologic disorder associated with proximal fusion of the radius and ulna has been reported; the hematologic manifestations are somewhat variable and include adult onset of generalized bone marrow failure and amegakaryocytic thrombocytopenia presenting in childhood. The latter presentation has been associated with a mutation in homeobox genes *HOXA11*. The homeobox genes encode regulatory proteins that have a role in skeletal morphogenesis and hematopoiesis.[57,67,63]

In the most severe form of aplastic anemia, the intertrabecular marrow space is occupied predominantly by adipose tissue with scattered lymphocytes, plasma cells, tissue mast cells, and hemosiderin-laden macrophages (Fig. 39.13). In less severe processes, there is an increased amount of fat tissue and scattered small collections of erythroblasts, granulocytes, and megakaryocytes; in some instances, the decrease in megakaryocytes is disproportionate to other cell types. The blood findings in aplastic anemia are characterized by varying degrees of pancytopenia.

Uncommonly, the marrow biopsy in a patient with aplastic anemia contains aggregates of well-differentiated lymphocytes similar to the lesions that occur in a variety of immune disorders; these are described in this chapter as polymorphous lymphoid aggregates. Unusually large aggregates of benign T lymphocytes have been observed in aplastic marrows in patients with invasive malignant thymoma with an associated nonclonal T lymphocytosis in the blood (Fig. 39.14).[68]

Hypoplastic marrows may be encountered in some newly diagnosed cases of acute leukemia and MDS. These can generally be distinguished from true aplastic anemia by the population of blasts and immature granulocytes, in contrast to the mature lymphocytes, plasma cells, and tissue mast cells in aplastic/hypoplastic marrows. The use of CD34 is an additional aid in identifying blast cells.[69] However, it is important to note that not all blasts express CD34 and a negative reaction does not exclude a blast population. Concurrent staining for myeloperoxidase should be performed. Cytogenetic studies show distinct clinical outcomes for cytogenetic abnormalities arising in aplastic anemia.[70]

The use of hematopoietic cell transplantation as a therapeutic approach to aplastic anemia in patients who do not respond to immunosuppressive therapy has gained wide acceptance. Evidence of marrow reconstitution usually is present in biopsies obtained 2–3 weeks following transplantation and consists of foci or islands

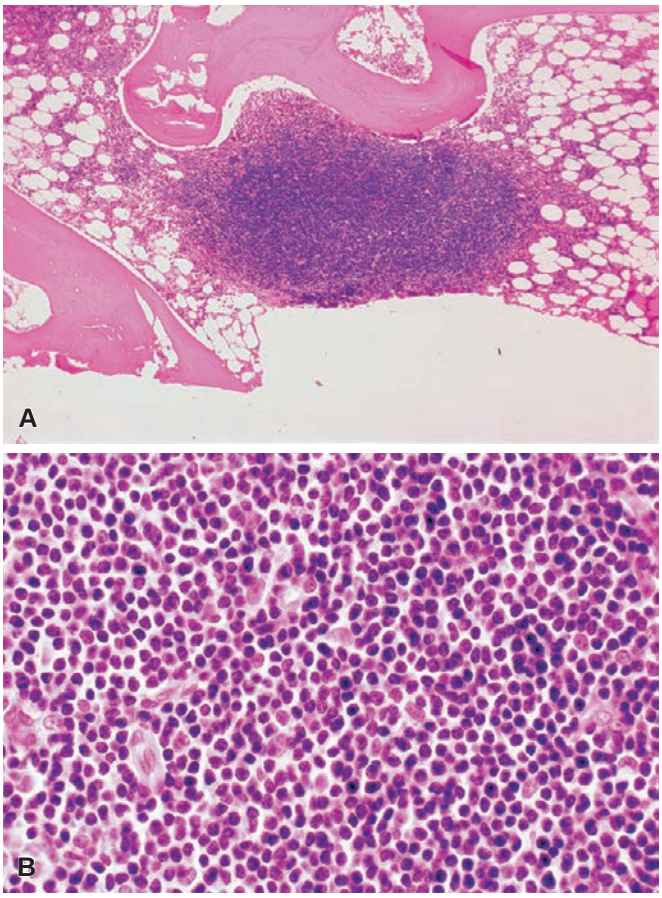

Figure 39.14 **A,** Marrow biopsy from a 75-year-old man with invasive thymoma and nonclonal T-cell CD3+, CD4+, CD5+, CD8+ lymphocytosis. The markedly hypocellular marrow contains several large aggregates of small lymphocytes as illustrated; the predominant lymphocytes in the marrow specimen had the same phenotype as the blood and were nonclonal by molecular studies. The repeat marrow biopsy following thymectomy showed regression of the lymphocytic aggregates but persistence of hypoplasia. **B**, High magnification of specimen in **A**.

of hematopoietic cells. Sequential marrow biopsies in the subsequent 5- to 10-week period show increasing numbers of erythroid precursors, granulocytes, and megakaryocytes in patients with engraftment. Impending rejection of engraftment may be heralded by a decrease in one marrow cell line. An association between high mast cell counts in post marrow transplant specimens from patients with aplastic anemia and marrow rejection has been reported, but this has not been a uniform observation.[71,72]

Growth factor therapy and immunosuppressive and antibiotic therapy may alter the morphology of the proliferating engrafted cells, and evidence of dyserythropoiesis and dysgranulopoiesis may be present. At times, agranulocytosis with a "maturation arrest" of the proliferating neutrophil precursors at the promyelocyte stage may occur as a result of antibiotic or other drug therapy. The use of recombinant granulocyte growth factor may result in a marked shift to immaturity in the developing neutrophils. Selective hypoplasia of myeloid cell lines may occur and is frequently related to specific drug- or virus-related immune mechanisms. Selective erythroid hypoplasia may occur in patients with parvovirus B19 infection and in association with some drugs such as the immunosuppressive drug mycophenolate mofetil, used after solid organ transplantation.[73–75]

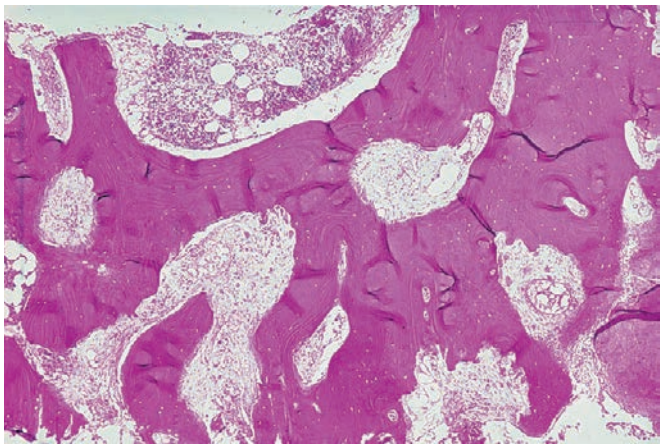

Figure 39.15 **Osteitis Fibrosa Cystica.** Marrow biopsy from posterior iliac spine from a patient with chronic renal disease and secondary hyperparathyroidism. A portion of normal-appearing marrow is at the top. The remainder of this area shows new bone formation, loose marrow fibrosis, and increased osteoblasts and osteoclasts.

Marrow Hyperplasia

Hyperplasia of one or more myeloid cell lines (erythroid, granulocytic–monocytic, megakaryocytic) may be found in several hematopoietic disorders. Several benign hematologic disorders are characterized by hypercellularity; these include cell maturation defects such as the megaloblastic and sideroblastic anemias or disorders with increased rates of destruction or utilization of various cell types in which the hypercellularity is due to compensatory hyperplasia. Hemolytic anemias are generally characterized by a marked erythroid hyperplasia. In immune thrombocytopenia in which there is an increased rate of platelet destruction, the megakaryocytes are normal to increased in number. One of the major problems in evaluation of marrow from patients with benign disorders, such as megaloblastic anemia in which the marrow may be very hypercellular and precursor cells may show striking nuclear changes, is that the proliferating erythroblasts or other myeloid cells may be misinterpreted as a leukemic proliferation; examination of the blood and marrow smears in combination with review of the clinical history and laboratory data should prevent the possibility of this type of error.

Infrequently, a posterior iliac spine biopsy may contain findings unrelated to the reason for which the biopsy is performed. One such finding is osteitis fibrosa cystica related to secondary hyperparathyroidism in patients with chronic renal disease (Fig. 39.15). It is imperative for pathologists and hematologists to recognize the potential for diseases other than hematologic disorders that manifest in marrow biopsies.

Gelatinous Transformation (Serous Atrophy/ Degeneration)

Gelatinous (serous) transformation is a degenerative change of the marrow characterized by atrophy of the fat and hematopoietic cells and accumulation of serous fluid in the interstitium.[76–79] It is an epiphenomenon associated with several disorders that are usually accompanied by extreme malnourishment and weight loss; it is potentially reversible with resolution of the underlying problem and restoration of normal nutritional status. The etiologic bases are somewhat age related: anorexia nervosa, human immunodeficiency virus (HIV) syndrome, and acute febrile illnesses are the most common factors in young individuals; alcoholism and lymphomas in middle

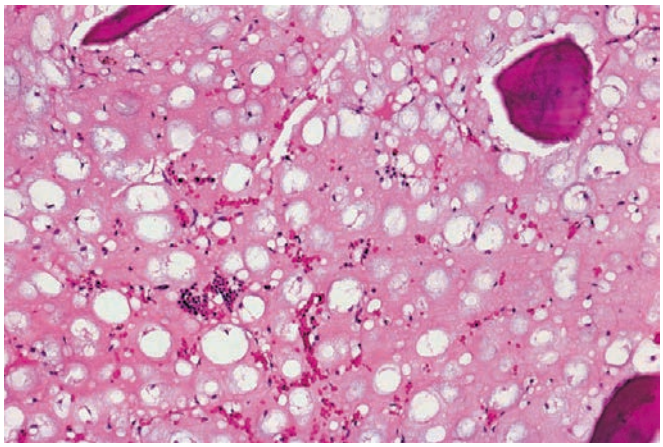

Figure 39.16 Bone marrow section from a 19-year-old man with anorexia nervosa and severe weight loss showing marked serous degeneration (gelatinous transformation). There is marked reduction in hematopoietic and fat cells with accumulation of an amorphous, eosinophilic substance.

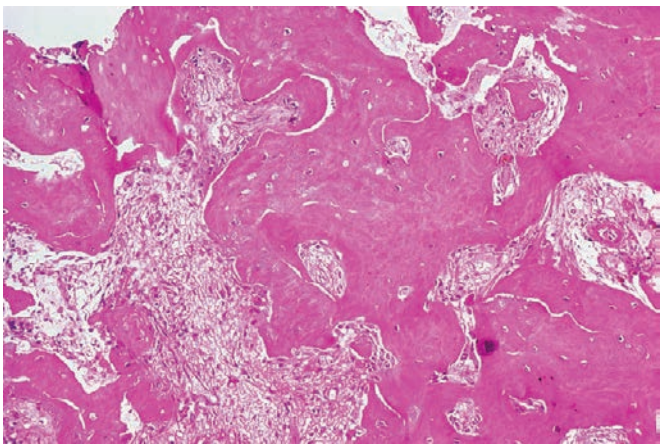

Figure 39.17 Decalcified Posterior Iliac Spine Bone Marrow Trephine Biopsy From an 8-Month-Old Girl With Osteopetrosis. Marrow space is markedly reduced as consequence of widely expanded bone structure. Lighter areas in bone structure represent cartilaginous plates. Numerous osteoclasts are present in some areas along the endosteal surface.

age; and carcinomas, lymphomas, and congestive heart failure in older individuals. It may also be observed in the pediatric population.[80,81] The majority of patients are anemic.

The areas of gelatinous transformation in the marrow biopsy may be focal with intervening areas of normal hematopoietic and fat cells, or the entire biopsy may manifest the transformation, which appears as a homogeneous lightly eosinophilic appearance in sections stained with hematoxylin and eosin; it is pale pink with periodic acid–Schiff (PAS) and slightly bluish with Giemsa (Fig. 39.16). Bone marrow aspirate smears contain a dense metachromatic, mucoid-appearing material with Giemsa stain.

Osteopetrosis

Osteopetrosis is a rare genetic disorder of osteoclast function and/or development, characterized by impaired bone resorption and increased bone sclerosis.[82–84] There are several possible genetic mutations that may result in osteoclast dysfunction or lack of development.[82,83,85] Several classifications have been proposed. Generally two major groups are recognized: autosomal recessive osteopetrosis and autosomal dominant osteopetrosis. A rare sex-linked form has also been reported. There is wide variation in the clinical severity of the disease, both in the autosomal dominant group (also known as Albers–Schönberg disease, which includes asymptomatic individuals and adults) and the autosomal recessive group. The most severe forms of the disease, which occur in young infants, are lethal unless treated with hematopoietic cell transplantation and are usually autosomal recessive (infantile malignant osteopetrosis).[82,86] A less severe form of autosomal recessive osteopetrosis is caused by a mutation in the gene encoding carbonic anhydrase II, resulting in carbonic anhydrase II deficiency; in addition to the osteopetrosis, these patients have renal tubular acidosis and cerebral calcifications. The few X-linked cases have been associated with ectodermal dysplasia, lymphedema, and immune deficiency.[82–84,87] The incidence of infantile malignant osteopetrosis is 1 in 300,000 births, except in Costa Rica where it is 3–4 in 100,000 births.

Most cases of osteopetrosis are associated with a failure of osteoclast function resulting in disturbances of intracellular and extracellular pH of the osteoclast resorption compartment which leads to impaired resorption of organic and inorganic bone matrix.[83] In some cases there is a failure of osteoclast development; this autosomal recessive form is associated with mutations of a variety of genes in 70% of cases that disrupt osteoclast development, differentiation, and function.[82,84,86–88] In the severe forms of the disease there is sclerosis of all of the bones. In the less severe forms there is sclerosis of the bones of the skull, pelvis, vertebrae, and phalanges.

The radiographs in osteopetrosis show increased bone density. The increased bone sclerosis results in reduced marrow space and impaired myeloid hematopoiesis, essentially a form of bone marrow failure; this is accompanied by extramedullary hematopoiesis with hepatosplenomegaly and a leukoerythroblastic blood picture. Reduction in the size of the foramina in the skull leads to optic and auditory nerve compression with visual and auditory defects. Although the bones are dense there is increased fragility and propensity for fractures. Dentition problems are also a part of the clinical picture. The only known cure for the infantile malignant form of the disease is hematopoietic cell transplantation. Many cases of the autosomal dominant form of osteopetrosis are asymptomatic; the most common clinical manifestation is increased fragility of bone leading to fractures.

Posterior iliac crest biopsy may be performed prior to and following hematopoietic cell transplantation. The diagnostic features of the disorder include marked thickening of the bone trabeculae and marked reduction in the medullary cavity (Fig. 39.17). There is usually increased connective tissue in the medullary space, although this may be difficult to judge because of the overall reduction in the space. The bone structures contain cartilaginous plates, which in nondecalcified specimens show calcium deposition. Osteoclasts are frequently numerous along the endosteal surface. The osteoclasts lack a normal ruffled border.[89] In the small number of cases of failure of osteoclast production associated with a mutation of the *RANKL* gene, there is an absence of osteoclasts.

Following successful allogeneic transplantation there is gradual resorption of the abnormal bone structure, regression of the cartilaginous plates, and expansion of the medullary space with abundant hematopoietic tissue. This is accompanied by regression of splenomegaly and reversal of the leukoerythroblastic blood picture.[90,91]

Bone Marrow Necrosis

Bone marrow necrosis unrelated to chemotherapy or radiation therapy occurs occasionally in patients with acute leukemia, malignant

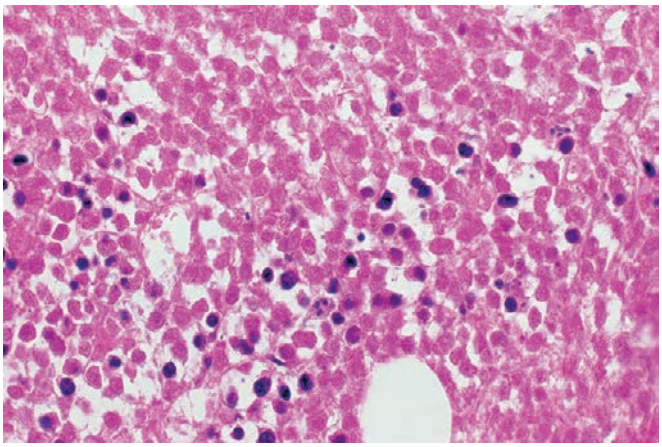

Figure 39.18 Marrow Biopsy From a Patient With Marrow Involvement by Burkitt Lymphoma. Most of the lymphoma cells show evidence of karyolysis; a few scattered pyknotic cells are present.

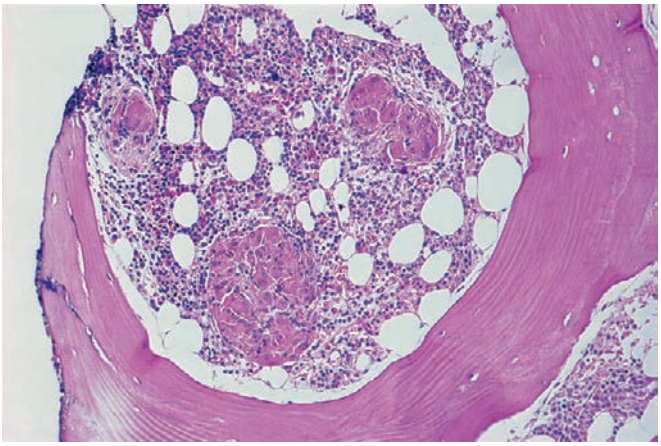

Figure 39.19 Multiple noncaseating granulomas in marrow biopsy of a 33-year-old man admitted with marked hypercalcemia. A clinical diagnosis of sarcoidosis was established.

lymphoma, and metastatic tumor[92–97]; it has also been observed in patients with sickle cell anemia, infectious processes, systemic lupus erythematosus, caisson disease, voluntary starvation, and megaloblastic anemia complicated by infection.[93,94,97] The process may be accompanied by severe and generalized bone pain.

The aspirated marrow specimens from these patients frequently have a gelatinous consistency. The microscopic picture in the trephine section reflects the stage of necrosis; different stages are frequently found in the same biopsy specimen. In the early stages, the nuclei show pyknosis and karyorrhexis, and the cells have a granular appearance; this is followed by karyolysis. In advanced stages, all cell outlines disappear, and the marrow space is replaced by amorphous, granular, eosinophilic debris. The trabeculae may be involved and show loss of osteocytes. The necrosis may be patchy or involve virtually all of the cells in the biopsy specimen (Fig. 39.18).

Inflammatory Disorders

Granulomatous Inflammation

The inflammatory diseases that are most readily identified in marrow biopsies are those associated with a granulomatous reaction; the etiologic bases include fungi, *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*, sarcoidosis, *Mycoplasma pneumoniae*, and viral infections such as Epstein–Barr.[98–110] Marrow granulomas have been observed in patients with cytopenias who are on the antidysrhythmic agent amiodarone.[111,112] Granulomas may also be found in patients with Hodgkin disease and non-Hodgkin lymphomas, with or without marrow involvement by the lymphoma, and in occasional cases of a drug reaction.[107,113,114] Perivascular granulomas may be related to hypersensitivity states. With a combination of studies, including histochemical stains, microbiologic culture, serology, enzyme immunoassay of body fluids, and molecular analysis, the etiologic basis for the granulomas should be established in a very high percentage of cases, approximately 80%–90%. In approximately 80% of the cases, the etiologic basis is identified by culture, stain, or molecular studies.[102,103,115]

Granulomas in the marrow are similar to those in other sites; the most commonly encountered are composed only of a collection of epithelioid histiocytes that may be surrounded by a rim of well-differentiated lymphocytes. Others may contain large numbers of multinucleated giant cells. The number may range from a single lesion to numerous and confluent granulomas (Figs. 39.19–39.21).

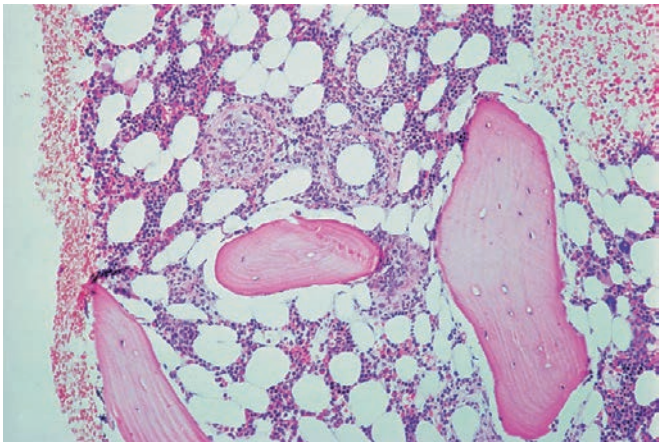

Figure 39.20 Marrow biopsy with scattered granuloma-like lesions; many of the lesions had a central lumen and were interpreted as "doughnut" granulomas. No etiologic basis was identified.

An unusual granulomatous lesion referred to as a "doughnut" or ring granuloma, because of a central clear area or lumen, has been described in the bone marrow of some patients with Q fever.[99,106] The appearance of these lesions, which is similar to those in other organs, such as the liver, varies from what appear to be vascular structures or fat globules encircled by a rim of fibrinoid material, polymorphonuclear leukocytes, and monocytes to a collection of epithelioid histiocytes surrounding a clear space (see Fig. 39.20). The vascular-associated granulomas observed in hypersensitivity states are similar in appearance. In addition to Q fever, these lesions may be observed in marrows from patients with a variety of diseases, both neoplastic and non-neoplastic.[105] In one series the most frequent association was with Epstein–Barr virus (EBV) infection.

Cells with prominent intranuclear inclusions may be found in granulomas in the marrow of patients with cytomegalovirus or other viral infection.

Acute parvovirus B19 infection in immunocompetent individuals may be associated with marked erythroblast hypoplasia and very immature giant erythroblasts; scattered erythroblasts may contain intranuclear inclusions (Fig. 39.22).[49] Recovery from the erythroid hypoplasia may be marked by a wave of regeneration with a large number of erythroblasts at an early stage of maturation, analogous

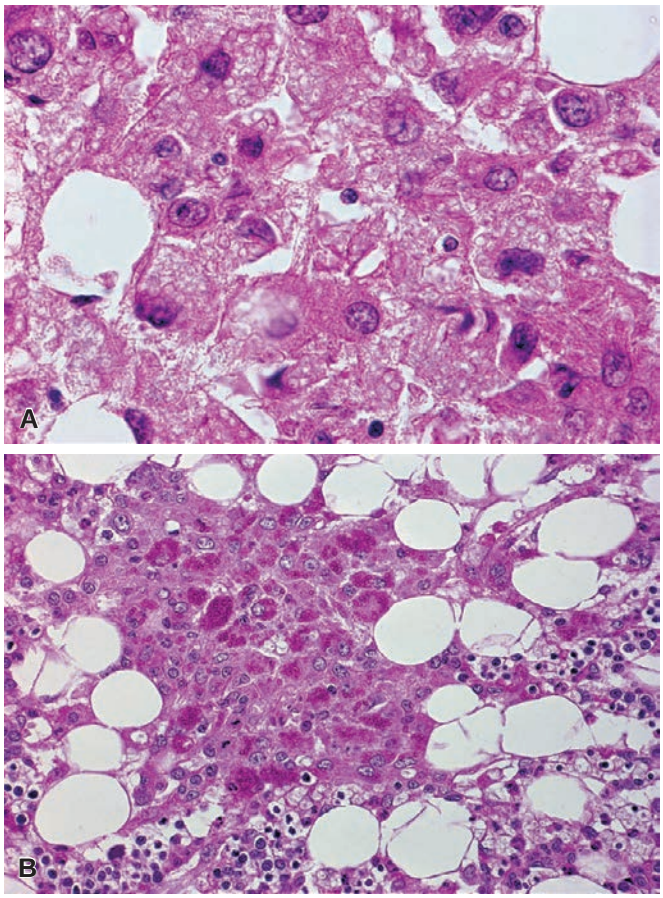

Figure 39.21 Marrow Biopsy From a Patient With Treated Hodgkin Disease. Numerous granulomas contain macrophages with numerous organisms **(A)** which were intensely PAS positive **(B)**. Culture studies were positive for histoplasmosis.

to the proliferation of promyelocytes and myelocytes that occurs in agranulocytosis. Immunodeficient patients may develop a chronic parvovirus B19 infection; in these cases there may be an erythroid hyperplasia with numerous intranuclear inclusions in the erythroid precursors; the inclusions are most prominent in the basophilic and polychromatic stages of maturation (see Fig. 39.22C).[49] The parvovirus B19 relationship to the inclusions may be demonstrated with immunohistochemical or in situ hybridization studies.

As with other tissues, stains for acid-fast bacilli (AFB) and fungi should be performed in all cases of marrow granulomas. Failure to detect AFB does not exclude infection with *M. tuberculosis*; organisms are found in approximately 25%–35% of marrow specimens from patients with documented disease by culture studies.[107,116–118] Occasional patients with negative culture studies have AFB stain–positive biopsies. The need for culture of a portion of the bone marrow aspirate for AFB and fungi should be anticipated in all patients suspected of having a granulomatous disorder, particularly those with acquired immune deficiency syndrome (AIDS) or patients being investigated for a fever of undetermined etiology.[103,109,115]

Bone marrow biopsies performed on immunosuppressed patients should always be thoroughly examined for opportunistic infections (Figs. 39.23–39.25; see also Fig. 39.21). Typical granuloma formation may not be present in the marrows of some patients with disseminated fungal or mycobacterial disease. Marrow biopsies from patients with HIV may contain scattered macrophages with AFB in the absence of granuloma formation (see Fig. 39.25). Uncommonly, *Pneumocystis*

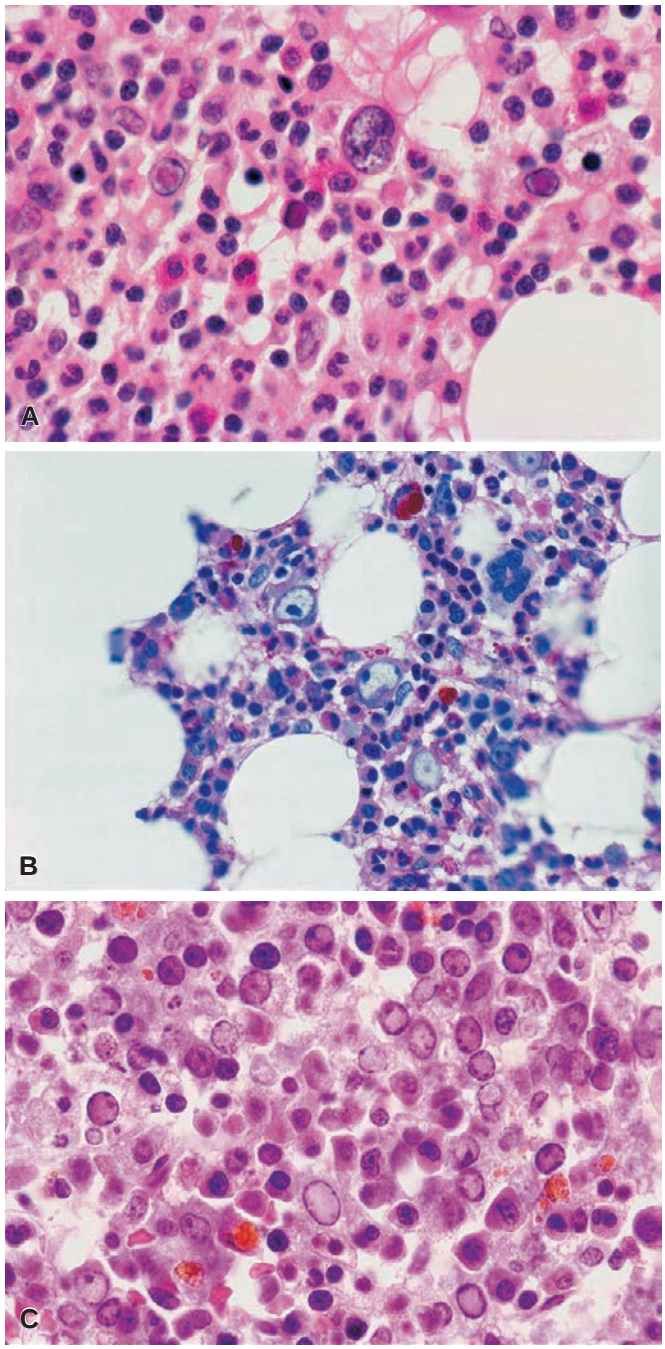

Figure 39.22 A, Pre-transplant marrow biopsy from a 4-year-old child with Hunter syndrome (acid mucopolysaccharides, type II) and erythroid aplasia. Several cells that reacted with antihemoglobin A contained intranuclear inclusions. Giant erythroblasts were present in the marrow smear and biopsy as illustrated and the findings were interpreted as consistent with infection with parvovirus B19. **B**, Marrow biopsy from a 17-year-old being treated for metastatic medulloblastoma; occasional, very large erythroblasts with abundant cytoplasm and very prominent nucleoli were present. These cells and the overall marked erythroid hypoplasia are characteristic findings in parvovirus B19 infection. (Wright–Giemsa) **C**, Marrow biopsy from an adult male with AIDS and concurrent parvovirus B19 infection. There are numerous erythroid precursors at all stages of maturation. Many of the more immature erythroblasts contain prominent intranuclear inclusions. (**C,** Contributed by Dr. Robert W. McKenna, Dallas, USA.)

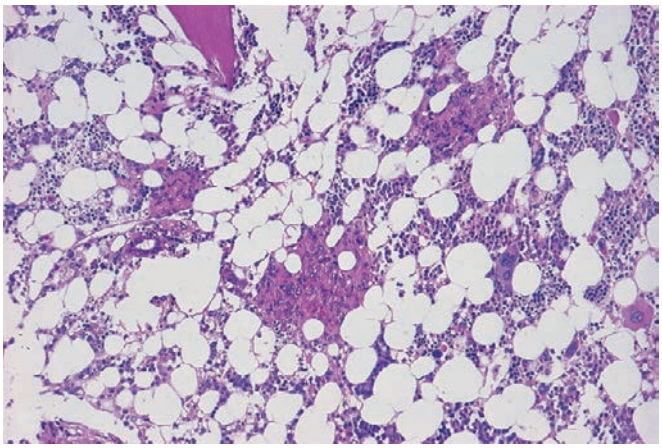

Figure 39.23 Post-Chemotherapy Marrow Biopsy From Patient With Marrow Involvement by Mantle Cell Lymphoma. Several granulomas containing microorganisms interpreted as cryptococcus are shown. The organisms were positive with Gomori methenamine silver; culture studies were confirmatory of cryptococcus.

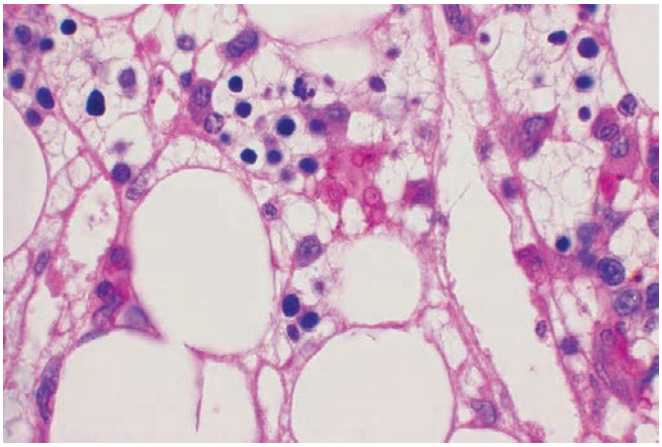

Figure 39.24 Marrow from a patient with AIDS with scattered *Pneumocystis jirovecii* microorganisms occurring both singly and in small clusters. Microorganisms are not associated with any recognizable tissue response. (Periodic acid–Schiff.)

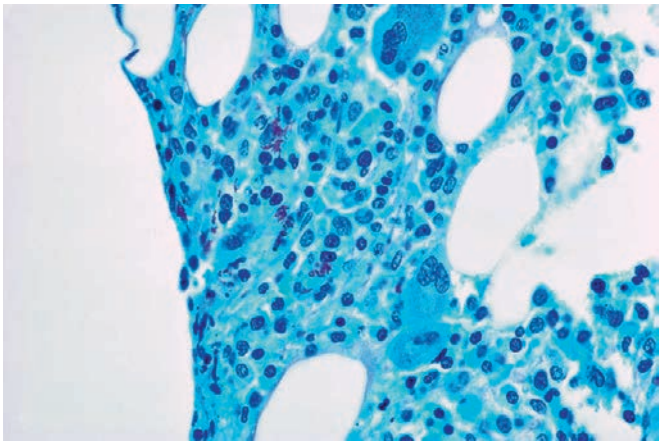

Figure 39.25 Marrow Biopsy From an AIDS Patient. No granulomas were identified but numerous macrophages containing acid-fast bacilli were scattered throughout the marrow interstitium, some in perivascular locations as illustrated.

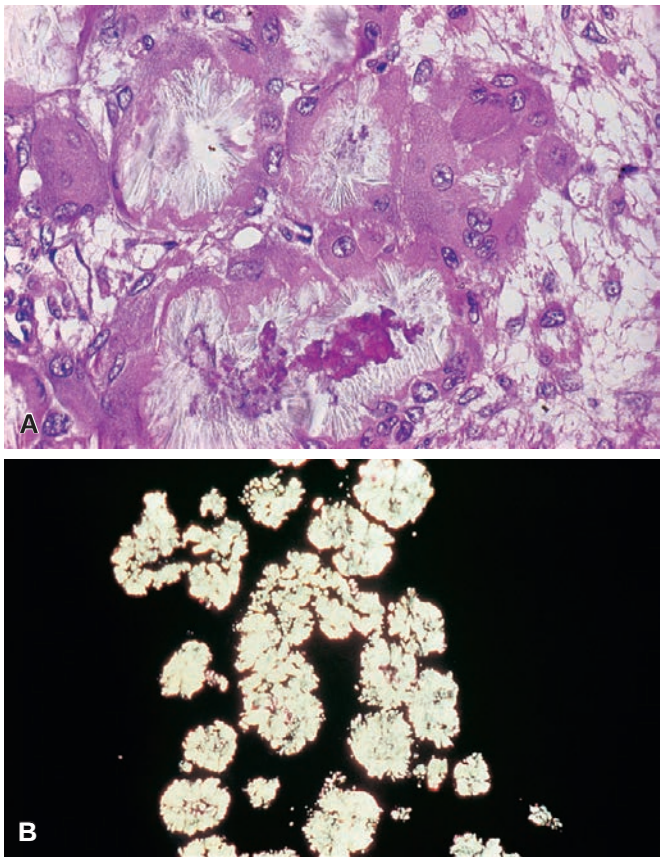

Figure 39.26 A, Section of bone marrow trephine biopsy from a child with primary oxaluria. Calcium oxalate crystals in giant cells form a radial pattern. **B**, Calcium oxalate crystals are doubly refractile in polarized light.

jirovecii (formerly *P. carinii*) may be observed in scattered macrophages in sections stained with PAS or methenamine silver (see Fig. 39.24). An increased number of macrophages with or without evident phagocytosis is sufficient reason to perform special stains for microorganisms.

The presence of infection-related granulomas in the bone marrow sections may occasionally be accompanied by macrophages containing microorganisms in the Romanowsky-stained bone marrow smears or trephine imprints. The morphology of the organisms in these preparations is usually sufficient to establish a diagnosis.

Lipid granulomas, which have been reported to be the most frequent type of granuloma in bone marrow, are similar to those found in the liver, spleen, and lymph node.[119,120] These granulomas range from 0.2 to 0.8 µm in size and usually are associated with lymphocytic aggregates or sinusoids. The loosely spaced macrophages contain fat vacuoles of varying size. The lesions also contain admixed lymphocytes, plasma cells, and eosinophils; giant cells are found in approximately 5% of cases. Some of these granulomas resemble those found in sarcoidosis.

An unusual form of granulomatous reaction can be found in the bone marrow of patients with the genetic disorder of glyoxylate metabolism, primary hyperoxaluria.[121,122] This finding is secondary to the deposition of calcium oxalate crystals. The crystals, which have a slightly yellowish tinge, form a radial pattern, are encircled or engulfed by epithelioid and giant cells, and are doubly refractile with polarized light (Fig. 39.26). Substantial portions of the marrow biopsy may be replaced by these lesions, which are similar to those found in the kidneys and other tissues.

Nonspecific Inflammatory Reactions

Nonspecific inflammatory alterations may be noted in the marrow from patients with a variety of systemic disorders, including acute infection, malignancy, connective tissue disease, and immune disorders, most notably AIDS. These alterations generally are characterized by changes in both the vascular structures and parenchyma. The terms tumor myelopathy and myelitis have been applied to the nonspecific marrow changes that are observed in a high percentage of patients with malignant lymphoma.[123] These changes include edema of the vessel walls, plasma cell and mast cell proliferations in the adventitia, protein deposits adjacent to the vessels, patchy edema, depressed erythropoiesis, and increased granulopoiesis and megakaryocytopoiesis. Acute necrosis of bone marrow tissue is reported in patients with tuberculosis and typhoid fever.[124]

Human Immunodeficiency Virus Syndrome (HIV, AIDS)

Marrow biopsies from untreated patients with HIV have been generally reported to be hypercellular, although normocellular and hypocellular specimens may be observed; nonspecific findings include marrow damage, increased plasma cells, myelodysplasia, serous degeneration, lymphocytic infiltration, increased reticulin and "naked" megakaryocytic nuclei.[125–131] The marrow specimen may serve as a vehicle for the rapid diagnosis of febrile illnesses in HIV-infected patients.[126,132,127] Opportunistic organisms including AFB and *P. jirovecii* and fungal organisms may be present, occasionally without granuloma formation (Fig. 39.27; see also Figs. 39.24 and 39.25).[102,133–135] Immune thrombocytopenia may be observed,[135–137] but the frequency of severe thrombocytopenia in HIV-infected patients has decreased with the use of anti-retroviral therapy.[138]

HIV-infected individuals may develop a persistent parvovirus B19 infection because of ineffective production of IgG parvovirus-neutralizing antibodies.[73,139] This may result in chronic anemia and erythroid hyperplasia with all stages of maturation in contrast to the erythroid aplasia that may occur in acute parvovirus B19 infection. The erythroid precursors in these patients may show intranuclear inclusions primarily in the basophilic and polychromatic erythroblasts (see Fig. 39.22C).

Negative stains for microorganisms and absence of granulomas do not exclude the possibility of infection by microorganism; a minority of patients with infection by *M. avium* complex have demonstrable granulomas or AFB in their marrow biopsies. In addition, although infrequent, marrow with only mild nonspecific changes may contain scattered macrophages with mycobacteria. These macrophages may resemble pseudo-Gaucher cells in hematoxylin and eosin–stained sections. Scattered macrophages containing *P. jirovecii* may also be present in a background of essentially normal-appearing or only slightly altered marrow. As a result, it is considered prudent by some observers to routinely stain marrows from HIV patients for AFB and fungi, regardless of the appearance of the marrow with routine stains.

The marrow damage that may be present in HIV patients is characterized principally by a loosely structured, hypocellular interstitium. Areas of fibrinoid necrosis may be present. The changes resemble those found in marrows from patients recovering from chemotherapy with myelotoxic agents and are distinct from serous degeneration, which usually occurs in severely malnourished individuals and which may also be present in marrow biopsies from patients with HIV. Both of these alterations may be accompanied by an increase in plasma cells.

Lymphocytic aggregates of varying size occur in the marrow of a relatively high percentage of patients with HIV.[140,141] These are randomly distributed without any preferential paratrabecular distribution; in some cases the lesions appear to be preferentially perisinusoidal. They are composed primarily of small lymphocytes, some of which may have irregularly shaped nuclei. There are usually associated plasma cells, histiocytes, and increased vascular structures; eosinophils may be increased (Fig. 39.28). Occasional immunoblasts may be noted. This type of lymphocyte proliferation, polymorphous reactive lymphoid hyperplasia, is not unique to patients with HIV and may be observed in marrow biopsies in a wide range of immunologic disorders. Because of the large size and cellular composition, these aggregates may be difficult to distinguish from the lesions of peripheral T-cell lymphoma; the latter lesions are frequently accompanied by numerous epithelioid histiocytes and scattered large transformed cells. In some instances, the distinction between the two processes based on morphologic criteria may not be possible.[141] Peripheral T-cell lymphoma in HIV patients, however, is quite rare, and such a diagnosis should be established with considerable caution and only after review of all pathology specimens.[142] Biopsy of other organ sites as well as molecular studies for T-cell receptor rearrangement may be necessary.

Occasionally, marrow specimens from patients with HIV contain benign lymphoid follicles with germinal centers.

In addition to reactive lymphocytic lesions, the marrow biopsies from AIDS patients may rarely exhibit a florid plasmacytoid immunoblastic proliferation that may resemble a neoplastic process because of the degree of replacement of marrow. The use of immunohistochemical studies with anti-kappa and anti-lambda antibodies can be very useful in demonstrating the polyclonal nature of these lesions.

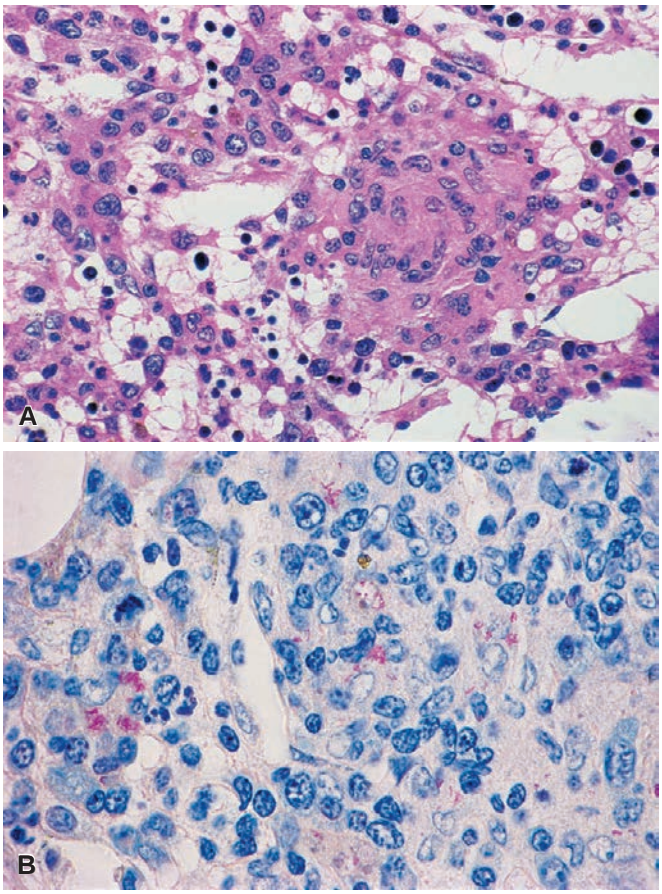

Figure 39.27 **A**, Marrow biopsy from a patient with AIDS showing granuloma without evident necrosis. **B**, One of the granulomas in **A** showing numerous intracellular acid-fast bacilli. (**B** Fite.)

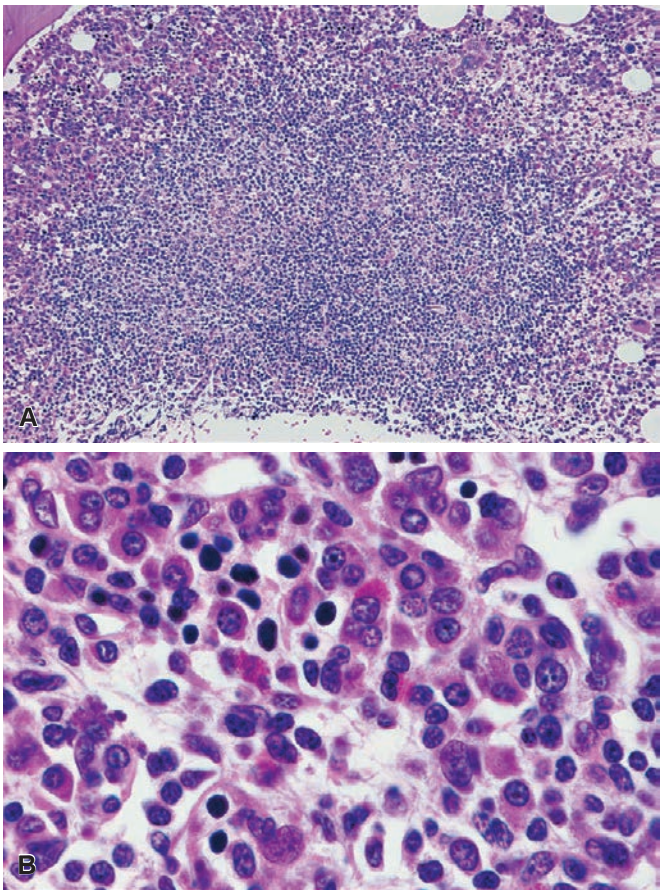

Figure 39.28 **A**, One of several lymphocytic–histiocytic aggregates in marrow biopsy from a patient with advanced AIDS. Acid-fast bacilli were also identified in this specimen. **B**, High magnification of specimen in **A** illustrating polycellular characteristics of the lesion.

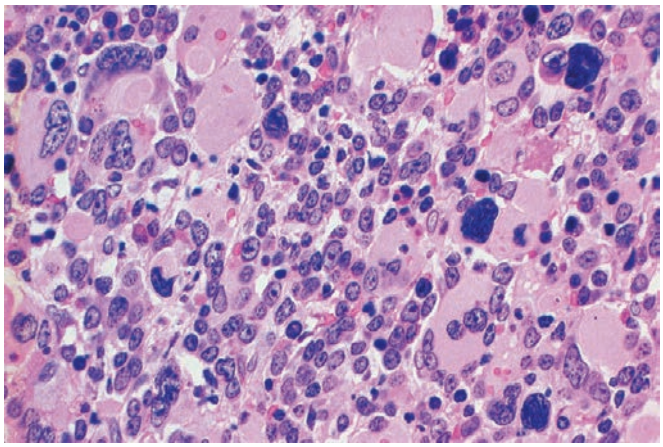

Figure 39.29 **Marrow From a Patient With Acute Megakaryoblastic Leukemia.** The predominant cell population consists of blasts and numerous megakaryocytes at varying stages of maturation. Mature megakaryocytes have abundant cytoplasm that is uniformly eosinophilic.

Although it is important to recognize that marrow biopsies from patients with HIV may show a variety of reactive lymphocytic proliferations, it is equally important to appreciate that these patients have an increased incidence of malignant lymphoma, of either non-Hodgkin or Hodgkin type, and the marrow biopsy may be the initial diagnostic specimen.[142,143] The most common HIV-associated lymphomas that may involve the marrow are B-cell lymphomas, including Burkitt lymphoma, diffuse large B-cell lymphoma, and plasmablastic lymphoma. A single biopsy may contain both reactive lymphocytic lesions and malignant lymphoma. In suspected cases of Hodgkin disease, adherence to established criteria for marrow involvement by Hodgkin disease should be observed.

Patients with HIV who are receiving zidovudine (AZT) may develop evidence of marrow suppression such as anemia and neutropenia. Marrow hypoplasia may be present.[144] Abnormal megakaryocytes with sparse cytoplasm, "naked" megakaryocyte nuclei, may be numerous; this finding is not specific for AIDS and may be present in other disorders, including the MPNs. The incidence of immune thrombocytopenia is increased in individuals with HIV.[145]

Leukemias and Related Disorders

Acute Leukemia

The diagnosis and classification of the acute leukemias are optimally established from examination of Romanowsky-stained blood and bone marrow smears in conjunction with appropriate immunophenotypic, cytogenetic, and/or molecular genetic and cytochemical techniques; this approach forms the basis for the World Health Organization (WHO) classification.[146–148] Terminology from the French–American–British (FAB) Cooperative Group classification remains in common usage, but this classification system should no longer be used.[149] Chromosome analysis has an important role in the evaluation of cases of acute leukemia, primarily in regard to prognostic significance, and is incorporated into the diagnosis of many categories of acute leukemia in the 2016 WHO classification.[148,150,151] The ideal approach to the diagnosis and classification of acute leukemia requires correlation of clinical and peripheral blood findings, bone marrow aspirate smear morphology, and the bone marrow trephine biopsy.[152] Immunophenotyping and cytogenetic or molecular genetic studies, which are now performed on all cases, are best performed on marrow aspirate material. Although smears and imprint preparations are generally superior to sections in classifying the majority of cases of acute leukemia, there are some types of acute leukemia that are accompanied by fibrosis or with unusual morphologic patterns, such as acute megakaryocytic leukemia with an associated t(1;22)(p13.3;q13.1) cytogenetic abnormality that occurs in infants in which the bone marrow sections are often more informative than the bone marrow smears (Figs. 39.29–39.31). In addition, as noted in the section on immunohistochemistry, the development of antibodies reactive in paraffin-embedded tissue, most notably myeloperoxidase, lysozyme, TdT, and CD34 antibodies, has greatly enhanced the recognition of myeloid leukemia in trephine biopsy sections.[24,25,38]

The 2016 WHO classification of acute leukemia includes general categories of AML, precursor lymphoid neoplasms, which include the related acute lymphoblastic leukemias (ALLs) and their corresponding lymphoblastic lymphomas, and acute leukemias of ambiguous lineage. AML (Box 39.1) is further subdivided into AML with recurrent genetic abnormalities, AML with myelodysplasia-related changes, therapy-related myeloid neoplasms, myeloid proliferations of Down syndrome, and AML, not otherwise specified.[153–158] AML with myelodysplasia-related changes may be diagnosed by the presence of: (1) a history of prior myelodysplasia; (2) presence of a myelodysplasia-related cytogenetic abnormality (Box 39.2); or (3) multilineage dysplasia defined as dysplasia in 50% or more of two nonblast cell lines; and the absence of prior cytotoxic chemotherapy

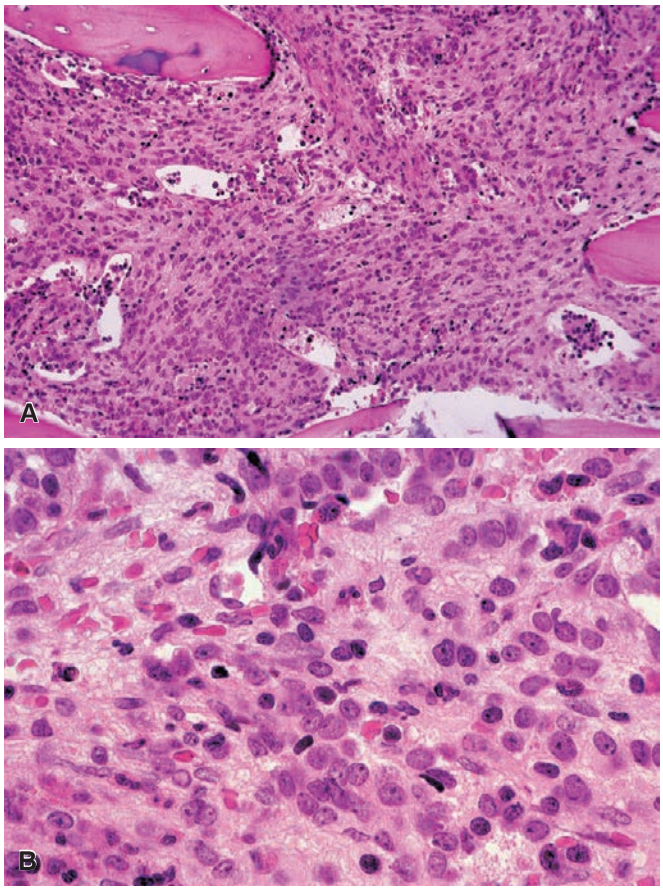

Figure 39.30 **A**, Marrow biopsy from a 14-month-old child with acute megakaryoblastic leukemia with an associated t(1;22)(p13.3;q13.1) cytogenetic abnormality. The blasts frequently have a spindle shape and sometimes form intertwining bundles resembling metastatic tumor. **B**, High magnification of the specimen in **A** showing undifferentiated blasts.

for an unrelated disease and absence of any of the genetic abnormalities of AML with recurrent genetic abnormalities. All cases of AML are defined by the presence of 20% or more blast cells in the peripheral blood, except for cases of AML with t(8;21)(q22;q22.1), AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22), and acute promyelocytic leukemia with *PML-RARA* in which a diagnosis of AML can be made with less than 20% peripheral blood and bone marrow blast cells. A large number of gene mutations occur in AML and detection of some *(NPM1, CEBPA, RUNX1)* are critical for a complete diagnosis, whereas others assist in defining prognostic disease groups.[148,158,159] Testing for multiple gene mutations using next-generation sequencing methods is quickly becoming routine in evaluation of AML.

ALL (Box 39.3) is subdivided into precursor B- and T-cell types, with precursor B-ALL further subgrouped into cases with recurrent genetic abnormalities and B-ALL, not otherwise specified.[148,160–162] ALL is biologically and morphologically identical to lymphoblastic lymphoma, although the clinical presentation varies between the two. For this reason, the two are combined in the WHO classification. While most cases of ALL are of precursor B lineage, lymphoblastic lymphoma is of precursor T-cell origin in approximately 80% of cases and B-cell precursor type in 20%. Precursor T-cell ALL/lymphoma has a high incidence of mediastinal mass, occurs in young adults, more frequently in males, and has a predilection for early blood and marrow involvement (see Fig. 39.31).[160–164] Lymphoblasts of both precursor B and T lineage are TdT positive. The blood and marrow may be involved at the time of initial diagnosis and the designation of a case as lymphoblastic lymphoma or ALL is arbitrary. The presence of extramedullary tumor masses and evidence of sparing of marrow function as indicated by a normal platelet count, hemoglobin levels greater than 10 g/dL, and a normal number of neutrophils in the blood are more compatible with a diagnosis of lymphoma with marrow involvement as opposed to ALL. The Children's Cancer Study Group proposed distinguishing leukemia from lymphoblastic lymphoma on the basis of the percentage of lymphoblasts in the marrow.[165] If there are less than 25% lymphoblasts, the case is classified as lymphoma; if there are 25% or more lymphoblasts, the case is classified as leukemia. In the cases of lymphoma, there may be substantial residual normal marrow with the lymphoma cells diffusely scattered in the interstitium. The therapeutic approach in these two fundamentally similar processes is the same. B lymphoblastic lymphoma appears to have lower propensity for blood and marrow involvement than T lymphoblastic lymphoma.[164]

The acute leukemias of ambiguous lineage (Box 39.4) are divided into acute undifferentiated leukemia and mixed phenotype acute leukemias.[166] The latter group also includes specific genetic subtypes.

In the majority of cases of acute leukemia, both myeloid and lymphoblastic, in children and adults, the marrow is markedly hypercellular because of the proliferation of leukemic cells, with replacement of normal hematopoietic cells. In a small minority of patients, particularly older individuals, AML and, rarely, ALL may present with a hypocellular marrow (i.e., hypoplastic or hypocellular acute leukemia).[167–169] The marrow biopsies in these patients may, on low magnification, suggest the diagnosis of aplastic anemia (Fig. 39.32). In contrast to aplastic anemia, in which the residual cells are well-differentiated lymphocytes and plasma cells, the cell population in the interstitium is principally blasts; some normal cells may be present but are markedly reduced. The diagnosis is confirmed by examination of blood and bone marrow smears and the use of appropriate immunohistochemical studies, particularly myeloperoxidase, lysozyme, CD79A, TdT CD117 *(KIT)*, and CD34. In rare instances, ALL in children is preceded by an aplastic or hypocellular phase.

Myelofibrosis with a slight-to-moderate increase in reticulin fibers may be present in the initial or late stages of acute leukemia in a minority of cases; it may occur in both acute lymphoblastic and AML.[170] The presence of myelofibrosis in acute leukemia may result in difficult and inadequate marrow aspiration and an erroneous diagnosis of aplastic anemia if trephine biopsy sections are not available. This emphasizes the importance of obtaining adequate marrow biopsies. The long-held view that difficult aspirations in acute leukemia are caused by "packed" marrows has little basis in fact. The vast majority of hypercellular marrows in acute leukemia are readily aspirated. If aspiration is difficult, it is probably a result of poor biopsy technique or an increase in reticulin fibers.

The trephine biopsy provides the only accurate assessment of marrow cellularity and is of considerable importance in monitoring changes following treatment for leukemia. The rapidity of development and degree of necrosis and aplasia following the institution

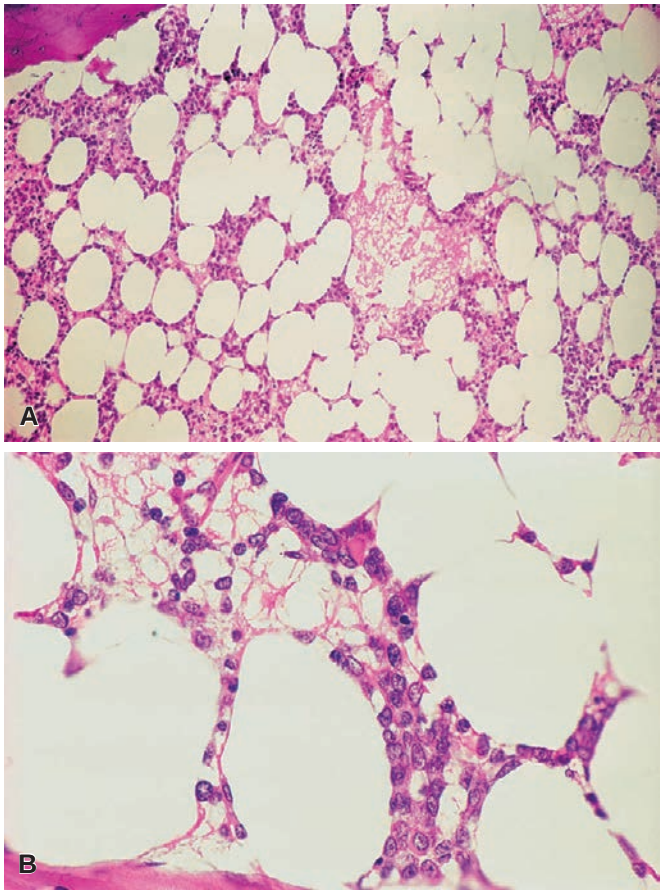

Figure 39.32 **A**, Marrow section from a 67-year-old man with acute myeloid leukemia with markedly hypocellular marrow. **B**, Higher magnification of the same specimen showing numerous blast cells in the interstitium.

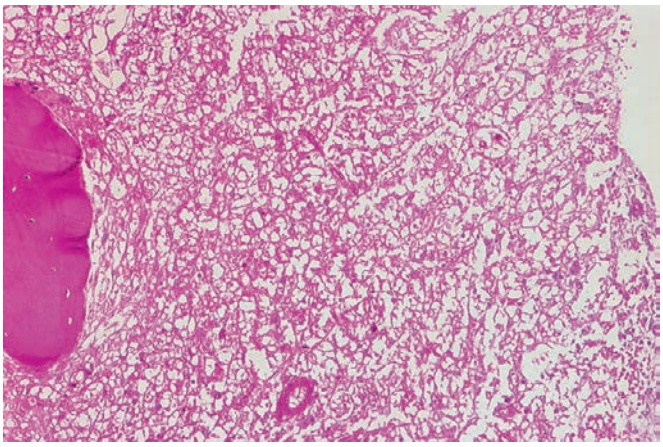

Figure 39.33 Marrow biopsy 14 days after institution of therapy with daunorubicin and cytosine arabinoside for acute myeloid leukemia. Marrow is markedly hypocellular with dilated sinuses. Interstitial areas contain lightly eosinophilic, proteinaceous debris that represents residue of leukemic cell necrosis.

of therapy will vary with the different chemotherapeutic agents or combination of agents used. In general, the sequence of histopathologic events is marked initially by nuclear karyorrhexis followed by karyolysis; the cells then disintegrate into relatively uniform granular, eosinophilic debris.[171] Subsequently the marrow shows a somewhat irregular, loosely structured appearance with scattered fat cells, vessels, stromal elements, and distended sinusoids (Fig. 39.33). Regeneration of fat cells is followed by regeneration of normal hematopoietic cells in the successfully treated patient. The erythroid cells are usually the first to recover and frequently manifest dyserythropoietic changes as the result of chemotherapeutic drugs.[172] The regeneration of the erythroid cells is followed in sequence by that of the granulocytes and megakaryocytes. This sequence may be altered with different drug regimens and the use of recombinant growth factors. The marrow from patients receiving recombinant granulocyte growth factor may show an early marked increase in neutrophil promyelocytes and myelocytes. In some patients, particularly in the pediatric age group, the post-chemotherapy marrow may contain numerous hematogones, which may resemble lymphoblasts. These can usually be distinguished from lymphoblasts by careful morphologic assessment and immunophenotypic characteristics.[173] The bone marrow biopsy can be particularly useful in this differential diagnosis, as leukemic blasts tend to cluster on biopsy sections, while hematogones represent a spectrum of B lymphocyte maturation dispersed throughout the biopsy. The infiltration pattern can be further assessed by immunohistochemical markers for CD34 or TdT to identify the clusters of leukemia cells versus the more scattered B cell progenitors (hematogones).

As noted, the course of events described in the preceding discussion is characteristic of effective therapy. In those patients in whom there has been partial or no response to treatment, the marrow will show varying numbers of leukemic cells. In the totally nonresponsive patient, the findings are essentially those of the pretreatment specimen; scattered isolated areas of necrosis may be present. In a partial response, the areas of residual leukemia will be intermixed with necrotic or regenerating normal marrow cells. In some patients, the areas of residual leukemia may be very small and difficult to distinguish from foci of regenerating normal cells, particularly early erythroblasts and promyelocytes. Careful comparison of suspicious foci with the cytologic pattern in the initial diagnostic biopsy should always be performed. Distinguishing foci of normal regenerative promyelocytes from the foci of leukemic promyelocytes in patients being treated for acute promyelocytic leukemia may be particularly troublesome. Normal promyelocyte regeneration is usually accentuated along the endosteal surface of the bone trabeculae and in perivascular locations. Acute promyelocytic leukemia in marrows with partial response may manifest as large or small focal lesions unrelated to bone trabeculae or vascular structures (Fig. 39.34). The cytoplasm of the leukemic promyelocyte may be more abundant than in normal promyelocytes.

In addition to assessment of the effects of chemotherapy, post-chemotherapy biopsy specimens should always be carefully evaluated for the presence of granulomas or other evidence of infection. In some instances, a focus of microorganisms may be present only as an area of nonspecific necrosis with a few histiocytes. These foci may be very difficult to recognize in a marrow biopsy showing cell necrosis as a result of chemotherapy. Any suspicious lesion should be studied with special stains. Proliferation of histiocytes, with and without hemophagocytosis, may be prominent in infected patients. The histiocytes are widely dispersed throughout the interstitium and in the sinusoids; in some patients this may be a very prominent feature.

Patients being monitored for the effects of chemotherapy will usually have sequential marrow biopsies at relatively short time intervals. If a specimen is from the area of a recent biopsy procedure, there may be evidence of granulation tissue and new bone formation (see Fig. 39.1). The biopsy repair site will usually be relatively well

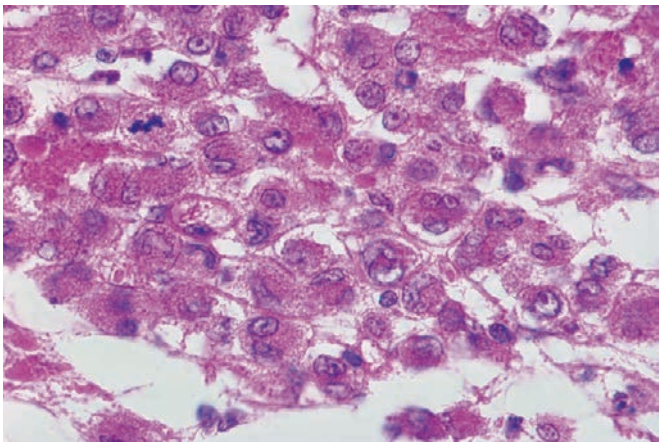

Figure 39.34 Marrow biopsy from an adult woman with acute promyelocytic leukemia following two courses of chemotherapy which did not include all-*trans*-retinoic acid. Large areas of marrow are replaced by leukemic promyelocytes.

demarcated from the remainder of the biopsy specimen but at times may lead to difficulties in interpretation.

Myeloid Sarcoma

Myeloid sarcoma (granulocytic sarcoma; extramedullary myeloid tumor) is an unusual variant of myeloid malignancy in which there is an extramedullary tumor mass composed of myeloblasts, with or without mature neutrophils.[174–183] The tumor may occur as an isolated finding or may be associated with AML, CML, primary myelofibrosis (PMF), hypereosinophilic syndrome, and PV.[178,184–186] An association of myeloid sarcoma and AML with the t(8;21) chromosome abnormality has been reported[181] and appears to be more common in children. These tumors have also been associated with AML with abnormalities of chromosome 16. In earlier literature, the term chloroma was used for these lesions because of the green appearance of the freshly cut surface of the tumor. The green color, which is due to the presence of peroxidase in the leukemic cells, is not present in all tumors of this type, and the less specific designation of myeloid sarcoma is preferred. Although tumors of monocytes have not previously been classified with the myeloid sarcomas, they represent a similar process with a similar predilection to leukemic evolution, primarily acute monoblastic leukemia,[187,188] and are now considered in the spectrum of myeloid sarcoma if they create a tumor mass.[180]

The myeloid sarcomas are more frequent in children than in adults and are most commonly associated with the subperiosteal bone structures; the most common sites are the skull, paranasal sinuses, sternum, ribs, vertebrae, and pelvis; lymph nodes and skin are also relatively frequently involved. Orbital masses leading to proptosis and spinal canal lesions resulting in neurologic manifestations are two of the clinical presentations associated with these tumors (Fig. 39.35). A high incidence of myeloid sarcomas involving the orbit has been reported in Turkish children with acute myelomonocytic leukemia.[189] Myeloid sarcomas may present as a mediastinal mass and clinically resemble a mediastinal lymphoma.[185]

A myeloid sarcoma may occur simultaneously with a typical blood and bone marrow pattern of AML or other type of MPN or may antedate leukemia by many months or rarely years.[176] It may be the first evidence of relapse in a patient with AML on maintenance chemotherapy and may be the only evidence of recurrence. These tumors may also represent the initial manifestation of a blast crisis

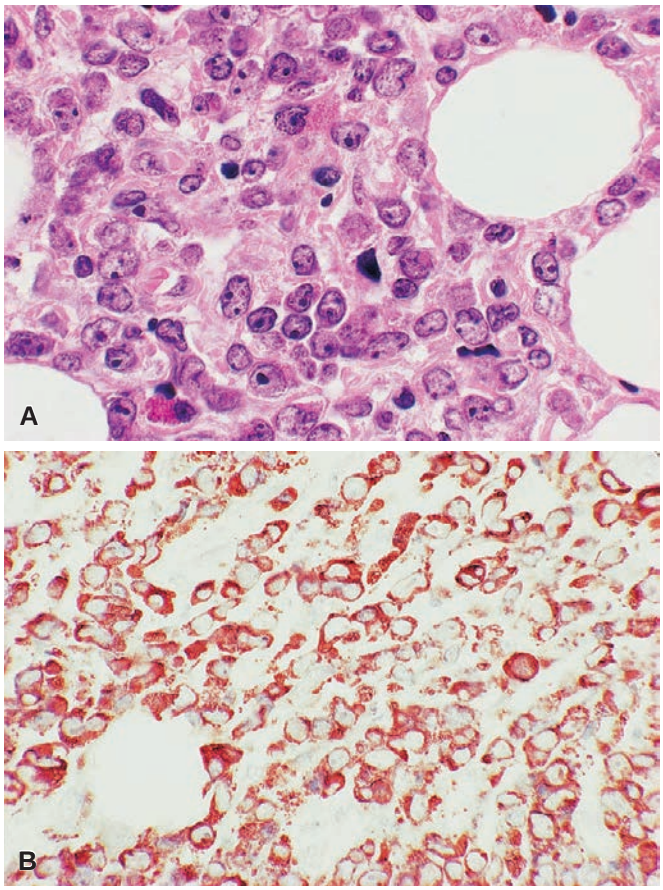

Figure 39.35 **A**, Biopsy of orbital myeloid sarcoma from a 6-year-old child who presented with bilateral proptosis. Numerous blasts are present. Cytogenetic studies of this lesion showed t(8;21)(q22;q22.1) chromosome abnormality. Blood and marrow smears showed acute myeloid leukemia with maturation. **B**, The same specimen reacted with antibody to myeloperoxidase. Virtually all blasts are positive. (**B**, Immunoperoxidase.)

of CML, and an isolated tumor mass or enlarged lymph node in a patient with CML should be evaluated for this possibility, including cytogenetic studies for the t(9;22)(234.1;q11.2) or molecular studies for evidence of the *BCR/ABL1* fusion gene.[178,186]

Histologically, the tumor is composed of a relatively uniform population of immature cells and may be misdiagnosed as an aggressive malignant lymphoma; this is particularly a problem with those lesions comprised predominantly of blasts. Occasionally, the presence of immature eosinophils and maturing neutrophils may indicate the true nature of the lesion. Attempts at histopathologic classification have generally resulted in three levels of differentiation: blastic, immature, and differentiated.[176,178,182] The blastic type is composed primarily of myeloblasts with little evidence of maturation to the promyelocyte stage (Fig. 39.36). The myeloblasts have a slight-to-moderate rim of basophilic cytoplasm, fine nuclear chromatin, and two to four nucleoli. Eosinophil myelocytes are not usually found with this degree of maturation. The immature type with an intermediate degree of differentiation contains principally myeloblasts and promyelocytes; eosinophil myelocytes are usually present. The differentiated type primarily consists of promyelocytes and later stages of maturation. Eosinophil myelocytes are most abundant in this type. Immunohistochemistry using antibodies to myeloperoxidase, lysozyme, CD68 (PGM1), CD34, and CD117 *(KIT)* are very useful in identification (see Fig. 39.35B).[36] The naphthol

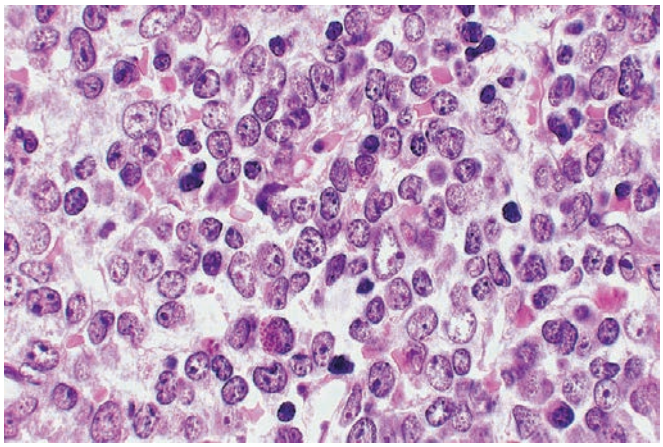

Figure 39.36 Biopsy of a Myeloid Sarcoma From Subcutaneous Tissue of the Chest Wall of a 49-Year-Old Man. The tumor is composed of poorly differentiated blast cells interpreted as myeloid sarcoma. There is essentially no evidence of differentiation. Blood and marrow showed no evidence of leukemia.

ASD chloroacetate esterase reaction, which is positive only in neutrophils and mast cells, is also useful for the diagnosis of some of the lesions; however, the reaction is partially ablated by mercury-based fixation and has largely been replaced by immunohistochemical reactions.[190] In the unusual myeloid lesions composed of immature erythroid cells or megakaryocytes, antibodies to hemoglobin A, glycophorin A and E-cadherin for red blood cells, and von Willebrand factor (factor VIII-related antigen), CD41, CD61, and CD31 for megakaryocytes may be used. Monocytic lesions react with antibodies to lysozyme, CD14, CD68 (KP1 and PGM1), and CD163.

Imprint preparations of tumor masses may be particularly useful in identifying the myeloid nature of the cells. Auer rods may be found, and the myeloblasts may show intense staining with the myeloperoxidase cytochemical reaction.

Localized tumor masses occurring in the absence of blood or marrow involvement may respond to local radiation therapy. Eventually the process in the majority of patients will evolve into a form of AML or may be associated with additional tumor masses at other sites. The leukemic evolution may be characterized by a gradual increase in myeloblasts in the blood and marrow; frequently, blasts containing Auer rods are identified. Rarely the leukemic cells may be identified in body fluids due to the occurrence of myeloid sarcoma in one of these areas.

In 7 of 16 patients with isolated granulocytic sarcomas reported by Meis et al.,[176] the process did not show a leukemic evolution, although three of the seven patients developed granulocytic sarcomas at additional sites and died 2–8 months following initial presentation. The other four patients showed no evidence of recurrent disease from 3.5 to 16 years following presentation.

Unlike the myeloid sarcomas that occur in patients with established hematologic disorders, which are usually correctly diagnosed, the predominantly blastic myeloid sarcomas occurring as isolated lesions in the absence of some type of leukemia may be initially misdiagnosed as a malignant lymphoma or poorly differentiated tumor because of the lack of diagnostic features.[176] In lymph nodes involved by myeloid sarcoma, the germinal centers are frequently preserved; the infiltrate is usually present in the sinuses and occasionally in the paracortical and medullary areas. In other tissues, the cells usually display an infiltrative pattern with the overall architecture remaining intact. The presence of immature eosinophils or cells with lobulated nuclei should evoke suspicion of a myeloid sarcoma.

Myelodysplastic Syndromes

The MDS are a heterogeneous group of myeloid disorders with varying potential for bone marrow failure and evolution to AML.[191–194] The MDS are basically disorders of ineffective myelopoiesis with hyperplastic marrows and cytopenias, dysplastic changes, and frequently pancytopenia with or without an increase in blasts. In a minority of cases, the marrow is hypocellular.[69,195] The 2016 WHO Classification of hematopoietic neoplasms has changed the terminology in MDS, but most categories are similar to the prior classification. The major categories are: (1) MDS with single lineage dysplasia (previously termed refractory anemia); (2) MDS with ring sideroblasts (refractory anemia with ring sideroblasts); (3) MDS with ring sideroblasts and multilineage dysplasia; (4) MDS with multilineage dysplasia (refractory cytopenia with multilineage dysplasia); (5) MDS with excess blasts-1 (refractory anemia with excess blasts-1); (6) MDS with excess blasts-2 (refractory anemia with excess blasts-2); (7) MDS, unclassified; and (8) MDS with isolated del(5q).[148,192] The classification is based primarily on examination of blood and bone marrow smears. However, marrow section specimens may add important diagnostic information, such as foci of blasts, increased fibrosis, and megakaryocyte dysplasia.[194,196–200] Marrow sections in MDS with isolated del(5q) may be particularly informative in demonstrating megakaryocytes with hypolobulated nuclei characteristic of the disorder.[201,202]

The WHO proposal also includes a category of myeloid disorders, referred to as MDS/MPN, for those myeloid processes that share features of both an MDS and a myeloproliferative process.[152] This category includes chronic myelomonocytic leukemia, juvenile myelomonocytic leukemia, atypical CML, MDS/MPN with ring sideroblasts and thrombocytosis, and MDS/MPN, unclassified.[148,203]

The trephine biopsy has a very important role in the evaluation of MDS and may provide important prognostic information.[69,192,194–196,200,204] The cell population in biopsy specimens varies according to the subtype.[192] In MDS with ring sideroblasts (sideroblastic anemia), there is generally a marked increase in erythroid precursors, with greatly increased iron accumulation in macrophages. In MDS with excess blasts 1 and 2, the marrow is hypercellular in the majority of patients, with an increase in neutrophil precursors. Chronic myelomonocytic leukemia, which is classified by the WHO as a myelodysplastic/MPN, is characterized by a hypercellular marrow with an increase in both monocytes and neutrophils.[203] In any of these types of MDS, the marrow may be hypocellular in a minority of patients (Fig. 39.37).[69,195] This has been associated with an adverse prognosis in some studies.

Increased reticulin fibers may be observed in chronic myelomonocytic leukemia and MDS with excess blasts but is not usually a prominent feature.[197,204] In approximately 10% of patients there is a marked increase in reticulin fibers (Fig. 39.38). These cases usually satisfy the criteria for MDS with excess blasts. These cases have been associated with an adverse prognosis in some studies.

A finding referred to as abnormal localization of immature precursors (ALIPs), characterized by aggregates (3–5 cells) and clusters (>5 cells) of myeloblasts and promyelocytes in central areas of the marrow tissue away from the endosteal surface of the bone trabeculae and vascular structures, has been described in the MDS (Fig. 39.39)[200]; the finding of three or more ALIPs in a bone marrow section has been reported to have predictive value for evolution to leukemia. Apoptosis may be a prominent feature in some cases (Fig. 39.40).

Although the precise classification of the MDS is based principally on the evaluation of blood and marrow smears, there are some types of MDS in which the bone marrow biopsy findings are highly suggestive of a specific classification. The de novo MDS with isolated

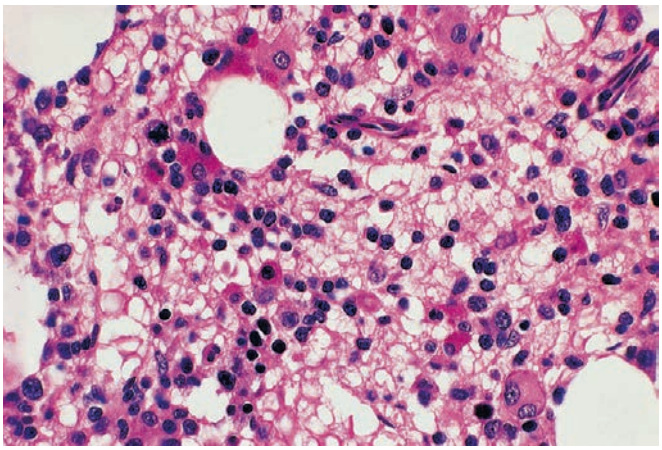

Figure 39.37 Marrow biopsy from a 2-year-old child with myelodysplastic syndrome associated with isolated monosomy 7 cytogenetic abnormality. Marrow is moderately to markedly hypocellular for age with increased fat and prominent interstitial cell depletion. Small megakaryocytes with hypolobulated nuclei are present.

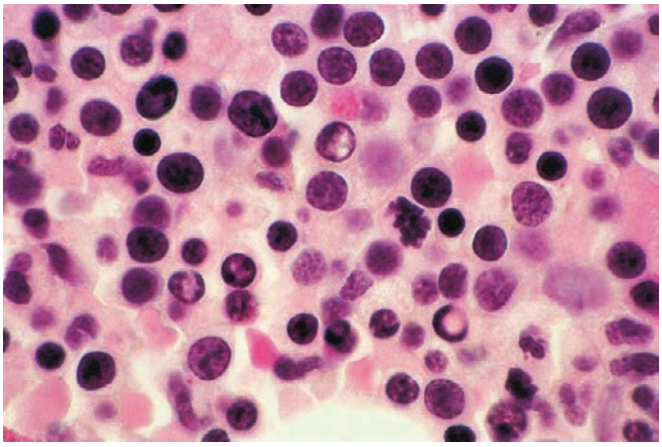

Figure 39.40 Marrow from a patient with MDS with single lineage dysplasia (refractory anemia) with marked erythroid hyperplasia and dyserythropoiesis. Several erythroid precursors with apoptotic nuclei are present.

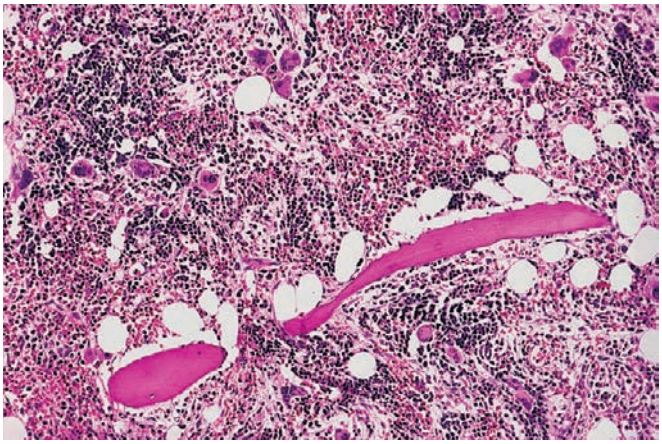

Figure 39.38 Bone marrow biopsy from an adult man with MDS with excess blasts-2 based on presence of 18% marrow blasts and myeloblasts with Auer rods. There is marked fibrosis with numerous megakaryocytes.

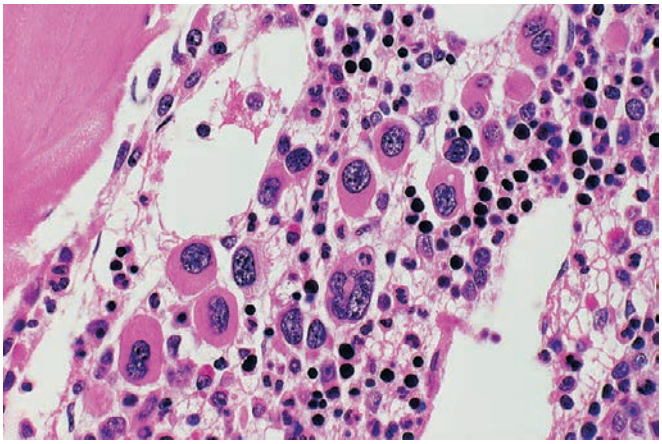

Figure 39.41 Marrow biopsy from an adult woman with de novo myelodysplastic syndrome associated with an isolated del(5q) (q21;q32) cytogenetic abnormality. There is an increase in megakaryocytes, many of which have hypolobulated nuclei. The majority of megakaryocytes are normal in size; small megakaryocytes are present.

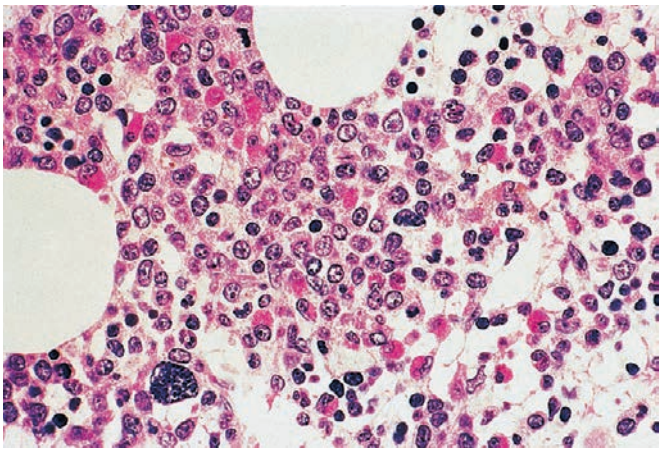

Figure 39.39 Marrow Biopsy From an Adult With MDS With Excess Blasts-2. Marrow is hypercellular. There are occasional foci of immature myeloid cells in the central marrow in nonparatrabecular and nonperivascular locations (ALIP).

del(5q) occurs primarily in older women who present with a macrocytic anemia that is often severe, normal-to-increased platelet count, and usually prolonged survival; the blast percentage in the marrow is less than 5% and less than 1% in the blood.[201,202] The marrow biopsy usually shows increased normal sized to slightly small megakaryocytes, many with hypolobulated nuclei (Fig. 39.41). There is usually no significant dysplasia in the erythroid and neutrophil series. The presence of an isolated del(5q) cytogenetic abnormality with the described findings characterizes the del(5q) syndrome. Despite the name, patients with a second clonal cytogenetic abnormality (other than −7) have a similarly favorable prognosis to those with isolated del(5q) and may now also be diagnosed with this disorder.[148,205,206] Three clonal abnormalities that included del(5q), however, are not allowed and are associated with a worse prognosis. Patients with this syndrome may respond favorably to treatment with the thalidomide analogue, lenalidomide. Patients with del(5q) and more than one additional cytogenetic abnormalities or blasts in excess of 5% in the marrow may also benefit from lenalidomide but have a generally worse prognosis and should not be diagnosed as MDS with isolated del(5q).

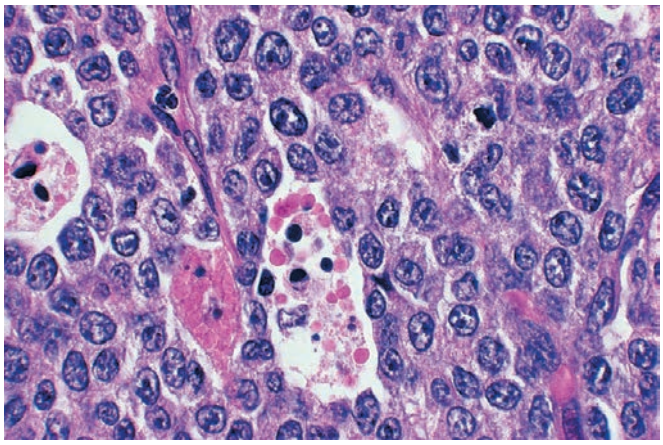

Figure 39.42 Portion of a myeloid sarcoma presenting as a subcutaneous chest wall mass in an elderly woman with a 1-year history of chronic myelomonocytic leukemia with less than 5% blasts in marrow and blood. The mass consists of a relatively uniform population of blasts; scattered mitotic figures are present. Numerous tingible body macrophages impart a "starry sky" appearance to the lesion. Many of the blasts reacted with antibody to myeloperoxidase and CD68 (KP1). Blood and marrow examination at the time of appearance of the chest wall mass was essentially unchanged from the previous year, with less than 5% blasts.

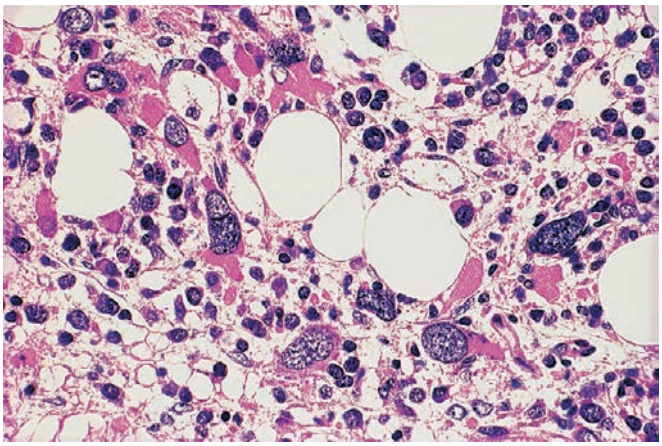

Figure 39.43 Bone Marrow Biopsy From a Patient With Therapy-Related Myelodysplasia With Myelofibrosis. There is predominance of neutrophils and megakaryocytes. Megakaryocytes show marked dysplasia.

Increased megakaryocytes may also be observed in association with inv((3)q21.2q26.2) or t(3;3)(q21.3;q26.2), which may present as MDS or AML. The megakaryocytes in cases with this association are abnormally small, many with hypolobulated nuclei, as well as more pronounced dyspoiesis in other cell types. The very small megakaryocyte size and associated multilineage dyspoiesis are not features usually seen in MDS with isolated del(5q).

Similar to the AMLs and MPNs, extramedullary myeloid sarcomas may occur in the course of a MDS (Fig. 39.42).

The therapy-related myeloid neoplasms (AML and MDS) occur in patients who have been treated with chemotherapy, radiation therapy, or both for a variety of malignant and nonmalignant conditions. Two major forms have been recognized: alkylating agent/radiation-related type and topoisomerase II inhibitor–related type, but many patients have received both types of therapeutic agents.[157] The alkylating agent–related type is generally a panmyelopathy, which may evolve to acute leukemia; in either instance, AML or MDS, it is a poor prognosis lesion with relatively short survival. The topoisomerase II–related type usually presents as acute leukemia with specific cytogenetic abnormalities, notably abnormalities involving chromosome 11q23.3. The bone marrow cellularity in the therapy-related MDS related to alkylating agents is more variable than with de novo MDS: in approximately 50% of patients the marrow is hypercellular; in 25% normocellular; and in 25% hypocellular.[192] In addition to changes characteristic of an MDS, the marrow specimen may show evidence of the initial lesion for which treatment was indicated. Megakaryocyte abnormalities may be particularly prominent in marrow biopsies (Fig. 39.43). Reticulin fibrosis may be marked, and some of these cases have been described as acute myelodysplasia with myelofibrosis when there is a pronounced shift to immature cells.

Immunohistochemistry may be very useful in evaluating the MDS. CD34 may be particularly useful in identifying blast in cases of hypoplastic MDS that may resemble aplastic anemia.[204] However, the absence of CD34 reactivity does not exclude blasts since not all myeloblasts are CD34 positive. Myeloperoxidase, CD15, CD117, and lysozyme antibodies are useful for recognizing myeloblasts and monoblasts. Antibodies to von Willebrand factor (factor VIII–related antigen), CD41, CD61, and CD31 may facilitate the recognition of small and abnormal megakaryocytes.

Cytogenetic studies performed on an aspirate specimen have a critical role in the evaluation of the MDS, both for determining clonality and for prognostic factors (see Box 39.2).[192,200,201,207]

The WHO classification recognizes refractory cytopenia of childhood (RCC) as a provisional entity.[152,208,209] Although this entity is reported to be the most common subtype of MDS in children, accounting for approximately 50% of MDS, it is very uncommon since MDS accounts for approximately 4% of hematologic malignancies in children. Patients present with persistent cytopenias; there are less than 5% blasts in the bone marrow and less than 2% blasts in the blood. Dysplastic features are present in all cell lineages in the smears. Evaluation of a marrow biopsy is critical for the diagnosis. About 75% of the patients have a markedly hypocellular marrow biopsy, which may have the appearance of aplastic anemia. The distinction may not always be possible on initial examination and repeat biopsies may be necessary.

The disorder occurs in all childhood age groups, and both sexes are affected with equal frequency. The evaluation of marrow biopsies is critical to the diagnosis.

The majority of children with RCC have marrows with a cellularity of 5%–10%. There are one to several foci of 10 or more immature erythroid precursors with increased mitoses. Megakaryocytes are usually markedly decreased to absent. Rare micromegakaryocytes may be found and are helpful in establishing a diagnosis; anti–von Willebrand factor (factor VIII–related antigen) and CD61 may facilitate their detection. Granulopoiesis is sparsely distributed and left shifted. In the minority of patients with RCC who present with normal or hypercellular marrows there is a slight-to-moderate increase in erythropoiesis, with a predominance of proerythroblasts with increased mitoses. Granulopoiesis is slightly to moderately decreased with a shift to immaturity. Blasts are less than 5% of the cells. Most cases show a normal karyotype; the most common cytogenetic abnormality when one is present is monosomy 7. The demonstration of a clonal abnormality is extremely helpful in establishing the diagnosis.

As noted, it may be very difficult to distinguish RCC from aplastic anemia and also, as noted, more than one observation may be necessary. In aplastic anemia there is generally no evidence of dysplasia in the smears. The erythropoiesis in the marrow sections is markedly

decreased to absent; the several foci characteristic of RCC are usually not found, and if one is present it contains fewer than 10 cells that show evidence of maturation. Dysplastic megakaryocytes are not present. Granulocytes are markedly diminished and show normal maturation.

Myeloproliferative Neoplasms

Considerable progress has been made in the classification of the MPNs in the past decade. This progress is the result of several discoveries of molecular alterations which may accompany these disorders. These discoveries have had impact on both the classification of these neoplasms as well as the recognition of entities, which previously were grouped under a nonspecific morphologic classification.[152]

The discovery of the *JAK2*V617F mutation has been the most significant contribution to the classification of the MPNs since the discovery of the Philadelphia chromosome in 1959 and subsequently of its molecular counterpart, the *BCR/ABL1* fusion gene in CML. Since then, additional mutations in *MPL* and *CALR* have been reported, mostly in the *JAK2* negative cases. The relationship of the these mutations to the specific MPNs will be noted in the diagnostic criteria for these individual disorders.

Although affecting a much smaller number of patients, the discovery of the genetic abnormalities in the *PDGFRA*, *PDGFRB*, and *FGFR1* genes has important implications, at least in some of them, for possible therapy with tyrosine kinase inhibitors for a group of diseases previously refractory to most forms of therapy. The recognition of this group of diseases is based on cytogenetic studies, fluorescence in situ hybridization (FISH), and molecular genetic analysis. Most, but not all, of these patients present with marked eosinophilia.

Chronic Myeloid Leukemia

CML is a stem cell disorder arising from fusion of the *ABL1* gene on chromosome 9 with the *BCR* gene on chromosome 22. The altered chromosome 22 is referred to as the Philadelphia chromosome.[210,211] CML, *BCR/ABL1* positive, is distinct from other myeloproliferative disorders, which are *BCR/ABL1* negative.[152,212] CML usually has three clinical pathologic stages, not always clearly distinguished: chronic, accelerated, and blast. The vast majority of patients present in the chronic phase; uncommonly patients present in an accelerated or blast phase.

The initial presentation in the chronic phase is characterized by marked leukocytosis, thrombocytosis, and basophilia and usually splenomegaly.[211] Atypical presentations such as marked thrombocytosis or basophilia without leukocytosis may occur. The number of myeloblasts in the blood and marrow smears in the chronic phase does not usually exceed 5%. The trephine sections are markedly hypercellular, primarily because of an increase in granulocytes and megakaryocytes.[211,213] Macrophages resembling Gaucher cells, usually occurring singly, may be present in the bone marrow smears and sections; they are more prominent in perivascular locations. Increased reticulin fibers are present in approximately 30% of cases and megakaryocytes are increased in approximately 40% of cases. Many of the megakaryocytes are small with hypolobulated nuclei. The increase in reticulin fibers correlates with an increase in microvascularity.[213,214]

The chronic phase, usually of 3–4 years' duration, is followed by the accelerated phase of shorter duration, characterized by increasing blasts in the blood and marrow, progressive basophilia, increasing myelofibrosis, and additional cytogenetic changes. The blast phase usually occurs abruptly and may occur without an intermediate accelerated phase; the blasts exceed 20% in the blood or marrow

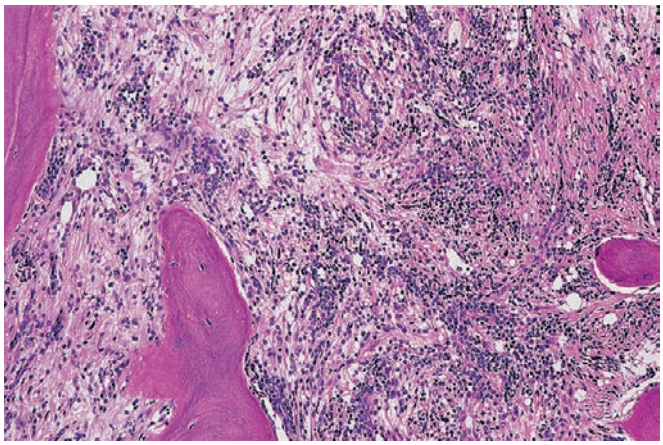

Figure 39.44 Marrow Biopsy From a Patient in Accelerated Phase of Chronic Myeloid Leukemia. There is marked reticulin fibrosis and small clusters of blasts.

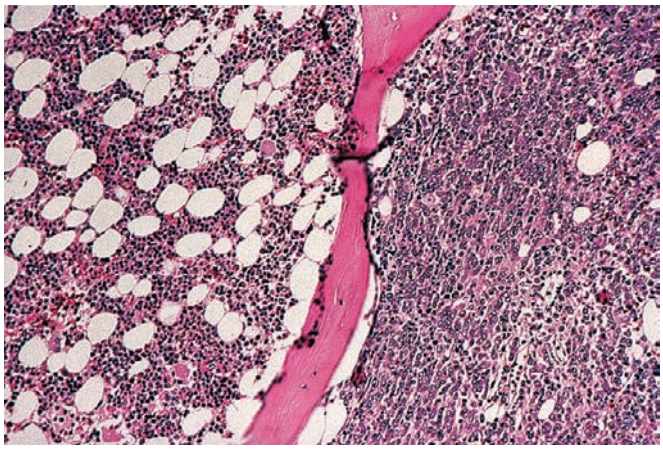

Figure 39.45 Erythroblastic Crisis of Chronic Myeloid Leukemia. The marrow to the left of the bone trabecula shows the findings of treated chronic phase. The proliferation of primitive erythroblasts to the right of the bone represents a focus of blast transformation.

(Figs. 39.44–39.46).[210,211,215] Approximately 70% of blast crises are morphologically and immunophenotypically myeloid, and 30% are lymphoblastic. The myeloid type may be characterized by proliferation of any of the myeloid cell lineages, including myeloblasts, erythroblasts, and megakaryoblasts. Immunohistochemical studies may be very useful in identifying the distribution and lineage of blast populations. In some patients, blast transformation may be initially manifest in bone marrow sections as large, irregular, focal collections of blasts. Extramedullary manifestation of blast crisis also occurs, and the diagnosis should be suspected in any patient with CML who develops a tumor mass or lymphadenopathy.

The development of extensive myelofibrosis in patients with CML usually occurs late in the disease and has been associated with a more aggressive clinical course.[211,216,217] Exceptions to this generalization have been reported and myelofibrosis may occur in the early stages of CML with the same prognostic implications as when it occurs late in the disease.[216,218] The myelofibrosis in CML is usually characterized by an increase in reticulin fibers; collagenous fibrosis is not common but may occasionally occur (see Fig. 39.44). As noted, the increase in reticulin fibers correlates with an increase in angiogenesis. Reversal of myelofibrosis may occur following hematopoietic cell

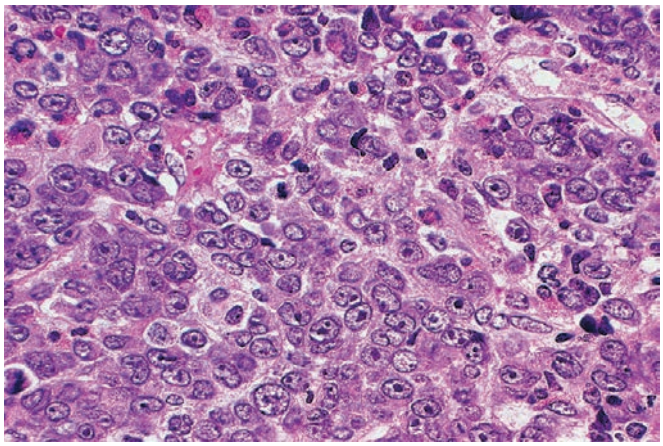

Figure 39.46 High magnification of marrow biopsy from a patient with erythroblastic transformation of chronic myeloid leukemia. Cells are large with prominent nucleoli and basophilic cytoplasm.

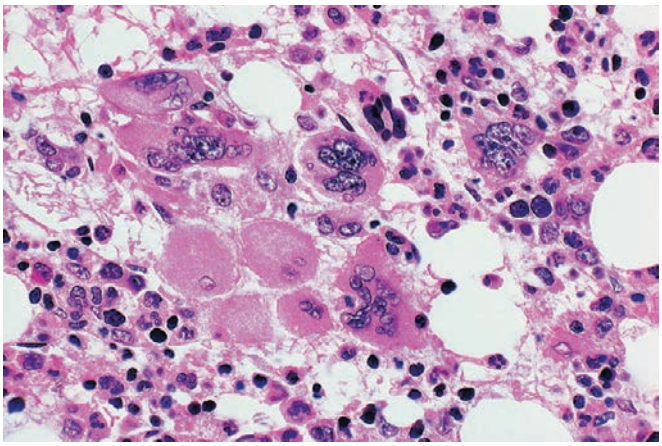

Figure 39.47 Hyperplastic Bone Marrow From a Patient With Polycythemia Vera. All cellular elements are increased. Megakaryocytes are prominent and show considerable variation in size; many are unusually large with hyperlobulated nuclei.

transplantation and imatinib therapy.[219,220] A positive correlation between the degree of reticulin fibrosis and the number of CD61-positive megakaryocytes has been reported both pre- and post-allogeneic marrow transplant.[221]

The introduction of therapy with the tyrosine kinase inhibitor imatinib mesylate (Gleevec), and now next-generation tyrosine kinase inhibitors, for CML has been one of the major success stories in the field of leukemia therapy; the agent induces hematologic remission in a high percentage of patients with CML in the chronic phase and accelerated phases of the disease.[218,222–225] The hematologic remission is accompanied by morphologic normalization or near normalization of the bone marrow in most cases. The normalization of the marrow may occur even with persistence of the Philadelphia chromosome, or evidence of the *BCR/ABL1* fusion gene. The normalization of the marrow usually may lag behind remission of blood findings and may not be complete for several months.[222] Other therapies for CML are now less common. Treatment with interferon usually results in a decrease in overall marrow cellularity and an increase in erythroid precursors. There may be a concurrent increase in megakaryocytes and reticulin fibers. Hydroxyurea therapy generally results in a decrease in cellularity and no increase in megakaryocytes or reticulin fibers.[226]

Box 39.5 2016 World Health Organization diagnostic criteria for polycythemia vera

Major criteria

1. Hemoglobin >16.5 g/dL in men; >16.0 g/dL women, or Hematocrit >49% in men; >48% in women, or
2. Other evidence of increased red blood cell mass (>25% above mean normal predicted value). Bone marrow biopsy showing hypercellularity for age with trilineage growth (panmyelosis) including prominent erythroid, granulocytic, and megakaryocytic proliferation with pleomorphic mature megakaryocytes (differences in size)
3. *JAK2*V617F or *JAK2* exon 12 mutation

Minor criterion

- Subnormal serum erythropoietin level.

Diagnosis requires either all three major criteria or the first two major and the minor criterion

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

Polycythemia Vera

PV is an MPN in which the major diagnostic feature is an increased red blood cell mass. There is usually splenomegaly and some degree of leukocytosis and thrombocytosis.[227] Precise criteria for the diagnosis of PV have been established by the Polycythemia Vera Study Group (PVSG); these were modified in the WHO proposal for the classification of hematopoietic neoplasms. An important addition to the diagnostic criteria for PV in the 2008 WHO classification is the recognition of the Janus 2 kinase gene mutation *JAK2*V617F or similar mutations, such as *JAK2* exon 12 mutation, present in over 95% of cases (Box 39.5).[227–232] The discovery of this mutation has also led to the identification of a marker for familial cases of PV.[233]

Three clinical phases of PV are recognized: (1) prodromal pre-polycythemia phase with borderline to slight erythrocytosis; (2) overt PV with a significant increase in red blood cell mass; and (3) spent phase or post polycythemia with myelofibrosis.[227,234–240]

The blood smear in the overt phase shows increased erythrocytes, reflecting the increased red blood cell mass, leukocytosis, and thrombocytosis. The bone marrow is usually markedly hypercellular.[227,241–244] However, this is not an invariant finding; 13% of the patients enrolled in the National Cancer Institute Polycythemia Vera Study had marrow biopsies with cellularity of less than 60%.[242] The cellularity of the marrows from patients in the study ranged from 37% to 100%, with a mean of 82%. The hypercellularity is due to a panhyperplasia of myeloid cells, principally erythroid precursors and megakaryocytes; the megakaryocytes range in size from small to unusually large, frequently with hyperlobulated nuclei and in clusters (Fig. 39.47).[227,241–244] The clusters may be accentuated in perisinusoidal and paratrabecular locations. Stains for iron usually show decreased or no hemosiderin deposits.[241] A slight increase in reticulin fibers is present at the outset of the disease in 25% of cases; 11% of pretreatment biopsies show a marked increase in reticulin fibers.[241] The increase in reticulin corresponds, in general, to an increase in marrow cellularity and the number of megakaryocytes. An increase in reticulin fibers in pretreatment marrow biopsies is not necessarily indicative of the spent phase of the disease. Similar to other MPNs, there is an increase in vascular structures in PV.[214,245]

Approximately 20% of patients with PV have cytogenetic abnormalities; the most frequently detected are +8, +9, del(20q), del(13q), and del(9p). The incidence increases with disease progression.[227]

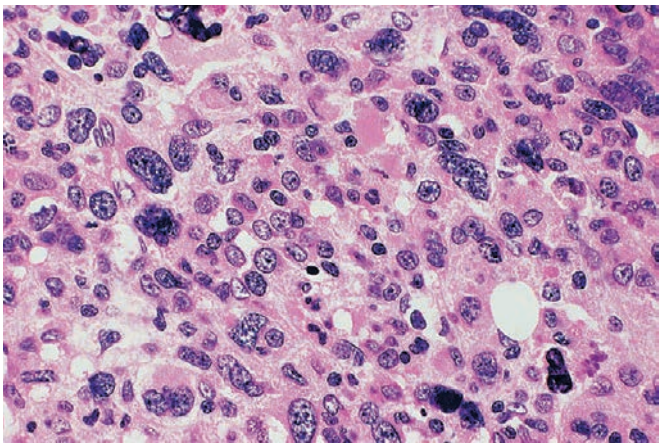

Figure 39.48 Marrow Biopsy From a Patient in Spent Phase of Polycythemia Vera. Marrow is markedly hypercellular as a result of granulocytic and megakaryocytic hyperplasia. Megakaryocytes show dysplastic features.

PV may be difficult to distinguish from the other non-CML MPNs based solely on marrow examination. As a result, it is critical to adhere to established diagnostic guidelines when making a diagnosis.[227,244] Although the *JAK2*V617F mutation readily distinguishes PV from other causes of erythrocytosis, the mutation is shared by essential thrombocythemia and PMF, albeit less frequently. Morphology continues to have a central role in the diagnosis along with the clinical data.[227,243,244,246,247]

The evolution of PV to the spent or post-polycythemic phase may be marked by a decrease in red blood cell mass with anemia and the development of myelofibrosis with a marked increase in reticulin fibers, increased angiogenesis, collagenous fibrosis, and clusters of abnormal megakaryocytes; the incidence of this complication varies from 9% to 20% (Fig. 39.48).[227,235–239,247] This is accompanied by a leukoerythroblastic blood picture and increased red blood cell poikilocytosis with numerous dacryocytes and increasing splenomegaly due to extramedullary hematopoiesis. An additional complication in some patients is the development of acute leukemia and myelodysplasia; the incidence is higher in patients treated with chemotherapy or radiation as opposed to those treated only with phlebotomy.[248–251]

Essential Thrombocythemia

Essential thrombocythemia (ET) is a myeloproliferative disorder that is closely related to PV but lacks the essential diagnostic criteria of PV, most notably an increase of red blood cell mass.[229,252–254] The principal morphologic findings relate to the increased megakaryocytes and thrombocytosis. The marrow is usually normocellular for age but may be hypercellular or hypocellular. The bone marrow findings are principally related to increased and large megakaryocytes with hyperlobulated nuclei (Fig. 39.49).[235] The megakaryocytes occur singly and in clusters. The erythroid and granulocytic cell lines are usually normal. Reticulin is usually normal but may be slightly increased, and there may be an associated increase in angiogenesis.[255] There is no specific molecular marker for ET, such as the *BCR/ABL1* fusion gene in CML, but half of patients with ET have the *JAK2*V617F mutation, which may also be present in PV and PMF.[230,254] Another approximately 25% of cases show mutations of *CALR*, and 3%–5% have *MPL* mutations, both usually in the absence of a *JAK2* mutation.[256,257] The WHO criteria for diagnosis of ET are listed in Box 39.6.

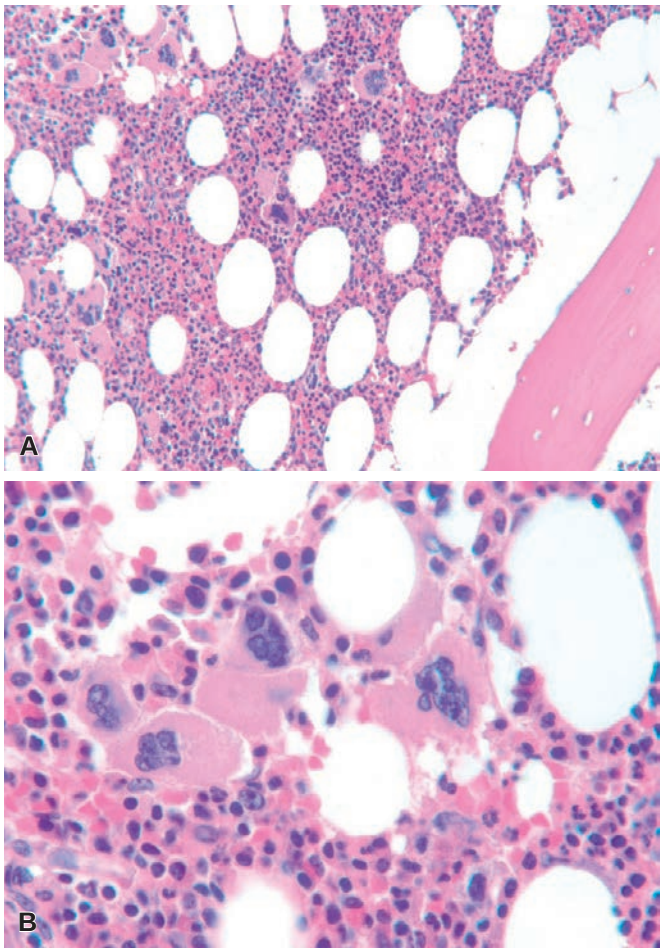

Figure 39.49 **A**, Marrow biopsy from a patient with essential thrombocythemia. Marrow is normocellular with numerous scattered large megakaryocytes. **B**, High magnification of specimen in **A** showing the very large megakaryocytes, some with hyperlobulated nuclei.

Box 39.6 2016 World Health Organization diagnostic criteria for essential thrombocythemia

Major criteria

1. Platelet count of ≥450 × 10^9/L
2. Bone marrow biopsy showing proliferation mainly of the megakaryocyte lineage with increased numbers of enlarged, mature megakaryocytes with hyperlobulated nuclei. No significant increase or left shift in neutrophil granulopoiesis or erythropoiesis and very rarely minor (grade 1) increase in reticulin fibers
3. Not meeting WHO criteria for *BCR-ABL1*+ chronic myeloid leukemia, polycythemia vera, primary myelofibrosis, myelodysplastic syndrome or other myeloid neoplasms
4. Presence of *JAK3*, *CALR* or *MPL* mutation

Minor criterion

Presence of a clonal marker or absence of evidence for reactive thrombocytosis

Diagnosis requires meeting all four major criteria, or the first three and the minor criterion

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

The distinction between essential thrombocytosis and secondary forms of thrombocytosis may be difficult from routine morphologic studies.[255] The clinical history is important in excluding possible causes for a secondary thrombocytosis. Demonstration of the *JAK2*V617F or other ET-associated mutations would be definitive in excluding a secondary thrombocytosis.[228–230,258] However, other mutations may be detectable in reactive cases, associated with so-called clonal hematopoiesis of indeterminate prognosis (CHIP), and the detection of a mutation alone does not equate with neoplasia.[259–261]

ET is an indolent disease in most patients, with survival of 10–15 years. Transformation to AML occurs in less than 5% of patients and may be related to chemotherapy.[254]

Primary Myelofibrosis

PMF (chronic idiopathic myelofibrosis, agnogenic myeloid metaplasia) is a clonal myeloproliferative disease of undetermined etiology characterized by myeloid cell proliferation and reactive fibrosis.[229,237,262–272] It occurs primarily in adults; the average age at diagnosis is approximately 60 years.[262,269,273] Rare cases have been reported in the pediatric population.[274] There is some degree of detectable hepatosplenomegaly caused by extramedullary hematopoiesis.

PMF may, at times, be confused with CML or other types of MPNs because of occasional similarities in the blood findings; the important differentiating clinical and laboratory findings have been described in detail.[265,268,269] The principal clinical and morphologic features have been described in the WHO Classification (Boxes 39.7 and 39.8).[148,269] The most important distinguishing biologic feature is the presence of the Philadelphia chromosome or molecular evidence of the *BCR/ABL1* fusion gene in the hematopoietic cells in CML and its absence in the cells from patients with PMF and the possible presence of a *JAK2*V617F (50%–60%), *CALR* (30%) or *MPL* (5%–10%) mutation in PMF.[228–230,268,275] Marrow fibrosis in CML is generally a late occurrence, and its onset usually heralds a more aggressive evolution, unlike PMF in which marrow fibrosis is present to some extent from inception and is generally associated with a more prolonged clinical course.[276,277] Approximately 30% of patients have a cytogenetic abnormality at presentation; the incidence increases with leukemic progression. The most common abnormalities are del(13q), del(20q), +8, +9, and abnormalities of chromosomes 1, and 7.[268,278]

PMF is usually characterized by progression from an early or prefibrotic stage to a fibrotic stage, although biopsies from different sites have been reported to show substantial variation in the degree of fibrosis. Approximately 20%–30% of patients with PMF present in the early or prefibrotic stage.[268,269] The marrow in this stage is hypercellular for age; there is an increase in abnormal megakaryocytes and granulocytes (Fig. 39.50). Erythroid precursors may be reduced. The megakaryocytes may form clusters adjacent to sinuses and bone trabeculae. The megakaryocytes vary in size and are frequently very large with abnormal clumping of the chromatin. There is minimal increase in reticulin fibers in the early or prefibrotic stage. Aggregates of well-differentiated lymphocytes may be present. The fibrotic stage is marked by variable degrees of reticulin and/or collagen fibrosis; the marrow varies from hypocellular to hypercellular. Expansion of the bone trabeculae may be present. The density of reticulin fibers may vary substantially in different areas of the biopsy. Sinusoids are usually increased in number and distended and contain hematopoietic cells. Megakaryocytes may be particularly prominent in the sinusoids (Fig. 39.51). In some cases, the marrow may be almost uniformly densely fibrotic with scattered foci of hematopoietic cells (Fig. 39.52). Scattered abnormal megakaryocytes may be the only recognizable hematopoietic cells. In approximately 40% of the patients with PMF, osteosclerotic changes can be demonstrated by radiographic

Box 39.7 2016 World Health Organization diagnostic criteria for early/pre-primary myelofibrosis

Major criteria:

1. Megakaryocytic proliferation and atypia, without reticulin fibrosis > grade 1, accompanied by increased age-adjusted bone marrow cellularity, granulocytic proliferation and often decreased erythropoiesis
2. Not meeting the WHO criteria for *BCR-ABL1*+ chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR* or *MPL* mutation or in the absence of these mutations, presence of another clonal marker or absence of minor reactive bone marrow reticulin fibrosis[a]

Minor criteria:

Presence of at least one of the following, confirmed in two consecutive determinations:

a. Anemia not attributed to a comorbid condition
b. Leukocytosis ≥11 × 10^9/L
c. Palpable splenomegaly
d. LDH increased to above upper normal limit of institutional reference range

Diagnosis of early/prePMF requires meeting all three major criteria, and at least one minor criterion

[a]minor (grade 1) reticulin fibrosis secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

Box 39.8 2016 World Health Organization diagnostic criteria for overt primary myelofibrosis

Major criteria

1. Presence of megakaryocytic proliferation and atypia, accompanied by either reticulin and/or collagen fibrosis grades 2 or 3
2. Not meeting WHO criteria for *BCR-ABL1*+ chronic myeloid leukemia, polycythemia vera, essential thrombocythemia, myelodysplastic syndromes, or other myeloid neoplasms
3. Presence of *JAK2*, *CALR,* or *MPL* mutation or in the absence of these mutations, presence of another clonal marker or absence of reactive myelofibrosis[a]

Minor criteria

Presence of at least one of the following, confirmed in two consecutive determinations:

1. Anemia not attributed to a comorbid condition
2. Leukocytosis ≥11 × 10^9/L
3. Palpable splenomegaly
4. LDH increased to above upper normal limit of institutional reference range
5. Leukoerythroblastosis

Diagnosis of overt PMF requires meeting all three major criteria, and at least one minor criterion

[a]BM fibrosis secondary to infection, autoimmune disorder or other chronic inflammatory conditions, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

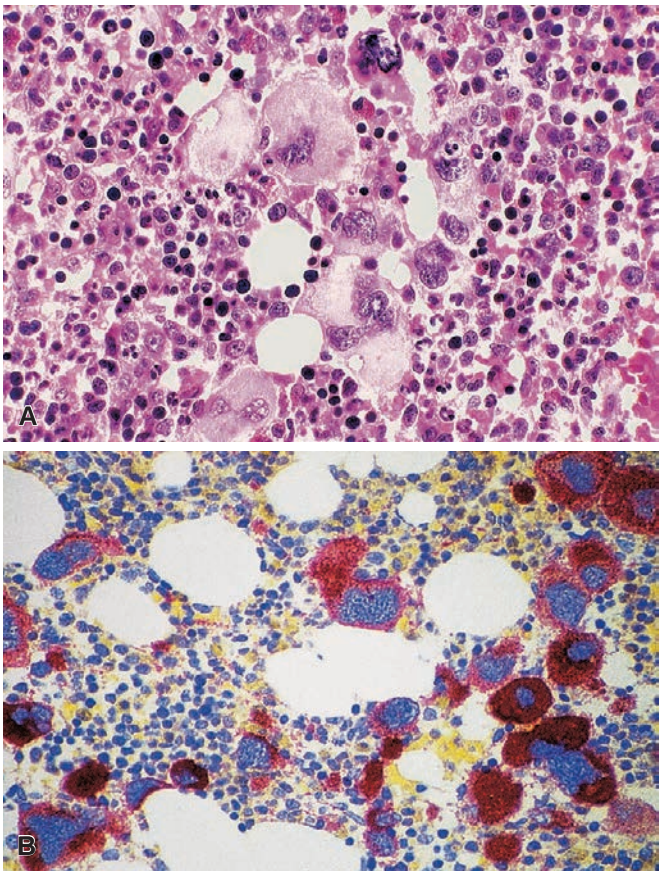

Figure 39.50 **A**, Marrow biopsy from the prefibrotic stage of primary myelofibrosis. There is a cluster of megakaryocytes which vary in size. Several are large with marked variation in nucleocytoplasmic ratio. **B**, Bone marrow section from prefibrotic stage of primary myelofibrosis stained with antibody to CD61. This highlights the megakaryocytes, which vary in size from small to large. The nuclei show markedly abnormal chromatin clumping. (**B,** Contributed by Dr. J. Thiele, Cologne, Germany, and reproduced from Jaffe ES, Harris NL, Stein H, Vardiman JW, eds. World Health Organization Classification of Tumours: Pathology and Genetics of Tumours of Haematopoietic and Lymphoid Tissues. Lyon: IARC Press; 2001.)

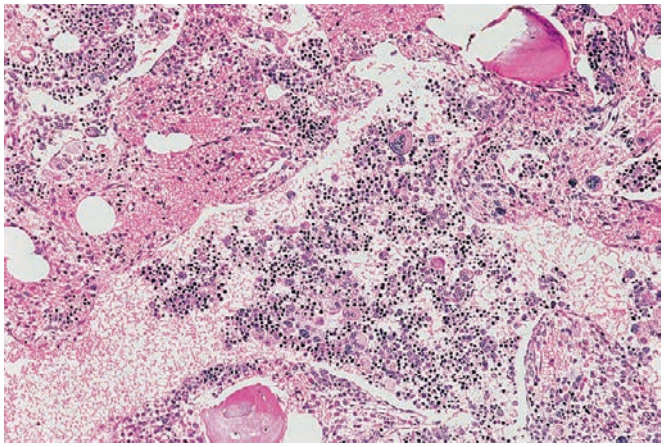

Figure 39.51 Bone marrow biopsy from a patient with primary myelofibrosis showing prominent intrasinusoidal hematopoiesis. Predominant cells in the sinusoid are erythroid precursors and megakaryocytes.

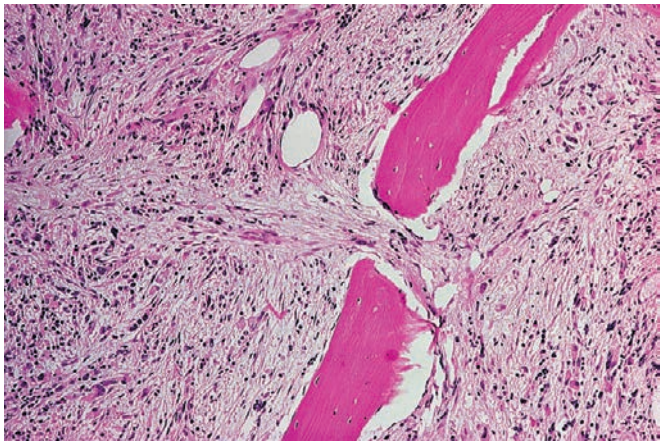

Figure 39.52 Trephine biopsy from an adult with a 7-year history of primary myelofibrosis (agnogenic myeloid metaplasia). There is extensive marrow fibrosis with marked reduction in hematopoietic tissue.

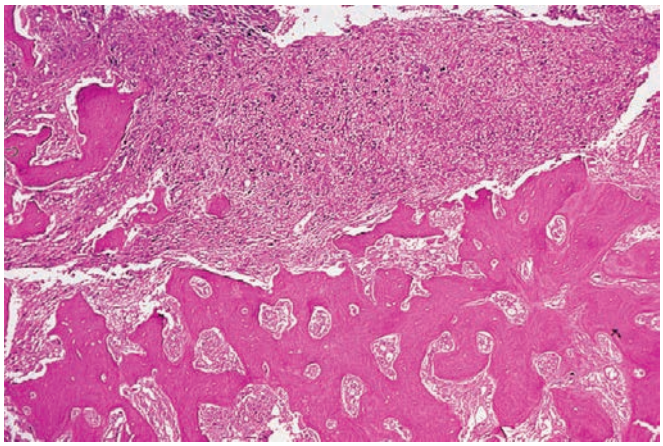

Figure 39.53 Marrow biopsy from a patient with primary myelofibrosis shows extensive osteosclerosis and a cellular area composed predominantly of blasts.

examination, most notably in the bones of the axial skeleton and the proximal portions of the long bones.[270] The relative proportion of hematopoietic cells and fibrous tissue has been generally assumed to vary with the stage of disease, the amount of fibrous connective tissue progressively increasing, with the end stage characterized by marked marrow fibrosis and marked splenomegaly. Studies have been reported that show no correlation between extent of marrow fibrosis and duration of disease and spleen size.[272]

Similar to CML, PMF may progress to an accelerated phase with increased blasts (Fig. 39.53). These may be present diffusely or uncommonly in focal aggregates. Myeloid sarcomas have been reported in patients with longstanding PMF.[184] The lesions occur most frequently in the retroperitoneum, pelvis, mesentery, and pleura; lymph node and skin may also be involved. The tumors are usually composed primarily of hematopoietic cells with varying degrees of stromal reaction. The megakaryocytes may be particularly prominent because of their number and frequently bizarre appearance. Rarely, marked fibrosis may be present.[184] A hyperplasia of hematogones has been reported in the bone marrow of patients with PMF following therapy.[279]

The majority of patients with PM have a relatively long clinical course, with an estimated median survival of 3–5 years from the onset of disease.[268] A minor population of patients with this disorder

has a more aggressive clinical course with a median survival of approximately 2 years.[280,281] Amyloidosis has been reported as a concurrent condition.[282]

Marrow fibrosis may be an accompaniment of several disorders, both hematologic and nonhematologic, including autoimmune disorders, and a diagnosis of PMF should be based on firm diagnostic criteria.[283,284]

Myeloid/Lymphoid Neoplasms With Eosinophilia and Rearrangement of *PDGFRA*, *PDGFRB*, or *FGFR1* or With *PCM1-JAK2*

PDGFRA Abnormalities

The most common MPN associated with an abnormality of *PDGFRA* results from an *FIP1L1/PDGFRA* fusion gene. This results from a cryptic deletion on chromosome 4 at band q12.[285–287] The deletion also results in the loss of the *CHIC2* gene; this finding serves as a reliable surrogate marker for the *FIP1L1/PDGFRA* fusion.[288,289] There is a marked male predominance in the disorder and the median age is in the late 40s. There is usually marked eosinophilia, and cardiac and pulmonary symptoms are frequent, but rare cases occur without eosinophilia.[290] Splenomegaly is common. The serum vitamin B12 level is elevated. The presentation is similar to chronic eosinophilic leukemia (CEL). The bone marrow is hypercellular with markedly increased eosinophils and frequently increased mast cells, which are dispersed or in loose nonparatrabecular, nonperivascular clusters; occasionally the mast cells appear in dense bundles virtually indistinguishable morphologically from systemic mastocytosis (Fig. 39.54). The mast cells are highlighted by reaction with mast cell tryptase and are usually CD2–, CD25+. Importantly, this neoplasm is responsive to the tyrosine kinase inhibitor imatinib and for this reason, differentiation from mastocytosis is of importance.[285–287,291,292]

Because of the finding of increased mast cells in the marrow of patients with *FIP1L1/PDGFRA* fusion, there may be cases in which the distinction between this disorder and systemic mastocytosis is difficult based solely on the morphologic findings.[293] The definitive distinguishing finding is molecular evidence of the fusion gene. However, there are several clinical and laboratory findings which, viewed in aggregate, may aid in distinguishing the two processes. There is a marked male predominance in myeloid/lymphoid neoplasms with *PDGFRA* rearrangement; in systemic mastocytosis the sex distribution is more evenly distributed. Patients with systemic mastocytosis commonly have a history of urticaria pigmentosa and gastrointestinal symptoms; patients with myeloid/lymphoid neoplasms with *PDGFRA* rearrangement uncommonly have these manifestations. The laboratory findings for the two disorders are more distinctive; patients with systemic mastocytosis have much higher serum tryptase levels, a median level of 207 ng/mL compared to a median level of 24 ng/mL in other eosinophilias. The median peak absolute eosinophil count is 2187/mm^3 in mastocytosis and 12,474/mm^3 in myeloid/lymphoid neoplasms with *PDGFRA* rearrangement.[289,294] In systemic mastocytosis there are dense aggregates of mast cells in the marrow biopsy, whereas in myeloid/lymphoid neoplasms with *PDGFRA* rearrangement the mast cells are usually dispersed. However, this finding is not always a reliable distinguishing feature (see Fig. 39.54). The molecular studies are definitive, with the mastocytosis usually showing mutations of *KIT* and not showing *PDGFRA* rearrangements.

PDGFRB Abnormalities

The most frequent MPN associated with rearrangement of the *PDGFRB* gene on chromosome 5q31–33 usually has the morphologic features similar to chronic myelomonocytic leukemia (usually with eosinophilia) or atypical CML with eosiniphilia.[285] The disease is more

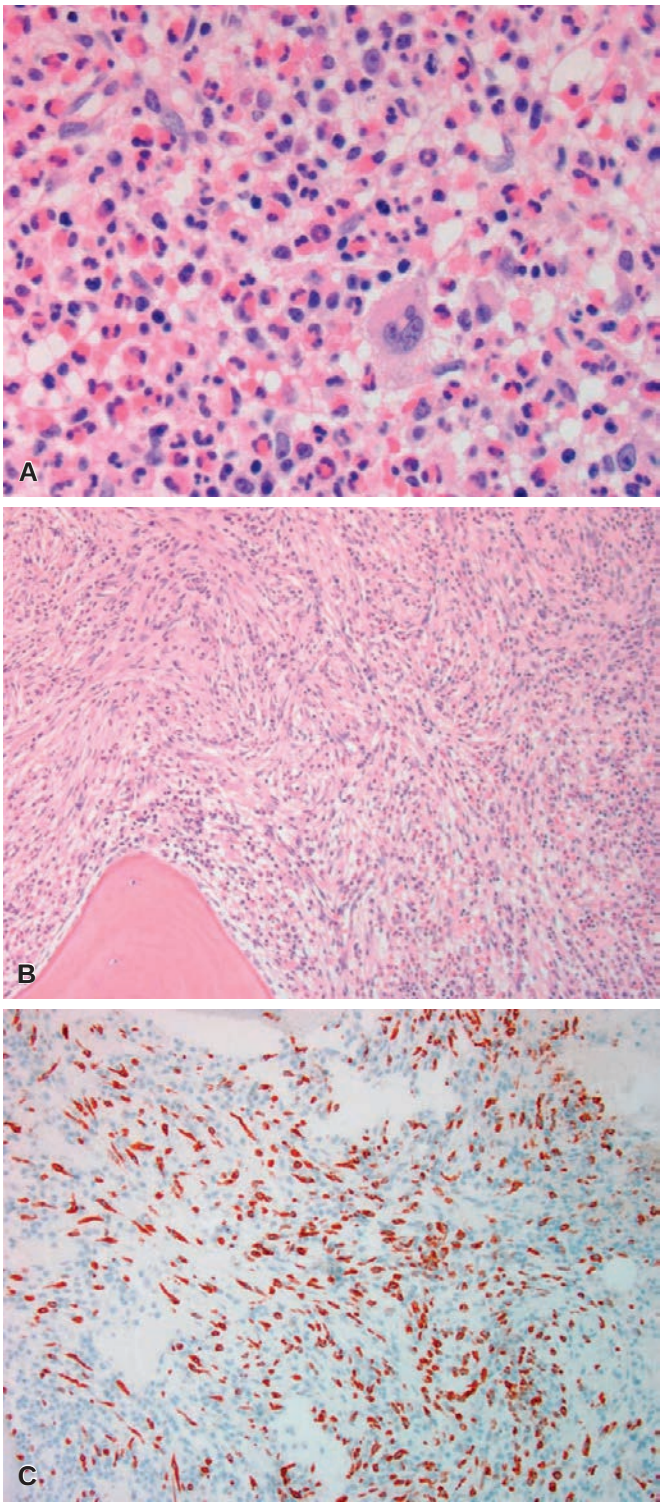

Figure 39.54 **A**, Bone marrow biopsy from an adult man with a WBC count of 18.6 × 10^9/L with 86% eosinophils. The marrow is markedly hypercellular with a marked increase in mature eosinophils. **B**, Another area of the same biopsy showing an aggregate of intertwining mast cells, most of which are fusiform in shape. The mast cell infiltrate is partly juxtaposed to a bone trabecula. **C**, Mast cell tryptase of the lesion in **B** highlighting the mast cells. Genetic studies showed a deletion of *CHIC2*, a surrogate marker for *PDGFRA/FIP1L1* fusion gene. The patient is in remission 3 years following initiation of therapy with imatinib. (Contributed by Dr. Curt Hanson, Rochester, MD.)

common in men, with a median age at presentation in the upper 40s and an age range of 8–72 years. Most patients have splenomegaly. Cytogenetic studies show a t(5;12)(q31–33;p12) abnormality and molecular analysis shows an *ETV6/PDGFRB* fusion gene.[295] The bone marrow is hypercellular with increased eosinophils, and there may be an increase in mast cells, which may be spindled or fusiform in shape. Other types of myeloid presentation with other fusion genes have been reported. The disorder is responsive to the tyrosine kinase inhibitor imatinib.

FGFR1 Abnormalities

The hematopoietic neoplasms associated with *FGFR1* rearrangement are somewhat heterogeneous and include MPNs, AML, T- and B-lymphoblastic lymphomas/leukemias, and mixed phenotype acute leukemia.[285] There is a wide age range; the median age is 32 years. The associated cytogenetic abnormality is often t(8;13)(p11;q12), but numerous 8p11 variant translocations are described. Patients presenting with a myeloproliferative disorder usually have eosinophilia. The cases presenting with lymphoma usually show eosinophilic infiltration of the lymphoma.

In contrast to the lesions associated with abnormalities of *PDGFRA* and *PDGFRB*, the neoplasms associated with abnormalities of *FGFR1* are not responsive to imatinib and the prognosis is poor.

PCM1-JAK2 Fusions

The 2016 WHO classification now includes myeloid/lymphoid neoplasms with *PCM1-JAK2* as a provisional entity that is commonly associated with eosinophilia.[296] These are usually myeloid neoplasms that show a t(8;9)(p22;q24.1). In addition to eosinophilia, the marrow shows left-shifted erythroid hyperplasia and lymphoid aggregates and may demonstrate myelofibrosis that may mimic PMF. These rare tumors may also present as lymphoblastic leukemia/lymphomas and may respond to *JAK2* inhibitors.[297]

Systemic Mastocytosis

Systemic mastocytosis is a relatively rare disorder characterized by mast cell proliferation in several organs. It usually occurs in combination with urticaria pigmentosa but may present in patients without cutaneous involvement.[298–300] The median age for patients presenting with systemic mastocytosis with urticaria pigmentosa is 45 years; the median age for patients presenting with systemic mastocytosis without urticaria pigmentosa is around 75 years.[298,301–303] The clinical symptoms are varied and include diarrhea, weakness, fractures, weight loss, arthralgia, flushing episodes, and bronchospasm.[298,304–306] An occasional patient may experience anaphylactoid shock. Slight splenomegaly may be present. Osteoblastic, osteolytic, or concurrent osteoblastic–osteolytic lesions may be found on radiologic examination; generalized osteoporosis may also occur (Fig. 39.55).

The WHO classification of mastocytosis is shown in Box 39.9.[148,301,307] The WHO proposes one major and four minor criteria for the diagnosis of systemic mastocytosis, which is the type with bone marrow involvement (Box 39.10).[301] The blood findings in systemic mastocytosis may include eosinophilia, anemia, leukocytosis or leukopenia, thrombocytopenia, and pancytopenia.[308,309]

The bone marrow is the most frequent site of noncutaneous involvement in systemic mastocytosis; lesions may be found as a result of a specific search or may be detected in a biopsy performed for some purpose unrelated to suspected mastocytosis. In the latter instance, when there is no clinical suspicion of the disease, the lesions may be overlooked or misinterpreted because of the difficulty in identifying mast cells in routine sections and because of the changes inherent in the mast cells in this disease; the cells are frequently large, spindled, or have lobulated nuclei and decreased granules that may be much smaller than normal mast cell granules.[301,306,307,310] Smears obtained by bone marrow aspirate may suggest the diagnosis of mastocytosis if large numbers of atypical mast cells are present; however, up to 7% of mast cells have been reported in aspirate preparations in patients without mast cell disease. An increase in mast cells may also be observed in lymphocytic and lymphoplasmacytic lymphomas and hairy cell leukemia.[311] A marked increase in mast cells in the marrow has been observed following the administration of stem cell growth factor. Because systemic mastocytosis may be associated with marked fibrosis, mast cells may not be readily aspirated.

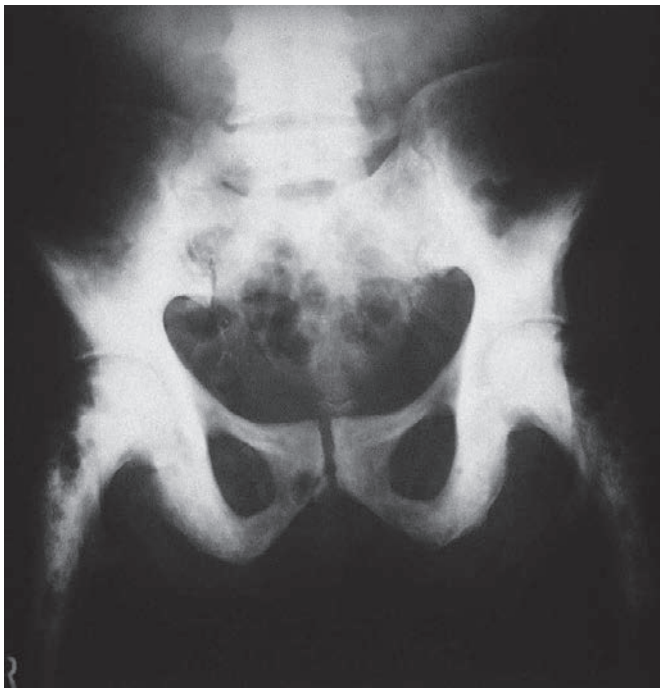

Figure 39.55 Radiograph of pelvis and upper femurs from a patient with systemic mastocytosis; both osteosclerotic and osteolytic changes are prominent.

Box 39.9 2016 World Health Organization classification of mastocytosis

1. Cutaneous mastocytosis
2. Systemic mastocytosis
   a. Indolent systemic mastocytosis[a]
   b. Smoldering systemic mastocytosis[a]
   c. Systemic mastocytosis with an associated hematological neoplasm[b]
   d. Aggressive systemic mastocytosis[a]
   e. Mast cell leukemia
3. Mast cell sarcoma

[a]These subtypes require information regarding B and C findings for complete diagnosis,[308] all of which may not be available at the time of initial tissue diagnosis.

[b]This category is equivalent to the previously described "systemic mastocytosis with an associated clonal hematological non-mast cell lineage disease (SM-AHNMD)."

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

Box 39.10 World Health Organization diagnostic criteria for systemic mastocytosis

Major criterion

Multifocal dense infiltrates of mast cells (≥15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s).

Minor criteria

1. In biopsy sections of bone marrow or other extracutaneous organs, >25% of mast cells in the infiltrate are spindle shaped, have atypical morphology or, of all mast cells in bone marrow aspirate films, >25% are immature or atypical.
2. Detection of an activating point mutation at codon 816 of *KIT* in bone marrow, blood or another extracutaneous organ.
3. Mast cells in bone marrow blood or other extracutaneous organs express CD25 with or without CD2 in addition to normal mast cell markers.[a]
4. Serum total tryptase persistently exceeds 20 ng/mL (unless there is an associated clonal myeloid disorder, in which case this parameter is not valid).

[a]CD25 is the more sensitive marker, both by flow cytometry and by immunohistochemistry.

The diagnosis requires the major criterion and at least one minor criterion, or at least three minor criteria

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

The marrow lesions may be focal or diffuse. Focal lesions are more common and may be paratrabecular, perivascular, or randomly distributed.[298,299,301,303–307,310,312] The paratrabecular lesions frequently are marked by a margination of the infiltrate along the bone trabeculae or juxtaposition of a lesion to a bone spicule. The perivascular lesions may be associated with prominent medial and adventitial hypertrophy and collagen fibrosis. The focal lesions are variable in appearance but generally can be classified into two primary types based on cell composition: polycellular and monocellular. Both types may be observed in the same specimen. The polycellular lesions are characterized by mast cells, lymphocytes, histiocytes, eosinophils, neutrophils, fibroblasts, and endothelial cells in varying proportions; the eosinophils are frequently more numerous at the margins of the lesion. In some cases the different cell types appear to be randomly distributed; in others, the mast cells occur in a central aggregate and are surrounded by well-differentiated lymphocytes, or the mast cells encircle a focus of lymphocytes (Fig. 39.56). The mast cells in these lesions are frequently atypical and characterized by spindle shape and abundant eosinophilic cytoplasm with very fine granules. In the monomorphic lesions, the cellular composition is predominantly mast cells with only scattered lymphocytes and eosinophils (Fig. 39.57). The mast cells in these lesions may appear as intertwining bundles and vary in shape from round in cross section to spindle shaped in longitudinal cut. The cytoplasm is pale to lightly eosinophilic. The nuclei are round or oval; occasionally the nuclei have a monocytoid configuration. Nucleoli are inconspicuous, and mitotic figures are rare. Some of these lesions may resemble aggregates of histiocytes or granulomas. The marrow exclusive of the mast cell lesions is usually hypercellular or normocellular with a granulocytic hyperplasia.[298,301,303–307] The diffuse lesions are characterized by the same cell types as the focal lesions. Changes in the bone trabeculae may be present; both widening and erosion of the trabeculae may be observed. Rarely, evidence of new bone formation may be present (Fig. 39.58). Reticulin stains show varying degrees of reticulin fibrosis.

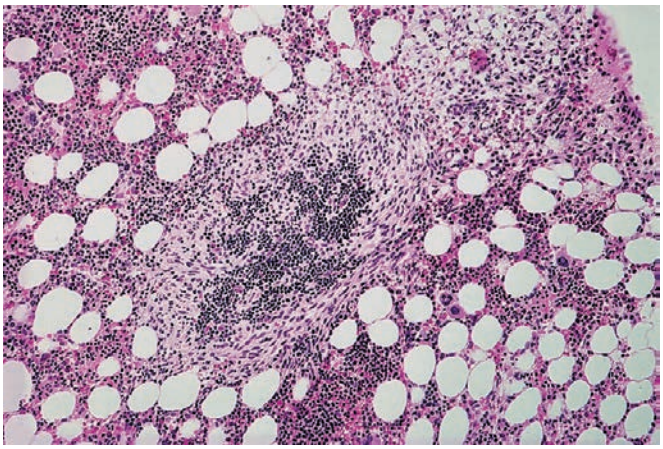

Figure 39.56 Lesion in Bone Marrow From a Patient With Systemic Mastocytosis and No Evidence of Urticaria Pigmentosa. A central focus of well-differentiated lymphocytes is surrounded by lighter-staining mast cells.

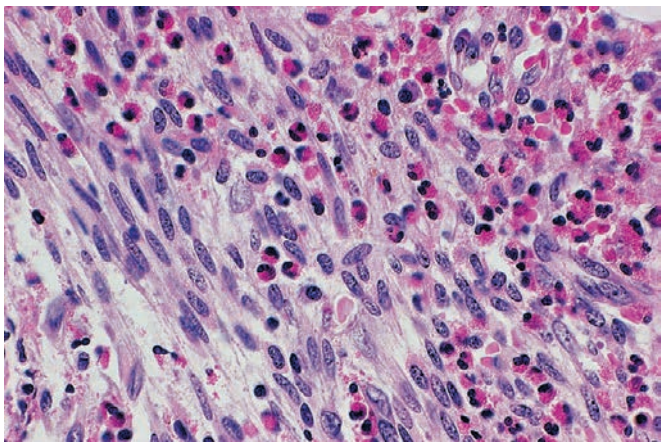

Figure 39.57 High Magnification of a Marrow Lesion in Systemic Mastocytosis. The mast cells have a spindle appearance. There are numerous interspersed eosinophils.

Mast cell leukemia is a very rare variant of mast cell disease and is defined by the presence of 20% or more atypical mast cells in aspirate smears away from spicules. The marrow shows diffuse replacement with immature-appearing mast cells, which may be hypogranular and resemble histiocytes. The disease is usually nonresponsive to traditional therapy and has a very aggressive clinical course. New tyrosine kinase inhibitors, presumably targeting the *KIT* gene mutation product, however, have shown promise in mast cell leukemia and aggressive systemic mastocytosis.[313]

There is an increased incidence of myeloid disorders in patients with systemic mastocytosis: this is recognized in the WHO classification. The spectrum of disorders includes acute leukemia, MDS, and chronic MPNs (Fig. 39.59).[301,308,309] Philadelphia chromosome–positive CML, however, is rarely encountered. Lymphoproliferative disorders have also been reported in association with mastocytosis but are considerably less frequent than myeloid neoplasms and, in contrast to myeloid disorders, the lymphoid neoplasms are probably incidental and clonally unrelated to the mast cell proliferation. The chronic myeloproliferative disorder occurring with systemic mastocytosis has more the features of chronic myelomonocytic leukemia or an unclassified chronic MPN. Caution should be exercised in the diagnosis of a concurrent myeloproliferative process in patients with mastocytosis

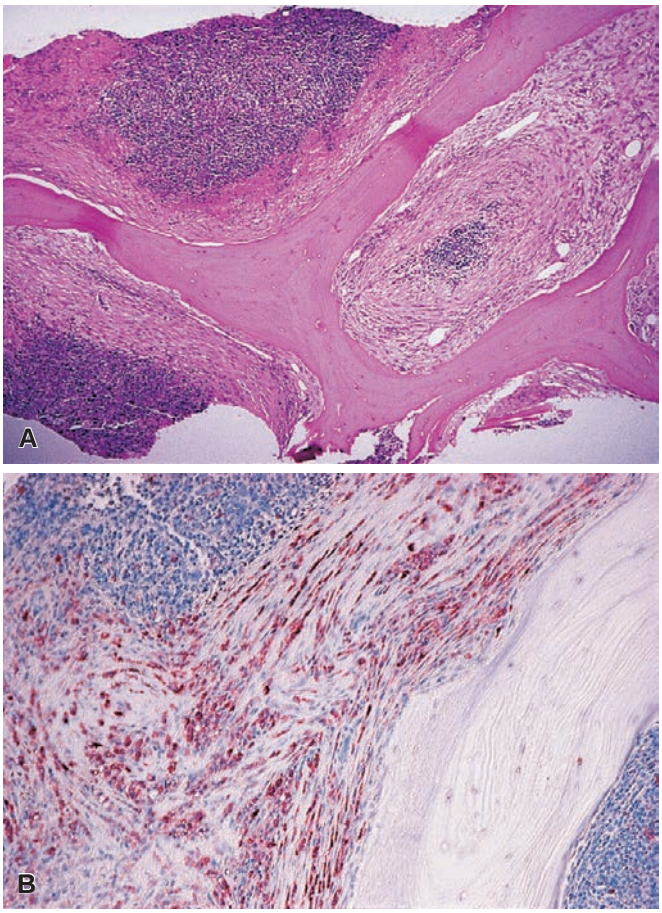

Figure 39.58 **A**, Marrow biopsy from an adult man with systemic mastocytosis associated with a myeloproliferative disorder and no evidence of urticaria pigmentosa. There is extensive paratrabecular fibrosis and widening of bone trabeculae. The intervening marrow is markedly hypercellular, principally due to myeloid hyperplasia. Radiographic studies showed diffuse osteoblastic changes. **B**, Mast cell tryptase stain of the lesion in **A** showing numerous reactive cells.

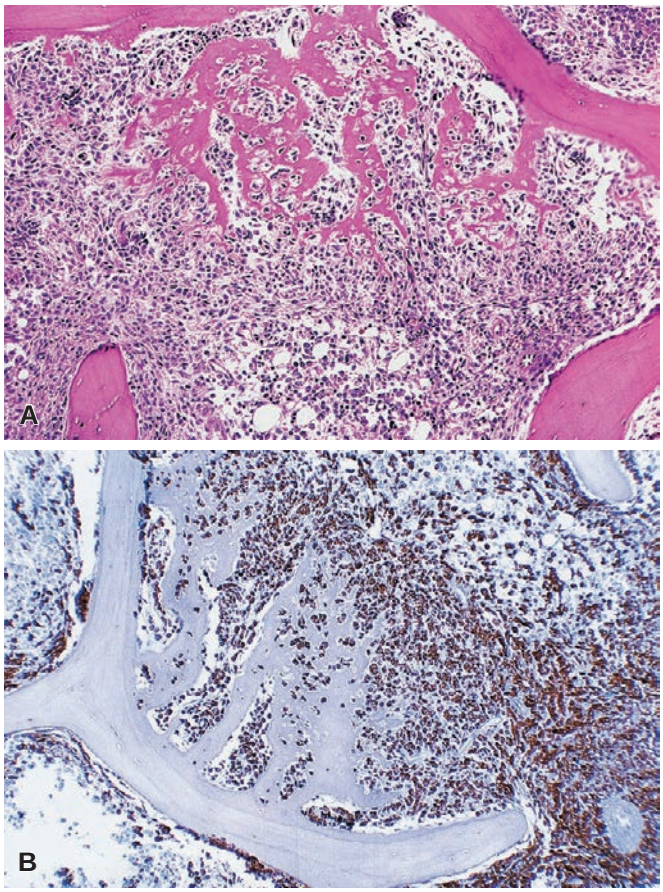

Figure 39.59 **A**, Bone marrow biopsy from a patient with concurrent acute myeloid leukemia and systemic mastocytosis. Mast cell infiltration in this area of biopsy was associated with new bone formation. No other areas in bilateral biopsies show this finding. This was the patient's first marrow biopsy. **B**, Specimen in **A** reacted with antibody to mast cell tryptase. (**B**, Immunoperoxidase.)

as it is possible that marked myeloid hyperplasia may occur as the result of cytokines produced by the mast cell proliferation.

A highly specific antibody to human mast cell tryptase that may be used on decalcified and routinely fixed and processed paraffin-embedded specimens is invaluable for identification of mast cell lesions (see Figs. 39.58 and 39.59B).[314] Although less specific, strong CD117 expression is seen in virtually all cases of mastocytosis, and this antibody is very useful for initial screening for the disorder.[303,306,315]

Normal mast cells express CD9, CD43, CD45, CD68, and CD117. Mast cells are negative for CD14 and CD15. Neoplastic mast cells also express CD2, CD25, and/or CD30. Expression of CD2 and/or CD25 is one of the minor criteria for the diagnosis of mastocytosis in the WHO criteria, although CD2 expression is often difficult to identify by paraffin section immunohistochemistry.[301,308]

The differential diagnosis of mast cell lesions in the marrow includes angioimmunoblastic T-cell lymphoma, Hodgkin disease, PMF, and granulomatous inflammation. The eosinophilic fibrohistiocytic lesion described by Rywlin and colleagues has many of the histopathologic characteristics of mastocytosis lesions and in most instances is a form of mast cell disease.[316] The primary distinction of mastocytosis from the other disorders is based on the immunohistochemical demonstration of mast cells with antibodies to CD117 and mast cell tryptase. Mast cells may be increased in lymphocytic and lymphoplasmacytic lymphomas and hairy cell leukemia in marrow biopsies but are diffusely scattered among the lymphoma cells and do not form mass lesions.[311] Aberrant mast cells, usually without clustering, are also common in the previously mentioned eosinophilic disorders with recurring genetic rearrangements, but those genetic abnormalities trump the diagnosis of systemic mastocytosis.

The treatment of systemic mast cell disease has generally been unsatisfactory with most antineoplastic agents. Fortunately for most patients with indolent systemic mastocytosis, treatment is unnecessary as the disease follows an indolent clinical course. For patients with aggressive systemic mastocytosis or mast cell leukemia, several agents including interferon alpha2b, corticosteroids, and cladribine (2-chlorodeoxyadenosine) have been used with very limited degrees of success.[306,317] Imatinib (Gleevec) has been successful in occasional patients with the wild-type *KIT* or when variant (non-D816V) *KIT* mutations are present, while newer tyrosine kinase inhibitors have shown promise in aggressive cases with the *KIT* D816V mutation, which are typically imatinib resistant.[313]

Because of the lack of satisfactory therapy for most patients with mastocytosis, it is important to exclude the possibility of an abnormality of *PDGFRA* or *PDGFRB* in which there may be an increase in marrow mast cells; these disorders may respond to the imatinib with a distinctly more favorable prognosis than mastocytosis without this association. These entities are described in more detail in the section on MPNs.

Mature B-Cell Neoplasms

Mature B-cell neoplasms may involve the bone marrow as primary leukemias or may represent lymphomas secondarily involving the marrow. Lymphomas that frequently involve marrow and blood may present terminology problems because of their close relationship to leukemic processes: these include small B-lymphocytic lymphoma, Burkitt lymphoma, lymphoblastic lymphoma, and adult T-cell leukemia/lymphoma. The designation of these processes as leukemia or lymphoma may be arbitrary.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL), as currently defined, is a monoclonal B-cell disorder that is characterized by weak surface immunoglobulin heavy and light chain and CD20 expression, as well as expression of CD5 and CD23.[318–323] Cases previously diagnosed as T-cell CLL[324] are now considered to be other specific T-cell neoplasms involving the blood, including T-cell prolymphocytic leukemia (PL) and T-cell large granular lymphocytic leukemia (T-LGL). The diagnosis of B-cell CLL is usually established when there is a persistent absolute lymphocytosis in excess of 10×10^9/L, although the diagnosis can be made when a persistent, monoclonal absolute lymphocyte count exceeding 5×10^9/L is present with a characteristic CLL immunophenotype.[319,325] CLL is usually accompanied by some degree of lymphadenopathy and hepatosplenomegaly. The morphology of the proliferating lymphocytes in CLL and small lymphocytic lymphoma is the same, and the two disorders are considered by the WHO as different manifestations of the same process.[322,323] The distinction between these two closely related entities is based on arbitrary criteria; if the marrow shows a pattern of infiltration by small lymphocytes, and the absolute lymphocyte count in the blood is less than 5×10^9/L, the diagnosis of small lymphocytic lymphoma is more appropriate. Small lymphocytic lymphoma may progress to blood involvement, but the magnitude of the leukocytosis does not usually reach the levels observed in CLL.

Clinical staging systems based on both laboratory and clinical features have been introduced: the higher the stage, the greater the tumor burden.[319,326,327] The system proposed by Rai et al. includes five stages: 0, lymphocytosis in blood and marrow; I, lymphocytosis and lymphadenopathy; II, lymphocytosis and hepatomegaly and/or splenomegaly; III, lymphocytosis and anemia; and IV, lymphocytosis and thrombocytopenia.[327] The system introduced by Binet has three stages: (A) no anemia, no thrombocytopenia, fewer than three lymphoid areas enlarged (cervical, axillary, and inguinal lymphadenopathy, spleen, liver); (B) no anemia, no thrombocytopenia, more than three lymphoid areas involved; and (C) anemia (hemoglobin <10 g/dL) and/or platelet count less than 100×10^9/L.[326] The higher clinical stages are generally associated with a shorter survival compared to the lower clinical stages. Additionally, high CD38 or ZAP70 expression on the lymphocytes has been reported to be associated with a significantly shorter survival than cases lacking CD38 or ZAP70 expression regardless of clinical stage.[328–330] Two factors have been shown to have major prognostic impact on prognosis in CLL: the mutation status of the surface immunoglobulin variable region gene and the presence and type of genomic aberrations.[329,331] Patients in whom the leukemic cells have apparently traversed the germinal center and undergone somatic mutations of the immunoglobulin variable region gene have a significantly better prognosis than patients in whom the mutation has not occurred (pre-germinal center lymphocytes). There appears to be an inverse relationship in the majority of cases between expression of CD38 and/or ZAP70 on the lymphocytes and the mutation status. CD38 and ZAP70 expression, however, do not always correlate with mutational status[328,330] and is often difficult to measure in a reliable manner by flow cytometry; therefore, determination of the mutation status is considered the most reliable means of assessing this prognostic factor.

The detection of genomic aberrations in the lymphocyte in CLL by FISH has shown significant differences in survival patterns, and such changes are detectable in over 80% of cases. Patients with 17p13, 11q22–23, and 6q21 deletions appear to have a worse outcome than patients with trisomy 12, normal karyotype, and 13q14.3 deletion. Patients with 17p– have the shortest survival, and patients with 13q– have the longest survival.[331] *TP53* abnormalities (located at 17p13) in B-CLL have been associated with an excess of prolymphocytes and poor prognosis,[332] while patients with trisomy 12 often have an atypical or mixed morphology. In addition to *TP53*, mutations in *ATM*, *NOTCH1*, *SF3B1*, and *BIRC3* are common in CLL and are associated with a worse prognosis.[333,334]

Histopathologic staging of B-CLL is based on the pattern of involvement in bone marrow sections.[323,335] Five possible patterns are generally recognized: focal, diffuse, interstitial, focal and interstitial, and focal and diffuse (Fig. 39.60). In small lymphocytic lymphoma, the focal pattern is the most common, whereas in CLL the pattern is usually interstitial, mixed interstitial and focal, or diffuse. Patients with focal, interstitial, or a combination of focal and interstitial involvement are predominantly in low clinical stages. The diffuse or focal and diffuse patterns generally occur in patients with advanced clinical stages. The diffuse pattern of marrow involvement has been found to have adverse prognostic significance in several studies.[323,336,337]

Marrow biopsies from approximately 25% of patients with B-CLL demonstrate a slight increase in reticulin fibers.

In some patients with B-CLL, there is a dedifferentiation or transformation of the proliferating cell type; this usually occurs late in the course of the disease in less than 5% of the patients and has been referred to as "prolymphocytoid" transformation.[338] This dedifferentiation is distinct from B PL, which is a de novo process with different morphologic features. In these patients, the marrow infiltration may contain foci of prolymphocytoid lymphocytes and paraimmunoblasts (Fig. 39.61). The prolymphocytoid lymphocytes have a moderate amount of basophilic to amphophilic cytoplasm, coarsely reticular nuclear chromatin, and relatively prominent single nucleoli. The paraimmunoblasts are larger, with more abundant cytoplasm, more dispersed nuclear chromatin, and frequently a single prominent eosinophilic nucleolus. These foci may be circumscribed by more well-differentiated lymphocytes and are similar to the immature foci or proliferation centers noted in the lymph nodes of some patients with this process (Fig. 39.62).[335] Difficulties may occur in distinguishing foci of transformation in CLL from follicular lymphoma. An important feature in CLL is the residual population of well-differentiated lymphocytes. In most instances, examination of the blood and marrow smears aids considerably in distinguishing these processes, as well as immunophenotyping studies demonstrating aberrant CD5 expression in CLL as opposed to the common expression of CD10 on the B cells of follicular lymphoma. Concurrence of CLL and other B-cell neoplasms, including multiple myeloma and hairy cell leukemia, has been reported.[339]

Monoclonal B-Cell Lymphocytosis

Monoclonal B-cell lymphocytosis is defined as a peripheral blood monoclonal B-cell proliferation of less than 5×10^9/L in patients without adenopathy, organomegaly, other tissue involvement or evidence of another lymphoproliferative disorder.[340] The cells usually have the immunophenotype of CLL but may have an atypical or non-CLL immunophenotype. Some cases will have small nodules of monotypic B cells in the bone marrow, similar to CLL, but should

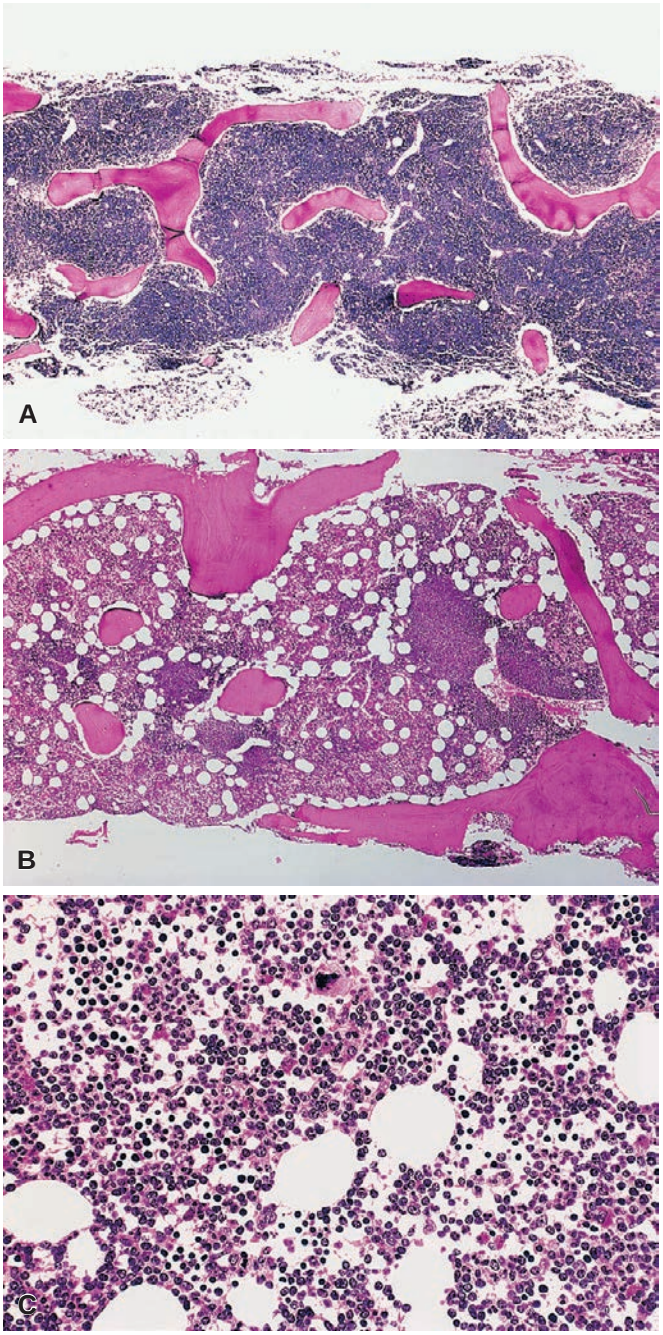

Figure 39.60 **A**, Marrow biopsy from a patient with chronic lymphocytic leukemia (CLL) showing diffuse pattern of involvement. The small lymphocytes completely replace normal marrow cells. **B**, Marrow biopsy from a patient with CLL with focal involvement. Leukemic cells occur in relatively well-demarcated foci, which are randomly distributed and surrounded by normal-appearing marrow. **C**, Marrow section from a patient with CLL illustrating an interstitial pattern of involvement; overall marrow architecture is preserved.

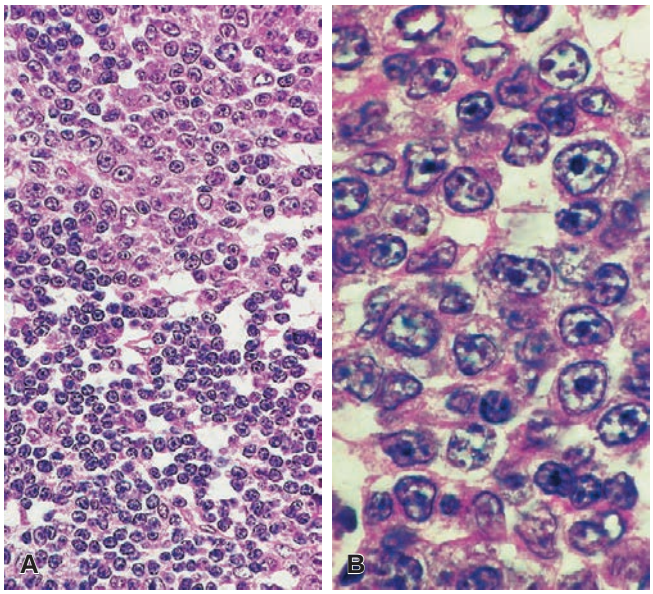

Figure 39.61 **A**, Marrow biopsy from an adult woman with a 4-year history of untreated B-cell chronic lymphocytic leukemia. There are two morphologic populations of lymphocytes; the lower portion of the figure is predominantly small lymphocytes; the upper portion is predominantly prolymphocytoid lymphocytes and paraimmunoblasts. **B**, High magnification of the upper area of the specimen illustrating the prominent prolymphocytoid lymphocytes and paraimmunoblasts with very prominent, usually single, nucleoli.

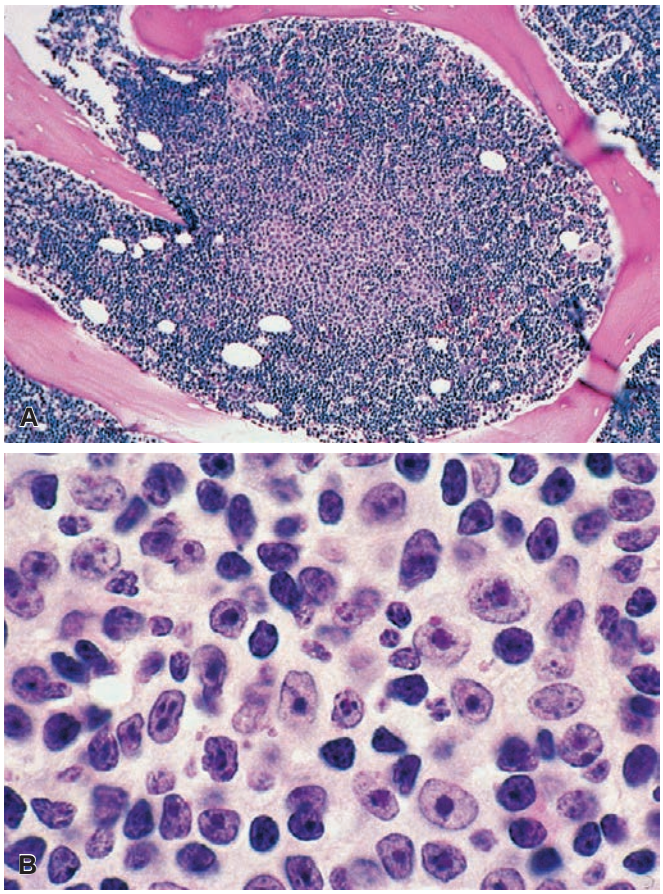

Figure 39.62 **A**, Marrow biopsy illustrating a proliferation center in a patient with B-CLL. **B**, High magnification of the central portion of the proliferation center with prominent prolymphocytoid lymphocytes and paraimmunoblasts.

be diagnosed as MBL if there is no other tissue disease and the peripheral blood involvement is low. Cases with very low numbers of circulating monoclonal cells ($<0.5 \times 10^9$/L) are now termed "low-count MBL" and are unlikely to progress to CLL.[341,342] Those with higher counts, however, require close follow-up and have features similar to Rai stage 0 CLL.

Richter Syndrome

Richter syndrome is the occurrence of an aggressive lymphoma, usually diffuse large B-cell lymphoma, in a patient with a prior history of B-CLL[343–349] or another low-grade B-cell lymphoproliferative disorder. The reported incidence in B-CLL ranges from less than 1% to 10%.[349] The syndrome is usually characterized by an abrupt change in clinical course with the onset of fever, weight loss, localized adenopathy, dysglobulinemia, and histopathologic evidence of an aggressive lymphoma frequently containing multinucleated giant cells. A Hodgkin-type variant has been described[350] but is less common than diffuse large B cell lymphoma and should show the typical background of classical Hodgkin lymphoma so as not to be confused with cases of CLL with admixed Reed–Sternberg cells.[351] The locus of the lymphomatous process is not restricted to hematopoietic organs.[343] A high incidence of lytic bone lesions has been reported.[349] The bone marrow may be involved by the aggressive lymphoma; evidence of CLL and the supervening lymphoma may be present in the same biopsy specimen (Fig. 39.63). The blood smear usually shows no involvement by the non-CLL cells, and there may be lymphocytopenia. This transformation is marked by an aggressive clinical course and rapid deterioration. The term Richter transformation has been used to describe a somewhat broader spectrum of pathologic findings in patients with B-CLL who present with a similar clinical evolution.[352]

The biologic events resulting in Richter transformation are not completely understood, but a dedifferentiation or transformation of the well-differentiated lymphocyte has been suggested.[353,354] This theory is supported by evidence in some cases in which an identical clone has been detected in the patient's CLL as in the transformed lymphoma (Fig. 39.64).[348,355] This clonal relation appears to occur more commonly in the unmutated type of CLL, and instances in which the lymphocytes of the CLL and the cells of the second lymphoma are different clones are more commonly associated with mutated type of CLL.[356] Approximately half of cases of CLL transformation demonstrate abnormalities of cell cycle regulation involving *TP53* or *CDKN2A*.[357]

Prolymphocytic Leukemia

Prolymphocytic leukemia (PL), initially described by Galton et al.,[358] is a very rare disease that occurs primarily in older individuals and is characterized by a predominant proliferation of lymphocytes referred to as prolymphocytes. The disorder is distinct from CLL and prolymphocytoid transformation of CLL. Approximately 80% of the initially reported cases of this type of leukemia were of B-cell origin, the remainder of T-cell type.[359] The exact ratio of B- to T-cell PL is difficult to determine because of the low frequency of both disorders and the reclassification of many of the B-cell disorders into other B-cell lymphoma categories. The lymphocyte count in PL of either B or T type is usually moderately to markedly increased; the number of prolymphocytes in the blood usually exceeds 55% of lymphocytes and may be more than 90%.

B-PL is a clonal B-cell disorder that may lack expression of CD5 and/or CD23 and does not include cases of transformed CLL, CLL with increased prolymphocytes, or cases with cyclin D1 expression or evidence of t(11;14)(q13;q32).[360] The patients with B-PL usually have massive splenomegaly without prominent peripheral lymphadenopathy.[361,362] The prolymphocytes in B-PL are more uniform in appearance than the prolymphocytoid cells in prolymphocytoid transformation of B-CLL. In B-PL the prolymphocytes are medium to large in size, with a moderate amount of basophilic cytoplasm. There is usually a single prominent nucleolus. The marrow infiltration is usually diffusely interstitial. Mitotic activity is reported as low, although cases with increased mitotic activity have been observed.[363,364] B-PL is usually marked by an aggressive clinical course; occasionally patients have a prolonged survival. The leukemic phase of the blastic variant of mantle cell lymphoma may be characterized by large lymphocytes with prominent nucleoli[365,366]; it can be distinguished from PL by cytogenetic and molecular studies for t(11;14)(q13;q32).[367]

A very uncommon variant of B-CLL intermediate between typical B-CLL and B-PL and referred to as CLL/PL, atypical CLL or mixed-type

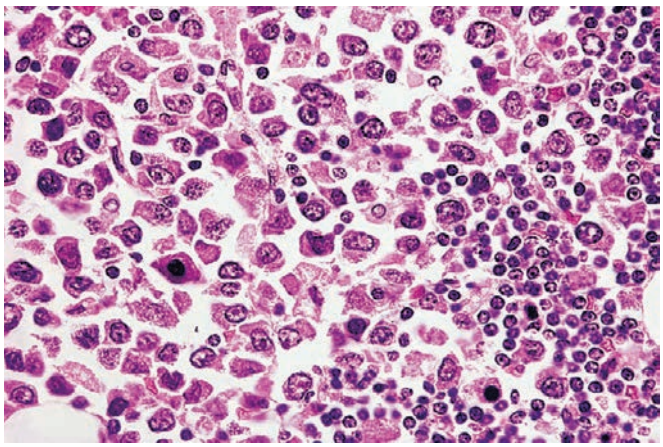

Figure 39.63 Bone marrow trephine biopsy from a patient with a history of chronic lymphocytic leukemia who developed a pleomorphic lymphoma (B-immunoblastic lymphoma) and a clinical picture typical of Richter syndrome. Biopsy contains two distinct cell populations, small lymphocytes, and large pleomorphic cells, some of which are multinucleated.

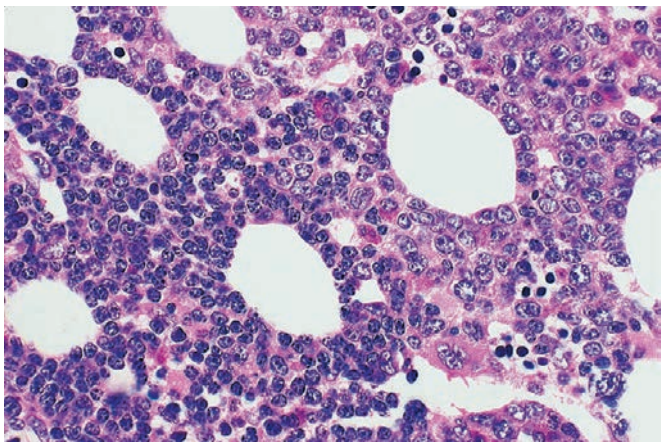

Figure 39.64 Marrow Biopsy From an Adult Man With a 9-Year History of B-CLL. The patient had recent onset of fever, night sweats, myalgia, and axillary, cervical, and inguinal adenopathy prior to this biopsy. A population of small lymphocytes is at lower left. Burkitt lymphoma cells predominate at upper right. Blood and marrow smears contained two lymphocyte populations: small well-differentiated lymphocytes and Burkitt lymphoma cells. Cytogenetic studies of the marrow specimen showed t(8;22)(q24;q11) cytogenetic abnormality.

CLL has been described; it is distinguished by the presence of 11%–55% prolymphocytoid lymphocytes in the blood.[361,362] Typical B-CLL has less than 11% prolymphocytes in the blood; B-PL is distinguished by more than 55% prolymphocytes. The degree of splenomegaly in patients with CLL/PL is disproportionate to the degree of lymphadenopathy. Two major clinical patterns are described in this variant: one is characterized by a course similar to typical CLL and the other by a more rapidly progressive clinical evolution. The distinction of B-CLL/PL from prolymphocytoid transformation of B-CLL may be very difficult unless prior material more typical of CLL is available (which would suggest transformation). Leukemic mantle cell lymphoma may resemble CLL/PL and because of its more aggressive clinical course it is important to exclude the possibility of leukemic mantle cell lymphoma when findings suggest CLL/PL.

T-PL has a somewhat variable presentation. Patients often have hepatosplenomegaly and lymphadenopathy, and 20% have skin lesions. While the absolute lymphocyte count is usually over 100×10^9/L, some cases may show only a modest elevation.[359,368] Unlike B-PL, the lymphocytes of T-PL may not have an unusually prominent nucleolus. Such cases are often termed small cell variant of T-PL, and this type of T-PL was considered as T-CLL in the past. Marrow infiltration may be modest with very substantial sparing of normal myeloid cells. T-PL is a clonal T-cell disorder that may show weak CD3 expression and is usually CD4 positive. Increased expression of CD52 and T-cell leukemia 1 (TCL-1) is characteristic of the disorder. The majority of cases of T-PL have inv(14)(q11;q32) or t(14;14)(q11;q32). Most cases also have abnormalities of chromosome 8. Recently, mutations in the JAK-STAT signaling pathway (*JAK3*, *JAK1*, or *STAT5B*) have been reported in T-PL.[369,370]

Hairy Cell Leukemia

Hairy cell leukemia is a clonal chronic lymphoproliferative disorder of B-cell origin that is manifest primarily in blood, marrow, and spleen. There is a male predominance.[318,371–374] The age range is 20–80 years, with a median of approximately 50 years. The patients generally have cytopenias or pancytopenia and splenomegaly without prominent peripheral lymphadenopathy; there is usually an associated monocytopenia. The majority of patients present with leukopenia and only occasional leukemic cells in the blood. Some 5%–10% of patients have white blood cell counts exceeding 10×10^9/L; the hairy cells usually comprise the majority of the blood leukocytes in these patients.

The typical hairy cell measures 10–14 µm. The clear to lightly basophilic cytoplasm is variable in amount. The surface of the cell is marked by numerous delicate and broad projections; this finding is particularly striking in specimens examined by phase and electron microscopy.[375] Vacuoles and occasionally delicate azurophilic granules may be identified in the cytoplasm. The nucleus is oval, folded, or indented; the chromatin is coarsely reticular, and nucleoli are inconspicuous.

Aspiration biopsy of the marrow in patients with hairy cell leukemia is unsuccessful in 30%–50% of cases because of increased reticulin fibrosis.[372,373] The interstitial pattern of marrow infiltration in trephine sections is virtually diagnostic in most patients.[376–379] The marrow in the majority of patients is hypercellular; in 10%–15% of patients the involved marrow is hypocellular.[380] The involvement may be diffuse or partial; the diffuse type is more common (Fig. 39.65). Leukemic infiltrates in partial involvement are irregular in outline and poorly demarcated from the normal marrow cells. In the very early stages of the disease, partial involvement may take the form of relatively small, indistinctly outlined foci of leukemic cells. In formalin-fixed tissue, there is frequently a halo-like effect or clear area around the nucleus because of the abundant cytoplasm.

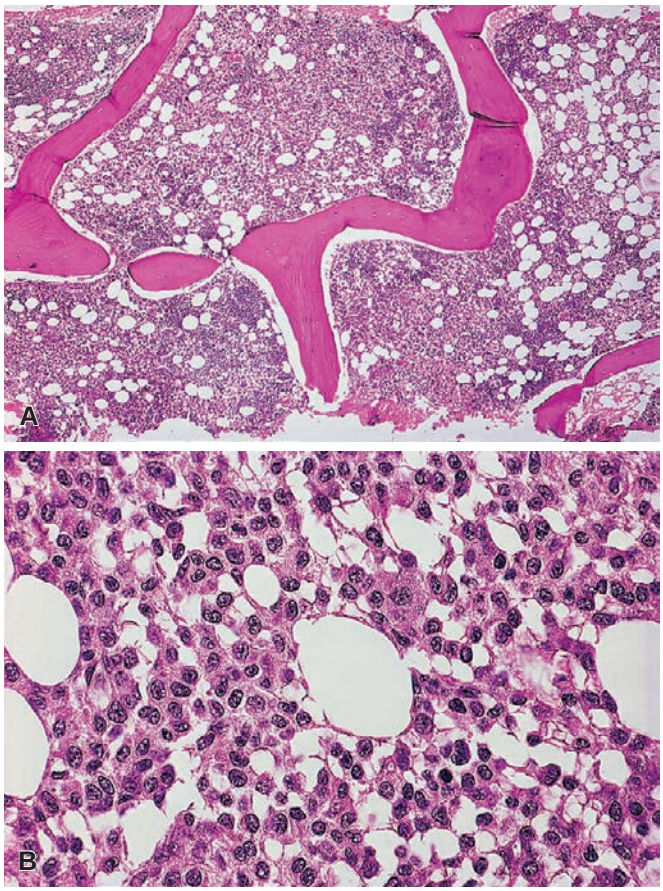

Figure 39.65 **A**, Bone marrow section from a patient with extensive replacement by hairy cell leukemia; scattered foci of normal hematopoiesis are present. **B**, High magnification of specimen in **A**. Hairy cells are loosely spaced, in contrast to aggregates of lymphocytes in chronic lymphocytic leukemia and small lymphocyte lymphoma. Hairy cells have a relatively abundant, lightly eosinophilic cytoplasm. Many of their nuclei are folded or irregular in outline. Nucleoli are inconspicuous and mitotic figures rare. The halo effect around nuclei, characteristic of formalin-fixed tissue, is not prominent in this specimen fixed with Zenker acetic acid.

The cell borders have an interlocking appearance. With some fixatives, such as Zenker, the cytoplasm of the hairy cells is retracted with a resultant loosely structured appearance. The loosely structured appearance and widely spaced nuclei in hairy cell leukemia contrast with the marrow infiltrates in the lymphocytic lymphomas and CLL in which the nuclei of the cells are in close apposition. The nuclear chromatin of the hairy cells is relatively fine. Nucleoli are distinct but not usually prominent, and mitotic figures are infrequent. In an occasional case, the hairy cells have a spindled or fusiform appearance and may resemble the marrow lesions in systemic mastocytosis (Fig. 39.66). A morphologic variant with hyperlobulated nuclei resembling T-cell lymphoma has been described.[381] Marrow uninvolved by the leukemic process may be hypocellular or hypercellular. Morphologic subtypes of hairy cell leukemia based on histopathology have been reported to have prognostic significance.[382] Normal-appearing mast cells may be increased.

Reticulin stain shows increased deposition of thickened reticulin fibers in the areas of the infiltrates; the reticulin fibers often appear to encircle individual cells. The reticulin fibers frequently extend into the adjacent normal-appearing marrow.

Hairy cells express light chain–restricted cytoplasmic and surface immunoglobulin and pan-B-cell antigens, including CD19, CD20,

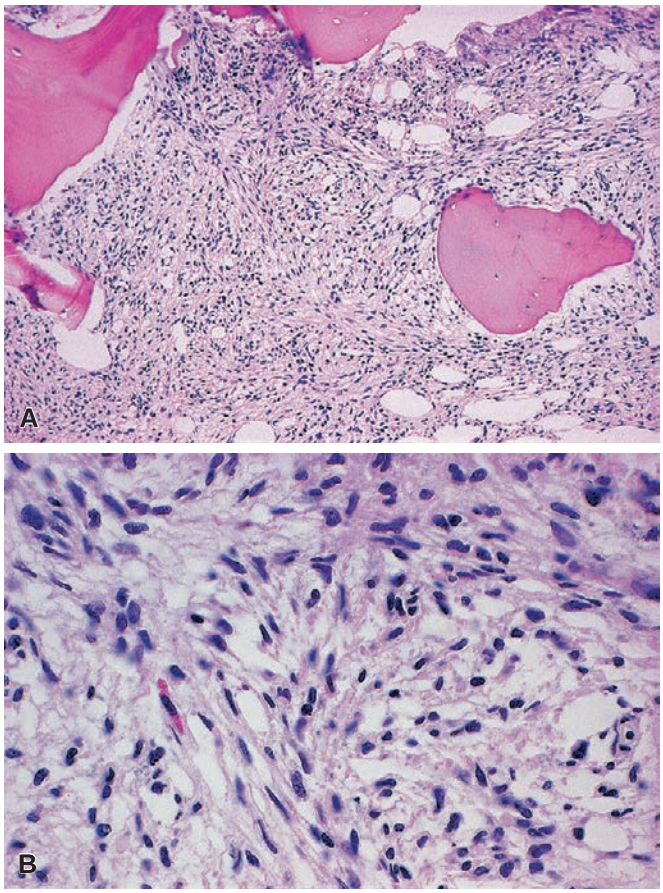

Figure 39.66 **A**, Marrow biopsy from a patient with the stromal variant of hairy cell leukemia. **B**, High magnification of the biopsy in **A**. Many leukemia cells are elongated or spindle shaped.

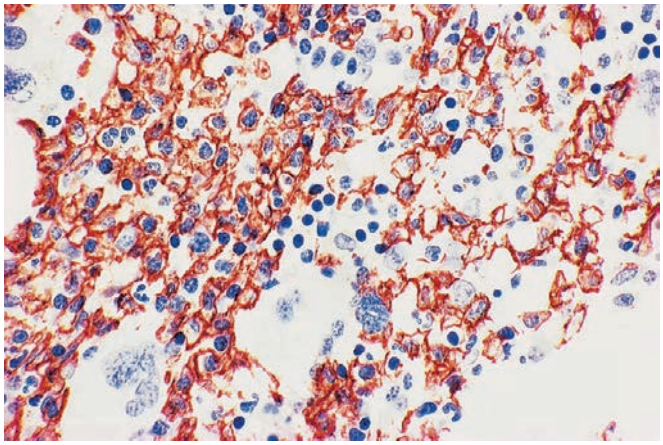

Figure 39.67 **Bone Marrow Biopsy From a Patient With Hairy Cell Leukemia Reacted With Antibody to CD20.** Reactivity accentuates the leukemic infiltrate. Scattered normal myeloid cells, principally erythroid precursors, are present. (Immunoperoxidase.)

CD22, DBA44, CD79a, and PAX5 but not CD79b[371,383]; CD20 and DBA44 are of considerable aid in evaluating the extent of the leukemic infiltrate and in assessing the effects of chemotherapy in paraffin-embedded biopsy sections (Fig. 39.67).[384] In addition, they express CD11c, which is also expressed on myeloid cells, CD25, interleukin-2 receptor, CD123, CD103, cyclin D1, and annexin A1,[385,386] and mark with mutation specific BRAF (V600E) antibodies.[387] They are negative for CD5, a T-cell antigen, and CD23, which are expressed on the lymphocytes in the majority of cases of B-CLL, but a subset of cases express CD10.[388] Hairy cells also contain tartrate-resistant acid phosphatase (TRAP),[389] although this finding alone by immunohistochemistry is not entirely specific, and paraffin section detection of annexin A1 and V600E-mutated BRAF protein on B cells is considered more specific for hairy cell leukemia.[385,387] While no recurring karyotypic abnormalities occur in hairy cell leukemia, essentially all cases demonstrate V600E mutations of *BRAF*,[390] which, as mentioned above, can be detected by immunohistochemistry.

Rarely, hairy cell leukemia may focally involve the skeleton as a painful localized destructive lesion. This usually occurs in a patient with an established diagnosis; more rarely, hairy cell leukemia may present as a localized skeletal lesion as the initial and only manifestation of the disease.[391–394] These lesions occur principally in the upper portion of the femurs. Although the majority of these localized lesions are osteolytic, osteoblastic lesions may also occur. The localized lesions appear to respond to the purine analogues 2-deoxycoformycin and 2-deoxyadenosine and to radiation.

Treatment of hairy cell leukemia with the purine analogues, often coupled with rituximab or other monoclonal antibodies, results in durable complete or partial remissions in the majority of cases.[374,395–397] The bone marrow biopsies from these patients generally show a return to normal marrow hematopoiesis. As noted, the recognition of residual leukemia is facilitated by the use of pan-B-cell monoclonal antibodies reactive in paraffin-embedded biopsies; anti-CD20, BRAF V600E, and T-bet are particularly good antibodies for this purpose.[384,398,399] Treatment with the interferons frequently results in characteristic marrow changes with some evidence of residual leukemia.[400] Despite the success with purine analogues and rituximab, targeting mutated BRAF has shown great success in patients who have relapsed with this approach,[401] and more targeted therapy may become first line therapy in the near future. Approximately 0.25% of cases of hairy cell leukemia develop abdominal lymphadenopathy, as demonstrated by CT studies. The incidence is higher in patients who relapse after previously successful therapy or have long-standing disease. The development of abdominal adenopathy may be associated with resistant disease and with the appearance of large hairy cells in both the bone marrow and the enlarged lymph node. This constellation of clinical and morphologic findings has been interpreted as a type of transformation.[402]

Hairy Cell Leukemia Variant

Hairy cell leukemia variant is a lymphoproliferative disorder usually presenting with a marked leukocytosis and was originally restricted to cases with lymphocytes with morphologic characteristics intermediate between hairy cells and prolymphocytes (Fig. 39.68).[318,403,404] In those cases, the cells are large with basophilic cytoplasm with stellate projections and relatively prominent nucleoli. Other morphologic variants, including cases with blastic or convoluted nuclear features, as well as cases showing immunophenotypic variations, are not included in this category, which is felt to be biologically distinct from typical hairy cell leukemia.[405] The disease is very rare and occurs primarily in older individuals. In contrast to typical hairy cell leukemia, there is no associated neutropenia and monocytopenia and cases do not demonstrate mutations of *BRAF*.[390] The cells may be TRAP positive. The cells usually express CD11c but are negative for CD25; they express CD103 and annexin A1 less commonly than typical cases of hairy cell leukemia.[404] The marrow shows a diffuse interstitial pattern of infiltration similar to typical hairy cell leukemia. The pattern of splenic infiltration is similar to hairy cell leukemia, with a predominantly red pulp involvement. Hairy cell leukemia

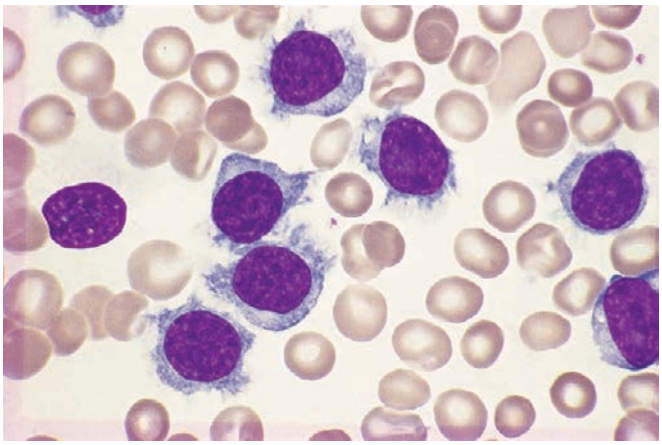

Figure 39.68 Hairy Cell Leukemia Variant. Several lymphoid cells in the blood smear of an adult man with markedly elevated leukocyte count. The hairy cell variant lymphocytes are large with a moderate amount of basophilic cytoplasm with stellate projections. The nuclei of several cells contain variably prominent nucleoli. (Wright–Giemsa.)

variant, unlike typical hairy cell leukemia, does not respond to interferon alpha or purine analogues but still has a relatively indolent clinical course.

Splenic Marginal Zone Lymphoma

Splenic marginal zone lymphoma (SMZL) is a clonal proliferation of small B lymphocytes with clinical and hematologic features that may resemble hairy cell leukemia.[406–409] When it involves the blood, it often shows morphologic features that have also been described as splenic lymphoma with villous lymphocytes (SLVL). The disease shows no sex predilection and usually occurs in adults over 50 years of age. With blood involvement, there is a slight-to-moderate lymphocytosis; the leukocyte count is less than 25×10^9/L in the majority of patients. Anemia and thrombocytopenia are present in approximately 50% of cases with blood involvement. Most patients have marked splenomegaly.[408]

The lymphocytes in the blood often have short villous projections that may have a polar distribution. Villi may not be present on all of the lymphoma cells, and there may be considerable variation in the appearance of the cells. Some have a distinct but not prominent nucleolus (Fig. 39.69A). Plasmacytoid lymphocytes may be present.

The lymphocytes express moderate-to-intense surface immunoglobulin and pan-B-lymphocyte markers, including CD19, CD22, and CD24,[407,410] while they are usually negative for CD5, CD10, CD43, BCL6, cyclin D1, BRAF V600E, and annexin A1. Many cases have a low IgM monoclonal gammopathy.[409] In general, SMZL lacks balanced cytogenetic translocations, including those common to extranodal marginal zone lymphoma, the t(14;18) of follicular lymphoma, and the t(11;14) of mantle cell lymphoma. Chromosome 7q deletion is found in approximately 30% of cases; trisomy 3 or gain of 3q is present in 17% of cases.[407] No gene mutations specific for SMZL have been identified, and *MYD88* mutations, common in lymphoplasmacytic lymphoma, are uncommon in SMZL.

Virtually all patients with SMZL have some degree of marrow involvement. The degree and pattern of marrow involvement vary substantially; the pattern may be focal nonparatrabecular, focal paratrabecular, interstitial, diffuse, or intrasinusoidal; there may be a predominance of one pattern in an individual case, but mixed patterns are common (see Fig. 39.69B,C).[407,411–415] The lymphoma cells may be predominantly small lymphocytes or an admixture of small lymphocytes and scattered large lymphocytes with relatively abundant cytoplasm, slightly dispersed chromatin, and variably prominent nucleoli. Mitotic figures are usually sparse. Some degree of plasma cell proliferation may be present. Occasionally, foci of lymphoma with remnants of germinal centers may be found (Fig. 39.70).

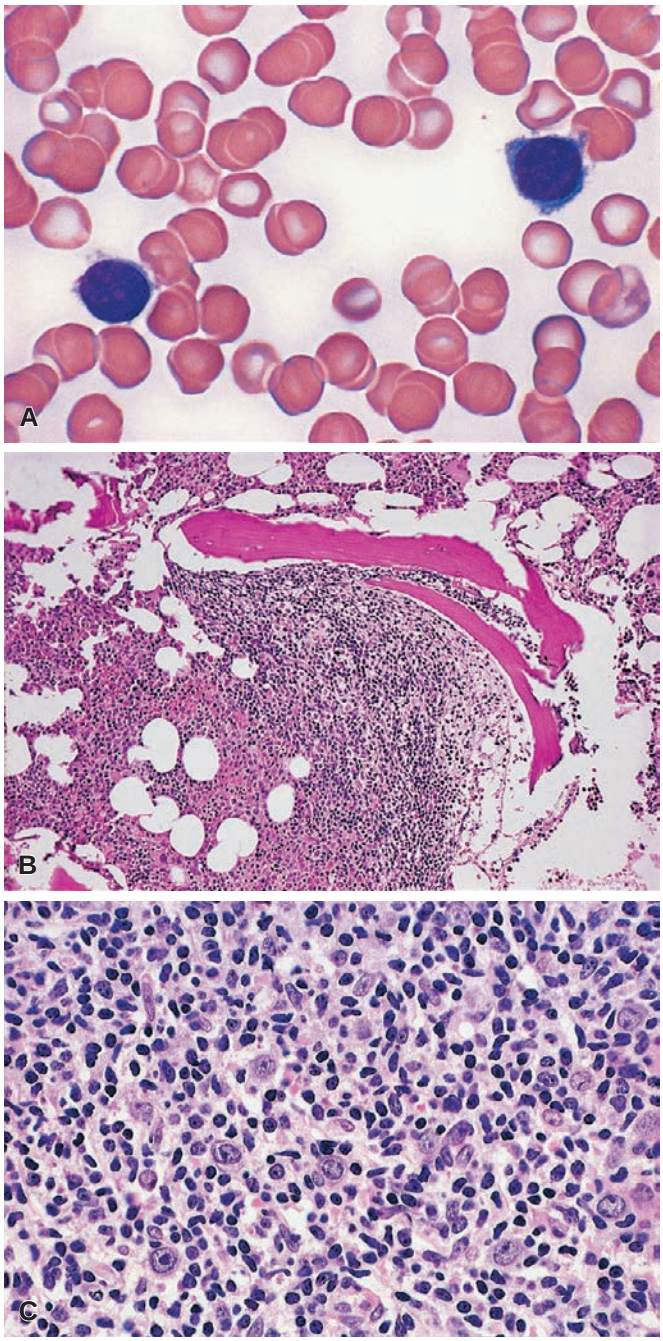

Figure 39.69 **A**, Lymphocytes in blood smear from an adult male with splenic marginal zone lymphoma (SMZL) with villous lymphocytes. The cytoplasm of two of the lymphocytes has small villous projections. Nuclear chromatin is coarse. There are distinct but not prominent nucleoli. **B**, Bone marrow biopsy from a patient with SMZL showing a paratrabecular, poorly demarcated aggregate of lymphocytes. **C**, High magnification of a lesion from a patient with SMZL showing a predominant population of small lymphocytes with scattered large cells with abundant cytoplasm and prominent nucleoli. (**A**, Wright–Giemsa.)

Patients with SMZL generally have a prolonged clinical course. Splenectomy is frequently beneficial in patients with severe anemia,

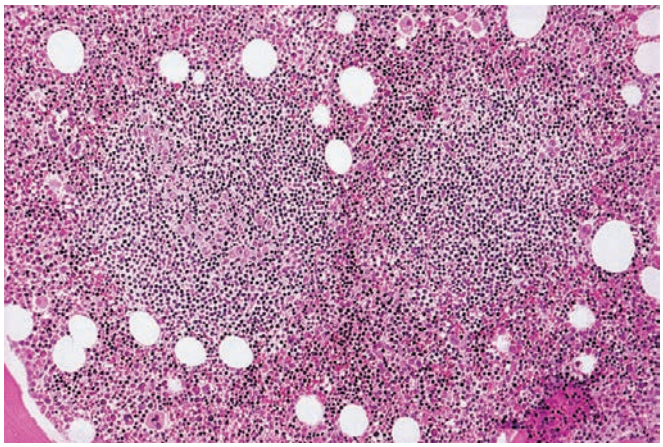

Figure 39.70 Bone Marrow Biopsy From a Patient With Splenic Marginal Zone Lymphoma Illustrating Two Well-Circumscribed Foci of Lymphocytes. The lesion on the left contains a central area suggesting remnants of a germinal center with several centroblast-like cells.

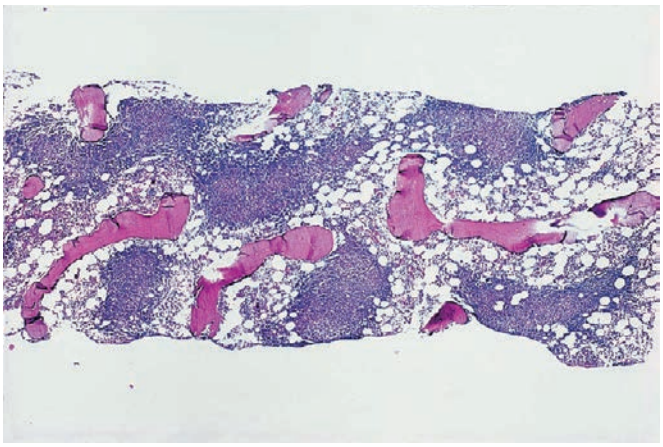

Figure 39.71 Several Focal Aggregates of Lymphocytes in Marrow in a Patient With Small Lymphocytic Lymphoma. Foci of lymphocytes vary in size and have irregular, poorly circumscribed outlines.

neutropenia, and thrombocytopenia. Rare cases have recurred as diffuse large B-cell lymphoma at other sites.[416]

A small number of patients with SMZL and concurrent hepatitis C infection have undergone remission of the lymphoma with antiviral therapy.[417]

Burkitt Lymphoma/Leukemia

Burkitt lymphoma presents with marrow involvement in 15%–30% of patients.[418–422] In the WHO classification of hematopoietic tumors, the FAB designation of ALL L3 has been replaced by combining the leukemic presentation with Burkitt lymphoma, reflecting the fundamental identities of these two different manifestations of the same process.[411,423] A leukemic presentation is frequently associated with Burkitt lymphoma involving the ileocecal region of the small bowel with a t(8;14)(q24;q32) or variant chromosome translocation, (t(2;8)(q12;q24), t(8;22)(q24;q11)) and is TdT negative.[418,420,423] The diagnostic terminology used in these cases should reflect the status of the marrow and blood. If tumor cells are present in the blood and the marrow is diffusely replaced, Burkitt leukemia is an appropriate designation. If few or no tumor cells are present in the blood, and the marrow is partially involved with substantial sparing of normal hematopoiesis, a diagnosis of lymphoma is more appropriate. The therapeutic approach in these two situations is the same. Marrow involvement in Burkitt lymphoma is usually characterized by diffuse infiltration of the interstitium with some preservation of adipose tissue, although small focal lesions may occur. The "starry sky" appearance characteristic of lymph nodes in Burkitt lymphoma is infrequently present in bone marrow biopsies. In contrast to the majority of cases of B-cell precursor ALL in which mitotic figures are sparse, there is prominent mitotic activity in Burkitt lymphoma/leukemia. Burkitt lymphoma is a mature B-cell neoplasm, expressing CD20 and clonal surface immunoglobulin light chains as well as CD10. In contrast to B-ALL, it does not express CD34 or TdT.

Non-Hodgkin Lymphoma

B-Cell Lymphoma

The incidence of marrow involvement in non-Hodgkin lymphoma at the time of initial diagnosis, other than those previously described with a leukemic presentation, varies with the different histopathologic subtypes; the incidence in aggregate for all types ranges from 40% to 55% in most of the larger studies of adults.[424] The incidence is higher in the low-grade lymphomas than in many of the high-grade lymphomas. Approximately 60%–70% of the cases of follicular center cell lymphoma have marrow involvement at the time of initial diagnosis, compared to 25%–33% for large cell lymphomas. Splenic marginal zone B-cell lymphoma is reported to have a very high incidence of involvement, approximately 80%–90%; a similarly high incidence of involvement has been observed in mantle cell lymphoma.[378,425–427] Marrow involvement in mucosa-associated lymphoid tissue (MALT) lymphoma was reported in approximately 20% of cases in one study.[428] The incidence of marrow involvement in peripheral T-cell or node-based T-cell lymphoma varies from 30% to 70% in different series.[429–431] Blood involvement may occur with all types of lymphoma.[320,425,432–435]

The extent of lymphomatous infiltration varies considerably; it is less than 30% in more than half of cases with involvement.[411,433,436] In general, the small lymphocytic and follicular center cell lymphomas are characterized by substantial sparing of normal bone marrow.

The pattern of marrow involvement may be diffuse, focal paratrabecular, focal nonparatrabecular, interstitial, intrasinusoidal, and rarely intravascular (Figs. 39.71–39.78); uncommonly, marrow lesions of follicular lymphoma are characterized by recapitulation of the neoplastic follicle as found in the lymph node (see Figs. 39.74 and 39.75).[411,433,437–443] The diffuse and focal nonparatrabecular patterns may occur with all types of lymphoma of both B- and T-cell type. The focal paratrabecular pattern occurs principally but not exclusively in the follicular center cell lymphomas; follicular lymphomas may also involve the marrow in a focal nonparatrabecular pattern. The marrow biopsies from patients with mantle cell lymphoma and splenic marginal zone B-cell lymphoma may also show both focal paratrabecular and nonparatrabecular lesions.[411,444] The infiltrate in an occasional case of mantle cell lymphoma and splenic marginal zone B-cell lymphoma may contain remnants of benign germinal centers (see Fig. 39.76B).[445] Splenic marginal zone B-cell lymphoma and hepatosplenic T-cell lymphoma may occur principally in an intrasinusoidal pattern (see Fig. 39.78).[415]

The interstitial pattern of involvement, in which the lymphoma cells infiltrate the interstitium of the marrow with preservation of the overall marrow architecture with some sparing of normal hematopoiesis, may occur with all types of non-Hodgkin lymphoma.

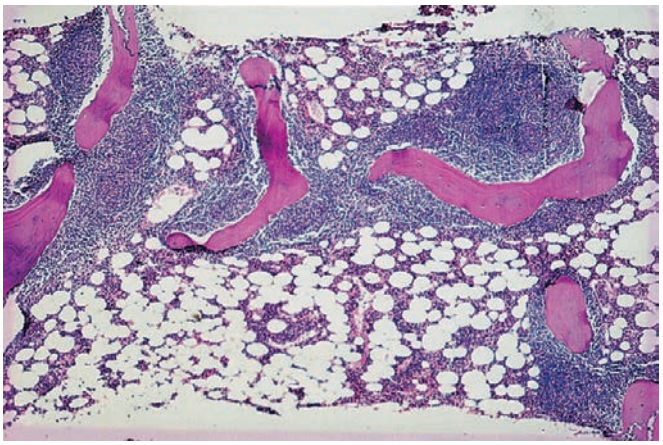

Figure 39.72 Bone marrow section from a patient with follicular lymphoma illustrating the prominent paratrabecular distribution of the infiltrate.

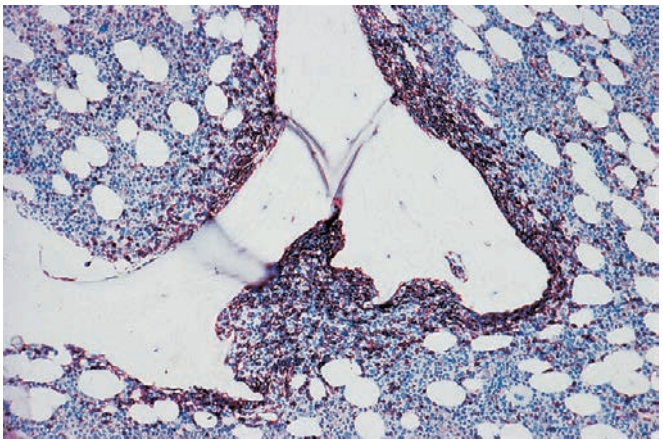

Figure 39.73 Marrow from a patient with marrow involvement by follicular lymphoma with prominent paratrabecular involvement reacted with antibody to CD20. The infiltrate is accentuated by CD20 antibody. (Immunoperoxidase.)

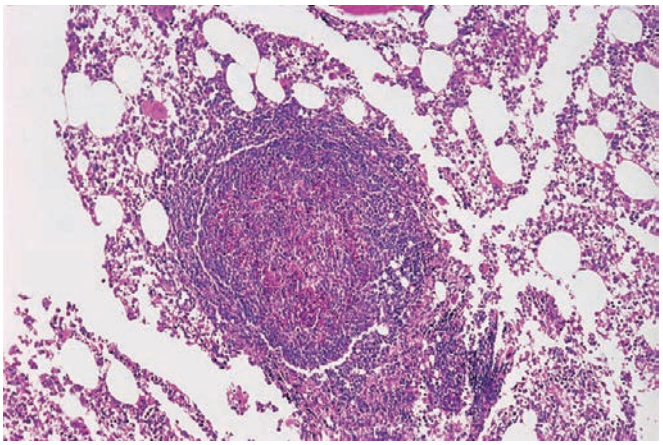

Figure 39.74 Marrow Biopsy From a Patient With Follicular Lymphoma With Focal Paratrabecular and Nonparatrabecular Involvement. A few of the nonparatrabecular foci, as illustrated, recapitulate neoplastic follicles. Amorphous eosinophilic proteinaceous debris is deposited in the central portion of the lesion.

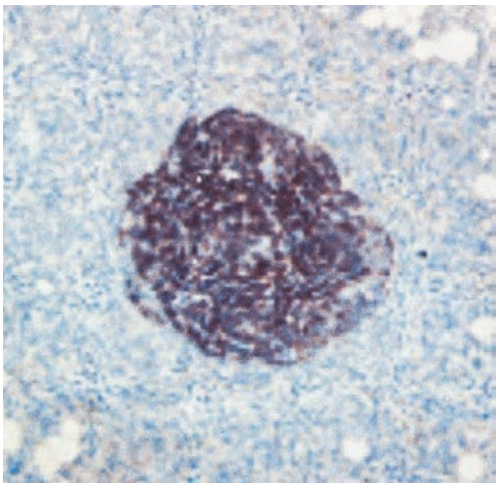

Figure 39.75 Neoplastic Follicle in Marrow Reacted With Antibodies to CD21 and BCL2. The dendritic cells express CD21 and the lymphocytes express CD20. (Immunoperoxidase.) (Reproduced from *Am J Clin Pathol*. 2002 American Society for Clinical Pathology. Reprinted with permission.)

The bone marrow in this type of involvement may be deceptively normal in appearance at low magnification and emphasizes the importance of examination of marrow biopsies at high magnification when evaluating for lymphoma involvement (see Fig. 39.77). This pattern of infiltration may be present at the time of initial diagnosis or in patients who have received chemotherapy. Interstitial involvement in the more aggressive lymphomas may be accompanied by considerable depletion of normal hematopoietic cells.

The intrasinusoidal pattern of involvement may be particularly difficult to identify in routinely stained sections, even in well-prepared specimens. The use of immunohistochemistry has been particularly important in recognizing this type of lesion, which appears to occur most frequently with splenic lymphomas, including splenic marginal zone B-cell lymphoma and hepatosplenic T-cell lymphoma, in which it may be the predominant pattern of involvement (see Fig. 39.78). It may be observed in other types of lymphoma, usually combined with other patterns.[415]

The follicular pattern of follicular lymphoma as observed in lymph nodes is uncommonly recapitulated in the marrow lesions (see Fig. 39.74).[411,443] Occasionally foci of transformation in B-CLL may mimic follicle formation (see Fig. 39.62). As noted, benign germinal centers may be found in occasional cases of mantle cell lymphoma and splenic marginal zone B-cell lymphoma (see Fig. 39.76).[445] In some marrow lesions of follicular lymphoma, the margins of the lymphomatous focus may be composed of transforming cells, imparting a somewhat reverse germinal center character to the lesion. In addition, the paratrabecular lesions may show a zoning phenomenon with a less differentiated population of cells immediately adjacent to the endosteal surface.

The cytopathology of the lesions in the marrow sections usually parallels the cytologic characteristics in the lymph node; this is particularly true for the T-cell lymphomas and Burkitt lymphoma.[446,447] In 20%–25% of lymphomas, predominantly follicular, there may be discordance between the predominant cell type in the lymph node and the predominant cell type in the marrow.[411,426,440,448,449] In these cases, the marrow lesions usually consist of small cleaved cells, and the lymph node findings are a mixed or large cell type; the converse occurs but is less frequent. Those patients with diffuse large cells in the lymph node and small cleaved cells in the bone

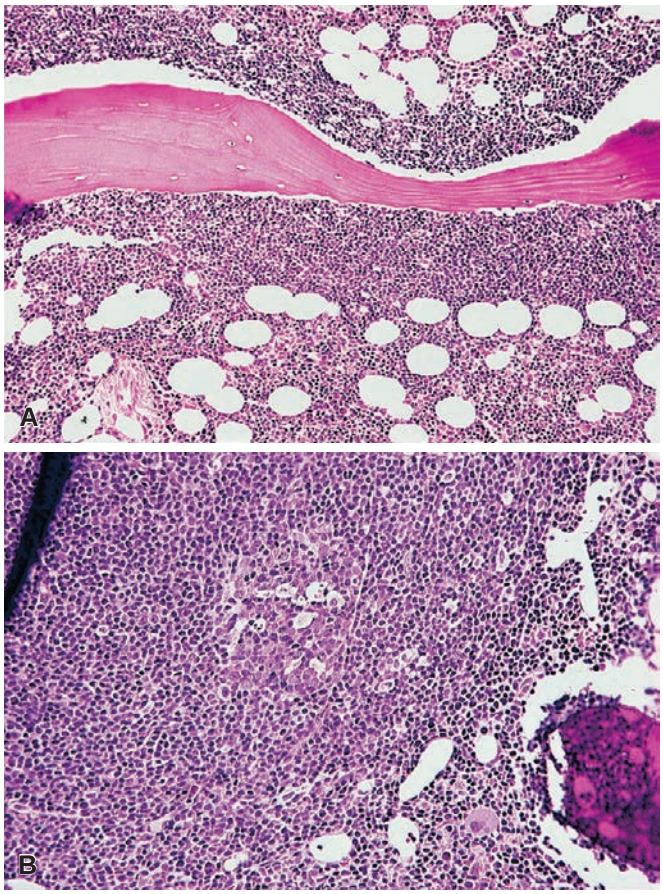

Figure 39.76 **A**, Bone marrow biopsy from an adult man with extensive blood and marrow involvement by mantle cell lymphoma. Lymphoma cells expressed pan-B-cell markers, CD5, and intense surface immunoglobulin. In some areas, lymphoma marginates along the bone trabecula. **B**, Focus of marrow involvement from the same biopsy showing structure with remnants of germinal center including dendritic histiocytes.

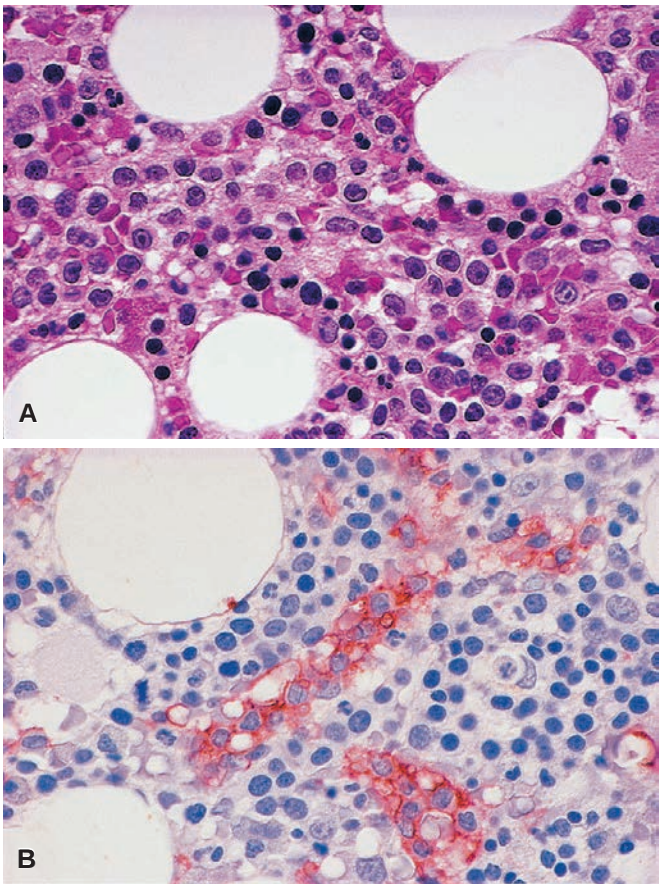

Figure 39.78 **A**, Bone marrow biopsy from a patient with splenic marginal zone B-cell lymphoma showing a preferential intrasinusoidal localization of the lymphoma cells. **B**, The same specimen as **A** reacted with antibody to CD20 illustrating the preferential intrasinusoidal location of lymphoma cells. (**B**, Immunoperoxidase.)

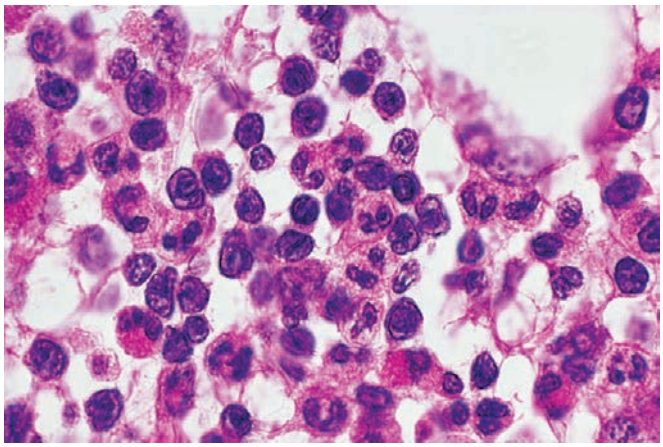

Figure 39.77 **High Magnification of a Marrow Biopsy From a Patient Being Treated for Follicular Lymphoma.** There is an infiltration of the interstitium by a population of small lymphocytes, several of which have irregular and cleaved nuclei.

marrow usually have a high rate of complete remission and a high rate of 5-year survival compared to patients with large cells in the lymph node and bone marrow that have a low rate of complete remission with low 5-year survival.[449] In either instance, the cytologic characteristics in both sites are usually those of follicular center cell lymphoma. Molecular studies of microdissected lesions in 21 cases of discordant lymphoma have shown the same clone in the lymph node and marrow lesions in 44% of the specimens.[450] In two cases different clones were identified and in four cases the marrow lesions were polyclonal. These studies emphasize the importance of critical evaluation of lesions in post-therapy marrow; it cannot be assumed that all lymphocytic infiltrates are residual lymphomas, nor can it be assumed that a small lymphocyte proliferation in the marrow of a patient with large cell lymphoma elsewhere is benign. These caveats are particularly important in those instances where there is discordant morphology following antibody therapy.

Immunohistochemistry with an appropriate panel of antibodies has an important role in the evaluation of marrow biopsies in patients with lymphoma. It has utility in defining the cell type, extent of involvement, and detection of residual disease following therapy.[29,451]

Similar to the findings in lymph nodes, lymphomas of predominantly small lymphocytes in the marrow, B-cell CLL or B small

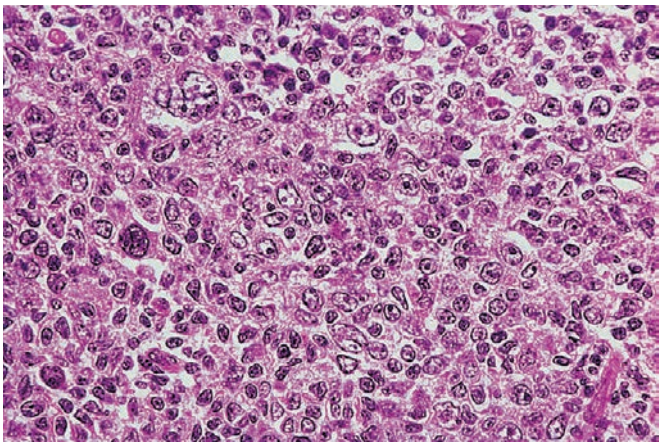

Figure 39.79 Bone Marrow Section From a Patient With a 6-Year History of Follicular Lymphoma. Cells resembling Reed–Sternberg cells and mononuclear variants are present.

lymphocytic lymphoma, may show foci of transformation. In occasional cases of follicular cell lymphoma or CLL, transformed cells resembling Reed–Sternberg cells or Reed–Sternberg mononuclear variants may be present (Fig. 39.79).[351,452]

There is no relationship between a diffuse or follicular pattern in the lymph node and the presence of focal or diffuse lesions in the marrow. Cases in which the lymph node has a diffuse pattern of involvement, such as small lymphocytic lymphoma or CLL, may manifest as focal lesions in the marrow. Cases with a follicular pattern in the lymph node may manifest as diffuse marrow involvement. Only rarely is the follicular pattern recapitulated in the marrow.[411,443]

Unusual variants of non-Hodgkin lymphoma involving marrow may lead to diagnostic problems because of the unusual morphology of the lymphoma cells or because of an accompanying proliferation of reactive cells. In anaplastic large cell lymphoma, the lymphoma cells may by virtue of size and nuclear irregularity mimic megakaryocytes. The problem is accentuated when the foci of lymphoma are small and indistinctly demarcated from the surrounding normal marrow tissue or when the lymphoma cells are intermingled with normal marrow cells. In cases of the small cell variant of anaplastic large cell lymphoma, the marrow infiltration may be scattered in the interstitium and difficult to recognize among the normal myeloid cells.[431] Despite this, marrow involvement by anaplastic large cell lymphoma can be detected on hematoxylin and eosin–stained sections alone in most cases. Antibody studies, including CD30, may be useful in clarifying the origin of the abnormal cells in equivocal cases.[431,453,454] The lymphoma cells in histiocyte-rich B-cell lymphoma and T cell–rich B-cell lymphoma may be partially obscured by the nonmalignant cell proliferation.[455] In T-cell/histiocyte-rich B-cell lymphoma, reactions with antibodies to B lymphocytes such as CD20 and histiocytes (CD68) are useful in delineating the two cell populations (Fig. 39.80). The blastic variant of mantle cell lymphoma may resemble ALL. Reactions for TdT (positive in lymphoblastic lymphoma/leukemia) and cyclin D1 (positive in mantle cell lymphoma) will help to distinguish those two processes.[456]

Post-transplant lymphoma of B-cell type does not commonly involve the marrow; when it does, the degree of infiltrate varies considerably.[457,458] Immunohistochemical reactions for B-cell origin and EBV in situ hybridization (EBER) studies may be very helpful in establishing the diagnosis (Fig. 39.81).

Granulomas may be found in all types of lymphoma in the marrow, with and without marrow involvement.[113]

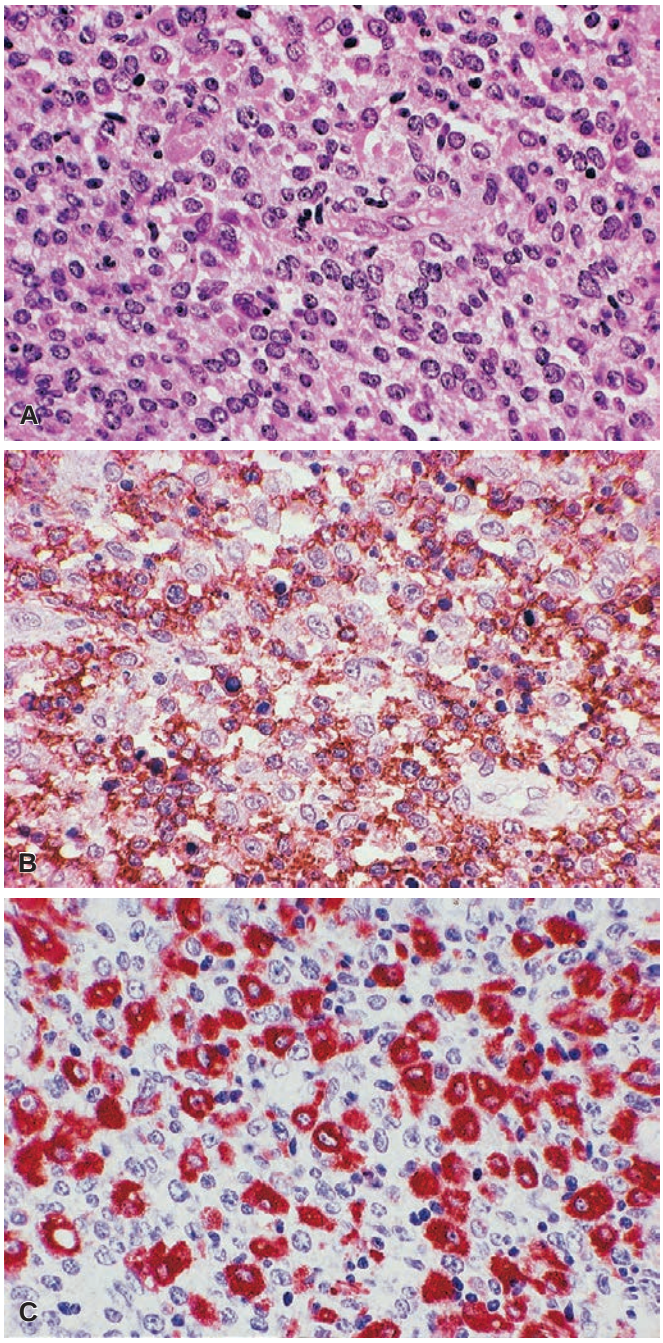

Figure 39.80 **A**, Marrow from a patient with T-cell/histiocyte-rich B-cell lymphoma. Histiocytes predominate in this area. **B**, The specimen in **A** reacted with antibody to CD20. The numerous lymphocytes are reactive, contrasting with the negative histiocytes. **C**, The marrow biopsy in **A** reacted with antibody to CD68 (KP1). The numerous positively reacting histiocytes in this area contrast with the negatively reacting lymphoma cells. (**B** and **C**, Immunoperoxidase.)

Other types of lymphoma with marrow involvement may present with blood involvement. Twenty to 40% of the cases of follicular center cell lymphoma with lymphoma in the marrow have lymphoma cells in the blood.[411,434] In some instances, the count may be very high and resemble CLL. The distinction is based on the presence of lymphocytes with cleaved nuclei and the characteristic pattern of focal paratrabecular involvement in small cleaved cell lymphoma.

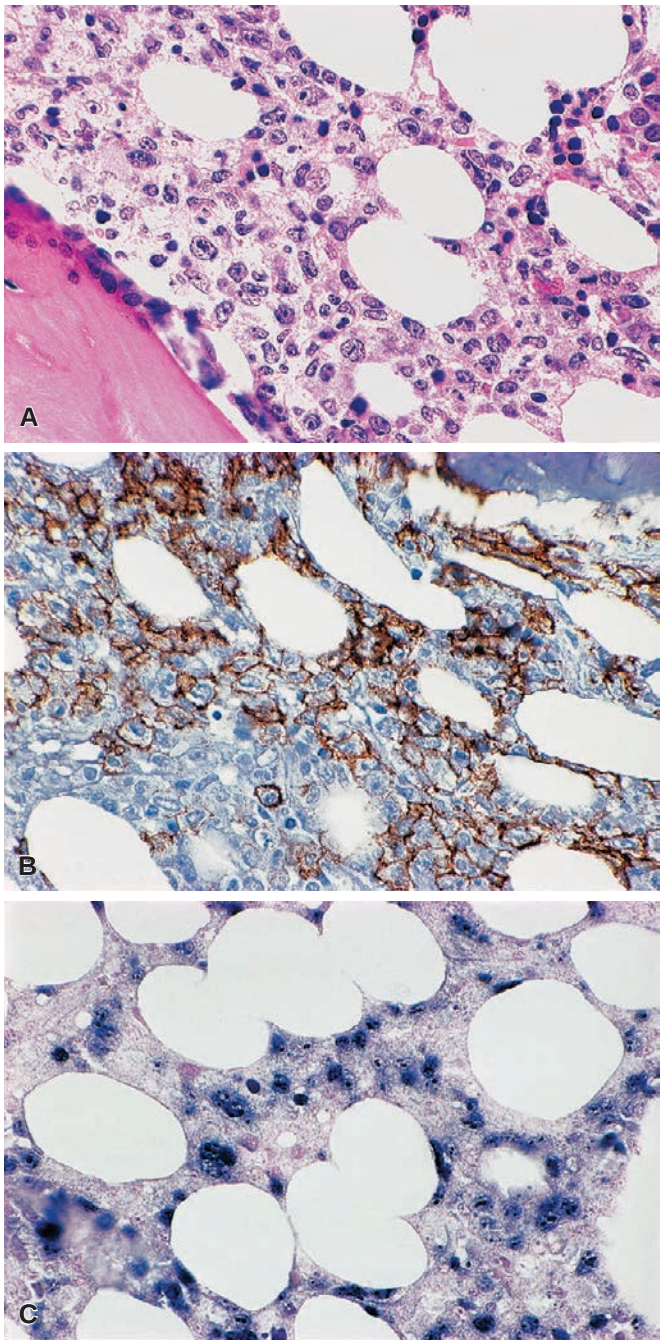

Figure 39.81 Post-transplant B-Cell Lymphoma. A, The lymphoma cells extensively infiltrate the marrow interstitium in this area; some residual myelopoiesis is present. **B**, The same specimen as **A** reacted with antibody to CD20; large lymphoma cells are positive. **C**, Numerous lymphoma cells are positive for EBV. (**B**, Immunoperoxidase; **C**, EBER.)

Expression of CD5 and weak surface immunoglobulin on the lymphocytes supports a diagnosis of CLL; lack of CD5 and expression of CD10 and intense surface immunoglobulin are more compatible with follicular lymphoma.[320,459] The lymph node findings are definitive.

Mantle cell lymphoma may present with marked involvement of the marrow and blood, and blood involvement is present in approximately half of cases with marrow disease.[411] Leukocyte counts of 270 × 10^9/L have been reported.[435,460,461] The blood findings may

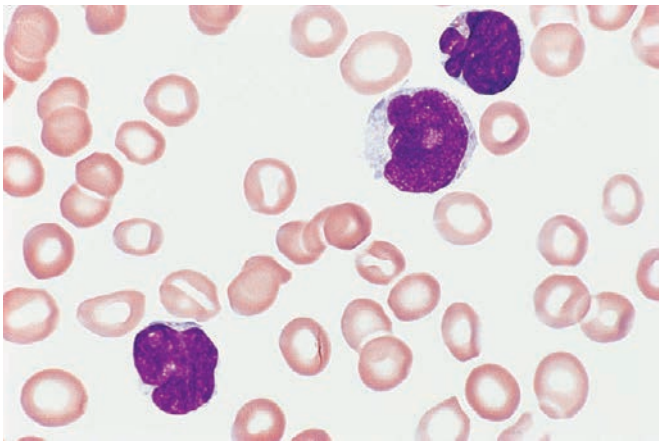

Figure 39.82 Blood Smear From an Adult Man With Leukemic Mantle Cell Lymphoma. The lymphoma cells vary considerably in size, nuclear lobulation, and degree of chromatin clumping. The large cell with a prominent nucleolus resembles a prolymphocyte. The smear is from the same patient as the specimen illustrated in Fig. 39.76.

resemble CLL, CLL/PL, PLL, and small cleaved cell lymphoma. The lymphoma cells may be quite pleomorphic with variation in size, nucleocytoplasmic ratio, degree of nuclear irregularity, and prominence of nucleoli (Fig. 39.82).[365] The lymphocytes express pan-B-cell antigens, CD5, and strong surface immunoglobulin. The lymphocytes usually do not express CD23 or CD10. The bone marrow involvement may be diffuse or focal; the focal involvement may be paratrabecular or nonparatrabecular. Rarely, naked germinal centers may be observed in the marrow lesions. The lymphoma cells express cyclin D1 by immunohistochemistry and the t(11;14)(q13;q32) chromosome abnormality by fluorescence in situ hybridization. The latter assay is particularly useful on peripheral blood samples.

T- and NK-Cell Lymphomas/Leukemias

Peripheral T-Cell Lymphoma, Not Otherwise Specified

Peripheral T-cell lymphoma, not otherwise specified (PTCL, NOS) consists of all mature T-cell lymphomas that do not correspond to any of the more specific disease entities in the WHO classification.[462,463] It has such unusual features in bone marrow biopsies as to warrant separate consideration.[429,430,464,465] This type of lymphoma is characterized by a high incidence of marrow involvement at the time of initial diagnosis, ranging from 30% to 70% in some studies. The marrow lesions are diffuse in approximately 60% of involved cases and focal in 40%.[430] The focal lesions are usually randomly distributed in contrast to the preferential paratrabecular involvement in follicular center cell lymphomas; occasional cases present with a focal nonparatrabecular and paratrabecular pattern. The infiltrates vary substantially in size and are usually irregular in configuration with poorly demarcated margins; in many instances the lesions appear to extend almost imperceptibly into adjacent normal marrow (Fig. 39.83). The diffuse lesions are characterized by complete intertrabecular replacement of marrow; in some instances the entire biopsy specimen is replaced (Fig. 39.84). Increased reticulin fibers are present in the area of lymphomatous involvement and frequently extend into the adjacent normal-appearing marrow.

The predominant cytologic pattern in the marrow lesions usually corresponds to the pattern in lymph node or other tissue biopsies

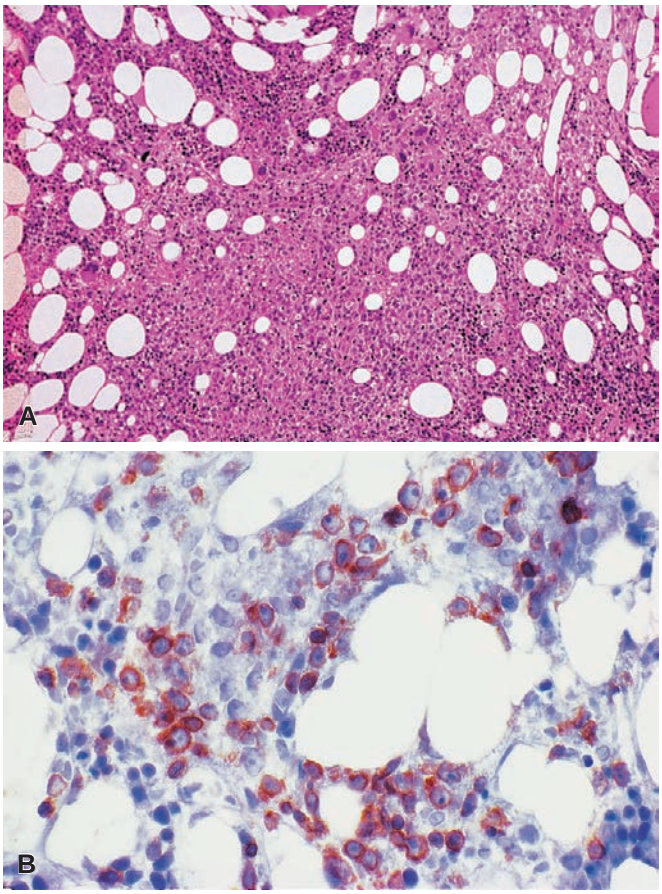

Figure 39.83 **A**, Marrow section from a patient with partial involvement by peripheral T-cell lymphoma. The lymphoma population is poorly demarcated and infiltrates the interstitium with some preservation of normal architecture. **B**, Margin of the lesion in **A** reacted with antibody to CD3. Numerous large lymphocytes, some with prominent nucleoli, are positive. (**B**, Immunoperoxidase.)

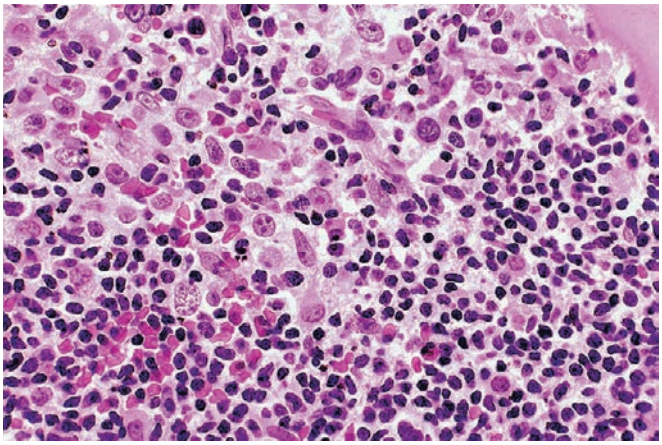

Figure 39.84 Marrow biopsy from a patient with peripheral T-cell lymphoma, showing extensive diffuse marrow involvement. The predominant cell population consists of small lymphocytes with a focus of large lymphocytes that have prominent nucleoli.

and can be heterogeneous, ranging from small cells with irregular nuclei to cases with predominantly large, pleomorphic cells. Mixed and large cell infiltrates are most frequently encountered. In some instances there is a relatively distinct demarcation between large and small cells. Large lymphoid cells with abundant amphophilic cytoplasm and prominent eosinophilic nucleoli, resembling Reed–Sternberg cells and mononuclear Reed–Sternberg variants, may be present. The small- and medium-sized lymphocytes have nuclei with condensed chromatin, which vary from regular to irregular in outline. The mixed cell and large cell/immunoblastic types usually have an associated polycellular infiltrate consisting of histiocytes, plasma cells, eosinophils, and neutrophils. Epithelioid histiocytes are frequently noted, either in focal clusters or scattered throughout the lesions. The focal collections frequently have a granulomatous appearance. Increased vascularity may be a prominent feature; the vascular component is primarily an endothelial cell proliferation with straight-lined channels. Immunohistochemical reactions are useful in identifying the atypical cells as T cells.

The differential diagnosis of PTCL, NOS in marrow includes Hodgkin disease, systemic mastocytosis, and polymorphous reactive lymphoid hyperplasia.[429,430] The most difficult problem relates to the last lesion, which may be present in marrow specimens from patients with a wide variety of immunologic disorders, including AIDS. Polymorphous reactive lymphoid hyperplasia has many histopathologic features similar to PTCL, NOS, including a heterogeneous population of lymphocytes with intermixed plasma cells, immunoblasts, eosinophils, endothelial cells, and epithelioid histiocytes. Distinction between the focal lesions of PTCL, NOS and the polymorphous reactive lymphoid lesions may not be possible solely on morphologic features. Markedly atypical cells with prominent nucleoli are more compatible with lymphoma. The size of the lesions is not always a reliable distinguishing feature; reactive lesions may show extensive marrow replacement, particularly in patients with AIDS. The lesions of PTCL, NOS may be relatively small. Correlation with non-marrow tissue biopsies and molecular genetic studies to detect a clonal T-cell population, supportive of T-cell lymphoma, may be useful in this differential diagnosis.

Hodgkin disease in the marrow may appear similar to the lesions of PTCL, NOS. The presence of classical Reed–Sternberg cells and the lack of atypia in the background lymphocyte population are suggestive of Hodgkin disease. Multinucleated immunoblasts resembling Reed–Sternberg cells may be present in PTCL, NOS; in these instances, review of lymph nodes and other tissue biopsies and immunohistochemical studies are critical in distinguishing PTCL, NOS from Hodgkin disease.

The lesions of systemic mastocytosis may be distinguished from PTCL by the reactivity of mast cells with CD117 and mast cell tryptase. The cells of systemic mastocytosis, however, may aberrantly express the T lineage-associated marker CD2 but should not express other T-cell markers, such as CD3, CD5, or CD7.

Genotypic studies to determine T-cell clonality are an important advance in distinguishing PTCL in marrow biopsies or other tissues from the disorders considered in the differential diagnosis.[466] Clonal rearrangement of one of the T-cell receptors is substantial evidence of a malignant process. The determination of clonality may be made on fresh aspirate or trephine biopsy specimens and fixed, paraffin-embedded tissue,[467] but decalcification and/or heavy metal fixation often destroys nucleic acids needed for these assays.

Adult T-Cell Leukemia/Lymphoma

Adult T-cell leukemia/lymphoma is an unusual form of mature (post-thymic) T-cell lymphoma occurring primarily in Japan; it is associated with the human retrovirus HTLV-1.[468–470] The highest

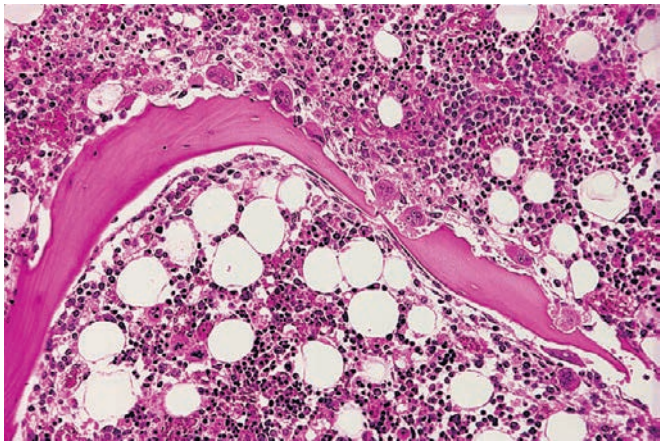

Figure 39.85 Marrow Biopsy From a Patient With Adult T-Cell Leukemia and Hypercalcemia. Marked osteoclastic activity with bone resorption is present.

incidence of this disease is in the Kyushu region of Japan; other endemic areas include the Caribbean basin and parts of western Africa. Sporadic cases are observed in other areas of the world, including the United States. The disease occurs in three principal clinical forms: smoldering, chronic, and acute. There are several histopathologic types including small, medium, and large pleomorphic cell types, large cell anaplastic, and Hodgkin-like. Blood and marrow involvement occurs principally in the acute form. Marrow involvement is characterized by a patchy infiltration of abnormal lymphocytes with lobulated or round nuclei. The distribution may be patchy even in cases with marked leukocytosis. Hypercalcemia is present in 28% of patients at diagnosis and in 50% of patients at some time during the course of the disease. The vast majority of patients with hypercalcemia have bone marrow involvement. However, increased osteoclastic activity may be present in cases with or without marrow involvement by the lymphoma and the findings may be those of osteitis fibrosa generalisata (Fig. 39.85).[468,471]

Sézary Syndrome

Sézary syndrome is a lymphoproliferative disorder, usually of CD4-positive T-helper lymphocytes, defined by the presence of erythroderma, generalized lymphadenopathy, and neoplastic T cells in the blood, skin, and lymph nodes.[472–476] The leukocyte count may be normal or markedly elevated with a high percentage of Sézary cells. The Sézary cells, as observed in Romanowsky-stained blood smears, have distinctive features. The nucleus frequently has an unusual configuration that has been characterized as cerebriform (Fig. 39.86A). Cytoplasmic vacuoles, which stain positively with the PAS reaction, may be present in a perinuclear location. Large and small cell variants have been described.[472] Ultrastructurally, the cells show marked nuclear convolutions (see Fig. 39.86B).[476,477] Despite the generalized nature of the disorder, the bone marrow sections in the majority of patients are normal. Involved cases usually show a sparse, interstitial infiltrate.[478] Marked marrow infiltration with replacement of normal hematopoietic cells is very uncommon. Rarely, small aggregates of Sézary cells may be observed.[472]

T-Cell Large Granular Lymphocytic Leukemia

T-LGL is characterized by a persistent, defined as 6 months or more, increase in peripheral blood large granular lymphocytes with no apparent cause and is usually associated with neutropenia.[479–483] The

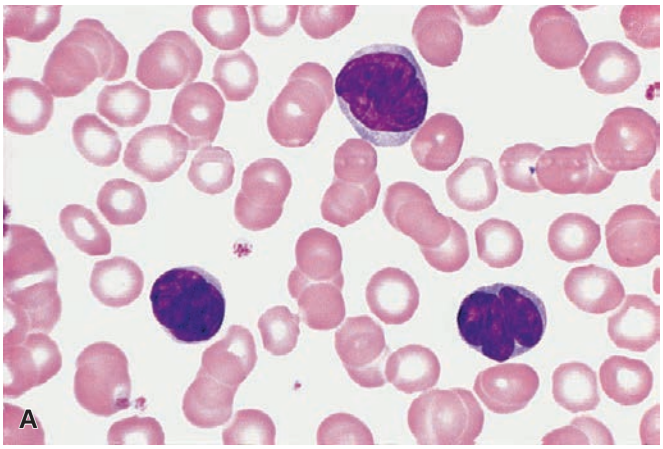

Figure 39.86 A, Three Sézary cells in blood smear. The nucleus in the larger cell in the upper field has delicate folds imparting a "cerebriform" appearance. The two smaller cells in the lower field have a more condensed chromatin and markedly lobulated nuclei. **B**, Ultrastructure of a Sézary cell; extreme convolution of the nucleus is a characteristic feature. (**B**, Uranyl acetate–lead citrate; ×22 000.)

characteristic lymphocytes in the blood are medium to large, with abundant slightly basophilic to pale cytoplasm containing a variable number of coarse azurophilic granules, and are frequently abundant in reactive processes, most notably viral infections and immune reactions. They may also be increased after myocardial infarction. Immunophenotypic and clonal studies are essential to the diagnosis.

There frequently are cytopenias, especially severe neutropenia, in T-LGL. Approximately 50% of patients have splenomegaly, but lymphadenopathy is uncommon. Rheumatoid factor and hypergammaglobulinemia are present in a subset of patients. The lymphocytes in T-LGL characteristically express CD3 and CD8, and are CD4 negative; CD11b, CD56, and CD57 are variably present.[484–486] Occasional cases express CD4 or CD4/CD8, and some cases may express primarily NK-cell markers. The definitive diagnostic evidence is based on a combination of T-cell receptor gene rearrangement studies, which usually show TRB and TRG rearrangements, and clinical features.[479,487–492]

The marrow involvement in T-LGL, which is usually interstitial, may be very difficult to recognize in routine sections; reactivity with antibody to CD8 is particularly useful in identifying the infiltrates (Fig. 39.87).[479,480,487,491] Approximately 50% of cases also have an

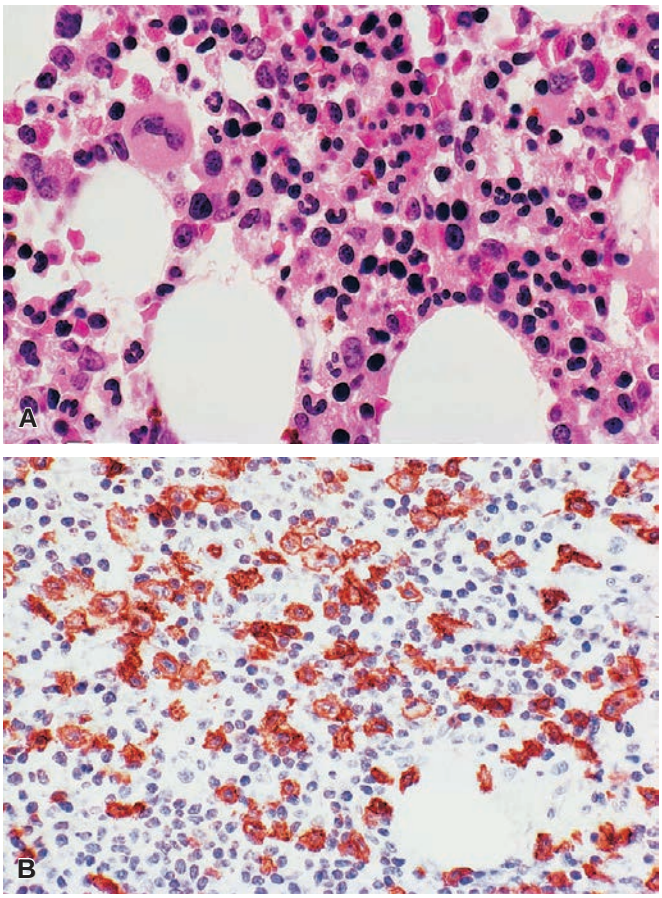

Figure 39.87 **A**, Bone marrow biopsy from an adult woman with large granulated T-cell lymphocytic leukemia. The leukemic lymphocytes are interspersed in the interstitium. **B**, Specimen in **A** reacted with antibody to CD8. There are numerous CD8-positive cells in the interstitium. (**B**, Immunoperoxidase.)

intrasinusoidal distribution of the leukemic lymphocytes. Occasional aggregates of lymphocytes may be present, and they usually contain an admixture of T and B cells. The T cells in these aggregates are usually CD4 positive and are not part of the leukemic process. The splenic infiltration is principally in the red pulp.

T-LGL does not show recurring cytogenetic abnormalities but usually demonstrates T-cell antigen receptor clonality and approximately one-third of cases have mutations of *STAT3*.[493]

Angioimmunoblastic T-Cell Lymphoma

The reported incidence of marrow involvement in this lesion, originally described as angioimmunoblastic lymphadenopathy, is 50%–70%.[494–496] The blood may show several abnormalities, including reactive lymphocytes, immunoblasts, and eosinophilia.[497,498]

The bone marrow lesions may be diffuse or focal; focal involvement is more common.[499,500] The margins of the focal lesions are usually somewhat indistinct, with poor demarcation from the surrounding hematopoietic tissue. In some cases, confluent multifocal lesions replace extensive areas of normal marrow. The lesions of angioimmunoblastic T-cell lymphoma are somewhat loosely structured and contain varying proportions of lymphocytes, immunoblasts, plasma cells, and histiocytes; neutrophils and eosinophils are also present (Fig. 39.88). Vascular proliferation, endothelial cells, and fibroblasts are frequently identified. Stains for reticulin show a marked

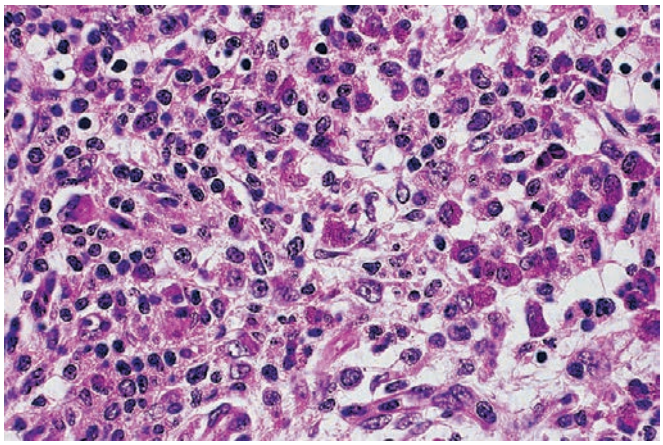

Figure 39.88 Bone marrow biopsy from a patient with lymph node diagnosis of angioimmunoblastic T-cell lymphoma. Marrow is diffusely involved by the process with a heterogeneous cell population.

increase in reticulin fibers in the involved areas. Collections of epithelioid histiocytes, imparting a granulomatoid appearance to some of the lesions, are reported. The amorphous PAS-positive material found in lymph node biopsies is less frequently encountered in bone marrow lesions. Immunohistochemical studies for kappa and lambda light chains show a polyclonal proliferation of immunoblasts and plasma cells in most cases, but coexisting B cell and clonal plasma cell proliferations may occur with some cases.[501] The neoplastic T cells are of germinal center origin in this lymphoma and often express CD10, CXCL13, and PD1 and scattered EBV-positive B cells are present in some cases by in situ hybridization.[500] The uninvolved marrow is frequently hypercellular. The hypercellularity may be a result of panhyperplasia or principally erythroid hyperplasia. The bone marrow and blood smears may contain varying numbers of lymphocytes at varying stages of development, including immunoblasts and mature plasma cells. Reactive lymphocytes and eosinophilia may be observed. Because of the high number of admixed reactive cells in the marrow with this disease, gene rearrangement studies for T-cell clonality are often useful if a prior lymph node or other tissue diagnosis of lymphoma has not been made.[466] Most cases show nonspecific clonal cytogenetic abnormalities and mutations in *TET2*, *IDH2*, *DNMT3A*, and *RHOA* are also common in this disorder.[502–504]

The significance of marrow involvement in regard to clinical outcome is unclear. Some, but not all, studies have indicated that patients with marrow involvement have a shorter survival than patients without marrow involvement.[494,498]

Anaplastic Large Cell Lymphoma

The diagnosis of anaplastic large cell lymphoma is now restricted to cases of T- or null-cell type and are subdivided into anaplastic lymphoma kinase (ALK)-positive and ALK-negative types.[505,506] Peripheral blood involvement is rare and is associated with extensive extranodal disease, including marrow involvement.[507] The marrow usually shows massive involvement, but in rare cases the cells may be almost imperceptibly scattered among the normal hematopoietic cells. The interstitium in the cases with marrow involvement may be very loosely structured with cell depletion (Fig. 39.89). The cases with lymphoma cells scattered among the normal hematopoietic cells may be overlooked in routinely stained sections, and immunohistochemical study for CD30 expression will detect these subtle cases (Fig. 39.89B).[453,454]

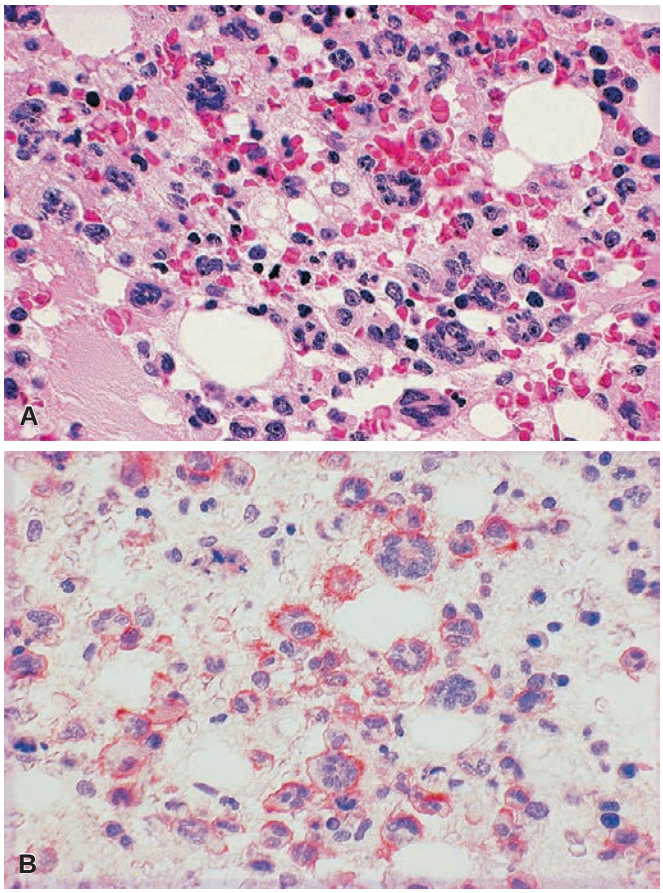

Figure 39.89 **A**, Area of marrow biopsy from a patient with anaplastic large cell lymphoma. The lymphoma cells are intermixed with normal marrow cells. **B**, Specimen in **A** reacted with antibody to CD30. The lymphoma cells are positive. (**B**, Immunoperoxidase.)

The small cell variant of anaplastic large cell lymphoma has a high incidence of marrow involvement when evaluated by routine morphology and immunohistochemistry (Fig. 39.90)[431] and appears to be more commonly associated with peripheral blood involvement. The degree of marrow involvement may be difficult to appreciate in routinely stained sections, and immunohistochemistry may be useful in such cases (see Fig. 39.90B). Because many cases of anaplastic large cell lymphoma show aberrant expression of the myeloid-associated marker CD13,[508,509] detection of CD30 and T-cell antigens, as well as evidence of a clonal T-cell gene rearrangement, are helpful in the differential diagnosis with AML.

Hepatosplenic T-Cell Lymphoma, Post-Transplant T-Cell Lymphoma, and Aggressive NK-Cell Lymphoma

Several uncommon types of T-cell lymphomas and NK-cell lymphomas have been reported in which the marrow is commonly involved. They include hepatosplenic T-cell lymphoma, post-transplant T-cell lymphoma, and aggressive NK-cell lymphoma. These are of relatively rare occurrence, and it is difficult to generalize about patterns of involvement.

Hepatosplenic T-cell lymphoma may be marked by an intrasinusoidal pattern but may also show subtle interstitial involvement without the characteristic intrasinusoidal pattern (Fig. 39.91).[465,510–512] The lymphoma cells may have blastic features or be very atypical.

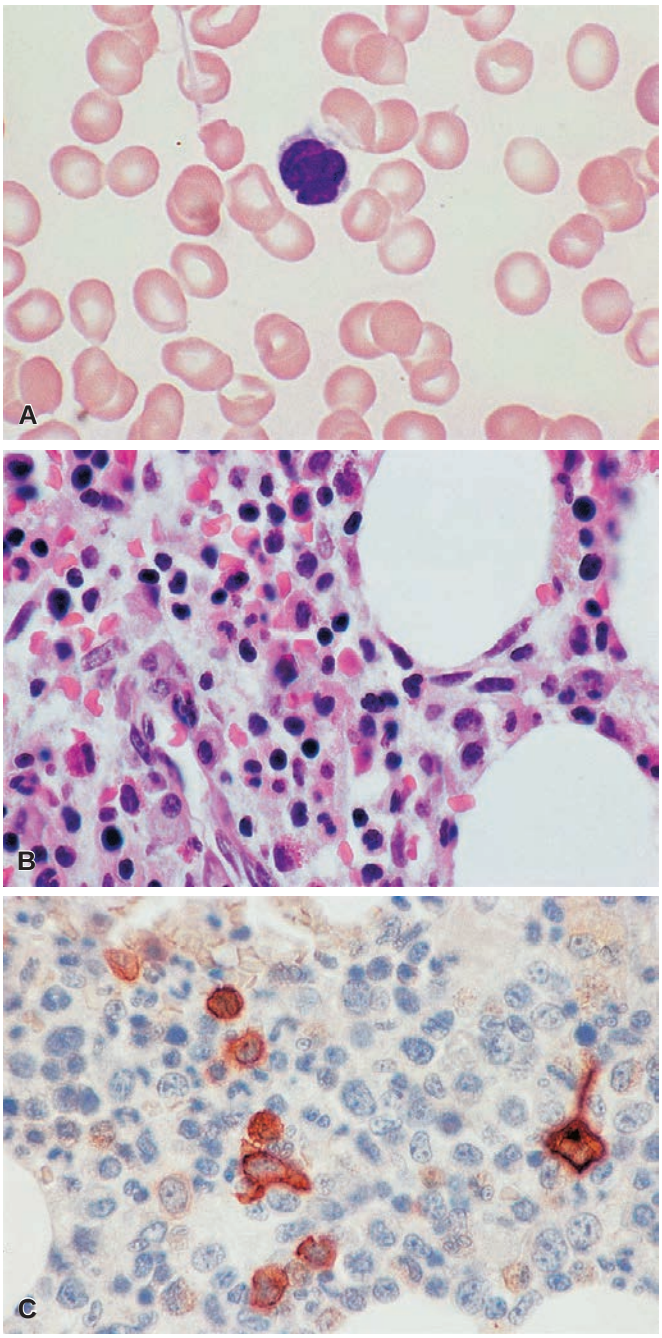

Figure 39.90 **A**, Lymphoma cell in blood smear from a 17-year-old male with small cell variant of anaplastic large cell lymphoma with associated t(2;5)(p23;p35). The cell has a convoluted nucleus. **B**, Bone marrow section from the same patient. The few lymphoma cells are scattered in the interstitium and difficult to recognize in this H&E stain. **C**, The same specimen as **B** reacted with antibody to CD30, which highlights the small and large lymphoma cells. (**C**, Immunoperoxidase.)

Cases with interstitial blast-like cells may be misinterpreted as MDS with excess blasts. The lymphoma cells are CD3+, TCRγδ+, TCRαβ–, CD56+/–, CD4–, CD8–/+, and CD5+ in most cases, but TCRαβ-positive cases occur and are otherwise similar to the TCRγδ cases. Immunohistochemistry, particularly anti-CD3, is very important in identifying the extent of disease and the intrasinusoidal pattern of involvement. Cytogenetic studies usually show

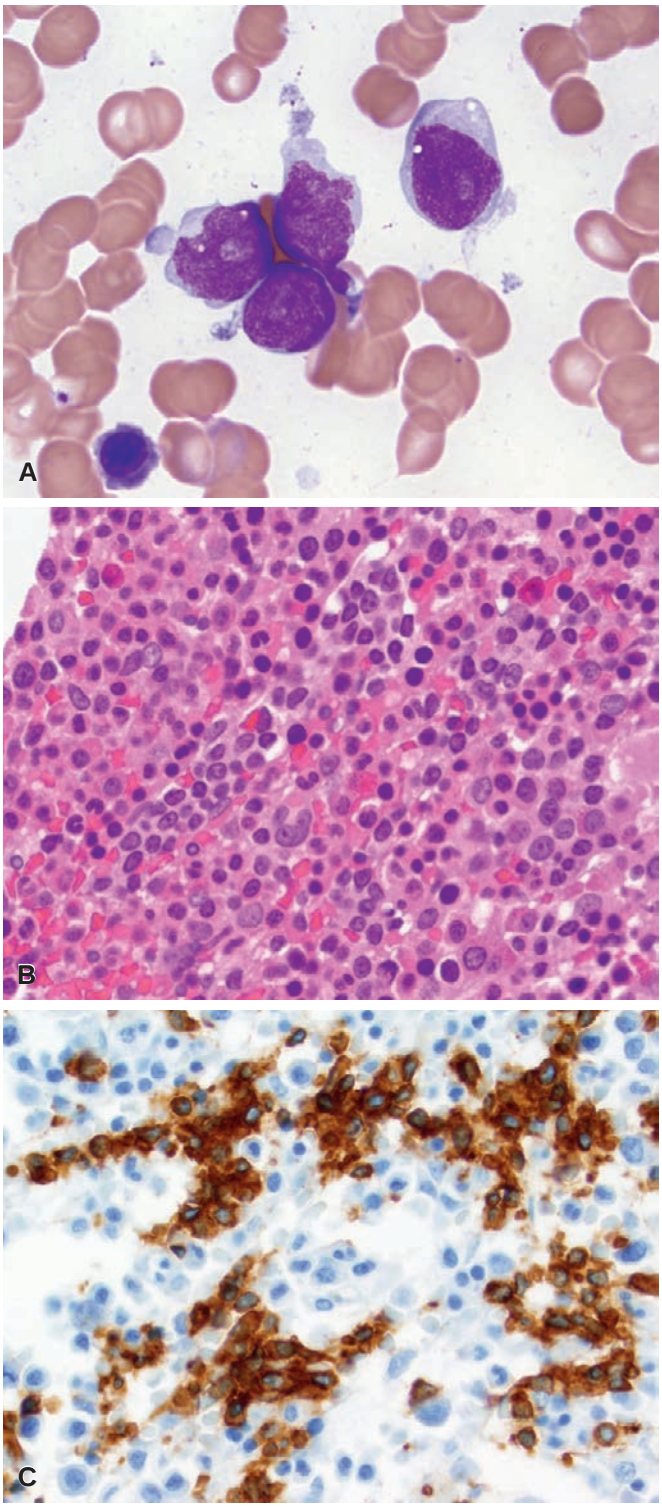

Figure 39.91 **A**, Bone marrow smear from a 17-year-old male with hepatosplenic gamma/delta T-cell lymphoma. The lymphoma cells vary in appearance and some have blast-like features. **B**, The marrow biopsy is markedly hypercellular, with extensive involvement and both an interstitial and intrasinusoidal pattern. **C,** Specimen in **B** reacted with anti-CD3 which highlights the intrasinusoidal pattern. (**C,** Immunoperoxidase.)

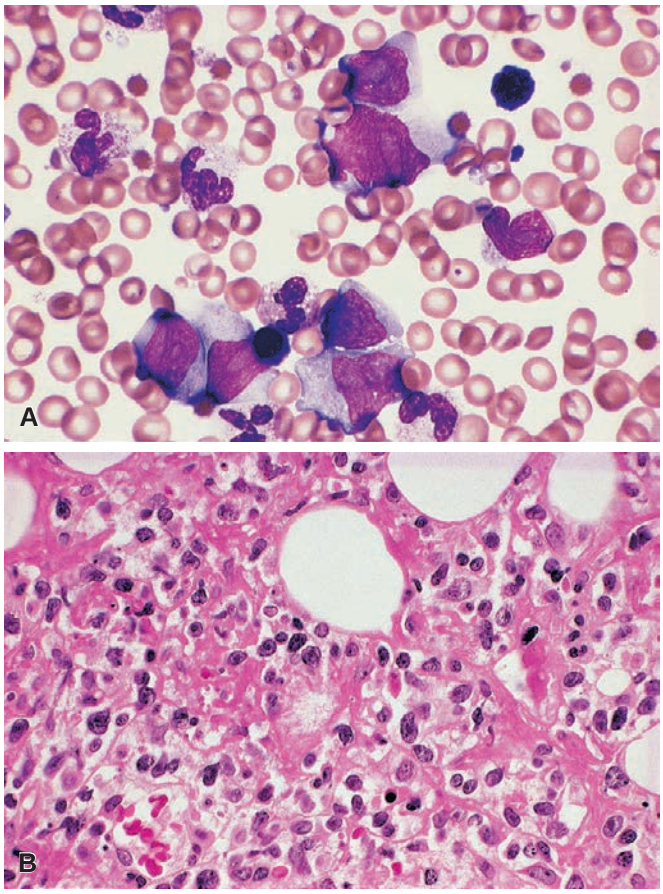

Figure 39.92 **Post-Transplant T-Cell Lymphoma. A**, Bone marrow smear from a 40-year-old woman, 28 and 8 years following renal transplantation. The lymphoma cells, which expressed CD2 and CD3, are large with abundant cytoplasm and very prominent nucleoli. **B**, High magnification of marrow section showing extensive interstitial involvement by noncohesive lymphoma cells. There is substantial depletion of normal hematopoiesis with cellular debris.

isochromosome 7, which is frequently associated with trisomy 8 and other abnormalities.[513–515]

Post-transplant T-cell lymphoma may be characterized by focal or extensive interstitial marrow involvement (Fig. 39.92). The use of immunohistochemistry may be important in identifying the presence, extent, and nature of these lesions since they may be overlooked in suboptimally prepared specimens. Examination of cytologic preparations, immunophenotyping, cytogenetics, and molecular studies may be important in classifying these lymphomas.

Aggressive NK-cell leukemia is a rare type of leukemia/lymphoma; it occurs most frequently in Asian teenagers and young adults.[516,517] This disorder may represent the leukemic counterpart of extranodal NK/T-cell lymphoma, nasal type.[518] The blood, marrow, liver, and spleen are commonly involved. The leukemia/lymphoma cells are large with ample and pale to slightly basophilic cytoplasm, which may contain fine or coarse azurophilic granules (Fig. 39.93A). The bone marrow infiltrates in biopsy sections may be diffuse, focal, or minimally interstitial. The leukemic cells appear monotonous with regularly shaped nuclei, coarse chromatin, and small nucleoli (see Fig. 39.93B). The cells usually mark as true NK cells, lacking surface CD3, but expressing cytoplasmic CD3 and CD56 and positive for EBV. The disease generally follows an aggressive clinical course as the name implies.

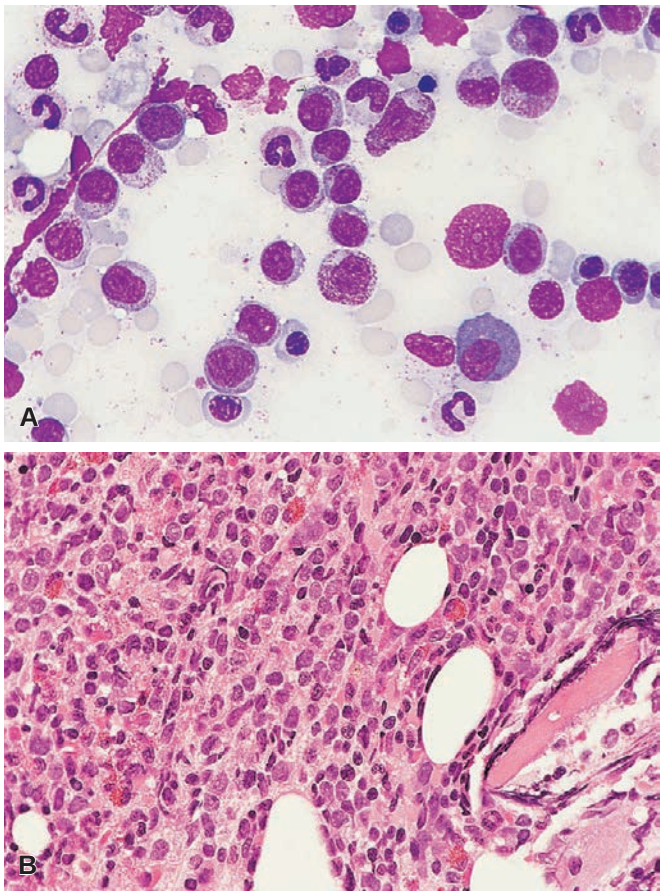

Figure 39.93 Aggressive NK-Cell Leukemia. A, Bone marrow smear from a patient with aggressive NK-cell leukemia. The lymphoma cells have relatively abundant cytoplasm containing numerous coarse azurophilic granules; the lymphoma cells are distinguished from neutrophil myelocytes by the lack of specific granules. **B**, Marrow biopsy from the patient in **A** showing extensive replacement. The lymphoma cells are relatively uniform in appearance with round nuclei and abundant cytoplasm. (Slides contributed by Dr. John K.C. Chan, Hong Kong.)

Benign Lymphocytic Aggregates

Benign lymphocytic aggregates occur relatively frequently in bone marrow trephine and particle sections. The incidence in biopsy specimens varies from 3% to 47%.[519–521] The reported incidence in autopsy specimens is 26%–62%. The incidence appears to increase with age and is higher in females than males. The aggregates occur in patients with a wide range of disorders, and the number and size in individual specimens vary considerably. Although lesions up to 1000 µm have been reported, the majority of aggregates are relatively small and well circumscribed.[522] Unusually large aggregates may occur in the marrows of patients with diseases related to the immune system, such as AIDS and rheumatoid arthritis. Large and numerous lymphoid aggregates, sometimes with germinal center formation, may be observed in the marrow of patients receiving immunotherapy. These lesions may occasionally be paratrabecular (Fig. 39.94), but paratrabecular aggregates should be viewed with a high suspicion for malignancy, particularly follicular lymphoma. The biologic significance of marrow lymphocytic aggregates in the majority of patients is unknown.[523]

The morphologic distinction between benign lymphocytic aggregates and malignant lymphoma, of small lymphocytes, in marrow biopsies from adults may be very difficult on morphology alone, and usually require immunophenotyping studies. Such studies show a T-cell predominance in most reactive lymphoid aggregates and a clonal B-cell predominance with aberrant CD5 expression in small lymphocytic lymphoma. Although general guidelines for making this distinction have been proposed, it is important to recognize that exceptions to these generalizations occur with distressing frequency.[524,525]

Benign aggregates are usually few in number, well circumscribed, loosely structured, and contain histiocytes and plasma cells and frequently mast cells in addition to lymphocytes. The lymphocytes are usually small with generally round nuclei that have condensed chromatin and inconspicuous or no evident nucleoli. Occasional nuclei may have irregular outlines. Vascular structures are frequently present. Germinal centers are uncommon in lymphocytic lesions in the marrow but when present are usually but not always evidence of a benign process. As previously noted, germinal centers may be observed in marrow lesions of mantle cell lymphoma and splenic marginal zone B-cell lymphoma. A preferential paratrabecular margination of a lymphoid infiltrate, usually associated with reticulin fibrosis, is evidence for a diagnosis of lymphoma. A random distribution of lymphoid aggregates with an occasional aggregate juxtaposed to a trabecula has no diagnostic specificity, since this pattern may occur with benign or malignant lesions. In occasional cases of follicular lymphoma, the follicular pattern in the lymph node is recapitulated in marrow lesions.

A particularly difficult diagnostic problem is the lymphocytic lesion referred to as polymorphous reactive lymphoid hyperplasia (see Fig. 39.28). These lymphoid aggregates are usually focal, poorly circumscribed, and randomly distributed. The lymphocytes are generally well differentiated; the nuclei of some and sometimes of many of the lymphocytes may be irregular. The infiltrate may be predominantly T-lymphocytes or have associated populations of plasma cells, immunoblasts, eosinophils, endothelial cells, phagocytic histiocytes, and epithelioid histiocytes. This lesion may occur in the marrow in any age group and is frequently associated with immune disorders such as immune cytopenias, collagen vascular disease, and, most notably, AIDS. The aggregates may be very large and in certain instances be virtually indistinguishable from the lesions of PTCL. Lesions of this type in marrow specimens from patients with AIDS are almost invariably reactive. In other instances in which the clinical or other tissue findings are equivocal, immunophenotypic or genotypic studies for clonality may be necessary.

It is important to recognize that benign lymphocytic aggregates may be present in marrow of patients with a prior diagnosis of marrow involvement by lymphoma; lymphoid aggregates in marrow specimens following chemotherapy should be evaluated as critically as those in the initial staging marrow biopsy. Marrow involvement by lymphoma in a patient with no other manifestation of the disease is very uncommon, and the diagnosis in such a situation should be approached with considerable caution and only if supporting immunophenotypic or genotypic evidence of a clonal process is present.

Marrow biopsies containing lymphocytic aggregates from patients treated with rituximab therapy for lymphoma should be carefully evaluated with immunohistochemistry to ascertain if the lymphocytes express the same antigens as the lymphoma cells which were present in the pretreatment specimen. Some loosely structured lesions, both randomly distributed and in paratrabecular locations, may be composed of reactive T cells rather than the B-cell lymphoma; this phenomenon is probably related to the therapeutic effects of the antibody (Fig. 39.95). Because rituximab is directed against CD20, other B-cell markers, such as CD79a and PAX5, are needed to exclude the presence of admixed neoplastic B cells in this setting.[451,526]

The application of antibodies that react with lymphocytes in paraffin-embedded, decalcified specimens often aids in distinguishing benign from malignant lymphocytic aggregates; as noted, this may be particularly critical after chemotherapy or therapy with monoclonal antibodies.[23,28] However, antibodies to B lymphocytes and T lymphocytes do not provide information about clonality. Antibodies to kappa and lambda light chains which may impart evidence of clonality are not sufficiently sensitive in most instances to identify surface immunoglobulins in lymphomas in paraffin-embedded biopsies. Despite this, most reactive marrow lymphocytes are T cells, and detection of an increased B-cell population in the marrow in the absence of germinal centers is usually supportive of B-cell lymphoma. One exception is in the setting of autoimmune disease in which B cells may predominate in reactive lymphoid aggregates. The presence of a mixed reactivity pattern (i.e., lymphocyte populations expressing both T and B surface antigens) in marrow lesions has been found to be more consistent with reactive lesions with the exception of follicular lymphoma which characteristically shows a mix of B and T cells when involving the marrow. A panel of antibodies, including CD10, CD5, CD3, and CD20, has been suggested as useful in distinguishing benign or atypical lymphocytic aggregates in the marrow from lymphoma; most benign aggregates do not express CD10 and CD23. As mentioned, in the setting of anti-CD20 therapy, the addition of other B-cell markers such as CD79a and PAX5 may also be useful. There are exceptions to all generalizations, and caution should be exercised in the interpretation of immunohistochemical studies. Careful analysis of both lymph node and bone marrow specimens with the same panel of antibodies is necessary in evaluating marrow biopsies for lymphoma. Genotypic studies should be performed in those instances in which the marrow findings are indeterminate, and a therapeutic decision is contingent on the presence or absence of marrow involvement. Even with this approach, difficulties in distinguishing benign from malignant lesions persist, especially in the setting of autoimmune disease,[527] and continued observation is the most prudent course in some patients. In cases in which the morphologic and immunophenotypic studies are inconclusive, some authors have suggested the terminology "indeterminate for lymphoma" for staging marrows.[524,528]

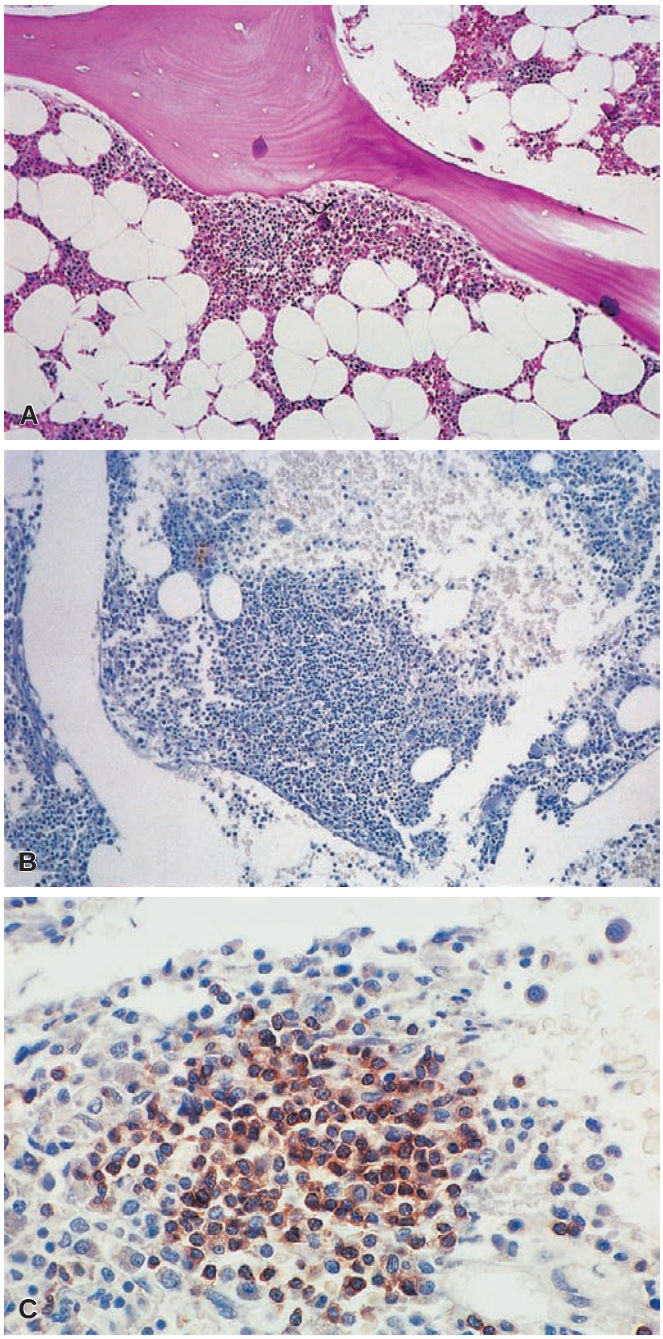

Figure 39.95 Post Rituximab Therapy. A, One of several paratrabecular and nonparatrabecular lymphocytic aggregates in bone marrow biopsy following rituximab therapy. **B**, Same specimen as **A** evaluated with antibody to CD20; the lymphocytes are nonreactive. Similar results were found with antibody to CD79a. **C**, Same specimen as **A** and **B** reacted with antibody to CD3. Most of the lymphocytes are intensely reactive. Similar results were found in other lymphocytic aggregates. (**B** and **C**, Immunoperoxidase.)

Hodgkin Lymphoma

The incidence of marrow involvement in Hodgkin lymphoma varies with the histopathologic type: it is approximately 10% in classical Hodgkin mixed cellularity type and approximately 1% in lymphocyte-predominant Hodgkin and lymphocyte-rich classical Hodgkin disease.[529–531] Nodular sclerosis has an incidence of approximately 3%.[531–533] The overall incidence of bone marrow involvement in patients with stage IV disease is reported to be 32% and varies with the histologic subtype: 3% lymphocyte predominant, 37% nodular sclerosis, 49% mixed cellularity, and 10% unclassified type.[533] The

prognosis for patients with stage IV disease does not appear to be adversely affected by bone marrow involvement.

The lymphocyte depletion type of Hodgkin lymphoma, which has a high incidence of marrow involvement, approximately 50%, is an uncommon form of Hodgkin lymphoma.[534,535] Because the clinical presentation in some patients with lymphocyte depletion–type disease is characterized by little or no peripheral lymphadenopathy, the initial diagnostic specimen may be the bone marrow biopsy. In the vast majority of patients, however, other sites of disease, especially above the diaphragm, are present at the time of marrow involvement by classical Hodgkin lymphoma.

The detection of marrow involvement appears in part to be related to the amount of tissue available for examination. Marrow involvement in most instances results from widely disseminated disease, is significantly associated with B symptoms, bulky disease, involvement of lymph nodes both above and below the diaphragm, and is negatively correlated with a large mediastinal mass.[533] Forty percent to 50% of patients with AIDS who develop Hodgkin lymphoma have marrow involvement; the marrow may be the initial diagnostic specimen and the only site of involvement in this situation.[143]

The histopathologic classification of Hodgkin lymphoma should not be based on examination of involved bone marrow because of different manifestations of the disease in lymph node and bone marrow tissue. Fibrosis is a common finding in Hodgkin lesions in the marrow and is not limited to nodular sclerosis and lymphocyte depletion types.

Definitive histopathologic criteria for the diagnosis of marrow involvement in Hodgkin lymphoma include typical Reed–Sternberg cells in a cellular background characteristic of Hodgkin lymphoma or mononuclear Reed–Sternberg variants in a cellular background typical of Hodgkin lymphoma if typical Reed–Sternberg cells are identified in other specimens (Fig. 39.96).[536–538] The presence of atypical cells lacking the features of Reed–Sternberg cells or mononuclear variants in a characteristic Hodgkin environment in a patient with histopathologically proven disease has historically been considered highly suspicious for involvement; however, if the atypical cells express CD30 and CD15, typical immunophenotypic features of classical Hodgkin lymphoma, the marrow can be considered involved by disease. Foci of fibrosis in the absence of Reed–Sternberg cells or mononuclear variants in a patient with an established diagnosis of Hodgkin lymphoma is not in itself sufficient evidence for a definitive diagnosis of marrow involvement but should be viewed as suspicious. In the latter instance, multiple levels of the biopsy should be examined, and when immunophenotyping studies of atypical cells are not conclusive, repeat biopsies should be performed.

Hodgkin lesions in marrow may be diffuse or focal; the extent of involvement ranges from a single, small lesion to complete replacement of multiple biopsy specimens. Diffuse involvement is found in 70%–80% of positive marrow biopsies; the Hodgkin tissue in these cases replaces the entire area between trabeculae.[539] Focal lesions are variable in size and may be surrounded by normal hematopoietic tissue or scattered in a hypocellular background (Fig. 39.97); the latter pattern is more frequent following chemotherapy. The focal lesions tend to be polycellular, with a predominant population of small lymphocytes with admixed neutrophils, eosinophils, plasma cells, histiocytes, Reed–Sternberg cells, and mononuclear variants. The diffuse lesions may manifest in several patterns. In the majority of cases, the Hodgkin tissue is hypercellular with a population of cells characteristic of mixed cellularity Hodgkin lymphoma in the lymph node (see Fig. 39.96). In some patients the marrow shows extensive hypocellularity characterized by a generally loose, sparsely cellular connective tissue with scattered, variably sized hypercellular areas containing lymphocytes, histiocytes, Reed–Sternberg cells, and mononuclear variants. Areas of necrosis may be present and are more common in post-therapy specimens than at initial diagnosis (Fig. 39.98). Varying degrees of fibrosis may be present. In some cases, entire biopsy specimens show replacement by dense fibrous connective tissue with few identifiable lymphocytes or histiocytes (Fig. 39.99). In others, scattered islands of cells are interspersed among the collagen fibers: some of these cells show features suggestive of Hodgkin cells; others are too distorted for accurate identification. In some instances the Hodgkin lesions are very hypercellular with a predominant population of Reed–Sternberg cells or mononuclear variants. Various combinations of these patterns may be present in the same biopsy specimen or in different specimens from the same patient. Necrosis and hypocellularity are more common in marrow from treated patients than untreated patients. In marrow involvement with lymphocyte depletion Hodgkin lymphoma, a typical consolidated lesion characterized by an inflammatory cellular infiltrate accompanied by a distinct amorphous deposition of eosinophilic background substance and Reed–Sternberg cells has been described.[534]

The presence of Reed–Sternberg cells or mononuclear variants is of critical importance to the recognition of Hodgkin lymphoma in marrow, and a definitive primary diagnosis should not be established without their identification in the appropriate cellular milieu.

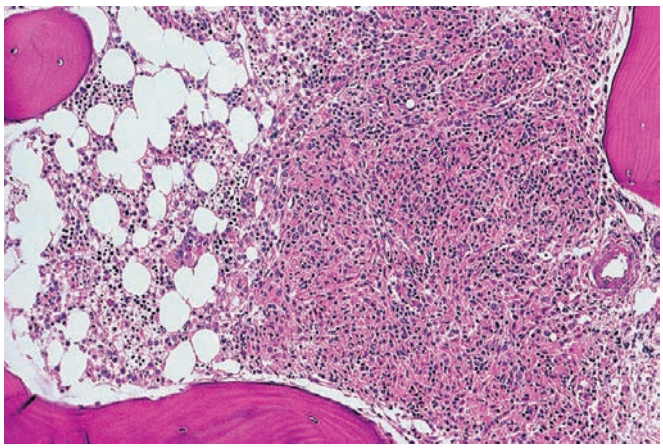

Figure 39.96 Bone marrow biopsy from a patient with mixed cellularity Hodgkin lymphoma. There is extensive involvement in this area of the biopsy.

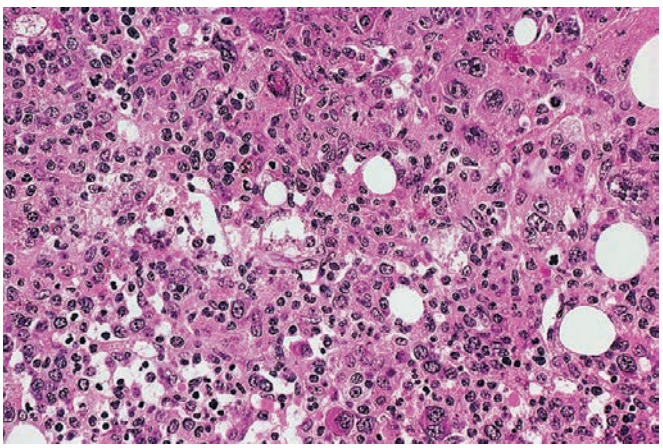

Figure 39.97 Marrow With Several Scattered Foci of Hodgkin Lymphoma. The lesions, which contain several Reed–Sternberg cells, are indistinctly demarcated from normal marrow.

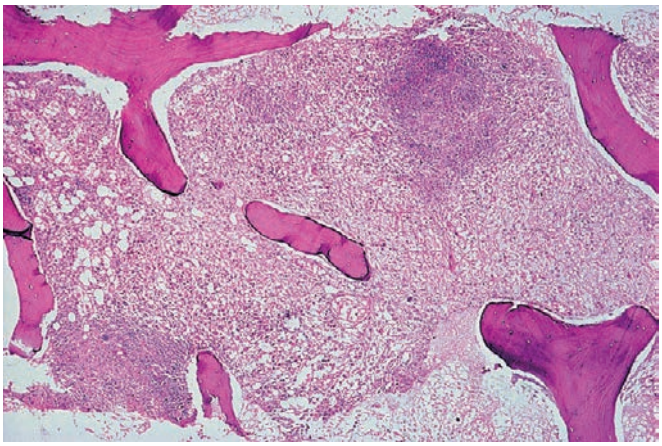

Figure 39.98 Two foci of Hodgkin lymphoma in a large area of necrotic debris in a post-treatment marrow specimen.

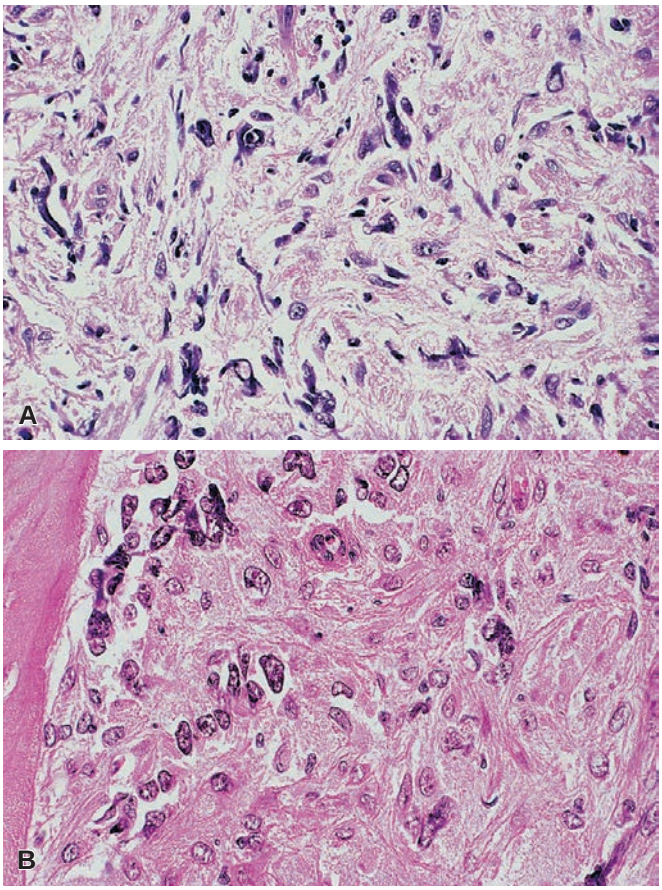

Figure 39.99 **A**, Marrow biopsy from a patient with Hodgkin lymphoma. The marrow space is completely replaced by dense fibrous connective tissue. Numerous vascular structures and small foci of distorted cells resembling Reed–Sternberg cells and mononuclear variants are present. **B**, Same specimen as **A** showing several focal collections of cells that resemble distorted Reed–Sternberg cells and mononuclear variants.

Several serial sections of the marrow biopsies may have to be examined before satisfactory Reed–Sternberg cells or mononuclear variants are detected. It is important not to misinterpret megakaryocytes as forms of Reed–Sternberg cells; this problem can be avoided by strict adherence to the principle of identifying Reed–Sternberg cells or variants only in the appropriate cellular background and by the use of immunohistochemical studies. Reed–Sternberg-like cells may be observed in marrow specimens with involvement by follicular lymphoma, PTCL, and anaplastic large cell lymphoma (see Fig. 39.79); the clinical history, membrane surface marker studies, and characteristic tissue changes of Hodgkin lymphoma should aid in distinguishing these disorders.[452] In classical Hodgkin lymphoma, the Reed–Sternberg cells and mononuclear variants express CD30 and usually express CD15. The cells also show weak nuclear expression of PAX5, may show weak and variable expression of CD20, and are CD45 and CD3 negative. Approximately 40% of cases are EBV positive by in situ hybridization. In some instances, in which a T-cell lymphoma such as anaplastic large cell lymphoma is in the differential diagnosis, genotypic studies for T-cell clonality may be necessary.

Although marrow involvement by lymphocyte-predominant Hodgkin lymphoma is rare, when present it shows features more similar to histiocyte and T cell–rich large B-cell lymphoma than classical Hodgkin lymphoma, with large atypical cells admixed with T cells and histiocytes, and usually lacking a prominent eosinophil component.[530,540] In contrast to classical Hodgkin lymphoma, the neoplastic cells of lymphocyte-predominant Hodgkin lymphoma are strongly and uniformly CD20 positive and usually CD30 negative.[529,531]

Uninvolved areas of marrow in specimens with involvement by Hodgkin lymphoma may be hypercellular, normocellular, or hypocellular.[541] Nonspecific alterations, including stromal damage, inflammatory cell infiltration, and disturbed hematopoiesis, may be present.[542] These alterations may occur singly or in combination.

Similar to spleen, liver, and lymph nodes, benign granulomatous lesions may be present in bone marrow sections in patients with Hodgkin lymphoma.[539] The marrow is the least likely organ in this group to contain the granulomas, but their presence may lead to diagnostic difficulty. The lack of typical Reed–Sternberg cells or mononuclear variants is an important feature in distinguishing these lesions from Hodgkin lymphoma. The presence of granulomas does not constitute evidence of involvement. Granulomas in post-therapy patients should always be evaluated for the possibility of an infectious agent.[539,543] Benign lymphocytic aggregates may also be present.

Rarely, a patient whose disease is being staged for marrow involvement by Hodgkin lymphoma has a concurrent parvovirus B19 infection. The presence of very large erythroid precursors in the smears or sections may result in confusion with Reed–Sternberg cells and consideration of marrow Hodgkin lymphoma (see Fig. 39.22B). The lack of a characteristic cellular environment and the usually marked erythroid hypoplasia are strong evidence of parvovirus B19 infection. Serologic or molecular studies for parvovirus B19 should be performed in suspected cases.

Histiocytic Disorders

Malignant Histiocytosis

Malignant histiocytosis is a rare disease that uncommonly involves marrow. As a result, any comments about the characteristics of these lesions in the marrow are based on limited observations. The histiocytic and dendritic cell neoplasms arise from phagocytic and accessory cells which have major roles in the processing and presentation of antigens to lymphocytes.[544–546] The changing concept of "malignant histiocytosis," and the recognition that many of the lesions previously classified under this term represent other disorders, mean that prior descriptions of marrow involvement in malignant histiocytosis may no longer be valid.[313,547,548,549–553] Generalizations about patterns of marrow involvement must be qualified because of the rare occurrence of the disorder and the even more rare

occurrence of marrow involvement. If the morphologic characteristics of a marrow lesion suggest a histiocytic disorder, appropriate immunohistochemical, cytogenetic, and molecular studies should be performed. The diagnosis is essentially one of exclusion. Other poorly differentiated neoplasms of the hematopoietic system may have morphologic features that have been associated with malignant histiocytosis.[553] Cell marker studies for B- and T-cell lineage should be performed to exclude poorly differentiated lymphomas, but true histiocytic neoplasms arising from, and clonally related to, B-cell lymphomas are now well described.[554] Poorly differentiated carcinomas and plasmablastic tumors must also be excluded. Since the macrophage is derived from the monocyte system it may be difficult in some instances to distinguish between what is termed malignant histiocytosis and what is monoblastic/monocytic leukemia. The use of one or other of these terms may be arbitrary based on the constellation of clinical and morphologic findings.

In marrow biopsies, the infiltration by malignant histiocytes may be focal or diffuse (see Fig. 39.102). Bone marrow involvement may be extremely difficult to recognize in sections that contain only scattered malignant cells. In smear preparations, the cells occur singly or in small groups scattered among the normal hematopoietic cells or, because of their large size, at the edges of the smears. The malignant histiocytes vary in size; cells up to 40–50 µm or larger may be found. The cytoplasm is usually abundant, with evidence of pseudopod formation and fragmentation; it is variably basophilic, occasionally with numerous small, sharply defined vacuoles in some cells. Very small azurophilic granules may be present in the cytoplasm of some of the larger cells. Occasional malignant histiocytes show evidence of phagocytosis; prominent hemophagocytosis is a relatively uncommon finding in unequivocally malignant-appearing cells. The nucleus may be round or contorted; the larger cells generally have more contorted nuclei. The chromatin is coarsely reticular. Nucleoli may be very prominent or inconspicuous. Stains for nonspecific esterase and acid phosphatase are positive. The demonstration of nonspecific esterase reactivity in poorly differentiated cells, however, is not sufficient to establish a diagnosis of malignant histiocytosis since this enzyme may be present in other poorly differentiated malignant cells. The malignant histiocyte should be reactive with antibodies to lysozyme and CD68 (KP1 and PGM1) and nonreactive to antibodies to T and B lymphocytes (Fig. 39.100B). There may be some degree of reactivity with antibody to S100 protein. The proliferation of the malignant histiocytes may be accompanied by a proliferation of benign-appearing histiocytes with abundant cytoplasm and prominent hemophagocytosis; this probably results from cytokine stimulation related to the malignant cell proliferation.

Cytogenetic studies may be helpful in identifying a clonal abnormality in the malignant cells, for example, the presence of an abnormality involving chromosome 11 at band q23.3 characteristic of monoblastic leukemia.

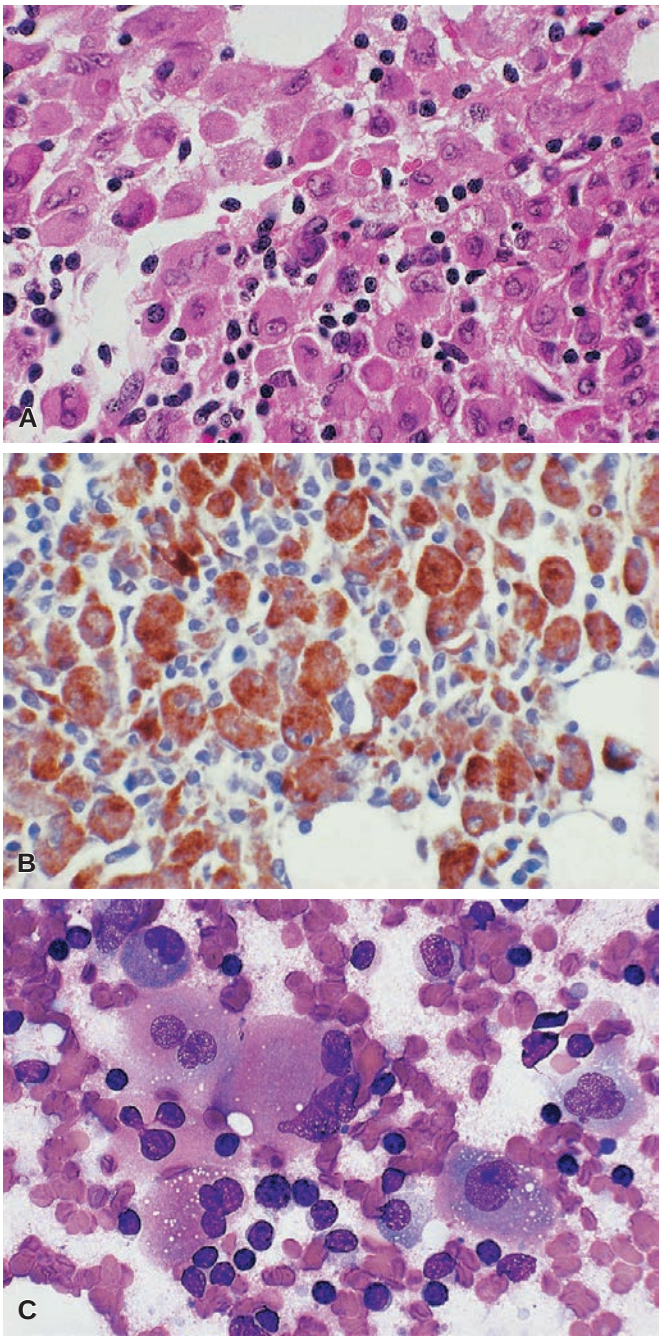

Figure 39.100 **A**, Marrow biopsy from an adult woman with marrow involvement by a histiocytic proliferation with an associated clonal t(9;11)(p21.3;q23.3) cytogenetic abnormality. The histiocytes have a somewhat bland appearance with abundant cytoplasm. **B**, The biopsy in **A** reacted with antibody to CD68 (KP1). **C**, Smear from the specimen in **A** and **B** showing several histiocytes, most of which have lobulated nuclei and abundant cytoplasm. (**B**, Immunoperoxidase.)

Hemophagocytic Syndromes

The hemophagocytic syndromes are a group of disorders with the unifying morphologic features of a proliferation of phagocytic histiocytes that may be present in all hematopoietic organs. These processes usually have systemic manifestations and may be accompanied by a fulminant clinical course and high mortality.

The hemophagocytic syndromes occur both as genetic and acquired disorders.[555–558] The genetic disorders include primary (familial) hemophagocytic lymphohistiocytosis (PHLH), which is an autosomal recessive disorder and in which the hemophagocytosis is the only manifestation of the disease, and the immune deficiency syndromes Chédiak–Higashi syndrome, Griscelli syndrome, and X-linked lymphoproliferative syndrome which have additional clinical features. Several genetic abnormalities associated with lymphocyte cytotoxic defects are involved in PHLH: 13%–50% of the patients have mutations in the perforin 1 *(PFR1)* gene, which results in impaired perforin production.[559,560] Mutations of the *UNC13D* gene, which is on chromosome 17q25, occur in 17%–30% of cases and result in impaired granule exocytosis.[555,557,560,561] Recent studies have found numerous other genetic abnormalities associated with PHLH.[546]

The acquired hemophagocytic syndromes occur at all ages. Several agents, including viruses and other infectious organisms, and malignant lymphomas have been implicated as causative factors. The viruses most frequently implicated include EBV, cytomegalovirus, adenovirus, and parvovirus B19.[555,562–575] The syndrome has also been associated with protozoan infections including *Babesia microti* and *Leishmania*.

The macrophage activation syndrome (MAC) is a subtype of the secondary hemophagocytic syndromes which is a complication of systemic inflammatory diseases in children, particularly juvenile rheumatoid arthritis.[576,577] Similar to other types of these syndromes, it appears to be related to hyperactivation and proliferation of T lymphocytes and macrophages.

The hemophagocytic syndromes are an epiphenomenon in which the underlying mechanism appears to be activation of the immune system including NK cells, cytotoxic T lymphocytes, and the monocyte–macrophage system, which then interact. Defective cytotoxic activity on the part of this system leads to sustained high cytotoxic levels, which result in the constellation of the findings in the syndrome.[556,557,564,566,568,570–583]

The hemophagocytic syndromes frequently have an abrupt onset. Evidence of multisystem disease is usually present, particularly in patients with viral infections.[556,569,575] A high percentage of patients have coagulation abnormalities with disseminated intravascular coagulation. Laboratory studies show elevated triglycerides, ferritin, transaminases, and lactate dehydrogenase. The fibrinogen level is decreased. There are usually cytopenias, frequently pancytopenia.

The marrow smears contain numerous histiocytes, many showing evidence of phagocytosis of erythrocytes and precursors, platelets, and granulocytes. There is frequently an accompanying depression of erythroid precursors, granulocyte precursors, or both; megakaryocytes may be normal or increased in number. In biopsy sections, the increased histiocytes are dispersed throughout the interstitium and sinuses; occasional clusters may be present (Fig. 39.101). The evidence of phagocytic activity may be less prominent in sections compared with smear preparations (Fig. 39.102). In addition to the histiocytic proliferation, granulomas may be noted, and areas of cellular necrosis are frequently present. The bone marrow findings may change substantially over a period of days, with fluctuations in the number of granulocyte and erythroid precursors and megakaryocytes. Lymph nodes may show a marked increase in histiocytes in the sinusoidal spaces; evidence of hemophagocytosis may be much less marked than in the bone marrow or there may be marked erythrophagocytosis. The spleen may be markedly enlarged with prominent histiocytic infiltration in the red pulp. Areas of nonsuppurative necrosis have been observed in lymph nodes and spleen.[579]

The mechanism of macrophage activation in the hemophagocytic syndromes is not completely understood but appears to be related to the release of chemokines and cytokines, including macrophage inflammatory protein-1 alpha and interferon gamma.[570] The phenomenon appears to be preceded in some patients by proliferation of activated or neoplastic EBV-infected T lymphocytes that produce tumor necrosis factor alpha (TNF-α).

The EBV or T cell–related hemophagocytic syndromes may be difficult to distinguish morphologically from primary hemophagocytic lymphocytic histiocytosis. The latter disorder appears to be related to mutation of the perforin gene and diminished perforin in cytotoxic T cells and T/NK cells.[559,560] This contrasts with the normal levels of perforin in cytotoxic cells in patients with secondary hemophagocytic syndromes.

The clinicopathologic features of virus-associated hemophagocytic syndrome (VAHS) have been reported in 80% of a group of patients with fatal infectious mononucleosis.[571] The VAHS phase was preceded by features of a viral-like illness. Sequential changes were present in the marrows of these patients; initially there was infiltration by atypical lymphoid cells with areas of necrosis, followed by depletion of normal hematopoietic cells and histiocytic activation with prominent hemophagocytosis; the end stage was marked by marrow aplasia. A similar sequence of histopathologic changes was found in the lymph nodes, spleen, and thymus gland.

Hemophagocytic histiocytosis has been reported as a terminal event in patients with T-cell lymphomas and T/NK-cell lymphomas; uncommonly it is associated with B-cell lymphoma.[564,566,581] The pathologic findings are similar to those in VAHS. The production of macrophage-activating cytokines by the malignant cells has been suggested as a causative mechanism of the histiocyte proliferation. The hemophagocytic syndrome may be associated with other types of lymphoma, including ALK-positive anaplastic large cell lymphoma.[562]

The distinction between the hemophagocytic syndrome and "malignant histiocytosis" may be difficult because of similarities in clinical presentation.[584,585,568,569] The cells in the hemophagocytic syndrome are morphologically distinct; they have a low nucleocytoplasmic ratio and abundant lightly staining cytoplasm containing large vacuoles of varying sizes and phagocytosed cells or cellular

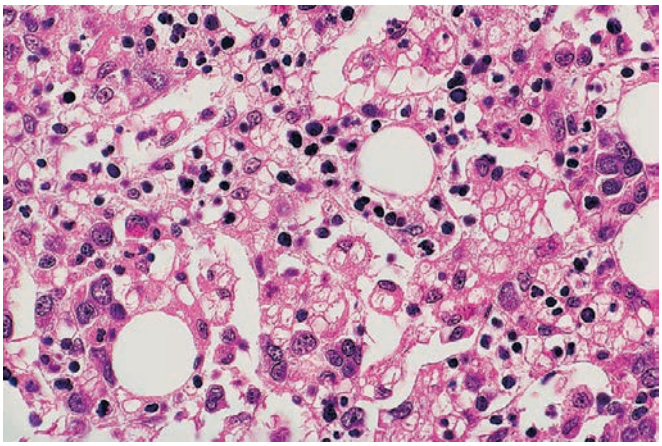

Figure 39.101 Marrow biopsy from an adult man who developed hemophagocytic syndrome associated with bacterial infection. Numerous histiocytes, some showing hemophagocytosis, are present in sinusoids and interstitium.

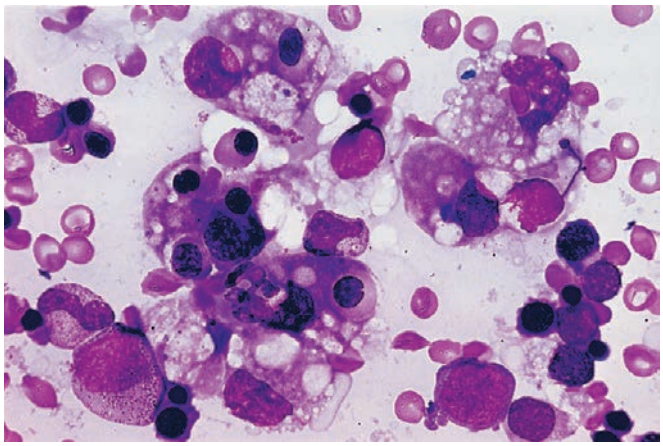

Figure 39.102 Bone marrow smear from a lupus erythematosus patient with virus-associated hemophagocytic syndrome. Numerous macrophages with ingested red blood cells and erythroblasts are present. (Wright–Giemsa.)

products. Nucleoli, when present, are not prominent, and mitotic figures are rare. Although the hemophagocytic histiocyte proliferation may coexist with "malignant histiocytosis" or a malignant lymphoma, there is no evidence of a transition from the obviously malignant cells to the benign histiocytes.

Serologic studies for viral infection in patients with the picture of a hemophagocytic syndrome may not be reliable because impaired immune function may preclude a detectable antibody response. In these cases, in situ hybridization studies may be useful in documenting an EBV or parvovirus B19 infection.[565,568,569] In addition to studies for a viral infection, it is important that patients with a hemophagocytic process be carefully evaluated for immune suppression and non-Hodgkin lymphoma. Patients with a hemophagocytic syndrome with both an EBV infection and a malignant lymphoproliferative lesion may be observed.

Treatment for both primary and secondary hemophagocytic syndromes is to control hyperinflammation, which may include etoposide therapy.[586] Hematopoietic cell transplantation, however, is considered the only possible cure for PHLH.[587]

Langerhans Cell Histiocytosis

Marrow involvement in Langerhans cell histiocytosis (histiocytosis X) is uncommon and usually associated with the multisystem multifocal form of the disease (Letterer–Siwe disease).[588] The marrow lesions may be focal and small and barely perceptible or confluent and extensive replacing large areas of a biopsy (Fig. 39.103).[589] The small lesions may have a granulomatous appearance. Similar to the lesions in other organs, the Langerhans cells have a low nucleocytoplasmic ratio; the nuclei are grooved, folded, or lobulated with dispersed chromatin and inconspicuous nucleoli. Hemosiderin and lipofuscin-like granules may be present in the cytoplasm. Mitotic activity is variable. The lesions may be relatively monocellular or polycellular with admixed phagocytic histiocytes, multinucleate giant cells, lymphocytes, plasma cells, eosinophils, and neutrophils. Stains for reticulin show an increased number of reticulin fibers. Immunohistochemical reactions for S100 protein, langerin, and CD1a highlight the Langerhans cell infiltrate. However, with some fixatives and decalcifying agents, the reaction with antibody to CD1a may be suboptimal in bone marrow biopsies. The cells are variably reactive for CD68 (KP1), HLA-DR, CD45, lysozyme, and nonspecific esterase.[588] In smear preparations and touch imprints, the Langerhans cell has abundant cytoplasm, which frequently contains particulate green–blue debris (see Fig. 39.103C). Characteristic Birbeck granules are observed on ultrastructural examination.

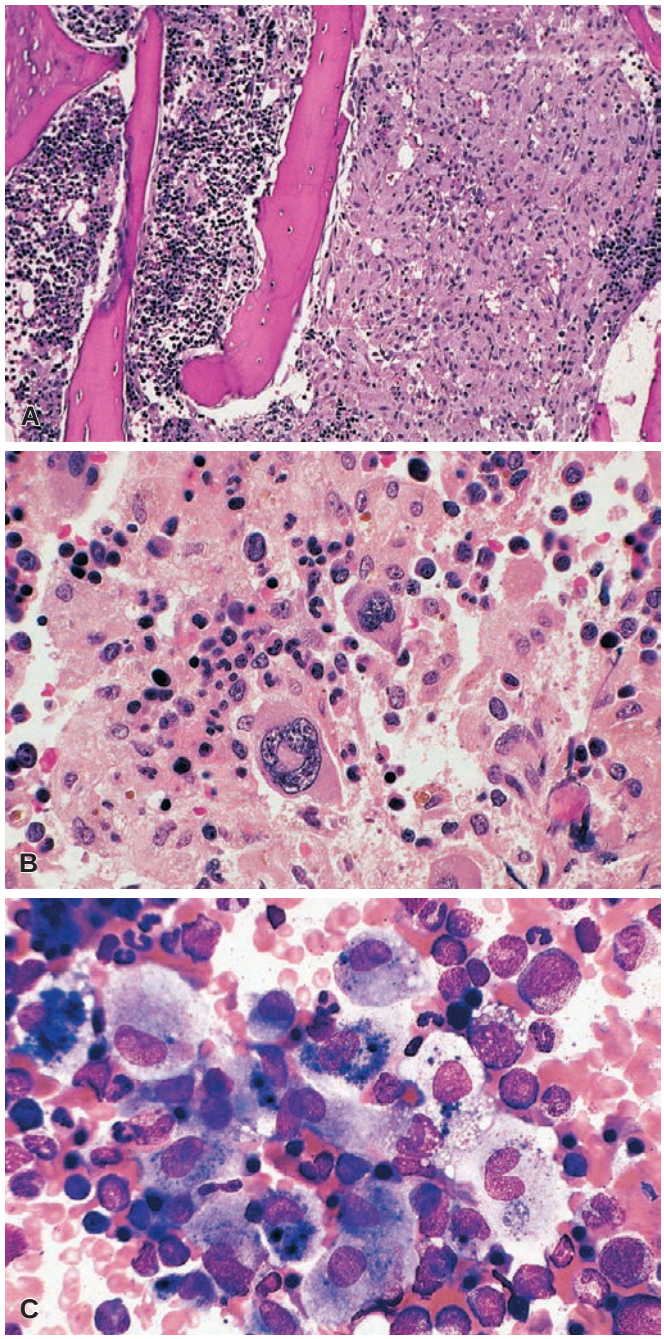

Figure 39.103 **A**, Marrow biopsy from a child with Langerhans cell histiocytosis showing extensive replacement. **B**, High magnification of the lesion in **A** showing giant cells and several histiocytes. Some residual myeloid cells are present. **C**, Bone marrow smear from the case illustrated in **A** and **B**. The Langerhans cells are very large with abundant cytoplasm; several histiocytes contain nonspecific debris and occasionally red blood cells.

Plasma Cell Dyscrasias

The plasma cell dyscrasias are proliferations of immunosecretory cells generally associated with perturbation of serum immunoglobulins. This group of diseases includes the plasma cell proliferations and lymphoplasmacytic lymphoma, although the latter is included as a mature B-cell lymphoma in the WHO classification.

The prototype disorder for this group of diseases is plasma cell myeloma (PCM), of which the clinical syndrome is multiple myeloma. Monoclonal gammopathy of undetermined significance (MGUS) is viewed as a precursor lesion.

The criteria for the diagnosis of symptomatic and asymptomatic PCM are listed in Box 39.11.[590]

Plasma Cell Myeloma

PCM is a neoplastic proliferation of plasma cells accompanied by the production of a monoclonal immunoglobulin detectable in the serum, urine, or both.[590–592] There are several clinical variants, including asymptomatic or smoldering myeloma, nonsecretory myeloma, and plasma cell leukemia. The peak incidence is in the seventh decade; the disease is slightly more frequent in males than females. Osteolytic lesions in the skull, ribs, sternum, vertebrae, and pelvis are present in approximately 70% of cases; in rare cases, x-ray films reveal osteosclerotic lesions.

Box 39.11 2016 World Health Organization diagnostic criteria for plasma cell myeloma

Symptomatic plasma cell myeloma

Clonal bone marrow plasma cells >10%, or biopsy-proven plasmacytoma,

AND

any one or more of the following:

- End-organ damage attributable to the plasma cell proliferation
- Hypercalcemia (serum calcium >0.25 mmol/L [>1 mg/dL] higher than the upper limit of normal or >2.75 mmol/L [>11 mg/dL])
- Renal insufficiency (creatine clearance <40 mL per minute or serum creatinine >177 μmol/L [>2 mg/dL])
- Anemia (hemoglobin value of >20 g/L below the lower limit of normal or a hemoglobin value <100 g/L)
- Bone lesions (one or more osteolytic lesions on skeletal radiology, CT or PET-CT)

AND

any one or more of the following:

- Clonal marrow plasma cell percentage >60%
- Involved:uninvolved serum free light chain ratio >100
- >1 focal lesions on MRI studies

Asymptomatic (smoldering) myeloma (both required)

- Serum M-protein (IgG or IgA) >30 g/L, or urine M-protein >500 mg per 24 hours, and/or clonal marrow plasma cells of 10%–60%, and
- Absence of myeloma-defining events or amyloidosis

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

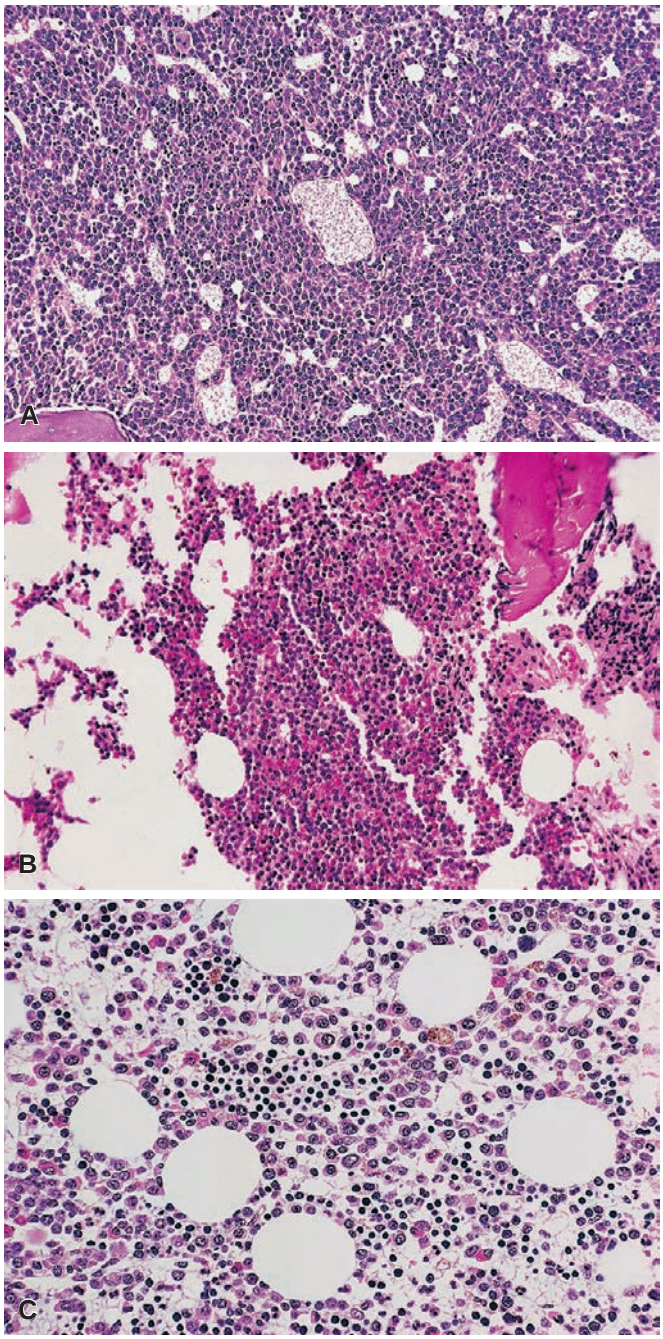

Figure 39.104 **A**, Marrow biopsy from a patient with plasma cell myeloma with extensive diffuse replacement by myeloma cells. **B**, Marrow biopsy with a large focus of myeloma cells. **C**, Marrow biopsy showing essentially normal marrow architecture and interstitial infiltration by myeloma cells.

Marrow involvement in myeloma may be patchy, and the percentage of plasma cells may vary in aspirates and biopsies from different sites. In trephine sections, the distribution of plasma cells may be focal, interstitial, diffuse, or a combination of these patterns (Fig. 39.104).[593–596] There is variability in the appearance of the plasma cells in different cases from very immature plasma cells with a blast-like appearance to pleomorphic cells to mature-appearing plasma cells (Fig. 39.105).[597–599] Nucleoli may be very prominent in some of the more immature types, and binucleate cells resembling Reed–Sternberg cells may be found. Nuclear and cytoplasmic inclusions of varying types may be noted; these are usually related to immunoglobulin production (Fig. 39.106). The marrow in approximately 10%–20% of cases shows associated fibrosis (Fig. 39.107).[600,601]

Several approaches to the staging of myeloma have been introduced: these have included the correlation of myeloma cell mass with presenting laboratory findings, including hemoglobin, monoclonal immunoglobulin, and calcium levels and the presence of osteolytic bone lesions.[602–606] The serum β_2-microglobulin level and the plasma cell labeling index have been found to be significant prognostic factors.[599,607–609] β_2-Microglobulin levels above 3.5 ng/μL and plasma cell labeling index greater than 0.4% are associated with a shorter survival than β_2-microglobulin levels less than 1 ng/μL and labeling index of 0.[608–611]

The occurrence of genetic abnormalities detected by interphase FISH has been reported in up to 90% of patients with PCM. The most frequent abnormalities are del(13q14), hyperdiploidy, t(11;14), t(4;14), *MYC* translocations, and del(17p13). del(13q14) is frequently associated with t(4;14) or del(17p13).[612–616] The most frequent translocations involve 14q32 and occur in 55%–70% of cases. The five major translocations involving 14q32 are t(4;11), t(4;14), t(14;16), t(14;14), and t(14;20); combined these translocations occur in approximately 40% of cases.[590,612,617] t(4;14), t(14;16), and t(14;20) have been associated with poor response to conventional induction therapy and short overall median survival.[617] del(17p13) has also been associated with a poor prognosis. The prognosis of cases with monosomy 13 or del(13q14) with concurrent t(4;14) or del(17p13) appears to be dictated by the non-13 abnormality. In a large multi-institutional study, the most important predictive genetic factors for survival were t(4;14) and del(17p13) combined with the serum β_2-microglobulin level. The combination of one of these genetic abnormalities and an elevated β_2-microglobulin level was an adverse predictive factor.[618]

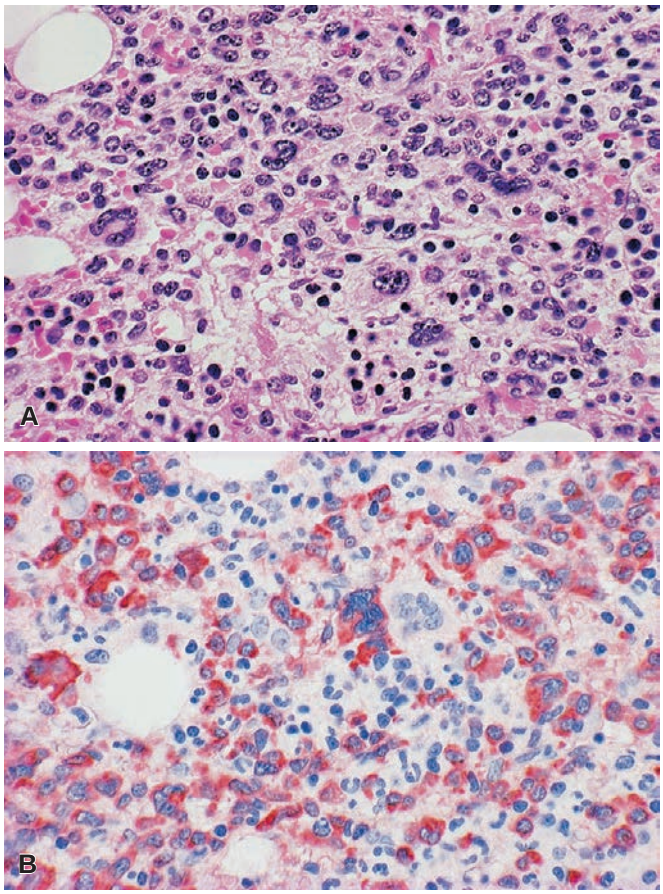

Figure 39.105 **A**, Marrow from a patient with anaplastic myeloma; many of the plasma cells are large with lobulated nuclei. **B**, Specimen in **A** reacted with antibody to lambda light chains. The plasma cells show intense cytoplasmic reactivity. Numerous nonreactive residual myeloid cells are present. (**B**, Immunoperoxidase.)

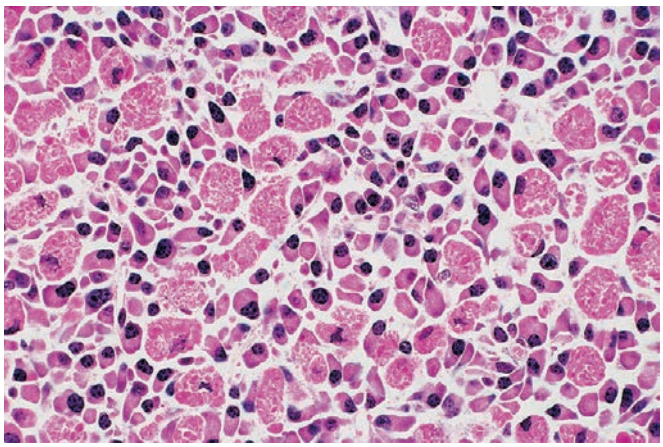

Figure 39.106 Marrow biopsy from a 63-year-old patient with plasma cell myeloma with hypogammaglobulinemia and kappa light chain Bence Jones proteinuria. The cytoplasm of myeloma cells is distended by numerous, frequently confluent eosinophilic inclusions.

Similar to mantle cell lymphoma with t(11;14)(q13;q32), the nuclei of the myeloma cells in patients with this translocation are cyclin D1 positive.[619,620]

Histopathologic staging of myeloma in bone marrow biopsies based on cytologic features of the myeloma cells and the degree of plasma cell infiltration has been shown to have prognostic significance.[590] The more mature type of PCM, plasmacytic, and less than 20% marrow replacement are favorable prognostic factors. The more immature or poorly differentiated the myeloma cells, that is, plasmablastic, and the more extensive the marrow involvement (>50% replacement), the more unfavorable the prognosis. An anaplastic evolution of myeloma may occur, and some of these cases have the histopathologic features of immunoblastic lymphoma.[621] Studies comparing anaplastic myeloma with B-immunoblastic lymphoma have demonstrated clinical and immunologic differences.[622,623] The plasma cells in anaplastic myeloma are usually of the IgG or IgA heavy chain class in contrast to B-immunoblastic lymphoma, in which the cells are IgM. The cells in immunoblastic lymphoma usually express pan-B-cell antigens; the plasma cells in approximately 80% of cases of myeloma do not express pan-B-cell antigens. Exceptions to these generalizations occur. All clinical and laboratory findings should be considered. Histopathologic staging of myeloma in the marrow, using an approach similar to that used for CLL, has shown good correlation between pattern of marrow involvement and clinical stage; a diffuse pattern of involvement is usually associated with a more advanced clinical stage.[596] In some patients, the pattern of marrow involvement may be somewhat inconsistent from biopsy to biopsy, and focal involvement may be associated with an advanced clinical stage. Immunohistologic studies on paraffin-embedded biopsy specimens, utilizing antibodies to CD38 and CD138, are very useful in identifying myeloma cells and detecting extent of marrow involvement.[33,624–626] Anti-kappa and anti-lambda antibodies are used for detection and determining monoclonality. Immunohistochemistry is particularly helpful following chemotherapy and hematopoietic cell transplant for detecting residual disease.

As noted, the myeloma cells in patients with an associated t(11;14)(q13;q32) are usually cyclin D1 positive; a substantial number of these cases are reported as having lymphoplasmacytoid morphology and extensive marrow infiltration.[619,620]

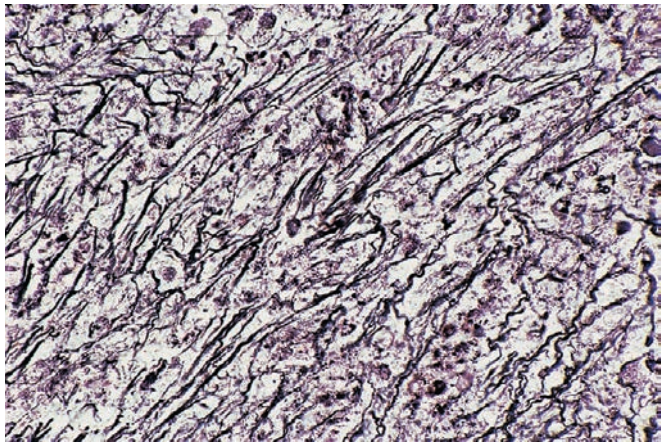

Figure 39.107 Marrow biopsy from a patient with plasma cell myeloma and marked reticulin fibrosis.

Nonsecretory Myeloma

Approximately 3% of patients with PCM present with the clinical, radiographic, and histopathologic features of multiple myeloma but lack evidence of monoclonal immunoglobulin production in the serum or urine. These cases have been referred to as "nonsecretory" myeloma.[627,628] Considerable caution should be exercised in the use of this term, since striking reactive plasmacytosis may be observed with nonmalignant conditions, including liver disease, connective

tissue disorders, chronic granulomatous disorders, hypersensitivity states, and drug-related agranulocytosis.[629] When a nonsecretory myeloma is suspected, the monoclonal nature of the proliferating plasma cells should be confirmed by immunoperoxidase or immunofluorescent techniques that will demonstrate kappa or lambda light chain restriction.[33,605,626] An increase in reactive plasma cells will be characterized by a relatively balanced population of kappa- and lambda-containing cells.

Asymptomatic (Smoldering) Plasma Cell Myeloma

Asymptomatic and smoldering myeloma are the terms used for cases of PCM in which the criteria for myeloma are present but there is no related organ or tissue impairment, that is, no hypercalcemia, renal insufficiency, anemia, or bone lesions (so-called CRAB features).[590,592,630] Approximately 8% of patients presenting with myeloma are of this type. The majority of these cases have between 10% and 20% plasma cells in the marrow, but some have up to 60%, and there is no morphologic cutoff to distinguish smoldering from symptomatic myeloma when plasma cells are below 60% of marrow cells. The cumulative probability of progression to symptomatic myeloma is 10% per year for the first 5 years following diagnosis and approximately 1% per year for the next 10 years.

Plasma Cell Leukemia

The term plasma cell leukemia is applied to those processes in which a patient presents with a plasma cell proliferation in the blood; the plasma cells exceed 20% of the blood leukocytes, or the absolute plasma cell count exceeds 20×10^9/L (Fig. 39.108).[590,631–633] The term should be reserved for cases with this finding at initial presentation. In contrast to cases of PCM presenting with detectable monoclonal immunoglobulin production, usually of IgG or IgA type, cases of plasma cell leukemia frequently present with a higher incidence of light chain disease, IgD or IgE paraprotein than the other forms of myeloma.[590,634] The marrow in plasma cell leukemia usually shows diffuse and extensive replacement of normal hematopoietic cells by the plasma cells. In some cases, the myeloma cells have a lymphoid appearance. Patients with plasma cell leukemia have a higher incidence of organomegaly than those with other forms of myeloma, and the disease is usually associated with an unfavorable prognosis with a higher incidence of unfavorable cytogenetic profiles than other patients with PCM.[635,636] Osteolytic lesions and bone pain are less frequent than other forms of myeloma.

Multiple myeloma or amyloidosis may occur in patients with the adult Fanconi syndrome; the renal abnormalities may precede the overt manifestations of the plasma cell dyscrasia by several years. Bence Jones proteinuria of kappa light chain type is a common finding. A high percentage of the patients with this variant of myeloma manifest crystalline inclusions in the cytoplasm of the proliferating plasma cells and renal tubular cells.[637]

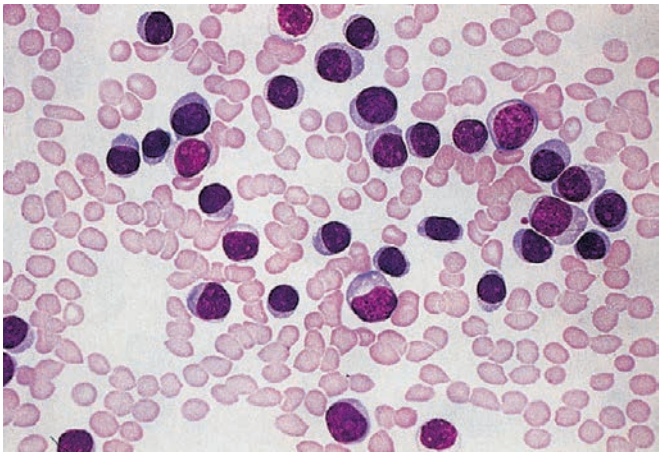

Figure 39.108 Blood smear from a 47-year-old woman with leukocytosis of 24.0×10^9/L and 90% plasma cells. Many of the plasma cells have "lymphoid" features. There was a serum IgG kappa monoclonal protein. (Wright–Giemsa.) (Reproduced from Brunning RD, McKenna RW. Tumors of the Hematopoietic System. Atlas of Tumor Pathology, series 3, fascicle 9. Washington, DC: Armed Forces Institute of Pathology; 1994.)

Osteosclerotic Myeloma and POEMS (Polyneuropathy, Organomegaly, Endocrinopathy, Monoclonal Gammopathy, and Skin Changes) Syndrome

Osteosclerotic myeloma is a form of plasma cell dyscrasia characterized by sclerotic bone lesions and progressive demyelinating polyneuropathy.[590,638–642] The bone marrow aspirate usually contains less than 10% plasma cells. The plasma cell proliferation is usually evident as a plasmacytoma in the sclerotic lesions or in lymph nodes (Fig. 39.109A,B). The marrow from areas uninvolved by the sclerotic process may show typical myeloma cell infiltration, or commonly show lymphoid aggregates surrounded by lambda monotypic plasma cells.[643] The megakaryocytes in the noninvolved areas may be increased and large with hyperlobulated nuclei, which may incorrectly suggest a MPN (see Fig. 39.109C). The involved lymph nodes may show angiofollicular hyperplasia with a parafollicular infiltration of monoclonal plasma cells, the plasma cell variant of Castleman disease.[638] A high percentage of patients with osteosclerotic myeloma have multiorgan involvement, including polyneuropathy, organomegaly, endocrinopathy, and skin changes, the so-called POEMS syndrome.[590,638–642,644–646] Approximately 75% of patients have a thrombocytosis. Polycythemia and leukocytosis are present in about one-third of cases. There is usually a low level of monoclonal protein of IgG or IgA class, with a predominance of lambda light chain type.

The median age of onset is 51 years compared with 64 years for typical myeloma; median survival is 14.7 years, in contrast to 3–4 years for typical myeloma. The disease appears to be more common in Japan than in the United States or Europe.

An association of giant lymph node hyperplasia with osteoblastic bone lesions and the POEMS syndrome has been reported.[638,644]

The recently described telangiectasias, elevated erythropoietin level and erythrocytosis, monoclonal gammopathy, perinephric fluid collections, and intrapulmonary shunting (TEMPI) syndrome is related to POEMS syndrome and characteristically shows an erythroid hyperplasia in the marrow accompanied by monotypic plasma cells.[647]

Plasmacytoma

A solitary plasmacytoma, in contrast to the disseminated proliferation of plasma cells in multiple myeloma, is a single focus of plasma cells occurring in either bone or soft tissue.[33,590,623,648–660] Solitary plasmacytomas are more frequent in males than females and have a peak incidence in the sixth decade, slightly earlier than multiple myeloma. Plasmacytomas are generally divided into two broad groups based on location: plasmacytoma of bone and extramedullary or soft tissue plasmacytoma. The recommended diagnostic criteria for solitary plasmacytoma of bone are shown in Box 39.12.[651]

Evidence for different biologic behavior of these two types has been reported: plasmacytoma of bone has been reported to have a greater predilection to progress to multiple myeloma than soft tissue

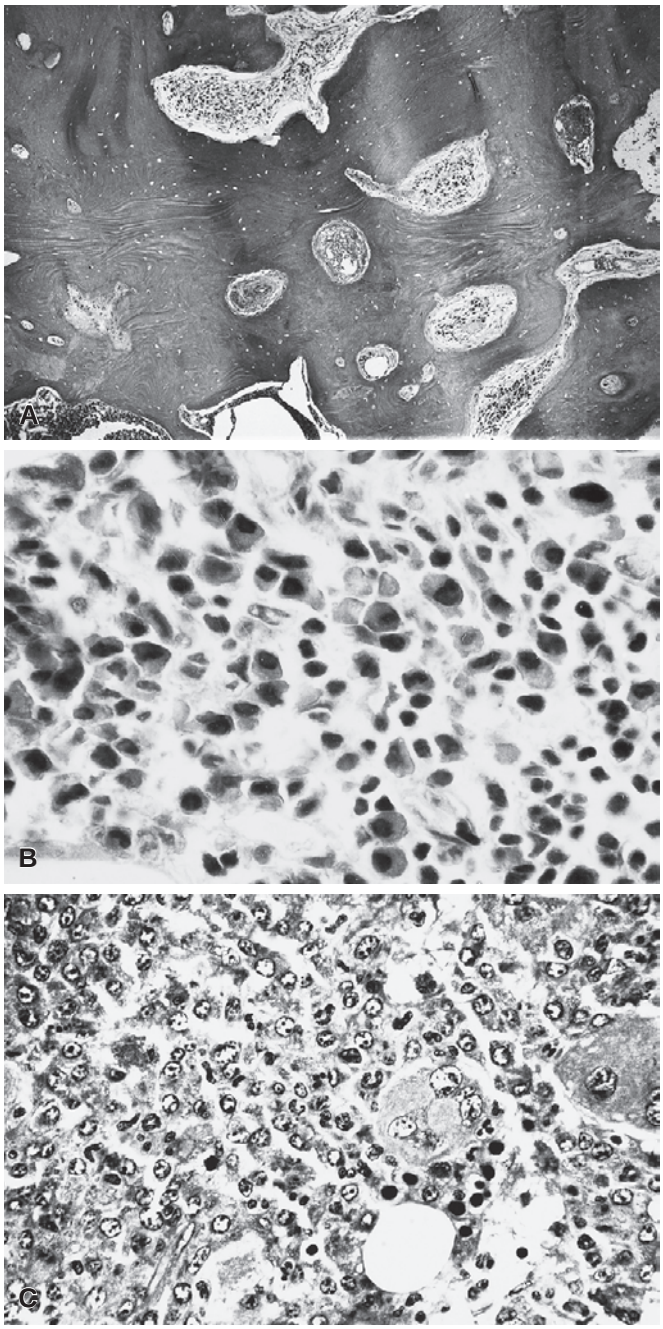

Figure 39.109 **A**, An osteosclerotic bone lesion from a patient with osteosclerotic myeloma. **B**, High magnification of the marrow in the specimen in **A**. This area shows a large number of plasma cells that were lambda light chain restricted on immunohistochemical study. **C**, Marrow biopsy from a nonsclerotic area from a patient with osteosclerotic myeloma with POEMS syndrome. There was a thrombocytosis. The marrow in this area shows an infiltration by immature plasma cells. There was also an increase in large megakaryocytes, two of which are at right.

plasmacytoma. Other studies have shown no significant difference between these two locations and the incidence of evolution to myeloma.[655] The solitary plasmacytoma of bone may occur in both flat and long bones; the most common site is the axial skeleton, particularly a vertebra.[590,649,650,652,654,655] The thoracic vertebrae are more frequently involved than the cervical or lumbar vertebrae. Soft tissue extension from bone lesions may occur. The majority of

Box 39.12 Criteria for diagnosis of solitary plasmacytoma

- Biopsy-proven solitary lesion of bone or soft tissue consisting of clonal plasma cells
- Normal random bone marrow biopsy with no evidence of clonal plasma cells[a]
- Normal skeletal survey and MRI or CT except for the solitary lesion
- Absence of end-organ damage attributable to a plasma cell proliferative disorder

[a]A diagnosis of solitary plasmacytoma can be made with minimal bone marrow involvement as long as all other criteria are met and the clonal plasma cells represent <10% of marrow cells on a random biopsy. These small clonal populations are usually identified by flow cytometry.

Data from Arber DA, Orazi A, Hasserjian R, et al. The 2016 revision to the World Health Organization classification of myeloid neoplasms and acute leukemia. *Blood*. 2016;127(20):2391–2405.

plasmacytomas of bone show osteolytic change on radiologic examination, although osteolytic/osteoblastic lesions may occur.[660] The most frequent sites of extramedullary or soft tissue plasmacytomas are the nasal fossa, maxillary sinus, and nasopharynx.[654,655] Extension into adjacent bone tissue may occur, and multiple lesions may be present.

On microscopic examination the plasmacytoma is frequently very vascular with a minimal stromal component and consists of sheets of plasma cells of varying degrees of differentiation (Fig. 39.110).[649] The plasmacytic nature of the proliferating cells is readily recognized in the better-differentiated lesions. In plasmacytomas with a predominant population of more immature cells with a dispersed nuclear chromatin and single prominent nucleolus, there usually is a minor population of more differentiated plasma cells. Amyloid may be present and was noted in 25% of the lesions in one series.[655]

Immunohistochemical study with antibodies to kappa and lambda light chains is an important approach to the evaluation of a suspected plasmacytoma.[33] A kappa or lambda light chain-restricted population confirms a diagnosis of plasmacytoma (see Fig. 39.110B). There is a predominance of IgG heavy chain type in solitary plasmacytoma of bone and IgA heavy chain type in plasmacytomas from the upper respiratory tract.

Patients with an apparent solitary plasmacytoma should be carefully evaluated for the presence of disseminated disease; studies should include bilateral iliac crest bone marrow biopsies, radiologic skeletal survey, MRI of the spine, pelvis, humeri, and femurs, immunoelectrophoretic examination of the serum and urine, and β_2-microglobulin assay. The patient with a solitary plasmacytoma usually has a normal hemoglobin level and no hypercalcemia. The diagnosis of a solitary plasmacytoma should be made only if all studies for disseminated disease are negative.

Approximately 50% of patients with a plasmacytoma have a monoclonal protein in the serum and/or urine; the level almost invariably is less than 20 g/L, and the nonmonoclonal immunoglobulins are normal in contrast to multiple myeloma, in which they are generally decreased. A marked reduction or disappearance of the monoclonal immunoglobulin will usually occur following tumoricidal radiation; the maximum reduction may not occur for several years.[655] Persistence of the monoclonal protein for more than 1 year after radiotherapy of the plasmacytoma has been identified as an adverse prognostic factor.[658]

Approximately 35% of patients with a solitary plasmacytoma who receive treatment, including radiation, chemotherapy, and surgical excision, will eventually develop multiple myeloma; this evolution may occur up to 12 years following initial diagnosis.[655,657] The presence of nuclear immaturity with prominent nucleoli appears

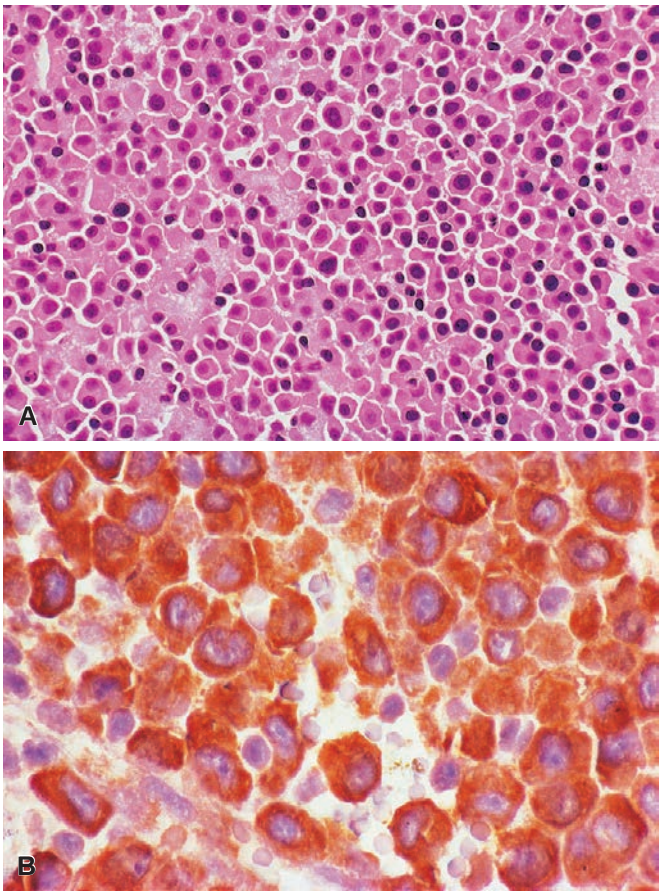

Figure 39.110 **A**, Extramedullary plasmacytoma from the region of the nasopharynx. **B**, Plasmacytoma reacted with antibody to kappa light chains. The plasma cells show intense cytoplasmic reactivity. (**B**, Immunoperoxidase.)

to have some positive predictive value for the development of multiple myeloma. However, the presence of a monoclonal protein in serum, urine, or both does not predict the development of disseminated disease. Plasmacytomas of non-IgG class have been reported to have a higher predilection for systemic spread than IgG-producing tumors. Local recurrence of the lesion is uncommon.

The differential diagnosis of a plasmacytoma includes plasma cell granuloma, plasmacytoid lymphoma, large cell lymphoma of immunoblastic type, and plasmablastic lymphoma. The plasma cell granuloma shows a balanced proliferation of kappa- and lambda-reacting cells on immunohistochemical evaluation. The plasmacytoid lymphoma comprises a mixture of lymphocytes and plasma cells. Some of the large cell lymphomas, particularly the B-immunoblastic lymphoma, may be difficult to distinguish from a plasmacytoma. Immunoblastic lymphoma will usually involve lymph nodes in contrast to plasmacytoma. Immunophenotypic studies of plasmacytoma and immunoblastic lymphoma using a panel of monoclonal antibodies have shown significant immunophenotypic differences between these two processes.[623] The immunoblastic lymphomas have cytoplasmic IgM heavy chain and express pan-B-cell surface antigens such as CD19 and CD20. The plasmacytomas contain IgA or IgG heavy chain and are generally negative for pan-B-surface antigens; approximately 20% of plasmacytomas and myelomas are positive with pan-B-cell antibodies. Plasmablastic lymphomas are usually EBV positive by in situ hybridization, a finding that should not be present in plasmacytoma.

Monoclonal Gammopathy of Undetermined Significance

Approximately 3%–5% of individuals over the age of 50 and 2%–3% of patients over age 65 have a serum monoclonal gammopathy without other evidence of a plasma cell dyscrasia; this constellation of findings is referred to as MGUS.[661–663] The monoclonal protein in these individuals is usually less than 30 g/L, and there is usually no or minimal Bence Jones protein in the urine. There is no associated hypercalcemia, anemia, renal impairment, or radiologic evidence of bone lesions.[664] The bone marrow in these patients may be entirely normal or may manifest a slight increase in mature-appearing plasma cells; the increase is less than 10%. Some of these cases represent incipient myeloma or another type of plasma cell dyscrasia or lymphoproliferative disorder; others continue for several years without undergoing an obvious neoplastic evolution. In a study from the Mayo Clinic, MGUS constituted approximately 50% of the cases of monoclonal gammopathy.[662]

The incidence of MGUS varies in different studies. In one very large contemporary study of the population of Olmsted County in Minnesota in the United States using sensitive laboratory techniques, MGUS was identified in 3.2% of individuals 50 years of age or older and 5.3% of patients 70 years of age or older.[663] The concentration of monoclonal immunoglobulin was less than 10 g/L in 63.5% of individuals and greater than 20 g/L in 4.5%. The incidence of MGUS is higher in black individuals than in whites.

Two important issues must be addressed when contemplating a diagnosis of MGUS: distinction from overt myeloma and probability of progression to an overt plasma cell dyscrasia if a diagnosis of MGUS is made. If the morphologic or clinical findings are suspicious for but not diagnostic of overt myeloma, the patient should be followed with marrow examination and repeat protein electrophoresis at 6-month intervals. An increase in the number of abnormal plasma cells or light chain-restricted plasma cells and an increase in the amount of monoclonal immunoglobulin suggest evolution to a neoplastic process.[664–667] A stable immunoglobulin level and plasma cell percentage are more reflective of MGUS. The plasma cell labeling index as described by Greipp and Kyle has been useful in distinguishing MGUS and smoldering myeloma from overt multiple myeloma.[664] The diagnostic accuracy of a plasma cell labeling index of greater than 0.4 was 83% in distinguishing myeloma from MGUS and smoldering myeloma. The accuracy is increased when combined with the percentage of marrow plasma cells. Approximately 8% of patients with MGUS eventually develop a neoplastic plasma cell dyscrasia or related process; the interval to occurrence ranges up to 29 years, and the rate of progression is approximately 1% per year.[666–668] Factors predicting transformation have varied in different studies: percentage of marrow plasma cells greater than or equal to 5% and paraprotein isotype at initial presentation have been found to have some value. Bone marrow angiogenesis is reported to increase progressively in those patients who manifest progression of MGUS to overt myeloma; median microvessel density correlated with the bone marrow plasma cell labeling index and the percentage of marrow plasma cells.[33] In a large series of patients with MGUS, the only independent risk factors for progression to an overt myeloma or related plasma cell dyscrasia was concentration of the serum monoclonal protein at diagnosis and the type of monoclonal protein. The risk for progression to myeloma or a related disorder at 10 years was 6% for an initial monoclonal protein of 5 g/L or less compared to 34% for an initial monoclonal protein of 30 g/L. Monoclonal proteins of IgM or IgA type had a higher risk of progression than an IgG paraprotein.[667] Patients with an abnormal serum light chain ratio have a significantly higher rate of progression to an overt plasma cell malignancy. Several cytogenetic abnormalities, including

monosomy 13, t(4;14)(p16.3;q32), and t(14;16)(q32;q23), have been found in MGUS; no obvious clinical or biologic correlations have been established. Similar cytogenetic findings are present in overt myeloma.[669]

Immunohistochemistry on paraffin-embedded specimens using antibodies to kappa and lambda light chains can be a very important approach to the study of myeloma and related disorders.[33] The primary use of the technique in this group of diseases is to determine the relative proportion of kappa- or lambda-reacting cells; a predominant population of plasma cells reacting with a single light chain antibody is evidence for a monoclonal proliferation (see Fig. 39.2). A balanced proliferation of kappa- and lambda-reacting plasma cells usually indicates a benign process. A light chain ratio determined by dividing the number of positively reacting plasma cells for the predominant light chain by the number of positively reacting cells for the other light chain has been proposed as an aid in the distinction of myeloma from MGUS or a reactive increase in plasma cells.[33] Patients with overt myeloma generally have values above 16; patients with MGUS or a reactive process have values less than 16. These results should not be viewed in isolation but should be combined with the plasma cell labeling index.

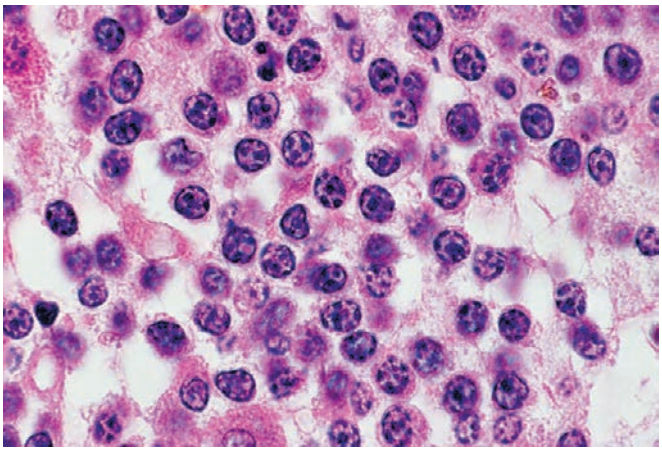

Figure 39.111 Marrow From a Patient With Lymphoplasmacytic Lymphoma and Associated IgM Gammopathy. The predominant lymphocytes have nuclei with very clumped chromatin and a slight to moderate amount of cytoplasm. Some lymphocytes contain small cytoplasmic and intranuclear inclusions. There is an increase of tissue mast cells.

Lymphoplasmacytic Lymphoma

In 1944, Waldenström described a clinical syndrome characterized by hyperglobulinemia, increased serum viscosity, and a proliferation of lymphocytes in hematopoietic tissue as well as other organs.[670] The clinical syndrome is referred to as Waldenström macroglobulinemia in recognition of the original description and identification of the globulin as a macroglobulin in the majority of patients. The median age of onset is 60 years, and there is a slight male predominance. Hepatosplenomegaly, lymphadenopathy, and neurologic abnormalities are frequent findings; anemia and hyperviscosity are commonly noted laboratory abnormalities.[670–672] The lymphoproliferative process associated with this syndrome usually involves the small B lymphocyte or the small B lymphocyte and plasmacytoid lymphocyte, that is, lymphoplasmacytic lymphoma in the WHO classification.[340,672,673] Although commonly used to describe the histopathologic lesion occurring in patients with this syndrome, the term Waldenström macroglobulinemia should be reserved for those patients with IgM paraproteinemia and bone marrow involvement by lymphoplasmacytic lymphoma.[672] Cases of lymphoplasmacytic lymphoma may also be associated with paraprotein of IgG and IgA type,[674] but clinical features of PCM should be excluded before making such a diagnosis. Some cases of lymphoplasmacytic lymphoma have no associated serum gammopathy.[672] IgM gammopathy may occur with other hematopoietic tumors and has been reported in cases of multiple myeloma and marginal zone lymphoma.[675–677] The recent discovery of *MYD88* L265P mutations in approximately 90% of cases of lymphoplasmacytic lymphoma has helped to clarify and define this disease entity.[678]

The peripheral blood shows a leukemic picture in approximately 30% of cases; the predominant cells are small lymphocytes or a mixture of small lymphocytes and plasmacytoid lymphocytes. A similar population of cells predominates in the bone marrow (Fig. 39.111).[673,679,680] Mature plasma cells, tissue mast cells, and histiocytes may also be increased. In some cases, plasma cells may predominate. In marrow sections, the infiltrate may be focal or diffuse; the focal lesions may be preferentially paratrabecular, interstitial or nonparatrabecular.[411] Marrow involvement may be very extensive with a marked decrease in normal hematopoietic cells. Intranuclear inclusions, frequently referred to as Dutcher bodies, may be observed in some of the lymphocytes and plasma cells[679]; these inclusions, which are variably PAS positive, may be observed in other lymphomas, multiple myeloma, and reactive proliferations, and are not diagnostic of lymphoplasmacytic lymphoma.[681] In some cases of plasmacytoid lymphoma, the plasma cells and plasmacytoid lymphocytes contain abundant cytoplasmic inclusions. These inclusions may be numerous, and some of these cells resemble histiocytes; the inclusions are usually intensely PAS positive (Fig. 39.112). Plasma cells with similar inclusions may occasionally predominate in multiple myeloma. Like other small lymphocytic lymphomas, the lymphoplasmacytic lymphoma associated with Waldenström macroglobulinemia may terminate with a clinicopathologic picture of Richter syndrome.[344]

The differential diagnosis of lymphoplasmacytic lymphoma in the marrow includes multiple myeloma and marginal zone lymphoma. The presence of an IgM paraprotein, as well as lack of clinical features of multiple myeloma, would favor lymphoplasmacytic lymphoma. Correlation with clinical features and lymph node morphology and *MYD88* mutation studies is often necessary to exclude marginal zone lymphoma, and this differential diagnosis cannot always be resolved on marrow biopsy tissue alone.[411,675]

Heavy Chain Disease

The heavy chain diseases are clinical syndromes that are associated with the production of heavy chain fragments of the immunoglobulin molecule.[354,682–686] Gamma-chain disease has more of the features of a malignant lymphoma, lymphoplasmacytic type, than of multiple myeloma. The median age for this disease is 61 years, but it has been reported in individuals younger than 20.[686] Weakness, fatigue, fever, and lymphadenopathy are common symptoms; hepatomegaly, splenomegaly, and peripheral lymphadenopathy are each present in slightly more than half of the cases. There are frequently anemia, leukopenia, and thrombocytopenia. Atypical lymphocytes and plasma cells may be found in the peripheral blood. The bone marrow is usually abnormal and shows an increase in lymphocytes, plasma cells, or both. Occasionally the marrow is normal. There may be an accompanying eosinophilia. *MYD88* mutations have not been reported in this disease. Most of the reported cases of mu-chain disease have features similar to CLL, but the patients usually have hepatosplenomegaly rather than the typical lymphadenopathy of CLL.[683–685] The marrow in several of the reported cases contained vacuolated plasma

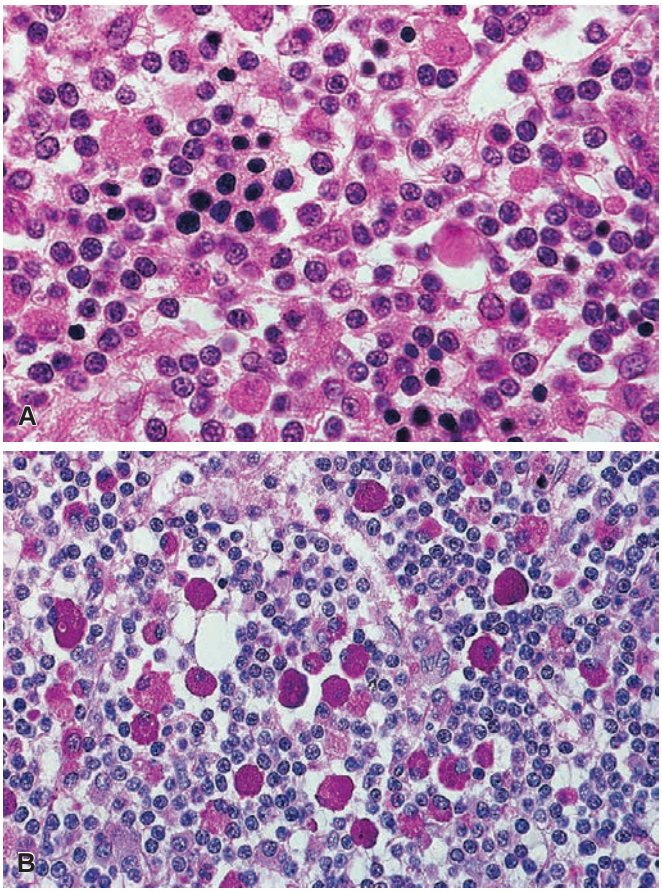

Figure 39.112 **A**, Marrow section from a patient with lymphoplasmacytic lymphoma associated with serum IgM monoclonal gammopathy. Marrow is replaced by an infiltrate of lymphocytes and plasma cells; many of the plasma cells contain numerous cytoplasmic inclusions. Some lymphocytes contain prominent intranuclear inclusions (Dutcher bodies). **B**, Specimen illustrated in **A** reacted with PAS stain. Inclusions in plasma cells are strongly positive.

cells. Alpha-chain disease, also known as immunoproliferative small intestinal disease or Mediterranean lymphoma, is considered a variant of extranodal marginal zone B-cell lymphoma (MALToma); the marrow is not usually involved. The occurrence of tumors composed of undifferentiated lymphoid cells in patients with heavy chain disease has been reported.[685,687]

Amyloidosis

Amyloidosis is the primary monoclonal immunoglobulin deposition disease to involve the bone marrow.[592,688] Bone marrow biopsies in patients with systemic amyloidosis are performed to detect evidence of the disease and to ascertain the number of plasma cells and whether there is a light chain predominant population of plasma cells. In a large single institution study of 474 patients with primary systemic amyloidosis, 56% of marrow biopsies were positive; abdominal fat aspirate was positive in 80%.[689] One or both sites were positive in 89% of patients. In rare cases, amyloid may be detected in marrow biopsies from patients without any clinical evidence of disease.

Primary systemic amyloidosis is associated with another form of plasma cell dyscrasia in approximately 35% of patients; the two most common disorders are multiple myeloma and MGUS,[689–693]

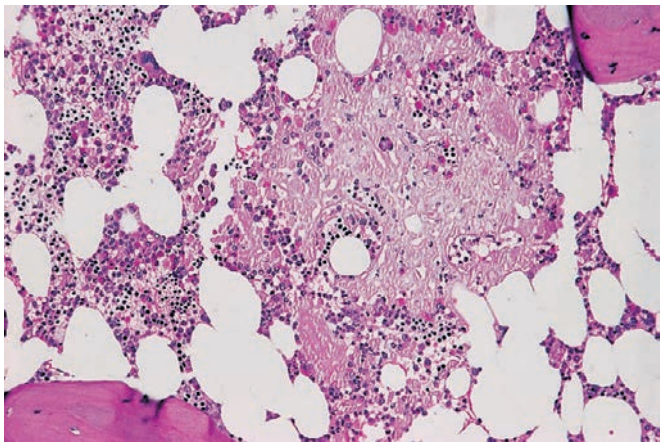

Figure 39.113 Marrow with amyloid accumulation from a 50-year-old woman with primary amyloidosis.

although amyloidosis may also occur with lymphoplasmacytic lymphoma. The distinction between primary amyloidosis with or without associated myeloma can be difficult and is usually based on a constellation of clinical and morphologic findings. The majority of patients with concurrent myeloma and primary systemic amyloidosis have more than 10% marrow plasma cells, which show either lambda or kappa light chain predominance demonstrated by flow cytometric or immunohistochemical studies.

Marrow involvement may manifest either as small focal lesions or as extensive marrow replacement.[694] Early involvement is characterized by focal deposits of amyloid in the medullary vessels; these range from small deposits in the media to large accumulations that greatly expand the vessel walls, resulting in narrowing of the lumen. With more extensive involvement, the accumulation of amyloid is present in the perivascular tissue and marrow substance (Fig. 39.113). Congo red staining should be performed to confirm the diagnosis.

Very rarely a proteinaceous deposition resembling amyloid but lacking the histochemical and electron microscopic characteristics of amyloid, similar to the findings in proteinaceous lymphadenopathy, may occur in the marrow in association with immune disorders (Fig. 39.114). The origin of the proteinaceous substance appears to be immunoglobulin or portions of the immunoglobulin molecule produced by cells of the immune system, and the findings have been referred to as monoclonal light and heavy chain deposition diseases.[590,695–698]

Systemic Polyclonal B-Immunoblastic Proliferation

A florid polyclonal proliferation of B immunoblasts accompanied by a polyclonal hypergammaglobulinemia may occur in patients with a variety of immune disorders and involve blood, bone marrow, and lymph nodes.[699–702] The leukocyte count may be elevated with a high percentage of B immunoblasts, cells with intensely basophilic cytoplasm, relatively coarse nuclear chromatin, and distinct nucleoli. There frequently is some evidence of maturation of these cells to plasma cells. The bone marrow may show extensive infiltration and may resemble lymphoma or plasmablastic myeloma with immunoblasts, plasma cells, and intermediate forms (Fig. 39.115). Lymph nodes may show a similar infiltrate, with complete effacement of the normal architecture. Immunologic studies are critical in the evaluation of these lesions. The polyclonal nature of the infiltrate is demonstrated with immunohistochemical reactions that show

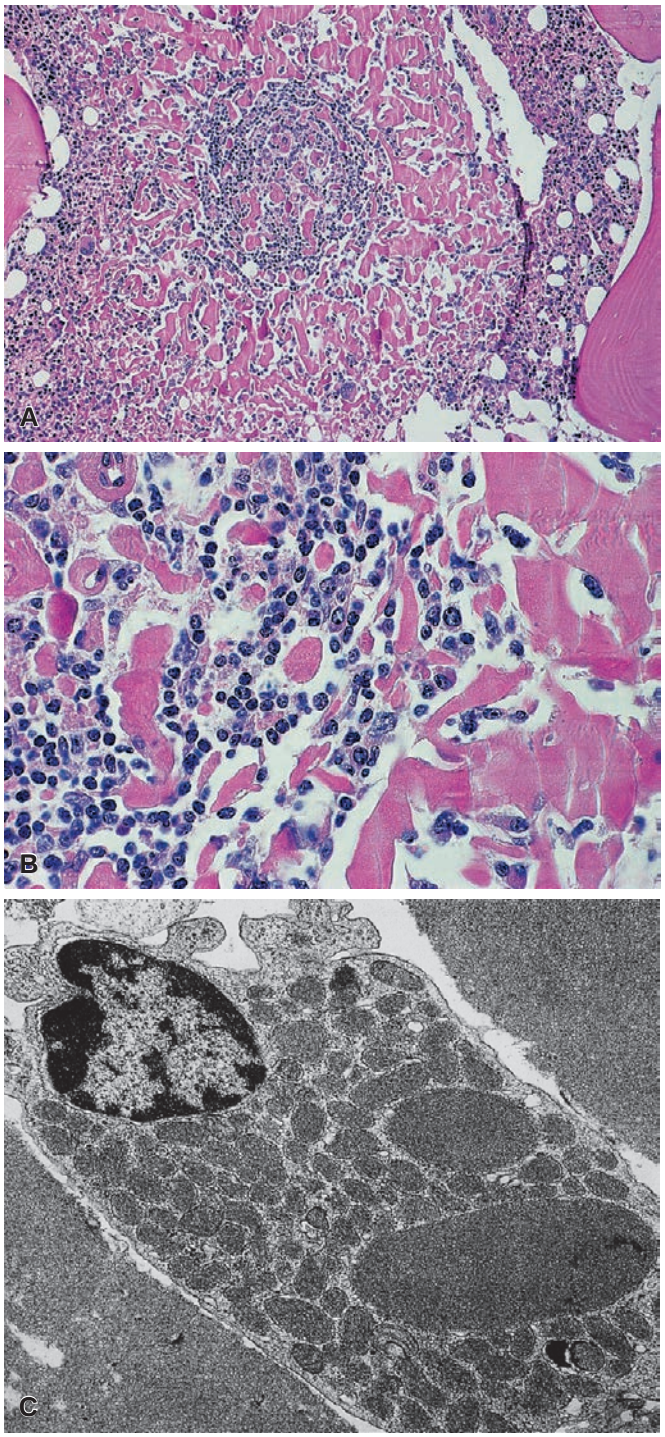

Figure 39.114 Proteinaceous Myelopathy. A, Marrow biopsy from a 25-year-old woman with a 10-year history of lupus erythematosus. There is extensive intercellular accumulation of an amorphous eosinophilic substance resembling amyloid but lacking the histochemical and ultrastructural findings of amyloid. There is an associated proliferation of plasma cells and small lymphocytes. The plasma cells consisted of both kappa and lambda light chain positive populations. **B**, High magnification of the specimen in **A**. **C**, Ultrastructure of the intracellular and extracellular material. There was complete regression of the finding following high dose steroid and vinblastine therapy.

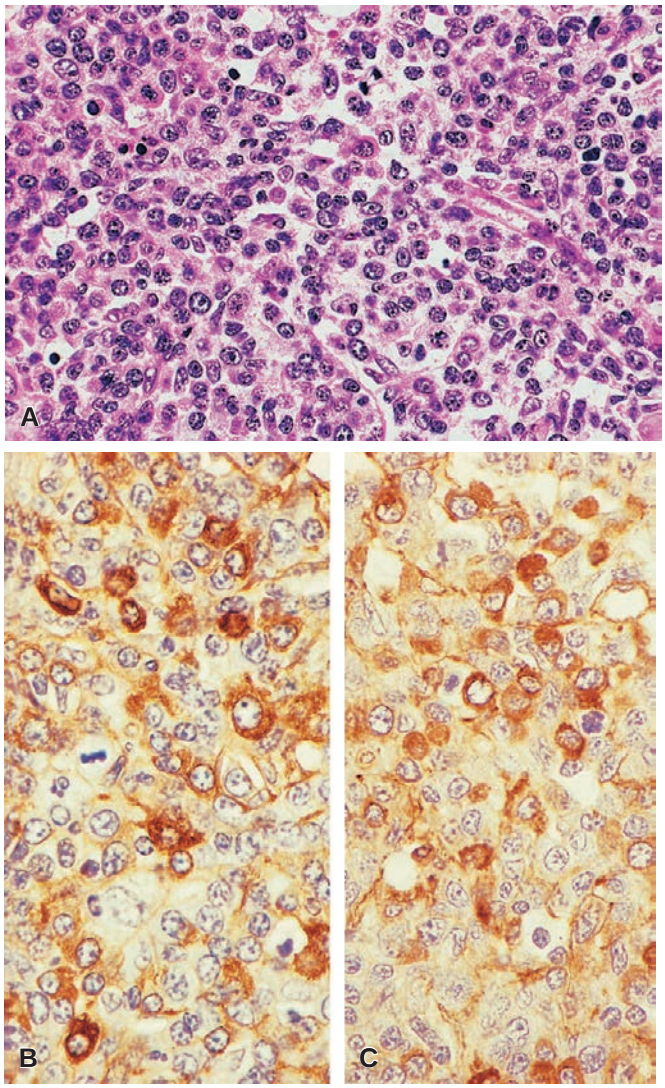

Figure 39.115 A, Marrow biopsy from a 28-year-old woman with an autoimmune disorder characterized by extensive infiltration of marrow by plasma cells, lymphocytes, and immunoblasts. **B** and **C**, Specimen in **A** demonstrated balanced reactivity for kappa (**B**)- and lambda (**C**)-reacting cells. (**B** and **C**, Immunoperoxidase.)

essentially a balanced population of kappa- and lambda-reacting cells (see Fig. 39.115B and C).[33]

The biology of this process is not completely clear; in some patients it appears to represent an acute immune reaction, and it has been observed in patients with laboratory findings of acute lupus erythematosus. It may in some instances be analogous to the polymorphous lymphoid lesions observed in transplant patients. There may be dramatic regression following steroid therapy.[701,702]

Metastatic Tumors

Bone marrow biopsies are used frequently for the staging of patients with histologically documented malignancies; they also may be performed on patients with suspected malignancy in an attempt to obtain material for a histologic diagnosis.[11,703–709] Due to the focal nature of marrow involvement by metastatic disease, the yield of marrow biopsies is increased by the amount of biopsy tissue obtained.

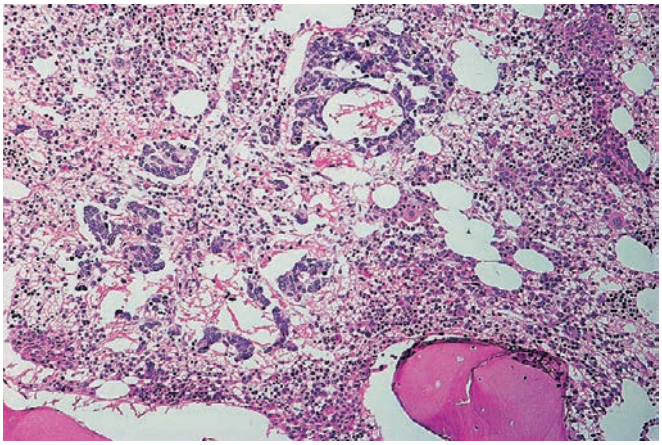

Figure 39.116 Marrow biopsy from a child with metastatic neuroblastoma. Several foci of tumor are present.

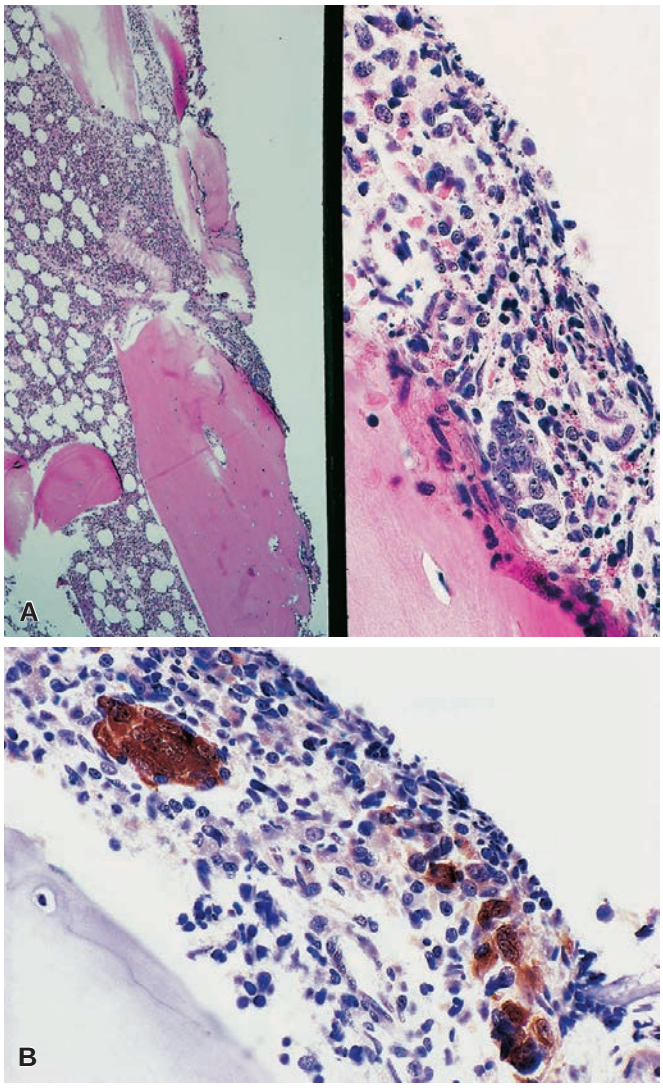

Figure 39.117 **A**, Low *(left)* and high *(right)* magnification of a marrow biopsy from a child with metastatic neuroblastoma with small focal lesions. **B**, Specimen reacted with antibody to neuron-specific enolase. Small clusters of reactive cells are present. This was the only involved area in the biopsy. (**B**, Immunoperoxidase.)

For this reason, either bilateral iliac crest biopsies or two biopsies from a single site are recommended for adequate staging.[3,11] The tumors most frequently detected in bone marrow biopsies in adults are carcinoma of the breast, lung, prostate, stomach, colon, kidney, and thyroid gland. The bone marrow biopsy is widely used for staging small cell carcinoma of the lung.[706,710–721] Sarcomas have a relatively low incidence of marrow metastasis in adults.[722] In the pediatric age group, neuroblastoma is the most common metastatic lesion, followed by rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma.[705,723–725] Wilms tumor metastatic to marrow is extremely uncommon.

In smears, tumor cells frequently, but not invariably, occur in clusters. This may be an important diagnostic feature because tumors of hematopoietic origin generally do not occur in cohesive aggregates. In marrows with extensive involvement, both clusters and individual cells may be present. In some small cell tumors the individual cells may resemble malignant lymphoid cells. In trephine sections, metastatic tumor may occur as small focal lesions surrounded by normal hematopoietic cells, or it may replace virtually the entire specimen. In focal lesions or those occupying only a portion of the biopsy, the tumor foci may be sharply demarcated from the adjacent hematopoietic tissue or may be associated with an irregularly shaped area of fibrosis (Figs. 39.116 and 39.117). Many tumors, most notably breast and prostate, may be associated with a marked desmoplastic reaction, and attempts at aspiration may be unsuccessful. These tumors also may be accompanied by marked osteosclerosis (Figs. 39.118 and 39.119). In the unusual occurrence of a metastatic sarcoma in the marrow, the lesion may resemble PMF.

In the majority of cases of metastatic tumor in marrow smears and aspirates, the tumor cells have characteristics that clearly distinguish them from normal hematopoietic cells. This distinction is aided by the frequent desmoplastic reaction that accompanies some of the tumors that most commonly metastasize to the marrow. In some instances the metastatic tumor cells may have features suggesting a hematopoietic origin, particularly megakaryocytes. This may be a particular problem with some cases of rhabdomyosarcoma in which the tumor cells may react with antibodies to platelet glycoproteins (Fig. 39.120). Antibody studies for actin, desmin, and myogenin and cytogenetic studies may be useful in recognizing this tumor (see Fig. 39.120B). Less commonly, individual tumor cells may involve the marrow and such cases may require immunohistochemical studies even in the absence of obvious marrow involvement on hematoxylin and eosin–stained slides. Metastatic lobular carcinoma and neuroblastoma are the two most common tumors to infiltrate the marrow as individual tumor cells, and routine immunohistochemical studies may be warranted if either of these diagnoses is suspected.[721,726]

The approach to determining the site of origin of a metastatic tumor in a patient without a known primary lesion should be the same as for determining metastatic lesions in other sites. Immunohistochemical techniques may be particularly useful both for determining the possible site of origin and for detecting small lesions.[705,707,721] Antibodies to the common leukocyte antigen are useful in distinguishing a malignant lymphoma from metastatic carcinoma or sarcoma. As with other tissue, it is important to use a panel of antibodies that has the capacity to recognize all reasonable possibilities. For metastatic carcinoma of unknown primary, a panel that includes cytokeratins 7 and 20 as well as synaptophysin, TTF1, and estrogen receptor and BRST1 in women and prostate-specific antigen in men will suggest a primary tumor in most cases.[705] In instances in which small foci are identified with the

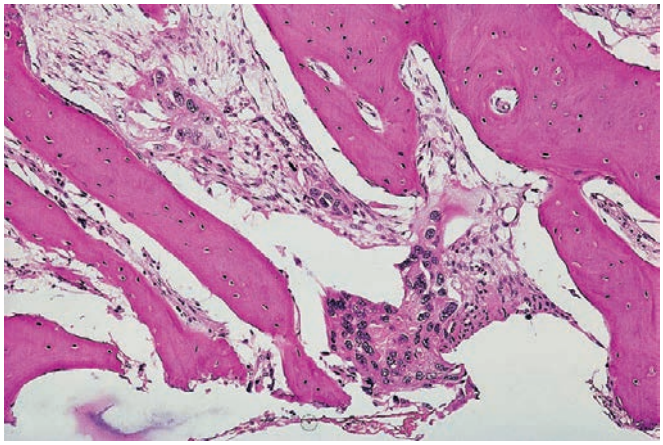

Figure 39.118 Marrow from a patient with metastatic carcinoma of breast with osteosclerotic reaction and foci of tumor cells.

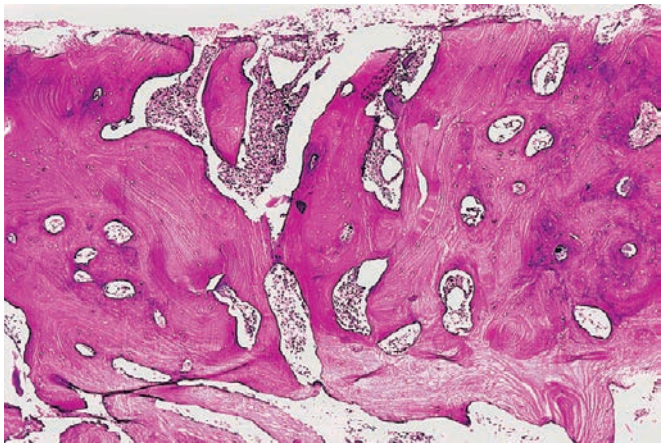

Figure 39.119 Marrow biopsy from a patient with metastatic carcinoma of prostate with a marked osteoblastic lesion.

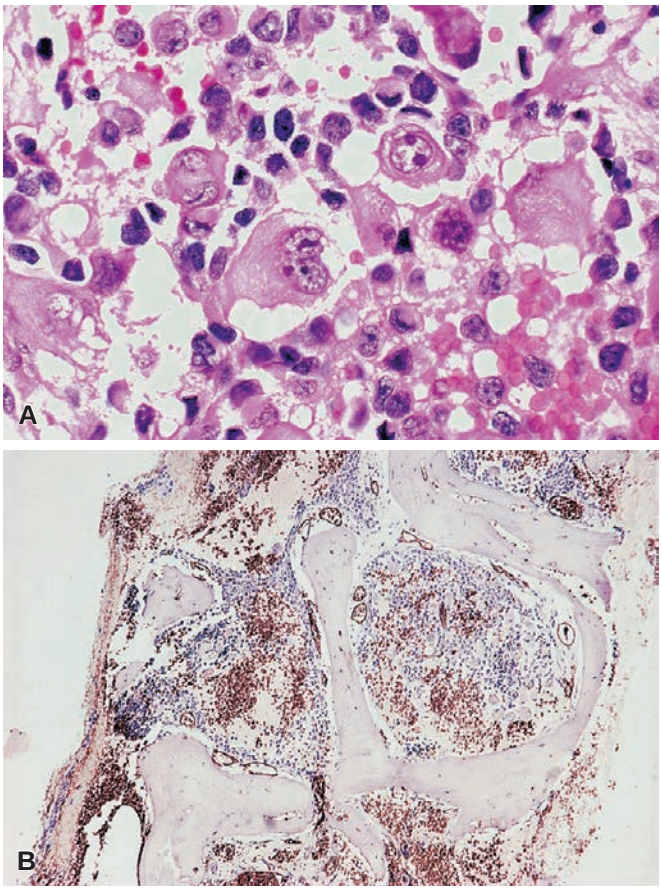

Figure 39.120 **A**, Bone marrow biopsy from a 17-year-old male with partial replacement of marrow by a pleomorphic population of cells, some of which are large with very abundant cytoplasm. Larger cells have one or two nuclei with distinct and frequently prominent nucleoli. The majority of the cells reacted with antibodies to actin (**B**) and desmin; chromosome studies of the cells showed a t(2;13)(q35;q14) abnormality, a characteristic cytogenetic finding in alveolar rhabdomyosarcoma.

immunohistochemical reaction, the tumor should be found in adjacent sections stained with hematoxylin and eosin.

Detection of micrometastasis from lung and breast carcinoma in bone marrow is increased with the use of immunologic markers applied to smears prepared from Ficoll Hypaque–separated specimens of bone marrow aspirate.[727–729] Molecular techniques for the identification of markers increase the detection level of micrometastasis.[730]

Special note is made here of neuroblastoma because the bone marrow biopsy may serve as the primary diagnostic specimen in patients with neuroblastoma if the aspirate or trephine biopsy specimen contains unequivocal tumor cells and there is significantly increased serum or urinary catecholamines or metabolites.[731–733] Because the detection rate increases with multiple biopsies, two aspirates and one trephine biopsy specimen from each posterior iliac crest are recommended for assessment of marrow involvement. Patients with stage 4S disease have less than 10% involvement; if there is more than 10%, the disease is stage 4.[732]

Tumor cells may be detected in bone marrow smears, particle sections, trephine imprints, or trephine biopsies. The relative merits of these various techniques for detecting tumor have been the subject of considerable discussion. The yield of positive results has increased with the performance of multiple trephine biopsies. Metastatic neuroblastoma in marrow sections may show varying degrees of differentiation. Following therapy, the lesions may show marked differentiation to ganglion cells (Fig. 39.121).

Immunologic markers may be used for the identification of neuroblastoma cells; antibodies to neuron-specific enolase, synaptophysin, and chromogranin have been recommended by the Second International Neuroblastoma Staging System Conference.[732] Newer and more specific markers of neuroblastoma, including GD2 synthetase, also appear to be useful in the primary diagnosis of neuroblastoma.[726,734,735] Immunohistochemical quantification of neuroblastoma cells in bone marrow and blood at diagnosis and in marrow during induction therapy can identify patients with very high-risk disease.[736]

Lipid Storage Diseases

Gaucher Disease

Gaucher disease is an autosomal recessive sphingolipid storage disorder resulting from the accumulation of glucosylceramide (glucocerebroside) in organs and tissues as a result of a deficiency in lysosomal β-glycosidase (glucocerebrosidase) which is encoded by the *GBA* gene on chromosome 1q22.[737–741] It occurs in three forms: type I, chronic non-neuronopathic (adult) type which is the

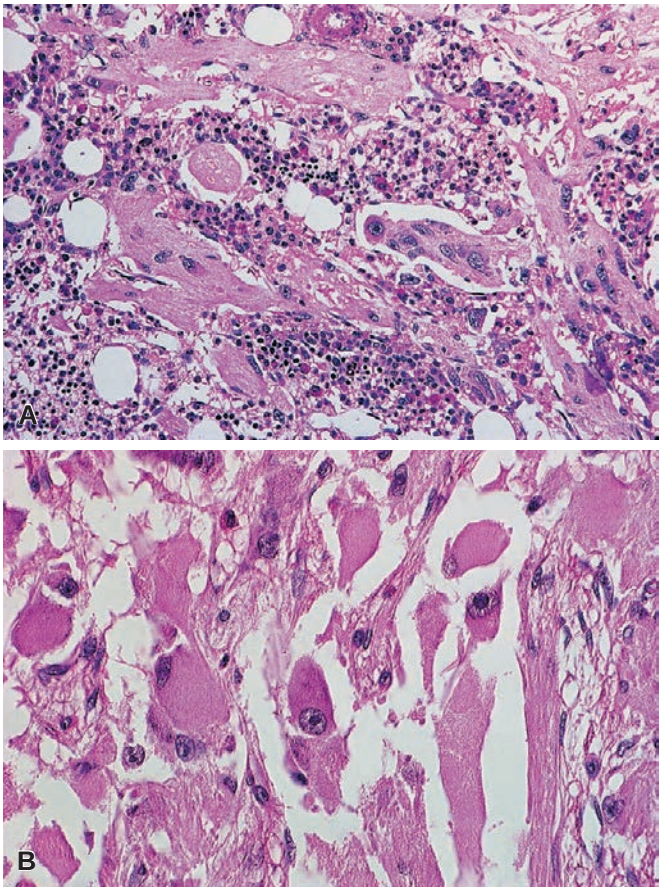

Figure 39.121 **A**, Marrow biopsy from a child with metastatic neuroblastoma with ganglion differentiation. **B**, High magnification of the specimen in **A** showing marked variability in size of the tumor cells. In contrast to megakaryocytes, some tumor cells contain single, very prominent, nuclei. (See Fig. 39.10, which is the same specimen reacted with antibody to neuron-specific enolase.)

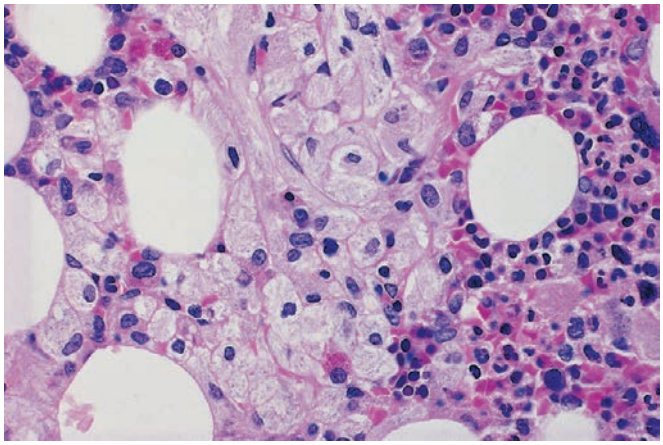

Figure 39.122 Bone marrow section from an adult with type I chronic non-neuronopathic Gaucher disease. The cytoplasm of many Gaucher cells has a fibrillary or granular appearance. Nuclei are small and usually eccentric in location.

most common Ashkenazi Jewish disorder; type II, acute neuronopathic type which is the most severe form; and type III, subacute neuronopathic (juvenile) type.

The characteristic diagnostic morphologic feature of the disorder is the presence of Gaucher cells in the bone marrow, spleen, liver, and lymph nodes and other organs.

In the bone marrow sections, Gaucher cells may be found in small focal accumulations or may replace large portions of a biopsy. There is an associated increase in reticulin fibers. In imprint and smear preparations, the Gaucher cell is large, 30–100 µm in diameter, and has one or more centrally or eccentrically located nuclei.[742,743] The cytoplasm has a characteristic fibrillary or striated pattern and is pale blue–gray in color. In sections stained with hematoxylin and eosin, the cytoplasm is slightly eosinophilic; a fibrillary pattern may be very prominent (Fig. 39.122). The Gaucher cells are variably and often intensely positive with the PAS reaction. The cells also stain positively for iron in older children and adults. Cells similar to Gaucher cells, pseudo-Gaucher cells, may be found in the marrow of some patients with CML,[744–748] type II congenital dyserythropoietic anemia, and thalassemia.[749]

A monoclonal gammopathy may be present in patients with chronic Gaucher disease and may be associated with a marrow plasmacytosis.[750] The coincidence of multiple myeloma, plasmacytoid lymphoma, and Gaucher disease has been reported.[751]

Treatment of patients with type I (adult type) Gaucher disease with recombinant β-glucocerebrosidase (imiglucerase) results in a decrease in the relative volume of bone replaced by Gaucher cells and an increase in hematopoietic and fat cells and a decreased cortical bone structure. The decrease in amount of marrow replaced by Gaucher cells is the result of a decrease in both the number and size of Gaucher cells.[744,745,748] An additional form of therapy is directed at substrate reduction which may be used in addition to enzyme replacement.

Niemann–Pick Disease

Niemann–Pick (NP) disease is a group of autosomal recessive sphingomyelin–cholesterol lipidoses characterized by organomegaly and the accumulation of sphingomyelin and other lipids throughout the tissues of the body as a result of a deficiency of lysosomal acid sphingomyelinase.[743,747,752,753,754] The gene encoding acid sphingomyelinase in types NPA and NPB *(SMPD1)* is located at 11p15.4. Three major clinical types are recognized: an acute neuronopathic form (A); a chronic form without nervous system involvement (B); and chronic neuronopathic forms (C1 and C2).[743,747,752,753] The foam cell, as seen in the bone marrow in NP disease, does not have diagnostic specificity and may be found in other disorders of lipid metabolism such as hypercholesterolemia and Tangier disease; in NP disease type C1 the enzymatic defect results in cholesterol accumulation in the macrophages in the marrow and elsewhere.[742,745] In Romanowsky-stained smears, the cell measures 20–50 µm; the cytoplasm is filled with clear vacuoles of varying size.[742,745] In sections, the cells are randomly scattered singly and in aggregates; the cytoplasm of the NP cell is marked by confluent clear vacuoles of varying size. The cells may be difficult to appreciate because of the very light-staining cytoplasm. The nucleus is randomly located (Fig. 39.123). The vacuoles are PAS negative and positive with lipid stains.

NP disease types C1 and C2 are panethnic autosomal recessive lipidoses associated with mutations of *NPC1* (at 18q11.2) and *NPC2* (at 14q24.3).[743,747,753,754] The basic defect involves a unique error in cellular trafficking of exogenous cholesterol that is associated with a lysosomal accumulation of unesterified cholesterol; the disease is distinct from the sphingomyelin lipidoses, NP disease types A and B. Foam cells or sea-blue histiocytes may be present in the marrow; these, however, are not distinctive and may be observed in several different lipidoses.

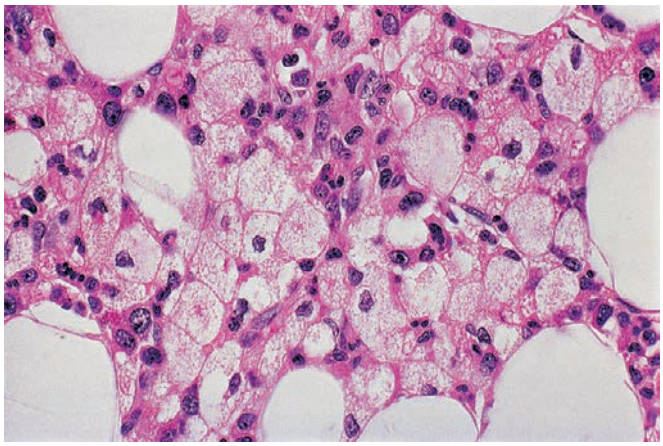

Figure 39.123 Biopsy From a 14-Month-Old Child With Niemann–Pick Disease. Focal accumulations of foam cells are present. The cytoplasm of the foam cells is clear, with the suggestion of numerous confluent vacuoles.

Fabry Disease

Fabry disease is an X-linked recessive inborn error of glycosphingolipid metabolism caused by variants of the *GLA* gene that results in deficient activity of α-galactosidase.[755] It is characterized by multiorgan involvement with accumulation of globotriaosylceramide in cells throughout the body, including macrophages in the marrow. The characteristic storage cells in bone marrow specimens in this disease are filled with small globular inclusions that stain blue in Romanowsky-stained smears and are lightly eosinophilic in sections stained with hematoxylin and eosin.[742] The cytoplasmic substance reacts intensely with the PAS and Sudan black B stains.

Similar to Gaucher disease, therapy for Fabry disease consists of enzyme replacement, substrate reduction, and enzyme enhancement.[745]

Sea-Blue Histiocyte Syndrome

The macrophages of the sea-blue histiocyte syndrome[743,756] contain a substance that stains blue in Romanowsky-stained smears and yellow to tan in sections stained with hematoxylin and eosin. Positive reactions occur with the PAS and Sudan black B stains. In some instances, the substance appears to be ceroid; in others the material has not been well characterized. Macrophages containing blue pigment may be observed in several unrelated disorders and lack diagnostic specificity. This cell type has also been reported in some cases of NP disease. The sea-blue histiocytes may resemble the macrophages in Whipple disease, which may rarely be detected in marrow specimens.[757]

Hematopoietic Cell Transplantation

Hematopoietic cell transplantation, using either bone marrow or peripheral blood cells, is now commonly used as a therapeutic approach in patients with primary bone marrow disease.[758] Bone marrow examination is performed for a variety of reasons following hematopoietic cell transplantation. While evaluation for residual or recurrent disease in these specimens remains important, the marrow also provides clues to the success of engraftment and to possible infectious complications of the procedure.

The objective of hematopoietic cell transplantation is reconstitution of normal hematopoiesis in marrows that are aplastic; the aplasia may be the result of aplastic anemia or the marrow is rendered aplastic with chemotherapy and radiation in the preparative regimen employed prior to marrow transplantation for various neoplastic processes or, less commonly, inherited disorders.

The source of the graft may be the patient's own marrow or peripheral blood cells that have been harvested prior to the preparatory regimen (autologous) or from another individual (allogeneic). Autologous stem cells in some cases are "purged" with chemotherapeutic agents and/or monoclonal antibodies to eradicate malignant cells. Umbilical cord blood stem cells are also being used.[759]

Hematopoietic cell transplantation involves preparing the patient for transplant with a regimen utilizing chemotherapy with or without total body irradiation therapy. The preparative regimen has two purposes: to immunosuppress the patient and to eradicate malignant cells that may be present in the recipient. For patients with severe aplastic anemia, cyclophosphamide alone or cyclophosphamide plus antithymocyte globulin or cyclophosphamide plus total lymphoid irradiation has been utilized most commonly and now provides long-term success rates of over 80% in matched sibling donor patients. For patients with leukemia, regimens including chemotherapy and total body irradiation have most commonly been used; the combination of busulfan and cyclophosphamide has been successful in the preparation of patients with AML.

The major complications associated with hematopoietic cell transplantation involve infection in the severely immunosuppressed host, graft rejection, and graft-versus-host disease.[760] Recurrent disease is also a cause of failure in patients with malignant diseases. Infection continues to be a major cause of peritransplant morbidity and, in some cases, mortality. The use of better antibiotics and growth factors to accelerate white blood cell production has decreased but not eliminated infectious complications. Graft rejection is an infrequent complication of matched sibling donor transplant; however, it is a significant complication in patients undergoing unrelated donor transplant, especially for diseases such as aplastic anemia. Certain methods of graft-versus-host disease prophylaxis, specifically T-cell depletion, may be associated with an increased risk of graft rejection.

The rate of engraftment following hematopoietic cell transplantation is influenced by several factors, and although some generalizations can be made about reconstitution of hematopoiesis, there are frequent exceptions.[71,760–763] The amount of marrow damage incurred prior to the transplant from chemotherapy and radiation used for treatment of the disease for which the transplant is necessary may influence the success rate. Autologous marrow specimens that have been purged with antibodies or chemotherapeutic agents may reconstitute less quickly than allogeneic marrow grafts. The disease for which the transplant was performed may recur early in the transplant period.

Marrow biopsies are not usually performed in the first 7 days following transplantation. However, the marrow biopsies performed during this period show marked hypocellularity with hemorrhage and proteinaceous debris. Scattered fat cells and macrophages are present. The findings are similar to those in patients treated with myelotoxic agents for acute leukemia.[71,761–763] At 7–14 days, adipose tissue is reconstituted. The appearance of the marrow in the second to third week is variable; there may be evidence of hematopoiesis, or the marrow may be markedly hypocellular (Figs. 39.124 and 39.125). The initial stages of engraftment are usually characterized by foci of hematopoietic cells scattered throughout the adipose tissue in what appears to be a random distribution. These foci initially are usually unilineage and composed of tight clusters of erythroid precursors followed by aggregates of promyelocytes and myelocytes (see Fig. 39.124B). Blasts are not increased. There is no preferential paratrabecular distribution of the promyelocyte and myelocyte islands in this period. Megakaryocytes are usually sparse. Following this stage there is progressive spreading of the hematopoietic cells

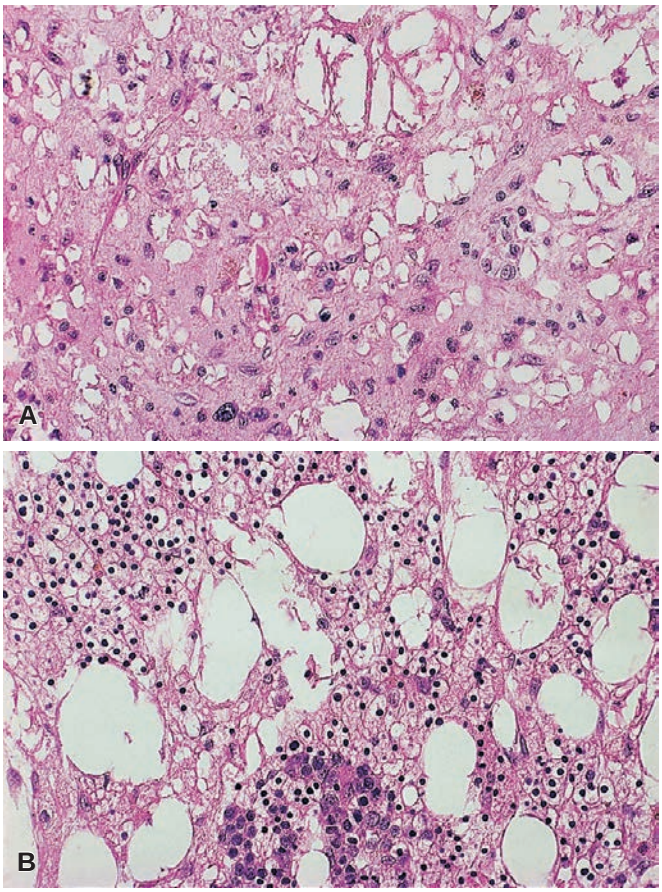

Figure 39.124 **A**, Marrow biopsy 4 days post allogeneic marrow transplantation for blast crisis of chronic myeloid leukemia. The marrow is markedly hypocellular with scattered cells and abundant interstitial proteinaceous debris. **B**, Marrow biopsy from the patient illustrated in **A** 28 days post transplant. Evidence of engraftment is characterized principally by erythroid precursors at a late stage of maturation and foci of more immature forms. There was no evidence of a t(9;22) cytogenetic abnormality in either biopsy.

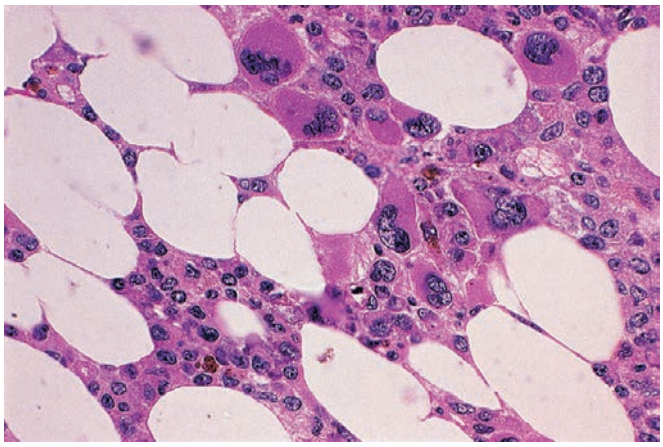

Figure 39.126 Marrow from an adult man 18 days post unrelated marrow transplantation for acute myeloid leukemia. The marrow is markedly hypocellular with scattered clusters of normal-appearing megakaryocytes; there is no evidence of leukemia.

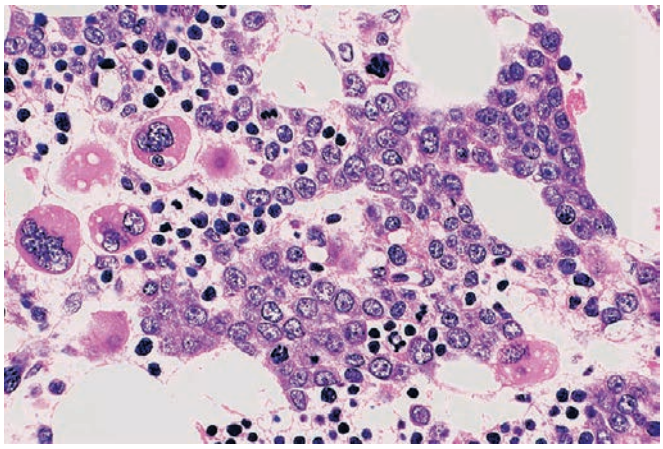

Figure 39.127 Marrow from an adult woman 21 days post autologous marrow transplantation for chronic myeloid leukemia illustrating a focus of erythroid precursors at an early stage of maturation in an overall hypocellular marrow. Erythroid precursors at a late stage of maturation are located in the surrounding interstitium; there are several normal-appearing megakaryocytes.

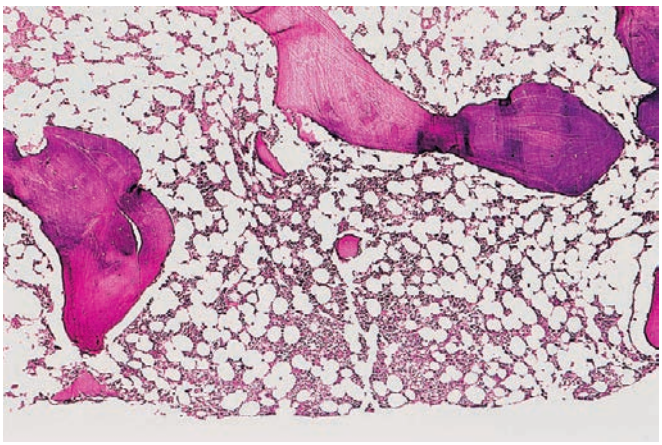

Figure 39.125 Marrow biopsy from a 7-year-old child 14 days post allogeneic bone marrow transplantation for aplastic anemia. The marrow is moderately to markedly hypocellular. Subsequent biopsies showed failure of engraftment.

throughout the interstitium and gradual regression of adipose tissue; the foci of hematopoiesis at this stage of recovery are usually multilineage, although predominantly monolineage proliferation may persist (Figs. 39.126 and 39.127). Megakaryocyte reconstitution may lag behind the granulocytic and erythroid cells for prolonged periods. In some patients, megakaryocytes appear early in the engraftment period and may form small aggregates. There may be considerable variability in the amount of hematopoietic tissue in different areas of a large biopsy specimen; clot sections, small specimens, or fragmented specimens may be misleading.

There may be a marked shift to promyelocytes and myelocytes early in the post-transplant period; this is accentuated by the administration of recombinant granulocyte growth factor (Fig. 39.128). This shift to immaturity is not usually accompanied by an increase in blasts. During this period, patients frequently receive a large number of drugs, some of which may be associated with agranulocytosis. This factor should be considered in patients who manifest prolonged neutropenia with a morphologic appearance of "maturation arrest" of neutrophils in the marrow specimen.

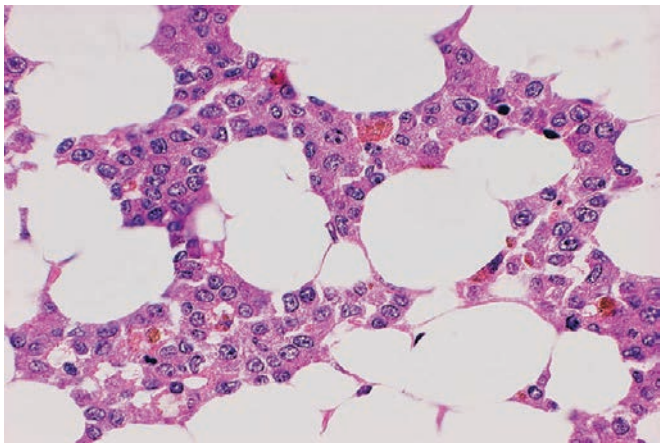

Figure 39.128 Marrow biopsy 20 days post allogeneic sibling transplantation for chronic myeloid leukemia; 3 days prior to the biopsy the patient received granulocyte colony-stimulating factor for marked neutropenia. The cells in the interstitium are neutrophil precursors at the promyelocyte–myelocyte stage of maturation, a characteristic early effect of growth factor stimulation.

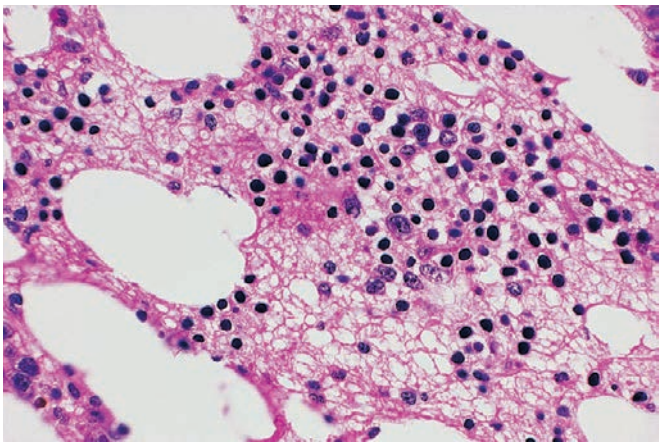

Figure 39.130 Marrow biopsy from an adult 8 months following autologous marrow transplantation for chronic myeloid leukemia. The marrow is markedly hypocellular with markedly decreased granulocytes and megakaryocytes. The interstitium is markedly depleted with principally late-stage erythroid precursors.

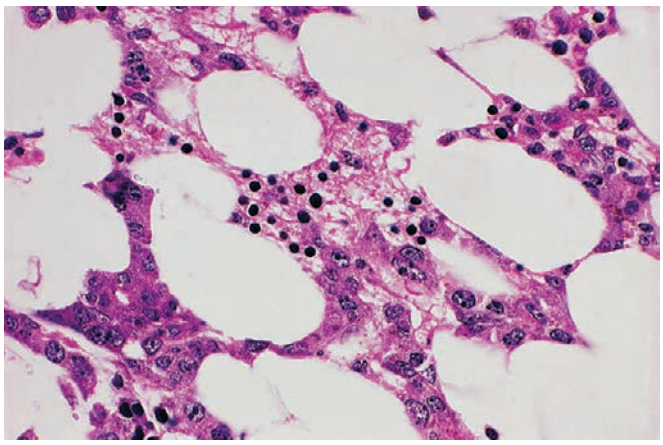

Figure 39.129 Marrow biopsy from an 11-year-old child 100 days following unrelated donor marrow transplantation for chronic myeloid leukemia. The marrow is moderately to markedly hypocellular with erythroid and granulocyte precursors and only rare megakaryocytes.

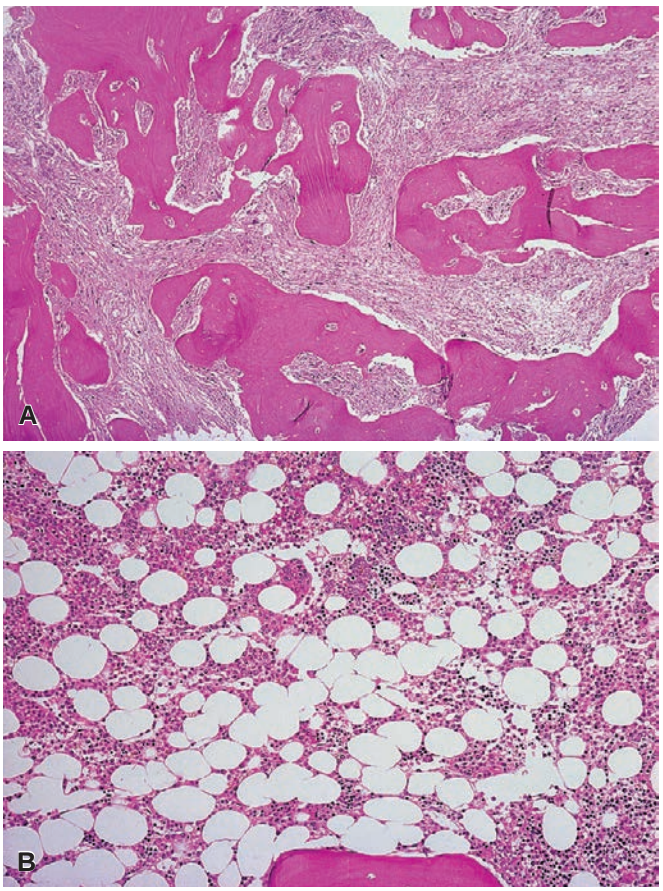

Figure 39.131 **A**, Marrow biopsy with marked osteosclerosis from a 32-year-old patient with Philadelphia chromosome–positive chronic myeloid leukemia immediately prior to marrow transplantation. **B**, Marrow biopsy from the patient illustrated in **A** 5 months post allogeneic marrow transplantation. There is complete resolution of the osteosclerosis. The cytogenetics from this specimen were normal.

Granulomas occur with greater frequency in post-transplant marrows than in marrows from other groups of patients; these granulomas usually consist of only a small collection of epithelioid histiocytes. In some cases, giant cells are present. Phagocytic histiocytes may be increased and diffusely scattered throughout the marrow. The histiocytes may manifest marked phagocytic activity; this finding warrants evaluation for an infectious process.

The rate of growth of the graft varies substantially in the first 3–4 weeks. In some cases the marrow may remain hypocellular for many months or years; in other cases one of the major myeloid cell lines remains depressed (Figs. 39.129 and 39.130). Remission of myelofibrosis and osteosclerosis may occur (Fig. 39.131).

Loss of graft is reflected by decreasing marrow cellularity and progressive cytopenias. This may occur gradually or abruptly. In some instances, there is a discrepancy between the blood counts and marrow cellularity, with very hypocellular marrows and normal blood counts or normocellular marrows and blood cytopenias. Marrow sampling may be the basis of the discrepancy when normal

blood counts occur with hypocellular marrow. There are no specific marrow findings reflecting graft-versus-host disease.

Marrow transplants in patients with leukemia present the additional problem of recognition of recurrent disease. Cytogenetics, membrane surface markers, and molecular studies are very important adjuncts to morphology in the evaluation of these patients. In addition, molecular genetic studies for engraftment now focus primarily on the ratio of donor to recipient histocompatibility markers.[764]

Bone

Normal Anatomy

Adult bones are classified according to their shape into long (such as femur), flat (such as pelvis), and short (such as bones of hand and feet). Long bones (and some short bones, such as metacarpal bones) are divided topographically into three regions: epiphysis, metaphysis, and diaphysis. The epiphysis, or secondary ossification center, occupies the region of the bone extending from the articular cartilage to the physis. The diaphysis, or shaft of the bone, is separated from the epiphysis by the metaphysis, or primary ossification center. An apophysis is a secondary ossification center on which a tendon or ligament is attached (such as the greater trochanter of the femur). Bone growth occurs at the physis by endochondral ossification, a process by which longitudinal, regularly spaced columns of vascularized cartilage are replaced by bone.[1] At skeletal maturity, endochondral ossification ceases and the physis "closes" by becoming totally ossified. The time of closure of the physis differs in various bones and between sexes. Not only is the physeal region a common site of occurrence for primary bone tumors, but its state of being open or closed influences the extension of pathologic processes in the sense that cartilage is often at least a partial barrier to spreading osteosarcoma. If the physis is closed and cartilage is no longer present, this area is more easily invaded.[2]

Bones are also classified according to their embryologic development. With intramembranous ossification, the bone forms de novo from primitive connective tissue (mainly flat bones). In contrast, with endochondral ossification, the bone formation is preceded by a cartilaginous anlage; this occurs primarily in tubular bones.[1,3]

Topographically, mature bones have an outer *compact layer* (cortex, cortical bone, compact bone) and a central *spongy region* (spongiosa, medulla, cancellous bone). Cortical bone contains vascular channels, which are divided into two types on the basis of their orientation and their relation to the lamellar structure of the surrounding bone: longitudinal (haversian canals) and transverse/oblique (Volkmann canals). Except for the region of the articular cartilage, the cortex is surrounded by the *periosteum*, which consists of an outer fibrous layer and an inner cellular (cambium) layer of osteoprogenitor cells. The periosteum also contains nerve filaments that carry proprioceptive and sensory impulses; small nerve filaments also may pass with the nutrient vessels into the medullary canal. Coarse bundles of collagenous fibers penetrating the outer compact layer from the outer layer of the periosteum are called Sharpey fibers or perforating fibers.[1]

The periosteum may become detached and elevated from the bone in pathologic processes such as trauma, infection, and neoplasms. When this happens, new bone formation between the elevated periosteum and the bone will occur. This appears by radiographic examination as fine spicules placed perpendicular to the long axis of the bone. This finding is often considered a manifestation of a primary malignant neoplasm, particularly osteosarcoma and Ewing sarcoma. However, periosteal bone proliferation also can occur in a wide variety of neoplastic and non-neoplastic conditions.

An understanding of the blood supply of bone helps to explain the spread and limitation of infection, the healing of fractures, and the involvement of bone by primary or secondary neoplasms. The metaphysis is mainly supplied by end arteries that enter from the diaphysis and terminate at the level of the growth plate. The epiphyses receive their blood supply from a network of widely anastomosing vessels. The diaphyseal cortex is supplied by vessels that enter through Volkmann canals and communicate with the haversian system. A nutrient artery enters the medullary canal near the center of the diaphysis, divides, and extends both distally and proximally. Lymphatic vessels exist in the connective tissue overlying the periosteum, but apparently not in the cortex or medulla.[4]

Abstract

This chapter describes the radiographic, gross, and microscopic features of diseases of the bones and joints. A wide spectrum of diseases is covered in this chapter, including both non-neoplastic and neoplastic processes. Where applicable, radiographic information is included, and differential diagnoses are discussed.

joint disease

The constituent cells involved in bone production include *osteoblasts* and *osteocytes*. *Osteoblasts* are bone-producing cells derived from marrow-residing osteoprogenitor cells under direction of the master gene *Runx2*. They have a plump appearance and often exhibit a perinuclear halo resulting from a prominent Golgi zone that gives them a plasmacytoid appearance. They have a high cytoplasmic content of alkaline phosphatase and produce RANKL.[5] Ultrastructurally, they resemble fibroblasts by virtue of a well-developed rough endoplasmic reticulum and Golgi apparatus. Indeed, osteoblasts are regarded as a specialized form of fibroblast. Once these are incorporated into the bone matrix and housed in lacunae, they are referred to as *osteocytes*. SATB2 (special AT-rich sequence-binding protein 2) has been shown to be an excellent marker of osteoblast differentiation, and while not entirely specific for bone-forming neoplasms, it can be useful in distinguishing osteosarcoma from histologic mimics.[6]

Osteoclasts are multinucleated giant cells involved in bone resorption.[7] As such, they typically are found in shallow concavities in the surface of bone called *Howship lacunae*. Osteoclasts arise from mononuclear monocyte–macrophage precursors.[8] Osteoclasts contain abundant tartrate-resistant acid phosphatase, respond to osteotropic hormones, and contract under the influence of several inhibitors, including calcitonin. Osteoclasts develop from bone marrow stromal cells under the influence of receptor activator of nuclear factor kappa-beta (RANK ligand), which is produced by osteoblasts. Ultrastructurally, the cytoplasm of osteoclasts has a very large number of mitochondria and lysosomes; a ruffled edge is present in the area of the cell membrane that is in the process of bone resorption.

Osteoid is the unmineralized organic precursor matrix of bone. It is composed of a mixture of collagen (mainly type I), acid mucopolysaccharides, and noncollagen proteins.[9] These include osteopontin, osteocalcin, and bone morphogenetic protein. Although only one component of a very complex process, the latter is thought to play a critical role in initiating the process that begins with cartilage resorption and ends with bone formation.[10] Osteoid is not a homogeneous mass but rather shows a constant, patterned sequence of maturation and organization. It has acidophilic properties in hematoxylin–eosin-stained sections, and it may be difficult to distinguish from hyalinized collagen.

Bone is formed through mineralization of the organic matrix of the osteoid. Extracellular matrix vesicles are present at or near the mineralization front and constitute the initial site of hydroxyapatite mineral deposition.[11] In immature *woven bone*, there is a haphazard arrangement of collagen fibers within the matrix, which is best appreciated with reticulum stains or under polarized light. *Lamellar bone* is characterized by concentric or parallel lamellae, best appreciated with polarized light. Four types of lamellar bone exist in the skeleton: circumferential, concentric, and interstitial lamellar bone comprise the cortex, while cancellous lamellar bone is found in the medullary cavity.

Bone production can be recognized by the presence of well-stained small spicules of bone with cells in their lacunae and a prominent row of osteoblasts lining their surfaces. New bone formation can be found in a variety of physiologic and pathologic processes, including healing fracture, Paget disease, metaplastic ossification, myositis ossificans, and hyperparathyroidism, among others. However, woven bone in a skeletally mature patient is not normal and indicates an abnormality. *Bone resorption (destruction)* can be recognized by the presence of numerous osteoclasts in the bone margins and in Howship lacunae. It can involve necrotic bone or viable bone. Molecules thought to regulate the growth plate thickness and bone length through their action on chondrocytes during endochondral ossification are fibroblast growth factor receptor-3, parathyroid hormone (PTH)-related protein, and tartrate-resistant acid phosphatase. The interactions between the various bone cells and bone matrix, as well as bone homeostasis, is a complex system regulated by a variety of factors, including integrins, PTH, calcitonin, 1,25-dihydroxyvitamin D3, and estrogen. Bone remodeling is also a complex process, and bone formation and resorption is regulated by such factors as RANKL, transforming growth factor (TGF)-β, fibroblast growth factor, and bone morphogenetic proteins.[12]

Skeletal substitute material of an increasingly varying nature is being used by orthopedic surgeons to replace or "extend" bone grafts, and these can be found by the pathologist in biopsy and resection specimens in which a previous operation had taken place. Bauer has provided a useful list of these substitutes and the criteria for their recognition.[13]

Metabolic Bone Diseases

A thorough discussion of metabolic bone diseases is outside the scope of this chapter. Some metabolic bone diseases will be mentioned briefly, but for a detailed discussion the reader is referred to the books, monographs, and excellent articles that have been written on the subject.[14,15] **Osteoporosis** refers to a decreased mass of normally mineralized bone, resulting in microarchitectural deterioration and an increased risk for fractures. It develops when an individual is unable to repair and maintain the mass of bone tissue that has been acquired throughout growth and maturation.[16] Quantitative microradiographic studies have shown that the main difference between the bone in most forms of osteoporosis and normal bone is an increase in the amount of resorption, bone formation levels being generally normal.[17] Osteoporosis occurs frequently after menopause, largely due to deficiencies of estrogen. However, there are many causes of osteoporosis.

Histologic parameters are seldom used to assess for osteoporosis currently, and dual energy/photon x-ray absorptiometry, or DEXA scan, is the gold standard.[18,19] This radiographic technique compares bone mineral density to a reference population, and a measurement greater than 2.5 standard deviations below the mean is considered osteoporotic. The most common scenario in which pathologists see osteoporotic bone is in fracture specimens, particularly in the proximal femur.

The treatment of osteoporosis is based on medications that slow down bone resorption by inhibiting the formation or activity of osteoclasts, and on those that promote bone formation, such as growth factors and hormones.[20]

Osteomalacia (or rickets in a skeletally immature patient) refers to the accumulation of unmineralized bone matrix resulting from a diminished rate of mineralization. It may be secondary to a wide spectrum of congenital and acquired metabolic abnormalities that result in sufficient decrease in serum calcium, phosphorus, or both to impair mineralization of the skeleton and physeal growth.[21] Some cases have been seen as a complication of bone and soft tissue neoplasms, a phenomenon termed "tumor-induced osteomalacia" (see Chapter 41).[22] Osteomalacia changes can be demonstrated in adequate biopsies from long bones and iliac crests with preparation of nondecalcified specimens and examination with bright-field and phase-contrast microscopes and with the use of fluorescent tetracycline markers.[23]

Sophisticated methods of investigating these metabolic bone processes have been devised, but many of them are difficult to implement in the routine pathology laboratory.[24]

Fractures

Fractures are breaks in the continuity of bone, usually with interruption of periosteum, blood vessels, and sometimes muscles.

The speed of return of bone to a normal state following fracture depends on factors such as the age and nutrition of the patient, severity of the fracture, vascularity of the area, and type of treatment. Fractures may fail to heal because of improper immobilization, complete devascularization of the fractured bone segments, persistent infection, and interposition of soft tissue between the ends of the bone.

Following a fracture, a hematoma forms between the two severed ends of bone. Organization of this hematoma begins with the ingrowth of capillaries. Shortly thereafter, bone in the area of the fracture becomes necrotic. Seven to 10 days following the fracture, the hemorrhage becomes more organized, and fibroblastic, chondroid, and osteoid matrix (fracture callus) begin to appear, resulting in a histologic appearance potentially confused for osteosarcoma or chondrosarcoma. Assuming fixation is adequate and the fracture is properly immobilized, the callus is eventually remodeled to normal bone once the fracture has completely healed. The formation and persistence of cartilage largely depend on mechanical factors.[25]

With early proper reduction of the fracture, adequate blood supply, no infection, and normal metabolism, the fracture heals rapidly with little visible callus. Exuberant callus usually means slow fracture healing. In children, even with prominent angulation or deformity, the bone remodels itself to an astonishing degree. For this reason, open reduction and internal fixation of fractures in children are seldom justified. Shortening of a long bone resulting from overriding of fragments will nearly always correct itself in children by overgrowth of bone.

The formation of exuberant cartilage and disorderly woven bone in rapidly forming primary callus results in a bewildering microscopic pattern that may be confused with osteosarcoma or chondrosarcoma. This phenomenon is particularly troubling in osteogenesis imperfecta.[26] The organization and gradual transition between the various components of fracture callus help distinguish it from neoplastic processes.

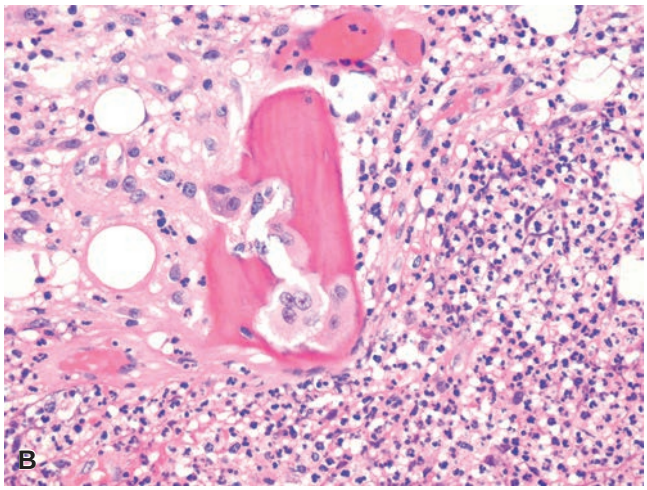

Figure 40.1 **A,** Coronal-plane MRI shows a diffuse infiltrate of variable signal intensity in the proximal tibia with adjacent soft tissue edema. **B,** In acute osteomyelitis, the inflammatory infiltrate consists primarily of neutrophils, and necrotic bone is resorbed by osteoclasts.

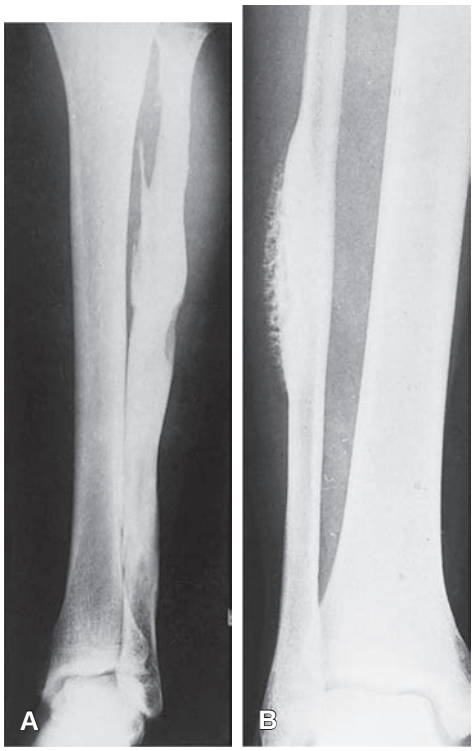

Osteomyelitis

Bacterial osteomyelitis may be caused by a large variety of microorganisms. About 70%–90% of the cases are due to *Staphylococcus aureus* (Fig. 40.1).[27] Other common offending organisms include *Klebsiella*, *Pseudomonas*, *Escherichia coli*, *Streptococcus*, and *Salmonella*. The latter organism is often involved in the osteomyelitis that affects individuals with abnormal hemoglobin, particularly sickle cell disease.[28] These various organisms gain access to bone via hematogenous spread or through direct extension or inoculation (compound fracture, spread from an adjacent cutaneous ulcer).[29] In skeletally immature patients, the metaphyses of long bones are prone to hematogenously spread osteomyelitis due to intricacies of the vascular supply near the growth plate. The vertebral column is a more common site for osteomyelitis in adult patients.

Early after the onset of osteomyelitis, plain radiographs may show vague radiolucency or no changes at all, and at this stage magnetic resonance imaging (MRI) may be necessary to identify the abnormality.[30] However, as the infection evolves, aggressive radiolucent lesions with prominent periosteal reaction can develop which simulate malignant lesions, particularly Ewing sarcoma and lymphoma, prompting biopsy.[31]

Histologically, osteomyelitis can be described as acute, subacute, or chronic. Acute osteomyelitis is characterized by acute inflammation, edema, and bone necrosis. In subacute osteomyelitis, the inflammatory infiltrate contains more lymphocytes and plasma cells, and in chronic osteomyelitis fibrosis and creeping substitution are prominent (Fig. 40.2). When the plasma cell population is particularly prominent, the disease has been designated *plasma cell osteomyelitis*,[32] and when foamy macrophages are abundant, it has been called *xanthogranulomatous osteomyelitis*.[33]

In the acute phase, the suppurative component may extend through the cortex into the subperiosteal space. A segment of necrotic cortex trapped in pus is termed a ***sequestrum***. The subperiosteal inflammation stimulates a periosteal reaction surrounding the sequestrum termed an ***involucrum***. A fenestration in the involucrum is referred to as a ***cloaca***. Osteomyelitic sinus tracts in the adult may become lined by squamous epithelium that extends deeply into the bone and becomes discontinuous with the cutaneous surface. Despite apparent healing of the overlying skin, large epidermal inclusion cysts can slowly develop in the underlying bone. These are filled with keratin-containing debris similar to that present in epidermal inclusion cysts of the skin. Rarely, after a long period, squamous cell carcinoma develops within these sinuses. This complication is heralded by the appearance of pain and increasingly malodorous discharge.[34] Chronic osteomyelitis may be accompanied by prominent periosteal bone proliferation.

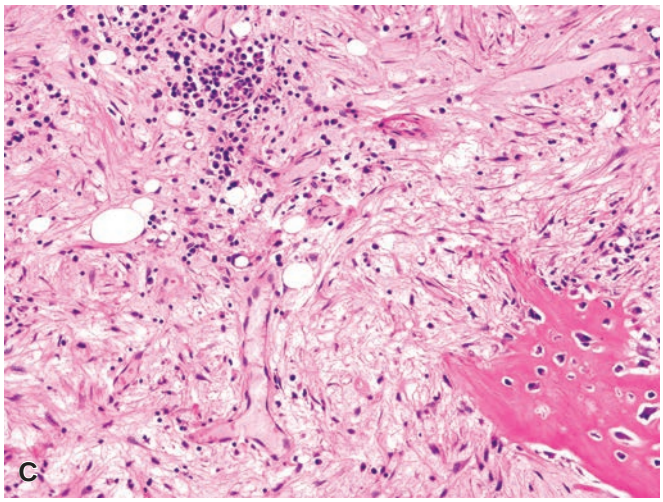

Figure 40.2 Two Examples of Chronic Osteomyelitis Involving the Fibula. A, Dense, irregular bone is evident. **B,** Prominent periosteal bone formation may cause confusion with a primary bone tumor. **C,** In chronic osteomyelitis, there is extensive fibrosis of the marrow space and a chronic inflammatory infiltrate.

A Brodie abscess is a localized form of osteomyelitis commonly occurring in the long bones. Imaging studies typically show a circumscribed, radiolucent lesion with surrounding reactive bone that may be mistaken for an osteoid osteoma.[35] Despite a predominance of neutrophils in this lesion, cultures are often negative.

A form of osteomyelitis characterized by recurrent multifocal involvement in children, sometimes associated with palmoplantar pustulosis, has been described (see also SAPHO syndrome); bacterial cultures are negative and the etiology is unknown.[36] Another variant of osteomyelitis characterized by very extensive regenerative bone changes is referred to as Garré sclerosing osteomyelitis. This form is particularly common in the jawbone.[37] It is unclear whether these variants of osteomyelitis are due to an organism or represent rheumatologic conditions.

Figure 40.3 Gummatous involvement of tibia in a 45-year-old woman.

Tuberculous osteomyelitis has increased in incidence with the AIDS epidemic and in underdeveloped countries and can be seen in children and adults.[38] The bones most often infected are the vertebrae (tuberculous spondylodiscitis, Pott disease), pelvis, knee, ankle, elbow, and wrist. The areas usually involved are the metaphysis, epiphysis, and synovium.[39]

There has been considerable controversy as to which of these areas is the one first involved. Metaphyseal infection is more common in children, and epiphyseal infection is more common in adults; however, with progression of the disease, all zones become affected. Tuberculous granulomatous synovitis destroys the joint and articular cartilage, allowing the inflammation to extend into the epiphysis and finally into the metaphyseal area. If the process begins in the epiphysis, granulomatous tissue quickly extends into the adjacent joint. When the process begins in the metaphyseal area, extension into the joint may be heralded by the development of fluid in it.

Histologically, tuberculous synovitis and osteomyelitis contain the same caseating granulomas seen in pulmonary tuberculosis. The acid-fast organisms may be identified by histochemical stains, but culture and polymerase chain reaction may be necessary for definitive diagnosis. Other causes of granulomatous inflammation in synovium and bone should be considered in the differential diagnosis, such as sarcoid and fungal infections.

Fungal infections of bone include blastomycosis, actinomycosis, histoplasmosis, and coccidioidomycosis.[40] Actinomycosis is particularly common following osteoradionecrosis.[41]

Bone involvement by **syphilis** most often occurs in congenital and tertiary syphilis but may also be encountered in secondary syphilis.[42] Tertiary syphilis may also lead to neuropathic arthropathy through tabes dorsalis.[43] Both bone destruction and periostitis can occur, resulting in the classic "saber shin" deformity when the tibia is involved (Fig. 40.3). The necrotic, well-defined defects are mainly cortical and periosteal and are surrounded by reactive bone. They may occur in the vertebrae, small bones of the hands and feet, and

diaphysis of long tubular bones. Treponemal spirochetes cause microangiitis and obliterative endarteritis, ultimately leading to granuloma-like lesions, or gummas. The spirochetes can be demonstrated by silver stain or by specific immunohistochemical stains.

Malakoplakia of bone has been described. As in the bladder and other sites, it probably represents an unusual host reaction to bacterial infection.[45]

Bone Necrosis

Necrotic bone can be recognized by the loss of osteocytes and changes in the marrow, including fat necrosis, fibrosis, and calcification. The histologic changes in the bone are identical regardless of the cause of the necrosis (Fig. 40.4).

Bone Infarct

Bone infarct can be the result of a large number of etiologic factors. Radiographically, the changes depend on the age of the lesion and the degree of repair. During the first 1 or 2 weeks, no abnormalities are detected on a plain radiograph. Resorption of the dead bone results in areas of decreased density, whereas new bone formation growing in apposition to necrotic trabeculae ("creeping substitution") leads to an increase in bone density. The increased bone density is due to both creeping substitution and calcification of the fibrotic marrow space, resulting in a lesion that vaguely resembles an enchondroma radiographically (Fig. 40.5).

An increased incidence of primary malignant bone tumors has been seen in association with large infarcts of long bones. Most of the reported cases have occurred in the medulla of the femur or tibia of male adults and have been diagnosed as undifferentiated pleomorphic sarcoma, osteosarcoma, "fibrosarcoma," or angiosarcoma.[46–49]

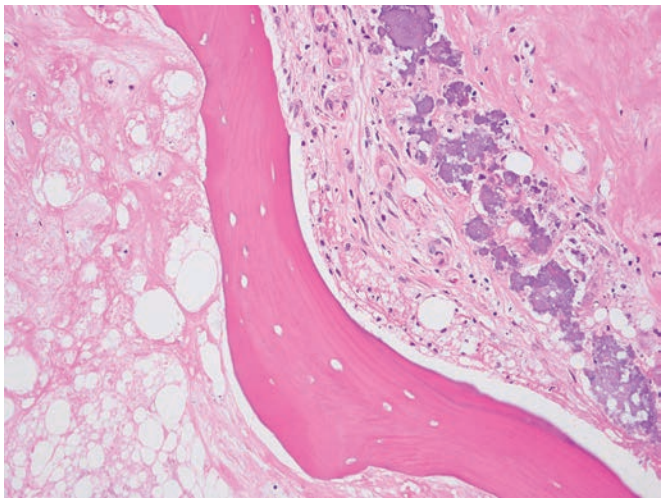

Figure 40.4 Bone necrosis is characterized by loss of osteocytes and necrosis or fibrosis of the fatty marrow.

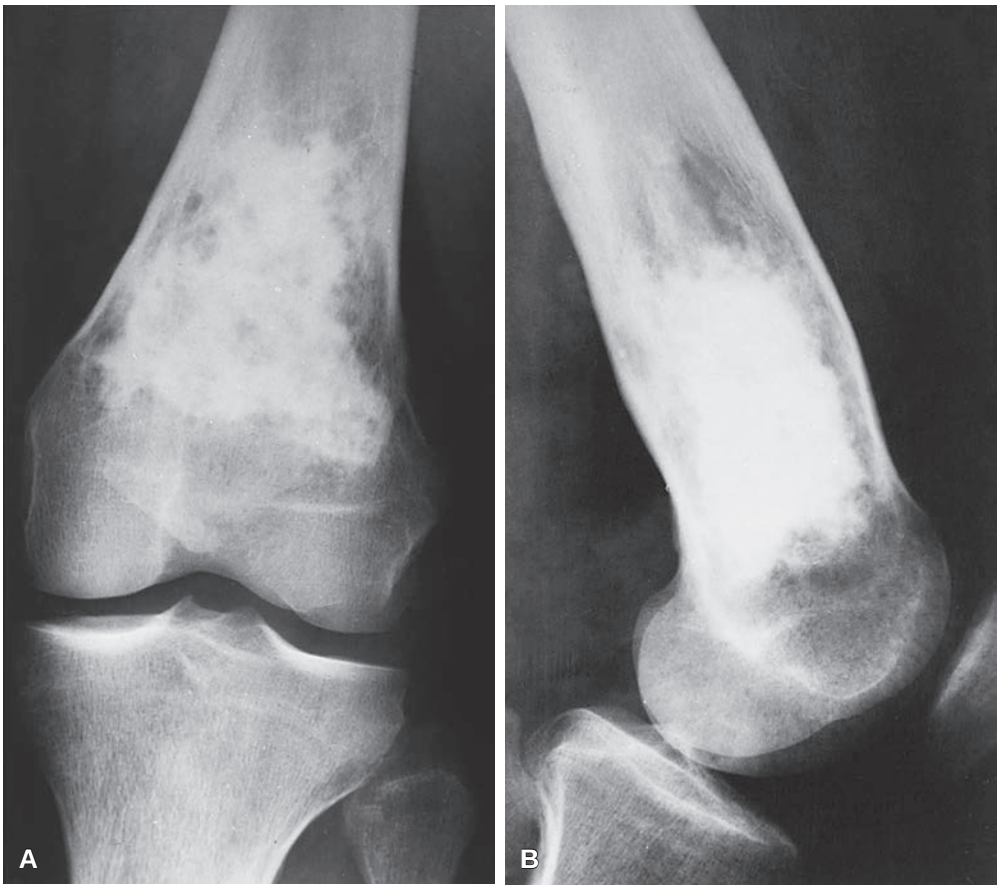

Figure 40.5 AP **(A)** and lateral **(B)** radiographs show a large metadiaphyseal bone infarct of femur. The irregular area of increased radiodensity is indicative of new bone production superimposed on necrosis. (Courtesy of Dr H Danziger, Welland, Ontario, Canada)

Osteonecrosis (Avascular/Aseptic Bone Necrosis)

Osteonecrosis (avascular/aseptic necrosis) is a common abnormality that has been reported at the ends of virtually all long bones, most commonly the proximal femur and proximal humerus (Fig. 40.6).[50] Many of these sites have been described separately and given eponymic designations such as Legg-Calvé Perthes disease (osteonecrosis of the femoral head in childhood), Kienbock disease (osteonecrosis of the lunate), or Freiburg disease (osteonecrosis of the metatarsal).

When the blood supply to the involved bone is interrupted, whether intrinsically (thrombosis induced by sickle cell disease) or extrinsically (by fracture or dislocation), an infarct occurs in the subchondral bone.[51,52] In the femoral head, the area of osteonecrosis appears radiodense, and a "crescent sign" may be present representing separation of the subchondral plate and overlying articular cartilage from the remainder of the bone.[53] Osteonecrosis of the femoral head is mistaken for severe osteoarthritis with some frequency, and the underlying cause may not be recognized until the femoral head is examined pathologically.[54]

Grossly, the necrotic bone of avascular necrosis has a yellow, friable appearance. Often the articular cartilage and subchondral plate are separated from the underlying bone. With collapse, and the onset of secondary arthritis, the infarct may be difficult to identify. Histologically, the well-defined area of osteonecrosis is surrounded by fibrovascular tissue and reactive bone. The interface between the infarct and viable bone is rich in osteoclastic activity, and necrotic bone is eventually replaced by a process referred to as "creeping substitution" in which woven bone is directly deposited onto necrotic bone trabeculae.

Osteochondritis Dissecans

Osteochondritis dissecans results from a small area of necrosis involving the articular cartilage and subchondral bone that totally or partially separates from the adjacent structures. The etiology is uncertain but is probably related to trauma in most of the cases.[55,56] It occurs most frequently on the lateral aspect of the medial femoral condyle, near the intercondylar notch (Fig. 40.7). Microscopically, a portion of articular cartilage is always present, often exhibiting secondary calcification; in addition, a fragment of subchondral bone is found in approximately half of the cases.[57] If this osteocartilaginous fragment remains attached to the joint surface or synovium, both components remain viable. If, instead, it becomes completely detached, its osseous portion dies, but the cartilage remains alive, apparently through nutrients obtained from the synovial fluid, resulting in an osteocartilaginous loose body. Patients with bilateral symmetric involvement and cases with familial incidence have been described.

Osteochemonecrosis

Bisphosphonates and other osteoclast inhibitors, vascular endothelial growth factor (VEGF) inhibitors, and tyrosine kinase inhibitors have all been associated with osteonecrosis of the jaw.[58,59] The devitalized bone is often accompanied by inflammation and actinomyces, and there may be evidence of bone resorption without accompanying osteoclasts.[60]

Radiation Necrosis

Damage to the underlying bone can be a major complication of radiation therapy, whether alone or combined with chemotherapy.[61] Radiation changes resulting in serious complications have been reported in the jaw, ribs, pelvis, spine, humerus, and several other bones. The changes usually occur within 3 years of the therapy. Microscopically, these changes consist of necrotic bone, fibrosis of the bone marrow, and neovascularization. Irregular, heavily staining cement lines may develop and lead to confusion with Paget disease. Radiation necrosis of the jaw can be complicated by actinomycosis, an often underdiagnosed occurrence.[41]

Paget Disease

Paget disease is a preneoplastic condition characterized by increased bone turnover, followed by compensatory bone formation. The highest incidence occurs in England, Australia, and western Europe.[62] In an often-quoted autopsy series from England, about one in 30 patients over 40 years of age had Paget disease.[63] The majority of patients with Paget disease are over 55 years of age at diagnosis, and the disease is rare before the age of 40 years. Cases of juvenile Paget disease are described in which patients have osteoprotegerin deficiency.[64] Paget disease affects men slightly more often than women (4 : 3). It can be monostotic or polyostotic, and the most common sites include the pelvis, lumbosacral spine, and craniofacial bones, but long bones are commonly involved as well. Patients with Paget disease are commonly asymptomatic but may present with bone pain, deformities, pathologic fracture, or arthritis.[62]

Radiographically, early Paget lesions are radiolucent, resulting in "osteoporosis circumscripta" in the skull and mimicking a neoplasm in long bones. However, over time the affected bone becomes enlarged, and cortical thickening and coarsening of the trabecular architecture becomes more prominent. During the inactive, terminal phase of Paget disease, the blastic features become even more prominent, resulting in cotton wool-like densities in the skull and bowing deformities of long bones (Figs. 40.8 and 40.9).[65]

Microscopically, early Paget lesions are characterized by osteoclastic resorption, peritrabecular fibrosis, and prominent vascularity, very similar to what is seen in hyperparathyroidism (Fig. 40.10). During the middle phase of Paget disease, bone formation becomes more prominent. Bone trabeculae tend to be enlarged and irregular, with prominent osteoblastic activity and irregular cement lines. In the final phase of Paget disease, osteoblastic and osteoclastic activity diminishes, leaving markedly thickened, irregular bone trabeculae with prominent "mosaic pattern" cement lines. It is not uncommon to identify all phases of Paget disease simultaneously in a tissue sample. "Mosaic pattern" cement lines are not specific for Paget disease and can be identified in any high turnover condition involving the bone.

One very important, albeit uncommon, complication of Paget disease is the development of a sarcoma. Osteosarcoma is by far the most common type (about 80% of all cases), but chondrosarcoma, fibrosarcoma, and giant cell tumors have also been observed.[66,67] Instances of familial or geographic clustering of this complication have been reported. The most common locations of sarcomas arising in Paget disease are the femur, humerus, pelvis, tibia, and skull. Osteosarcoma should be distinguished from the periosteal (juxtacortical) bone masses that can be seen as an exaggerated expression of the basic pathologic process of Paget disease.[68] The prognosis of Paget sarcoma remains very poor.

Proposed etiologies for Paget disease have historically included infectious, environmental, and genetic factors.[69] The suggestion that it might be of viral origin has been raised by the finding of nuclear inclusions resembling paramyxovirus nucleocapsids in the lesional osteoclasts but is unlikely. Mutations in the coding region of the sequestosome 1 *(SQSTM1)* gene, which produces the p62 protein, are associated with both sporadic and familial Paget disease.[69,70]

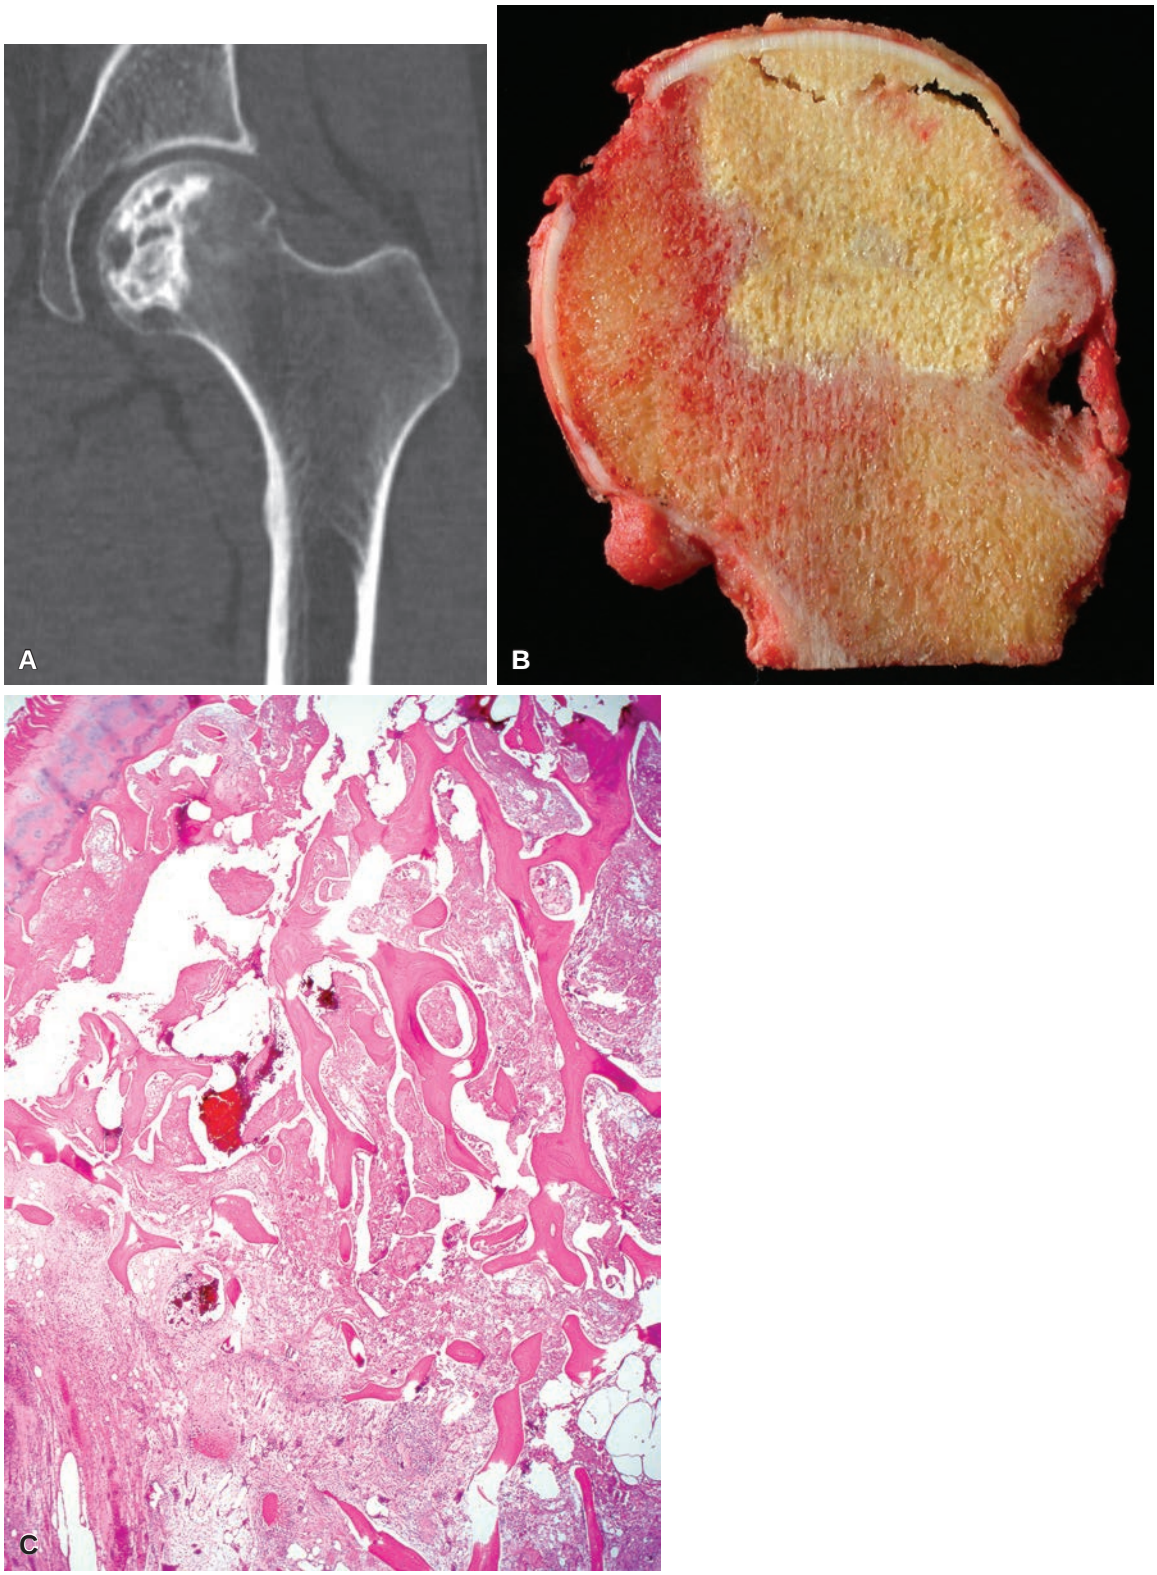

Figure 40.6 **A,** Coronal CT shows a discrete area of subchondral density with cystic change, indicative of avascular necrosis. **B,** A discrete area of avascular necrosis, which appears yellowish on cut section. Separation of the articular cartilage and subchondral bone is characteristic. **C,** The infarct is contained by a hypervascular reactive zone. The separation of the articular cartilage and subchondral bone is evident histologically.

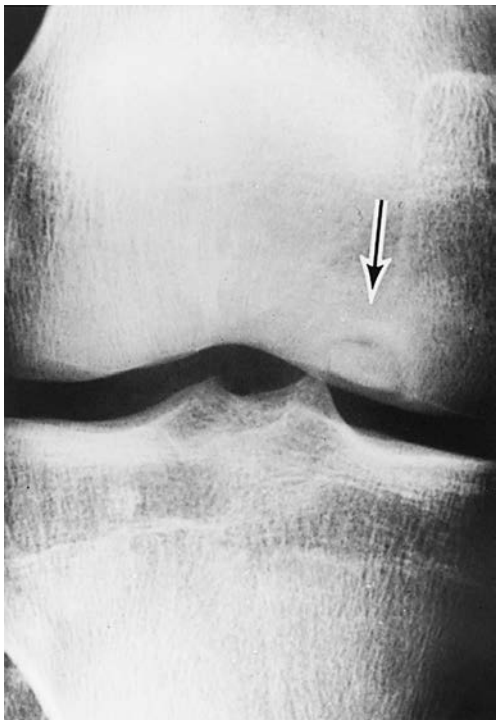

Figure 40.7 Sharply delimited area of osteochondritis dissecans of medial condyle *(arrow)*. This was easily enucleated.

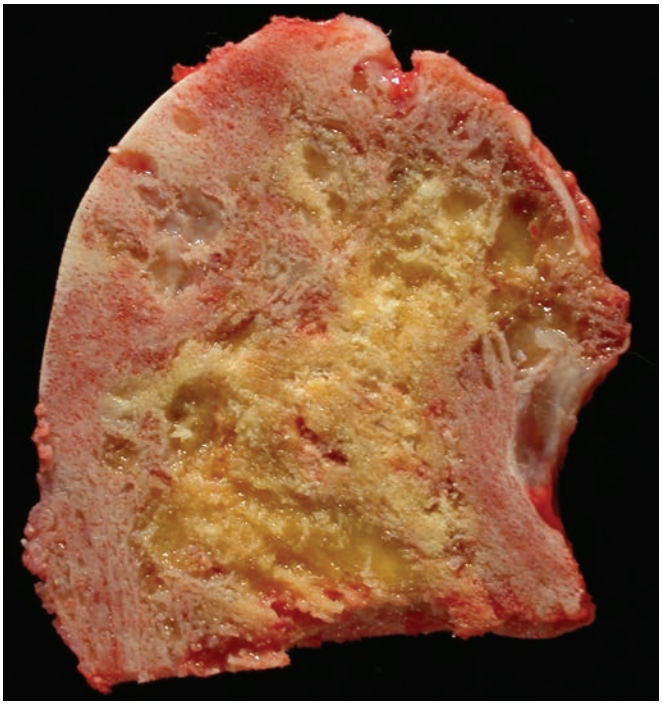

Figure 40.9 Paget disease involving the femoral head. There is marked deformity of the femoral head with coarsening of the bone, as well as secondary osteoarthritis.

Figure 40.8 Radiograph of Paget disease involving the tibia. Both cortical thickening and coarsening of the cancellous bone is accompanied by an anterior bowing deformity.

Genome-wide association studies have identified other genes also associated with Paget disease.

Osteopetrosis

Osteopetrosis (Albers–Schönberg disease, marble-bone disease) is a group of genetically determined disorders resulting from defects in osteoclast function or development.[71,72] At least 10 genes have been identified as causative, such as those encoding molecules involved in acidification machinery (e.g., *TCIRG1*, *CLCN7*, *OSTM1*, and *CLCN7*) and those affecting osteoclast differentiation, which result in the osteoclast-poor form of the disease (e.g., *LRP5*, *RANKL*).[73,74]

Microscopically, the disorder is characterized by persistence in the marrow cavity of unresorbed primary spongiosa, with or without alterations in osteoclast number and morphology, depending on the subtype of the disease.[75] Infantile forms of osteopetrosis, generally inherited autosomal recessively, have a poor prognosis, whereas adult forms, generally inherited autosomal dominantly, have a good prognosis but are often complicated by severe arthritis. The disease has been reversed by bone marrow transplantation, and complications such as arthritis and fracture typically require surgical intervention.

Tumors

Classification and Distribution

The terminology and classification of bone tumors and tumorlike lesions are largely those recommended by the World Health Organization (WHO).[76]

In the WHO classification, neoplasms are classified as either benign, intermediate (locally aggressive or rarely metastasizing), or malignant. In the most recent WHO publication, several entities have been shifted from one of these categories to another. For example, grade 1 chondrosarcoma/atypical cartilaginous neoplasm, while traditionally thought of as "malignant," is now found in the "intermediate (locally aggressive)" category. Most malignant bone tumors arise de novo, but there are a small number of benign bone lesions that predispose the patient to the development of skeletal

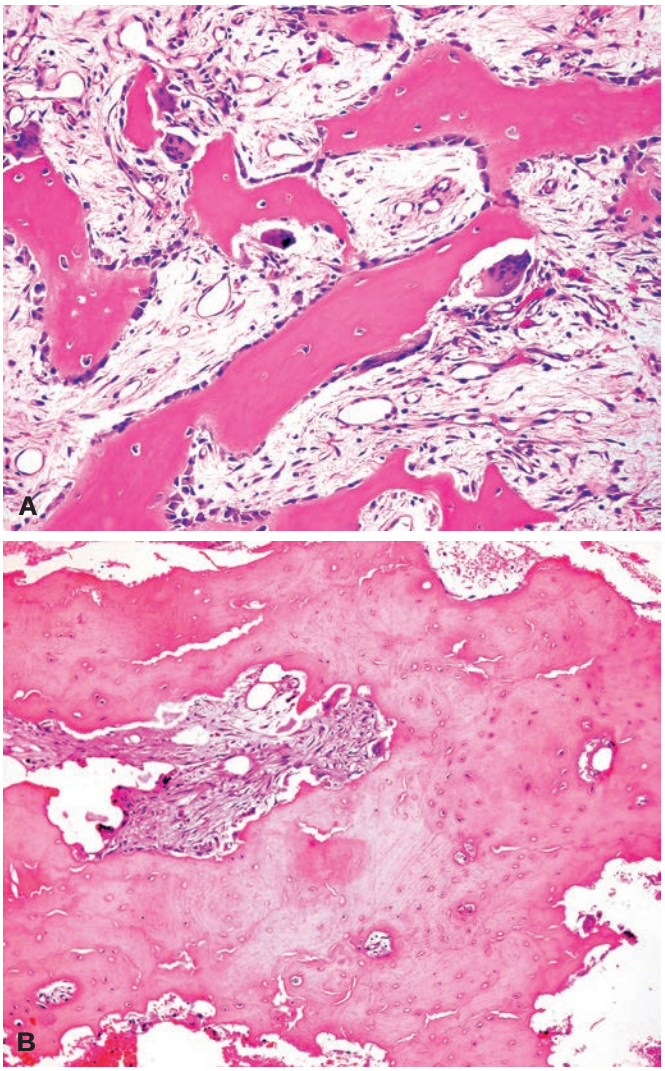

Figure 40.10 Paget Disease. A, Early changes. There is prominent osteoclastic activity, osteoblastic activity, and fibrosis. **B,** A well-established case, with thick, irregularly shaped bone trabeculae and cracking artifact along reversal lines.

malignancies; these include Paget disease, enchondromatosis, osteochondromatosis, and fibrous dysplasia.[77]

Tumors of the skeletal system are relatively constant in their pattern of presentation when one takes into consideration the patient's age and status of the growth plate, the bone involved, the specific area within the bone that is involved (epiphysis, metaphysis, diaphysis, medullary cavity, cortex, bone surface), the radiographic appearance, and the histologic appearance. Table 40.1 should assist in providing a quick orientation for the pathologist confronted with a bone neoplasm.

Bone-Forming Tumors

Osteoma

Osteoma is seen primarily in the flat bones of the craniofacial skeleton, typically arising from the surface of the involved bone. It may protrude into the orbit or a paranasal sinus (particularly the frontal and ethmoid) and block the normal drainage from these sinuses. Similar lesions, albeit smaller in size, located within the medullary cavity are referred to as enostoses or "bone islands." Microscopically, osteoma is composed of dense, mature lamellar bone. Occasional cases of sino-orbital osteoma contain foci that closely resemble osteoblastoma (Fig. 40.11).[78]

Osteoma is benign and probably not a true neoplasm. Some cases may represent end stages of fibrous dysplasia, related fibro-osseous lesions, or even subperiosteal hematomas. Patients with familial adenomatous polyposis (intestinal polyposis and soft tissue tumors) may have multiple osteomas and other abnormalities,[79] whereas cases of solitary osteoma are usually nonsyndromic.[80] Osteopoikilosis is an autosomal dominant form of sclerosing bone dysplasia characterized by multiple, symmetrically distributed bone islands.[81]

Occasionally, osteomas involve non-craniofacial bones. Most of these have a parosteal location and need to be distinguished from parosteal osteosarcoma.[82]

Osteoid Osteoma and Osteoblastoma

Osteoid osteoma is a benign bone neoplasm that is found most frequently in patients between 10 and 30 years of age and that exhibits a 2:1 male-to-female ratio. Intense pain relieved by nonsteroidal anti-inflammatory drugs is the most prominent symptom; the pain is often sharply localized, more severe at night, and unaccompanied by clinical or laboratory evidence of infection. Vertebral lesions may be associated with scoliosis.[83]

Osteoid osteoma has been reported in practically every bone but occurs most frequently in the femur, tibia, humerus, bones of the hands and feet, vertebrae, and fibula.[84,85] Lesions of long bones are usually metaphyseal, but they may be epiphyseal and even juxta-/intra-articular (arising within the portion of the bone contained within the joint capsule).[86] Most are centered in the cortex (85%), but they may also occur in the medullary cavity (13%) or subperiosteal region (2%).[87] Vertebral lesions typically affect the posterior elements.

Radiographically, osteoid osteomas contain a radiolucent central nidus smaller than 1.5 cm that may or may not contain a radiodense center (Fig. 40.12). This nidus is surrounded by a peripheral sclerotic reaction that may extend for several centimeters along both sides of the cortex; however, osteoid osteomas arising within the medullary cavity may lack this reaction. The radiographic differential diagnosis includes Brodie abscess, sclerosing osteomyelitis, and stress fracture. Juxta-articular lesions may be mistaken for an inflammatory arthropathy due to the induction of a marked chronic synovitis, and lesions in this location may be better visualized with MRI scans.[86]

Microscopically, the sharply delineated central nidus is composed of more or less calcified osteoid and woven bone lined by plump osteoblasts and growing within highly vascularized connective tissue, without evidence of inflammation (Fig. 40.13). The appearance is so characteristic that the lesion can still be diagnosed when removed piecemeal. Surrounding the nidus, there is a variably thick layer of dense bone.

The pain associated with osteoid osteoma is characteristically more intense at night, relieved by nonsteroidal anti-inflammatory drugs such as aspirin, and eliminated by removal of the nidus. It has been attributed by some authors to the effect on nerves and vessels of osteoblast-produced prostaglandin E2, which is typically present in large amounts in these lesions.[88,89] Others believe that the pain is simply related to the presence of entrapped and proliferating nerves within and around the nidus.[90,91]

CT-guided radiofrequency ablation has largely replaced surgical excision for osteoid osteoma, and proven to be an extremely effective treatment modality for both spinal and extra-spinal tumors. This technique provides excellent pain relief, reduces operative morbidity, and is associated with a low recurrence rate.[92–94]

Table 40.1 Usual age, gender, location, and behavior of the most common primary bone tumors and tumorlike lesions[a]

TUMOR OR TUMORLIKE LESION	AGE (YR)	GENDER (M:F)	BONES MOST COMMONLY AFFECTED (IN ORDER OF FREQUENCY)	USUAL LOCATION WITHIN LONG BONE	BEHAVIOR
Osteoma	40–50	2:1	Skull and facial bones	—	Benign
Osteoid osteoma	10–30	2:1	Femur, tibia, humerus, hands and feet, vertebrae, fibula	Cortex of metaphysis	Benign
Osteoblastoma	10–30	2:1	Vertebrae, tibia, femur, humerus, pelvis, ribs	Medulla of metaphysis	Benign
Osteosarcoma	10–25	3:2	Femur, tibia, humerus, pelvis, jaw, fibula	Medulla of metaphysis	Malignant; 20% 5-year survival rate
Juxtacortical (parosteal) osteosarcoma	30–60	1:1	Femur, tibia, humerus	Juxtacortical area of metaphysis	Malignant; 80% 5-year survival rate
Chondroma	10–40	1:1	Hands and feet, ribs, femur, humerus	Medulla of diaphysis	Benign
Osteochondroma	10–30	1:1	Femur, tibia, humerus, pelvis	Cortex of metaphysis	Benign
Chondroblastoma	10–25	2:1	Femur, humerus, tibia, feet, pelvis, scapula	Epiphysis, adjacent to cartilage plate	Practically always benign
Chondromyxoid fibroma	10–25	1:1	Tibia, femur, feet, pelvis	Metaphysis	Benign
Chondrosarcoma	30–60	3:1	Pelvis, ribs, femur, humerus, vertebrae	Central: medulla of diaphysis; peripheral: cortex or periosteum of metaphysis	Malignant. 5-year survival rate: low grade, 78%; moderate grade, 53%; high grade, 22%
Mesenchymal chondrosarcoma	20–60	1:1	Ribs, skull and jaw, vertebrae, pelvis	Medulla or cortex of diaphysis	Malignant; extremely poor prognosis
Giant cell tumor	20–40	4:5	Femur, tibia, radius	Epiphysis and metaphysis	Potentially malignant; 50% recur; 10% metastasize
Ewing sarcoma/PNET	5–20	1:2	Femur, pelvis, tibia, humerus, ribs, fibula	Medulla of diaphysis or metaphysis	Highly malignant; 20%–30% 5-year survival rate in recent series
Malignant lymphoma, large cell, and mixed cell types	30–60	1:1	Femur, pelvis, vertebrae, tibia, humerus, jaw, skull, ribs	Medulla of diaphysis or metaphysis	Malignant; 22%–50% 5-year survival rate
Plasma cell myeloma	40–60	2:1	Vertebrae, pelvis, ribs, sternum, skull	Medulla of diaphysis, metaphysis, or epiphysis	Malignant; diffuse form uniformly fatal, localized form often controlled with radiation therapy
Hemangioma	20–50	1:1	Skull, vertebrae, jaw	Medulla	Benign
Desmoplastic fibroma	20–30	1:1	Humerus, tibia, pelvis, jaw, femur, scapula	Metaphysis	Benign
Fibrosarcoma	20–60	1:1	Femur, tibia, jaw, humerus	Medulla of metaphysis	Malignant; 28% 5-year survival rate
Chordoma	40–60	2:1	Sacrococcygeal, spheno-occipital, cervical vertebrae	—	Malignant; slow course; locally invasive; 48% distant metastases
Solitary bone cyst	10–20	3:1	Humerus, femur	Medulla of metaphysis	Benign

Table 40.1 Usual age, gender, location, and behavior of the most common primary bone tumors and tumorlike lesions—cont'd

TUMOR OR TUMORLIKE LESION	AGE (YR)	GENDER (M:F)	BONES MOST COMMONLY AFFECTED (IN ORDER OF FREQUENCY)	USUAL LOCATION WITHIN LONG BONE	BEHAVIOR
Aneurysmal bone cyst	10–20	1:1	Vertebrae, flat bones, femur, tibia	Metaphysis	Benign, sometimes secondary to another bone lesion
Metaphyseal fibrous defect	10–20	1:1	Tibia, femur, fibula	Metaphysis	Benign
Fibrous dysplasia	10–30	3:2	Ribs, femur, tibia, jaw, skull	Medulla of diaphysis or metaphysis	Locally aggressive; rarely complicated by sarcoma
Langerhans cell histiocytosis	5–15	3:2	Skull, jaw, humerus, rib, femur	Metaphysis or diaphysis	Benign

[a]It should be emphasized that these data correspond to the typical case and should not be taken in an absolute sense. Isolated exceptions to practically every one of these statements have occurred.
PNET, Primitive neuroectodermal tumor.

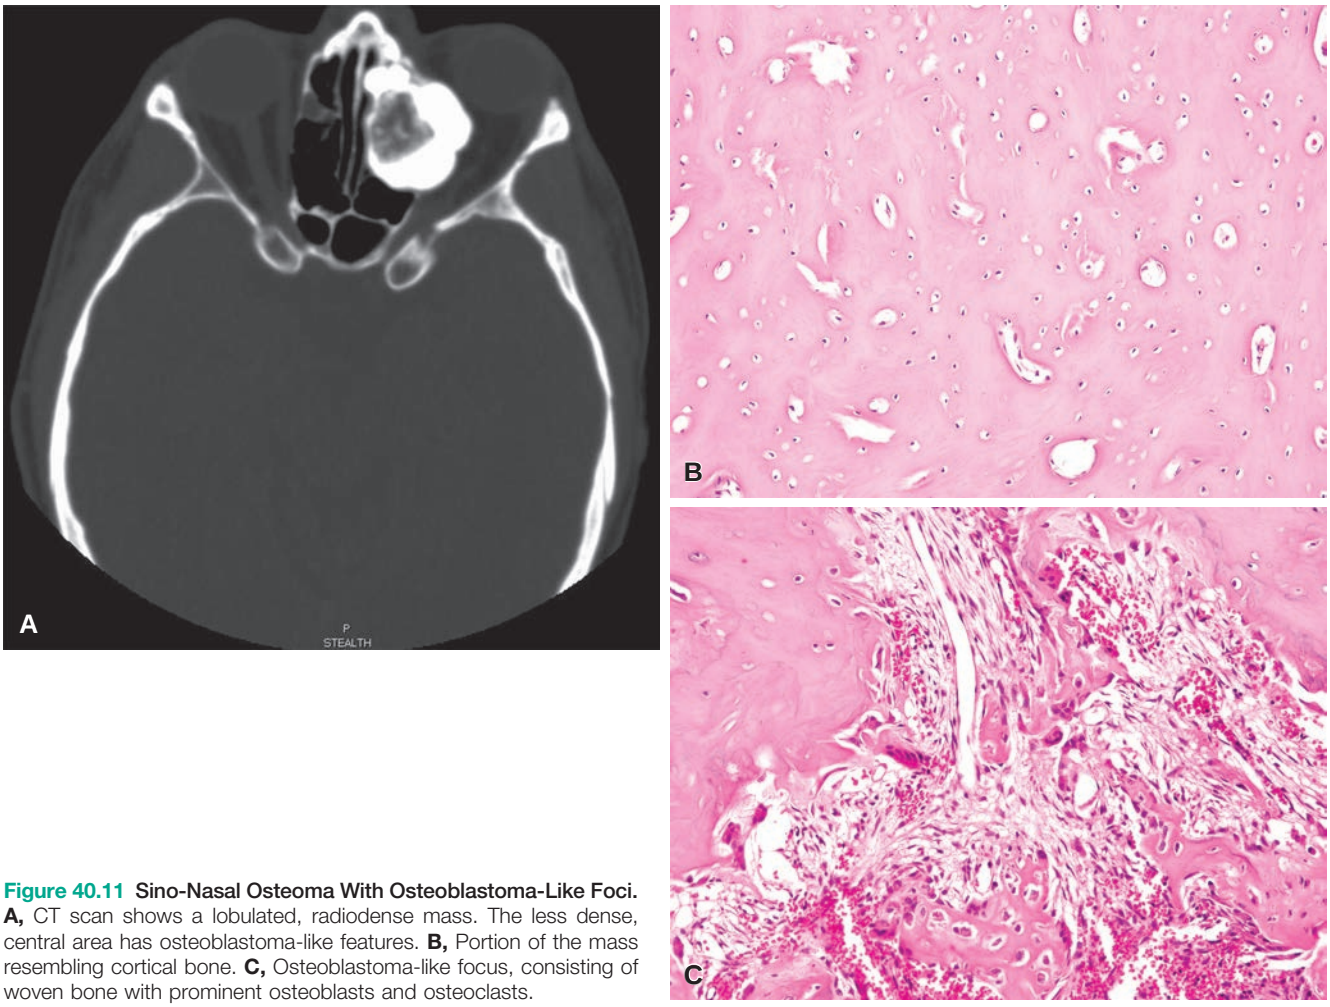

Figure 40.11 Sino-Nasal Osteoma With Osteoblastoma-Like Foci. **A,** CT scan shows a lobulated, radiodense mass. The less dense, central area has osteoblastoma-like features. **B,** Portion of the mass resembling cortical bone. **C,** Osteoblastoma-like focus, consisting of woven bone with prominent osteoblasts and osteoclasts.

Osteoblastoma is a tumor closely related to osteoid osteoma both microscopically and immunohistochemically (Fig. 40.14).[95] It is distinguished from osteoid osteoma by its larger size, the absence or inconspicuousness of a surrounding area of reactive bone formation, and less intense pain.[96] Most cases arise in the medullary cavity of the bone, but cortical and subperiosteal forms also occur. The majority of the cases are located in the spine or major bones of the lower extremity.[97]

Figure 40.12 AP radiograph of an osteoid osteoma of the tibia. The radiolucent central nidus is surrounded by dense, reactive bone.

Radiographically, osteoblastomas appear as well-defined radiolucent lesions with haphazardly distributed foci of mineralization. Their size (>2 cm) is larger than osteoid osteoma, and the perilesional reactive bone is typically less pronounced. When osteoblastomas arise in flat bones, they may have radiographic findings that mimic a malignant bone tumor.[98]

Microscopically, the features of osteoblastoma are very similar to the nidus of osteoid osteoma. It is sharply circumscribed from adjacent bone, and those that extend beyond the cortex are encompassed by a thin rim of reactive bone. Anastomosing trabeculae of woven bone prominently lined by osteoblasts are separated by a loose fibrovascular stroma, and multinucleated giant cells may be prominent. A cartilaginous matrix may be encountered in rare cases.[99] The differential diagnosis between osteoblastoma and osteosarcoma can be extremely difficult because the latter may be very well differentiated and the former is sometimes accompanied by the presence of scattered bizarre tumor cells probably of a degenerative nature[100,101] or may be composed of large epithelioid cells accompanied by telangiectatic features.[102] Permeation of host bone trabeculae should raise suspicion for osteosarcoma, as should foci of necrosis and the presence of mitotic activity. As is the case in many other bone tumors, the radiographic pattern is of great assistance in this differential diagnosis. However, in some cases of osteoblastoma the radiographic picture suggests a malignant neoplasm.

Epithelioid (aggressive) osteoblastoma and related lesions. Some lesions with the radiographic and architectural features of osteoblastoma show atypical cytologic features that some authors believe correlate with a tendency for local recurrence. These tumors have been designated epithelioid (aggressive) osteoblastomas. According to Dorfman and Weiss, these tumors are distinguished microscopically from the ordinary osteoblastomas mainly by the presence of large, epithelioid-appearing osteoblasts, which are at least twice the size of ordinary tumor osteoblasts.[103] They are distinguished from conventional osteosarcomas because of a low mitotic rate and the absence of the following features: lace-like osteoid, permeation of surrounding intertrabecular spaces, and atypical

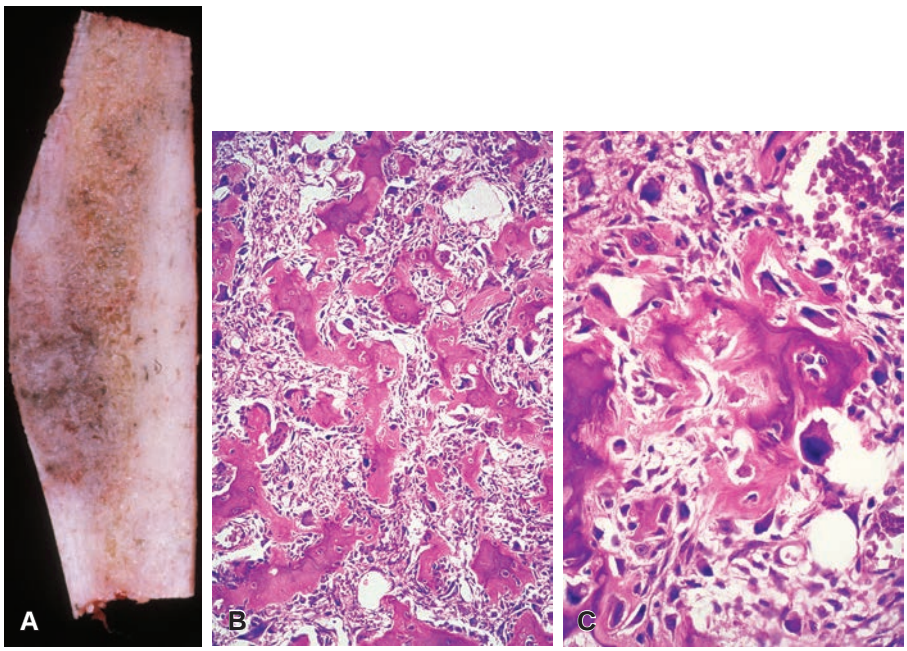

Figure 40.13 Osteoid Osteoma. A, Grossly, the gritty 8-mm nidus of the osteoid osteoma is evident within dense bone. **B,** Medium-power and **C**, high-power microscopic views of osteoid osteoma. There is woven bone surrounded by plump osteoblasts. The stroma is cellular and well vascularized.

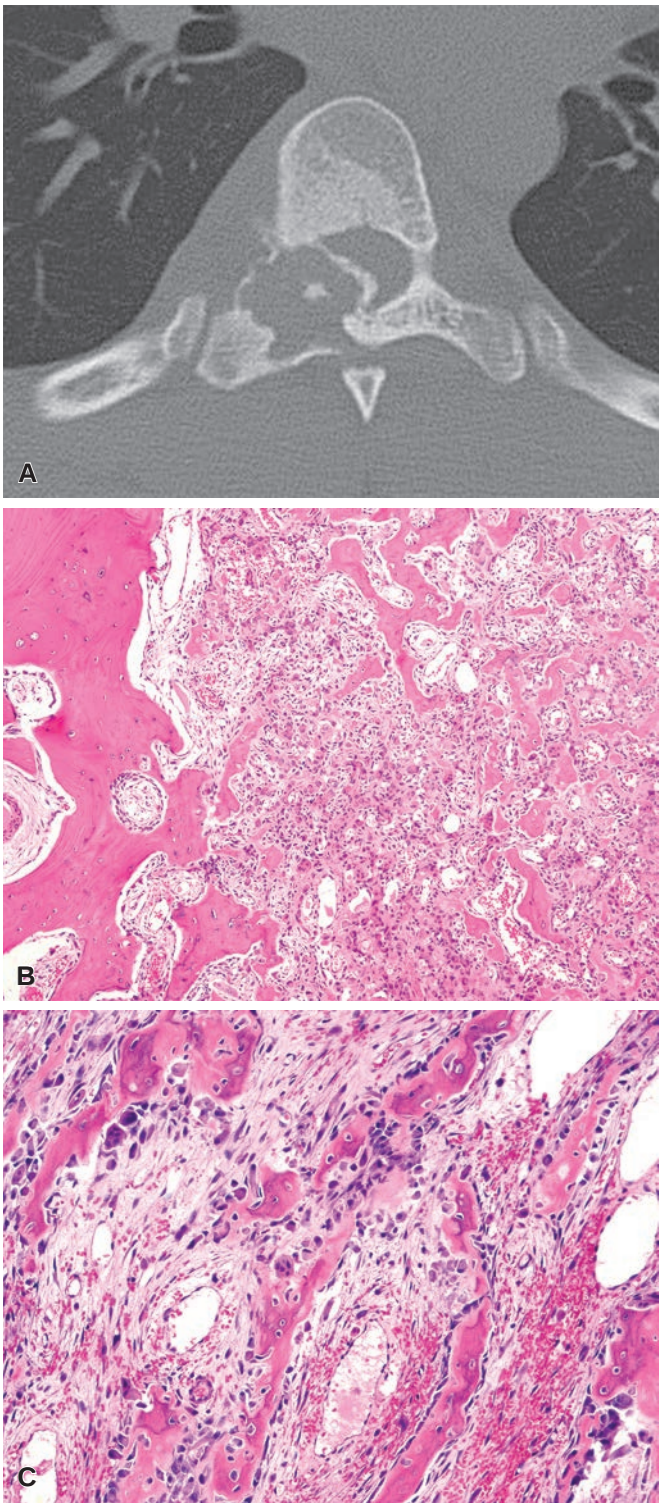

Figure 40.14 Osteoblastoma of the Spine. A, CT scan shows a well-circumscribed radiolucent lesion with central density arising in the posterior elements of the vertebra. Reactive bone formation is evident in the vertebral body adjacent to the lesion. **B,** Low-power view shows a sharply circumscribed border. **C,** Woven bone with prominent osteoblasts, fibrovascular stroma, and ectatic blood vessels characterize osteoblastoma.

mitoses. The entity "epithelioid multinodular osteoblastoma" is characterized by multiple nodules of epithelioid osteoblasts either lacking bone formation or containing irregular blue-staining osteoid.[104] The entities of epithelioid osteoblastoma, malignant osteoblastoma,[105] pseudoanaplastic osteoblastoma,[106] osteosarcoma resembling osteoblastoma,[100] and osteoblastoma-like osteosarcoma[107] are histologically similar lesions, some of which have been reported to metastasize.

Osteosarcoma

The WHO defines osteosarcoma as a malignant neoplasm in which the neoplastic cells produce bone.[76,108] It is the most common primary malignant bone tumor, exclusive of hematopoietic malignancies. It usually occurs as a painful mass in patients between 10 and 25 years of age and is exceptionally rare in very young children. A second peak age incidence occurs after 40, usually in association with other preexisting disorders (see the following discussion). There is a slight male predominance (1.5:1).

Predisposing factors. Most osteosarcomas arise de novo, but others arise within the context of a preexisting condition:

1. *Paget disease*. A high number of osteosarcomas developing in patients over the age of 40 are located in bones affected by Paget disease.[109]
2. *Radiation exposure*. One of the classic cases of human carcinogenesis occurred in a group of factory workers in Illinois who developed osteosarcomas from moistening brushes in their mouths when applying radium paint to create luminous numerals on watches.[110,111] Some cases of osteosarcoma have also been reported years after Thorotrast administration.[112] However, in more recent times, osteosarcoma is known to be a complication of external beam radiation therapy.[113] The average latency period ranges from 10 to 15 years in the various reported series.[114] While many radiotherapy-associated sarcomas of bone are osteosarcomas, many are not classifiable at the microscopic and immunohistochemical level.
3. *Chemotherapy*. Children treated with alkylating agents for retinoblastoma and other malignancies have an increased risk of osteosarcoma.[115] Genetic factors probably play an important contributory role.
4. *Preexisting benign bone lesions*. These include fibrous dysplasia, bone infarct, and osteogenesis imperfecta[116] (see respective sections).
5. *Foreign bodies*. Rare well-documented cases of osteosarcoma have been reported arising at the site of a total hip replacement or at sites of other orthopedic implants.[117,118]
6. *Genetic predisposition*. Patients with Li–Fraumeni syndrome (usually caused by germline mutation of the *TP53* gene), hereditary retinoblastoma (caused by germline mutation of the *RB1* gene), Rothmund–Thomson syndrome, Werner syndrome, and familial Paget disease have an increased risk of developing osteosarcoma.[119,120]
