Normal Anatomy of the Anus

The anus and anal canal comprise a complex anatomic region with historically controversial nomenclature, due to the fact that the extent of the zones from person to person is variable and that the macroscopic and microscopic zones often do not correspond. The anal canal is a tubular structure measuring 3–4 cm in length and includes the squamous zone, the transition zone, and the colorectal zone (Fig. 18.1).[1–4] The most proximal zone of the anal canal is the colorectal zone. The squamous zone is the most distal aspect of the anal canal, and it extends from the perianal skin to the lower end of the rectum and is demarcated by the proximal and distal margins of the internal sphincter muscle. The junction between the anal canal and the perianal skin is known as the anal verge or Hilton's white line. Although no specific structure corresponds to Hilton's line, this transition is identified microscopically by the appearance of cutaneous adnexa and the presence of keratinized squamous epithelium.[1–3] The perianal skin contains a wide variety of adnexal structures, including apocrine glands, eccrine glands, and anogenital sweat glands.[1,2,5] The anal orifice forms a triradiate or Y-shaped opening, with the trunk of the "Y" at the posterior midline. The three folds outlined by the "Y" are known as the anal cushions.[1,2]

The dentate (pectinate) line is located within the anal canal and represents the line formed by the anal valves, anal sinuses, and the bases of the anal columns.[1–4] The anal columns (of Morgagni) are longitudinal folds with depressions between them known as anal sinuses (of Morgagni); homologous structures in the lower rectum are designated rectal columns and sinuses (of Morgagni). The anal columns are connected at the dentate line by the anal or semilunar valves (transverse plicae). These valves form the inner boundary of minute pockets known as anal crypts (of Morgagni). Of note, ganglion cells are normally absent or sparse within 1 cm of the dentate line, which is important to recognize when evaluating patients for Hirschsprung disease.[6]

Anal papillae are tooth-like, raised projections located on top of the anal columns and extending upward into the rectum, representing ridges of squamous mucosa directly joining the rectal mucosa.[1,2] Both anal crypts and papillae show marked individual variation and are occasionally absent. The anal glands discharge into the anal crypts through anal ducts, which can extend upward or, more commonly, downward. They penetrate the sphincters and sometimes extend into the perianal fat (Fig. 18.2).[7,8] The epithelium that lines these ducts is similar to that of the overlying transitional epithelium, including sparse mucin production characterized by scarcity or absence of *O*-acylated sialic acids; goblet cell metaplasia may be present.[9]

Immunohistochemically, the anal glands are strongly positive for CK7 and CK19 but negative for CK20, a pattern similar to that of the overlying mucosa.[10,11]

The anal canal is lined by glandular epithelium in the colorectal zone and by nonkeratinized squamous epithelium in the squamous zone, which is known as pecten.[1–4] The transition zone (also known as the intermediate or cloacogenic zone) lies in between the two, roughly corresponding to the area of the dentate line. This circular zone, 0.3–1.1 cm in width, has a glistening, wrinkled appearance made discontinuous by the presence of the anal papillae.[1–4] The transitional epithelium consists of four to nine cell layers, extending

Abstract

This chapter covers the major inflammatory and neoplastic entities that the surgical pathologist will encounter in the anus.

from the small basal cells at the bottom to the surface cells (which can be columnar, cuboidal, or polygonal) at the top, and somewhat resembles bladder epithelium or immature squamous epithelium at the light microscopic level (Fig. 18.3).[1–3] Mature squamous epithelium, glandular epithelium, and simple columnar epithelium may also be present here. Some people lack transitional epithelium altogether and have an abrupt transition from glandular to squamous mucosa. As previously discussed, the transition zone expresses keratins 7 and 19 but not keratin 20.[10,11] Scattered neuroendocrine cells are sometimes identified in the basilar portion of this epithelium.[12] Melanocytes are more common in the anal squamous zone than in the transitional zone and may give rise to nevi in either location.[13]

The vascular supply of the anal canal originates from the superior, middle, and inferior rectal arteries. Individual peculiar vessels characterized by a complex convoluted appearance have been referred to as anal glomeruli, and the network formed by these structures has been designated as corpus cavernosum recti.[1] The two most important components of the anal musculature are the internal anal sphincter (a continuation of the circular muscle coat of the rectum)

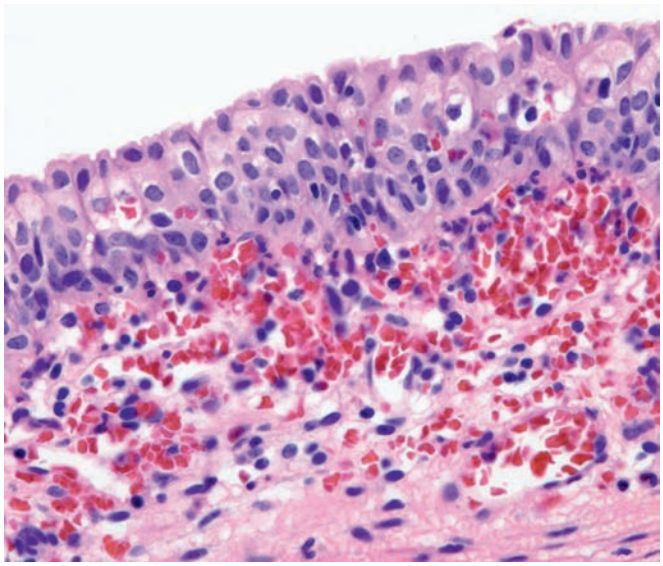

Figure 18.3 Normal transition zone mucosa of anal canal. The stratified epithelium somewhat resembles bladder epithelium or immature squamous epithelium histologically.

and the external anal sphincter (a complex triple-loop structure).[1,2,4] The lower part of the anal canal (below the dentate line) and the anal skin drain to the superficial inguinal nodes; the upper part has a wide draining field, which includes hypogastric, obturator, and internal iliac nodes.

Embryologic Defects of the Anus

Anorectal malformations occur in approximately 1 of every 3000–5000 births and comprise a complex group of congenital anomalies involving the rectum and anus.[14,15] They are often associated with other anomalies, including cardiovascular, musculoskeletal, spinal, and other gastrointestinal defects.[14] There are several classification systems, but most divide anorectal malformations into three major types, depending on the relationship of the rectal pouch to the puborectalis component of the levator ani muscle (puborectal sling).[14–16] **High** or **supralevator anomalies** (40%) include rectal atresia, anorectal agenesis, and cloacal malformations. They have a serious prognosis because of severe obstruction, common association with other congenital anomalies, and defective innervation of the pelvic muscles. A fistulous tract from the rectum to the bladder, urethra, or vagina is often present. **Low** or **translevator anomalies** (40%) include ectopic (perineal, vestibular, or vulvar) anus, anal stenosis, and imperforate (covered) anus. In these forms, obstruction is rarely severe. The pelvic innervation is normal, and associated anomalies are rare. Fistulas may or may not be present. **Intermediate anomalies** are less common (15%) and include anal agenesis, anorectal stenoses, and anorectal membrane. The remaining varieties, which are quite rare (5%), include **perineal groove** and **persistent anal membrane**.

Imaging studies, typically including plain radiographs, ultrasound, MRI, and VCUG (if urogenital anomalies are suspected), are essential for accurate diagnosis and therefore proper treatment. The surgical approach to repairing these defects changed dramatically in 1980 with the introduction of the posterior sagittal approach, allowing the direct visualization and repair of these complex malformations.[5–16] Unsuccessful surgery can lead to incontinence, loss of sexual function, stricture, and colonic obstruction, which may eventually necessitate a permanent colostomy.

Inflammatory and Non-Neoplastic Conditions

Anal Fissures

Anal fissures are linear tears in the anal mucosa overlying the internal sphincter muscle (Fig. 18.4).[17,18] Approximately 90% of anal fissures are found at the posterior midline overlying the bifurcation of the sphincter as it divides to circle the rectum. Many conditions contribute to the formation of anal fissures, including constipation, chronic diarrhea, childbirth or other trauma, and stress-related clenching of the sphincters. These lesions usually pursue a chronic course or healing and exacerbation over many years. Treatment options include stool softeners, topical agents, and sphincterotomy.[18] The microscopic appearance is nonspecific, featuring acute and chronic inflammation with associated ulceration, granulation tissue, fibrosis, and reactive epithelial changes.

Anal Fistulae

Anal fistulae are abnormal inflammatory tracts having two or more internal openings within the anal canal.[19,20] The fistulous tract may lead to the skin, or it may end blindly in the perianal soft tissues and/or musculature (Fig. 18.5). A classification of anal fistulas into five categories on the basis of their anatomic relationships has been proposed.[21] The lining of the fistula is made of acute and chronic inflammation and granulation tissue, although epithelium (sometimes hyperplastic and with reactive epithelial changes) may eventually grow at either end of the tract. Fibrosis, foreign body giant cell reaction, and abscess formation may also be present.[19] Although some small fistulae heal on their own, many require surgery, and there are several operative approaches that ideally balance healing of the fistula with preservation of continence.[20,22]

Most anal fistulae are caused by an intersphincteric infection/abscess originating in a traumatized or infected anal crypt[19,20] and as previously discussed have a nonspecific microscopic appearance. Fistulae are also associated with numerous conditions including

Figure 18.5 Multiple fistulous tracts *(arrows)* in a patient with Crohn disease. (Courtesy of Dr. Jason Mizell).

trauma, radiation, tumors, and Crohn disease[23]; it is important, therefore, that tissue obtained from an anal fistula be examined microscopically. Fistulae caused by Crohn disease are often complex and painless, with irregular edges and little induration. The diagnosis may be suggested by the presence of noncaseating granulomas, but it is important not to confuse them with the foci of foreign body reaction that can be seen in nonspecific fistulas. Anal fistulae may also be a manifestation of infections, such as tuberculosis[24,25] and actinomycosis.[26] The incidence of tuberculosis as a cause of anal fistulas dropped from 16% to less than 1% at St. Mark's Hospital (London) in a 50-year period.[24] Because these patients almost invariably show radiological evidence of pulmonary tuberculosis, this may well reflect a decline in tuberculosis in industrialized nations overall.

Hypertrophic Anal Papillae, Fibroepithelial Polyps, and Skin Tags

Anal papillae can enlarge as a result of edema, inflammation, and fibrosis and protrude into the anal canal in a polypoid fashion. Their appearance is similar to that of cutaneous fibroepithelial polyps, skin tags, and acrochordons, and many consider these lesions of the anus to be essentially identical. They are often confused with hemorrhoids on clinical examination.

Microscopically, these benign lesions are covered by squamous epithelium and contain a central core of edematous and inflamed, sometimes hyalinized fibrovascular stroma (Fig. 18.6).[27–29] Occasionally, atypical stromal cells with large and/or multiple nuclei and stellate cytoplasmic outlines occur in them.[30,31] These cells are immunoreactive for CD34.[29] Hyalinized vessels are a frequent

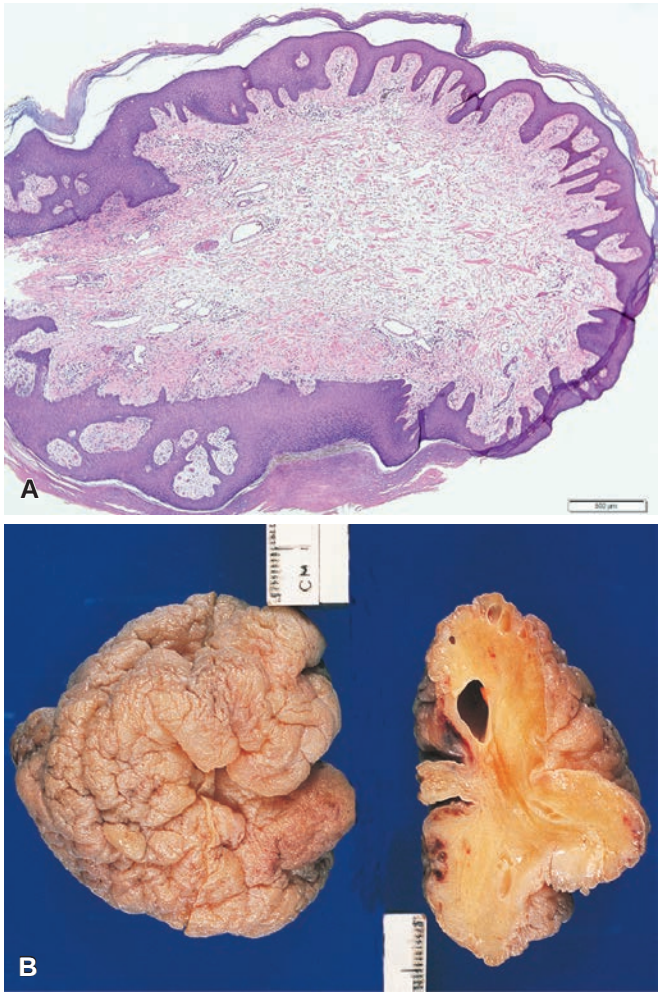

Figure 18.6 **A,** Fibroepithelial polyps, anal skin tags, and hypertrophic papillae are essentially identical and consist of a central core of edematous and inflamed fibrovascular stroma covered by squamous epithelium. (Courtesy of Dr. Sara Shalin.) **B,** These lesions can grow to an impressive size.

accompanying change, but the characteristic dilated submucosal vessels of hemorrhoids are absent.[29] Hypertrophied papillae may be associated with chronic anal ulcers, which are usually of oval shape and extends into the muscular layer. Typically the hypertrophied papilla is above the ulcer, and behind the papilla is an infected crypt. Anal ulcers have a nonspecific microscopic appearance and are surrounded by chronic edema and fibrosis.

Inflammatory Cloacogenic Polyps

Inflammatory cloacogenic polyps are within the spectrum of mucosal prolapse polyps that occur throughout the large bowel.[32–34] Patients typically present with anorectal bleeding, and these lesions are often clinically mistaken for hemorrhoids.[33–35] Although most often recognized in adults, these lesions also occur in children and should not be confused with hamartomatous polyps that are also seen in the pediatric population.[36]

Inflammatory cloacogenic polyps typically present as a single 1–2 cm polypoid mass in the anterior wall of the anorectum. Histologically, due to the location, these polyps may contain glandular colorectal mucosa, anal stratified squamous epithelium, transition zone epithelium, or a combination. Inflammatory cloacogenic polyps often have a striking villiform morphology of the surface epithelium (Fig. 18.7), which can mimic a villous adenoma at low power[33,35]; however, inflammatory cloacogenic polyps lack cytologic dysplasia. Similar to other prolapse type polyps, there may be stromal hyalinization with prominent capillaries; thickened and disorganized muscularis mucosa with perpendicular extension into the lamina propria; elongated irregular crypts that occasionally extend into the submucosa; and surface erosion.[35]

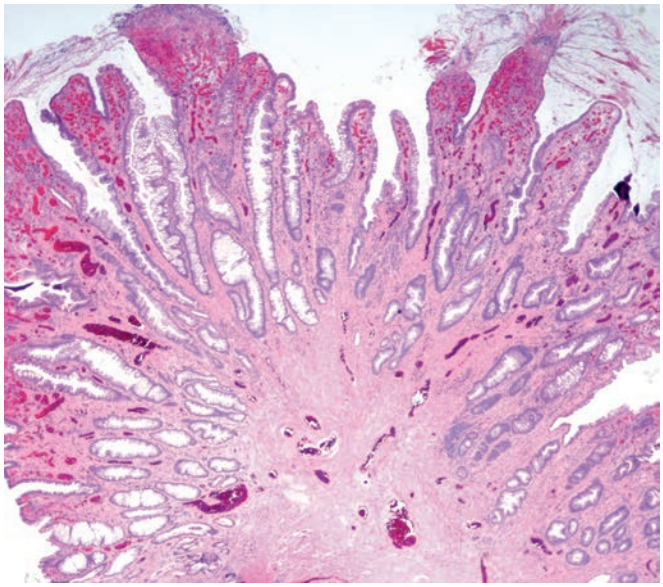

Figure 18.7 Inflammatory cloacogenic polyp featuring perpendicular fibromuscular hyperplasia, prominent lamina propria capillaries, and a villiform appearance to the surface mucosa with overlying erosion and fibrinopurulent exudate. (Courtesy of Dr. Rhonda Yantiss).

Hemorrhoids

Hemorrhoids (Fig. 18.8) are the result of ectasia of the hemorrhoidal vascular plexus. They are divided into external (derived from the external/inferior hemorrhoidal plexus below the dentate line, and covered by skin or squamous mucosa) and internal (derived from the superior hemorrhoidal plexus above the dentate line, and covered by rectal or transitional mucosa).[37–39] Patients typically present with hematochezia, itching, and anorectal pain.

Stasis of blood in the veins of the hemorrhoidal plexus is usually caused simply by dependency, and the formation of hemorrhoids is then furthered by deterioration of the surrounding connective tissues due to age and downward displacement of the anal cushions.[38] However, increased intravascular pressure due to pathologic processes may cause engorgement of the hemorrhoidal veins, and thus the presence of hemorrhoids may be an indication of some other condition, such as chronic constipation, pregnancy, or tumors. It is important to distinguish between hemorrhoids in patients with portal hypertension and actual anorectal varices, as treatment may be very different.[40] Indeed, patients with portal hypertension and varices actually do not have an increased incidence of hemorrhoids.[39] Treatment options include conservative measures such as dietary modification and topical analgesics/anti-inflammatory agents. Some cases require more aggressive measures such as sclerotherapy, rubber band ligation, or surgical excision.[39]

Histologically, hemorrhoids feature dilated submucosal vessels with thick or thin walls and variably present thrombosis with hemorrhage and recanalization (Fig. 18.9). Thrombosis of external hemorrhoids is frequent, and the organization and recanalization of these

Figure 18.8 Large external hemorrhoid protruding through the anal orifice. (Courtesy of Dr. Jason Mizell.) Engorged vessels are clearly visible.

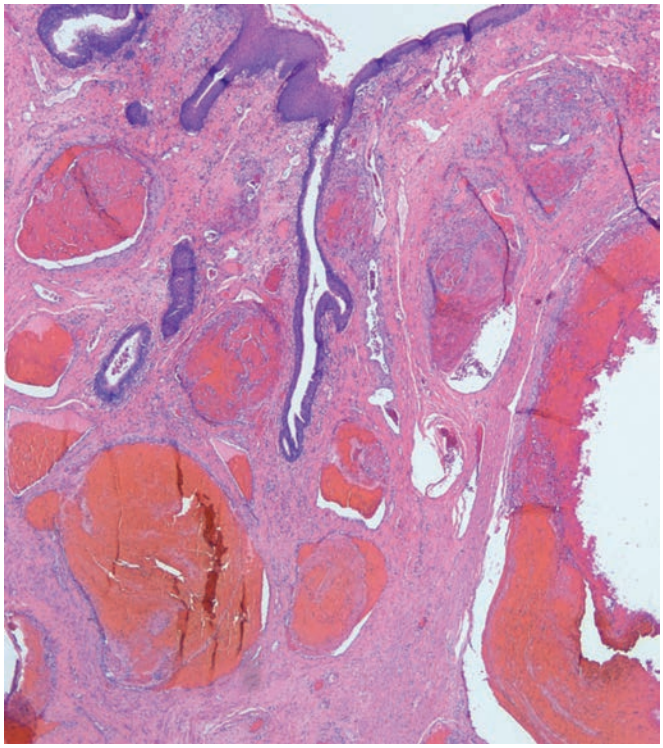

Figure 18.9 Hemorrhoid with markedly dilated submucosal vessels containing numerous thrombi. The overlying epithelium is both squamous and transitional.

thrombi can lead to florid papillary endothelial hyperplasia, a process that can be overinterpreted as angiosarcoma.[41] As a matter of fact, the original description of this process by Pierre Masson was in a hemorrhoidal vessel. Inflammatory changes, surface ulceration, and associated prolapse changes are also frequent findings in hemorrhoids.[37,42]

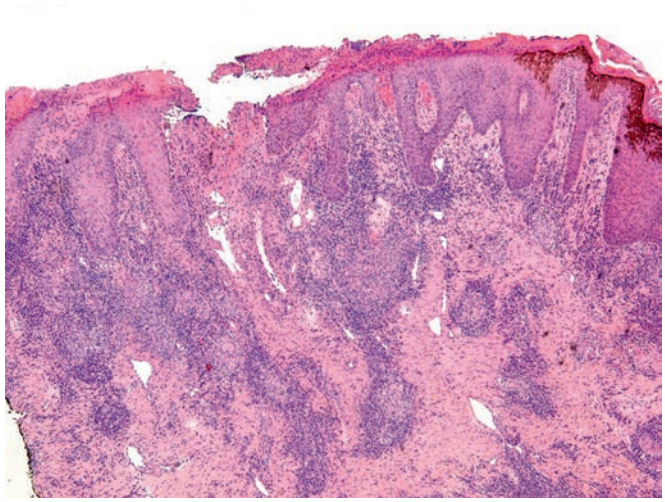

Figure 18.10 Perianal Crohn disease featuring noncaseating epithelioid granulomas with scattered multinucleated giant cells and associated chronic inflammation, fibrosis, and ulceration of the squamous epithelium.

Microscopic examination of tissue submitted with the clinical diagnosis of hemorrhoids rarely shows unsuspected findings such as infections, anal squamous intraepithelial lesions (SILs) and squamous cell carcinoma (SCC), or even nevi and malignant melanoma.[43–45] The latter is sometimes interpreted clinically as a thrombosed hemorrhoid because of its polypoid shape and dark brown color. The practice of histologically evaluating all hemorrhoidectomy specimens remains controversial (although this author is an advocate of it). However, most authors at least agree that hemorrhoids from patients at risk for, or with a history of, anorectal infection or malignancy should be submitted for histologic evaluation, as should any hemorrhoid with a macroscopic abnormality.[43–45]

Crohn Disease

Reportedly 10%–80% of patients with Crohn disease have perianal involvement; the variability in reporting is believed to be due to differing definitions of "perianal disease," duration of follow-up, and composition of patient population.[23] The anal manifestations of Crohn disease are also quite variable and include strictures, fissures, fistulae, ulcers, abscesses, and skin tags. Patients with lower tract disease are more likely to have perianal manifestations than those with upper tract disease.[46] The risk of anal carcinoma in Crohn disease remains controversial, but there may be a slight increased risk in patients with longstanding and/or severe perianal disease.[47,48] Histologic findings are nonspecific and include noncaseating epithelioid granulomas (Fig. 18.10) with associated chronic inflammation, fibrosis, and multinucleated giant cells.[49,50] Overlying ulceration of the skin or mucosa is common. The differential diagnosis is broad, and granulomatous infections such as tuberculosis, as well as entities such as hidradenitis suppurativa and sarcoidosis, must be considered. Diagnosis may be particularly challenging if the patient does not have a known history of Crohn disease.

Infections Involving the Anus

A number of infections may involve the anus, many of which are sexually transmitted. **Granuloma inguinale (donovanosis)** is caused by the coccobacillus *Calymmatobacterium granulomatis*. It is primarily a disease of tropical regions, and although many cases are sexually

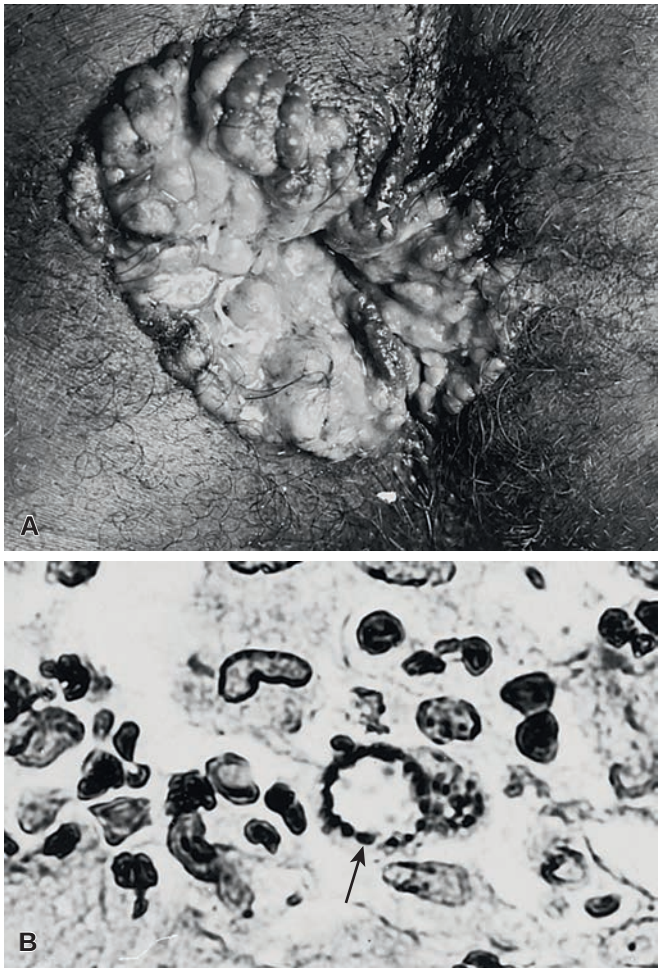

Figure 18.11 **A,** Granuloma inguinale clinically simulating carcinoma. **B,** Donovan bodies *(arrow)* within cyst in cytoplasm of macrophage in a patient with granuloma inguinale (Warthin–Starry stain).

Figure 18.13 Lymphogranuloma venereum complicated by squamous cell carcinoma.

transmitted, transmission is not exclusively venereal. The genitalia and inguinal areas are most commonly involved, but the anus is involved in approximately 7% of cases (Fig. 18.11).[51] Patients present with necrotizing ulcers that progressively enlarge and that may be confused clinically with SCC.[51,52] In addition, SCC may rarely complicate cases of longstanding granuloma inguinale.[53] Biopsy will allow a definite diagnosis if Donovan bodies are found using Warthin–Starry or Giemsa preparations. Otherwise, the histologic features are nonspecific and include a mixed inflammatory infiltrate composed primarily of macrophages (which contain the Donovan bodies), with variably present numbers of admixed neutrophils and mononuclear cells.[52] Older lesions may consist predominantly of granulation tissue.

Lymphogranuloma venereum (LGV) is a sexually transmitted disease caused by *Chlamydia trachomatis*, the incidence of which is rising, particularly in patients who engage in anal intercourse.[54] Clinically, anorectal LGV presents with ulcers, often accompanied by lymphadenopathy, fever, bleeding, and anal pain.[55] Microscopically, the main changes are a dense lymphohistiocytic infiltrate with prominent plasma cells (Fig. 18.12) and associated lymphoid aggregates, which may be associated with neuromatous hyperplasia, extensive transmural fibrosis, and occasionally granulomas.[55,56] These histologic changes may be easily confused with chronic idiopathic inflammatory bowel disease. In contrast to Crohn disease and ulcerative colitis, however, LGV typically has only mild to moderate acute inflammation, and well-developed changes of chronicity (basal plasmacytosis, architectural distortion, and Paneth cell metaplasia) may be absent (this is discussed in greater detail in Chapter 17).[55] Longstanding cases may lead to the formation of abscesses, strictures, and fistulae. Occasionally, SCC develops in association with these lesions (Fig. 18.13), although it is not known if LGV itself is a risk factor, especially as there are confounding risk factors in many patients with LGV.

Cultures, nucleic acid probes, and serologic studies may be very useful in confirming the diagnosis.

In addition to those already discussed in this section, immunocompromised patients (particularly HIV-infected patients) may develop a variety of inflammatory diseases of the anal region. In addition to some of those already listed in this section, these include gonorrhea, syphilis, herpes simplex virus, and cytomegalovirus.[57–59] Human papillomavirus (HPV)-related processes are discussed next.

Tumors and Precursor Lesions of the Anus

Squamous Intraepithelial Neoplasia (Including Condyloma Acuminatum)

Anal squamous intraepithelial neoplasia is relatively uncommon compared to the incidence in the female genital tract, but its incidence is rising, particularly in homosexual men who practice anal receptive intercourse and/or are HIV positive.[60,61] An overall slight female predominance remains, however, as patients with genital HPV-related disease are at high risk for anal neoplasia as well.[62] Many institutions are developing screening programs utilizing high-resolution anoscopy in combination with anal Pap smear for use in high-risk populations.[63] A detailed discussion of HPV and its relation with dysplastic and malignant conditions of squamous epithelia is to be found in Chapter 32, Cervix.

The terminology of HPV-associated anal squamous lesions has historically been confusing and nonstandardized, including terms originally used in cervical (Pap smear) cytology and later extended to cervical biopsy pathology, as well as terms adapted from cutaneous SCC that were applied to anogenital mucosae. In 2012, a project undertaken by the College of American Pathologists (CAP) and the American Society for Colposcopy and Cervical Pathology (ASCCP) recommended standardized terminology for anogenital squamous lesions.[64,65] The CAP-ASCCP Lower Anogenital Squamous Terminology (LAST) project recommends dividing anal squamous dysplasias into two tiers, based on the presence of low-grade or high-grade dysplasia.

Low-grade squamous intraepithelial lesion (LGSIL) is usually (but not always) associated with low-risk HPV genotypes such as 6 and 11, which have a lower risk of progression to malignancy than high-risk genotypes. High-grade squamous intraepithelial lesion (HGSIL) and invasive squamous carcinoma are typically associated with high-risk HPV genotypes such as 16 and 18.[66,67] Although these genotype associations are typical, some LGSIL are associated with high-risk HPV genotypes, and conversely HGSIL may harbor low-risk genotypes.[68] In addition, many HIV+ patients are infected by multiple HPV genotypes.[67] Although recurrence is common, actual progression rates of HGSIL to anal SCC remain controversial, primarily due to the fact that high-grade lesions are typically removed or ablated. However, immunosuppressed patients with multifocal disease appear to be at the highest risk of progression.[69] It is also believed that LGSIL can progress to HGSIL, particularly in HIV+ patients.[70]

Despite their overall recommendations, the older terminology of "anal intraepithelial neoplasia" (AIN) and "perianal intraepithelial neoplasia" (PAIN) remain in the LAST project nomenclature.[64] AIN is used for lesions in squamous mucosa of the anal canal itself, whereas PAIN refers to lesions affecting the perianal skin within 5 cm of the anal verge. These older terms reflect the division of squamous dysplasia into three grades (AIN 1, 2, and 3). Using current criteria, LGSIL encompasses AIN 1, and HGSIL includes AIN grades 2 and 3. Anal squamous lesions should be reported using the LGSIL/HGSIL nomenclature but can be further classified with the P/AIN grade in parenthesis (e.g. "LGSIL (AIN 1)"). HGSIL (AIN3) includes the term "Bowen disease of the anus," which should no longer be used.

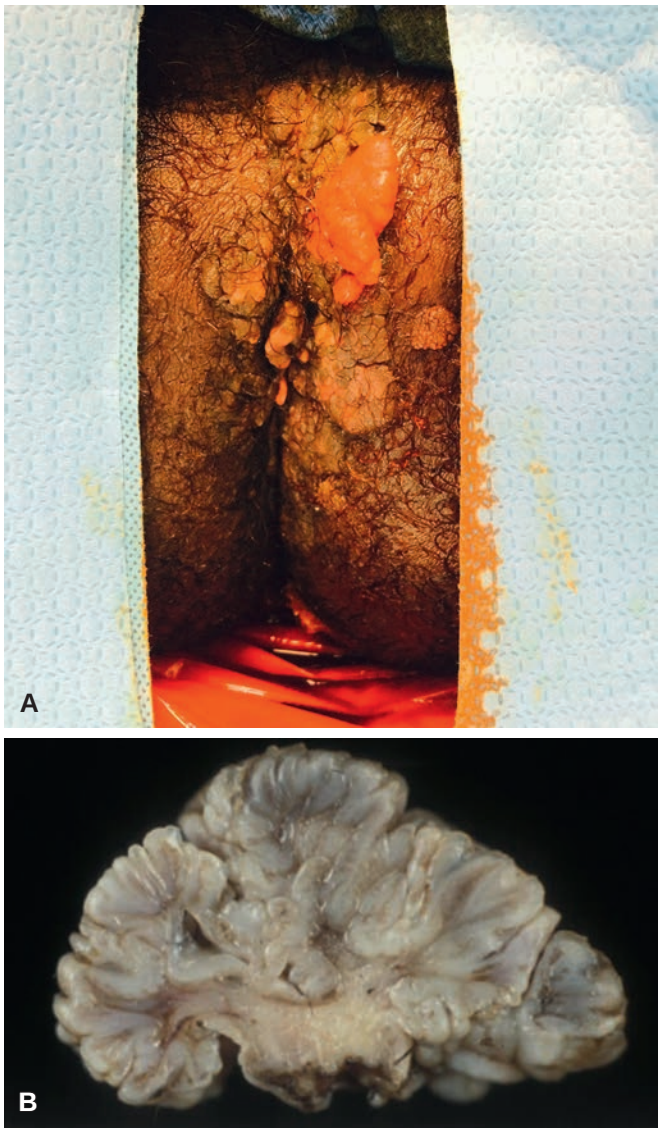

Figure 18.14 **A,** This HIV+ patient has multiple condylomata complicated by SCC. **B,** The cut surface of this anal condyloma shows the typical papillary, cauliflower-like appearance. (**A,** Courtesy of Dr. Rhonda Yantiss; **B,** Courtesy of Dr. George F. Gray, Jr.)

Grossly visible lesions featuring koilocytes and squamous hyperplasia or acanthosis have historically been known as "condyloma acuminatum," and this is perhaps the most common and best known HPV-associated anorectal lesion. This term is commonly used clinically and is considered synonymous with anogenital wart. According to the LAST criteria, these lesions generally harbor low-grade dysplasia and are therefore included in the category of LGSIL. Patients typically present with anal bleeding, pain, and itching. Condylomata typically appear as fleshy, pink/white papillary or "cauliflower-like" masses (Fig. 18.14) that may be single or multiple.[71] They often occur in clusters and may cover large areas of skin or mucosa. In addition to condylomata, squamous lesions of the anus may present clinically as white, pigmented or erythematous areas, as well as papules or scaly plaques; multicentricity is common here as well. Although the anal canal is the usual location of SIL, lesions can also be encountered in the perianal skin. Similar to the cervix, acetic acid may be used to highlight the lesions.

The morphologic changes of HPV infection and AIN can occur within the context of (and be confined to) a condyloma, or occur in flat mucosa.[71] LGSIL/(P)AIN 1 is characterized by squamous atypia and dysmaturation restricted to the basal third of the epithelium, whereas in HGSIL these abnormalities involve roughly the lower two thirds (P/AIN 2) or full-thickness atypia/dysplasia (P/AIN 3 or effectively "carcinoma in situ").[64,65] The histologic feature most often associated with HPV infection, particularly in examples of LGSIL, is koilocytic change (Fig. 18.15). The characteristic features of koilocytes include wrinkled nuclear contours or "raisinoid"

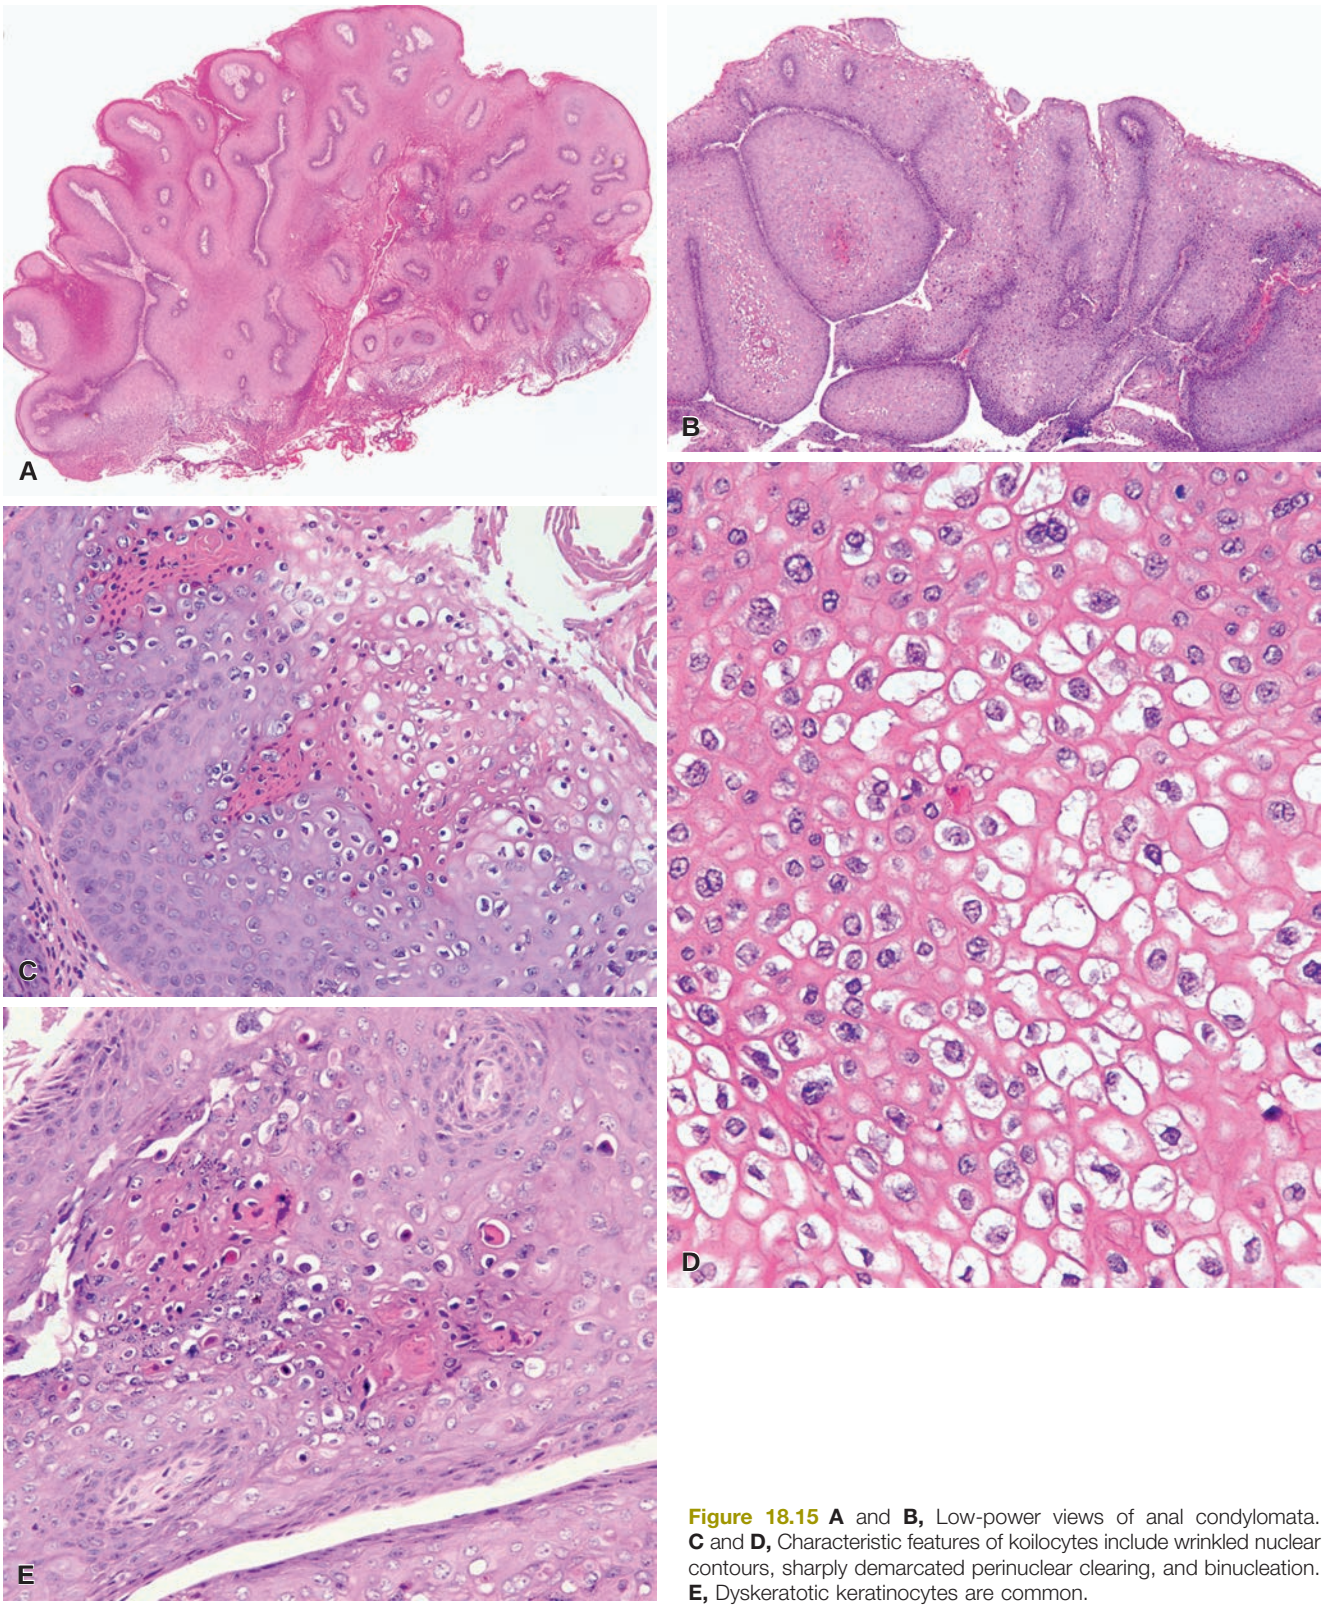

Figure 18.15 **A** and **B,** Low-power views of anal condylomata. **C** and **D,** Characteristic features of koilocytes include wrinkled nuclear contours, sharply demarcated perinuclear clearing, and binucleation. **E,** Dyskeratotic keratinocytes are common.

appearance; sharply demarcated perinuclear clearing or halo; and variably present binucleation. Dyskeratotic keratinocytes are frequently seen as well. Koilocytic changes are not invariably present in HPV-associated lesions, however.[71] Features of the dysplastic cells in HGSIL include nuclear membrane irregularity, hyperchromasia, enlargement, and pleomorphism (Fig. 18.16). Overlying atypical parakeratosis and mitoses in the upper third of the mucosa are often present as well.

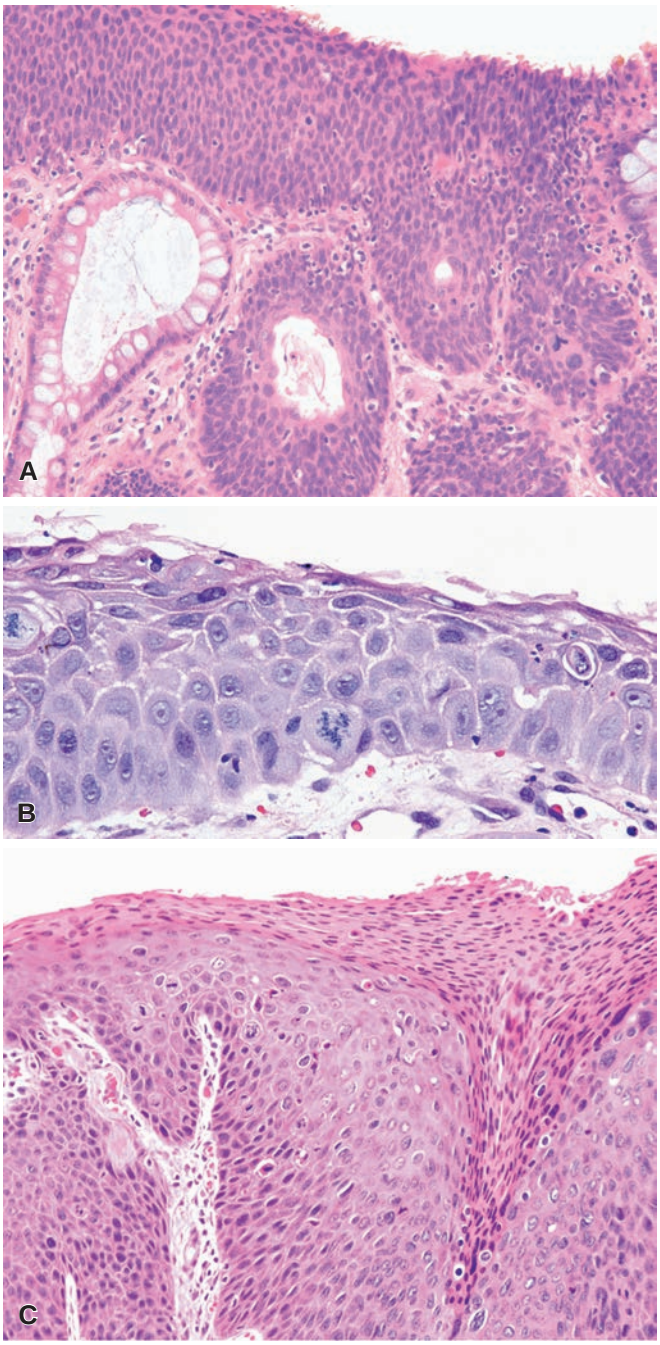

Figure 18.16 High-Grade SIL (AIN2/3) Features Full Thickness Nuclear Atypia. A, Increased nuclear density and loss of maturation are apparent, as seen here at the transition zone. **B,** Dysplastic cells are characterized by nuclear membrane irregularity, hyperchromasia, enlargement, and pleomorphism; increased mitoses are obvious as well, including atypical mitoses mitotic figures present well above the basal zone. **C,** Overlying atypical parakeratosis is common. (Courtesy of Dr. Keith Lai.)

Infection with high-risk HPV genotypes upregulates p16 (a tumor suppressor gene product that is a surrogate marker of HPV infection) and is associated with increased cellular proliferation. HGSIL typically shows diffuse, block-like overexpression of p16 (Fig. 18.17), whereas LGSIL and reactive processes usually show absent or weak, patchy staining.[72–74] Both LGSIL and HGSIL typically show abnormal Ki-67 staining, defined as nuclear positivity in the upper two thirds of the epithelium.

Some workers have subclassified SIL into a bowenoid type (more common, and synonymous with conventional-type SIL as discussed previously) and a differentiated (or simplex) type (Fig. 18.18) using criteria similar to those used for vulvar intraepithelial neoplasia (marked basal atypia with eosinophilic cytoplasm and preservation of squamous maturation).[75] While both types of SIL express 14-3-3σ (a p53-regulated G2/M inhibitor), the conventional type exhibits strong and diffuse p16 immunoreactivity but negative p53 staining, whereas the differentiated type exhibits increased basal p53 immunostaining but is typically negative for p16. These data are interesting both from a diagnostic standpoint and because they suggest the possibility of different pathogenetic mechanisms for the differentiated type of SIL.

A number of reactive conditions of the anus can mimic SIL. Glycogenated squamous cells can mimic koilocytes, and inflamed

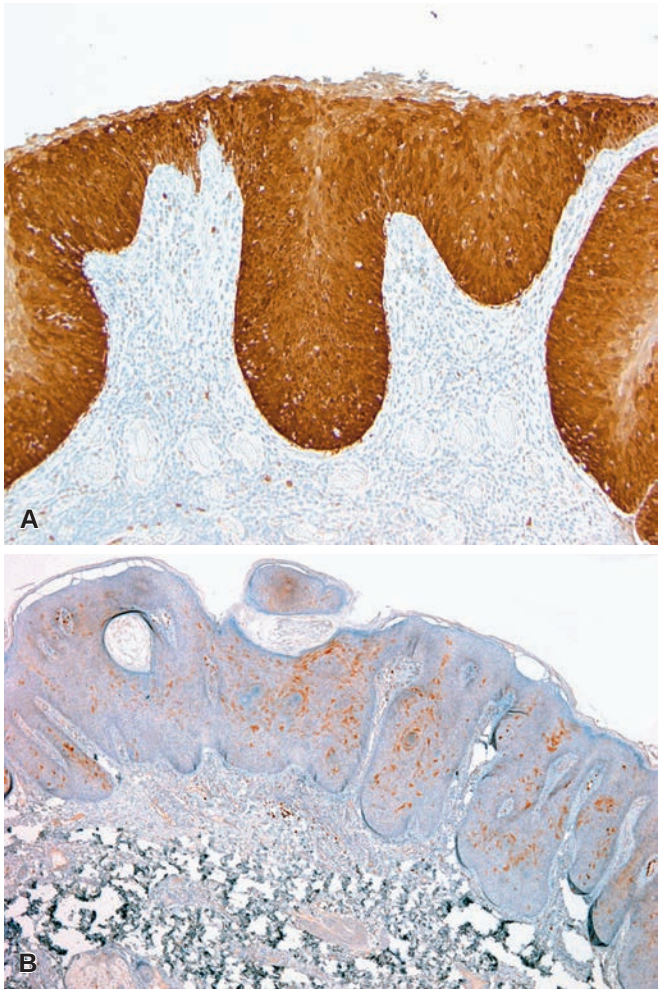

Figure 18.17 A, Diffuse, 'block-like' staining with p16 in a case of anal HGSIL. **B,** In contrast, LGSIL and reactive processes usually show absent or weak, patchy staining. (**A,** Courtesy of Dr. Keith Lai.)

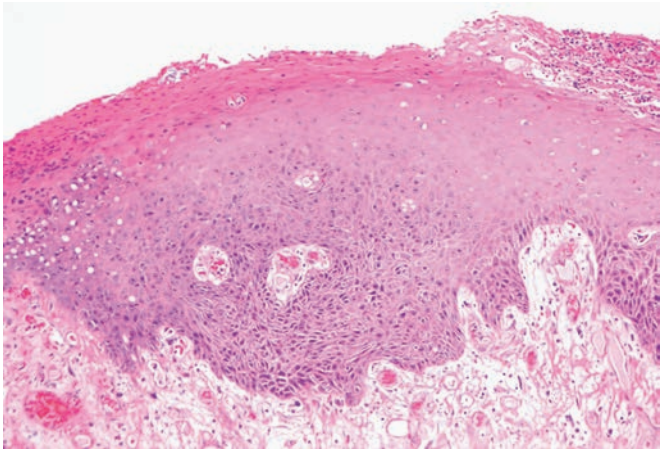

Figure 18.18 The differentiated (or simplex) type of SIL shows marked basal atypia with eosinophilic cytoplasm and preservation of squamous maturation, similar to vulvar SIL. (Courtesy of Drs. Keith Lai and Brad Fogel.)

squamous mucosa and skin may have reactive atypia that mimics dysplasia as well. Finally, as mentioned previously, the anal transition zone is lined by multilayered transitional epithelium that can also undergo squamous metaplasia. These changes can closely mimic HGSIL, particularly when reactive changes are present. As discussed previously, p16 and Ki-67 immunohistochemistry can aid in making the distinction between true squamous dysplasia and reactive atypia. Furthermore, CK7 positivity is characteristically seen in transition zone mucosa but is absent in HGSIL.

Squamous Cell Carcinoma

General and Clinical Features

SCC is the most common primary neoplasm of the anus, although it accounts for less than 5% of large bowel malignancies. The incidence of anal carcinoma is increasing in both males and females.[76] Although historically females outnumbered males with this disease, the male to female ratio has begun to equalize in recent years and is now approximately equal.[77] Clinically, the disease presents with bleeding, anal pain (much more commonly than in colorectal cancer), mass, and pruritus. Unfortunately, diagnosis is often delayed because presenting signs and symptoms are attributed to benign disease such as hemorrhoids. A significant minority of patients is asymptomatic.

There is strong evidence that sexually transmitted HPV infection is an important cause of anal cancer (see also the previous section), and approximately 80%–90% of anal SCC are associated with HPV infection.[78,79] HPV 16 is the specific genotype in the majority of cases, followed by HPV 18.[79] In particular, a strong association has been found between anal SCC and receptive anal intercourse, as well as multiple lifetime sexual partners. There is also a statistical association between anal carcinoma and smoking.[60]

There is no significant difference in HPV positivity among the major morphologic types of anal SCC.[78,80] Instead, the presence of HPV in tumor cells is significantly associated with an increased proliferative rate and aneuploid status.[81] In some instances, anal SCC develop in association with other diseases such as Crohn disease[82] or other immunosuppressive conditions.[83] Patients with HPV-negative SCC appear to have a worse prognosis (shorter disease-free survival) than patients with HPV-positive tumors.[84]

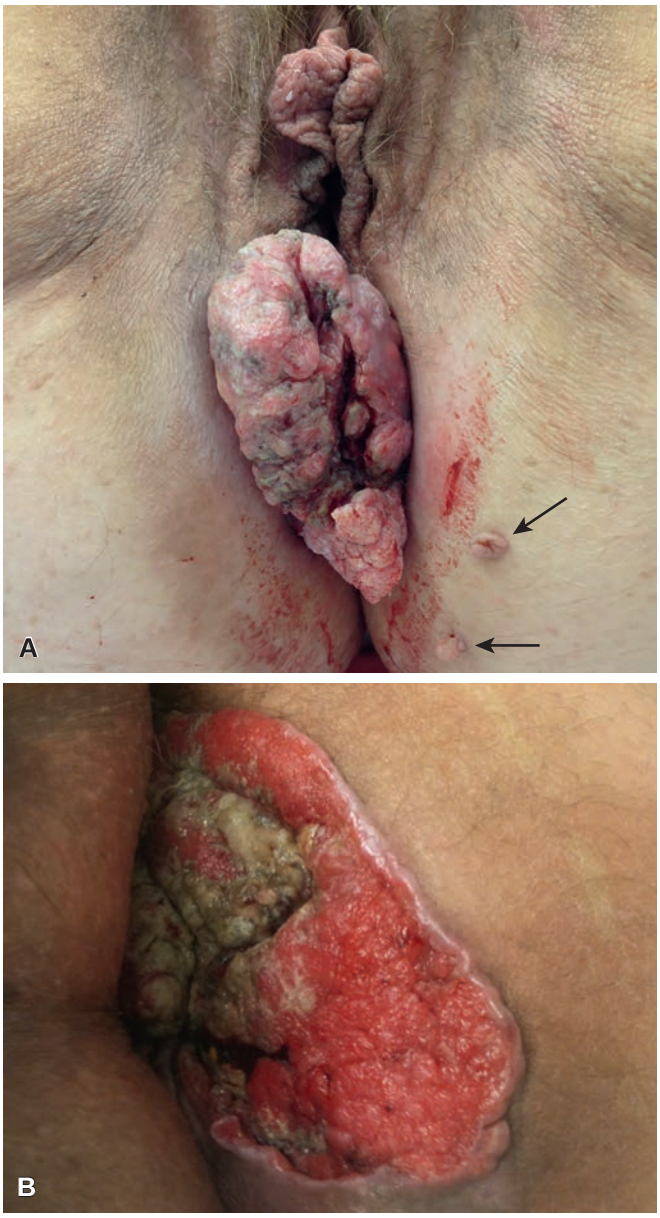

Figure 18.19 **A,** This squamous cell carcinoma (SCC) of the anal canal has a verrucoid appearance and protrudes out through the anal orifice. Note the small adjacent condylomata *(arrows)*. **B,** This ulcerated SCC with rolled edges extends out to involve the perianal skin. (**A,** Courtesy of Dr. Jason Mizell; **B,** Courtesy of Dr. Jason Mizell.)

Pathologic Features

Conventional SCC of the anal canal most often arise distal to the dentate line. Grossly, early lesions are often small and mobile, sometimes with a verrucoid appearance (Fig. 18.19). They may grow either upward into the rectum, in which case the gross appearance may be indistinguishable from that of an adenocarcinoma of the rectum, or outward to the perianal tissues.[85,86] Involvement of the perianal skin may be superficial, with only surface ulceration and slightly elevated margins. Such lesions can be mistaken for an inflammatory process. In other instances, a deeply ulcerated neoplasm with rolled edges can be seen, or a large fungating mass (which occasionally may protrude from the anal orifice). Tumors with upward local extension may burrow beneath the overlying

epithelium to ulcerate at a higher level in the rectum. It is important to remember that tumors above the dentate line may not be visible on external physical examination, and that the basaloid variant of SCC often arises proximal to the dentate line. Lymphadenopathy may be present at initial presentation, indicating spread to regional nodes.

Anal SCC have a variety of morphologic patterns, and the terminology has changed considerably in the course of the years. Traditionally, these tumors were regarded and classified as squamous cell (epidermoid) carcinomas.[87,88] It was then proposed that there were two distinct types of carcinoma in this area: (1) SCC, analogous to its counterpart elsewhere in the skin; and (2) cloacogenic (also known as transitional or basaloid) carcinoma, supposedly originating from the transitional epithelium of the region and recapitulating the features of this zone at both a light and electron microscopic level.[89,90] It is now recognized that both of these (as well as the vast majority of the other subtypes, discussed later) are variants of SCC and that distinguishing these two tumor types is not only difficult in practice but also unwarranted from a therapeutic and prognostic standpoint.[91]

Conventional keratinizing SCC (Fig. 18.20) features invasive nests of malignant squamous cells, similar to its counterparts elsewhere in the body. Keratin whorls or "pearls" may be present, along with intercellular bridges and variably present necrosis. This form of SCC is often found in a background of squamous dysplasia. As with other conventional SCC, it may vary from well to poorly differentiated.

Nonkeratinizing SCC (also known as basaloid or cloacogenic carcinoma in the past, as previously discussed) consists of irregular, angulated, or trabecular nests of basophilic cells with relatively scant cytoplasm and peripheral palisading (Fig. 18.21). Squamous nests may be present but lack keratinization.[86,91] This type of carcinoma can mimic basal cell carcinoma arising in the perianal skin, as well as neuroendocrine carcinomas that rarely occur in this area (see section later). Compared to true cutaneous basal cell carcinomas, nonkeratinizing (basaloid) SCC have more cytologic pleomorphism and often have areas with more recognizable squamous differentiation.

Some anal SCC contain mucinous microcysts; these have also been referred to as mucoepidermoid, adenoid cystic pattern, or microcystic SCC (Fig. 18.22).[91,92] Some have suggested that this morphologic variant is associated with a worse prognosis, but this assertion is based on a limited number of cases.[93] This variant should be distinguished from true adenoid cystic carcinoma of salivary gland type, from which it differs at the immunohistochemical level.[92]

Other Variants of Anal Squamous Cell Carcinoma

Verrucous SCC are polypoid tumors that grossly resemble condylomas and typically are very impressive clinically. Indeed, this lesion was formerly known as the giant condyloma acuminatum of Buschke–Löwenstein, which reflects the difficulty in distinguishing between a large condyloma and verrucous carcinoma. Although they are also HPV-related, morphologic features of both viral infection and dysplasia are typically difficult to find histologically, which adds to the difficulty in diagnosing this type of malignancy.[91] Verrucous SCC are well differentiated and often have extensive and well-developed surface maturation; for these reasons, superficial biopsies may only sample benign-appearing, hyperparakeratotic epithelium, leading to a benign diagnosis (particularly on superficial biopsy) that is at odds with the clinically impressive and worrisome appearance. These tumors have a pushing (Fig. 18.23), rather than infiltrative, pattern of invasion, but verrucous SCC are aggressive neoplasms, invading local structures and sometimes involving the deep soft tissues of the pelvis. There is some evidence that these deceptively well-differentiated carcinomas are more closely associated with low-risk HPV genotypes, in contrast to conventional SCC.[91] These lesions are morphologically identical to those seen in the lower female genital tract and other sites (see Chapter 32, Cervix). Most verrucous SCC are locally destructive but do not metastasize.

Spindle cell (sarcomatoid) carcinoma is much more rare here than in the upper digestive tract, but it does occur.[94] A spectacular case showing neuroendocrine and rhabdomyoblastic features has been described.[95] Others SCC are accompanied by a massive infiltration of eosinophils,[96] a feature again analogous to that seen in carcinomas of other mucosal sites, particularly squamous cell type.

Immunohistochemical and Molecular Genetic Features

Immunohistochemically, most anal squamous carcinomas exhibit reactivity for keratins 4, 5/6, 13, 17, 18, and 19, with a minority expressing keratins 1, 7, and 10.[97,98] p63 and SOX2 (an HMG-box embryonic stem cell transcription factor) are also expressed by the vast majority of anal SCC.[99,100]

HPV infection is an initiating event in most cases, but HPV infection alone is not sufficient to promote progression to malignancy. HPV DNA integration into host cell chromosomes (with subsequent expression of several oncoproteins) appears to be a significant step in the transition from SIL to malignancy.[100] Loss of heterozygosity at 11q appears to be a common event in anal carcinogenesis, similar to cervical cancer carcinogenesis, although the number of cases that have been studied in detail is limited.[100] Loss of heterozygosity involving several other chromosomes has also been reported,[100] and it is likely that progression towards invasive carcinoma requires additional molecular alterations, such as allelic losses at 5q *(APC)*, 17p *(TP53)*, and 18q *(DCC)*.[100] HIV-positive patients progress more rapidly from AIN to invasive carcinoma, and HPV-induced genomic instability (such as microsatellite instability) may play a more significant role. Chromosomal instability (e.g. loss of heterozygosity as described previously) is much less common in anal SCC in HIV-positive patients.[100] Aberrant DNA methylation is also frequent (>70%) in HGSIL and anal carcinoma, while methylation is not seen in LGSIL and normal mucosa.[101]

Spread and Metastases

As far as lymph node metastases are concerned, carcinomas arising above the dentate line typically metastasize to pelvic, perirectal, and para-aortic/paravertebral nodes, whereas those distal to the dentate line typically metastasize to inguinal nodes. Metastatic disease in perirectal lymph nodes is classified as N1 (AJCC 7th edition), whereas metastasis to unilateral internal iliac and/or inguinal lymph nodes is classified as N2. Metastases in perirectal and inguinal nodes and/or bilateral internal iliac and/or inguinal nodes are classified as N3. Lymph node involvement is present in 30%–40% of cases at presentations, while systemic spread is much less common (5%–8% of patients).[102]

Therapy

The primary goals of management are to achieve a cure via locoregional control, while ideally preserving anal function. Until the mid-1980s, the traditional therapy for anal carcinomas was abdominoperineal resection, sometimes combined with hypogastric lymph node dissection and with posterior vaginectomy in women. Surgery is no longer regarded as the primary therapeutic intervention, however, although its role as a salvage therapy is accepted.[102,103] Currently,

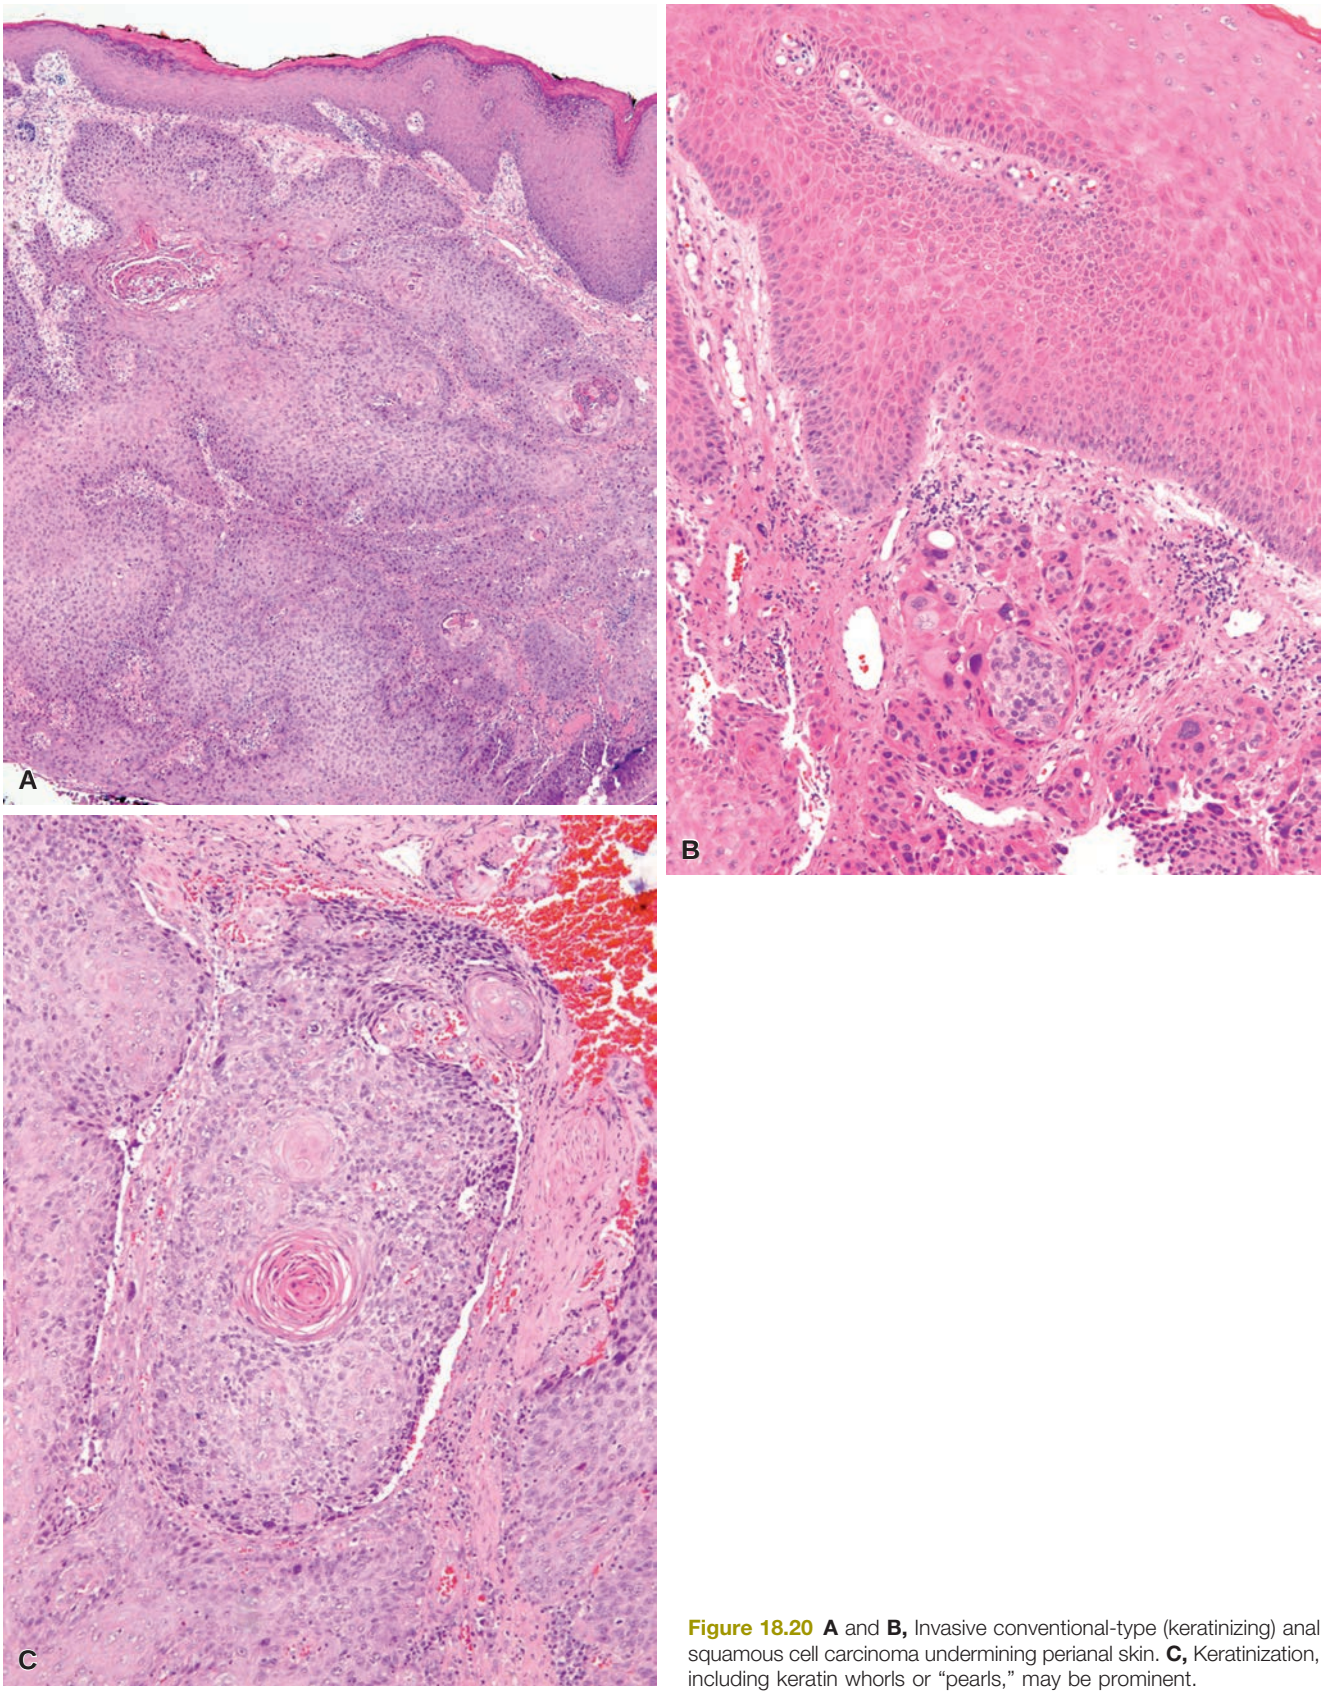

Figure 18.20 **A** and **B,** Invasive conventional-type (keratinizing) anal squamous cell carcinoma undermining perianal skin. **C,** Keratinization, including keratin whorls or "pearls," may be prominent.

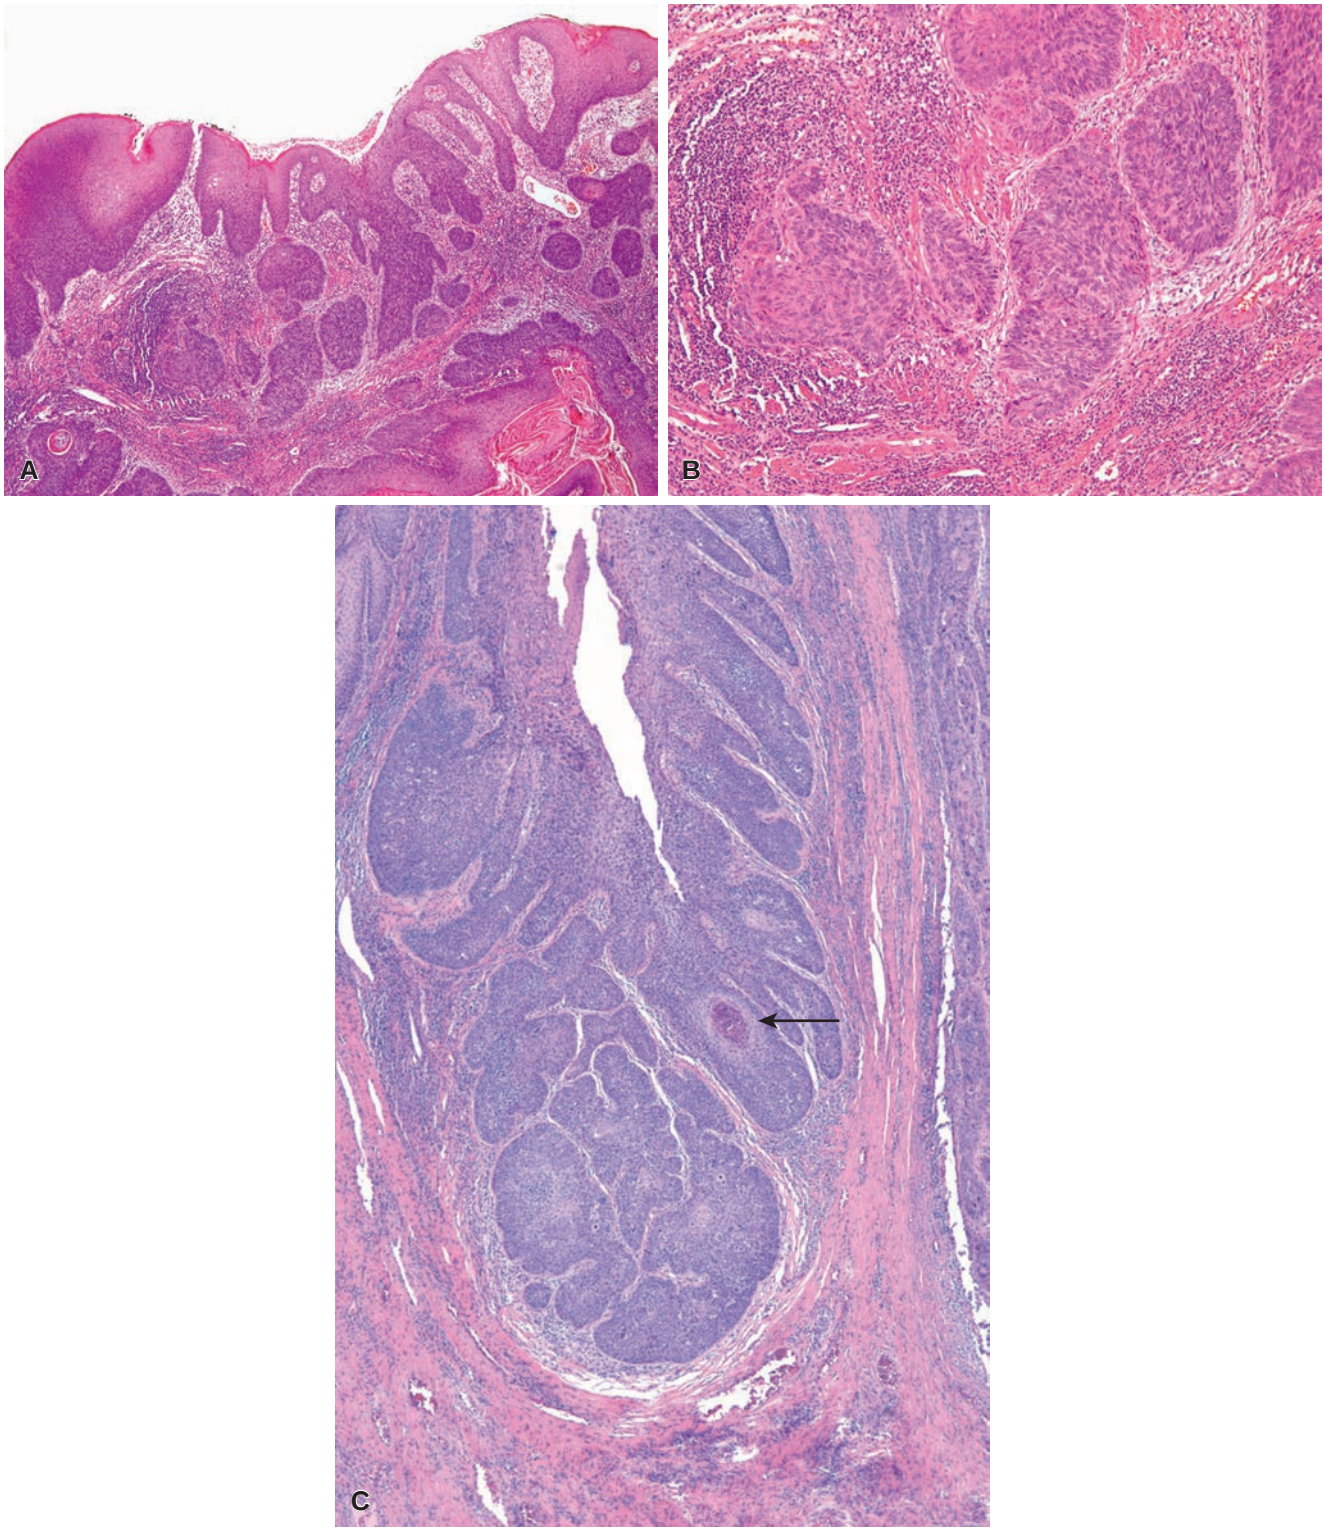

Figure 18.21 **A** and **B,** Basaloid (nonkeratinizing) SCC features irregular nests of basophilic cells that may have peripheral palisading of nuclei. **C,** Some have focal keratinization *(arrow)*.

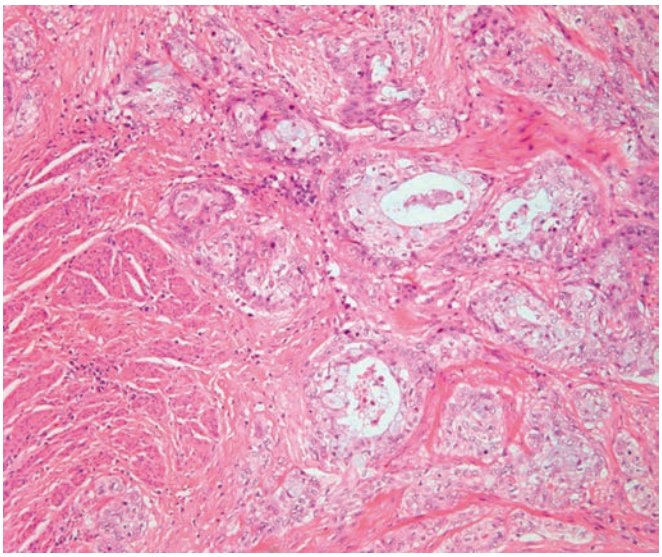

Figure 18.22 Squamous cell carcinoma (SCC) with mucinous microcysts has also been referred to as microcystic SCC or mucoepidermoid carcinoma of the anus.

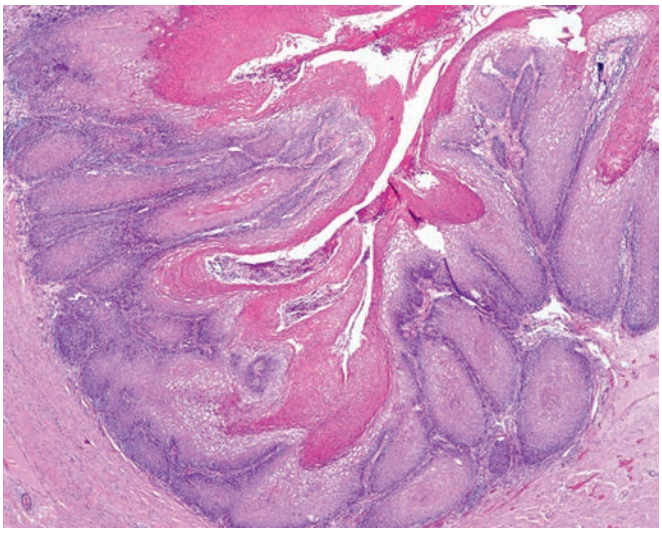

Figure 18.23 Verrucous carcinoma of the anus has a pushing, rather than an infiltrative, border. Note the juxtaposition of the tumor with the muscle of the anal canal wall.

standard of care is a combined approach of chemotherapy and radiation therapy, which achieves complete tumor regression in 80%–90% of patients, with a local treatment failure rate of about 15%.[102,103] Overall, the 5-year disease-free survival rate using a combination chemoradiation protocol is 68%, while the overall survival rate is 58%–67% and the colostomy free survival rate is 85%.[104] Local excision is sometimes used for small (< 2.0 cm) tumors of the anal margin and can be adequate if margins are clear by more than 0.5 cm.[102]

Prognosis

The prognosis of carcinoma of the anal canal is related to several parameters.

1. Patient age, gender, and race. It is worse in older (≥65 years) individuals, men, and African-American patients.[105]
2. Tumor location. Although the literature has shown conflicting results over time, current studies indicate that tumors above the dentate line have a better overall prognosis than those below the dentate line.[106]
3. Tumor size and stage. The prognosis depends largely on the stage of the disease, as determined by depth of invasion, nodal involvement, and presence of distant metastases.[105]
4. Microscopic grade. As discussed previously, histologic subtype does not affect prognosis. Poorly differentiated tumors are associated with shorter survival.[105]
5. Presence of HPV. Patients with HPV-negative SCC appear to have a worse prognosis (shorter disease-free survival) in some studies than patients with HPV-positive tumors.[84]

Anal Duct/Gland Adenocarcinoma

Adenocarcinoma involving the anal canal usually represents a downgrowth of a rectal tumor, and this is the main entity in the differential diagnosis of **primary anal adenocarcinoma**. These rare tumors are thought to arise from the mucus-producing epithelial cells of the anal transition zone, as well as the glandular epithelium of the perianal glands/ducts. Association with HPV remains controversial. These tumors generally present in older adults (60–70 years of age), and there is a male predominance.[107–109] Patients often have a painful buttock mass and/or a mucinous anal discharge, and many also present with bleeding.[107,109] These tumors are aggressive, with high risk of both local and distant recurrences. The overall 5-year survival rate is 30% or less;[108] prognosis is stage dependent, however, and staging is similar to anal SCC.

Macroscopically, anal adenocarcinomas arise within the deep soft tissues of the anal region (Fig. 18.24A), and intraluminal anal canal growth is rare. Tumors may protrude from the anal orifice or form an ulcerated mass that involves the squamous mucosa and therefore causes confusion. Primary anal gland/duct carcinomas typically have one of two patterns.[109,110] The first is a relatively well-differentiated infiltrative process composed of tubules or glands with minimal luminal material. The second is a mucinous or "colloid" pattern, with clusters of malignant cells associated with large pools of paucicellular mucin (see Fig. 18.24B–D). The latter type can present with multiple fistulous tracts and, on rare occasions, as vaginal cysts.[111] Pagetoid spread of tumor cells is frequently seen.[109] Poorly differentiated tumors with signet ring cell features have also been reported, although some of these may represent distal rectal adenocarcinomas.[112] Rare anal carcinomas have clear cell features,[113] which must be distinguished from the equally rare metastases of clear cell tumors (such as renal cell carcinoma) to the anus.[114] Anal duct/gland adenocarcinomas are typically CK7 positive and CK20 negative, which is in contrast to colorectal adenocarcinomas that are frequently CK20 positive and CK7 negative. Rare mucinous anal adenocarcinomas are also CK20 positive, however.[109,110] Patients are generally treated by surgical excision, which may be extensive; surgical therapy may also be combined with chemotherapy and radiation.

Paget Disease

Paget disease of the anal region is a malignant glandular neoplasm having a predominantly or exclusively intraepithelial location and characterized by infiltration of the epithelium by malignant mucin-containing cells. It affects both women and men, although women are more commonly affected, and typically presents in middle-aged to older patients.[115] Clinically, it presents as erythematous, scaly, or ulcerated lesion of eczematoid appearance located anywhere between the dentate line and perianal skin (Fig. 18.25A). Patients typically present with bleeding and/or itching.

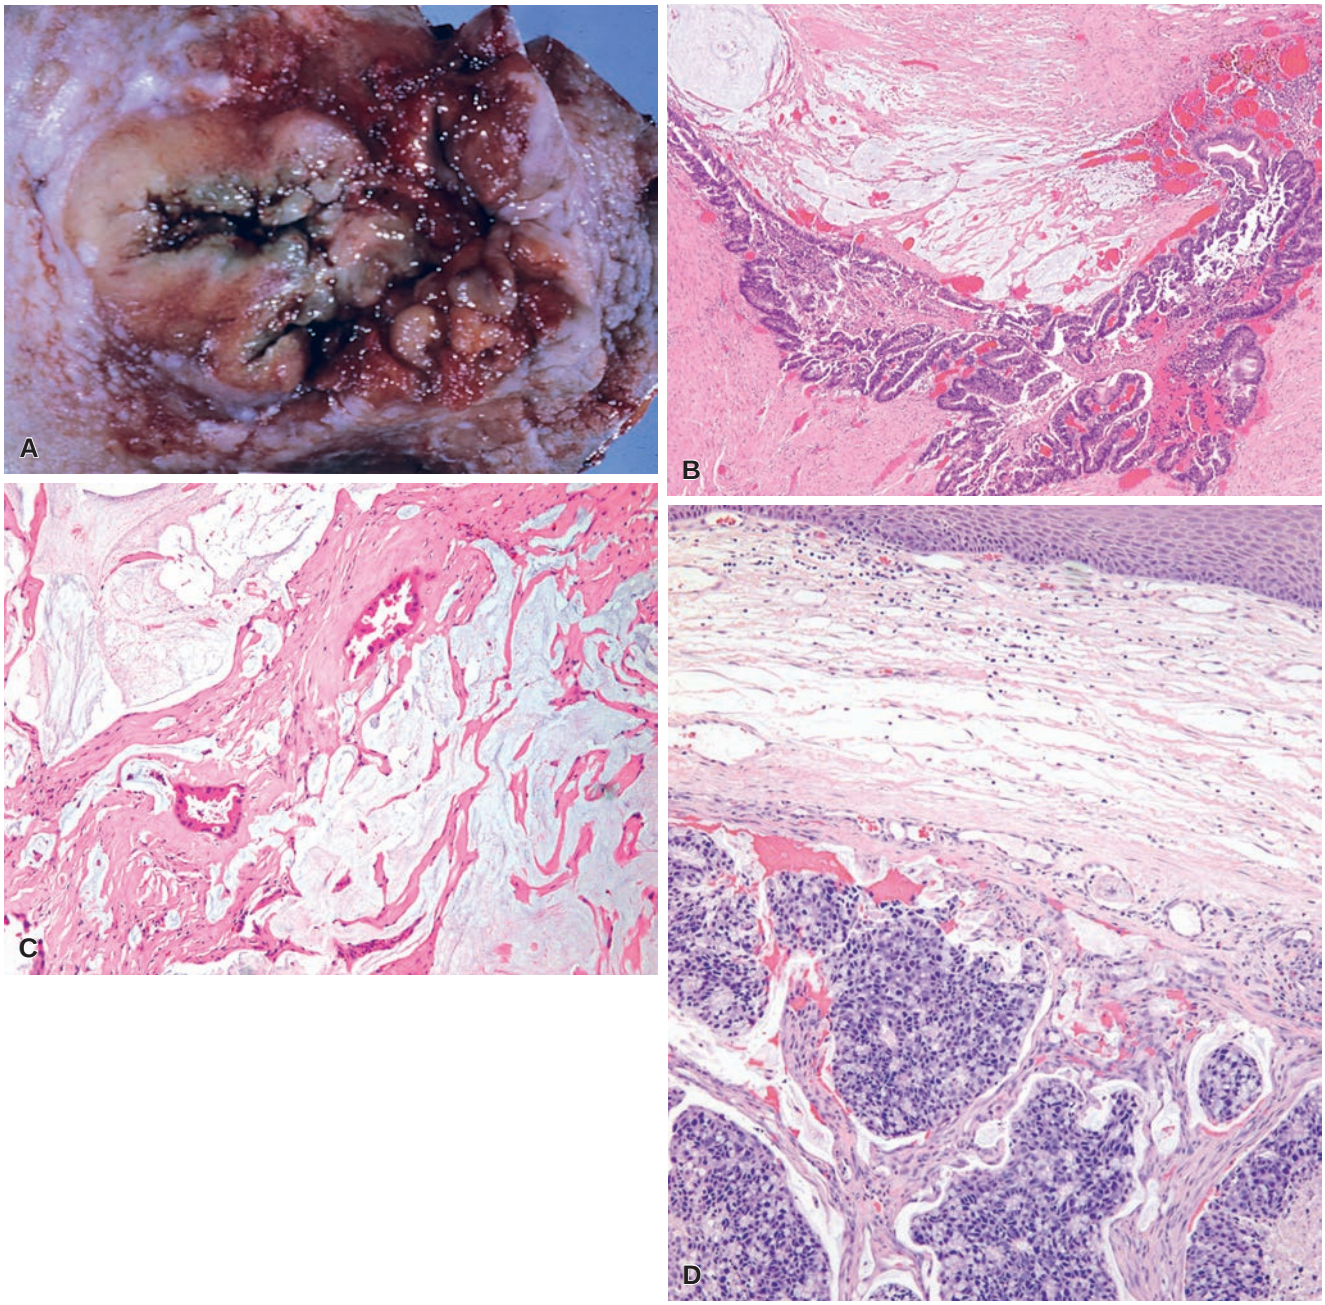

Figure 18.24 **A,** This anal duct adenocarcinoma infiltrates the perianal soft tissues and forms a large mass that undermines the overlying epithelium. **B** and **C,** This anal duct adenocarcinoma features deeply infiltrating well differentiated glands associated with large pools of dissecting mucin. The glands are present deep within the anal musculature. This example **(D)** shows clusters of poorly differentiated cells (including signet ring cells) in pools of mucin. This tumor was CK7+ and CK20–, consistent with an anal primary.

Paget disease of this region can be subdivided into two types.[116] Primary anal/perianal Paget disease is histologically similar to that seen in the vulva and perineum, though it can occur in both sexes. Primary Paget disease is believed to arise from neoplastic cells of either apocrine or eccrine origin.[117] Secondary anal/perianal Paget disease arises from neoplasms that are centered in the rectum, with individually infiltrating cells extending distally to involve the anal mucosa. Primary Paget disease is much less common than the secondary form, reflecting the more frequent occurrence of colorectal adenocarcinoma in general.

In either form of Paget disease, the Paget cells are predominantly located along the epithelial basal layer, infiltrating the squamous mucosa or perianal skin in a pattern known as "pagetoid spread" (see Fig. 18.25B). Most of them are arranged individually, but occasionally there are nests and gland-like formations; neoplastic cells may spread down pilosebaceous units and adnexal structures. The cells are large and have abundant pale cytoplasm, and often contain recognizable mucin vacuoles. Occasionally they have a signet ring appearance.[116] Mucin-containing Paget cells can be highlighted using cytochemical stains, such as mucicarmine, and/or immunohistochemical

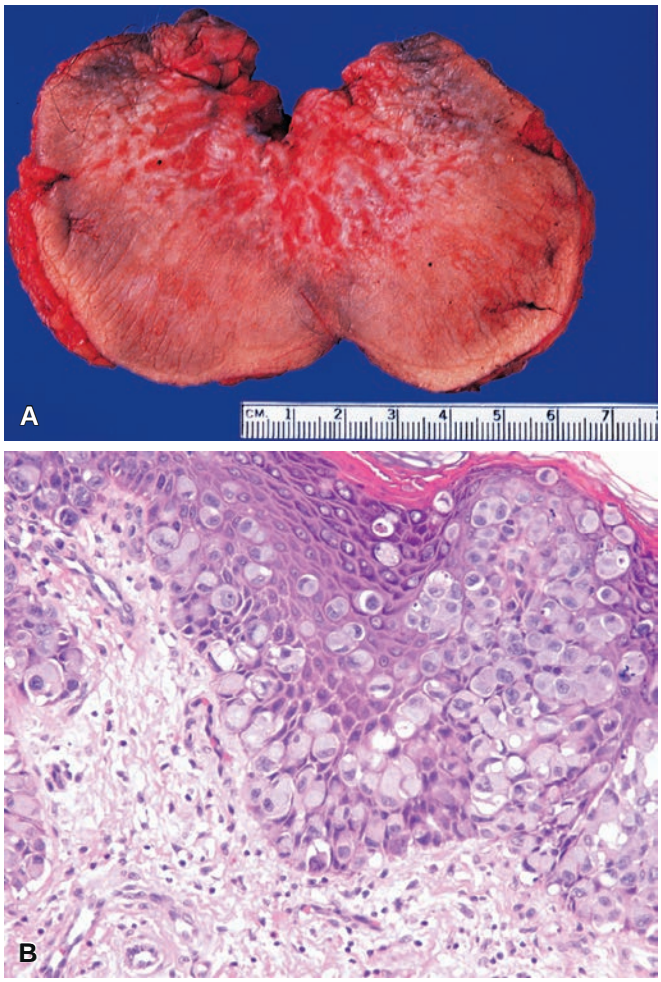

Figure 18.25 Gross Appearance of Paget Disease of the Anus. **A,** The lesion is erosive and hyperemic and has ill-defined borders. **B,** Paget cells are predominantly located along the basal layer, infiltrating the epithelium as individual cells or nests. The cells are large with atypical nuclei, abundant pale cytoplasm, and occasional mucin vacuoles.

markers of mucin production, an important feature (more in the past than now) in the differential diagnosis with melanoma and Bowen disease.[118,119] The infiltrative nature of the process often causes reactive changes in the adjacent squamous epithelium, including hyperparakeratosis, acanthosis, and basal atypia. Cases of coexistent Paget disease and squamous neoplasia have also been reported at this site.[120]

Immunohistochemistry can aid in both the diagnosis of anorectal Paget disease and in distinguishing between the two forms.[116,121] Distinction between the two types of Paget disease is important because secondary Paget disease may be the presenting sign of a rectal neoplasm. Paget cells are reactive for keratin, CEA, and EMA.[119] As expected, secondary PD has an immunophenotype consistent with colonic adenocarcinoma, expressing CK20, CDX-2, and MUC2; as with other colorectal adenocarcinomas, there may be CK7 positivity as well. In contrast, primary Paget disease of the anus has a phenotype identical to vulvar disease and much more analogous to mammary carcinoma. Specifically, CK7, MUC5AC, and GCDFP-15 are positive, while CK20 and CDX-2 are negative. GCDFP-15 ("gross cystic disease fluid protein") is a marker of apocrine differentiation expressed by many breast carcinomas and may suggest an apocrine origin for primary anal Paget disease as well.[116] Interestingly, the cells of extramammary (including anal) Paget disease consistently lack estrogen and progesterone receptors but frequently express androgen receptor.[122]

The therapy and prognosis of anorectal Paget disease depends on the specific type. For primary cases, wide local excision is the mainstay of treatment,[123] although local recrudescence is very common because of the ill-defined nature of the process, its sometimes multifocal nature, and the difficulties in delimiting it grossly and surgically. Topical and/or noninvasive modalities are effective in some cases. Secondary cases with associated underlying rectal cancer should be treated accordingly, and prognosis in these latter cases depends on the stage of the underlying adenocarcinoma but is usually poor.

Anorectal Paget disease must be distinguished from other tumors of this region that can have pagetoid spread, including primary anal gland/duct adenocarcinoma, melanoma, and SCC. The pagetoid cells of melanoma are keratin negative and express melanoma markers, such as S-100, HMB-45, and/or melan-A. SCCs with pagetoid growth express squamous markers, such as p63 and CK5/6, are mucin negative, and often have evidence of HPV infection. The immunophenotype of anal gland/duct carcinoma generally overlaps with that of primary anorectal Paget disease, so correlation with clinical findings is often necessary to differentiate between these diagnoses. Reactive vacuolated squamous cells may also mimic Paget disease, but these cells should not have significant cytologic atypia and should not contain mucin. It is also interesting that cells identical to those described by Toker in the nipple have been detected in the anal region (V Eusebi, personal communication, 2003), which may also enter into the differential diagnosis.

Other Microscopic Types of Carcinoma

Neuroendocrine carcinoma is exceedingly rare in this location. The histologic and immunophenotypic appearance is reminiscent of the pulmonary homonymous tumors, and they may have either a small cell or large cell phenotype.[124] These tumors should express at least one neuroendocrine marker (synaptophysin, chromogranin, CD56) and are variably keratin positive.[124] Their behavior is extremely aggressive.[93] Some cases have been associated with HPV infection and intraepithelial neoplasia,[125] and some have been reported in HIV-infected patients.[126] There are also very rare reports of Merkel cell carcinoma of the anal canal, with characteristic dot-like keratin positivity.[127] Well-differentiated neuroendocrine (carcinoid) tumors of the "anorectum" have been occasionally reported, but it is unclear in many cases if these tumors are truly arising in the anus, or represent extension from a low rectal tumor.

Basal cell carcinoma is occasionally encountered in perianal skin. Before making this diagnosis, the more likely probability of basaloid SCC should be considered, especially when the tumor encroaches on the anal canal. Some patients develop perianal basal cell carcinomas in association with genetic syndromes, such as the basal cell nevus (Gorlin) syndrome; therefore, patients with these conditions should be carefully examined for perianal lesions.[128]

Perianal basal cell carcinomas develop at or below the anal verge, in hair-bearing skin, in contrast to basaloid SCC that involve the anal canal itself. As in other sites, perianal basal cell carcinomas have a nodular, pearly appearance with variably present ulceration[129,130] and are occasionally mistaken for benign lesions such as anal tags or hemorrhoids. Histologically, analogous to their counterparts elsewhere, they are composed of nodules of basaloid cells with prominent peripheral palisading, and they can sometimes be seen "budding" from the basal surface of the epidermis (Fig. 18.26).

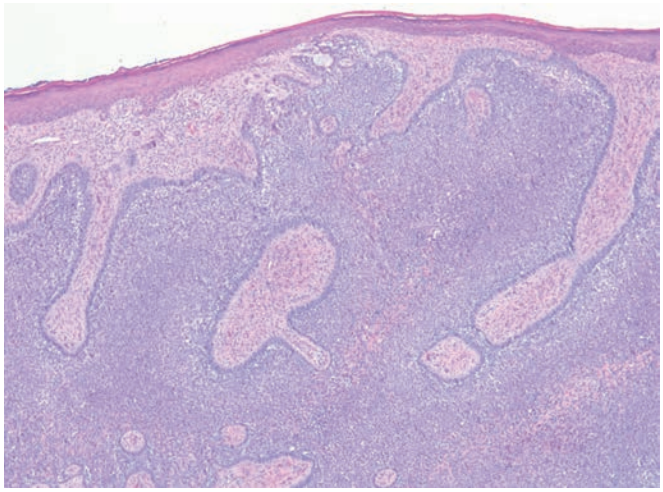

Figure 18.26 This basal cell carcinoma "buds" from the overlying perianal skin and shows a nodular tumor composed of basaloid cells with prominent peripheral palisading.

Retraction artifact may be prominent around the tumor nests, and microcystic spaces filled with mucoid material or foci of abrupt keratinization are sometimes present as well.[129,130] In contrast to basaloid SCC, true cutaneous perianal basal cell carcinomas usually have less nuclear pleomorphism and less mitotic activity. Immunohistochemistry for EpCAM/Ber-EP4 can aid in distinguishing the two, as it tends to be positive in perianal basal cell carcinoma and negative in basaloid SCC.[131] Conversely, basaloid SCC are typically positive for markers of squamous differentiation such as SOX2. Of note, p63 and CK5/6 can mark either tumor.[131] The distinction is of great importance because of the vast difference in therapy and behavior between the two tumors.[130] Wide local excision is the therapy of choice for cutaneous perianal basal cell carcinoma, which is usually curative.[129,130] As previously mentioned, chemoradiation is the standard of care for basaloid SCC of the anal canal. These tumors typically have a more aggressive course than cutaneous perianal basal cell carcinomas.

Malignant Melanoma

Malignant melanoma of the anus is rare, accounting for less than 0.01% of all mucocutaneous melanomas.[132,133] These tumors are believed to arise from normal melanocytes that exist in the anal squamous mucosa and the anal transition zone. Most cases occur in adults, but they can also affect children and adolescents.[134] The typical gross appearance is that of a polypoid, variably pigmented mass with a smooth overlying surface that is often ulcerated (Fig. 18.27A). These lesions are often quite large at presentation (2–5 cm).[132,135] In the early stages, anal melanoma can simulate hemorrhoids or a prolapse polyp, which unfortunately may lead to a delay in diagnosis.[136] The tumor is usually close to the dentate line but can also lie at the anal verge. Sometimes these lesions extend proximally along the submucosa and emerge through the mucosa at a high point, thus simulating a primary rectal tumor.[132] Rectal bleeding, palpable mass, and pain are the most common complaints.[132]

Microscopically, anal melanoma is composed of large, epithelioid, pleomorphic tumor cells with variably present pigment (see Fig. 18.27B and C). Two-thirds show a "junctional" component with a lentiginous appearance in the adjacent mucosa.[137] The appearance and histologic variability are similar to those of melanomas of skin and other mucosal membranes, including the desmoplastic variety featuring spindle cells in an abundant collagenous matrix, and often lacking pigment (see Fig. 18.27D).[138,139] The immunohistochemical profile is also similar to that of cutaneous melanoma,[139] with the caveats that many desmoplastic melanomas lack HMB-45 immunoreactivity (but S-100 protein expression remains fairly sensitive), and that many melanomas are CD117 positive.[140]

Prognosis, which in general is extremely poor, is directly related to tumor stage;[133] the overall 5-year survival rate is 27.3% for localized disease, and 14.5% for regional disease. Surgery is the mainstay of therapy, and options include both wide local excision and abdominoperineal resection.[133] No other morphologic or immunohistochemical features seem to correlate with prognosis.[139]

Malignant melanoma should be distinguished from other epithelioid malignancies of the anus, as well as the exceptionally rare adenocarcinoma of this region which contains abundant melanin in the tumor cells, perhaps through a colonization mechanism similar to that sometimes seen in breast carcinoma.[141]

Mammary Analogue Tumors

Historically, anogenital mammary-like glands were believed to represent ectopic breast tissue along the milk line. Currently, however, these glands are considered to be normal in this location. These glands give rise to a wide variety of lesions that bear a resemblance to their counterparts in the breast (Fig. 18.28), including fibroadenomas, hidradenoma papilliferum, phyllodes tumor, and mammary-type carcinomas.[142,143]

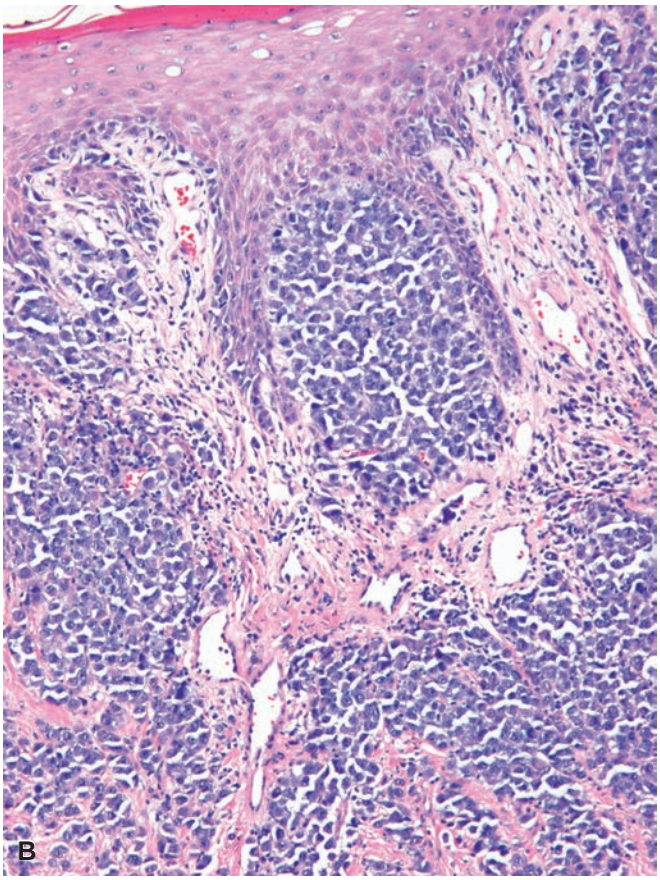
Other Tumors and Tumorlike Conditions

Ectopic prostatic and gastric tissue have been reported in the anal canal.[144,145]

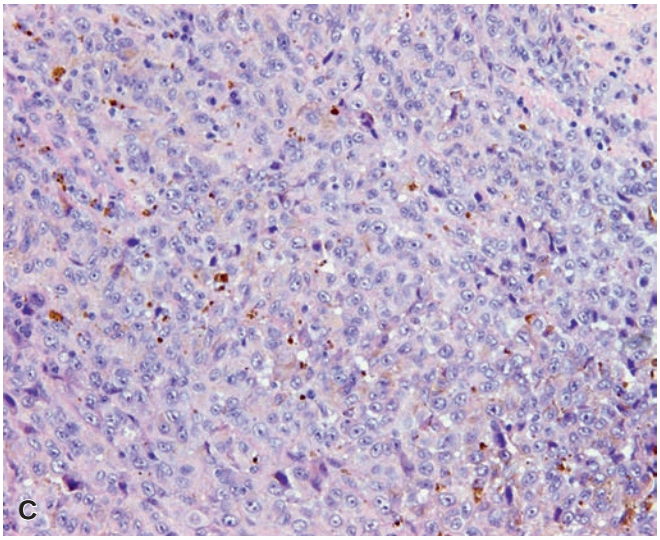
Langerhans cell histiocytosis can involve the perianal skin.[146]

Endometriosis may involve the anus and perineum, typically secondary to an episiotomy scar.[147]

Keratinous cysts of epidermal type located in the anal canal are probably of the so-called epidermal inclusion cyst type.[148]



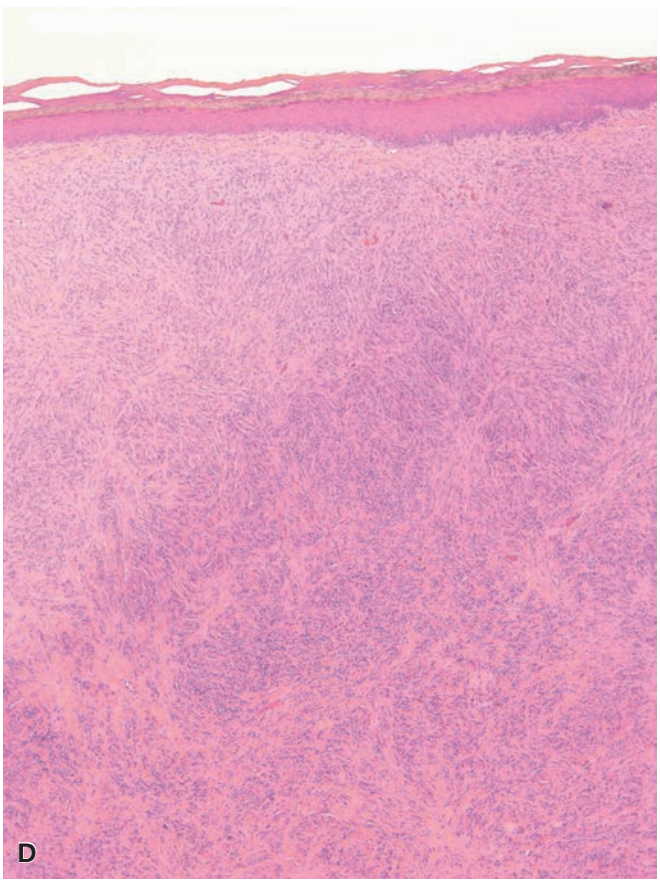
Benign mesenchymal tumors are very rare in this location, if one avoids labeling hypertrophied anal papillae as 'fibromas.' True **leiomyomas** as well as gastrointestinal stromal tumors (GISTs) are occasionally seen in this location.[149,150] **Granular cell tumors** may grow to a relatively large size and ulcerate, thus simulating clinically the appearance of a malignant tumor.[151] These benign tumors are generally cured by excision, and occur more commonly in African Americans.[152] **Perianal spindle cell lipoma**[153] has been rarely reported. **Leiomyosarcoma** is the most common primary malignant stromal tumor in the region.[150] Sometimes it is difficult to decide whether to classify these tumors as anal or rectal. The differential diagnosis includes GIST and spindle cell/desmoplastic melanoma.



Rhabdomyosarcoma can occur in the perianal region of infants and children and may present as a perirectal abscess. Both alveolar and embryonal patterns have been reported (Fig. 18.29).[154] Kaposi sarcoma can also involve the anus.[155]

Malignant lymphoma of the anorectal region has been observed, most often in HIV-infected patients.[156,157] Some of these tumors have been found to be EBV-related.[158]

Metastases to the anal region often arise from rectal carcinomas (Fig. 18.30). Sometimes these have been seen to develop at the site of a recently performed hemorrhoidectomy.[159] Metastases have also been reported from distant sites such as the kidney, breast (Fig. 18.31), and pancreaticobiliary tree, which can mimic primary anal adenocarcinoma or extension from a low rectal adenocarcinoma.[114–161]



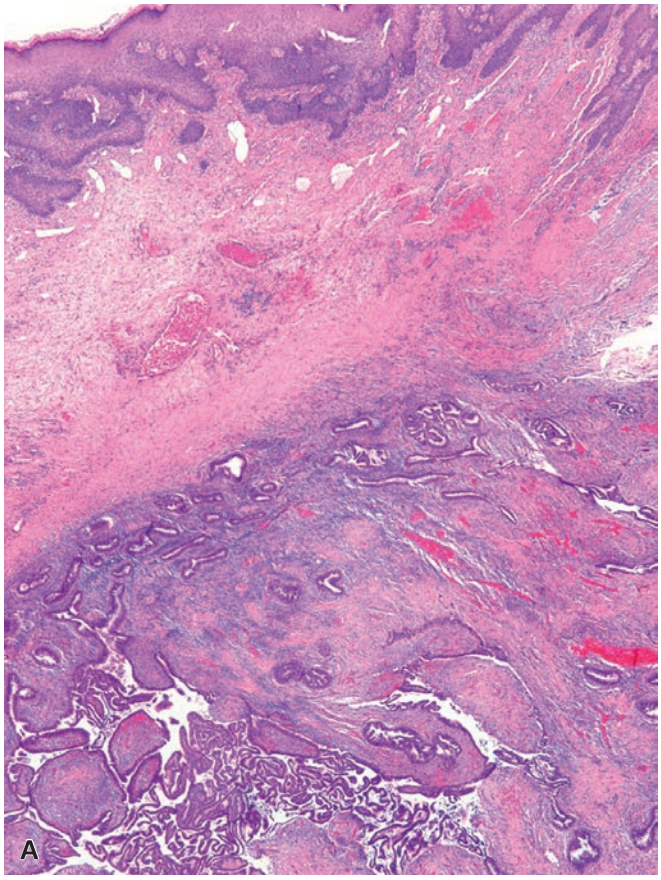


Figure 18.27 **A,** Cross section from excision specimen of an anal melanoma demonstrates the polypoid configuration of the tumor as well as the pigmentation. Note the extension into the surrounding mucosa. **B,** This biopsy from an anal melanoma demonstrates involvement at the dermal/epidermal junction. **C,** High-power view shows large, epithelioid tumor cells with abundant pigment. **D,** This desmoplastic anal melanoma features a spindle cell proliferation with a prominent collagenous matrix and no pigment.

Normal Anatomy

Several structural and functional units have been proposed in the microanatomy of the liver. Of these, the most relevant for the diagnostic histopathologist are the liver lobule and the liver acinus. For several years the liver acinus[1] was the preferred concept in textbooks of pathology and hepatology, as it appeared to better explain the "bridging" type of lesions connecting afferent and efferent vascular landmarks, that is, portal–central bridging necrosis and fibrosis. The simple liver acinus corresponds to the small area of parenchyma vascularized by a single terminal branch of the portal vein (portal venule) and hepatic artery, and drained by the neighboring terminal hepatic venules. In spite of its popularity in recent years, the liver acinus did not withstand the scrutiny of further detailed angioarchitectural, morphologic, and histochemical investigations, and virtually all later studies support the lobular concept of liver architecture, albeit with several types of subunits.

The classical hexagonal liver lobule[2] is centered on a terminal twig of the hepatic vein (centrilobular or central vein), and surrounded by (on average) six portal tracts. The portal vein ramifications in

Abstract

This chapter covers the major entities and differential diagnoses in non-neoplastic liver pathology, including viral hepatitis, drug-induced liver disease, steatohepatitis, cholestatic liver disease, autoimmune hepatitis, storage and metabolic diseases, vascular diseases, infections, and transplant pathology.

the portal tracts give off a series of branches in the plane between adjacent portal tracts; these in turn give rise to sinusoids that drain the blood toward the center of the lobule. The lobular equivalents of the acinar zones 1, 2, and 3 are the periportal zone, midzonal or midlobular zone, and centrilobular area.

The liver parenchymal cell or hepatocyte is a polygonal cell with a characteristically central, single nucleus. Hepatocytes are arranged in plates one to two cells thick with a sinusoid on either side, thus exposing each hepatocyte to portal blood on two surfaces. Within the cell plate each hepatocyte adjoins adjacent parenchymal cells at its intercellular surface. This intercellular domain of the cell membrane forms a groove (hemicanaliculus) as a girdle around the cell. The hemicanaliculi of two adjacent hepatocytes form the intercellular bile canaliculus, which is separated from the rest of the intercellular space and the blood compartment by tight junctions.

The virtual cleft between the sinusoidal lining cells and the sinusoidal domain of the hepatocyte surface is the space of Disse. It is not typically visible in biopsy material but appears dilated in autopsy specimens. The hepatic sinusoids are lined by different cell types. The sinusoidal endothelial cells are of the fenestrated type. Kupffer cells, which are resident members of the mononuclear phagocyte system that undergo enlargement and proliferation in response to a wide variety of stimuli, bulge out on the luminal side of the sinusoids. Hepatic stellate cells (previously known as Ito cells, fat-storing cells or lipocytes) are contractile perisinusoidal "pericytes" located in the space of Disse. They store vitamin A in their cytoplasmic lipid droplets and are able to switch their phenotype to myofibroblast-like cells under appropriate stimulation. Stellate cells are matrix producers in both normal liver and in pathologic intralobular fibrosis. Hepatic stellate cells are only identified with difficulty in routinely stained preparations; immunostaining for synaptophysin marks both resting and activated cells, and immunostaining for alpha-smooth muscle actin reveals activated stellate cells.[3] Located on the inside of sinusoidal endothelial cells are some scattered "pit cells," which are resident intrahepatic lymphocytes, primarily natural killer phenotype.

The portal tracts at the lobular periphery are composed of connective tissue, ensheathing branches of the hepatic artery, portal vein, bile duct, and lymphatics. The caliber of portal tracts and their composing structures decreases from the hilum of the liver toward its periphery; this explains why surgical liver biopsies and autopsy specimens usually contain larger portal areas than needle biopsy specimens. The microarchitectural variability is also greater in the peripheral liver. On average, one may expect two interlobular bile ducts, two hepatic arteries, and one portal vein per portal tract, but in peripheral liver, portal dyads (containing only two of the three artery, vein, or bile duct profiles) are almost as common as portal triads.[4]

Interlobular bile ducts, usually located in the center of the portal tract, are connected with the lobular canaliculi by ductules (or cholangioles) and canals of Hering, the latter being short stretches lined by both hepatocytes and cholangiocytes.[5] These finer structures are hardly visible on hematoxylin–eosin (H&E) staining but clearly revealed by cytokeratin immunostains.[6]

Liver cell plates and sinusoids have a more regular radial arrangement in the center of the lobule, whereas the periportal zone is characterized by a less regular, anastomosing network pattern of these structures.

Hepatocytes are polygonal in shape, with clearly outlined cell membranes in H&E preparations. The cytoplasm is granular and eosinophilic, with basophilic aggregates of rough endoplasmic reticulum in a perinuclear distribution. The nucleus is centrally placed and carries one or more easily identifiable nucleoli. Mitotic figures are very rare. Hepatocytes are rich in glycogen, with diurnal and diet-related variations in amount and distribution. Glycogen accumulation in nuclei occurs as clear vacuoles, predominantly in periportal hepatocytes. This is common in childhood and may be conspicuous in some adult diseases (e.g., diabetes and Wilson disease) but is not by itself of diagnostic significance. Lipofuscin occurs as fine, light brown, periodic acid–Schiff (PAS)-positive and acid-fast granules in the pericanalicular region of centrilobular hepatocytes (Fig. 19.1); it should not be mistaken for bile. Stainable iron is absent or demonstrable in only scant amounts in the adult liver. An occasional hepatocyte in normal liver may contain fat.

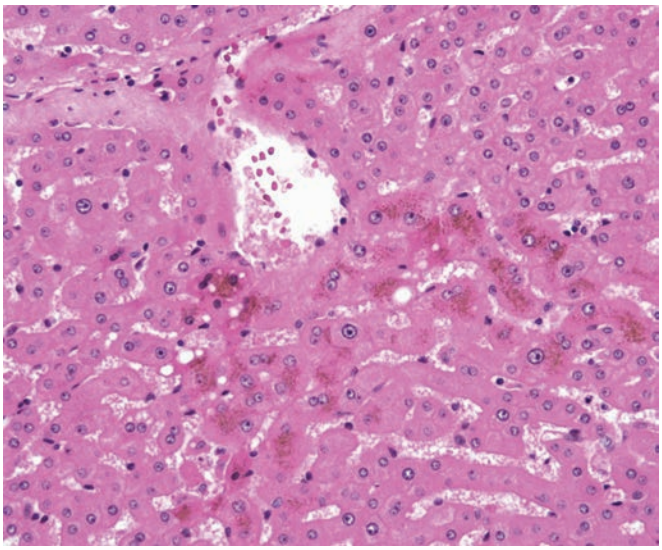

Figure 19.1 Lipofuscin appears as a finely granular brown pigment within hepatocytes, most prominent in zone 3.

There is some variation in hepatic microscopic appearance with age. In neonates, extramedullary hematopoiesis may persist during the first weeks of life. With increasing age, there is more variation in nuclear size (anisokaryosis), somewhat more pronounced centrilobular lipofuscinosis ("wear and tear pigment"), some atrophy of centrilobular hepatocytes and correspondingly broader appearance of perivenular sinusoids, occasional hyalinization of the wall of hepatic artery branches, and thickening of the liver capsule with some fibrous extensions reaching for 1–2 mm into the underlying parenchyma.

Physiologic postnatal liver development comprises three structural components: enlargement of the hepatocytes and expansion and proliferation of the liver lobules. Enlargement of the lobules is exclusively responsible for the regenerative liver growth following partial hepatectomy; the number of hepatic lobules does not change during this latter reaction, but they gain a more complex, irregular structure.[7]

Biopsy

Light microscopic examination of liver tissue remains an essential part of the diagnostic procedure and of the follow-up of the majority of liver diseases. Biopsies obtained during surgical procedures may show "surgical hepatitis," appearing as a neutrophilic infiltrate that may be accompanied by coagulative necrosis of single or small groups of hepatocytes (Fig. 19.2). The lesion is usually centrilobular, but its extent depends on the duration of the operation and the degree of manipulation of the liver.[8] For this reason, biopsies obtained during surgery should be performed immediately on entering the peritoneal cavity. It is also important to note that the

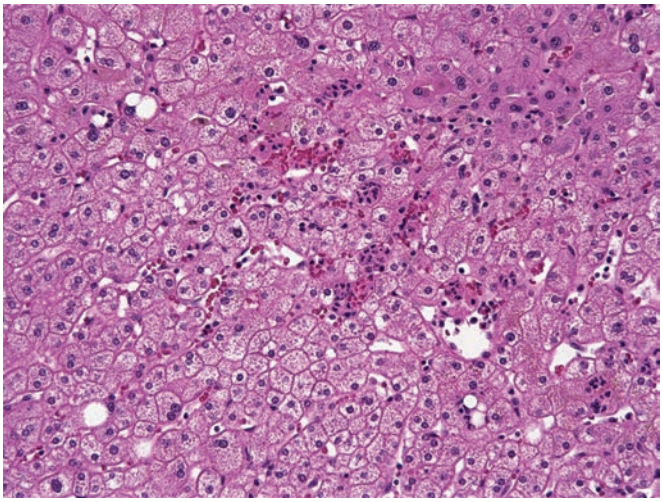

Figure 19.2 "Surgical hepatitis" features a neutrophilic infiltrate associated with necrosis of single hepatocytes or small groups of hepatocytes.

subcapsular area is not representative of the entire organ; marked subcapsular fibrosis may coexist with minimal changes deeper in the liver, and contraction of the elastic fibers in the capsule after wedge biopsy may mimic cirrhosis.[9,10] Therefore, the surgeon should perform not only an incisional biopsy but also a deeper needle biopsy.

The indications for and diagnostic usefulness of liver biopsy change over time. The availability of serologic tests for the etiologic diagnosis of acute viral hepatitis has reduced the need for liver biopsy in this condition, and transient elastography (FibroScan) is replacing biopsy for extent of fibrosis in chronic viral hepatitis in some settings.[11] The refinement of liver imaging techniques and of endoscopic retrograde cholangiopancreatography (ERCP) has also rendered the use of liver biopsy for the diagnosis of large bile duct obstruction largely obsolete. However, liver histopathology remains a mainstay in the diagnostic work-up of most liver diseases, and several studies over the years have emphasized its diagnostic usefulness and importance to therapy.[12–15] With the advent of liver transplantation, liver biopsy remains the gold standard for the diagnosis of cellular rejection[16] and for diagnosis of infection, vascular complications, and recurrence of disease in the transplant setting.[17] In an appreciable number of cases, the pathologist may discover the presence of an unsuspected diagnosis in addition to the clinically presumed diagnosis, for example, α1-antitrypsin (α1-AT) deficiency or nonalcoholic fatty liver disease (NAFLD) in a patient with known chronic viral hepatitis B or C. In a recent Canadian study, such findings amounted to 20% of hepatitis biopsies.[18]

As in all of diagnostic histopathology, the H&E stain is the mainstay in liver pathology. Special stains are useful for visualizing inapparent or easily overlooked features, but the number and type performed routinely is a matter of personal preference, and varies from one laboratory to the next. The strict minimum is an H&E and a connective tissue stain. Many pathologists also routinely employ an iron stain for assessing iron deposition; PAS–diastase stain for ceroid macrophages, α1-AT inclusions, fungi, and thickened basement membranes of interlobular bile ducts; the rhodanine stain for copper (in Wilson disease, chronic cholestasis, and copper toxicosis); and a reticulin stain for examining the reticulin framework and revealing parenchymal collapse. Immunohistochemical staining for "bile duct type keratins" (keratins 7 and 19) may be extremely useful in cholestatic liver diseases, for recognizing early stages of cholate stasis, cholestatic liver cell rosettes, ductular reaction, and ductopenia.[15,19]

Over the years, the accuracy and diagnostic yield of liver histopathology have been steadily increasing through expanding availability of immunohistochemistry.[20]

The diagnostic accuracy of liver histopathology depends on numerous factors, which are not always optimal in every instance and which hardly lend themselves to quantitative evaluation. Several factors relate to the biopsy specimen. Size is important, although not in an absolute way; because the average needle biopsy represents 100 thousandth to 150 thousandth (0.00001–0.000006666) of the liver organ, sampling variability and error is an obvious possibility. A reliable diagnosis of a disease with unequal involvement of portal tracts (such as chronic hepatitis or primary biliary cirrhosis [PBC]) often requires a larger sample than a condition with diffuse involvement (such as classic acute hepatitis). The minimum size requirements for a diagnostic biopsy and the minimum number of portal tracts remain controversial. One study evaluating grading and staging in chronic hepatitis indicated that smaller specimens result in both undergrading and understaging disease, and that a minimum biopsy sample should be 15 mm or a core comprising at least 11 complete portal tracts.[21] Another study suggested that a length of at least 25 mm is necessary to evaluate fibrosis accurately with a semiquantitative score.[22] In NAFLD, a significant relationship was also found between diagnostic yield and sample length.[23] On the other hand, there are studies that show that the level of experience in evaluating liver biopsies is more important than the length of the core.[24] Regardless, the pathologist should carefully examine even inadequately sized specimens in order to ensure maximum yield of information from an invasive procedure. The diagnostic accuracy of focal lesions (e.g., granulomas, cytomegalovirus [CMV] inclusions) is also improved by examining multiple sections. Other factors affecting diagnostic yield include experience of the pathologist, availability of clinical information, and knowledge of clinical implications. Even under optimal circumstances, however, an adequate biopsy may not provide a complete diagnosis, or may even fail to give helpful information.

Although a reliable final diagnosis definitely requires knowledge of laboratory information and the clinical background of the patient, it is equally true that objectivity in analysis and conclusion is best served by examination of the slides without any other clinical or laboratory information. Several reviews on how to systematically examine a liver biopsy are available,[25–28] including a position paper from the American Association for the Study of Liver Diseases (AASLD) addressing pathologic considerations of specimen size and quality, tissue allocation, tissue processing, specimen interpretation, and sampling error.[29]

Viral Hepatitis

Viral hepatitis, or liver inflammation due to viral infection, may be caused by specific hepatotropic viruses (the "hepatitis viruses") and by several other viruses that primarily cause generalized infection that may involve the liver (e.g., CMV, Epstein–Barr virus [EBV]).

Viral Hepatitis Caused by Hepatotropic Viruses

Historically, when adequate diagnostic tests for hepatitis A virus (HAV) and hepatitis B virus (HBV) became available in transfusion centers for screening of donor blood, it became evident that a fraction of post-transfusion viral hepatitis was not due to HAV or HBV, and thus designated by the term non-A, non-B hepatitis.[30] After more than a decade of intensive research, hepatitis C virus (HCV) was discovered and found to be responsible for the majority of non-A, non-B hepatitis.[31–33]

Table 19.1 Major hepatitis viruses

VIRUS	TYPE AND FAMILY	INFECTION ROUTE	DISEASE
Hepatitis A (HAV)	Single-stranded RNA virus Picornaviridae family	Fecal–oral, oral	Acute
Hepatitis B (HBV)	Partially double-stranded DNA virus Hepadnaviridae family	Parenteral, sexual, perinatal	Acute, chronic
Hepatitis C (HCV)	RNA virus Flaviviridae family	Parenteral, sexual, perinatal	Acute, chronic
Hepatitis D (HDV, Delta agent)	Defective RNA virus	Parenteral, sexual Requires coinfection with or superinfection of HBV	Acute, chronic
Hepatitis E (HEV)	Single-stranded, nonenveloped RNA virus Caliciviridae family	Vertical, oral, parenteral	Acute

Now there are at least five distinct hepatotropic viruses, belonging to entirely different families (Table 19.1). They have very little in common except that they affect the liver as a target organ, and some degree of shared epidemiology.[34] All have a worldwide distribution. Two of these viruses (HAV and HEV) are spread principally by the fecal–oral route, and three (HBV, HCV, HDV) are spread mainly by exposure to blood, although HBV and HCV may also be spread by unprotected sex. HEV causes a self-limited and often anicteric hepatitis in the West,[35] where it is likely underdiagnosed.[36] It is a major health problem in developing countries, however, causing high morbidity and often fulminant hepatitis in pregnant women in certain geographic areas (e.g., India).[37]

More recently identified hepatitis viruses (non-A-E viruses) include hepatitis G virus (HGV or GBV-C, family Flaviviridae)[38]; Torque teno virus (TTV), a DNA virus of the family Circoviridae[39]; and SEN virus, a transfusion-transmitted DNA virus.[40] The clinical significance of HGV, particularly in the context of patients with chronic liver disease due to HBV or HCV, remains controversial. There is some evidence that although coinfection of HGV in patients with chronic hepatitis B or C does not affect disease severity, it may accelerate the progression of chronic liver disease and the development of hepatocellular carcinoma.[41] TTV and SEN viruses appear to be extraordinarily diverse and to be ubiquitous in >90% of adults worldwide, but no human pathogenicity has been fully established.

Acute Viral Hepatitis

The introduction of serologic and molecular tests for hepatitis viruses has decreased the indication for liver biopsy in acute hepatitis. However, biopsy may still be used to confirm a diagnosis, to assess severity and evolution of the disease, and to exclude concomitant disease (e.g., alcoholic liver disease superimposed on viral hepatitis).

The morphologic features of viral hepatitis have been extensively described.[34,42,43] The histologic picture of acute hepatitis due to different hepatitis viruses may be sufficiently similar to cause problems in differentiation. The general changes of hepatitis are described later, followed by some characteristics specific to individual viruses.

Typical acute viral hepatitis is a panlobular disease, although the changes may predominate in the centrilobular region in HBV and HCV, and in the periportal zone in HAV. Hepatocellular alterations are variable and include a predominantly mononuclear lobular inflammation and spotty hepatocyte necrosis. Some parenchymal cells show swelling, with increased cell volume and pale-staining, granular cytoplasm (so-called hydropic change). The heterogeneous

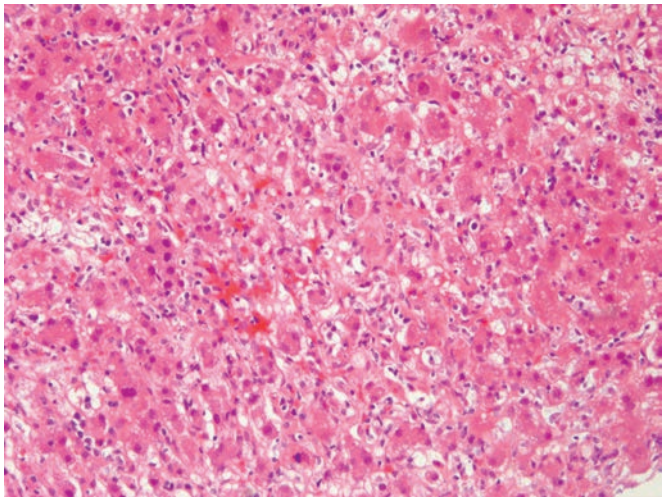

Figure 19.3 Acute hepatitis B infection characterized by ballooning of hepatocytes, lobular disarray, and mononuclear (mainly lymphocytic) inflammatory infiltration.

appearance of the parenchymal cells (due to hepatocyte swelling and necrosis), together with cell dropout and regeneration of surviving hepatocytes, leads to a loss of the normal regular liver cell plate pattern; this "lobular disarray" is also a very diagnostically helpful feature (Fig. 19.3). Reactive hepatocellular changes may be prominent, including hepatocytes undergoing mitosis. Syncytial, multinucleated giant hepatocytes, which are typical of neonatal hepatitis, may sometimes be found in adults as well, but this does not indicate a specific etiology.

There is a predominance of mononuclear and lymphocytic cell types. The majority of lymphocytes are activated memory T cells.[44,45] Also, plasma cells may be found in the early stage.[46] Small clusters of lymphocytes, whether or not in close proximity to apoptotic bodies, represent foci of cytotoxic lymphocyte–mediated target cell attack and represent the lesion indicated by the terms "focal inflammation," "focal necrosis," and "spotty necrosis."

Kupffer cells enlarge and become more prominent; they phagocytose cell debris from dying hepatocytes, which results in the intracellular accumulation of clumps of golden brown, lipid-rich "ceroid" pigment, which is best revealed in PAS–diastase stains. In the earlier stages, these "ceroid macrophages" are small and scattered as single cells; later on, they may be larger and form

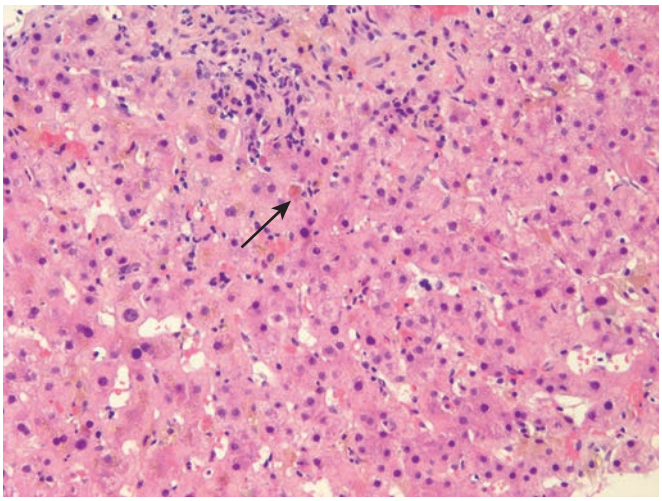

Figure 19.4 Acute viral hepatitis with scattered apoptotic hepatocytes *(arrow)* and cholestasis.

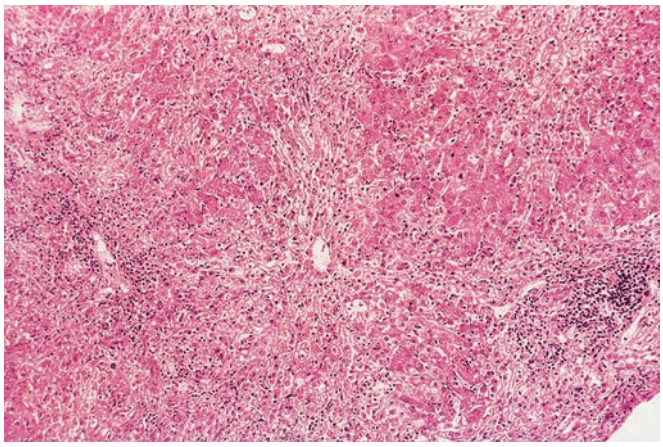

Figure 19.5 Severe Necrotizing Acute Viral Hepatitis B. There is mild to moderate mononuclear cell infiltration in portal tracts, as well as bridging portal–central confluent lytic necrosis with parenchymal loss.

clusters that predominate in centrilobular and midzonal areas. In still later stages, they are found migrated into the portal connective tissue. Ceroid macrophages in acute viral hepatitis may stain for iron in some cases. Some degree of cholestasis is common as well (Fig. 19.4).

Although the lobular pattern predominates in acute viral hepatitis, the portal tracts often also become involved by a mononuclear cell infiltrate, sometimes admixed with neutrophils, eosinophils, and—especially in the later stages—pigment-laden macrophages. The infiltrate may remain confined within the portal connective tissue, or may spill out into the adjacent periportal parenchyma. An increase in ductular profiles at the portal–parenchymal interface ("ductular reaction") also occurs in acute hepatitis; this is typically very mild in classic acute lobular hepatitis, and better revealed by keratin 7 immunostains. The extent of ductular reaction increases with the severity of the necrotizing parenchymal lesions. Lymphocytic infiltration between and inside bile duct lining cells, and some degree of bile duct epithelial damage may rarely occur, particularly in HCV,[47] although acute HCV is rarely seen on liver biopsy.

In the later stages of acute self-limited hepatitis, most of the parenchymal and portal changes gradually disappear. Residual changes such as mild portal inflammation, focal lobular inflammation, pigmented macrophages, and reactive hepatocellular changes may persist for several months.

In severe disease, the death of larger groups of hepatocytes with more extensive parenchymal damage leads to "confluent necrosis." This may initially involve zone 3, but with increasing severity, there may be dropout of parenchyma between portal tracts and central veins (bridging hepatic necrosis[48]; Fig. 19.5). A still higher degree of severity results in necrosis of all acinar zones, resulting in panlobular necrosis. For unexplained reasons, this necrosis usually has an irregular distribution throughout the liver, rendering needle biopsy less reliable for estimating the extent of necrosis in fulminant hepatitis.[49]

Necrotic bridges change in appearance over time. Freshly necrotizing bridges reveal lobular areas where the parenchyma has disappeared, with no or minimal collapse of the reticulin framework. Resolving necrotizing areas are infiltrated by mononuclear cells and some small ceroid macrophages. Later stages are characterized by collapse of the reticulin fibers, proliferation of mesenchymal cells and collagen deposition, possibly bulging of the regenerating remaining parenchyma, and larger numbers of ceroid macrophages. Older necrotic bridges heal with fibrous scars, resulting in portal–central bridging fibrosis ("post-necrotic cirrhosis").

Obvious fibrosis is a characteristic of chronic rather than of acute hepatitis, and thus the distinction between post-necrotic cirrhosis and cirrhosis in the context of chronic liver disease is critical. Fibrous bridges in the context of chronic hepatitis can be recognized by the fact that gradual deposition of elastic fibers takes place. Thus, bridging fibrosis in chronic hepatitis stains with an elastin stain, whereas bridges in acute hepatitis do not contain elastin.[50] Severe necrotizing hepatitis is also characterized by a higher degree of periportal ductular reaction. The areas of surviving parenchyma reveal the changes of acute hepatitis described previously for classical lobular hepatitis but usually with more marked spotty necrosis and cholestasis.

Submassive hepatic necrosis. Progressive severe necrotizing hepatitis, which occurs in a minority of patients, may correspond clinically to fulminant hepatitis with acute liver failure and coma. In such patients, lytic confluent necrosis of the parenchyma typically involves the entire liver lobule (panlobular necrosis) and often affects several adjacent lobules (multilobular necrosis). Extensive confluent necrosis is usually distributed in a heterogeneous way throughout the liver organ, thus needle biopsies may not be representative.[49] In surviving patients, multilobular (or submassive) necrosis results in collapse and fibrous scarring of necrotic zones, alternating with nodular regeneration of surviving parenchymal territories.

Ductular reaction is prominent in multilobular necrosis and represents an attempt at regeneration by liver progenitor cells. The epithelial proliferation comprises not only bile ductular cells but also elements with a phenotype intermediate between that of cholangiocytes and hepatocytes—so-called transitional cells.[51] Some of the ductules may contain inspissated bilirubin-stained concrements in cases with severe necrosis or with sepsis[52]; this lesion should not be mistaken as a sign of biliary obstruction.

Severe necrotizing hepatitis may have causes other than infection by hepatitis viruses, such as autoimmune hepatitis, adverse drug reactions, toxic insults, and Wilson disease. As all or most of the parenchymal cells have disappeared due to necrosis by the time of histologic evaluation, there are few markers pointing to a particular etiology, thus it is often impossible to pinpoint the etiology on histologic grounds alone.

Causative viruses. It is usually not possible to histologically diagnose with certainty the etiology of acute viral hepatitis, since the main histopathologic traits are quite similar; correct diagnosis

typically requires serologic and/or molecular testing. Nevertheless, there are suggestive trends and patterns. One has to keep in mind, however, that the histopathologic picture may be confused by coinfection with more than one virus, or by the presence of another form of liver disease (such as fatty liver disease, for example).

Acute hepatitis A[53–56] may reveal a picture dominated by centrilobular bilirubinostasis with only minimal liver cell damage and inflammation; this may be mistaken for other causes of cholestasis (e.g., drug-induced cholestasis). Particularly in adults, HAV infection may cause cholestatic hepatitis, even occasionally showing bile duct damage.[57] The inflammatory changes often show a periportal predominance, with dense, plasma cell–rich portal infiltrates that may mimic autoimmune hepatitis.[58] Periportal parenchymal necrosis with interruptions of canals of Hering may contribute to the cholestatic features.[55] Fulminant hepatic failure is rare in HAV infection but has been described.[59] Fibrin ring granulomas have also been reported.[60–61] HAV may occasionally present with a prolonged and polyphasic clinical course characterized by two or more relapses with concomitant rise in transaminases.[62]

Acute hepatitis B. The histopathology is roughly similar to that of other forms of acute viral hepatitis,[58,63–65] with centrilobular predominance of liver cell damage and inflammation (see above). Lymphocytes may lie in close contact with hepatocytes (peripolesis) and even inside them (emperipolesis). In fully developed acute HBV, immunostains for hepatitis B surface antigen (HBsAg) and hepatitis B core antigen (HBcAg) are often negative; this correlates with loss of HBsAg serologically and may indicate early efficient elimination of viral antigens.[66] Whether or not a chronic course of disease can be predicted based on liver biopsy findings during the acute phase of HBV has caused controversy for years; a tentative conclusion is that no single lesion has predictive value in the early stage of infection. Ground-glass hepatocytes are not seen in the acute form, and their presence indicates chronicity. As in other parenterally transmitted hepatitides, such as hepatitis D and C, intravenous drug abuse may be recognized by the presence of birefringent spicules of talc in portal tracts.[67,68]

A particular clinicopathologic variant of HBV is so-called *fibrosing cholestatic hepatitis*, which may occur after liver transplantation and in other conditions associated with immune compromise (status post transplantation, HIV infection). It typically has a poor prognosis with a rapidly progressive course. The histopathology of this variant is characterized by a relatively mild portal infiltrate, periportal and pericellular fibrosis, hepatocyte ballooning, marked ductular reaction, prominent parenchymal and sometimes ductular bilirubinostasis, and very high viral load (strongly positive immunostains for HBcAg).[69,70]

Acute hepatitis C. Because acute hepatitis C is often asymptomatic, detection and diagnosis are usually difficult, and it is rarely seen on biopsy. An average of 26% of patients experience spontaneous clearance of the virus, primarily during the first 3 months.[71] The pathologic features of acute HCV are essentially those described in previous years for non-A, non-B hepatitis,[64,72,73] including hepatocyte swelling, apoptosis, cholestasis, and lobular lymphocytic infiltration. Bile duct damage and development of portal lymphoid aggregates and lymphoid follicles, the most characteristic features of hepatitis C in the chronic stage, may also occur in the acute phase.

Lymphocytic infiltration may be prominent in the sinusoids ("Indian file" appearance) in the absence of noticeable parenchymal damage, resembling EBV hepatitis. Steatosis is fairly common. Fulminant hepatitis with multilobular necrosis does occur but is rare in the Western world. Immunohistochemical demonstration of viral antigens with different antibodies has been repeatedly reported, but the overall results appeared to lack specificity. The same criticism applies to in situ hybridization (ISH) for HCV RNA.[74,75] As in viral

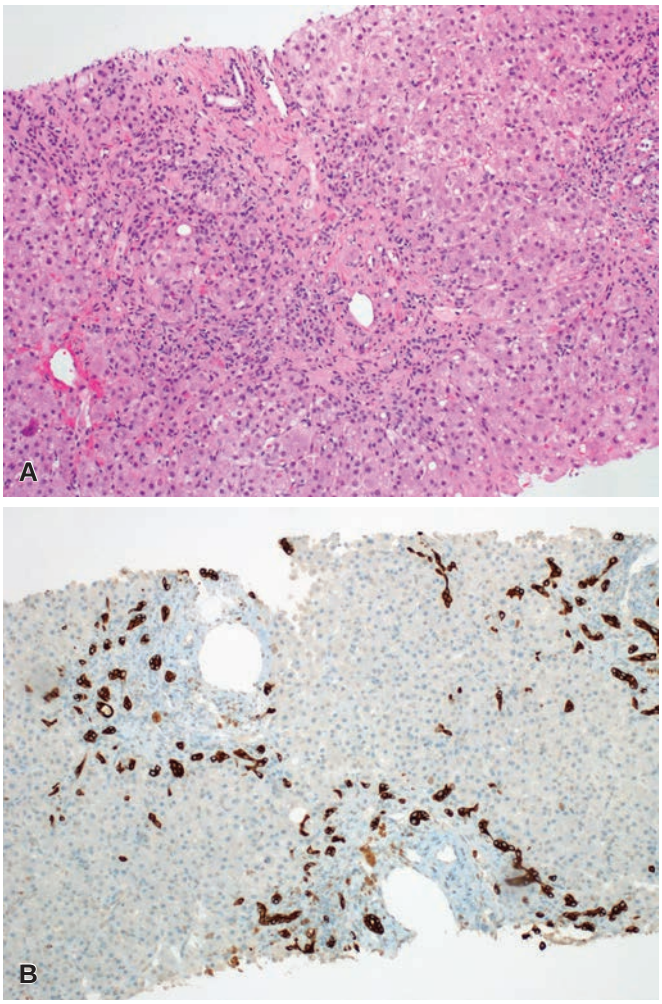

Figure 19.6 Fibrosing Cholestatic Hepatitis C. A, Fibrous expansion of portal areas with marked ductular reaction. There is mild hepatocyte ballooning and hepatocellular cholestasis. **B,** Cytokeratin 7 immunostain highlights the ductular reaction.

HBV, a severe, progressive variant of "fibrosing cholestatic hepatitis" may occur in immune deficient conditions (Fig. 19.6A and B).[76,77]

Acute hepatitis D can occur in the setting of acute co-infection with HBV or can be superimposed on chronic HBV.[78] The histologic picture of HDV hepatitis is similar to that of other forms of hepatitis, and although it tends to be more severe, it cannot be reliably distinguished histologically from hepatitis B or C.[79–81] In parts of South America and Africa, acute HDV infection has been associated with microvesicular change in hepatocytes[82]; this "spongiocytic change" or "morula cell degeneration" was attributed to accumulation of small lipid droplets in damaged hepatocytes.

Acute hepatitis E. Outbreaks of hepatitis E occur throughout the developing world, primarily transmitted by contaminated water. The epidemiology in industrialized countries is less well understood, although some cases appear to be zoonotic.[83,84] Hepatitis E typically causes self-limited acute infection. Histologically it is characterized by a cholestatic type of hepatitis, with mixed portal infiltrate, ductular reaction, prominent bilirubinostasis, cholestatic rosettes, and marked apoptosis, bearing some resemblance to acute HAV.[85]

Differential diagnosis. Acute viral hepatitis with marked cholestasis can be differentiated from obstructive forms of cholestasis by the lobular necroinflammatory lesions that are typical of acute viral

hepatitis. Drug-induced hepatitis may be indistinguishable histologically from viral hepatitis; hence it follows that drug-induced liver disease should always be kept in mind when facing a case of acute hepatitis that is of questionable etiology. Features suggestive of a drug-induced lesion include sharply delineated centrilobular necrosis, abundant eosinophils, and granulomas (particularly microgranulomas); however, the absence of these features does not exclude drug-associated hepatitis. Autoimmune hepatitis can have an acute onset, histologically similar to viral hepatitis, but typically autoimmune hepatitis has more fibrosis and a more plasma cell-rich infiltrate than that seen in most cases of acute viral hepatitis.

Differentiation of acute from chronic viral hepatitis is generally based on the predominance of portal and periportal changes and fibrosis in the latter, whereas lobular lesions prevail in acute hepatitis, and fibrosis is typically not increased. However, the distinction may be very difficult, if not impossible, in the absence of clinical and laboratory data.

Chronic Viral Hepatitis

History and classification. The introduction of needle aspiration biopsy of the liver[86] greatly contributed to the recognition of noncirrhotic forms of chronic inflammatory liver disease. In the 1960s, chronic hepatitis was presumed to be a sequel of viral hepatitis, although a causative agent had not been identified. Autoimmune hepatitis was considered to be the "classic" form of chronic active hepatitis at that time. Because of marked semantic confusion, a simple classification of chronic hepatitis, based on histology, was proposed by a group of hepatologists and pathologists in 1968.[87,88] Because immunosuppression was the standard treatment, reserved for the more "active" forms of the disease, the classification distinguished between a milder form (chronic persistent hepatitis [CPH]) with a low degree of necroinflammatory activity, and more severe variants (chronic aggressive or active hepatitis [CAH]) featuring higher degrees of necroinflammatory activity. This classification of chronic hepatitis became widely accepted and was used worldwide for nearly 40 years. Although it was emphasized that CPH and CAH were not to be considered distinct disease entities, but as variations in the degree of disease activity, this message was frequently, and with the passage of time, increasingly, ignored.

Remarkable progress has been achieved in the elucidation of the multiple etiologies of chronic hepatitis since 1968, particularly with the discoveries of HBV, HCV, and HDV.[89] A drug-induced form of chronic hepatitis was recognized in 1971[90] and is now established as a classic cause of the disease.[91] Chronic autoimmune hepatitis remained a diagnostic category, with gradual refinements in clinical and serologic diagnosis.[92] Wilson disease was also shown to resemble chronic hepatitis clinically and histologically in some cases[93,94]; the same appeared to apply to another metabolic disease, α1-AT deficiency.[95] Furthermore, piecemeal necrosis, a very important diagnostic criterion in CAH, but (incorrectly) thought by some to be pathognomonic of and synonymous with chronic hepatitis, was also observed in chronic biliary diseases such as PBC and primary sclerosing cholangitis (PSC).

Investigations into the natural course of disease in chronic HBV infection revealed successive phases of viral replication, elimination, and integration, associated successively with less, higher, and again decreasing degrees of necroinflammatory disease activity.[96,97] This implied the successive occurrence of CPH and CAH variants in individual patients over the course of their disease, confusing those who considered CPH and CAH to be distinct disease entities. This precipitated a change of view on chronic hepatitis.[98] Most importantly, the development of more efficient treatment for chronic viral hepatitis (interferons and antiviral agents) urgently necessitated a revision of chronic hepatitis classification.[99–102] In 1994, two proposals for a new classification of chronic hepatitis (both viral and other etiologies) were published.[103,104] Both are largely parallel, although the latter includes chronic biliary and metabolic diseases (which may mimic chronic hepatitis) under that heading. There appears to be general agreement to restrict the term "chronic hepatitis" to its original meaning: a clinical and pathologic syndrome with several causes, characterized by varying degrees of hepatocellular necrosis and inflammation. For lack of a better definition of chronicity, chronic hepatitis is still defined (as in 1968) as a continuing disease (indicated by elevated liver tests) without improvement for at least 6 months.[104]

In order to be comprehensive and clinically useful, these classifications consider: (1) the etiology; (2) the grade of disease activity; and (3) the stage of progression of the disease. The first question to be asked by the pathologist when classifying chronic hepatitis remains: "Is this chronic hepatitis, or another liver disease?" Several liver diseases may have clinical and histologic features resembling those of chronic hepatitis, as mentioned previously, and need to be considered in the differential diagnosis, but do not correspond to "chronic hepatitis" in its strictest sense. The second step concerns determination of the etiology, which cannot be based on histology alone and requires consideration of clinical and serologic data. Histopathologic study of the liver biopsy, however, may be useful in establishing, confirming, or refining an etiologic diagnosis. The next step corresponds to grading of disease activity, which is evaluated by clinical symptoms, by aminotransferase levels, and by histopathology of the liver biopsy. Histologically, the degree of disease activity is evaluated by considering the main components in the histopathologic picture: portal inflammation, interface hepatitis, lobular damage and inflammation, and confluent necrosis. Several systems can be utilized to express the degree of disease activity in the liver biopsy. In daily practice, an adequate report consists of an accurate estimate of the various lesions, described as minimal, mild, moderate, or severe. For specific purposes, such as comparison of pre- and post-treatment biopsy specimens and for evaluation of therapeutic trials, semiquantitative scoring systems may be indicated (see Grading and staging, later).

Staging of the disease is an attempt to place the patient's disease at a specific point in time along an assumed course or time of progression. The histologic evaluation of disease stage is based on the extent of fibrosis and the development of cirrhosis, which has significant prognostic and therapeutic implications. Connective tissue stains are essential for staging. As is the case for histologic grading, staging can also be expressed descriptively, which is an appropriate method for daily reporting of biopsies. Again, however, for specific purposes, semiquantitative scoring systems can be used (see later).

Histopathology. The basic lesions that compose the histopathologic picture of chronic hepatitis (viral and otherwise) include "spotty necrosis," portal inflammation, interface hepatitis, and fibrosis. Occasionally confluent necrosis may be seen and, if disease progresses, parenchymal regeneration and cirrhosis.[65] "Spotty necrosis" is an older term, loosely applied to apoptosis and genuine necrosis of single hepatocytes; this finding may also be seen in acute hepatitis (see earlier). A more appropriate morphologic term would be "focal necroinflammation," recognizable as a small cluster of mononuclear cells (lymphocytes, possibly with histiocytes) with or without an adjacent identifiable apoptotic body or bodies. Spotty necrosis in chronic hepatitis looks the same as in acute hepatitis. Confluent parenchymal necrosis of the lytic type, or dropout of contiguous groups of hepatocytes with collapse of the reticulin framework, occurs in more severe forms of chronic hepatitis, and often coincides with clinical episodes of disease exacerbation.[105] As in acute hepatitis, the extent of confluent necrosis may range from focal to zonal confluent necrosis to "bridging" confluent necrosis (Fig. 19.7), and then to

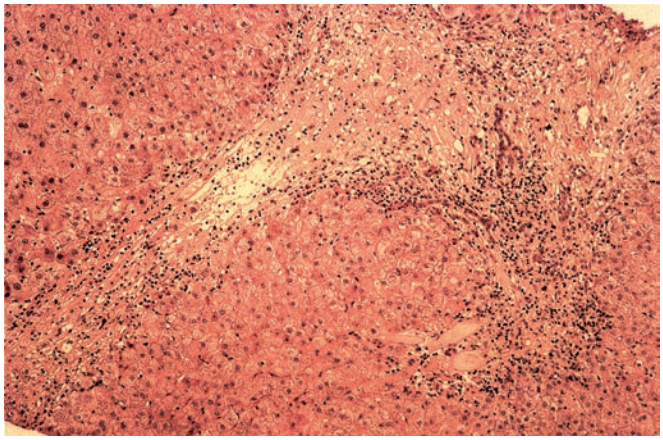

Figure 19.7 Bridging confluent lytic necrosis in severe chronic viral hepatitis B, connecting an inflamed portal tract with a centrilobular area *(lower left)*. The upper right part corresponds to an area of extensive lytic necrosis and postnecrotic collapse of the reticulin framework.

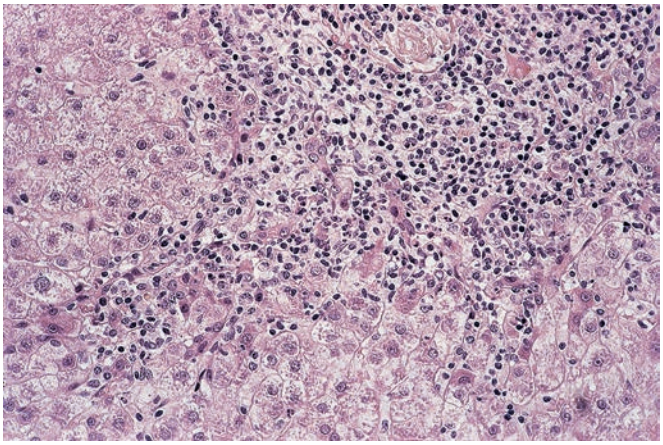

Figure 19.9 Marked interface hepatitis ("piecemeal necrosis") in chronic viral hepatitis B. Note the inflamed portal tract *(upper right)* with an irregular interface between the portal periphery and adjacent parenchyma.

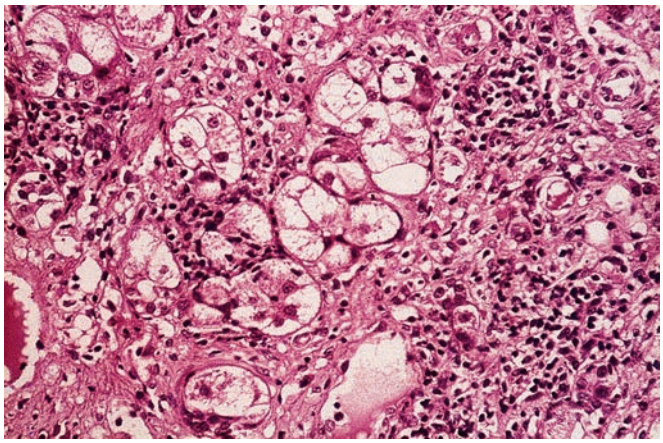

Figure 19.8 Severe Chronic Viral Hepatitis B. Several small islands of surviving hepatocytes, appearing swollen and pale, and sometimes arranged in tubular fashion ("hepatitic-type liver cell rosettes"), are present within an area of postnecrotic collapse and early fibrosis.

the more extensive panlobular and multilobular extent. Severe parenchymal necrosis is often accompanied by the development of small, glandlike clusters of surviving hepatocytes within the inflamed tissue (Fig. 19.8). These "hepatitic rosettes" are usually surrounded by connective tissue, and presumably represent attempts at regeneration from surviving hepatocytes in an unfavorable environment.

Portal inflammation in chronic hepatitis may be mild, moderate, or dense. It is predominantly composed of mononuclear cells, mainly lymphocytes, with variable numbers of plasma cells and histiocytes. Lymphoid aggregates and true lymphoid follicles may develop. Interface hepatitis was originally termed "piecemeal necrosis."[106] This term refers to the extension of the lymphocytic portal infiltrate beyond the limits of the portal tract, along with the death and "piecemeal" dropout of hepatocytes. Surviving hepatocytes are ultimately trapped within the inflammatory infiltrate, neoangiogenesis, and fibrosis, leading to an irregular portal/periportal interface (Fig. 19.9). Interface hepatitis is thus a better term, particularly as the mode of liver cell death is apoptosis and not necrosis,[107–109] and the lesion is located at the interface between mesenchyme (portal tract or septum) and parenchyma. Interface hepatitis may be mild (one or a few foci around the portal perimeter without noticeable fibrous extension), or severe (with wedge-shaped extension of the necroinflammatory lesion and obvious fibrosis deep into the lobule).

Interface hepatitis is responsible for the enlargement of portal tracts with irregular outlines in chronic hepatitis. The distinction should be made between true "lymphocytic piecemeal necrosis" as described previously, and "biliary piecemeal necrosis," which occurs in chronic biliary disease. In the latter variety, the irregular outline of the enlarging portal tract is not due to "invading" lymphocytes but to ductular reaction with associated neutrophil infiltration and cholate stasis of periportal hepatocytes[110] (see later).

Fibrosis may develop with ongoing inflammation.[111] Septal fibrosis may occur as periportal, portal–portal and portal–central septa. Periportal and portal–portal septa presumably result from interface hepatitis, whereas portal–central septa seem to be sequels of portal–central (bridging) confluent necrosis. Ongoing necroinflammation, associated with progressive fibrosis and parenchymal regeneration, eventually leads to cirrhosis. Parenchymal regeneration results from multiplication of mature hepatocytes, and to a variable extent proliferation of hepatic progenitor cells.[112] In the cirrhotic stage, the necroinflammatory changes may have subsided (inactive cirrhosis) or may continue unabated (active cirrhosis).

Grading and staging. Several systems for semiquantitative scoring have been proposed for evaluation of liver biopsies in chronic hepatitis (Tables 19.2 and 19.3).[113-120] Originally, the most widely used was the Histological Activity Index (the HAI or Knodell index) published in 1981.[120] A simple scoring system was proposed by Scheuer[102] and found to be easily applicable and reproducible.[117] A "modified HAI" was published as an extension of the original Knodell system, with a series of modifications attempting to overcome some of the problems that had emerged in its use.[118] This modified HAI has been validated for intra- and interobserver variability.[121] For the evaluation of chronic hepatitis C, the system proposed by the French METAVIR Cooperative Study Group[115,122,123] has been applied to very large numbers of biopsies, especially for staging purposes.[124]

Several papers have commented on the different scoring systems, with discussions of their advantages and disadvantages.[125–127] One review considers all scoring systems for chronic hepatitis as well as for other liver diseases.[128] The conclusion is that each of the systems currently in use has strengths and weaknesses, and all suffer from the problems that apply to any form of histologic scoring of liver biopsies in chronic hepatitis, including lack of scientific validation, observer variation, sample variation, and etiologic differences.[126] In

this era of evidence-based medicine,[129] numerical scoring of liver biopsies continues to have a place, and the pathologist engaged in semiquantitative scoring of liver biopsies has plenty of published advice available in the literature.[123,125,126,130] Numerical staging and grading is particularly useful for comparing pre- and post-treatment biopsies for a single patient; as a research method for studying the course of a disease; and for use in clinical therapeutic trials.[103]

The need for estimating the degree of liver fibrosis in chronic viral hepatitis C in order to support treatment decisions has stimulated the search for noninvasive markers of liver fibrosis[131] because of sampling variability in needle biopsies.[29,132] A noninvasive technique that is being used with increasing frequency is transient elastography.[11,133,134] Noninvasive methods have even been proposed as substitutes for liver biopsy; however, biopsy and noninvasive alternatives are not mutually exclusive options, and a clear understanding of the significance and limitations of each tool is required.[135] The strengths and weaknesses of liver biopsy and of noninvasive markers were reviewed and their respective roles in management of patients with chronic hepatitis C discussed in a paper by P. Bedossa.[136]

Chronic hepatitis B. During some stages of chronic infection with HBV, overload of some cellular compartments with viral antigens may be so extensive as to be recognizable by light microscopy, creating helpful diagnostic markers of disease. Two such markers are "ground-glass hepatocytes" and "sanded nuclei." *"Ground-glass hepatocytes"*[137] are parenchymal liver cells with a pale, homogeneous, more finely granular appearance in part or all of their cytoplasm; the "ground-glass" area is often separated from the cell membrane by a clear halo, which is an artifact, albeit a helpful one (Fig. 19.10A and B). The ground glass appearance is due to marked hypertrophy of the smooth endoplasmic reticulum, which displaces the cytoplasmic organelles to the periphery of the cell, and which contains excess filamentous structures of HBsAg in its cisternae.[138,139] This ground-glass appearance of hepatocytes is, however, not entirely specific, and also occurs in other liver diseases, including drug-induced hypertrophy of the smooth endoplasmic reticulum (which predominates in centrilobular hepatocytes)[140,141]; fibrinogen storage disease, in which fibrinogen inclusions in parenchymal cells in patients with hypofibrinogenemia resemble ground-glass hepatocytes[142]; Lafora disease (myoclonus epilepsy)[143]; glycogenosis type IV (amylopectinosis or Andersen disease)[144]; and abnormal glycogen metabolism in polypharmacotherapy or following liver transplantation.[145,146] Ground-glass hepatocytes from several causes may, in fact, coexist in the same biopsy.[147]

Table 19.2 Modified histological activity index—staging: architectural changes, fibrosis and cirrhosis

CHANGE	SCORE
No fibrosis	0
Fibrous expansion of some portal areas, with or without short fibrous septa	1
Fibrous expansion of most portal areas, with or without short fibrous septa	2
Fibrous expansion of most portal areas with occasional portal–portal (P-P) bridging	3
Fibrous expansion of portal areas with marked bridging (portal–portal (P-P) as well as portal–central (P-C))	4
Marked bridging (P-P and/or P-C) with occasional nodules (incomplete cirrhosis)	5
Cirrhosis, probable or definite	6
Maximum possible score in staging	**6**

Additional features which should be noted but not scored:
Intralobular fibrosis, perivenular ("chicken-wire" fibrosis).
Phlebosclerosis of terminal hepatic venules (central veins).
Data (adapted to new terminologies) from Ishak K, Baptista A, Bianchi L, et al. Histological grading and staging of chronic hepatitis. *J Hepatol*. 1995;22(6):696–699; Westin J, Lagging LM, Wejstal R, Norkrans G, Dhillon AP. Interobserver study of liver histopathology using the Ishak score in patients with chronic hepatitis C virus infection. *Liver*. 1999;19(3):183–187, with permission from authors and publisher.

Table 19.3 Batts–Ludwig grading and staging of chronic hepatitis

GRADE		STAGE	
0	No activity Portal inflammation only No interface activity No lobular activity	0	No fibrosis
1	Minimal activity Portal inflammation Minimal interface activity Occasional lobular apoptotic hepatocytes	1	Portal fibrosis (fibrous portal expansion)
2	Mild activity Interface activity involving some or all portal tracts Mild lobular activity with little hepatocyte damage	2	Periportal fibrosis (portal expansion plus periportal irregularity; rare portal/portal septa)
3	Moderate activity Interface activity involving all portal tracts Moderate lobular activity with obvious hepatocyte damage	3	Septal fibrosis (bridging fibrous septa with architectural distortion; no obvious nodularity)
4	Severe activity ± bridging necrosis Prominent diffuse hepatocyte damage	4	Cirrhosis

Batts KP, Ludwig J. Chronic hepatitis. An update on terminology and reporting. *Am J Surg Pathol*. 1995;19(12):1409–1417.

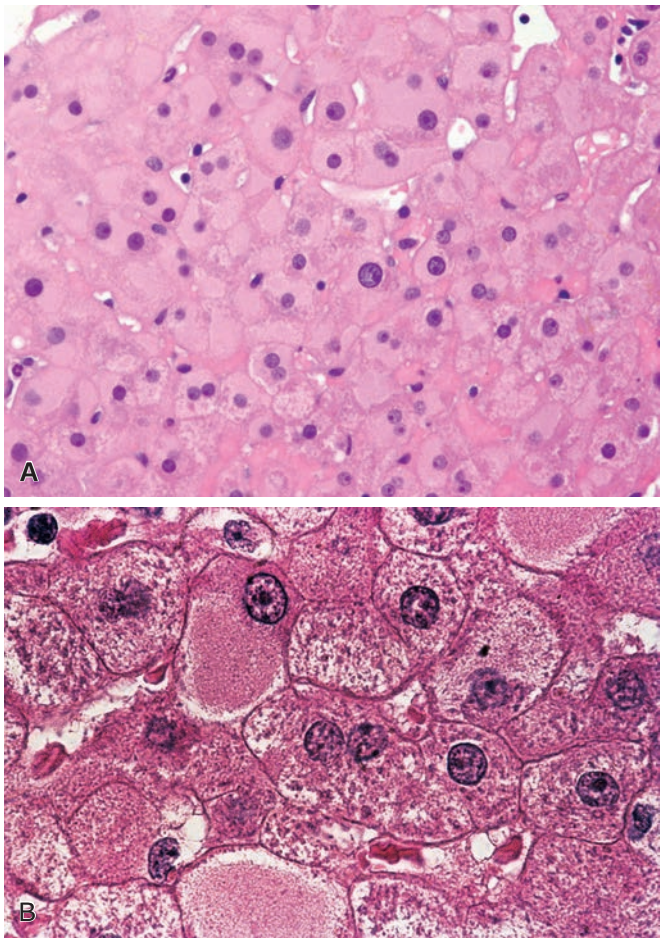

Figure 19.10 **A,** Ground-glass hepatocytes, characterized by eosinophilic, homogeneous and paler cytoplasm than surrounding normal hepatocytes. **B,** Note the artifactual cleft between the "ground-glass" cytoplasm and the hepatocellular cell membrane.

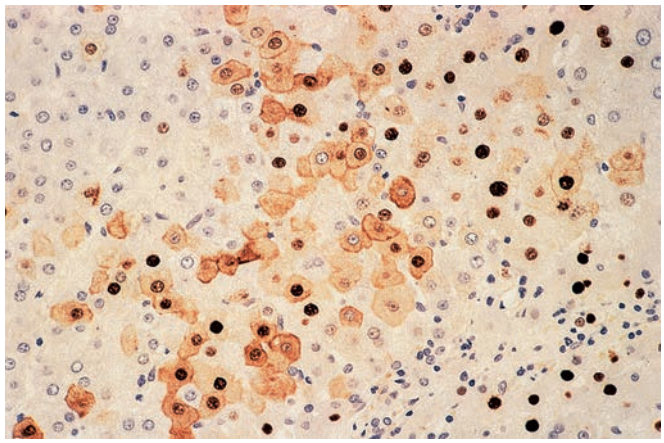

Figure 19.11 **Chronic Viral Hepatitis B, Viral Replicative Phase.** Hepatitis B core antigen is localized in hepatocellular nuclei and, in several hepatocytes, also in the cytoplasm and cell membrane. (Immunoperoxidase stain for HBcAg.)

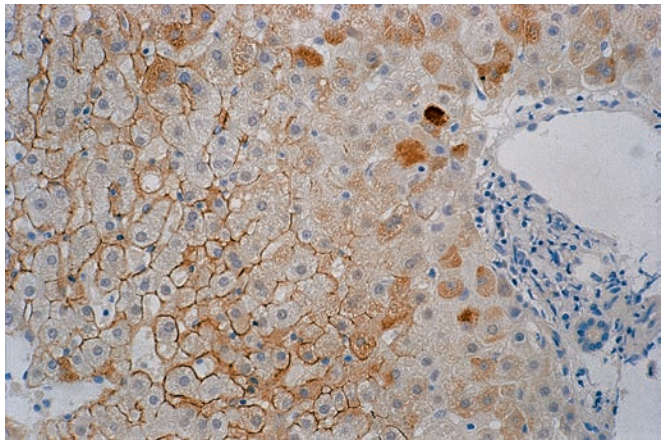

Figure 19.12 **Chronic Viral Hepatitis B, Viral Replicative Phase.** Hepatitis B surface antigen is localized in variable quantities in the cytoplasm and in the cell membrane of several hepatocytes. Note there is only a mild lymphocytic infiltrate in the portal tract and lobule. (Immunoperoxidase stain for HBsAg.)

Special stains such as Shikata orcein stain,[148] Victoria blue,[149] and aldehyde fuchsin[150] confirm the HBsAg relationship of the ground-glass appearance, and even more convincing is immunohistochemical staining with specific anti-HBsAg antibody. *Sanded nuclei*[151] are hepatocellular nuclei with a finely granular, pale eosinophilic appearance in the larger central part of the nucleus, due to massive accumulation of HBcAg. They are not easily recognized, and specific immunohistochemistry is far more helpful in identifying HBcAg.

The clinical, histopathologic, and immunohistochemical findings in chronic HBV have been summarized in several overviews[152,153]; they vary over the course of the disease depending on viral load, quality of immune response, and possibly associated comorbidity.[154] Under most circumstances, HBV is not cytopathic, and it is the immune response of the host that determines the outcome of infection. The most complete immune response is associated with the most severe liver injury and the greatest likelihood of viral clearance, whereas an immature immune response leads to chronic hepatitis. The natural history of chronic HBV has been viewed in four stages by some authors,[155–158] and three stages by other, earlier workers.[157,159,160]

The first stage is characterized by high viral loads and immune tolerance. In acute infection, this corresponds to the incubation period, but with neonatal chronic infection, this period often lasts for decades. During the early viral replication and immune tolerance phase in chronic hepatitis, liver biopsy reveals only minimal hepatocellular damage and inflammation. Immunohistochemically, this viral replicative phase is characterized by nuclear and cytoplasmic localization of HBcAg[161] and HBeAg,[162,163] which also localize in the liver cell membranes (Fig. 19.11). HBsAg is found in the cytoplasm of some scattered hepatocytes and in the membrane of numerous parenchymal cells, revealing a honeycomb-like pattern (Fig. 19.12).[164,165] The second stage, or viral elimination phase, is characterized by immune clearance of hepatocytes, histologically correlating to hepatocyte necrosis. Liver biopsy reveals necroinflammatory lesions, including confluent lytic necrosis of variable extent in more severe cases.[166,167] Immunostaining reveals nuclear, cytoplasmic, and membranous staining for HBcAg; HBsAg appears as weak positivity in the cytoplasm of some hepatocytes, associated with a membranous staining pattern.[96,165] HBeAg staining reveals nuclear and cytoplasmic localization.[168] In patients with chronic infection, stage 2 may persist for 10–20 years and lead to cirrhosis and its complications.

When the immune response decreases the number of infected cells, a third stage featuring low viral replication begins, referred to as the "inactive carrier" state. In this stage, HBeAg is no longer detectable and antibody to HBeAg becomes detectable. A marked

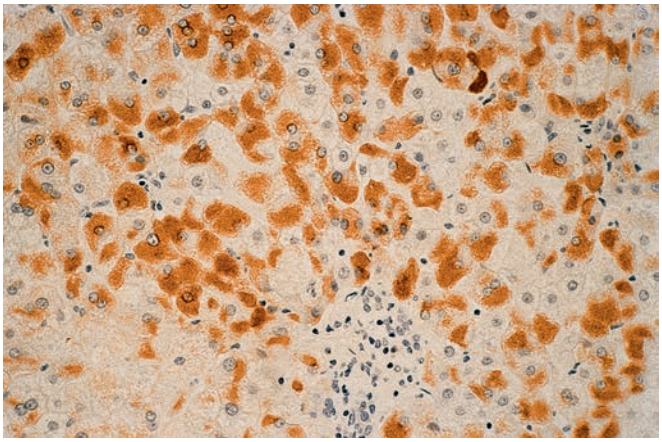

Figure 19.13 Chronic Viral Hepatitis B, Viral Nonreplicative (Integration) Phase. Hepatitis B surface antigen is localized in considerable quantity in the cytoplasm of a contiguous group ("clone") of hepatocytes. Note the relatively mild lymphocytic infiltrate in the portal tract and lobule. The more intensely staining cells appear as "ground-glass hepatocytes" on H&E staining. (Immunoperoxidase stain for HBsAg.)

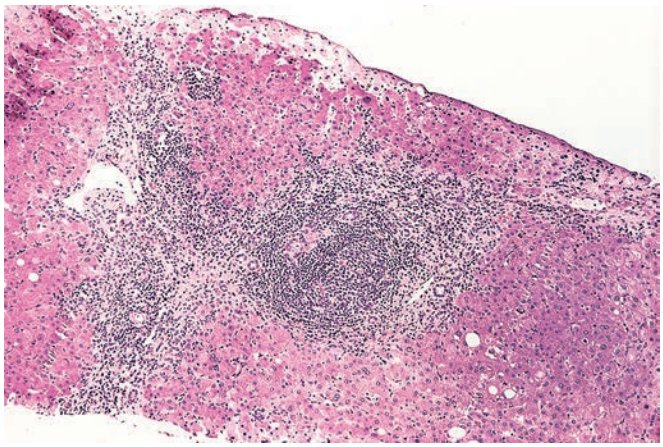

Figure 19.14 Chronic Viral Hepatitis C. Low-power view of two portal tracts connected by bridging fibrosis, with dense mononuclear cell infiltration and a prominent lymphoid aggregate. The portal–parenchymal interface is irregular due to interface hepatitis. Minimal steatosis is also present.

decrease in HBV viral load is observed, and although many patients remain positive for HBV DNA, it is only detectable by polymerase chain reaction (PCR) and aminotransferase levels become normal. Active replication of HBV has ceased, but HBsAg is continuously produced by liver cells that contain integrated HBV genome[169] and the patient becomes an HBsAg carrier (viral integration phase). HBsAg accumulates in clusters of hepatocytes, appearing as ground-glass cells or staining in the periphery of parenchymal cells (Fig. 19.13). HBcAg is usually absent. Mild inflammation may persist for some time after loss of HBsAg in the serum,[170] but substantial necroinflammation at this stage should raise the possibility of superinfection with another virus. The annual negativation (i.e., spontaneous return to seronegativity) rate for HBV surface antigen is approximately 1%.[171]

Some patients continue to have high levels of serum HBV DNA and aminotransferases[172] (stage 4, referred to as HBeAg-negative chronic hepatitis), due to precore mutant HBV variants characterized by deficient synthesis of the immune tolerogen HBeAg.[173,174] Immunostaining then reveals cytoplasmic HBcAg.[175]

If the patient's immune system succeeds in eliminating the virus, the fibrogenesis/fibrolysis balance may change in the direction of the latter, resulting in regression of fibrosis to considerable extent due to the action of metalloproteinases from hepatic stellate cells and hepatocytes.[176] During stage 4, some patients can reactivate their HBV when given chemotherapy or immunosuppressive treatment. Patients with active HBV replication are at increased risk for cirrhosis, hepatic decompensation, and hepatocellular carcinoma compared to inactive carriers. Available evidence indicates that control of HBV replication with antiviral agents decreases the incidence of these complications.

Cirrhosis developing in the viral integration phase of HBV will progress slowly over 20–30 years, eventually with decompensation and other complications. Initially micronodular, the cirrhosis becomes more macronodular,[96] and hepatocellular carcinoma may develop as a further consequence (see also Chapter 20). Even in patients without cirrhosis in the integration phase (so-called healthy HBsAg carriers), the risk for developing hepatocellular carcinoma is higher than in noncarriers.

Chronic hepatitis B + D. Chronic hepatitis D is in decline in Italy, but not in the rest of Europe,[177] and it remains a major health problem in the many underdeveloped areas of the world where HBV is uncontrolled.[178] Chronic hepatitis D tends to be more severe, with higher activity and risk of progression, than chronic HBV alone.[160,179] Rapid progression to cirrhosis is the fate in a minority of patients; more commonly, the disease evolution is slow and insidious, evolving into cirrhosis over many years.[180,181] HDV selectively suppresses HBcAg and HBeAg, but not HBsAg,[182] although it depends on low-grade HBV multiplication and release.[183] Immunohistochemically, HDAg is found mainly in liver cell nuclei,[184] which may show a sanded appearance[185] due to excess HDAg, and in the cytoplasm and membranes of hepatocytes.[186] Double immunostaining for HBV and HDV antigens often shows separate expression of HDAg versus HBsAg or HBcAg, but coexpression does occur.[187]

Chronic hepatitis C. HCV infection is characterized by a silent onset in most infected individuals, a high rate of viral persistence, and the potential for development of chronic liver disease, ranging from chronic hepatitis to cirrhosis and occasionally to hepatocellular carcinoma.[188] The sheer magnitude of the infected population will result in a large number with severe, life-threatening disease, thus rendering chronic HCV infection, with 170 million chronically infected people, a staggering worldwide problem.[189,190]

Histologically, chronic HCV is often mild initially, with little parenchymal damage other than focal inflammation and hepatocellular apoptosis.[190,192] A carrier state with normal liver biopsy has been reported,[193] and conversely abnormal liver histology has been recorded in HCV RNA-positive patients with normal serum alanine aminotransferase.[194,195] The histopathology of chronic HCV, although not pathognomonic, is highly characteristic, and several reviews are available.[192,196–198]

The portal infiltrate is rich in lymphocytes, often forming lymphoid aggregates (Fig. 19.14) and even follicles with prominent germinal centers.[199–203] Lymphoid follicles are not specific for chronic HCV, however, and are also found in HBV,[199,201] autoimmune hepatitis,[199] and PBC. Nevertheless, they are particularly prominent in hepatitis C. Lesions of interlobular bile ducts are not uncommon (Fig. 19.15), with frequencies ranging from 15%–91% of biopsies.[198,199] This broad variation likely indicates a poor consensus on the definition of "bile duct lesion." The most frequently observed bile duct lesions consist of infiltration of the bile duct epithelium by lymphocytes, with variable degrees of cytoplasmic vacuolization, nuclear stratification,

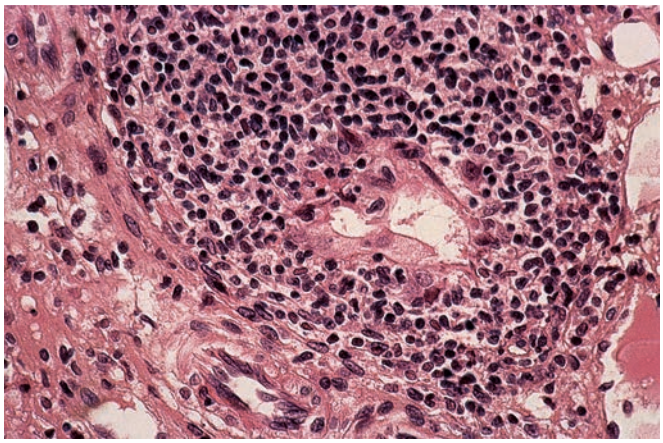

Figure 19.15 Chronic Viral Hepatitis C. Detail of a portal tract showing a lymphoid follicle containing an irregular and damaged bile duct near its center. Note the biliary epithelial irregularity and intramural lymphocytic infiltrate.

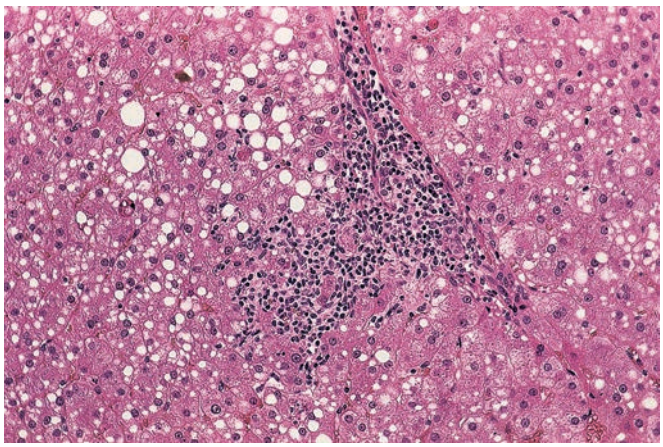

Figure 19.16 Chronic viral hepatitis C showing moderate to marked steatosis in addition to portal inflammation and mild interface hepatitis.

and crowding of the biliary ductal epithelial cells. The most pronounced bile duct lesion, originally described before HCV was even discovered,[204] is characterized by swelling and stratification of bile duct lining cells and infiltration by lymphocytes, yet preservation of the basement membrane of the bile duct.[205] This type of bile duct lesion must be differentiated from that occurring in PBC, which tends to be more destructive, but on occasion the distinction may be difficult.

The lobule in chronic HCV may contain a striking number of acidophil bodies. Oxyphil granular hepatocytes (or oncocytes, cells rich in mitochondria) have been reported in more than a third of biopsies.[206] There is typically patchy lymphocytic infiltration with spotty necrosis; the lymphocytic infiltrate may form rows along the sinusoids (so-called Indian file) resembling hepatic mononucleosis. Mild to moderate steatosis, usually of the macrovesicular type, has been described in frequencies ranging from 40% to 80% (Fig. 19.16), depending on the features of the population studied in terms of alcohol consumption and prevalence of other risk factors for fatty liver including obesity and diabetes. Steatosis is more frequent and more severe in patients with genotype 3.[207] HCV interferes with lipid metabolism via at least three ways, which are not mutually exclusive: impaired secretion of lipid, impaired degradation, and increased synthesis.[208] Steatosis favors viral replication, since the lipid droplet represents an organelle that functions as an assembly platform for the different viral components (HCV core, functional replication complexes, viral RNA, envelope proteins).[209,210] Steatosis is believed secondary to direct viral effect in patients with genotype 3, but is likely secondary to insulin resistance and/or alcohol use in patients infected with other genotypes.[207,211,212] Steatosis and steatohepatitis in chronic hepatitis C are also associated with more inflammatory activity and faster fibrosis progression.[211,213] Insulin resistance appears to be a specific feature of chronic HCV (much less so than in chronic HBV) and is particularly associated with genotypes 1 and 4 and high HCV RNA levels.[214] Thus, it appears that chronic HCV, nonalcoholic steatohepatitis (NASH) and NAFLD may have mutual reinforcing effects: HCV genotype 3 infection may potentiate NAFLD/NASH by providing the "first hit" (steatosis)[215] and by inducing insulin resistance,[216–218] whereas on the other hand, NAFLD/NASH may potentiate HCV replication by providing fat droplets as scaffold for viral assembly.[209,210] Bedossa et al. also found that in patients with NASH and chronic HCV of genotype 3 there was no associated metabolic syndrome, suggesting that NASH may complicate steatosis in chronic HCV irrespective of the etiology of the steatosis.[215]

A number of other histologic alterations in chronic HCV infection have been described. Periportal hepatocytes may contain coarse clumps of eosinophilic cytoplasm, resembling Mallory–Denk bodies (MDBs).[201,219] Venous lesions resembling the endotheliitis observed in acute cellular liver allograft rejection have also been reported and may further confuse the already difficult distinction between those two conditions.[220] Increased amounts of hepatic iron have been reported in patients with chronic hepatitis C, even in the absence of a history of blood transfusion or alcohol abuse,[221] and iron overload has been shown to impair response to interferon therapy.[180,222,223] Increased hepatic iron in the context of chronic hepatitis C, however, may also be due to associated hemochromatosis, porphyria cutanea tarda (PCT), alcohol abuse, oral iron intake, and previous treatment with ribavirin.[224,225]

Another confusing lesion is the occurrence of epithelioid granulomas in a small minority (5%) of cases,[226,227] sometimes as a transient feature.[228] The development of granulomas has been correlated with interferon-α therapy[229] and has been associated with both favorable[230] and adverse responses to therapy.[231] In the post-transplant setting, granulomas have been observed in association with pegylated interferon-treated recurrent viral hepatitis C.[232] Of course, other causes of granulomas must be excluded before the etiology of the granulomas is attributed to hepatitis C. The presence of epithelioid granulomas may also render the distinction of chronic HCV from PBC more difficult, particularly if lymphocytic cholangitis and mild epithelial damage is present (see earlier).[233] A rare case of fibrin-ring granuloma has also been reported.[234]

Syncytial giant cell hepatitis is a rare histologic finding among HIV-infected patients with chronic hepatitis C; specific treatment with pegylated interferon and ribavirin can lead to its histologic resolution.[235]

The natural history of chronic hepatitis C is one of progressive fibrosis, even in cases with mild disease.[236] Adverse risk factors for progression include young age at infection, infection acquired via intravenous drug abuse, and HCV genotype 3.[237] It has also been noted that in HCV-infected children, inflammation, fibrosis, and steatosis were milder than in treatment-naive HCV-infected adults, but there were still several cases with bridging fibrosis or cirrhosis. The positive correlation of inflammation with duration of infection and fibrosis, as well as the correlation between obesity/metabolic syndrome and fibrosis, suggests that children with chronic hepatitis C will be at risk for progressive liver disease as they age and possibly acquire other comorbid risk factors.[238,239]

A strong correlation has also been noted between portal fibrosis and periportal ductular reaction (hepatic progenitor cell expansion), exacerbated by steatosis and associated with impaired hepatocyte replication, suggesting that an altered regeneration pathway may drive ductular reaction, which in turn triggers fibrosis at the portal tract interface.[240] Portal and periductal macrophages expressing matrix metalloproteinase-9 have also been associated with increased ductular reaction and progression of fibrosis.[241] Greater inflammatory activity has also been associated with disease progression.[242]

As noted previously, demonstration of viral antigens by immunohistochemistry has been reported in multiple studies, but reproducible and clinically useful results in paraffin-embedded material have been lacking. The same criticism regarding specificity applies to ISH for HCV RNA.[74,75]

Combined pathology in chronic viral hepatitis. Combined infection with HBV and HCV increases the severity of the histologic liver lesions.[243,244] Triple infection with HBV, HDV, and HCV results in severe disease in the acute superinfection stage; however, the overall course is relatively benign, slowly progressive, and usually dominated by HCV.[244,245] HIV infection may result in reactivation of HBV, with higher levels of HBV replication and more immunocytochemically demonstrable HBcAg and HBeAg, but typically without an increase in necroinflammation.[246] Necroinflammatory activity is also higher in HIV-positive patients with chronic hepatitis C, and cirrhosis is more frequent.[247] The combination of steatosis, steatohepatitis, HIV, and HCV infection is associated with a more advanced degree of fibrosis as well.[248] Infection with multiple hepatitis viruses is quite common and may be difficult to histologically diagnose without knowledge of pertinent clinical and laboratory data.

Foci of hepatocellular hemosiderosis (iron-rich foci) have been described in both chronic HCV and HBV, highlighting the potential for irregular iron storage in chronic viral liver disease and potential confusion with genetic hemochromatosis.[249] Heterozygosity for hereditary hemochromatosis[250] and hepatic iron overload[251] in the context of chronic viral hepatitis may also influence progression toward liver fibrosis.

Some patients with chronic HCV have autoimmune features, including a greater degree of inflammatory activity (often with prominent plasma cells), positive autoimmune serological markers, higher levels of immunoglobulins, and an association with HLA-DR3. These patients have a greater frequency of cirrhosis.[252]

Chronic infection with HBV and HCV can certainly occur in patients with many other unrelated liver diseases, such as PBC, PSC, and alcohol-related liver injury.

Hepatitis Caused by Nonhepatotropic Viruses

Several viruses not belonging to the group of specific "hepatitis" viruses discussed earlier may also induce liver inflammation, as either a primary disease or, more often, as part of systemic infection.

CMV infection. CMV is an important cause of opportunistic hepatitis in immunodeficient patients, particularly transplant patients[253] and HIV-positive patients, and it also causes neonatal hepatitis.[254] CMV inclusions may occur in any type of hepatic cell, including hepatocytes, bile duct cells, endothelial cells, and portal fibroblasts[255]; nuclear inclusions may have the typical "owl's eye" morphology, whereas cytoplasmic inclusions are often basophilic and granular (Fig. 19.17A and B). CMV immunohistochemistry may be very helpful in identifying inclusions, particularly when inclusions are not well formed.[256,257] Neutrophilic microabscesses or aggregation of neutrophils in sinusoids[256] is a useful diagnostic feature that should prompt a diligent search for viral inclusions or antigens. In immunocompetent patients a picture resembling EBV-associated hepatitis may occur (see later).[258,259]

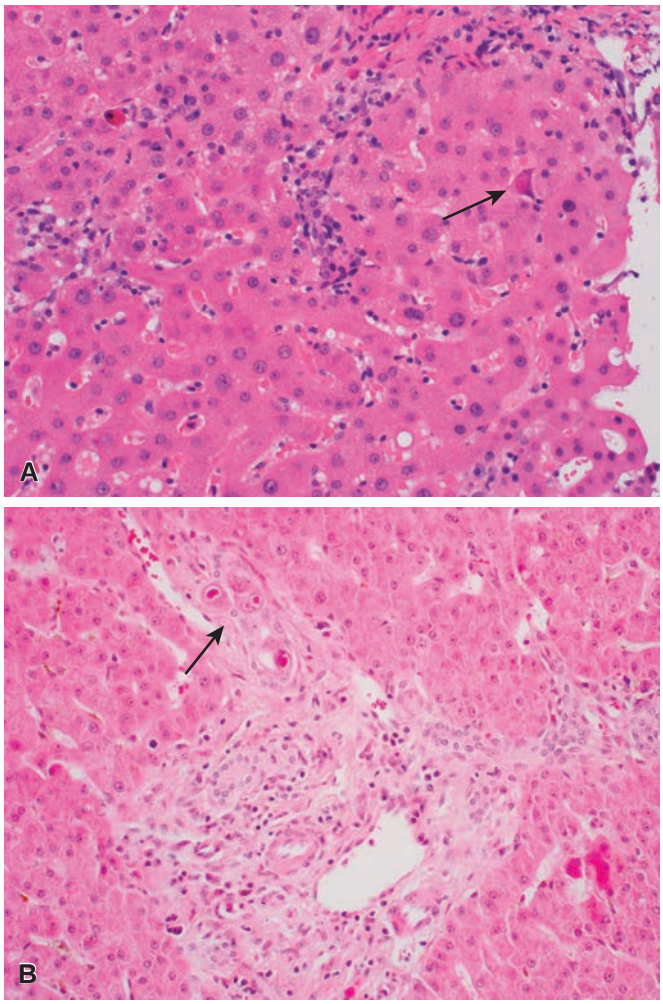

Figure 19.17 **A,** A poorly formed basophilic, granular CMV inclusion is present within an endothelial cell *(arrow)* in the sinusoids. There is surrounding patchy inflammation and scattered apoptotic hepatocytes. **B,** Several "owl's-eye" inclusions are seen within biliary epithelial cells *(arrow)*.

Infectious mononucleosis. EBV infection deserves consideration in the differential diagnosis in all age groups. The liver is affected in over 90% of patients with infectious mononucleosis, although this is often subclinical. Symptomatic liver involvement develops in only 5%–10% of patients. ISH is a useful ancillary tool in confirming the diagnosis of EBV hepatitis in equivocal cases; however, EBER-positive cells can be sparse and easily overlooked.[260] Histologically, dense mononuclear infiltrates, often containing large atypical lymphocytes, are found in portal tracts and sinusoids. In the latter, they spread in a distinctive single-file, "string-of-beads" or "Indian-file" array (Fig. 19.18). Kupffer cells are hypertrophic, and epithelioid and fibrin-ring granulomas are occasionally found. Small foci of hepatocellular necrosis and acidophil bodies may be seen, but generally the parenchymal damage is not in proportion with the density of the infiltrate.[261] Cholestatic hepatitis may also be encountered, albeit rarely.[262] Occasionally EBV-associated hepatitis must be distinguished from hepatic involvement by leukemia or lymphoma.

Acquired immunodeficiency syndrome (AIDS). A wide spectrum of liver abnormalities may be observed in AIDS and HIV infection.[263,264] Although Kupffer cells can serve as a reservoir for HIV,[265] the liver is not a primary target of HIV infection, and most of the

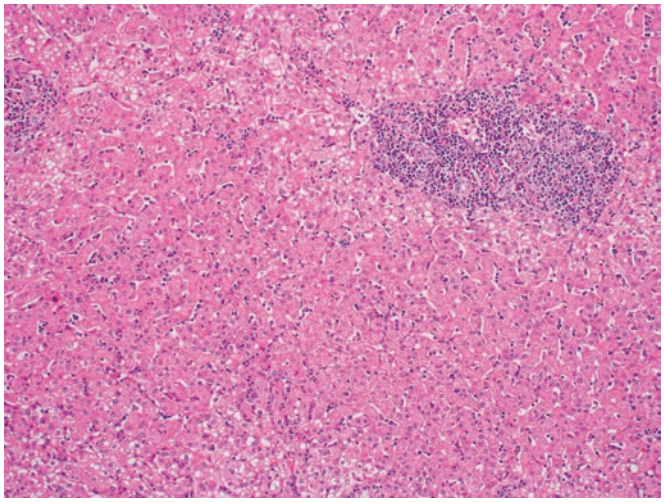

Figure 19.18 EBV hepatitis showing dense lymphocytic portal infiltrates, and a sinusoidal lymphocytosis in a "string of beads" configuration.

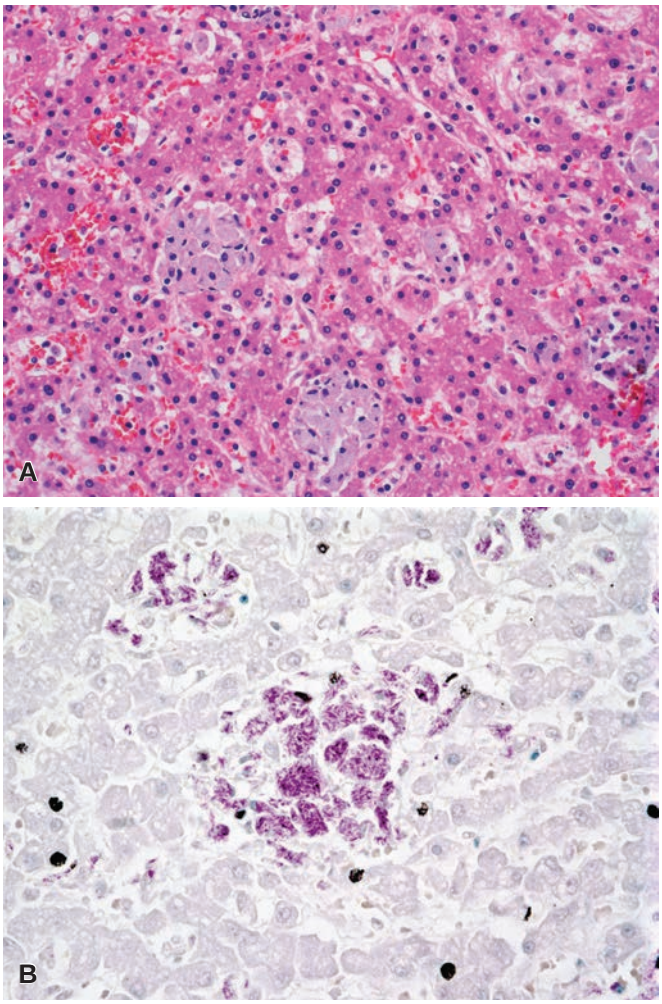

Figure 19.19 Mycobacterium Avium-Intracellulare Complex in the Liver. A, A foamy macrophage infiltrate with virtually no other attendant inflammation. **B,** Ziehl–Neelsen stain highlights organisms within macrophages.

hepatic manifestations reflect opportunistic infections, lymphoma, and Kaposi sarcoma.[266] The patterns of opportunistic infection vary significantly in different parts of the world, depending on the local prevalence of infection, as well as on the availability of treatment and thus the survival of HIV-infected patients. It is also important to recognize that the pathologist may encounter an opportunistic infection well outside its usual geographic distribution, due to travel or immigration. Hepatic involvement by CMV is quite common (see earlier)[266]; other opportunistic infections involving the liver and bile ducts in AIDS patients include *Mycobacterium avium intracellulare*, *Mycobacterium tuberculosis*, *Cryptococcus* species, *Candida* species, *Histoplasma*, and malaria.[266,267] A frequently encountered hepatic lesion is the occurrence of multiple granulomas containing *Mycobacterium avium-intracellulare*, visualized to better advantage by PAS–diastase, Ziehl–Neelsen, or Gomori methenamine silver stains.[268] The mycobacteria are packed in the foamy histiocytes that constitute the granulomas and often show a striated appearance (Fig. 19.19A and B). Small numbers or even single mycobacteria may also be present in scattered Kupffer cells. *Pneumocystis carinii* may cause multiple foci of eosinophilic foamy exudate, similar to that seen in pulmonary infection.[269] *Bartonella henselae*-associated bacillary angiomatosis may also be seen.[270]

Nonspecific histologic changes can also be found in the livers of patients with HIV, including mild mononuclear portal inflammation, scattered lobular lymphocytes and apoptotic bodies, fibrosis, ductular reaction, steatosis, and Kupffer cell siderosis. Lipid-laden perisinusoidal hepatic stellate cells have also been reported in AIDS.[271]

AIDS-associated cholangiopathy is an important biliary disorder caused by opportunistic infection of the biliary epithelium, which resembles sclerosing cholangitis.[272] *Microsporidia*[273] and *Cryptosporidia*[274] are two such biliary pathogens. CMV-associated ductopenia has also been reported as a cause of vanishing bile duct syndrome in an AIDS patient with signs and symptoms of obstructive jaundice and cholestasis.[275]

A number of noninfectious lesions occur in this patient population as well. ***Hepatoportal sclerosis (HPS)***, characterized by varying degrees of portal fibrosis, sclerosis of portal vein branches and dilation of sinusoidal spaces (see also later), has been identified as a cause of noncirrhotic portal hypertension in patients with HIV.[276] ***Highly active antiretroviral therapy (HAART)*** is also a cause of hepatotoxicity and may cause fatty liver disease as well as other patterns of liver injury.[277,278] From a neoplastic standpoint, ***non-Hodgkin lymphomas***, especially of the Burkitt and immunoblastic types, may involve the liver, occurring as portal infiltrates or as nodular masses.[279] Hepatic involvement by ***Kaposi sarcoma*** also occurs.[280]

Drug-Induced and Toxic Liver Injury

The frequent occurrence of adverse drug reactions and toxic damage to the liver is not surprising, as this organ is the main site of biotransformation of endo- and xenobiotics. The incidence is high, with an estimated incidence of up to 14 cases per 100,000 inhabitants in France[281]; drug-induced liver injury (DILI) is also the leading cause of acute liver failure in the United States.[282]

Recognition of DILI is challenging for several reasons. It can mimic virtually any other type of liver disease, and clinical signs of a hypersensitivity reaction may not occur in all cases. DILI can occur with drugs from all classes,[282,283] and the same drug may cause different patterns of liver damage in different patients[91]; for example, mitochondrial dysfunction, a major mechanism of liver injury, may cause fulminant hepatitis, micro- and macrovesicular steatosis, or steatohepatitis.[284] It is often impossible to pinpoint the causative agent

in patients on multiple drug therapy, which usually is the case in elderly patients, and a patient's drug history is often far from reliable. DILI may also be potentiated by the concomitant administration of other pharmacologic agents. Furthermore, hepatotoxicity may not yet have been reported for the drug in question, even when it has been on the market for a long time. Besides medicinal drugs, one also has to consider hepatotoxicity from herbs and dietary supplements.[285,286]

The pathologist should be aware of the types of lesion most likely to be induced by drugs, and how to try to differentiate these from features less likely to be caused by drugs. Although it is useful to be aware of specific sources of information such as books[287–290] and comprehensive reviews on this subject,[282,291–295] because of the growing diversity of drugs, current information is often more accessible on PubMed and other internet sources.

A distinction has been made between predictable (or intrinsic, or drug-dependent) toxicity effects on the one hand, and unpredictable (or hypersensitive, or idiosyncratic, or host-dependent) reactions on the other hand.[282] Predictable reactions are due to the intrinsic hepatotoxicity of the molecule, are typically dose dependent and occur in all exposed individuals, occur with a relatively short (though variable) latent period, and are reproducible in experimental animals. Acetaminophen overdose is an example of this type of toxicity. Of far more concern is the more frequent, unpredictable type of DILI. It occurs in only a small fraction of the population exposed, there is no clear dose relationship, the latent period may be quite long (weeks or months), and it is not reproducible in experimental animals. Exceptional sensitivity to a particular drug may be based on genetically determined differences in drug metabolism ("metabolic idiosyncrasy") or to immunologically based reactions to neoantigens formed by interaction between a drug metabolite and some tissue or cell membrane component ("immunoallergic idiosyncrasy").[282,296,297] The latter mechanism is believed to be the most frequent type of idiosyncratic DILI.[298]

Conclusive proof that a particular drug or combination of drugs is responsible for DILI in an individual case is often impossible to obtain; rechallenge would be an obvious effective test but is clearly unethical. Inadvertent rechallenge may provide strong circumstantial evidence, even many years after a first episode.[299]

Drug-induced adverse reactions in the liver may cause structural and functional changes in all cellular components of the organ, which then coalesce to produce various patterns of injury. Individual histologic features, as well as patterns of drug-induced injury, are briefly summarized next.

Histologic Features

Hepatocytes. In view of the parenchymal heterogeneity in the liver lobule, with predominance of microsomal biotransformation enzymes in the centrilobular zone, it is not surprising that drug-induced effects may show a zonal distribution or predominance.

A ground-glass appearance of hepatocytes in the centrilobular area, due to hypertrophy of the smooth endoplasmic reticulum (similar to that seen in chronic HBV infection, see earlier) with associated enzyme induction, can be caused by a number of drugs such as phenobarbital, rifampin, dioxin, and cyanamide.[141,300]

Lipofuscinosis, or increased accumulation of lipofuscin (wear and tear pigment) in centrilobular hepatocytes is induced by prolonged intake of some drugs such as phenacetin, aminopyrine (aminophenazone), chlorpromazine, Cascara sagrada,[301] and by anticonvulsant therapy.[140] It must be differentiated from the pigment accumulation in Dubin–Johnson syndrome.

Steatosis (see also later) is a frequently occurring effect of xenobiotics. Macrovesicular steatosis can be seen with drugs such as tamoxifen, estrogens, methotrexate, and ethanol.[302] Microvesicular steatosis may be associated with clinical manifestations of severe liver injury, even in the absence of overt hepatocellular necrosis. It is apparently due to inhibition of mitochondrial fatty acid β-oxidation and mitochondrial dysfunction.[284,303] It has been associated with intravenous tetracycline, amiodarone, valproate, and acetyl salicylate in children (Reye syndrome).[302] Microvesicular steatosis has also been reported with several antiviral nucleoside analogs (e.g., fialuridine).[304] A similar alteration is observed in mitochondriopathies[305] and in acute fatty liver of pregnancy (AFLP).[306]

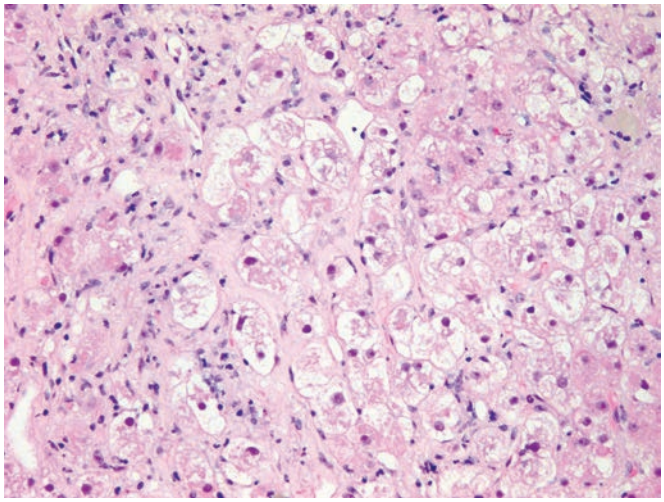

Figure 19.20 Foamy cytoplasmic vacuoles, ballooning, and numerous Mallory–Denk bodies characterize amiodarone toxicity.

Phospholipidosis is characterized by foamy cytoplasmic vacuoles and enlargement of hepatocytes and Kupffer cells due to phospholipid accumulation. Electron microscopy reveals lamellated myeloid bodies (fingerprints) in enlarged lysosomes. Associated drugs include gentamycin, perhexiline maleate, fluoxetine, and amiodarone (Fig. 19.20)[307]; drug toxicity from the latter may even lead to cirrhosis.[308]

Reactive hepatocellular changes. Binucleated hepatocytes increase in number with sulindac, and multinucleated hepatocytes have been reported in several instances of acute and chronic drug-induced hepatitis (e.g., clometacin).[309]

Hepatocellular death: apoptosis and necrosis. Both modes of hepatocellular death may be induced by toxic drug metabolites and immunoallergic hypersensitivity reactions. Hepatocellular necrosis may be variable in appearance (coagulative or lytic), in topography (centrilobular or periportal), and in extent (focal, zonal, bridging, lobular, or multilobular). With larger doses, many hepatotoxic drugs (e.g., chloroform, acetaminophen) and hepatic poisons (e.g., the mushroom *Amanita phalloides*, carbon tetrachloride) produce centrilobular necrosis, often associated with ballooning and steatosis in adjacent non-necrotic parenchymal cells, and with minimal or no inflammation.[283] Other chemicals (e.g., ferrous sulfate, the yellow form of inorganic phosphorus) may cause periportal necrosis. Many of these agents cause fatal massive necrosis when administered in sufficient doses; in smaller doses, apoptosis of liver cells occurs, which, with time, may result in fibrosis and cirrhosis.[310]

Kupffer cells are involved in storage of foreign materials and in granuloma development. Materials stored in Kupffer cells include talc and cellulose in drug addicts, silica and anthracotic pigment in coal miners, polyvinyl pyrrolidone and hydroxyethyl starch[311] from infusion of plasma expanders, and silicone from prosthetic heart valve devices.

Numerous drugs—amongst them sulfonamides, methyldopa, and phenylbutazone—have been incriminated in the production of *hepatic granulomas*.[312] A special variant, the *fibrin ring granuloma*, can be seen in hypersensitivity to allopurinol.[313,314] *Mineral oil granulomas* are composed of lipophages and occur in portal tracts and near central veins. They have been attributed to the absorption and deposition of mineral oil taken as a medicinal agent (laxative) or ingested as a food additive or food contaminant from food packaging.[315] Gold has been identified in lipophages and granulomas in patients who received gold therapy for rheumatoid arthritis.[316]

Vascular changes. *Periportal sinusoidal dilation* has been related to oral contraceptive use.[317] *Peliosis hepatis* (see also later) has been associated with the administration of anabolic–androgenic steroids, contraceptive steroids, and azathioprine.[318] *Sinusoidal obstruction syndrome* (SOS; formerly known as *veno-occlusive disease)*,[317] characterized by nonthrombotic narrowing of central vein lumina by loose connective tissue, is associated with pyrrolizidine alkaloids, radiation, conditioning for bone marrow transplantation, and chemotherapeutic agents, (e.g., irinotecan and oxaliplatin).[319–321] *Thrombosis of hepatic veins* (Budd–Chiari syndrome [BCS]) and of portal vein branches is a rare complication of contraceptive steroids. *Phlebosclerosis of portal vein branches (HPS)* has been associated with long-term use of inorganic arsenicals (Fowler solution), Thorotrast, vinyl chloride, vitamin A, and methotrexate.[317] *Arteritis* due to drug hypersensitivity may affect intrahepatic branches of the hepatic artery, resulting in multifocal hemorrhagic necrosis and exceptionally rupture of the liver.[317] *Angiosarcoma* has been associated with inorganic arsenicals, Thorotrast, anabolic–androgenic steroids, cyclophosphamide, oral contraceptives, vinyl chloride, and radium therapy.[317,322]

Hepatic stellate cell (Ito cell) hyperplasia, corresponding to an increased number of hepatic stellate cells (Fig. 19.21), has been associated with a number of drugs including hypervitaminosis A,[323] niacin,[324] and in patients undergoing methotrexate therapy, although to less extent than once thought.[325] Hepatic stellate cell hyperplasia may lead to increased fibrosis.[326]

Cholestatic reactions are the most frequent side effects of drugs overall. Simple *drug-induced cholestasis* is histologically characterized by bland bilirubinostasis without accompanying inflammation (Fig. 19.22). Such "simple" or "pure" cholestasis is seen with many drugs, the prototypes being anabolic and contraceptive steroids.[327,328]

Bile duct damage and ductopenia may be due to the effects of many drugs.[295,329,330] Because of the ductopenia, cholestasis of this type is usually prolonged, and may last for months and even years.[331] The mechanism may be direct toxicity to bile duct cells or immunoallergic injury.[297] Ductopenia has been reported in association with a large number of drugs, including chlorpromazine, haloperidol, ajmaline, glycyrrhizin, and several antibiotics.[329]

Histologic Patterns of Injury

Drug-induced acute hepatitis typically features hepatocellular damage and apoptosis/necrosis (variable in degree) with varying degrees of portal and lobular inflammation (Fig. 19.23A and B). Reactive hepatocellular changes and prominent Kupffer cells are also frequently seen, and cholestasis may be present as well.[295] Eosinophils may or may not be prominent in the inflammatory infiltrate. Fibrosis is absent. Numerous drugs of diverse classes can cause this reaction; classic examples include isoniazid (a tuberculostatic agent), ibuprofen, halothane (an anesthetic), phenytoin, and sulfonamides.[295] The histopathology is virtually indistinguishable from that of other forms of acute hepatitis, including acute viral hepatitis.

Drug-induced chronic hepatitis occurs in a minority (5%–10%) of patients.[295,332] The histologic features can mimic several other types of chronic liver disease, including autoimmune hepatitis (e.g., minocycline and nitrofurantoin) and chronic viral hepatitis (phenytoin).[295,333,334] Serologically, the presence of autoantibodies in cases of drug-induced autoimmune hepatitis may cause further confusion with de novo autoimmune hepatitis.[335] The diagnosis relies on a high degree of suspicion of a possible drug etiology in the absence of viral markers, and close cooperation with clinician and patient. Recognition of this pattern of DILI is important, as withdrawal of the drug is often essential to treatment and prognosis.

Drug-induced steatohepatitis is rarely caused directly by the offending pharmaceutical; more often, the drug exacerbates or initiates steatohepatitis in the context of other risk factors for fatty liver disease.[295] Associated drugs include amiodarone,[336] antiretroviral therapy,[337,338] irinotecan, and parenteral nutrition (total parenteral nutrition [TPN]; Fig. 19.24A and B).[339]

Drug-induced cholestatic hepatitis combines features of acute drug-induced hepatitis with cholestasis and variably present ductular reaction.[294,295] Differentiation from large bile duct obstruction can

be very difficult. Portal edema and neutrophilic cholangitis favor large bile duct obstruction but are not always present, and correlation with medication history is often essential. Although most cholestatic drug reactions resolve when the offending agent is discontinued, some cases become chronic, with associated interlobular bile duct damage and occasionally ductopenia (Fig. 19.25A–C). A number of antibiotics as well as antifungals and ACE-inhibitors have been associated with cholestatic drug reactions.[295,297,340]

Drug-induced granulomatous hepatitis typically features noncaseating granulomas that can be present in portal tracts, lobules, or both (Fig. 19.26A). Cholestasis and an eosinophilic infiltrate may be helpful clues indicating DILI in addition to the granulomas (Fig. 19.26B). As mentioned previously, fibrin ring granulomas may also represent DILI.[295,312]

TPN-associated liver disease is worthy of additional mention given the frequency of occurrence, particularly in the pediatric population.[341] TPN-associated liver disease develops in 40%–60% of infants and 15%–40% of adults who require long-term TPN. The spectrum of injury includes hepatic steatosis, cholestasis (which occurs more frequently in children than adults), cholelithiasis, and hepatic fibrosis. Progression to biliary cirrhosis and the development of portal hypertension and liver failure occur in a minority but are also more common in infants and neonates than in adults.[342] In infants, histologic features include canalicular cholestasis, cholestatic liver cell rosettes, and ductular cholestasis (Fig. 19.27). Giant hepatocytes and ductular reaction may also occur. The portal tracts variably contain a mixed inflammatory infiltrate, and with longer duration of TPN, periportal fibrosis develops.[342,343] In adults, TPN may lead to steatosis, cholestasis, and periportal fibrosis as well, with periportal copper accumulation (sometimes marked) that is independent of the total duration of TPN.[344] In infants requiring TPN, the liver histology may mimic other cholestatic diseases of infancy, including neonatal hepatitis and biliary atresia (BA).

Diagnostic hints for the histopathologist. One should always maintain a high degree of suspicion for a drug-induced etiology, especially in elderly patients. A histologic picture resembling viral hepatitis, but with a disproportionately severe degree of parenchymal necrosis in relation to the patient's clinical condition, or with associated steatosis, granulomas, an eosinophilic infiltrate, or associated bile duct damage, should arouse suspicion for drug-induced disease.[283] The same applies for centrilobular necrosis sharply delineated from non-necrotic parenchyma, especially if associated with steatosis, with only mild or minimal inflammation, and with numerous ceroid macrophages. Parenchymal giant cell hepatitis in adult patients, and

the association of hepatocyte necrosis with SOS, should also act as an alert for a drug-induced etiology.[297] The final conclusion concerning the diagnosis of drug-induced and toxic liver damage is that it can mimic a wide variety of other liver diseases and thus requires a sustained high degree of suspicion and alertness on the part of both the clinician and the pathologist. An impressive example is the detective story of the Epping jaundice, caused by chemically contaminated daily bread.[345]

Steatosis and Steatohepatitis

Steatosis

Steatosis (fatty liver, fatty change) corresponds to accumulation of triglycerides in the cytoplasm of hepatocytes. It is a frequent finding and represents a manifestation of reversible cell injury.[346,347] Steatosis is a nonspecific lesion induced by a variety of causes. The degree of lipid accumulation is variable, ranging from occasional fat droplets to diffuse deposition involving most parenchymal cells. Histologically, in routinely fixed tissue, steatosis is represented by cytoplasmic vacuoles left behind when lipid is dissolved during processing. Very small droplet steatosis may be difficult to recognize, and thus histochemical staining may be helpful. Lipid can be demonstrated in frozen sections using oil red O or Sudan black, or in tissue that has been postfixed in osmium tetroxide.[348] The clinical presentation of steatosis can include hepatomegaly and elevated levels of serum aminotransferases, alkaline phosphatase, and/or γ-glutamyl transferase (γ-GT).

For a long time, fat droplets in the cytoplasm were considered inert deposits. However, lipid droplets are now regarded as dynamic organelles with neutral lipids as the core, surrounded by a monolayer of amphipathic lipids (phospholipids and cholesterol) and specific proteins (perilipin/ADRP/TIP47 [PAT] proteins and proteins involved in the turnover of lipids and in the formation and trafficking of the droplets). Lipid droplets are formed at microsomal membranes as primordial droplets with a diameter of 0.1–0.4 micron and increase in size by fusion.[349] In mammals, the PAT family of lipid droplet proteins includes perilipin, adipose differentiation–related protein (ADRP), tail-interacting protein of 47 kDa (TIP47), S3–12, and OXPAT. Positioned at the lipid droplet surface, PAT proteins manage access of other proteins (lipases) to the lipid esters within the lipid droplet core and can interact with cellular machinery important for lipid droplet biogenesis. Thus, rather than inert cytoplasmic inclusions, lipid droplets are dynamic organelles that are critical for management of cellular lipid stores.[350,351] The pathogenesis of steatosis is complex, and alterations at many points of the complicated pathway of lipid metabolism can lead to accumulation of neutral fat within hepatocytes. The reader is referred to reviews on this topic.[352–354]

Patterns and distribution. Two morphologic patterns are recognized: macrovesicular and microvesicular steatosis. Both may occur together to some extent in the same biopsy specimen. *Macrovesicular steatosis* (large droplet fatty change, Fig. 19.28) is the most common pattern, in which a single large vacuole distends the hepatocyte and displaces the nucleus to one side. Uncomplicated macrovesicular steatosis used to be regarded as a benign and potentially fully reversible lesion, but this notion has been challenged.[355] Its zonal distribution is variable. It is most often centrilobular but may extend into the mid-zonal areas and eventually the steatosis may become panlobular. Steatosis in periportal zones is more commonly seen in cachexia and protein–energy malnutrition (kwashiorkor), AIDS, after TPN administration, with phosphorus poisoning, and in steroid therapy. There are exceptions to the rule, however, and it is not possible to define the etiology solely on the pattern of lipid distribution in the individual case; identification of the cause requires close clinicopathologic correlation.

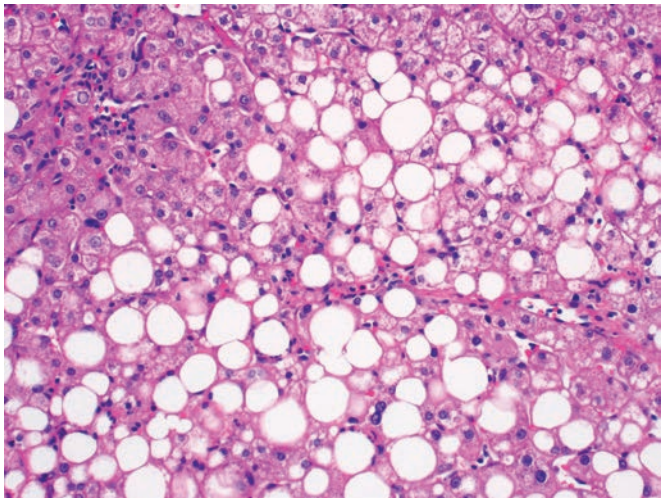

Figure 19.28 Macrovesicular steatosis featuring large droplets of fat.

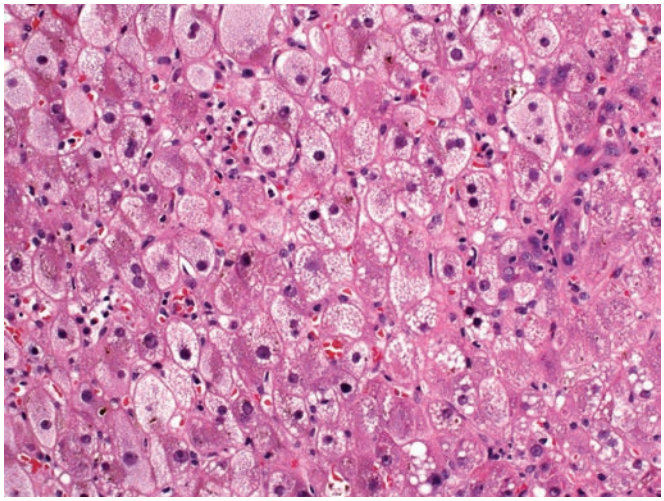

Figure 19.29 **Accumulation of Tiny Lipid Droplets in Microvesicular Steatosis.**

The pathologist should provide information on severity by indicating the approximate amount of parenchyma involved (mild: less than one-third; moderate: one-third to two-thirds; severe: more than two-thirds).[356] Further useful information for the clinician is the finding of a mixed pattern of macro- and microvesicular steatosis because this may be of prognostic importance in relation to alcoholic liver disease.[355] Of note, foci of steatosis may mimic metastatic liver disease radiographically.[357]

Microvesicular steatosis (Fig. 19.29) is often more difficult to recognize, and its demonstration may require histochemistry. Hepatocytes contain many tiny droplets of fat that may even be difficult to identify as such.[347] It is generally a serious lesion associated with impairment of β-oxidation of lipids and frequently accompanied by disturbed liver function and coma.[306] The causes are multiple. The first to be recognized, more than half a century ago, was *AFLP* (see later). *Reye syndrome* (see also earlier) occurs principally, but not exclusively, in young children; it presents clinically with an initial acute, mild viral illness, followed by vomiting, lethargy, and coma, resulting in death in about one-third of patients. The steatosis

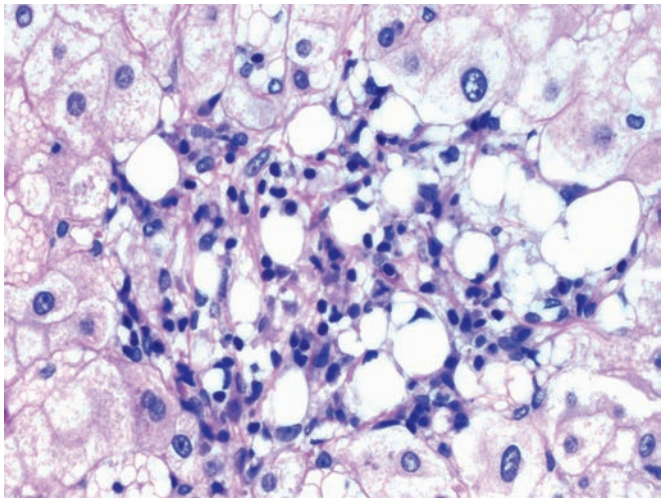

Figure 19.30 Lipogranuloma featuring adipocytes mixed with lymphocytes and macrophages. (Courtesy Dr. Joe Misdraji.)

is usually panlobular, with smaller droplets in centrilobular areas and somewhat larger fat vacuoles in periportal regions. There may be necrosis of periportal hepatocytes. A number of Reye syndrome cases may be attributable to salicylate use.[358] Many patients once thought to have Reye syndrome have been found subsequently to have defects in fatty acid oxidation, a form of *primary mitochondrial hepatopathy*.[359–361] A number of inborn errors of mitochondrial fatty acid β-oxidation and inherited urea cycle disorders have been found to cause microvesicular steatosis.[305,346] Conditions associated with microvesicular steatosis are potentially life threatening, with impairment of liver function and effects on other tissues as well. In the event that the patient survives, there are no long-term effects on the liver.

A number of therapeutic drugs have also been associated with the development of microvesicular steatosis (see earlier). Other causes include alcohol, fulminant hepatitis D in the Amazon basin,[82] and multiple hornet stings.[362]

Lipogranuloma (or fat granuloma) represents a focal response to rupture of lipid-laden hepatocytes. It contains macrophages, occasional lymphocytes, eosinophils, and sometimes giant cells (Fig. 19.30), in addition to adipocytes. Serial sections may be required to identify a central fat globule and to differentiate the lesion from other forms of granuloma.[363] They can be abundant, especially in fatty liver disease and hepatitis C. Lipogranulomas may lead to focal fibrosis without great clinical significance.[364]

Grading and Staging of Steatohepatitis

The understanding of hepatic steatosis has progressed considerably in recent years. Several studies have challenged previous assertions that macrovesicular steatosis is entirely benign,[355] and indicate that fatty liver of either alcoholic or non-alcoholic etiologies can coincide with or lead to necroinflammation and fibrosis. The mere presence of oxidizable fat within the liver appears to be enough to trigger lipid peroxidation in animal studies.[365] Nevertheless, many patients with steatosis never progress to necroinflammation or fibrosis.[355] These observations have led to the "two-hit" hypothesis, which proposes that in addition to steatosis (the first "hit"), the development of steatohepatitis requires the presence of some other factor(s) (second "hit").[366] It is likely that multiple factors together result in accumulation of fat in the liver and cause tissue injury, including insulin resistance, oxidative stress, mitochondrial dysfunction,[367] bacterial (+ endo) toxins, tumor necrosis factor alpha (TNF-α), interleukin (IL)-β, IL-6, low adiponectin levels, high leptin, high resistin, genetic predisposition, and of course factors that are still unknown.[368]

The two most common types of steatohepatitis in the world, by far, are alcoholic steatohepatitis (ASH) and NASH.[347] The pathogenesis and progression of hepatic disease appears to be driven by similar mechanisms in both conditions, although with superimposed toxicities of alcohol and its metabolite acetaldehyde in ASH, in part explaining why a greater proportion of patients with ASH develop cirrhosis and liver-related mortality.[369]

Alcoholic Steatohepatitis

In its early stages, ASH affects predominantly the centrilobular zone and includes a constellation of changes that need not all be present in any individual case. The most essential features are: (1) liver cell injury reflected in ballooning of hepatocytes with or without MDBs and liver cell death by necrosis and/or apoptosis[370]; (2) inflammatory infiltrates composed predominantly, though not exclusively, of neutrophils; and (3) pericellular fibrosis (so-called chicken-wire fibrosis), sometimes accompanied by perivenular fibrosis and phlebosclerosis. The severity of the changes and the extent of lobular involvement may vary considerably and do not necessarily correlate directly with clinical and biochemical data. There have been numerous reviews of the histopathology of ASH over the years, in which it has also been referred to as acute alcoholic hepatitis, acute hepatitis of the alcoholic type, alcoholic steatonecrosis, and fatty liver hepatitis.[371–374]

Ballooning degeneration (Fig. 19.31A and B) is considered a hallmark of steatohepatitis, but enlarged hepatocytes may also be observed in a variety of other acute and chronic liver diseases. It has been reported that keratin 8/18 immunostaining is drastically reduced or lost in the cytoplasm of ballooned hepatocytes in alcoholic and NASH, chronic cholestatic conditions, ischemia/reperfusion injury, and in ballooned hepatocytes in chronic hepatitis C cases with concurrent steatohepatitis. In contrast, substantial decrease or loss of keratin 8/18 immunostaining is not noted in cases of acute hepatitis, giant cell hepatitis, chronic HBV, or autoimmune hepatitis. Therefore, keratin 8/18 immunostaining may serve as an objective marker of a specific type of ballooning degeneration of hepatocytes.[375] Ballooned hepatocytes may contain so-called Mallory bodies (recently renamed "Mallory–Denk bodies"),[376] which are homogeneous, eosinophilic, perinuclear inclusions of variable size and shape (Fig. 19.31C). MDBs are protein aggregates consisting of ubiquitinated K8/K18, chaperones, and sequestosome 1/p62 (p62) as their major constituents. The constant presence of p62 in MDBs suggests that binding of p62 to abnormal keratins may allow hepatocytes to dispose potentially harmful proteins in a biologically inert manner.[377] Genetic contributions help explain why some patients develop MDBs, whereas others are less likely to do so.[378] The pathobiology of these intriguing cell inclusions has been periodically reviewed.[379,380] In florid cases, MDBs are easily discernible in routinely stained sections. In mild disease, they may be small and difficult to identify. Immunostaining of keratins or ubiquitin is helpful. Neutrophil granulocytes often surround and even invade hepatocytes containing MDBs (so-called satellitosis). Macrophages, and lymphocytes may also be found, and cholestasis is variably present.

Steatosis is frequently a feature, although not always, and is usually macrovesicular. As mentioned, a mixed macro- and microvesicular pattern carries a worse prognosis (Fig. 19.32).[355] Still worse is an almost panlobular, predominantly microvesicular steatosis with canalicular bilirubinostasis (so-called alcoholic foamy degeneration).[381] Megamitochondria appear as eosinophilic, PAS–diastase-negative, round, oval, or cigar-shaped inclusions of variable size.

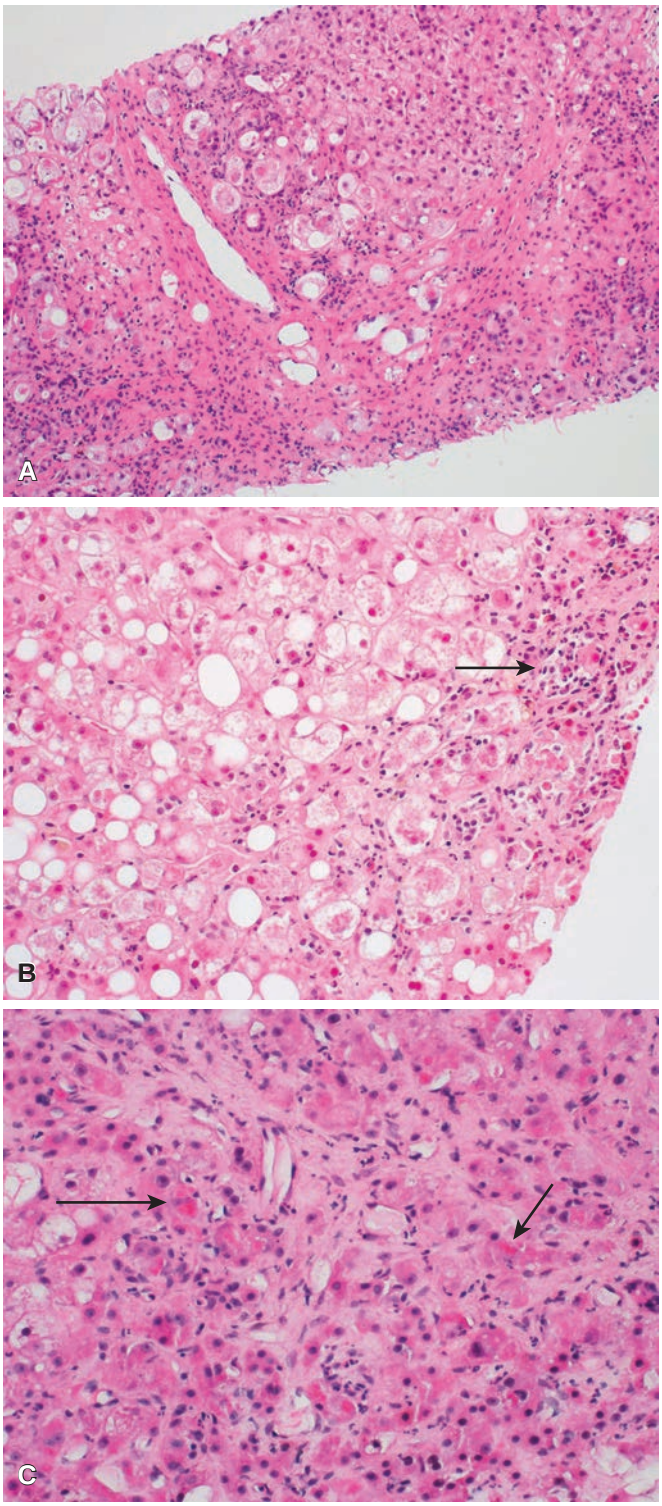

Figure 19.31 **A,** Alcoholic liver disease featuring marked hepatocyte ballooning, a neutrophilic infiltrate, and Mallory–Denk bodies. Steatosis is minimal in this case. **B,** Steatosis with well-developed ballooning and "satellitosis" of neutrophils around apoptotic hepatocytes *(arrow)*. **C,** Higher power view of Mallory–Denk bodies *(arrows)*.

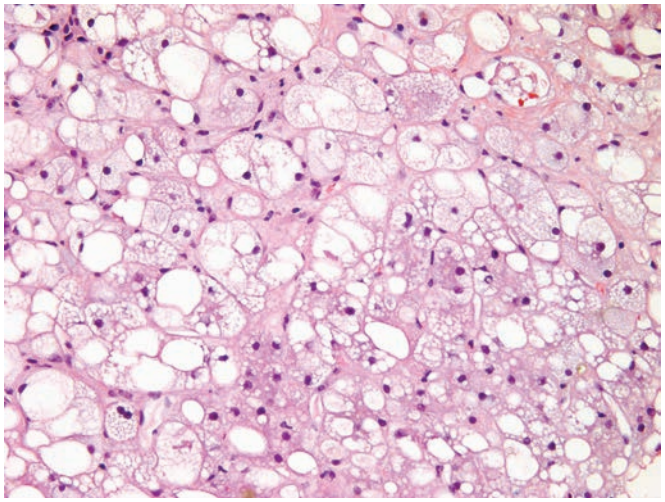

Figure 19.32 **Mixed Macrovesicular and Microvesicular Steatosis.**

They can be better visualized with chromotrope–aniline blue (CAB) stain and immunohistochemistry.[382] They are not specific for alcohol-induced liver disease, but several authors found them more frequently in liver with alcohol-related fibrosis.[383] Oxyphilic granular hepatocytes[384] or oncocytes are another common, though not pathognomonic, cellular component in acute and chronic alcoholic liver disease. Ultrastructurally, they are characterized by an extraordinary number of mitochondria (mitochondriosis).

Fibrosis is a constant feature in ASH, although it appears in different patterns. The most characteristic is pericellular (or perisinusoidal) "chicken-wire" fibrosis, ensheathing hepatocytes (Fig. 19.33A).[385] Its adequate identification usually requires collagen stains. Fibrosis may also involve the central vein, resulting in thickening of its wall (perivenular fibrosis). It has been suggested that this lesion is a marker of future cirrhosis, but others give more prognostic importance to pericellular fibrosis.[386] When pericellular fibrosis is severe and associated with perivenular liver cell necrosis, this pattern is known as sclerosing hyaline necrosis (Fig. 19.33B),[387] and the fibrosis may result in portal hypertension even in the absence of true nodular cirrhosis.[371] In chronic alcoholic liver disease there may also be significant portal tract/septal fibrosis, and in later stages, necrotic bridges and fibrous septa start to link central veins with portal tracts, obscuring lobular topography, which together with parenchymal regeneration, lead to cirrhosis.[388] A semiquantitative scoring system suitable for alcoholic fibrosis has been published.[389]

Cirrhosis of alcoholic origin is typically of the micronodular type (Fig. 19.34). Ongoing superimposed lesions of steatohepatitis worsen the prognosis[390] and suggest the etiology. In their absence, an alcoholic etiology can be suspected (but not proved) on account of the micronodular pattern, pericellular fibrosis, steatosis, and central vein occlusions. When the patient stops alcohol intake, parenchymal regeneration improves, nodules increase in size, and all features of alcoholic etiology may disappear. Patients with established alcoholic cirrhosis have a 5-year cumulative risk of developing hepatocellular carcinoma of approximately 8%.[391]

Several authors have drawn attention to other histologic features in the spectrum of alcoholic liver disease, including veno-occlusive lesions, portal tract inflammation and fibrosis, cholestasis, ductular reaction, and iron overload. Hepatocellular siderosis occurs in some alcoholics and may be confused with genetic hemochromatosis. Difficult cases may be solved by quantitative tissue iron determination

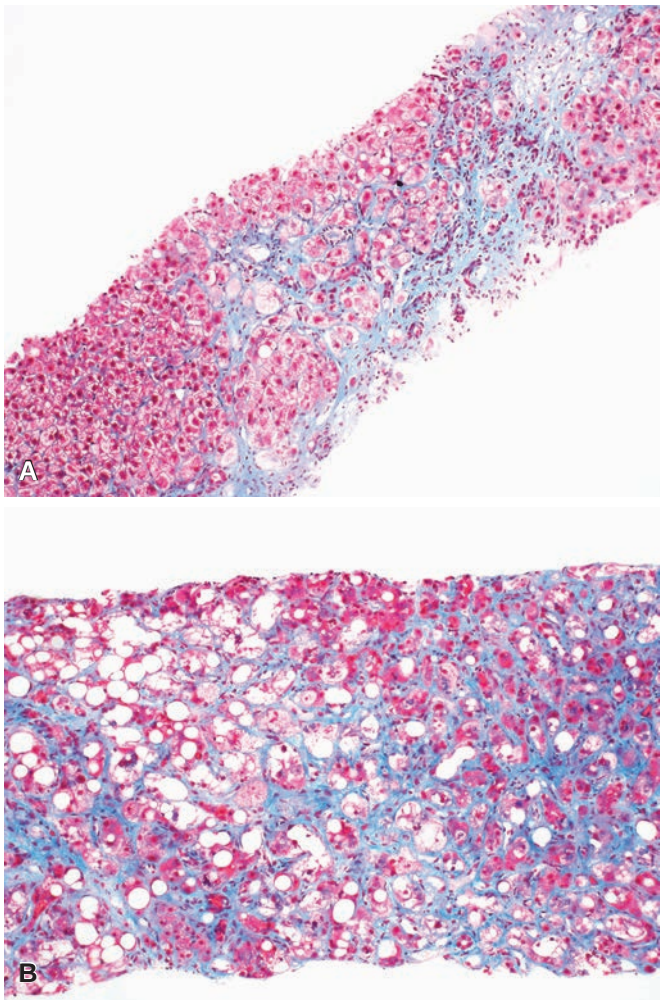

Figure 19.33 **A,** Pericellular or "chicken-wire" fibrosis ensheaths individual hepatocytes and small groups of hepatocytes, many of which show ballooning (Trichrome stain). **B,** Severe pericellular fibrosis in a case of sclerosing hyaline necrosis.

Figure 19.34 A markedly enlarged, pale yellow liver with micronodular cirrhosis from the autopsy of a patient with alcoholic liver disease. (Courtesy Dr. George F. Gray, Jr.)

and calculation of the hepatic iron index (HII).[392] The morphology of alcoholic liver disease can also be significantly affected by abstinence; furthermore, the clinical and morphologic phenotype can be influenced by the presence of comorbid conditions such as NAFLD, viral hepatitis, or hemochromatosis.[371]

Differential diagnosis of ASH. The primary entity in the differential diagnosis is NASH (see later), and this dilemma cannot be solved by histology alone because of the essentially identical histopathology.[393] An incomplete picture of ASH, with only perivenular and pericellular centrilobular fibrosis, may be confused with chronic venous congestion. MDBs, neutrophils, and fibrosis can be seen in diseases unrelated to alcohol, such as amiodarone toxicity and Wilson disease; the latter is a differential diagnosis that should always be considered with alcoholic liver disease, especially in younger patients. MDBs and hepatocyte ballooning are occasionally seen in chronic cholestatic disease, but there is typically a periportal predominance of these changes (rather than a centrilobular distribution). Viral hepatitis is usually suspected clinically, and the liver histopathology is quite different from ASH. Hypervitaminosis A (see earlier) may cause pericellular fibrosis progressing to cirrhosis,[323] and the pathologist should be alert for hepatic stellate cell hyperplasia.

Non-alcoholic liver disease in the alcoholic patient. Patients with a heavy alcohol intake may also suffer from a variety of non-alcoholic liver diseases, such as others cholangitis, viral hepatitis, and passive venous congestion.[394] Alcohol intake may hasten the onset of hepatic and cutaneous manifestations of *PCT*.[395] The hepatocytes contain birefringent acicular cytoplasmic inclusions[396] and usually some degree of siderosis. Chronic alcohol ingestion may also increase the risk of acute DILI, such as acetaminophen-induced centrilobular necrosis.[397] Alcoholic patients undergoing aversion therapy with cyanamide (see earlier) may develop a dramatic form of ground-glass change in periportal hepatocytes, which may lead to cirrhosis.[398] Severe siderosis in the alcoholic patient may be the result of genuine genetic hemochromatosis, which can be confirmed by quantitative iron determination and genotyping. Chronic venous congestion resulting in centrilobular fibrosis can be seen in patients with alcoholic cardiomyopathy.[399]

Chronic alcoholic pancreatitis may lead to stricturing of the common bile duct and cause lesions of extrahepatic bile duct obstruction with or without cholangitis,[400] and some of these patients may develop biliary cirrhosis.[401] An exclusively or predominantly periportal pattern of fibrosis in alcoholic patients should arouse suspicion for some other cause, particularly in the absence of other histologic features of alcoholic liver disease.[402] It should also be remembered that alcoholic hepatitis often coexists with chronic HBV and/or HCV infection.

Non-Alcoholic Steatohepatitis and Non-Alcoholic Fatty Liver Disease

The known causes of NASH are numerous and include jejunoileal bypass surgery, gastroplasty, and other causes of rapid and profound weight loss in obese subjects; TPN; drugs (amiodarone, perhexiline maleate, estrogens and estrogen receptor ligands, methotrexate, retroviral therapy); occupational hepatotoxicity as reported from a petrochemical plant in Brazil[403]; vinyl chloride exposure[404]; copper toxicity; and disorders characterized by insulin resistance. In most cases, the etiopathogenesis of NASH appears multifactorial (obesity, type 2 diabetes, and hypertriglyceridemia) and can be regarded as the hepatic consequence of the metabolic syndrome (also known as cardiovascular dysmetabolic syndrome or syndrome X).[405] The liver pathology was first recognized by H. Thaler in 1962[406–407] and later extensively described (including the histologic components of fatty change, lobular inflammation, and pericellular fibrosis) and termed NASH by Ludwig et al.[408] This study also proposed a subclassification differentiating primary NASH (related to obesity and insulin resistance) from secondary NASH (post bypass surgery, drugs, and toxins).[408] Very soon, however, the term NASH became reserved for the disease associated with the "metabolic syndrome" or "insulin

resistance syndrome," an aggregate of disorders related to obesity, insulin resistance, type 2 diabetes, hypertension, and hyperlipidemia, and related to the emerging epidemic of obesity in the West and in other parts of the world.[409–410] It is estimated that in the United States, NAFLD affects about 20%–30% of adults and 10% of children.[411]

Visceral fat accumulation is more important in the pathogenesis of the metabolic syndrome than general obesity.[412] In human visceral obesity, white adipose tissue is enriched in macrophages. The presence of macrophages in omental white adipose tissue participates in the cellular mechanisms favoring hepatic fibroinflammatory lesions in obese patients.[413] Mildly inflamed adipose tissue functions as an endocrine organ with the capacity to release protein signals, including the adipokines involved in energy and glucose metabolism: leptin, adiponectin, resistin, and visfatin.[414] Visceral fat appears to be directly associated with liver inflammation and fibrosis by itself, independent of insulin resistance and hepatic steatosis.[415] Pessayre and Fromenty suggested that NASH can be considered to some extent to be a mitochondrial disease, since mitochondrial dysfunction is involved at each successive step leading to NASH.[416] Chemokines, cytokines,[417] and innate immune processes, occurring both within and outside the liver, are also involved in insulin resistance and end-organ damage in the form of NAFLD.[418]

The histologic criteria put forth by Ludwig et al.[408] included patterns of injury that are similar to those of ASH. However, the minimal criteria for the diagnosis of NASH were originally controversial.[419–421] The term NAFLD has been proposed as a more inclusive term that incorporates the various grades of severity in the entire spectrum of non-alcoholic steatotic syndromes.[420] The topic was discussed in a review by Brunt, who observed that not all of the lesions of alcoholic liver disease are present in NASH, and conversely, that not all of the lesions of NASH are seen in alcoholic liver disease.[422] Lesions in alcoholic liver disease that have not been seen in NASH include sclerosing hyaline necrosis, veno-occlusive lesions, ductular reaction and cholangiolitis, and acute cholestasis.[410] Further discussion of criteria and terminology resulted in accepted criteria for both mild and more severe NAFLD. The presence of steatosis alone has been considered a rather mild alteration (simple steatosis or non-alcoholic fatty liver [NAFL]); this concept, on second thought, might deserve reconsideration (see also earlier).[423] The condition is less benign when steatosis is associated with portal and/or lobular inflammation and fibrosis, known as NAFLD (Fig. 19.35A and B). The addition of hepatocellular ballooning and Mallory–Denk inclusions results in NASH[410,420,424]; at this point the disease becomes potentially more serious and progressive, even resulting in cirrhosis and/or hepatocellular carcinoma (Fig. 19.36). There appears to be a relationship between the severity and zonal location of steatosis and the presence of the histologic features of NASH; that is, as compared to centrilobular steatosis, panlobular steatosis is more often associated with ballooning, MDBs, and advanced fibrosis.[425]

As in alcoholic liver disease, MDBs can be better visualized by ubiquitin and p62 immunostaining.[426]

Further alterations include microvesicular steatosis, glycogenated nuclei, megamitochondria, and glycogen-rich hepatocytes[410]; the latter resembles the hepatocellular changes described in diabetes-associated glycogenic hepatopathy and must be differentiated from hepatocellular ballooning.[427] It is important to realize that no qualitative histologic differences exist between ASH and NASH that would allow classification of any *individual case* as alcoholic or non-alcoholic in etiology, on the basis of morphology alone.[422] However, when larger groups of patients are compared, NASH is usually associated with more fat and nuclear glycogen, but less hepatocellular damage, inflammation, and fibrosis, and fewer MDBs

than ASH. However, progression to cirrhosis is definitely possible in patients with NASH.[428,429] Ethnicity also influences metabolic derangements, as well as histology, in NAFLD.[430] One study found that African Americans showed a lower degree of steatosis than whites, but that, in contrast, Asians and Hispanics showed more ballooning and MDBs, respectively, than whites and other ethnicities combined, thus highlighting the need for prospective studies to evaluate ethnic differences in NAFLD.[431]

The diagnosis of NASH is not dependent on a single histopathologic feature but involves assessment of multiple elements. A semiquantitative scoring system for grading and staging the histologic lesions in NASH has been published by Brunt et al.[422,432] The Pathology Committee of the NASH Clinical Research Network designed and validated a histologic scoring system that addresses the full spectrum of lesions of NAFLD and proposed a NAFLD activity score (NAS) for use in clinical trials. The proposed NAS is the unweighted sum of steatosis, lobular inflammation, and hepatocellular ballooning scores. This represents a scoring system and activity index for NAFLD and NASH with reasonable interrater reproducibility that should be useful for studies of both adults and children with any degree of NAFLD. A value of NAS of ≥5 correlates with a diagnosis of NASH.[356] Note that this system is intended for use in clinical trials and not as a tool for diagnosing NASH in routine clinical practice. It always has to be kept in mind that parenchymal injury and fibrosis may vary in different regions of the liver, thus creating the possibility of sampling variability in needle biopsy specimens.[433]

Brunt et al. noted that significant portal mononuclear inflammation is associated with many clinical and pathologic features of progressive NAFLD in both adults and children, and that such infiltrate in liver biopsies of untreated NAFLD may be considered a marker of advanced disease.[434] However, significant portal inflammation may also be a sign of co-existent disease, such as hepatitis C or autoimmune hepatitis.

Portal fibrosis in the absence of other features of NASH, termed isolated portal fibrosis (IPF), has received less attention and has not been classified as a feature of NAFLD. Nevertheless, a significant subset of morbidly obese individuals has portal fibrosis in the absence of features of NASH associated with glycemic dysregulation. It resembles the pattern of NAFLD in the majority of affected children (see later). Therefore, IPF could be considered a part of the spectrum of NAFLD that may precede NASH in morbid obesity.[435]

Periportal and septal fibrosis is a key feature of progressive disease in NASH. Fatty liver impairs hepatocellular regeneration, which triggers a reserve replicative pathway using the bipotential, periportal, hepatic progenitor cells. Activation of this pathway by cell injury in NASH induces a periportal ductular reaction that plays a promoting role in periportal fibrogenesis.[436] When cirrhosis develops, the other histologic features of NASH activity may persist or disappear. In the latter instance, the underlying diagnosis of NASH is often no longer recognizable, and the case falls in the category of cryptogenic cirrhosis. How often this occurs has not been established, but it has been suggested on reasonable grounds that many cases of cryptogenic cirrhosis derive from NASH.[437] When appropriate criteria are used, NAFLD appears to account for close to two-thirds of cases currently labeled as cryptogenic cirrhosis;[438] however, it would be erroneous to assume that all cryptogenic cirrhoses derive from NASH, since cirrhoses from various other etiologies may "burn out" as well.[410] Recurrent fatty liver disease is common following liver transplantation for NASH cirrhosis but does not typically lead to early allograft failure.

Recurrent NASH can occur despite normal liver enzymes, and features of metabolic syndrome are associated with disease recurrence.[439] NASH-related cirrhosis carries a substantial risk for early HCC development. Given the epidemic of obesity and diabetes, the incidence of NASH-related HCC is expected to increase (see also Chapter 20).[440,441]

Histologic evaluation was fundamental to the initial studies that introduced and defined the concept of fatty liver disease, and liver biopsy remains essential in the diagnosis and evaluation of NAFLD and NASH. Currently, liver biopsy in NAFLD serves multiple roles: confirmation (or exclusion) of the diagnosis; distinction of steatohepatitis from "simple steatosis"; assessment of extent of necroinflammatory activity, fibrosis, and architectural alterations[442,443]; and excluding other causes of liver disease, such as viral hepatitis.[444] The histologic severity of liver injury and inflammation is strongly associated with an increased cardiovascular risk and an atherogenic lipid profile.[445] With early biopsy, and early intervention, the ability to prevent advanced liver disease was found to be high,[446] and biopsy may be indicated even in patients with normal alanine transaminase who are suspected to have NAFLD.[447] In view of the huge numbers of patients involved, and the risk, cost, and limitations of liver biopsy, intensive efforts are underway for establishing valuable noninvasive methods for diagnosis in this context.[448]

Given the current worldwide epidemic of pediatric obesity, NAFLD is increasingly diagnosed in children, and NAFLD is now the most common cause of chronic liver disease in children.[449] The rising incidence in children is not restricted to Western populations; epidemiologically, there is a male predominance and frequent Asian and Hispanic ethnicity.[409] It is not exactly identical to NAFLD in adults, perhaps in part because the metabolic derangements of the disease occur during periods of active growth (infancy, mid-childhood, and puberty).[450] The histopathology of pediatric NAFLD and NASH is also reported to be somewhat different from that in adults. Studies noted a minority of what was termed type 1 (similar to classic or adult NAFLD), and predominance of type 2, characterized by more severe steatosis, little or no ballooning degeneration, less lobular inflammation, few or no polymorphonuclear leukocytes, more portal tract inflammation, less zone 3 chicken-wire fibrosis, and more periportal fibrosis, thus making childhood NASH look a bit more like a "chronic hepatitis."[356,451–453] However, a recent multicenter study reported that in the vast majority of the studied patients, overlapping features of both type 1 adult NASH and type 2 pediatric NASH were found and that although portal-based injury is frequently found in children, it is almost universally associated with some elements of the centrilobular pattern identified in adults.[454] Liver biopsy is also required for an adequate evaluation of the severity and pattern of pediatric NAFLD and NASH in children.[455]

It is important to note that the coexistence of NASH and chronic viral hepatitis C causes a mutual synergistic effect in fibrosis progression and evolution to cirrhosis, as discussed earlier. This association may also affect the response to antiviral therapy; patients chronically infected with HCV genotypes 2 and 3, and with insulin resistance, were six times more likely to achieve sustained viral response if their insulin resistance was mild (Homeostasis Model Assessment of Insulin Resistance [HOMA-IR] <2) than those with more severe insulin resistance (HOMA-IR >2).[456]

It has been suggested that,[215] given that NASH is a negative term (*non*-alcoholic) for a condition that is caused by many different etiologies (viruses, metabolic syndrome and/or obesity, drugs, rapid weight loss, inherited metabolic disease), that a positive nomenclature would be more informative. Some have advocated discarding the acronym NASH, and making diagnoses according to etiology, such as viral-associated steatohepatitis (VASH, e.g., in HCV genotype 3), drug-associated steatohepatitis (DASH), alcohol-associated steatohepatitis (AASH), metabolic-associated steatohepatitis (MASH), and perhaps—why not?—CASH (cryptogenic-associated steatohepatitis).[457] But nomenclature is tough to change!

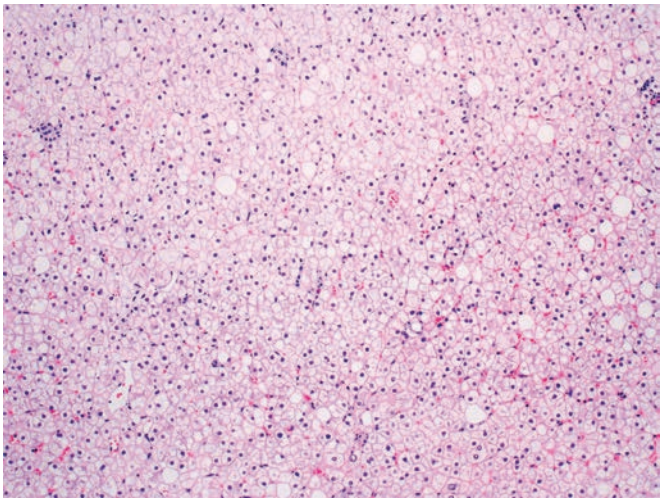

Figure 19.37 Glycogenic hepatopathy featuring enlarged, markedly pale, swollen hepatocytes due to glycogen accumulation.

Fatty liver disease may also act synergistically with other chronic liver diseases to aggravate parenchymal injury. There is evidence that steatosis and its metabolic abnormalities also exacerbate alcoholic liver disease, hemochromatosis, and, possibly, drug-induced liver disease.[458]

Glycogenic Hepatopathy and Other Features of Diabetes Mellitus in the Liver

As discussed previously, a major cause of hepatomegaly in patients with diabetes is steatosis. In both adults and children with type 1 diabetes mellitus, hepatomegaly and abnormalities of liver enzymes also occur as a consequence of hepatocellular glycogen accumulation. This is believed to be a function of the body habitus and state of insulin resistance rather than glycemic control. The livers of affected patients are characterized by marked glycogenosis, a pathologic overloading of hepatocytes with glycogen, known as *glycogenic* or *diabetic hepatopathy*.[427] Liver biopsy shows diffusely pale staining hepatocytes on H&E stains (Fig. 19.37), with excessive glycogen accumulation demonstrated by PAS stains. Ultrastructural examination reveals marked glycogen accumulation in the cytoplasm and nuclei.[427] If accompanied by cushingoid features, growth retardation, and delayed puberty, a diagnosis of Mauriac syndrome can be made.[459] The distinction between steatosis and glycogenosis is important: whereas steatosis may progress to fibrosis and cirrhosis, glycogenosis does not, but reflects the need for better diabetic control. Glycogenosis and steatosis cannot be distinguished reliably on ultrasound examination; the histology, however, is definitive.[460] Patients undergoing dietary management of urea cycle defects with diets containing essential amino acids may have similar focal or diffuse glycogen accumulation in hepatocytes which—except for the focality in deposition—resembles that in glycogen storage disease.[461] Glycogenosis was also described in a patient with anorexia nervosa where it was interpreted as an adaptive response to starvation.[462]

Sinusoidal lesions may also be part of the changes seen in the liver in diabetes. Marked sinusoidal fibrosis has been reported secondary to longstanding diabetes mellitus, in the absence of NASH. The patients have evidence of microvascular complications, including retinopathy, nephropathy, and peripheral and autonomic neuropathy. Liver biopsy shows extensive dense perisinusoidal fibrosis, and immunostaining reveals basement membrane components in a perisinusoidal distribution. The term diabetic hepatosclerosis (DHS) has been suggested for this entity, indicating a form of diabetic microangiopathy affecting the liver.[463] Electron microscopy of sinusoids and sinusoidal cells reveals numerous thick collagen bundles in the space of Disse, and increased basement membrane–like material underlying the sinusoidal cell population. Perisinusoidal cells appear active with abundant rough endoplasmic reticulum and thick cellular processes.[464] The prevalence of DHS was 12% in an autopsy series, suggesting that it is not uncommon, but in the majority of patients it was clinically silent[465]; another more restricted study of autopsied diabetic patients revealed DHS in only one case out of 57, associated with nodular glomerulosclerosis and hepatic hyaline arteriolosclerosis.[466]

Cholestasis, Biliary Diseases, and Autoimmune Hepatitis

Cholestatic Liver Disease

The histologic changes in the liver in cholestatic liver diseases can be conceptualized in two ways: (1) features of cholestatic liver diseases in general; and (2) features characteristic of individual cholestatic liver diseases. The former allows the diagnostic histopathologist to distinguish between cholestatic and noncholestatic disorders, whereas the latter serves to differentiate between diseases *within* the group of cholestatic disorders.

The term *cholestasis* refers to an arrest, or at least a marked reduction, in bile secretion and bile flow. It may be caused by a functional secretory disturbance of the hepatic parenchymal cells, and/or by obstruction at any level in the excretory pathways of bile, from the canaliculi to the papilla of Vater.[467] *Intrahepatic cholestasis* refers to those conditions in which the primary lesions are located inside the liver itself; this term thus encompasses diseases of the parenchymal cells and of the intrahepatic bile ducts. Some conditions combine both; for instance, progressive familial intrahepatic cholestasis (PFIC) type 3 involves both a deficit of canalicular phospholipid transport and damage to interlobular ducts.[468] *Extrahepatic cholestasis* occurs when the bile excretory block is located in larger ducts: outside the liver along the extrahepatic bile ducts (e.g., gallstones, bile duct tumors, bile duct strictures) but also in larger hilar intrahepatic ducts. Some cholestatic disorders affect both the intra- and extrahepatic segments of the biliary tree, and hence qualify as combined intra- and extrahepatic cholestatic diseases. Examples are neonatal extrahepatic bile duct atresia and PSC.

The block in bile secretion may be complete or variably incomplete. Complete cholestasis denotes a total arrest of bile secretion, with retention of bile salts and bilirubin, be it functional or obstructive. Incomplete cholestasis usually indicates an incomplete or partial obstruction of the intrahepatic and/or extrahepatic bile ducts, with retention of bile salts but not of bilirubin.

Incomplete intrahepatic cholestasis is mostly due to destructive diseases of intrahepatic bile ducts such as PBC and PSC. Incomplete extrahepatic cholestasis corresponds to incomplete obstruction (narrowing or strictures) of segments of larger bile ducts.

Cholestasis may be acute or chronic. Acute cholestasis is usually complete cholestasis, corresponding to either total functional exocrine secretory failure of the hepatocytes (e.g., drug-induced cholestasis), or complete obstruction of the extrahepatic bile ducts (e.g., impacted gallstone). Chronic cholestasis indicates a cholestatic condition of longer duration (weeks, months, years), which may be complete (e.g., chronic total extrahepatic bile duct obstruction by a carcinoma of the pancreas) or variably incomplete (e.g., PBC, PSC).

Cholestasis and icterus (or jaundice) are not synonymous terms: the distinction must be made between icteric and anicteric conditions of cholestasis. Patients with incomplete cholestasis may remain

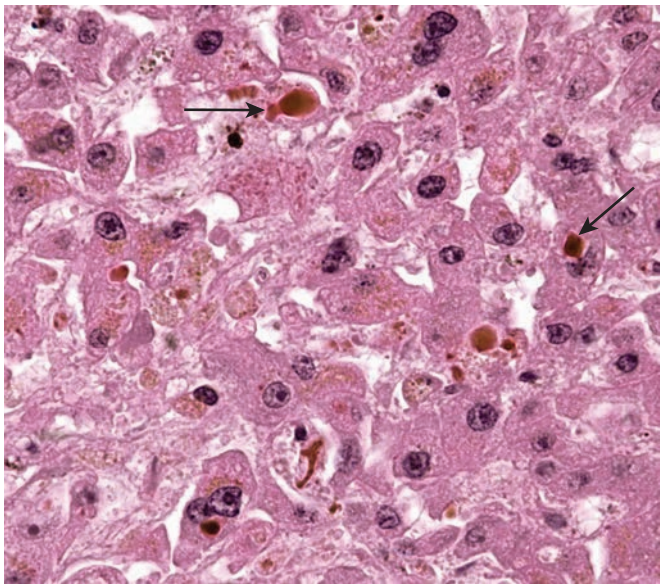

Figure 19.38 Marked bilirubinostasis in hepatocytes and bile canaliculi, leading to bile plugs in the latter *(arrows)*.

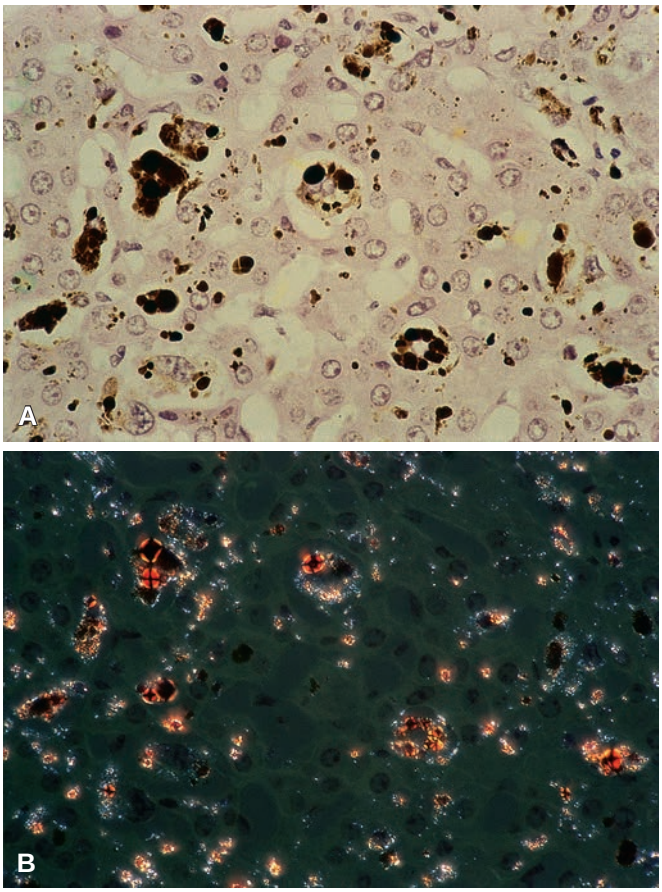

Figure 19.39 Erythropoietic Protoporphyria. A, Dark brownish-black deposits of protoporphyrin in hepatocytes, canaliculi, Kupffer cells, and ductules. **B,** The deposits are birefringent under polarized light, and show a Maltese cross configuration of red birefringence in the larger deposits.

anicteric for long periods. In parallel, histologic cholestasis is not necessarily characterized by the microscopically visible accumulation of the bile pigment bilirubin in liver tissue sections. This underscores the usefulness of distinguishing between *bilirubinostasis* (which many pathologists do, in fact, use interchangeably with the term cholestasis) and *cholate stasis*, or accumulation of bile salts with accompanying characteristic histologic changes. These features may be seen in cholestatic liver diseases either separately or in combination. A comprehensive overview of the pathology of cholestasis was published by Li and Crawford.[469]

Acute complete cholestasis. An acute cholestatic liver disease associated with complete cholestasis is characterized by microscopically demonstrable bilirubin accumulation (Fig. 19.38) which starts in the centrilobular zone; it features pigment granules in parenchymal cells (hepatocellular bilirubinostasis) and inspissated bilirubin-stained bile plugs in dilated intercellular canaliculi (canalicular bilirubinostasis). Retention of detergent bile acids results in hepatocellular damage and even death (necrotic or apoptotic), leading to Kupffer cell activation. The hypertrophic Kupffer cells phagocytose the debris from dying parenchymal cells and the liberated canalicular bile plugs, resulting in Kupffer cell bilirubinostasis. The latter feature indicates a cholestatic condition of at least several days' duration.[470] Acute complete cholestasis, especially in cases of extrahepatic obstructive origin, is further characterized by edema of the portal tract connective tissue, causing some rounding of portal contours, and an incipient ductular reaction (described later).

Bilirubinostasis in its various locations should not be confused with lipofuscin (see earlier), or with the dark brown to black deposits (in hepatocytes, canaliculi, Kupffer cells, and ductules) in liver biopsies from patients with erythropoietic protoporphyria. The latter deposits are darker brown or black and easily identified by the use of polarized light; protoporphyrin deposits have a red to yellow birefringence with a Maltese cross configuration in coarser (ductular) deposits (Fig. 19.39A and B).[471]

Chronic complete cholestasis. The parenchymal changes in complete cholestasis of longer duration include a number of lesions appearing over time and superimposed on the early bilirubinostasis, which gradually extends toward the periportal parenchyma. In most forms of chronic cholestasis lasting for weeks, some lymphocytic inflammatory infiltrate occurs in the areas with bilirubinostasis, apparently secondary to cholestatic changes. Unlike the inflammation in acute hepatitis, this infiltrate is mild and restricted to the area with bilirubinostasis. The parenchymal, portal, and periportal alterations observed in chronic complete cholestasis also occur in chronic incomplete cholestasis, as described in the following section. The basic difference between chronic complete cholestasis and the incomplete variety consists in the absence of bilirubinostasis in the incomplete category and the occasionally more pronounced expression of some of the other lesions in the complete variety.

Chronic incomplete cholestasis. As mentioned previously, bilirubinostasis (as well as clinical jaundice) is not a feature of liver diseases associated with incomplete cholestasis, except in the terminal decompensating phase of the disease or in the case of superimposed pathologic changes (e.g., drug-induced liver damage). Thus, the histopathologist may be required to identify the presence of a chronic cholestatic liver disease in the absence of what used is often regarded as a characteristic feature of cholestasis (bilirubinostasis). The histopathologic diagnosis of chronic (complete as well as incomplete) cholestasis relies on several parenchymal, portal, and periportal alterations. The parenchymal changes include cholate stasis, cholestatic liver cell rosettes, feathery degeneration, xanthomatous cells, and bile infarcts.[110] These alterations occur despite the activation of a series of defense mechanisms on behalf of the parenchymal cells, including repression of bile acid synthesis and induction of basolateral

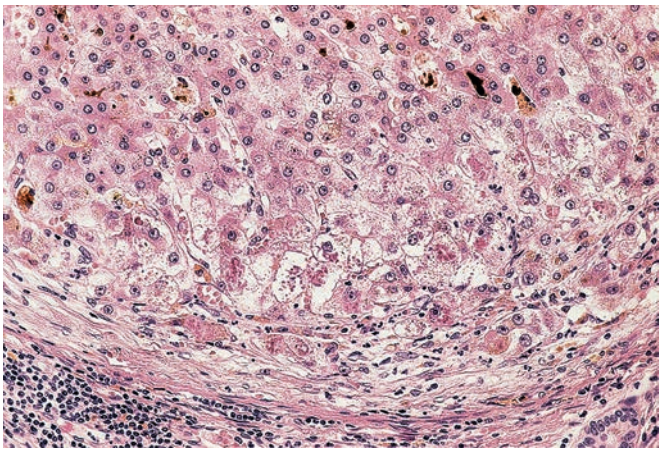

Figure 19.40 Cholate stasis in periphery of parenchymal nodule in cirrhotic liver of patient with end-stage primary sclerosing cholangitis. The hepatocytes near the fibrous septum *(lower part)* show hydropic swelling, clumping of the cytoplasm, and Mallory bodies.

bile acid export by the alternative bile acid efflux pump MRP4 as adaptive mechanisms to limit the bile acid burden in chronic cholestasis. These mechanisms, however, do not sufficiently counteract cholestatic liver damage.[472]

Cholate stasis is thought to be due to the membrane-damaging effect of retained bile acids, and primarily affects periportal hepatocytes.[110] The affected hepatocytes appear swollen, pale, and coarsely granular (Fig. 19.40); they contain granules of lysosomal copper, complexed with copper-binding protein (metallothionein), which are stainable with orcein (metallothionein) and rhodanine (copper) stains (Fig. 19.41A and B). With time, MDBs develop in these cells, and bilirubin inclusions also may appear in the very late stages. The earliest stages of cholate stasis may be revealed by immunostaining for keratin 7, revealing a phenotypic switch to a biliary type of intermediate filament cytoskeleton in periportal hepatocytes (Fig. 19.42). With time, keratin 7 expression extends with a decreasing gradient from the limiting plate toward the center of the lobule, over a distance of several cells.[6]

Cholestatic liver cell rosettes[473] represent a very useful diagnostic feature in any chronic cholestatic condition. They correspond to a tubular rearrangement of the liver cell plates that are normally one cell thick. Under the light microscope, they appear as glandular or tubular structures lined by four or more hepatocytes around a central lumen (Fig. 19.43A and B). The lumen may vary greatly in diameter; it may appear empty, or filled with eosinophilic or bilirubin-stained material in variable degrees of inspissation. Some or all of the lining hepatocytes may show feathery degeneration (see later) and express bile duct–type keratins (keratin 7 and tissue polypeptide antigen [TPA]), indicating a partial shift toward a bile duct cell phenotype.[6,19,474] This should not be misinterpreted as expression of hepatocellular regeneration.

Feathery degeneration is another lesion observed in chronic (incomplete and complete) cholestasis. It affects single cells or groups of parenchymal cells characterized by hydropic swelling. There may be some bilirubin impregnation of the remaining visible cytoplasm in cases of chronic complete cholestasis. *Xanthomatous cells* are a feature of longstanding incomplete and complete cholestasis as well. They are lipid-laden histiocytes with foamy cytoplasm, accumulating in the parenchyma but also in portal tracts, appearing singly or in clusters. They are believed to represent the expression of the hyperlipidemia that accompanies chronic cholestasis.

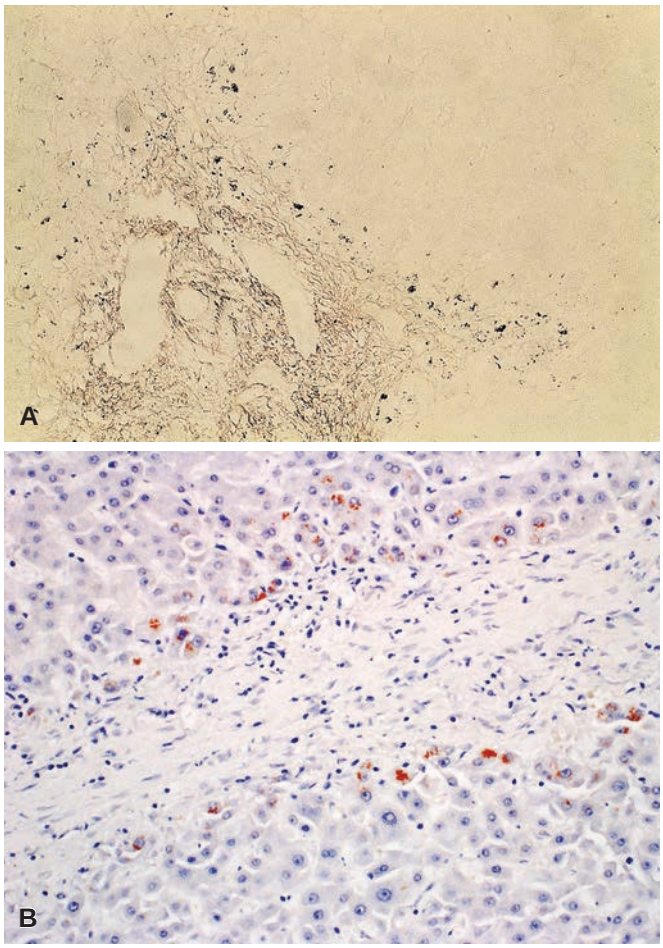

Figure 19.41 **A,** Cholate stasis in chronic cholestatic liver disease. The picture shows orcein-positive granules in periportal hepatocytes, representing lysosomal localization of copper binding protein (metallothionein). **B,** Lysosomal copper–metallothionein complexes appear as red-stained granules in the copper-specific rhodanine stain.

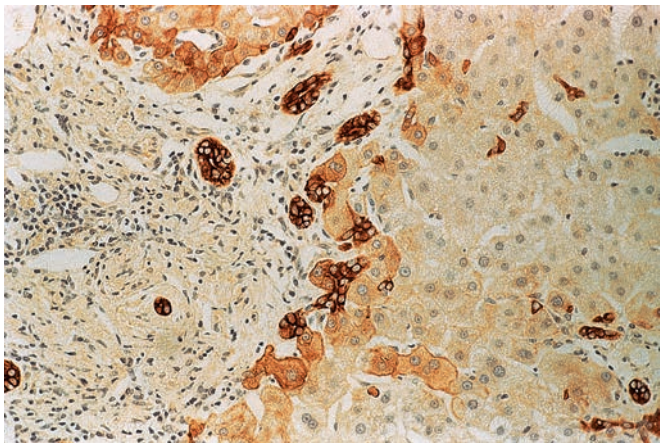

Figure 19.42 Keratin 7 immunostain highlights an increase in the number of ductular structures at the portal tract periphery; expression of keratin 7 in periportal hepatocytes is an indicator of early cholate stasis. A few scattered, small keratin 7 positive cells at some distance from the portal tract are presumed hepatic progenitor cells.

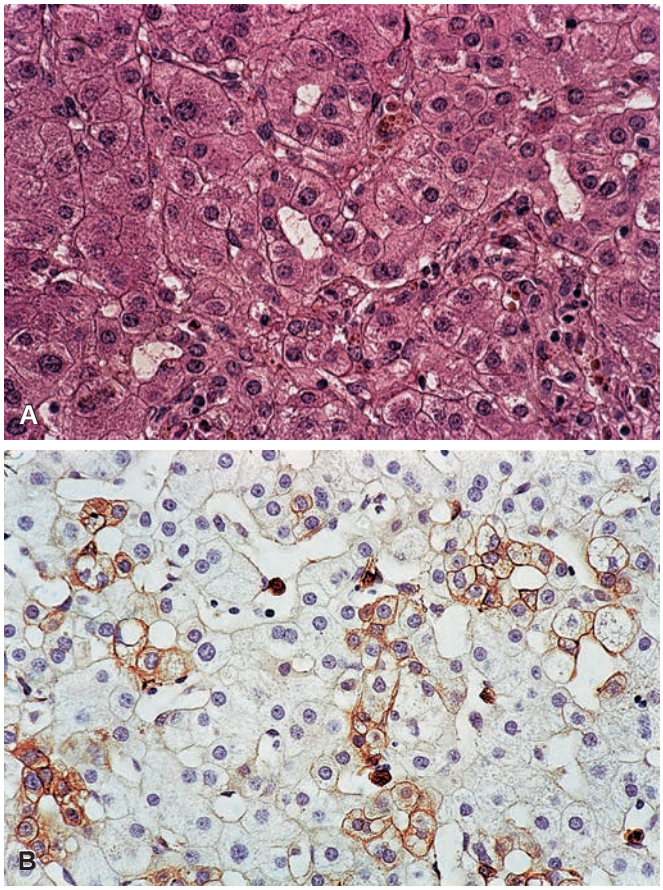

Figure 19.43 Cholestatic Liver Cell Rosettes. A, Liver biopsy of patient with primary sclerosing cholangitis. The involved hepatocytes form small tubules or rosettes. **B,** Immunostaining for keratin 7. Normal hepatocytes do not express keratin 7, whereas cells in cholestatic rosettes express this intermediate filament to variable extent.

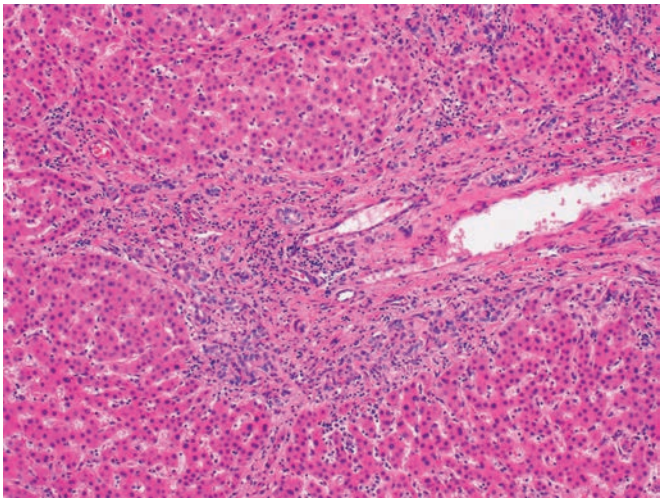

Figure 19.44 Ductular Reaction in Chronic Cholestasis. Liver biopsy from a patient with primary sclerosing cholangitis. The picture shows a mildly inflamed portal tract with ductular reaction at the periphery.

So-called *Charcot–Gombault infarcts* are a late parenchymal lesion in severe cholestasis of long duration, mainly (but not exclusively) seen in large duct obstruction. The lesions consist of necrotic hepatocytes, mostly in a periportal location, sometimes showing bilirubin impregnation of the central necrotic area. Bile infarcts are gradually replaced by organizing mesenchymal tissue, finally resulting in fibrous scars.

Ductular reaction is recognized as an increased number of ductular profiles at the periphery of the portal tract, gradually extending into the periportal parenchyma toward the neighboring portal tracts, and often accompanied by edema and neutrophils (Fig. 19.44).[475] It can be visualized to better extent by keratin 7 or 19 immunostaining.[6] The origin of the increased number of ductules is debated; it is apparently multiple. Ductular reaction in diseases with extrahepatic bile duct obstruction is mainly due to increased bile pressure,[476,477] and involves elongation rather than sprouting of preexisting bile ductules.[477] In other cholestatic diseases, not necessarily obstructive in origin, proinflammatory cytokines may be the predominant triggers.[478] In chronic cholestatic diseases, ductular metaplasia of periportal hepatocytes also plays a role,[474,475] as does activation and proliferation of hepatic progenitor cells.[479] The cholangiocytes lining the ductules may show signs of reabsorption, reflected in vacuolization of their cytoplasm and accumulation of bilirubin and lipofuscin. The wedge-shaped periportal extension of ductular reaction with accompanying inflammation into the periportal parenchyma, which may show features of cholate stasis, results in an irregular portal–parenchymal interface, termed "biliary piecemeal necrosis"[480] or biliary interface activity.[481] For reasons that have not been finally elucidated, chronic states of cholestasis in some patients lack an obvious ductular reaction; this may be the case in Alagille syndrome (AGS), some cases of PSC, and chronic liver allograft rejection.

Ductular reaction may be accompanied by periductular fibrosis, with a significant correlation between the progression rates of fibrosis and of the ductular reaction. The fibrosis is produced by myofibroblasts that derive from portal/periportal mesenchymal cells.[482] However, several recent studies equally emphasize contributions from cholangiocyte–mesenchymal transition.[483,484] Relief of bile duct obstruction or cessation of the cause of cholestasis results in the disappearance of bile duct hyperplasia by apoptosis of cholangiocytes accompanied by a similarly rapid loss of the mesenchymal cells.[485,486] Ductular reaction may be the only histologic change in some biopsies (termed isolated ductular hyperplasia). This has been found in 10% of adults biopsied for persistent mild liver function test abnormalities unrelated to viral hepatitis. The picture consists of well-differentiated hyperplastic ductules in the absence of significant inflammation. It is thought to represent a nonspecific reaction pattern to mild liver damage.[487]

When progressive, ductular reaction with periductular fibrosis eventually results in fibrous linkage of adjacent portal tracts. This stage of *biliary fibrosis* (portal–portal septal fibrosis) is a potentially reversible lesion[488] since the basic angioarchitectural pattern of the liver is preserved.[489] Biliary fibrosis may progress to true *biliary cirrhosis*, which represents the final stage in disturbance of the lobular architecture, characterized—like any cirrhosis—by additional portal–central fibrous septa and nodular parenchymal regeneration. Persistent disease at the point of biliary cirrhosis is characterized by persistence of ductular reaction with accompanying edema and periductular inflammation and fibrosis. Together with lesions of cholate stasis in the nodular periphery, this creates at low magnification the impression of a clear "halo" between the cirrhotic nodules and the fibrous septa. Several staging schemes exist for chronic biliary disease, based on histologic features including interlobular bile duct damage, ductular reaction, and progressive biliary fibrosis. Historically, the stages have been defined as portal (stage 1), periportal (stage 2), septal (stage 3), and cirrhotic (stage 4).[490,491] New staging systems

have been proposed more recently, which take inflammatory activity into consideration as well as fibrosis and other features of chronic cholestasis.[492]

In addition to the general features of cholestasis discussed previously, two other changes that often characterize the histologic picture in neonatal cholestatic liver diseases should be mentioned. *Multinucleated giant cells* result from syncytial fusion of several mononucleated hepatocytes. The number of nuclei and their location are variable. Giant cells often contain pigment granules corresponding to bilirubin, lipofuscin, hemosiderin, or a combination thereof. They may appear necrotic and be surrounded by neutrophils. Giant cell transformation of parenchymal cells occurs in a variety of conditions; they are considered a nonspecific reaction of the infant's hepatocytes to various types of injury and appear to be more specific for age than disease. They are occasionally observed in adult liver as well.[493] Foci of *extramedullary hematopoiesis*, consisting of clusters of erythrocyte precursor cells, myeloid precursor cells, and megakaryocytes, or a combination of these, are often observed in cholestatic liver specimens of young infants as well.[493] They are not a reliable criterion for differentiation between various cholestatic diseases such as BA and neonatal hepatitis.

Individual cholestatic liver diseases. Cholestatic liver diseases can be subdivided in several different ways: intrahepatic versus extrahepatic; medical versus surgical; neonatal versus adult, etc. In the following section, an attempt is made to classify the disorders according to the primary focus of the disease along the pathways through which bile has to travel from its source in the hepatocytes to its destination in the gut.

It is realized that such a categorization is imperfect: first, because the etiology and pathogenesis of several major cholestatic liver diseases remain incompletely clarified; and second, because some disorders involve two or more sites simultaneously.

Hepatocellular (parenchymal) diseases. For this group of disorders, it is useful to consider the serum levels and hepatic expression of the enzyme γ-GT. In most cholestatic conditions, serum γ-GT is increased. This is due to the fact that γ-GT, an enzyme normally inserted in the canalicular membrane of hepatocytes, is eluted from this membrane by the detergent action of bile salts after their export in the canaliculi, explaining the presence of γ-GT in bile. In cholestasis, bile (along with γ-GT) regurgitates through the canalicular tight junctions that have become leaky in these conditions. Thus, increased serum levels of γ-GT in cholestatic liver disease requires the presence of canalicular expression of γ-GT, its elution by bile salts, and regurgitation through leaky tight junctions.

Some cholestatic diseases, however, are characterized by a normal serum level of γ-GT or a serum activity of the enzyme that is unusually low for the degree of cholestasis ("low γ-GT cholestasis"). Cholestasis with (near-) normal serum γ-GT occurs in these circumstances[494–496]:

1. When γ-GT cannot insert in the membrane due to inadequate phospholipid asymmetry in the membrane caused by *ATP8B1* (previously *FIC-1*) mutation, and hence cannot be eluted from the membrane (e.g., progressive familial intrahepatic cholestasis [PFIC] type 1; benign recurrent intrahepatic cholestasis [BRIC] type 1).
2. When the bile salt export pump (BSEP) is absent from the membrane, due to *BSEP* mutation, and hence no bile salts are secreted (e.g., PFIC type 2; BRIC type 2).
3. When no appropriate normal bile salts are synthesized, and hence no bile salt secretion occurs through canalicular membranes (metabolic disorders of bile salt synthesis defects).

These primarily pediatric disorders are discussed in detail later. Several *acquired* cholestatic disorders are also characterized by predominantly parenchymal/hepatocellular features, including intrahepatic cholestasis of pregnancy (ICP; see later) and some forms of postoperative cholestasis,[497] as well as acute viral hepatitis, ASH, and drug-induced liver disease (see earlier).

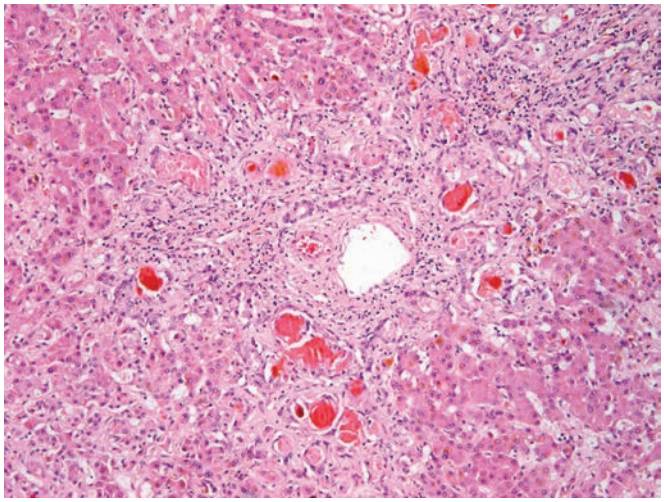

Figure 19.45 Ductular bilirubinostasis featuring markedly dilated ductules filled with bile concrements.

Ductular pathology. In some cholestatic disorders, the disease appears to focus on the ductules and canals of Hering. Most of these conditions are characterized by ductular reaction and ductular bilirubinostasis; the latter is represented by smaller or larger bilirubin-impregnated deposits or concrements in more or less dilated ductular segments (Fig. 19.45). Ductular bilirubinostasis occurs in diverse situations and is thought to result from damage to ductular cells with total paralysis or partial impairment of their normal secretion of bicarbonate-rich fluid. Ductular bilirubinostasis is observed in patients with massive liver cell necrosis[52]; in septicemia and endotoxic shock (see also later) [498,499]; in extrahepatic BA[500]; in TPN[343]; and in some patients with mucoviscidosis (cystic fibrosis [CF]).[501] In extrahepatic bile duct atresia, the ductular bilirubin deposits often appear as a string of pearls in a series of ductular dilations. TPN-associated liver injury is discussed in detail earlier; CF and extrahepatic BA are discussed later with pediatric liver diseases.

Ductal pathology and vanishing bile duct diseases. A number of cholestatic liver diseases are associated with progressive inflammatory destruction of intrahepatic bile ducts of a particular caliber. These may be classified as ductopenic or vanishing bile duct disorders and represent a vast and intriguing chapter in liver pathology (Box 19.1). They all result in reduction of the number of interlobular bile ducts, also termed paucity of ducts or ductopenia.[502] Vanishing bile duct diseases in the neonatal period and childhood include paucity of interlobular bile ducts (PILBD), both syndromic and nonsyndromic, and/or BA, which are discussed in detail in the section on pediatric liver disease.

A sound morphologic diagnosis of ductopenia requires a sufficiently large biopsy specimen to allow quantitative evaluation of interlobular ducts. Although historically a surgical biopsy was recommended,[503] a needle biopsy may certainly suffice provided that the specimen contains at least five portal tracts.[4,504] Recognition of a missing duct is facilitated by comparing with branches of the hepatic artery. As 70%–80% of arterial branches are normally accompanied by a duct of approximately similar size near the center of the portal tract, a "widowed" or unpaired artery signals a missing duct.[504,505] Immunostains for keratin 7 (or 19) or TPA are helpful for better visualization of interlobular ducts,[6] especially in very young children.[506]

Paucity of interlobular ducts (or ductopenia) was originally defined as a ratio of the number of interlobular ducts to the number of portal tracts of less than 0.5. In normal children and adults this

ratio lies between 0.9 and 1.8.[503] This definition of ductopenia as a ratio of 0.5 or less was valid at the time of its definition in neonatal disease, but since 1975 evidence has accumulated that ductopenia in general is not a static condition but reflects a progressive destruction of interlobular ducts. It follows that a reduced bile duct to portal tract ratio higher than 0.5 (i.e., a less pronounced degree of ductopenia) can still be considered "ductopenia," especially when damaged or inflamed ducts are also observed.[507]

The histopathology in ductopenic diseases is mainly that of chronic incomplete cholestasis, with variably present features specific for an individual disease. One has to keep in mind, however, that such features are not consistently present in every biopsy specimen and may not persist throughout the entire course of the disease; in addition, the specificity of the histopathology may decrease with advancing disease and progression toward cirrhosis.

Primary Biliary Cirrhosis

PBC is considered an autoimmune disease, often associated with other autoimmune disorders.[508,509] The pathogenesis is complex, involving genetic predisposition as well as environmental factors, which remain incompletely understood.[510] The basic lesion is a chronic, nonsuppurative, destructive cholangitis, eventually ending in cirrhosis.[511] The disease is nearly 10 times more frequent in females than in males and usually has an insidious onset starting with pruritus. Characteristic of PBC is the presence of antimitochondrial antibodies (AMAs), the most specific being directed against the M2 component of the pyruvate dehydrogenase complex, detectable in over 90% of patients.[512] Liver biopsy plays an important role in the diagnosis and staging of PBC.[513,514]

The bile duct lesion in the early stage of PBC initially affects ducts ranging from less than 40 to more than 80 µm in external diameter, destroying the smaller ducts first.[515] Septal ducts are affected to a lesser degree.[505] Canals of Hering are also destroyed in PBC in concert with the destruction of small bile ducts; this destruction appears to be an early event.[516] The actual size of the ducts may on occasion be difficult to estimate since some of them tend to enlarge, apparently through damage to the basement membrane and reactive hyperplasia of the lining epithelium.[517] The early lesions are focal in the liver and segmental within the duct system. The affected duct

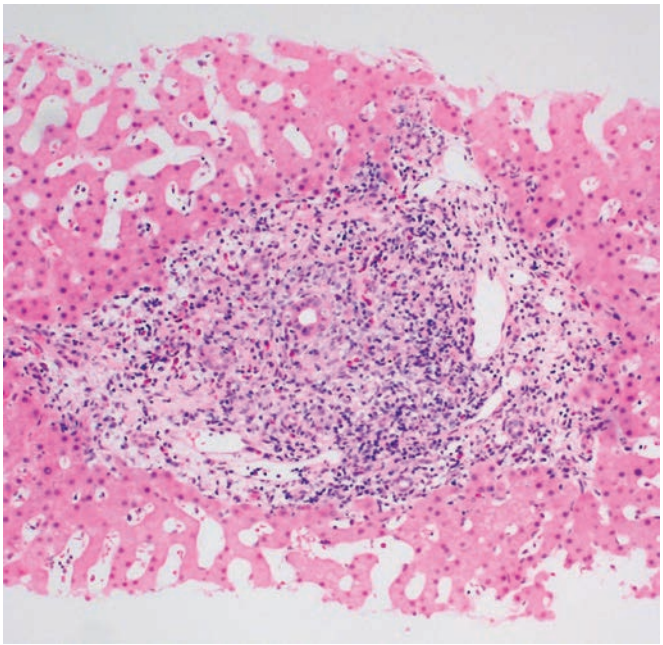

Figure 19.46 A portal tract in primary biliary cirrhosis contains a nodular mixed inflammatory infiltrate consisting of lymphocytes, plasma cells, numerous eosinophils, and histiocytes. There is a damaged bile duct in the center of the portal tract.

segments show epithelial swelling and cytoplasmic vacuolization, nuclear disarray, and infiltration by lymphocytes and plasma cells, which may accumulate beside or around the duct. The inflammatory infiltrate is predominantly lymphocytic and sometimes forms lymphoid follicles with a germinal center. Plasma cells may be abundant, eosinophils quite prominent, and neutrophils may also be present (Fig. 19.46). Plasma cells in the portal tracts are predominantly IgM+, whereas in autoimmune hepatitis, plasma cells are predominately IgG+; therefore, immunostaining for IgM and IgG can be helpful in differentiating PBC from AIH.[518,519] An Italian study reported that the mean counts of IgM plasma cells in portal tracts correlated significantly with female gender; serum alkaline phosphatase, γ-GT and IgM values; positivity for AMA M2, and, on liver biopsy, with bile duct changes, orcein-positive granules, and granulomas. In contrast, IgG plasma cell mean counts correlated more with alanine aminotransferase levels. IgG/IgM ratios lower than 1 were found not only in PBC but also in all cases of autoimmune cholangitis. In contrast, all patients with overlap syndrome showed IgG/IgM ratios higher than 1.[520]

Single or small clusters of epithelioid cells may be present, and in some cases epithelioid granulomas develop close to or surrounding the bile duct. The florid bile duct lesion in PBC can thus be categorized as lymphocytic, pleomorphic, or granulomatous cholangitis (Fig. 19.47), the latter being the most diagnostic.[480] Smaller ducts may be surrounded by edema or fibrosis, presumably as a result of more distal obstruction, and damage of the basement membrane (often most visible with PAS/diastase stain) may lead to rupture of the duct. Parenchymal lesions of chronic cholestasis are absent or minimal at the early stage.

Sampling variability means that not every liver biopsy from a patient with PBC in this stage reveals the characteristic bile duct lesions, making a firm histologic diagnosis challenging. The presence of periportal copper deposition may be extremely helpful.[521]

The majority of patients show histologic progression within 2 years; a minority (20%) remain histologically stable, whereas sustained

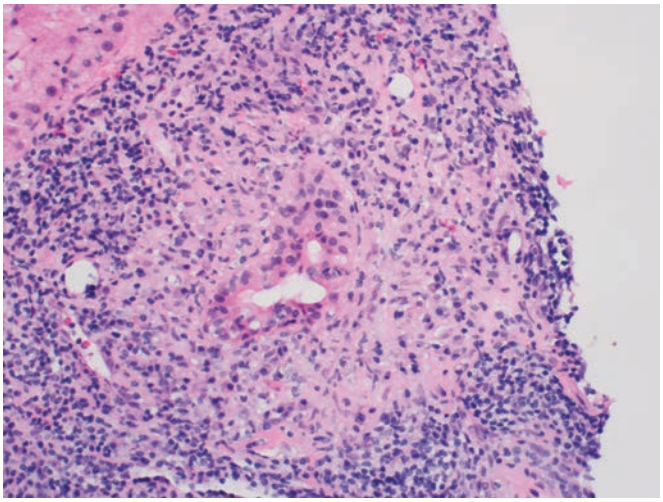

Figure 19.47 Florid Duct Lesion in Primary Biliary Cirrhosis. A loose portal granuloma with admixed lymphocytes and plasma cells is centered on a damaged duct that is infiltrated by lymphocytes and shows marked epithelial disarray.

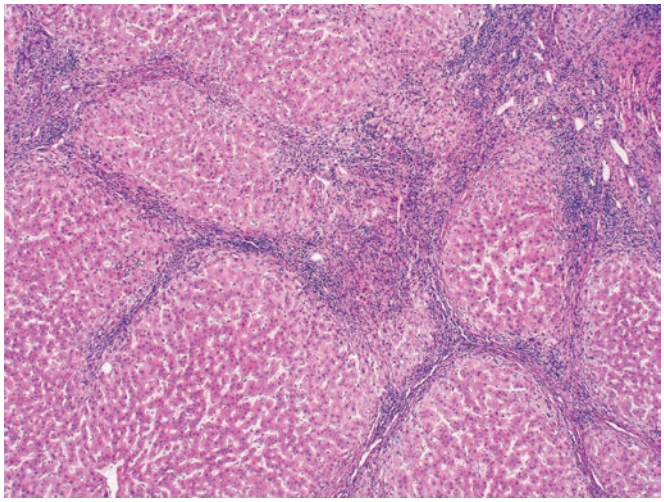

Figure 19.48 Biliary-type cirrhosis in primary biliary cirrhosis, featuring irregular cirrhotic nodules, lymphocytic interface hepatitis, and ductopenia.

regression is rare (2%).[522] Basically, two processes appear to drive histologic progression: the periportal and architectural changes associated with chronic cholestasis (see earlier), and lymphocytic interface hepatitis (piecemeal necrosis).[492,523] As in chronic hepatitis, the intralobular "invading" lymphocytes of interface hepatitis play a role in the development of septal fibrosis,[524] and some degree of lobular necroinflammatory activity may be present as well.[525] However, prominent interface activity and lobular inflammation should raise the question of an overlap syndrome (see later). Histologic stage and severity of lymphocytic interface hepatitis are independent predictive factors for the development of cirrhosis in ursodeoxycholic acid (UDCA)-treated patients with PBC, which suggests that liver biopsy may be necessary to follow UDCA-treated patients who might require additional therapy.[526,527]

Ultimately, progressive ductopenia develops, and in advanced cases, portal lymphoid aggregates mark the former site of bile ducts that have disappeared. Telomere shortening and accumulation of DNA damage coincide with increased expression of p16(INK4a) and p21(WAF1/Cip1) in the damaged bile ducts, reflecting ongoing biliary cellular senescence, and play a role in subsequent progressive bile duct loss in PBC.[528]

The combination of cholestatic and hepatitic features results in progressive fibrosis with portal–portal septum formation, followed by additional portal–central septa.[524] When cholestatic features predominate, the eventual resulting cirrhosis is of the biliary type (Fig. 19.48), whereas in cases with predominance of hepatitic features, the cirrhosis may be macronodular; any combination of the two patterns can also occur. The hepatitic-type lesions appear to be the most important for the progression of fibrosis.[492,529] One study suggested that aberrant expression of keratin 7 in hepatocytes (see earlier) may be a marker for the degree of cholestasis and for progression in PBC,[530] expressing the failure of adaptive mechanisms against bile acid overload.[472]

Several staging systems have been proposed for PBC.[490,491] The most popular staging system, which is applicable to any vanishing bile duct disease, is that of Ludwig et al.,[490] which distinguishes four stages: portal (stage 1); periportal (stage 2); septal fibrosis (stage 3); and cirrhosis (stage 4). Staging of PBC in small needle biopsy specimens is valuable as long as it is interpreted with caution, bearing in mind that there is considerable variability in the degree of fibrosis in different parts of the liver.[531] As mentioned previously, new staging systems have been proposed more recently, some of which aim to provide more correlation with clinical laboratory data,[532] and some of which take inflammatory activity into consideration as well as fibrosis and other features of chronic cholestasis.[492,532]

Liver cell dysplasia of the large and small cell type may be present,[533] and the risk for development of hepatocellular carcinoma is also increased in PBC, particularly in patients with cirrhosis.[534–536] Nodular regenerative hyperplasia has also been described in association with PBC[537]; together with narrowing of portal vein branches,[538] this may explain the development of portal hypertension in some patients even before the development of fibrosis and cirrhosis.

The differential diagnosis of PBC requires consideration of two groups of diseases. Early-stage PBC must be distinguished from other diseases characterized by portal inflammation and bile duct damage, such as chronic hepatitis C, and later stage PBC must be differentiated from other chronic ductopenic diseases.

In the bile duct lesion in viral hepatitis C, the affected duct segment shows vacuolization and stratification of cholangiocytes, with less marked duct damage and preservation of the basement membrane.[204] Cholestatic features are absent as well. Although focal lymphocytic cholangitis and mild bile duct damage is occasionally seen in autoimmune hepatitis, significant duct damage and copper deposition are not, and the degree of inflammatory activity is typically much less in PBC than autoimmune hepatitis. As mentioned previously, immunohistochemistry for IgM and IgG may also be helpful. Drug-induced bile duct damage is also in the differential diagnosis, and clinical history and a positive AMA may be invaluable in this circumstance. Other conditions characterized by bile duct damage and granulomas include sarcoidosis and granulomatous infections. The latter may cause real problems of differentiation, as it also may lead to ductopenia and chronic cholestatic liver disease (see later); the final diagnosis requires consideration of the clinical context and laboratory data.

Autoimmune cholangitis[539] or *autoimmune cholangiopathy*[540] is clinically, biochemically, and histologically very similar to PBC, but AMAs are negative, hence the alternative term AMA-negative PBC.[541,542] Clinically and histologically there are no discernable differences, although the diagnostic threshold tends to be higher, and the treatment and prognosis mirror that of classic PBC.

Primary Sclerosing Cholangitis

PSC is a rare but important liver disease that leads to cirrhosis and the need for liver transplantation in a high proportion of cases.[543] The disease occurs in approximately 1 per 100,000 people per year and usually presents in adulthood but does occur—albeit rarely—in children; men are affected more often than women. The natural history of PSC is variable, the average survival being 12–17 years. The cause remains unknown, although a number of genetic associations have been identified, many of which overlap with those found in other autoimmune diseases.[543] Other hypotheses include ischemic injury ("arteriosclerosis of the bile duct") initiated by toxic biliary lipids,[544] and alterations in the gut microbial composition.[543] Many patients (approximately 70%) with PSC suffer from inflammatory bowel disease as well, often a distinct phenotype that most resembles ulcerative colitis but has a higher incidence of pancolitis, backwash ileitis, and rectal sparing.[545] It has also been hypothesized that aberrant expression of endothelial adhesion molecules, cytokines, and chemokines secondary to colitis may contribute to the development of PSC.[543]

PSC is characterized by inflammation, strictures, and saccular dilations in the biliary system; any part of the biliary tree may be involved. The majority of PSC patients have involvement of both large and small ducts. "Small duct PSC" corresponds to involvement of only the microscopically identifiable (septal and interlobular) intrahepatic bile ducts, previously classified by the now obsolete term "pericholangitis."[546] A high prevalence of small duct PSC is found among patients with overlapping features of AIH and PSC.[547] Cholangiography and microscopic examination of a liver biopsy are complementary investigations in PSC, with primary importance given to cholangiography.

The histopathologic changes in the liver biopsy of patients with PSC depend on the stage of the disease and on the site of the biopsy in relation to the duct lesions caused by the disease. In portal tracts proximal to strictures, only features of obstruction and cholangitis may be seen.

Portal tracts affected by the primary disease may show pleomorphic and fibro-obliterative cholangitis,[480] the characteristic lesion of PSC, occasionally characterized by onion-skin type periductal fibrosis (Fig. 19.49A and B) with degeneration and atrophy of the epithelial lining. Chronic portal inflammation is variably present. This results in disappearance of the duct and its eventual replacement by a fibrous scar. Occasionally, however, biopsies show only duct atrophy with associated ductular reaction (Fig. 19.50). Loss of ducts is more frequent in smaller portal tracts, whereas periductal fibrosis is more often seen in medium-sized tracts.[548] Periductal fibrosis is not a pathognomonic lesion, as it can also be observed in other types of biliary disease, but it is a very suggestive and helpful finding. It is important to recognize, however, that it is not present in every stage of the disease or in all cases and is found in fewer than 40% of biopsy specimens.[480] PAS–diastase staining may reveal thickening of the basement membrane around damaged ducts (Fig. 19.51), or wrinkled empty basement membranes.[549] In some patients, the scars of the vanished bile ducts are unusually prominent, resembling keloid scars.[550,551] The parenchymal changes in PSC are less striking than the portal ones, and correspond to features of chronic cholestasis when present, including periportal copper deposition.

In patients with longstanding and more severe disease, portal fibrosis is more marked, fibrous septa develop, and biliary cirrhosis ensues. More progressive disease is characterized by moderate to severe lymphocytic interface hepatitis.[552]

The most dreaded complication of PSC is cholangiocarcinoma.[553] Patients with PSC and inflammatory bowel disease also have a high long-term risk of developing colorectal carcinoma, however, and

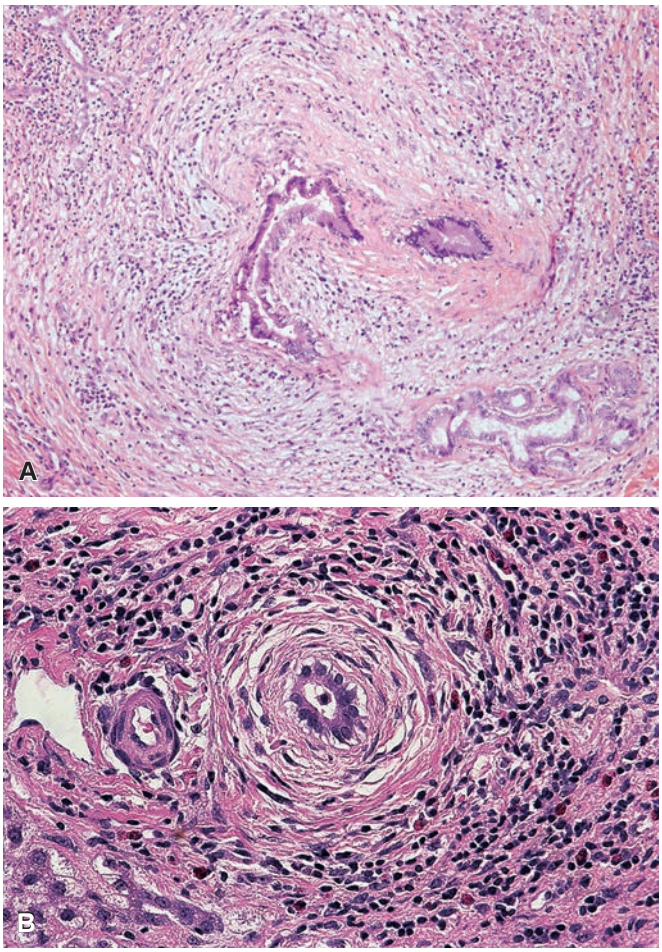

Figure 19.49 **A,** Primary sclerosing cholangitis showing a damaged bile duct with surrounding edema, concentric fibrosis, and lymphoplasmacytic inflammation. **B,** Detail of portal tract with moderately dense inflammatory infiltrate (mainly lymphocytes, some eosinophils) and concentric, lamellated, periductal fibrosis ("onion skin" fibrosis) around the interlobular bile duct.

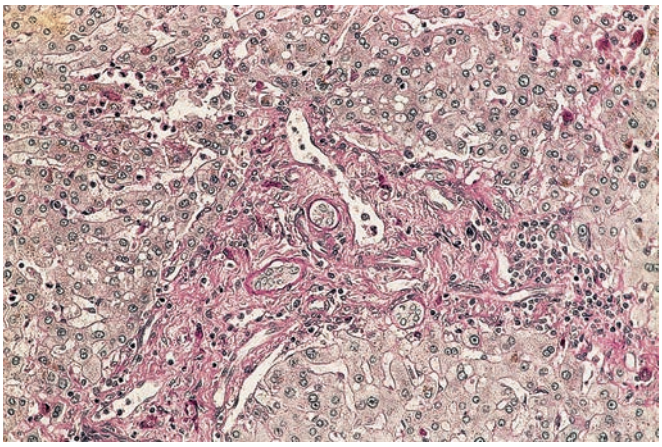

Figure 19.51 Primary Sclerosing Cholangitis. Overview of portal tract and periportal parenchyma. This portal tract shows only mild inflammation; two interlobular bile ducts show clear-cut thickening of their basement membrane on PAS/diastase, a helpful diagnostic feature.

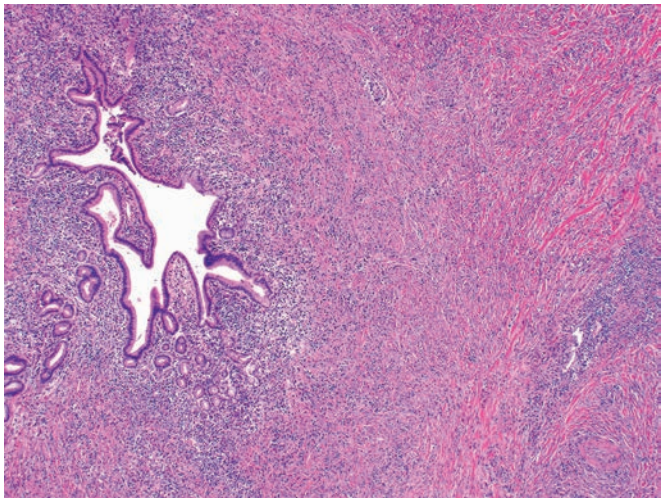

Figure 19.52 IgG4-associated sclerosing cholangitis featuring marked periductal lymphoplasmacytic inflammation and surrounding storiform fibrosis in a large intrahepatic bile duct.

this risk is about threefold higher than the risk for cholangiocarcinoma.[554] A strong association has been found between dysplasia of bile duct epithelium and cholangiocarcinoma in PSC, suggesting that biliary dysplasia might be used as a marker for current or developing malignancy (see also Chapters 20 and 21).[555] The results of a review of 100 consecutive formalin-fixed PSC liver explants (including 30 with cholangiocarcinoma) strongly supported a metaplasia–low-grade dysplasia–high-grade dysplasia–carcinoma sequence in PSC-associated cholangiocarcinoma, and underscored the lack of correlation between patient age, duration of PSC, and the development of cholangiocarcinoma. Dysplasia is generally confined to large and septal-size bile ducts, and its presence may not be recognized unless multiple sections of this caliber duct are examined.[556]

The main differential diagnoses for PSC are chronic hepatitis and other ductopenic diseases, particularly PBC and IgG4-associated sclerosing cholangitis (see later). Chronic hepatitis lacks periductal fibrosis, ductopenia, and other cholestatic features; in addition, PBC may be difficult to differentiate from PSC in the later stages, but in earlier stages PBC typically features more prominent inflammation, florid duct lesions, and granulomas. Of note, however, epithelioid granulomas can also be found in about 4% of PSC cases but not as part of granulomatous cholangitis.[557] Female gender and positive AMA also strongly favor PBC. An overlap syndrome between autoimmune hepatitis and PSC has been described (see later).

IgG4-Related Sclerosing Cholangitis (IgG4-SC; IgG4-Related Hepatopathy; Autoimmune Pancreatocholangitis)

Although first described in 1961, autoimmune pancreatitis was not widely recognized as an autoimmune condition until 1995. It has now become apparent that this form of pancreatitis is part of a clinical syndrome that commonly affects multiple organs (see also Chapters 21 and 22).[558] Many terms have been proposed to describe the condition, but "IgG4-related systemic sclerosing disease" appears most appropriate. Affected extrapancreatic tissues include the biliary tract, liver, kidneys, and lung, but a wide range of other sites may be involved.[559]

Grossly, IgG4-SC may produce fleshy lesions along the biliary tree, and imaging studies may mimic either PSC or cholangiocarcinoma.[558] One of the most common histopathologic features is the presence of numerous IgG4+ plasma cells within involved tissues, as well as lymphoplasmacytic infiltration of the duct with extensive storiform fibrosis, and obliterative phlebitis, similar to IgG4-associated sclerosing pancreatitis (Fig. 19.52). Peribiliary glands are also severely affected. Bile duct epithelia are relatively spared in IgG4-SC in comparison with those of PSC. In some cases numerous IgG4+ plasma cells are also found in small portal tracts. The distinction from PSC may be very difficult, but the finding of more than 10 IgG4-positive plasma cells per high-power field and an IgG4/IgG ratio of more than 40% favor IgG4-SC, as does the presence of storiform fibrosis, elevation of serum IgG4, and involvement of other organs.[558,560,561] However, these histologic changes are often lacking on needle biopsy.[558] Although cases of PSC may show increased numbers of IgG4+ plasma cells, they are typically not as numerous as IgG4-SC, and IgG4-SC does not typically have "onion-skin" fibrosis or significant ductopenia affecting small ducts; however, we have seen rare cases of IgG4 disease with these features. Interestingly, hepatic inflammatory pseudotumor (HIP) has also been associated with IgG4-SC and is considered a local exaggeration of IgG4-SC.[562] Therapeutically, IgG4-SC responds very well to steroid therapy, and thus the distinction from PSC has considerable clinical importance.[563,564]

Secondary Sclerosing Cholangitis

Progressive sclerosing cholangitis after septic shock and trauma represents a more recently described variant of vanishing bile duct disorders in which the liver may progress rapidly to cirrhosis.[565–568] It is probably caused by ischemia of the intrahepatic bile ducts via the peribiliary capillary plexus due to arterial hypotension.[569] A similar variant of secondary sclerosing cholangitis occurring after long-term treatment in intensive care units (ICU-SSC) has also been described.[570] *Ischemic cholangitis* (or cholangiopathy) is a result of impaired blood supply to the biliary tree, often due to injury during surgery, infusion of hepatic arterial chemotherapy, or radiation.[571]

Although PSC certainly occurs in the pediatric population (see earlier), several other forms of sclerosing cholangitis in childhood are worthy of mention.[568] Sclerosing cholangitis may occur in the context of common variable immunodeficiency and other immune deficiency disorders, CF, and Langerhans cell histiocytosis.[572,573] *Neonatal sclerosing cholangitis* is a poorly understood entity that presents

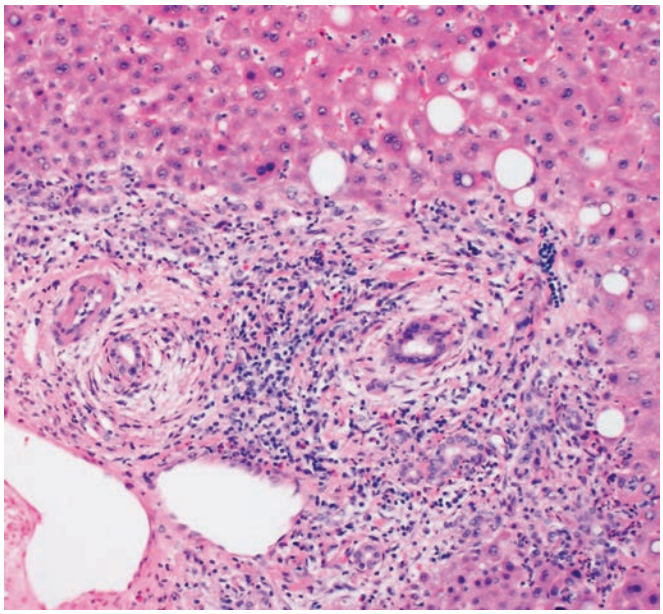

Figure 19.53 Extrahepatic large bile duct obstruction featuring portal edema, a mixed portal inflammatory infiltrate, and ductular reaction with admixed neutrophils.

within the first 2 weeks of life and is associated with parental consanguinity and extrahepatic manifestations. The pathology on liver biopsy resembles BA.[573]

Large Duct Obstruction (Hilar and Extrahepatic)

A very large number of entities, such as gallstones, bile duct strictures, and tumors, may cause complete or incomplete obstruction of the larger bile ducts. Acute complete obstruction induces the full clinical picture of obstructive jaundice, and histopathologically the sequence of changes described previously under acute complete cholestasis (Fig. 19.53). Chronic complete obstruction shows all the components of chronic cholestasis also described previously and eventually results in secondary biliary cirrhosis. An additional rarely seen lesion, which is near-pathognomonic for longstanding large duct obstruction, is rupture of an interlobular duct with escape of bile into the portal connective tissue, giving rise to a *bile extravasate*, which in turn induces a foreign body giant cell reaction. Chronic incomplete obstruction presents clinically as an anicteric cholestasis, with elevated serum levels of alkaline phosphatase, 5′-nucleotidase, and γ-GT, but no increase in serum levels of conjugated bilirubin. In parallel, histologic bilirubinostasis remains absent for long periods of time, and liver biopsy shows parenchymal and periportal features of chronic cholestasis. Chronic incomplete obstruction may arise in the context of postoperative strictures of the common bile duct, large duct sclerosing cholangitis, and annular pancreas, among others.[574]

Miscellaneous Ductopenic Diseases

Ascending cholangitis. Incomplete bile duct obstruction predisposes to bacterial infection. In bacterial ascending cholangitis, the number of neutrophils infiltrating the portal tracts is higher than in aseptic bile duct obstruction, and numerous neutrophils are typically found in the wall and inside the lumen of portal ducts as well. Interlobular ducts are often more affected than larger ducts.[575] The inflamed duct may rupture, resulting in portal abscess formation. Associated lesions include lobular abscesses and sinusoidal neutrophil infiltration, and thrombosis and thrombophlebitis of portal vein branches with the sequel of parenchymal necrosis. Bilirubinostasis is not an obligate feature.[576,577] Ascending cholangitis may be caused by choledocholithiasis, cholecystitis, strictures of any cause, biliary parasites, cholangiocarcinoma, and Caroli disease. In immunodeficient patients (e.g., AIDS), cholangitis is often due to *Cryptosporidium*, CMV, or species of *Microsporidia*.[274,578] Cholangitis easily gives rise to septicemia, in which the lesion of ductular bilirubinostasis is an important diagnostic feature (cholangitis lenta; see earlier). Persistent cholangitis may result in biliary-type cirrhosis.

PILBD is subdivided according to associated clinical features into a syndromic (e.g., AGS) and a nonsyndromic variety. The paucity of ducts is determined by calculating the bile duct to portal tract ratio as mentioned previously. However, in premature infants, a ratio of less than 0.9 may be normal due to the incompleteness of bile duct development at the time of birth.[579] Full development of the finest ramifications of the intrahepatic bile duct system takes an additional 4 weeks.[580] Both categories are characterized by a nonspecific, inflammatory destruction of interlobular ducts, resulting in progressive ductopenia. Both syndromic and nonsyndromic forms typically occur in the pediatric population and are characterized by histopathologic changes of neonatal cholestasis (see earlier) in addition to duct loss. These entities are discussed in detail later. Vanishing bile duct diseases in adulthood comprise a number of different disorders, listed in Box 19.1.

Idiopathic adulthood ductopenia is a term proposed for chronic cholestasis and ductopenia in adults in whom all other possible causes of ductopenia has been excluded.[581,582] Familial cases have been described.[583] Studies of biliary transporter proteins have identified a subgroup of patients with *MDR3-related sclerosing cholangitis*, in which a missense mutation in the phospholipid translocase *MDR3* was found to be responsible for ductopenic chronic liver disease in adulthood in a family from an isolated population in Transylvania. Allelic status correlated with severity of liver disease, ranging from ICP through fibrosis, cirrhosis, and death in both childhood and adulthood, leading to the recommendation that mutational analysis of *ABCB4* should be considered in all patients with cholestatic liver disease of unknown etiology regardless of age at onset of disease.[584] Another study detected heterozygous *MDR3* mutations in 34% of adults with unexplained cholestasis, mostly without biliary symptoms but sometimes resulting in significant liver fibrosis.[585] These findings resemble the bile duct injury in the ortholog of human *MDR3* (Mdr2) (abcb4) knockout mice (Mdr2(−/−)) as a novel model of sclerosing cholangitis.[586,587] Interestingly, patients with idiopathic adulthood ductopenia may be entirely asymptomatic.[588] Some of these cases may be drug related, which is discussed earlier.

Chronic liver allograft rejection is characterized by ductopenia ("ductopenic rejection"), as is **chronic graft-versus-host disease** (see later). Finally, ductopenia is a possible sequel of sarcoidosis, histiocytosis X, Hodgkin lymphoma, mucoviscidosis, and hemophagocytic lymphohistiocytosis.[589]

Autoimmune Hepatitis

Autoimmune hepatitis is a chronic disease, typically affecting women, which is divided into two main types depending on the autoantibody profile: Type 1, associated with positive ANA and/or anti-smooth muscle antibodies, and Type 2, associated with anti-liver kidney microscomal type 1 or type 3 antibodies, or anti-liver cytosol type 1 antibody.[590,591] Correct diagnosis is important, as patients often benefit from immunosuppressive therapy.

The histopathology may overlap with chronic hepatitis of other etiologies, but there are some suggestive features.[590,592,593] Necroinflammatory activity tends to be marked in untreated patients and may

include confluent bridging necrosis, marked interface hepatitis, and hepatocyte rosettes (Fig. 19.54A–C).[119] Multinucleated giant hepatocytes may be found,[594,595] although they also occur in other types of hepatitis.[119] The inflammatory infiltrate is mainly composed of lymphocytes, but plasma cells are a prominent component, often in clusters.[199] Lymphoid aggregates and follicles may be present but less often than in viral hepatitis C.

Immunosuppressive treatment reduces the severity of necroinflammation and fibrosis.[596] "Overlap" syndromes with features of both autoimmune hepatitis and biliary disease have been reported (see later); this issue is confounded by the fact that bile duct lesions, even destructive ones, may occur in genuine autoimmune hepatitis, particularly in severe cases.[597] Centrilobular necrosis with a relatively mild portal infiltrate has been described in some patients with steroid-sensitive AIH, making differentiation from toxic hepatitis difficult.[598] AIH may also occur in childhood, in which case multinucleated hepatocytes are more frequent.

AIH is considered a chronic disease, but it may have an acute onset.[599] Acute AIH and acute exacerbations in chronic AIH may show features of severe acute hepatitis, including interface or lobular hepatitis with lymphoplasmacytic infiltration, hepatocyte rosettes, centrilobular necrosis with plasmacytic infiltration, and giant cell hepatitis. CK19-positive cholangiolar cell proliferation can occur in the periportal areas in cases of massive necrosis, and bile duct injury may be seen more frequently than in classic chronic AIH.[600]

AIH is mainly a clinical and serologic diagnosis, with histopathology serving as supporting or suggestive evidence, but biopsy findings are an important source of information on degree and stage of liver damage, and possibly superimposed disease. For clinical diagnosis, diagnostic scores based on several parameters are used.[590,601–602]

Differentiation from PBC may be difficult. AIH typically lacks the florid duct lesions, bile duct loss, copper deposition, and granulomas often seen in PBC; in addition, AIH typically features markedly elevated transaminases, whereas PBC patients more often have normal or near-normal transaminases in the face of an elevated alkaline phosphatase. Immunostaining for IgG and IgM may be helpful, since plasmacytic infiltrates expressing predominantly IgM are characteristic of PBC, while other forms of liver disease, including AIH, typically show an IgG-predominant plasma cell infiltrate.[518,519] However, this is not always the case. Some studies have also reported increased numbers of IgG4+ plasma cells in a subset of patients with AIH, but the significance of this remains to be elucidated.[603]

Overlap syndromes have been described in which patients present with clinical, serologic, and histologic features of both PBC and AIH, or of AIH and PSC, either simultaneously or sequentially. The AIH–PBC overlap syndrome is the most common form, affecting almost 10% of adults with AIH or PBC. Such cases are histologically characterized by higher serum transaminases and more prominent interface and lobular necroinflammatory activity than typically seen in PBC, and these cases may require immunosuppressive therapy in addition to UDCA.[604]

The AIH–PSC overlap syndrome is predominantly found in children,[605,606] adolescents, and young adults with AIH or PSC (up to 25% of cases with PSC), in which it is often termed *autoimmune sclerosing cholangitis*.[607] The histologic changes of PSC may be absent in one-fourth of pediatric patients with abnormal cholangiograms, however, in which case this overlap syndrome can only be diagnosed by cholangiographic studies.[608] A French study of a cohort of adult patients with AIH noted that the prevalence of sclerosing cholangitis was only 1.7%, with only mild abnormalities of the intrahepatic bile ducts on imaging in one-fourth of patients.[609,610]

A significant reduction in survival has been reported in patients with PSC–AIH overlap syndrome versus those without. Patients with PSC–AIH also have a significantly worse prognosis than patients

Figure 19.54 Autoimmune Hepatitis. with AIH or PBC–AIH overlap. Without treatment, there is progressive course towards liver cirrhosis and liver failure.[611,612]

Cirrhosis

Cirrhosis is the end stage of many chronic liver diseases. This term refers to diffuse hepatic fibrosis with replacement of normal lobular architecture by parenchymal nodules separated by bands of fibrous tissue.[613] Portal–central fibrous septa linking portal tracts and central veins are an important component of cirrhosis, as they create portohepatic vascular shunts. Cirrhosis may be strongly suspected on clinical, laboratory, and imaging parameters, but the final diagnosis mostly requires morphologic confirmation by liver biopsy. Architectural changes are histologically best appreciated on a trichrome or reticulin stain.[614]

Biologically, cirrhosis is the final result of the interplay between ongoing inflammation, parenchymal damage, fibrogenesis and fibrolysis, and hepatocellular regeneration. Chronic or repetitive liver damage incites an inflammatory response and activation and proliferation of mesenchymal cell populations within the liver, which remodel the extracellular matrix similar to that which occurs in a wound-healing response. Progressive scarring (fibrosis) takes place, which eventually alters organ structure and function, resulting in cirrhosis and ultimately liver failure. The mesenchymal cells (fibroblasts) are derived from sources both within and outside the liver. Within the liver, fibroblasts expressing alpha-smooth muscle actin (myofibroblasts) are derived from the trans-differentiation of quiescent hepatic stellate cells; others emerge from the portal tracts. In chronic liver disease, at least a proportion of the fibroblasts originate from the bone marrow. In addition, fibrogenic fibroblasts may be generated through liver epithelial (hepatocyte and biliary epithelial cell)–mesenchymal transition. Regardless of origin, the fibrogenic fibroblast is sensitive to the cytokines and chemokines coming from the resident liver macrophages and infiltrating inflammatory cells. Insight into the complexity of hepatic fibrogenesis has markedly increased in recent years, with growing evidence for the participation of epithelial–mesenchymal transition in chronic liver disease. Several comprehensive reviews of the topic are available.[483,615–619]

Mesenchymal tissue in the liver is not static, and homeostasis of connective tissue is ensured by a correct balance between fibrogenesis and fibrolysis. Fibrosis results from an imbalance that favors fibrogenetic mechanisms. When the trigger(s) causing the imbalance disappear(s), either spontaneously or as result of therapy, the normal equilibrium may be restored and fibrosis regresses either completely or partially, depending on a number of variables, including the amount, the composition, and the structure of the excess connective tissue. The implication of this is that fibrosis in chronic liver diseases is reversible (to variable extent), on the condition that the underlying necroinflammatory processes cease, and as long as the fibrosis is not yet associated with complications such as vascular thromboses,[620] neovascularization of fibrotic areas,[621] portovenous shunts in collapsed zones of parenchymal confluent necrosis, and nodular parenchymal regeneration. Therefore, for prognostic reasons, it is important to distinguish lesser degrees of fibrosis from established cirrhosis.[622,623]

Historically, the morphologic classification of cirrhosis is based on the size of the nodules.[613] Cirrhosis is *micronodular* if nearly all of the nodules are less than 3 mm in diameter (Fig. 19.55), and *macronodular* if greater than 3 mm in diameter (Fig. 19.56). A mixed pattern consists of approximately equal numbers of nodules greater than and less than 3 mm in diameter. The size of the nodules has some use in defining the etiology of the process, but this is relative since many cases of cirrhosis have a mixed pattern, as well as the fact that micronodular cirrhosis may convert into a macronodular type under circumstances more favorable for parenchymal regeneration.[624]

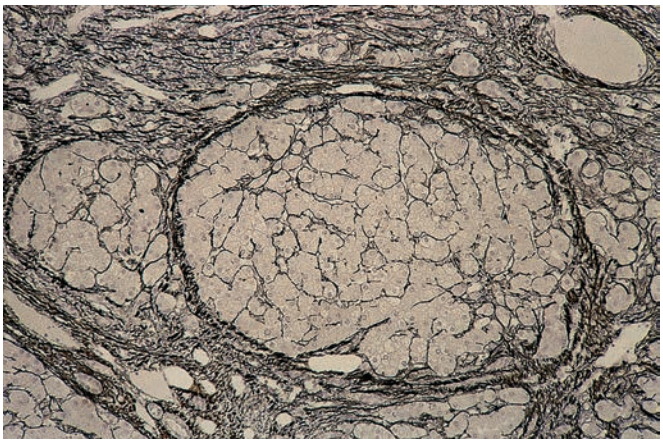

Figure 19.55 Detail from micronodular cirrhosis, reticulin stain.

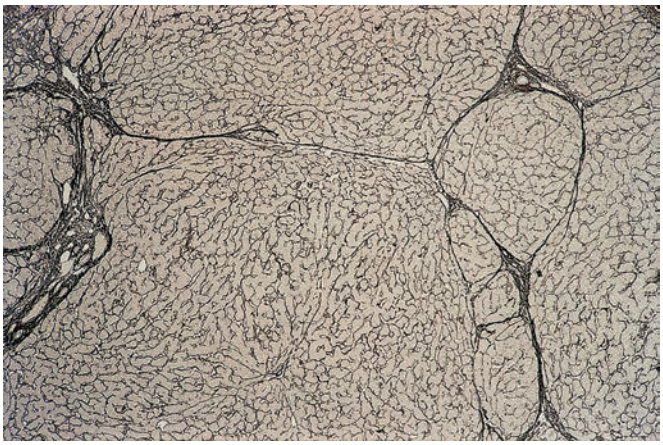

Figure 19.56 Detail from macronodular cirrhosis, reticulin stain. Note larger nodules, thin, fibrous septa, and irregular orientation of liver cell plates.

Nodular size is more important in determining the ease with which the diagnosis of cirrhosis can be made in needle biopsy specimens. Nodularity and septa may be readily evident in specimens from micronodular cirrhosis, whereas morphologic clues may be more subtle in macronodular cirrhosis. Helpful criteria in this latter situation include fragmentation of the biopsy specimen (especially with slender tissue cylinders provided by thin aspiration type needles such as the Menghini needle); thin layers of connective tissue adhering to rounded edges of nodular biopsy fragments; abnormal orientation of reticulin fibers resulting from different rates of parenchymal growth in different areas; abnormal spacing of portal tracts and central veins, and excess numbers of draining veins in relation to the number of portal tracts; presence of minute and poorly formed portal tracts ("mini-portal tracts"); hepatocellular features of regeneration—double-cell plates over widespread areas, different appearance of hepatocytes in adjacent areas; and liver cell dysplasia of the large cell and small cell type (see also Chapter 20).[625]

The most difficult anatomic type to recognize is *incomplete septal cirrhosis* (Fig. 19.57). This is characterized by vague nodularity; slender septa, some of which end blindly; mini-portal tracts; excess efferent veins; and sinusoidal dilation. There is evidence of parenchymal hyperplasia with corresponding compression of reticulin fibers in

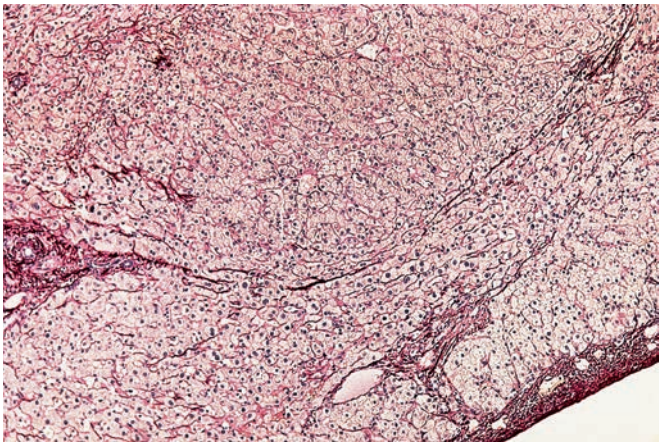

Figure 19.57 "Incomplete septal–type" cirrhosis can be considered a macronodular variety of cirrhosis with large multilobular nodules, thin, incomplete septa, and little inflammatory activity (Sirius red stain).

adjacent areas. Inflammation and necrosis are generally absent or minimal.[626] Many consider this to be a part of the spectrum of macronodular cirrhosis and, furthermore, that it may represent actual regression of cirrhosis (see later).[627] The ease with which cirrhosis is diagnosed further depends on the type of specimen (resection or needle biopsy), the type of needle used (aspiration type, Tru-cut, or transjugular), and the quality of the histologic preparation. In some instances, particularly on needle biopsy, the pathologist can only hint at the possibility of cirrhosis.

Besides confirming the presence or absence of cirrhosis and the size of the nodules, liver biopsy may further permit assessment of the underlying etiology of the liver disease. In many instances this may require additional stains, as well as knowledge of clinical and laboratory data. Unfortunately, in many cases of fully developed cirrhosis, the original etiology of the liver disease is not apparent.

The pattern of nodules and fibrosis may be helpful. Biliary cirrhosis is characterized by garland-shaped nodules, and clues to a biliary etiology include a clear halo in the nodular periphery due to edema, cholate stasis, and ductular reaction. Ductopenia may be a further indicator of chronic biliary disease. Chronic venous outflow obstruction leads to central–central fibrous septa, and may result in "cardiac-type cirrhosis" or cardiac sclerosis with normal-looking portal tracts centered within the parenchymal nodules.[628] Although the degree of steatosis may significantly regress in both NASH patients who have had the underlying causes of their disease treated, and patients with alcoholic liver disease who have stopped drinking, pericellular fibrosis may be a residual clue to the original disease. In fact, many patients with cirrhosis who lack any other etiologic markers ("cryptogenic" cirrhosis) are believed to have "burned-out" NASH.[629]

Ground-glass hepatocytes may help in recognizing HBV infection, and HCV is suggested by lymphoid aggregates and lymph follicles. Numerous plasma cells are suggestive (but not proof) of autoimmune hepatitis. Genetic hemochromatosis is indicated by severe parenchymal siderosis.[630] Perinodular copper suggests biliary disease; however, copper deposition (rhodanine stain) and metallothionein (orcein stain) are found in cirrhosis of many causes,[631] so this finding is not specific. Positive staining of entire nodules may be seen in Wilson disease, although other nodules may be entirely negative. Abundant copper deposition is also noted in Indian childhood cirrhosis (ICC).[632] α1-AT deficiency is recognized by hepatocellular inclusions of this glycoprotein; they are eosinophilic, PAS positive, and diastase resistant and may be highlighted by immunostaining.[633] Of note, a characteristic of cirrhotic nodular parenchyma is the variability between individual nodules; that is, features such as steatosis, siderosis, and ground-glass hepatocytes may be abundant in one nodule but absent in the next, making needle biopsy evaluation even more difficult.

The histologic activity of a cirrhotic liver should be noted, as it may reflect ongoing disease even in the face of established cirrhosis. Activity consists of the various forms of liver cell damage and inflammation seen in the precirrhotic stage of the disease, for example, interface hepatitis or features of ongoing steatohepatitis. Inactive cirrhosis is characterized by the near absence of necroinflammatory lesions, and a sharp delineation between the paucicellular septa and nodules. Further useful information for the clinician that can be recognized in cirrhotic liver include some of the complications of cirrhosis. Coagulative necrosis of entire nodules or of their centers (*"nodular infarction"*) is seen in hypoperfusion (caused by hypotension due, for instance, to bleeding from esophageal varices).[634] The decompensation phase of a cirrhotic liver often shows severe bilirubinostasis in a background of nonbiliary cirrhosis.[614] *Hepatocellular carcinoma* may arise in the cirrhotic liver, and its putative precursor lesions (dysplastic foci, large cell and small cell change) should be reported (see also Chapter 20).

As mentioned previously, there are ongoing investigations regarding the reversibility of cirrhosis. Reversibility of cirrhosis is rarely complete, due to the advanced stage of fibrosis and the vascular complications that are often present in end-stage liver disease. The reversibility appears to depend on several variables; early fibrosis is more reversible than older, more established fibrous tissue; thin septa resorb more easily than broad fibrous scars; acellular septa are more resistant to degradation than cellular ones; and perisinusoidal fibrosis disappears more easily than septa. Portal–portal and central–central septa may ultimately disappear to a large extent, whereas portal–central septa and areas of multilobular collapse are virtually irreversible due to the development of portohepatic venous shunts.[622,623] A decrease in necroinflammation is also associated with improved hepatocellular regeneration and increased size of parenchymal nodules. As noted previously, incomplete septal cirrhosis appears to correspond either to not yet fully developed macronodular cirrhosis or an intermediate regressive stage of cirrhosis.[627,635] Morphologic correlates to reversal of cirrhosis include delicate perforated septa, isolated thick collagen fibers, delicate periportal fibrous spikes, portal tract remnants, hepatic vein remnants with prolapsed hepatocytes, minute regenerative nodules, and aberrant parenchymal veins.[627]

Cirrhosis has to be distinguished from other nodular and fibrotic conditions of the liver. The differential diagnosis comprises nodular regenerative hyperplasia, congenital hepatic fibrosis (CHF), and focal nodular hyperplasia. Confusion with the latter is easily avoided if information is provided of a focal lesion in the liver rather than a diffuse process.

Childhood Disorders and Disorders of Metabolism

The histologic diagnosis of liver disease in neonates and young children requires knowledge of the particular lesions and diseases that are of diagnostic importance in this age group. Useful recommendations to general pathologists for handling of special pediatric liver biopsy specimens have been provided by subspecialty experts.[636]

Cholestatic Disorders

Several neonatal liver diseases are associated with cholestasis, rendering "neonatal cholestasis" a particular challenge for the pathologist.

The differential diagnosis involves BA, PILBD, biliary transporter deficiencies, disorders of bile acid metabolism, metabolic disorders, and viral infections, and the clinical and prognostic implications are significant.

Transporter deficiencies. This group includes PFIC types 1, 2, and 3, mentioned briefly previously; Greenland familial cholestasis; benign recurrent intrahepatic cholestasis (BRIC); and CF (mucoviscidosis).

PFIC-1 and *BRIC-1* are clinically distinct hereditary disorders. PFIC-1 patients suffer from chronic cholestasis and develop liver fibrosis. BRIC-1 patients experience intermittent attacks of cholestasis that resolve spontaneously. Mutations in *ATP8B1* (previously *FIC-1*, encoding adenosine triphosphatase (ATPase) class I, type 8B, member 1/phospholipid transporting ATPase IC) may result in either PFIC-1 or BRIC-1. *ATP8B1* is expressed in the canalicular membrane of normal hepatocytes and the apical membrane of ileal enterocytes, suggesting a role in the enterohepatic circulation of bile constituents. It functions as an aminophospholipid translocase (flippase), which flips phosphatidylserine and phosphatidylethanolamine from the outer into the inner leaflet of the cell membrane, ensuring membrane asymmetry, which is essential for maintaining the normal functional capacity of integral membrane proteins.[637–641] Mutation analyses of 180 families with PFIC or BRIC identified 54 distinct disease mutations, and the mutation type or location correlates overall with clinical severity, that is, the development of PFIC or BRIC. Mutations causing the complete absence of canalicular expression result in PFIC-1, whereas in BRIC-1 and ICP, residual protein is expressed in the canalicular membrane.[642]

PFIC-1 is a hereditary autosomal recessive syndrome, initially known as *Byler disease*. Clinically, it is characterized by severe low γ-GT cholestasis in infants and children and extrahepatic symptoms of diarrhea and pancreatitis. Histologic features include bland bilirubinostasis, minimal ballooning of hepatocytes, little or no ductular reaction, and slowly progressive fibrosis, ultimately ending in cirrhosis. Electron microscopy reveals a coarsely granular aspect of the canalicular bile deposits (Tables 19.4 and 19.5).[495,496,640] A severe variant of the disease is *Greenland familial cholestasis*,[643] a syndrome of intrahepatic cholestasis leading to death in early childhood, which was described among indigenous Inuit families in Greenland (Nielsen syndrome).[644]

Table 19.4 Morphologic distinction between progressive familial intrahepatic cholestasis-1 and progressive familial intrahepatic cholestasis-2

PFIC TYPE 1	PFIC TYPE 2
Bland bilirubinostasis is the most consistent feature	Severe neonatal hepatitis
Positive immunostaining for BSEP	Negative immunostaining for BSEP
EM: coarsely granular bile	EM: amorphous bile
Portal fibrosis with eventual progression to cirrhosis	Portal fibrosis with eventual progression to cirrhosis
Variably present bile duct injury and ductular reaction	Variably present bile duct injury and ductular reaction
Negative or decreased immunohistochemical staining for canalicular GGT	Intact immunohistochemical staining for canalicular GGT

PFIC-2 is a disease of low γ-GT cholestasis caused by mutations in the *ABCB11* gene on chromosome 2q24, which encodes the canalicular BSEP.[645] Human BSEP mutations are the molecular basis for at least three clinical forms of liver disease: PFIC-2, BRIC-2, and ICP. Mutations are associated with protein instability and ubiquitin-dependent degradation. The clinical phenotypes of PFIC-2, BRIC-2, and ICP may directly correlate with the amount of mature protein that is expressed at the canalicular cell surface.[646] The histopathology corresponds to that of severe so-called neonatal giant cell hepatitis, characterized by prominent centrilobular bilirubinostasis, clusters of ballooned hepatocytes, multinucleated parenchymal giant cells, increasing perivenular, pericellular, and periportal fibrosis that eventually evolves into cirrhosis, and mild ductular reaction. The canalicular bile plugs appear on electron microscopy as delicate wispy, amorphous material, contrasting with the coarsely granular appearance in PFIC-1. Phenotypic severity appears to correlate with BSEP immunohistochemistry and clinical outcome, in that BSEP as detected by immunohistochemistry is typically absent, or much reduced, in severe disease (see Tables 19.4 and 19.5).[495,496,647] BSEP deficiency in PFIC-2 also represents a previously unrecognized risk for hepatocellular carcinoma in young children.[648] In addition, development of intrahepatic cholangiocarcinoma has been reported in PFIC-2.[649] These observations suggest the need for surveillance for the development of hepatobiliary malignancy, and early consideration for liver transplantation. Interestingly, a subset of patients who undergo liver transplant for PFIC-2 develop post-transplant autoantibodies to BSEP, effectively resulting in disease recurrence.[650]

PFIC-3 is caused by mutations of the *MDR3* gene, encoding the canalicular phospholipid export pump MDR3.[651] This is a phospholipid translocase that flips phosphatidylcholine from the inner to the outer leaflet of the canalicular membrane, ensuring phospholipid–cholesterol–bile acid micelle formation in bile. Mutations lead to the formation of phosphatidylcholine-poor bile with a normal bile acid concentration. The high concentration of bile acids, in the absence of phospholipid–cholesterol–bile acid micelles, renders this bile toxic to the hepatocytes and to the bile duct epithelium, thus explaining the hepatocellular and cholangiocytic damage. Defects of *MDR3* result in impaired biliary excretion of phosphatidylcholine and a variety of cholestatic syndromes, ranging from PFIC-3 in neonates to biliary cirrhosis in adults. Moreover, *MDR3* mutations also predispose to ICP and drug-induced cholestasis.[652] Recent investigations in adult patients with unclarified chronic cholestasis revealed that *MDR3* mutations may also be involved in cholestatic liver disease of unknown etiology[585] or mysterious sclerosing cholangitis resulting in ductopenia.[584] In short, there is evidence that a biallelic or monoallelic *MDR3* defect causes or predisposes patients to six human liver diseases (PFIC-3, adult biliary cirrhosis, low phospholipid-associated cholelithiasis syndrome, transient neonatal cholestasis, ICP, and drug-induced cholestasis).[653]

PFIC-3 is characterized by elevated serum levels of γ-glutamyl transferase (γ-GT). Its histology, in contrast to most cases of PFIC-1 and PFIC-2, is characterized by inflammatory infiltration in portal tracts, damage to interlobular bile ducts, and ductular proliferation (see Table 19.5).[640] PFIC-3 corresponds to the previously recognized subgroup of patients with Byler syndrome characterized by elevated γ-GT in the serum, and ductular reaction morphologically.[654]

BRIC, as mentioned previously, is a recurrent cholestatic disorder in children and adults, caused, like PFIC-1 and PFIC-2, by mutations of the *ATP8B1* gene[655,656] and the *ABCB11* gene.[646] Contrasting with

BRIC, Benign recurrent intrahepatic cholestasis; *CFTR*, cystic fibrosis transmembrane conductance regulator; *HCC*, hepatocellular carcinoma; *MGCT*, multinucleated parenchymal giant cell transformation; *MRP2*, multidrug resistance associated protein 2 (canalicular multispecific organic anion transporter or cMOAT); *PFIC-1*, progressive familial intrahepatic cholestasis type 1; *PFIC-2*, progressive familial intrahepatic cholestasis type 2; *PFIC-3*: progressive familial intrahepatic cholestasis type 3.

PFIC-1, BRIC-1 is characterized by recurrent episodes of cholestasis that do not progress to cirrhosis. Nevertheless, considerable overlap may exist between the clinical presentations of PFIC-1 and BRIC-1, and both conditions may represent the extremes of a broad spectrum of cholestatic syndromes.[656] Analogously, PFIC-2 and BRIC-2 are both caused by mutations in the *ABCB11* gene, and phenotypic differences appear to correlate with the degree of mutation-dependent BSEP degradation.[646,657] Histologically, BRIC is characterized by simple or bland bilirubinostasis, with bilirubin deposits in hepatocytes, canaliculi, and Kupffer cells only during the episodes of clinical cholestasis. BRIC was previously also known as Summerskill–Tygstrup–De Groote disease.

Bile acid synthetic defects (BASDs) are uncommon genetic disorders that are responsible for approximately 2% of persistent cholestasis in infants.[658] These defects appear as familial and progressive infantile or late-onset "low γ-GT" cholestasis. Inborn errors have been demonstrated for four single enzymes involved in modification of the sterol nucleus and in five steps in modification of the side chain to form cholic and chenodeoxycholic acids, the primary bile acids. The degree of liver disease varies from mild to severe, depending on the defect. Although they may be life threatening, the disease is treatable, usually by replacement of deficient primary bile acids. Pathologic findings may include intralobular bilirubinostasis with multinucleated giant cell transformation, prevalence of necrotic hepatocytes including giant cell forms, and hepatitic injury confined to the portal limiting plate where the smallest bile ductules may be injured and where fibrosis typically develops. Interlobular bile ducts are usually spared. The ultrastructure of the liver reveals nonspecific changes with the possible exception of unusual canalicular morphology in some defects. The histopathology as such is not really diagnostic, falling into the category of "neonatal giant cell hepatitis" or "cryptogenic neonatal cholestasis" but may have a remarkable degree of multinucleated giant cell transformation.[659] Diagnosis rests on screening of biologic fluids (bile, blood, and urine) for abnormal bile acids by mass spectrometry.[660]

In *syndromic PILBD* (also known as AGS or *arteriohepatic dysplasia*), the absence of small interlobular bile ducts is associated with a set of clinical features (abnormal facies, vertebral, cardiac, ocular, and renal abnormalities) which, according to their presence or absence, result in a complete or incomplete syndrome.[661] The majority of patients have mutations of the *JAG1* gene.[662] Most patients have pruritus, elevated serum bile acids, and variable hyperlipidemia, which may be severe with formation of xanthomas.

Liver biopsy in early infancy shows variable bilirubinostasis and multinucleated giant cell transformation; later on, there may be clusters of xanthomatous cells and mild periportal fibrosis. Controversy exists about the initial presence of and ultimate disappearance of interlobular ducts, which is surprising since ductopenia is actually the hallmark of the disease. Interlobular bile duct proliferation and damage may be seen in newborns, but the ductopenia appears to be progressive and may be more easily seen in late infancy and early childhood as compared to newborns.[662] Approximately 15% of patients progress to cirrhosis requiring transplantation, but it is difficult to predict progression based on histologic or clinical features.[662] Lack of hepatocellular CD10 expression along bile canaliculi is physiologic in early childhood and persistent in AGS, which may help distinguish AGS from BA.[663]

The exact mechanism(s) leading to paucity of ducts in AGS remains unclear, but it does not appear to be due to an initial failure of interlobular bile duct development. The duct abnormalities may, in fact, result from defects in hepatic angiogenesis related to the underlying genetic mutations.[662]

Nonsyndromic paucity of interlobular ducts is a common diagnosis in patients with conjugated hyperbilirubinemia in the first month of life.[664] It may be an isolated hepatic abnormality (idiopathic) or one component of a more complex systemic process with or without a known cause. It is associated with many diseases including α1-AT deficiency, rubella, trisomy 21, Turner syndrome, and Byler disease. The destruction of interlobular ducts starts early (typically before 3 months of age), and the progression has been described as faster than in syndromic paucity.[664,665]

Extrahepatic bile duct atresia or BA. Despite the terminology "extrahepatic," BA is not restricted to the extrahepatic segments of the biliary system but also affects the intrahepatic ducts. It is a panbiliary disease characterized by progressive necroinflammatory destruction of the bile ducts with involvement of part or all of the extrahepatic duct system (see also Chapter 21). Two clinical patterns of BA have been described: a perinatal (or acquired) form, accounting for approximately 80% of affected infants, and an embryonic form, the latter often associated with congenital anomalies, including preduodenal portal vein, midline symmetric liver, intestinal malrotation, situs inversus, asplenia, and polysplenia. The former group is asymptomatic and anicteric at birth and develop jaundice during the first postnatal weeks, whereas the infants with the second pattern are jaundiced at birth.[666] Primary treatment consists of hepatic portoenterostomy or Kasai operation with resection of the obliterated extrahepatic ducts. The histopathology of these fibrous remnants reveals variable degrees of nonspecific inflammation, duct epithelial desquamation and necrosis, ulceration, and fibrosis.[667,668]

Attempts to correlate the number and size of the patent ducts in the porta hepatis at the time of portoenterostomy with the success of the procedure and future prognosis has yielded controversial results. Historically, pediatric surgeons insisted on assessment of bile duct luminal size in frozen sections of the proximal resection margin during a Kasai procedure, as some consider the total diameter of all the prehilar structures an important prognostic parameter, with a total diameter of more than 400 μm indicating a favorable prognosis for adequate bile drainage.[669] A later study showed no correlation between duration of patient survival and size of the bile ducts at the resection margins, however.[670]

Liver biopsy remains the cornerstone of diagnosis. The histopathology evolves over time, as in any case of extrahepatic bile duct obstruction. In the perinatal form of BA, the detrimental cholestatic liver injury, later characteristic, only begins at the time of birth despite a prenatal occlusive biliary pathology, presumably due to the onset of the perinatal bile surge.[671] During the first two or so weeks of life, biopsy mostly reveals nonspecific bilirubinostasis, occasional multinucleated parenchymal giant cell transformation, and foci of extramedullary hematopoiesis (Fig. 19.58). Gradually, portal edema and ductular reaction set in. The latter is considered the most reliable feature, although it is not pathognomonic;[672–673] it was recently reconfirmed in a study of the diagnostic accuracy for BA of prelaparotomy biopsies in developing countries.[674] The extent of ductular reaction at the time of portoenterostomy also correlates with poor prognosis.[675] Patients with conjugated hyperbilirubinemia have been reported, however, in whom the initial liver biopsy findings showed a lack of ductular proliferation, despite subsequent development of BA. In some instances, sequential liver biopsies may be indicated until clinical improvement occurs or until BA can be excluded from the differential diagnosis.[676] The ductules often contain inspissated bile concrements (ductular bilirubinostasis; Fig. 19.59).

In later stages, periportal fibrosis develops, ultimately resulting in biliary cirrhosis. Important for the differentiation from other causes of obstruction (mainly choledochal cyst in this neonatal period) are the degenerative lesions of the intrahepatic ducts, which are part of the basic necroinflammatory and fibrotic process in BA. The ducts show irregularity of their lining cholangiocytes, which feature vacuolization, nuclear pyknosis, atrophy, and infiltration by

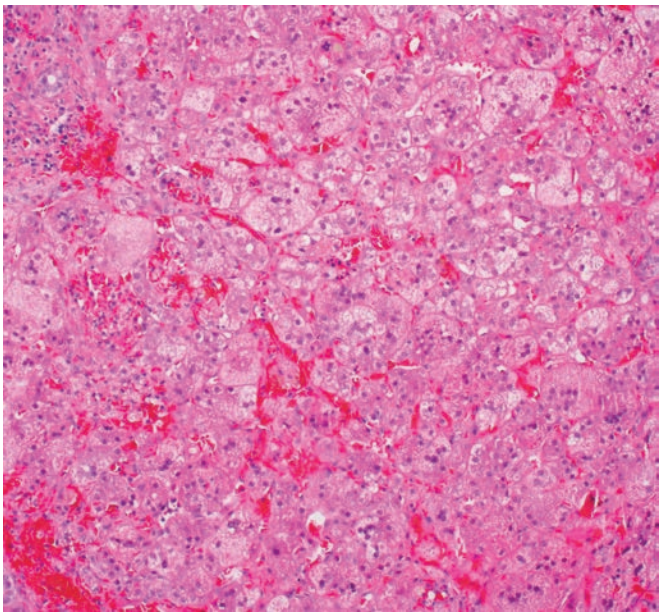

Figure 19.58 Biliary Atresia. Early disease featuring cholestasis and neonatal giant cell transformation.

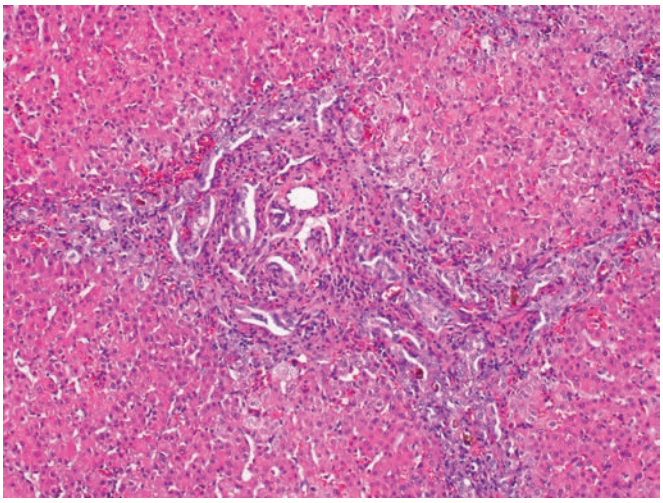

Figure 19.59 Biliary Atresia. Expanded portal tract with marked ductular reaction and ductular cholestasis.

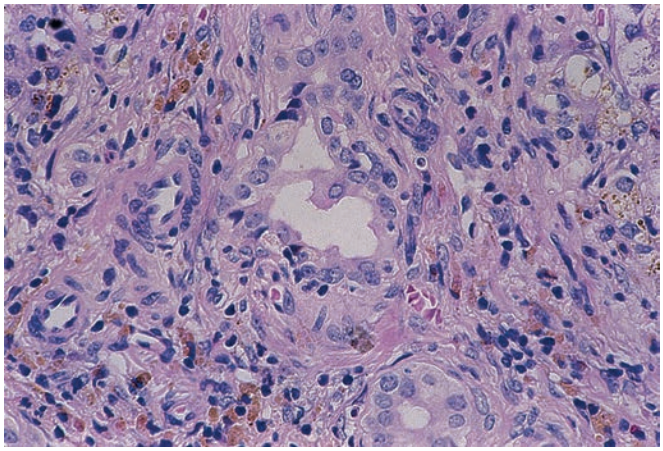

Figure 19.60 Detail of a bile duct from a neonate with biliary atresia, showing an irregular outline and epithelial damage including vacuolization of some cholangiocytes, apoptosis in others, and some inflammatory cells inside the basement membrane.

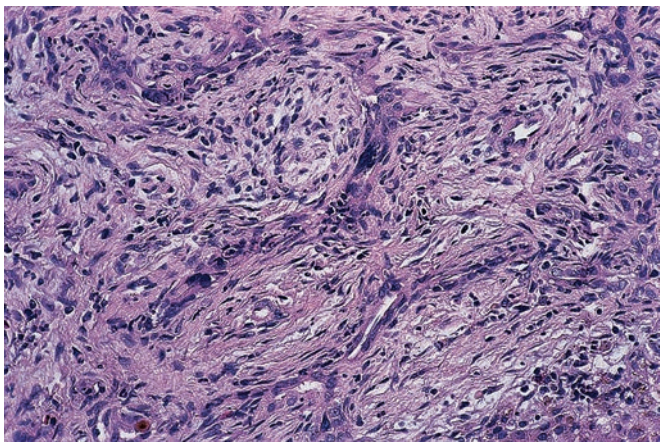

Figure 19.61 Biliary atresia, "early severe" type with advanced fibrosis. The picture shows part of a large, fibrous portal area, with recognizable hepatic artery branches, barely visible or no portal vein branches, and bile duct structures in ductal plate configuration ("ductal plate malformation"). The lining cholangiocytes show involutional changes such as flattening, shrinkage, and nuclear pyknosis.

inflammatory cells (Fig. 19.60). Thickening of the basement membrane occurs, associated with progressing atrophy and disappearance of the ducts. Progressive ductopenia of intrahepatic ducts develops, constituting an ominous sign for the success of hepatic portoenterostomy.[669] A bile duct to portal tract ratio equal to 0 or between 0.1 and 0.5 is frequently observed in BA.[677]

In about a fourth[678] or more[679] of patients, the interlobular bile ducts have been interpreted as retaining their early embryologic shape (so-called ductal plate malformation [DPM]; Fig. 19.61), suggesting an antenatal start of the disease associated with arrest of remodeling of the embryonic ductal plates.[680] In such patients, histology reveals an advanced degree of fibrosis at only a few weeks of age, justifying the term "early, severe" variant of BA. In an independent follow-up study, DPM occurred in 38% of cases, and its presence was predictive of poor clinical outcome.[681] A further study reported that the presence of DPM in the liver predicts poor bile flow after hepatoportoenterostomy in infants with BA,[682] while in another investigation the degree of fibrosis and DPM turned out to be markers of poor prognosis.[683] The broad variation in the few reports (involving relatively small numbers of patients) about the percentage of DPM in BA may relate to variable interpretation of unusual bile duct structures in diagnostic needle and surgical liver biopsies, which in neonates are mostly derived from the liver organ periphery and often of small size. This problem was addressed in a study that addressed DPM in early explants after failed Kasai procedures, and compared the percentage of affected portal tracts in classical perinatal BA patients with that found in patients with the embryonic form of BA, the latter defined as BA associated with splenic malformation syndrome (heterotaxy) or BASM. DPM-like arrays considered "definite" were typically found in larger portal areas of 300 µm diameter or more, and observed in the explanted livers from both BA and BASM patients, with a frequency of about 10% in each group, indicating that DPM does not identify the classical embryonic form of BA defined as BASM, but occurs with equal frequency in both BA and BASM patients. Furthermore, no correlation appeared to exist between the degree of fibrosis and the intensity of portal inflammation with

the number of DPM-like arrays.[684] However, more recent studies have indicated that DPMs in BA are correlated with an adverse prognosis.[685]

Marked fibrosis is already present in many cases of BA at the time of portoenterostomy. Computerized fibrosis scores[686] and intensity of alpha-smooth muscle actin expression may be predictors of outcome after operation.[687]

The differential diagnosis of BA includes bile duct obstruction by choledochal cyst, and differentiation from causes of intrahepatic cholestasis, including so-called neonatal giant cell hepatitis (no or much less ductular reaction, more intralobular than perilobular fibrosis, more hepatocyte swelling and multinucleation), chronic liver injury by parenteral nutrition, paucity of intrahepatic bile ducts, and several inborn errors of metabolism. Differentiation of BA from nonobstructive causes of neonatal cholestasis is crucial in order to avoid unnecessary surgery in patients with nonobstructive disease. Histologic scoring systems have been proposed with the purpose of improving diagnostic accuracy.[673,688]

The etiology of BA remains unknown. One hypothesis is that of viral infection (CMV, reovirus, and rotavirus) with resulting autoimmune-mediated bile duct injury.[689] Laterality genes (transcription factors *ZIC3* and *CFC*) may contribute to the phenotype of BA in patients with polysplenia syndrome.[690] Most likely, BA is a heterogeneous condition representing the common phenotype of several underlying disorders.[666,691]

Other cholestatic disorders (primarily intrahepatic) affecting the pediatric population include the metabolic disorders *galactosemia* and *hereditary fructose intolerance,* which show a histologic picture of severe bilirubinostasis with bile deposits in pseudoglandular tubules of hepatocytes and steatosis; the early stage is characterized by a periportal ductular reaction.[500] *Tyrosinemia* shows a similar histopathology, along with parenchymal siderosis, extramedullary hematopoiesis, and foci of nodular parenchymal regeneration.[692] *α1-AT deficiency* is discussed later.

The term *cryptogenic neonatal cholestasis* (also referred to as *neonatal giant cell hepatitis*) is histologically characterized by cholestasis, variably present multinucleated giant cell transformation, and extramedullary hematopoiesis, with occasional parenchymal siderosis and intralobular fibrosis, in which no cause is elucidated. Many patients previously termed cryptogenic are now known to have PFIC or another inherited disorder. More recently, other entities have been that were previously considered idiopathic have been identified, including *familial hypercholanemia*;[693] *neonatal ichthyosis sclerosing cholangitis* (NISCH) *syndrome*;[694] *North American ICC*[695]; *arthrogryposis, renal dysfunction, cholestasis (ARC) syndrome*[696]; and *neonatal intrahepatic cholestasis caused by citrin deficiency* (NICCD).[697] A rare disease (of older date) is the lymphedema–cholestasis syndrome (Aagenaes syndrome).[698]

CF or *mucoviscidosis* is one of the most common inherited diseases in the white population, caused by mutations in the CF transmembrane conductance regulator *(CFTR)*. *CFTR* is a cAMP-dependent chloride channel but also a "regulator" of other membrane proteins and channels,[699] thus governing the fluid balance across epithelial cells.[700] The most common mutation of *CFTR* amongst the 1400 reported in CF is ΔF508 (66%), resulting in misfolding of the protein and proteasomal degradation. Clinically, the abnormal electrolyte transport results in thick secretions and blockage of glandular ducts. In the liver, CFTR is located in the apical membrane of bile duct epithelial cells contributing to bile formation.[701] Bile duct epithelial cells in patients carrying the ΔF508 mutation display aberrant cytoplasmic immunolocalization of CFTR, as determined with confocal laser scanning microscopy, in contrast to the distinct CFTR expression at the luminal surface seen in controls.[702]

Significant liver disease is seen in 4%–6% of patients, but biochemical evidence of liver involvement occurs in 20%–50%, mainly in the first decade of life.[703] The most common pathologic change in the liver is steatosis; ductular reaction with concrements may also be seen. Increasing periportal fibrosis may ultimately end in cirrhosis, typically a focal pattern known as "focal biliary fibrosis" or "multilobular biliary cirrhosis."[704] The concrements in the dilated ductular lumina (Fig. 19.62), a pathognomonic lesion for CF, are PAS positive and diastase resistant with variable degrees of bilirubin impregnation.[501,700] The diagnosis of CF should be kept in mind in children who present with unexplained liver disease, since in some cases the diagnosis of CF has only been made after histologic examination of a liver specimen.[705]

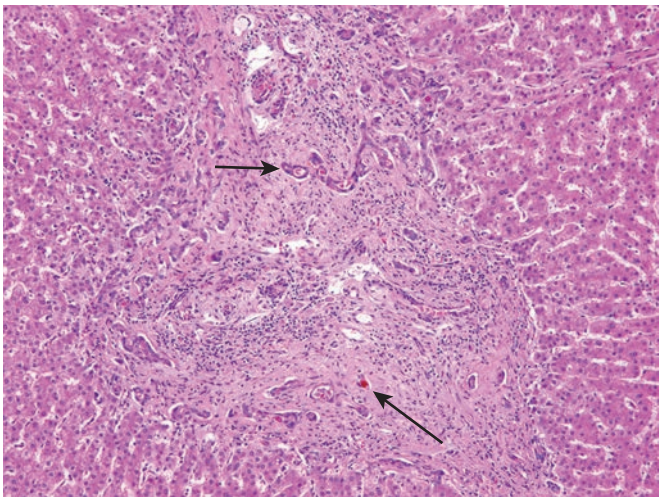

Figure 19.62 Cystic Fibrosis. An expanded portal tract has associated ductular reaction and inspissated pink-brown concretions *(arrows)*.

Hyperbilirubinemias. *Gilbert syndrome* is a common form of familial unconjugated hyperbilirubinemia, caused by a decreased conjugation rate of bilirubin associated with decreased transcription of *UGT1A1*, the gene of the bilirubin conjugating enzyme UDP-glucuronosyltransferase. Liver biopsies may show increased zone 3 lipofuscin. *Crigler–Najjar syndrome* (CNS) type 1 results from a mutation in one of the five exons of the gene coding for UDP-glucuronosyltransferase, resulting in complete absence of enzyme activity with very high levels of unconjugated bilirubin in the blood. CNS type 2 is caused by a single base pair mutation leading to a decreased but not totally absent enzyme activity.[706] The liver histology is normal except for an occasional slight degree of parenchymal siderosis. *Dubin–Johnson syndrome* is a deficiency of the canalicular multispecific organic anion transporter multidrug resistance associated protein 2 (MRP2, coded by the gene *ABCC2*), a member of the multidrug resistance protein subfamily localized exclusively to the apical membrane domain of polarized cells, such as hepatocytes, renal proximal tubule epithelia, and intestinal epithelia. This localization supports the function of MRP2 in the terminal excretion and detoxification of endogenous and xenobiotic organic anions, particularly in the unidirectional efflux of substances conjugated with glutathione, glucuronate, or sulfate, as exemplified by bilirubin, leukotriene C(4), glucuronosides, and some steroid sulfates.[707] Dubin–Johnson syndrome is characterized mainly by hyperbilirubinemia of the conjugated type and absence of cholestasis. Liver biopsy reveals the presence of coarsely granular, dark brown pigment in a pericanalicular location, primarily in the centrilobular zone (see Table 19.5).[708] The pigment resembles lipofuscin and melanin histologically and histochemically (variably PAS positive and acid fast, oil red O positive on frozen sections, and positive Fontana stain). Electron microscopy may allow differentiation.[709] A case of

digenic mixed hyperbilirubinemia, a distinct type of constitutive jaundice resulting from coinherited defects in *ABCC2/MRP2* and *UGT1A1* genes causing *combined Gilbert and Dubin–Johnson syndrome*, has been reported. Although the brown granular lipopigment reported in Dubin–Johnson syndrome was present in hepatocytes, liver histology was otherwise normal.[710] *Rotor syndrome* is a rare familial conjugated hyperbilirubinemia without hepatocellular pigment, and normal liver histology. The cause is unclear. It is not an allelic variant of MRP2 deficiency.[711]

Inherited Metabolic Disorders

Inherited metabolic defects leading to hepatic abnormalities are many and involve disorders of porphyrin, carbohydrate, protein and glycoprotein, amino acid, lipoprotein, lipid, and metal metabolism. Comprehensive reviews and texts should be consulted for a full description of morphologic changes and differential diagnoses.

The **endoplasmic reticulum storage diseases** are a group of inborn errors of metabolism affecting secretory proteins, resulting in retention of the protein in the endoplasmic reticulum and deficiency of the corresponding protein in the plasma.[712] The most important is α1-AT deficiency. Others include α1-antichymotrypsin (α1-ACT) deficiency and fibrinogen storage disease. The storage results from a molecular abnormality of the protein, thus hindering its transfer through the endoplasmic reticulum.

α1-Antitrypsin deficiency. α1-AT is a serum glycoprotein and protease inhibitor (Pi). As an acute phase reactant, serum levels are increased by hormonal influences, inflammatory stimuli, and most liver diseases. More than 70 allelic variants of α1-AT have been described.[713,714] The usual phenotype of the Pi system is PiM, and the most common deficiency alleles are PiZ and PiS. Liver abnormalities are mainly found in individuals carrying the Z allele. An amino acid substitution (lysine for glutamic acid at position 342) causes abnormal folding and retention of α1-AT in the rough endoplasmic reticulum, resulting in failure of secretion and plasma deficiency.[715]

α1-AT deficiency may be associated with cholestasis in neonates and may also present with liver disease in adults, including older people.[716,717] Periportal hepatocytes contain eosinophilic, PAS-positive, diastase resistant globular inclusions ranging in diameter from 1 to 10 µm (Fig. 19.63A and B). The inclusions are difficult to detect in infants less than 3 months of age. Immunostaining with polyclonal anti-α1-AT antibody may be useful, but there is often high background staining. Use of a specific monoclonal antibody allows identification of the PiZ gene products.[633] The abnormal globules can be seen within the endoplasmic reticulum on electron microscopy as well.[718] Immunoreactive globules may be found in several other liver diseases,[719] thus necessitating α1-AT phenotyping in plasma by immunodiffusion or electrophoresis for final diagnosis.

In children, the most common presentation is neonatal cholestasis, which is seen in 11% of infants and usually resolves without therapy by 6 months of age. The histologic changes may include parenchymal giant cells, ductular reaction, and fibrosis, and in some cases also PILBD.[720] The disease in this instance may resemble BA, hence the need to screen for α1-AT deficiency prior to a Kasai procedure. Persistence of hyperbilirubinemia beyond 1 year of age heralds a poor prognosis.[721,722]

The course is highly variable, however, and many children with abnormal transaminases and jaundice normalize spontaneously.[723]

α1-AT–deficient adults usually present with pulmonary emphysema.[724] The incidence of liver disease increases with age[725]; about one-third of genetically susceptible adult patients with the most severe phenotype, PiZZ, develop clinically significant liver injury.[714] An increased prevalence of HBV and HCV has been found in α1-AT deficiency patients and may contribute to the development of liver disease.[726,727] An increased incidence of hepatocellular carcinoma has been documented in adult homozygous PiZ patients with or without cirrhosis.[728] Heterozygosity for α1-AT Pi types does not appear to be associated with an increased risk for hepatocellular or bile duct carcinoma[729]; however, heterozygosity for PiZ type confers an increased risk for chronic liver disease in middle-aged or elderly adults.[730]

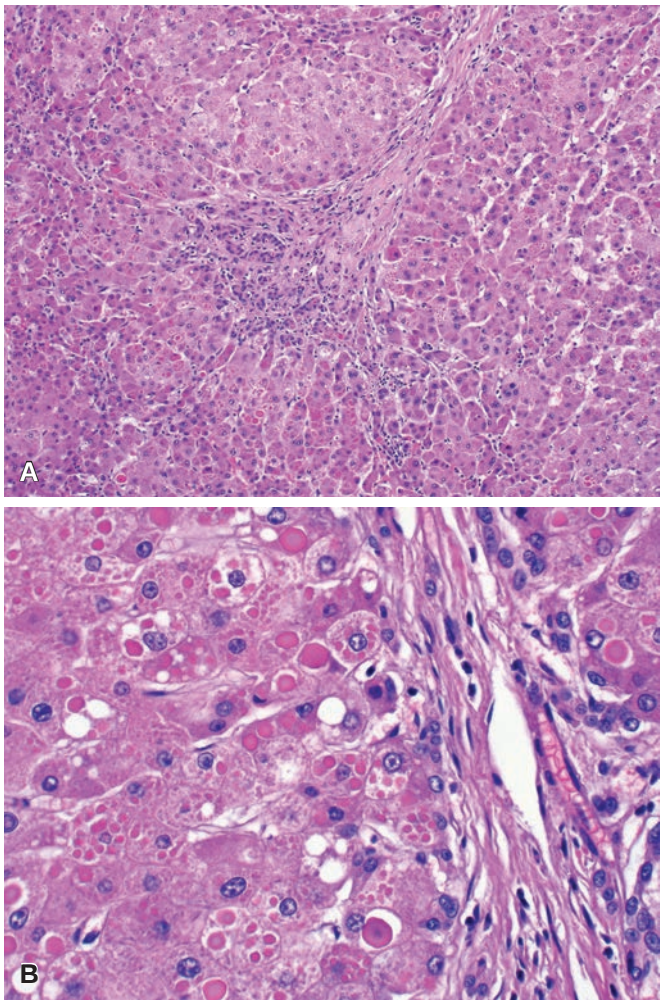

Figure 19.63 Alpha1-Antitrypsin Deficiency. A, Cirrhosis with numerous globules present on H&E stain. **B,** High-power view of globules of various sizes in periportal hepatocytes.

α1-ACT deficiency has also been described in a few cases with granular *α1*-ACT inclusions in periportal/periseptal hepatocytes.[728] Eosinophilic, PAS-positive, diastase-resistant globules have also been described in *antithrombin deficiency*.[712,731]

Fibrinogen storage disease (afibrinogenemia and hypofibrinogenemia) is associated with hepatocellular inclusions which are small and irregular or large and spherical. They are weakly PAS–diastase positive, stain with phosphotungstic acid–hematoxylin (PTAH), and are immunoreactive with antifibrinogen antibodies. In some patients, cirrhosis may develop.[142] The ground-glass cells of fibrinogen storage disease need to be differentiated from those caused by other etiologies (see earlier). Fibrinogen storage disease may occur without hypofibrinogenemia and manifest as minimal hepatitis without coagulopathy.[732] On rare occasions, fibrinogen storage disease without hypofibrinogenemia has been observed in association with acute infection.[733]

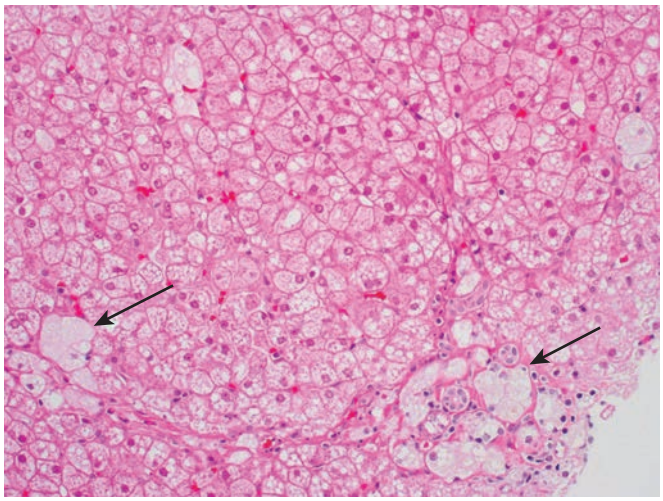

Figure 19.64 Niemann–Pick cells are pale, enlarged histiocytes with amphophilic foamy cytoplasm *(arrows)*, which are clearly seen amidst the hepatocytes. Vacuolated pale inclusions are present within the cytoplasm.

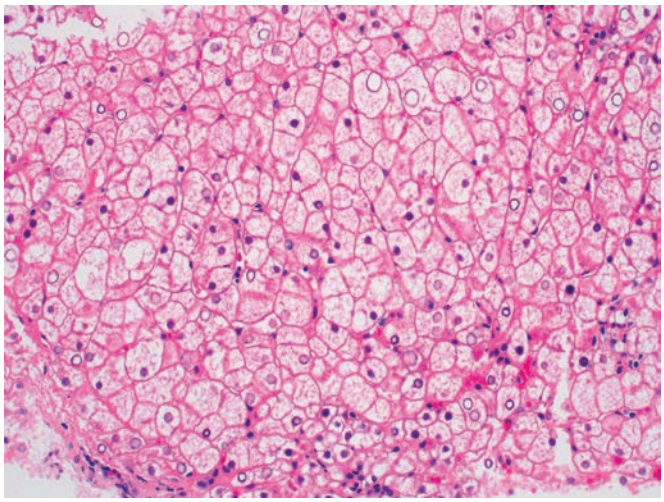

Figure 19.65 Glycogen storage disease type 1 featuring the characteristic "mosaic" pattern, featuring swollen hepatocytes with prominent cell membranes that compress sinusoids. Glycogenated nuclei are also easily visible.

Other storage diseases that may affect the liver include *Gaucher disease*,[734] an autosomal recessive sphingolipid storage disease resulting in the accumulation of glucosylceramide; *Niemann–Pick disease*,[735] a similarly autosomal recessive storage disease resulting in the accumulation of sphingomyelin (Fig. 19.64); and the *glycogen storage diseases*, due to inborn errors of carbohydrate metabolism due to mutations in the genes involved in glycogen metabolism (Fig. 19.65).[736] All of these may result in cirrhosis, and some subtypes of glycogen storage disease are associated with an increased risk of developing hepatic adenoma and hepatocellular carcinoma.

Disorders of Copper and Iron Metabolism

Indian Childhood Cirrhosis

ICC, originally thought to be specific to the Indian subcontinent, has also been reported elsewhere, even in whites.[737–739] This copper overload disease carries a high mortality and sometimes appears familial. The pathogenesis was originally believed to involve both genetic factors and increased exogenous copper intake (tap water, cooking utensils), but the importance of exogenous copper exposure has been questioned in more recent studies.[740]

Histopathology reveals hepatocellular swelling and ballooning in the early stages, with MDBs and necrosis. Accumulations of neutrophils (satellitosis) may be seen as well as pericellular fibrosis, similar to steatohepatitis, but fatty change is virtually absent. Huge amounts of copper and copper-binding protein can be demonstrated in the hepatocytes by rhodanine and orcein stains, respectively.[741,742] Ultimately patients develop a type of cirrhosis characterized by very small parenchymal nodules.

Endemic Tyrolean infantile cirrhosis, clinically and pathologically indistinguishable from ICC and hepatic copper toxicosis, has similarly been attributed to the synergy of an autosomal-recessive inherited defect in copper metabolism and excess dietary copper, although like ICC the role of exogenous copper has come into question.[740] Replacement of untinned copper cooking utensils by modern industrial vessels has apparently eradicated the disease, however, strongly suggesting that the endemic Tyrolean childhood cirrhosis—and by analogy non-Wilsonian hepatic copper toxicosis occurring elsewhere—is an ecogenetic disorder requiring the involvement of both genetic and environmental factors for the disease to become manifest.[743]

Wilson Disease (Hepatolenticular Degeneration)

Wilson disease results from tissue injury by copper overload in the liver and other organs (brain, cornea, and kidneys). It is a rare autosomal recessive disorder, the gene mutation of which is localized on chromosome 13q14–21. The implicated gene is a P type ATPase that transports copper.[744] Copper deposition in the hepatocytes is complex, with several factors involved besides the Wilson ATPase, including copper transporters, metallochaperones, and metallothionein.[745]

Homozygous subjects have increased copper levels in the liver at a very young age, but symptoms of liver disease do not typically develop before the age of 5 years.[746] The disease may manifest itself as acute hepatitis or as chronic hepatitis. In untreated patients, the disease progresses to cirrhosis. Fulminant hepatic failure may be the first manifestation of Wilson disease, associated with extensive parenchymal necrosis, collapse of the reticulin framework, nodular parenchymal regeneration, and postnecrotic cirrhosis.[747]

Histologic liver abnormalities precede the clinical appearance of disease. In the early stage there is usually steatosis and sometimes lipogranulomas. Lipofuscin may be strikingly abundant in periportal hepatocytes, as may glycogen vacuoles in their nuclei.[748] Kupffer cells may be laden with iron as a result of the acute hemolytic crises that frequently complicate the disease. Electron microscopy may reveal characteristic mitochondrial and lysosomal changes.[749] Progressive fibrosis develops with fine septa extending from portal tracts. In some patients portal tracts become infiltrated with mononuclear inflammatory cells, creating a picture indistinguishable from chronic hepatitis due to other causes.[93,94,748] Helpful diagnostic clues include steatosis, ballooned hepatocytes, glycogenated nuclei, moderate to marked copper deposition, presence of MDBs in periportal hepatocytes, lymphocytic portal and interface inflammation, and occasionally occlusive venous lesions (Fig. 19.66A).[748] The MDBs associated with copper intoxication resemble those present in fatty liver disease. Accumulation of p62 in Wilson disease, ICC, and idiopathic copper toxicosis and deposition in MDBs indicates a central role of protein misfolding induced by oxidative stress in copper-induced liver toxicity.

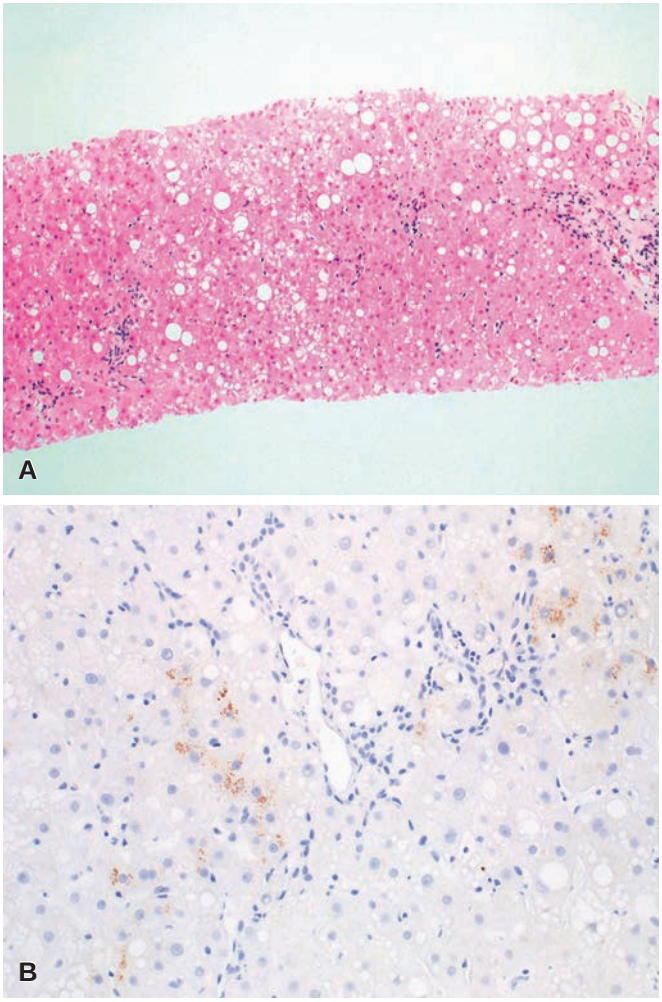

Figure 19.66 **A,** Biopsy from a patient with Wilson disease shows features of steatohepatitis. **B,** Patchy copper staining is a clue to the diagnosis (rhodanine stain).

By sequestering potentially harmful misfolded ubiquitinated proteins as inert cytoplasmic inclusion bodies (e.g., as MDBs), p62 may be a major player in an important cellular rescue mechanism in oxidative hepatocyte injury.[750]

Cytochemical staining for copper and copper-binding protein may be useful in establishing the diagnosis (Fig. 19.66B). However, stains may be negative in some stages of the disease, thus it is important to remember that a negative copper stain does not exclude the diagnosis. In young asymptomatic patients with Wilson disease, hepatic copper levels are often high, but staining may be difficult to demonstrate histochemically because of diffuse distribution in the cytoplasm of hepatocytes; copper stains may reveal at most a faint cytoplasmic staining. In older patients with signs of disease, the metal is both diffusely distributed and intralysosomal, while in patients with advanced disease all the copper is confined to lysosomes,[751] resulting in a granular pattern that is more easily recognized. In the cirrhotic stage, parenchymal nodules may vary strikingly in copper content. On the other hand, copper and metallothionein may accumulate in other diseases (e.g., chronic cholestatic liver disease, ICC) and, furthermore, neonatal liver usually contains high levels of copper.[752] Quantitative determination of hepatic copper may be necessary for final diagnosis; this can be performed on routinely processed paraffin-embedded tissue.[753] Timm silver stain appears to be the most sensitive technique,[754] but the sensitivity of this method in revealing copper deposits in liver cells appears to be dependent on the dewaxing time in xylene; rinsing sections in xylene for 24 hours give the best results.[755] Copper–metallothionein complexes show autofluorescence (which is quenched by paraffin embedding) in frozen sections from snap frozen specimens.[756] Staining results for copper and copper-binding protein are usually equal but may on occasion give divergent results.[757]

The great variety of possible lesions in Wilson disease creates difficult problems for the histopathologist. It must become a habit to consider Wilson disease in the differential diagnosis of hepatocellular disease at all ages but especially in the young. This may save lives. Treatment (penicillamine or zinc acetate) may arrest the disease in patients and prevent its development in siblings.

Iron Overload

The terms siderosis and hemosiderosis refer to the presence of demonstrable iron in tissues. The causes of iron overload are many, including but not limited to genetic hemochromatosis, siderosis secondary to chronic anemia, neonatal iron overload, blood transfusion, hemolysis, chronic renal failure, and PCT. It is preferable not to use the terms hemosiderosis and hemochromatosis as synonyms for iron overload and to reserve the term hemochromatosis specifically to indicate genetic (or hereditary) iron overload. Faced with hepatic siderosis, the pathologist should always consider the possibility of genetic hemochromatosis.

Siderosis is usually demonstrated by the Perls stain (using acid ferrocyanide), which gives the Prussian blue reaction with the ferric compounds ferritin and hemosiderin. Ferritin dispersed in the hyaloplasm gives a diffuse bluish tint to the cell's cytoplasm, whereas intense blue granules correspond to ferritin and hemosiderin packed together within siderosomes (or iron-laden lysosomes).[758] Evaluation of the Perls stain requires attention to both the extent (grade or amount) of stainable iron and its distribution in all the different cell types of portal tract and lobule. Because of the sensitivity of the iron stain, and in view of the numerous conditions in which iron deposition of more or less diagnostic importance may be identified, many recommend that a Perls stain be routinely performed in all liver biopsies.

Iron distribution may vary according to the cause of siderosis. It is predominantly parenchymal in hemochromatosis and neonatal iron overload. Secondary siderosis may preferentially affect Kupffer cells, but both hepatocytes and Kupffer cells store iron in thalassemia. Dense Perls-positive granules are found in endothelial cells in various liver diseases, including acute hepatitis and alcoholic liver disease.

Semiquantitative assessment of stored tissue iron can be achieved in different ways. The simplest system grades from 1 (minimal) to 4 (massive deposits), with grades 2 and 3 indicating intermediate amounts. Basset and colleagues[759] introduced the HII, representing the chemically measured hepatic iron concentration (HIC; µmol/g dry weight) divided by the patient's age in years. It enables the distinction of genetic hemochromatosis (HII of 1.9 or more) from heterozygous individuals and patients with siderosis from other causes. The HII is based on the principle that progressively increasing HIC is found in homozygotes for genetic hemochromatosis, unlike what happens in heterozygotes or in patients with alcoholic siderosis. Chemical determination of tissue iron can be performed on a separate piece of liver tissue obtained when the biopsy is performed, or on the deparaffinized block after histopathologic study is completed. The latter procedure ensures that the adequacy of the sample is known.[392]

The semiquantitative and quantitative procedures mentioned previously have lost a considerable part of their importance since

the genetic diagnosis of hemochromatosis became possible.[760] As it often happens with the development of noninvasive diagnostic techniques for liver diseases, genetic screening has changed the need for liver biopsy. The latter is no longer considered necessary for diagnosis or for simple visualization or semiquantitation of excess hemosiderin deposition, and modern MRI obviates the necessity of tissue procurement for biochemical quantification.[761] However, liver biopsy remains of interest in the assessment of fibrosis and for determining the possible existence of other concurrent liver diseases.[762] Furthermore, only liver biopsy evaluation allows determination of the cellular and zonal deposition of hemosiderin.[763]

Hereditary Hemochromatosis

Hereditary hemochromatosis is an autosomal recessive disease and the most common inherited disorder in whites.[764] Classic hemochromatosis is caused by a missense mutation in the *HFE* gene located on the short arm of chromosome 6. In Northern Europe, more than 90% of *HFE*-linked hemochromatosis patients are homozygous for the C282Y mutation.[760] A less common missense mutation is a substitution at amino acid 63 (H63D), with fewer clinical effects. However, a compound heterozygosity for C282Y and H63D may also cause disease expression.[760]

The pathogenetic mechanism leading to the gradual accumulation of iron stores in the body consists of a persisting minor increase in dietary iron absorption that overrides the dietary regulator during the lifetime of a patient. The precise details of the mechanism of iron overload still need further elucidation, but since the discovery of the *HFE* gene in 1996, a better insight has been reached regarding the players involved. In addition to previously known molecules (transferrin and transferrin receptors [TfR1 and 2], ferritin), these include a number of newcomers: the duodenal enterocytic divalent metal transporter (DMT1), iron regulatory proteins (IRPI and IRPII), ferroportin (a transmembrane protein exporting iron from inside to outside the cell), hephaestin (a ferroxidase and ceruloplasmin homolog), the regulatory peptide hormone hepcidin (encoded by the evolutionary conserved *HAM* gene), and hemojuvelin (a regulator of hepcidin expression, encoded by the *HJV* gene).[765–767]

In brief, hereditary hemochromatosis includes both *HFE*-linked and non-*HFE*-linked hemochromatosis. Non-*HFE*-linked disease with iron overload can be caused by deficiencies of various molecules involved in iron transport, and are categorized as juvenile hemochromatosis (or hemochromatosis type 2; this category is subdivided into the more frequent juvenile hemochromatosis type 2A with *HJV* mutation, and the less frequent juvenile hemochromatosis type 2B, caused by *HAMP* mutation); TfR2-linked hemochromatosis (or the rare hemochromatosis type 3, with mutations in TfR2, mostly in Japanese patients), and ferroportin-linked iron overload (or hemochromatosis type 4 or ferroportin disease, with mutation in the ferroportin gene *SLC40A1*).[765–767] The classic *HFE*-linked variant remains the standard against which other forms of iron overload are compared.[763]

Classic *HFE*-linked hemochromatosis (hemochromatosis type 1). The standard histopathology corresponds to the original descriptions of Scheuer et al.[768] and consists of an intrahepatocellular accumulation of hemosiderin granules in a lysosomal (pericanalicular) location (Fig. 19.67), occurring in a decreasing zonal gradient of hepatocellular iron storage from portal to central zones that persists even in stages of heavy iron overload. However, this pattern is neither specific nor exclusive to C282Y homozygosity, since it is also observed in varying combinations of heterozygosity for C282Y and/or H63D, and with other forms of chronic liver disease.[763,769] It has otherwise been established that not all subjects with *HFE* mutations have complete phenotypic expression of the classical clinicopathologic manifestations of hereditary hemochromatosis.[770]

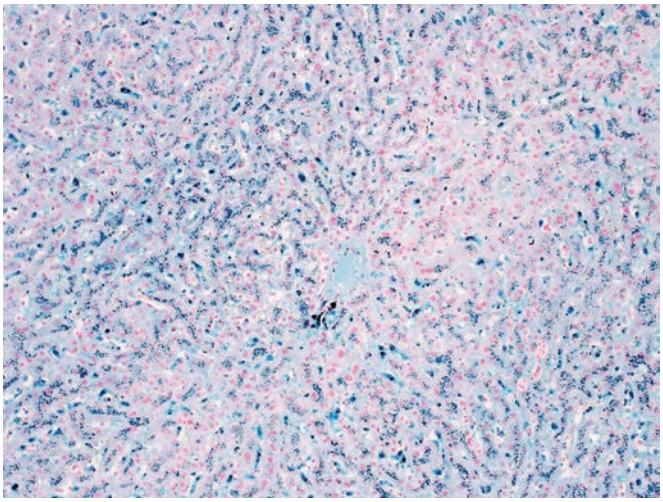

Figure 19.67 Siderosis in Hepatocytes and Macrophages in Genetic Hemochromatosis. There is a decreasing portal–central gradient that can be appreciated even in advanced disease. (Perls iron stain.)

In young homozygotes, the first abnormality is the appearance of stainable iron in periportal hepatocytes, with positivity in males generally being greater than in females of the same age. Unexplained small amounts of iron in hepatocytes should always raise suspicion about a possible early stage of genetic hemochromatosis. This is highly important because cirrhosis can be prevented by appropriate treatment in both the patient and homozygous relatives, with return of life expectancy to normal.[771] With advancing age, the deposition of hemosiderin progresses toward the centrilobular area but usually maintains a portal—central gradient. Biliary epithelium, Kupffer cells, sinusoidal and vascular endothelial cells, and macrophages in portal tracts and septa may also accumulate iron. Some authors report the occurrence of foci of eosinophilic or lytic hepatocellular necrosis of iron-laden hepatocytes, often in close association with clusters of macrophages (so-called sideronecrosis). This provides a dynamic view of the iron overload process and suggests that sideronecrosis and progressive sinusoidal iron overload play a role in the development of fibrosis in human genetic hemochromatosis.[772] Later studies confirmed a correlation between inflammatory cell markers, proinflammatory and profibrotic cytokines, and iron deposition in hemochromatosis.[773] With progressing siderosis, fibrosis indeed develops with expansion of portal tracts and appearance of small fibrous spurs conferring a spiked contour to portal tracts (holly leaf–like). The enlarged portal tracts carry iron-laden macrophages, and there is some increase in ductular profiles, often with only mild inflammation. The cholangiocytes of ductules and interlobular ducts begin to accumulate granules of stainable iron. The proportion of iron located outside hepatocytes versus hepatocellular iron rises progressively.

Periportal fibrosis proceeds with slender periportal septa that join portal tracts and progressively envelop the lobules, resulting in a combination of discrete parenchymal nodules and partially preserved lobules, a pattern characteristic of hemochromatosis.[774] Still further advancement of disease results in a diffuse micronodular cirrhotic pattern with portal-based septal fibrosis.

Excessive alcohol consumption induces a shift of hemosiderin from parenchymal to Kupffer cells and macrophages in the fibrous septa.[774] In later stages of heavy iron overload, occasional small areas can be found with or without very little parenchymal siderosis

and with only some Kupffer cell iron deposition. Such parenchymal iron-free areas are most often seen in established cirrhosis and may indicate a preneoplastic or neoplastic lesion.[775] Hepatocellular carcinoma occurs with an incidence of approximately 15%, predominantly in males. Tumor development is not prevented by removal of iron.[771]

Effective treatment with therapeutic phlebotomies results in a steady disappearance of stainable iron; the pattern of iron removal is the reverse of its accumulation, with periportal hepatocytes remaining iron positive for longer. Iron encrusted in portal collagen is most resistant to removal. Iron removal unmasks a brown lipofuscin-resembling pigment in hepatocytes and portal mesenchyme.

The range of hepatic pathology in C282Y/H63D compound heterozygous patients with and without known underlying liver disease has been studied, and considerable histologic fibrosis can be found in compound heterozygous patients without known underlying liver disease.[776] However, heterozygosity for the hemochromatosis defect is rarely associated with liver damage due to iron alone.[777] One study compared the hepatic histopathologic features and HIC among patients with phenotypic hemochromatosis and different HFE genotypes. C282Y/H63D compound heterozygotes and other non-C282Y homozygotes who expressed the hepatic hemochromatosis phenotype frequently had evidence of steatosis or chronic hepatitis and lower body iron stores than C282Y homozygotes, suggesting that concomitant liver disease may explain the expression of the hemochromatosis phenotype among non-C282Y homozygotes.[778] There are marked differences in the prevalence of the C282Y mutation of the *HFE* gene in patients with different liver diseases, with the highest prevalence rates in AIH and PBC. The C282Y mutation alone leads to only a mild increase in iron accumulation in the majority of the patients, with the exception of H63D/C282Y compound heterozygotes.[779]

Non-HFE-linked hemochromatosis. In this group of disorders, the histopathologic changes may or may not be indicative of a particular mutation.[763,765,766] The entities C282Y *HFE*, TfR2 and hepcidin *(HAM)*-linked mutations result mostly, although not exclusively, in predominantly hepatocellular pericanalicular hemosiderin deposition, with higher periportal iron load, and therefore cannot be distinguished by histopathologic examination. In contrast, the disease(s) caused by ferroportin mutation are characterized initially and predominantly by Kupffer cell iron load, also in the periportal zone. Of interest is the observation that the liver is one of the primary damaged organs in all forms of hemochromatosis with the exception of hepcidin *(HAM)*-linked hemochromatosis, in which endocrine and cardiac manifestations prevail.[763,765,766]

Neonatal Hemochromatosis

Neonatal hemochromatosis (NH) is a rare and enigmatic disease that has been clinically defined as severe neonatal liver disease in association with extrahepatic siderosis.[780] Liver histopathology is characterized by marked hepatocellular necrosis, parenchymal giant cell transformation, siderosis of hepatocytes and cholangiocytes, fibrosis, and parenchymal nodule development during fetal life and in the perinatal period (Fig. 19.68).[781] The etiology is unknown; there is no relationship with genetic hemochromatosis. Putative environmental agents have been suspected to interact with one or more factors intrinsic to the developing fetal liver.[782] An alloimmune mechanism is also considered for the pathogenesis of this disorder.[780]

Hepatic Siderosis of Varied Etiology and Secondary Hemosiderosis

The human fetal and neonatal liver often shows prominent hepatocellular siderosis, mostly in periportal hepatocytes[782]; the iron content

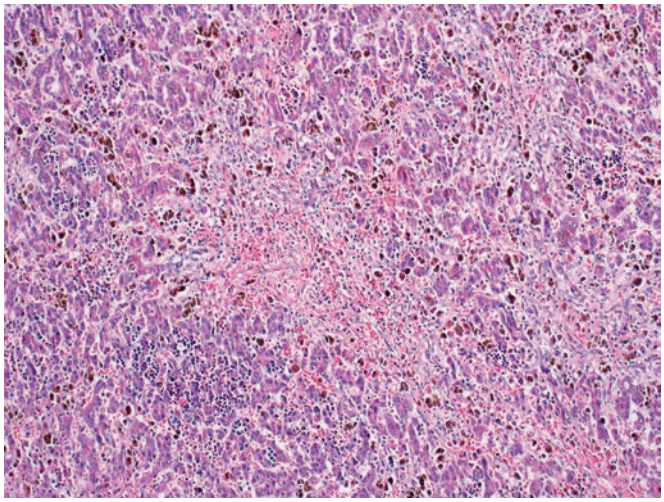

Figure 19.68 Neonatal hemosiderosis is characterized by iron deposition in hepatocytes and Kupffer cells, giant cell transformation, and increased fibrosis. Extramedullary hematopoiesis is also prominent in this case from a neonatal autopsy.

shows a striking interindividual variability and uneven distribution throughout the liver.[783] Hepatic iron overload associated with fibrosis and cirrhosis occurs in patients with thalassemia and other forms of chronic anemia (often termed "secondary hemochromatosis"); in these cases, Kupffer cell and macrophage siderosis is present from the early stages. In contrast with genetic hemochromatosis, there is often more portal and lobular lymphocytic infiltration, which in the past has often been due to transfusion-related viral hepatitis C.[784]

African iron overload (AIO), previously termed Bantu siderosis, has been thought to be due to ingestion of excessive amounts of iron (among others self-medication with iron compounds and use of iron containers by native South Africans for brewing traditional beers). It is now postulated that AIO may have both dietary and genetic components.[785] Histopathology reveals combined reticuloendothelial and hepatocellular siderosis.

Some degree of hepatic siderosis is common in chronic liver disease and cirrhosis in general,[786] including iron accumulation of varying degree secondary to chronic HCV infection, alcoholic liver disease, NAFLD, hepatocellular carcinoma, and PCT.[787] Patients with NAFLD and hepatic iron overload (dysmetabolic hepatic iron overload [DHIO]) show appropriate regulation of mRNAs encoding proteins involved in iron uptake and efflux but dysregulation of hepcidin production.[788] A significant association exists between *PCT* and these liver disorders (including chronic HCV infection, alcohol abuse, iron overload, and hereditary hemochromatosis). Siderosis is present in a majority of these patients.[789]

Fibropolycystic Diseases (Ductal Plate Malformation)

Hepatobiliary fibropolycystic diseases[790] comprise a series of congenital abnormalities involving the intrahepatic bile ducts, most of them related to an abnormal remodeling of the embryonic ductal plate.[791–794] The primitive embryonic form of the developing intrahepatic bile ducts corresponds to a double, perforated epithelial cylinder that surrounds the future portal tracts and is termed the ductal plate.[791] Progressive remodeling of the ductal plate results in the formation of mature tubular ducts located in the portal mesenchyme. Lack of such remodeling results in the persistence of the primitive embryonic

pattern,[794] termed DPM.[795] According to the plane of section and the degree of remodeling, DPM appears in cross sections as a circular lumen containing a fibrovascular axis in its center, as rings of interrupted curved lamina around a central fibrovascular axis, or as a grossly dilated duct containing a polypoid projection.[791,794]

Modern imaging techniques of the liver allow visualization of the macroscopic abnormalities of DPM in larger branches of the intrahepatic bile duct.[796] DPM is usually associated with abnormalities in the ramification pattern of the developing portal vein, resulting in too many, too small, and too closely spaced branches ("pollard willow" pattern).[791] Two main groups of congenital diseases of intrahepatic bile ducts are characterized by DPM: a subgroup of cases with extrahepatic bile duct atresia (so-called early severe form; see earlier); and diseases characterized by a variable degree of ectasia of intrahepatic bile ducts associated with more or less fibrosis—the "fibrocystic" diseases.[792,794]

Most congenital fibrocystic liver disorders are associated with variants of renal cystic disease. The mechanism of cyst formation is quite similar in renal and biliary cystogenesis in the combined renal–hepatic cystic diseases, with a remarkable role played by the primary cilia on the apical pole of renal tubular and bile duct epithelial cells. The gene products involved in the respective mutations (fibrocystin, polycystin 1 and 2) are components of the primary cilium, which plays the role of a sensory antenna in maintaining normal polarity of tubular epithelia.[797,798] The cystogenetic mechanism in isolated polycystic liver disease (PCLD) appears to be different from renal cystogenesis. Moreover, the differential findings for PRKCSH- and SEC63-associated PCLD suggest a divergent mechanism for cystogenesis in these two genetic groups of isolated PCLD.[799]

Autosomal Recessive Polycystic Kidney Disease (Infantile-Type Polycystic Disease)

The gene of autosomal recessive polycystic kidney disease (ARPKD) has been localized to chromosome 6p21–p12. It is termed polycystic and hepatic disease 1 *(PKHD1)* and encodes a receptor-like protein named fibrocystin/polyductin that is localized in the primary cilium of renal tubular cells and cholangiocytes lining the intrahepatic bile ducts.[800] Mutations of *PKHD1* result in bile duct abnormalities of the DPM type and fusiform dilation of renal collecting tubules. The hepatic lesions are fairly uniform and seldom give rise to macroscopically visible cysts. Microscopically, the portal tracts may be enlarged and contain numerous, somewhat dilated bile duct profiles corresponding to incompletely remodeled ductal plates, which sometimes are irregular in shape and extend into the periportal parenchyma. During portal tract maturation, myofibroblastic cells disappear in normal development but persist in fibrosis following DPM.[801] In surviving children, the liver and kidney lesions seem to progress, with a decrease in epithelial (hepatic and renal) tubular profiles and an increase in interstitial (hepatic and renal) fibrosis.[792,802]

Congenital Hepatic Fibrosis

CHF has been considered by several authors as the "juvenile" form of ARPKD.[803] This recessively inherited disorder classically presents with signs of portal hypertension in childhood, more rarely in adults.[804] Besides the classical portal hypertensive CHF, clinical variants include cholangitic CHF, combined portal hypertensive and cholangitic CHF, and latent CHF.

Grossly, the liver is enlarged and very hard, showing a fine reticular pattern of fibrosis. The histopathologic picture varies; some cases only reveal enlarged portal tracts with bile ducts in ductal plate configuration, whereas others show bands of connective tissue of variable thickness that link adjacent portal tracts and contain ductal plate vestigia (Fig. 19.69). The bile duct lumina may contain inspissated bile. Degradation of matrix proteins in the ductal basement membranes plays a role in cystic dilation of the ductal structures.[805] The portal vein branches are usually hypoplastic ("pollard willow" pattern); the hepatic artery branches instead may be numerous and conspicuous. In some cases, mild features of cholate stasis can be found.[803] There is usually no or only minimal inflammation, no necrosis, and no parenchymal regeneration.

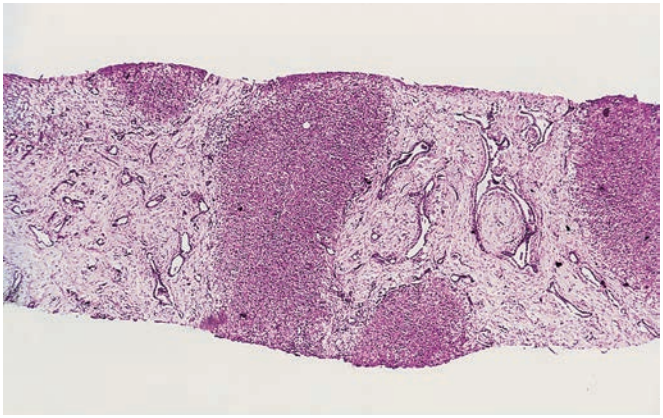

Figure 19.69 Congenital Hepatic Fibrosis. Low-power view of needle biopsy specimen. Portal tracts are enlarged and joined by portal–portal fibrous connections. Bile ducts appear in their immature, embryonic shape (ductal plate malformation). Note the mature aspects of fibrous tissue and virtual absence of inflammation.

The more fibrotic forms of CHF might be confused with biliary fibrosis and secondary biliary cirrhosis, in which the overall pattern of fibrosis may be similar; however, in the latter case the septa are inflamed, with ductular reaction at the septal–parenchymal interface, usually more marked signs of cholate stasis and bilirubinostasis, absence of ductal plate structures, and normal size of portal vein branches.

Hepatic lesions of CHF are present in a number of malformation syndromes, including medullary cystic kidney disease 1 (MCKD1); MCKD2; mutation of *UMOD2*, the gene of uromodulin; nephronophthisis–CHF (mutation in gene *NPHP1*); Meckel–Gruber syndrome (*MKS* genes); renal–hepatic–pancreatic dysplasia or Ivemark syndrome; chondroectodermal dysplasia or Ellis–van Creveld syndrome; asphyxiating thoracic syndrome or Jeune syndrome; Sensenbrenner syndrome,[806] phosphomannose isomerase deficiency or congenital disorder of glycosylation type 1b[807,808]; Joubert syndrome; vaginal atresia syndrome; and tuberous sclerosis.[792]

Caroli Disease (Congenital Dilation of the Intrahepatic Bile Ducts)

Caroli disease corresponds to a congenital dilation of the larger intrahepatic bile ducts. Two variants are recognized: a pure type characterized by only ectasia of larger intrahepatic bile ducts (Caroli disease); and a combined type in which Caroli disease is associated with lesions of CHF (Caroli syndrome).[794]

Caroli disease consists of moniliform or saccular dilations of the larger intrahepatic bile ducts, predominantly segmental ducts. The ectasias predispose to repeated attacks of cholangitis, and complications such as intrahepatic lithiasis, amyloidosis, and cholangiocarcinoma.[809] The polypoid projections or cross bridges often seen in the dilated bile duct lumina attest to the DPM nature of the lesions.[792,794] Also their appearance on liver imaging techniques as dilated ducts with a central dot is most compatible with a DPM

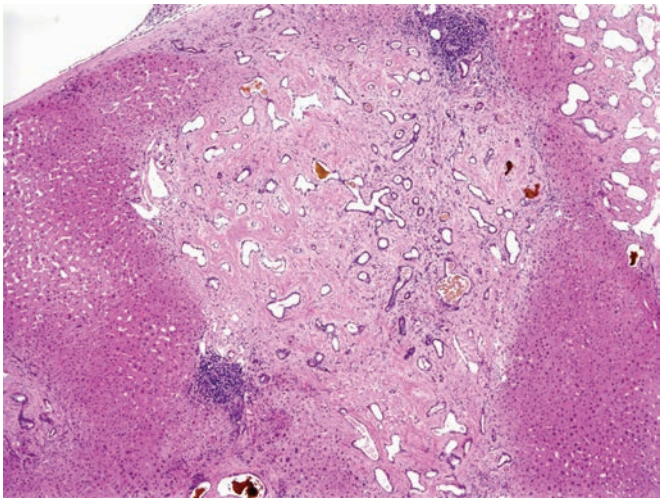

Figure 19.70 Von Meyenburg complex featuring dilated bile ductules containing inspissated bile, embedded in dense fibrous stroma. The lesion is located directly under the capsule.

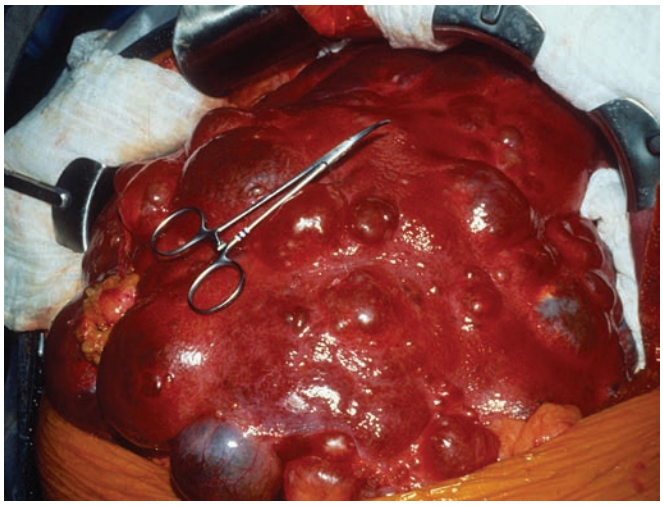

Figure 19.71 Intraoperative Photograph of Adult-Type Fibropolycystic Liver Disease. The liver is markedly enlarged and distorted by numerous cysts. (Courtesy Dr. George F. Gray, Jr.)

pattern.[810,811] Monolobar involvement in Caroli disease has been described in about 35 cases.[812] Microscopically the ducts show lesions of acute purulent cholangitis, usually superimposed on chronic sclerosing changes. Patients with *Caroli syndrome* have additional lesions of CHF.

Von Meyenburg Complex (Microhamartoma)

Von Meyenburg complexes (VMCs) are small, often multiple nodules occurring close to portal tracts throughout the liver. They may be visible as 1–2 mm white nodules on the liver surface. They may occur in an otherwise normal liver, or in association with CHF, Caroli syndrome, or adult polycystic disease.[813]

The lesion features a variable number of dilated bile ducts embedded in a fibrous, sometimes hyalinizing stroma (Fig. 19.70). Some profiles may contain inspissated bile, and some may reveal DPM configurations. VMCs do not normally cause symptoms and are often incidental findings, sometimes mistaken for hepatic metastases at surgery. The lesion apparently represents DPMs of smaller, more peripheral interlobular bile ducts in portal tracts with a "pollard willow" branching pattern.[794] Through luminal dilation and fluid filling, VMCs may be the origin of liver cyst development in subjects carrying the mutations for autosomal dominant polycystic kidney disease (ADPKD).[814] VMCs may give rise to cholangiocarcinoma[815] and have been rarely associated with hepatocellular carcinoma.[816]

Autosomal Dominant Polycystic Kidney Disease (Adult-Type Polycystic Disease)

ADPKD affects 1 in 400 to 1 in 1000 persons, representing the most common hereditary kidney abnormality. ADPKD is caused by mutations in the genes *PKD1* and *PKD2*, encoding the proteins polycystin 1 and 2, respectively.[817] Liver cysts are found in most patients with ADPKD, and their prevalence increases with age. Grossly, the liver contains multiple cysts of variable diameter (Fig. 19.71) that are disseminated throughout the organ or—more rarely—restricted to one lobe. The cavities are lined by biliary-type epithelium, surrounded by a fibrous capsule, and located in or close to portal tracts (Fig. 19.72). The cysts contain a colorless fluid with a composition close to that of the bile salt–independent fraction of bile. They may collapse,

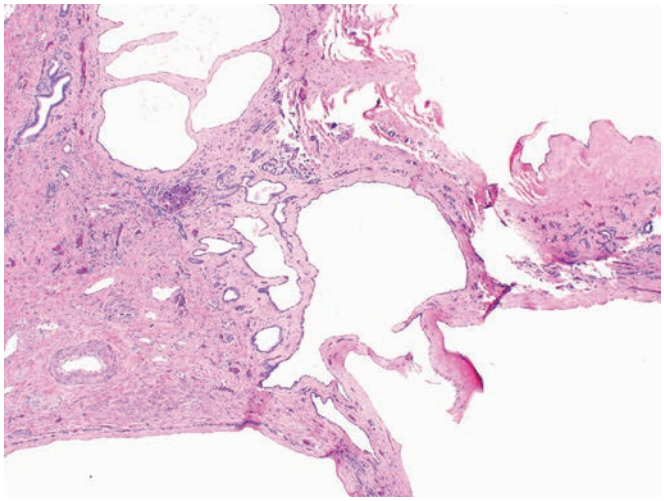

Figure 19.72 Adult-type polycystic liver/kidney disease featuring multiple cysts lined by a thin biliary epithelial lining, with a thick fibrous wall. Cysts are often associated with von Meyenburg complexes or congenital hepatic fibrosis.

resulting in structures resembling corpora atretica in the ovary. The cysts are usually associated with VMCs or with CHF. Complications are infection or rupture of the cysts. In addition to genetic factors, cyst development is further modulated by age, pregnancy, female gender, and severity of the kidney lesions.[818]

Isolated Autosomal Dominant Polycystic Liver Disease (Isolated Autosomal Dominant Polycystic Hepatic Disease or Isolated Polycystic Liver Disease)

Isolated PCLD represents a more recently discovered entity that is genetically heterogeneous. One gene for PCLD is *PRKCSH* located on chromosome 19p13.2–13.1 which codes for the "β-subunit of glucosidase II" or "protein kinase substrate 80K-H" (PRKCSH) or hepatocystin. A second gene associated with PCLD is *SEC63*, encoding an integral membrane protein of the endoplasmic reticulum, which

is part of the multicomponent translocon comprising the translocation machinery for integral and secretory proteins.[819]

The gross pathology is similar to that of ADPKD. Similar to ADPKD, the liver contains—besides the cysts—variable numbers of VMCs, the dilation of which contributes to cyst formation together with dilation of peribiliary glands of the larger bile ducts.[820] Although PCLD is characterized by larger and greater numbers of hepatic cysts than in patients with ADPKD, the clinical course is relatively benign compared with ADPKD.[821] Carbohydrate antigen 19-9 (CA 19-9), used as a biomarker to differentiate benign from malignant gastrointestinal disorders, shows high values in the cyst fluid and serum of PCLD patients due to production and secretion by cyst epithelia. These do not reflect malignancy in these patients and may be of value as a biomarker for intervention efficiency assessment.[822]

Vascular Disorders

Several comprehensive reviews of vascular disorders of the liver, including clinical guidelines, are available.[823,824] In general, hepatic vascular lesions can be subdivided functionally into those that obstruct hepatic vascular inflow (portal vein thrombosis, hepatic artery thrombosis, presinusoidal vascular obstruction); those that obstruct blood flow through the liver (intrasinusoidal malignancy, amyloid, sickle cell disease, etc.); and those that obstruct hepatic vascular outflow (hepatic venous outflow obstruction [HVOO]).[824] They can also be divided anatomically (portal venous system, hepatic venous system, sinusoids).

Diseases of the Portal Venous System

Portal hypertension is most often caused by cirrhosis of the liver but is occasionally a result of noncirrhotic etiologies including (but certainly not limited to) sarcoidosis, schistosomiasis, portal vein disorders, venous outflow obstruction, and massive liver infiltration by malignancy or amyloidosis.[825] Knowledge of the causes of noncirrhotic portal hypertension is important, as liver biopsies are often done to determine the cause of portal hypertension in patients who are not known to have cirrhosis.

HPS is a term referring to fibrous intimal thickening of the portal vein or its branches, resulting in noncirrhotic portal hypertension.[826] In the majority of patients, HPS is of unknown cause. In a small number of cases, the cause is identified as a toxin, such as arsenic,[827] vinyl chloride,[828] or cytotoxic drugs.[829] Recently, as noted previously, HPS has been identified in patients with HIV, postulated to be due to intrahepatic microthrombosis or altered hepatic fibrogenesis related to HAART or due to HIV itself.[276] Endothelial to mesenchymal transition of the portal venous endothelium via TGF-β1/Smad activation is associated with portal venous stenosis in idiopathic portal hypertension and has been suggested to be the mechanism of the portal venous obliteration.[830] What is described as "intrahepatic portal venopathy" of unknown etiology is reported as a major cause of portal hypertension in India (termed noncirrhotic portal fibrosis) and in Japan (termed idiopathic portal hypertension).[831]

Needle biopsies are not always diagnostic. The lesions are heterogeneous within the liver, and not all abnormalities are found in the same case. The hallmarks of the disease are thrombosis/sclerosis of portal vein branches and the presence of aberrant intrahepatic vessels.[832] In disease of the portal vein itself, eccentric intimal thickening suggests organized thrombosis, and smooth muscle hyperplasia of the venous media suggests arterialization of the vessel.[833] The hepatic lesions are often patchy in distribution. Microvascular portal vein disease results in a more homogeneous phlebosclerosis of smaller portal tracts.[826] Recent and old thromboemboli, with or without recanalization, may be superimposed, which characterizes the "obliterative portal venopathy" noted by Indian authors. The vein may have completely disappeared, leaving only a fibrous scar surrounded by several thin-walled vascular spaces presumably resulting from proliferating or recanalized venules ("cavernous transformation").[834] The vascular changes are accompanied by portal and periportal fibrosis of varying extent. In areas without phlebosclerotic lesions, this fibrosis may be the only histologic abnormality. Abnormal vessels occur in the periportal area, termed megasinusoids,[834] periportal angiomatosis,[626] or aberrant intrahepatic vessels,[835] which correspond to dilated terminal portal vein branches or inlet venules.[832] Similar thin-walled vessels occur randomly in the lobules; efferent veins may show sclerosis or dilation.[834]

According to some, nodular regenerative hyperplasia is always present to some degree in patients with HPS—not surprisingly so, since the pathogenesis of the two entities is similar.[832] The mild to moderate incomplete septation and development of parenchymal nodules seen in HPS is similar to that of incomplete septal cirrhosis in the nosologic spectrum of noncirrhotic portal hypertension. Furthermore, the progression from HPS to incomplete septal cirrhosis has occasionally been noted.[836] HPS, nodular regenerative hyperplasia, and incomplete septal cirrhosis are characterized by portal hypertension with only mild liver function abnormalities,[626] supporting the suspicion that these entities represent a spectrum of diseases in which nonuniformity of blood supply to the parenchyma plays a pathogenetic role. In some rare instances the cause of the portal hypertension is obscure: the liver histology is normal and no occlusion of portal or splenic veins can be identified (truly idiopathic portal hypertension).[837] A review describing practical guidelines for the histopathologic study of liver biopsies from patients with noncirrhotic portal hypertension has been published.[826]

Hepatic Venous Outflow Obstruction

HVOO, which may be caused by a number of things, should be specifically characterized by the location, cause, and nature of the occlusive lesion, in order to avoid the inappropriate and confusing use of the term *Budd–Chiari syndrome*.[838]

The histopathology of HVOO varies according to its severity and duration (acute or chronic), independent of its cause. *Acute HVOO* is characterized by dilation and congestion of sinusoids, predominantly in the centrilobular area. In mild cases, the liver cell plates may be thinned, but in severe cases, the hepatocytes become atrophic and may disappear, leaving a denuded framework of lining cells and perisinusoidal fibers. Severe disease creates a hemorrhagic, blood lake-like appearance. Erythrocytes may extravasate into the space of Disse and permeate the liver cell plates, supplanting the hepatocytes (Fig. 19.73),[839] a pattern most visible when sinusoidal red blood cells have drained out during tissue processing. *Chronic HVOO* results in centrilobular fibrosis of variable extent. The fibrotic areas eventually join, resulting in central–central bridging fibrosis that encircles normal portal tracts and their surrounding parenchyma (so-called reversed lobulation). A cirrhosis-like nodularity can evolve in advanced cases (termed cardiac cirrhosis, Fig. 19.74).

BCS is the eponym for hepatic venous outflow tract obstruction, whatever the level or the mechanism of obstruction, although it is often equated with hepatic vein thrombosis. A collaborative study involving several European centers, designed to characterize the causes and treatment of incident BCS, found that most patients with BCS have at least one thrombotic risk factor, and many have more than one; myeloproliferative disorders are most common.[840] BCS is primary when due to a primarily venous disease (thrombosis or phlebitis, Fig. 19.75) and secondary when related to compression or invasion by a lesion originating outside the veins (benign or

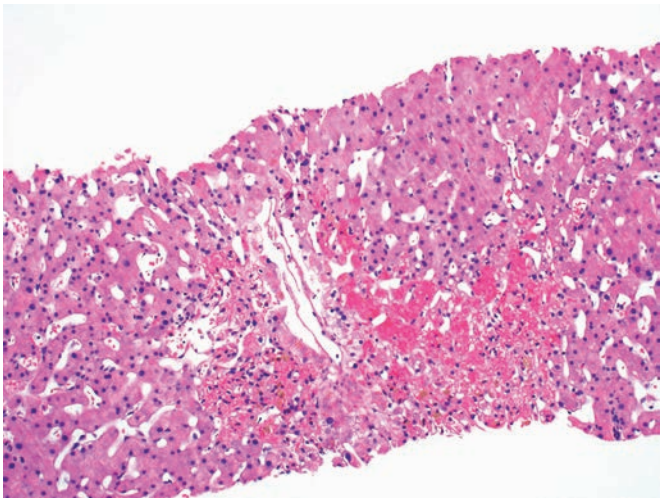

Figure 19.73 Acute hepatic venous outflow obstruction featuring sinusoidal dilatation in zone 3, with atrophy of the cell plates and extravasation of red blood cells.

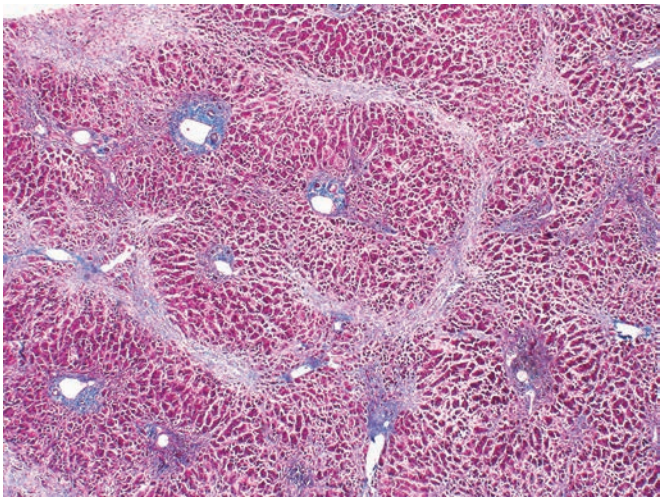

Figure 19.74 So-called cardiac cirrhosis, in which central vein to central vein fibrous bridges form nodules that encircle portal tracts. This patient had chronic congestive heart failure.

malignant tumor, abscess, cyst, etc.).[841] Late consequences of thromboses may take the form of fibrous webs.[842] The microscopic lesions are those of venous outflow obstruction. The centrilobular and lobular veins may contain recent or organized thrombi, presumably extensions of thrombus in the larger veins. With time, the fibrous lesions of chronic venous outflow obstruction develop. The surviving periportal parenchyma often shows evidence of regeneration; nodular hyperplasia and even cirrhosis-like nodularity may develop.[843] The liver is often unevenly affected.

Sinusoidal Obstruction Syndrome

The term *veno-occlusive disease* indicates the fibrous occlusion of the small branches of the hepatic vein less than 1 mm in diameter, without large hepatic vein occlusion. This initial lesion is followed by a cascade of events that leads to circulatory compromise of centrilobular hepatocytes, fibrosis, and venular narrowing, with obstruction of liver blood flow; hence this form of liver injury is now termed SOS.[844] This lesion can often be detected in needle biopsies. Several studies have suggested that SOS is a result of toxin-mediated injury to the sinusoidal endothelial cells. The historical cause of SOS is ingestion of pyrrolizidine alkaloids,[845] which remains a hazard.[846] It has also been described in patients who have undergone bone marrow, kidney, or liver transplantation, liver irradiation, or chemotherapy, and in those who suffer from arsenic poisoning, and heroin addiction.[847,848] Veno-occlusive lesions are further observed in alcoholic liver disease.[849] The histologic lesions include occluded hepatic venules, luminal narrowing of hepatic venules, phlebosclerosis, and centrilobular sinusoidal fibrosis and necrosis.[850]

Sinusoidal dilation is an integral feature of HVOO, but it is further observed in some drug-induced lesions (including azathioprine, long-term contraceptive use, and vitamin A toxicity), in rheumatoid arthritis, in malignant or granulomatous diseases,[851,852] and in preeclampsia and eclampsia, associated with sinusoidal fibrin thrombi and periportal ischemic hepatocellular necrosis.[853] The distribution is often zonal, and centrilobular sinusoidal dilation is the most common variety, with prominent involvement of the perivenous region extending to the midzonal region in more severe forms. Periportal dilation affects the periportal sinusoids, eventually extending more centrally. Irregular or nonzonal sinusoidal dilation is noted in many settings and is often of unknown causation; it may also be an artifact of tissue extrusion from the biopsy needle. Of diagnostic importance is its occurrence in the vicinity of intrahepatic space-occupying lesions (granulomas, tumors, and abscesses), sometimes combined with obstructive-type periportal ductular reaction. This finding in a biopsy specimen may provide evidence of a missed mass lesion and prompt additional investigation.[854]

Miscellaneous Other Vascular Lesions

Peliosis hepatis consists of the presence of cystic blood-filled spaces in the liver parenchyma.[855] The lesions may be macro- or microscopic, ranging in size from less than one to several millimeters in diameter. Lesions are randomly distributed without zonal preference. The endothelial lining is often incomplete. Classification on the basis of the presence or absence of endothelium is not warranted.[856] Peliosis occurs in association with numerous conditions including malignancy, organ transplantation, treatment with steroid hormones, and chemotherapy.[857] The lesions may be incidental findings, but occasional cases have ruptured resulting in fatal hemoperitoneum.[858] Peliotic lesions in immunosuppressed patients (e.g., AIDS), known as *"bacillary peliosis hepatis"* or *"bacillary angiomatosis,"* are caused by rickettsial organisms *(Bartonella)*, and are characterized by a myxoid stroma and clumps of microorganisms demonstrable with the Warthin–Starry

stain or molecular assays.[270] A number of vasculitides involve the liver, including *polyarteritis nodosa*,[859] which may be associated with HBV, and *Churg–Strauss syndrome*.[860] The liver may also be involved in *hereditary hemorrhagic telangiectasia*.[861]

Liver Disease in Pregnancy

Normal pregnancy does not entail specific light microscopic hepatic changes. Diseases affecting the liver in pregnancy can be subdivided into those which occur exclusively during pregnancy and those which occur simultaneously but not exclusive to gestation.[862–865]

Acute Fatty Liver of Pregnancy

AFLP is a rare but grave complication that develops in the last 10 weeks of gestation and affects predominantly primigravidae. It is the most serious of the pregnancy-associated diseases, but over the last couple of decades the prognosis has improved dramatically.[866] It is caused by a fatty acid transport and mitochondrial oxidation (FATMO) disorder of the fetus.[360] Affected livers are grossly yellow and frequently small, a reflection of substantial loss of parenchyma. The most characteristic microscopic feature is microvesicular steatosis, usually involving the entire liver lobule but sometimes sparing a narrow periportal rim of hepatocytes (Fig. 19.76). Hepatocytes containing very fine fat droplets of less than 1 µm diameter may not be recognized as steatotic, but rather appear as ballooned hepatocytes on routinely stained sections. This mimics the hydropic swelling of liver cells in acute viral hepatitis and may cause problems with diagnosis in the 10%–20% of cases in which a lymphoplasmacytic infiltrate and acidophil bodies occur.[866,867] Histochemical fat stains on frozen sections may be extremely helpful; therefore, in patients with unexplained jaundice in late pregnancy, it is wise to reserve part of the biopsy specimen for frozen sectioning and oil red O staining.[865] Fibrin thrombi are occasionally demonstrable in the hepatic sinusoids, and some patients show cholestasis, hepatocellular necrosis, extramedullary hematopoiesis, and giant mitochondria.[866,867] Termination of pregnancy and supportive care for hepatic encephalopathy and extrahepatic complications may be necessary for patient survival. AFLP rarely recurs in subsequent pregnancies; exceptions are very rare.[868]

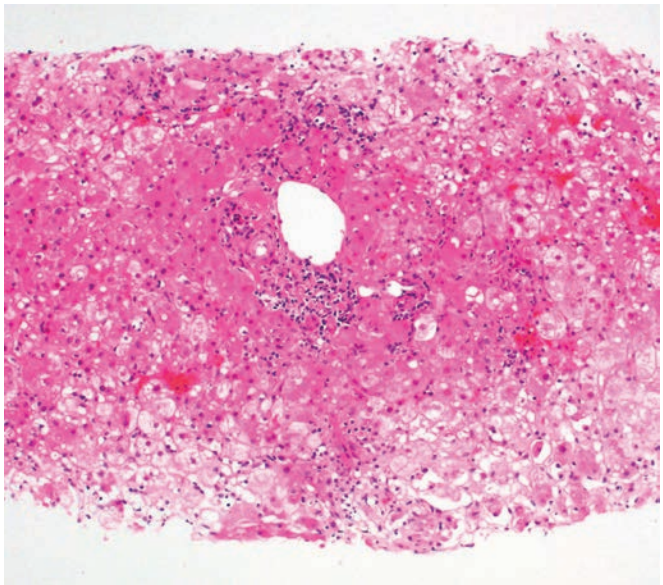

Figure 19.76 Acute Fatty Liver of Pregnancy. Ballooned hepatocytes with microvesicular steatosis are present, with a small zone of spared parenchyma around the portal tract.

Toxemia of Pregnancy (Preeclampsia/Eclampsia)

Preeclampsia is characterized by hypertension that is either induced or aggravated by pregnancy, in association with proteinuria, peripheral edema, and occasional coagulation abnormalities.[869] Convulsions and coma may follow, corresponding to eclampsia.[853,865] Preeclampsia develops in 5% of pregnancies, generally during the third trimester, and especially in primigravidae. The incidence is increased in patients with AFLP.[867] Severe preeclampsia and eclampsia cause hepatocellular dysfunction reflected by elevation of serum transaminases and/or alkaline phosphatase. Macroscopically, the liver shows diffuse, fine or blotchy hemorrhages over the capsule and on the cut surface.[853,865] Endothelial injury and disruption cause intravascular coagulation. Histologically, fibrin thrombi are found in portal vessels and periportal sinusoids, in variable combination with hemorrhage and hepatocellular necrosis. Fibrin can be identified by PTAH staining or immunohistochemistry. Extensive liver damage may lead to liver failure, and two rare complications—rupture preceded by subcapsular hematoma and infarction of the liver—often prove fatal.[853]

HELLP Syndrome

The acronym HELLP stands for hemolysis, elevated levels of liver enzymes, and low platelet count. The syndrome is exceedingly rare and occurs in preeclamptic women.[870] The characteristic features are periportal hemorrhage, hepatocellular necrosis, and fibrin exudate.

Intrahepatic Cholestasis of Pregnancy

ICP is a reversible form of cholestasis, usually occurring in late pregnancy and persisting until delivery.[871] The incidence of ICP in Europe is approximately 10–150 per 10,000 pregnancies. Quality of life can be impaired by pruritus, jaundice, and fat malabsorption; the prognosis for the mother is good, but ICP may be a condition with lethal outcome for the unborn child. Heterozygote mutations of hepatobiliary transport proteins (*MDR3* and *BSEP*)[646,651] predispose to ICP. However, overall ICP is a syndrome with a heterogeneous pathogenesis, including genetic, hormonal, and environmental factors.[872] In general, liver biopsy is unnecessary for diagnosis. Histopathology reveals canalicular and hepatocellular bilirubinostasis, especially in the centrilobular area.[651,873]

Coincident liver diseases that may be encountered during pregnancy include viral hepatitis, cholelithiasis, and preexisting liver disease.

Liver Involvement in Systemic Diseases

This section is restricted to some more frequently observed lesions. For full coverage of the topics, the reader is referred to comprehensive textbooks of hepatic pathology.

Granulomatous Liver Disease

Epithelioid granulomas are present in 3%–10% of liver biopsies,[264] the incidence varying according to geographic location and method of selection of patients for biopsy. An adequate evaluation of hepatic granulomatous lesions requires careful histologic evaluation of the granulomas themselves and of the associated changes (e.g., hepatitis, bilirubinostasis, bile duct damage), as well as correlation with clinical history and laboratory information. Special techniques may be helpful,

for example special histochemical stains (Ziehl–Neelsen, silver methenamine), immunohistochemistry, or molecular assays for organisms; polarizing microscopy for inclusions; and x-ray microanalysis (e.g., for gold, barium, silicon).[264,874] According to one study, a combined histologic, clinical, serologic, and molecular approach can clarify the etiology in up to 64% of cases.[875]

Sarcoidosis

Hepatic sarcoidosis covers a broad spectrum from asymptomatic hepatic granuloma formation and slightly deranged liver function tests to clinically evident disease with cholestasis or, in advanced cases, cirrhosis and portal hypertension.[876] The incidence of granulomas in livers of patients with established sarcoid varies in the literature from 21% to 79%. In liver biopsies from patients with sarcoidosis and clinical evidence of hepatic disease (a discrete subset of all patients suffering from sarcoidosis), granulomatous inflammation was found in 100% in a series of biopsies referred to the Armed Forces Institute of Pathology.[877] In this study, three broad categories of abnormalities were noted besides the granulomatous inflammation: cholestatic (58%), necroinflammatory (41%), and vascular (20%). Histologic mimics of several other disorders, including PBC, PSC, drug-induced liver disease, bile duct obstruction, and viral hepatitis were noted. Hepatic fibrosis was found in 21% of biopsies, including 6% with cirrhosis. Although these numbers may reflect referral bias, they do suggest that some patients with hepatic sarcoidosis have progressive liver disease. The epithelioid granulomas of sarcoidosis typically occur with greatest frequency in the portal and periportal areas, often in clusters (Fig. 19.77A). The granulomas may be of differing "ages" and typically heal with fibrosis, so that varying numbers and degrees of epithelioid cells, inflammation, giant cells, and scarring are often seen in the same biopsy. In a few cases, masses of granulomas and fibrosis may develop (sarcoidoma), raising clinical suspicion of a neoplasm.[877]

PBC can at times be particularly difficult to differentiate from sarcoidosis since both conditions may lead to portal granulomas, lymphocytic cholangitis, bile duct injury and destruction, ductopenia, and chronic cholestasis (Fig. 19.77B).[878,879] It is also possible that both conditions might even coexist.[880] Some sarcoidosis patients initially present with portal hypertension due to portal granulomas and fibrosis.[881] It is important to note that a final diagnosis of sarcoidosis cannot be made by histopathologic study of a liver biopsy alone, due to the multiplicity of histologically similar granulomatous diseases.

Fibrin-ring (or doughnut) granulomas show a distinctive ring pattern in which fibrin is deposited circumferentially within or at the margin of the granuloma, which is composed of epithelioid cells, giant cells, and neutrophils, and a central fat vacuole (Fig. 19.78). Serial sectioning may be required to detect the typical "fibrin-ring" configuration.[882] Originally described in Q fever, it has also been reported in allopurinol hypersensitivity, CMV and EBV infection, leishmaniasis, toxoplasmosis, HAV, Hodgkin lymphoma, giant cell arteritis, and systemic lupus. It has been suggested that it may represent a nonspecific reaction to liver injury.[313]

Echinococcus (Hydatid Cyst)

Since leakage of antigen-containing cyst fluid into the circulation may result in possibly fatal anaphylactic shock, liver biopsy is not recommended, but fine-needle aspiration is a safe diagnostic procedure.[883] The diagnosis rests on liver imaging and positive serology.

Hydatid disease is caused by the larval or cystic stage of echinococcus tapeworms, of which *Echinococcus granulosus* is the most frequent;

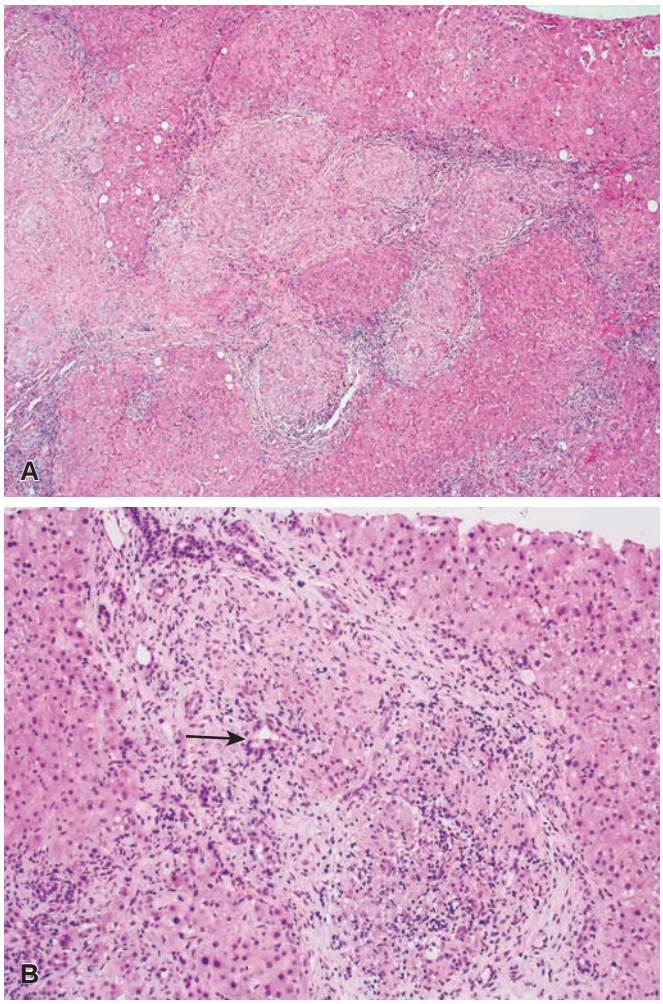

Figure 19.77 Sarcoidosis. A, Multiple confluent, noncaseating, epithelioid granulomas with associated fibrosis. **B,** Cholestatic sarcoidosis mimicking primary biliary cirrhosis. Note bile duct damage *(arrow).*

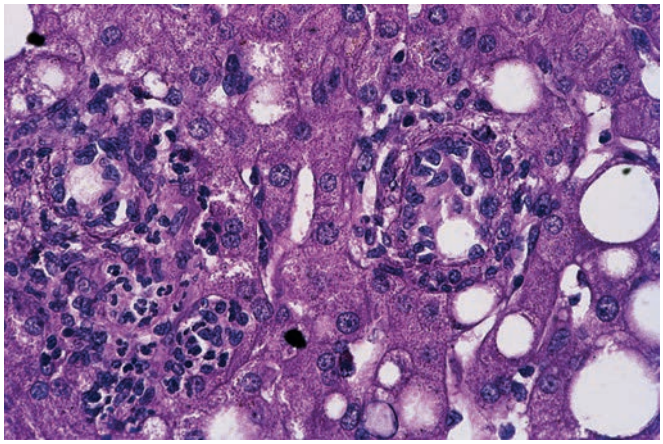

Figure 19.78 Q Fever. Detail of lobular parenchyma with some steatosis and two fibrin ring granulomas. The granuloma is composed of a central fat vacuole, a layer of histiocytes and lymphocytes, a fibrin ring, and additional accumulation of inflammatory cells.

Figure 19.79 Echinococcosis of the liver featuring multiple cysts in a resection specimen.

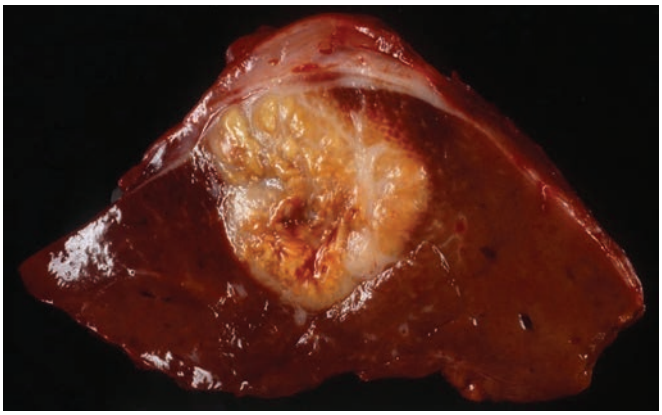

Figure 19.80 Liver Abscess With Necrotic Center and Associated Fibrosis. (Courtesy Dr. George F. Gray, Jr.)

the adult parasites are found in dogs and jackals in all continents.[884] After ingestion of eggs of *E. granulosus*, the eggs hatch and the larval oncospheres pass to the liver by the portal vein. Three-fourths of infected individuals develop one or more hepatic cysts, which grow slowly. The typical hydatid cyst is spherical and may measure up to more than 30 cm in diameter. The majority occur in the right lobe, but they may be multiple, involving all lobes (Fig. 19.79).[885,886]

Histologic examination of the cyst wall shows an outer chitinous (or fibrous laminar) layer and an inner germinal layer. The cyst wall may be surrounded by either granulation tissue or a fibrous capsule (so-called pericyst layer). Calcification in the latter layer signifies that the cyst is dead. The adjacent liver parenchyma often shows pressure atrophy and a portal infiltrate in which eosinophils may be prominent. The viable cyst is filled with colorless fluid, which contains daughter cysts and brood capsules with scolices. In some patients, daughter cysts are found outside the chitinous layer of the cyst; these are referred to as extracapsular or satellite cysts.[887] The scolices can be easily identified after macerating a portion of the germinal layer in saline solution. They have characteristic hooklets of 20–40 µm length.

Communication with the biliary tract and superimposed infection are frequent in echinococcosis of the liver.[888] Rupture of the cysts into the peritoneal cavity may result in a fatal anaphylactic reaction or in the formation of innumerable small granulomas grossly resembling peritoneal tuberculosis. Identification of fragments of germinal membrane or scolices in the center of a granuloma points to the diagnosis. Hepatic echinococcus cysts can also rupture inside the gallbladder or through the diaphragm into the pleural space and lung. Hydatid cysts occasionally rupture into the bile ducts and cause severe eosinophilic cholangitis with extensive parenchymal destruction, apparently resulting from a hypersensitivity reaction to parasitic antigens.[889]

Echinococcus multilocularis is less common but causes a more aggressive clinical disease. The liver lesions appear as multilocular, necrotic, cystic cavities containing thick pasty material, not surrounded by a fibrous wall. Histologically, the irregular cysts have a laminated membrane, but no nucleated germinal membrane or protoscolices. The laminated membrane is clearly visualized by the PAS stain; it is often fragmented. The lesion may be surrounded by a granulomatous reaction containing neutrophils and eosinophils, or a peripheral rim of necrosis, fibrosis, and focal calcification.[890]

A number of other infections cause granulomas, the majority as part of systemic disease, including *M. tuberculosis*, atypical mycobacteria, cat-scratch disease *(B. henselae)*, and fungal infections (*Histoplasma capsulatum*, *Cryptococcus* species).[264]

Malaria

The most distinctive feature is the presence of finely granular, dark brown or black pigment (hemozoin), initially in Kupffer cells and later in portal macrophages. It is birefringent and negative with PAS and iron stains. It resembles the artifactual formalin pigment and is likewise soluble in saturated alcoholic picric acid. It strongly resembles schistosomal pigment, although it differs biochemically. Anthracotic pigment, which resembles malarial pigment, is not birefringent.[891] Additional histologic changes may include focal necrosis, steatosis, and a mild mononuclear portal infiltrate.

Hepatic Abscess

The incidence of hepatic abscess had been fairly stable over the past five or six decades. However, the character of the disease has changed drastically during that time. In the past, hepatic abscesses often affected young adults; most were amebic (see later) or secondary to pylephlebitis. Today, pyogenic hepatic abscesses in the United States are often due to enteric bacteria and seen in older patients (often with diverticulosis)[892] or in HIV-infected or other immunocompromised young individuals. In the latter population, an increasing number of tuberculous "abscesses" of the liver have been detected.[893] The mortality rate for pyogenic abscess, which ranged from 30% to 80% in the past, has dropped to 10%–20% in more recent studies on the subject.[894] Important predisposing factors include liver transplantation, diabetes, alcoholism, and history of malignancy.[895] Historically *Escherichia coli* has been the primary causative pathogen, but the incidence of abscesses due to *Klebsiella* is increasing and has surpassed *E. coli* in several countries.[896] Neonatal hepatic abscesses are rare but should be considered in a neonate with ongoing sepsis.[897] They may occur in association with misplaced central (umbilical) catheters.

Hepatic abscesses vary considerably in size and may mimic tumors grossly and radiographically (Fig. 19.80). Multiplicity of lesions is seen in about half of pyogenic abscesses and 25% of amebic abscesses.[898] In slightly less than half of cases, there is communication

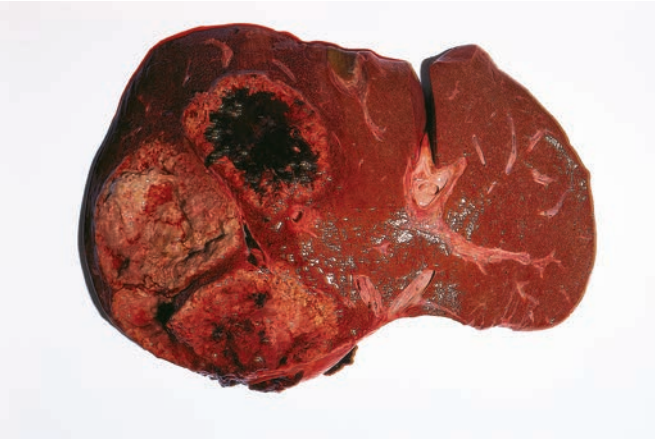

Figure 19.81 Amebic Abscesses Occupying Most of the Right Lobe of the Liver. Three distinct lesions are seen. (Courtesy Dr. RA Cooke, Brisbane, Australia; from Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

between the abscess and the intrahepatic biliary system.[899] Treatment of hepatic abscess includes antibiotic therapy and drainage or excision.[900]

Amebic abscess is usually single, most frequently right sided, and close to the liver dome[901] (Fig. 19.81). In immunocompromised patients, it has a greater tendency for multicentricity. Most cases occur in adults, but they can also develop in infants and children.[902] The necrotic center usually contains an odorless, pasty, chocolate brown fluid. Microscopically, the bulk of the lesion consists of necrotic material with few if any neutrophils, surrounded by a layer of fibrin, macrophages, lymphocytes, and a few fibroblasts. The abscess wall is thinner than that of a bacterial liver abscess. Clusters of ameba are usually found, but extensive search may be necessary for their detection. Superinfection by bacteria may supervene, as well as extension and perforation into pleuropulmonary structures, subphrenic space, peritoneal cavity, and—less commonly—pericardial sac, bile ducts, kidney, mediastinum, chest wall, abdominal wall, and flank.[903]

Amyloidosis and Light Chain Deposition Disease

Although systemic amyloidosis commonly involves the liver, it rarely gives rise to clinically evident hepatic disease. Amyloid is recognized as a homogeneous eosinophilic or amphophilic extracellular material (Fig. 19.82A and B) displaying apple green birefringence after positive Congo red staining. Primary myeloma-associated (AL) amyloidosis and reactive (AA) amyloidosis cannot reliably be distinguished by the topographic distribution pattern of the deposits. Immunohistochemistry and mass spectrometry are typically used for amyloid subtyping.[904]

Amyloid is usually deposited in the hepatic artery branches or along the sinusoids in the space of Disse, and often occurs in both locations. Perisinusoidal deposition leads to atrophy of liver cell plates and narrowing of sinusoids, occasionally resulting in intrahepatic cholestasis and portal hypertension.[905,906] Much more rarely, amyloid is deposited in globular form. Intracellular amyloid globules and transitional forms of globular to linear deposits suggest that this is an early form of hepatic involvement by systemic amyloidosis.[907]

Homogeneous perisinusoidal and portal depositions closely resembling amyloid are seen in hepatic involvement in *light chain deposition disease*, which usually causes renal symptoms but rarely

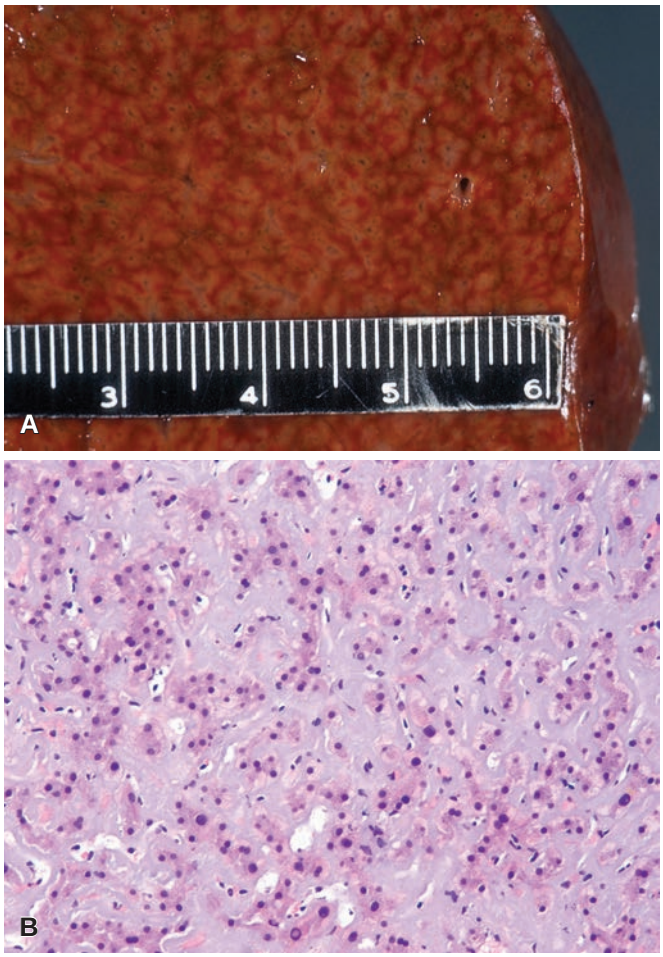

Figure 19.82 Amyloidosis. A, Gross specimen showing sinusoidal amyloid deposition. **B,** Lobular parenchyma with massive amyloid deposition in the space of Disse and corresponding marked atrophy of liver cell plates. (**A,** Courtesy Dr. George F. Gray, Jr.)

affects the liver. Immunohistochemical staining for kappa and lambda light chains permits identification of the deposits, which usually mark as kappa (Fig. 19.83). Light chain deposits are Congo red negative and show no green birefringence with polarized light. In exceptional cases, light chain deposition and amyloid are found in the same patient, even more rarely associated with intrahepatic cholestasis.[908]

Nonspecific Reactive Changes

Several primarily extrahepatic diseases, including febrile, inflammatory, and neoplastic conditions, especially in older patients, are associated with nonspecific reactive changes in the liver. One may find portal and lobular inflammation, steatosis, Kupffer cell hypertrophy, reactive hepatocellular changes, and even focal necrosis of hepatocytes. Clinical information is required for adequate distinction from mild chronic or residual hepatitis.[9,909]

In endotoxic shock and sepsis, there may be marked ductular cholestasis; the ductules may appear broadly dilated, and the bilirubin concrements may show variable degrees of inspissation and admixture of PAS-positive material. Part or all of the lining ductular cells may appear flattened, desquamating, or necrotizing, and infiltrated with neutrophil polymorphs. The dilated ductules may appear all around the perimeter of some portal tracts (see earlier, Fig. 19.45). This lesion is highly suggestive of septicemia and constitutes a

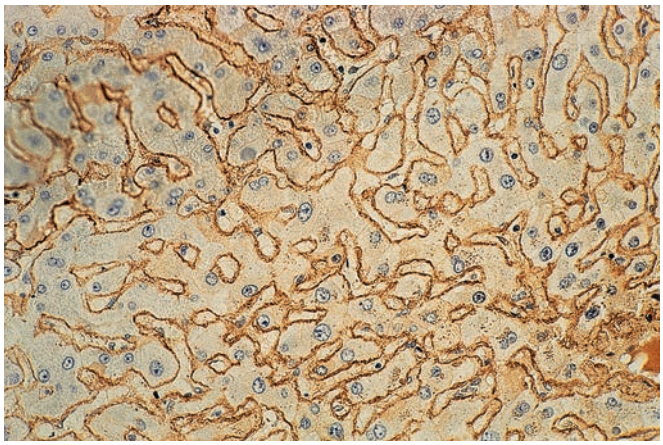

Figure 19.83 Light Chain Deposition Disease. Detail of lobular parenchyma with kappa chain deposition in the space of Disse. (Immunostain for kappa light chain.)

prognostically ominous sign ("cholangitis lenta").[499] Experimental evidence suggests that proinflammatory cytokines and nitric oxide have crucial roles as Kupffer cell–derived mediators of cholestasis. Sepsis-associated cholestasis (in its truest meaning) is caused by reduced expression and function of hepatocellular transport systems. Periductal inflammatory infiltrates, as seen in cholangitis lenta, reflect the ability of the bile-duct epithelium (i.e., cholangiocytes) to actively secrete cytokines and recruit inflammatory cells, which results in impaired ductular bile secretion. In view of its sinister prognosis, the finding of cholangitis lenta necessitates urgent reporting to the clinician.[910]

Liver Pathology in Organ Transplantation

Hepatic abnormalities may be associated with transplantation of the liver and of other organs.

If close clinicopathologic collaboration is essential in modern medicine in general, it is a necessity par excellence in the field of organ transplantation. In transplantation centers, the pathologist is part of the clinical care team, involved in evaluation of the patient's primary disease before transplantation, in identification of underlying donor liver disease (e.g., steatosis, cancer) at the time of allograft procurement, and in recognition of a wide variety of complications following transplantation.[911–913] As liver transplantation centers become established all over the world, pathologists in local hospitals who do not routinely encounter specimens from liver transplant patients may be confronted with them during patients' post-transplant medical care and follow-up, and thus need some familiarity with hepatic transplant pathology.

Most centers obtain percutaneous liver biopsies when the clinician is warned by symptoms or signs of deterioration of liver function. Some centers, however, perform biopsies, often referred to as "protocol biopsies," on a planned schedule irrespective of liver chemistry.[914,915]

Preexisting Donor Lesions

The pathologist may be requested to exclude preexisting disease in a potential donor liver by frozen section, as marked macrovesicular steatosis carries the risk of primary graft dysfunction.[916] Parenchymal involvement should be semiquantitated as absent, mild (<30%), moderate (30%–60%), or marked (>60%),[917] since the latter category is considered unsuitable for use because of the high risk of primary dysfunction of the allograft.[917,918] Although livers with lesser degrees of steatosis (<30%) can usually be transplanted safely, a period of liver dysfunction (rise in transaminases, prolonged prothrombin time) may occur in the early post-transplant period and even lead to reduced graft survival. A retrospective study comparing frozen-section analysis with routine histologic permanent slides and the outcomes of grafts in liver biopsies from 294 candidate donors led to the conclusion that intraoperative histologic evaluation of biopsies from cadaveric liver donors by frozen section is an accurate, time-effective, and predictive method for the assessment of graft suitability.[919] One study does recommend biopsies of two sites to evaluate donor livers.[920] Most fat appears to be cleared during the first post-transplant week.[921]

Due to the urgent need for liver grafts, some centers—noting that the majority of the European centers currently reject liver grafts with severe steatosis—have tested the use of severely steatotic livers with good results, though emphasizing that maximal effort must be expended when dealing with these high-risk organs.[922] A trans-Atlantic survey in 2002 between centers in the USA and the UK noted that current practice policies differed not only between nations, but also among centers in each country, concluding that lack of scientific evidence necessitated more research in the field to allow the safe use of all viable livers.[923] Microvesicular steatosis is not a contraindication.[924,925] Demonstration of a primary or metastatic malignant tumor is a contraindication to liver transplantation.

A study with the primary goal of determining the contribution of biopsy findings to potential living donor evaluation found that a minority (42%) of biopsies from a potential donor population were completely normal; the remainder showed steatosis (37%), steatohepatitis (15%), or unexplained low-grade/early stage chronic hepatitis, PBC, or nodular regenerative hyperplasia (6%). Biopsy findings disqualified 29 out of 56 donors, leading to the conclusion that liver biopsies provide valuable information about otherwise undetectable liver disease in potential liver donors.[926]

Diseases of the Transplanted Liver

The liver graft is subject to many of the same diseases that affect native livers, and, in addition, to a multitude of other abnormalities, including preservation/reperfusion injury (PRI), allograft rejection, various post-transplant complications (e.g., surgical mishaps, hepatic artery and portal vein thrombosis, bile duct problems such as dehiscence, leaks, necrosis, strictures, concrement formation, infection), drug reactions, opportunistic infections, recurrence of the original disease, and post-transplant lymphoproliferative disorders.

Preservation Reperfusion Injury

PRI is nonimmunologic graft damage resulting from the harvesting, ischemic preservation, transportation, and reperfusion of the donor liver.[927,928] This injury appears early (first 2 weeks post-transplant) and regresses spontaneously over several weeks.[929] For evaluation of possible PRI, specimens are obtained at the time of transplantation directly after revascularization of the graft (time zero biopsies).[930] Surgical hepatitis is quite common, as in any surgical specimen,[8] consisting of clusters of neutrophils and scattered acidophil bodies (see earlier, Fig. 19.2). Another preservation injury is so-called functional cholestasis, with bilirubinostasis in hepatocytes and canaliculi.[931,932] This should be distinguished from cholestasis associated with acute rejection, drug toxicity, hepatitis, bile duct obstruction, or sepsis.

Another lesion due to PRI is hepatocellular ballooning of variable degree, centrilobular or panlobular, often associated with bilirubinostasis and some hepatocyte dropout; the presence of all three features represents serious PRI associated with a poor graft outcome.[933]

However, centrilobular hepatocyte loss in early post-transplant biopsies may also represent a rejection-related phenomenon, even if typical portal tract changes are not prominent, and augmentation of immunosuppression should be considered.[934]

Allograft rejection. Hepatic allograft rejection is defined as injury to the transplanted liver caused by the immunologic reaction of the host. Rejection has been classified as humoral, acute (cellular), or chronic (ductopenic).[935] The histopathologic lesions have been well characterized and described in the literature.[936–939]

Humoral rejection (hyperacute or *antibody-mediated rejection)* is rare; it develops in patients with preformed or subsequently formed antibodies to an ABO blood group–incompatible donor.[940] The antibodies react with the graft vasculature and cause endothelial damage and thrombosis within the first few hours, ultimately resulting in coagulative and hemorrhagic necrosis in a few days. Immunohistochemistry for vascular C4d staining may be helpful in making the diagnosis.[941]

Acute (cellular) rejection is the most common form of rejection. Historically, clinically significant rejection has been reported to occur in 20%–40% of patients, whereas histologic abnormalities are seen in up to 80% of protocol biopsies obtained around the first week after transplantation. The incidence of clinically significant rejection appears to be declining, however, presumably related to improved immunosuppression.[942] It generally develops within the first 3 weeks after transplantation, and its median onset ranges between 7 and 10 days (with exceptions, of course).[943] It results from a cell-mediated immune reaction directed at bile duct epithelium and the endothelium of portal and centrilobular veins.[944] Histologically, cellular rejection is characterized by the triad of portal infiltration, bile duct damage, and endotheliitis (also termed endothelitis or endothelialitis; Fig. 19.84). None of these features is, by itself, entirely specific for rejection, and at least two of these three features should be required for diagnosis.[935] The portal infiltrate consists of a mixture of inflammatory cells; small lymphocytes predominate, intermixed with larger lymphoid type cells, immunoblasts, macrophages, plasma cells, neutrophils, and eosinophils. In some cases eosinophils are abundant and represent a helpful diagnostic feature of rejection.[945] The infiltrate typically expands the portal tract but may be focally and unevenly distributed; for this reason, it is recommended that sections at several levels of the specimen be examined, including a minimum of five portal tracts.[946] Occasionally, the infiltrate extends beyond the limits of the portal tract and even leads to portal–portal bridging.[946]

Endotheliitis can be present in either portal or central veins, consisting of supraendothelial and subendothelial lymphocytes, endothelial damage, and lifting off of endothelium from the underlying layers. Endotheliitis of centrilobular veins, accompanied by necrosis of centrilobular hepatocytes and periportal extension of the portal inflammatory infiltrate, is indicative of severe cellular rejection.[946] A less frequent form of cellular rejection with endothelial predominance appears as isolated central venulitis (without typical portal changes) in adult and pediatric liver allograft recipients[947,948] and may result in perivenular fibrosis and a veno-occlusive syndrome.[949] Endotheliitis is not a constant feature and may be absent, especially in cases of acute rejection occurring beyond the early post-transplant period.[950]

Bile ducts are infiltrated by lymphocytes and lymphoid-type cells (lymphocytic cholangitis); bile duct epithelial damage is indicated by anisonucleosis, cytoplasmic vacuolization, areas of cell stratification or occasional dropout, and irregularities in duct outlines. Immunostaining for keratin 7 may be helpful in demonstrating presence and lesions of bile ducts.[951]

In differentiating cellular rejection from cholangitic lesions, portal eosinophilia, endotheliitis, and necroinflammation favor rejection, whereas bilirubinostasis, neutrophilic infiltration, ductular proliferation, and periductal fibrosis/edema favor cholangitis.[952]

Several grading systems of cellular (acute) rejection have been proposed. A review of grading systems was updated by Batts.[936] A consensus document,[946] published by an international panel that met in Banff, Canada, recommends the grading scheme given in Table 19.6.

Additional features that are less consistently present include bilirubinostasis, some lobular inflammatory mononuclear infiltrate, and, in cases of severe rejection, centrilobular confluent parenchymal necrosis.

Chronic rejection. Chronic liver allograft rejection can be defined as an immunologic injury to the allograft that usually evolves from severe or persistent acute cellular rejection and results in potentially irreversible damage to the bile ducts, arteries, and terminal hepatic

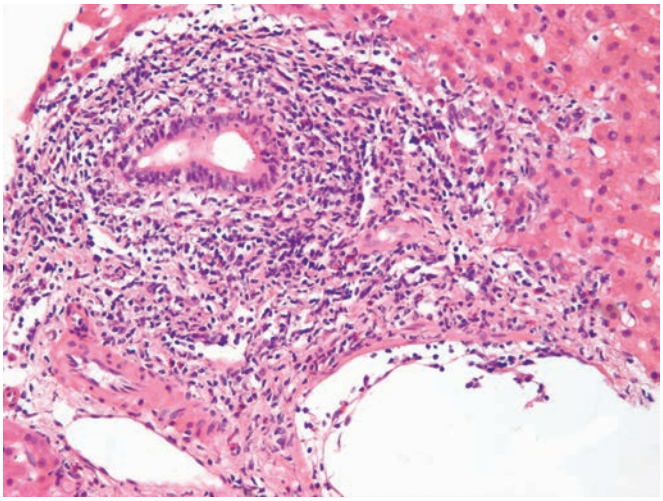

Figure 19.84 Acute cellular rejection of liver allograft, characterized by a dense mixed portal infiltrate (including eosinophils), endotheliitis, and lymphocytic cholangitis.

Table 19.6 Grading of acute cellular rejection

GLOBAL ASSESSMENT[a]	CRITERIA
Indeterminate	Portal inflammatory infiltrate that fails to meet the criteria for the diagnosis of acute rejection
Mild	Rejection infiltrate in a minority of the triads, generally mild, and confined within the portal spaces
Moderate	Rejection infiltrate, expanding most or all of the triads
Severe	As above for moderate, with spillover into periportal areas and moderate to severe perivenular inflammation that extends into the hepatic parenchyma and is associated with centrilobular hepatocyte necrosis

[a]Verbal description of mild, moderate, or severe acute rejection could also be labeled grades I, II, and III respectively.

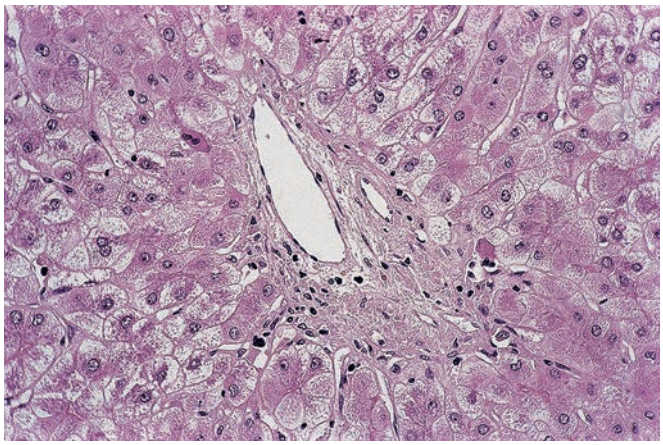

Figure 19.85 Chronic "Ductopenic" Rejection of Liver Allograft. Portal tract without a bile duct and with very sparse lymphocytic infiltration.

veins and surrounding parenchyma.[953] Terms such as "vanishing bile duct syndrome" and "ductopenic rejection" are no longer recommended, because bile duct loss is just one aspect of chronic liver allograft rejection.[935] Nevertheless, "ductopenic rejection" remains a frequently used synonym for chronic rejection.

The clinical diagnosis of chronic rejection is suspected in patients with a history of acute cellular rejection who develop progressive cholestasis, and ultimately should be based on a combination of the clinical, radiologic, laboratory, and histopathologic findings. Histologically, the minimal diagnostic criteria are: (1) the presence of bile duct atrophy/pyknosis, affecting a majority of the bile ducts, with or without bile duct loss; (2) convincing foam cell obliterative arteriopathy; or (3) bile duct loss affecting more than 50% of portal tracts. Since arteries with pathognomonic changes predominate in the hilar region and are rarely present in needle biopsy specimens, considerable significance is placed on damage and loss of small bile ducts. Obviously, other causes of ductal injury and loss should be reasonably excluded; these include biliary tract obstruction and bile duct ischemia due to hepatic artery thrombosis.[946]

The histopathologic changes of the liver in chronic rejection mainly affect the portal tracts and centrilobular areas. Within the portal tracts, chronic rejection reveals itself initially by bile duct damage, followed by loss of small bile ducts and small branches of the hepatic artery (Fig. 19.85). Early bile duct changes include uneven nuclear spacing, nuclear enlargement and hyperchromasia, loss of polarity, and interrupted epithelial lining of the ducts, giving a "dysplastic" or atrophic appearance. Expression of the senescence-related p21(WAF1/Cip1) protein is increased in cholangiocytes during early chronic rejection and decreases with successful recovery. Replicative senescence accounts for the characteristic bile duct cell cytologic alterations used for the diagnosis of early chronic rejection.[954] As the process advances, bile duct loss starts in the smaller interlobular ducts, associated with decreasing portal cellular infiltrate, resulting in a "burned out" appearance of the portal areas. Bile duct loss should be present in at least 50% of portal tracts in order to ensure a firm diagnosis of chronic rejection. Reliable counting of missing ducts requires adequate biopsy specimens, containing at least 20 portal tracts and/or the demonstration of ductopenia in several sequential biopsies.[955] A remarkable feature is the absence of ductular reaction and of periportal fibrosis, except in the presence of associated distal biliary obstruction. Possible causes are the absence of vagal innervation in the transplanted liver, which is important for hepatic progenitor cell activation,[956] and increased cholangiocytic apoptosis.[957]

Early arterial lesions consist of accumulation of subintimal, medial, and adventitial foamy macrophages, but, as mentioned, these lesions are not routinely sampled in peripheral needle biopsies. The macrophages and mesenchymal cells in arterial lesions are of recipient origin.[958] In some cases of chronic rejection inflammatory and/or foam cell lesions may also be observed in portal and hepatic venules, particularly in those cases with a more acute presentation, suggesting an overlap with acute cellular rejection.[959] Late arterial damage is mainly evaluated by the extent of loss of these structures; arterial loss is considered present when less than 77% of the portal tracts contain hepatic artery branches.[946]

In the centrilobular area, the early lesions of chronic rejection are characterized by bilirubinostasis, sinusoidal foam cells (presumably related to chronic cholestasis), and subendothelial and perivenular mononuclear inflammation of the centrilobular vein, accompanied by zone 3 hepatocyte dropout, pigment-laden macrophages, and mild perivenular fibrosis. A "transitional hepatitis," sometimes difficult to distinguish from viral hepatitis, may occur during the evolution to later stages of chronic rejection.[960] Late chronic rejection may also feature severe (bridging) perivenular fibrosis, with at least focal central–central or central–portal bridging and occasional obliteration of terminal hepatic venules.

The features used to define chronic rejection are not uniformly present in all cases. Bile duct loss can occur without arteriopathy, and vice versa, and severe (bridging) centrilobular fibrosis may be present without significant bile duct loss or obliterative arteriopathy. An individual patient may have late features of one component (e.g., bile duct loss), but early features of another component (e.g., perivenular necrosis).[946,953] Besides the two main patterns of chronic rejection (ductopenic and arteriopathic), the possibility of a "chronic hepatitis–like" pattern of chronic rejection has been postulated. It is discussed later, under "Late changes in liver allografts."

A working formulation for histopathologic staging and reporting of chronic liver allograft rejection has been proposed. Early chronic rejection is diagnosed if only one of the target structures shows late changes. An overall diagnosis of late chronic rejection requires that at least two or more of the target structures show late changes.[953]

A set of consensus criteria for the most common and problematic causes of late liver allograft dysfunction, including late-onset acute and chronic rejection, recurrent and new-onset viral and autoimmune hepatitis, biliary strictures, and recurrent PBC and PSC, including a discussion of differential diagnosis, has been published by the Banff Working Group on Liver Allograft Pathology.[962]

Other Complications

Fatty liver disease is a frequent late complication of liver transplantation. Post-transplant obesity, tacrolimus-based regimens, diabetes mellitus, hyperlipidemia, arterial hypertension, alcoholic cirrhosis as the primary indication for transplantation, and pre-transplant graft steatosis are risk factors for post-transplant steatosis.[963] The release of fat globules from dying hepatocytes may also result in the formation of cystic lesions (fat microcysts surrounded by macrophages) which resemble peliosis hepatis (so-called *lipopeliosis*).[964]

Bile duct strictures at the site of anastomosis or elsewhere (due to ischemic cholangitis) can be a cause of graft dysfunction. The classical histopathology of biliary tract obstruction in native livers is also applicable to the diagnosis of biliary complications in transplants.[965]

Hepatic artery thrombosis, alone or in combination with *portal vein thrombosis*, occurs more commonly in children. The consequences are ischemic injury (infarction) of varying extent, distribution, and age, including ischemia of the biliary tree.

Infections are frequent complications, given that hepatic allograft recipients, like other immunocompromised individuals, are susceptible to a wide range of pathogens. These include CMV, EBV, adenovirus and herpes virus infections, and sepsis due to gram-negative bacilli.

Drug-induced injury. Several of the drugs in the therapeutic regimen for immunosuppression are capable of causing hepatic damage, and because of the numerous confounding features, it may be difficult to incriminate a specific drug. Of note, *azathioprine* may cause hepatitis,[966] and *cyclosporine* (cyclosporin) may cause canalicular bilirubinostasis, hepatocyte ballooning, and vacuolization of bile duct epithelial cells.[967]

Recurrent Disease

The diagnosis of recurrent disease can be controversial on liver biopsy because some of these pretransplant disorders have histopathologic features that overlap with those seen in rejection or post-transplant biliary stricture. The risk of recurrent disease increases with time but does not directly correlate with the rate of graft loss.[968] The risk of graft loss from recurrent disease was greatest, when compared to PBC, in those transplanted for HCV, PSC, and AIH, and the overall risk of graft loss was also significantly greater in HCV, PSC, and AIH than in PBC.[969]

Recurrent HBV may cause typical features of acute and chronic hepatitis, cirrhosis, and minimal histologic changes (carrier state). In a minority of cases, atypical features of disease develop in the form of so-called *fibrosing cholestatic hepatitis*, as described previously.[69] The latter typically occurs early (before 150 days),[970] is associated with rapidly progressive graft dysfunction, and is histologically characterized by ductular reaction with associated fibrosis, prominent bilirubinostasis, hepatocellular ballooning with cell loss, and a mild mixed inflammatory reaction.[69] Fibrosing cholestatic hepatitis is associated with high viral load and occurs in other types of immunodeficiency states such as HIV infection and in renal transplant patients.[70] Recurrence of HBV in the graft has significantly decreased with the use of passive immunoprophylaxis with HBV immunoglobulin and lamivudine.[971]

HCV recurrence as defined by histologic injury is almost universal.[972–973] HCV antigens can be detected in liver biopsies within a few days after transplantation.[974] In a small group of patients graft injury is severe, and may result in graft loss.[974,975] The development of direct acting antivirals (such as sofosbuvir) has dramatically changed the treatment options for recurrent hepatitis C after liver transplantation, as they yield a sustained virological response in the great majority of patients and are typically well tolerated.[976,977]

Differentiation from acute cellular rejection is one of the most common and difficult problems in the assessment of post-transplant biopsies,[978] since morphologic features similar to those seen in rejection, such as bile duct damage, and, less generally acknowledged, endotheliitis, portal eosinophils, and pericentral fibrosis may also be due to hepatitis C.[979] It may require sequential biopsies and grading of lesions to document the progressive appearance of hepatitis C features.[980] The portal infiltrate in recurrent hepatitis C is more prominently lymphocytic and less mixed, bile duct infiltration by lymphocytes is milder, endotheliitis is absent or minimal, bile duct loss is absent, and fibrosis is more likely. In addition, the lobular parenchyma may show mild panlobular apoptotic changes (contrasting with perivenular necrosis in rejection), macrovesicular steatosis (missing in rejection) and—except in fibrosing cholestatic forms—cholestasis is rare. Recurrence of HCV often coexists with other causes of liver allograft dysfunction, such as residual PRI, biliary sludging, acute cellular and chronic rejection, and autoimmune hepatitis. The determination of the most important cause of injury is important, but may be extremely challenging.[981] A granulomatous response to HCV infection occurs in a subset of patients after transplantation without portending a worse clinical outcome.[982] Treatment with pegylated-interferon alpha-2a and ribavirin has been reported to trigger rapidly progressive chronic ductopenic rejection with or without first inducing acute cellular rejection,[983] but this is not an issue with the newer direct-acting antivirals (see earlier).

As noted previously, a severe progressive cholestatic syndrome, reminiscent of *fibrosing cholestatic hepatitis* in recurrent HBV infection, has been reported with an incidence of 2%–10%, apparently due to direct viral cytopathic effect in the context of a high viral load.[984] When studying the evolution of these cases, the first abnormality to appear is recurrent hepatitis C and cholestasis, fibrosis develops soon after, and both continue to worsen until the point of allograft failure or patient death.[985]

Recurrent PBC. In most patients, AMA persists after transplant and do not correlate with disease recurrence. Diagnosis of recurrent PBC is defined by histology, thus liver biopsy remains the gold standard.[968] Florid bile duct lesions and epithelioid granulomas are the most helpful features, although granulomatous cholangitis has also been observed in chronic viral hepatitis C.[982] Portal lymphoid aggregates and ductopenia are less helpful, as they may also occur in chronic hepatitis C and in allograft rejection. Ductular reaction and progressive cholate stasis (including the presence of copper deposition) are useful for diagnosis of PBC recurrence, as those features are unusual in hepatitis C and rejection. The presence of plasma cells in the portal infiltrate has been suggested as an early marker of recurrent PBC.[986] A definite diagnosis of recurrent PBC rests on a combination of all clinical, biochemical, and histologic criteria; ultimately, however, recurrence in the graft does not appear to affect either graft survival or patient outcome.[987,988]

Recurrent PSC. This diagnosis is extremely difficult, if not impossible, to distinguish from other causes of biliary strictures or sclerosing cholangitis in allografts using needle biopsy evaluation alone.[989] It is diagnosed by histology and/or imaging of the biliary tree and exclusion of other causes of nonanastomotic biliary strictures.[936,968]

Recurrent fatty liver disease is common following liver transplantation for NASH. In one study, recurrent fatty liver disease was seen in 70% of patients, of whom 25% had recurrent NASH, and 18% had stage II/IV or greater fibrosis at a mean of 18 months. Histologic features may be present despite normal liver enzymes.[439] The development of NAFLD even after liver transplantation for non-NAFLD cirrhosis is also being increasingly recognized. The pretransplant risk factors include immunosuppression, a higher age at transplant, male gender, a history of smoking, the patient's and the donor's pretransplant body mass index, pretransplant diabetes, type of underlying liver disease that resulted in transplantation (hepatitis C, cryptogenic cirrhosis, or alcohol), and marital status.[990]

The diagnosis of recurrent *autoimmune hepatitis* is based on a combination of clinical, biochemical, serologic, and histologic criteria.[968] Portal and periportal inflammation (interface hepatitis) containing plasma cells, although nonspecific, is consistent with recurrent disease.[988]

De novo autoimmune hepatitis, also termed post-transplant plasma cell hepatitis, is defined as clinical and histologic features of AIH in patients who were not transplanted for that disease.[991] This may be a particular diagnostic problem in hepatitis C patients, who may develop a plasma cell-rich hepatitis in the presence of HCV RNA.[992] Some also consider this a histologic variant of rejection,[993] although this remains controversial, and separating rejection from autoimmunity in the liver allograft long after transplantation may be an exercise in semantics given that epitope spreading occurs with all immune responses.[993,994]

Late Changes in Liver Allografts

Besides changes due to recurrence of primary diseases, other abnormalities are also observed in liver biopsies obtained more than a few months after transplantation, including fibrosis and inflammatory changes. Importantly, these lesions are usually not recognized by alterations in liver function tests but detected by the use of "protocol" biopsies performed as part of the systematic follow-up of the condition of the liver allograft (see earlier). It has been reported that only 20% of liver grafts show normal histology at 5 and 10 years post-transplant,[995] decreasing to only 7.4% at 5 years and 1.6% at 10 years.[996]

In long-term pediatric liver transplant survivors, liver fibrosis is a common finding,[995,997] as is the case in adult patients.[914] One study has shown that fewer than 5% of liver grafts at 3 years post-transplant have no fibrosis,[997] and in another,[998] the prevalence of fibrosis increased from 31% to 65% from 1 year to 5 years after transplantation but remained stable for several years thereafter. At 10 years, however, the percentage of patients with "severe" fibrosis had increased from 10% (at 5 years) to 29%. Of the children without fibrosis at 1 year post-transplantation, 64% had developed some degree of fibrosis at 10 years. Fibrosis was strongly related to transplant-related factors such as prolonged cold ischemia time, young age at the time of transplantation, high donor/recipient age ratio, and the use of partial grafts.[998]

Inflammatory lesions in long-term liver grafts include so-called central perivenulitis, corresponding to centrilobular necroinflammation, sometimes not associated with portal inflammation ("isolated" central perivenulitis),[999,1000] and a nonspecific chronic hepatitis termed idiopathic post-transplant chronic hepatitis (IPCH).[996,1001,1002]

Isolated central perivenulitis requires differentiation from all other causes of centrilobular necroinflammation, including ischemia, acute and chronic rejection, recurrent or acquired viral hepatitis B and C, recurrent or acquired autoimmune hepatitis, and IPCH, discussed in an editorial by Hübscher.[999] It appears that isolated central perivenulitis most probably represents a form of late-onset acute rejection, associated with a worse outcome than purely portal-based (classical acute cellular) rejection.[999]

IPCH is probably also best interpreted as a form of late cellular rejection.[1002] Studies from the Birmingham group suggest that IPCH is associated with progressive fibrosis, even leading to bridging fibrosis and cirrhosis in up to 50% of patients at 10 years post-transplant,[1002] but important clinical problems have not been reported to the same extent in other studies.[1003]

Ultimately, difficult diagnostic problems must be resolved by close clinicopathologic collaboration. It must be kept in mind that several pathologic conditions may coexist in the liver allograft concurrently, including drug toxicity, viral hepatitis, disease recurrence, and rejection.

Neoplastic disease. Malignancies occurring after liver transplantation primarily include hepatocellular carcinoma[1004] and post-transplant lymphoproliferative disease. The primary risk factor for de novo hepatocellular carcinoma is cirrhosis developing after transplant.[1005,1006] Post-transplant lymphoproliferative disease is mostly a nodal and extranodal B-cell lymphoma that is a complication of immunosuppressive treatment in transplanted patients. Some other types of neoplasia (skin, lung, head and neck, colon, and rectum) are also more frequent in liver transplant recipients than in age- and sex-matched controls.[1006]

Bone Marrow Transplantation: Graft-Versus-Host Disease

Bone marrow transplantation may cause several hepatic complications. The injury can be due to pretransplant conditioning regimens, to immunosuppression-related infections, and to graft-versus-host disease (GVHD).[1007,1008] The histopathology of hepatic GVHD depends on the timing post-transplant. *Acute hepatic GVHD*, occurring within 90 days after transplantation, is characterized by cholestasis and bile duct damage. Affected ducts show an irregular profile, epithelial atypia with nuclear pleomorphism, cytoplasmic vacuolation, cell necrosis, and possible duct destruction. Lymphocytes infiltrate the duct epithelium, although portal inflammation is typically mild. Early biopsies (<35 days) reveal less bile duct damage and marked hepatocellular apoptosis,[1009] a picture easily confused with viral hepatitis C. Other lesions include endotheliitis, siderosis, and veno-occlusive disease.[1010]

Chronic GVHD, although usually preceded by acute GVHD, occurs de novo in about 25% of cases, and develops more than 3 months after transplantation. Hepatic involvement shows similar lesions to acute GVHD, but with the development of ductopenia, cholate stasis, progressive periportal fibrosis, and occasionally even cirrhosis in advanced disease.[1011–1013] Portal infiltration is dense, and in some cases associated with periportal extension and interface hepatitis. The lymphocytic infiltrates in the liver (and also in other involved tissues of the gastrointestinal tract and skin) are almost exclusively derived from the alpha/beta expressing T-cell subset, and are of the memory cell subset of T cells (CD45RO).[1014] Lobular changes include bilirubinostasis and apoptotic bodies.

Hepatic Tumors and Tumorlike Conditions

Surgical pathologists encounter a wide variety of nodules and tumors of hepatic origin, including both neoplastic and non-neoplastic lesions. Distinguishing between them can be challenging, but the distinction is critically important given the differing prognostic and therapeutic implications. Therefore, pathologists must understand the diagnostic criteria of these entities as well as the pitfalls inherent in interpreting small samples, such as core needle biopsies or fine needle aspirate (FNA) specimens. Furthermore, it is necessary to be aware of how the differential diagnosis varies in a cirrhotic versus a noncirrhotic liver, and to be aware of the context of the background liver, ideally from the tissue but at least from radiographic studies.

Nodular Regenerative Hyperplasia

Nodular regenerative hyperplasia (NRH) is a rare condition characterized by transformation of the liver parenchyma into regenerative, non-neoplastic nodules that are not delimited by fibrous septa.[1,2] It is an important cause of noncirrhotic portal hypertension (see also Chapter 19) and is associated with a wide range of conditions, including autoimmune diseases,[1,2] common variable immunodeficiency,[3] hematological disorders,[1,4] and numerous drugs, including azathioprine, didanosine, and oxaliplatin.[1,2,5,6] NRH may also occur in livers containing metastatic or primary tumor.[7,8] Wanless originally postulated that the pathogenesis appears to be related to abnormalities of portal hepatic blood flow (particularly portal venous thrombosis), leading to localized areas of hypo- and hyper-perfusion.[2] Patients may have elevated alkaline phosphatase, GGT, and/or transaminases.[9]

Macroscopically, the surface of the liver may be nodular and resemble micronodular cirrhosis.[1] The histopathologic diagnosis of NRH is easier on wedge biopsies or surgical specimens than on needle biopsies, as the features can be difficult to appreciate in small specimens. Microscopically, NRH is characterized by nodules of hyperplastic hepatocytes arranged in plates more than one cell thick, whereas the parenchymal cells adjacent to the nodules (usually centrilobular areas, but not always) are compressed and atrophic (Fig. 20.1A). Fibrous septa must be absent, which differentiates the lesion from cirrhosis[10]; however, in some cases, the compressed parenchyma between the nodules shows perisinusoidal fibrosis. In general, there is no or only minimal inflammation and no evidence of liver cell damage, although sinusoidal lymphocytosis has been reported in association with NRH.[9] The nodularity is better revealed on a reticulin stain (see Fig. 20.1B).[1,2,10] Vascular changes may be subtle and inconspicuous in needle biopsies and may include periportal angiomatosis as well as obliteration of portal vein branches; the latter is strongly associated with clinically evident portal hypertension.[9]

Partial nodular transformation is a rare entity in which the nodules may be larger than in NRH and are often restricted to the perihilar region, mimicking a neoplasm. Again, portal venous thrombosis is invoked in the pathogenesis of the lesions but in this instance situated near the porta hepatis in the larger portal vein branches.[11–13]

Abstract

This chapter covers neoplastic and non-neoplastic but tumorlike lesions of the liver.

Keywords

nodular regenerative hyperplasia,
cirrhosis,
focal nodular hyperplasia,
hepatocellular carcinoma,
adenoma,
cholangiocarcinoma,
hepatoblastoma,
microhamartoma,

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) can occur in any age group, including childhood; most cases, however, are seen during the third to fifth decades of life. The female to male ratio has ranged from 2 : 1 to 8 : 1 in the various adult and pediatric series.[14,15] In approximately 80% of cases, the lesion is asymptomatic.[14] In contrast to hepatocellular adenoma, hemoperitoneum as a complication is extremely rare, although it has been described.[16] FNH is usually solitary; multicentricity has been described in 20% of adult cases, however, and in an even higher percentage of pediatric cases.[15] Multicentric cases may be associated with other lesions (particularly vascular), including hemangiomas of the liver, telangiectasias of the brain, berry aneurysm, and portal vein atresia, as well as neoplasms of the brain including astrocytoma and meningioma.[17]

Overall, the pathogenesis of FNH remains controversial. A possible relationship to oral contraceptives has been postulated,[18] but it is not as clear-cut as for liver cell adenoma.[19] There is no question that this disease occurred prior to the widespread use of oral contraceptives and that it can occur in males, particularly in association with chronic alcohol abuse.[20] It has also been associated (together with hepatocellular adenomas and large regenerative nodules) in patients with hepatic venous outflow obstruction[21] and following orthotopic liver transplantation,[22] suggesting that vascular anomalies or a hyperplastic/regenerative response to a localized insult to the liver parenchyma may also play a role in pathogenesis. This hypothesis is also supported by the fact that lesions indistinguishable from nodular hyperplasia have been reported in cirrhotic livers.[23] Clonality studies of FNH have shown mixed results.[24,25]

Grossly, FNH usually presents as a subcapsular, gray-white, solid mass that is sometimes pedunculated. On cut section, a white depressed area of fibrosis is often seen in the center, with broad strands radiating from it to the periphery in a stellate configuration (Fig. 20.2A and B). This can be detected in more than half of cases by MRI techniques.[26–28] Microscopically, FNH has a nodular appearance with a central stellate scar (Fig. 20.3A), although it is important to note that the scar (at least a well-formed one) is not invariably present. Large, often thick-walled vessels are present in the fibrous bands (see Fig. 20.3B), but they do not have accompanying bile ducts. Patchy areas of ductular reaction are characteristically present at the junction of the fibrous septa with the hepatocellular component (see Fig. 20.3C), and this may be an important clue to the diagnosis, particularly in needle biopsies.[29] Acute or chronic inflammation is common. The hepatocytes may contain increased amounts of glycogen and fat.

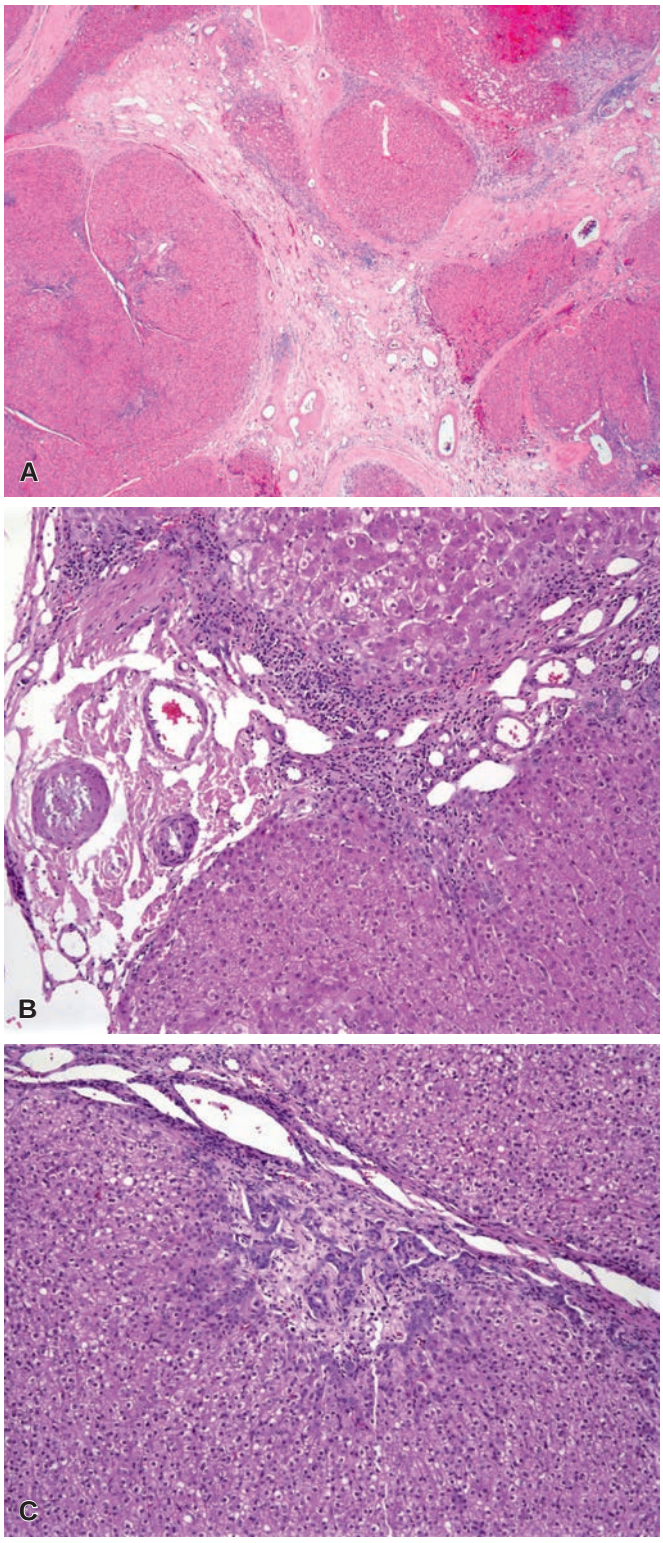

Figure 20.3 **A,** Central portion of focal nodular hyperplasia showing the interface between the fibrous scar and the nodules. Vessels within the scar are often prominent **(B)**, and may be thick-walled. **C,** Patchy ductular reaction is common, particularly at the interface between fibrous septa and liver parenchyma.

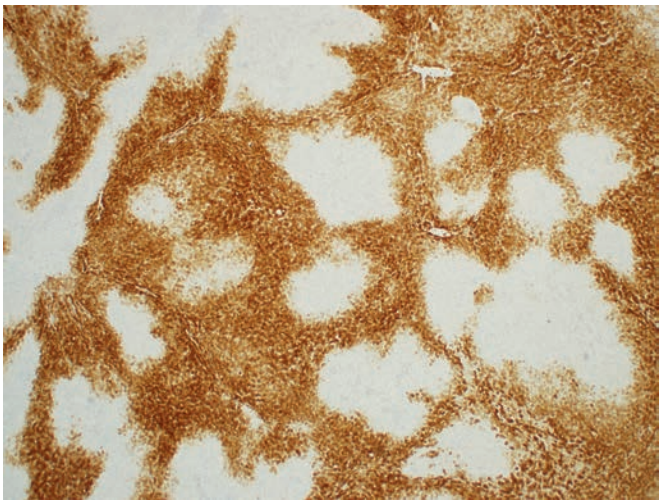

Figure 20.4 Map-like pattern of immunoreactivity with glutamine synthetase in focal nodular hyperplasia. (Courtesy of Dr. Sanjay Kakar.)

FNH typically shows a map-like staining pattern with glutamine synthetase (GS) (Fig. 20.4), which may help to distinguish them from hepatocellular adenoma. CK7, CK19, and neuronal cell adhesion molecule may be used to highlight the ductular reaction.[30] Immunostains for estrogen hormone receptors have yielded mixed results.[31–32]

The differential diagnosis of FNH includes—at both the clinical, radiographic, and histologic level—hepatocellular adenoma, well-differentiated hepatocellular carcinoma (HCC), and cirrhosis; the latter is a particular problem on needle biopsy, and knowledge of the state of the background liver (cirrhotic vs. noncirrhotic) is invaluable in this instance. The lack of a fibrous scar may also be challenging, although often the presence of nodularity, ductular reaction, dysmorphic vessels, and/or a poorly formed fibrous scar may aid in diagnosis.[33] Reticulin stain is useful in distinguishing between FNH and HCC, in that FNH has no loss of reticulin, and immunohistochemistry may aid in distinguishing FNH from hepatocellular adenomas. A summary of the histologic and immunohistochemical differences between FNH and liver cell adenoma is given in Table 20.1. This distinction is clinically important, as asymptomatic FNH may be followed, but hepatocellular adenomas (particularly those with β-catenin mutations, as discussed later) are more likely to be resected or ablated.

Hepatocellular Adenoma

True adenomas of the liver are rare. They have a striking predilection for females and are pathogenetically related to the use of oral contraceptives,[34,35] a fact supported by their occasional total regression following discontinuation of the hormones.[36] These neoplasms have also been reported following anabolic–androgenic steroid therapy,[37] following long-term carbamazepine therapy,[38] in association with glycogen storage diseases and other genetically determined diseases,[39–42] and in children with sex hormone disturbances.[43] When compared with FNH, the adenomas are more often symptomatic and can lead to severe and even fatal intraperitoneal hemorrhage.[44] Most of the patients are in the third to fifth decades of life, but cases have also been reported in children.[45–46]

Hepatocellular adenomas (HA) arise in noncirrhotic livers, and approximately 70% of the lesions are solitary.[47] They can occur anywhere in the liver but are usually located in the right lobe. Adenomas are usually visualized as defects on ^{99m}technetium–sulfur colloid liver scans and may also have characteristic CT and MRI findings;

Table 20.1 Summary of histologic and immunohistochemical features of focal nodular hyperplasia and hepatic adenomas

FEATURE	FOCAL NODULAR HYPERPLASIA	LIVER CELL ADENOMA
Capsule	No capsule	Well demarcated but unencapsulated
Stellate scar	Typically present	Absent
Parenchyma	Nodular	Homogeneous
Hemorrhage, necrosis	Rare	Common
Ductular reaction	Present	Absent
Vascularity	Large thick-walled vessels	Thin-walled sinusoids Telangiectasia, dysmorphic vessels (inflammatory HA)
Background liver	Noncirrhotic	Noncirrhotic
Cytologic atypia	Rare	Can be present
Acinar change	Typically absent	May be focally present
Reticulin framework	Intact	Intact overall
Glutamine synthetase	Positive, map-like pattern	Positive in β-catenin activated HA only
β-Catenin	Negative	Positive in β-catenin activated HA
LFABP	Positive	Negative in HNF1α inactivated HA
Glypican 3	Negative	Negative
SAA/CRP	Negative	Positive in inflammatory HA

LFABP, Liver fatty acid–binding protein.
Adapted from Bioulac-Sage P, Cubel G, Balabaud C, Zucman-Rossi J. Revisiting the pathology of resected benign hepatocellular nodules using new immunohistochemical markers. *Sem Liv Dis*. 2011;31(1):91–103.

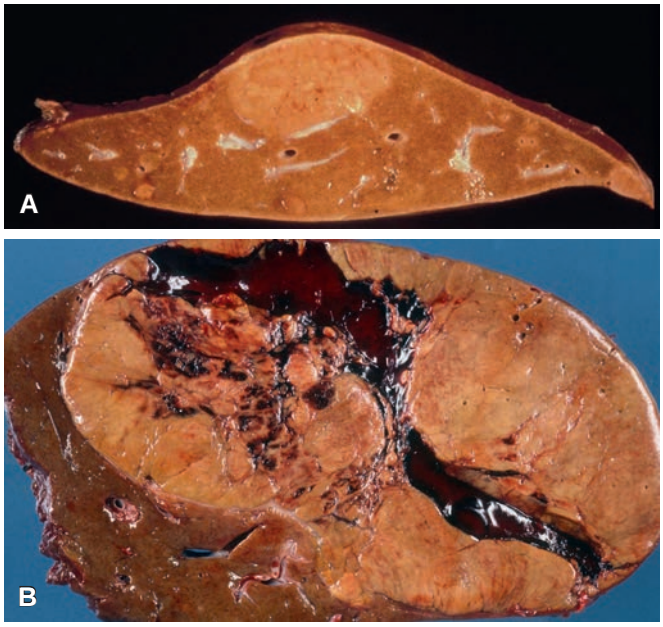

Figure 20.5 **A,** Well-demarcated hepatocellular adenoma but without a well-defined capsule. It is paler than the surrounding liver. **B,** This case has a large central area of recent rupture and hemorrhage. (Courtesy of Dr. George F. Gray Jr.)

however, many adenomas do exhibit typical radiographic features, and thus biopsy may be required for diagnosis.[47] Grossly, they are well demarcated but usually unencapsulated and are more pale and yellow than the surrounding liver. The typical central scar of FNH is absent (Fig. 20.5A and B).

Advances in molecular biology have resulted in the classification of hepatic adenomas into four major groups, based on both genotypic and phenotypic characteristics.[48,49] Adenomas with hepatocyte nuclear factor 1α *(HNF1α)* mutations account for 30%–50% of cases and are characterized by biallelic inactivating mutations of the *HNF1α* gene (both somatic, or one germline and one somatic).[50] These tumors are associated with steatosis, insulin resistance, and absence of liver fatty acid–binding protein (LFABP) expression by immunohistochemistry (as compared with positive staining in normal liver); they may be single or multiple.[47,48,51] Microscopically, adenomas with *HNF1α* mutations are diffusely steatotic, with numerous thin-walled vessels (Fig. 20.6A). The reticulin framework should be intact, and inflammation and nuclear atypia are absent.

The second group are those with *CTNNB1* mutations, accounting for 10%–15% of cases.[49,52] These are the most highly correlated with malignant transformation, and they are associated with male gender, androgen use, and glycogenesis. Immunohistochemically, they overexpress GS, and show nuclear positivity with β-catenin staining (see Fig. 20.6B), although it may be very focal. Microscopically, the features are nonspecific (see Fig. 20.6C), but mild cellular atypia and focal rosette formation can be seen. They typically do not have steatosis.[51]

The third group is known as inflammatory or telangiectatic adenomas, which were previously thought to represent a variant of FNH.[53] They are the most common, comprising 40%–50% of adenomas. These tumors are associated with increased BMI and occasionally present with fever and clinical signs of inflammation; these are also the type most commonly seen in men.[51] Histologically, they have characteristic inflammation, sinusoidal dilatation, and dystrophic vessels (see Fig. 20.6D and E), and they express serum amyloid A and C-reactive protein by immunohistochemistry. LFABP is normally expressed. From a molecular standpoint, they lack *HNF1α* mutations, but 10% harbor *CTNNB1* mutations, and thus are at risk for malignant transformation. The fourth group (<10%), known as unclassified adenomas, lacks specific molecular and phenotypic features.

Other features occasionally seen in hepatocellular adenomas include oncocytic changes,[54] presence of Mallory hyaline,[55] and pigmentation.[56] An associated granulomatous reaction can also be seen with hepatic adenoma, and the granulomas may be within or outside of the tumor.[57] In addition to the immunohistochemical features discussed previously, estrogen and progesterone receptors are present in about 75% of hepatic adenomas, whereas androgen receptors are expressed in only 20% of cases.[58]

The risk of malignant transformation in adenomas is approximately 5%, and risk factors include male gender, size, and adenoma subtype (see earlier).[36] Multiple sections and reticulin stains should

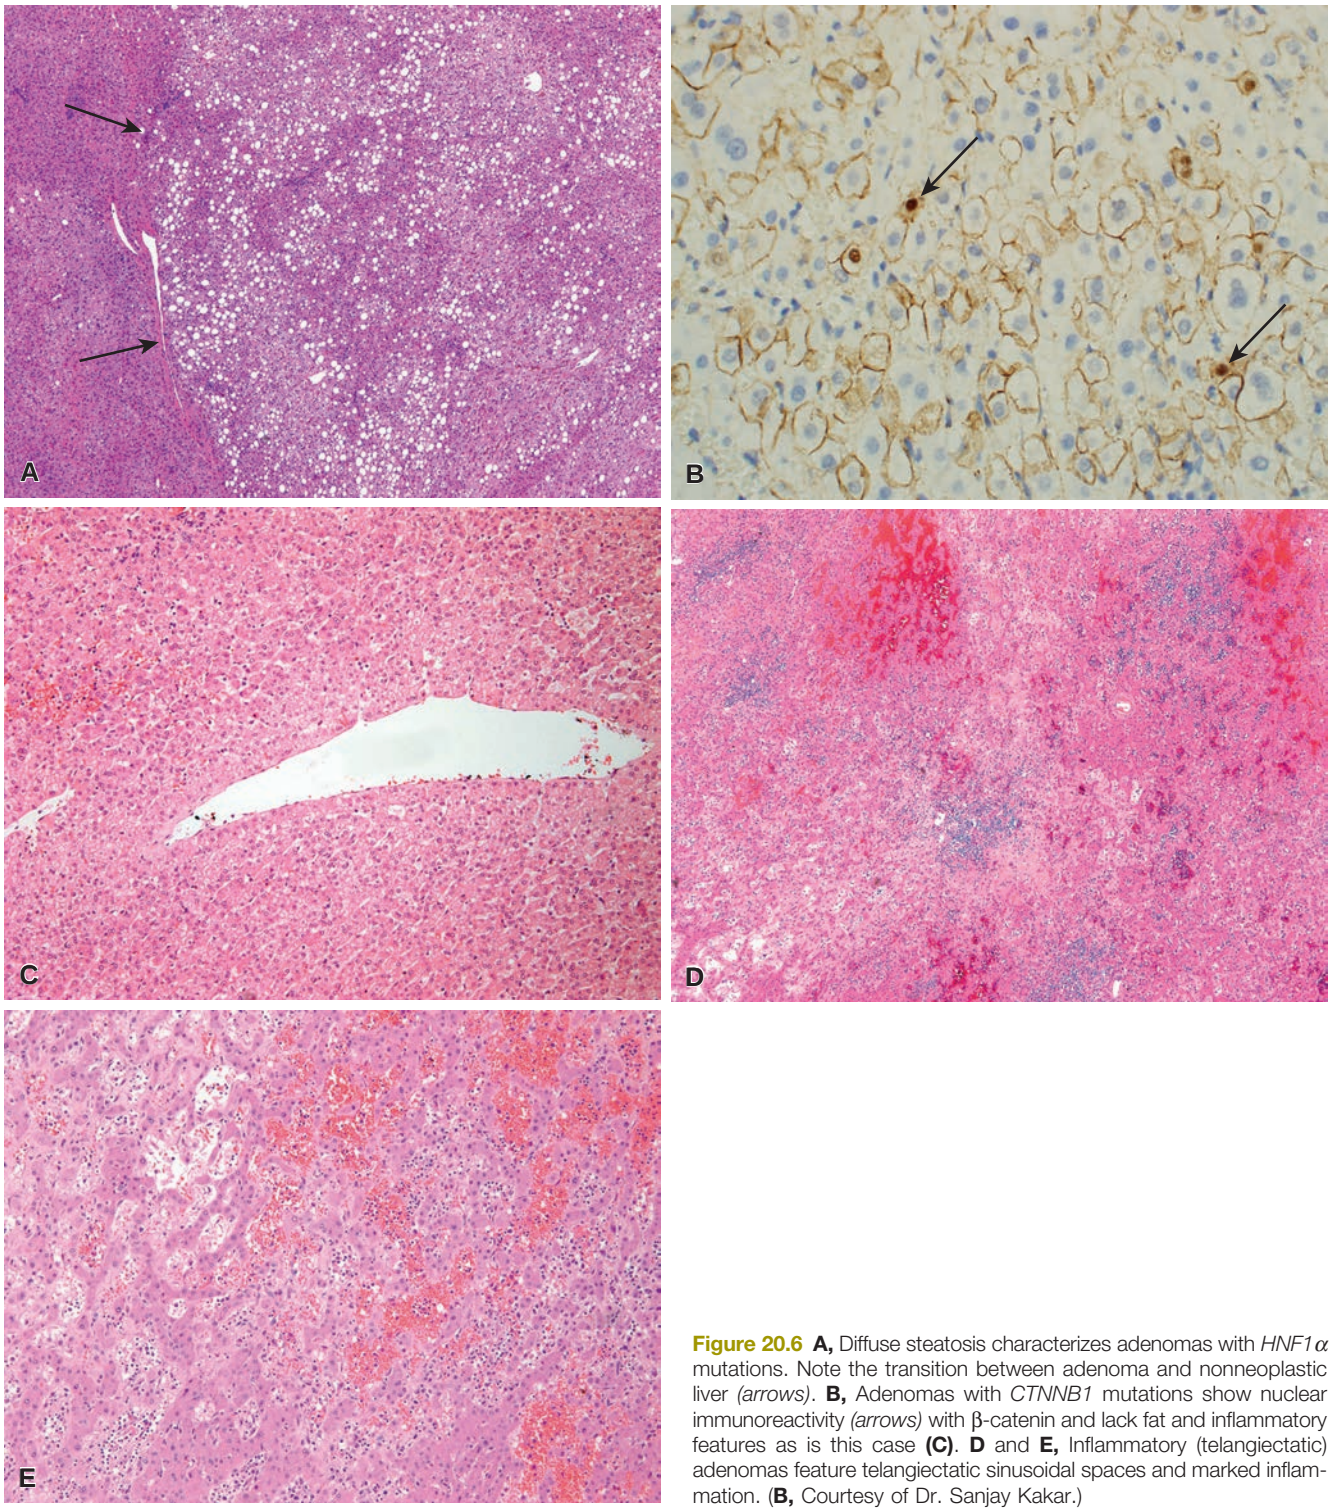

Figure 20.6 **A,** Diffuse steatosis characterizes adenomas with *HNF1α* mutations. Note the transition between adenoma and nonneoplastic liver *(arrows)*. **B,** Adenomas with *CTNNB1* mutations show nuclear immunoreactivity *(arrows)* with β-catenin and lack fat and inflammatory features as is this case **(C)**. **D** and **E,** Inflammatory (telangiectatic) adenomas feature telangiectatic sinusoidal spaces and marked inflammation. (**B,** Courtesy of Dr. Sanjay Kakar.)

be carefully evaluated in these tumors in order to rule out a well-differentiated HCC. The distinction between hepatocellular adenoma and well-differentiated carcinoma may be extremely difficult, however. Recent studies have suggested that GS and heat-shock protein 70 (HSP70) may be useful in this scenario, as these markers are more likely to be positive in cases of well-differentiated malignancy,[59] but the usefulness of this remains controversial.[60] Occasionally, an unequivocal and distinct focus of hepatocellular carcinoma is seen arising within an hepatic adenoma, indicating that these tumors do have a potential for malignant transformation.[61,62] In rare instances, coexistence of adenoma and carcinoma in the same liver have been described.[63]

Reportedly one third of patients with hepatic adenomas have multiple tumors, most commonly associated with the HNF1α subtype.[36] When 10 or more tumors are present, this condition is referred to as *liver cell adenomatosis*. A proportion of cases are familial, due to germline mutations in the *(TCF1/HNF1α)* gene, which also causes maturity-onset diabetes of the young type 3 (MODY3).[64,65]

Regenerative and Dysplastic Nodules

Advances in imaging have made it possible to detect increasingly smaller lesions in cirrhotic patients, which are often biopsied to exclude HCC. The terminology used for these lesions has historically been inconsistent and confusing and has included terms such as ordinary and atypical adenomatous hyperplasia, minimal deviation hepatoma, paraplasia, large regenerative nodule, types I and II macroregenerative nodule, adenomatous hyperplasia, and low-grade dysplastic nodule. In a laudable attempt to standardize the diagnostic criteria and terminology for these lesions, a multinational panel of liver pathologists has proposed the following classification, which has been generally accepted by experienced hepatopathologists.[66]

Regenerative nodules (also known as large regenerative nodules, macroregenerative nodules, adenomatous hyperplasia, and low-grade dysplastic nodules) are greater than 1.0 cm, with normal architecture and intact reticulin framework (Fig. 20.7). The majority of regenerative nodules are probably not premalignant, and, like the rest of a cirrhotic liver, they may contain iron, fat, bile, Mallory hyaline, or large cell change but should not feature small cell change (see later). There are no histologic criteria to distinguish a non-clonal regenerative nodule from a nodule with low-grade dysplasia, as clonality is assessed via molecular means and the likelihood of progression to malignancy is unclear. For these reasons, most pathologists avoid this term.

High-grade dysplastic nodules (HGDNs, also known as borderline nodules or atypical adenomatous hyperplasia) have both architectural and cytologic atypia, and are believed to be precursors of HCC. They may contain a number of abnormalities, including thickening of cell plates up to three cells thick, focal acinar formation, and occasional unpaired arterioles (Fig. 20.8). Small cell change is often present as well (see later). HGDN may contain fat, bile, and Mallory hyaline, as in regenerative nodules, but iron is often absent. Reticulin should be intact or only focally decreased. Both regenerative nodules and HGDNs may differ in color from the surrounding liver and may protrude out from the cut surface.

There are two types of liver cell dysplasia. *Large cell change* is defined by both nuclear and cytoplasmic enlargement (i.e. preserved N:C ratio), nuclear pleomorphism, nuclear hyperchromasia, and occasional multinucleated hepatocytes (Fig. 20.9).[67] Large cell change can be seen throughout a cirrhotic liver, including within regenerative nodules and HGDNs, and the biologic significance remains unelucidated.[68] However, the presence of large cell change in cirrhotic livers due to hepatitis B has been reported as an independent risk factor for the development of HCC.[69,70] *Small cell change* is characterized by a decreased volume of hepatocytic cytoplasm associated with moderately enlarged nuclear size, resulting in an increased nucleocytoplasmic ratio and low-power appearance of increased nuclear density (Fig. 20.10).[67] Small cell change is considered to be a premalignant lesion, based on its proliferative activity, molecular characteristics, and presence within both HGDN and HCCs.[71] Both large cell change and small cell change should be noted in the pathology report.

Hepatocellular Carcinoma

General and Clinical Features

HCC (also known as liver cell carcinoma, and previously termed hepatocarcinoma or hepatoma) is the sixth most common malignancy worldwide and the second most common cause of cancer-associated death.[72] Historically, it has been relatively rare in the United States,

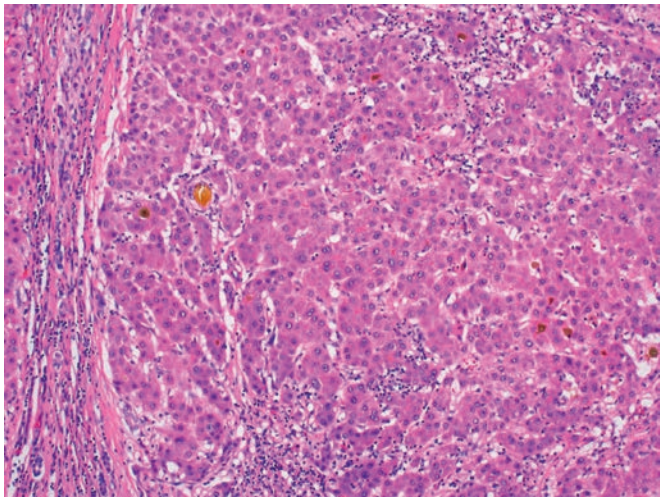

Figure 20.8 High-grade dysplastic nodule showing focal thickening of cell paltes, bile, and focal acinar architecture. Reticulin stain was intact.

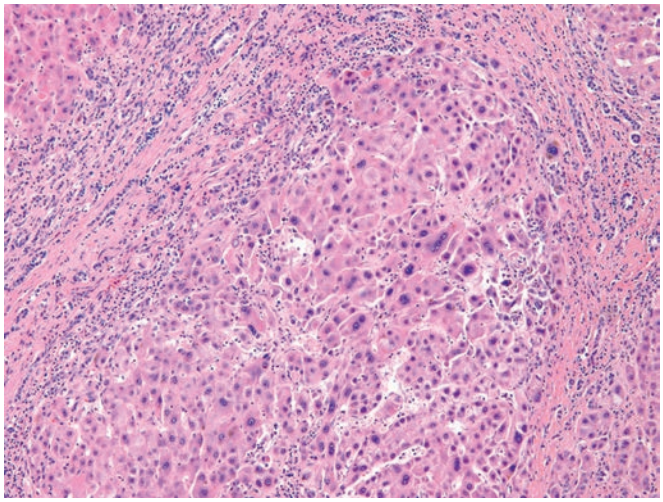

Figure 20.9 Large cell change within a cirrhotic liver, featuring nuclear and cytoplasmic enlargement, nuclear pleomorphism and hyperchromasia, and multinucleated hepatocytes.

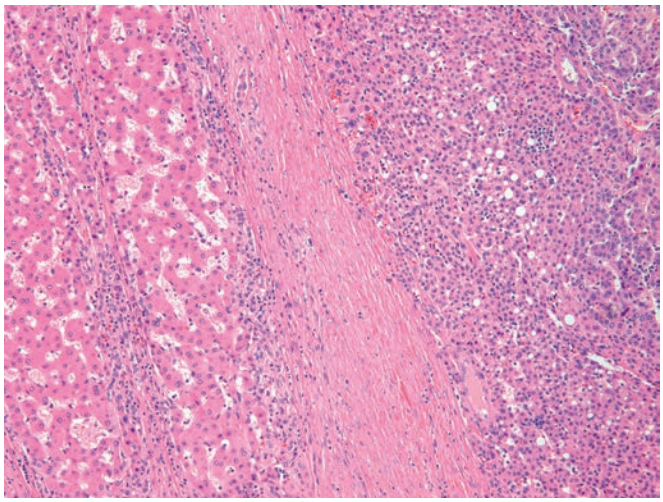

Figure 20.10 Small cell change, indicated by increased nuclear density, is seen in the right half of the picture; cirrhotic liver with hepatocytes of normal size is seen on the left.

but during the past two decades the incidence has tripled secondary to the hepatitis C epidemic.[73] The highest incidence is still in regions with endemic hepatitis B infection, such as Southeast Asia and Subsaharan Africa[73]; China alone accounts for over half of the world's cases of HCC.[74] Most cases are seen in patients older than 40 years, with a peak at 70 years of age,[73] but this tumor can also occur in younger individuals and even in children.[75–78] Some cases have even occurred as second malignancies in successfully treated Wilms tumor patients.[79] Currently, the greatest increase in HCC is among Caucasians and Hispanics between 45 and 60 years of age.[73]

HCC is 2–4 times more common in males than in females.[73] It usually presents with anorexia, malaise, abdominal pain, ascites, and liver enlargement.[80] Obstructive jaundice may result from tumor invasion into the common bile duct.[81] HCC has also been associated with numerous systemic manifestations such as hypoglycemia, hypercholesterolemia, erythrocytosis, hypercalcemia, carcinoid syndrome, ectopic production of chorionic gonadotropin and prostaglandin, and dysfibrinogenemia, and several others.[82–86]

Serum elevation of alpha-fetoprotein (AFP) occurs in a majority of patients with HCC, but up to 40% of HCC patients have normal AFP levels, particularly when tumors are small.[87] Elevated serum AFP can also be seen with malignant germ cell tumors, liver metastases, liver trauma, cirrhosis, chronic hepatitis, and cholangiocarcinoma. For these reasons, recent studies have argued that AFP is not an effective screening or surveillance tool for HCC.[87]

Predisposing and Associated Factors

The major risk factors for HCC include the hepatotropic viruses hepatitis B virus (HBV) and hepatitis C virus (HCV), alcoholic liver disease, and probably non-alcoholic fatty liver disease (NAFLD).[72–74,88]

The majority of the risk factors for HCC result in cirrhosis, which is present in over 80% of patients with HCC.[73] Patients with cirrhosis have an estimated 5-year cumulative risk of developing HCC of 5%–30%, depending on the underlying risk factor, geographic area, and ethnicity of the patient.[73]

Hepatotropic Viruses

Hepatitis B infection is associated with approximately half of the cases of HCC in the world and virtually all childhood cases.[73] Although both hepatitis B and hepatitis C can cause HCC in the absence of cirrhosis, the vast majority of patients with hepatotropic virus-related HCC have cirrhosis.[73] Patients with chronic HBV have a 5–15-fold increased risk of developing HCC, whereas the increased risk for patients with HCV is 15–20 times that of the general population.[73,74] The risk of developing HCC in patients with chronic HBV is further increased in men, elderly patients, and those of Asian or African race; with exposure to aflatoxin; with alcohol and tobacco use; if there is coinfection with HCV or the delta virus; with high levels of HBV DNA, positivity for hepatitis B e antigen (HBeAg), or infection with HBV genotype C; and with increasing length of time of infection.[73,74,89] Similar factors are associated with increased risk of HCC in patients with chronic HCV infection, including older age, male gender, metabolic syndrome, and alcohol use.[73,74]

Integration of hepatitis virus DNA into host genomic DNA is believed to be an early event in the development of HBV-associated HCC.[90] HBV DNA integration induces both genomic instability and mutagenesis of several cancer-related genes. A major role is also played by the HBV-associated protein HBx, which stimulates virus gene expression and replication, and also activates a number of cell cycle pathways that are critical to hepatocyte growth and survival.[90,91] HBV DNA is detectable in patients who are HBsAg negative, but the risk of progression to HCC is unclear in these individuals.[92] The role of the hepatitis C virus in the development of HCC remains less well elucidated, but animal studies have indicated that the core protein of HCV appears to have oncogenic potential.[93]

Alcohol Use

Heavy alcohol intake is a well-established risk factor for the development of HCC, although the direct carcinogenic effect of alcohol remains unproven and there is also evidence of a synergistic effect of heavy alcohol use and HBV or HCV infection.[74,88] The overall risk of developing HCC in the context of alcoholic cirrhosis is estimated at 15%.[88]

Non-Alcoholic Fatty Liver Disease

There is a growing body of evidence that NAFLD is associated with the development of HCC, even in the absence of cirrhosis,[94] and that the annual incidence of NAFLD-associated HCC in the United States increased by almost 10% between 2004 and 2009.[95] The prevalence of HCC in the context of NAFLD is expected to rise as more and more adults develop this disease worldwide, given the

increasing rates of obesity, diabetes, and dyslipidemia. HCC in this context is also associated with a higher mortality rate.[95]

A number of drugs and toxins are associated with the development of HCC. *Thorium dioxide* suspension (Thorotrast), a radiographic contrast medium, has resulted in the development of many liver cell carcinomas, the average latent period being 20 years.[96] The geographic distribution of HCC has also suggested a relationship with the ingestion of aflatoxins, which are metabolic products of the ubiquitous fungus *Aspergillus flavus*[97]; contamination of food with aflatoxins remains a serious problem in parts of the world where the incidence of HCC is highest. Although the exact mechanism remains to be elucidated, it is known that aflatoxin B1 induces p53 mutations and may act synergistically with HBV to contribute to carcinogenesis.[98] Rare cases of HCC have been reported in males in association with long-term administration of androgenic–anabolic steroids.[88,99,100] Data on a potential association between oral contraceptive pills and HCC remain controversial. Although some studies have shown an increased risk of HCC in women with long-term oral contraceptive use (>5 years),[101] the studies are generally small, and more recent studies have shown no definite evidence of an increased risk.[102] There is also little information regarding the risk in patients who are taking newer generation, low-dose contraceptive pills.[74]

A number of metabolic disorders are risk factors for HCC as well.[88] *Tyrosinemia* type 1 is associated with a high incidence of liver cell carcinoma, usually in a background of cirrhosis.[103] In one series, 37% of patients surviving beyond 2 years of age developed this malignancy in childhood.[104,105] Cases of HCC associated with *α1-antitrypsin deficiency* have also been reported.[105,106,107] Patients with the PiZ variant of antitrypsin deficiency seem to be particularly prone to this complication and also to the development of cholangiocarcinoma.[108]

Other hereditary disorders associated with HCC include *ataxia–telangiectasia*;[109] *glycogen storage disease*, particularly type 1a;[105,110] *hereditary hemochromatosis*, in which the risk of HCC is approximately 20 times higher than in the general population[105,111]; and porphyria.[105] Cases of HCC have also been reported following the Kasai procedure in patients with biliary atresia,[112] in association with familial cholestatic cirrhosis of childhood,[113,114] and with congenital hepatic fibrosis associated with adult polycystic kidneys.[115]

Gross Features

Grossly, HCC may present as a single mass, multiple nodules, or as diffuse liver involvement, simulating cirrhosis (Fig. 20.11A–C).[116,117] Some lesions are poorly circumscribed, whereas others are surrounded by a grossly distinct capsule.[118,119] In rare cases, the tumor is pedunculated, presumably because it arises in an accessory lobe.[120,121] Tumor size varies a great deal from case to case. In recent years, progress in radiographic procedures has led to the detection of an increased number of small (<2.0 cm) HCC; however, it can be difficult to distinguish these small HCC from regenerative or HGDNs on imaging studies. Portal vein thrombosis (including thrombosis with tumor) is found in a high proportion of advanced cases and may be the presenting sign of an otherwise undetected HCC.[122]

Figure 20.11 **A,** Poorly encapsulated hepatocellular carcinoma consisting of two dominant nodules with multiple smaller satellite nodules, arising in a background of cirrhosis. **B,** Well-circumscribed, solitary mass with foci of hemorrhage and necrosis. **C,** Hepatocellular carcinoma with central necrosis and bile staining, arising in a patient with hereditary hemochromatosis. A satellite nodule is present some distance from the main tumor mass *(arrow)*. (**A** and **C,** Courtesy of Dr. George F. Gray Jr.)

Microscopic Features

Microscopically, the pattern of growth of HCC may be trabecular, solid, or pseudoglandular[123] (Fig. 20.12A–C), and multiple growth patterns are often present within the same tumor. The latter, which has also been referred to as acinar, may result in glands and papillary-like formations that can lead to diagnostic confusion with bile duct carcinoma.[124] Unpaired arteries may be prominent, and endothelial cells may peripherally "wrap" nests of tumor cells.[125] A feature of great diagnostic significance is the thickness of the trabeculae, as estimated in the H&E sections but better evaluated on reticulin stain; the hepatocytic plates are typically more than three cells wide in HCC.[123] The stroma is usually scant, in contrast to that of cholangiocarcinoma, with the exception of the sclerosing or "scirrhous" form (see later). Invasion of portal venules is a frequent finding. Cytologically, there is a wide range of differentiation (Fig. 20.13A–B).

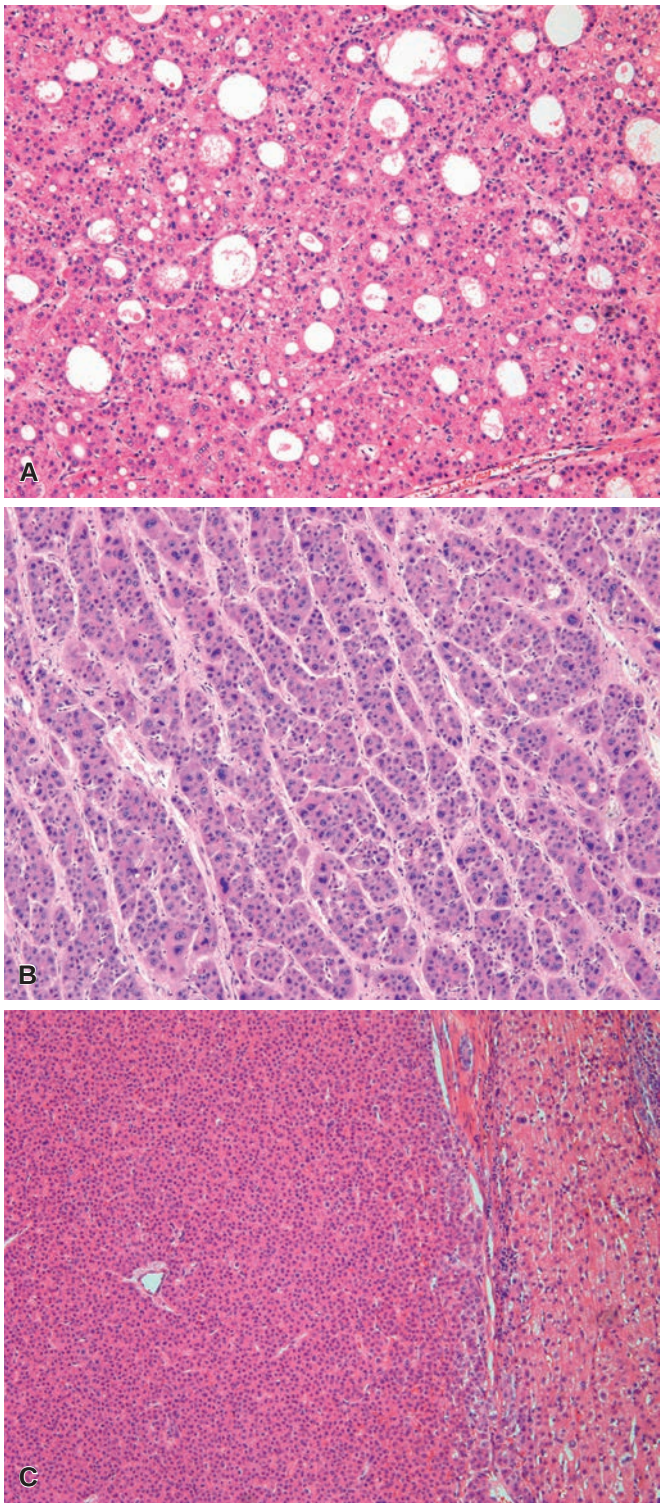

Figure 20.12 Typical growth patterns in hepatocellular carcinoma include pseudoglandular **(A),** trabecular **(B),** and solid **(C)**. Note the diffuse small cell change in **(C),** as compared with the cirrhotic liver on the right.

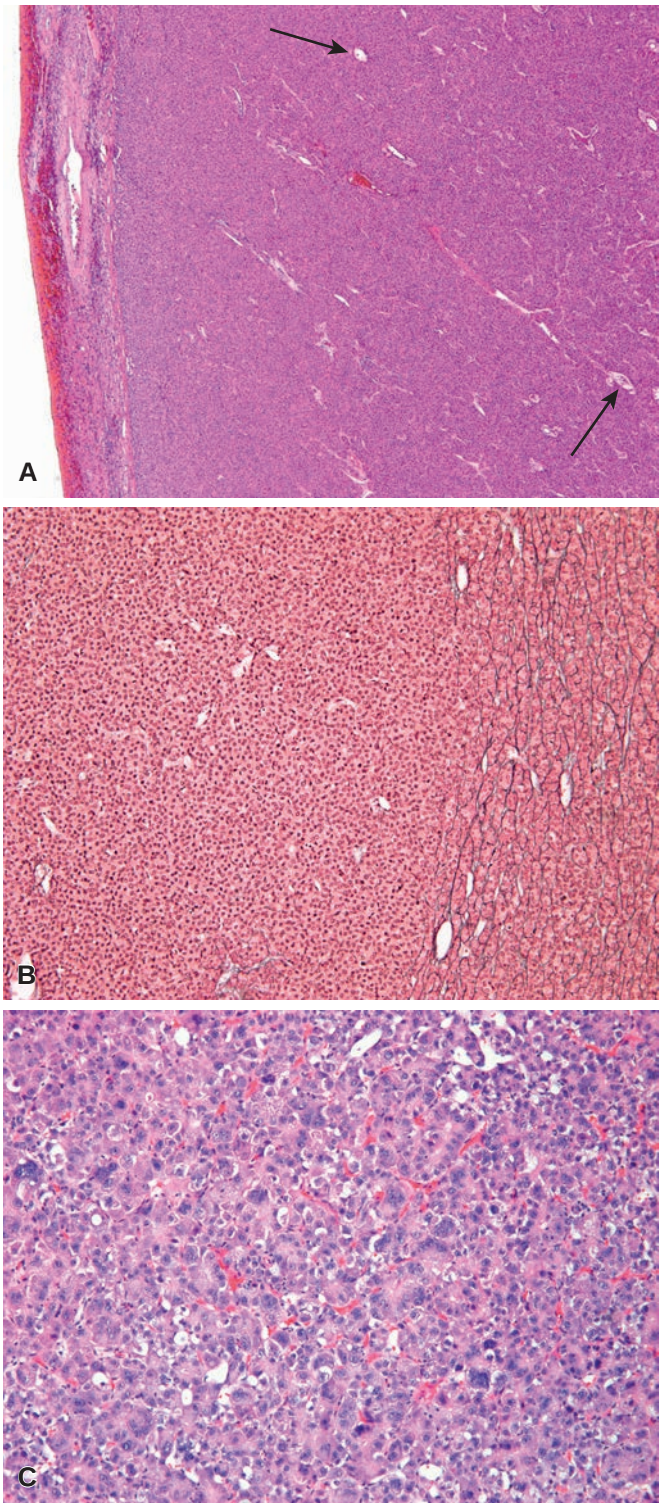

Figure 20.13 **A,** Very well-differentiated HCC with numerous unpaired vessels *(arrows)*. Note the lack of portal tracts within the tumor. **B,** Loss of the normal reticulin framework helps to make the diagnosis; compare with the cirrhotic liver with intact reticulin framework on the right. **C,** Poorly differentiated hepatocellular carcinoma that is difficult to recognize as such without stains.

More poorly differentiated cases may show great pleomorphism, bizarre mitotic figures, and tumor giant cells; nuclei and nucleoli are often prominent (Fig. 20.13C).[123] It may be difficult to identify these tumors with certainty as HCC without immunostains. Conversely, well-differentiated tumors are easily recognized as being composed of hepatocytes but may be difficult to categorize as malignant. Reticulin stain may be particularly helpful in this circumstance, as either loss of normal reticulin framework or reticulin highlighting of abnormal architecture may help to make the diagnosis of well-differentiated HCC (see Fig. 20.13B).[123,126] Tumor cells may exhibit intranuclear pseudoinclusions caused by cytoplasmic invaginations.[127]

The cytoplasm of the tumor cells may contain Mallory hyaline similar to that seen in alcoholic liver disease,[123] round hyaline globules (Fig. 20.14A),[128] copper,[129] "pale bodies" (seen ultrastructurally as a membrane-bound mass of granular or fibrillary material that is immunoreactive for fibrinogen),[130] ground-glass cells,[131] or bile (see Fig. 20.14B)[123]; the latter is an important diagnostic feature. The hyaline globules have been said to contain AFP and α1-antitrypsin,[128] but the interesting observation has been made that their major constituent is p62, a phosphotyrosine-independent ligand of p561ck kinase.[132] In one remarkable case, the tumor was black because of the accumulation of a Dubin–Johnson-like pigment.[133] Steatosis has long been recognized as a feature of HCC, and recently the steatotic variant of HCC has been described (Fig. 20.15), which is associated with underlying fatty liver disease, metabolic syndrome, and late tumor relapse.[134]

The concepts of "small" and "early" HCCs have received a great deal of attention in the recent literature because of the difficulty in distinguishing these lesions from a HGDN, particularly on needle biopsy. "Small HCC" is defined as a tumor measuring less than 2.0 cm. Small HCC can be further subdivided into early HCC, as described later, and progressed HCC, which are distinctly nodular, often encapsulated, and have thickened hepatic plates, and thus are typically easier to diagnose.[135-137] "Early HCC" (also known as vaguely nodular HCC or very well-differentiated HCC) is defined as a nodule with poorly defined margins, and a combination of histologic features including small cell change, intratumoral portal tracts, pseudoglandular architecture, diffuse steatosis, and/or unpaired arteries.[135-137] Stromal invasion (invasion of abnormal hepatocytes into portal tracts, fibrous septa, or adjacent non-neoplastic parenchyma) is the most reliable criterion of malignancy in this circumstance but may be difficult to appreciate on a needle biopsy (Fig. 20.16). The lack of a CK7+ ductular reaction at the periphery of a nodule can also

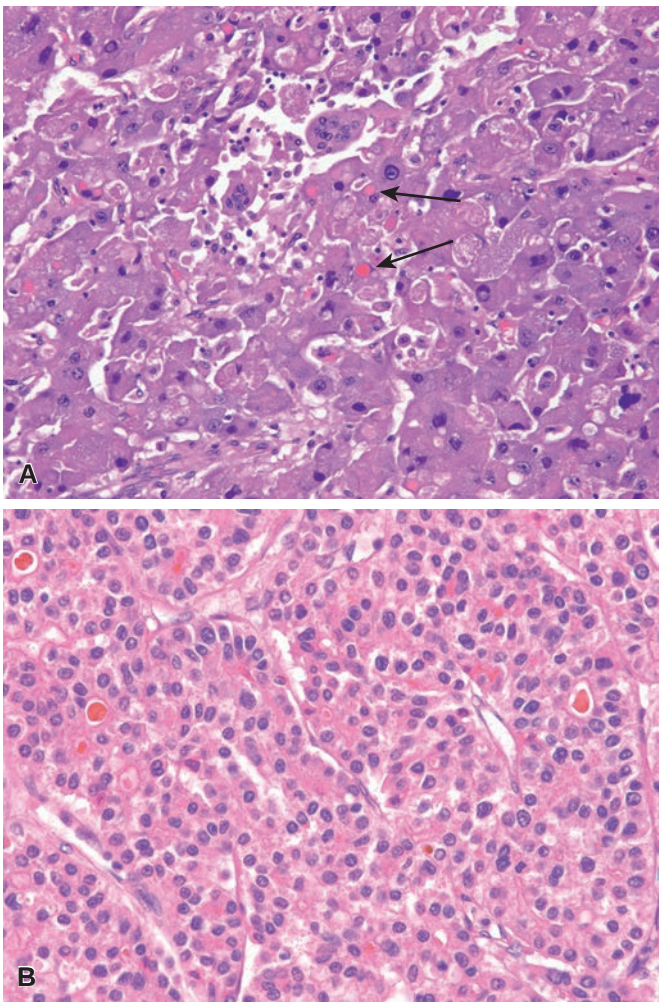

Figure 20.14 The tumor cells of hepatocellular carcinoma may contain hyaline globules (**A,** *arrows*) or bile **(B)**.

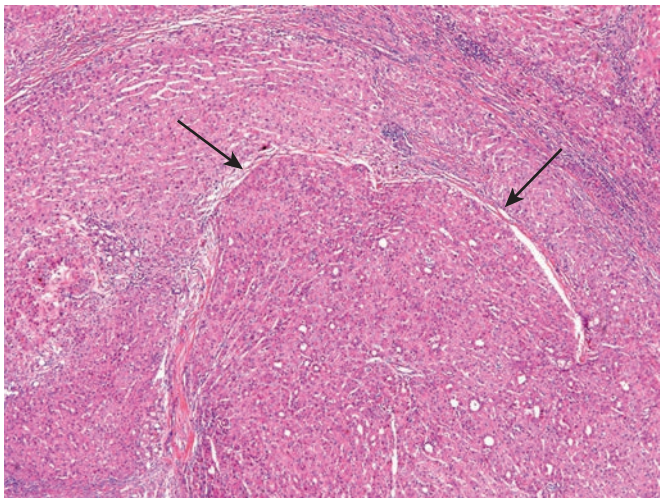

Figure 20.16 Focal parenchymal invasion *(arrows)* of an adjacent regenerative nodule by an early well-differentiated hepatocellular carcinoma.

help to make the diagnosis of malignancy.[136,138] GS, HSP70, and glypican-3 are also more likely to be positive in early HCC, and it is especially helpful if two of the three are positive.[135,136,139]

Immunohistochemical Features

Hep Par-1 (also known as hepatocyte-specific antibody, or HSA) is a monoclonal antibody that is believed to react with urea cycle enzyme carbamoyl phosphate synthetase 1 (CPS1), a rate-limiting enzyme in the urea cycle that is present in hepatocyte mitochondria.[140,141] Because of its good (although not absolute) specificity, it has become one of the most reliable markers of hepatocytic differentiation (Fig. 20.17A).[142–144] Unfortunately, it does not stain most poorly differentiated or sclerosing HCC; in addition, staining may be patchy within the tumor and thus not present on a small needle biopsy sample.[145] Adenocarcinomas of the lung, stomach, and esophagus may also have strong positive reactions, and as expected, it also stains hepatoid adenocarcinomas of the gastrointestinal tract and pancreatobiliary tract.[146,147]

Another more recently available marker that shows a high sensitivity and specificity for benign and malignant hepatocytes is arginase-1, a metalloprotein that catalyzes the hydrolysis of arginine to ornithine and urea.[148] The overall sensitivity of arginase-1 is 96% (compared with 84% for Hep Par-1) and is particularly better in poorly differentiated HCC (86% as compared with 47%). Furthermore, the specificity is extremely high, with only rare cases of non-HCC reportedly showing immunoreactivity.[149]

Glypican-3 is another more recent marker that has been added to the hepatocellular phenotype armamentarium. It is a member of the heparin sulfate proteoglycans family and plays a role in cell growth, differentiation, and migration.[150,151] Its positivity is cytoplasmic, membranous, and canalicular. It stains most (~80%–90%) of HCCs and is more likely to be positive in HCC arising in cirrhotic livers.[152] It also stains HGDN and occasionally cirrhotic nodules but not normal liver, FNH, or hepatic adenoma.[152,153] In addition, the sensitivity is lower in the fibrolamellar variant of HCC.[152] Unfortunately, it also stains yolk sac tumor, Wilms tumor, rhabdomyosarcoma, undifferentiated embryonal sarcoma, mesenchymal hamartoma, and a subset of hepatoblastomas,[154–156] as well as a number of metastatic tumors that can be encountered in the liver, such as melanoma, squamous cell carcinoma of the lung, and adrenal cortical carcinoma.[157]

Glutamine synthetase (GS) is an enzyme that plays a key role in nitrogen metabolism and is expressed in a number of hepatocellular lesions as well as focally in normal liver (see previous sections on **FNH** and hepatic adenoma). As noted previously, GS also stains a significant number (13%–70%) of early HCC, as well as a subset (10%–15%) of HGDNs, although the immunoreactivity in the latter is typically focal.[136]

An important diagnostic feature of HCC is the production of bile canalicular structures between the tumor cells. These can be demonstrated in cytologic or histologic preparations of normal and neoplastic liver with a polyclonal antibody for CEA (pCEA),[158,159] which cross reacts with biliary glycoprotein (see Fig. 20.17B). A similar staining pattern may be seen with CD10 (albeit with much lower sensitivity that pCEA) and bile salt export pump.[145,160,161] pCEA may also show cytoplasmic staining in both HCC and adenocarcinomas and may not show well-defined canalicular staining in poorly differentiated HCC.[145]

In contrast to the antibodies discussed previously, MOC-31, a recently described antibody directed against a cell surface glycoprotein, is regularly expressed in cholangiocarcinoma and metastatic adenocarcinoma but only extremely rarely in HCCs.[162,163] A panel consisting of MOC-31 and Hep Par-1 or arginase-1 is sufficient to distinguish the majority of HCC from cholangiocarcinoma and metastatic adenocarcinoma.

Less useful antibodies for the diagnosis of HCC are discussed here briefly. TTF-1, a transcription factor present in the nuclei of thyroid and lung epithelial cells, is often (~70%) expressed in the cytoplasm of the cells of HCC, a curious and unexplained result that seems to be dependent on the clone and antigen retrieval technique used, and which needs further evaluation.[145,164,165] AFP is a relatively specific but rather insensitive (~30%–50%) marker for hepatocellular differentiation.[145] The low sensitivity and the availability of much more sensitive and specific antibodies have rendered AFP much less useful in the diagnosis of HCC. Detection of albumin mRNA by in situ hybridization has proved diagnostically useful, both for HCCs and for extrahepatic hepatoid carcinomas, but is not as widely available as immunohistochemistry for Hep Par-1 and arginase-1.[166,167] On theoretical grounds, albumin itself ought to be an excellent marker of hepatocytic differentiation, as this molecule is selectively produced by liver cells. However, it is present in large amounts in the plasma, thus resulting in a high degree of diffuse tissue staining. Carcinoembryonic antigen (monoclonal CEA) is usually negative or only focally positive (in contrast to pCEA, discussed earlier), an important factor in the differential diagnosis with bile

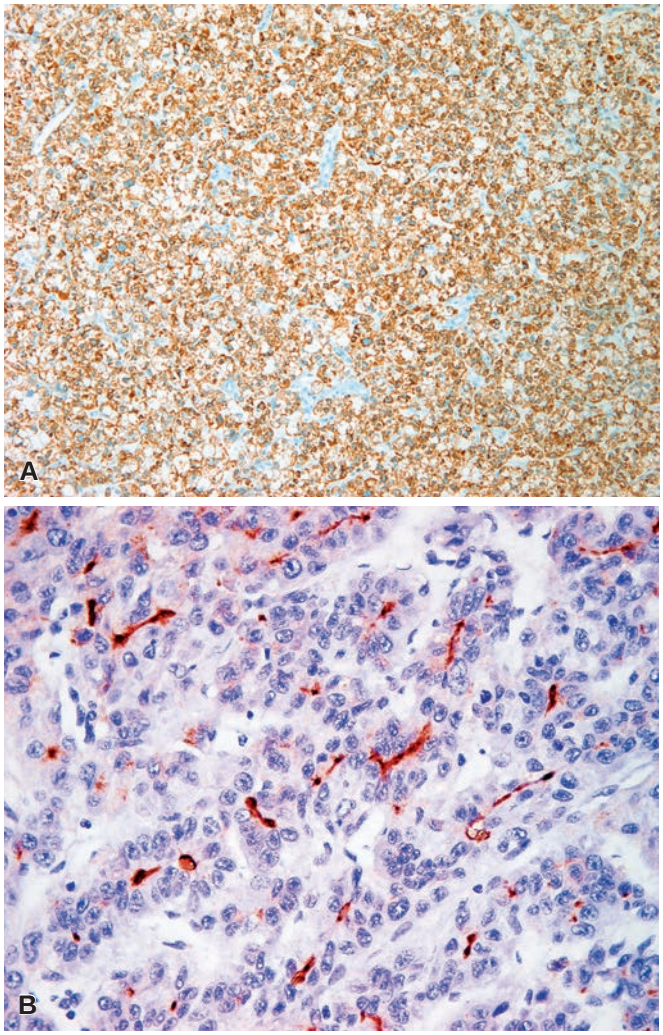

Figure 20.17 **A,** Diffuse cytoplasmic granular positivity with Hep Par-1 in hepatocellular carcinoma. This particular case had clear cell features, and the Hep Par-1 helped to confirm the diagnosis. **B,** Polyclonal CEA (pCEA) canalicular staining in a hepatocellular carcinoma.

duct carcinoma and metastatic carcinoma; however, MOC31 is a more sensitive antibody in this circumstance.[168]

CD34 marks the sinusoid-like vasculature in HCC, but similar staining may be encountered in FNH and hepatic adenomas, and better stains are now available for the distinction between HCC and adenocarcinomas.[145]

In regard to the keratins, both normal and neoplastic hepatocytes are typically positive for CK8 and CK18 and negative for CK7, CK20, and CK19. Therefore, most liver cell carcinomas are immunoreactive for CAM 5.2 and 35βH11 (which recognize keratin 8) but not for monoclonal antibody AE1 (which recognizes keratins 10, 14, 15, 16, and 19).[145,169] However, small foci of AE1/AE3-positive cells can be seen in poorly differentiated HCC.[145] This keratin pattern, which recapitulates that of normal hepatocytes,[170,171] is maintained in most HCCs. However, just as reactive or metaplastic hepatocytes can express "bile duct-type" keratins (e.g. CK7),[172] HCC may also show aberrant keratin expression. CK7 is present in a minority (~20%) of cases of HCC, and CK20 may be positive in an even smaller subset (~5%). CK19 may show patchy positivity as well.[145,171,173] We and others have seen several cases of primary neoplasms of the liver otherwise fulfilling all the criteria for this tumor type, in which a wide range of keratin immunoreactivity (including CK7 and/or CK19) was displayed.[174]

HCCs have been found to be immunoreactive for a seemingly endless array of other antibodies, many of which have questionable clinical utility, including epithelial membrane antigen (EMA), α1-antitrypsin,[175] transferrin receptor,[176] ferritin,[177] aromatase (an enzyme that converts androgen into estrogen),[178] integrins VLA-α_1 and VLA-β_1 (as in normal liver tissue),[179] CD15 (an adhesion molecule),[180] insulin-like growth factor II (more so than normal liver),[181] epidermal growth factor receptor,[182] and C-reactive protein.[183] The apparent expression of inhibin by HCC has been shown to be a spurious result due to the presence of endogenous biotin.[184] The cells of liver cell carcinoma have also been found to possess both estrogen and androgen receptors.[185,186]

Molecular Genetic Features

The molecular pathogenesis of HCC is extremely complex and remains incompletely understood. An increasing number of genetic and epigenetic changes are being reported, particularly given recent advances in whole genome sequencing and other techniques. The final common pathway for hepatocarcinogenesis, regardless of underlying etiology, appears to involve chronic hepatocyte damage resulting in cell death and regeneration, which ultimately leads to genetic instability and the initiation of carcinogenesis.

A large number of mutations have been reported in association with HCC, which appear to be further influenced by the underlying etiology.[72,187] Alterations of the *Wnt/β-catenin* pathway are some of the most common in HCC, but the particular mutations vary with HBV or HCV infection status.[72] For example, activating mutations in *CTNNB1* are more common in patients with HCV-associated HCC (30% vs. 10%–15% in patients with chronic HBV infection).[72] Other genes in this pathway, including *APC* and *AXIN1*, may also harbor mutations.[187,188]

TP53 mutations are common in HCC (up to 60% of cases) and are associated with aflatoxin exposure as well as HBV infection.[72,187,189] HCCs associated with HCV are more likely to harbor mutations in the *ARID1A* and *ARID2* genes, which affect chromatin remodeling.[72] Other commonly mutated genes in the pathogenesis of HCC include the *MLL* family of histone methylation writer genes, which may harbor mutations or HBV DNA insertions; genes in the *NFE2L2* oxidative stress pathway; genes involved in activation of the *P13K/AKT/MTOR* and *RAS/RAF* mitogen-activated protein kinase pathways; *JAK1*; and *SALL-4*, which is more strongly associated with Asian patients who have HBV infection.[72,187] Telomerase *(TERT)* promotor mutations, one of the most frequently encountered in HCC (~50%–60%), are found in preneoplastic cirrhotic nodules as well.[187] Gene amplifications, deletions, and translocations are also common in HCC,[188] including the fusion translocation of *DNAJB1* and *PRKACA* that is highly specific for fibrolamellar carcinoma.[190]

A number of epigenetic factors have also been implicated in hepatocellular carcinogenesis. Dysregulated DNA methylation targets multiple genes in HCC, and the genes targeted appear to vary with chronic HBV versus HCV infection.[191] In addition, *CDKN2A* promotor hypermethylation, leading to p16 suppression, is common in HCC.[192] Aberrant expression of microRNAs, groups of tiny RNAs with fundamental roles in the regulation of gene expression, has also been associated with hepatocarcinogenesis.[193]

Based on genetic profiling, a number of molecular classifications of HCC have been proposed in the past.[194,195] Recently, a molecular classification has been proposed that divides HCC into two major groups, termed the "proliferation subclass" and the "nonproliferation subclass."[187,196]

The proliferation subclass comprises about 50% of HCC and has heterogeneous molecular features related to cell proliferation and progression in the cell cycle. Clinically, this subclass is associated with more aggressive behavior, higher serum AFP levels, vascular invasion, and moderately or poor histologic differentiation. The nonproliferation class has molecular features generally resembling normal liver and is dominated by genetic alterations that activate the Wnt/β-catenin pathway. Clinically, tumors in this group are better differentiated histologically, have lower serum AFP levels, and less aggressive behavior. HCV-associated and alcoholic liver disease associated HCC are more common in this class.[187] Unfortunately, the majority of this genetic information has yet to result in targeted therapeutic strategies for treating HCC.

Other Microscopic Types

A number of variant histologic types of HCC have been described, the majority of which have no clinical implications. *Clear cell* HCC comprises about 9% of all malignant hepatocellular neoplasms.[197] The cytoplasmic clearing, which is due to the accumulation of glycogen and/or fat, may result in an appearance closely resembling that of clear cell renal cell carcinoma or adrenal cortical carcinoma (Fig. 20.18).[198-200] The differential diagnosis is facilitated by the performance of special techniques such as immunostaining for Hep Par-1 or arginase-1, PAX-8 (for renal cell carcinoma), and inhibin, MART-1, or SF-1 (for adrenal cortical carcinoma). Of note, ectopic adrenal tissue in the liver, or tumors arising from them, can mimic clear cell HCC as well.[201] As in most other organs (such as lung, thyroid, and breast), clear cell carcinoma is not a distinct entity but rather a clinically inconsequential morphologic variant of one of the major tumor types.[202] The clear cell variant of HCC should not be confused with the more recently described steatotic variant, as described previously, which is associated with fatty liver disease and metabolic syndrome.

Sclerosing or *scirrhous* HCCs comprise less than 5% of HCC and are characterized by marked fibrous stroma, lack of a fibrous capsule, preserved intratumoral portal tracts, and contiguous multinodularity (Fig. 20.19).[203,204] They are much less likely to express Hep Par-1, and more likely to express markers of adenocarcinoma, such as EpCAM, CK19, and CK7, leading to diagnostic confusion. The vast majority do mark with arginase-1 and glypican-3, however. A case has been documented associated with secretion of a parathyroid hormone (PTH)-like protein.[205]

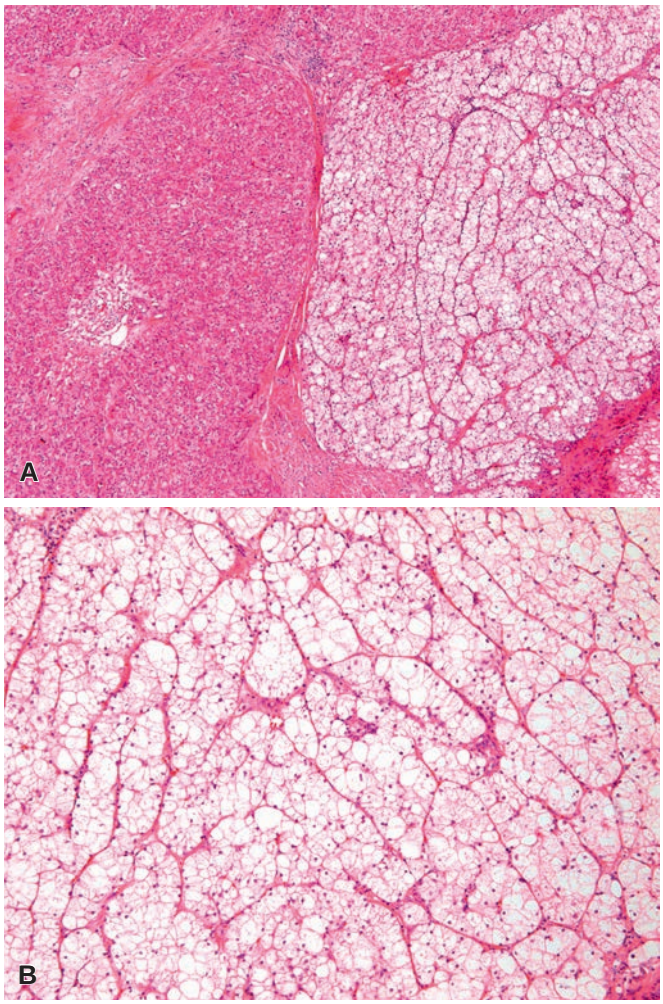

Figure 20.18 **A,** A focus of clear cell hepatocellular carcinoma (HCC) adjacent to conventional-type HCC. **B,** Another case at higher power shows how closely clear cell HCC can mimic metastatic clear cell renal cell carcinoma.

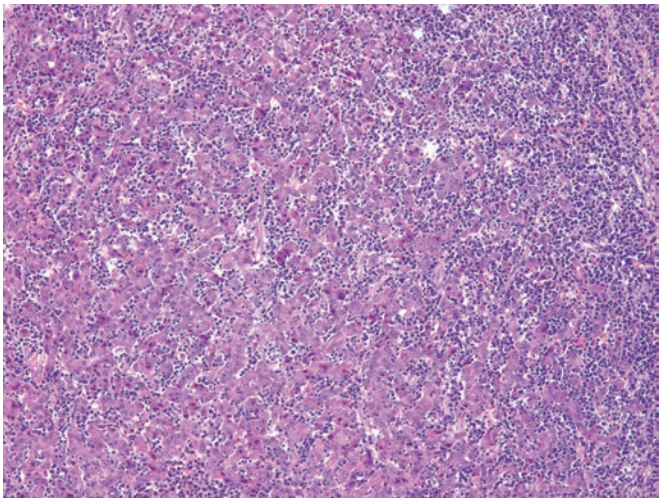

Figure 20.20 Large numbers of tumor-infiltrating lymphocytes are present in lymphoepithelioma-like hepatocellular carcinoma.

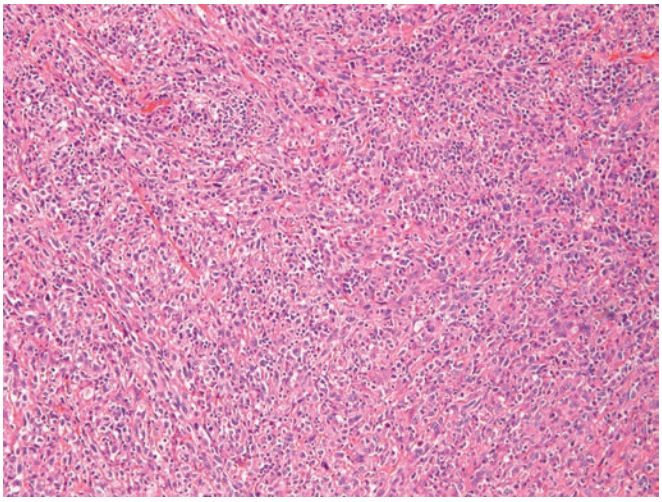

Figure 20.21 Sarcomatoid hepatocellular carcinoma comprised of sheets of neoplastic mesenchymal-type spindled cells and no features reminiscent of hepatocytes.

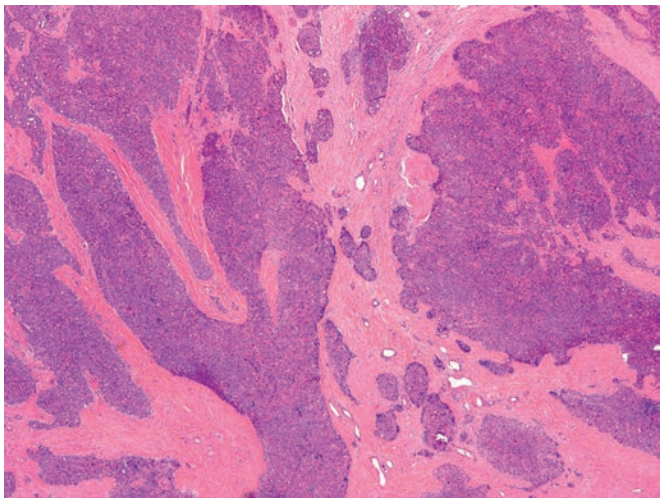

Figure 20.19 Abundant dense fibrous stroma characterizes the scirrhous variant of hepatocellular carcinoma.

Lymphoepithelioma-like HCC resembles its counterparts in the nasopharyngeal region, featuring large numbers of tumor-infiltrating lymphocytes (Fig. 20.20).[206,207] Although some cases have been associated with Epstein–Barr virus (EBV),[208] many are not. This tumor type is probably identical to the neoplasm that has been reported as HCC with lymphoid stroma.[209]

Sarcomatoid (spindle) cell HCC contains spindled and/or multinucleated cells of mesenchymal appearance (Fig. 20.21).[210–212] There may be areas of conventional HCC as well. Variable immunoreactivity with Hep Par-1 and keratins has been reported.[210–214] Osteoclast-like giant cells,[215–216] bone and cartilage, and skeletal muscle may also be present.[217] As in other organs, the term *carcinosarcoma* has been used when the carcinomatous and the sarcoma-like areas are sharply segregated.[218–219] Although some cases of sarcomatoid HCC have been associated with prior aggressive non-surgical therapies such as chemoembolization, radiofrequency ablation, and percutaneous ethanol injection, others have not.[214]

Fibrolamellar carcinoma (FLC, which has also historically been termed polygonal cell type HCC with fibrous stroma and oncocytic hepatocellular tumor) is a distinctive variant of liver cell carcinoma

seen predominantly in young patients without cirrhosis.[220,221] This type of HCC has been associated with a generally favorable prognosis, but more recent studies have indicated that the more favorable outcomes are associated with the absence of cirrhosis rather than the actual tumor type.[222] A case has been reported associated with Fanconi anemia.[223]

The most characteristic microscopic feature is nests and cords of neoplastic cells surrounded by variably dense lamellar bands of fibrosis (Fig. 20.22).[224] The tumor cells are polygonal with abundant deeply eosinophilic (oncocytic) cytoplasm, due to an increase in the number of mitochondria[225]; nucleoli are typically prominent. The collagen deposited around the tumor cells is predominantly composed of types I, III, and V.[226]

Immunohistochemically, fibrolamellar HCC expresses Hep Par-1, similar to conventional HCC, as well as cytokeratins 8 and 18.[224,227] Many cases also express glypican-3, but to less extent than conventional HCC.[152,224] FLC may also express CK7 and (to a lesser extent) CK19.[224,227] Recently, it has been demonstrated that CD68 is strongly expressed by fibrolamellar carcinomas (sensitivity of 96%, specificity of 80%) in a dot-like or stippled pattern[228]; this feature may be useful in distinguishing fibrolamellar HCC from the scirrhous variant. In addition, as noted previously, the fusion translocation of *DNAJB1* and *PRKACA* is highly specific for fibrolamellar carcinoma.[189] The distinction of the fibrolamellar variant is clinically important, given its better prognosis, even if patients present with larger tumors and nodal metastases.[229]

Another rare variant of HCC is the granulocyte colony-stimulating factor (G-CSF)-producing HCC, which may be associated with peripheral granulocytosis and elevated serum G-CSF and interleukin-6.[230]

Mixed HCC–cholangiocarcinoma are exceedingly rare tumors that exhibit dual differentiation into liver cell and bile duct lines, both at the morphologic and the immunohistochemical level; these tumors are less likely to be associated with chronic liver disease and cirrhosis.[231–233] To be classified as a combined HCC/cholangiocarcinoma, tumors should have areas of both unequivocal HCC and cholangiocarcinoma, although some have transitional areas that are intermediate between the two phenotypes (Fig. 20.23A). The areas of biliary differentiation are often accompanied by a chronic inflammatory infiltrate and a desmoplastic stroma, and the epithelium may show positivity for MOC31, CK7, CK19, and/or mucin; areas of hepatocellular growth may be confirmed using any of the markers discussed previously.[233–235] This is a somewhat different phenomenon from the presence of concomitant separate HCC and cholangiocarcinoma in the same liver or even in the same mass, which have been referred to as "collision tumors" (see Fig. 20.23B).[236,237] Recent studies have suggested that mixed (combined) HCC/cholangiocarcinoma arise from hepatocyte progenitor (stem) cells.[235,238,239] Mixed HCC/neuroendocrine carcinoma has also been rarely reported.[240,241]

Biopsy and Cytology

The diagnosis of HCC is often made by core or fine needle biopsy[242–244] or a combination of both.[245–246] The better differentiated the tumor, the more difficult the diagnosis of malignancy. In fine-needle material, the most useful diagnostic criteria are similarity of tumor cells to liver cells, prominence of nucleoli, trabecular pattern of growth, and presence of a sinusoidal stroma (Fig. 20.24A–C).[246–247] Reticulin stain on a core needle biopsy or cell block may be invaluable in establishing a diagnosis of malignancy (see Fig. 20.24D).[248]

At the cytologic level, features favoring the diagnosis of liver cell carcinoma over cirrhosis are absence of bile duct epithelial cells and chronic inflammatory cells, increased nucleocytoplasmic ratio, trabecular pattern, and atypical naked hepatocytic nuclei.[249]

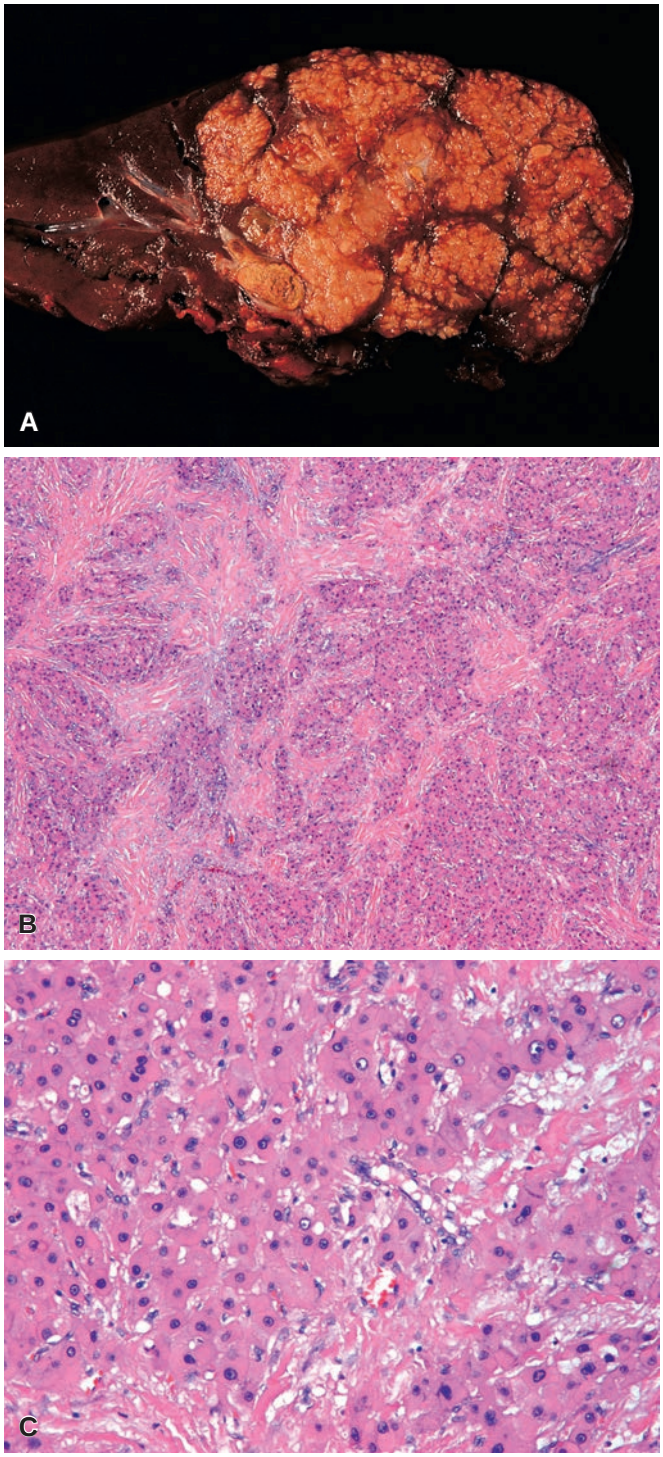

Figure 20.22 **A,** Grossly, fibrolamellar carcinoma is large, well circumscribed, multinodular, and yellow. The adjacent nonneoplastic liver is noncirrhotic. **B,** Fibrolamellar HCC features nests of eosinophilic tumor cells surrounded by dense lamellar fibrosis. **C,** The tumor cells have abundant cytoplasm and prominent nucleoli.

Features favoring liver cell carcinoma over metastatic carcinoma include polygonal cells with centrally placed nuclei, cells separated by sinusoidal stroma, nuclear pseudoinclusions, eosinophilic cytoplasmic globules, and bile secretion.[246,249] As with histologic preparations, the diagnosis can be aided by performing immunostains

on the cell block. Two rare but well-documented complications of needle biopsy are implantation along the tract and intra-abdominal hemorrhage.[250]

Grading, Spread, and Metastases

Although the most widely used grading system historically has been the Edmondson and Steiner four-tiered system,[251] many pathologists use a three-tiered system of well (G1), moderately (G2), and poorly (G3) differentiated HCC, ranging from a very close resemblance to normal liver in G1 tumors to pleomorphic tumors that may not resemble liver at all in G3 neoplasms. Higher grade does appear to correlate with worse prognosis; however, when assessing grade on a needle biopsy or FNA specimen, it is important to remember that grade may be heterogeneous within the same tumor, and thus a single small sample may not be representative of the overall grade.[252]

The portal venous system is involved in ~80% of HCC.[253] Tumor cells may also grow into the hepatic vein and from there reach the inferior vena cava and the right atrium.[254] Tumor invasion of the biliary tree is less common but it does occur.[255] The most common sites of extrahepatic spread are lungs, abdominal lymph nodes, and bone[256]; in some cases, a pathologic fracture or some other sign attributable to bone metastasis is the first sign of disease.[257] Unusual sites of metastasis include brain, adrenal, and head and neck.[258,259] Metastases to the ovary need to be distinguished from primary hepatoid tumors of this organ.[260]

Treatment and Prognosis

Resection remains the first line therapy for HCC, but liver reserve and tumor spread must be carefully assessed prior to surgery (the former is particularly important in cirrhotic patients). Unfortunately, recurrence is common, and postsurgical survival rates are approximately 80%–90% at 1 year, 60%–85% at 3 years, and 40%–75% at 5 years.[261,262]

Orthotopic liver transplantation is an option for patients with early stage disease, with 1-year survival rates of approximately 85%, and 5-year survival rates of approximately 70%.[261] The Milan criteria are widely used as the selection criteria for patients with HCC who are being considered for transplant (single tumor ≤5 cm, two to three nodules all <3 cm and without gross vascular invasion or extrahepatic spread).[263]

Patients with single small tumors who are not good surgical candidates may undergo ablative therapy, including radiofrequency ablation, microwave ablation, chemical ablation, or chemoembolization via selective injection of chemotherapeutic agents into tumor-feeding vessels.[261] The only first line systemic therapy with proven efficacy in HCC is sorafenib, an oral tyrosine kinase inhibitor, which can add months to the overall survival of patients with advanced disease.[264] Under exceptional circumstances, HCCs have been found to undergo spontaneous regression.[265]

The 1-year survival of untreated HCC patients is about 17.5% and approximately 7% at 2 years.[266] Clinicopathologic stage is the most important prognostic determinant, although staging of HCC is somewhat different from other cancers, as it must take into account hepatic function as well as tumor-related data. Many HCC staging schemes have been proposed, but the Barcelona Clinic Liver Cancer staging system is the most widely used; it incorporates variables including tumor stage, hepatic functional status, overall performance status, and linkage of clinical stage with treatment modalities.[261] The TNM staging system is widely used by pathologists but is limited as it does not take into account important clinical factors.[267]

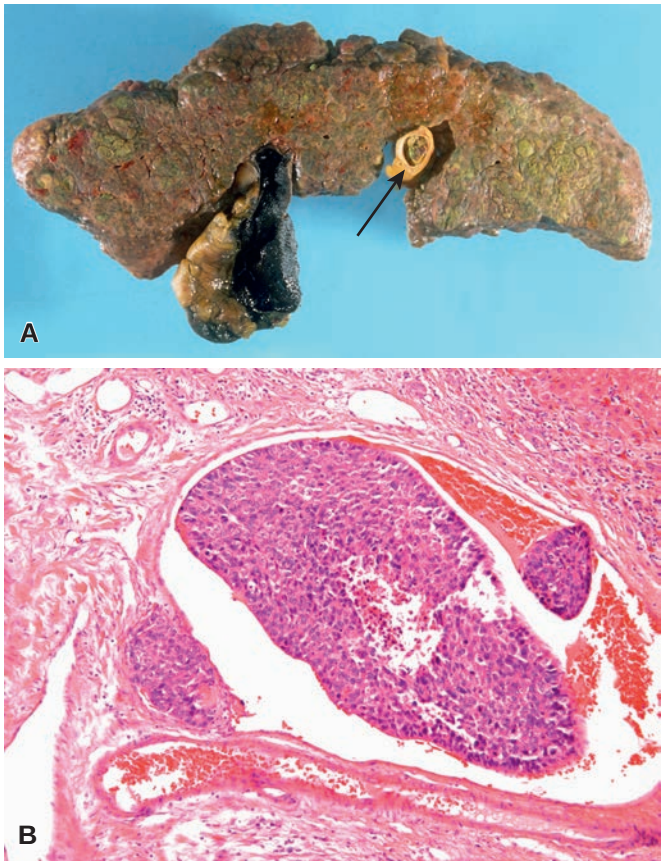

Figure 20.25 **A,** Grossly evident (macroscopic) portal vein involvement in a hepatocellular carcinoma (HCC) with a diffuse pattern of growth *(arrow)*. **B,** Microscopic involvement of a small vein.

A number of independent adverse prognostic factors have been reported, including presence of cirrhosis, poor performance status, presence of multiple tumors, significantly elevated preoperative serum AFP (typically 200 ng/mL or greater), vascular invasion, poorly differentiated histologic grade, and tumor size.[268,269,270] In many series, patients with tumors less than 2–3 cm have a significantly better prognosis.[268,269] Some authors, however, have not found size to be an important prognostic determinator.[271] Although some studies have shown that chronic viral infection had no effect on prognosis, others have shown that HBV and HCV infection are associated with worse outcomes.[272,273] In most series, age and gender have not been found to correlate with prognosis.

A number of other pathologic factors also have significant prognostic implications. Vascular invasion is one of the best predictors of recurrence following resection and is classified as macroscopic (identified grossly or on imaging, Fig. 20.25A) or microscopic (identifiable only by microscopy, see Fig. 20.25B), and both are predictors of recurrence.[274] Microvascular invasion has also been associated with decreased disease-free survival.[275,276] HCCs that are completely encapsulated also behave in a less aggressive fashion than those lacking this feature.[277] Other histologic factors that are independent predictors of poor prognosis are high nuclear grade and increased mitotic activity.[278]

Hepatoblastoma

Hepatoblastoma is the most common primary pediatric liver tumor, typically diagnosed within the first 3 years of life, and the incidence

appears to be slowly increasing.[279] Isolated instances in older children and adults have been reported, which have an overall poorer prognosis than hepatoblastoma occurring in young children.[280,281] The majority of cases are sporadic, but the tumor is associated with a variety of congenital abnormalities (particularly in the genitourinary tract), Beckwith–Wiedemann syndrome, trisomy 18, and familial colonic polyposis.[279,282–283] Some patients present with virilization as a result of ectopic sex hormone production.[284] Serum levels of AFP are often markedly elevated.[285] MRI and CT scans provide the most valuable preoperative assessment of the tumor location and extent.[286]

Grossly, hepatoblastoma is solid, well circumscribed, and more often solitary than multiple (Fig. 20.26A).[287] Microscopically, most (67%) of the tumors are composed exclusively of immature hepatocytic elements (embryonal and fetal) and are referred to as *pure* or *epithelial*.[279,288] Fetal elements consist of hepatocytes arranged in irregular laminae two cells thick, recapitulating those of the fetal liver (see Fig. 20.26B). Patients with tumors that are entirely of the well-differentiated fetal type and a low mitotic rate have a better prognosis.[279] Unfortunately, this is a small minority of cases. Embryonal elements have a more immature appearance and a pattern of growth that is predominantly solid, but that may also exhibit ribbons, rosettes, and papillary formations (see Fig. 20.26C).[289] Foci of extramedullary hematopoiesis are often seen, and multinucleated giant cells may be present, particularly in the tumors associated with hormone production.[289,290] Approximately 20%–30% of tumors (referred to as *mixed*) contain a mesenchymal component as well, which may consist of spindled cells, osteoid, skeletal muscle, or cartilage (see Fig. 20.26D); teratoid features (presence of squamous epithelium, neuroglial tissue, etc.) may also be seen.[291]

Some tumors contain a component of, or are largely made up of, small undifferentiated cells; this pattern may be associated with low AFP levels and a poor prognosis.[279,291,292] These cases may closely resemble malignant rhabdoid tumors, an important diagnostic and therapeutic distinction.[291] Another subset of hepatoblastoma is the cholangioblastic type, which contains a tubular component with cholangiolar features.[291,293] A *macrotrabecular type* of hepatoblastoma resembling liver cell carcinoma has been described, which can mimic HCC (see Fig. 20.26E).[291,294] Primary malignant hepatocellular tumors developing in older children and adolescents may have an appearance intermediate between those of hepatoblastomas and HCCs; these have previously been referred to as *transitional liver cell tumors* and more recently as *hepatocellular malignant tumor not otherwise specified*.[291,295]

Immunohistochemically, AFP is typically expressed by fetal and embryonal elements but negative in mesenchymal and undifferentiated components.[291] CPS1, Hep Par-1, and pCEA are predominantly expressed in fetal components as well.[291,296] Glypican-3 is expressed in the epithelial components of almost all cases of hepatoblastoma (but not in poorly differentiated small cell areas or mesenchymal elements) and not in normal liver tissue.[291,297] Aberrant nuclear immunostaining for β-catenin is a highly characteristic feature in epithelial, mesenchymal, cholangioblastic, and occasionally small cell undifferentiated areas, which is related to the mutation of the encoding gene.[291,298] Nuclear INI1 staining is also characteristic of hepatoblastoma, except for some cases of small cell undifferentiated type.[291,299] Pankeratin and low-molecular-weight keratin expression is variable; cytokeratins 7 and 19 are occasionally expressed by the cholangioblastic type.[291] Delta-like protein (DLK) has been reported to be useful in distinguishing hepatoblastoma from HCC,[300] but the utility of this is still under investigation.

Hepatoblastomas with focal neuroendocrine staining have been reported,[301,302] although the significance of this in hepatoblastomas remains unclear. Rare tumors have also been found to contain melanin and to express immunoreactivity for HMB-45.[303]

A high proportion of cases (>80%) exhibit abnormalities in the *Wnt* signaling pathway, including mutations in the *CTNNB1* (β-catenin) gene, which explains the abnormal nuclear translocation of the protein as detected by immunohistochemistry.[298,304–306] Activation of *TERT* and *MYC*, which play a role in *Wnt* signal activation, appear to play a role in more aggressive hepatoblastomas as well.[279,304]

The treatment of choice of hepatoblastoma is surgical excision. However, 60% of patients are unresectable at diagnosis and may require preoperative chemotherapy.[286,307,308] Liver transplantation is being increasingly used for patients whose tumors remain unresectable.[286,309,310] Over the past four decades, overall survival in hepatoblastoma has increased from approximately 30% to over 80%, primarily due to advances in chemotherapy and the ability to achieve complete resection.[286,308] The survival rate is substantially better than for HCC.

It is important to recognize the morphologic effects of presurgical chemotherapy, which include tumor necrosis, fibrohistiocytic response, an apparent increase in the presence and amount of osteoid, cytoarchitectural differentiation mimicking non-neoplastic liver (but can be distinguished from the latter by nuclear expression of β-catenin), and alterations reminiscent of HCC (e.g. nuclear atypia and thick trabeculae of neoplastic cells).[311,312]

Bile Duct Tumors and Tumorlike Conditions

Simple Cyst

Simple (also known as solitary or unilocular) biliary cysts are lined by a single layer of biliary epithelium overlying a fibrous wall (Fig. 20.27). They occur most commonly in adult women, and are often asymptomatic.[313] Rare cases of carcinoma, particularly squamous cell carcinoma, have been reported arising within simple cysts.[314] They can be distinguished from biliary cystadenomas by their unilocular configuration and lack of ovarian-type stroma.

Biliary Microhamartoma

Biliary microhamartoma (also known as bile duct hamartoma, von Meyenburg complex, or Moschcowitz complex), presents as multiple, small, white subcapsular nodules scattered throughout the liver, which may be mistaken for metastatic carcinoma during surgery or radiographic evaluation.[315,316] Microscopically, these nodules appear as a circumscribed but disorderly collection of dilated, angular biliary channels surrounded by abundant fibrous stroma, located within or at the edge of portal tracts (Fig. 20.28).[317,318] Although the pattern of growth of the individual glands may be irregular, the outline of the lesion as seen on low-power view is sharp, and cellular atypia is nil.

Biliary microhamartomas are believed to be secondary to congenital ductal plate malformations affecting the smallest intrahepatic bile ducts.[319] Although they can be sporadic, they are associated with fibropolycystic liver/kidney disease, congenital hepatic fibrosis, and Caroli disease.[317,319] Virtually 100% of individuals with adult type fibropolycystic liver/kidney disease have biliary microhamartomas in the liver, and approximately 17% of patients with biliary microhamartomas have biliary cysts.[320] Isolated instances of malignant transformation in the form of bile duct carcinomas have been reported.[321–323] A variant characterized by enlargement and cystic dilation of the biliary channels has been called *cystic* or *multicystic biliary hamartoma*.[324,325]

Peribiliary Gland Hamartoma (Bile Duct Adenoma)

Peribiliary gland hamartomas (bile duct adenomas) are solitary in over 80% of the cases. Macroscopically, they appear as well-circumscribed, wedge-like white masses, sometimes with a central depression, closely resembling metastatic carcinoma. Most of the lesions are less than 1 cm in diameter and are located subcapsularly.[326,327] Microscopically, they are made up of small tubular structures with little or no lumen, often embedded in fibrous stroma (Fig. 20.29). Inflammation is often present. A variant composed of clear cells and simulating metastatic renal cell carcinoma has been described.[328] Immunohistochemically, these lesions are reactive for CK7 and CK19, and have a mucin phenotype similar to that of pyloric gland metaplasia (expressing MUC6, MUC5AC, TFF2, D10, and IF6).[329] Occasionally, a neuroendocrine component resembling pulmonary tumorlet may be seen.[330] Interestingly, a small percentage of these lesions (about 7%) harbor *KRAS* mutations.[331] The behavior of these lesions is benign. The neoplastic versus hamartomatous nature of this process is disputed, and the distinction with von Meyenburg complexes is anything but sharp,[332] except that the latter are more often multiple and associated with fibropolycystic liver/kidney disease.

Biliary Cystadenoma and Cystadenocarcinoma

Benign and malignant cystic tumors of biliary origin can arise in the liver or, less frequently, in the extrahepatic biliary system (see Chapter 21). Practically all patients are adults, and there is a great predominance of females.[333,334] Grossly, the neoplasms are multilocular and contain mucinous or clear fluid. The benign tumors are lined by a single layer of cuboidal to tall columnar mucin-producing epithelium (similar to that of the intrahepatic bile ducts) (Fig. 20.30A). In the malignant variety the lining may be of intestinal type (including goblet and Paneth cells) or biliary type; there may be areas of frank stromal invasion as well as nuclear atypia and increased mitoses (see Fig. 20.30B).[333,335] In some cases (both cystadenoma and cystadenocarcinoma), occurring almost

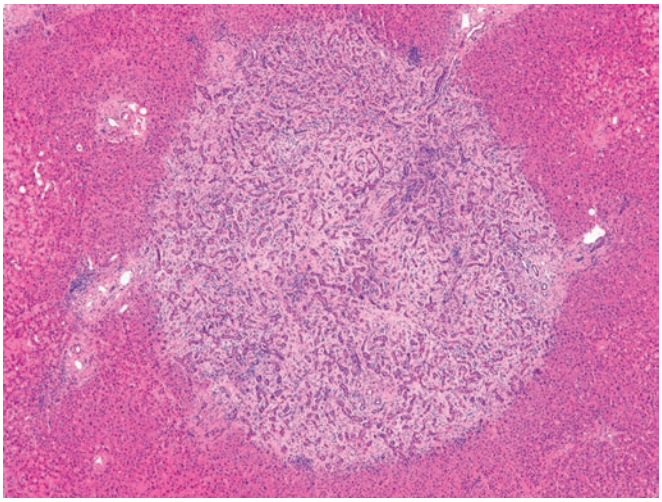

Figure 20.29 Peribiliary gland hamartoma (bile duct adenoma) consisting of small tubular structures with little or no lumen embedded in dense fibrous stroma.

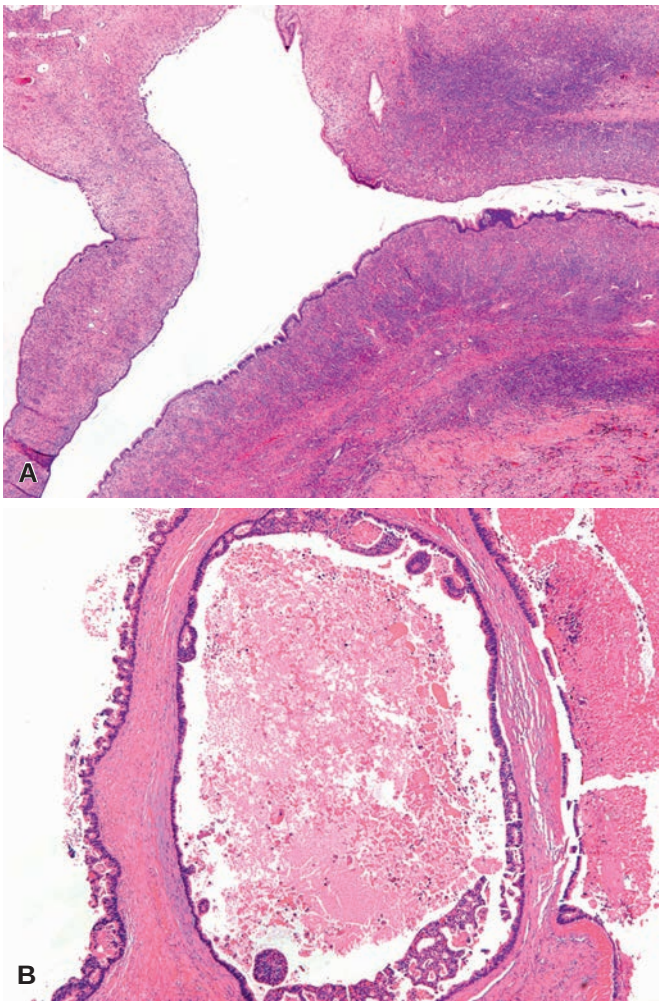

Figure 20.30 **A,** Biliary cystadenoma from a female patient, featuring multilocular cysts lined by a single layer of biliary-type epithelium with underlying cellular ovarian-type stroma. **B,** Cystadenocarcinoma consisting of multilocular cysts lined by markedly atypical neoplastic epithelium. There is necrotic debris within the cyst lumens. Note the absence of ovarian-type stroma.

exclusively in females, the underlying layer of connective tissue is very cellular and closely resembles ovarian stroma.[333,334] These cells are immunoreactive for vimentin, smooth muscle actin, hormone receptors, and inhibin.[336,337]An endocrine cell component may be seen both in the benign and in the malignant types,[338] and oncocytic differentiation has also been described.[339] Rare cases have also been reported that resemble serous cystadenoma of the pancreas.[333] Benign and malignant areas may coexist, emphasizing the need for thorough sampling, but also suggesting that cystadenocarcinomas may arise from their benign counterparts, at least in some cases. In rare cases, the malignant epithelial cells of cystadenocarcinoma acquire a spindle-shaped pseudosarcomatous appearance, as it occurs in the analogous tumor of the pancreas.[340] Immunohistochemically, biliary cystadenomas and cystadenocarcinomas with a biliary phenotype exhibit reactivity for CK7 and CK19.[341] Biliary cystadenocarcinomas with an intestinal phenotype may express CDX2, MUC2, and CK20.

It is difficult to make strong statements about prognosis regarding cystadenocarcinomas, given the rarity of these tumors. However, it has been reported that cystadenocarcinomas with ovarian-like stroma in females follow an indolent course, whereas those lacking this distinctive stroma (more often seen in males) follow a more aggressive course.[333,342] However, there are rare reports of high-grade cystadenocarcinomas with a very poor prognosis despite the presence of ovarian-type stroma.[342] The primary treatment of these tumors consists of complete surgical excision.[342]

Biliary cystadenocarcinomas may be distinguished from intraductal tubulopapillary neoplasms of the liver (see later) by the lack of ovarian-type stroma in the latter, as well as their communication with dilated bile ducts and prominent papillary architecture. Recently, a rare lesion with cystically dilated ducts and prominent fibrous stroma, known as *biliary adenofibroma*, has been described, but these also lack ovarian-type stroma and display an immunophenotype more closely analogous to von Meyenburg complexes.[343]

Intraductal Papillary Neoplasms of the Bile Duct

Intraductal papillary neoplasms of the bile duct, previously termed biliary intraductal papillary–mucinous neoplasms, are regarded as the biliary tract counterparts of the better known intraductal papillary mucinous neoplasms of the pancreas (Fig. 20.31).[344,345] As in the latter, there is a range of phenotypes (including biliary, gastric, intestinal, and oncocytic), as well as a range of dysplasia from low-grade to high-grade to invasive adenocarcinoma. These tumors lack ovarian-type stroma.[345] They can be associated with hepatolithiasis and, exceptionally, with cirrhosis.[346,347] Cases historically described as biliary papillomatosis[348] are now included in this category, similar to the extrahepatic biliary tree (see Chapter 21).

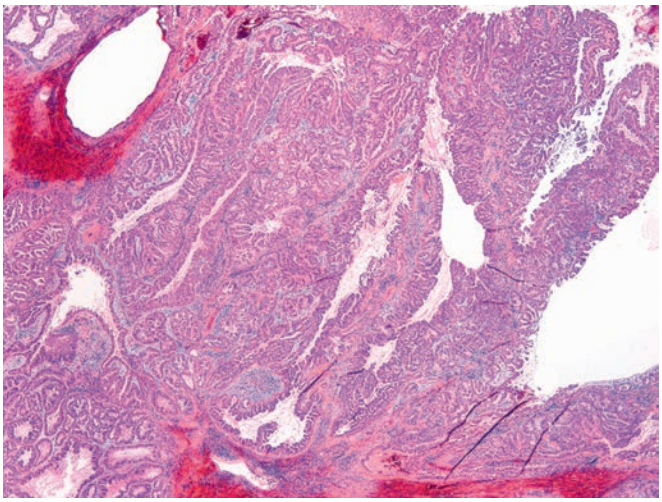

Figure 20.31 Tubular and papillary neoplasm arising within the dilated lumen of an intrahepatic bile duct.

Bile Duct Carcinoma (Cholangiocarcinoma)

Intrahepatic cholangiocarcinomas comprise approximately 10%–20% of all malignant primary liver tumors.[349] Although most cases seen in Western and African countries are unaccompanied by cirrhosis, some series have suggested that HCV-related cirrhosis is a major risk factor for cholangiocarcinoma.[350] Other risk factors include choledochal cysts, Caroli disease,[351] congenital hepatic fibrosis,[352] multiple bile duct hamartomas[353] (von Meyenburg complexes, see earlier), primary sclerosing cholangitis,[349] fluke infection (*Clonorchis sinensis* or *Opisthorchis viverrini*),[354] Thorotrast administration,[355] and intrahepatic lithiasis (hepatolithiasis).[356] Dysplasia of the biliary tree has been identified in association with several of these diseases, including primary sclerosing cholangitis, hepatolithiasis, and choledochal cysts.[357]

Most cases of bile duct carcinoma occur after the age of 60 years in Western countries.[358] The incidence is highest in Asians and Hispanics; there is a slight male predominance, with the exception of the Hispanic population, in which case the incidence is higher in women.[359] Clinically, intrahepatic cholangiocarcinomas are often asymptomatic, and thus large when finally discovered; when they are symptomatic, patients usually present with abdominal pain and weight loss (as opposed to obstructive jaundice, which is the usual form of presentation for their extrahepatic counterpart).[358] Grossly, these tumors tend to be firmer and whiter than liver cell carcinomas because of their greater amount of fibrous stroma (Fig. 20.32A). Multicentricity and perineural invasion are common.[360] Vascular invasion is not as common as in HCC, but it can certainly occur.[360]

Microscopically, tumor cells typically form tubules and glands (see Fig. 20.32B); a cribriform pattern may also be present.[349] Stroma is usually abundant. A common feature is the heterogeneity of the neoplastic epithelial cells within the same gland (see Fig. 20.32C).[361] This peculiarity, which is of great diagnostic significance, is shared by adenocarcinomas of the entire pancreatobiliary system. The tumor has a tendency to spread between hepatocyte plates, along duct walls, and in relation to nerves. In one series, perineurial invasion was found in 81% of the cases (see Fig. 20.32D).[362] The prominent vascularity of HCC is absent. Mucin stains are frequently positive,[361] their profile resembling in some cases those of the gastric foveolae and in others those of pyloric glands.[363] Morphologic variations of cholangiocarcinoma include mucinous,[349] signet ring cell,[364] adenosquamous (see Fig. 20.32E),[365,366] clear cell,[367] spindled/sarcomatoid,[368] with an osteoclast-like giant cell component,[369] with a lymphoepithelioma-like appearance[370,371] (some associated with EBV), and, rarely, with the appearance of a thyroid follicular neoplasm.[372]

Immunohistochemically, there are no specific markers for intrahepatic cholangiocarcinoma, similar to other neoplasms of the biliary tree. There is consistent reactivity for MOC31 (see earlier),[162,163] EMA, and monoclonal CEA, features of importance in the differential diagnosis with liver cell carcinoma.[373,374] Polyclonal CEA will also mark intrahepatic cholangiocarcinomas in a diffuse cytoplasmic, not canalicular, pattern.[374] Keratin immunoreactivity is seen not only with monoclonal antibody CAM 5.2 (as in HCC, indicating the presence of CK8 and CK18), but also with CK7 and CK19.[374] There is a reported difference in the keratin immunoprofile between

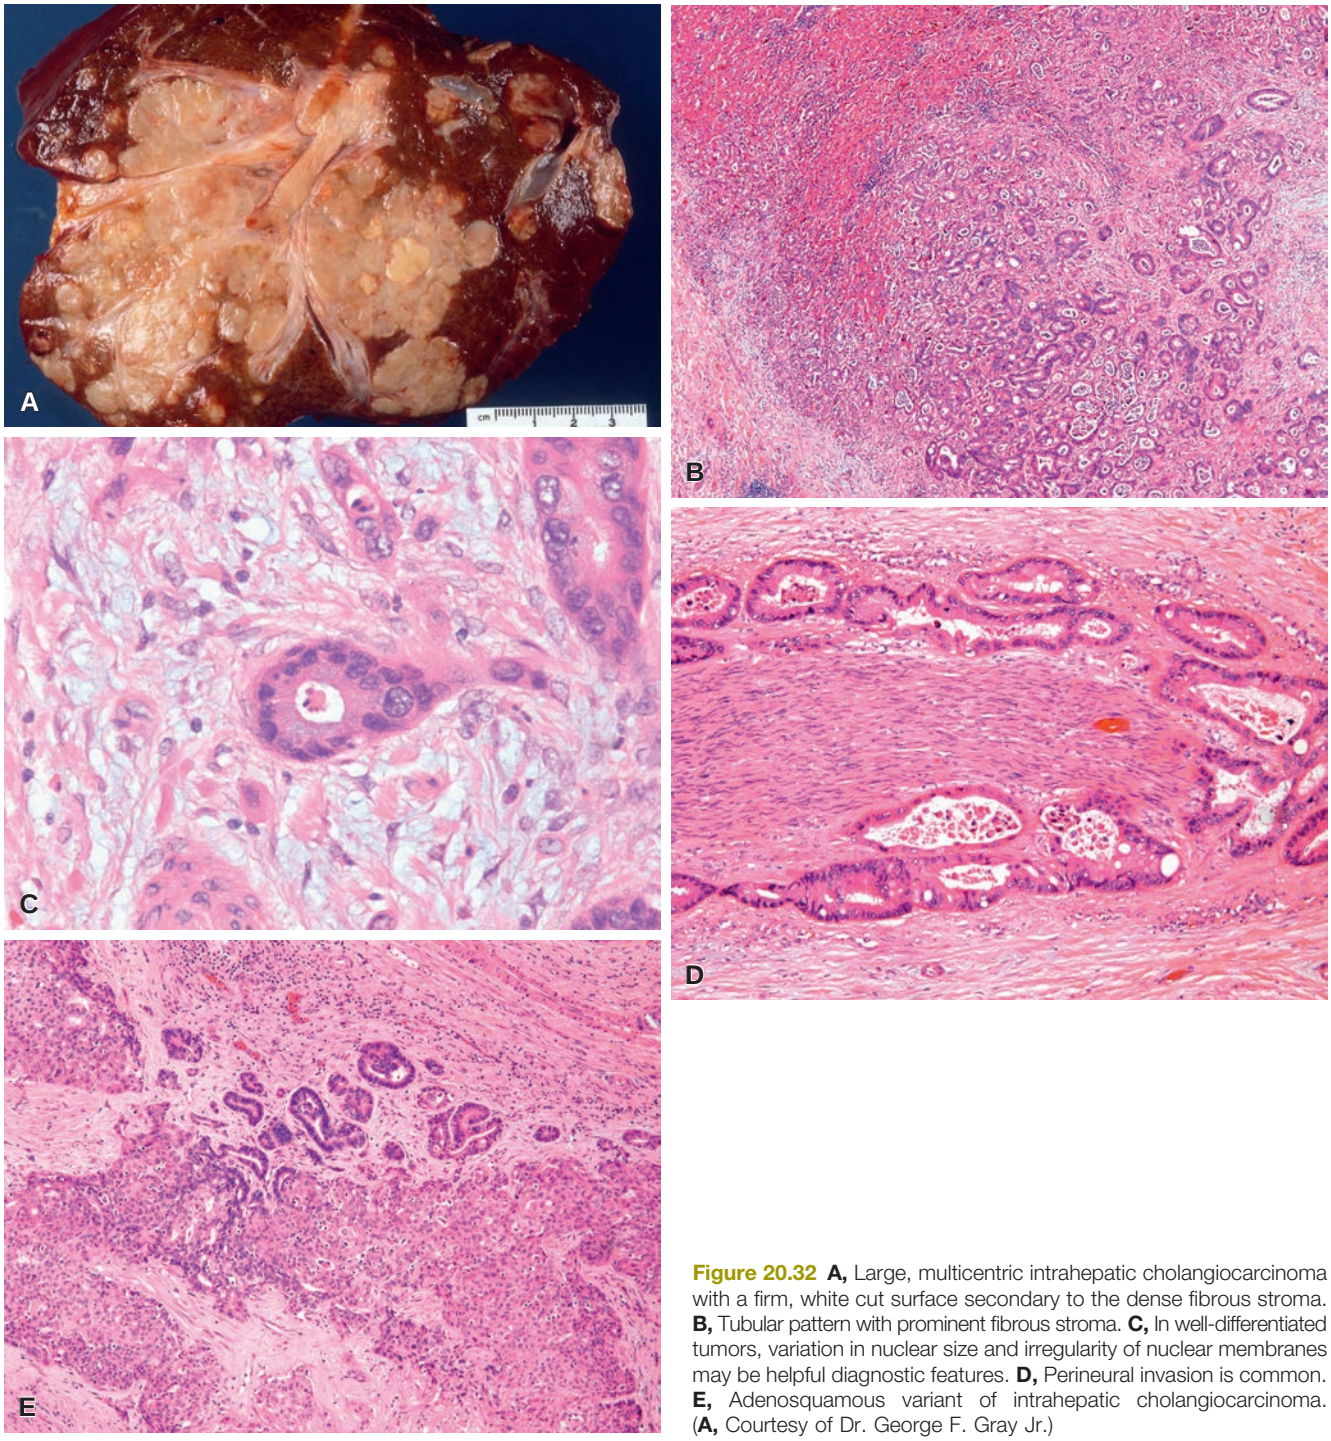

Figure 20.32 **A,** Large, multicentric intrahepatic cholangiocarcinoma with a firm, white cut surface secondary to the dense fibrous stroma. **B,** Tubular pattern with prominent fibrous stroma. **C,** In well-differentiated tumors, variation in nuclear size and irregularity of nuclear membranes may be helpful diagnostic features. **D,** Perineural invasion is common. **E,** Adenosquamous variant of intrahepatic cholangiocarcinoma. (**A,** Courtesy of Dr. George F. Gray Jr.)

intrahepatic and extrahepatic cholangiocarcinoma, in the sense that the former is usually CK7+/CK20–, whereas the latter is frequently CK7+/CK20+.[375,376] Claudin-4 (a component of tight junctions) has been found to be expressed in nearly all bile duct carcinomas but not in normal hepatocytes or in liver cell carcinoma.[377] In contrast to liver cell carcinoma, Hep Par-1 and arginase are typically negative.

A high incidence of *KRAS* gene mutations has been detected, the incidence and spectrum being similar to those reported in large bowel carcinoma.[378,379] Other common molecular changes in cholangiocarcinoma include increased expression of *EGFR* and *MET*, activation of *mTOR*, overexpression of cyclin D1, overexpression of P21, inactivating mutations of *DPC4* (13%–15% of hilar/intrahepatic and 55% of extrahepatic cholangiocarcinomas), and *TP53* mutations (one-third of cases).[380]

Intrahepatic, perihilar, and distal cholangiocarcinomas are staged differently per the seventh edition of the AJCC staging manual.[381] Intrahepatic cholangiocarcinomas may spread extensively within the liver, involving the portal areas, lymphatics, and liver capsule.[382] Perineural, lymphatic, and vascular involvement are also common, as discussed previously, as well as metastases to lymph nodes (in up to one-third of patients at time of diagnosis)[359] and to distant

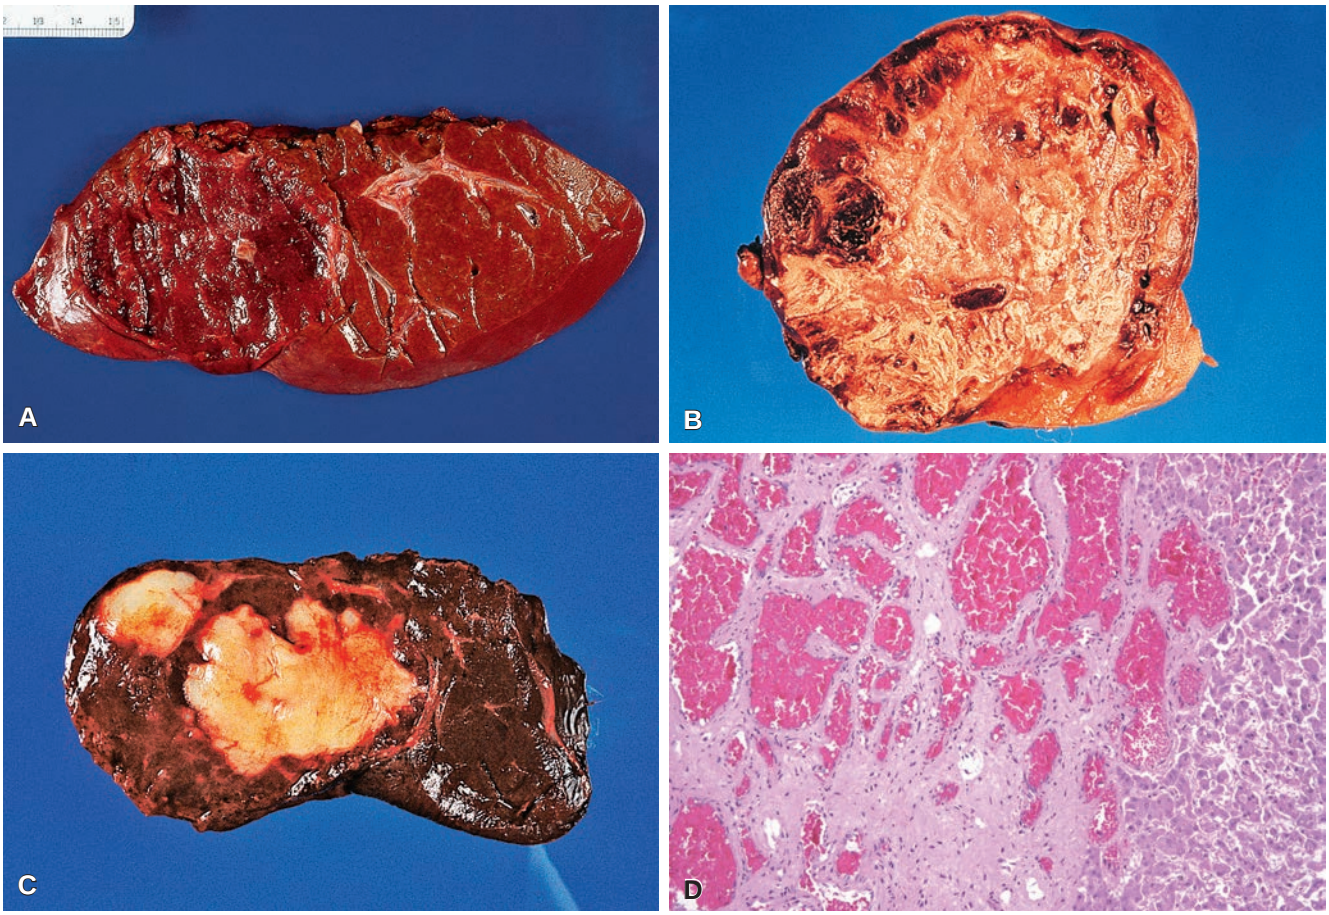

Figure 20.33 **A,** Typical spongy deep red cut surface in hemangioma of the liver. **B,** Tumor accompanied by large fibrin deposits secondary to thrombosis. **C,** An example with marked secondary fibrosis. **D,** Microscopically, there are dilated vascular spaces lined by flat endothelial cells, within dense fibrous stroma.

organs. Ovarian metastases can closely mimic primary ovarian mucinous neoplasms.[383] In rare cases, metastases to distant sites can occur many years following the original diagnosis.[384]

The treatment of bile duct carcinoma is surgical, in the form of partial or total hepatic resection, although curative resection is achieved in less than one-third of patients. Liver transplantation is not recommended for intrahepatic cholangiocarcinoma (unlike perihilar tumors) given the high risk of recurrence following transplantation.[360] The prognosis is poor, with 5-year survival rates of 22%–36%.[359]

Mesenchymal Tumors and Tumorlike Conditions

Vascular Tumors

Hemangioma is the most common benign tumor of the liver. In most cases, it is found incidentally at laparotomy or autopsy. Occasionally, it grows large enough to form a clinically apparent mass. When this is the case, complications such as spontaneous bleeding with rupture and sequestration of platelets resulting in thrombocytopenic purpura may develop.[385] The mass usually projects only slightly above the cut surface, but on occasion it may be pedunculated. On section, it has a characteristic spongy appearance and dark red color. Thrombi in different stages of organization are often encountered (Fig. 20.33A–C). Microscopically, most liver hemangiomas are composed of dilated vascular spaces lined by flat endothelial cells and supported by fibrous tissue (see Fig. 20.33D). Long standing lesions can show extensive hyalinization or calcification[386]; in fact, some authors hypothesize that the so-called *solitary necrotic nodule of the liver* is merely a thrombosed and necrotic hemangioma in many cases.[387] Large and/or symptomatic hemangiomas need to be surgically excised, although there are no agreed-upon criteria for the size at which resection should occur. Observation is justified in small and/or asymptomatic lesions.[385]

Benign (infantile) hemangioendothelioma is a highly cellular variant of hemangioma occurring almost exclusively in children and sometimes in neonates.[388,389] In the classic series reported by Dehner and Ishak,[390] 87% of the cases were diagnosed prior to 6 months of age. The tumors can be solitary or multiple. The latter are not infrequently associated with hemangiomas in other sites, particularly the skin.[391] They can also be seen as part of the Beckwith–Wiedemann syndrome.[392] There may be a serum elevation of AFP.[393] These tumors may be associated with hepatic failure, congestive heart failure, or hyperconsumptive coagulopathy (Kasabach–Merritt syndrome), although with modern surgical and medical therapeutic options, the mortality rate is much lower than in the past.[394] Some tumors

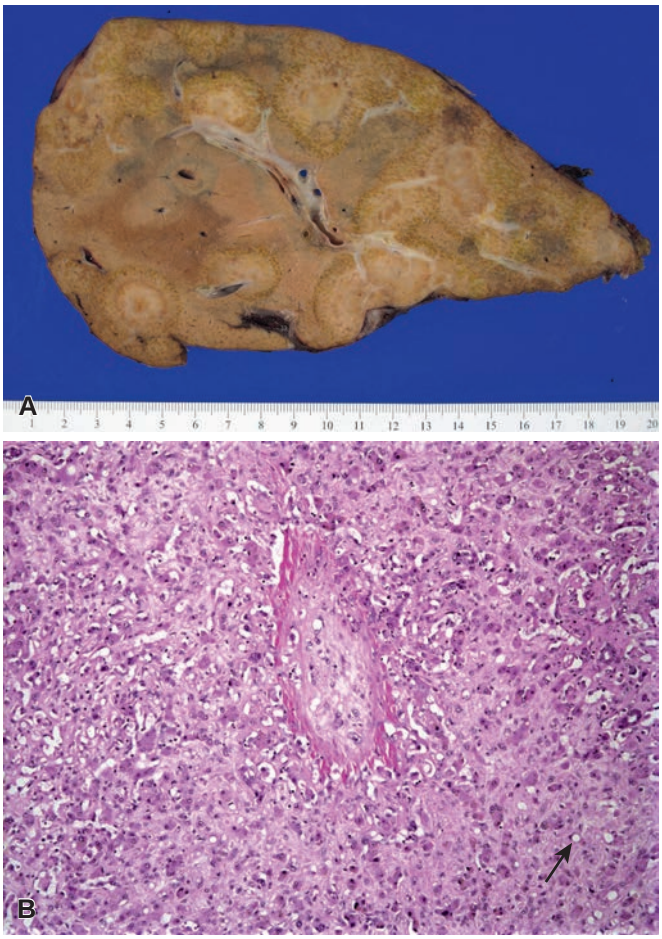

Figure 20.35 **A,** Hepatic epithelioid hemangioendothelioma with multifocal growth pattern and marked parenchymal congestion due to involvement of the hepatic venous system by tumor. **B,** Epithelioid tumor cells with occasional intracytoplasmic lumens *(arrow)* are present within abundant stroma. Note involvement of the central vein in the middle of the photograph.

regress spontaneously.[395] Microscopically and ultrastructurally, the blood vessels of hemangioendothelioma are lined by one or more layers of plump endothelial cells and surrounded by equally prominent perithelial cells (Fig. 20.34).[396] The lumen is small or collapsed in most vessels, but cavernous foci can sometimes be identified. A lobular configuration is focally apparent, and anastomosing channels are not a feature. Immunohistochemically, they show reactivity for GLUT-1, like their cutaneous counterparts, and in contrast to congenital hepatic vascular transformation.[397]

Epithelioid hemangioendothelioma is a rare, distinctive type of endothelial vascular neoplasm.[398–400] Most patients are adult females, and there may be a relationship with oral contraceptive use.[401] Clinically, the tumor may simulate the Budd–Chiari syndrome due to involvement of hepatic veins by tumor.[402] Grossly, the tumors are often multiple and involve both hepatic lobes (Fig. 20.35A). Microscopically, the tumor consists of spindled and epithelioid cells within abundant fibrous stroma, which may have myxoid, sclerotic, or calcifying features. The neoplastic cells infiltrate sinusoids and veins, both as tuft-like intravascular proliferations and as fibrothrombotic occlusions.[403,404] The tumor cells frequently contain intracytoplasmic lumina (see Fig. 20.35B), which may contain red blood cells. Mitoses are typically rare or absent. Immunohistochemically, they are positive for vascular markers (such as CD31, CD34, and ERG) and may also exhibit positivity for D2-40 and CD10.[404,405] Keratins, including pankeratin, CAM5.2, and CK7, may also be positive, leading to diagnostic confusion, particularly in small biopsies.[404,405] Weibel–Palade bodies may be seen ultrastructurally.[406,407] The prognosis is much more favorable than for angiosarcoma, although extrahepatic metastases occurred in 27% of the 137 patients reported by Makhlouf et al.[400] The lung metastases closely simulate the appearance of primary epithelioid hemangioendothelioma of the lung, that is, the lesion formerly known as intravascular bronchioloalveolar tumor (IV-BAT). Historically the treatment has been surgical or ablative, but liver transplant is now more frequently employed due to the fact that many patients have unresectable multifocal disease.[408,409] Exceptionally, the tumor will be seen recurring in the allograft.[410]

Angiosarcoma is characterized by malignant endothelial cells that infiltrate preexisting vascular structures. In the liver, this leads to progressive sinusoidal dilatation and consequent atrophy and disappearance of the liver parenchyma (Fig. 20.36).[411,412] The degree of differentiation varies a great deal from case to case and from region to region in the same case, with the better differentiated examples simulating peliosis hepatis or other benign conditions,[411] and the poorly differentiated types being difficult to distinguish from primary or metastatic epithelial neoplasms. Some of the tumors have an epithelioid appearance; they are distinguished from epithelioid hemangioendotheliomas on the basis of their greater degree of atypia, mitotic activity, and necrosis. Vascular markers (CD31, ERG) can be detected immunohistochemically in all but the most undifferentiated neoplasms. Of note, keratin expression can be seen, especially in epithelioid variants.[413]

Most cases occur in adults, but well-documented cases in infants also are on record.[414,415]

The prognosis is extremely poor. An increased risk for the development of angiosarcoma of the liver in adults has been documented in the following conditions:

1. *Cirrhosis:* Fibrosis or cirrhosis is present in approximately 30%–40% of the adult cases, although no causal relationship between chronic liver disease and angiosarcoma has been established.[416]
2. *Vinyl chloride exposure:* It has been shown that hepatic angiosarcoma occurs with undue frequency in workers at chemical plants that produce polyvinyl chloride (PVC), a component of most plastic

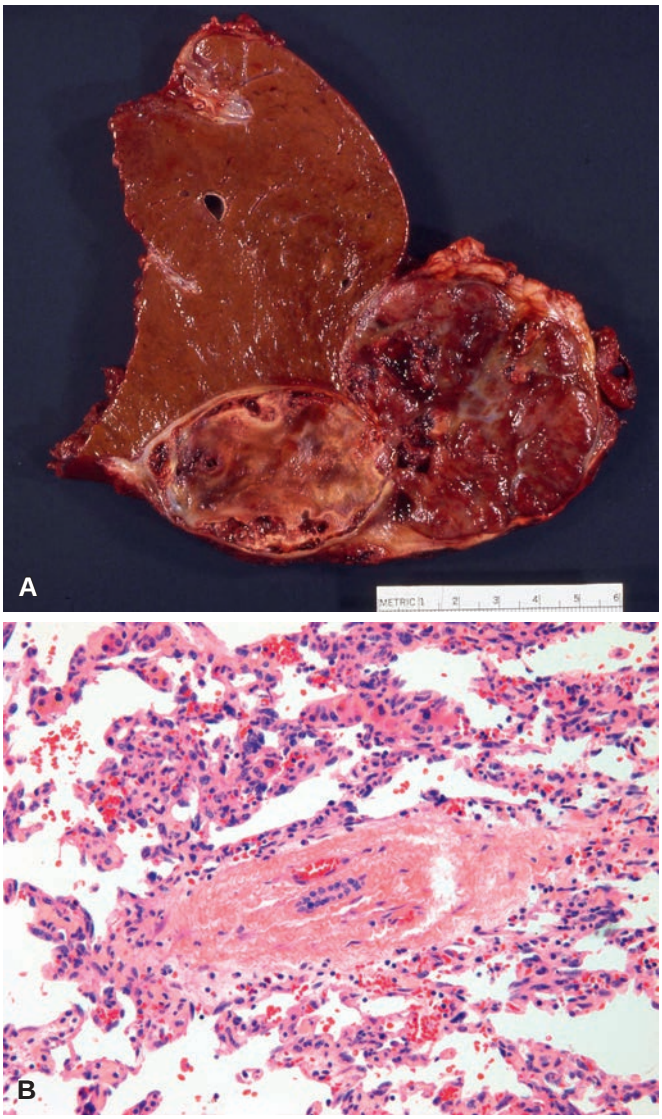

Figure 20.36 A, Hepatic angiosarcoma with areas of necrosis and hemorrhage. **B,** The sinusoids are dilated, and the liver parenchyma has essentially been replaced by malignant endothelial cells. A residual portal tract is in the center of the field.

products such as water pipes, wrapping materials, and building materials.[417] In the series of Makk et al.[418] the average time of exposure was 16.9 years. Grossly, most tumors are multicentric, hemorrhagic, and necrotic, with areas of cystic degeneration and fibrosis. The non-neoplastic liver often exhibits subcapsular and portal fibrosis, sinusoidal dilation, and endothelial hyperplasia.[419] The disease is invariably fatal; at autopsy, most of the cases are restricted to the liver or invade the local structures by direct extension. In contrast to the non-PVC-related hepatic angiosarcoma, distant metastases are rare.[418]

3. *Thorium dioxide exposure:* The administration of a suspension of thorium dioxide (Thorotrast) for radiographic purposes has been linked with the late development of hepatic angiosarcoma, the latent period ranging from 20 to 40 years.[420,421] As in the previous group, these tumors are often associated with sinusoidal dilation and endothelial hyperplasia in the non-neoplastic areas.[420] In some of these patients, the angiosarcoma may be combined with liver cell carcinoma and/or cholangiocarcinoma.[420]
4. *Arsenic exposure:* Some cases of hepatic angiosarcomas have followed prolonged therapeutic administration of arsenic in the form of Fowler solution.

Hemangioblastoma rarely occurs in the liver and has been reported in a patient with von Hippel–Lindau syndrome. Its appearance is identical to that of the homonymous cerebellar tumor.[422] *Kaposi's sarcoma* rarely develops in liver transplant patients, and is typically preceded by HHV-8 viremia.[423] *Lymphangioma* is usually seen in infants or children; in most reported cases, the liver involvement is part of a multicentric process affecting other organs, particularly spleen (lymphangiomatosis).[424–426]

Other Mesenchymal Tumors

Mesenchymal hamartoma is a rare benign lesion with a predilection for infants, in whom it appears as a solitary, spherical, reddish nodule, typically in the right lobe (Fig. 20.37).[427] Most patients present during the first 2 years of life with abdominal swelling and a palpable abdominal mass.[428] It has also been reported in adults,[429,430] in whom it may be associated with abdominal pain.[431] Some are solid, and others have a prominent cystic component[432] (see Fig. 20.37A–B); sometimes the lesion grows to a huge size. Microscopically, the main component is well-vascularized mature connective tissue intermixed with elongated branching bile ducts, hepatocytes, and cystic spaces. Some have likened the low-power appearance to fibroadenoma of the breast (see Fig. 20.37C).[433] Some have postulated that this lesion arises from the connective tissue of the portal tracts,[434] but others believe its origin is from hepatic stellate cells.[435] Its vascular pattern is similar to that seen in torsion of an accessory lobe of liver, which has suggested to some authors a related ischemic pathogenesis.[436] However, the detection of specific translocations involving chromosome 19q13.4[437,438] and the occasional occurrence of aneuploid lesions[439] speak in favor of a neoplastic nature. Exceptionally, it may undergo malignant transformation into an undifferentiated (embryonal) sarcoma (see next section).

Angiomyolipoma of liver is similar to its more common renal counterpart, being composed of tortuous blood vessels, smooth muscle, and fat.[440] As in other sites, it is believed that this tumor is a member of perivascular epithelioid cell tumor (PEComa) spectrum.[440–442] Histologically, these tumors consist of a mixture of smooth muscle cells, fat, and vessels (Fig. 20.38); the smooth muscle cells can be spindled or epithelioid, which may lead to diagnostic confusion with other tumors. Immunoreactivity for actin, desmin, S-100 protein (in the adipose component), and—most importantly—HMB-45, is the rule.[443–445] In contrast to the renal tumors, the reported hepatic angiomyolipomas have not been associated with tuberous sclerosis. A variant of this tumor involves the ligamentum teres and has a prominent clear cell component, thus resembling clear cell ("sugar") tumor of the lung.[446,447] The behavior of hepatic angiomyolipoma is generally benign, despite its sometimes invasive growth into the surrounding hepatic parenchyma.[448] However, exceptional instances of clinical malignancy are on record.[449,450]

Inflammatory myofibroblastic tumor was originally described as inflammatory pseudotumor but is now thought to be in most instances neoplastic in nature, although this is still debated.[451] It presents in both adults and children with fever and upper abdominal pain. Grossly, the lesions have a variegated appearance, accompanied by areas of necrosis and hemorrhage. Microscopically, they are composed of an inflammatory mononuclear component rich in mature plasma cells and abundant plump spindle cells (Fig. 20.39).[452,453] The latter have generally been identified as myofibroblasts, but the possibility of them being members of the accessory immune system (i.e. reticulum/dendritic cells) has been raised (see section below on follicular dendritic cell tumors of the liver).[454] Nuclear atypia

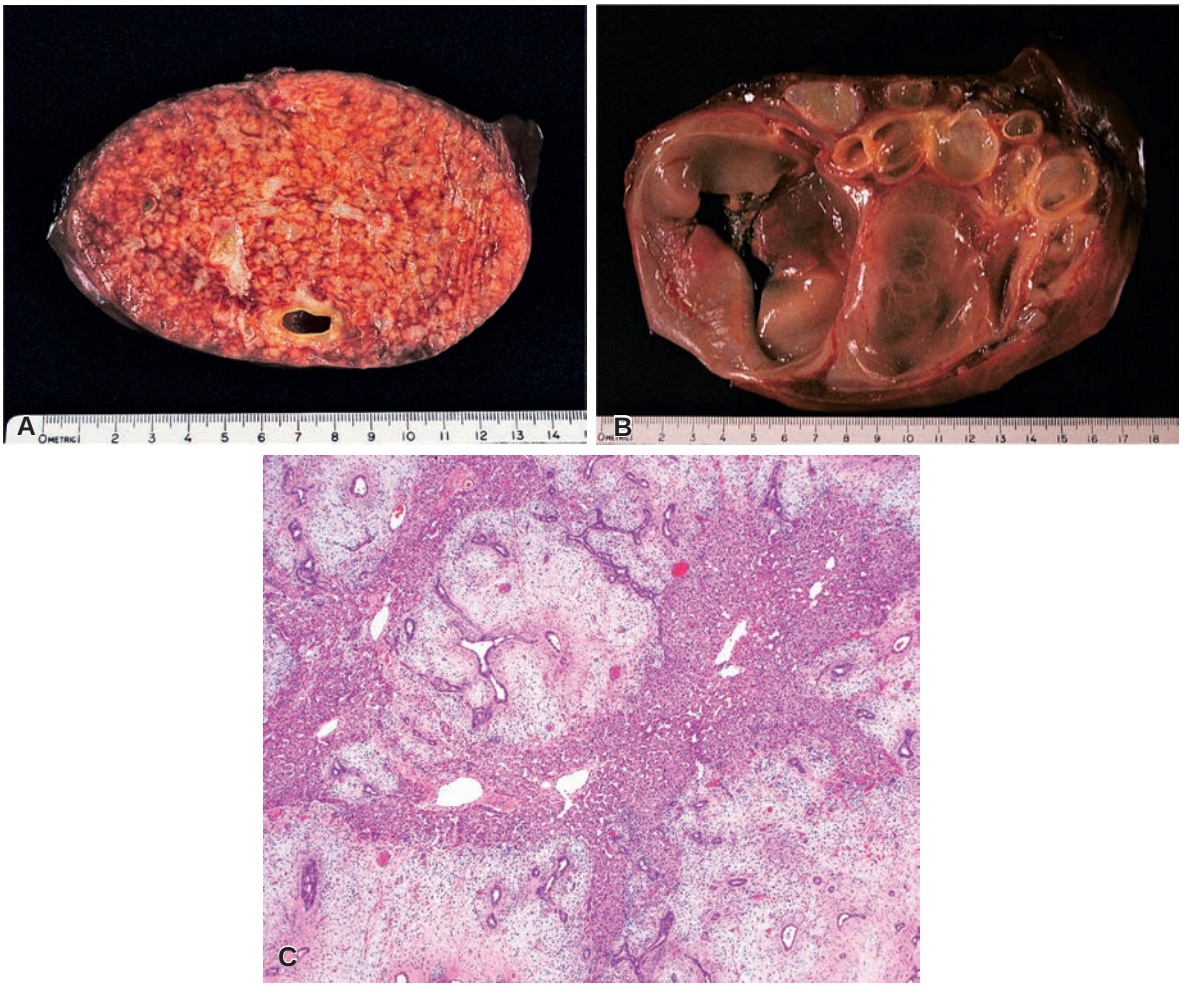

Figure 20.37 Mesenchymal hamartoma of liver, which grossly may have a solid micronodular **(A)** or multicystic appearance **(B)**. **C,** The microscopic appearance consists of abundant mesenchymal tissue with admixed blood vessels, bile ducts, and hepatocytes. (**C,** Courtesy of Dr. Grace Kim.)

may be prominent in some cases. As with inflammatory myofibroblastic tumors of other sites, ALK-1 immunohistochemistry can be helpful in the diagnosis.[455] It is probable that several different conditions are currently included under the terms inflammatory myofibroblastic tumor and inflammatory pseudotumor. Some may be reactive, particularly those associated with occlusive phlebitis and chronic cholangitis,[453,456] as well as those exhibiting spontaneous regression.[457] Others, probably the majority, are or become a true neoplastic process. For these, surgical removal is the treatment of choice.

Leiomyoma can rarely present as a solitary hepatic nodule, the main differential diagnosis being a metastasis from a well-differentiated leiomyosarcoma from the uterus or the gastrointestinal tract, or a metastatic gastrointestinal stromal tumor.[458,459] Some hepatic smooth muscle neoplasms have occurred in HIV-infected patients or following organ transplantation, and have been found to contain EBV by in situ hybridization.[460–462] These tumors can be multicentric,[463] and microscopically they often contain an abundance of intratumoral T lymphocytes.[463]

Myelolipoma is rarely encountered in the liver. It has an appearance similar to that of its more common adrenal counterpart, being composed of an admixture of fat and bone marrow–derived hematopoietic cells.[464,465] Hepatic *lipoma* presents as a single round intraparenchymal mass[466]; it should be distinguished from so-called *hepatic pseudolipoma*, which is a round nodule of fat attached to the Glisson capsule, probably representing entrapped, detached appendix epiploica.[467] *Solitary fibrous tumor* (previously known as localized fibrous mesothelioma or hemangiopericytoma) may arise from beneath the liver capsule or the parenchyma[468] (Fig. 20.40); as in other sites, this tumor is immunoreactive for vimentin, CD34, and BCL2.[469] *Schwannoma* and *malignant peripheral nerve sheath tumor* have been rarely reported in the liver, some of them developing in patients with von Recklinghausen disease.[470–472]

Sarcomas primary in the liver are exceptional. Their differential diagnosis includes metastases from sarcomas of other sites, and sarcomatoid liver cell carcinomas. Types of reported primary sarcoma of liver in adults are numerous, and include *fibrosarcoma*,[473,474] liposarcoma,[475] *leiomyosarcoma*[476–478] (some of them occurring in HIV-infected patients, see also earlier discussion),[479] *rhabdomyosarcoma*[480] (one of them associated with long-term oral contraceptive use),[481] so-called *malignant fibrous histiocytoma* (pleomorphic undifferentiated sarcoma),[482] *osteosarcoma*,[483,484] and *osteoclast-like giant cell tumor*.[485,486] In infants and children, there have been isolated reports of *embryonal rhabdomyosarcoma* and *rhabdoid tumor*.[487–490] As in other sites (except perhaps the kidney), rhabdoid tumor of the liver is probably not a distinct entity but rather a

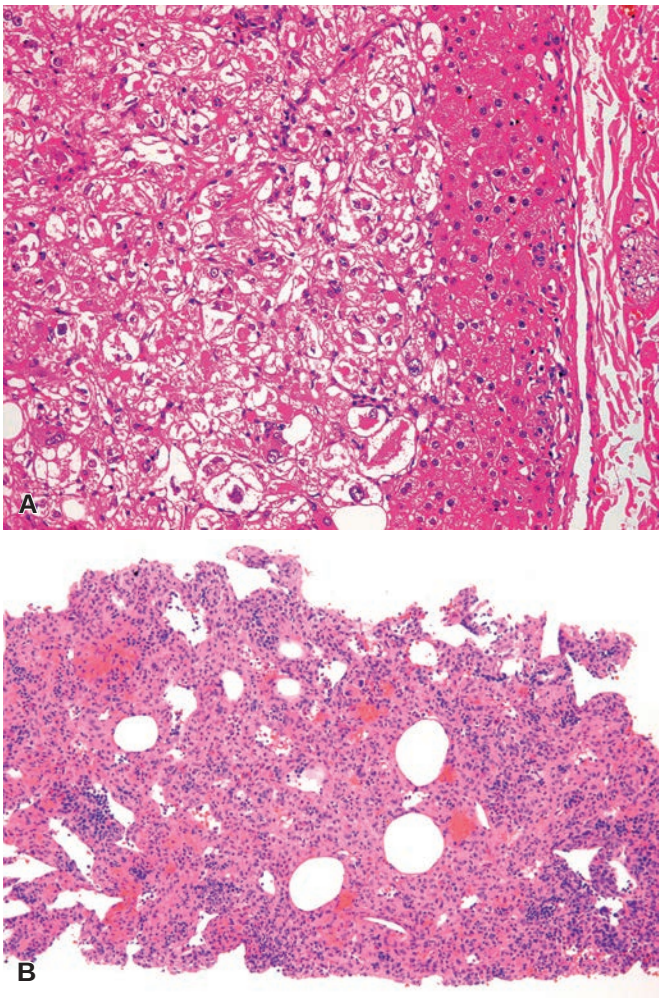

Figure 20.38 **A,** The solid pattern of growth and the epithelioid appearance of the tumor cells in angiomyolipoma, along with ballooned cytoplasm, may lead to a mistaken diagnosis of a hepatocellular neoplasm. **B,** Needle biopsy of another case with epithelioid smooth muscle cells, fat, and thin-walled vessels. Extramedullary hematopoiesis is also present.

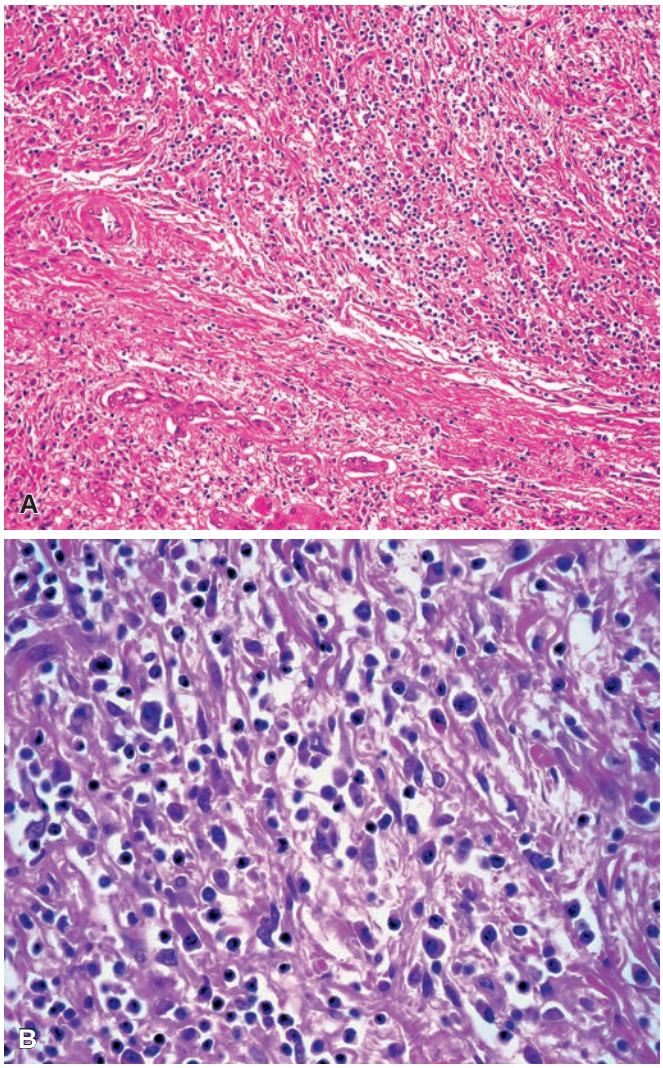

Figure 20.39 **A,** Inflammatory myofibroblastic tumor showing a well-circumscribed nodule with admixed plasma cells, histiocytes, and spindled fibroblasts. **B,** High-power view showing spindle cells admixed with lymphocytes, plasma cells, histiocytes, myofibroblasts.

morphologic and phenotypic pattern that can accompany a variety of cell types.

Undifferentiated (embryonal) sarcoma, also known as malignant mesenchymoma, occurs predominantly in children but has also been seen in adults.[491,492] Several cases are on record arising in conjunction with a mesenchymal hamartoma (see previous discussion).[493–495]

Grossly, these tumors are usually large, solitary, and well circumscribed, with multiple areas of necrosis, hemorrhage, and cystic degeneration (Fig. 20.41A). Microscopically, they are composed of a mixture of anaplastic spindle and giant cells, most of them having a sarcoma-like appearance (see Fig. 20.41B). The larger cells often contain numerous intracytoplasmic hyaline globules that are strongly periodic acid–Schiff (PAS) positive (see Fig. 21.41C). Scattered hyperplastic or degenerating bile duct-like structures surrounded by tumor cells are seen in most cases; since they show no clear-cut neoplastic features and are more numerous at the periphery of the tumor, they have been generally interpreted as entrapped elements.

Figure 20.40 Large solitary fibrous tumor of the liver. Microscopically, the tumor had malignant features.

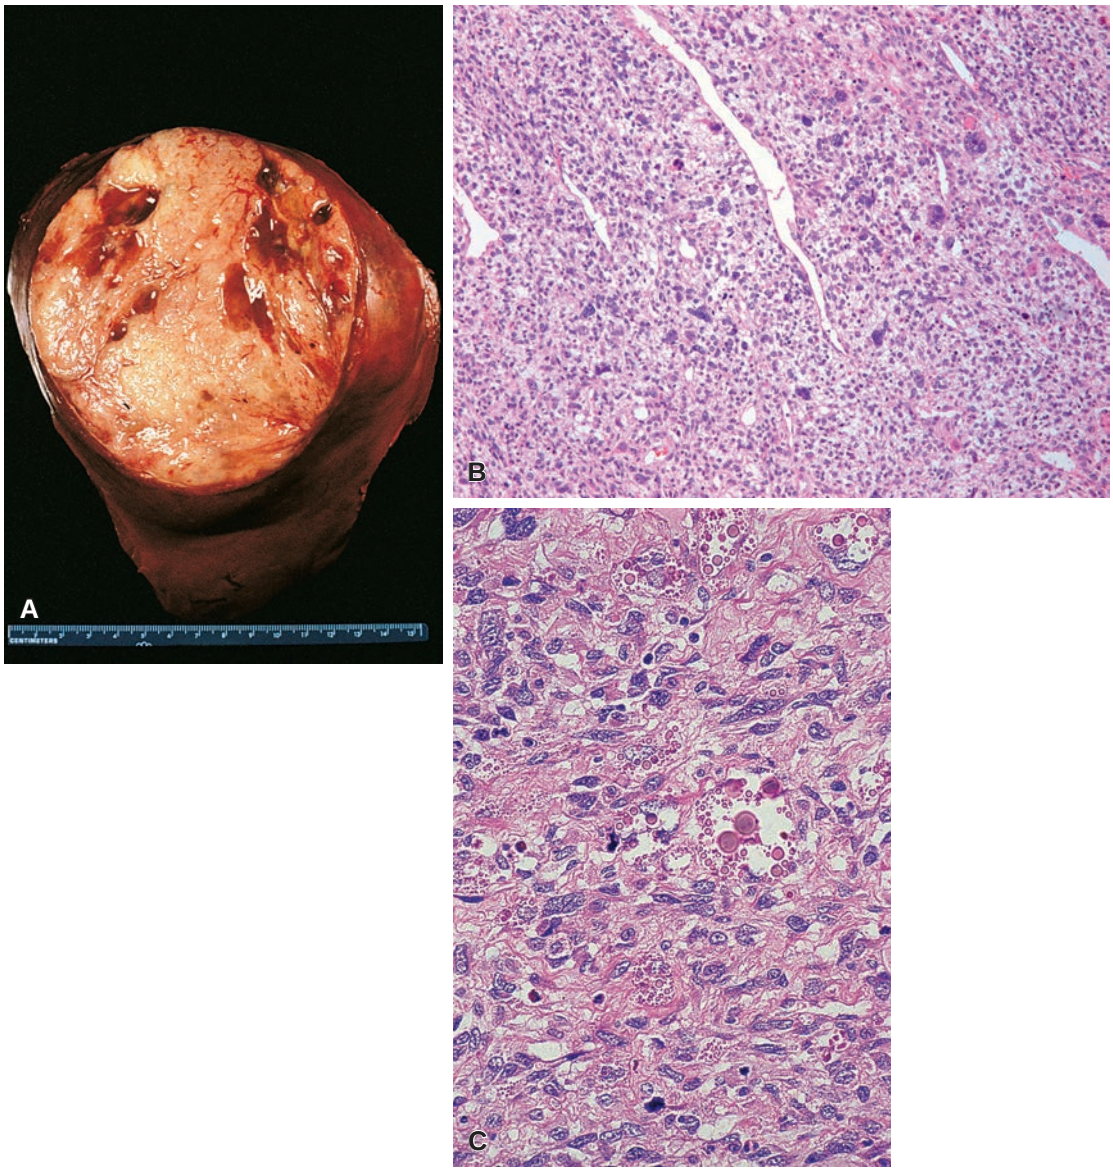

Figure 20.41 **A,** Grossly embryonal sarcoma is well circumscribed, largely solid, and has areas of cystic degeneration. **B,** Low power view shows undifferentiated spindle cells and giant cells, with prominent thin-walled vessels. **C,** Large eosinophilic hyaline globules are present within and between the tumor cells.

Ultrastructurally and immunohistochemically, most of the cells have features of undifferentiated mesenchymal cells, fibroblasts, and myofibroblasts, but others may show differentiation toward smooth and skeletal muscle elements on the one hand and toward epithelial cells on the other.[496] Thus, immunoreactivity has been described with α1-antitrypsin, α1-antichymotrypsin, lysozyme, CD10, glypican-3 (a feature it shares with mesenchymal hamartoma),[156] smooth muscle actin, desmin, and keratin.[496,497,498] This peculiar combination of phenotypic features has led some authors to postulate a histogenetic relationship with primary hepatic embryonal rhabdomyosarcoma and others to suggest that the tumor represents an anaplastic (sarcomatoid) variant of liver cell carcinoma.[499] Both of these seem unlikely prospects, particularly in view of the lack of immunoreactivity of these tumors for myogenin and Hep Par-1.[497,500]

Treatment consists of multiagent chemotherapy along with resection or, in some cases, liver transplantation. Historically the prognosis has been generally poor, with overall survival between 20% and 55%. However, more recent studies have shown overall survival of over 80%.[491]

Malignant Lymphoma and Related Lesions

Malignant lymphoma confined to the liver is a very rare occurrence, although secondary involvement in advanced stages of extrahepatic lymphoma is common.[501–503] In terms of relative frequency, the most common types of lymphoma involving the liver *are diffuse large B-cell lymphoma, Hodgkin lymphoma, peripheral T-cell lymphoma, follicular center cell lymphoma, mucosa-associated lymphoid tissue (MALT)-type marginal zone B-cell lymphoma,* and *anaplastic large cell lymphoma.*[504–509] Patterns of involvement include tumor nodules, infiltration of portal tracts, lymphoepithelial lesions of bile ducts, and infiltration of

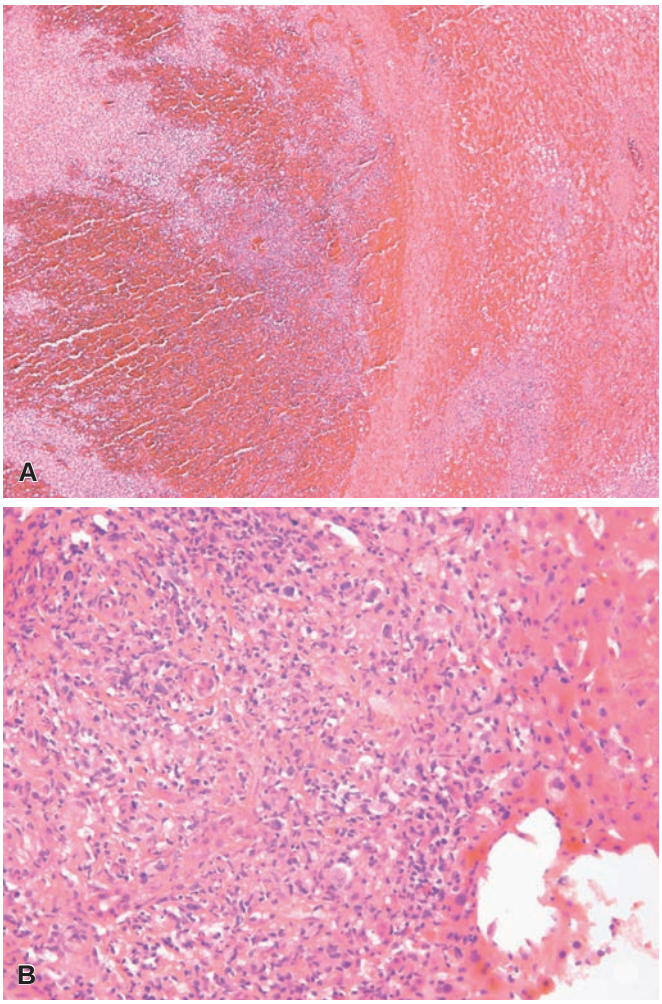

Figure 20.42 **A,** An anaplastic large cell lymphoma forms a large abscess-like mass that effaces the normal liver architecture. Portal involvement by Hodgkin disease. **B,** Note the mixed cellularity of the infiltrate, which has a vaguely granulomatous look and scattered large tumor cells.

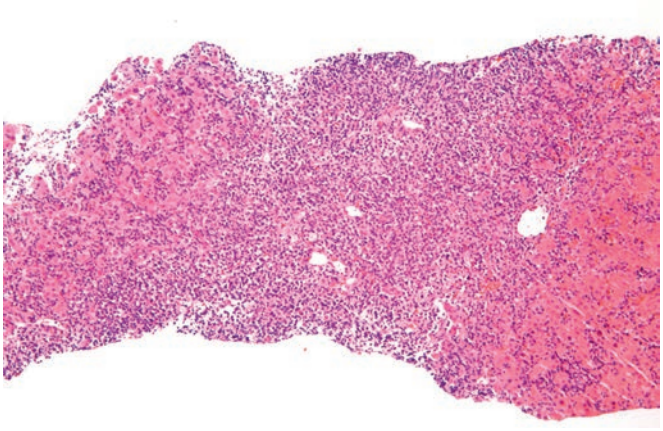

Figure 20.43 Both portal and sinusoidal involvement are seen in this case of chronic lymphocytic leukemia.

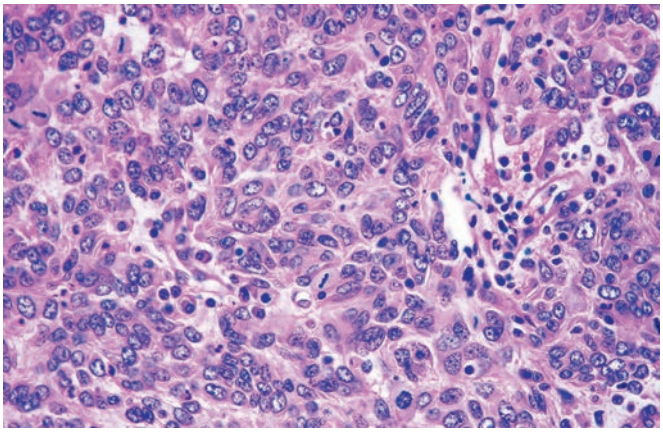

Figure 20.44 Follicular dendritic cell tumor of the liver featuring spindled and epithelioid cells with ovoid nuclei and a sprinkling of lymphocytes.

sinusoids (Fig. 20.42).[504,505,510] Some of the primary hepatic lymphomas have occurred in association with HCV infection.[511,512] Most cases occur in adults, but primary hepatic lymphomas may also affect children.[513–515]

Hepatosplenic (gamma-delta) T-cell lymphoma is a distinct entity characterized by occurrence in young adult males with hepatomegaly, B symptoms, peripheral blood cytopenias, absence of peripheral lymphadenopathy, presence of lymphoid infiltrates in the splenic red pulp, hepatic sinusoids and bone marrow sinuses, and an aggressive clinical course.[515,516] The *alpha-beta* variant of this tumor shows a female preponderance, and the liver infiltrates tend to be periportal. An isochromosome 7q or trisomy 8 are often present; the majority of tumors express gamma-delta T-cell receptors by molecular studies, and a minority express alpha-beta T-cell receptors or neither receptor.[517] Cases have been reported in immunocompromised patients.[518,519] Prognosis is poor overall. This disease is further discussed in Chapter 37.

Leukemic involvement of the liver can occur in both acute and chronic leukemia and may involve the periportal or sinusoidal regions.[504,520] In chronic lymphocytic leukemia, the infiltrate is predominantly periportal, and in chronic myelocytic leukemia predominantly sinusoidal, but many exceptions to this rule exist (Fig. 20.43). Specifically, myelocytic leukemia can present as a mass-like lesion (so-called myeloid or myelocytic sarcoma).[521]

Follicular dendritic cell tumor of the liver is extremely rare and shares several morphologic features with inflammatory myofibroblastic tumor (inflammatory pseudotumor) and may be pathogenetically related to it (Fig. 20.44). It is characterized by the presence of a neoplastic component of cells bearing the markers of dendritic follicular cells, such as CD21 and CD35.[522] In contrast to follicular dendritic cell tumors at other sites, there is evidence of EBV clonal proliferation in many of these tumors in the liver.[523–525] However, this is not always the case.[526]

Reactive lymphoid hyperplasia and *nodular lymphoid lesion* refer to benign reactive lymphoid processes that can mimic follicle center cell lymphoma and MALT lymphoma, respectively.[527,528] Some of these lesions have been referred to as *hepatic pseudolymphomas.*[529]

Post-transplant lymphoproliferative disease, which is typically of B-cell type and associated with EBV, may also involve the liver. It usually presents between 6 and 17 months after transplantation as a systemic illness.[530] *Multiple myeloma* can present as a space-occupying mass in the liver (plasmacytoma) or with sinusoidal involvement (Fig. 20.45).[531–532] *Langerhans cell histiocytosis* can involve the liver as an isolated event or as an expression of multisystem disease.[533]

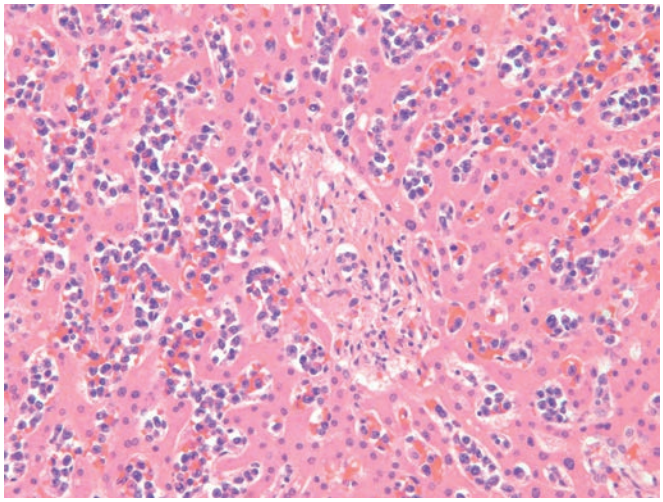

Figure 20.45 Diffuse sinusoidal involvement by neoplastic plasma cells in a case of liver involvement by myeloma.

Other Primary Tumors and Tumorlike Conditions

Squamous cell carcinoma of the liver has been reported as arising from congenital cysts, as a component of teratoma, and in association with intrahepatic lithiasis (hepatolithiasis).[534,535] Most of the latter cases probably represent the squamous component of the adenosquamous variant of cholangiocarcinoma.

Well-differentiated neuroendocrine tumor (carcinoid tumor) in the liver, whether solitary or multiple, is in the overwhelming majority of cases the result of metastatic involvement from a primary tumor, usually located in the gastrointestinal tract. However, on rare occasions, a typical carcinoid tumor has been seen in the liver in the absence of a neoplasm in any other site after prolonged clinical search or at autopsy.[536,537] That being said, primary neuroendocrine tumors (NETs) of the small bowel can be extremely small, and it is difficult to dismiss entirely the possibility of their having been missed during surgery or pathologic dissection. Yet, under these circumstances, it is appropriate to regard the NET as probably originating within the liver. Actually, this occurrence should not be unexpected, in view of the presence of neuroendocrine cells in the normal bile tract and the well-documented occurrence of NETs in the gallbladder and extrahepatic biliary system. As a matter of fact, one of the reported cases of NET of the liver was located within an intrahepatic bile duct.[538] Some of the tumors have been immunoreactive for gastrin and have been accompanied by the Zollinger–Ellison syndrome.[539,540] Others have resulted in symptoms resulting from VIP hyperproduction.[541] Primary hepatic neuroendocrine carcinomas have also been rarely described.[542,543] The occasional occurrence of neuroendocrine differentiation in liver cell carcinoma was discussed previously.

Desmoplastic nested spindle cell tumor (calcifying nested stromal–epithelial tumor) is a recently described primary liver tumor occurring in children and adolescents.[544–546] Grossly, they appear as well-circumscribed lobular white masses measuring up to 30 cm in diameter. Microscopically, they are characterized by the formation of nests and fascicles of bland-looking spindle and epithelioid cells, surrounded by an abundant desmoplastic stroma. Calcification (with psammoma body formation) and ossification are common. Immunohistochemically, the tumor cells react for pankeratin, vimentin, CD57, and WT1, but not neuroendocrine markers (other than NSE). Two of the reported cases were associated with ectopic ACTH production and Cushing syndrome. Most patients do well following tumor excision, but occasional patients can develop recurrence.

Benign and malignant teratomas of the liver are exceptionally rare neoplasms seen predominantly in children but also described in adults.[547] The malignant ones should be distinguished from the mixed type of hepatoblastoma, which is a much more common occurrence (see earlier).[548] Cases of apparently primary *yolk sac tumor* of the liver have been reported as well,[549–551] sometimes combined with hepatoblastoma[552] or with HCC.[553] Primary pure *choriocarcinomas* and *malignant mixed germ cell tumors* have also been described.[554–557]

Other tumors exceptionally involving the liver are *paraganglioma*,[558] pancreatic-type *acinar cell carcinoma*,[559] *glomus tumor*,[560] *benign multicystic mesothelioma*,[561,562] and solid-pseudopapillary (papillary-cystic) tumor of pancreatic type.[563] *Epithelial–myoepithelial carcinoma*, exceptionally reported in the liver, may also be related to the bile duct system.[564]

Tumorlike masses in the liver may result from abscesses, congenital hepatic fibrosis,[565] *ciliated foregut cyst*,[566] and *malakoplakia*.[567]

Metastatic Tumors

Primary malignant tumors of the gallbladder, extrahepatic bile ducts, pancreas, and stomach frequently involve the liver by direct extension. Those from the gallbladder tend to follow the portal tracts.[568] Carcinomas of the large bowel, lung, breast, pancreas, kidney, stomach, and other organs metastasize to the liver with appalling regularity. Sarcomas of soft tissues or internal organs and malignant melanomas also frequently metastasize to this organ. Within the highly receptive liver parenchyma, these metastases often grow to huge dimensions (Fig. 20.46A–D).

In a series of 8455 autopsies of adult patients with malignant tumors, 39% had liver metastases.[569] Only 6% of these were solitary. In 81 patients (2.5%), the metastases were confined to this organ; this phenomenon was seven times more frequent for tumors drained by the portal venous system than for the others.

Grossly, most metastatic tumors in the liver form discrete masses that may locally elevate the capsule. Central necrosis with umbilication occurs in the larger lesions. The absence of visible nodules on the external surface of the liver does not rule out the possibility of metastatic involvement. Sometimes large metastases are completely hidden within the parenchyma.[570] In some instances (particularly with colorectal carcinomas), the metastatic nodules are surrounded by a fibrous pseudocapsule.[571]

A certain correlation exists between the site of the primary tumor and the gross appearance of the liver metastases. Metastases from carcinoma of the large bowel often result in a few large nodules with marked central umbilication; when mucin production is abundant, they tend to undergo marked calcification that may be apparent radiographically. Well-differentiated squamous cell carcinomas result in very soft nodules because of necrosis and keratinization. The nodules from lung or breast carcinoma are usually medium sized, without extensive necrosis or hemorrhage and with early central umbilication. The metastases from gallbladder carcinoma cluster around the gallbladder bed and progressively diminish in size as they move farther into the hepatic parenchyma. Occasionally, extremely small, almost miliary metastatic lesions are seen spreading throughout the liver and even simulating cirrhosis[572]; they are usually the result of tumors from the breast, prostate, or stomach.[573]

It is often said that liver metastases from carcinomas of the right colon tend to be located in the right lobe and those from the left

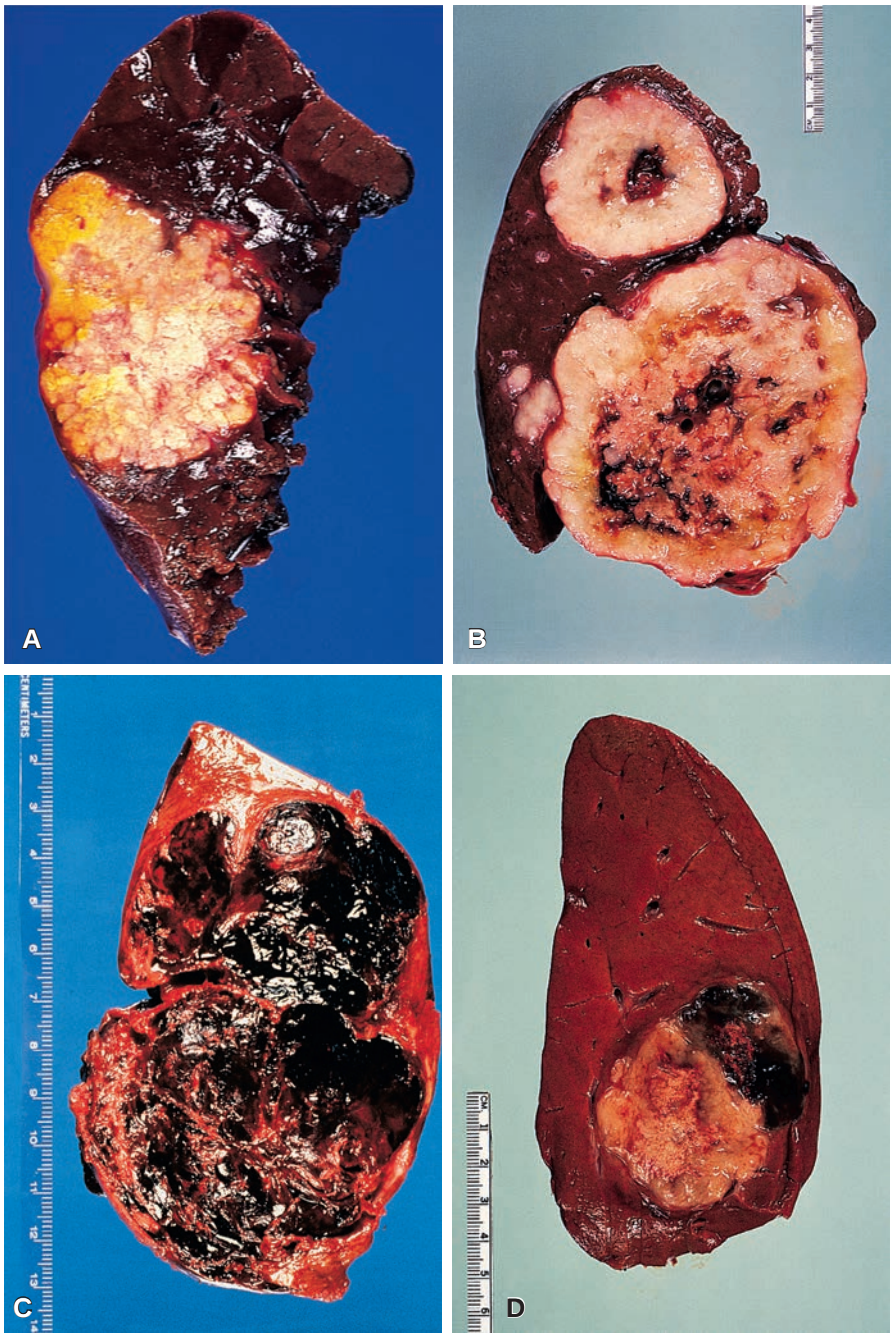

Figure 20.46 **A,** Large bowel carcinoma metastatic to liver. **B,** Leiomyosarcoma metastatic to liver. The primary tumor was located in the stomach. **C,** Choriocarcinoma metastatic to liver. The tumor has the highly hemorrhagic appearance that is characteristic of this entity. **D,** Malignant melanoma metastatic to liver. A portion of the tumor shows black melanin pigmentation.

colon and rectum in the left lobe,[574] but in some series the difference has not reached statistical significance.[575,576] Metastatic breast carcinoma treated with chemotherapy can result in the coarsely lobulated liver appearance known as *hepar lobatum*, traditionally associated with syphilis.[577]

A review of over 10,000 autopsies from Trieste, Italy, and Tokyo-Chiba, Japan, confirmed the often quoted anecdotal observation that metastases are very rare in cirrhotic livers; whatever the reason for this may be (nonreceptive soil for the metastatic growth or simply the fact that most cirrhotic patients do not live long enough to develop them), the conclusion can be drawn that the large majority of malignant tumors occurring in cirrhotic livers are primary.[578]

Many benign lesions may have a gross appearance similar to that of metastatic carcinoma. This is true of fibrous scars, healed granulomas, bile duct hamartoma and adenoma, and nodular hyperplasia. Therefore *it is imperative that a microscopic confirmation be obtained in every patient in whom lesions suggestive of liver metastases are detected*

during surgery, regardless of how typical they might seem grossly to the surgeon or the pathologist. As discussed previously, the microscopic differential diagnosis with primary liver tumors can be difficult. A particularly treacherous but fortunately very rare situation is that of the hepatoid carcinoma of stomach or other sites that metastasizes to the liver.[579]

Resection of hepatic metastases is particularly worthwhile in patients with metastatic carcinoid tumor because of the dramatic amelioration of the symptoms of the carcinoid syndrome that is often achieved.[580] It is also done frequently for metastases of colorectal carcinoma, as surgical resection offers the only long-term cure; recent studies indicate 5-year survival rates of up to 58%.[581,582]

Normal Anatomy

The gallbladder is a pear-shaped sac that lies in a shallow depression on the inferior surface of the right hepatic lobe. In the adult, it measures up to 10 cm in length and 3–4 cm in width, and the normal wall thickness is 1–2 mm.[1] The free surface is covered by serosa that is continuous with that on the hepatic surface, and the subserosal connective tissue of the gallbladder merges into the hepatic interlobular connective tissue at the hepatic surface. The gallbladder is divided into the *fundus*, *body*, and *neck* (Fig. 21.1). The portion of the body that joins the neck is referred to as the *infundibulum*; sometimes there is a small bulge in this portion, known as *Hartmann pouch*.

The blood supply of the gallbladder is via the cystic artery, which is usually a branch of the right hepatic artery (see later). Lymph drains to the node(s) at the gallbladder neck or cystic duct, from which it flows to nodes near the hepatic hilum and in the inferior portion of the hepatoduodenal ligament, the latter reaching nodes on the celiac axis.

The wall of the gallbladder is composed of three layers: mucosa, muscularis propria, and serosa (the latter only on the free surface) (Fig. 21.2). There is no muscularis mucosae or submucosa, and thus the lamina propria abuts directly onto the muscularis propria.[1,2] The mucosa is made up of variably sized branching folds consisting of a core of lamina propria lined by a single layer of columnar epithelium. The epithelial cells have eosinophilic cytoplasm with occasional small apical vacuoles, and basally located nuclei.[1,2] Smaller, darkly staining columnar cells known as *penciloid cells* are interspersed within the epithelium (Fig. 21.3), along with basal cells that are often inconspicuous. Scattered lymphocytes, plasma cells, mast cells, and histiocytes are normal and should not be interpreted as evidence of chronic cholecystitis. The muscular wall consists of loosely arranged bundles of longitudinal, circular, and oblique muscle fibers, but the gallbladder lacks the well-formed layers seen in the tubular gut.[1] Ganglion cells may be found anywhere in the wall of the gallbladder. Minute paraganglia are present in the subserosal region and are occasionally detected in random sections of the organ.[3]

In the gallbladder, true mucous glands are present only in the neck. They consist of cuboidal or low columnar epithelium with clear to lightly basophilic cytoplasm,[1] and scattered neuroendocrine cells may be found within them. The ducts of Luschka (Fig. 21.4) are small accessory bile ducts located in the perimuscular connective tissue, typically on the hepatic surface of the gallbladder. The epithelium is very similar to biliary epithelium, and there is a distinctive ring of surrounding connective tissue. These ducts may be mistaken for carcinoma on frozen section,[4] particularly when inflamed, and the lobular architecture may be a helpful distinguishing feature for these normal accessory ducts. Occasionally, accessory bile ducts are located in the gallbladder bed itself and may leak after cholecystectomy.[5]

The neck of the gallbladder connects with the cystic duct, joining the gallbladder to the biliary tree; the lining of the cystic duct is pleated, with large oblique folds containing smooth muscle

Abstract

This chapter covers the pathologic features of the major neoplastic and non-neoplastic entities that the surgical pathologist will encounter in the gallbladder and extrahepatic bile ducts, including congenital anomalies, inflammatory processes, and tumors and tumor-like conditions.

Keywords

gallbladder,
extrahepatic bile ducts,
cholangiocarcinoma,
choledochal cyst,
biliary atresia,
biliary intraepithelial neoplasia,
tumoral intraepithelial neoplasms,
intracholecystic papillary-tubular neoplasms

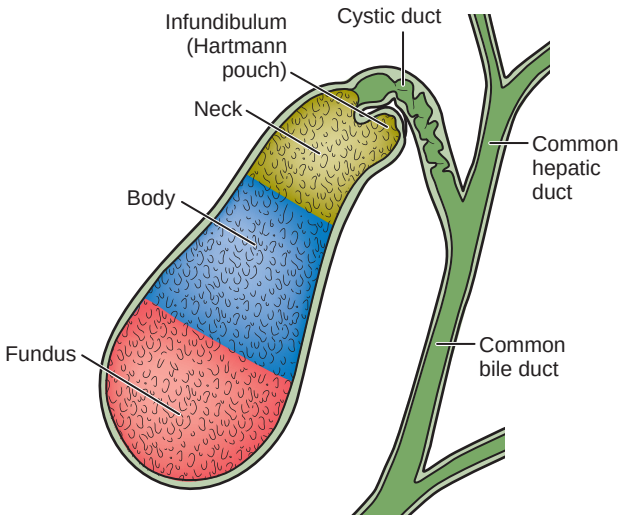

Figure 21.1 The gallbladder is divided into the fundus, body, and neck; the portion of the body adjoining the neck is referred to as the infundibulum. A small bulge in this portion is known as Hartmann pouch, notable because gallstones may become lodged here.

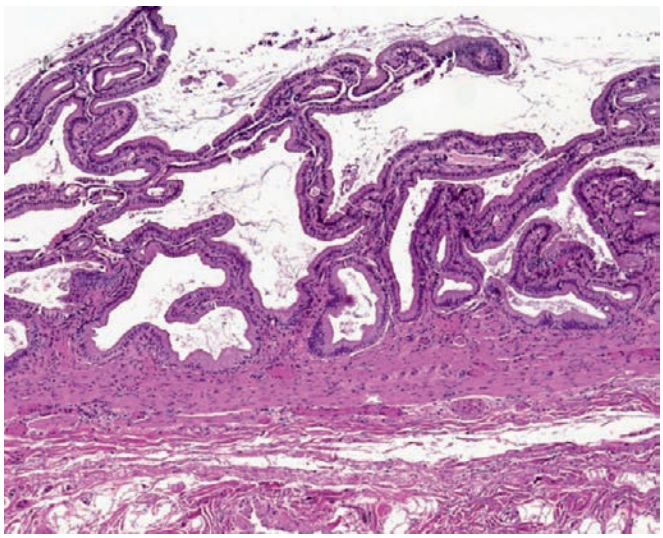

Figure 21.2 The gallbladder wall contains three layers: mucosa, muscularis propria, and serosa on the free surface. There is no muscularis mucosae or submucosa, thus the lamina propria abuts directly onto the muscularis propria. The mucosa is composed of variably sized branching folds consisting of a core of lamina propria lined by a single layer of columnar epithelium.

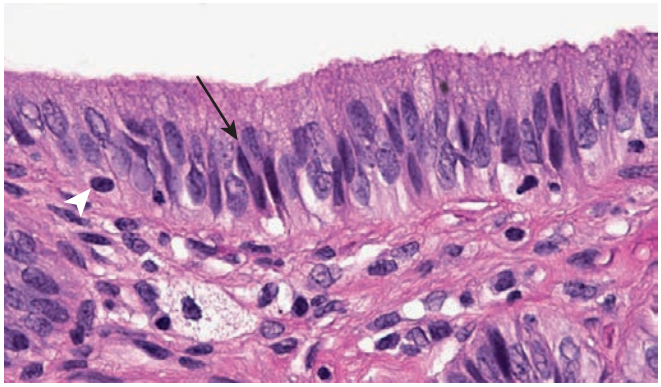

Figure 21.3 Gallbladder epithelial cells have eosinophilic cytoplasm with basally located nuclei. Smaller, darkly staining columnar cells known as *penciloid cells* are interspersed within the epithelium *(arrow)*, as well as basal cells that are often inconspicuous *(arrowhead)*.

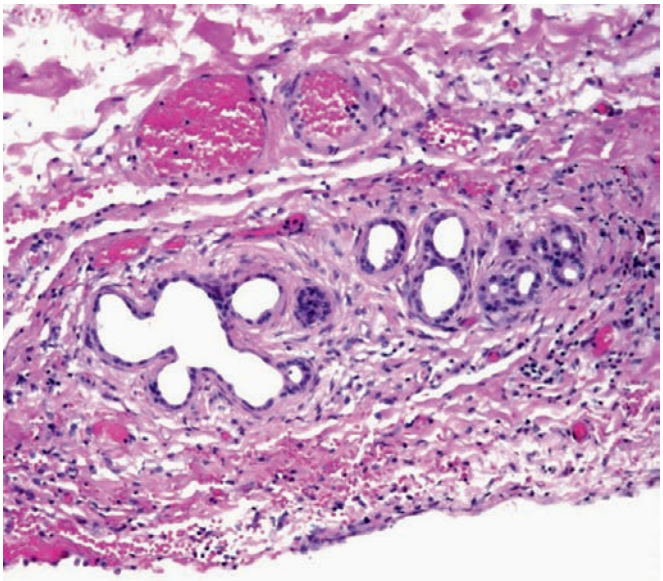

Figure 21.4 The ducts of Luschka are normal small accessory bile ducts typically located in the perimuscular connective tissue on the hepatic surface of the gallbladder. There is a distinctive ring of surrounding connective tissue, which helps distinguish them from carcinoma, particularly on frozen section evaluation.

(spiral valves of Heister), in order to prevent collapse. The other components of the extrahepatic biliary system are the *hepatic* (*right*, *left*, and *common*) *ducts* and *common bile duct*. Numerous variations in the anatomy of these ducts and their blood supply occur (Fig. 21.5).[6] The lymph drainage from the common bile duct is to nodes located along the duct, near the porta hepatis, around the pancreas, and ultimately into the celiac axis group.

Microscopically, the epithelium of all of the extrahepatic bile ducts is made up of a single layer of columnar cells resting on dense connective tissue (Fig. 21.6). Different patterns of smooth muscle distribution are seen in different portions of the extrahepatic biliary system, which may influence the estimation of depth of invasion of tumors. The upper portion of the common bile duct contains thin strands of muscle, whereas the lower third is invested by thick smooth muscle. Muscle is also present at the junction of the gallbladder and the cystic duct. The muscle coat is inconspicuous or absent in the upper third of the tract.[1,7] This epithelium penetrates into the stroma to form pits known as the *sacculi of Beale*, the larger of which can be seen grossly. Surrounding these saccules are small lobular mucous glands that are surrounded by dense stroma, known as peribiliary glands, biliary glands, or periductal glands; these may mimic well-differentiated carcinoma, and their lobular architecture seen on low-power microscopy is the most important identifying feature.[1,2]

Congenital Abnormalities

Gallbladder

Congenital abnormalities of the gallbladder are rare, and include *duplication*, *diverticula*, *absence (agenesis)*, *septation*, *phrygian cap*,

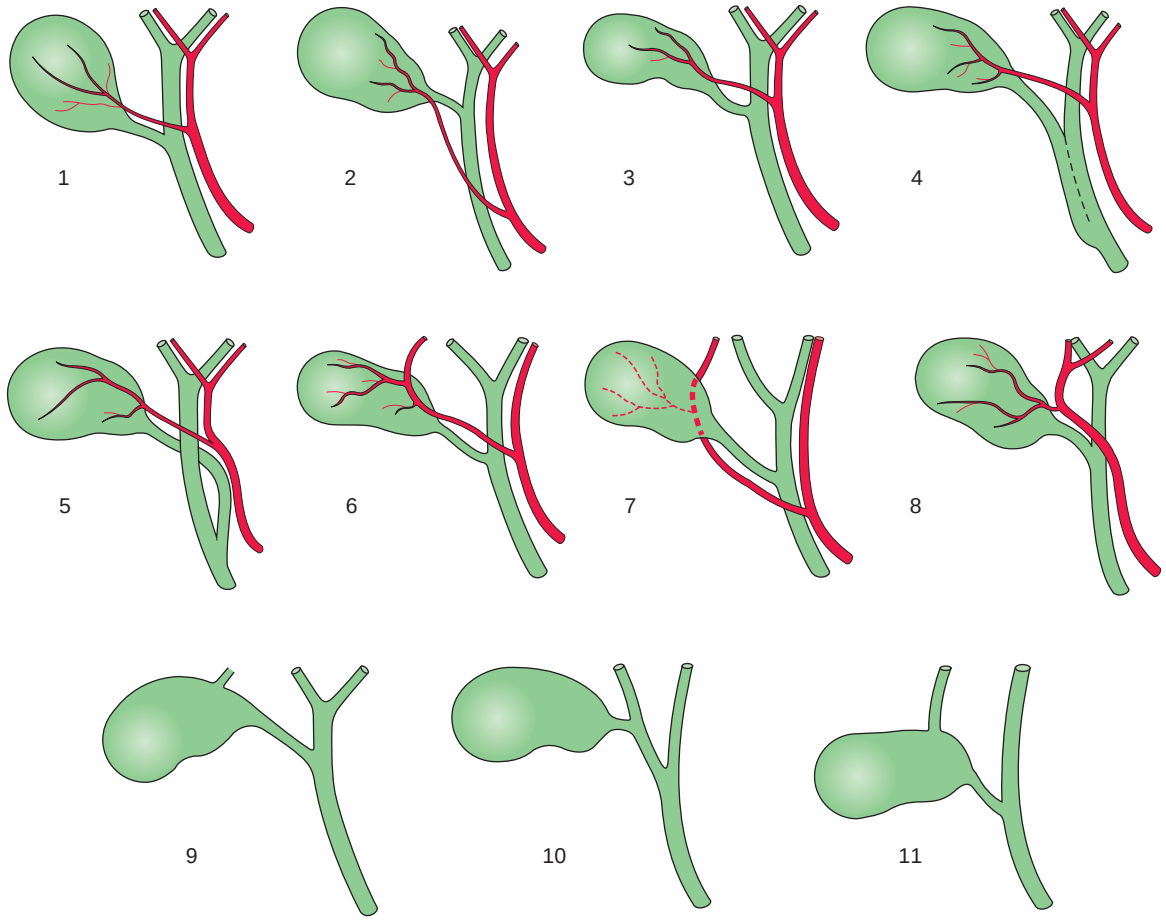

Figure 21.5 Normal and Anomalous Arrangements of Extrahepatic Bile Ducts and Their Adjoining Arteries. ***1,*** Normal arrangement. ***2,*** Caudad origin of cystic artery (frequent variation). ***3,*** Placement of cystic artery posterior to common hepatic duct. ***4,*** Long cystic duct attached to common hepatic duct for some distance before confluence to form common bile duct. ***5,*** Long cystic duct passing behind common hepatic duct and joining it medially at lower level. ***6,*** Normal ductal system with anomalous right hepatic artery reaching the gallbladder wall, where it gives off cystic artery and then turns into liver. In this anomaly, which is not rare, the right hepatic artery is often ligated either with the cystic duct or as a separate structure erroneously identified as the cystic artery. ***7,*** Anomalous right hepatic artery in posterior position presenting the same dangers mentioned in **6**. ***8,*** Very dangerous anomaly of entire hepatic artery that follows cystic duct to gallbladder before turning into liver. Accidental ligation of entire hepatic artery was almost always fatal before the advent of antibiotics, and it is still hazardous. ***9,*** Anomalous bile duct entering gallbladder through its bed in liver. Cholecystectomy in such instances is usually followed by profuse drainage of bile and is likely to result in fatal peritonitis unless external drainage is afforded. ***10,*** Anomalous insertion of cystic duct into right hepatic duct. The section of right hepatic duct caudad to its junction with cystic duct can easily be mistaken for cystic duct and ligated, thus shutting off drainage of right lobe of liver into intestine. ***11,*** Anomalous arrangement of right hepatic duct in which it enters gallbladder so that all the bile from right lobe of liver must drain through cystic duct.

anomalous positions, and the presence of *heterotopic tissues*.[8–12] Both duplication (Fig. 21.7) and triplication of the gallbladder have been reported and are classified depending on the presence of a shared cystic duct, or a separate cystic duct for each gallbladder.[8] Agenesis of the gallbladder may be found incidentally during surgery or associated with biliary atresia (see later), duodenal atresia, and other congenital anomalies.[9–11] Septations of the gallbladder may be acquired (from chronic cholecystitis and cholelithiasis) or congenital. The septations may be single or multiple, and either longitudinal or transverse.[12] "Hourglass" or "dumbbell" gallbladder refers to a transverse septum that divides the gallbladder into two compartments, with central narrowing. The *phrygian cap* or "folded fundus" deformity represents an inversion of the fundus into the body of the organ, producing a prominent notch or angulation of the distal portion of the fundus that apparently resembles caps worn by the people of ancient Phrygia in Asia Minor.[12–14] There is no clinical significance, although this anomaly may cause confusion with a stone or tumor on radiographic examination. Malposition of the gallbladder is quite rare, and anomalous locations include the intrahepatic position, retroplaced gallbladder, suprahepatic gallbladder, and the so-called wandering or floating gallbladder, which has little or no connection to the liver and is at risk of torsion.[12] A variety of heterotopic tissues may be found in the gallbladder, most commonly gastric or pancreatic tissue (Fig. 21.8).[15–16] Congenital diverticula have been reported in 0.0008%–9% of gallbladders. They consist of single or multiple outpouchings of the wall that may occur anywhere in the organ. The presence of all of the layers of the gallbladder wall histologically distinguish them from Rokitansky–Aschoff sinuses. Rare instances

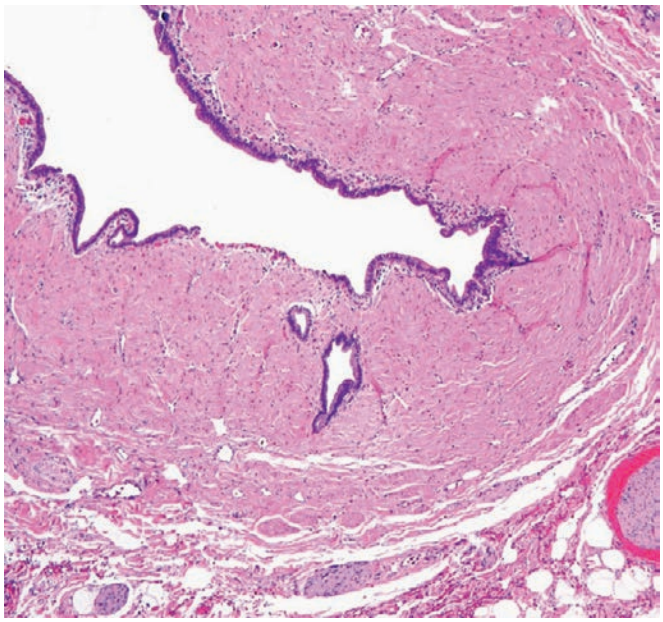

Figure 21.6 The epithelium within all the extrahepatic bile ducts is made up of a single layer of columnar cells resting on dense connective tissue.

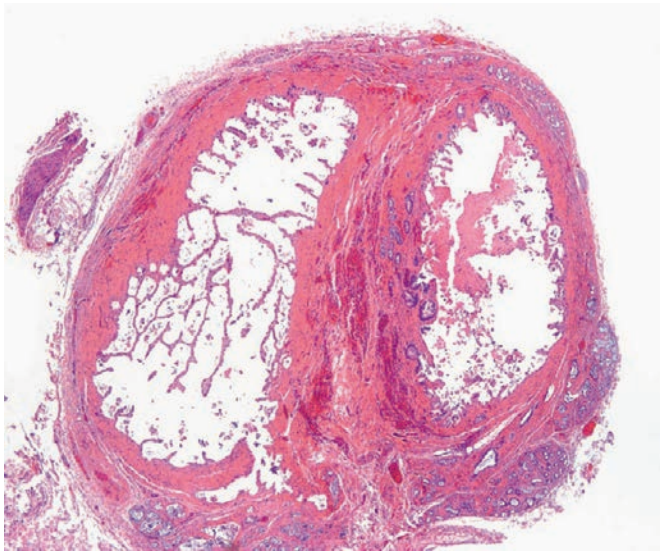

Figure 21.7 Cross section through a congenitally duplicated gallbladder showing duplication of all layers of the gallbladder wall.

of cholelithiasis, cholecystitis, and carcinoma occurring in congenital diverticula have been reported.[12,17]

Extrahepatic Biliary Tree

In **biliary atresia**, a progressive fibroinflammatory disease affecting both the extrahepatic and intrahepatic bile ducts, the gallbladder and extrahepatic ducts may be completely absent or may be represented by a fibrous cord without a lumen. This disease is the most common cause of pathologic jaundice in infants and the most common indication for liver transplantation in children. The etiology, which remains unknown, is likely multifactorial.[18,19] About 20% of patients have associated anomalies.[20] The histologic changes in the biliary tree are characterized by progressive inflammation and fibrosis (Fig. 21.9), with eventual obliteration of the lumen and intrahepatic

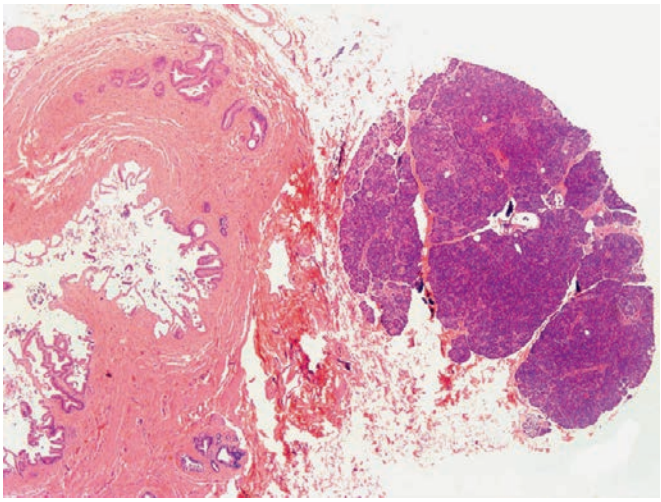

Figure 21.8 Island of heterotopic pancreas adjacent to gallbladder.

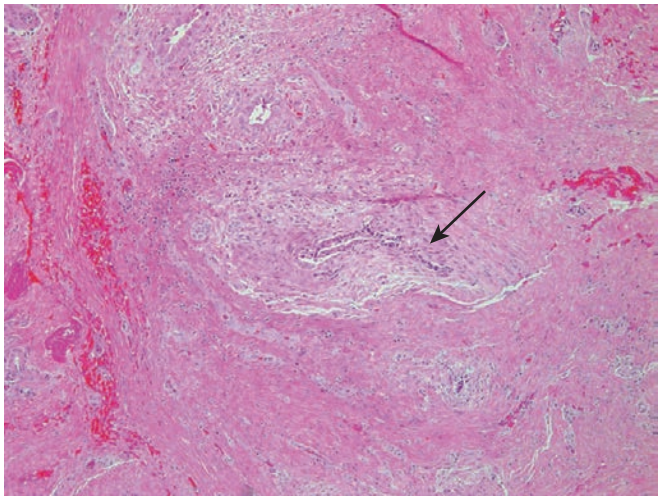

Figure 21.9 This section of the porta hepatis in an infant with biliary atresia shows extensive fibrosis and inflammation and severely damaged, atrophic biliary epithelium with a nearly obliterated lumen *(arrow)*.

bile duct injury and cholestasis (see Chapter 19).[20–23] Hypertrophic and hyperplastic changes of the hepatic artery and its branches are common.[22]

Biliary atresia has been divided into two types: (1) *fetal* (*congenital, syndromic or prenatal*; 10%–20% of cases), which is associated with other congenital anomalies, an earlier presentation, and abnormalities in Notch pathway signaling; and (2) *acquired* (*perinatal*; 80%–90% of cases), which is associated with a later presentation (1–2 weeks of age) and is not associated with extrahepatic congenital anomalies.[23] Biliary atresia is fatal within the first 2 years of life if untreated. Surgical interventions include portoenterostomy, that is, the Kasai operation, in which the fibrous tissue at the porta hepatis is transected and the open area anastomosed to a limb of jejunum (or to the gallbladder when present). This procedure is primarily palliative but may lead to 2 or more years before transplantation is necessary. Liver transplantation is essentially curative, and long-term survival post-transplant is excellent.[24]

Choledochal cysts are cystic dilatations of the biliary tree, typically extrahepatic, which may cause reflux of pancreatic secretions into the common bile duct. The majority develop in children under the age of 10, but they may also first present in adulthood.[25] It is more

Figure 21.10 Choledochal Cyst in a 5-Year-Old Female. The structure to the left is the attached gallbladder. (Courtesy of Dr. R.A. Cooke, Brisbane, Australia; from Cooke RA, Stewart B. *Colour Atlas of Anatomical Pathology*. Edinburgh: Churchill Livingstone; 2004.)

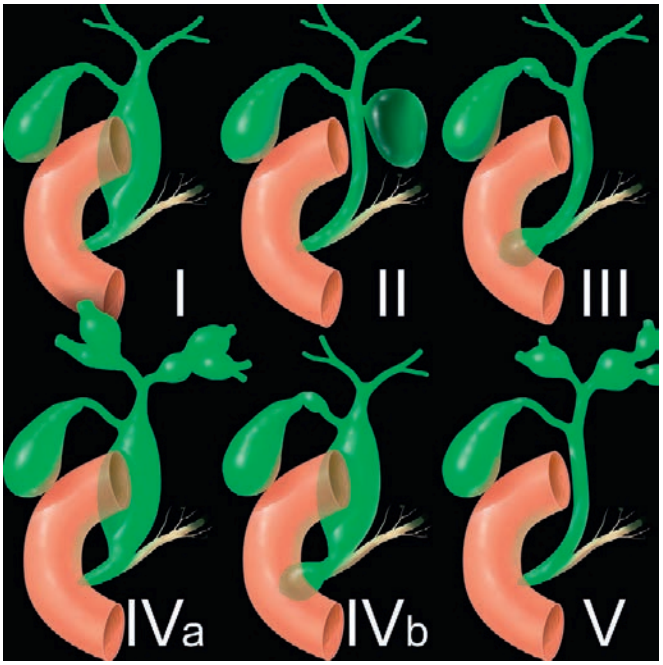

Figure 21.11 The Todani classification of choledochal cysts includes types I (segmental or diffuse dilatation of the common bile duct); II (isolated supraduodenal diverticulum); III (choledochocele, usually within duodenal wall); IVa (extrahepatic cysts and Caroli disease-like cystic dilatation of intrahepatic ducts); IVb (multiple extrahepatic cysts); and V (multiple intrahepatic cysts, equivalent to Caroli disease). Type I is the most common, accounting for 75%–90% of cases. (From Lamps LW, Kakar S. *Diagnostic Pathology: Hepatobiliary and Pancreas*. Salt Lake City: Amirsys; 2011.)

common in females and characteristically presents with pain, jaundice, and a mass.[25,26] Choledochal cysts are not true cysts, but rather a focal fusiform or spherical dilation of the common bile duct (Fig. 21.10), which may secondarily obstruct the other extrahepatic biliary ducts or even the duodenum. The pathogenesis is unknown.[26] Choledochal cysts may be associated with other congenital abnormalities of the biliary tract and other sites.[25]

Historically, choledochal cysts have been anatomically classified according to the Todani classification (Fig. 21.11).[27] Grossly, the cyst

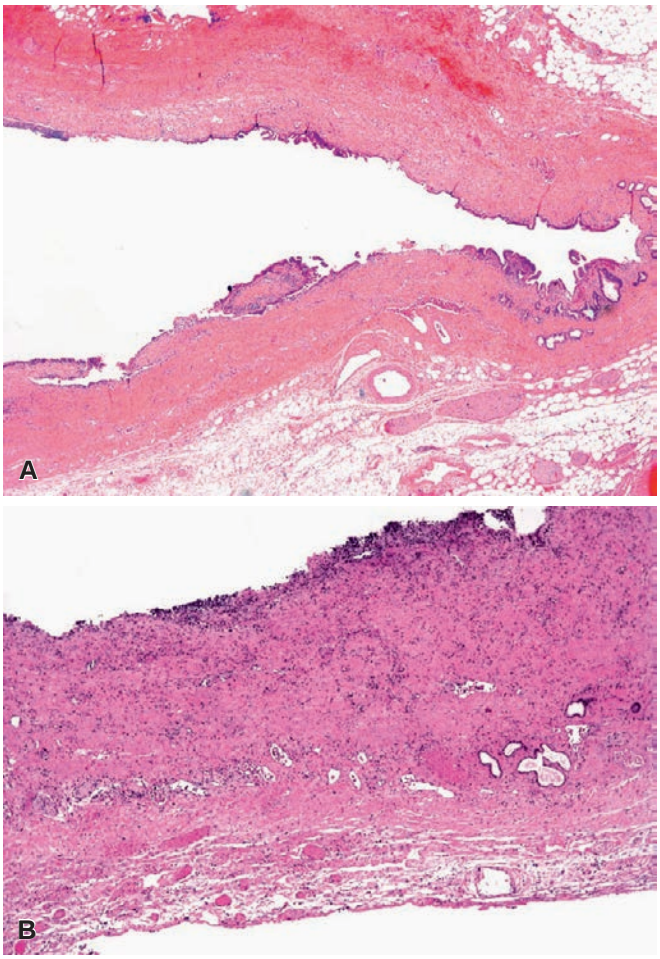

Figure 21.12 A, Choledochal cyst with an overall intact epithelial lining and minimal chronic inflammation. **B,** In contrast, this section from another case shows a completely denuded epithelial lining with underlying acute and chronic inflammation.

wall is fibrous and sometimes calcified, and the amount of bile in the cavity ranges from 30 to 5000 mL. Histologically, there is often chronic inflammation within the wall, and the epithelial lining may be intact, damaged/attenuated, or entirely absent (Fig. 21.12A). The microscopic appearance may also depend on the age of the patient at the time of excision[28]; infants are more likely to have intact columnar epithelium and scant inflammation, whereas older children typically have more pronounced inflammation and a discontinuous epithelial lining. In adults, there is often even greater inflammation as well as destruction of the epithelium (see Fig. 21.12B). Associated chronic cholecystitis is often present. There is a small but definite risk of cholangiocarcinoma associated with choledochal cyst, and thus complete resection is recommended to prevent the development of malignancy as well as pancreatitis and cholangitis.[25] Other tumor types have been reported within choledochal cysts as well, including well-differentiated neuroendocrine (carcinoid) tumor[29] and embryonal rhabdomyosarcoma.[30] The treatment of choice is excision with Roux-en-Y hepaticojejunostomy.[25]

Cholesterosis

Cholesterosis (or cholesterolosis) of the gallbladder is accumulation of lipid within macrophages in the lamina propria.[31] This lesion is fairly common, with surgical and autopsy series reporting a prevalence

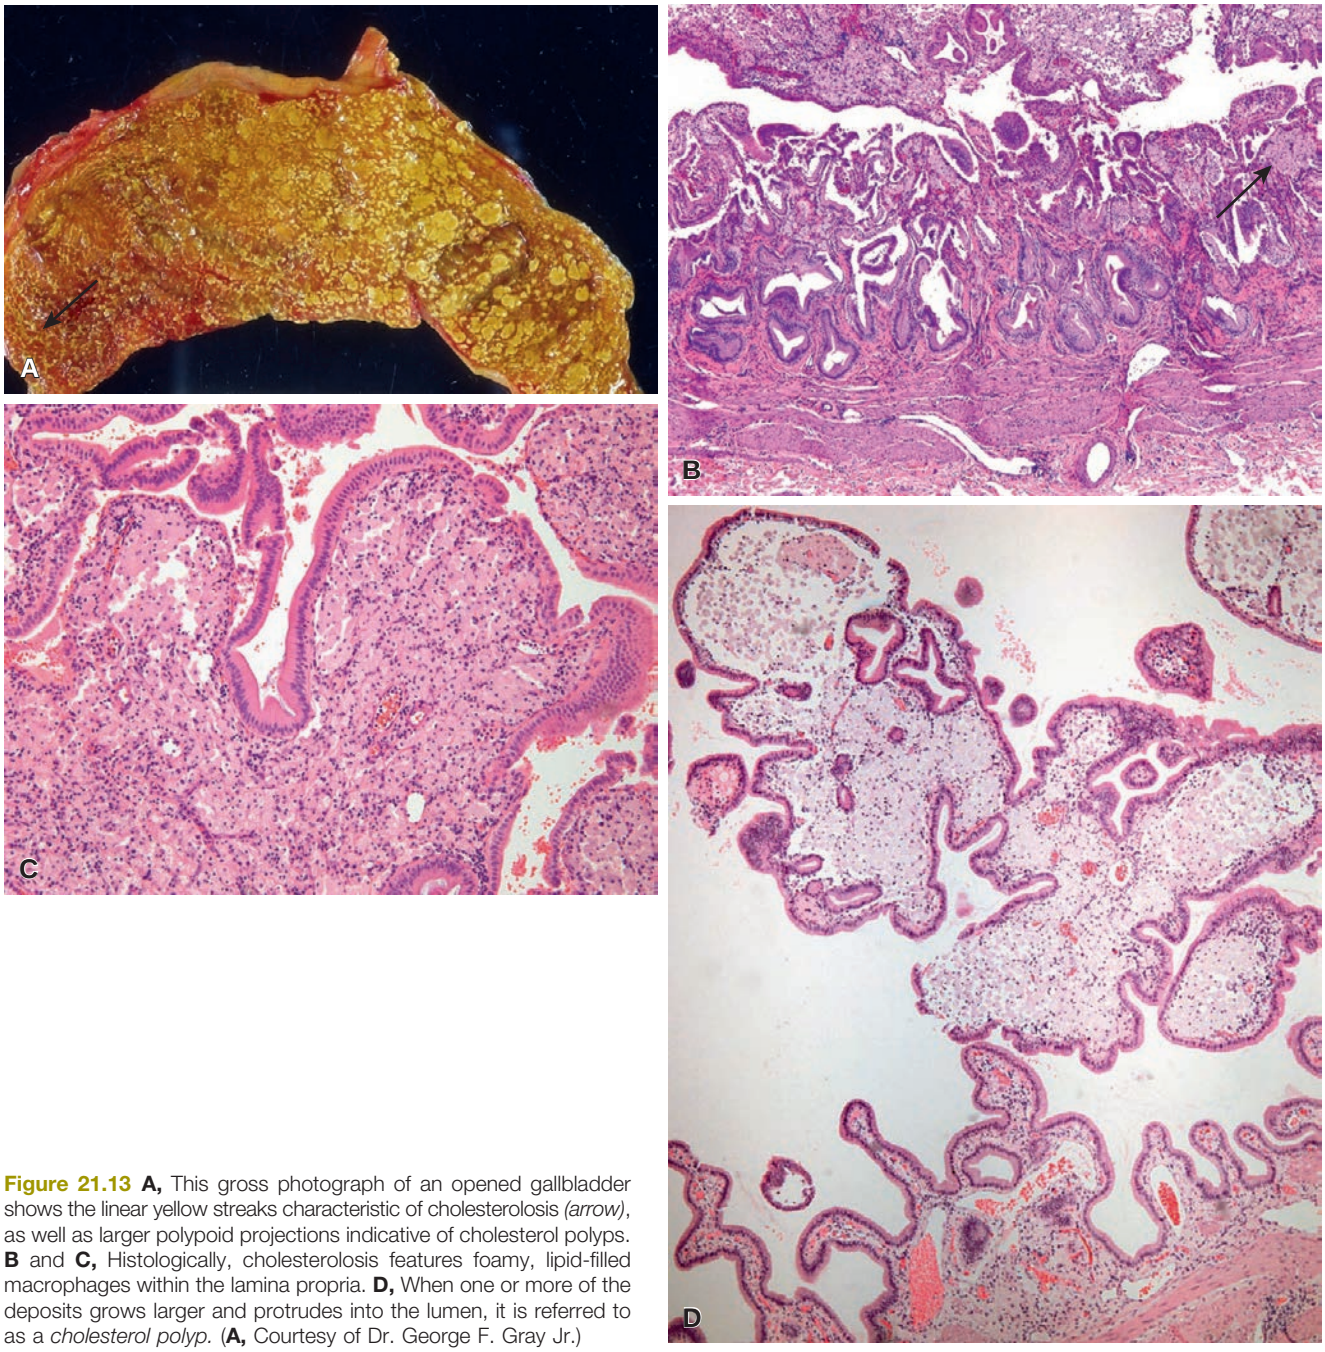

Figure 21.13 **A,** This gross photograph of an opened gallbladder shows the linear yellow streaks characteristic of cholesterolosis *(arrow)*, as well as larger polypoid projections indicative of cholesterol polyps. **B** and **C,** Histologically, cholesterolosis features foamy, lipid-filled macrophages within the lamina propria. **D,** When one or more of the deposits grows larger and protrudes into the lumen, it is referred to as a *cholesterol polyp.* (**A,** Courtesy of Dr. George F. Gray Jr.)

ranging between 9% and 26%.[32] The pathogenesis remains poorly understood, and the clinical significance also remains controversial. Cholesterolosis is often associated with cholesterol gallstones. The gross appearance is characteristic: linear yellow streaks are seen in the prominences of the mucosal ridges, surrounded by congested mucosa ("strawberry gallbladder"; Fig. 21.13A). Sometimes one or more of the deposits grow larger and protrude into the lumen, in which case they are referred to as *cholesterol polyps*. Microscopically, collections of lipid-filled foamy cells are present in the tips of the villi (see Fig. 21.13B–D). Inflammatory changes are usually insignificant, unless the cholesterosis is accompanied by stones in the cystic duct.

Cholelithiasis

Cholelithiasis is one of the most common gastrointestinal diseases worldwide, affecting 10%–20% of the population in Europe and the United States; the prevalence is particularly high in the Scandinavian countries, in Chile, and among Native Americans.[33,34] The incidence is 2–4 times higher in women than in men, and the risk of gallstones is associated with body weight, childbearing, and estrogens.[34] However, stones can occur in any age group, including infants and newborns, although cholelithiasis in this population is often associated with conditions such as hemolysis, Crohn disease, and congenital anomalies of the biliary tree.[35]

Gallstones are classified based on the amount of cholesterol in the stones, generally as cholesterol stones (>80% of stones in developed nations) and pigment stones, which are associated with a variety of medical conditions (see later). The proposed pathogenesis of cholesterol stones, based on human studies and experimental animal models, is bile supersaturation and destabilization, along with gallbladder hypomotility.[33,34] Before the appearance of stones, there is the formation of cholesterol crystals, which grow and aggregate with mucin proteins in bile to form stones.[34] Gallstones vary considerably in chemical composition and contain variable quantities of calcium bilirubinate, and calcium carbonate, either alone or in combination, in addition to cholesterol. The technique of ultrasonography has proven very successful in identifying gallbladder stones, and it has become the method of choice for their detection, as it detects cholelithiasis in approximately 98% of patients.[36]

Cholesterol gallstones, particularly *mixed* cholesterol stones, comprise the vast majority (80%) of stones in Western countries. They are composed of cholesterol, bile salts, and phospholipids. The prevalence of cholesterol gallstones increases with age, and risk factors also include female gender, pregnancy/multiparity, estrogen therapy, obesity, rapid weight loss, and many medications. Chronic cholecystitis is almost always present. *Mixed* cholesterol stones are typically multiple, round or faceted, and less than 2.0 cm in size (Fig. 21.14).[37] *Pure* cholesterol stones account for only 10% of gallstones. They are typically single, spheroidal, and coarsely nodular and may measure up to 4.0 cm in size. They have a translucent bluish white color, and on fracture, they show large, flat crystals. The gallbladder containing *pure* gallstones typically shows little or no inflammatory reaction if the cystic duct is not obstructed. Abnormal serum lipid profiles do not appear to correlate with the formation of cholesterol stones.[38] Sequential cholecystographic studies and carbon-14 dating suggest that gallbladder stones grow at a rate of approximately 1–2 mm/year and that they are usually present for 5–20 years before they are removed.[39]

Pigment stones account for approximately 10%–25% of gallstones in the United States but have a higher incidence in Africa and Asia. Black stones are composed of calcium bilirubinate, phosphate, and carbonate with very little cholesterol.[40,41] They are typically multiple, small, brown to jet black, and faceted; they measure 2–5 mm in diameter (Fig. 21.15). They are associated with hyperbilirubinemia and thus conditions such as cirrhosis and hemolytic disorders (sickle cell anemia, thalassemia, hereditary spherocytosis, and artificial cardiac valves); other associated conditions include malaria, total parenteral nutrition (TPN), and Crohn disease.[41,42] Brown stones contain calcium salts of bilirubin and palmitate, with a higher concentration of cholesterol than black stones. Calcium carbonate and phosphate are usually absent. Brown stones are soft, brown-green, and large. These are associated with infection, particularly *Escherichia coli* and biliary flukes.[40,41]

Other types of gallstones include calcium carbonate stones, phosphate stones, and various types of mixed stones. Some authors advocate more detailed classification of gallstones based on elemental composition analysis and microstructure.[43] *Barrel stones*, a type of combined stone, are usually two in number, large, and faceted on one surface, and the thick-walled gallbladder is closely wrapped around them. Combined stones are almost always accompanied by chronic inflammation of the gallbladder and occasionally by biliary fistulas.

Choledocholithiasis, with or without obstruction, is nearly always secondary to cholelithiasis, for in approximately 20% of cases of gallbladder stones there are synchronous common bile duct stones.[44] Gallstones are usually formed in the gallbladder, from which they may escape into the cystic and other extrahepatic ducts; therefore, the appearance of symptoms of choledocholithiasis sometime after cholecystectomy for stones is usually caused by stones that were overlooked at the time of surgery. The occasional finding of multiple small intrahepatic stones indicates that they can also form in the hepatic duct system outside the gallbladder; independent stone formation in the extrahepatic ducts is rare, however, and typically associated with brown gallstones and persistently dilated ducts or biliary diverticula.[45]

Impaction of a gallstone in the cystic duct may lead to hydrops[46,47] (an enlarged, distended gallbladder that is filled with clear, mucoid, or cloudy secretions; Fig. 21.16) or to acute cholecystitis. Impaction

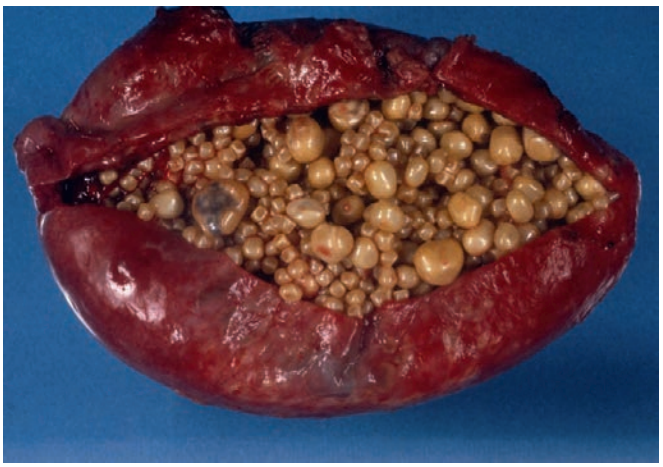

Figure 21.14 Numerous mixed cholesterol gallstones in a background of acute and chronic cholecystitis. (Courtesy of Dr. George F. Gray Jr.)

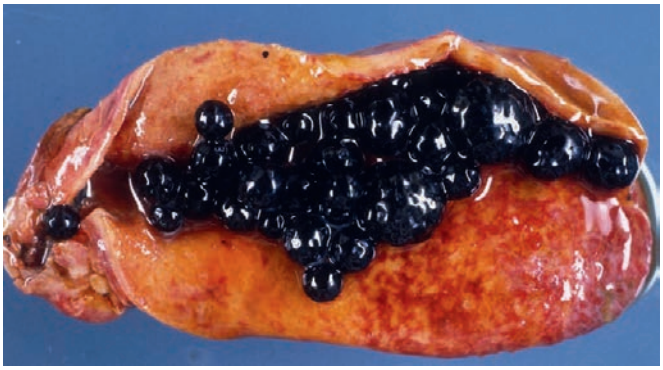

Figure 21.15 Dilated gallbladder containing multiple black (calcium bilirubinate) gallstones. (Courtesy of Dr. George F. Gray Jr.).

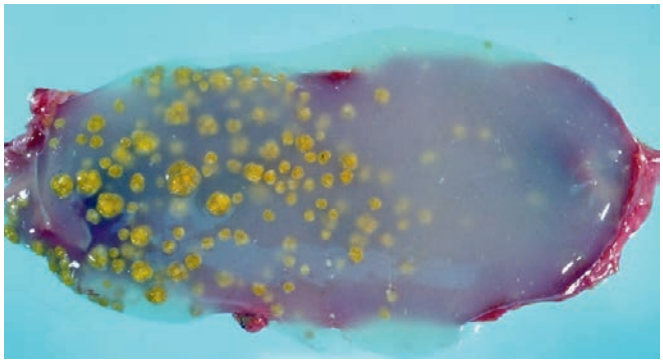

Figure 21.16 This opened gallbladder with hydrops features a very thin wall, abundant watery secretions, and numerous cholesterol stones within the lumen of the gallbladder. (Courtesy of Dr. George F. Gray Jr.)

of a stone in the terminal third of the common duct or ampulla of Vater will result in severe, colicky pain and obstructive jaundice. Sometimes an impacted cystic duct stone causes edema and compression/obstruction of the adjacent common hepatic duct, a condition known as *Mirizzi syndrome*.[48] Gallstones may also lead to *internal biliary fistulas*.[49] Over 90% of these fistulas are located between the gallbladder and the duodenum, the gallbladder and the colon, or the common bile duct and the duodenum. These fistulas are created by the formation of inflammatory adhesions between the biliary tree and adjacent organs and the subsequent erosion of a stone through the gallbladder or the common duct into the gastrointestinal tract. Continuing choledochal obstruction contributes to the persistence of the fistula. Biliary fistulas may become evident by the patient vomiting or passing per rectum a large gallstone, by detecting air in the biliary tree in a plain abdominal roentgenogram, or by seeing the outline of the biliary tree in an upper gastrointestinal series or a barium enema. With cholecystocolic fistulas, infection is often severe.

The standard treatment for symptomatic cholelithiasis is cholecystectomy, which is usually done laparoscopically.[50] Spillage of gallstones into the peritoneal cavity occurs not infrequently during this procedure and is generally of little consequence; however, sometimes it leads to peritonitis, intraperitoneal abscess, foreign body granuloma, and (exceptionally) implantation of the gallstones in the ovary.[51,52] The approach to individuals with asymptomatic gallstones remains controversial, but cholecystectomy for asymptomatic gallstones is not routinely recommended.[50] Although it has often been argued that all gallbladders containing stones should be removed surgically because of the risk of cancer, this argument lacks validity, since the incidence of carcinoma in gallbladders with lithiasis is less than 1%.[53]

Endoscopic sphincterotomy, sometimes combined with endoscopic papillary balloon dilatation, is being increasingly performed for the treatment of choledocholithiasis. Lithotripsy is also of interest in managing bile duct stones, but it requires special equipment and trained personnel and thus is not widely available. Lithotripsy is not recommended for treatment of stones within the gallbladder, due to the high recurrence rate and the chance of stone fragments migrating into the biliary tree.[44]

Acute Cholecystitis

The main clinical symptoms of acute cholecystitis are pain in the right upper quadrant, nausea and vomiting, and fever.[54] There are three types of acute cholecystitis: calculous, acalculous, and emphysematous.

Grossly, the gallbladder is enlarged and distended, with a hemorrhagic external surface (Fig. 21.17A).[47] There may be foci of gangrene or perforation as well. The wall is typically thickened and edematous, with variably present hemorrhage and pus. The luminal content often has a yellow, grumous appearance in acute calculous cholecystitis; this may appear grossly as empyema, but in reality the material is not pus but an emulsion of calcium carbonate and/or cholesterol. If the acute process is superimposed on chronic cholecystitis, which is often the case, fibrosis of the wall may be noted.

Histologically, acute cholecystitis features edema and fibrin within the gallbladder wall, often with mucosal ulceration and an overlying fibrinoinflammatory exudate (see Fig. 21.17B). Fresh thrombi are often found within small veins in the gallbladder wall as well. The presence of a significant neutrophilic infiltrate is very variable but, if present, is usually more prominent early in the course. In cases associated with common bile duct obstruction, intraepithelial aggregates of neutrophils in the mucosa have been reported and likened to the reaction seen in the wall of the common bile duct and liver as part of the process of ascending cholangitis.[55] A fibroblastic reaction occurs later in the course of disease (see Fig. 21.17C). Marked reactive changes can be present in the epithelium, which should not be confused with dysplasia or carcinoma in situ. Necrosis may be present, and if widespread, indicates gangrenous cholecystitis, a severe form of acute cholecystitis that is associated with diabetes, cardiovascular disease, and other comorbid conditions.[56]

Acute calculous cholecystitis accounts for more than 90% of cases.[57] The pathogenesis of most cases of acute calculous cholecystitis is probably chemical or ischemic rather than infectious. It is nearly always related to a stone impacted in the cystic duct,[57,58] which is thought to lead to changes in the concentration and composition of the bile as well as obstruction and congestion of the tortuous venous channels surrounding the cystic duct. Although primary bacterial infection is not thought to play a significant role in acute calculous cholecystitis, secondary infections (typically gram-negative enteric bacilli and anaerobes) complicates approximately 50% of cases.[58] Early (within 3 days) laparoscopic cholecystectomy is considered the therapy of choice for the majority of patients and is associated with shorter overall hospitalization.[57,59] Bile duct injury is the major complication of this procedure, but the incidence is quite low (<1%).[60]

Acute acalculous cholecystitis accounts for about 5%–10% of all cases of acute cholecystitis.[47] In adults, acute acalculous cholecystitis is often associated with serious medical and surgical illnesses such as major cardiac surgery, diabetes, end-stage renal disease, TPN, and sepsis, and the mortality rate is quite high (approaching 30%).[61,62] It accounts for more than 50% of acute cholecystitis cases in children, where it may also be seen in the context of critical illness. In otherwise healthy children, however, it is often associated with systemic infections such as hemolytic streptococcal septicemia, typhoid fever, or viral infection.[63] Acute acalculous cholecystitis has also been reported in HIV-infected patients secondary to cytomegalovirus (CMV) as well as a wide variety of other opportunistic infections.[64,65] Cases of chemical acalculous cholecystitis have been seen after the administration of hepatic arterial chemotherapy.[66]

Microscopically, in acute acalculous cholecystitis, there tends to be a greater degree of bile infiltration of the gallbladder wall and less mural necrosis than in the calculous counterpart, but there is a great deal of overlap.[47,67]

Bacterial invasion in acute calculous cholecystitis is usually a secondary event. If the organisms are of the gas-forming type, the condition known as *acute emphysematous* or *acute gaseous cholecystitis* may result[68]; this complication is particularly common in diabetics. Atherosclerosis of the cystic artery and its branches is thought to be a contributing factor. Many patients have positive blood cultures for clostridial organisms or gram-negative enteric bacilli, and the overall mortality rate approaches 15%. Histologically, the gallbladder shows acute inflammation with necrosis, and gas bubbles may be present within the wall of the gallbladder (see Fig. 21.17D).

Chronic Cholecystitis

Most cases of chronic cholecystitis are associated with cholelithiasis. However, the majority of people with gallstones have no history of pain. Those who are symptomatic typically experience upper abdominal or right upper quadrant pain, dyspepsia, belching, and bloating, but these symptoms are probably not related to the presence of gallstones, as they frequently persist after surgery.[69]

Grossly, the gallbladder may be enlarged, shrunken, or of normal size, and adhesions may be present. Stones are present in approximately 95% of cases. The wall is typically thickened, although this finding may not be impressive (Fig. 21.18A and B).[47] Microscopically,

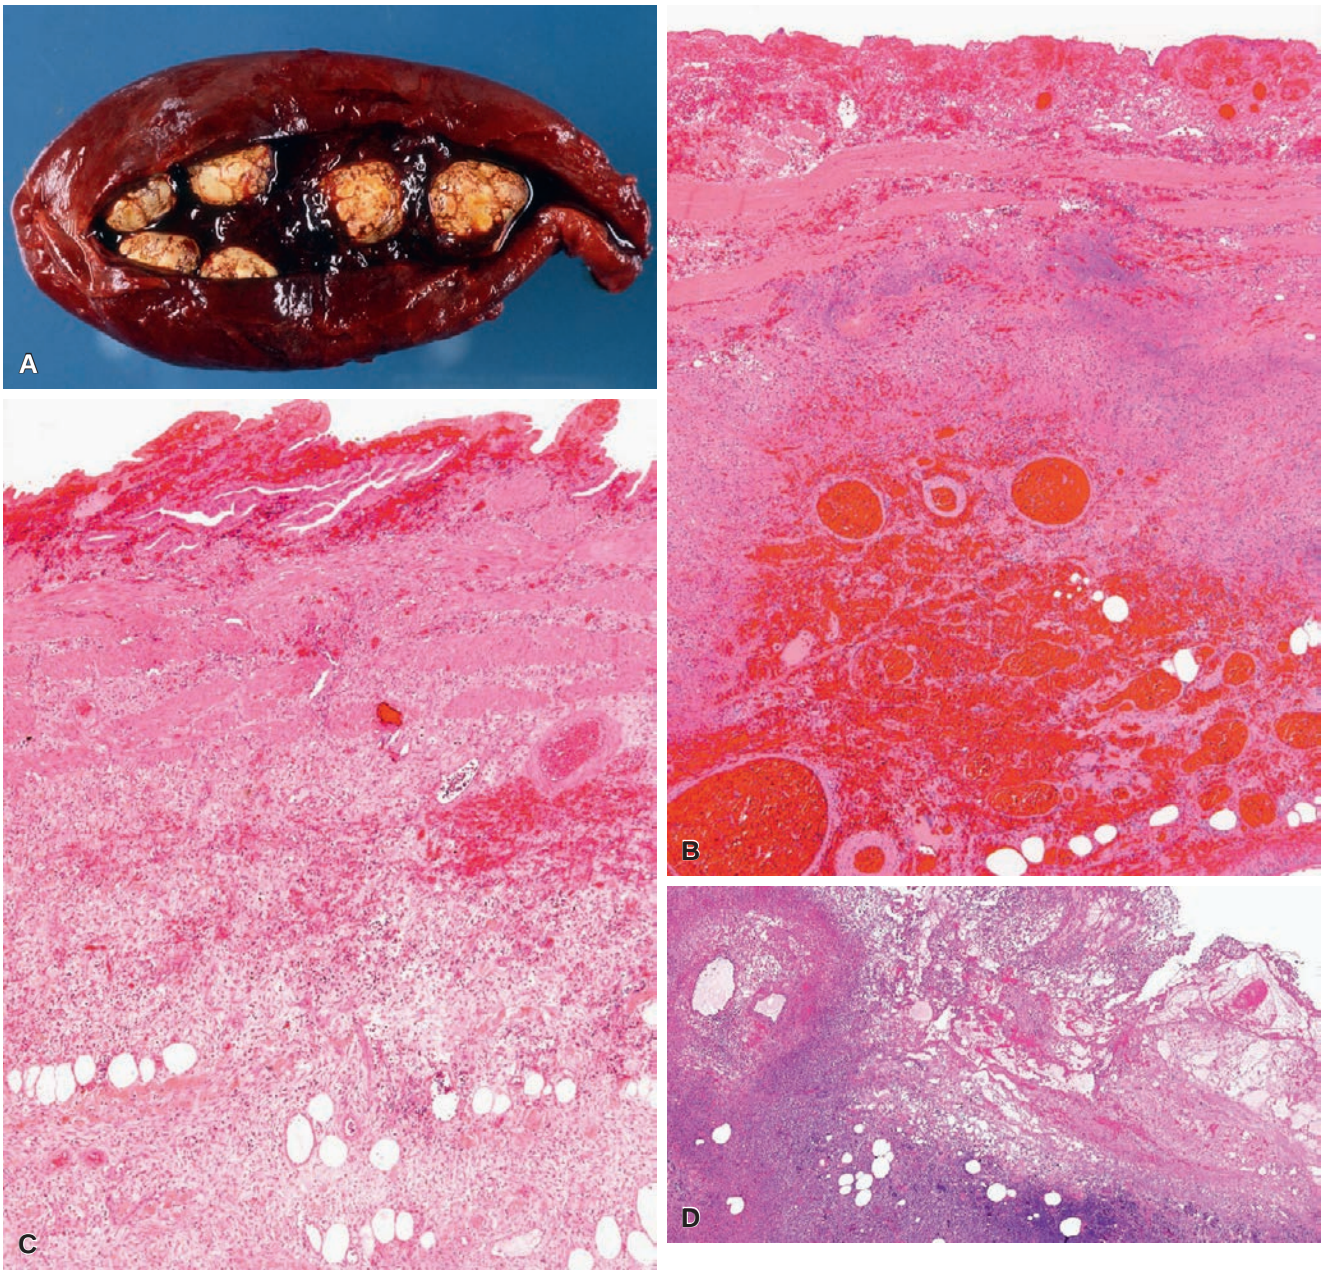

Figure 21.17 Acute Cholecystitis. A, Both the external surface and the mucosa have a characteristic "angry red" color; the mucosa also appears hemorrhagic. This example of acute calculous cholecystitis contains cholesterol stones. **B,** At low power, the mucosa has been replaced by a fibrinous exudate, and the wall contains extensive hemorrhage and necrosis. **C,** Another case of acute cholecystitis, later in the course of disease, shows mural edema, hemorrhage, and a fibroblastic response. Note that neutrophils are not prominent. **D,** This case of acute emphysematous cholecystitis shows both necrosis and gas bubbles in the wall of the gallbladder. (**A,** Courtesy of Dr. George F. Gray Jr. **D,** Courtesy of Dr. Jose Jessurun.)

the mucosa of a chronically inflamed gallbladder shows varying degrees of mononuclear infiltration and fibrosis (see Fig. 21.18C and D). Lymphocytes are usually the most prominent inflammatory cell, with admixed plasma cells and histiocytes; neutrophils and eosinophils may also be present. The inflammation may only involve the mucosa or may extend more deeply. It is important to note that, similar to the small bowel and colon, a complement of mononuclear cells is normally present within gallbladder mucosa, and this alone does not constitute a diagnosis of chronic cholecystitis. The gallbladder wall may show fibrosis, muscle hypertrophy, and/or encrusted stones. Irregularly shaped tubular structures, traditionally known as Rokitansky–Aschoff sinuses, are present within the wall in over half of cases. They are lined by columnar or cuboidal epithelium and may contain bile or stones.[47,70] These tubular structures are thought to represent herniations or diverticula resulting from increased intraluminal pressure.[71] The mucin present in Rokitansky–Aschoff sinuses can spill into the stroma and simulate mucinous adenocarcinoma.[72,73]

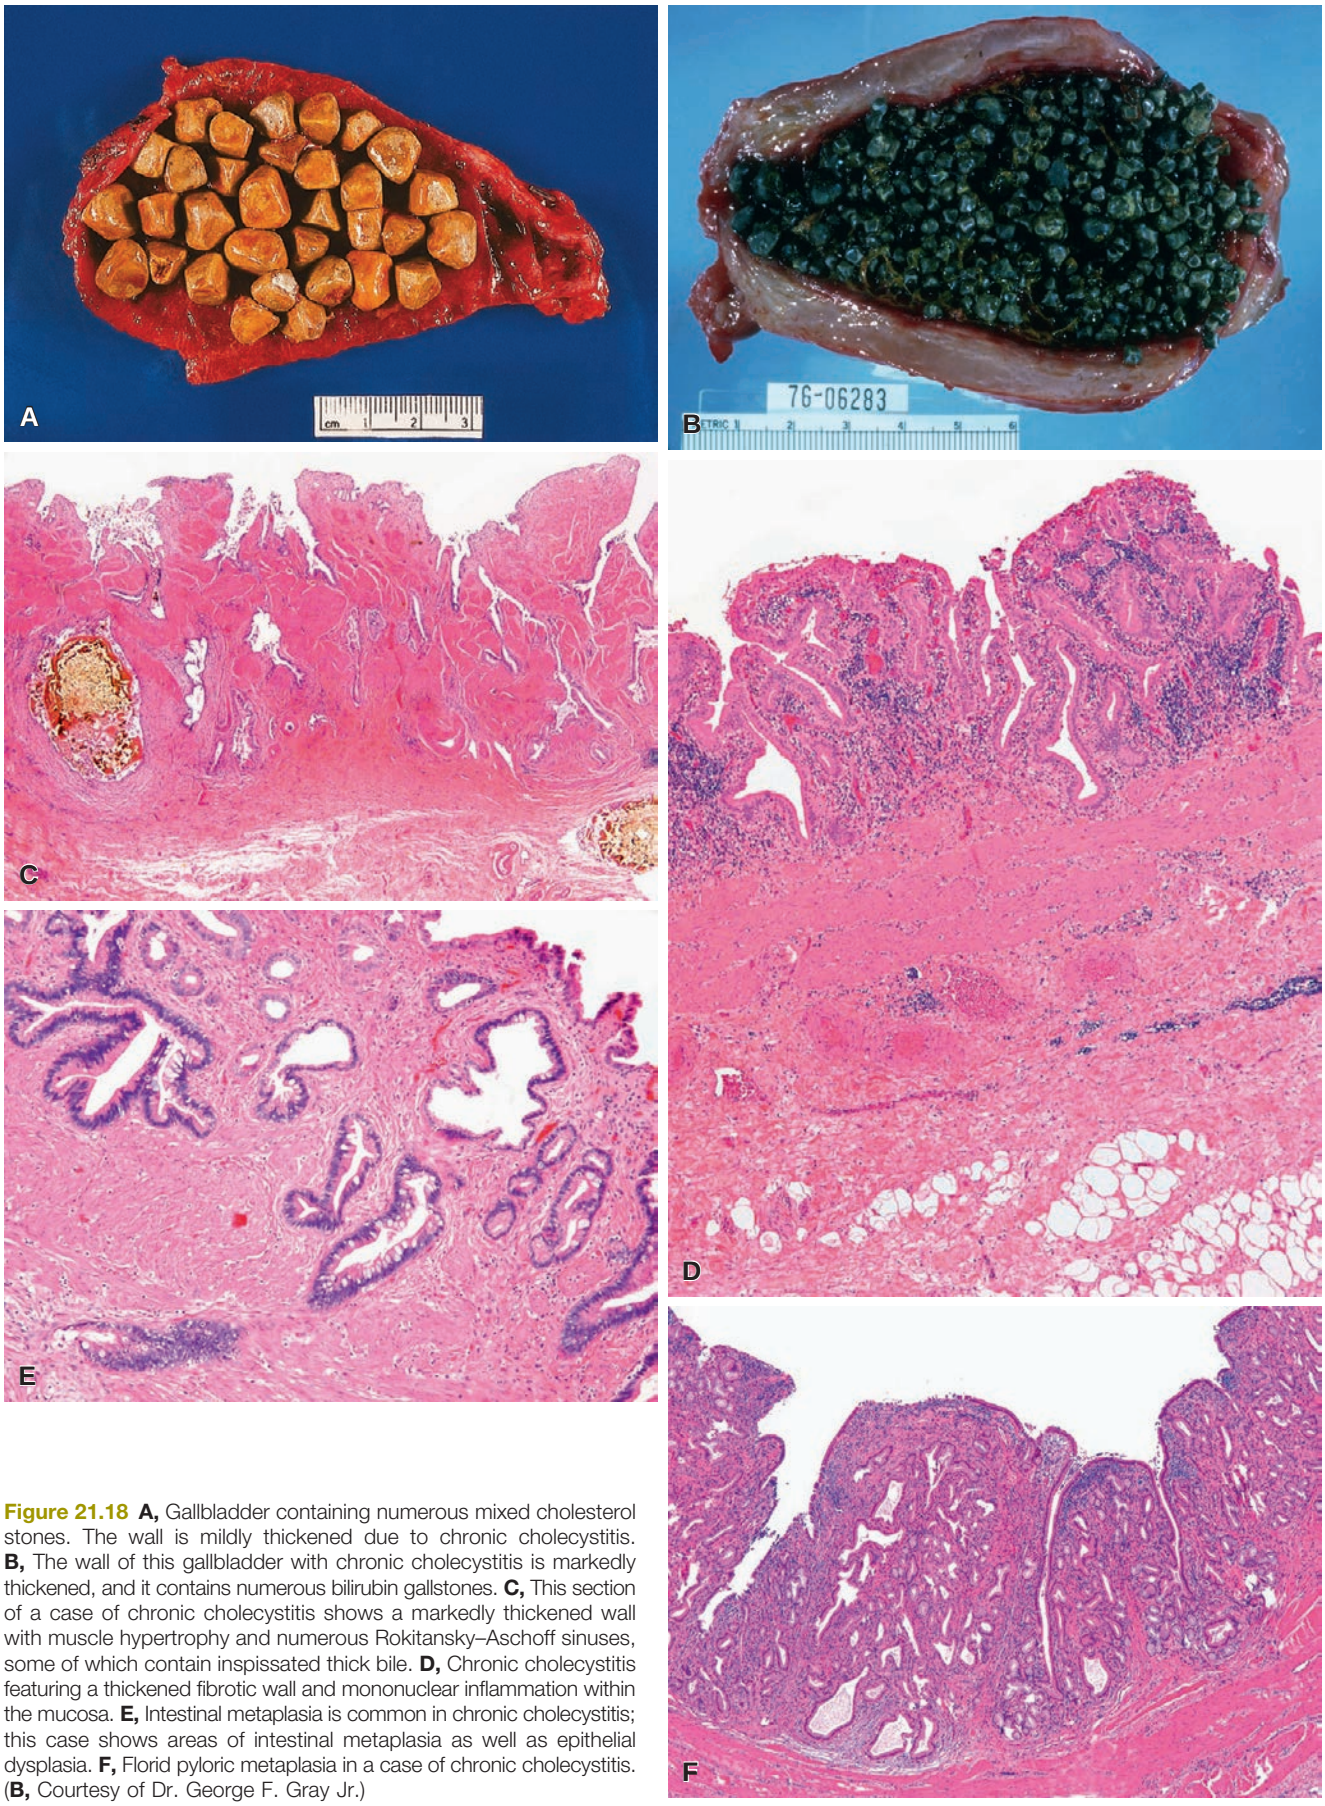

Figure 21.18 **A,** Gallbladder containing numerous mixed cholesterol stones. The wall is mildly thickened due to chronic cholecystitis. **B,** The wall of this gallbladder with chronic cholecystitis is markedly thickened, and it contains numerous bilirubin gallstones. **C,** This section of a case of chronic cholecystitis shows a markedly thickened wall with muscle hypertrophy and numerous Rokitansky–Aschoff sinuses, some of which contain inspissated thick bile. **D,** Chronic cholecystitis featuring a thickened fibrotic wall and mononuclear inflammation within the mucosa. **E,** Intestinal metaplasia is common in chronic cholecystitis; this case shows areas of intestinal metaplasia as well as epithelial dysplasia. **F,** Florid pyloric metaplasia in a case of chronic cholecystitis. (**B,** Courtesy of Dr. George F. Gray Jr.)

The epithelium in chronic cholecystitis may be relatively normal, atrophic, or show hyperplastic and metaplastic changes. The metaplasia can be of goblet cell (intestinal) or pyloric (antral) type, the former being accompanied by the appearance of Paneth cells and endocrine cells (see Fig. 21.18E and F).[47,74–76] Intestinal-type metaplasia is accompanied by CDX2 expression.[77] Pyloric metaplasia can be quite florid and may infiltrate smooth muscle fibers as well as surround nerves, mimicking perineural invasion.[78] The lobular arrangement of the metaplastic glands and the small, uniform nuclei help distinguish this change from adenocarcinoma. The incidence of these metaplastic changes increases steadily with age,[79] and these types of metaplasia can also be encountered in normal, uninflamed gallbladders. Osseous metaplasia has been rarely described as well.[80]

Several morphologic variants of chronic cholecystitis have been described. *Follicular cholecystitis* is characterized by widespread formation of lymphoid follicles in all layers of the gallbladder wall (Fig. 21.19).[47,81] Historically, this pattern has been associated with typhoid fever and other gram-negative enteric infections, as well as Crohn disease (see later).[47,81] *Xanthogranulomatous cholecystitis*,[82,83] also known as *cholecystic granuloma* or *ceroid granuloma*, is a reaction to bile that has penetrated into the wall of the gallbladder, often as a result of the rupture of Rokitansky–Aschoff sinuses (Fig. 21.20A). This form of cholecystitis features diffuse or nodular collections of macrophages containing neutral fat and granular brown lipofuscin (ceroid) pigment (see Fig. 21.20B). As these lesions age, they become densely fibrotic and may mimic cancer both radiographically and macroscopically.[83]

Gallbladders with marked diffuse calcification are known as *porcelain gallbladder* (Fig. 21.21). *Hyalinizing cholecystitis* is a recently proposed term for a type of chronic cholecystitis featuring replacement of the gallbladder wall by dense hyaline fibrosis, often with calcification and denuding of epithelium (Fig. 21.22). Inflammation is

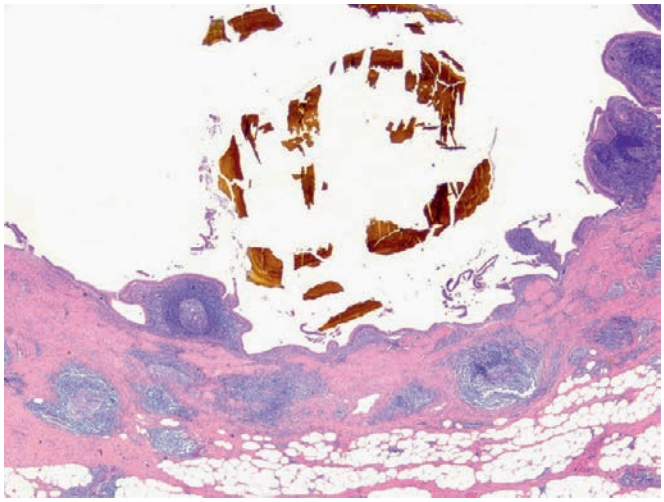

Figure 21.19 This case of follicular cholecystitis shows lymphoid follicles, many with germinal centers, throughout the wall of the gallbladder.

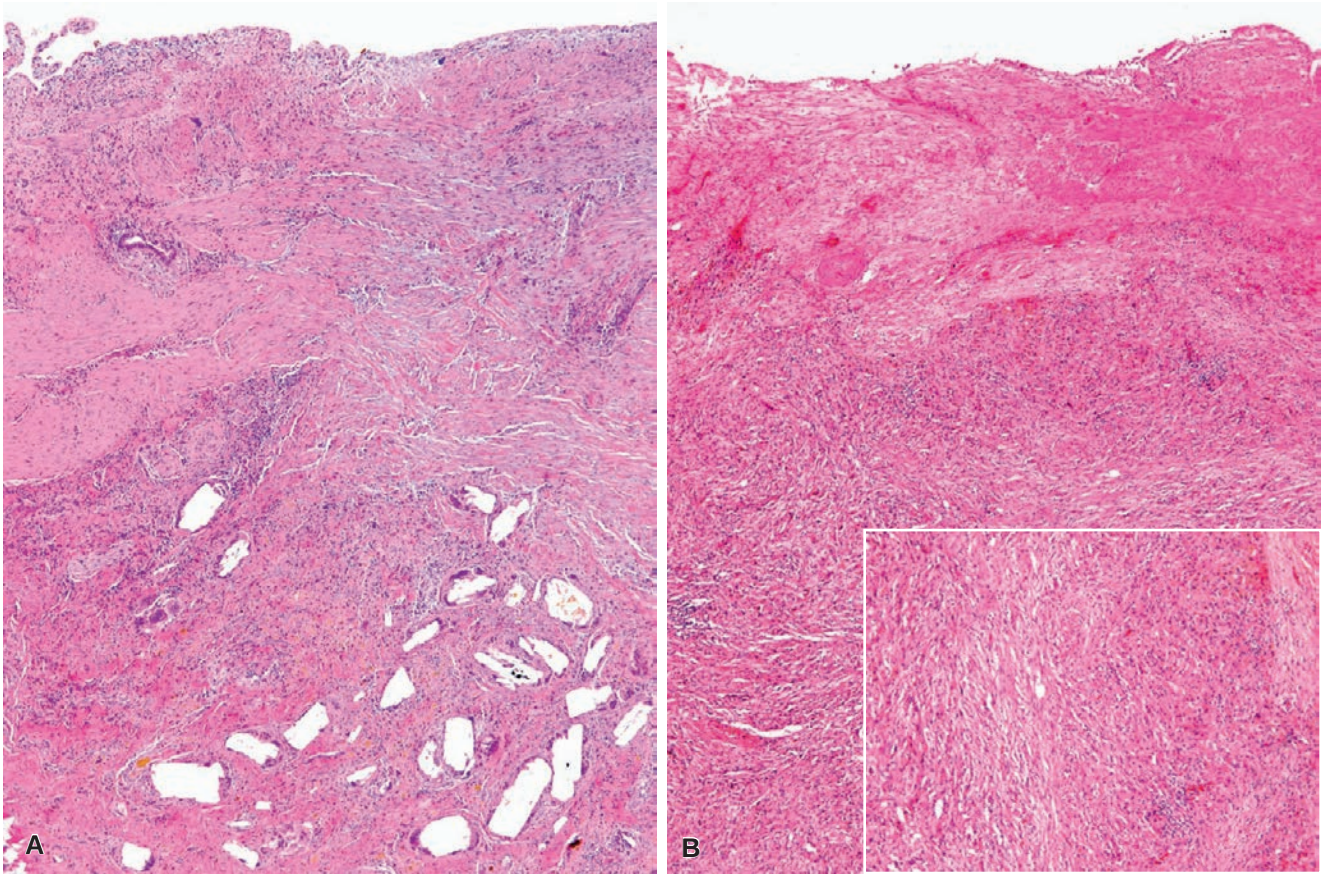

Figure 21.20 **A,** This case of xanthogranulomatous cholecystitis features a nodular collection of ceroid-laden histiocytes and cholesterol crystals with foreign body giant cell reaction in the wall of the gallbladder. **B,** Another case shows a more spindled nodule of histiocytes, with associated ceroid pigment and mural fibrosis (**B** inset).

Figure 21.21 This gallbladder wall is almost completely replaced by calcification, known as "porcelain" gallbladder.

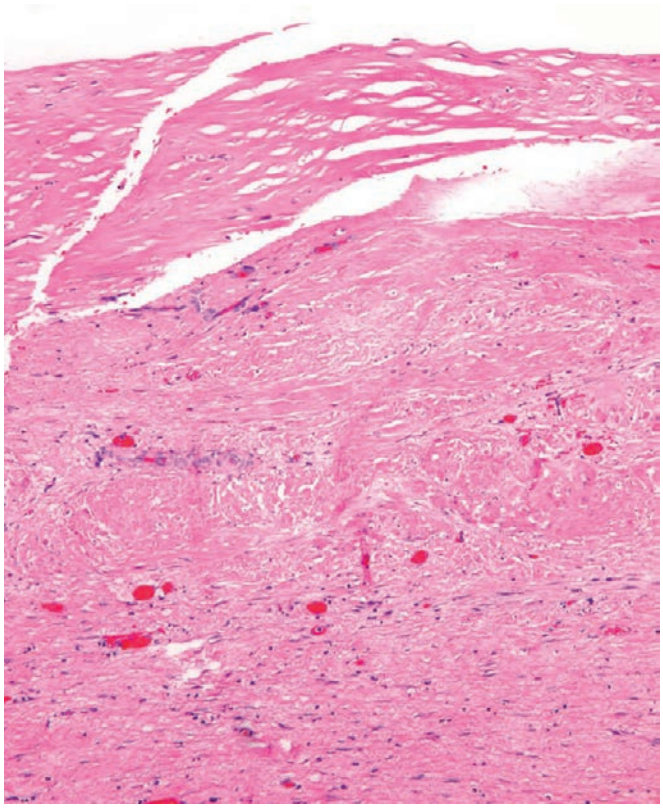

Figure 21.22 Hyalinizing cholecystitis features replacement of the gallbladder wall by dense hyaline fibrosis, with minimal inflammation and denuding of epithelium.

minimal, and the wall is typically attenuated. Cases with scant or no calcification, also known as "incomplete porcelain gallbladder," have been associated with a higher incidence of carcinoma.[84] In recent literature, diffusely calcified or "complete porcelain" gallbladders have not been associated with an increased risk of carcinoma.

Approximately 12%–13% of patients with chronic cholecystitis do not have stones,[58] and a variety of inflammatory conditions can be seen in this context. Three recently described inflammatory conditions within the spectrum of chronic acalculous cholecystitis are worthy of mention. *Eosinophilic cholecystitis* is usually acalculous and may be associated with hypersensitivity reactions or other eosinophilic diseases. "Pure" eosinophilic cholecystitis, as the name implies, features an infiltrate that is almost exclusively composed of eosinophils (Fig. 21.23), whereas "lymphoeosinophilic cholecystitis"

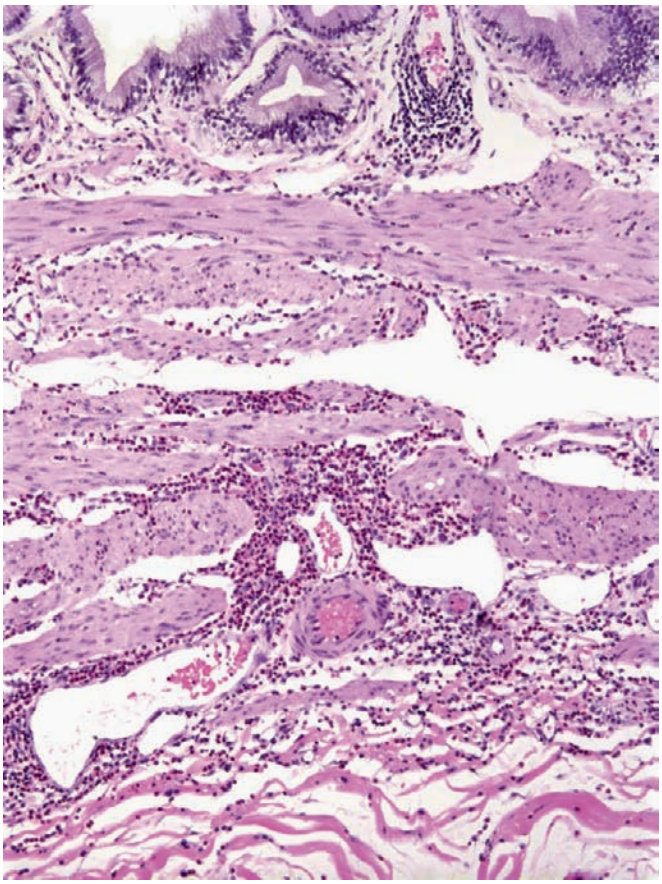

Figure 21.23 "Pure" eosinophilic cholecystitis contains an inflammatory infiltrate composed almost entirely of eosinophils.

contains a significant lymphocytic component, but at least 50% of the infiltrate must be composed of eosinophils.[85] *Diffuse lymphoplasmacytic cholecystitis* has been described in association with primary sclerosing cholangitis (PSC) and IgG4-related autoimmune pancreatitis (Fig. 21.24),[86,87] but it is not specific for either (see also later). Rare cases of acalculous cholecystitis featuring numerous intraepithelial lymphocytes have also been described, and this pattern has been termed *lymphocytic cholecystitis*; the pathogenesis is unknown.[88]

Other Inflammatory Processes Involving the Gallbladder

Ischemia of the gallbladder can result from atherosclerotic disease, compression of vessels by gallstones or tumor, or surgical misadventure.[89] Ischemia has also been described following transarterial chemoembolization for hepatocellular carcinoma using microspheres.[90] "Floating" gallbladders, or those that are surrounded by peritoneum and lack a firm attachment to the liver, are particularly susceptible to torsion and ischemia.[12] Similar to the bowel, ischemic gallbladders show thickened, edematous walls with hemorrhagic necrosis and sloughing of epithelium (Fig. 21.25).

A number of *vasculitides* affect the gallbladder, including (but not limited to) polyarteritis nodosa, Churg–Strauss syndrome, and vasculitis associated with rheumatoid arthritis.[91–94] Some patients with polyarteritis nodosa have isolated gallbladder involvement, although a subset of these may develop evidence of a multisystem disorder on follow-up. Other patients with polyarteritis nodosa involving the gallbladder have systemic autoimmune diseases such as lupus or scleroderma at the time of diagnosis, although finding

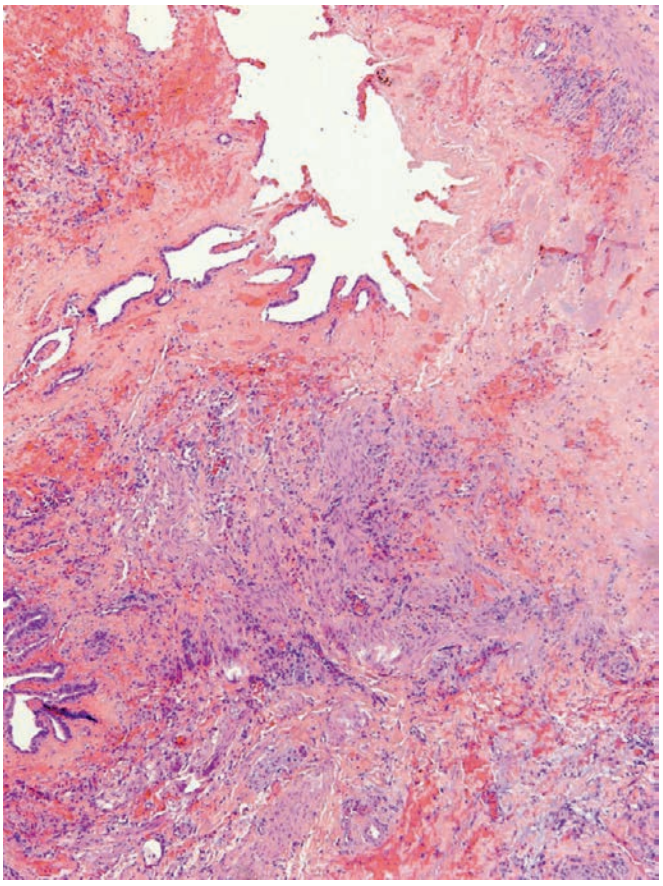

Figure 21.25 Hemorrhagic necrosis and mucosal ulceration in a case of gallbladder ischemia that occurred during liver transplant surgery.

vasculitis in a cholecystectomy specimen may precede the development of systemic disease (Fig. 21.26).

Infections of the gallbladder and extrahepatic bile ducts are discussed together later. Other inflammatory conditions that may rarely affect the gallbladder but are worthy of mention include *malakoplakia*, which is identified by a histiocytic infiltrate with

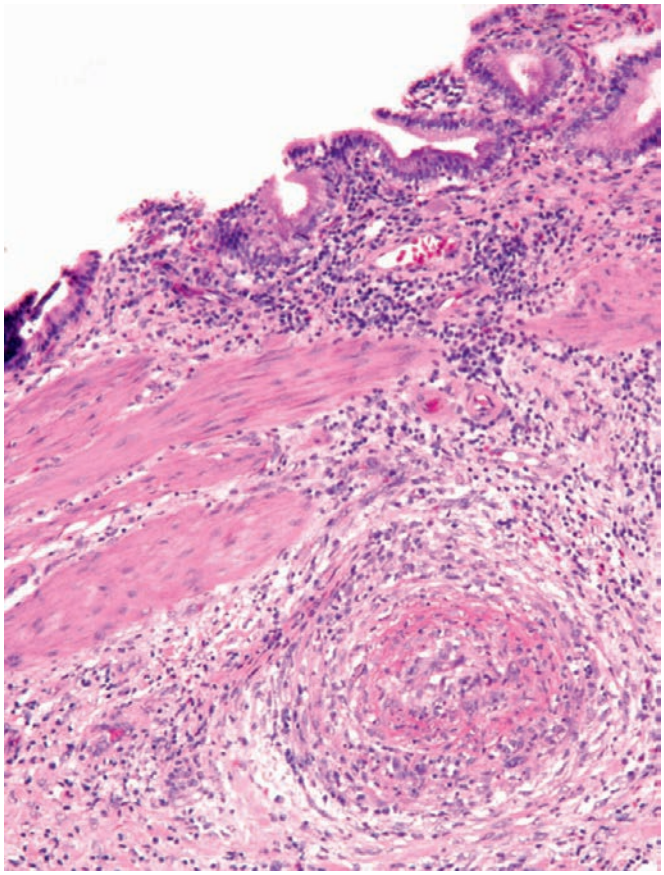

Figure 21.26 Fibrinoid necrosis in a medium-sized artery in a case of polyarteritis nodosa. At the time of cholecystectomy, the vasculitis was limited to the gallbladder.

calcium- and iron-positive Michaelis–Gutmann bodies in the cytoplasm.[95,96] Crohn disease of the gallbladder can feature a follicular cholecystitis pattern[97] or rarely granulomatous cholecystitis.[98,99] Although sarcoidosis frequently involves the liver, it has been only very rarely reported in the gallbladder.[100] So-called *pulse granulomas*, similar to those more commonly seen in the oral cavity and gastrointestinal tract, have also been described in the gallbladder in association with fistulae involving the gastrointestinal tract; they appear as hyaline rings that may be associated with inflammation, foreign body giant cells, calcifications or vegetable matter.[101]

Inflammatory Disorders of the Extrahepatic Bile Ducts

Strictures of the common duct are usually (~80% of the time) caused by surgical trauma in which the duct is inadvertently injured or ligated.[102,103] Anatomic variations of the ducts and blood vessels are often responsible for this complication, as well as obscuring fibrosis or inflammation.

Obstructive cholangitis may be seen in conjunction with calculous cholecystitis, secondary to stone impaction in the duct, or as a result of biliary cysts, fistulae, tumors, or iatrogenic obstruction. Histologic findings are nonspecific and include acute inflammation with reactive and regenerative epithelial changes. Chronically inflamed extrahepatic bile ducts may show metaplastic changes in the mucosa analogous to those more commonly seen in the gallbladder, that is, pyloric, intestinal, and squamous.[104]

PSC is a relatively rare disorder of unknown etiology characterized by fibrosis and inflammation of the intrahepatic and extrahepatic biliary tree,[105–107] ultimately leading to biliary strictures and cirrhosis (see also Chapter 19). This disease primarily affects men from 20 to 50 years of age, and it has been reported in association with retroperitoneal and mediastinal fibrosis, orbital pseudotumor, and chronic idiopathic inflammatory bowel disease (in particular, ulcerative colitis, which is present in ~70% of patients with PSC, but also Crohn disease).[108,109] A number of HLA susceptibility alleles have been identified, but none are specific for PSC, and the significance of the association has yet to be fully elucidated.[110] Many patients have antinuclear, perinuclear antineutrophilic cytoplasmic, and anti-smooth muscle antibodies as well, although these are also nonspecific.[111] The majority of cases involve both intrahepatic and extrahepatic bile ducts, which have alternating areas of short strictures with normal or dilated ducts, producing the characteristic beaded appearance on cholangiography.[111] The most typical microscopic changes seen in the early stages of the disease are not in the extrahepatic bile ducts but in the liver biopsy. Histologic findings within the bile ducts are nonspecific, featuring dense fibrosis, a lymphoplasmacytic infiltrate (sometimes containing eosinophils), and epithelium that may be intact or ulcerated (Fig. 21.27A).[111,112] Neural hyperplasia has also been described. Ultimately the fibrosis and inflammation lead to reduction or obliteration of the duct lumen (see Fig. 21.27B). Because the histologic changes are so nonspecific, cholangiography is considered the gold standard for diagnosis. Patients with PSC are at increased risk for cholangiocarcinoma in both the intrahepatic and extrahepatic ducts (see later), and it is very difficult to distinguish malignant from inflammatory strictures radiographically. No effective screening method has been established, but some patients with worrisome clinical or radiographic findings may benefit from ERCP with brush cytology or biopsy with fluorescence in situ hybridization (FISH) and measurement of serum CA 19-9.[113]

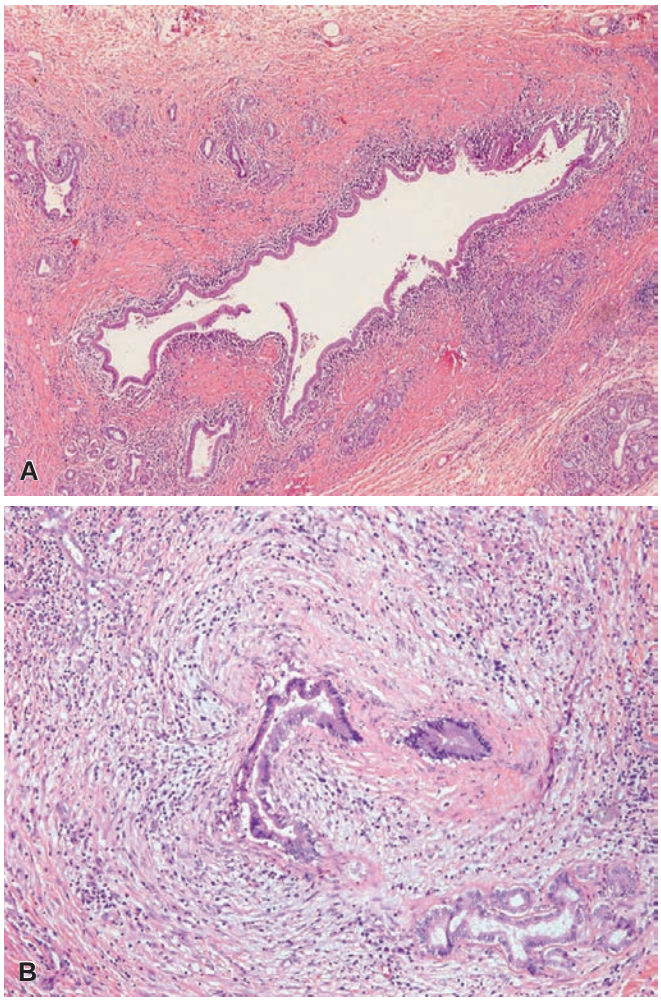

Figure 21.27 **A,** Common hepatic duct in primary sclerosing cholangitis shows a lymphoplasmacytic infiltrate underlying epithelium that is primarily intact. **B,** A more advanced case shows dense lymphoplasmacytic inflammation with fibrosis, epithelial disarray, and compromise of the duct lumen.

A recently described entity that may closely mimic PSC both clinically and radiographically is *IgG4-related sclerosing cholangitis*, which is part of the spectrum of IgG4-related diseases that includes sclerosing pancreatitis and a subtype of inflammatory pseudotumor (see also Chapters 19 and 22).[114–116] The majority of these patients (~90%) also have pancreatic involvement, which argues in favor of IgG4-related disease rather than PSC. Serum IgG4 is typically, but not always, elevated. Histologic findings include a dense lymphoplasmacytic infiltrate with associated fibrosis, obliterative phlebitis, and increased numbers of IgG4+ plasma cells (Fig. 21.28A–C); unfortunately, these findings are often not apparent on small mucosal bile duct biopsies. It should also be noted that bile duct carcinomas may be accompanied by increased numbers of IgG4+ plasma cells.[114] This disease responds extremely well to steroid therapy, and thus accurate diagnosis and distinction from PSC is important.

Other noninfectious inflammatory disorders of the extrahepatic bile ducts include *primary hepatolithiasis* (also known as recurrent pyogenic cholangitis or Oriental cholangiohepatitis), an idiopathic condition that occurs most commonly in Asians and infers an increased risk of cholangiocarcinoma;[117,118] and *eosinophilic cholangitis*, which may be associated with idiopathic eosinophilic gastroenteritis and can mimic carcinoma due to thickening of the duct wall.[119,120]

Infections of the Gallbladder and Extrahepatic Bile Ducts

A number of infections occur in the gallbladder and extrahepatic bile ducts, albeit rarely, and the majority are seen in the context of sclerosing cholangitis in immunocompromised patients. *Cryptosporidium*, an intracellular parasite, is the most commonly found biliary tract pathogen in patients with AIDS-associated cholangiopathy (Fig. 21.29A).[121–123] Other infections associated with AIDS-associated cholangiopathy, and cholecystitis, include *Microsporidia* (see Fig. 21.29B and C),[124] *Cystoisospora* (see Fig. 21.29D and E),[125] tuberculosis, *Mycobacterium avium-intracellulare*, and CMV, which is the second most common pathogen in AIDS-related biliary infections.[122,123,65] *Cystoisospora* has also been reported in the gallbladders of immunocompetent patients and appears to have little clinical significance in this context.[126]

Flukes, or trematodes, can infect the bile ducts, such as the liver flukes *Clonorchis sinensis*, *Opisthorchis* species, and *Fasciola* species (Fig. 21.30). Liver flukes are endemic in many parts of Asia, as well as Russia, Eastern Europe, and South America, and are acquired from eating contaminated fish, crawfish, or (in the case of *Fasciola*) watercress. Flukes can cause obstruction and/or biliary tract infections, and *Clonorchis* and *Opisthorchis* infection are risk factors for cholangiocarcinoma.[127,128] *Schistosoma* species (or blood flukes) rarely infect the extrahepatic bile ducts, causing fibrosis (see also Chapter 19).[129] The nematode *Ascaris lumbricoides* may occasionally migrate from the bowel into the bile ducts,[127] and amebiasis has been very rarely reported in the gallbladder.[130]

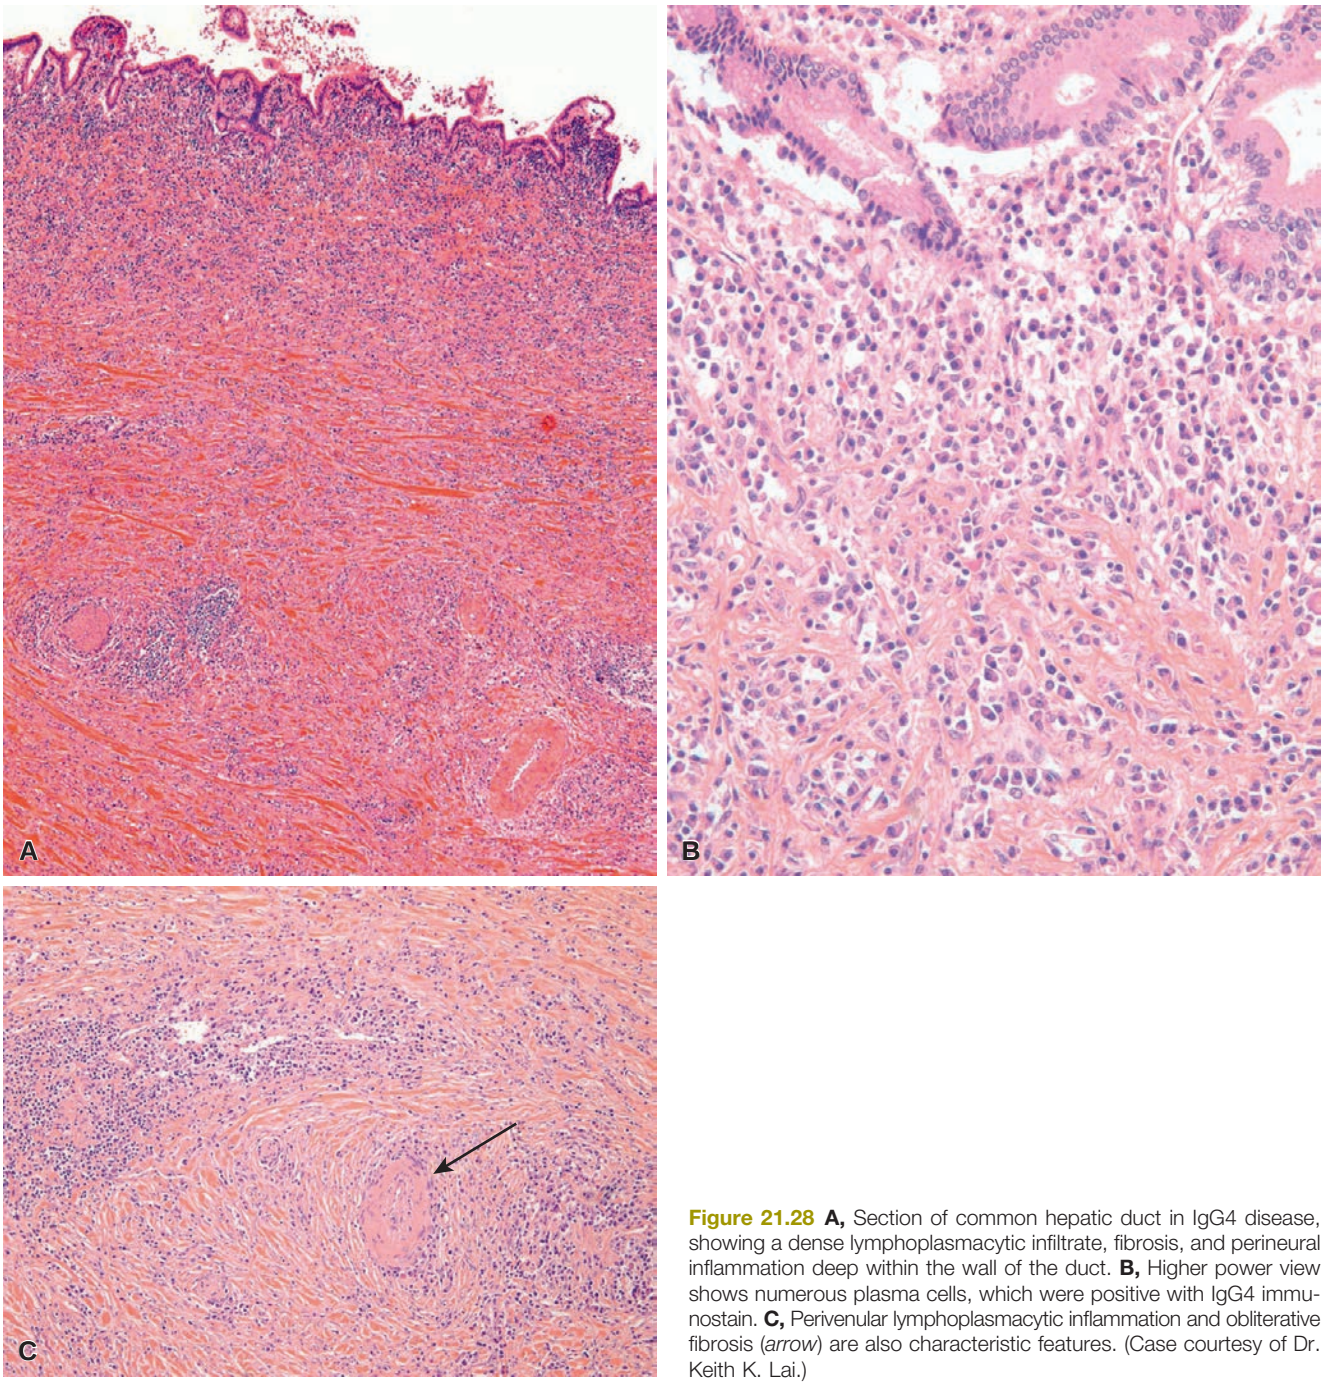

Figure 21.28 **A,** Section of common hepatic duct in IgG4 disease, showing a dense lymphoplasmacytic infiltrate, fibrosis, and perineural inflammation deep within the wall of the duct. **B,** Higher power view shows numerous plasma cells, which were positive with IgG4 immunostain. **C,** Perivenular lymphoplasmacytic inflammation and obliterative fibrosis (*arrow*) are also characteristic features. (Case courtesy of Dr. Keith K. Lai.)

Tumors and Tumorlike Conditions of the Gallbladder

Benign Tumors and Tumorlike Conditions

A variety of terms describing mucosal polyps of the gallbladder exist in the literature; these have poorly defined criteria, are often used interchangeably, and include *mucosal hyperplasia, hyperplastic polyp, villous hyperplasia,* and *inflammatory polyp*. Mucosal hyperplasia/hyperplastic polyps and inflammatory polyps are almost always seen in the context of chronic cholecystitis or some other inflammatory insult. These lesions are benign and typically clinically silent, and discovered incidentally at cholecystectomy. So-called *primary papillary hyperplasia* is a rare entity consisting of closely spaced villous folds that are taller than normal, but without a background of inflammation or metaplastic changes (hence the name primary hyperplasia).[131] Its significance is that it can mimic carcinoma radiographically. Both papillary mucosal hyperplasia and discrete polyps have been described in the gallbladders of both infants and adults with metachromatic leukodystrophy, which may result in massive hemobilia.[132,133] Cholesterol polyps are discussed previously.

Exaggerated examples of gallbladder ***diverticulosis*** associated with muscular hypertrophy have been dignified with the impressive but somewhat inaccurate names of ***adenomyomatous hyperplasia,***

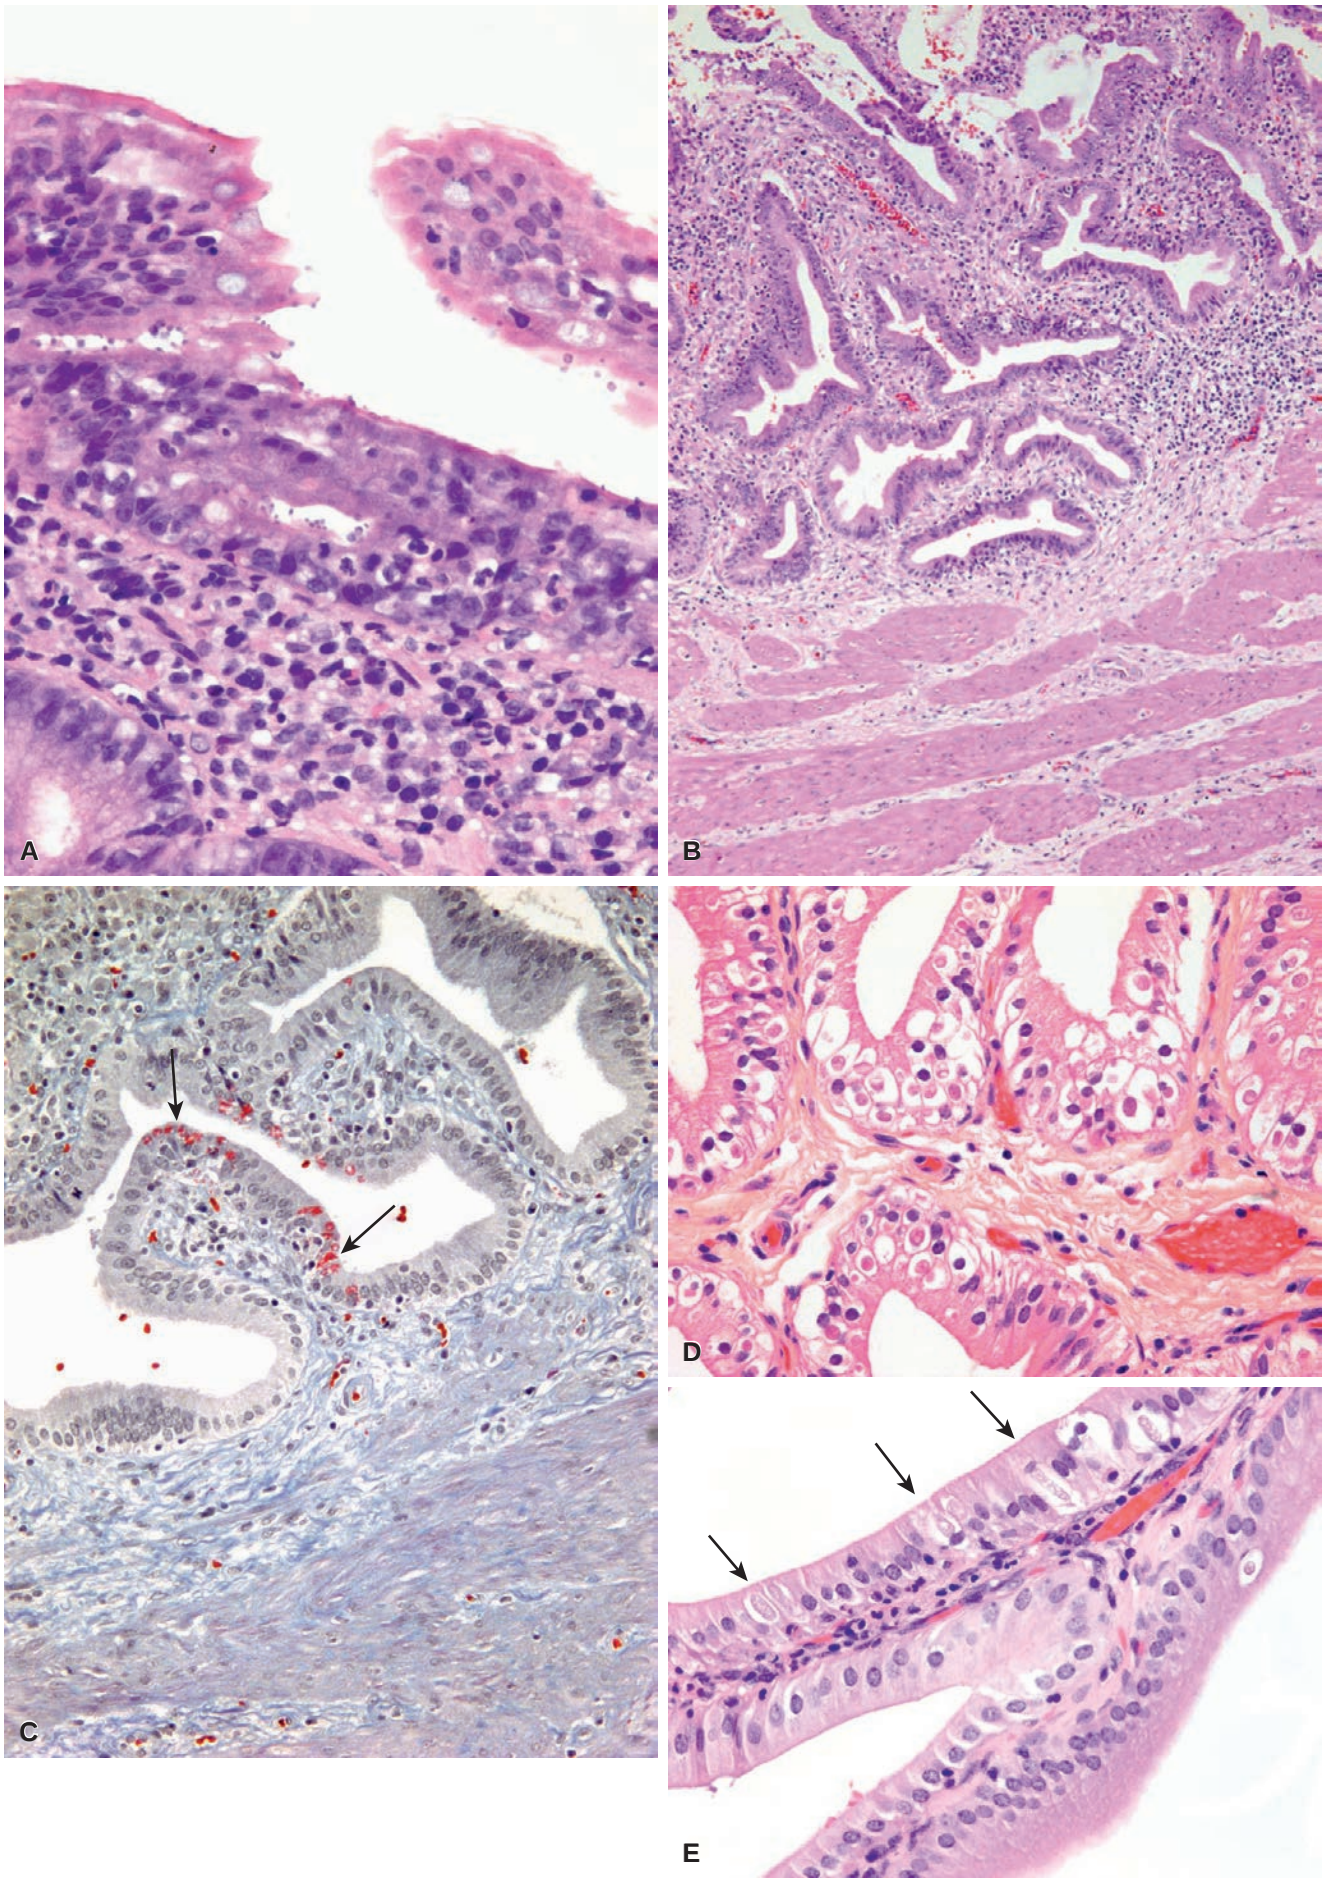

Figure 21.29 **A,** This ampullary biopsy shows round, basophilic organisms typical of *Cryptosporidia* within the apical cytoplasm of the epithelial cells. **B,** A gallbladder biopsy from a patient with microsporidiosis shows an increased mononuclear cell infiltrate in the lamina propria and increased intraepithelial lymphocytes. **C,** Modified trichrome stain highlights red-staining *Microsporidia* within the epithelium *(arrows)*. **D** and **E,** This gallbladder contains numerous *Cystoisospora* within parasitophorous vacuoles, with minimal inflammatory reaction (*arrows*; Case courtesy of Dr. Keith K. Lai).

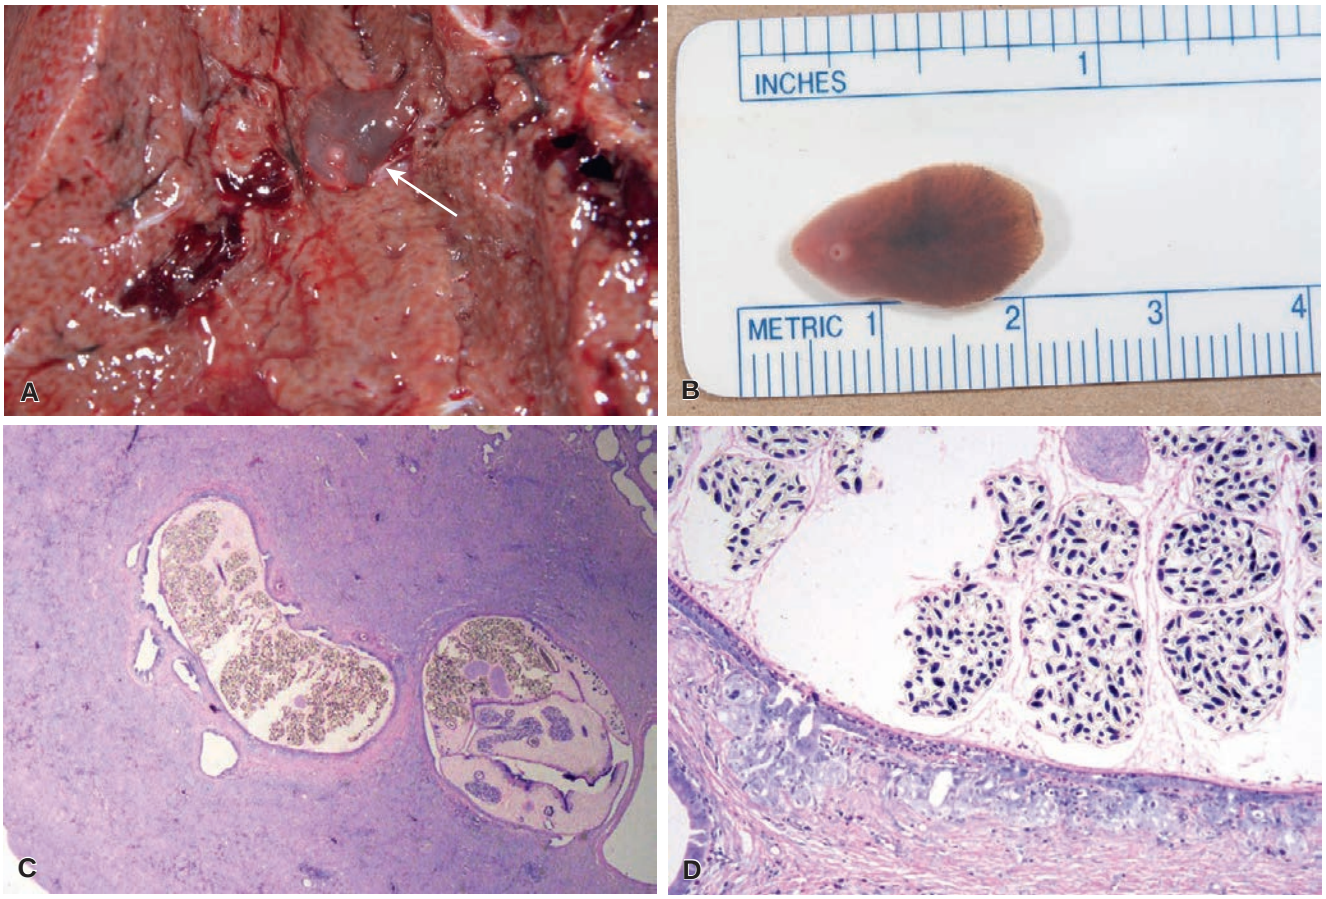

Figure 21.30 **A,** An autopsy specimen shows a fluke within a large intrahepatic bile duct *(arrow)*. **B,** Liver flukes are flat, slightly transparent, and tapered anteriorly with prominent oral and ventral suckers. **C,** *Clonorchis* within a large intrahepatic bile duct with associated cholangiocarcinoma **(D)**. adenomyoma (when focal or **segmental**), and ***adenomyomatosis*** (when diffuse) (Fig. 21.31A).[134,135] This is a common condition, occurring in approximately 5% of cholecystectomy specimens. The localized form may involve any segment of the organ but in most cases is located in the fundus, where it results in a sharply circumscribed lesion that can mimic adenocarcinoma both grossly and radiographically. The lesion consists of cystically dilated glands, representing extension of Rokitansky–Aschoff sinuses, within hypertrophic smooth muscle (see Fig. 21.31B and C); the epithelium may show metaplastic or reactive changes. The dilated glands may be seen in close approximation to nerves, simulating intraneural and perineural invasion, thus adding the gallbladder to the increasing list of organs in which this phenomenon can occur in the absence of true malignant disease.[136]

Tumoral Intraepithelial Neoplasia

Historically, the clinical, pathologic, and prognostic features of pre-neoplastic and neoplastic gallbladder polyps have been poorly characterized, in large measure due to differences in terminology and classification. Recently, the terminology of noninvasive neoplastic lesions that form masses in the gallbladder has been revised significantly in order to clarify nomenclature as well as clinical significance.[137]

Polypoid or papillary tumors, including lesions previously termed adenomas, noninvasive papillary neoplasms (including noninvasive carcinoma), and papillomatosis, are now grouped together as intracholecystic papillary-tubular neoplasms (ICPNs) (Fig. 21.32A–F). Dysplasia in these lesions is graded as low-grade or high-grade carcinoma in situ. Although the majority of invasive gallbladder cancers arise from flat dysplasia, approximately 5% arise from tumoral intraepithelial neoplasms,[137] and thus extensive sampling is required to exclude invasion. Grossly, ICPNs are typically villous and/or papillary and may grow to over 5 cm. They are typically very friable, and smaller ones may detach and be mistaken for necrotic tissue. Microscopically they are papillary, tubular, or tubulopapillary, and high-grade dysplasia and invasive carcinoma are more common in papillary and tubulopapillary lesions.[137]

ICPNs are frequently of mixed type, but the predominant cell type seen across the spectrum of ICPNs is biliary. ICPNs with a predominantly biliary cell type are most often papillary, and the most likely to be associated with invasive carcinoma. They express CK7 and MUC1, as well as other lineage markers in a minority. Other cell types include gastric, foveolar, oncocytic, pyloric, and intestinal. Most previous literature on "gallbladder adenomas" is based on pyloric-type lesions that may actually represent nodular metaplasia rather than a pre-neoplastic lesion. Some authors reserve

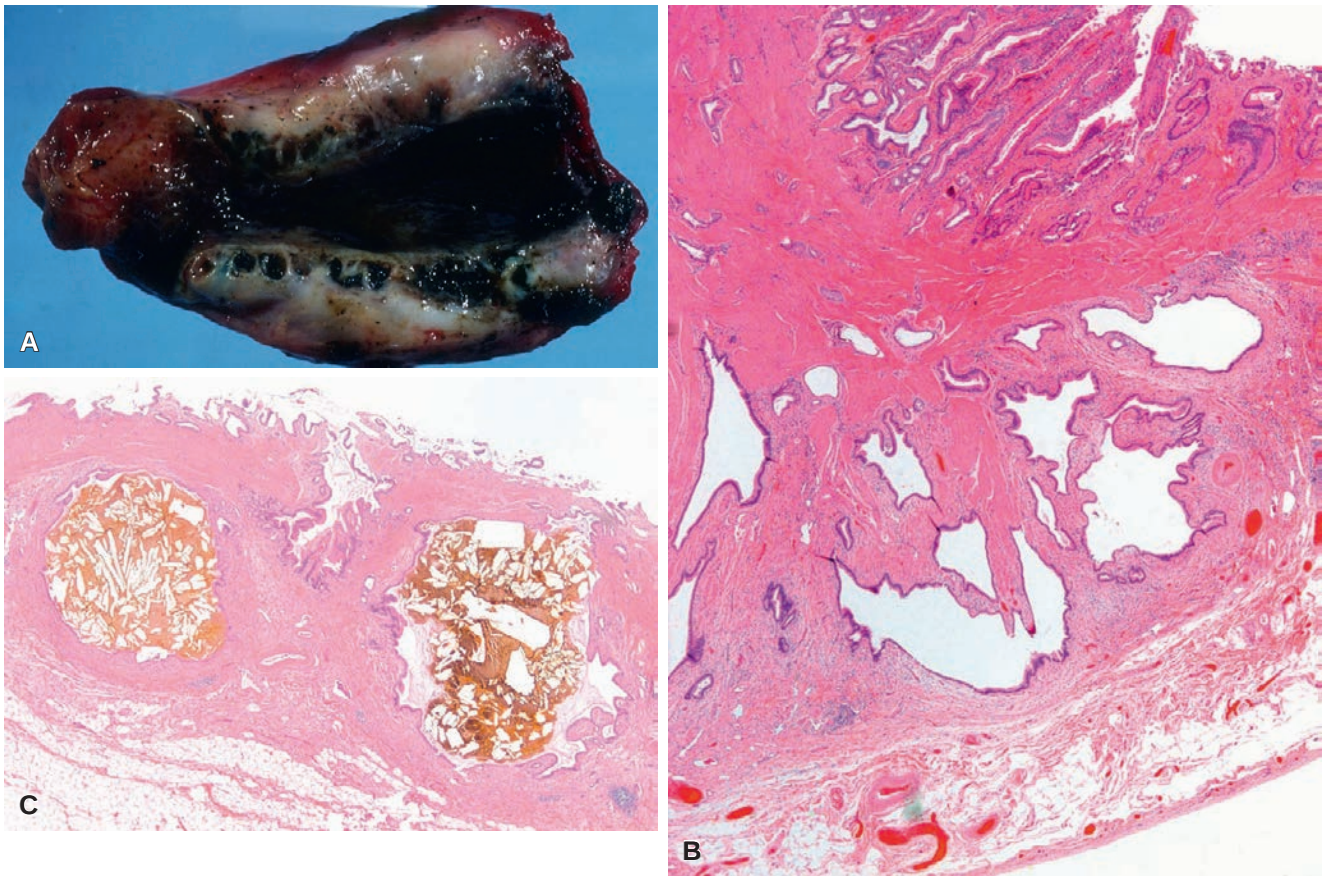

Figure 21.31 **A,** This gross specimen shows diffuse adenomyomatosis, characterized by a markedly thickened wall and grossly visible dilated glands filled with inspissated bile. **B,** This fundic adenomyoma shows hypertrophic, branching glands with prominent smooth muscle extending deeply into the wall of the gallbladder. **C,** Inspissated bile is a common finding. (**A,** Courtesy of Dr. George F. Gray Jr.)

the designation of neoplasm for discrete pyloric-type ICPNs that measure more than 1.0 cm and/or show obvious cytologic dysplasia.[137,138] These lesions are composed of tightly packed, small, pyloric-type glands with minimal stroma and no intracytoplasmic mucin. Squamous morules may be present,[138] and these lesions are characteristically MUC6 positive.[137] These lesions are infrequently associated with high-grade cytologic dysplasia or invasive adenocarcinoma, particularly if less than 1.0 cm.

A small minority of ICPNs resemble intestinal-type adenomas and have a similar CDX2+/CK20+ immunophenotype. As in the colorectum, the larger the lesion, the more likely that an area of dysplasia or carcinoma will be found. However, on the whole, they do not seem to represent an important precursor of gallbladder carcinoma (see next section). The frequent presence of *β-catenin* gene mutation in these lesions, but the rarity of this genetic change in gallbladder carcinoma provides, further evidence to support this observation.[139] Furthermore, *TP53*, *KRAS*, and *P16* mutations as found in gallbladder carcinomas are lacking in ICPNs.[140]

Flat/Nontumoral Preinvasive Lesions (Dysplasia/Carcinoma In Situ)

Unlike the mass-forming noninvasive neoplasms discussed above, flat (nontumoral) dysplasia is difficult to see grossly and often an incidental finding in cholecystectomy specimens. As in the stomach, it is believed that most cases of gallbladder adenocarcinoma are preceded by a sequence of intestinal metaplasia, dysplasia, and carcinoma in situ,[141–143] for which the term *biliary intraepithelial neoplasia* has also been suggested (Fig. 21.33A–C).[144] Flat dysplasia, like ICPNs, is also graded as low- or high-grade/carcinoma in situ. Because of the association between flat dysplasia and invasive carcinoma, extensive sampling of the gallbladder is required when dysplasia is found on initial sections. Intestinal metaplasia is also a very common finding in the gallbladder mucosa adjacent to both flat dysplasia and invasive adenocarcinoma (see Fig. 21.33D).[141,142] Flat dysplasia can have a totally flat or a papillary growth pattern and can consist of biliary, intestinal, or foveolar cell types; more than one cell type can be seen in a lesion. Interestingly, extension of dysplasia into Rokitansky–Aschoff sinuses is an adverse prognostic factor and predictor of recurrence (see Fig. 21.33E).[145] If flat dysplasia is detected in initial sections of a gallbladder, the remainder should be extensively sampled to exclude an adjacent adenocarcinoma (see Fig. 21.33E).

Overexpression of p53 and loss of heterozygosity in chromosome 5q have been found in gallbladder dysplasia, suggesting that they represent early events in the evolution of gallbladder carcinoma.[146,147] *KRAS* mutations and MSI have not been shown to play important roles in gallbladder dysplasia and carcinogenesis.[148]

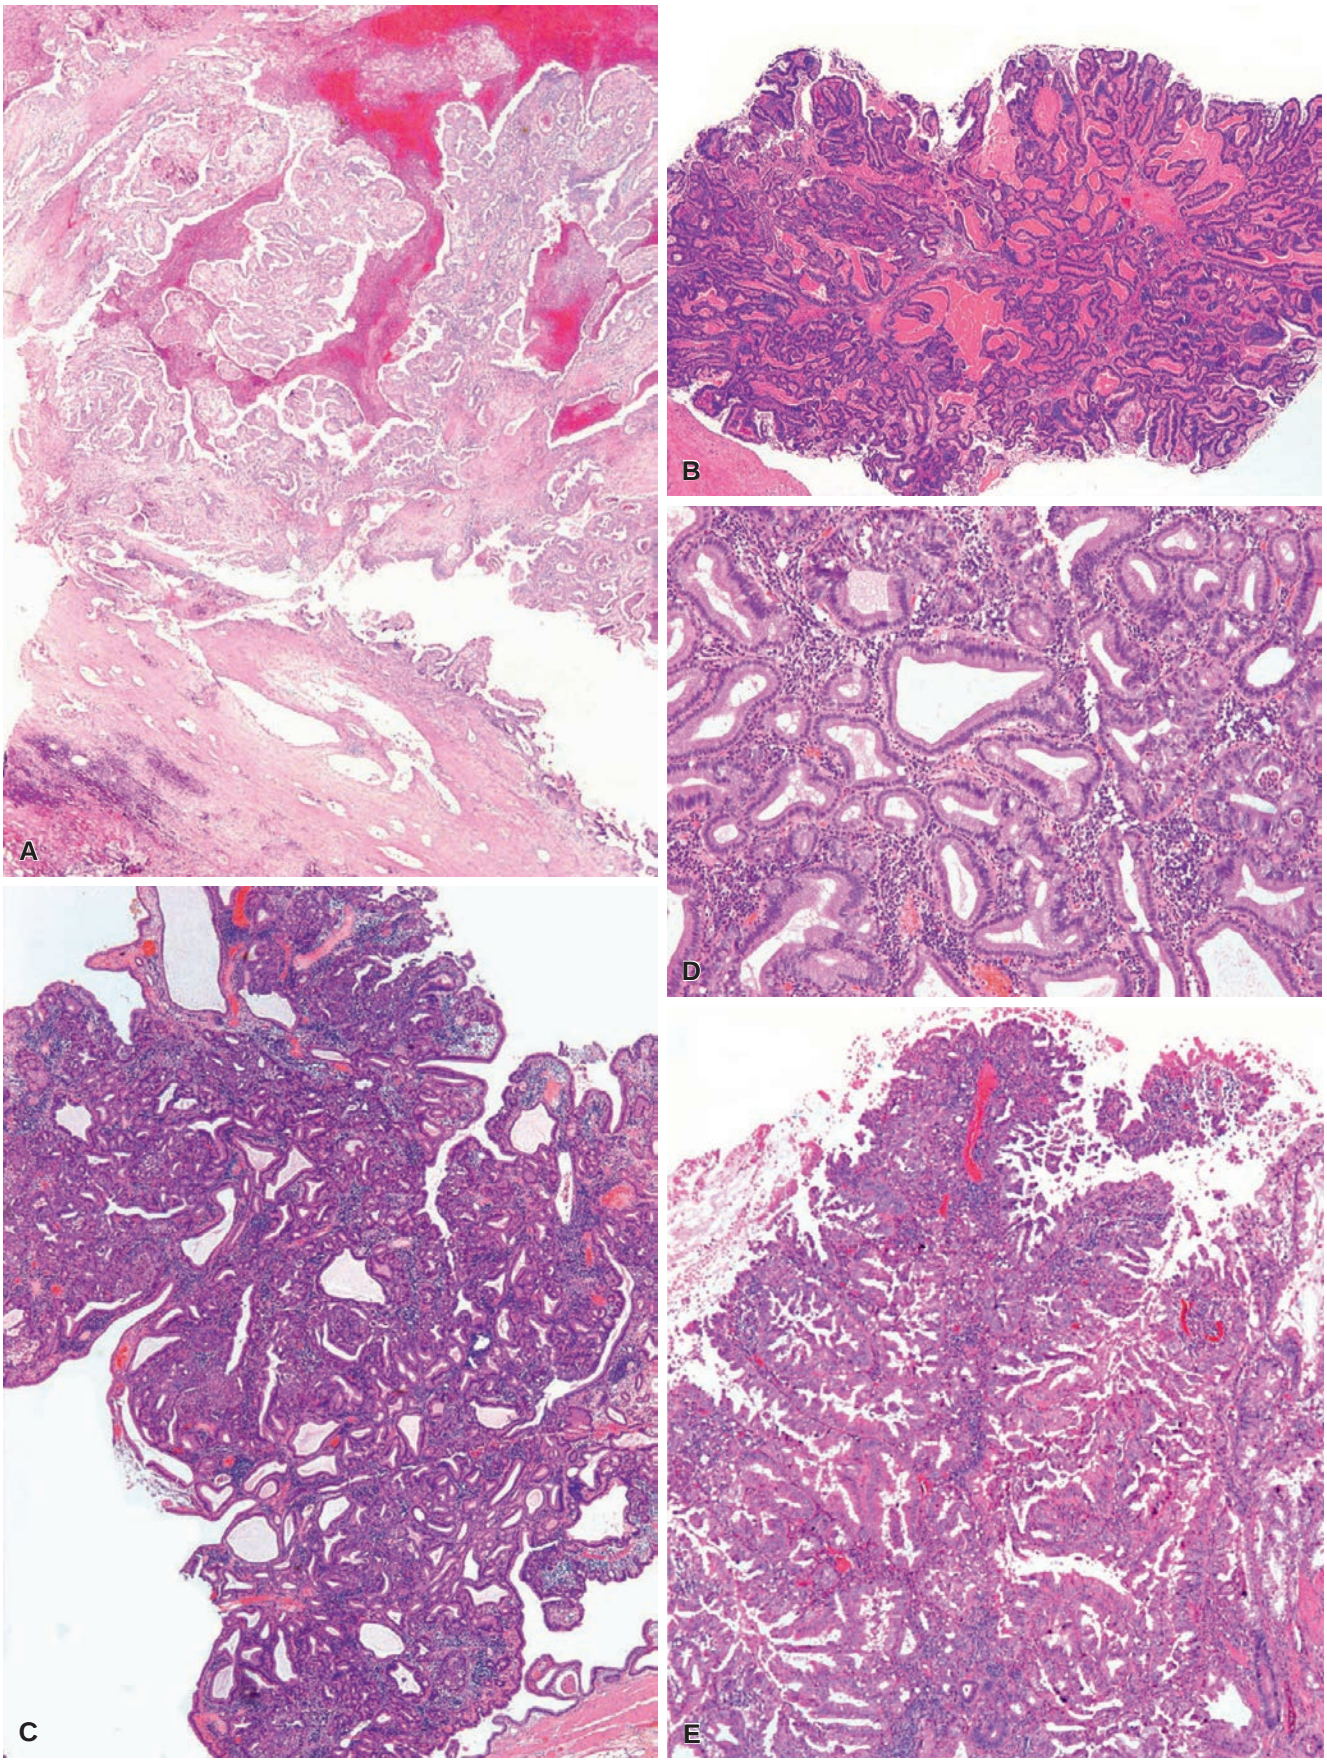

Figure 21.32 **A** and **B,** Intracholecystic papillary-tubular neoplasms (ICPNs) show a wide spectrum of papillary and tubular patterns and are often detached from the underlying gallbladder mucosa when the specimen is opened. The case illustrated in **B** would likely have been called an adenoma using previous terminology. **C** and **D,** This large ICPN has a gastric or pyloric cell type. **E,** This papillary lesion contained extensive high-grade dysplasia/carcinoma in situ and consisted of a mixture of cell types.

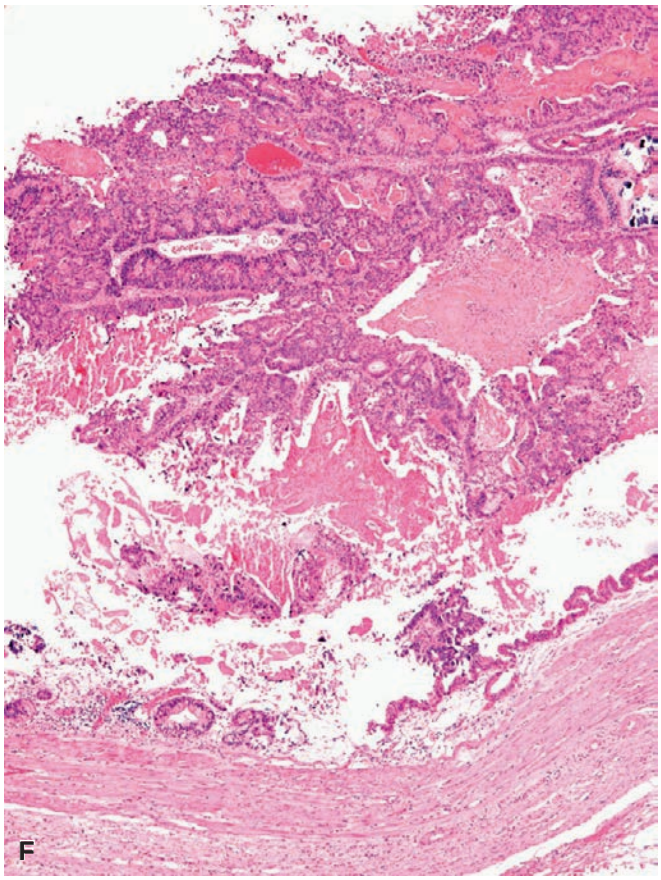

Figure 21.32, cont'd **F,** This ICPN also contains extensive high-grade dysplasia/carcinoma in situ; the original cell type is difficult to discern given the extensive dysplasia.

Carcinoma of the Gallbladder

General and Clinical Features

Adenocarcinoma of the gallbladder represents 80%–95% of biliary tract cancers.[148,149] Carcinoma of the gallbladder is more frequent in females than males (3–4 : 1 ratio), and over 90% of the patients are 50 years of age or older at the time of diagnosis.[148,149] It is much more common in some Latin American countries and parts of Asia than in the United States. In the United States, there is a concentration of cases in the southwest, north central, and Appalachian regions, and the incidence is high in Native Americans, relatively low in whites of European extraction, and very rare in blacks.[149,150] In Europe, the rate is very high in Germany and surrounding central countries, low in Mediterranean countries, and low and declining in Britain and Ireland.[149,151]

A definite epidemiologic parallel exists between gallbladder carcinoma and cholelithiasis, but the pathogenetic relationship between them remains controversial.[149] In the non-Native American, non-Hispanic population of the United States, the incidence of carcinoma in gallbladders with lithiasis is less than 1%.[149,152]

Other conditions said to be associated with an increased risk of gallbladder carcinoma are cholecystoenteric fistula, porcelain gallbladder, PSC, obesity, segmental adenomyomatosis,[153] familial adenomatous polyposis/Gardner syndrome,[154] and anomalous connection between the common bile duct and the pancreatic duct.[155] Many of the latter cases present at an advanced stage. Although almost half of gallbladder carcinomas are found incidentally at cholecystectomy, the most common clinical manifestations of gallbladder carcinoma are right upper quadrant abdominal pain and anorexia, and the most common abnormal laboratory finding is elevated alkaline phosphatase level.[156,157]

Gross Features

Grossly, gallbladder carcinoma may present as a diffusely growing (70%) or nodular, polypoid, or papillary mass (30%) mass (Fig. 21.34A–D).[158,159] When diffuse, the gross distinction from chronic cholecystitis may be difficult (see Fig. 21.34E and F); it is also important to note that a significant minority of gallbladder cancers (up to 30%) are not apparent grossly,[159] indicating the need for microscopic examination of every excised gallbladder. The vast majority arise in the fundus (70%–80%), with approximately one-third arising in the body and the remaining 10% in the neck.[159] Gallbladders with carcinomas usually also contain calculi (80%–90% of the cases) and exhibit marked fibrosis of the wall. The latter may represent a reaction to the tumor or the expression of a preexisting chronic cholecystitis. We (Dr. Juan Rosai) have seen several patients in whom an unexpected metastatic tumor was found in the liver sometime after the removal of a gallbladder thought to have only lithiasis and inflammation on gross examination by the surgeon and therefore discarded.

Microscopic Features

Microscopically, more than 90% of gallbladder cancers are adenocarcinomas, showing varying degrees of differentiation. Most tumors

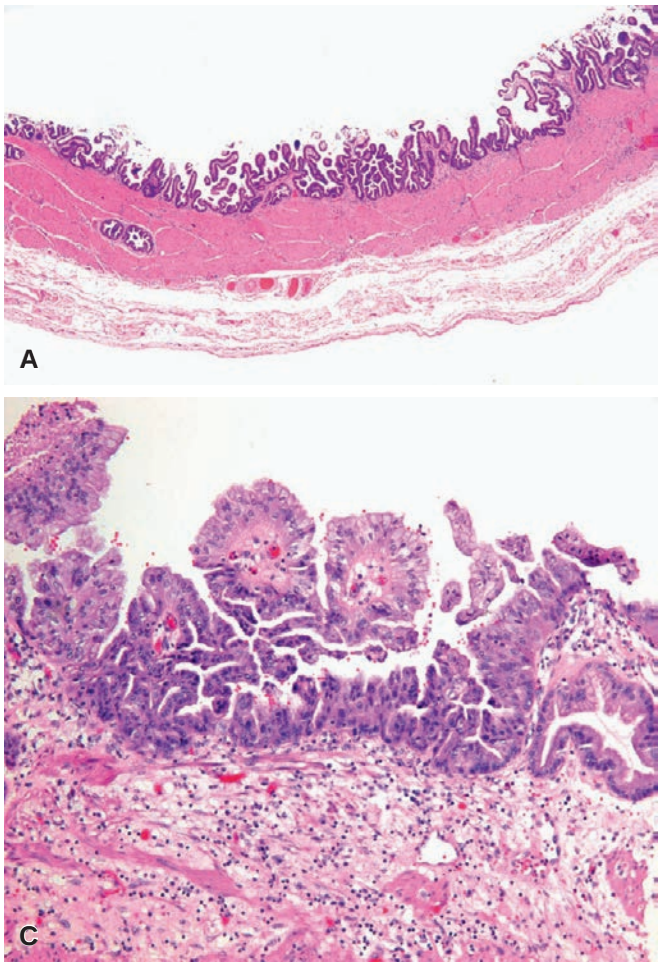

Figure 21.33 **A,** Flat dysplasia can have a flat or papillary growth pattern; the latter is seen here. Note involvement of a Rokitansky–Aschoff sinus. **B,** Flat, low-grade dysplasia with elongated, hyperchromatic, pseudostratified cells but no architectural complexity or loss of nuclear polarity. High-grade dysplasia in flat dysplasia with a biliary phenotype **(C)** and intestinal phenotype **(D)**.

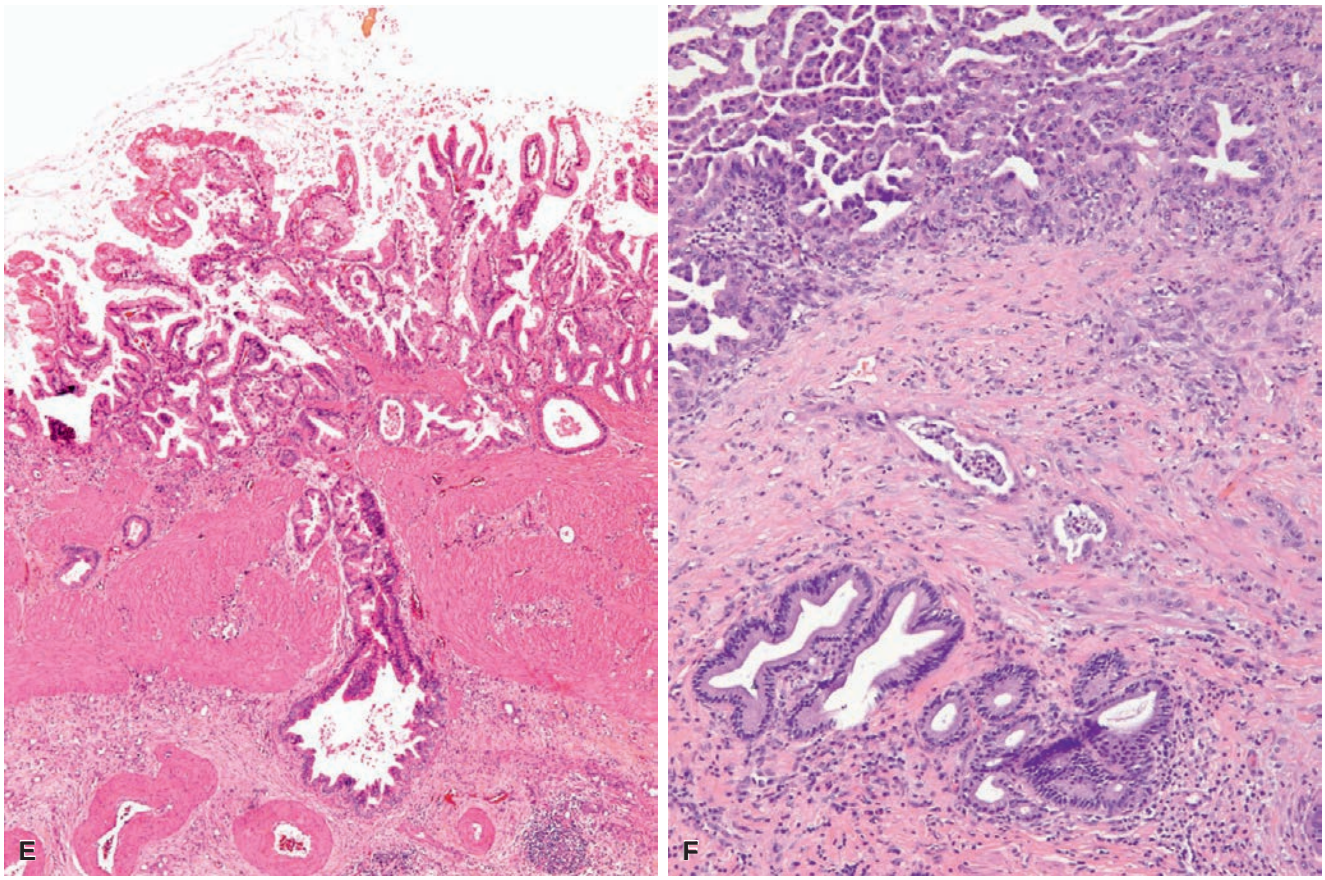

Figure 21.33, cont'd **E,** Extension of dysplasia into a Rokitansky–Aschoff sinus. **F,** Small focus of invasive adenocarcinoma arising beneath an area of flat dysplasia.

are of the pancreatobiliary type (Fig. 21.35A–E), having a morphologic appearance that is common to adenocarcinomas of the pancreatobiliary region—well-formed glands with wide lumina lined by one or a few rows of highly atypical cuboidal cells, surrounded by a dense cellular stroma often arranged concentrically.[158–160] It is characteristic for these glands to be well differentiated, or even atrophic-appearing, at an architectural level, but poorly differentiated at a cytologic level. The cytoplasm may be eosinophilic, or pale and almost clear or foamy. Sometimes the adenocarcinoma extends into Rokitansky–Aschoff sinuses in a manner analogous to endometrial adenocarcinoma extending into foci of adenomyosis; it is important not to misinterpret this finding as a sign of deep infiltration by the tumor.[161] Foci of perineurial invasion are common; however, as mentioned previously, the dilated glands of Rokitansky–Aschoff sinuses and adenomyomatosis may be seen in close approximation to nerves, simulating perineural invasion.[136]

As noted previously, *hyalinizing cholecystitis* is a recently proposed term for chronic cholecystitis featuring replacement of the gallbladder wall by dense hyaline fibrosis, typically with denuded epithelium.[84] Carcinomas are easily missed in these cases because of the thin, fibrous wall that lacks a discernible mass lesion. The malignant glands are typically widely spaced, well differentiated, and oriented parallel to the muscularis propria (Fig. 21.36A and B). The neoplastic epithelium may become markedly attenuated, leaving behind necrotic debris.

Other Microscopic Types

Tumors previous classified as noninvasive *papillary carcinomas* are now classified as ICPNs (see earlier). When there is an invasive component, it is typically pancreatobiliary and associated with a poor prognosis.[159,162] A micropapillary variant of gallbladder adenocarcinoma has also been recently described and, like those in other organ systems, is associated with aggressive behavior (Fig. 21.37).[163] *Adenosquamous carcinomas* of the gallbladder (Fig. 21.38) consist of both malignant glandular and squamous components (by definition, the squamous component must comprise 25%–99% of the tumor).[164] Pure *squamous cell carcinomas* are exceptional.

Mucinous adenocarcinomas are made up of more than 50% extracellular mucin (Fig. 21.39A),[159,165] and signet ring cells as well as clusters of neoplastic cells, including signet ring cells, can be seen floating in the mucin. These tumors are typically advanced at presentation and have a poor prognosis. *Clear cell* variants of adenocarcinoma have also been described,[159,166] which can mimic metastases from other clear cell neoplasms. *Signet ring cell* adenocarcinoma (see Fig. 21.39B) of the gallbladder[159,167] can mimic metastases from the breast and stomach and in turn can be mimicked by degenerative changes in mucosal goblet cells in cases of ulcerative cholecystitis.[168]

Occasionally, gallbladder adenocarcinomas are of *intestinal type* on morphologic, histochemical, and immunohistochemical grounds (Fig. 21.40A).[159,169] Patches of intestinal differentiation are frequent in pancreatobiliary gallbladder carcinomas as well (Fig. 21.40B), with the appearance of goblet cells, endocrine cells, and even Paneth cells[170]; in addition, differentiation may proceed along gastric foveolar lines. Sometimes the pattern of growth of the tumor is predominantly *cribriform*, closely resembling the appearance of the cribriform type of ductal carcinoma of the breast.[171]

Lymphoepithelioma-like carcinoma can be seen in the gallbladder or extrahepatic bile ducts; some of the cases were associated with

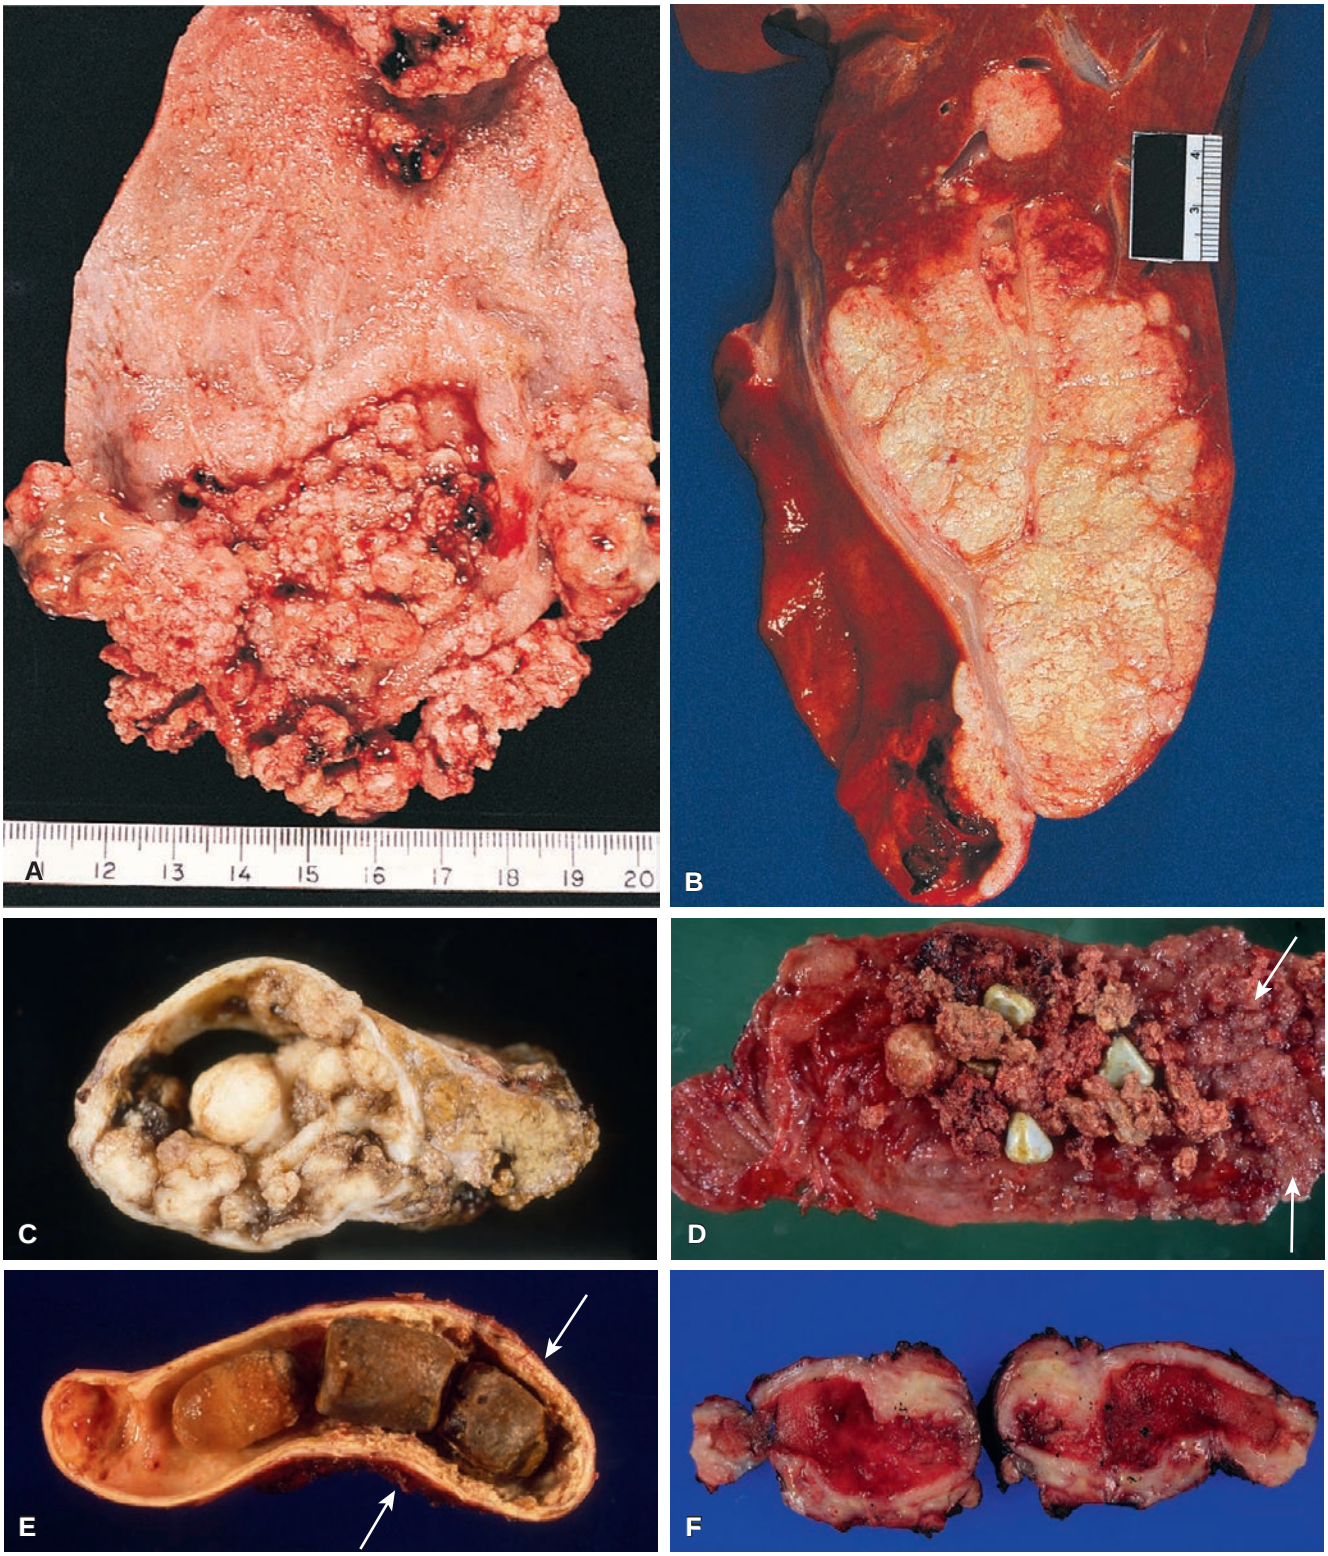

Figure 21.34 **A,** Grossly, gallbladder adenocarcinomas may have a polypoid, papillary, or diffuse configuration. This adenocarcinoma of the gallbladder has a predominantly papillary appearance. **B,** This tumor is growing in diffuse fashion in the distal wall of the gallbladder, associated with extensive involvement of the liver. **C,** This tumor has both polypoid and diffuse growth patterns; note the large polypoid tumor in the center, but the near-circumferential tumor visible around it. **D,** This tumor has a papillary component with admixed stones but a diffuse component indicated by the friable, thickened folds on the right *(arrow)*. It may be difficult to distinguish a diffuse pattern tumor from chronic cholecystitis. **E,** In this case, the adenocarcinoma appears as rough, thickened mucosa beneath three large stones *(arrow)*. **F,** The markedly thickened wall represents diffuse adenocarcinoma rather than chronic cholecystitis, and no distinct mass is easily identified. (**C–E,** Courtesy of Dr. George F. Gray Jr.)

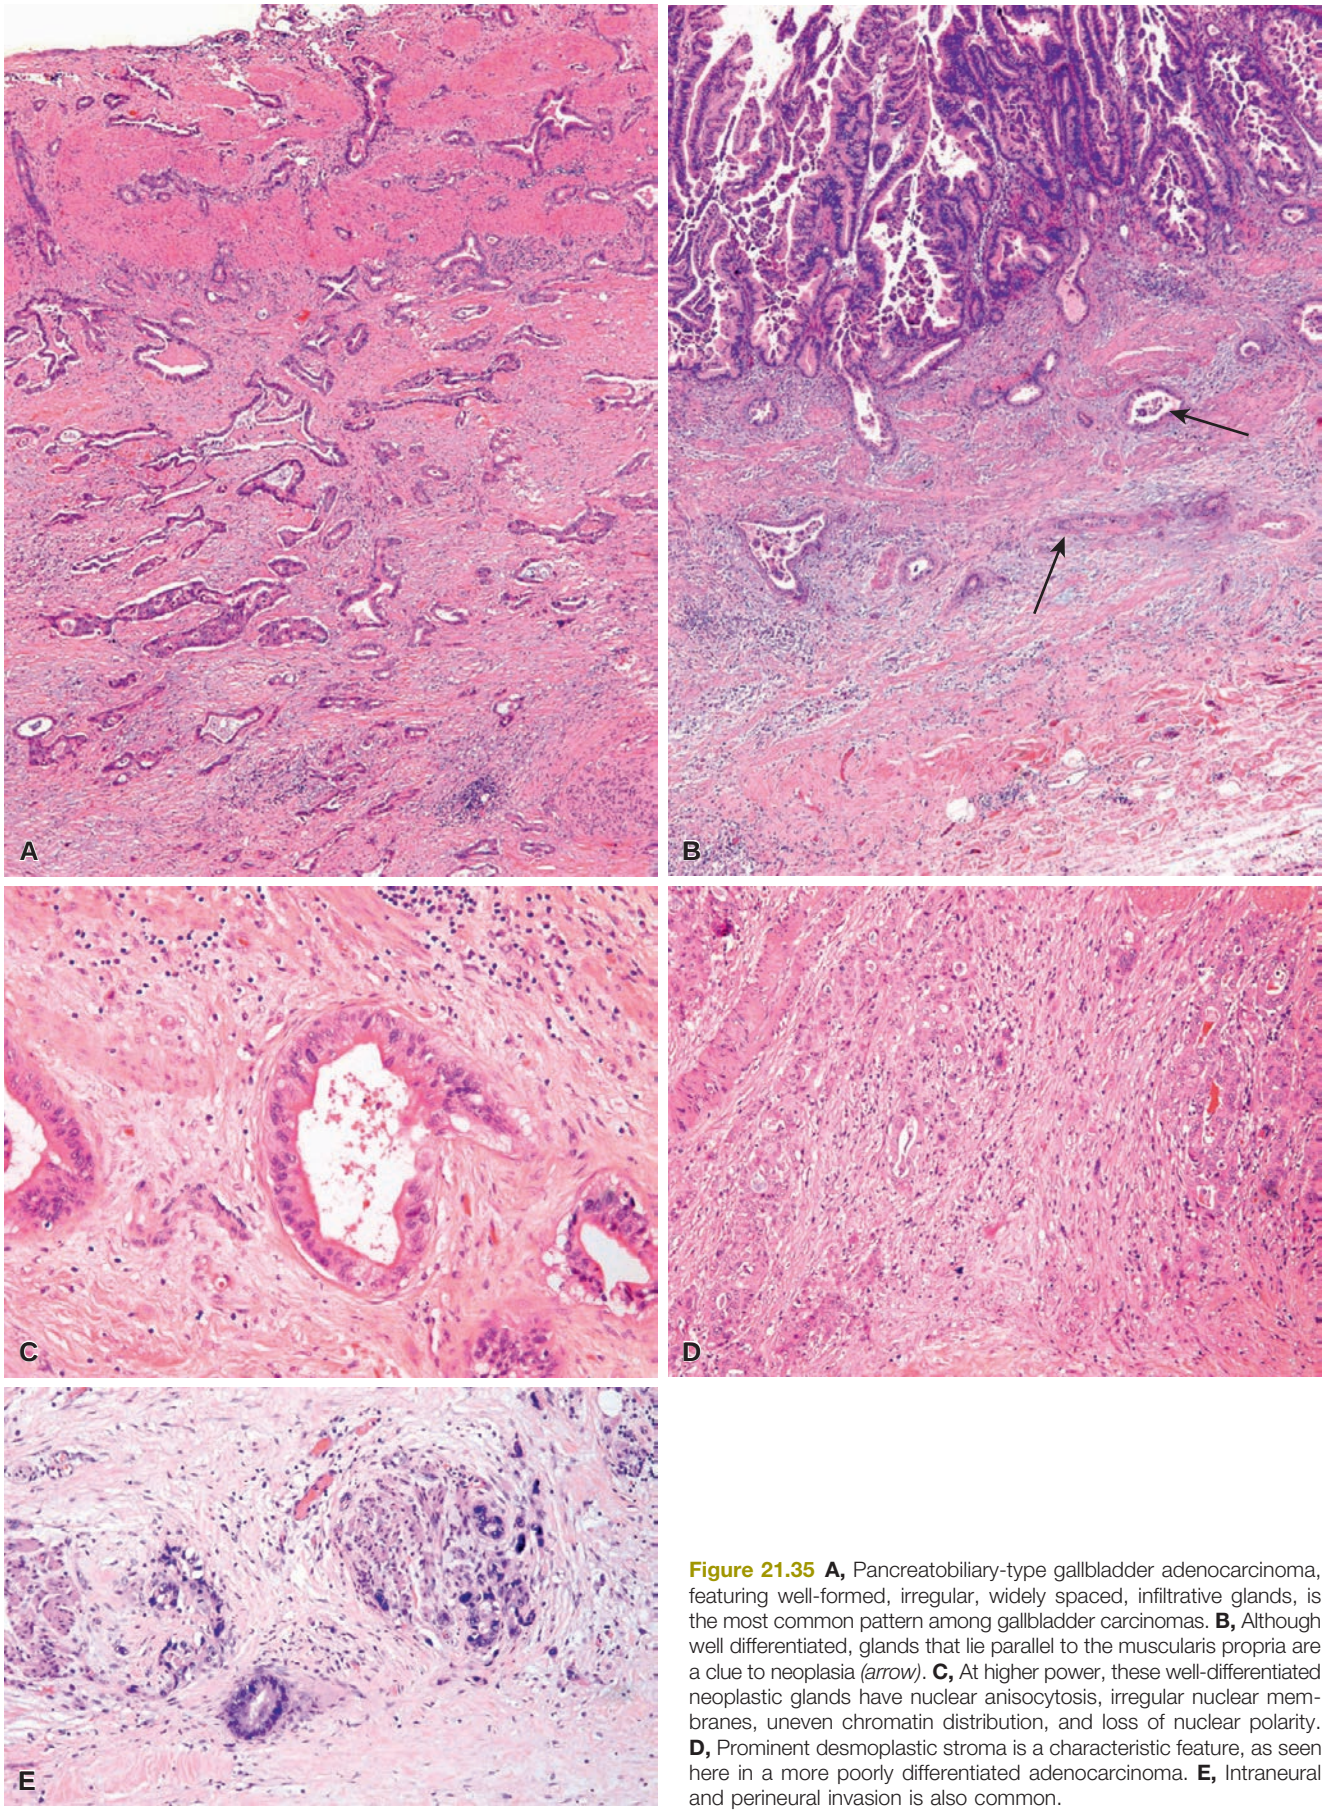

Figure 21.35 **A,** Pancreatobiliary-type gallbladder adenocarcinoma, featuring well-formed, irregular, widely spaced, infiltrative glands, is the most common pattern among gallbladder carcinomas. **B,** Although well differentiated, glands that lie parallel to the muscularis propria are a clue to neoplasia *(arrow)*. **C,** At higher power, these well-differentiated neoplastic glands have nuclear anisocytosis, irregular nuclear membranes, uneven chromatin distribution, and loss of nuclear polarity. **D,** Prominent desmoplastic stroma is a characteristic feature, as seen here in a more poorly differentiated adenocarcinoma. **E,** Intraneural and perineural invasion is also common.

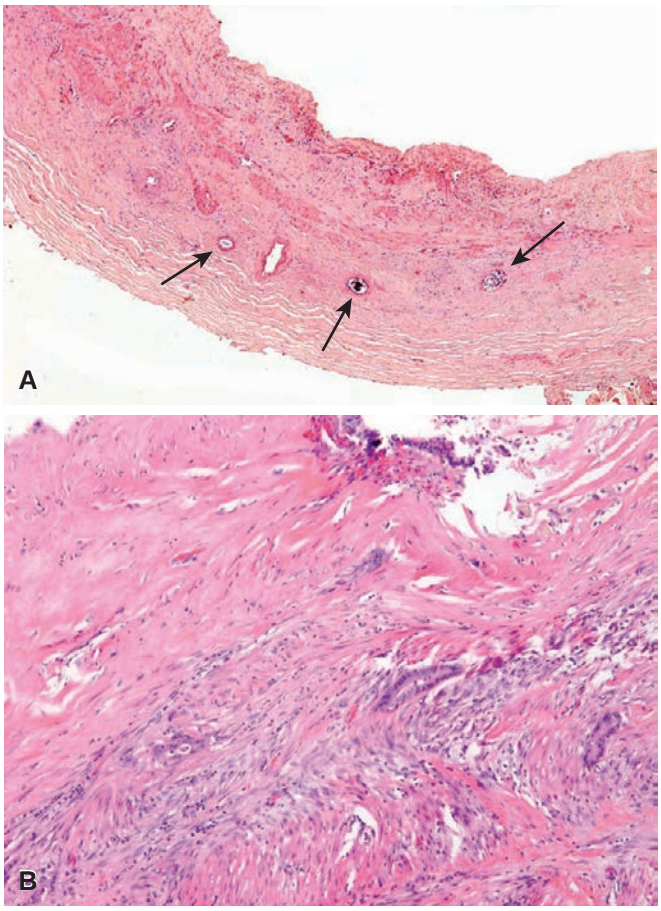

Figure 21.36 **A,** A low-power section from a case of hyalinizing cholecystitis with widely spaced, well-differentiated malignant glands with attenuated epithelium and prominent luminal debris *(arrows)*. Note that the overlying gallbladder epithelium is denuded. **B,** A higher-power view shows malignant glands lying parallel to the muscularis propria within densely hyalinized gallbladder wall.

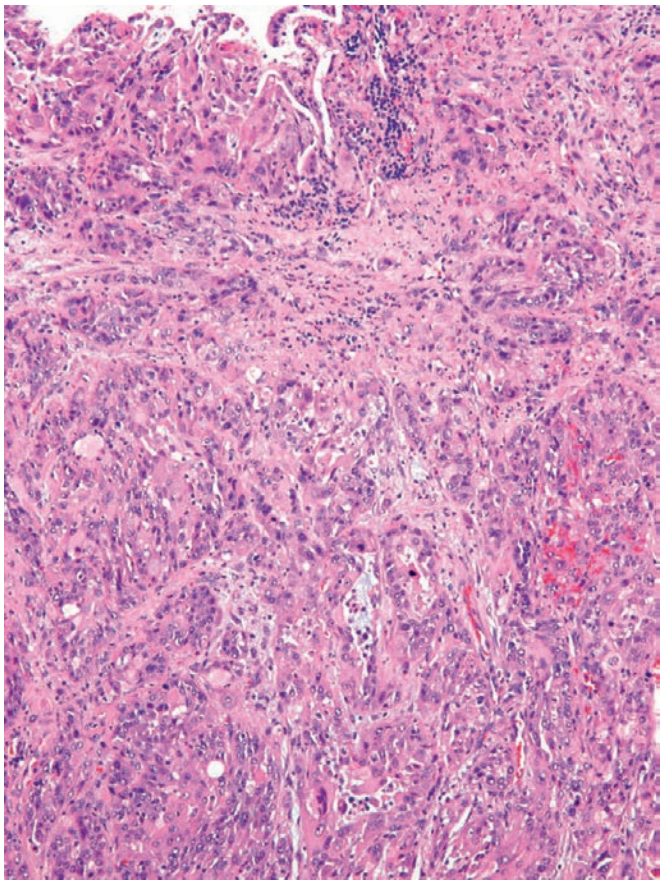

Figure 21.38 Adenosquamous carcinoma with overlying surface ulceration.

Epstein–Barr virus, but others were not.[172,173] *Undifferentiated (anaplastic, pleomorphic, spindle, sarcomatoid) carcinomas* (Fig. 21.41) are aggressive tumors that occur in various morphologic presentations (giant cell, spindle cell, pseudoangiosarcomatous), many of them closely simulating sarcomas (hence their alternative designation, carcinosarcoma, although most evidence suggests that the sarcoma-like component is also of epithelial derivation).[159,174–176] In exceptional cases, undifferentiated gallbladder adenocarcinomas or adenosquamous carcinomas have a component of osteoclast-like giant cells, similar to those seen more often in pancreatic adenocarcinoma.[159,177,178] Analogous to pancreatic tumors, the giant cells mark as histiocytes, whereas the undifferentiated tumors cells are epithelial. Other unusual types of gallbladder carcinoma include hepatoid adenocarcinoma, a rare variant that may closely resemble hepatocellular carcinoma morphologically and can express both alpha-fetoprotein (AFP) and hepatocyte antigen immunohistochemically; patients may also have an elevated serum AFP.[179,180] Adenocarcinoma with choriocarcinoma-like features has also been rarely reported; these tumors may be associated with β-hCG in the blood and urine.[181]

Neuroendocrine carcinomas (NECs) can manifest in the gallbladder with either a small or large cell phenotype; the former are morphologically analogous to the homonymous tumor in the lung and other sites (Fig. 21.42A and B).[182–186] These are highly aggressive neoplasms that metastasize early and cause death shortly after diagnosis. Mixed adenocarcinoma/NECs have also been described. As with adenocarcinomas in many other sites in the body, scattered neuroendocrine cells can be seen in conventional pancreatobiliary adenocarcinomas as well, but this has no clinical significance. Well-differentiated

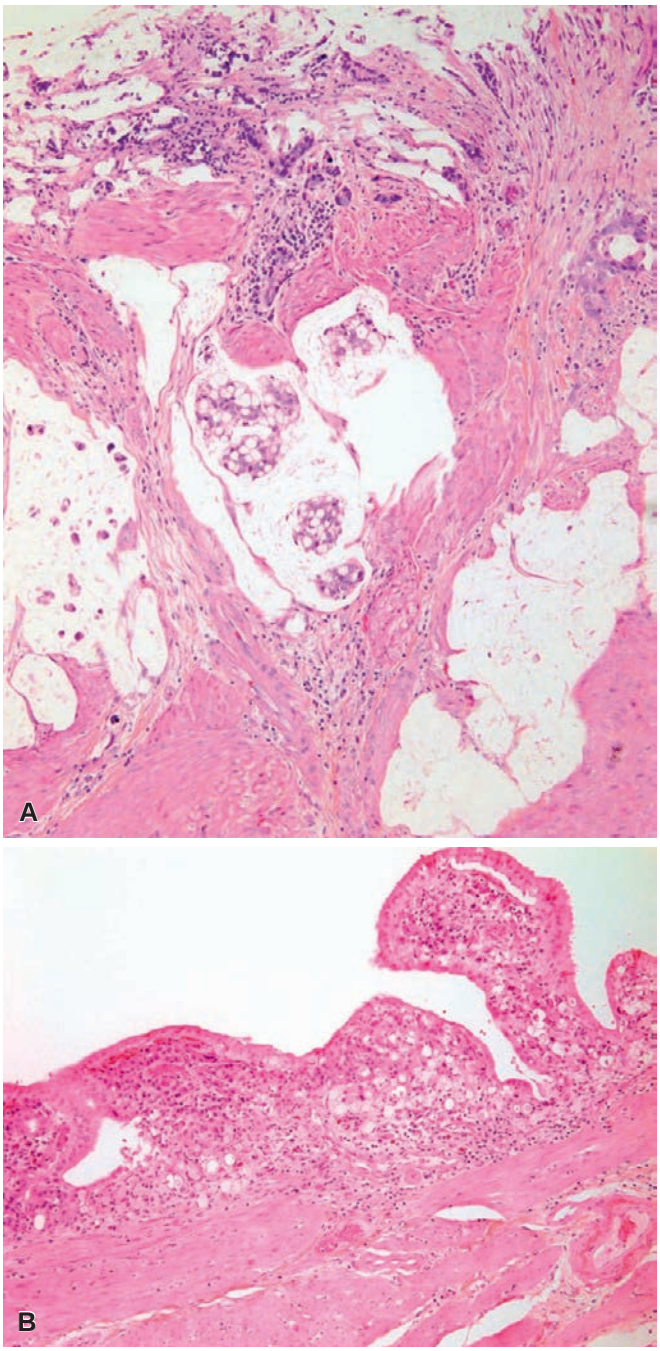

Figure 21.39 **A,** Mucinous adenocarcinoma of the gallbladder features abundant extracellular mucin. Clusters of malignant cells and individual signet ring cells float in the mucin. **B,** Primary signet ring cell carcinoma of the gallbladder. The majority of the malignant cells are in the lamina propria.

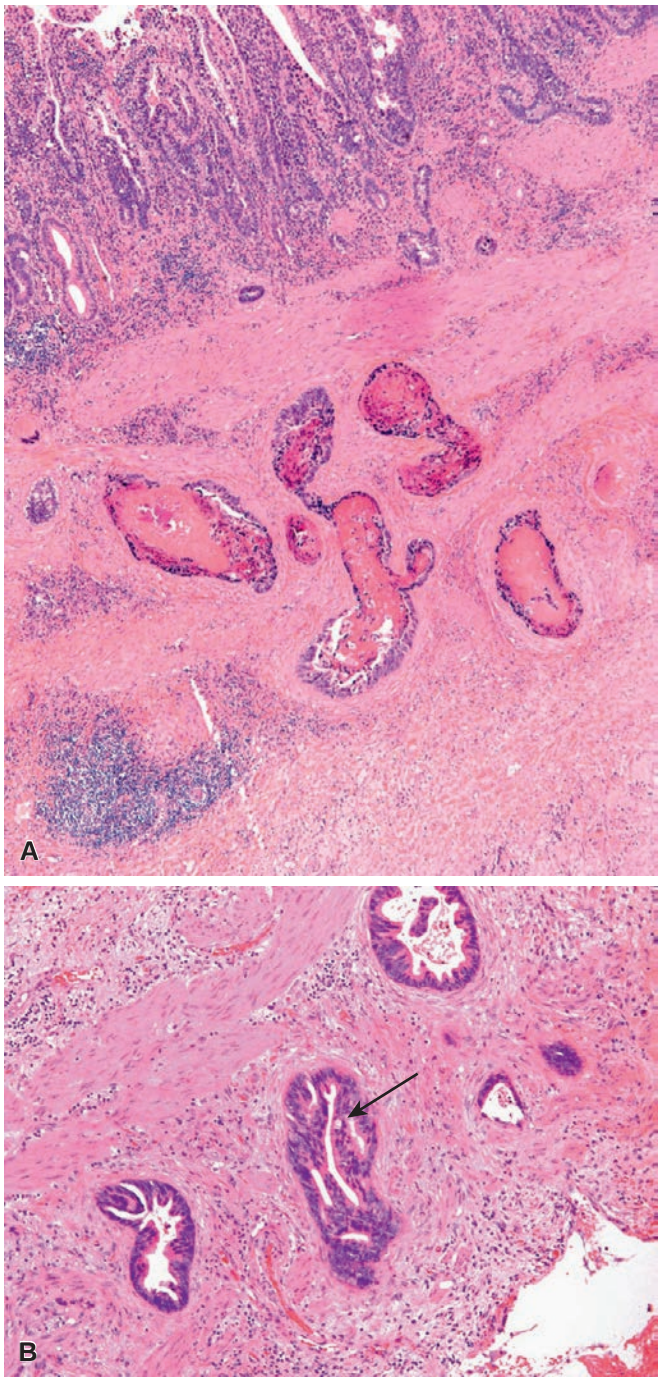

Figure 21.40 **A,** Adenocarcinoma of the gallbladder with intestinal features, including "dirty" luminal necrosis. Note the overlying dysplasia. **B,** This pancreatobiliary gallbladder carcinoma has both goblet cells *(arrow)* and a cribriform growth pattern in numerous foci.

neuroendocrine tumors (NETs) of the gallbladder *(carcinoid tumors)* also occur (Fig. 21.43A–C).[182,187] Clear cell NETs may be associated with von Hippel–Lindau disease but have also been described in patients who do not have it.[159,188]

Immunohistochemical Features

The usual keratin profile for carcinoma of the gallbladder and extrahepatic bile ducts is CK7+/CK20+, although the CK20 staining is often focal. In contrast, peripheral (intrahepatic) cholangiocarcinoma is usually CK7+/CK20–.[189,190] Other markers found in gallbladder adenocarcinoma include CK19, claudin-4, MUC1, CA19-9, and carcinoembryonic antigen (CEA).[159,191,192] A proportion of cases show CDX2 expression[193,194] but usually not as extensively and intensely as in colorectal carcinoma, and gallbladder adenocarcinomas may also express hepatocyte antigen.[193] Of note, the mucinous variant of gallbladder carcinoma is more likely to express CK7–, MUC5AC+, and MUC1–.[159]

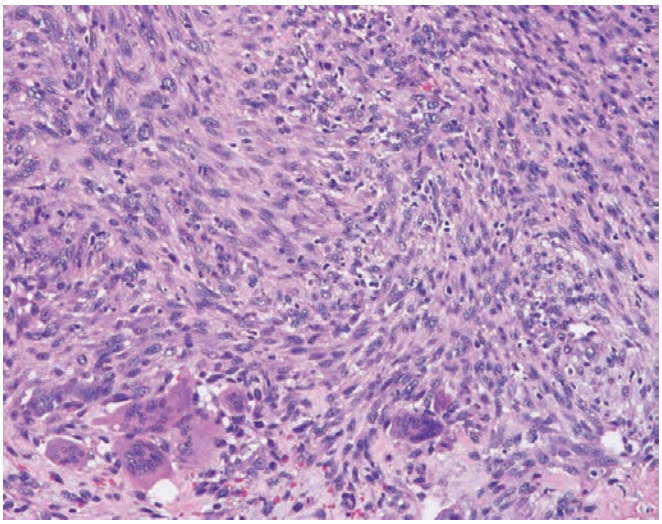

Figure 21.41 This undifferentiated adenocarcinoma shows a sarcomatoid epithelial component, along with scattered multinucleate giant cells. (Courtesy of Dr. Volkan Adsay.)

Molecular Genetic Features

Gallbladder carcinoma develops through accumulation of multiple genetic alterations, involving oncogenes, tumor suppressor genes, and DNA repair genes.[149,158,159] *KRAS* mutations have been reported with highly variable frequencies, ranging from less than 10% to over 60%,[158,159] and this phenomenon appears to be particularly prevalent in gallbladder carcinomas associated with anomalous arrangement of the pancreaticobiliary duct.[149,195] The demonstration of *KRAS* mutations does not appear to have prognostic significance, however.[196] HER-2/neu overexpression or gene amplification is seen in 10%–70% of gallbladder cancers, but this does not appear to correlate with prognosis.[158,159,197]

Among tumor suppressor genes, inactivation of *TP53* with associated accumulation of p53 appears in over 50% of cases.[158,159,198,199] This is more common in high-grade tumors.[200] Loss of fragile histidine triad expression is also common (75%) and may be an early event in gallbladder neoplasia.[159,201]

Other common molecular alterations include *p16* inactivation, telomerase activation, and mutations in cyclin D1, as well as a wide variety of other genes.[158,159,202] Microsatellite instability is present in approximately 10% of cases.[158,159] Despite this large number of identified molecular abnormalities, no clear model of carcinogenesis has been elucidated, and no promising molecular therapeutic targets exist as of yet.

Spread and Metastases

Gallbladder carcinoma has a great propensity to invade the liver directly,[203] and to less extent the stomach and duodenum; it also metastasizes frequently to liver (often through the portal tracts), cystic and pericholedochal lymph nodes in the lesser omentum, and lymph nodes behind the first portion of the duodenum.[204–206] The frequency of lymph node involvement is highly dependent on the depth of invasion of the primary tumor.[207] Almost half of the patients already have metastatic disease at the time of surgery.[208] Ovarian metastases from carcinoma of the gallbladder may simulate primary tumors of the ovary.[209]

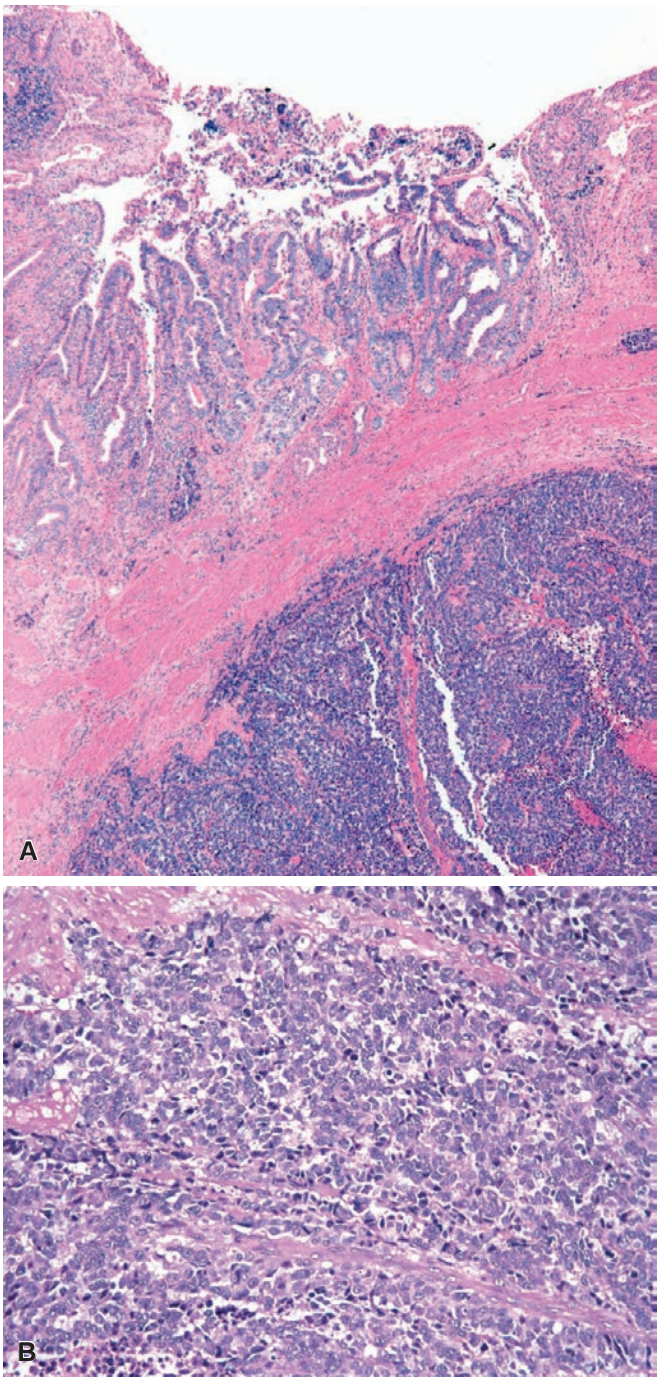

Figure 21.42 **A,** Neuroendocrine carcinoma of the gallbladder with overlying flat dysplasia. **B,** Higher-power view shows speckled chromatin, scant cytoplasm, and numerous mitoses. Synaptophysin and chromogranin were strongly positive.

Treatment and Prognosis

The treatment of gallbladder carcinoma is primarily surgical,[149,210–212] its extent depending on the stage of the disease. Current recommendations are simple cholecystectomy with negative margin for T1a disease (tumor limited to lamina propria). Some authors have advocated for more radical surgery for tumors in which the carcinoma involves Rokitansky–Aschoff sinuses, as this may portend a

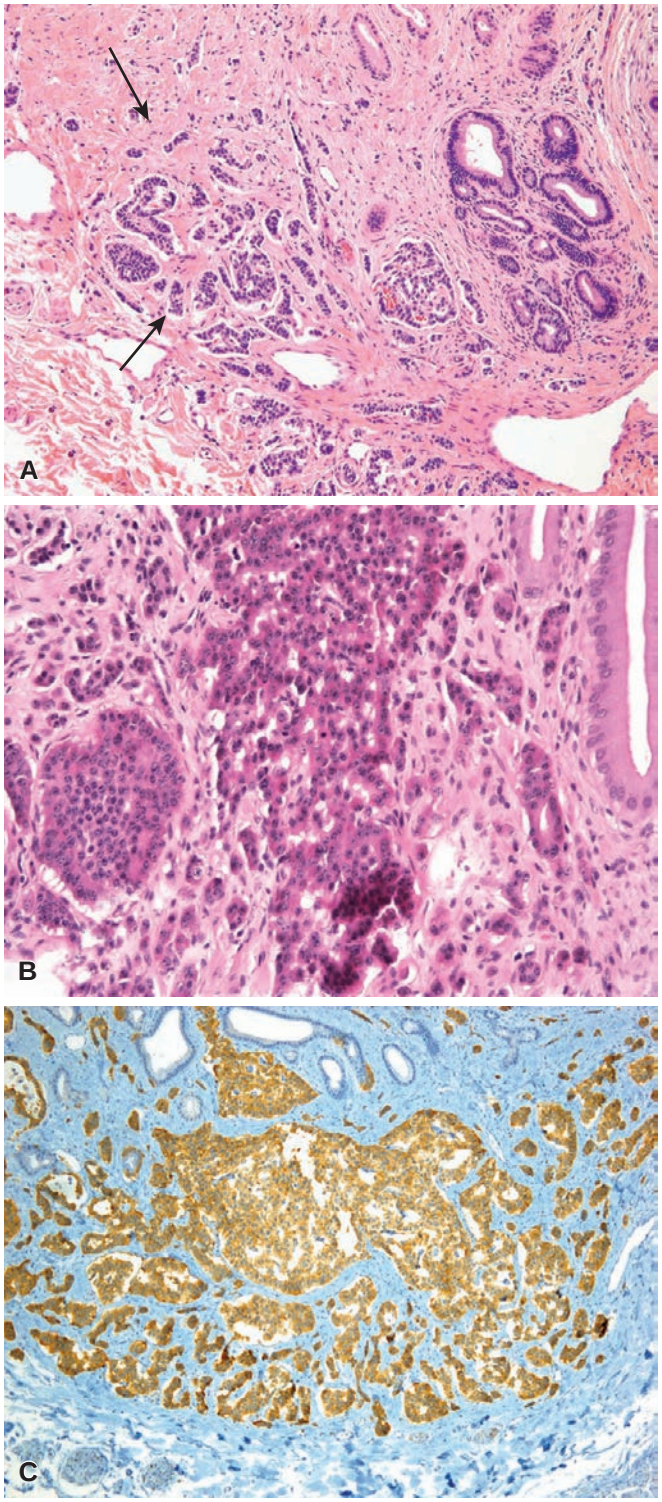

Figure 21.43 **A,** Incidental well-differentiated neuroendocrine tumor (carcinoid, *arrows*) within gallbladder wall. **B,** Another case, at higher power, shows uniform cells with a "salt and pepper" chromatin pattern. **C,** Synaptophysin highlights the tumor cells within the wall of the gallbladder.

worse prognosis.[145] Given the higher rate of lymph node metastases and tumor recurrence in T1b tumors (invasion of muscular wall), the treatment is more controversial, and some recommend more radical resection with lymph node dissection. T2 tumors (involving perimuscular connective tissue) are typically treated with radical cholecystectomy and lymphadenectomy. T3 (tumor penetrates visceral peritoneum or invades an adjacent structure) may be treated with radical surgery on a case-by-case basis, depending on resectability and the patient's fitness for surgery. T4 disease is treated palliatively. The importance of a systematic dissection of the various lymph node groups has been emphasized.[212] Historically, chemotherapy has been of limited benefit, although there is a growing opinion in favor of adjuvant chemotherapy in biliary tract carcinomas. Regardless, progression-free survival is typically measured in months,[213] and radiotherapy has shown survival benefit at the 1-year but not the 5-year mark in some studies.[149] Port site recurrences following laparoscopic cholecystectomy are a major concern and are reported in 14%–29% of patients within 6–10 months. These patients have a very poor prognosis (1-year survival of <30%); however, port site excision does not appear to improve survival.[214]

A number of factors have been evaluated as possible predictors of prognosis in gallbladder carcinoma. As in most other organs, the stage of the tumor is the most important prognostic determinant. The 5-year survival rate approaches 100% for T1a disease; however, very few cases are diagnosed at that early stage. Five-year survival in T1b disease is more variable, depending on the aggressiveness of the surgical procedure (see earlier) and ranges from 37.5% to 100%. The 5-year survival drops to 58%–70% for T2 disease and is 23% and 0%–12% for T3 and T4 disease, respectively.[214–216] By the time the diagnosis of carcinoma of the gallbladder can be made clinically, the tumor is advanced and usually inoperable (stage V).[216] Under such circumstances, the chances of cure—even after heroic surgical measures—are minimal, although some recent studies advocate for more radical surgical procedures in patients with advanced stages of gallbladder cancer.[215] The best possibility of cure is when the cancer is found incidentally by the pathologist on gross or microscopic examination.[217,218] Most such cases are stage I or II disease. Positive margin status, lymph node metastases, and moderate to poor tumor grade have unsurprisingly also been associated with a poorer prognosis.[219] A number of molecular targets have been evaluated as potential prognostic and therapeutic markers in gallbladder adenocarcinoma, but none are currently widely accepted for clinical use.[220]

Tumors of the Extrahepatic Bile Ducts

Benign Tumors of the Extrahepatic Bile Ducts

Benign tumors of the extrahepatic bile ducts are exceptional. *Granular cell tumors* may occur anywhere along the intrahepatic and extrahepatic biliary system (Fig. 21.44).[221,222] As in other sites, they may be associated with pseudoepitheliomatous changes of the overlying epithelium. *Traumatic neuromas* occur most often after operations in the area[223]; their most common site is the stump of the cystic duct following a cholecystectomy. They may cause post-cholecystectomy pain or obstructive jaundice. There are also isolated reported cases of *neurofibroma* and *PEComa* involving the common bile duct.[224,225]

Tumoral Intraepithelial Neoplasms

Preinvasive mass-forming neoplasms of the biliary tract are referred to as tumoral intraepithelial neoplasms and include intraductal

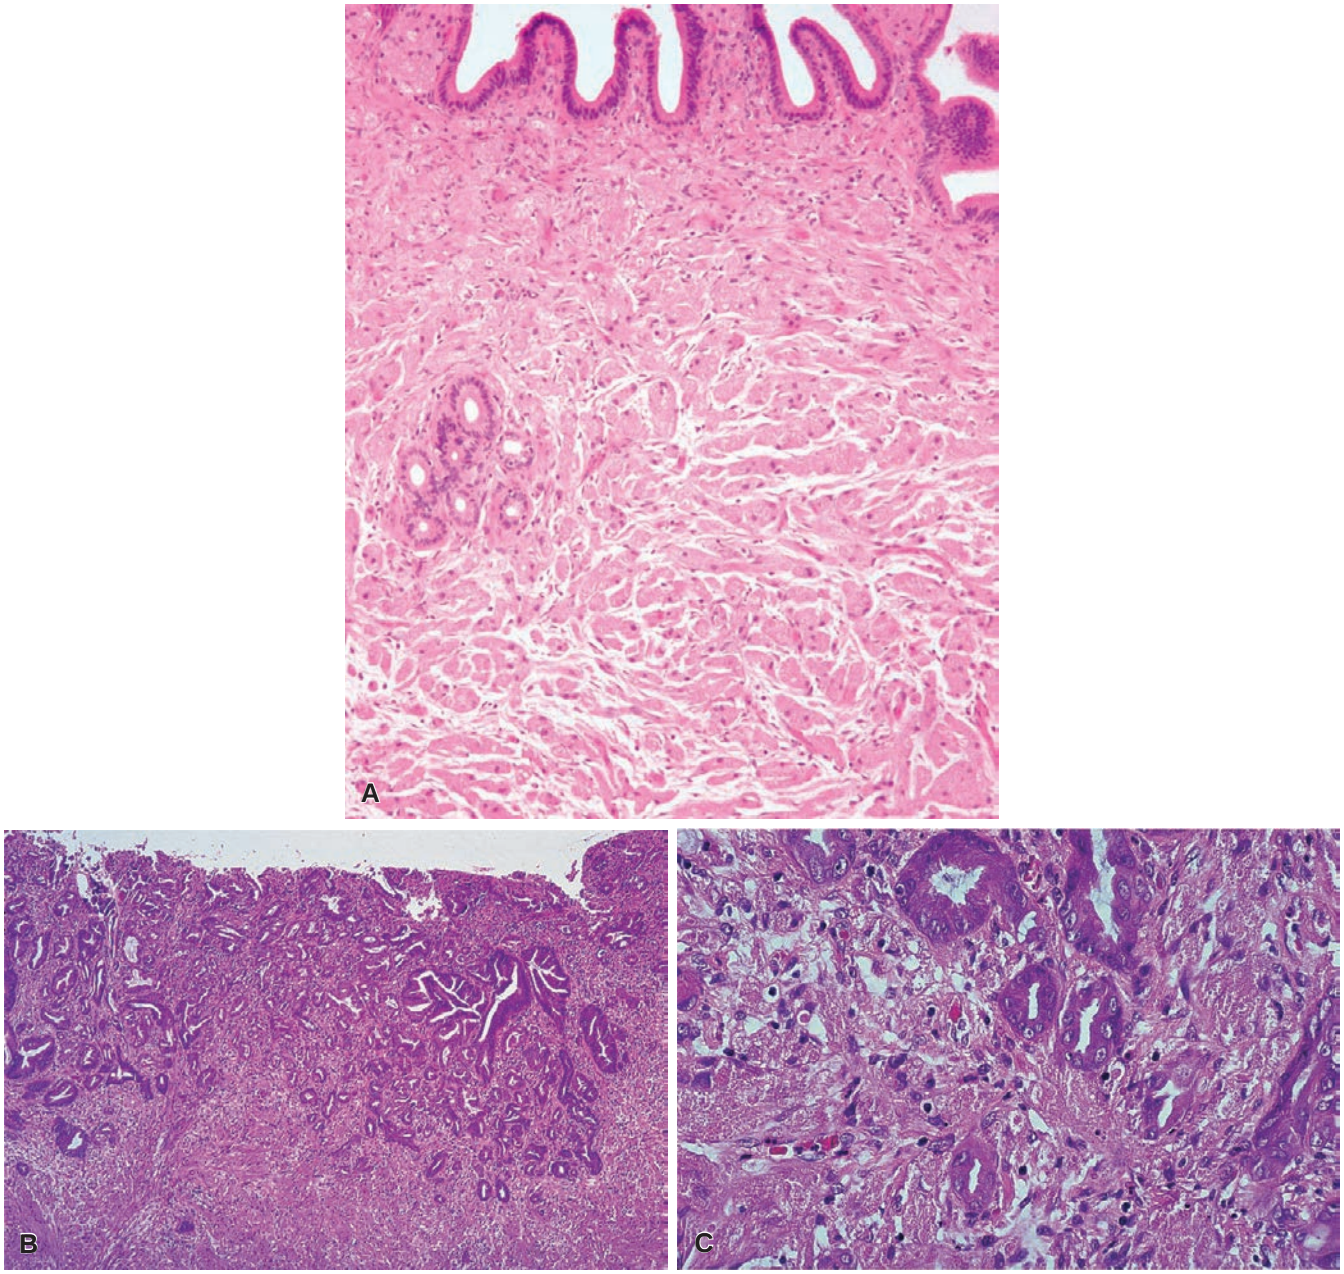

Figure 21.44 **A,** Granular cell tumor of the common bile duct from a young African-American woman. **B** and **C,** Some cases of granular cell tumor in the biliary tree are associated with hyperplasia of the overlying epithelium, similar to other organs. (**B** and **C,** Courtesy of Dr. Richard Eisen.)

papillary, tubular, and tubulopapillary neoplasms of the bile ducts as well as mucinous cystic neoplasms with ovarian-type stroma.[226–229] All of these neoplasms may show a spectrum of dysplasia ranging from low-grade to high-grade dysplasia/carcinoma in situ. The term intraductal papillary neoplasm of the bile duct (IPNB) encompasses those tumors previously designated papillary adenoma, papilloma, noninvasive papillary adenocarcinoma, and papillomatosis. The cell types are similar to homonymous lesions in the gallbladder (see earlier). High-grade dysplasia is common, and invasive components are often seen associated with these neoplasms (Fig. 21.45A–D). Tubular or tubulopapillary intraductal lesions are more commonly intrahepatic. The cystadenomas of the extrahepatic bile ducts resemble their more common hepatic, and pancreatic, counterparts.

Nontumoral (Flat) Dysplasia

These lesions are pre-invasive but also microscopic and flat, which distinguishes them from tumoral intraepithelial neoplasia. This spectrum of lesions is also known as biliary intraepithelial neoplasia, which is classified according to a three-tiered grading system.[144] Many pathologists continue to use a two-tiered grading system (low grade vs. high grade/carcinoma in situ), however. These lesions are typically incidental findings that are hard to detect grossly. As with their

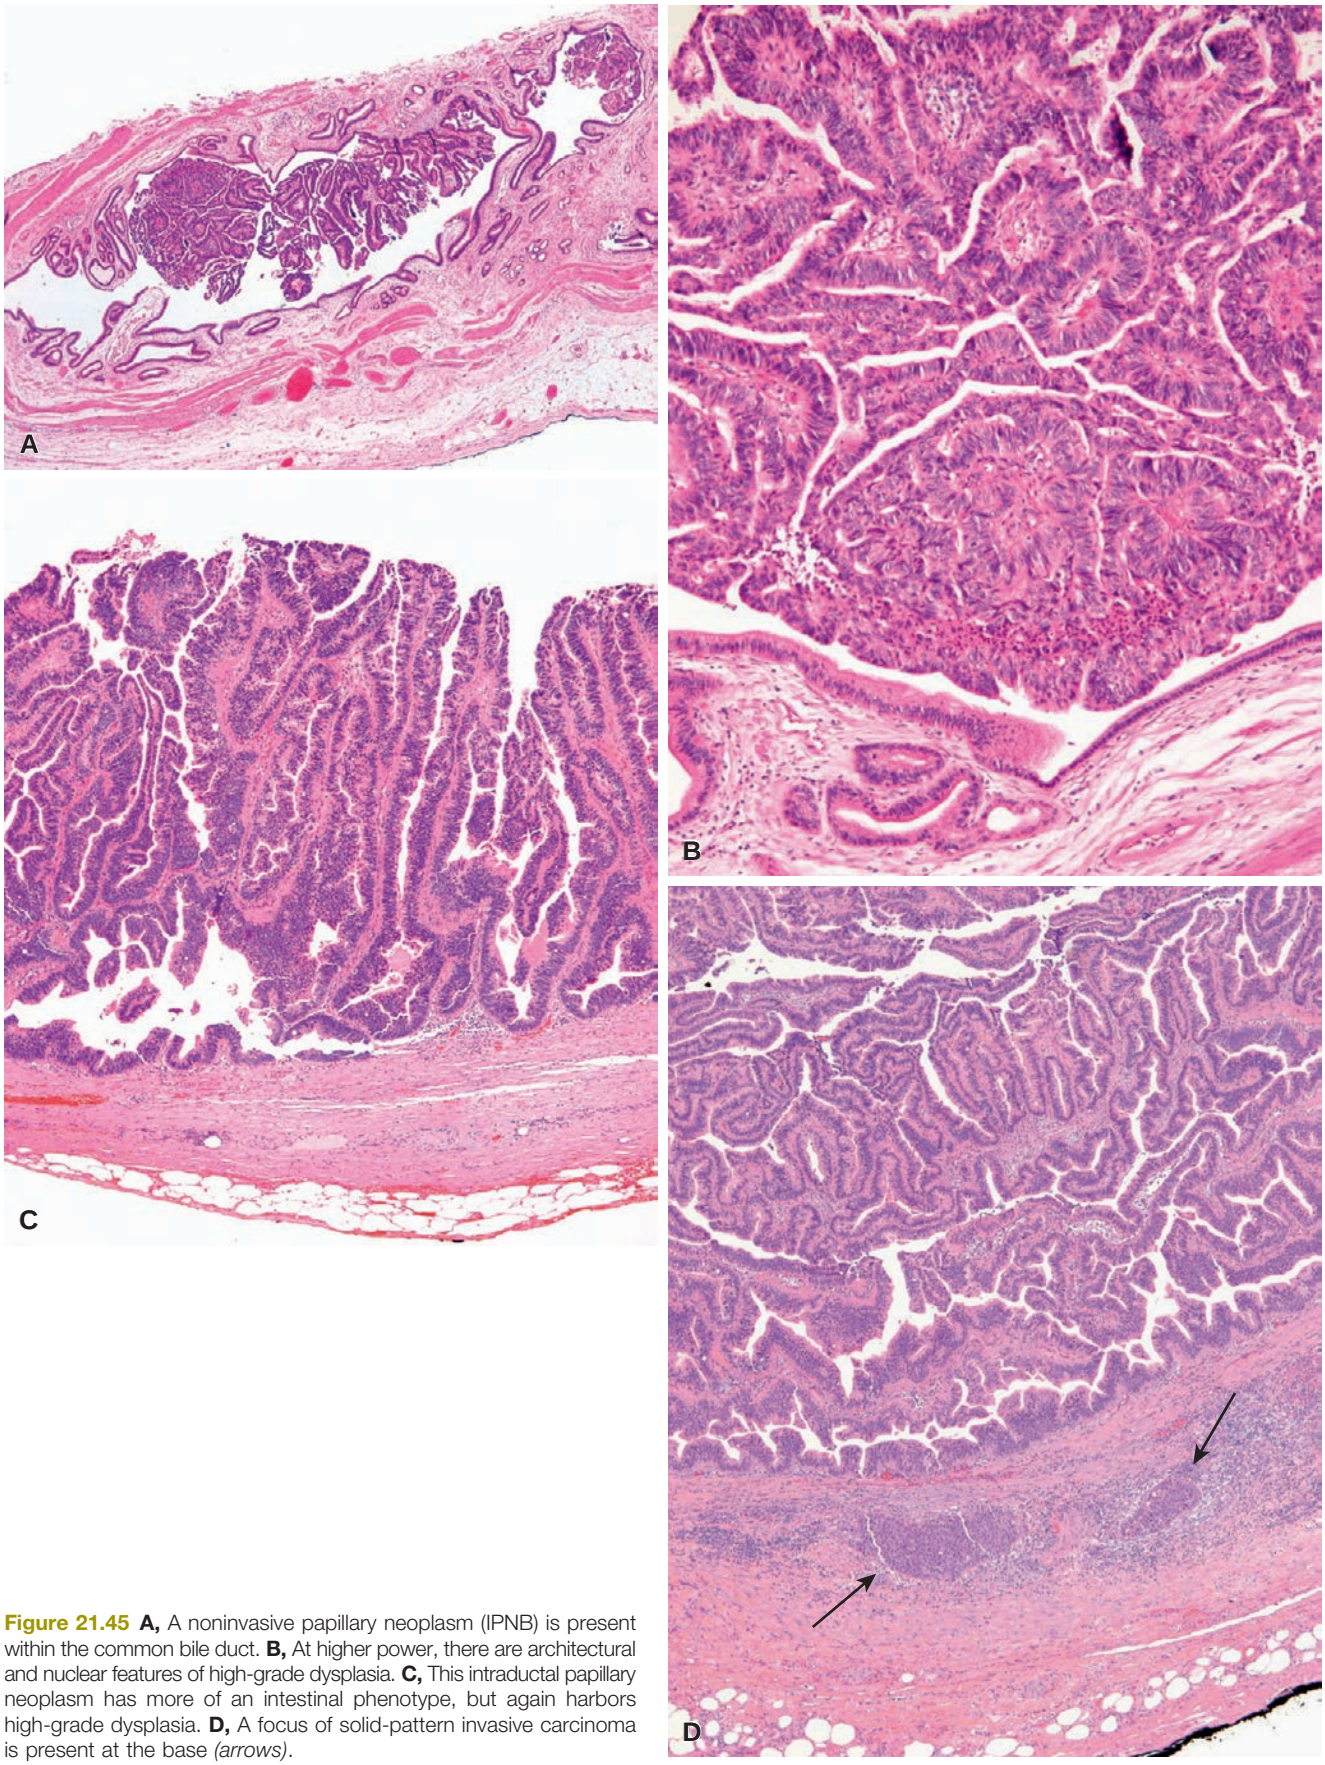

Figure 21.45 **A,** A noninvasive papillary neoplasm (IPNB) is present within the common bile duct. **B,** At higher power, there are architectural and nuclear features of high-grade dysplasia. **C,** This intraductal papillary neoplasm has more of an intestinal phenotype, but again harbors high-grade dysplasia. **D,** A focus of solid-pattern invasive carcinoma is present at the base *(arrows)*.

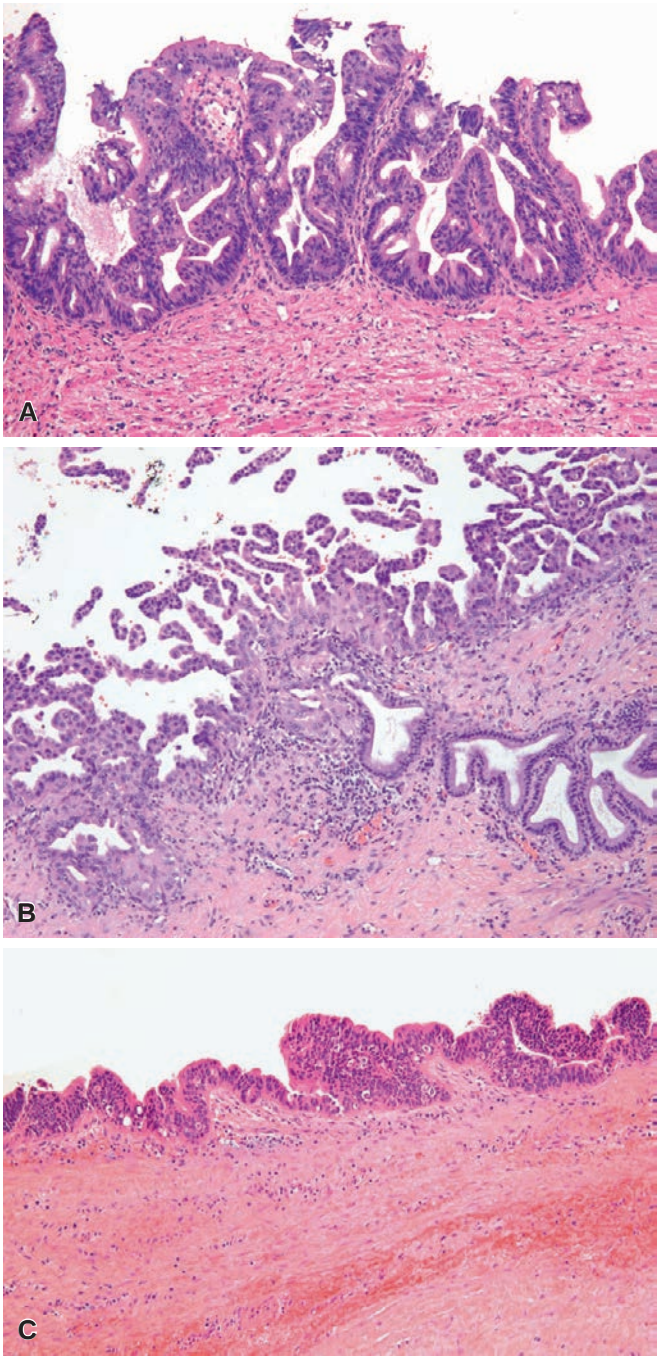

Figure 21.46 High-Grade Nontumoral Dysplasia. A, Although there are some small papillae, this lesion was found incidentally and did not form a mass. **B,** Another example shows fusion of the delicate epithelial projections, as well as oncocytic features. **C,** This example is virtually flat but shows enlarged, hyperchromatic nuclei with pseudostratification.

counterparts in the gallbladder, a number of cell types may be present (Fig. 21.46A–C). As these lesions are often found associated with invasive adenocarcinoma following resection, the natural history and risk implications are difficult to study. In many centers, high-grade dysplasia at a resection margin is cause for more extensive resection (if possible), whereas low-grade dysplasia at a margin is not. However, management of dysplasia at resection margins remains controversial.[230,231]

Adenocarcinoma of the Extrahepatic Bile Ducts

Bile duct carcinoma (cholangiocarcinoma) occurs with equal frequency in males and females[232] (in contrast with the female predominance for gallbladder carcinoma); the average age of presentation is 60 years. About 90% of patients present with jaundice. An increased incidence of this disease has been reported in patients with PSC,[233] *C. sinensis* infestation (see also earlier),[127,128] and in a variety of congenital abnormalities of the intrahepatic and extrahepatic bile ducts, such as congenital dilation of the bile duct (including choledochal cyst), Caroli disease, congenital hepatic fibrosis, and abnormal pancreaticocholedochal junction.[234–236]

These tumors can develop at any level of the biliary tree. They have been divided anatomically into those of the upper third, including the hilum (50%–75%); those of the middle third (upper half of the common bile duct, 10%–25%); and those of the lower third (distal half of the common bile duct, 10%–20%).[237,238] Brush cytology has a sensitivity of 45% and a specificity of 99% in the diagnosis of cholangiocarcinoma; intraductal biopsy has a similar sensitivity and specificity.[239] The use of fluorescence in situ hybridization may improve the sensitivity significantly.[240] Tumors arising from the intrahepatic bile ducts are discussed in this chapter and those located in the ampulla of Vater in Chapter 22.

Grossly, bile duct carcinomas can be polypoid and superficial, but most are nodular or sclerosing, with deep penetration into the wall (Fig. 21.47A).[241,242] Tumors previously classified as "papillary" carcinomas of the extrahepatic bile ducts predominantly represent intraductal tubular or papillary neoplasms (see earlier), or invasive adenocarcinomas associated with a prominent intraepithelial component. Occasionally, bile duct carcinomas are multicentric, accompanied by an extensive intraepithelial component,[243] or associated with carcinoma of the gallbladder.[242] Direct extension to the liver is common in upper third lesions (see Fig. 21.47B),[241,244] and distal lesions may involve the pancreas. Metastases to regional and peripancreatic nodes are also frequent; the lymph node groups most commonly affected are those around the lower portion of the hepatoduodenal ligament, the superoposterior pancreaticoduodenal group, and the superior mesenteric artery group.[245] Distant metastases to the ovary may develop and simulate primary tumors of this organ.[246]

Microscopically, the large majority of bile duct malignancies are well-differentiated pancreatobiliary-type adenocarcinomas similar to their counterparts in the gallbladder and pancreas (Fig. 21.48A). Bile duct carcinomas can be so well differentiated—even in metastatic sites—as to make their identification as malignant very difficult. Heterogeneity of cells within the same gland, increased nucleocytoplasmic ratio, nucleolar prominence, stromal and perineural invasion, and concentric layering of cellular stroma around the neoplastic glands are the most important identifying features (see Fig. 21.48B–E). As Weinbren and Mutum have emphasized,[247] the juxtaposition of normal-appearing cells and cells having large nuclei with prominent nucleoli is a particularly important diagnostic clue. Clusters of small acini, normally present in the wall of the bile duct and known as *periluminal sacculi of Beale*, should not be misinterpreted as invasive carcinoma.

In addition to these morphologic features, bile duct carcinoma resembles gallbladder carcinoma in its expression of mucosubstances and CEA,[248] frequent evidence of intestinal differentiation (as evidenced by the expression of CDX2 and MUC2),[249] common detection of metaplastic and dysplastic changes in the adjacent epithelium (biliary intraepithelial neoplasia),[144,250,251] and the occasional occurrence of variants with squamous metaplasia,[252] clear cell changes,[166] or signet ring cell features.[253] A type of extremely well differentiated adenocarcinoma featuring gastric foveolar-type epithelium and

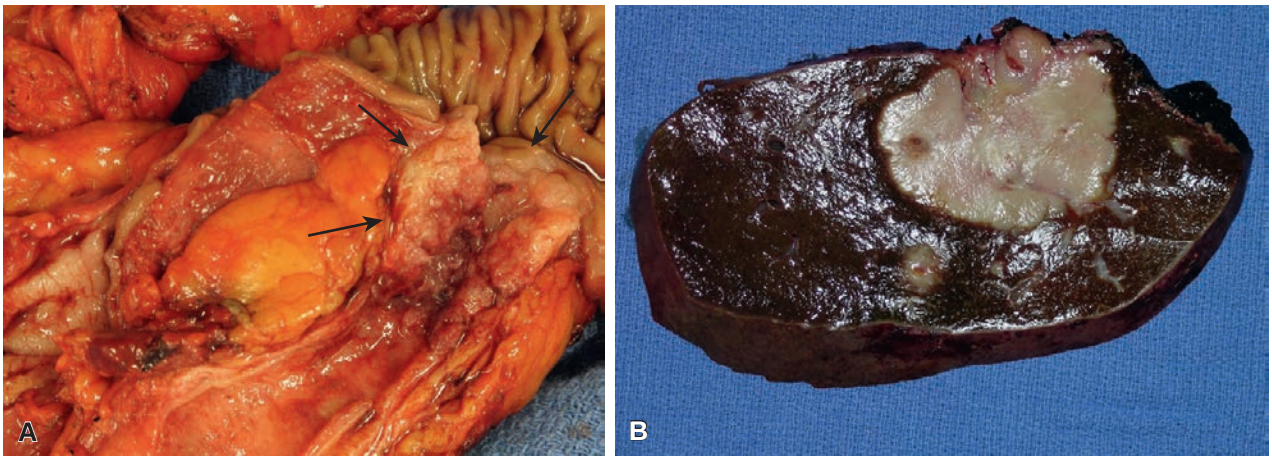

Figure 21.47 **A,** This Whipple resection shows a longitudinally opened common bile duct that contains a nodular tumor extending deeply into the wall *(arrows)*. **B,** Hilar cholangiocarcinoma with intraductal spread.

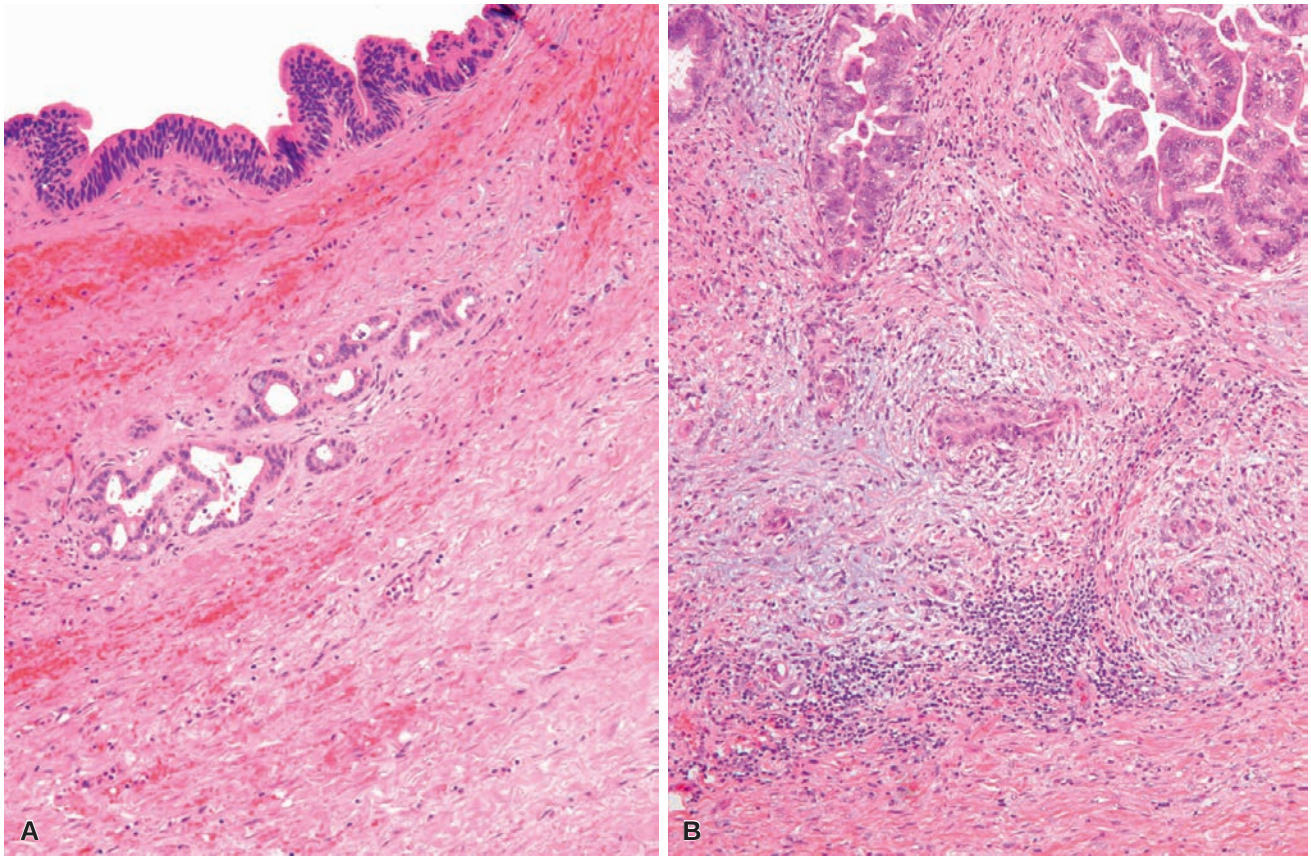

Figure 21.48 **A,** A focus of well-differentiated adenocarcinoma beneath flat dysplasia in the common bile duct. **B,** In this case, the infiltrative neoplastic glands are well differentiated, but the concentric layering of desmoplastic stroma around them is a clue to the diagnosis.

Continued

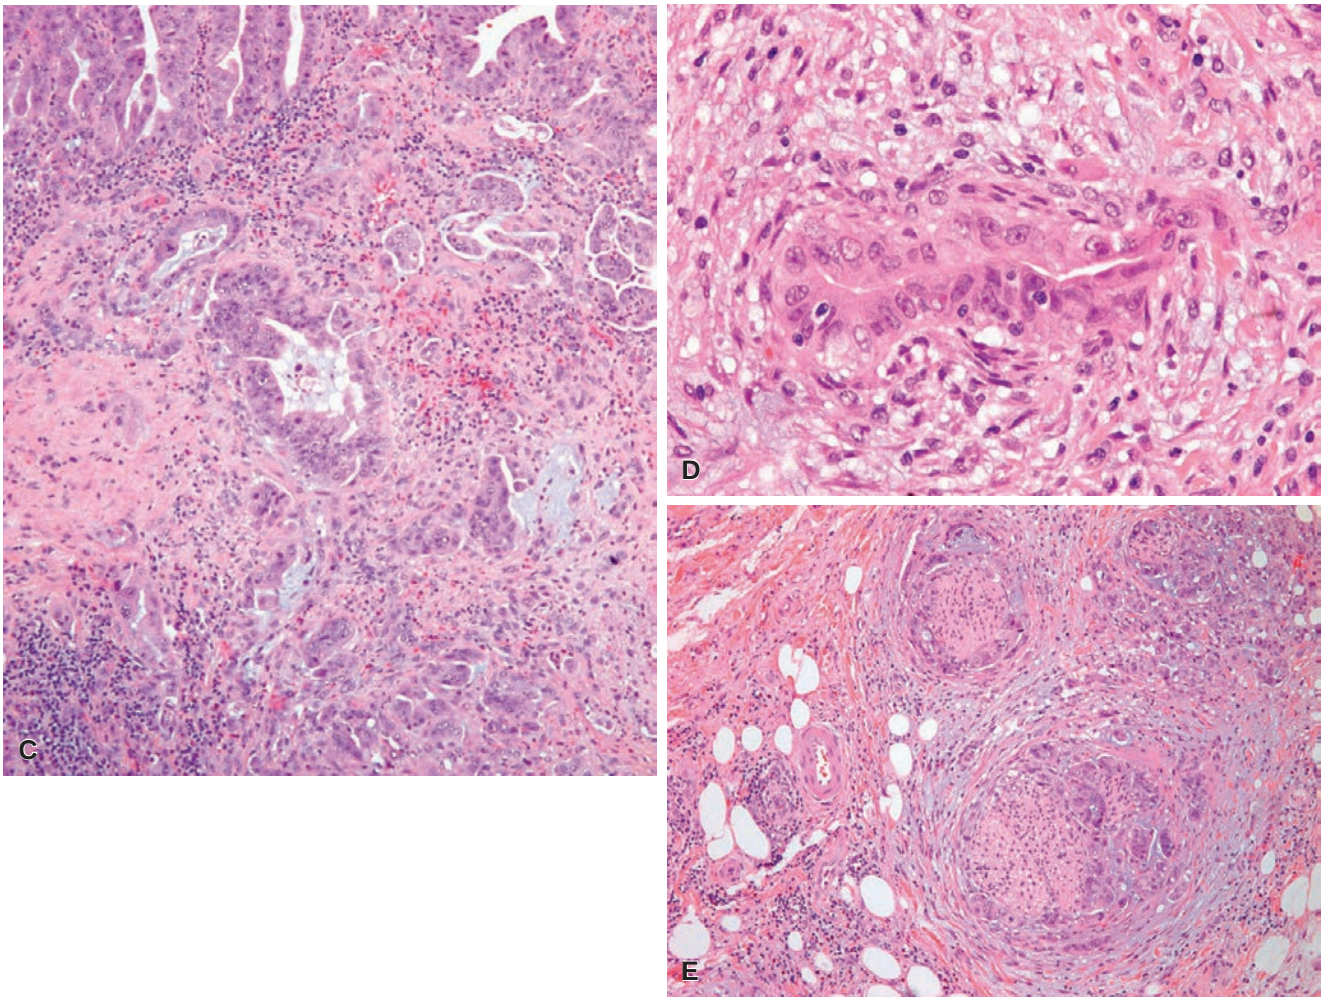

Figure 21.48, cont'd **C,** This more poorly differentiated example of adenocarcinoma of the extrahepatic bile duct has overlying dysplasia and associated lymphovascular invasion. **D,** Heterogeneity of cells within the same gland, increased nucleocytoplasmic ratio, nucleolar prominence, and loss of nuclear polarity are cytologic clues to the diagnosis of malignancy within this relatively well-formed gland. **E,** Perineural and intraneural invasion are frequent findings in adenocarcinomas of the bile ducts.

simulating adenoma has also been described.[254] NEC rarely occur in the extrahepatic biliary tract, as they do in the gallbladder.[255,256]

Tumors occurring at the hepatic duct junction have historically been termed *sclerosing carcinoma*, *Altemeier–Klatskin tumor*, or *Klatskin tumor*.[257,258] These lesions may spread to long segments of the biliary tree, and typically have a well-differentiated microscopic appearance associated with extensive fibrosis. The main differential diagnosis, both radiographically and pathologically, is with PSC.[259]

Molecular Features

Immunohistochemical features of extrahepatic bile duct carcinomas are similar to their gallbladder counterparts. p53 overexpression has been associated with adverse clinical features and poor prognosis, although studies have been conflicting.[260] Other studies have also found an interesting difference in the immunohistochemical overexpression of p53 in bile duct carcinomas but not in PSC.[261] Expression of p53, loss of expression of *DPC4* (a tumor-suppressor gene implicated in the genesis of pancreatic carcinoma), and *KRAS* mutations are significantly higher in distal than in proximal bile duct carcinoma.[262,263]

Treatment and Prognosis

Surgical resection offers the only possibility of cure for bile duct carcinoma; liver transplant may be considered in selected patients.[264] Proximal lesions are treated with resection (which may include hepatic lobectomy) and Roux-en-Y hepaticojejunostomy; distal lesions are treated by the Whipple procedure.[265] In advanced cases, often only palliative treatment is warranted in the form of biliary drainage, chemotherapy, and/or radiation therapy.[264] Although studies have shown conflicting data, some recent studies show a modest improvement in survival with a combined modality approach consisting of surgery, radiation therapy, and chemotherapy.[264,266]

For staging purposes, tumors of the bile ducts are divided into five groups: intrahepatic, perihilar, cystic duct, distal, and intraampullary common bile duct. Several authors have proposed modifications to the current AJCC/UICC TNM staging protocols to make them more reproducible and clinically relevant.[267,268] The overall 5-year survival rate is 11%,[267] although patients with completely resectable disease may have a better prognosis. Proximal carcinomas have a worse prognosis than distal ones, presumably due to the

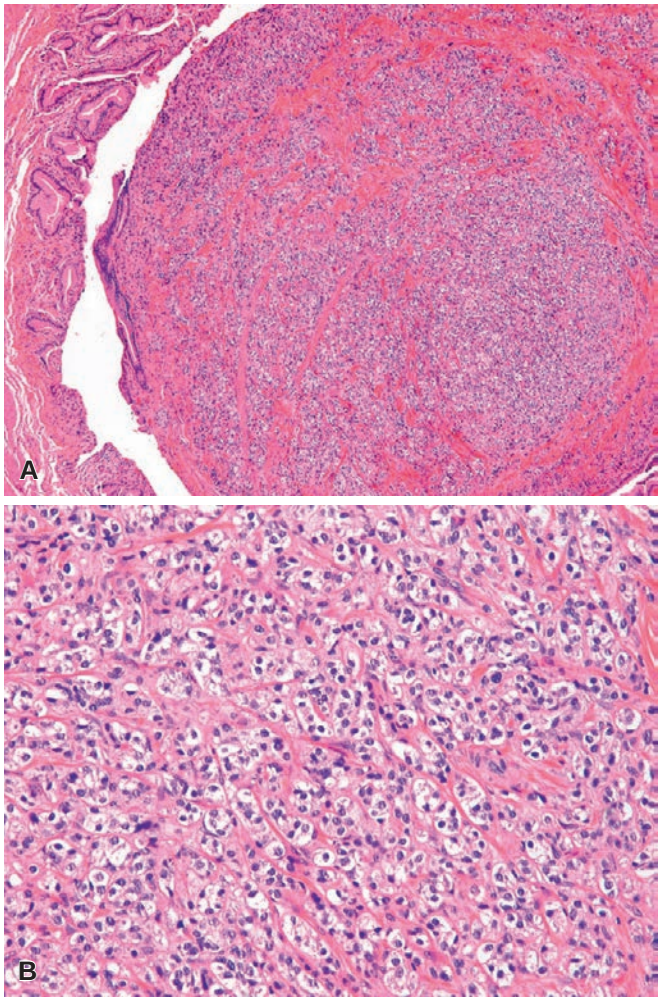

Figure 21.49 **A** and **B,** Clear cell well-differentiated neuroendocrine tumor (carcinoid) of the cystic duct.

feasibility of resection of distal tumors via Whipple.[265] In addition to location, stage of disease (particularly the presence and number of lymph node metastases), depth of invasion, and histologic grade are important prognostic indicators.[268–272]

Well-differentiated neuroendocrine tumors (carcinoid tumors) can occur in the extrahepatic bile ducts as well as the gallbladder (see earlier)[273–276] and can present with biliary obstruction. A *signet ring cell* variety has also been seen,[277] as well as a *clear cell variant* (Fig. 21.49A and B), sometimes in the setting of von Hippel–Lindau disease.[278,188]

Miscellaneous Tumors of the Gallbladder and Extrahepatic Bile Ducts

Primary malignant melanoma may present as a mass inside the gallbladder[279,280] or the extrahepatic bile ducts.[281–283] Some cases have occurred in the setting of the dysplastic nevus syndrome.[284] Most tumors have already metastasized by the time of diagnosis. Before making the diagnosis of primary melanoma of the gallbladder or biliary tree, the more likely possibility of a metastasis from a cutaneous or ocular source must be ruled out (Fig. 21.50A and B).

Malignant lymphoma and **leukemia** can involve the gallbladder or extrahepatic bile ducts as part of a systemic disease; their initial presentation in these sites is exceptional but has been recorded (Fig. 21.51).[285–287] As in other mucosa-lined organs, it has been postulated that some gallbladder lymphomas are of mucosa-associated lymphoid tissue (MALT) types, and cases have been reported to show the *API2–MALT1* gene fusion characteristic of this lymphoma type.[288–290]

The **botryoid variant of embryonal rhabdomyosarcoma** is the most common malignant tumor of extrahepatic bile ducts in children and is rarely described in adults.[291–294] It can also involve the gallbladder, and a few cases have been described in adults. Obstructive jaundice is the usual presenting sign. Grossly, it has a deceptively soft polypoid appearance. Microscopically, small, undifferentiated spindle cells concentrate beneath an intact epithelium ("cambium layer"). Cross striations may or may not be present (Fig. 21.52A and B). The combination of surgery, radiation therapy, and chemotherapy has resulted in many long-term survivals.

Other mesenchymal neoplasms of the gallbladder typically occur in adults and are usually malignant, such as *myxofibrosarcoma*,[295] *leiomyosarcoma*,[295] *angiosarcoma*[295,296] (including the epithelioid variety), and *gastrointestinal stromal tumor*.[295,297,298] Before a diagnosis of sarcoma is made in a spindle-cell lesion, however, the alternative possibility of sarcomatoid carcinoma should always be considered. *Kaposi sarcoma* of gallbladder has been seen in the setting of HIV infection.[299] Benign, mesenchymal tumors (other than granular cell tumors) rarely occur

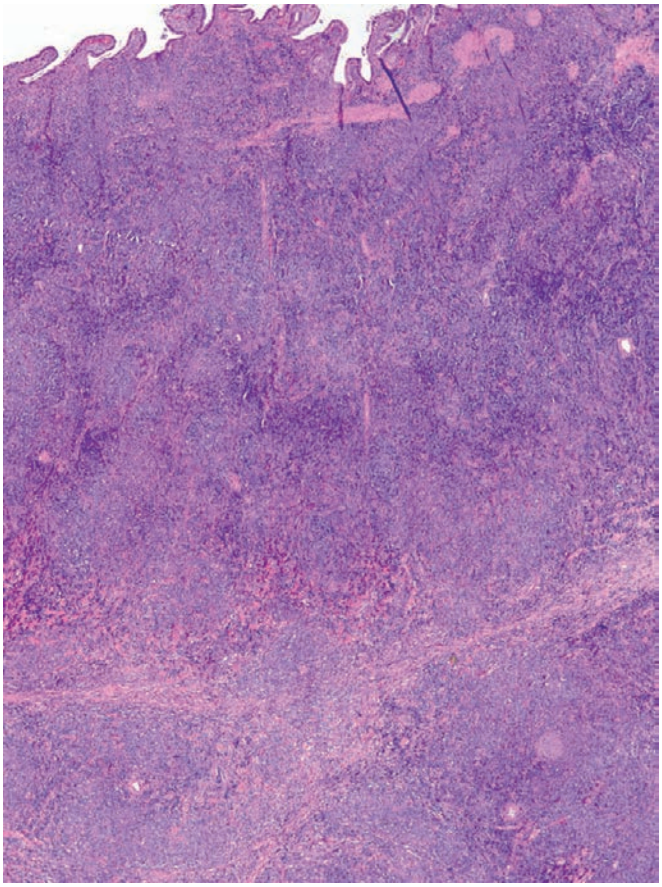

Figure 21.51 Diffuse large B cell lymphoma of the gallbladder, involving the entire thickness of the wall.

in the gallbladder and biliary tree. *Paragangliomas* arising from small paraganglia are known to occur in the gallbladder serosa and rarely in the extrahepatic bile ducts.[300–302] *Solitary fibrous tumors* have been rarely reported (Fig. 21.53A and B).[303]

Metastatic tumors to the gallbladder (Fig. 21.54) are exceptionally rare; most of the reported cases are malignant melanomas (see earlier). Metastases from renal cell carcinoma,[304,305] breast carcinoma,[306] and gastric carcinoma[307] have been reported. We have seen a single case of endometrial adenocarcinoma metastatic to gallbladder as well. Intrabiliary growth of colonic adenocarcinoma mimicking primary neoplasia at this site has also been observed.[308]

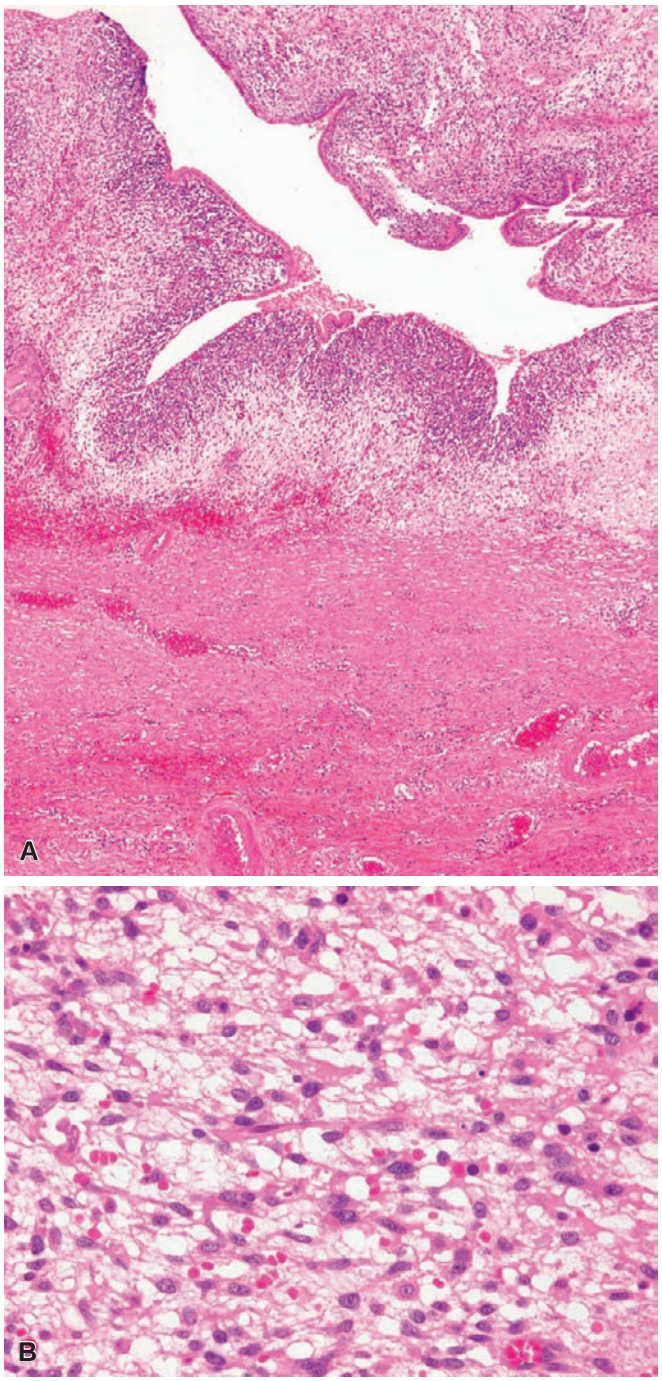

Figure 21.52 **Embryonal Rhabdomyosarcoma of Botryoid Subtype.** **A,** There is a prominent cambium layer beneath the biliary epithelium. **B,** High-power view of undifferentiated spindle cells.

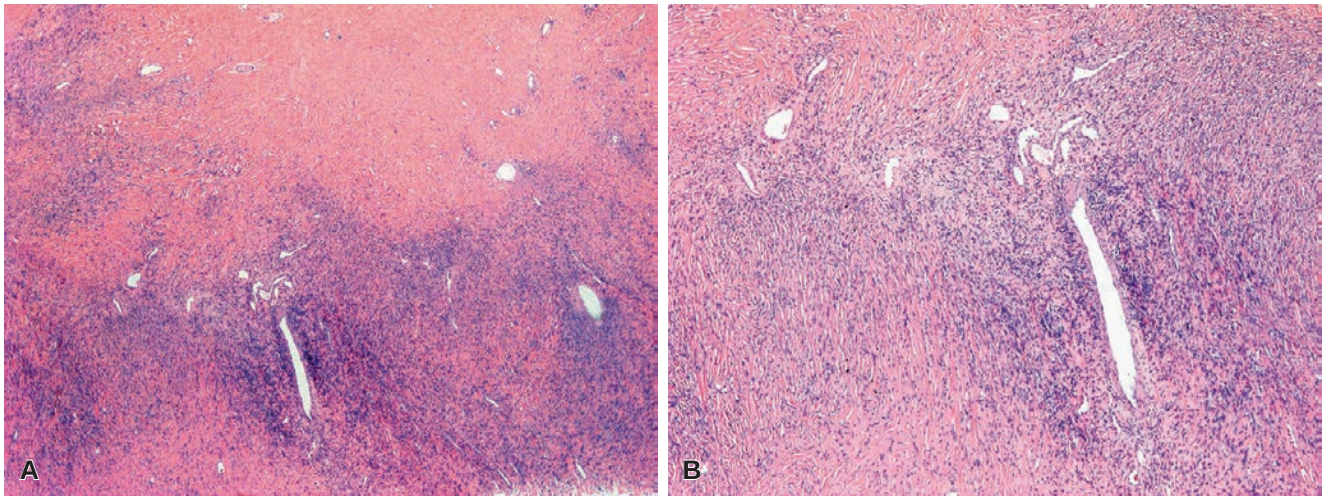

Figure 21.53 **A** and **B,** Solitary fibrous tumor of the gallbladder.

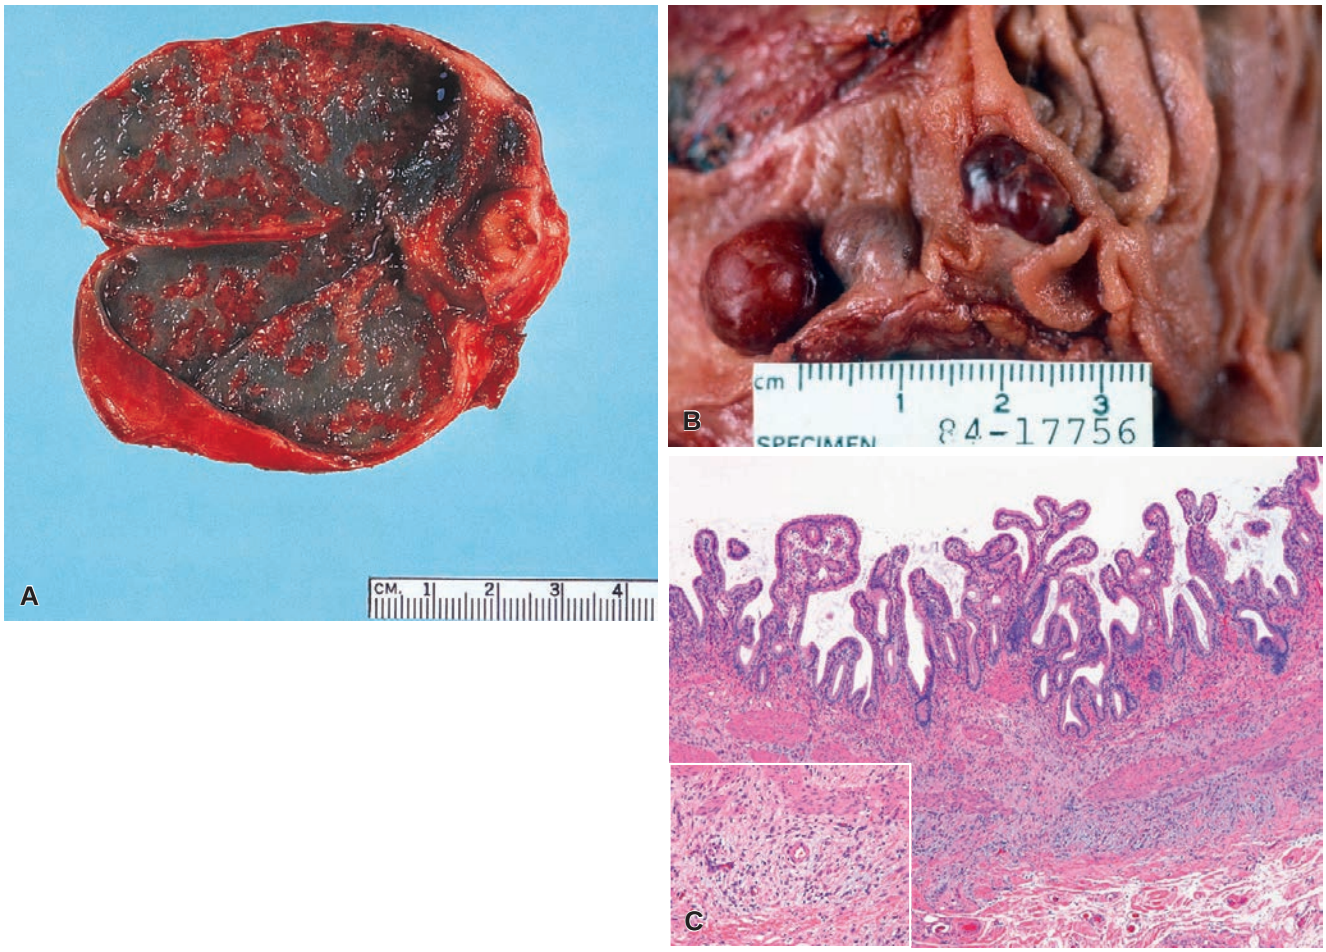

Figure 21.54 **A,** Gallbladder with metastatic breast carcinoma presenting in the form of multiple nodules protruding through the mucosa and associated with inflammatory changes. **B,** Metastatic renal cell carcinoma appears as multiple polypoid red nodules in the common bile duct. **C,** Metastatic lobular breast carcinoma is difficult to appreciate except for the prominent surrounding reactive stroma (low power; inset, high power).

Continued

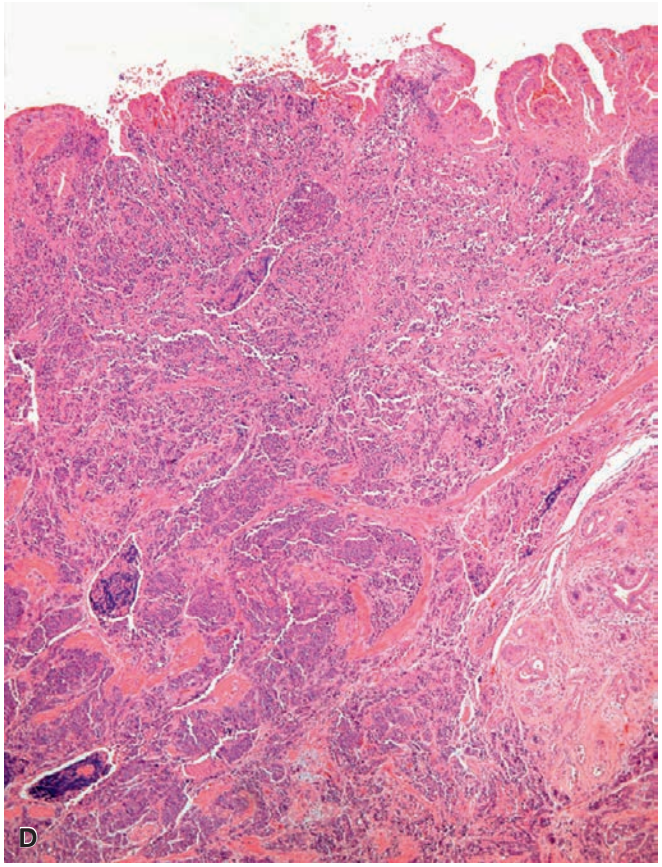

Figure 21.54, cont'd **D,** Metastatic endometrial cancer mimics a high-grade carcinoma of the gallbladder. (**B,** Courtesy of Dr. George F. Gray Jr.)

Pancreas

Normal Anatomy

The pancreas forms from two separate buds or *anlagen*, which later rotate and fuse. The ventral bud, which appears as a part of the developing hepatic duct, forms the posterior and inferior parts of the head and the uncinate process; the larger dorsal bud, which develops from the other side of the foregut and extends into the dorsal mesentery, forms the body, tail, and anterior part of the head. Abnormalities in this process result in *annular pancreas* and most types of *heterotopic pancreas* (see later). The pancreas is located in the retroperitoneum behind the stomach and transverse colon, and in front of the aorta and vena cava. It weighs on average between 40 and 180 g and measures 15–20 cm in length. It has no distinct capsule.[1,2]

The normal adult pancreas has a dual composition. The exocrine component is made of lobular units of acini, which comprise 80% or more of the gland (Fig. 22.1).[1] They empty into ducts of increasingly larger size that finally merge into the *main pancreatic duct (of Wirsung)* and the *accessory pancreatic duct (of Santorini)*. The duct of Wirsung ends in the *papilla of Vater*, usually in conjunction with the common bile duct (see also Chapter 21). The duct of Santorini ends separately in a minor duodenal papilla. Normally, the Wirsung and Santorini ducts are joined by numerous anastomotic connections; when this is not the case, and the duct of Santorini constitutes the principal drainage for the organ, the condition known as *pancreas divisum* results (see later).

Acinar cells are large, pyramidally shaped, and highly polarized. The luminal border has prominent microvilli, the apical cytoplasm is filled with markedly eosinophilic periodic acid–Schiff (PAS)-positive zymogen granules, and the basilar cytoplasm is intensely basophilic because of the abundance of granular endoplasmic reticulum. Centroacinar cells have paler cytoplasm and oval nuclei; as their name indicates, they are located in the central portion of the acinus. They blend with the cells of the intercalated duct, which drains the acinus. Focal collections of centroacinar cells sometimes occur and should not be confused with Langerhans islets.[3] The merging of intercalated ducts forms the intralobular ducts, which are lined by small cuboidal cells with pale cytoplasm.[1,4] These are continued by the much larger interlobular ducts, which are lined by mucin-producing columnar cells. The microscopic composition of Wirsung and Santorini ducts is similar to that of the interlobular ducts, except for a greater representation of goblet cells.

The endocrine component of the pancreas is mainly represented by the Langerhans islets (Fig. 22.2A and B).[1,4,5] These constitute 1%–2% of the adult pancreas but a much larger proportion (~20%) of the organ at the time of birth. Islets may be compact (90%) or diffuse; the latter are located in the portion of the pancreatic head derived from the ventral bud. Islets are not encapsulated and contain a rich capillary network. Their average diameter is 225 µm; individual variations in size exist, but any islet measuring over 400 µm should be regarded as abnormal. In adult humans, islets are composed of the following main cell types:

1. *B cells*. The insulin-secreting cells constitute two-thirds to three-fourths of the islet cell population and tend to group in center of the islet. B cells also secrete islet amyloid polypeptide (IAPP), a putative hormone that is thought to be co-released with insulin.[6]
2. *A cells*. The glucagon-secreting cells make up one-fifth to one-fourth of the total islet cell population and are mainly located at their periphery.
3. *D cells*. The somatostatin-secreting cells are scattered throughout the islets and represent less than 10% of islet cells.

Abstract

This chapter covers both the non-neoplastic and neoplastic pathology of the pancreas and ampullary region, including congenital anomalies, pancreatitis, cystic lesions, and exocrine and endocrine tumors.

Keywords

islet of Langerhans,
annular pancreas,
heterotopic pancreas,
congenital anomalies,
pancreatitis,
pseudocyst,
congenital cyst,
lymphoepithelial cyst,
ductal adenocarcinoma,
foamy gland,
medullary,
adenosquamous,
undifferentiated,
mucinous cystic neoplasm,
intraductal papillary mucinous neoplasm,
PanIN,
acinar cell tumor,
pancreatoblastoma,
nesidioblastosis,
cystic fibrosis,
diabetes,
solid-pseudopapillary tumor,
serous cystadenoma,
well-differentiated neuroendocrine tumor,
poorly differentiated neuroendocrine carcinoma,
ampullary carcinoma,
intra-ampullary tubulopapillary neoplasm

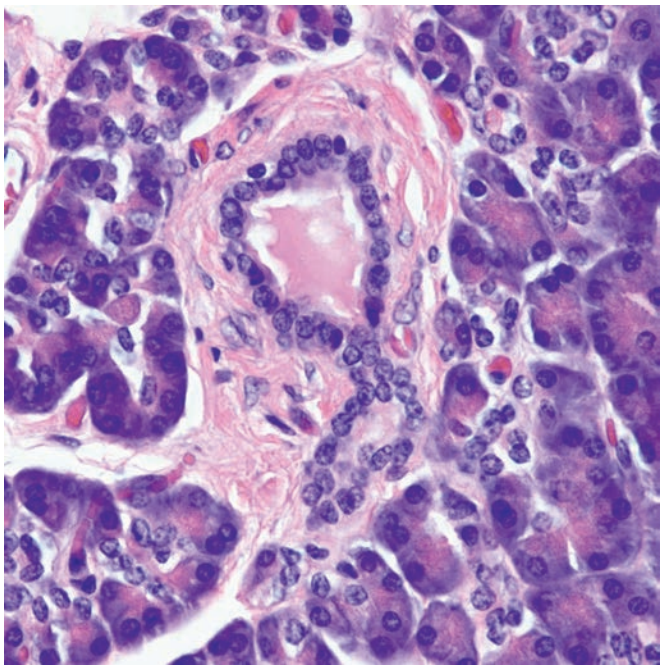

Figure 22.1 Normal pancreatic acini consist of tubular glands with round, basally located nuclei and prominent granules. A small duct is in the center of the photograph.

4. *PP cells*. The pancreatic polypeptide-secreting cells are scarce and usually present within diffuse islets.[7]

It should be pointed out that all of the endocrine cells present in the pancreas are of endodermal rather than neural crest derivation, as formerly believed.[8,9] Islet cells mark with synaptophysin, chromogranin, and CD56 and are typically pancytokeratin negative.

In addition to the Langerhans islets, endocrine cells can be found in connection with ducts and acini.[10] Most of these cells are of Kulchitsky (serotonin-producing) and PP type. It should be noted that G (gastrin-producing) cells are not normally present in the adult pancreas, a remarkable fact considering that this organ is the most common site for the occurrence of G cell tumors/gastrinomas.

Nesidioblastosis is a clinically heterogeneous term that refers to pancreatic islet hypertrophy in the context of hyperinsulinemic hypoglycemia.[11,12] It has been observed in infants with persistent neonatal hyperinsulinemic hypoglycemia, as well as infants of diabetic mothers, and has been associated with numerous conditions including Beckwith–Wiedemann syndrome and Zellweger syndrome.[11] Morphologically, islets are in intimate association with ducts, with formation of so-called *ductuloinsular complexes* (Fig. 22.3); islet cell hypertrophy and beta cells with pleomorphic nuclei may also be seen.[12,13] Focal and diffuse forms of this condition have been described.[12] The morphologic changes of nesidioblastosis can be seen in normal infants, as the endocrine component in neonates is more prominent than later in life.[11,14] The morphologic changes have been occasionally reported in adult patients with persistent hyperinsulinemic hypoglycemia and have also been encountered in adults who have had bariatric surgery.[15]

Congenital and Developmental Abnormalities

Complete pancreatic agenesis is an exceedingly rare lethal anomaly[16]; partial agenesis is also rare, and patients often present with diabetes.[17]

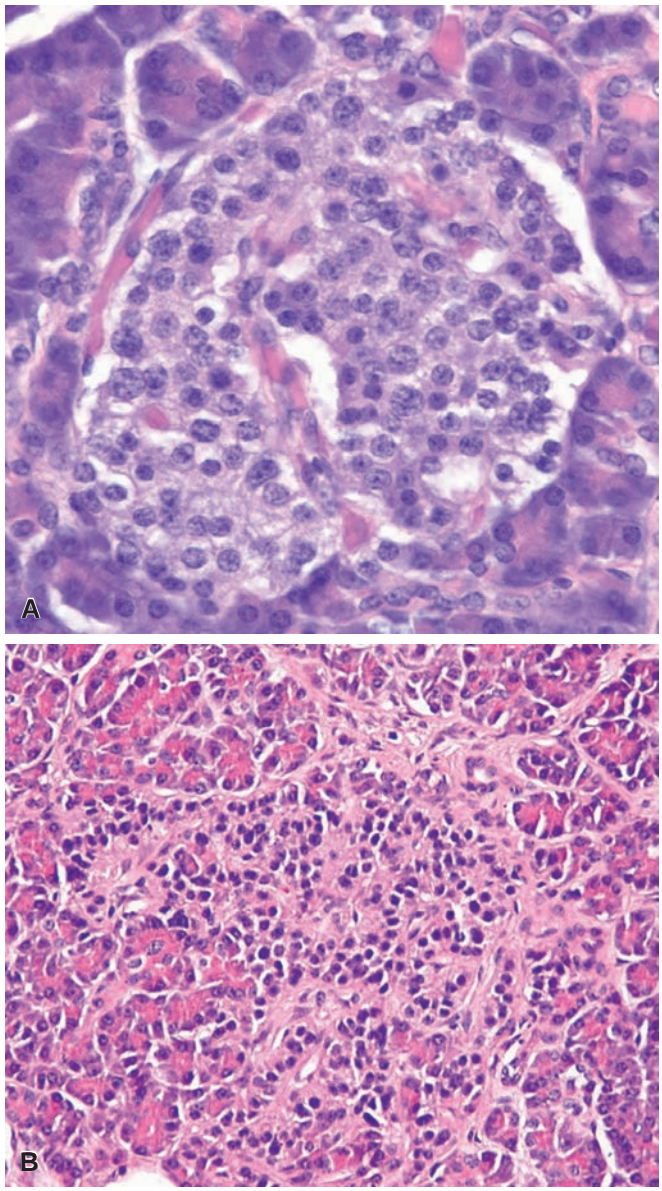

Figure 22.2 **A,** Compact islet with well-defined borders; note the small capillaries within the islet. Nuclei have speckled or "salt and pepper" chromatin typical of neuroendocrine cells. **B,** Diffuse islets have poorly defined borders and are often larger than compact islets; nuclei are typically more hyperchromatic.

Annular pancreas is a rare embryologic abnormality in which the ventral primordium of the pancreas fails to rotate properly.[18,19] It can be seen by itself or in combination with other congenital abnormalities of the gastrointestinal tract.[20] It is more common in females and is associated with Down syndrome.[21] Grossly, there is encirclement of the duodenum by pancreatic parenchyma, which may lead to constriction of the duodenal lumen.[22] The duct in the annular pancreas originates anteriorly and courses to the right over the duodenum and then posteriorly and to the left behind the duodenum, passing near the common duct and finally joining the main pancreatic duct.[23] These anatomic variations have to be kept in mind when surgery is contemplated. Microscopically, the annular pancreas contains a large number of PP cells in its many irregularly shaped islets, in keeping with its origin from the ventral bud (see

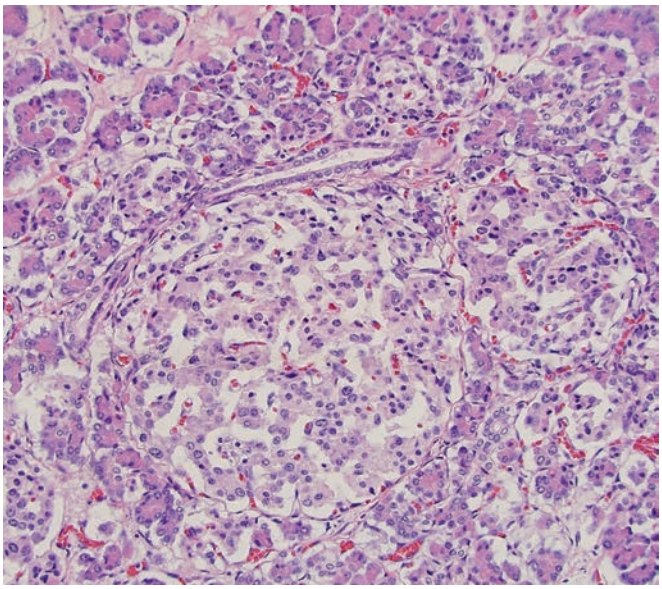

Figure 22.3 Hypertrophic, irregular islet with closely approximated duct (ductuloinsular complex) in a case of hyperinsulinemic hypoglycemia. (Courtesy of Dr. Jessica Comstock.)

previous section).[23] Pancreatitis may develop in association with this anomaly. *Pancreas divisum*, or a congenitally separate pancreatic ductal system, occurs in approximately 10% of individuals. It has been claimed to predispose to the development of pancreatitis, but the evidence for this is less than conclusive.[24,25]

Heterotopic Pancreas

Heterotopia of pancreatic tissue is a relatively frequent congenital anomaly.[26] It is most common in the duodenum (particularly the second portion), stomach, and jejunum but also occurs in the ileum, Meckel diverticulum, gastric and intestinal diverticula, gallbladder and bile ducts, large bowel, spleen (usually within or immediately beneath the capsule), omentum, abdominal wall, and several other locations.[26–29]

Grossly, the heterotopic tissue resembles normal pancreas. Firm, yellow, lobulated nodules measuring up to 4 cm are seen sharply circumscribed from the surrounding tissues (Fig. 22.4A). Central umbilication is often present in the cases located beneath mucosa, corresponding to a central duct that opens into the lumen (Fig. 22.4B); both the umbilication and the duct can be demonstrated radiographically and constitute an important diagnostic sign.[29] Microscopically, acinar and ductal tissues are always present, whereas islet tissue is found in only one-third of the cases (Fig. 22.4C and D). In some cases, there is also a component of pyloric-type mucous glands. The islet cell component contains all the major types of endocrine cells, but their relative number varies a great deal from case to case. In most instances, the islets are rich in A cells and poor in PP cells (dorsal type), but in others the reverse is true (ventral type).[30] True gastric heterotopic pancreas should be distinguished from pancreatic acinar metaplasia of the gastric or gastroesophageal junction mucosa.

Practically every pathologic change that occurs in the pancreas itself can occur in its heterotopic counterpart, including acute pancreatitis and neoplasms of either exocrine or endocrine type.[31–34] Heterotopic pancreas is often asymptomatic, but in the stomach may cause hemorrhage, ulceration, or pyloric obstruction.[35] When located in the area of the ampulla of Vater, it may result in obstructive jaundice. It has been postulated that some of the reported cases of intrasplenic mucinous cystadenomas and cystadenocarcinomas have arisen in heterotopic pancreatic tissue.[36]

Cystic Fibrosis

Cystic fibrosis is the most common inherited disorder among Caucasians and is due to genetic alterations in the cystic fibrosis transmembrane conductance regulator (CFTR) protein. The pancreas is the second most frequently affected organ after the lung; in fact, the disease was named for the cysts and fibrosis found in the pancreas in patients with this disease. The precipitation of secretions in the pancreatic ducts leads to obstruction and pancreatitis.[37] Pancreata often show fatty replacement, as well as cyst formation, and the accumulation of inspissated eosinophilic secretions in dilated pancreatic ducts (Fig. 22.5).[38]

Diabetes Mellitus

Both type 1 and type 2 diabetes may cause histologic changes in the pancreas. The pancreas decreases in size and weight as type 1 diabetes progresses, and islets show variability in size and shape, irregular shapes, reduced B cells, and patchy lymphocytic inflammation. Patients with type 2 diabetes also show reduction in number and density of islets, with reduction in A and B cells as well as islet amyloidosis (Fig. 22.6).[39,40]

Pancreatitis

Acute Pancreatitis

The main risk factors for acute pancreatitis are gallstones and alcohol abuse. Other factors include smoking (particularly when combined with alcohol use), type 2 diabetes, invasive pancreatobiliary procedures, and many drugs.[41] Experimental work has been hampered by the fact that most laboratory animals do not suffer naturally from this illness.

Duct obstruction from any cause results in upstream blockage of pancreatic secretions, with resulting autodigestive injury and inflammation.[41] Opie[42] postulated an obstructive mechanism in a classic work published in 1901, after demonstrating in his famous case of pancreatitis the presence of a small stone lodged in the ampulla, which had converted the common bile duct and the main pancreatic duct (duct of Wirsung) into a "common channel." The assumption was that the bile had passed from the common bile duct into the pancreatic duct and activated trypsinogen, thus beginning a series of events that included the digestion of the duct wall, adjacent parenchyma, and vessel walls by trypsin, as well as the splitting of fat and formation of calcium soaps by lipase. Fibrosis of the sphincter of Oddi or neoplasms in this region can induce a similar process, and cases of acute pancreatitis secondary to tumors of the ampullary area have been recorded.[43] The difficulty with this theory is that the formation of a common channel with a stone impacted in the ampulla, or another clearly identifiable anatomic cause of obstruction, occurs in less than 5% of patients with acute pancreatitis. This discrepancy could be explained by postulating a transient blockage of the ampulla of Vater by a migrating gallstone, by biliary sludge, or by a spasm of the sphincter of Oddi, all of which could produce a common channel in the absence of an identifiable impacted stone. Acosta and Ledesma[44] recovered gallstones in the feces of 34 of 36 patients with pancreatitis but in only 3 of 36 control subjects (patients with gallstones but no pancreatitis). Biliary sludge was found by Lee et al.[45] in 23 of 31 patients with "id iopathic" acute pancreatitis,

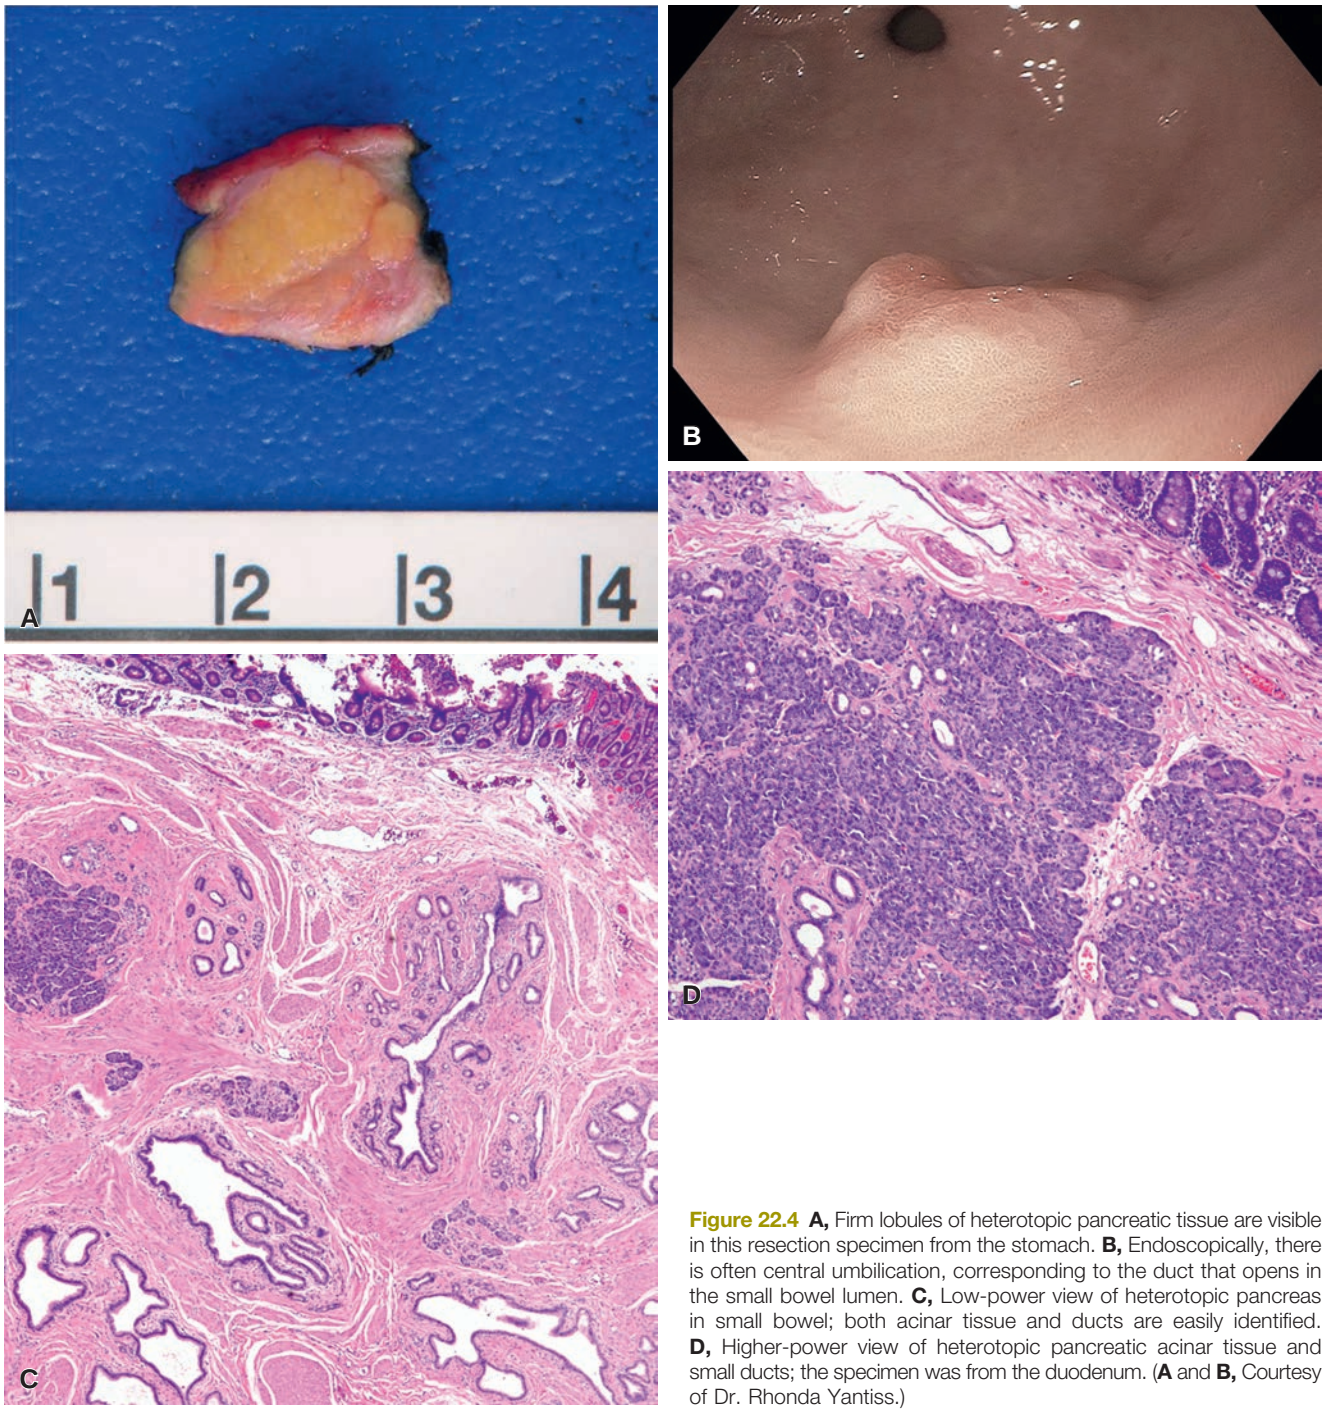

Figure 22.4 **A,** Firm lobules of heterotopic pancreatic tissue are visible in this resection specimen from the stomach. **B,** Endoscopically, there is often central umbilication, corresponding to the duct that opens in the small bowel lumen. **C,** Low-power view of heterotopic pancreas in small bowel; both acinar tissue and ducts are easily identified. **D,** Higher-power view of heterotopic pancreatic acinar tissue and small ducts; the specimen was from the duodenum. (**A** and **B,** Courtesy of Dr. Rhonda Yantiss.)

and sphincter spasm can be demonstrated in experimental animals and in humans under a variety of conditions. All these experiments demonstrate that a "common channel" may indeed occur under physiologic circumstances, and anomalous or variant pancreaticobiliary ductal anatomy may also contribute.[46]

The relationship between alcohol and acute pancreatitis remains poorly understood,[41,47] particularly as only a small percentage of alcohol users develop pancreatitis. Alcohol and its metabolites produce changes in acinar cells, which may promote activation of digestive enzymes and subsequent injury, but no specific predisposing or triggering factors have been identified. Regardless of the precise pathogenetic mechanism, it is a fact that the large majority of cases of acute pancreatitis are associated with biliary tract disease, alcohol use, and trauma.

The gross changes in acute pancreatitis vary from a swollen and edematous but otherwise well-preserved organ to a barely recognizable hemorrhagic and necrotic mass of tissue (Fig. 22.7A).[48] Yellow plaques and nodules representing fat necrosis are seen within the pancreas as well as throughout the mesenteric and peritoneal fat (Fig. 22.7B and C). The process sometimes spreads to the neighboring colon,

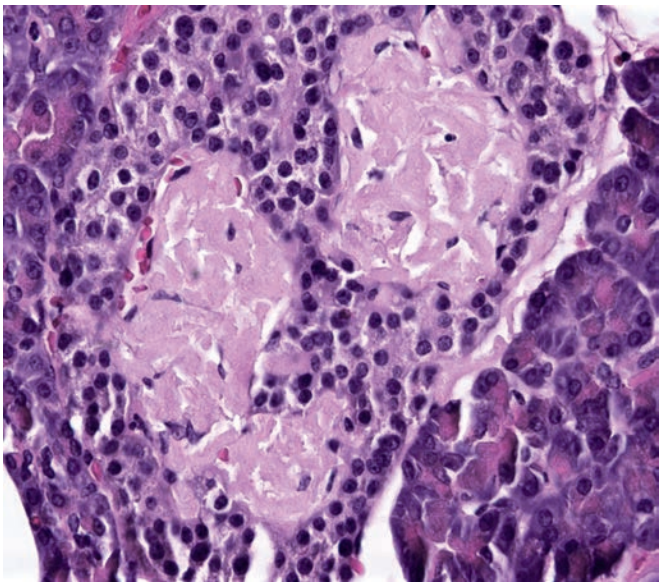

Figure 22.6 Islet cell amyloidosis in a patient with type 2 diabetes.

and it may result in localized ileus, stenosis, perforation, fistulous formations, or ischemic necrosis.[49]

Microscopically, early changes in the pancreas include acinar cell homogenization, ductal dilation with epithelial degeneration, diffuse interstitial edema, leukocytic infiltration, and fibroblastic reaction.[50] If the disease progresses, extensive necrosis and hemorrhage of pancreatic and peripancreatic tissue supervene (Fig. 22.7D). The foci of peritoneal fat necrosis become almost immediately surrounded and infiltrated by neutrophils; this population later changes to foamy histiocytes and lymphocytes. Calcification occurs early and extensively in these areas. The pancreatic necrotic foci can undergo secondary infection; this condition, termed *infected pancreatic necrosis*, is currently regarded as the most common, most severe, and most lethal of the infectious complications of acute pancreatitis.[51,52] Acute pancreatitis may evolve into a chronic form,[53] and in some clinical circumstances (such as alcoholic pancreatitis) the acute and chronic phases probably represent a continuum.[54]

Patients typically present with abdominal pain and serum amylase and/or lipase levels elevated above three times normal. Of note, however, patients with severe pancreatitis may have only mild enzyme elevations,[41] and elevated serum amylase can also be found with duodenal ulcer, volvulus, gangrenous cholecystitis, ruptured aortic aneurysm, and mesenteric thrombosis.[55] Serum C-reactive protein is a reliable marker for the presence of pancreatic necrosis and may correlate with disease severity.[56]

The overall mortality rate for acute pancreatitis is believed to be approximately 10%–20%, although both higher and lower mortality rates have been reported.[57,58] Prognosis worsens with increased pancreatic necrosis.[58] A number of classification schemes exist for stratifying severity of disease and prognosis.[41,58] Early treatment consists of supportive care (particularly fluid resuscitation), pain management, and nutritional support.[41] Endoscopic or surgical intervention may be necessary in patients with acute pancreatitis due to gallstones, and surgical necrosectomy may be required in patients with extensive pancreatic necrosis, particularly those who develop infected pancreatic necrosis, although many patients respond to antibiotics alone.[41,59]

Chronic Pancreatitis

The term "chronic pancreatitis" implies a chronic fibroinflammatory state that ultimately leads to pancreatic insufficiency. In addition to alcohol, there are a wide variety of causes, including autoimmune, metabolic, hereditary, and anatomic etiologies. Similar to acute pancreatitis, the pathogenesis of chronic pancreatitis is not well understood, although there are a number of proposed theories.[60] Some have proposed that alcohol predisposes patients to the formation of proteinaceous plugs and stones within the pancreatic ducts, leading to epithelial ulceration, scarring, and stricture formation. This theory has been questioned in the past, as only a minority of chronic pancreatitis patients have demonstrable stones or protein plugs within ducts, but has received renewed attention with the discovery of the link between chronic pancreatitis and the *CFTR* gene (see later).[61–63] Others have proposed oxidative stress, direct toxic effects of alcohol, and the consequence of repeated bouts of acute pancreatitis as explanations for chronic pancreatitis. It is likely that diverse causes lead to the fibroinflammatory condition known as "chronic pancreatitis" through different pathways. Alcohol continues to be the most important risk factor,[64–66] and smoking is also an important risk factor. Another contributing factor is prolonged ductal obstruction by tumor or stone (also known as chronic obstructive pancreatitis).

There is increasing evidence suggesting that a significant number of patients with idiopathic acute and chronic pancreatitis have underlying genetic alterations. Several of the identified mutations play a role in trypsinogen activation, pancreatic secretory function, or response to inflammation during pancreatic injury; affected genes include *PRSS1*, *SPINK1*, *CTRC*, and *CFTR*, as well as several others.[63] However, although these genes have been linked to pancreatitis, penetrance is incomplete and the presence of mutation does not necessarily confer disease.

Clinically, chronic pancreatitis characteristically presents with abdominal pain, which can be very severe and often radiates to the mid-back or scapula. Later in the course of disease, patients may present with diabetes or malabsorption due to deficiency of both exocrine and endocrine function.[67]

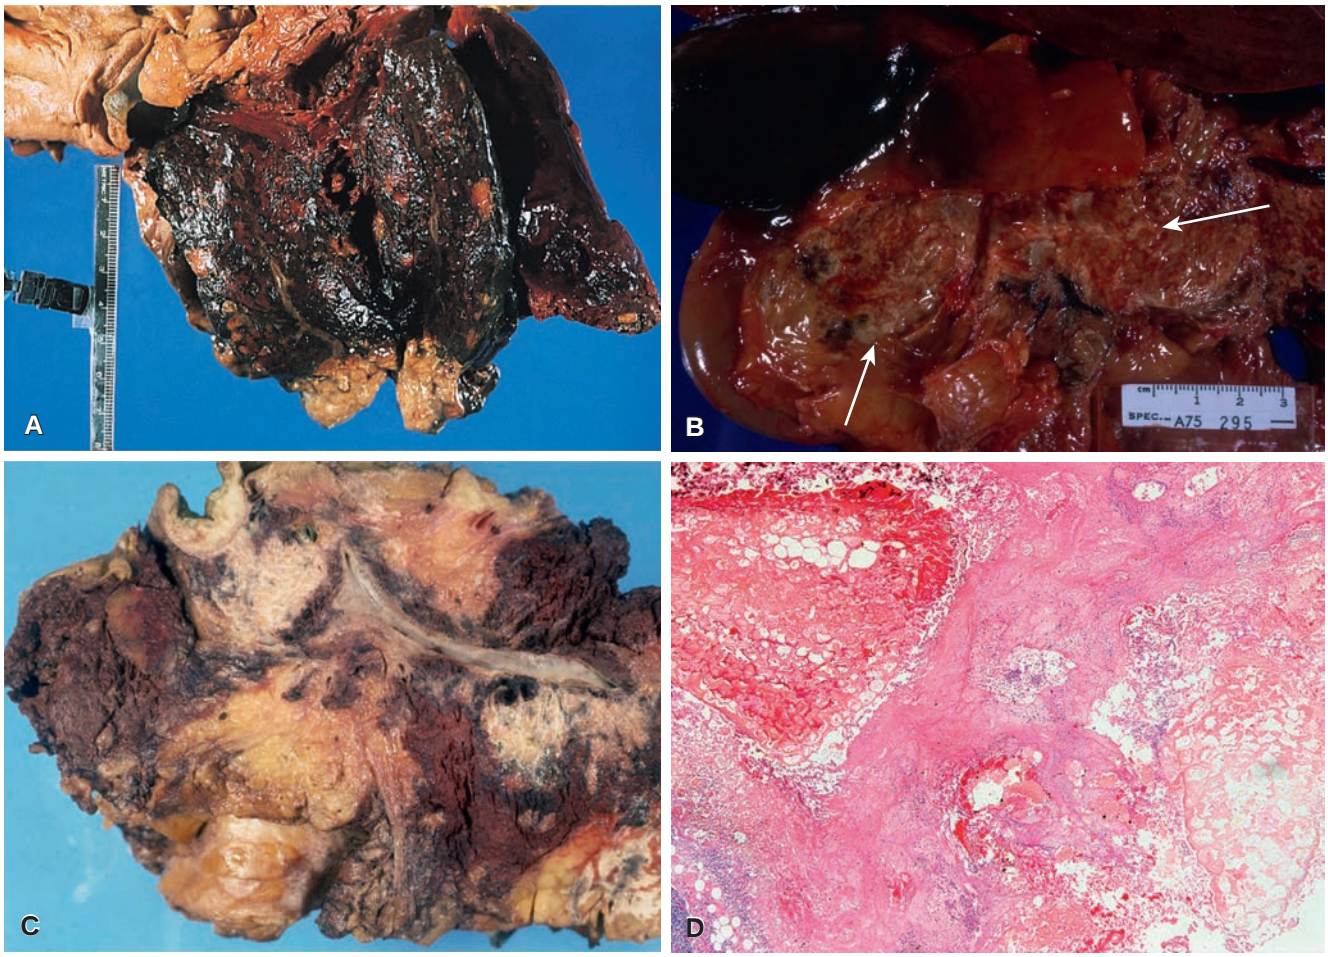

Figure 22.7 **A,** Extensive hemorrhagic necrosis of the pancreas spreads into the surrounding mesentery. **B,** A higher-power photograph from another case shows hemorrhagic acute pancreatitis with numerous foci of fat necrosis *(arrows)*. **C,** Hemorrhagic pancreatitis with large foci of fat necrosis extending into the mesenteric fat. **D,** Acute necrotizing pancreatitis with extensive hemorrhage and fat necrosis. There is no longer any recognizable pancreatic parenchyma. (**B** and **C,** Courtesy of Dr. George F. Gray Jr.)

Alcoholic Pancreatitis

Approximately 80% of chronic pancreatitis cases are due to alcohol.[68] The disease is characterized grossly by a nodular, firm, fibrotic, and misshapen pancreas that may be either enlarged or atrophic. The fibrosis typically affects the gland unevenly, leaving preserved architecture in some areas (Fig. 22.8A–C). Ducts embedded within the fibrosis may be irregular, stenotic, and/or dilated, and may contain calculi. Microscopically, the main features are fibrosis, initially interlobular, with chronic inflammation (Fig. 22.9A and B). As disease progresses, fibrosis increases, with loss of parenchyma, dilatation and distortion of ducts, and intraluminal eosinophilic mucoprotein plugs (which often calcify). When the calcification is very extensive, the term *chronic calcifying pancreatitis* has been used.[69] The ductal epithelium may be hyperplastic or contain squamous metaplasia, and eventually the epithelium may be atrophic or completely denuded.[68] Residual nerves and vessels may be prominent. The appearance of Langerhans islets in chronic pancreatitis varies considerably from case to case. Often, there is atrophy and distortion by the surrounding fibrotic tissue, with a relative decrease in the number of B cells.[70] Conversely, other cases show a marked proliferation of islet cells, which may grow in cords and small clusters (Fig. 22.9C).[68,71] Sometimes they may even simulate a malignant neoplasm (Fig. 22.9D).[71] Concomitant hyperplasia of Brunner glands in the duodenum is a common finding in chronic pancreatitis.[72]

A good correlation exists between the severity of the histologic alterations and pancreatic exocrine function tests.[73] Acinar necrosis and acute inflammation are seen more often in patients with persistent pain than in those who are free of pain.[74] However, cases exist in which severe abdominal pain of pancreatic origin is accompanied by minimal morphologic changes.[75]

Complications of chronic pancreatitis include both exocrine and endocrine insufficiency, stenosis of the common bile duct, pseudocysts, and pseudoaneurysm formation, which can lead to exsanguinating acute hemorrhage.[68,76,77] A rare complication of both acute and chronic pancreatitis is the occurrence of widespread metastatic fat necrosis, presumably as a consequence of the liberation of lipase by the damaged organ. Subcutaneous tissue (particularly in the legs), mediastinum, pleura, pericardium, bone marrow, periarticular fat, and liver can be involved.[78,79] Erythema nodosum–like lesions of the skin, polyarthropathy, and avascular bone necrosis are some of the alterations that may develop as a result.[78]

Endoscopy is playing a larger role in the treatment of chronic pancreatitis, including ERCP for treatment of strictures and stone removal, and endoscopic ultrasound for the treatment of pancreatic

fluid collections.[80,81] Surgical therapy may involve pancreatic duct drainage, partial pancreatic resection, and near-total pancreatectomy with or without islet autotransplantation.[81]

Autoimmune Pancreatitis

A great deal has been written recently on this disease, which is thought to have an autoimmune or hypersensitivity etiopathogenesis and shows good response to steroid therapy.[69,82–84] It is subclassified into two types, which appear to be two distinctly different diseases.[69] Occasional cases do not fit neatly into either of these two types but show intermediate histologic features.

Type 1 autoimmune pancreatitis is thought to be the pancreatic manifestation of a systemic fibroinflammatory disease that may involve a multitude of organs including the liver, gallbladder, biliary tree, lung, salivary gland, lacrimal duct, lymph node, kidney, and prostate.[82,83,85,86] A unifying theme is increased IgG4+ plasma cells, typically more than 20/HPF, although this is not an entirely sensitive or specific finding in either tissue samples or serum measurement of IgG4.[87,88] It occurs predominantly in middle-aged to elderly patients, with male predominance. Grossly, the pancreas is extremely firm, and the inflammatory process may form a mass lesion (most often in the pancreatic head) simulating pancreatic cancer clinically and intraoperatively (Fig. 22.10A).[82,89,90] Microscopically, it is characterized

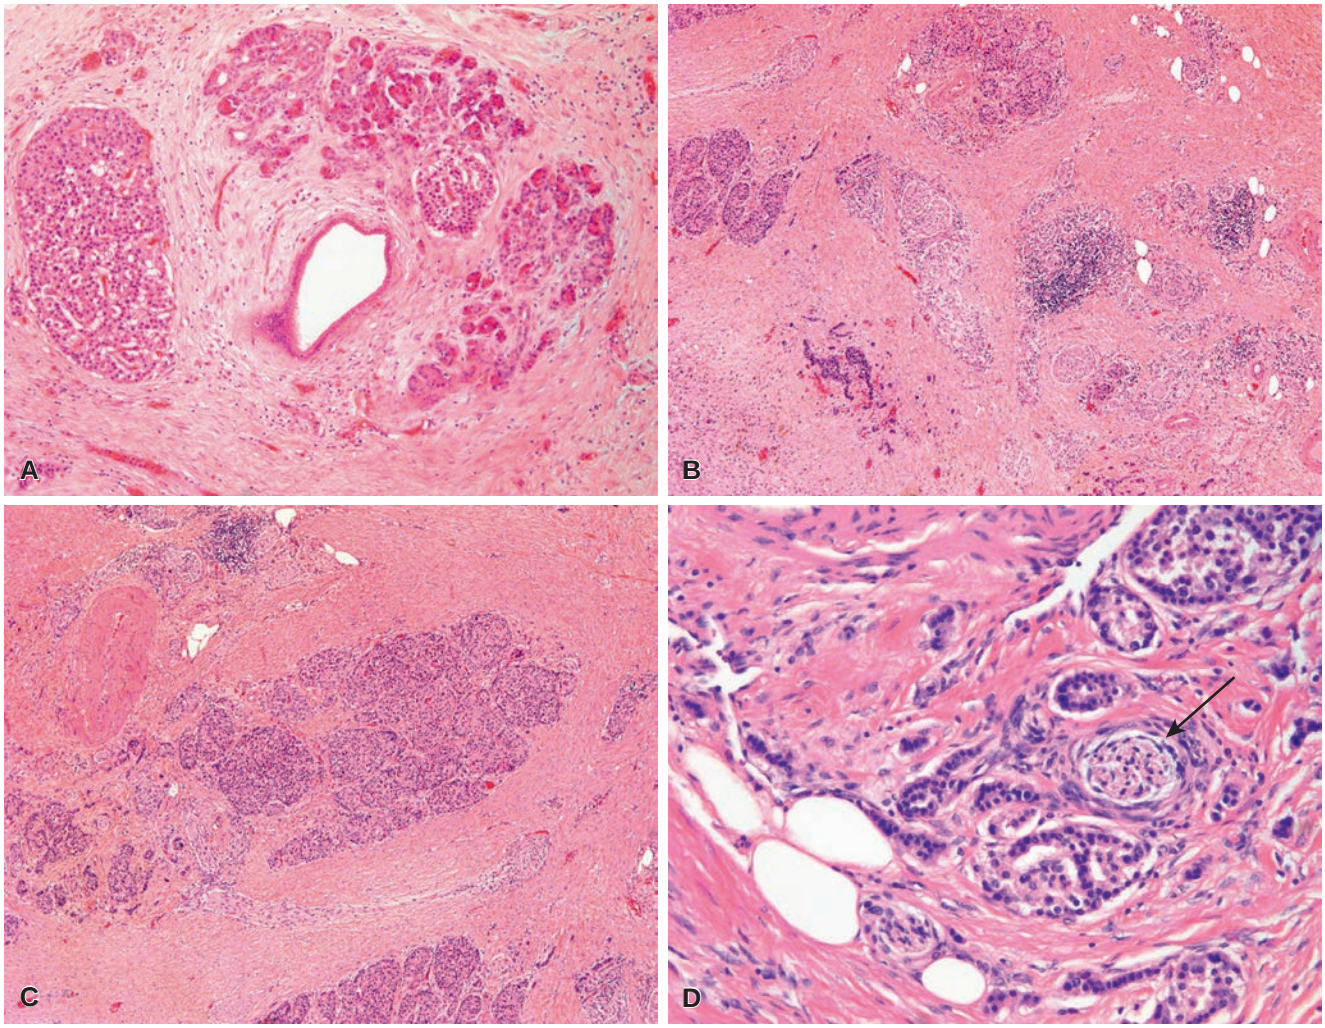

Figure 22.9 **A,** Chronic pancreatitis with fibrosis, mild chronic inflammation, and loss of acinar parenchyma. **B,** More extensive disease shows diffuse fibrosis, with prominent nerves, thick-walled vessels, and aggregates of islet cells. **C,** Residual islets may form aggregates (pseudohyperplasia) that can mimic a neuroendocrine neoplasm. **D,** Perineural extension of pancreatic endocrine cells *(arrow)* in chronic pancreatitis can mimic perineural invasion by a neoplasm.

by a dense lymphoplasmacytic infiltrate and fibrosis, hence the alternative term *lymphoplasmacytic sclerosing pancreatitis* (Fig. 22.10B–D). The fibrosis may be storiform, with plasma cells infiltrating between the stromal fibers. The fibroinflammatory process may center around the ducts, the lobules, or both, leading some workers to subdivide the disease into ductocentric, lobulocentric, and mixed subypes.[82,91] Non-necrotizing inflammation of veins and their surroundings ("venulitis" and "perivenulitis") are often present.[82,84,89,90] The inflammatory infiltrate can be patchy, rendering a biopsy diagnosis very difficult.[91] When the fibroblastic component is very prominent, the condition can be confused with inflammatory myofibroblastic tumor.[89] Increased numbers of IgG4-producing plasma cells may be found in ampullary/periampullary biopsies, as well as in pancreatic specimens,[88] and may be of some diagnostic assistance.[92]

Type 2 disease is also known as *idiopathic duct-centric chronic pancreatitis* or *autoimmune pancreatitis with granulocytic epithelial lesions*, and it is not associated with either elevated serum IgG4 or increased IgG4+ plasma cells, and thus some argue that it should not be called "autoimmune pancreatitis" at all.[93–95] Approximately one-third of cases are associated with chronic idiopathic inflammatory bowel disease, but patients do not manifest a multiorgan fibroinflammatory process like that seen in type 1 disease. Patients are typically younger than in type 1 disease, and there is no male predominance. A lymphoplasmacytic infiltrate is common, but diffuse inflammation, obliterative phlebitis, and storiform fibrosis are less common than in type 1 disease.[94] The most prominent feature is neutrophilic infiltration of the ductal epithelium ("granulocytic epithelial lesions") (Fig. 22.10E), which may lead to duct destruction. As mentioned previously, there are only rare or absent IgG4-positive plasma cells.

Paraduodenal Pancreatitis

This condition has also been described under a variety of names, including *cystic dystrophy of heterotopic pancreas, pancreatic hamartoma of duodenum, paraduodenal wall cyst,* or *groove pancreatitis,* the latter because it may involve the groove between the common bile duct, pancreas, and duodenum. The heterogeneity of names reflects various aspects of this disease.[96–98] This form of chronic pancreatitis typically occurs in male alcoholics, and it is clinically

significant because the dense fibrosis and irregular borders mimic neoplasia. Patients may present with signs and symptoms of duodenal obstruction.[97]

The fibroinflammatory process is typically centered on the duodenal wall, which is thickened, fibrotic, and trabecular, in the region of the minor papilla (Fig. 22.11).[96,97] Sometimes a scar plate develops between the head of the pancreas and the duodenum.[98] There are often numerous cysts, which may contain stones, fluid, or a grumous material, and which may be large enough to mimic intestinal duplication and/or compress the common bile duct.[96] Microscopically, there is myoid proliferation of the duodenal wall in the area of the minor ampulla, with associated cystically dilated ducts and sometimes acinar tissue and islets (although pancreatic elements may be difficult to locate).[96,97] The ducts contain inspissated secretions, which may rupture and induce a foreign body giant cell reaction. Neural hyperplasia and chronic inflammation may also

be prominent. Although alcohol is clearly a risk factor, it is hypothesized that some anatomic variation in ductal anatomy, such as obstruction of an accessory pancreatic duct, makes this region susceptible to injury.[96–98]

Other Forms of Chronic Pancreatitis

True idiopathic *eosinophilic pancreatitis* is extremely rare; numerous eosinophils in the pancreas are more likely to be secondary to autoimmune pancreatitis, allograft rejection, or histiocytosis X.[99] *Tropical pancreatitis*, also known as *tropical calculous pancreatitis* or *fibrocalculous pancreatic diabetes* if patients are diabetic, is limited to Brazil and other countries close to the equator in central Africa and southern Asia.[68] Although originally described in adolescents who were malnourished in childhood, more recent studies have emphasized that this disease can also occur in older patients, and a number of genetic abnormalities have also been described.[100] Morphologic features are similar to alcoholic chronic pancreatitis. *Obstructive chronic pancreatitis* is the result of narrowing or occlusion of the pancreatic ducts, the most common causes being carcinoma and stones. Most of the stones are found in the duct of Wirsung within 2–4 cm of the ampulla of Vater and often restricted to a small portion of the gland.[101] *Hereditary pancreatitis* is a rare autosomal dominant hereditary fibroinflammatory and necrotizing disease that begins in childhood or adolescence.[68,97] It is the cause of only 1%–2% of patients with chronic pancreatitis. Clinically and pathologically it simulates chronic alcoholic pancreatitis, although some patients (particularly adults) show marked fatty replacement of the pancreas. The genetic alterations involve mutations in the *PRSS1* (most common), *SPINK1*, or *CFTR* genes.[68,97,102]

Miscellaneous Inflammatory and Infectious Lesions

Pancreatic abscesses are most often seen as complications of acute pancreatitis. They are bona fide infections, characterized by the presence of pus and the microbiologic identification of bacteria in over 90% of the cases.[103] They have different presentation, clinical course, and outcome than infected pseudocysts and necrosis, from which they should be distinguished.[104]

Although relatively rare, a number of viruses, bacteria, fungi, and parasites can cause pancreatitis, including mumps,[105] adenovirus,[106] CMV,[107] *Candida* species,[108] tuberculosis (which may mimic pancreatic adenocarcinoma radiographically),[109] *Clonorchis*,[110] *Ascaris*,[111] and toxoplasmosis.[112] Many of these cases, particularly adenovirus, CMV, and toxoplasmosis cases, are associated with immunocompromise.

Other inflammatory conditions include *sarcoidosis*, an exceptionally rare condition that is a manifestation of systemic disease (Fig. 22.12)[113,114]; *malakoplakia*[115]; vasculitides, including *Henoch–Schönlein purpura* and *polyarteritis nodosa*[116,117]; and *rheumatoid nodules*, which have been described in the pancreas in an adult patient with long-standing rheumatoid arthritis.[118]

Pancreatic Transplantation

In the past decade pancreatic transplants in the United States have declined by approximately 20%–30%, although the numbers continue to increase in other countries.[119] The two main indications for pancreatic transplantation are chronic pancreatitis and insulin-resistant diabetes mellitus.[120–122] At present, pancreatic graft survival rates are between 78% and 86%, depending on the type of transplant.[121,122] The most common complication of pancreatic transplantation is graft thrombosis, which is believed to be related to multiple factors including vascular injury during procurement, preservation/perfusion variables, hypercoagulability, and decreased fibrinolysis found in diabetic recipients.[123] The second most common complication is "graft pancreatitis," which often occurs early in the post-transplant period and is also associated with reperfusion injury, donor factors, and cold ischemia time; early graft pancreatitis is associated with a high rate of graft loss.[124,125] The two other important complications, which tend to occur at a later stage, are recurrence of the original disease and rejection. Biopsy evaluation of the pancreas allograft is crucial in establishing the cause of allograft dysfunction.[126] Microscopic changes specific for rejection are vascular alterations such as "endothelialitis," vasculitis, and obliterative endarteritis.[127,128] Another common abnormality is a periductal lymphocytic or mixed infiltrate. Morphologic features found to correlate strongly with a negative outcome include moderate to severe inflammation of acinar tissue, acinar tissue loss and fibrosis, and vascular luminal narrowing.[129] Vasculitis is a more aggressive and clinically more significant lesion than endothelialitis and defines the existence of severe rejection.[129]

Transplanted pancreata show a significant increase in glucagon-producing islet cells and a corresponding decrease in insulin-producing cells, particularly in those that have rejection.[130]

Recurrent diabetes in the graft occurs in approximately 6%–8% of patients and is characterized by selective loss of insulin-secreting cells and the presence of "isleitis"; the presence of circulating autoantibodies; and the presence of autoreactive T cells in the blood, graft, or peripancreatic lymph nodes.[131]

Non-Neoplastic Cystic Lesions

Pseudocysts

Pseudocysts are the most common type of pancreatic cyst, comprising approximately 75% of pancreatic cystic lesions, and are related to acute or chronic pancreatitis, trauma, and, rarely, to neoplastic obstruction of large ducts.[132,133] They can become very large and spread beyond the substance of the pancreas into the lesser peritoneal cavity, retroperitoneum, perirenal space, or subdiaphragmatic space.[133] They range from 3 to 20 cm in size and are multiple in 10%–20% cases.[133] Grossly, the wall is thick and irregular (Fig. 22.13). The inner surface is ragged, and the intraluminal content is cloudy or bloody. Microscopically, the lack of epithelial lining is the main distinguishing feature between true cysts and cystic neoplasms, and any evidence of epithelium should prompt additional sections as cystic neoplasms with sloughed epithelial linings may mimic pseudocysts.[132] Fibrin, inflammation, hemorrhage, and fibrosis are often prominent. The intraluminal fluid has a high amylase content.[132,133] Communication with the ductal system may or may not be present.[134]

Complications of pancreatic pseudocyst include perforation, infection, and hemorrhage. The splenic artery is the most common source of the latter, which can be massive and result in sudden death.[133,135]

Traditionally, internal drainage has been done by open or laparoscopic surgery in the form of transgastric cystogastrostomy or cystojejunostomy to a Roux-en-Y loop of jejunum,[136] but endoscopic (transpapillary or transmural) drainage is becoming the preferred approach as the rate of pseudocyst resolution is comparable. External drainage is preferred for infected or ruptured pseudocysts. Pseudocysts in the tail of the pancreas (particularly if there is splenic vein involvement) and lesions that are anatomically not amenable to drainage should be surgically resected.

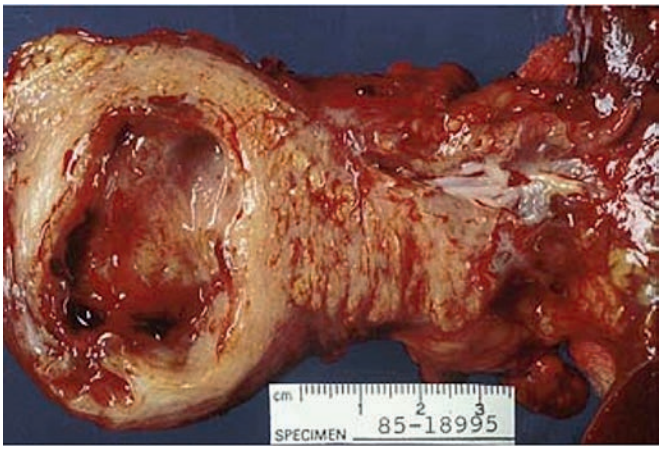

Figure 22.13 Pseudocyst with thick, irregular, fibrotic wall and hemorrhagic contents. (Courtesy of Dr. George F. Gray Jr.)

Congenital Cysts

These intrapancreatic cystic lesions do not communicate with the ductal system and are lined by a single layer of flat nonmucinous epithelium (Fig. 22.14).[133] They may be associated with von Hippel–Lindau (VHL) disease, fibropolycystic liver/kidney disease, or oral–facial–digital syndrome type I, particularly when multiple, and similar cysts of other viscera such as liver or kidney may be present.[133,137] This condition is also referred to as *pancreatic cystic dysplasia/dysgenesis* when associated with a malformation syndrome.[133,138]

Lymphoepithelial cysts are a distinctive variant of pancreatic cyst that are morphologically similar to the homonymous cysts of branchial pouch–derived structures. They are often multilocular and lined by squamous epithelium and feature abundant

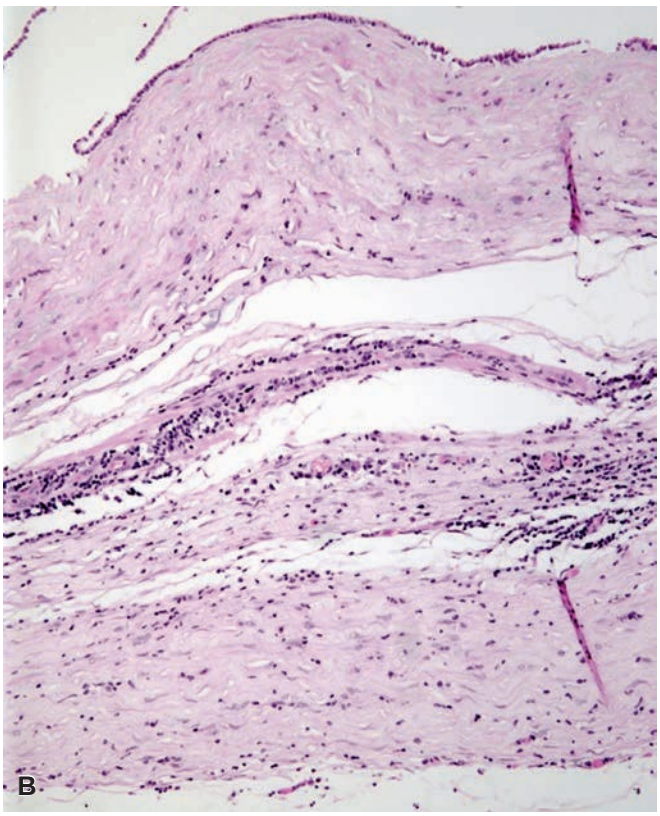

Figure 22.14 **A,** This large congenital cyst has a true epithelial lining and does not communicate with the pancreatic ductal system. **B,** Congenital cysts are lined by a single layer of flat nonmucinous epithelium.

lymphocytes in the wall, usually accompanied by germinal center formation (Fig. 22.15).[139–141] It has been suggested that these pancreatic lymphoepithelial cysts develop from pancreatic ducts protruding into a lymph node or an intrapancreatic accessory spleen.[139,142] Similar lesions include epidermoid cysts within intrapancreatic accessory spleens, and dermoid cysts (monodermal teratomas), which may contain sebaceous appendages, hair, and columnar or respiratory epithelium as well as squamous epithelium.[139]

Other non-neoplastic cysts of the pancreas include *retention cysts,* which are cystically dilated segments of pancreatic ducts that result from obstruction[133] (including *squamoid cysts*, lined by squamous epithelium but lacking lymphocytes in their wall)[143]; *para-ampullary duodenal wall cysts* (which may be derived from the ductal component of ectopic pancreatic tissue or be related to paraduodenal pancreatitis; see earlier)[133,144]; *enterogenous (enteric duplication) cysts*[133,145]; *mucinous non-neoplastic cysts*[146,147]; and *parasitic cysts* due to hydatid disease.[148] Mucinous non-neoplastic cysts can be unilocular or multilocular, and lack communication with the pancreatic ducts.[146,147] They have an apomucin phenotype different from that of intraductal papillary mucinous neoplasms (IPMNs), with which they can be confused.[147]

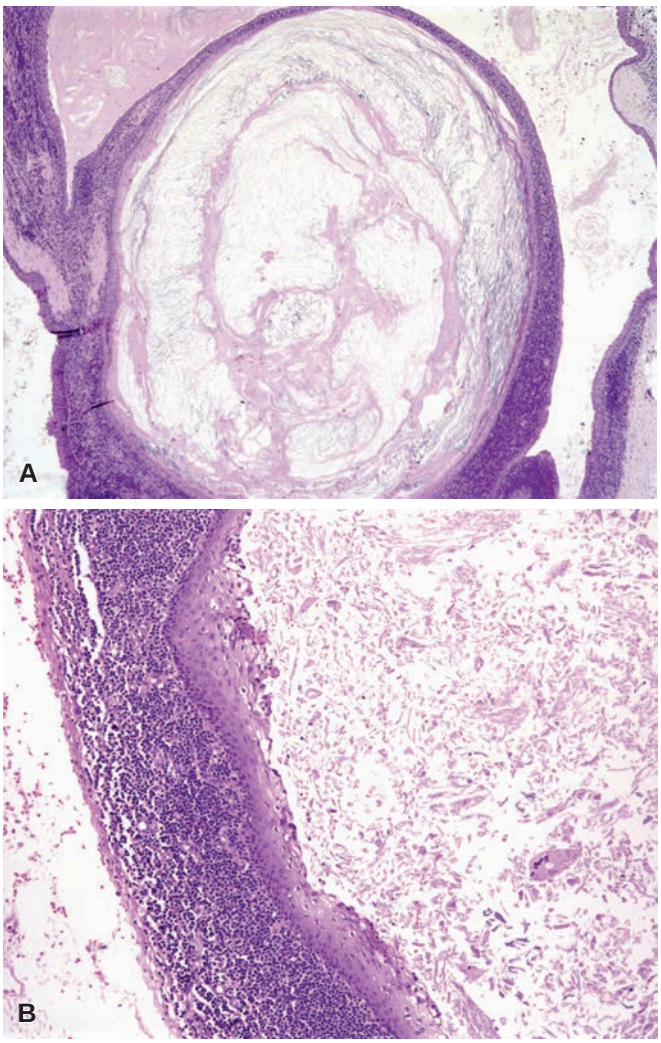

Figure 22.15 **A,** Lymphoepithelial cysts are often multilocular and contain abundant squamous debris. **B,** The cyst walls contain lymphoid tissue and are lined by squamous epithelium.

Cystic acinar transformation will be discussed later with acinar neoplasms.

Tumors

Ductal Adenocarcinoma

General and Clinical Features

Ductal adenocarcinoma of the exocrine pancreas comprises about 90% of all cases of pancreatic malignancy,[149] and it constitutes the fourth most common cause of death from cancer in the United States. Carcinomas of the pancreas share embryologic origin, differentiation pathways, population-related development, and microscopic features with tumors of the gallbladder, extrahepatic bile ducts, and ampulla of Vater, suggesting a field effect in carcinogenesis.[150]

Most patients with pancreatic carcinoma are elderly, and there is a slight male preponderance (1.6:1 ratio).[151,152] However, it can also occur in patients younger than 40 years.[153] With the exception of smoking, risk factors remain poorly elucidated.[149,151,152] It has been claimed that chronic pancreatitis is positively associated with an increased risk for pancreatic cancer, but the cause–effect relationship between the two diseases is often difficult to ascertain.[154–156] It has also been suggested that variations in pancreaticobiliary ductal anatomy may be related to the incidence of carcinoma, in view of the fact that lack of a common channel has been found at autopsy to be associated with microscopic abnormalities of the ductal epithelium.[157] There is an increase in the incidence of diabetes in patients with pancreatic carcinoma, but this usually develops within a short time after the diagnosis of cancer, suggesting that in most instances it represents a secondary event.[158] Overproduction of IAPP by beta cells may contribute to this complication.[159]

Presenting signs and symptoms depend on the location of the cancer within the pancreas, as well as the extent of disease at the time of diagnosis.[152] Vague abdominal pain is common, often in the upper abdomen and radiating to the back, which may be accompanied by nausea and weight loss.[152] Because of its strategic location in relation to the extrahepatic bile ducts, carcinoma of the head of the pancreas usually causes progressive jaundice that is associated with pain in at least half of the patients; however, the diagnosis in most cases is made when the tumor is relatively large (about 5 cm) and has extended beyond the pancreas (85% of the cases).[160] The rare small or microscopic pancreatic carcinomas that are found incidentally at autopsy also tend to be invasive and to be accompanied by perineural spread, regardless of small size.[161] Carcinomas of the body and tail of the pancreas grow insidiously and often have already metastasized at the time of diagnosis. Pancreatic adenocarcinoma is associated with deep venous thrombi in about 20% of patients, and the risk increases with initiation of chemotherapy[162,163]; these may be a late development in patients with overt carcinoma or may be present in patients with clinically silent tumor.[164,165] The syndrome is thought to be due to the release of tumor necrosis factor, interleukin-1, and interleukin-6 by macrophages present in tumor stroma. Another mechanism may be production of substances with procoagulant activity by the tumor cells themselves.[166]

It is estimated that about 10% of pancreatic cancers have an inherited component.[167,168] At least five such syndromes have been identified, including (1) hereditary breast and ovarian cancer syndrome associated with germline mutation of *BRCA2*; (2) familial atypical multiple mole melanoma syndrome with germline mutation in the *p16* gene; (3) Peutz–Jeghers syndrome with germline mutations in the *STK11/LKB1* gene; (4) hereditary nonpolyposis colorectal cancer with germline mutations in one of

the DNA mismatch repair genes; and (5) hereditary pancreatitis with germline mutations in the *PRSS1* gene that encodes cationic trypsinogen.[167–169]

Location and Gross Features

Pancreatic ductal carcinoma is located in the head of the pancreas in two-thirds of the patients and in the body or tail in the other third.[151] Multiple tumors are found in a minority of the cases. Most pancreatic ductal adenocarcinomas are poorly delineated, fibrotic, and firm, with a yellow-gray cut surface (Fig. 22.16).[170] It is frequently difficult to distinguish tumor from adjacent chronic pancreatitis grossly. Rarely, the tumor undergoes massive cystic degeneration and thus may mimic other cystic pancreatic tumors.[171] The duodenal wall is invaded by direct extension in one-fourth of the tumors arising from the pancreatic head. The involved pancreatic ducts may become greatly dilated and plugged with necrotic tumor, or compressed and even destroyed by tumor growth. Extrapancreatic extension is common; when extensive, it may be very difficult to determine whether or not a given tumor is of pancreatic origin versus ampulla, common bile duct, or duodenum.[172]

The non-neoplastic pancreas adjacent to the tumor may show extensive atrophy, chronic inflammation, and fibrosis, plus the ductal dilation previously mentioned. Precursor lesions, or pancreatic intraepithelial neoplasia (PanIN, see below) may also be present, especially in familial cases.[173,174]

Microscopic Features

Microscopically, typical pancreatic ductal adenocarcinomas consist of infiltrating, haphazard glands and ducts with surrounding desmoplastic stroma (Fig. 22.17A) and may be stratified as well, moderately, or poorly differentiated, although this has limited prognostic significance.[168,170] Poorly differentiated carcinomas often have more significant nuclear pleomorphism and less well developed glandular differentiation, along with areas of solid growth and easily identified mitoses. In well-differentiated tumors, the microscopic diagnosis in a biopsy specimen can be extremely difficult, and close attention must be given to cytologic details. At low-power examination, the glands are often well formed, have a large lumen, and are lined by one or a few layers of cylindrical or cuboidal epithelium. Their overall low-power appearance may not be particularly suggestive of carcinoma, except for the irregularities in the shape and distribution of the glands and the prominent concentric desmoplastic stroma that surrounds them; however, high-power examination of the lining epithelium will show one or more features that, in this location, are indicative of malignancy: marked nuclear pleomorphism, variation in nuclear size, loss of polarity, prominent nucleoli, and mitotic activity. This disparity between the high degree of cytologic atypia and the low level of architectural atypia is typical of tumors of the pancreaticobiliary region (Fig. 22.17B and C). Features useful in diagnosing carcinoma within small biopsy specimens include glands present outside the normal lobular architecture; the presence of glands immediately adjacent to muscular arteries (Fig. 22.17D); and necrotic debris within gland lumens.[170,175] Perineurial invasion (Fig. 22.17E), which is present in 90% of the cases, constitutes an additional important diagnostic sign. However, there are two caveats: benign epithelial inclusions have been observed in pancreatic nerves,[176] and perineurial extension of islet cells can occur in chronic pancreatitis (see earlier and Fig. 22.9D).[71] The perineurial invasion by carcinoma can extend from the intrapancreatic nerves into the extrapancreatic neural plexus, a fact that might have some bearing on the surgical procedure.[177] Invasion of blood vessels (Fig. 22.17F), particularly veins, is seen with half of the tumors. The presence of ducts surrounded by adipose tissue without intervening acini ("naked ducts") are also highly indicative of malignancy,[178,179] but this finding is rarely present in biopsy specimens.

The non-neoplastic lobular tissue surrounding ductal adenocarcinoma may show significant alterations as well. The islet tissue is usually well preserved; however, both atrophic and hypertrophic changes can occur in the islets, and rarely hypertrophy of the islets produces hypoglycemia. Most commonly, destruction of a variable amount of islet tissue mass results in a subclinical or overt diabetic picture. The surrounding parenchyma may be completely destroyed because of ductal occlusion by the invasive carcinoma and subsequent pancreatitis.

Microscopic precursor lesions, previously known as atypical hyperplasia, papillary hyperplasia, dysplasia, or carcinoma in situ, are currently classified as PanIN (Fig. 22.18).[170] This concept is supported by the realization that these lesions are often adjacent to invasive ductal adenocarcinomas and have been identified in pancreata years before the development of invasive carcinoma; and that the majority of the molecular alterations present in invasive ductal adenocarcinoma are present in PanIN, and the prevalence of genetic alterations increases with the degree of morphologic atypia.[180] Recently, the previous three-tiered system for classifying PanIN was combined into a two-tiered system, so that lesions formerly classified as PanIN-1 and PanIN-2 are now grouped as low-grade lesions (and are generally regarded as clinically inconsequential) and PanIN-3 is classified as a high-grade lesion.[181] Both low-grade and high-grade PanIN can be found in the duct epithelium adjacent to carcinoma in about 40% of cases, sometimes at a distance from the main tumor mass and even at the point of surgical transection.[182] Conversely, the incidence of these lesions, particularly high-grade PanIN, in the pancreata of control subjects is very low.[182] The

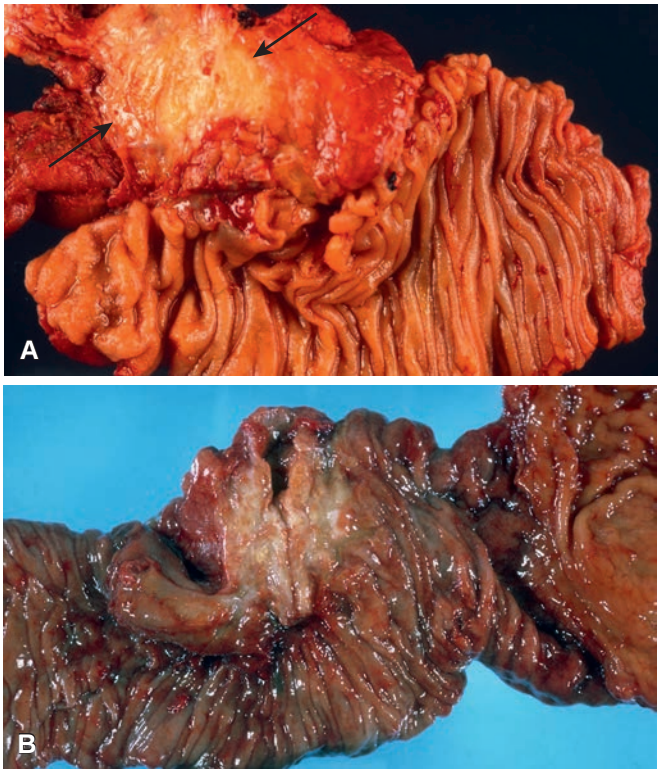

Figure 22.16 Gross Appearance of Invasive Pancreatic Ductal Adenocarcinoma. A, A poorly defined mass obliterates the normal pancreatic architecture *(arrows)*. **B,** A gritty, gelatinous poorly defined tumor surrounds common bile duct, which is markedly dilated. Figure 22.17 **A,** Well-differentiated ductal adenocarcinomas with infiltrating, haphazard glands and surrounding desmoplastic stroma. Well-differentiated neoplastic glands may be extremely bland at low power, and attention must be given to cytologic features such as marked nuclear pleomorphism, variation in nuclear size **(B)**, loss of polarity, prominent nucleoli, and mitotic activity (**C,** *arrow*). **D,** Neoplastic glands immediately adjacent to muscular arteries are a useful diagnostic feature of malignancy. Perineural invasion **(E)** and vascular invasion **(F)** are frequent findings in ductal adenocarcinoma.

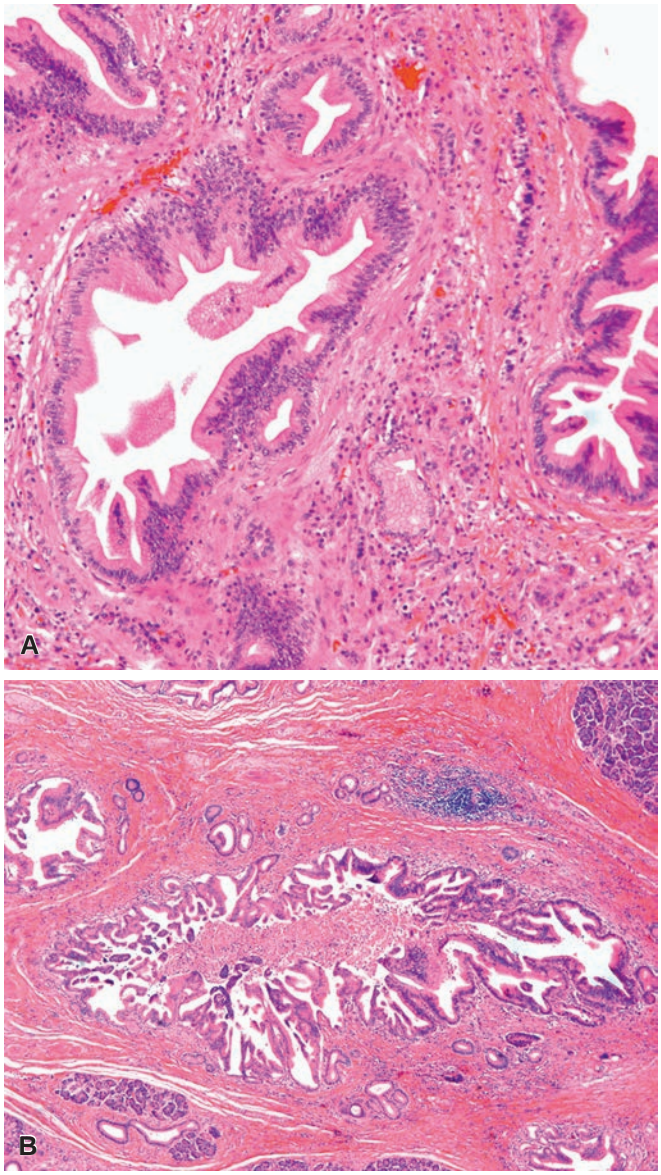

Figure 22.18 **A,** Low-grade PanIN characterized by tall columnar mucinous epithelium without nuclear atypia. **B,** High-grade PanIN features architectural complexity, unsupported tufts of epithelium in the lumen of the duct, and marked nuclear atypia.

presence of PanIN of any grade at a margin of resection for invasive ductal adenocarcinoma does not appear to affect patient survival, however.[181]

Other Microscopic Types

There are several patterns of ductal adenocarcinoma that do not differ significantly from the conventional type clinically or prognostically but do have distinctive morphologic features. The *foamy gland pattern* (Fig. 22.19A) has a deceptively benign appearance and may be confused with non-neoplastic mucinous ducts.[183] The *large duct pattern* has large, ectatic or microcystic malignant glands, which may be mistaken for benign dilated glands or a lower-grade noninvasive cystic neoplasm, particularly if the cytologic features are bland (Fig. 22.19B).[184] The *vacuolated pattern* consists of irregular or cribriforming nests of cells with prominent large, empty vacuoles, which may contain debris or mucin (Fig. 22.19C).[185] The *micropapillary pattern* resembles that in other anatomic sites. Some tumors may have a signet ring cell component or features that resemble colorectal adenocarcinoma.[186]

Other uncommon but reasonably distinctive variants of pancreatic adenocarcinoma include *adenosquamous* and *squamous carcinoma* (a term more accurate than mucoepidermoid carcinoma or adenoacanthoma) (Fig. 22.19D).[187,188] The squamous elements may range from benign-appearing to poorly differentiated or may show basaloid features (Fig. 22.19E).[189] Tumors should be at least 30% squamous to warrant the designation of adenosquamous per the WHO 2010 classification; pure squamous cell carcinomas of the pancreas are exceedingly rare, and some reported cases may represent adenosquamous carcinomas in which the squamous component has overrun the glandular elements, or the glandular elements were not sampled. *Medullary carcinoma* is similar to those found in the breast and GI tract (Fig. 22.19F), are sometimes multicentric, and are associated with wild-type (nonmutated) *KRAS*. Some have microsatellite instability as well, similar to their colonic counterparts, and regardless of MSI status they have been strongly associated with a family history of colon cancer.[190] Colloid carcinomas (Fig. 22.19G) are often associated with IPMNs or mucinous cystic neoplasms (MCNs) (see later) and have a more protracted clinical course than conventional ductal adenocarcinoma.[191,192] They express markers characteristic of intestinal differentiation (CDX2, CK20, and MUC2).[191] They are rarely associated with pseudomyxoma peritonei.[193] It has been postulated that the mucin in these tumors acts as a containment barrier, thus limiting the spread of the neoplastic cells.[191,192]

Poorly differentiated ductal adenocarcinomas may also have a *clear cell* phenotype (which is immunoreactive for hepatocyte nuclear factor-1 beta) or may have oncocytic features. These patterns can mimic both renal cell carcinoma and other oncocytic neoplasms.[194,195] *Hepatoid carcinomas* of the pancreas are a rare and heterogeneous group of tumors that may have pure hepatoid differentiation or exist in association with other histologic types, both ductal and neuroendocrine. These tumors are immunoreactive with Hep Par1, CD10, AFP, and polyclonal CEA, and must be distinguished from true hepatocellular carcinoma involving the pancreas.[196,197]

Microadenocarcinoma had originally been described as an allegedly distinct type of pancreatic ductal adenocarcinoma characterized by a microglandular appearance, but re-evaluation of the originally reported cases and study of new ones has led to the conclusion that it represents instead a pattern of growth associated with an aggressive clinical course rather than a distinctive morphologic entity.[198]

Tumors termed *undifferentiated carcinomas* of the pancreas include tumors previously classified as anaplastic carcinoma, sarcomatoid carcinoma, spindle cell carcinoma, pleomorphic carcinoma, carcinosarcoma, and undifferentiated carcinoma with osteoclast-like giant cells; the latter term also encompasses tumors previously known as giant cell tumors of the pancreas. In most cases these are variants of ductal adenocarcinomas; however, their appearance is so distinctive and their behavior so aggressive that a distinction from the ordinary ductal adenocarcinoma is warranted.[199,200] The majority of the patients are above the age of 50 at the time of diagnosis, and there is a male predilection. The prognosis is extremely poor overall.

Undifferentiated tumors with primarily anaplastic, spindled, or sarcomatoid morphology (Fig. 22.20A and B) often contain heterologous elements. Immunohistochemically, stains for keratin, EMA, and CEA are typically positive in the obvious epithelial component and sometimes, but certainly not always, in the sarcoma-like areas (Fig. 22.20C). Undifferentiated carcinomas can be accompanied by areas of conventional ductal adenocarcinoma, or a pre-invasive neoplasm such as a mucinous cystic tumor or intraductal papillary

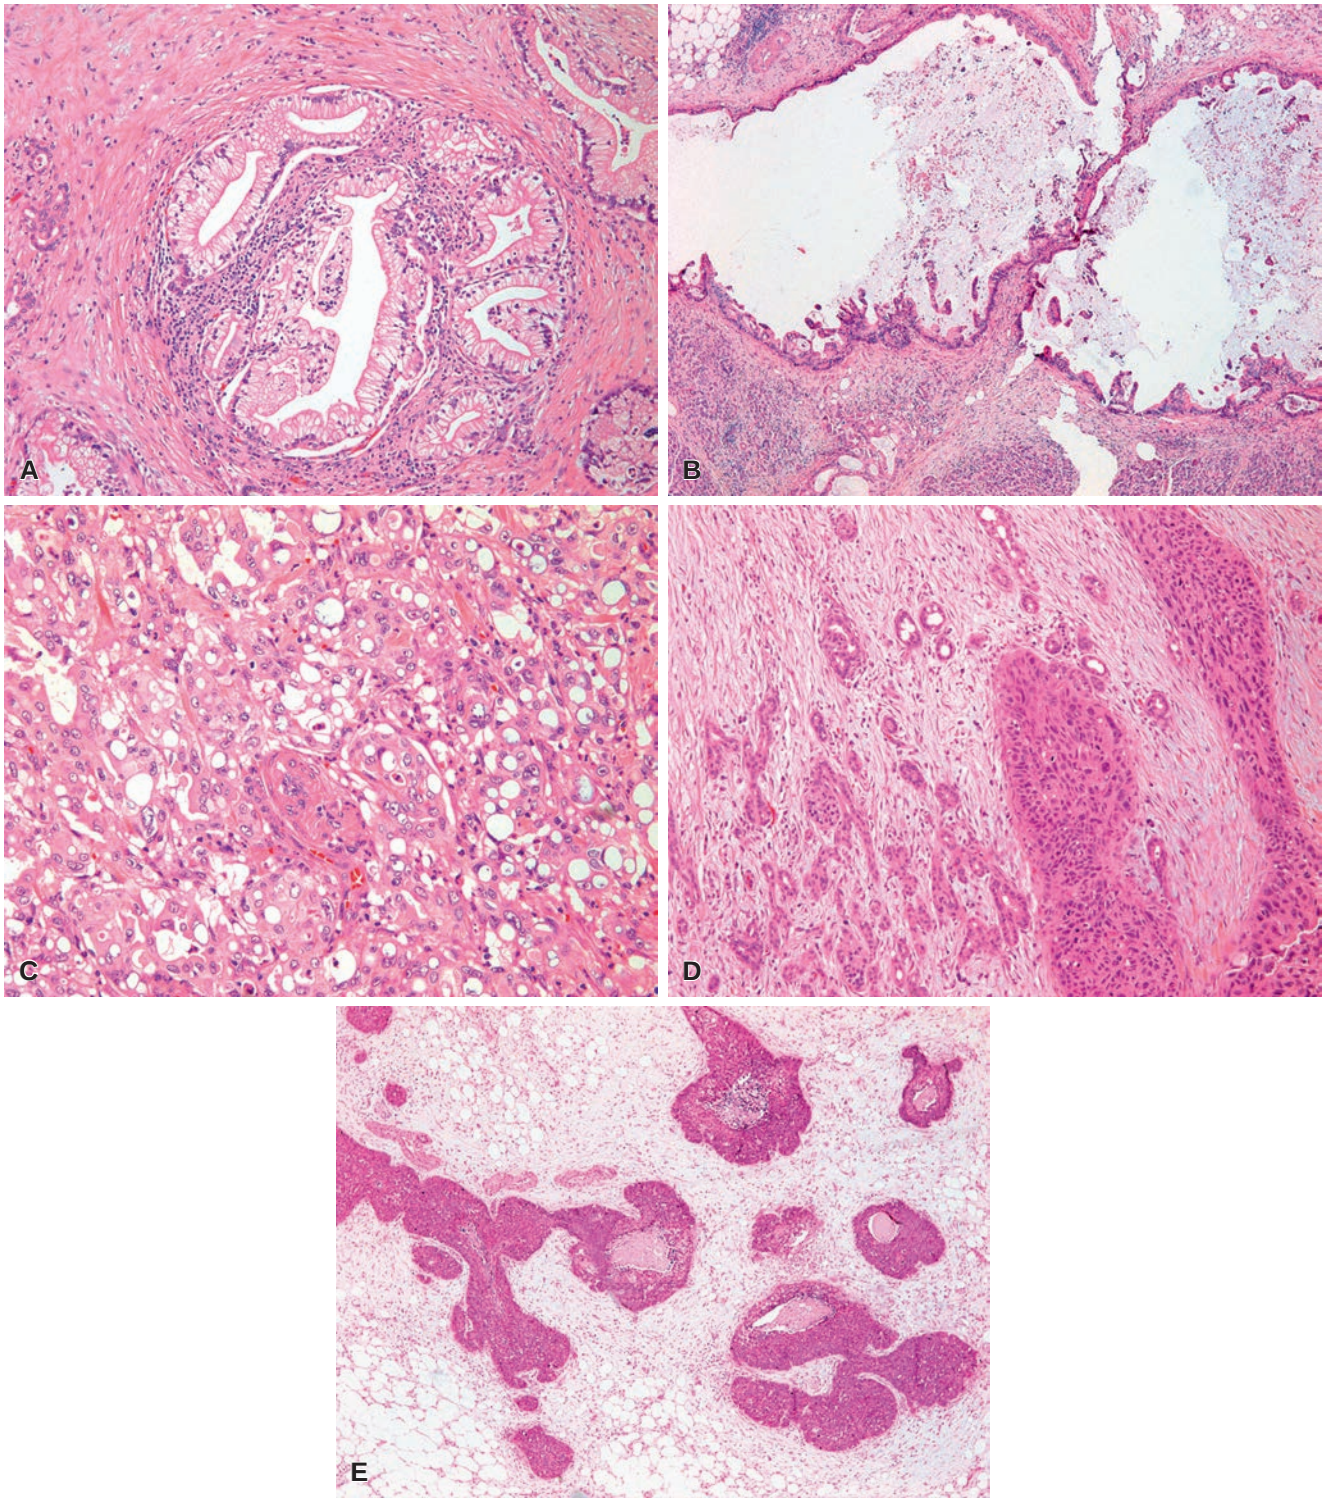

Figure 22.19 **A,** Foamy gland pattern of ductal adenocarcinoma features foamy, microvesicular cytoplasm; small, often basally located nuclei; and condensation of the cytoplasm at the luminal aspect of cell resembling a brush border. **B,** The neoplastic glands in the large duct pattern are large and microcystic, and may be mistaken for benign dilated glands or a lower-grade noninvasive cystic neoplasm. **C**, Vacuolated pattern with cribriformed nests of cells with prominent large, empty vacuoles. **D,** Adenosquamous carcinoma consists of both glandular and squamous components. **E,** Some adenosquamous variants may have prominent basaloid features.

Continued

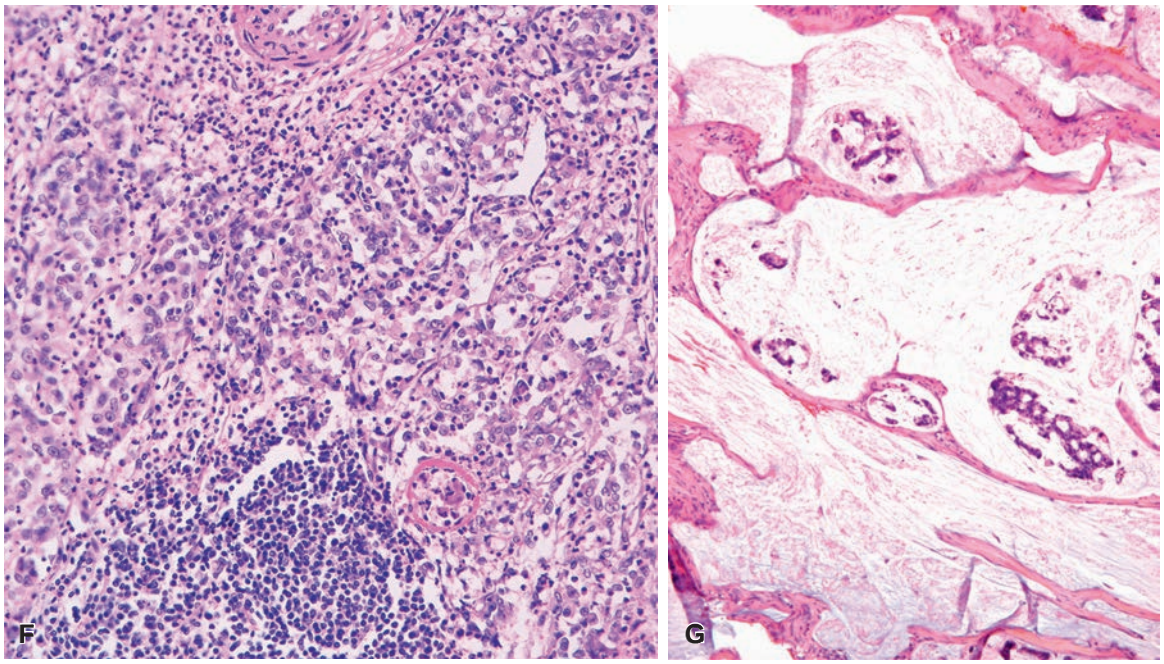

Figure 22.19 cont'd **F,** Medullary carcinoma is similar to that seen in other organs, with a solid growth pattern and numerous tumor-infiltrating lymphocytes. **G,** Colloid carcinoma features large pools of mucin-containing clusters of tumor cells, some of which have signet ring cell features. (**F,** Courtesy of Dr. Volkan Adsay.)

mucinous tumor[201–202]; biphasic tumors with a sarcomatoid component and a separate glandular component may be termed carcinosarcomas. The presence in both components of the same *KRAS* mutations suggests a common origin.[203–205]

Undifferentiated carcinomas with osteoclast-like giant cells are usually large and hemorrhagic, and occasionally they grow in a fashion simulating a pseudocyst.[206] Microscopically, the tumor has a dual population: relatively uniform spindle cells of mesenchymal appearance and atypical cytologic features (such as nuclear hyperchromasia and high mitotic activity) alternate with multinucleated giant cells having an appearance and a histochemical profile indistinguishable from that of normal osteoclasts.[200,207] The nuclei of these osteoclast-like cells are uniformly small, and mitoses are absent. Bizarre giant cells with atypical nuclei may also be found, however (Fig. 22.20D).

Histochemical and Immunohistochemical Features of Pancreatic Ductal Adenocarcinoma

Most pancreatic ductal adenocarcinomas express cell surface–associated mucins, including MUC1, MUC3, MUC4, and MUC5AC.[208–210] Immunohistochemically, glycoprotein MUC1 is expressed in over 80% of conventional invasive ductal carcinomas and in a similar percentage of high-grade PanIN, supporting a pathogenetic relationship between the two; this is in contrast to the intraductal papillary carcinomas discussed later, mucinous (colloid) carcinomas, ampullary carcinomas, and colorectal carcinomas, which are more often positive for MUC2.[211] MUC6 is expressed in approximately one-third of ductal adenocarcinomas.[212]

The keratins expressed are those of simple epithelia such as 7, 8, 18, and 19 (as normal ductal cells),[208] but also 20, 17, and occasionally cytokeratin 5/6.[213,214] Cytokeratin 20 is expressed less frequently in pancreatic ductal than in ampullary adenocarcinomas,[213] but the difference is not such as to be of diagnostic assistance. CK20 expression may be strong and diffuse in pancreatic colloid carcinomas, as they express markers of intestinal differentiation.[215] Ductal adenocarcinomas also frequently express EMA, CEA, CA125, mesothelin, TAG72, DUPAN2, and CA 19-9.[170,216–218] Unfortunately, ducts in cases of chronic pancreatitis also exhibit immunoreactivity for many of these markers, thus greatly diminishing their differential diagnostic utility. However, CEA, TAG72, and CA125 are not typically expressed in non-neoplastic ducts.[219–221] A high proportion of ductal adenocarcinomas also contain a minor population of neoplastic cells that are immunoreactive with neuroendocrine markers, such as synaptophysin or chromogranin.[222–223] There is also frequent expression of the neural cell adhesion molecule N-CAM.[224]

Molecular Genetic Features

A large number of molecular alterations have been described in pancreatic ductal adenocarcinoma.[170,225,226] The most commonly mutated genes include *KRAS, CDKN2A* (*p16*), *TP53, SMAD4/DPC4*, and *MKK4*. Mutations of the *KRAS* oncogene are found in over 90% of the cases and represent an early genetic alteration.[225] Mutations of *p16/CDKN2A*, *TP53*, and *SMAD4* occur in more than half of cases as well.[227,228] These molecular alterations are typical of pancreatic ductal adenocarcinoma and distinguish them at a molecular level from other pancreatic neoplasms.[229] It is worth mentioning that the search for genetic molecular alterations in the invasive component of pancreatic ductal adenocarcinoma and in precursor intraepithelial lesions of the same specimen have provided key information on the genetic progression of pancreatic carcinoma (Fig. 22.21).[230,231] It is important to point out that patients with chronic pancreatitis, but lacking microscopic features of invasive or in situ adenocarcinoma or ductal atypia, often have *KRAS* mutations in the non-neoplastic epithelium, indicating that this genetic alteration is not specific for malignancy or even premalignant conditions.[232] Obviously, this limits greatly the diagnostic utility of this marker in histologic or cytologic material. Since *DPC4* is inactivated in approximately half of

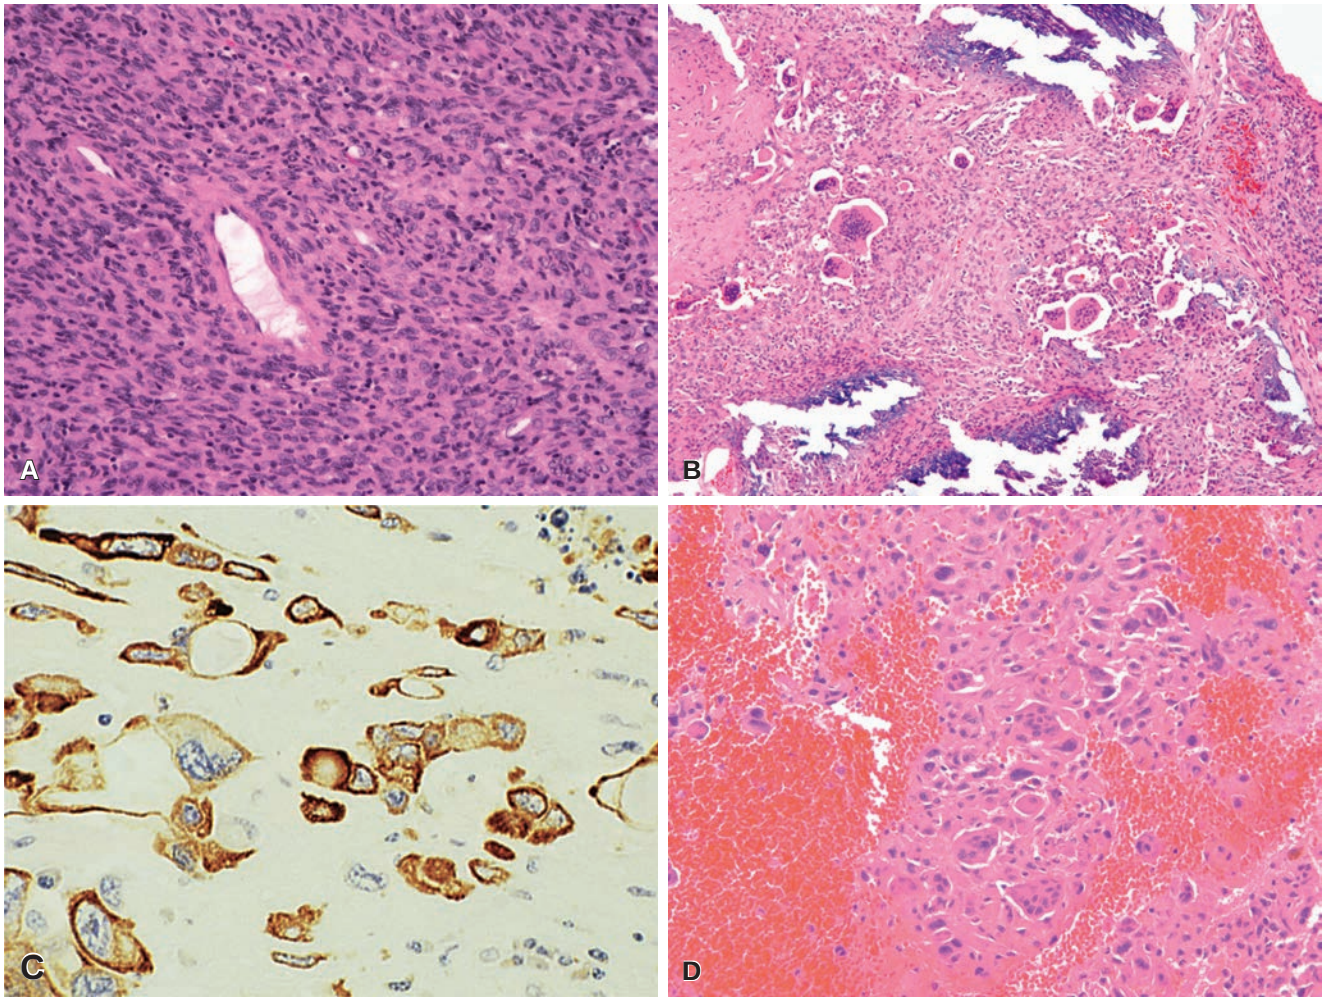

Figure 22.20 **A,** This undifferentiated carcinoma is composed entirely of spindle cells and should not be misinterpreted as a sarcoma. **B,** This example of undifferentiated carcinoma with osteoclast-like giant cells contains areas of cartilage with ossification. **C,** Anaplastic carcinoma of pancreas showing immunoreactivity for keratin. **D,** Some cases contain large anaplastic tumor cells as well as osteoclast-like giant cells (**A,** Courtesy of Dr. Volkan Adsay. **D,** Courtesy of Dr. Becky Wheeler.)

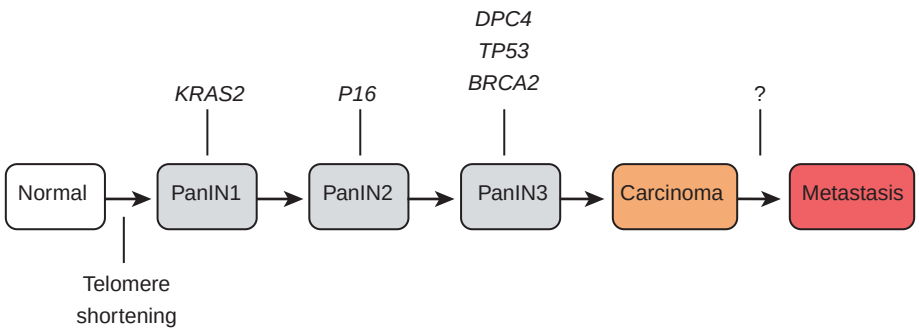

Figure 22.21 **Genetic Progression Model of Pancreatic Carcinogenesis.** The progression from histologically normal epithelium to low-grade pancreatic intraepithelial neoplasia (PanIN1 and PanIN2), to high-grade PanIN3, to invasive carcinoma *(left to right)* is associated with the accumulation of specific genetic alterations. On the basis of their temporal appearance in this progression model, the molecular abnormalities can be classified as early (*KRAS2* mutation, telomere shortening), intermediate (*P16/CDKN2A* loss), or late (mutations of *DPC4/SMAD4, TP53, BRCA2*). However, those changes that specifically promote progression to metastatic disease remain unknown. (From Yachida S, Iacobuzio-Donahue CA. The pathology and genetics of metastatic pancreatic cancer. *Arch Pathol Lab Med*. 2009;133:413–422.)

pancreatic ductal carcinomas but practically never in benign conditions, the immunohistochemical *absence* of the protein product in the ductal epithelium of a pancreatic biopsy specimen is strongly suggestive of carcinoma, while positive staining does not rule out this possibility.[170] Although Lynch syndrome patients have a seven- to eightfold increase in pancreatic ductal adenocarcinoma, MSI does not appear to play a significant role in sporadic ductal adenocarcinomas; the rare cases of pancreatic carcinoma that are MSI-high tend to have the medullary phenotype. These tumors typically do not have *KRAS* mutations but commonly exhibit mutations in the *BRAF* gene, a downstream component of the *KRAS* pathway.[226,233]

Spread and Metastases

Pancreatic ductal adenocarcinoma often spreads widely into the peripancreatic soft tissues.[234] Those located in the head may invade the duodenum (including the ampulla) and the common bile duct. They also tend to surround the mesenteric vessels and the nerve plexus, rendering a complete excision very difficult and often resulting in positive gross or microscopic margins.[235,236] Interestingly, nerve invasion has been correlated with expression of nestin (an intermediate filament found in neuroepithelial stem cells) in the tumor cells.[237]

Ductal adenocarcinomas also metastasize to multiple lymph nodes located around the organ. The lymph node groups most often involved in carcinoma of the head of the pancreas are those around the common hepatic artery, hepatoduodenal ligament, posterior pancreaticoduodenal, around the superior mesenteric artery, paraaortic, and anterior pancreaticoduodenal.[238–240] Of note, Cubilla et al.[241] found that in 33% of patients with pancreatic ductal carcinoma, nodal metastases were present in groups of nodes not usually removed with the standard Whipple procedure. Lymph node metastases may occur very early in the course of the disease, even in T1 and T2 tumors.[242,243] The most common sites of distant metastases are liver, peritoneum, lung, adrenal, bone, distant lymph node groups, skin, and central nervous system.[244] Sometimes, a distant nodal metastasis (particularly in the supraclavicular region) is the first manifestation of pancreatic carcinoma.[245]

Cytology

Endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) has become the method of choice for the diagnosis of both solid and cystic pancreatic tumors, with a sensitivity of approximately 85% and a specificity of approximately 98%, exceeding that of brush cytology.[246] The location of the lesion, size, consistency, and vascularity may all affect the ability to obtain a diagnostic specimen, however. Cytologic specimens may also be used for a variety of ancillary studies useful to the diagnosis of pancreatic ductal adenocarcinoma, including immunohistochemistry for *SMAD4* loss, mutational analysis for *KRAS* and *p16*, FISH (for a number of molecular abnormalities), and microRNA analysis.[247] It should be pointed out that EUS-FNA can also successfully identify cystic lesions such as IPMNs and mucinous cystic tumors,[248] and that in addition to the ancillary studies listed previously, cyst fluid can be analyzed for CEA and CA 19-9.

Surgical Exploration and Frozen Section

At the time of exploration for a presumptive or confirmed diagnosis of carcinoma of the pancreas or ampullary region, the surgeon will search for evidence of metastatic disease in the peripancreatic nodes, liver, and peritoneum, and typically a frozen section will be requested if a lesion at any of these sites is encountered. In the absence of detectable metastases, the surgery will proceed. If the diagnosis has not been confirmed preoperatively, and a mass is palpated in the pancreas, a frozen section on a core needle biopsy or an intraoperative fine-needle aspiration will often be requested. The last technique has become popular because it minimizes the possibilities of hemorrhage, pancreatitis, and tumor seeding that exist with the biopsy procedures.[249] When the pancreatic head is biopsied, experience is required to avoid the common bile duct, the gastroduodenal artery, and the portal vein.

Although current literature indicates that reexcision to try and achieve negative margin status is not associated with improved patient survival,[250,251] the performance of intraoperative frozen sections on margins during the resection of pancreatic adenocarcinomas is still routine practice in many institutions. Frozen section interpretation of pancreatic lesions can be very difficult because of the well-differentiated nature of many carcinomas on one hand, and the architectural distortion resulting from chronic pancreatitis on the other (see earlier).[252,253] One should search for perineurial invasion and also evaluate carefully the cytologic features of the glandular formations.[253] When examining sections from the terminal portion of the common bile duct or the ampullary region, one should be careful not to misinterpret accessory pancreatic ducts or periluminal sacculi of Beale as malignant.[254] If all of these precautions are heeded, the accuracy of the intraoperative frozen section diagnosis is very high, and the percentage of cases in which the diagnosis needs to be deferred is low.[255]

Treatment

Treatment of pancreatic adenocarcinoma may include surgery, chemotherapy, and radiation, depending on the stage of the tumor.[152,256] Surgery is considered to be the only curative treatment. Adenocarcinomas without distant metastases are categorized as resectable, borderline resectable, or locally advanced, although definitions of these terms are not standardized and depend on surgical techniques and the ability of a given center to perform en bloc resection of the portal vein, superior mesenteric vein, or both.[149,256] Surgical approaches include the Whipple operation (pancreaticoduodenectomy), total pancreatectomy, and distal pancreatectomy for neoplasms of the distal body/tail, and it is recommended that 12–15 lymph nodes be resected for optimal pathologic staging.[152] These operations have traditionally carried a 10%–20% mortality rate,[257,258] but this has decreased to less than 2% in recent times in specialized centers.[149] Surgical outcomes tend to correlate strongly with the volume of cases encountered by both the surgeon and the institution.[149,256] A plea has been made to include a retroperitoneal resection (with removal of nerve plexuses and lymph nodes) in curative resections for patients with stage I or II pancreatic carcinoma to diminish the frequency of retroperitoneal recurrence, but many authorities advise against this due to lack of evidence for survival advantage and compromised quality of life due to intractable diarrhea.[256]

Adjuvant chemotherapy may be given after surgery for resectable pancreatic cancer and may result in improved disease-free and overall survival; studies are ongoing regarding the optimal drug regimen.[152,256] The median overall survival remains at only 20–22 months, however.[152] The role of neoadjuvant chemotherapy in borderline resectable or locally advanced adenocarcinomas remains controversial.[149,256] Unfortunately the majority of patients present with metastatic disease, and chemotherapy is the mainstay of therapy for this group, typically with a gemcitabine-based regimen.[152] The advantages of adding radiation to a chemotherapy regimen remain controversial.[149,152,256] Patients requiring palliative care may benefit from surgical, radiologic, or endoscopic interventions for gastric, small bowel, or biliary obstruction.[256] Tumors treated with modern preoperative neoadjuvant chemoradiation regimes often show fibrosis and extensive necrosis.[259]

A certain number of Whipple operations (almost 10% in some large centers) performed for the clinical impression of pancreatic carcinoma will reveal only non-neoplastic disease upon microscopic examination of the resected specimen; a significant number of these cases are ultimately diagnosed as autoimmune pancreatitis (see earlier).[260] This occurrence should be reduced to a minimum, but at the current stage of knowledge it must be accepted as one of the inevitable occasional outcomes of the procedure.

Prognosis

As in most other organs, stage is the most important prognostic determinator. Pancreatic adenocarcinoma is staged using the tumor–node–metastasis classification (AJCC classification scheme in North America). Tumors are often clinically staged using contrast-enhanced CT scan, which is about 80% accurate.[149] Median overall survival is approximately 4 months. When segregated by stage, overall survival ranges from approximately 40% (stage I) to 8% (stage IV) at 1 year, to 12% (stage 1) and 0.7% (stage IV) at 5 years.[261] Tumor size, node status, and distant metastases are independent predictors of survival.[261] Other adverse prognostic factors include high tumor grade, markedly elevated serum CA 19-9, persistently elevated CA 19-9 postoperatively, and positive resection margins.[152] It has been claimed that cytokeratin 20 and maspin expression are associated with decreased overall survival,[262,263] and *SMAD4* gene inactivation is associated with a worse prognosis as well.[264]

Cystic Neoplasms

Secondary cystic changes can be seen in most types of pancreatic neoplasms, whether of exocrine or endocrine nature.[265] These are to be distinguished from tumors in which a cystic configuration is universally present and part of their definition (i.e., cystadenomas and cystadenocarcinomas). It is just as important for these to be clearly separated from the non-neoplastic cysts previously described, and it is recommended that confusing terms such as proliferative pancreatic cysts be avoided.[266] The large majority of cystic pancreatic neoplasms fall into two distinct categories—serous and mucinous—while acknowledging the fact that occasional examples are difficult to classify.[267]

Serous Cystic Neoplasms

Serous cystadenoma, also known as microcystic adenoma or glycogen-rich cystadenoma, usually presents grossly as a large multiloculated mass, the individual cystic cavities being small and filled with a clear ("serous") fluid (Fig. 22.22A and B).[268,269] The spongy appearance of the cut surface is reminiscent of that of infantile polycystic kidney. Occasionally, the gross appearance is macrocystic (either multilocular or unilocular) (Fig. 22.22C) or, rarely, solid.[268,269] Most cases are solitary, but a few multicentric examples are on record.[269] A central scar is present in nearly half of the cases.[269]

Microscopically, they are composed of multiple small cysts with varying amounts of fibrous stroma. The cysts are lined by small, flat, or cuboidal cells containing abundant glycogen but only an insignificant amount of mucin (Fig. 22.22D and E).[268–270] The nuclei are small and round, and the cytoplasm is clear. Small papillae that project into the cyst lumens may also be seen. The amount of stroma is very variable, ranging from delicate and highly vascular to dense and hyalinized[268]; exceptionally, the stroma of the tumor is found to contain amyloid deposits.[271] The stroma may feature calcifications, hemosiderin, or cholesterol clefts, and occasionally islets of Langerhans or acinar tissue can be present in the trabeculae.[268] Immunohistochemically, there is reactivity for EMA, low-molecular-weight and broad-spectrum keratins, alpha-inhibin, MUC6, and calponin.[272,273] The fluid contained in the cyst lumens has a low CEA level, in contrast to that of mucinous neoplasms.[274]

The patients are usually elderly, and these tumors occur more commonly in women.[269] The disease either is discovered incidentally or manifests as an abdominal mass with local discomfort or pain. Some of the cases occur in the context of VHL disease[275] and may harbor allelic deletions and mutations of the VHL tumor suppressor gene. Serous cystic tumors have been seen in pancreata harboring ductal adenocarcinoma, neuroendocrine tumors (NETs), or IPMN elsewhere.[269] Diabetes may be associated with these lesions if sufficient islet cell tissue is destroyed by the tumor. When located in the head of the pancreas, which is often the case, these tumors may result in gastrointestinal or biliary obstruction.[276] Excision is curative, although recent studies advocate for conservative management in the majority of these lesions.[276]

A malignant counterpart of this tumor has been described as *serous cystadenocarcinoma* or *microcystic adenocarcinoma*,[277,278] but the existence of a true malignant counterpart to serous cystadenomas remains controversial. Recent reappraisals have shown that most cases previously designated as "malignant" or "invasive" serous neoplasms were either adherent to or invading local structures, sometimes associated with inflammation and hemorrhage, but were neither cytologically malignant or truly metastatic.[269] Some cases have reportedly exhibited nuclear atypia, perineurial invasion, and an aneuploid DNA pattern,[279] but interestingly, aneuploidy has also been found in several morphologically unremarkable serous cystadenomas.[280] Exceptionally, true adenocarcinomas may arise from serous cystic neoplasms ("carcinoma ex microcystic adenoma").[281]

Mucinous Cystic Neoplasms

MCN of the pancreas are seen in a younger age group (mean age at diagnosis is late 40s) than the preceding type, and predominate in women. Most are found in the body and tail rather than in the head. The clinical presentation is similar to that of the microcystic adenomas and pancreatic pseudocysts.

MCN are typically large (over 10 cm) multilocular or, in rare cases, unilocular cystic neoplasms with smooth internal surfaces that may contain papillary projections or mural nodules (Fig. 22.23A).[282,283] The cysts are lined by tall, mucin-producing columnar cells (Fig. 22.23B), and the underlying stroma is often very cellular, its appearance closely resembling that of ovarian stroma; the presence of the ovarian-type stroma is a diagnostic criterion for this type of tumor. This similarity persists at the phenotypic level, in the sense that this stroma is reactive for estrogen and progesterone receptors and for inhibin (Figs. 22.23C and D).[284,285] Interestingly, stroma with these qualities is also present in neoplasms developing in male patients.[286] Degenerative changes such as hemorrhage, hemosiderin, cholesterol clefts, and calcification are common, as is sloughing of the epithelial lining; these features may lead to confusion with pseudocysts. Aspiration of the cyst fluid can be useful in the differential diagnosis, as the fluid contains higher levels of CEA than nonmucinous cysts.[287] MCN must be distinguished from intraductal papillary mucinous tumors (see later), some of which may exhibit a cyst-like fusiform dilation of the involved ducts; of note, MCN do not communicate with the pancreatic ducts.[288]

There is a range of epithelial atypia in MCN, ranging from bland, tall columnar mucinous epithelium with small, basally located nuclei to complex architecture with cribriforming, papillary formation, increased mitoses, and marked nuclear atypia. It is common to see a wide range of architectural and cytologic atypia within a single neoplasm (Fig. 22.23E and F). Previous classification schemes have divided MCN into mucinous cystadenomas,

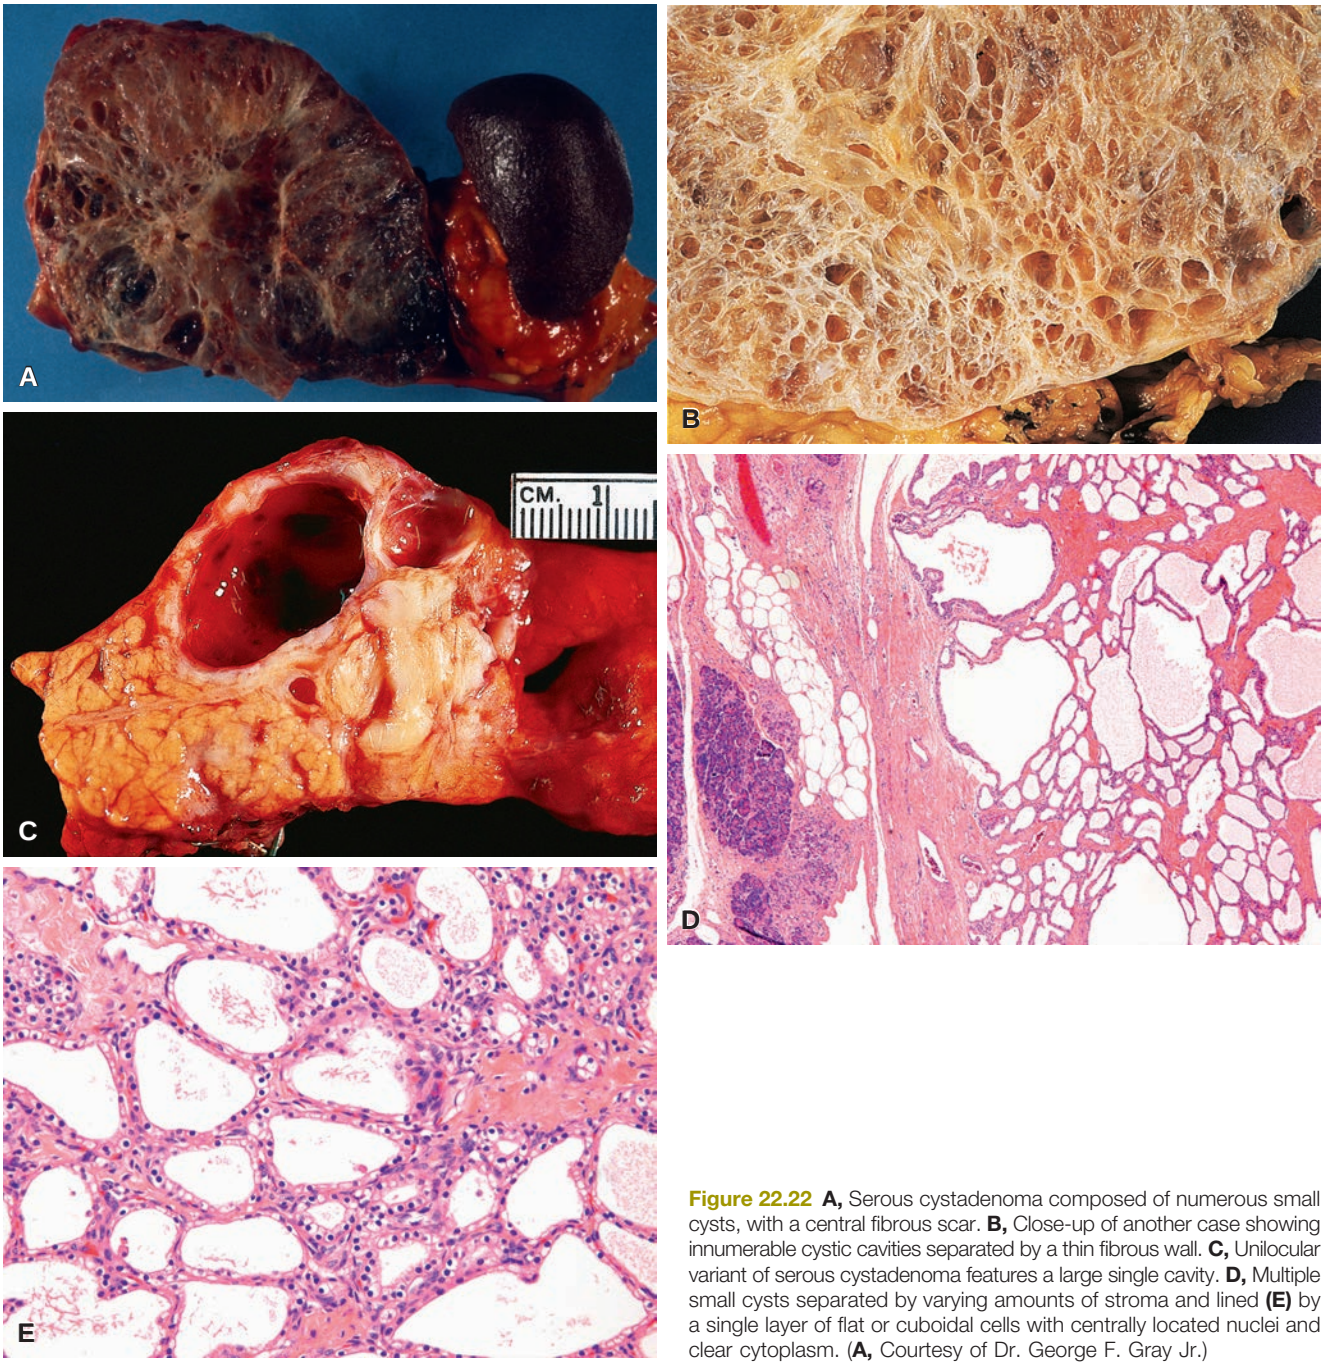

Figure 22.22 **A,** Serous cystadenoma composed of numerous small cysts, with a central fibrous scar. **B,** Close-up of another case showing innumerable cystic cavities separated by a thin fibrous wall. **C,** Unilocular variant of serous cystadenoma features a large single cavity. **D,** Multiple small cysts separated by varying amounts of stroma and lined **(E)** by a single layer of flat or cuboidal cells with centrally located nuclei and clear cytoplasm. (**A,** Courtesy of Dr. George F. Gray Jr.)

borderline MCN, and mucinous cystadenocarcinomas[282,283]; more recent authors have advocated for a two-tiered scheme (low grade/borderline vs. high grade/carcinoma in situ) so that greater uniformity of diagnosis and alignment with management considerations may be achieved.[181]

When invasive adenocarcinoma is present, a variety of patterns may be seen, including ductal adenocarcinoma, adenosquamous carcinoma, mucinous adenocarcinoma, and undifferentiated carcinoma (Fig. 22.24).[283] Invasive foci may be very small, and thus many authorities recommend entirely submitting these neoplasms following complete resection.[282,289] A morphologic variation on the theme of pancreatic MCN (which is again analogous to that having been reported more frequently in mucinous ovarian neoplasms) is represented by the occasional finding of a mural nodule with the features of a giant cell tumor, a pleomorphic sarcoma, or an anaplastic carcinoma.[290,291] As in the ovary, the nature of these various types of proliferation is debatable, but we regard all of them as neoplastic and of epithelial nature, as supported by the molecular evidence of a monoclonal origin.[292]

MCN without associated invasive adenocarcinoma tend to follow a benign course[289]; therefore, we do not subscribe to the extreme view that all MCN should be regarded as mucinous cystadenocarcinomas of low-grade malignant potential.[293] Noninvasive MCN have an excellent prognosis, but tumors with invasive components may

have an aggressive clinical course with a 5-year survival rate of approximately 26%.[294] Metastases of this tumor to the ovary may simulate a primary mucinous tumor of this organ.[295]

The cells of MCN express EMA, SOX9, and cytokeratins 7, 8, 18, and 19, as well as CK10 and CK20 in many cases.[296,297] MUC5AC and MUC6 expression is common but not absolute; MUC1 and MUC2 expression is often restricted to goblet cells, and MUC1 may also be limited to invasive components within MCN.[296,297] Reports of abnormal p53 expression in MCN have been inconsistent in the literature, but expression appears to increase with grade of dysplasia.[296] The majority of MCN with a component of invasive adenocarcinoma express EGFR and Her2/neu[296,298]; furthermore, the invasive component loses expression of the DPC4 protein, suggesting that loss of *DPC4* occurs late in neoplastic progression.[299]

Intraductal Neoplasms

Intraductal papillary mucinous neoplasm (IPMN) is a distinct type of intraductal pancreatic tumor that has been defined and segregated from other neoplasms of this organ (particularly MCN) only recently, and subsequently increasingly recognized in Europe and the United States as well as Japan.[132,300–302] As the name suggests, these tumors are defined grossly by their intraductal location and microscopically by the formation of papillary epithelial projections and the production of abundant intraluminal mucin that ultimately leads to dilatation of the ducts.[303] When fully developed, IPMN may feature cystic formations somewhat reminiscent of bronchiectasis in the lung, leading to the previous designations of mucus-hypersecreting, mucin-producing, or duct ectatic tumor.[304–308]

IPMN is most frequently found in the head of the pancreas, although it may involve any part of the ductal system. The tumor may involve the main pancreatic duct, branch ducts, or both (Fig. 22.25A).[303] It is imperative that documentation of the relationship between the tumor and the ducts occurs at gross evaluation. Some cases are multicentric, and multiple microscopic foci of IPMN have been described in atrophic pancreata from patients with a strong family history of pancreatic cancer.[174]

Microscopically, findings range from flat or papillary tall columnar mucinous epithelium with small, basally located nuclei (Fig. 22.25B and C) to complex architecture with high-grade nuclear features (Fig. 22.25D).[303,309] The epithelium is sometimes accompanied by a minor component of endocrine cells.[310] The supporting stroma is dense and fibrotic, but lacks the cellular "ovarian-type" appearance seen in MCN. Similar to MCN, previous classification schemes subclassified IPMN as to the degree of dysplasia (low, intermediate, or high grade),[309] but recent authors have advocated for a two-tiered scheme (low grade/borderline vs. high grade/carcinoma in situ).[181] IPMNs may consist of any one of several cell types, including intestinal (Fig. 22.25E), pancreatobiliary, gastric (null), and oncocytic (Fig. 22.25F), as identified by their respective immunohistochemical profiles; a mixture of cell types has also been described.[132,309,311–313] Although some have debated whether or not the oncocytic subtype is truly an IPMN, the principles discussed here apply regardless.[132] Intestinal type IPMNs are often large, located in the main pancreatic ducts, and frequently contain foci of high-grade dysplasia. Pancreatobiliary type IPMNs are frequently associated with high-grade dysplasia as well. Gastric-type tumors are often located in the branch ducts and may be easily confused with PanIN.[132,312]

The overall incidence of invasion in IPMN is approximately 15% for branch duct type lesions, and 30%–35% for main duct tumors.[309,314] The invasive component may be quite small, and thus submission of the entire IPMN is recommended so that invasive foci are not missed. Invasive adenocarcinomas associated with intestinal type IPMN are typically colloid type, whereas those associated with pancreatobiliary-type IPMN are typically tubular (Fig. 22.25G).[132,309,315] As discussed previously, cyst fluid analysis (particularly for CEA) may help to distinguish cystic mucinous lesions from cystic nonmucinous lesions, but it is not useful in distinguishing noninvasive from invasive IPMN. The prognosis of these tumors is largely dependent upon the presence and extent of the invasive component. Noninvasive IPMN have an excellent prognosis when completely resected with negative margins. IPMN with colloid carcinoma has a better prognosis than those with associated tubular carcinoma and much better than ductal adenocarcinoma without associated IPMN.[309,316] However, tubular carcinomas arising out of IPMN still have a better survival than those with ordinary ductal adenocarcinoma without associated IPMN.

At the molecular level, mutations of the *KRAS* gene are common (with the exception of the oncocytic type); they are found in IMPN with low-grade dysplasia and frequency appears to increase with grade of dysplasia, suggesting that this is an early event important to the neoplastic process.[132,309] Mutations in *GNAS* and *RNF43* are also common (again, with the exception of the oncocytic phenotype), whereas mutations in *TP53*, *STK11*, and *P16/CDKN2A* are much less frequent.[309] The protein product of the *DPC4* gene is present in virtually all cases, in contrast to its frequent absence in ordinary ductal carcinoma, suggesting a substantial difference in the pathogenesis of these two neoplasms.[317]

IPMNs are distinguished from MCN in that the latter do not communicate with the ductal system and usually have ovarian-type stroma beneath the epithelium.[309,318]

IPMNs (particularly gastric type) also have overlapping features with PanIN (see earlier). Strenuous attempts have been made to categorize the two processes and to separate them on the basis of

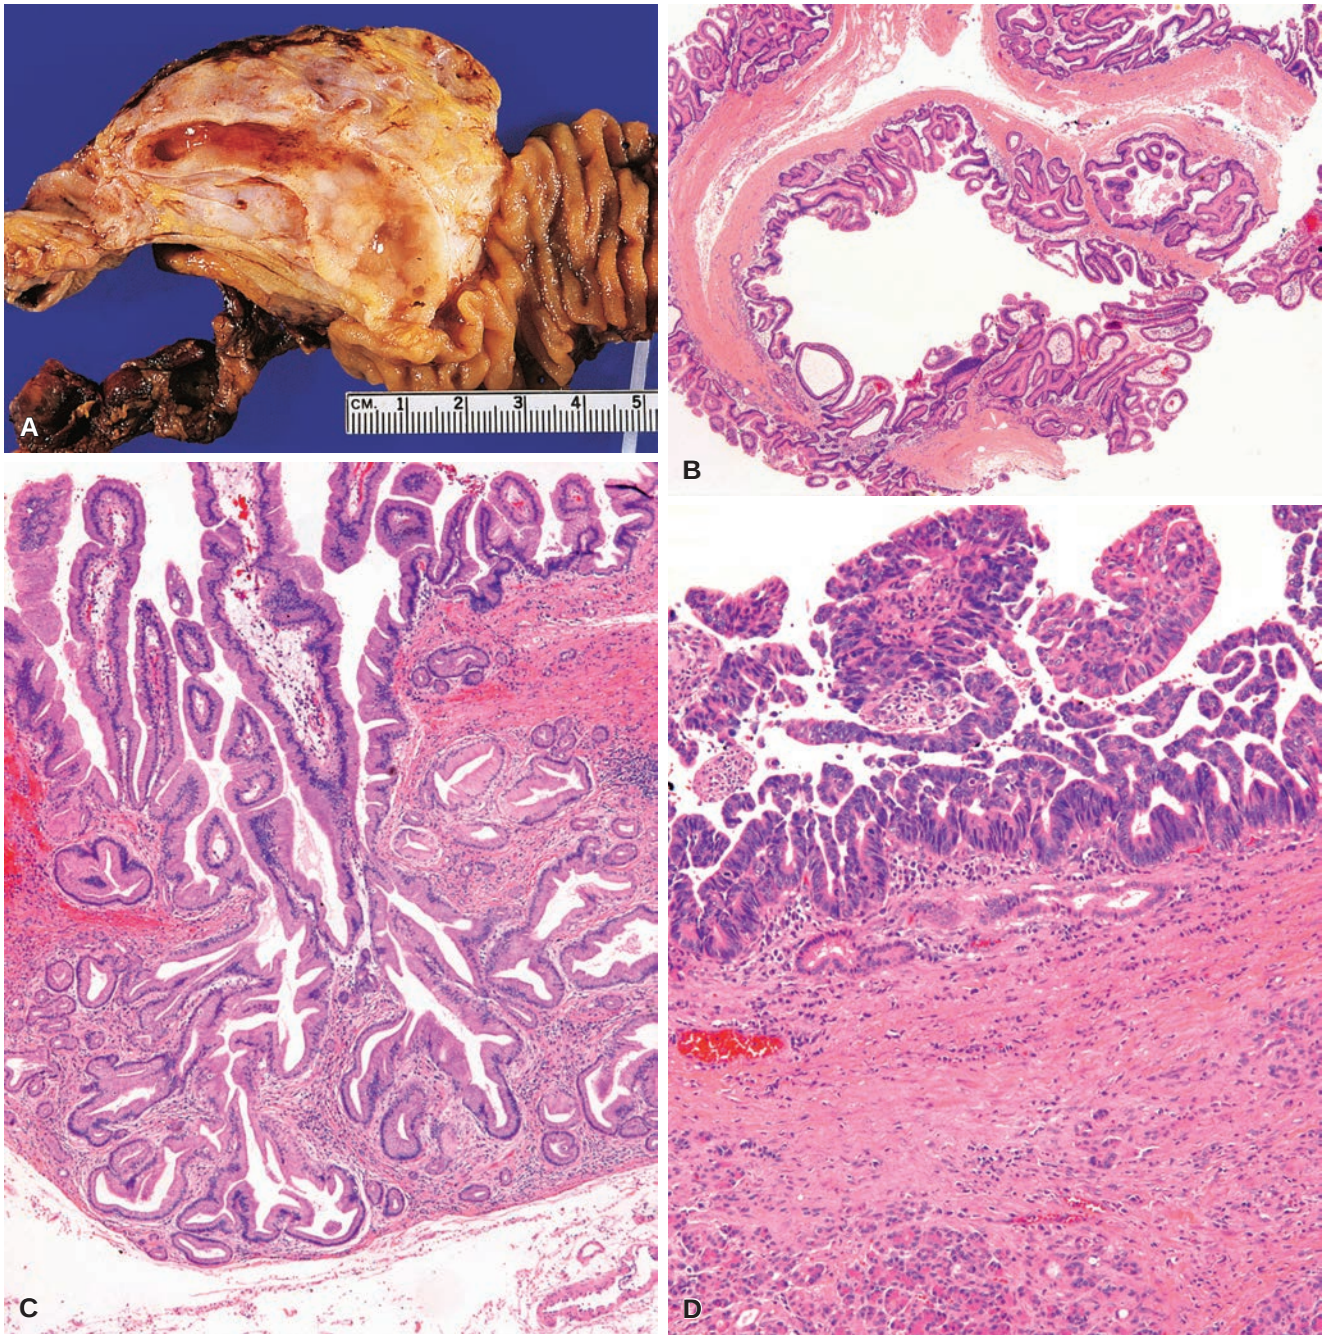

Figure 22.25 **A,** Intraductal papillary mucinous tumor showing marked dilation of the major pancreatic duct with grossly visible papillary excrescences. The duct contained a large amount of mucin in its lumen. The surrounding pancreas shows fibrosis and atrophy. **B,** Low-grade gastric-type IPMN with flat to papillary mucinous epithelium; note the relatively paucicellular dense fibrous stroma. **C,** In this low-grade IPMN, the epithelium is tall columnar with small, basally located nuclei. **D,** Pancreatobiliary type IPMN with high-grade dysplasia.

Continued

topographic, cytoarchitectural, immunohistochemical, and molecular genetic features. For practical purposes, IPMN is defined as a clinically detectable, grossly visible, mucin-producing, typically papillary lesion that produces a lesion of 1.0 cm or more. Conversely, PanINs are microscopic lesions typically involving ducts of less than 0.5 cm in diameter[319]; however, the overlap between the two lesions can produce a considerable amount of frustration. Fortunately, when this problem is encountered at a surgical margin, the important issue is to determine if there is high-grade dysplasia or carcinoma, because low-grade lesions are not clinically actionable.[309] It is obvious that a lot of additional work is needed in order to sort out this confusing state of affairs, which makes painfully clear—perhaps even more so than in other sites—how far we still are in reaching a full understanding of the elusive "precancerous conditions" in the pancreas.

Intraductal tubulopapillary neoplasms (ITPNs) are recently described, extremely rare neoplasms that can involve the head of the pancreas or the entire gland; they are similar to their counterparts in the bile

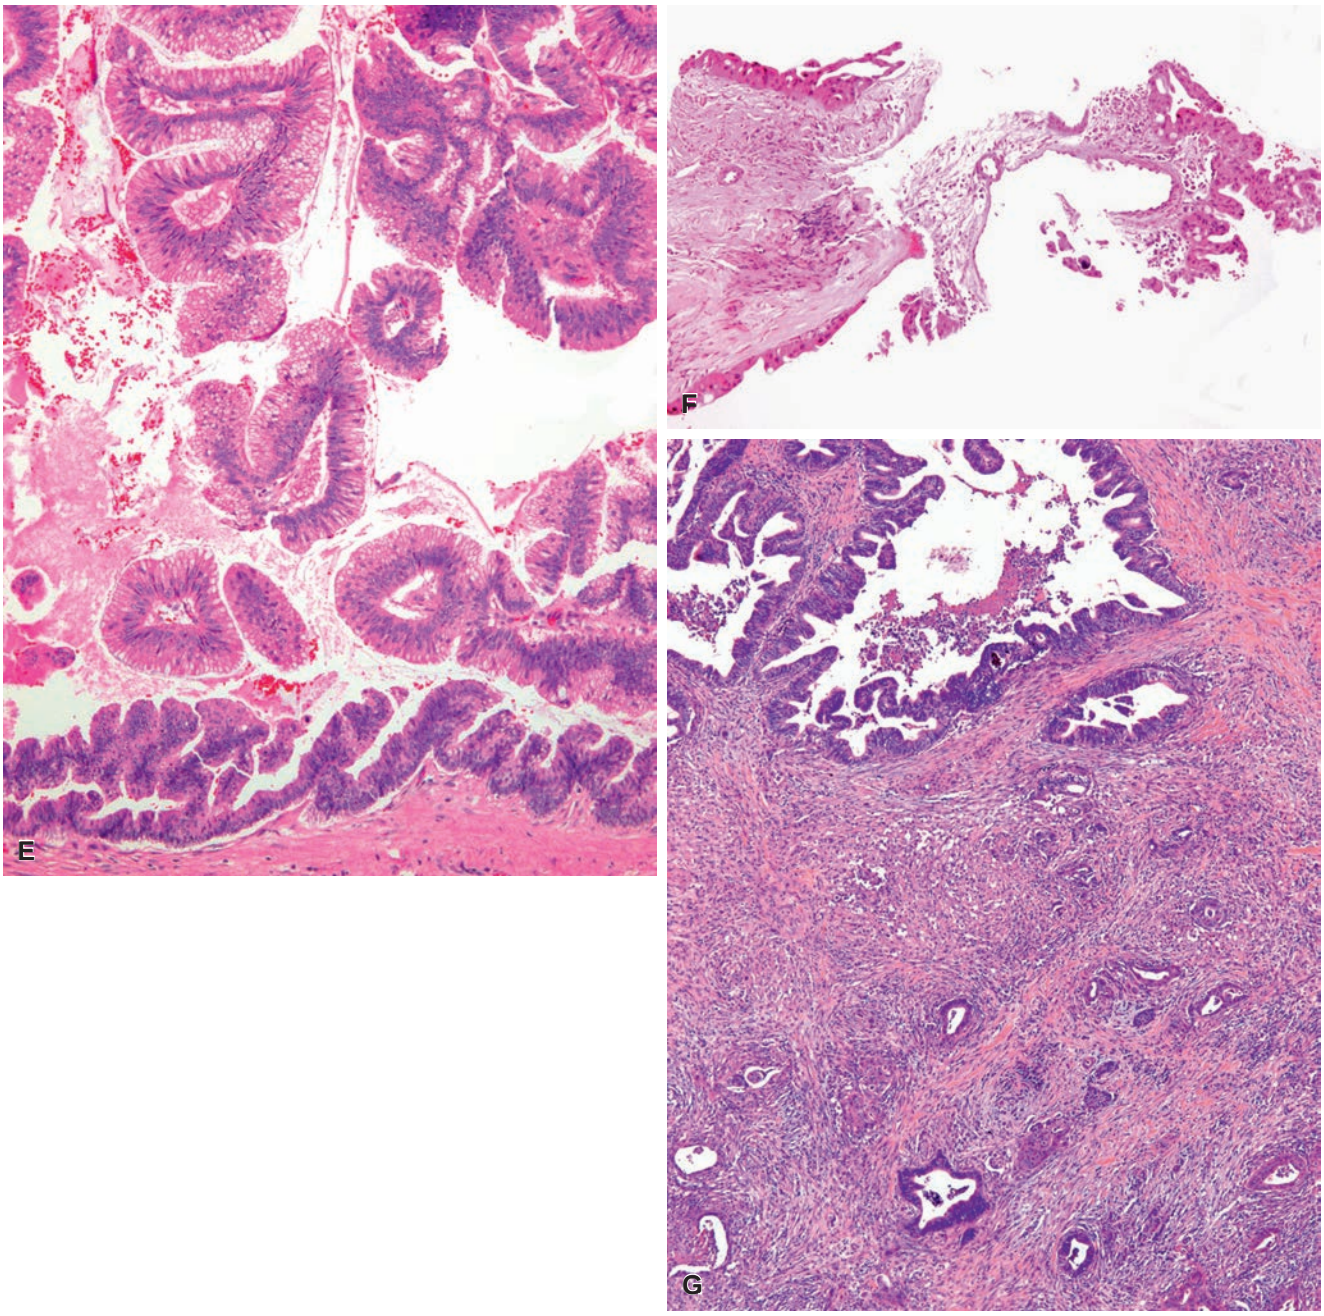

Figure 22.25 cont'd **E,** Intestinal-type IPMN with numerous goblet cells. **F,** Core needle biopsy of oncocytic type IPMN showing striking oncocytic epithelium with punched out spaces and scattered goblet cells. **G,** Adenocarcinoma with a tubular pattern arising from an IPMN with high-grade dysplasia. ducts.[320] These are solid, fleshy intraductal masses in which cyst formation is rare. The tumors consist of densely packed tubular glands with some degree of nuclear atypia (Fig. 22.26).[309,321] Occasionally there is formation of papillary structures, and some cases have comedo-type necrosis. Obvious mucin production is rare. In the majority of cases, tumor cells are positive for MUC1 and MUC6 but negative for MUC5AC and MUC2. An invasive component is present in about 40% of cases, but prognosis is better than in ductal adenocarcinoma.[309,322]

Intraductal tubular pyloric gland–type adenoma is a rare polypoid lesion that occurs in the main pancreatic duct of elderly individuals.[323–325] It can be sessile or pedunculated. Microscopically, it is composed of lobules of closely packed tubular glands resembling pyloric glands. Immunohistochemically, these tumors are CK7+/CK20– and express MUC5AC.[309,323] Local excision has been uniformly curative.

Acinar Cell Tumors and Related Neoplasms

Acinar cell carcinoma usually occurs in adults but may also develop in children.[326,327] In most cases, presenting signs are nonspecific, such as nausea, vomiting, and abdominal pain, and jaundice is rare.[327] Approximately 15% of patients present with widespread

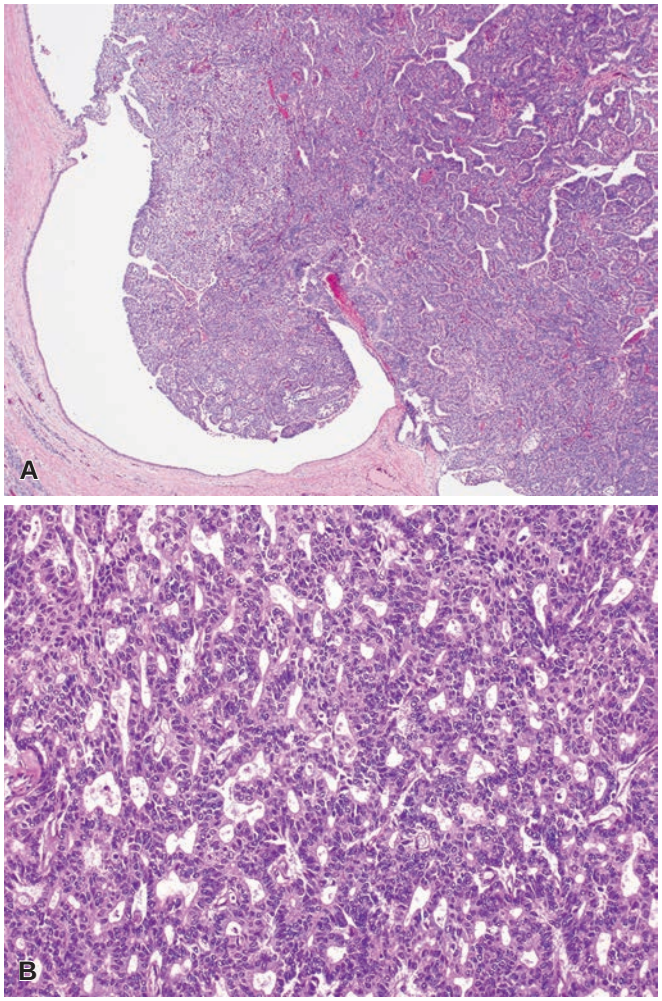

Figure 22.26 **A** and **B,** Intraductal tubulopapillary neoplasm showing intraductal growth of densely packed tubular glands and papillae with mild nuclear atypia. There is no mucin production. (**A** and **B,** Courtesy of Dr. Olca Basturk.)

subcutaneous fat necrosis, eosinophilia, and arthralgia, as a result of the secretion of lipase by the tumor.[327,328] This peculiar clinical syndrome is more common in patients with metastatic disease.

Acinar cell carcinoma presents grossly as a relatively well-circumscribed fleshy mass, averaging 11 cm in greatest diameter, with variably present hemorrhage, cystic degeneration, and necrosis (Fig. 22.27A). Occasionally the pattern of growth is primarily intraductal, a feature possibly associated with a less aggressive course.[329–331] Microscopically, the pattern of growth may be solid, trabecular, glandular, or papillary (Fig. 22.27B), or it may reproduce the normal acinar structure, sometimes to the point of simulating normal pancreas.[326,327] Stroma is typically not prominent. The nuclei are round to oval, with only mild pleomorphism, single prominent nucleoli, and variable mitotic activity (Fig. 22.27C). The cytoplasm tends to be abundant, eosinophilic, and granular. PAS-positive, diastase-resistant cytoplasmic zymogen granules may be present, but may be scant in some cases (Fig. 22.27D). There is typically immunoreactivity for trypsin, chymotrypsin, lipase, and amylase, as well as BCL10[326,327]; the latter shows homology with carboxyl ester hydrolase, an enzyme produced by pancreatic acinar cells.[332] Occasional examples of acinar cell carcinoma (and of pancreatoblastoma, which can be considered its infantile counterpart) can be accompanied by production of alpha-fetoprotein and elevated serum levels of this marker.[333] At the molecular genetic level, acinar cell carcinomas show mutations in the *APC*/β-catenin pathway in about 20% of tumors. Mutations in *KRAS*, *SMAD4*, and *TP53* are rare, a pattern distinct from pancreatic ductal adenocarcinoma[327,334] The prognosis is poor overall, with a 5-year survival of approximately 25%.[327] Metastases are already present at the time of diagnosis in approximately one-half of cases[326]; regional lymph nodes and liver are the most common metastatic sites, but metastases to other sites, such as the ovary, have been reported.[335]

Acinar cell cystadenoma is a rare entity consisting of a unicystic or multicystic lesion lined by well-differentiated acinar cells, usually not connected with the pancreatic ductal system.[336,337] It is regarded as the benign counterpart of acinar cell cystadenocarcinoma, which are large multilocular cystic tumors that may mimic serous cystadenoma grossly. They show a greater degree of cytologic atypia than acinar cell cystadenoma and manifest malignant behavior such as invasion of locoregional structures and metastases.[338,339]

Mixed Acinar Neoplasms

A minor endocrine component (identifiable with chromogranin and/or islet cell hormones) is present in one-third to one-half of the cases of acinar cell carcinomas, but if more than 25% of cells have neuroendocrine differentiation by morphology and/or immunohistochemistry, then the designation of *mixed acinar–neuroendocrine carcinoma (NEC)* should be used.[327,340,341] *Mixed acinar–ductal carcinomas* also occur, a surprising finding in view of the early embryologic divergence of the acinar and ductal cell lineages; the ductal component should comprise at least 25% of the tumor.[327,342] Rarely, cases of mixed acinar–neuroendocrine–ductal carcinoma have been reported.[327,342] It ought to be pointed out that one or more markers of acinar differentiation (such as lipase, chymotrypsin, or trypsin) are present in about two-thirds of pancreatic tumors having the otherwise typical features of pancreatic endocrine neoplasms; this feature is of no prognostic significance and should not alter the tumor designation.[343]

There are variations in acinar architecture that may mimic a neoplasm and have been termed *acinar cell nodule* (which may also mimic islets of Langerhans, Fig. 22.28), *focal acinar transformation*, *acinar cell hyperplasia*, or *eosinophilic degeneration*. These lesions have no known preneoplastic potential in humans.[344–347]

Pancreatoblastoma

Pancreatoblastoma is the most common form of pancreatic neoplasia in childhood, accounting for 25% of pancreatic tumors in the first 10 years of life,[327] but it can also occur in adults; there is a slight male predominance.[348] Isolated cases have been reported in patients with the Beckwith–Wiedemann syndrome and with familial adenomatous polyposis of the colon.[349] Overall survival is approximately 50%.[327]

The mean tumor size is 10 cm, and partial encapsulation is the rule. Microscopically, these are very cellular tumors, often lobular at low power, and made up of solid sheets and acini of uniform cells (Fig. 22.29). Squamoid nests or corpuscles are a constant and characteristic finding. The tumor cells present within these corpuscles often have optically clear nuclei, apparently due to the accumulation of biotin.[350] The stroma may be abundant and occasionally hypercellular, and there may be heterologous cartilage or bone. Neuroendocrine components, ductal components, and/or a primitive small round blue cell component may be present.[327] Immunohistochemically, these tumors show evidence of acinar (pancreatic enzymes), endocrine (synaptophysin and chromogranin), and ductal (CK7 and CK19) differentiation.[327,351] AFP may be produced by the tumor, in keeping with

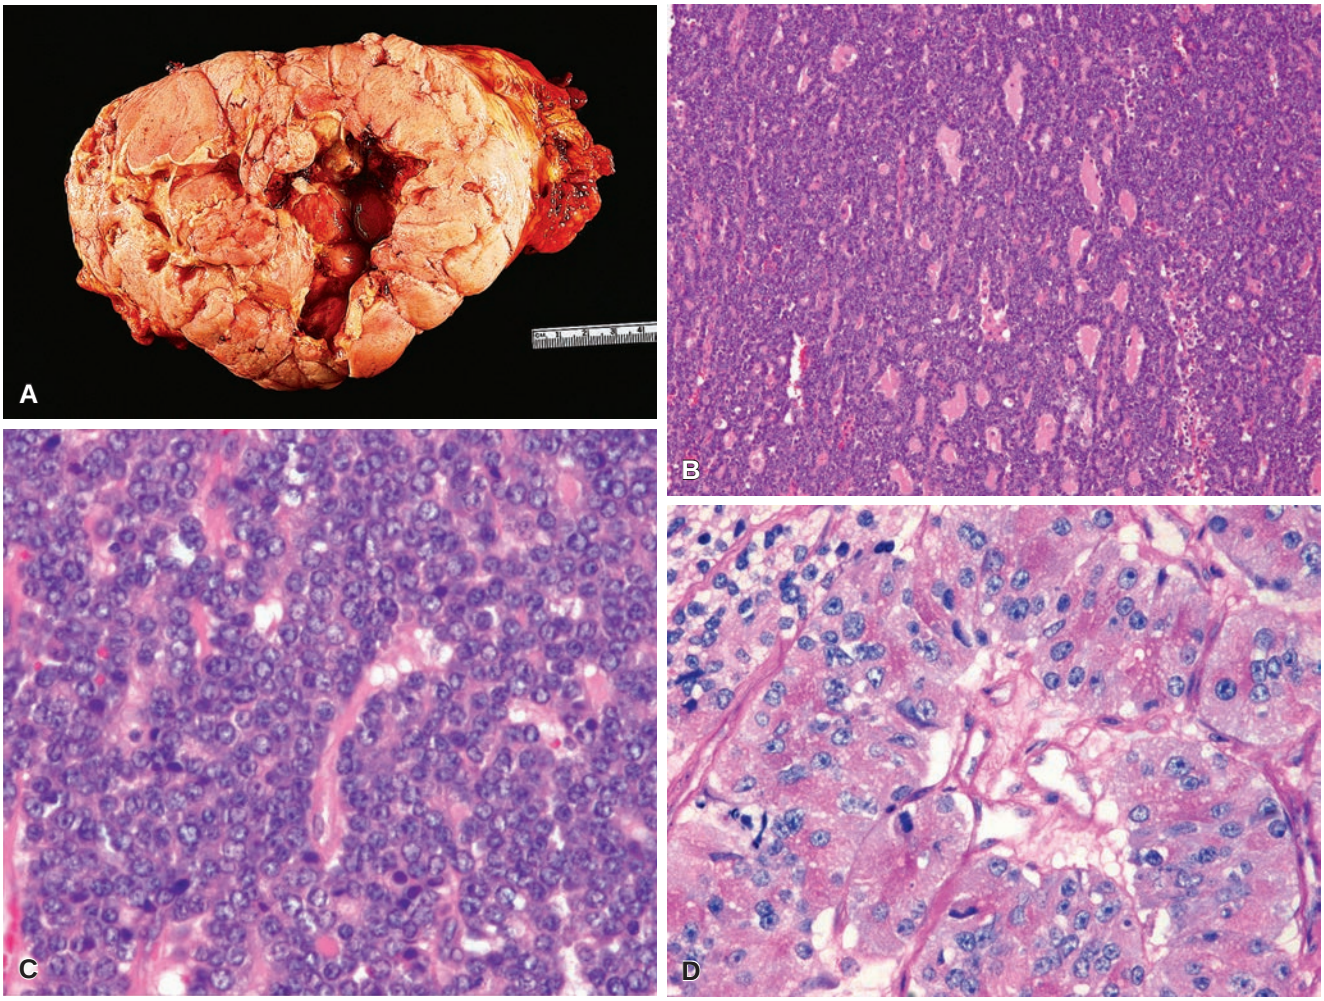

Figure 22.27 **A,** The cut surface of this acinar cell carcinoma is solid and has a necrotic center. It lacks the fibrous component usually seen in ductal adenocarcinoma. **B,** Prominent acinar architecture with minimal stroma is characteristic. **C,** The nuclei are round with mild pleomorphism and a single prominent nucleolus. **D,** PAS-positive, diastase-resistant cytoplasmic granules are seen in some cases (PAS stain).

its primitive nature.[333] The squamoid corpuscles have a characteristic phenotype: they are CK8/CK18/CK19/EMA positive and CK7 negative. There is characteristic nuclear translocation of β-catenin as a result of mutations in the β-catenin *(CTNNB1)* or *APC* gene, and the majority of cases show loss of heterozygosity of the highly imprinted region of chromosome 11p, similar to Wilms tumor and hepatoblastoma (both of which can occur as a component of Beckwith–Wiedemann syndrome).[226,327] Indeed, pancreatoblastoma could be regarded as the infantile counterpart of acinar cell carcinoma, just as hepatoblastoma is the infantile counterpart of hepatocellular carcinoma.[352] It should be kept in mind that not all pancreatic tumors in childhood are pancreatoblastoma; solid pseudopapillary tumors, endocrine tumors, lymphoma, and metastatic tumors also occur.[353,354]

Solid–Pseudopapillary Tumor

Solid–pseudopapillary tumor (SPPT) is the preferred term for a distinctive type of pancreatic tumor previously known as papillary and solid epithelial neoplasm, papillary–cystic neoplasm, or cystic–solid papillary carcinoma. Most (>90%) cases are found in young women, who typically present with abdominal pain. A significant minority of cases are found incidentally on imaging for another reason.[355] Grossly, tumors are usually large and solitary; multicentricity is exceptionally rare.[356] The appearance on cross section range from solid to almost entirely cystic, and often there are areas of hemorrhage and necrosis (Fig. 22.30A). Most cases are surrounded by a well-developed capsule, but in some instances the edges are infiltrative into the adjacent pancreas; invasion of adjacent organs is very rare.[355,357] A few cases have been found anatomically separate from the pancreas, arising from the ovary, retroperitoneum, or GI tract; some of these have occurred in the context of ectopic pancreas.[358]

Microscopically, SPPT is very cellular and simulates somewhat the appearance of a pancreatic endocrine neoplasm. They may have solid and cystic components, in addition to the most distinctive feature, which is the presence of pseudopapillae covered by several layers of epithelial cells (Fig. 22.30B).[355,359] The cells around the pseudopapillae are discohesive, and the fibrovascular cores are often hyalinized; there is also typically cystic degeneration, cholesterol crystals, and foamy histiocytes. Small vessels may be surrounded by a mucoid or myxoid material. The nuclei are ovoid and folded, with indistinct nucleoli and longitudinal grooves; mitoses are few (Fig. 22.30C). Hyaline globules may be present within the cytoplasm of

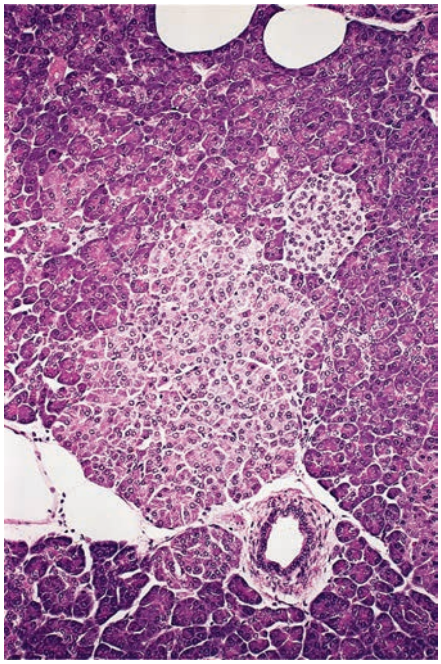

Figure 22.28 Incidental acinar cell hyperplasia, which may be confused with hyperplastic islets of Langerhans.

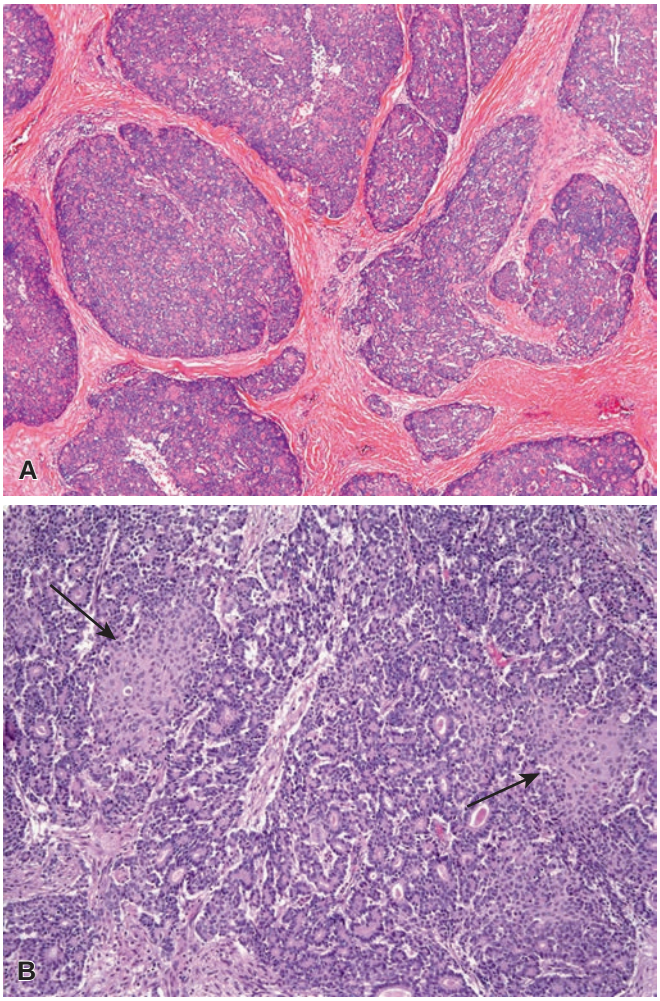

Figure 22.29 **A,** Pancreatoblastomas are often lobular at low power, with prominent stroma. **B,** The cells are arranged in a prominent acinar pattern, and squamoid corpuscles *(arrows)* are prominent.

the tumor cells (Fig. 22.30D). Clear cells can be prominent, and pleomorphic and oncocytic variants have also been reported.[355,360]

Immunohistochemically, there is usually only focal, faint reactivity for keratin. Synaptophysin and CD56 can be focally or diffusely positive, but chromogranin is characteristically negative.[355,361] Tumor cells may also stain with claudin 5 (membranous), claudin 2 (cytoplasmic), galectin 3, progesterone receptor, estrogen receptor beta, CD10, CD99 (dot-like), and α-antitrypsin.[355,361–366] Immunoreactivity for pancreatic enzymes is typically absent.[355] There is membrane loss and aberrant nuclear localization of E-cadherin and β-catenin, with the latter being the most helpful diagnostic immunohistochemical marker (Fig. 22.30E).[366,367] CD117 expression is found immunohistochemically in about half of the cases,[368] but it is not associated with mutations of *KIT* and therefore does not represent an indication for Gleevec therapy. DOG1 reactivity has also been reported.[369] FLI-1 expression has been described as well, but SPPT do not contain the *EWS/FLI-1* translocation.[370]

Despite extensive investigation, the histogenesis of SPPT remains elusive. Progesterone receptors have been detected both immunohistochemically and by the conventional biochemical method.[371,372] These results, in addition to the predilection of SPPT for females and the proximity of the pancreas to the genital ridges during embryogenesis, have led to the hypothesis that SPPT could be derived from genital ridge/ovarian anlage-related stem cells that were attached to the pancreatic tissue during early embryogenesis.[355,373] This theory may gain some support from the recent description of three cases of this tumor type primitive in the ovary.[374] Genetically, SPPTs of the pancreas are different from ordinary ductal adenocarcinomas and almost always exhibit β-catenin *(CTNNB1)* gene mutations.[375] The translocation der(17)t(13;17)(q14;p11) has been detected in a case,[376] and abnormalities have also been reported within chromosomes 11q, 13q, 17q, 1q, and 8q.[377]

The treatment is surgical, and the overall prognosis is excellent.[378,379] However, approximately 10%–15% of the reported cases have resulted in local recurrence and/or metastases, usually in the liver or peritoneum; however, even these patients may have significant long-term survival.[380,381] Therefore, SPPT should be regarded as a neoplasm of low malignant potential.[355] Larger tumor size, invasion into muscular vessels and/or adjacent structures, and histologic features such as diffuse growth pattern, extensive necrosis, and high mitotic rate have been correlated with aggressive behavior.[380,382] Cases having an undifferentiated component and a very aggressive clinical course have been seen rarely.[380]

Pancreatic Neuroendocrine Neoplasms

Endocrine tumors of the pancreas (PanNET) have historically been designated *islet cell tumors* but are now classified as *well-differentiated NET* or *poorly differentiated NEC*.[383] Endocrine tumors account for 5% all pancreatic malignancies.[383] Most occur in adults, although a few have been described in children and even in newborns and infants, typically in the context of a syndrome.[354,384] Several syndromes are associated with PanNET, including the multiple endocrine neoplasia (MEN) syndromes, VHL disease, neurofibromatosis type 1, and tuberous sclerosis (see later).[383] A few cases have been reported in association with chronic pancreatitis, although the relationship between the two is debatable[385]; caution should be exercised, however, not to overdiagnose as neoplastic the proliferating islet cells often seen in that condition (see above and see Fig. 22.9C).

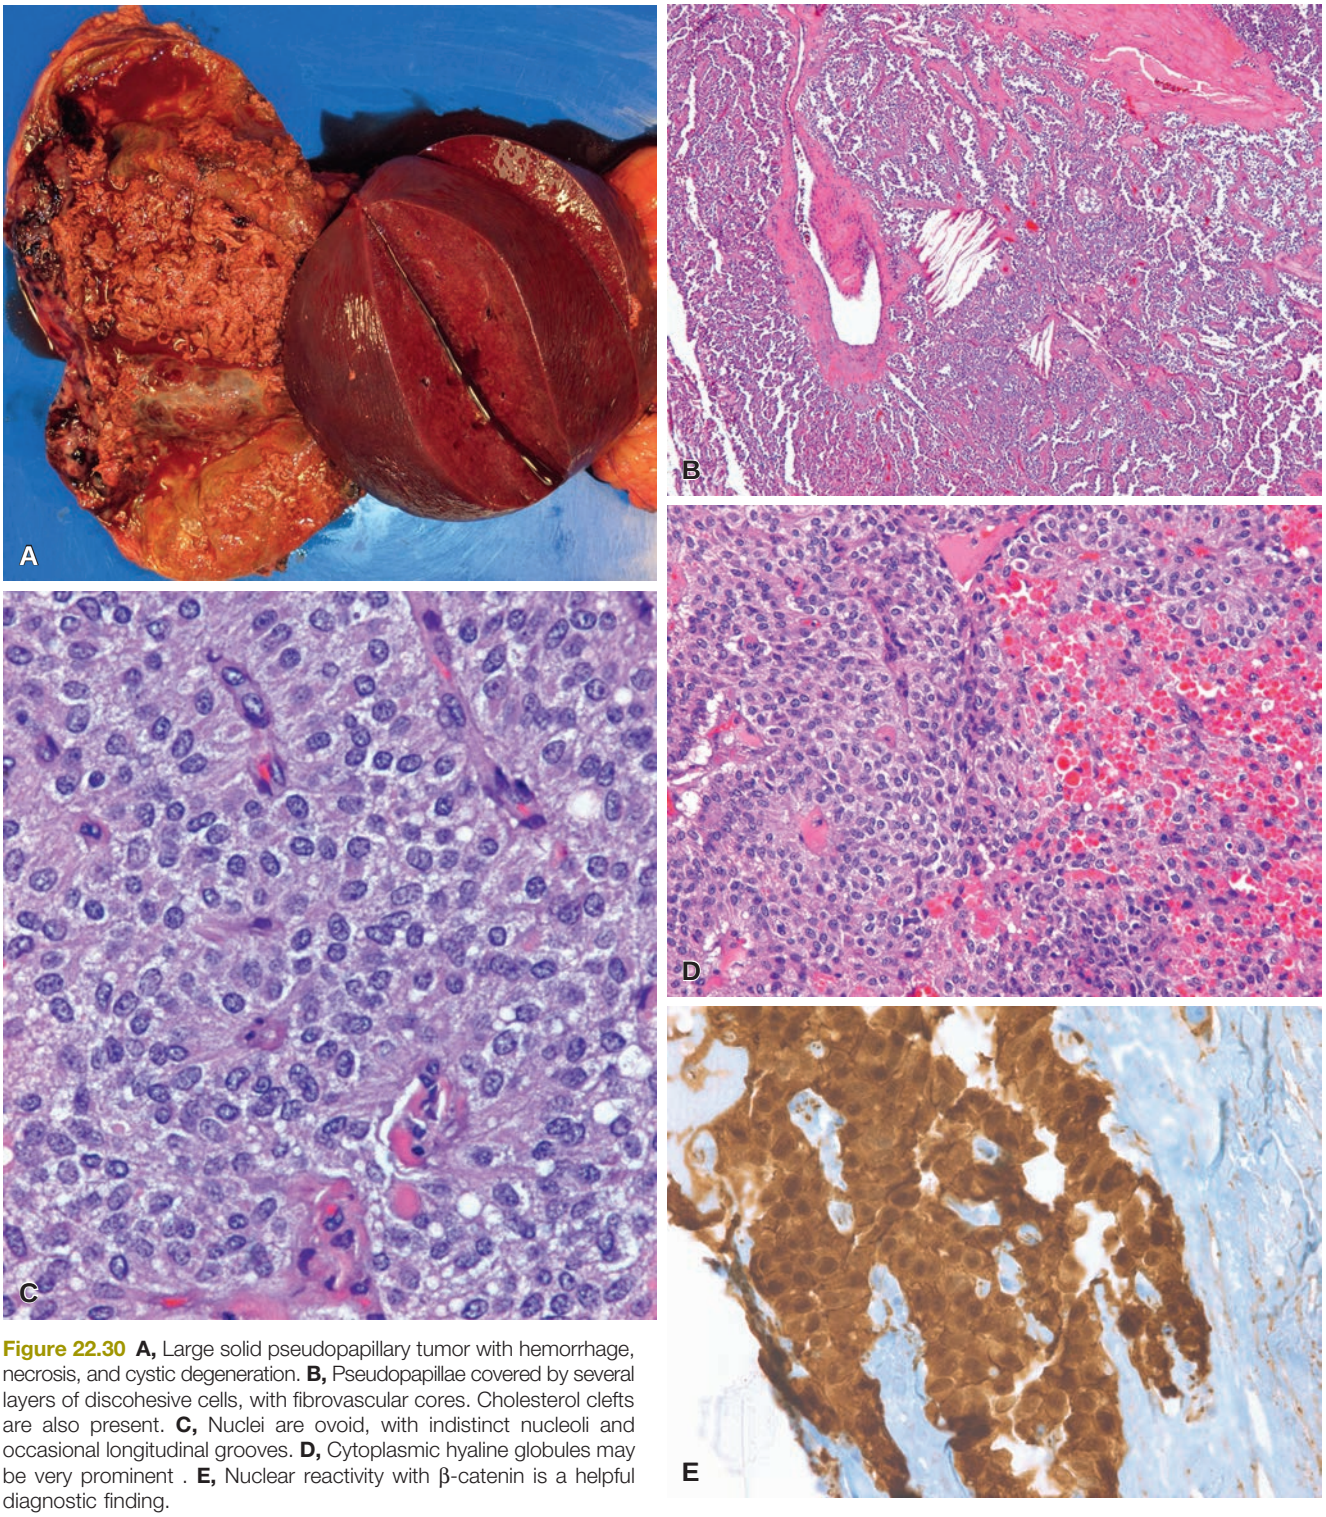

Figure 22.30 **A,** Large solid pseudopapillary tumor with hemorrhage, necrosis, and cystic degeneration. **B,** Pseudopapillae covered by several layers of discohesive cells, with fibrovascular cores. Cholesterol clefts are also present. **C,** Nuclei are ovoid, with indistinct nucleoli and occasional longitudinal grooves. **D,** Cytoplasmic hyaline globules may be very prominent . **E,** Nuclear reactivity with β-catenin is a helpful diagnostic finding.

PanNETs can be located anywhere in the pancreas. Grossly, they are usually solitary, homogeneous masses that lack a well-defined capsule (Fig. 22.31A–D).[386] The appearance of the cut surface depends on the amount of fibrous tissue and vascularity, ranging from tan-yellow to red, resembling spleen or a congested lymph node. Some tumors contain hemorrhage or necrotic foci (Fig. 22.31E), and some may even contain calcium and bone. A few have a predominantly cystic appearance, often in patients with MEN syndrome.[386,387] This secondary, probably degenerative change is to be distinguished from the exceptional PanNET arising within another type of pancreatic cystic neoplasm.[388] On occasion they may have a primarily intraductal pattern of growth.[389]

Microscopically, these tumors are usually composed of small, relatively uniform cuboidal cells with centrally located nuclei and acidophilic or amphophilic, finely granular cytoplasm (Fig. 22.32A). Marked nuclear enlargement and pleomorphism may be present

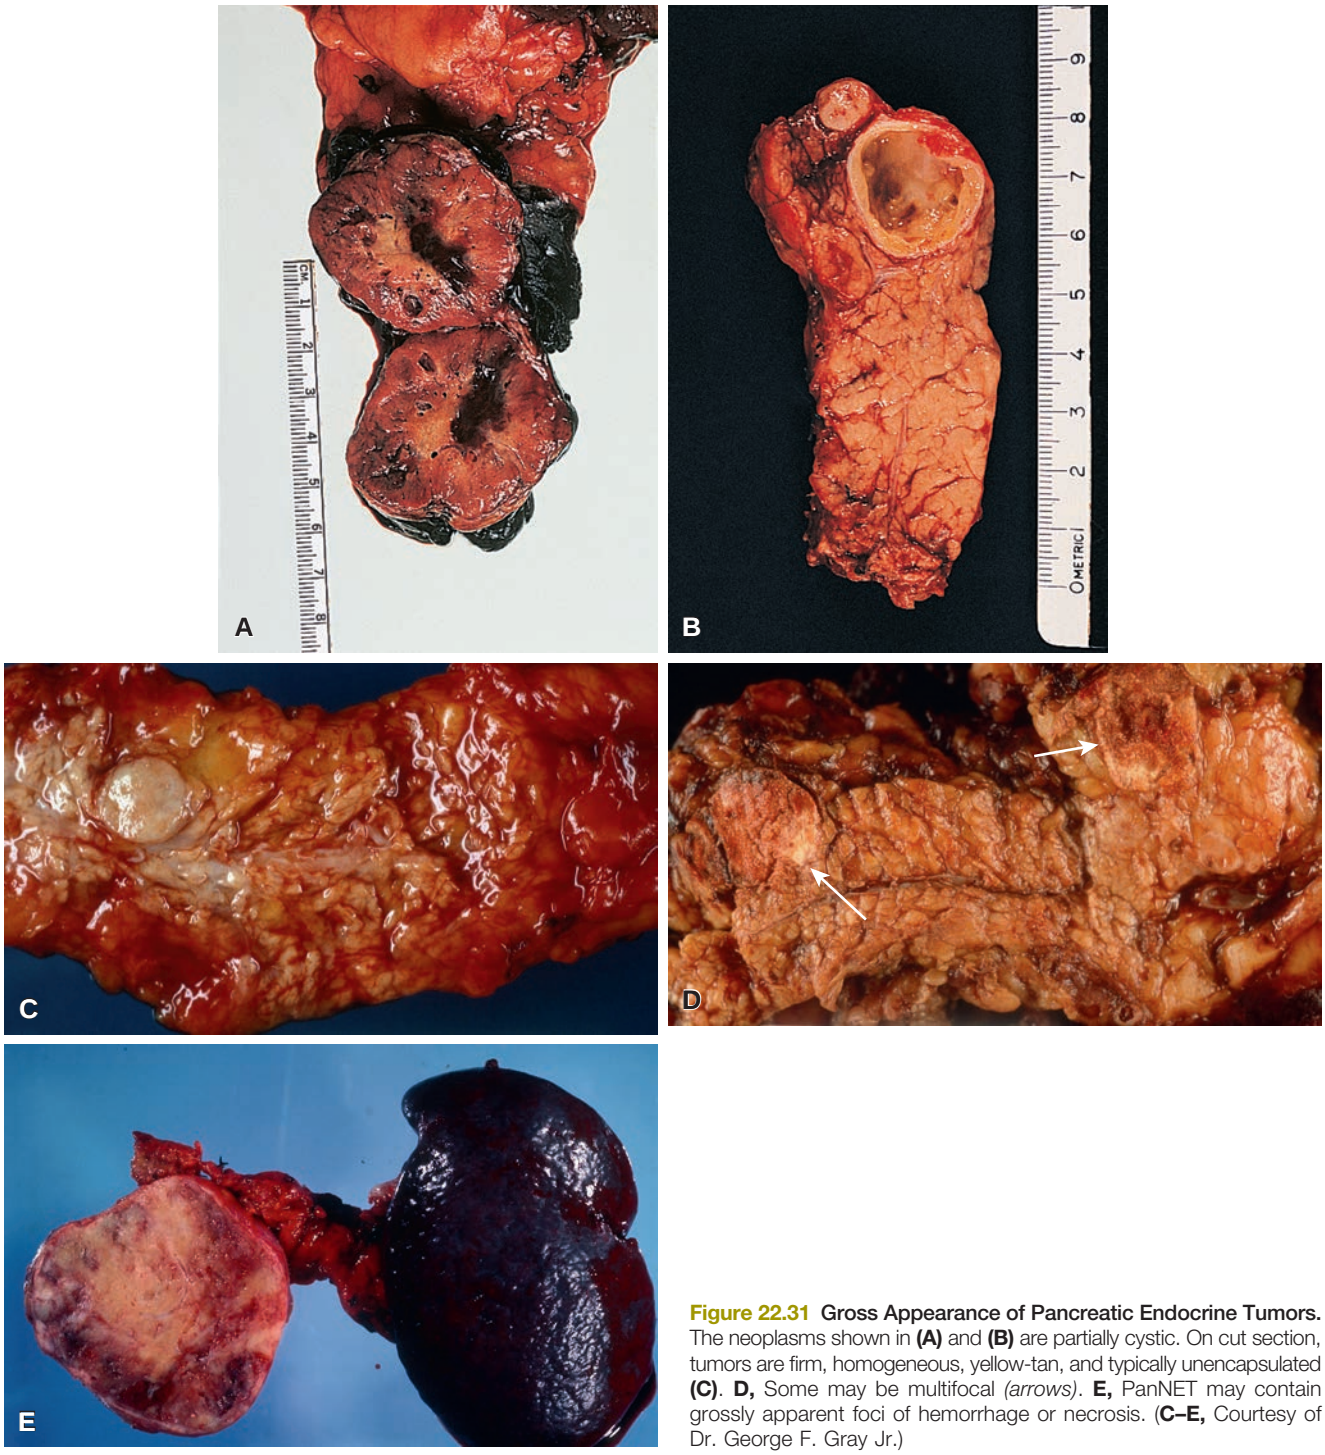

Figure 22.31 Gross Appearance of Pancreatic Endocrine Tumors. The neoplasms shown in **(A)** and **(B)** are partially cystic. On cut section, tumors are firm, homogeneous, yellow-tan, and typically unencapsulated **(C)**. **D,** Some may be multifocal *(arrows)*. **E,** PanNET may contain grossly apparent foci of hemorrhage or necrosis. (**C–E,** Courtesy of Dr. George F. Gray Jr.)

and on occasion can be extreme, but this has no clinical significance (Fig. 22.32B).[386,390] Architectural growth patterns include solid nests, trabecular patterns, and rosettes, and multiple patterns may be present within a single tumor (Fig. 22.32C–E).[383,386] There are a number of unusual morphologic variants. Clear cell PanNETs (Fig. 22.33A), which are associated with VHL syndrome but can also be seen in sporadic tumors, may mimic renal cell carcinoma histologically.[386,391,392] The cytoplasmic vacuolization is due to the accumulation of cytoplasmic lipid.[393,394] Oncocytic PanNETs are very rare but can mimic hepatocellular carcinoma morphologically (Fig. 22.33B).[386,395] Other unusual morphologic findings include mucin production,[396] black pigmentation (due to the presence of lipofuscin-type granules),[397] spindling of tumor cells (Fig. 22.33C),[398] psammoma bodies (often associated with somatostatinomas) (Fig. 22.33D), and rhabdoid features.[399,400] Rare cases of otherwise typical PanNET with foci of sarcomatoid transformation have also been reported.[401,402]

PanNETs are highly vascular, with small vessels surrounding nests of neoplastic cells. Stroma is typically not prominent (Fig. 22.34A), but in some cases, abundant hyaline stroma is present that may contain calcifications. Some tumors with dense stromal

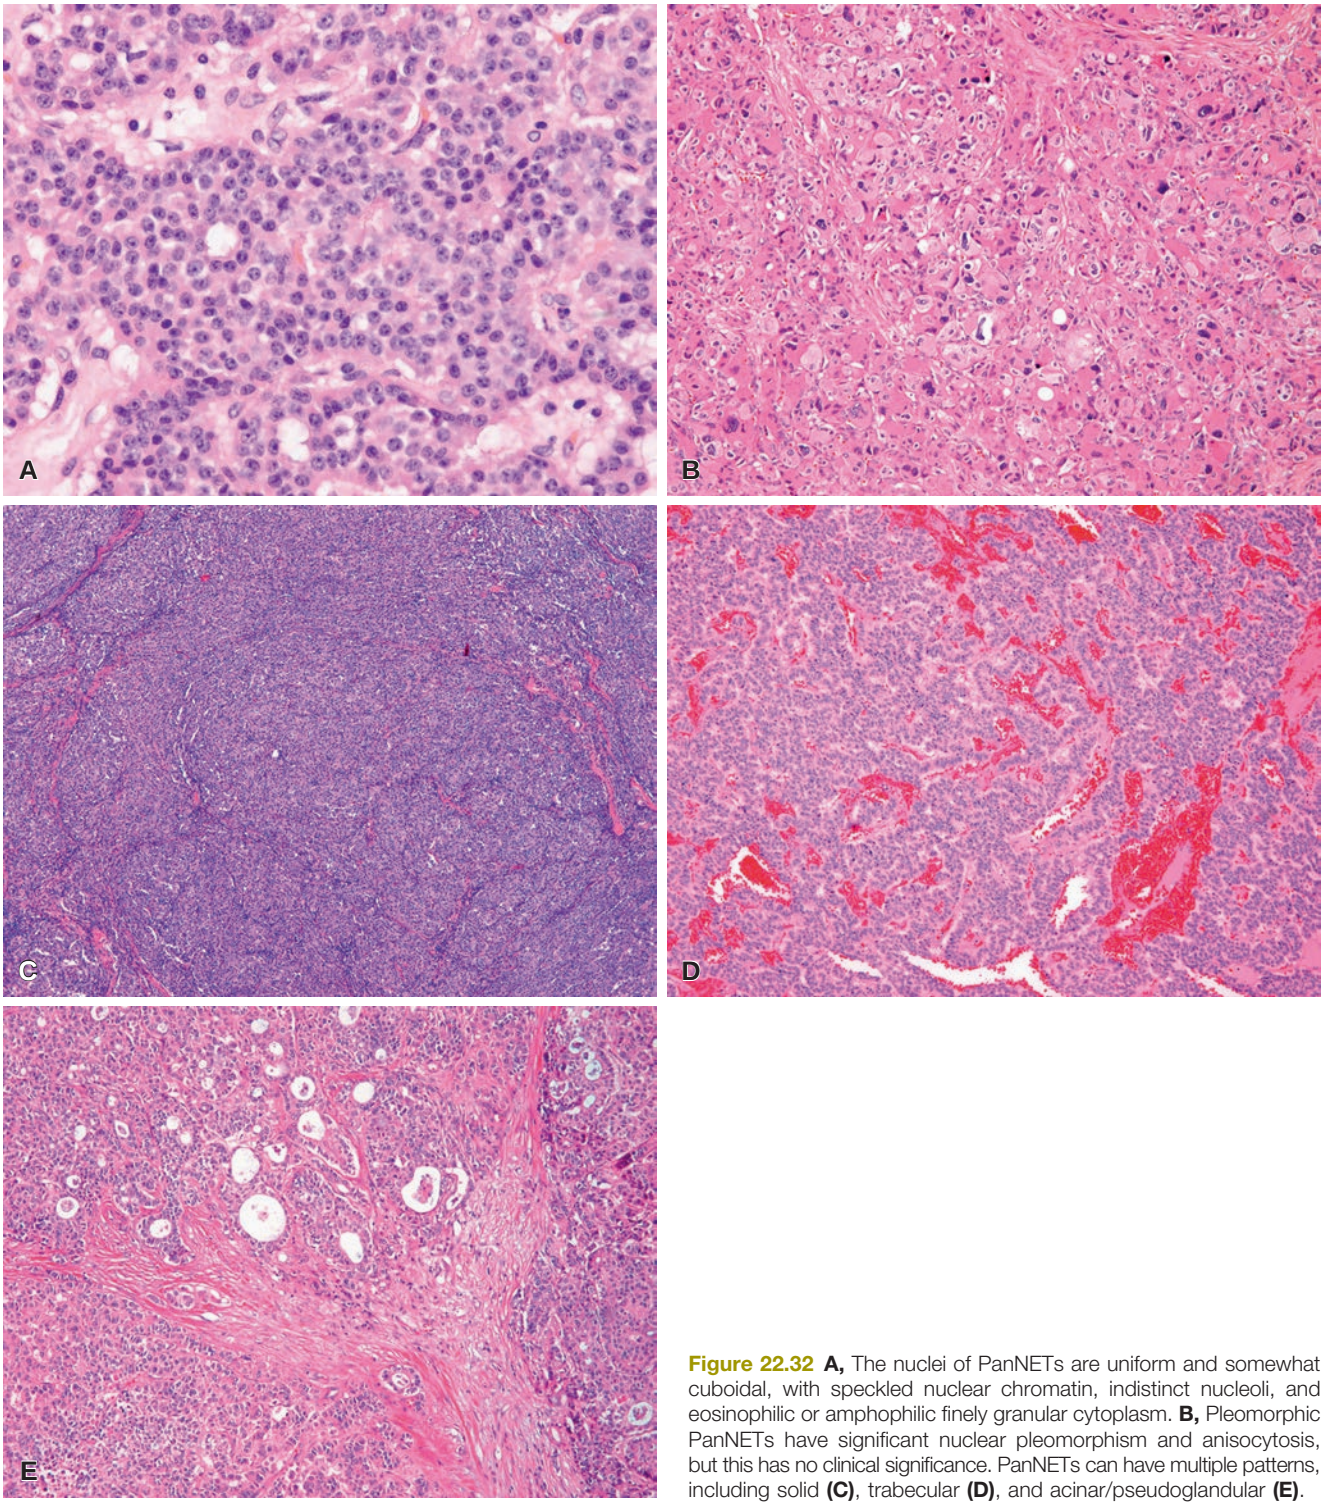

Figure 22.32 **A,** The nuclei of PanNETs are uniform and somewhat cuboidal, with speckled nuclear chromatin, indistinct nucleoli, and eosinophilic or amphophilic finely granular cytoplasm. **B,** Pleomorphic PanNETs have significant nuclear pleomorphism and anisocytosis, but this has no clinical significance. PanNETs can have multiple patterns, including solid **(C)**, trabecular **(D)**, and acinar/pseudoglandular **(E)**.

fibrosis contain neoplastic cells arranged in small nests or tubules and have an infiltrative growth pattern (Fig. 22.34B).[383] Amyloid (Fig. 22.34C) may be encountered in PanNETs, particularly in insulin-secreting neoplasms,[403] but also in other tumor types.[404] The amyloid in these cases, which may have a crystalline configuration, has been designated IAPP and can be detected immunohistochemically.[405,406]

The majority of PanNETs are nonfunctioning, although they may secrete a number of substances at a subclinical level.[407] In other instances PanNETs present with an endocrine abnormality resulting from the secretion of one or more hormones. *Insulinoma* is the most common of these, followed by gastrinoma, VIPoma, and glucagonoma.[383,407] Insulinomas (formerly known as beta cell tumors) typically occur in adults, with a slight female predominance.[407] Only a minority of patients (<10%) are affected by MEN 1. The classic syndrome, known as the Whipple triad, consists of: (1) mental confusion, weakness, fatigue, and convulsions; (2) fasting blood

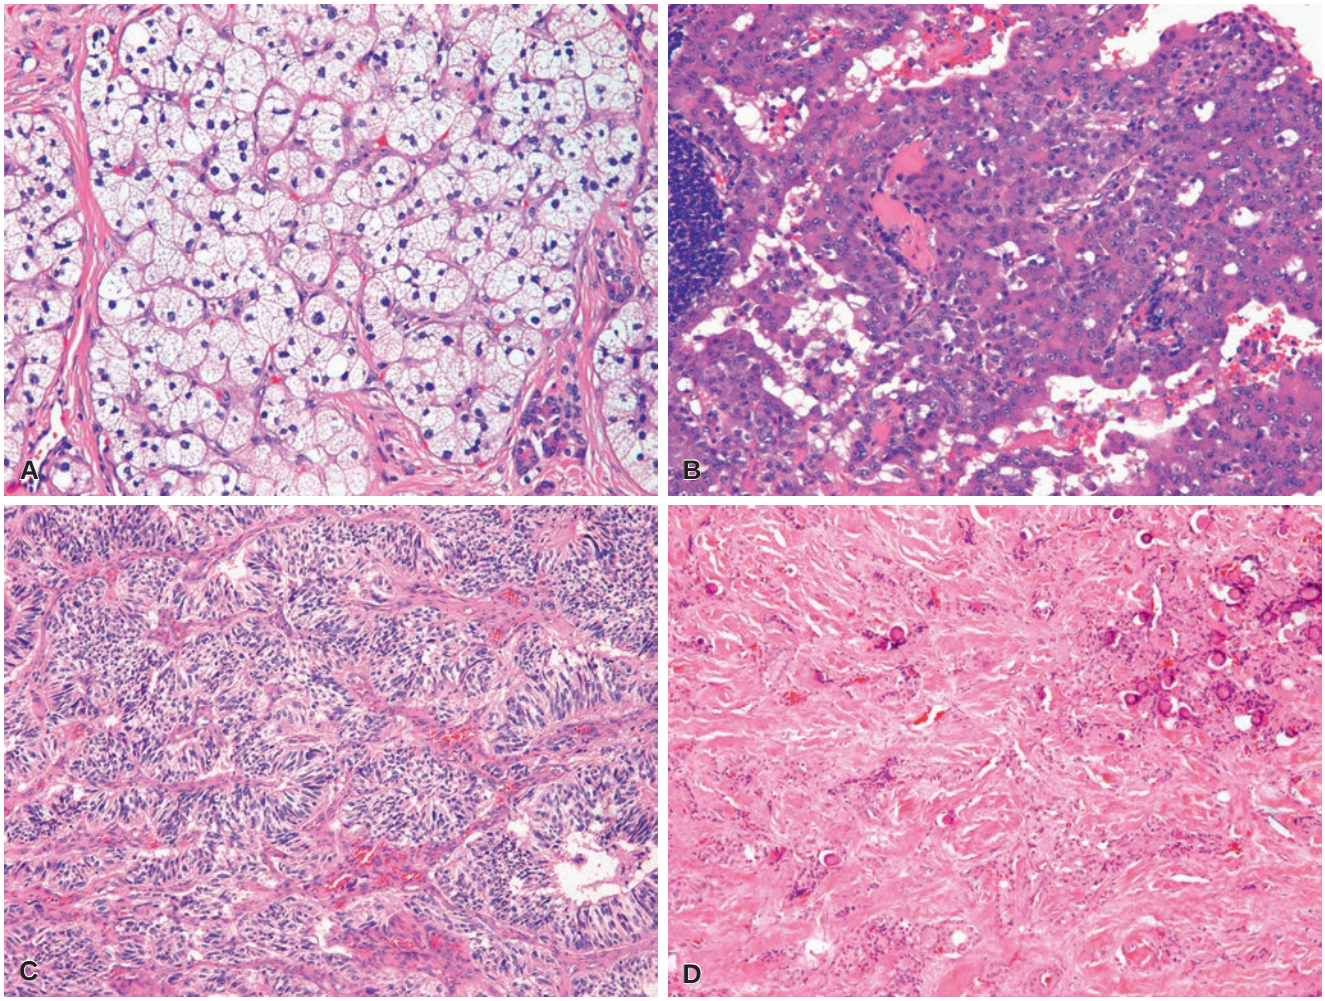

Figure 22.33 Morphologic variants of PanNET include clear cell **(A)** and oncocytic **(B)** tumors, as well as spindled variants **(C)**. Psammoma bodies are associated with somatostatinomas **(D)**.

glucose levels below 50 mg; and (3) relief of symptoms by the administration of glucose. Practically all insulinomas are located within the substance of the pancreas; only 2% of the cases are seen in adjacent areas, such as the duodenal wall. About 70% of them measure 1.5 cm or less, sometimes as little as 3 or 4 mm.[383,407] Presurgical localization of insulinomas is recommended so that the optimal procedure and extent of surgery can be planned. CT and MRI scans are commonly used noninvasive imaging modalities. Endoscopic ultrasound has become the test of choice in many centers, although this technique is most sensitive for tumors in the head of the pancreas. Angiography combined with arterial stimulation venous sampling is another highly sensitive technique for precise localization, with reported 94%–100% accuracy.[408] Over 90% of insulinomas are solitary, but a rare multicentric form also exists ("insulinomatosis").[409] Insulinomas typically pursue an indolent course, with only 7%–10% behaving in an aggressive manner.[383,407,410] Neither conventional morphology nor DNA ploidy patterns are good predictors of behavior.[411] The treatment of insulinomas is surgical, ranging from enucleation to subtotal pancreatic resection depending on the size and location of the tumor.[408]

It is important to recognize that extrapancreatic neoplasms may also be a source of hypoglycemia, which typically disappears upon removal of the tumor.[412] Most reported cases have been due to hepatocellular carcinomas or mesenchymal neoplasms, particularly solitary fibrous tumor[413]; the latter are typically found in the pleura or retroperitoneum, and they tend to attain a very large size. The hypoglycemia is caused by the secretion of insulin-like growth factor II by the tumor cells.[414]

Glucagonomas (formerly alpha cell tumors) can be divided into two distinct types. Those associated with the glucagonoma syndrome are usually solitary and large and have a high incidence of malignancy.[383,415] The glucagonoma syndrome features an abnormal glucose tolerance test, normocytic normochromic anemia, a skin rash known as necrolytic migratory erythema, sore red tongue, angular stomatitis, severe weight loss, depression, and deep vein thrombosis.[407] There are rare reports of glucagonomas that are not associated with the glucagonoma syndrome; they have been reported as multiple and small, and unlike their syndromic counterparts, are nearly always benign.[416] Approximately 20% of tumors are associated with MEN 1.[383]

Gastrinomas (formerly G-cell tumors) can produce the Zollinger–Ellison syndrome as a result of excessive production of gastrin.[417,420] Over half are found in the duodenum, and most of the remainder are located in the pancreas; in a minority of cases, gastrinomas are found in the gastric antrum or in lymph nodes adjacent to the pancreas.[407,417] In the latter, it is not clear whether the tumors arise in ectopic endocrine cells in the lymph nodes or whether they represent metastases from undetected small primary neoplasms.[418,419]

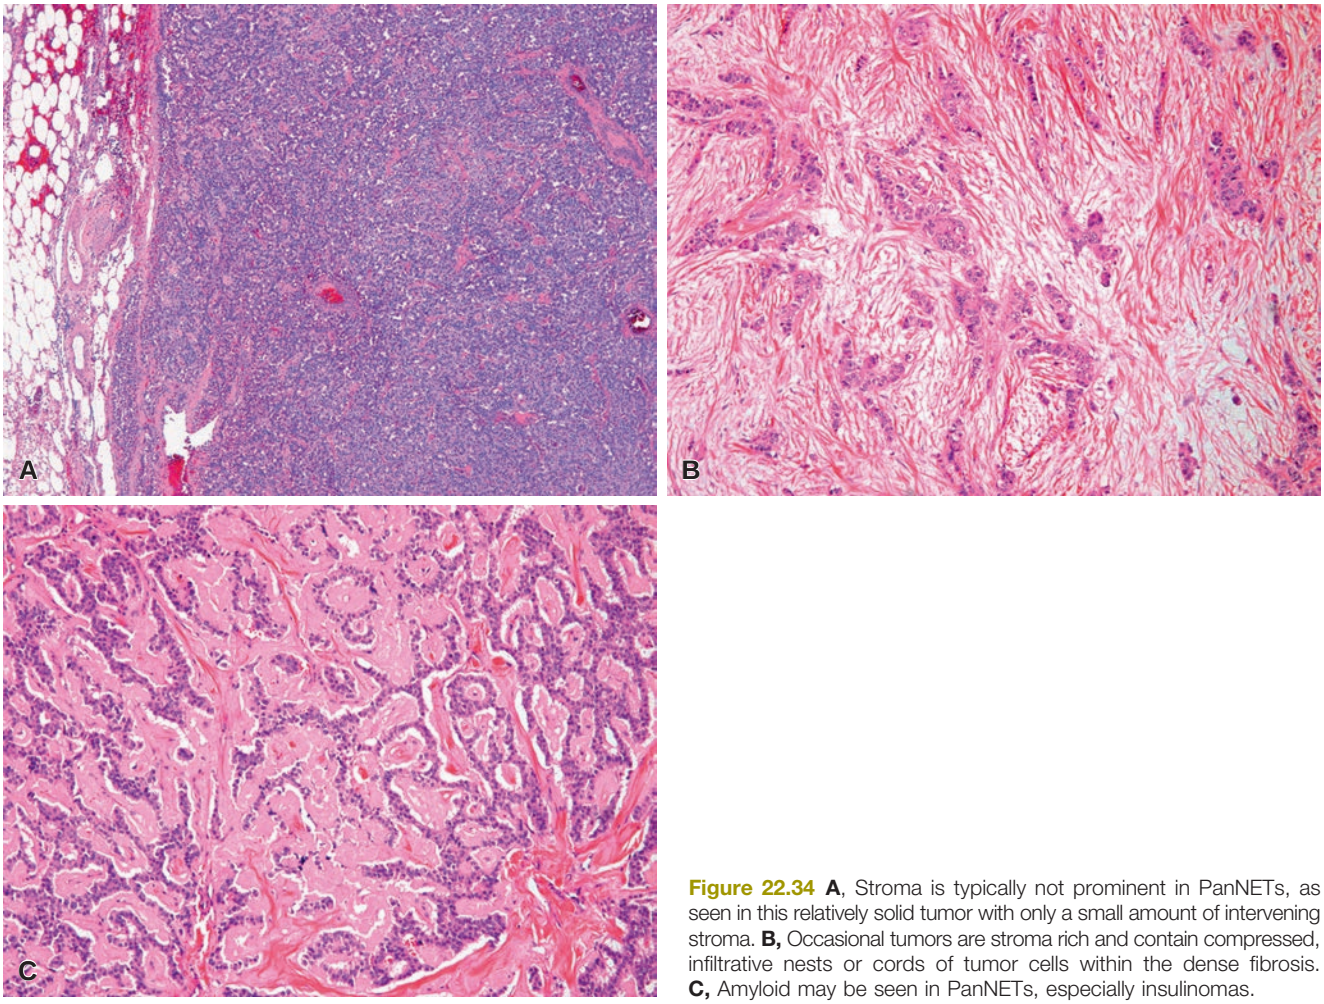

Figure 22.34 **A**, Stroma is typically not prominent in PanNETs, as seen in this relatively solid tumor with only a small amount of intervening stroma. **B,** Occasional tumors are stroma rich and contain compressed, infiltrative nests or cords of tumor cells within the dense fibrosis. **C,** Amyloid may be seen in PanNETs, especially insulinomas.

Rare cases of Zollinger–Ellison syndrome have also been reported in association with tumors of the ovary, mesentery, liver, and intra-abdominal (usually peripancreatic) lymph nodes.[420–423] The Zollinger–Ellison syndrome is characterized by gastric hyperacidity and the formation of gastric, duodenal, or jejunal ulcers. Diarrhea is seen in one-third of the patients as a result of the excessive gastric secretion. Although the original reports emphasized the atypical location of the ulcers, this has not been substantiated in subsequent series. Fasting gastrin levels and the secretin stimulation test are useful diagnostic assays.[417]

Sporadic gastrinomas associated with the Zollinger–Ellison syndrome are nearly always solitary, located in either the pancreas (slightly more often) or the duodenal wall, and often clinically malignant; cases presenting as a component of MEN 1 (~20%) tend to be multicentric, are usually located in the duodenal wall (and very rarely in the pancreas), and are less likely to be clinically malignant.[424,425] The non-neoplastic pancreas in patients with gastrinomas may show islet cell hyperplasia.[426]

Proton pump inhibitors have become the mainstay of medical therapy for patients with hypergastrinemia, and thus gastrectomy is no longer recommended.[417] Surgical approaches to gastrinomas differ between sporadic tumors and those associated with MEN 1. Surgery plays an important role in the management of sporadic gastrinomas, even those presenting with metastases, as resection is believed to decrease the prevalence of metastases and decrease the need for ongoing medical therapy. Resection of hepatic metastases may also be considered in selected patients.[427] Surgical therapy in patients with MEN 1 is more controversial, given that tumors are often small and multiple and that approximately 50% of patients with gastrinomas and MEN 1 present with nodal, hepatic, or distant metastases.[428] Regardless, most follow a protracted course with excellent 10-year survival rates.[427]

Other functional PanNETs include *VIPomas, somatostatinomas* (formerly known as delta cell tumors), and *PP cell tumors*. VIPomas are associated with a severe diarrheal illness (so-called pancreatic cholera) caused by the secretion of vasoactive intestinal peptide (VIP). Only a small percentage of tumors are associated with MEN 1, and an aggressive clinical course is seen in approximately half of cases.[383,407] The majority of somatostatinomas do not produce a clinical syndrome and are discovered incidentally or after evaluation for nonspecific symptoms.[429] The syndrome, seen only in a minority of patients, features diabetes, cholecystolithiasis, steatorrhea, indigestion, hypochlorhydria, and occasionally anemia. Some somatostatinomas are located in the duodenal wall instead of in the pancreas.[430] Psammoma bodies are commonly found among the tumor cells. PP cell tumors are rare if one restricts the definition of the term to neoplasms composed exclusively or predominantly of this cell type.[431] However, a secondary and minor component of PP cells is found in a high proportion of pancreatic endocrine neoplasms of other cell types, including their metastases.[432] Some authors have historically referred to PanNETs that secrete serotonin as "pancreatic carcinoid tumors,"[433] but most currently do not use this term and include

these lesions in the category of well differentiated pancreatic NET. PanNETs (as well as other neuroendocrine neoplasms) can also secrete the alpha and/or beta subunits of hCG. This phenomenon, which can be detected by serum assays or immunohistochemical staining of the tumor, is more commonly seen with malignant neoplasms.[434,435]

As discussed previously, surgery is the mainstay of therapy for the majority of PanNETs. Chemotherapy (particularly streptozotocin), molecular-targeted therapies, and radionuclide therapy may be offered to patients with symptoms and/or progressive disease.[383]

Historically, there has been a great deal of interest in the immunohistochemical staining of PanNETs for peptide hormones. Although it may be possible to document the production of a specific hormone in a given tumor, functional tumors are defined clinically, not by immunohistochemistry, and the hormone staining profile does not have clinical or prognostic significance.[436] For these reasons, staining for peptide hormones is now largely a matter of academic interest.

Examination of routine hematoxylin and eosin sections is often all that is needed to diagnose a PanNET. Immunohistochemically, synaptophysin and chromogranin A may be useful in confirming the diagnosis[383]; CD56 and NSE may also be expressed but are less specific. PanNETs may also express PDX-1, PAX8, Isl1, and GNAS (NESP-55), and CK7, TTF-1, CK20, and CDX2 may be useful in distinguishing NETs of pancreatic origin from those of pulmonary (CK7 and TTF-1 positive) and GI (CDX2 and CK20 positive) origin.[437–440]

The molecular genetics of PanNETs differ significantly from those of pancreatic ductal adenocarcinoma. PanNETs do not typically have mutations in *KRAS*, *CDKN2A*, or *SMAD4*, and only a small minority harbor *TP53* mutations. A total of 45% of sporadic PanNETs have mutually exclusive mutations in *DAXX* or *ATRX*, and *MEN1* mutations are seen in both patients with the syndrome and about half of patients with sporadic PanNETs. Mutations have also been found in elements of the *MTOR* pathway.[383,441,442]

Grading and Prognosis

The 2010 WHO classification of gastrointestinal NET classifies pancreatic NET into three grades, based on mitotic count and Ki-67 proliferation index. G1 (mitoses <2/10HPF and Ki67 index <3%) and G2 (mitoses 2–20/10/HPF or Ki67 index 3%–20%) tumors are considered well differentiated. G3 tumors (mitoses >20/10HPF or Ki67 index >20%) are considered poorly differentiated. Controversy remains over the classification of tumors with morphologic features of well-differentiated PanNETs, but proliferation indices that correlate with a G3 tumor.[383,443,444] In terms of other predictors of clinical malignancy, nuclear pleomorphism is a particularly unreliable criterion (see earlier). The clinical factors that correlate with prognosis in PanNET are age of the patient and extent of the disease at presentation.[445] A number of immunohistochemical markers are reported to be associated with aggressive behavior, including but not limited to CD117, CD10, CK19, PAX8, CD99 (loss), PTEN (loss), fibroblast growth factor receptor, palladin, and p21. However, these have not been tested in large studies and are generally not used for clinical purposes.[383,445–451]

Poorly differentiated neuroendocrine carcinoma (also known as small cell carcinoma of the pancreas) is morphologically similar to its more common pulmonary counterpart, although pancreas NEC often has a large cell phenotype (Fig. 22.35). Expression of at least one neuroendocrine marker is required for the diagnosis of large cell NEC but not for small cell NEC. Metastases to the pancreas from a lung primary must always be considered with the latter type of tumor.[383] It is sometimes associated with ectopic ACTH secretion[452] or hypercalcemia.[453] NECs should be distinguished from Ewing sarcoma/primitive neuroectodermal tumor (PNET), which has also been described in an intrapancreatic location.[454]

Mixed NEC are composed of neuroendocrine elements as well as exocrine elements, including acinar, ductal, or both components.[340,341,455–458] By definition, these tumors must contain morphologically and immunohistochemically separate components of neuroendocrine and ductal or acinar differentiation[443]; focal glandular differentiation or mucin positivity in a PanNET does not meet these criteria. The distinction is important as the ductal adenocarcinoma component implies more aggressive behavior, particularly if the neuroendocrine component is a poorly differentiated NEC. It is also important to be aware that non-neoplastic ducts may be entrapped by PanNETs, and this should not lead to a mistaken diagnosis of mixed endocrine–ductal carcinoma.[459]

Multiple Endocrine Neoplasia

MEN syndromes are inherited in an autosomal dominant fashion and are characterized by hyperplastic or neoplastic proliferation of more than one endocrine gland.[460,461] They are discussed here because some forms of MEN frequently have a clinically important pancreatic endocrine component. The classic forms of MEN include MEN 1 and MEN 2, but VHL, Cowden syndrome, Carney complex, and several other familial endocrine neoplasia syndromes (with both known and unknown genetic basis) also fall into this category.[462,463]

MEN type 1 (Werner syndrome) is characterized by involvement of the anterior pituitary gland (adenomas), pancreas (PanNETs), and parathyroid glands (chief cell hyperplasia).[462,464,465] The disease is due to a variety of inactivating mutations of the *MEN1* gene, located on chromosome 11q13.[462]

Gastrinomas occur in approximately 40% of patients with MEN 1, insulinomas in 10%, and the other functional PanNETs in less than 5% of patients.[462] Thus the main clinical manifestations are primary hyperparathyroidism, the Zollinger–Ellison syndrome, and acromegaly or hypopituitarism. Nonfunctional PanNETs are also very common in this syndrome. Other abnormalities, although less common, involve the adrenal cortex and thyroid gland (in the form of nodular hyperplasia or adenomas), carcinoid tumors of various locations but mainly of foregut derivatives (lung, thymus, and gastrointestinal tract), multiple soft tissue lipomas, multiple leiomyomas at various sites, and Ménétrier disease of the stomach.[462,466] We have seen patients with MEN 1 with thymic carcinoid tumors[467] and with multiple carcinoid tumors of the gastric fundus.[468]

MEN type 2 comprises three variants (MEN 2a, MEN 2b, and familial medullary thyroid carcinoma [FMTC]), all of them caused by germline mutations in the *RET* proto-oncogene, located on chromosome 10q11.2[462,469] and all sharing medullary thyroid carcinoma as part of the disease. Parenthetically, the *RET* oncogene is also commonly mutated in Hirschsprung disease[470,471] and frequently rearranged in papillary thyroid carcinoma (see Chapter 8).

MEN 2a (Sipple syndrome) is characterized by C-cell hyperplasia and medullary carcinoma of the thyroid gland (often multiple and/or bilateral), pheochromocytoma of the adrenal glands (often bilateral and accompanied by adrenal medullary hyperplasia), and primary hyperparathyroidism.[462,472] Thus the overlap between MEN types 1 and 2a is represented by the parathyroid involvement, which is morphologically and functionally similar in these two disorders. *MEN 2b (Gorlin syndrome)* is characterized by medullary carcinoma of the thyroid, adrenal pheochromocytoma (with features similar to those seen in MEN 2a), so-called mucosal neuromas (resulting in hypertrophied corneal nerves, bumpy lips, and enlarged nodular tongue), skeletal abnormalities, and a marfanoid habitus.[462,473,474] Mucosal neuromas (which Carney et al.[475] prefer to designate

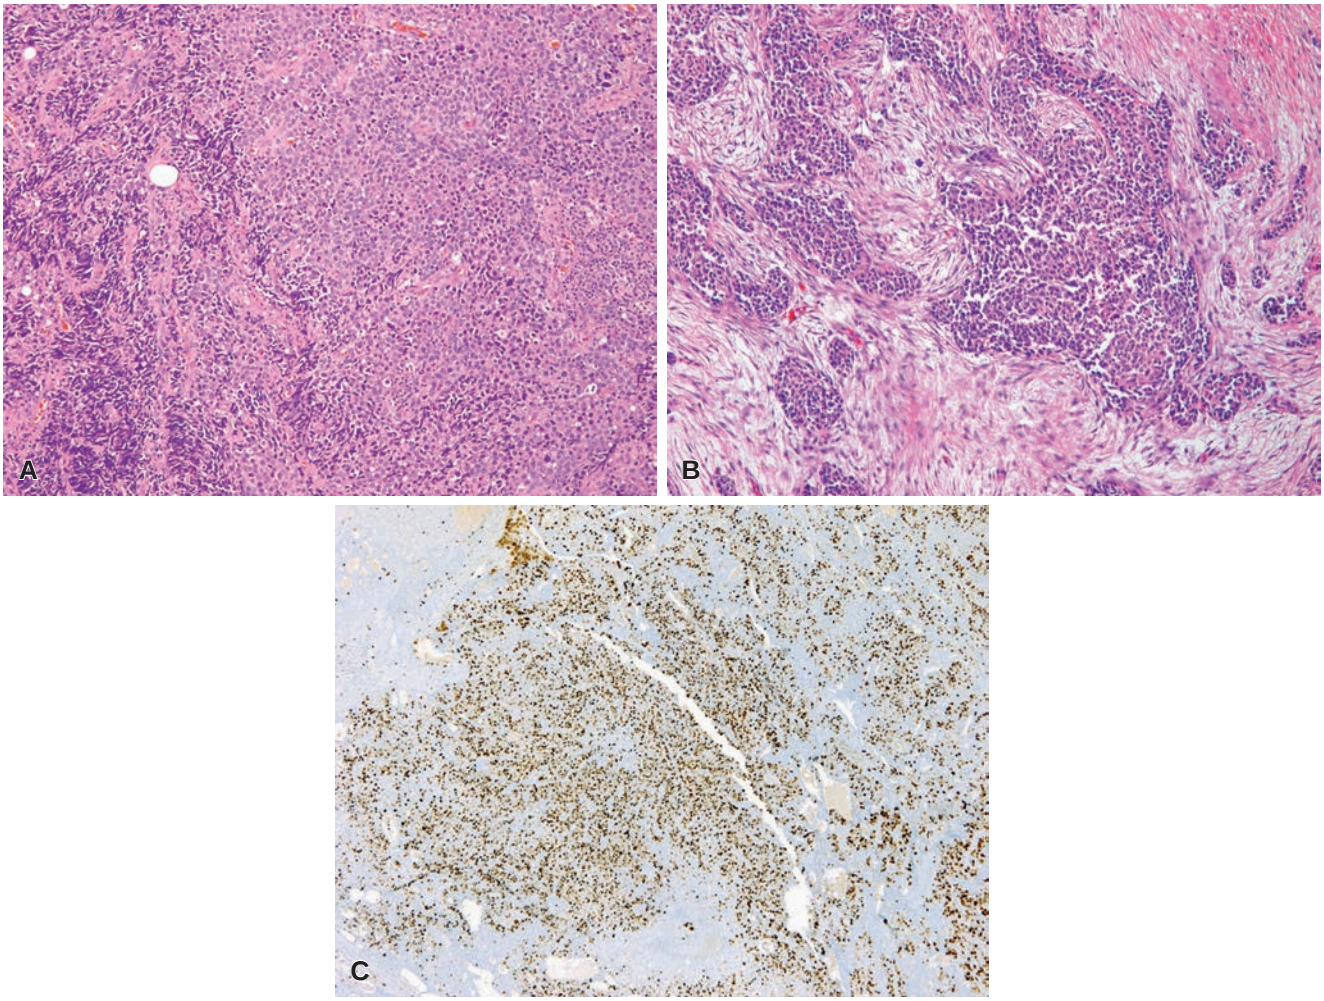

Figure 22.35 Poorly differentiated neuroendocrine carcinomas may have a large cell **(A)** or a small cell **(B)** phenotype. Necrosis and nuclear crush artifact are common, as in the lung. By definition these tumors are G3 **(C)**, with a Ki-67 proliferation index of greater than 20%.

mucosal ganglioneuromas or ganglioneuromatosis) represent the most constant feature of this syndrome. In many cases, there is extensive ganglioneuromatosis of the digestive tract, which may result in constipation, diarrhea, and even the production of megacolon.[476] Sometimes the gastrointestinal manifestations represent the initial manifestation of the disease, and patients with MEN 2b with adenomatous polyposis coli have been rarely reported.[477] Parathyroid disease is distinctly unusual in MEN 2b. It should be noted that in older reports MEN 2b (IIB) was referred to as MEN III.[478] *FMTC* is characterized by the development of medullary thyroid carcinoma in at least four family members, but patients do not have other endocrinopathies.[462] Other combinations of endocrinopathy have also been described, suggesting the existence of additional types or varieties of MEN.[479,480]

Lymphoid Tumors and Tumorlike Conditions

Most malignant lymphomas involving the pancreas originate in peripancreatic or retroperitoneal lymph nodes,[481,482] although rare cases of primary pancreatic lymphoma have been reported (Fig. 22.36), including *diffuse large B-cell lymphoma, lymphoblastic lymphoma,* and *anaplastic large cell lymphoma.*[483–485] *Post-transplant lymphoproliferative disorder* rarely involves the pancreas and may mimic pancreatitis or

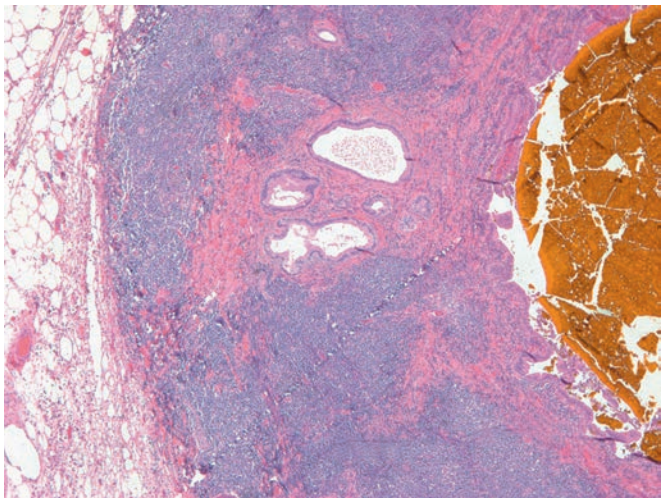

Figure 22.36 Primary diffuse large B-cell lymphoma extending to involve the common bile duct. The patient presented with jaundice and radiographically was thought to have pancreatic ductal adenocarcinoma.

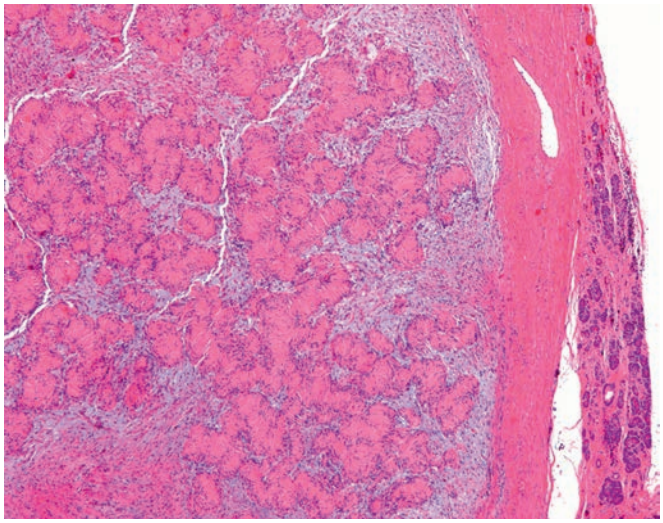

Figure 22.37 Intrapancreatic schwannoma with numerous Verocay bodies.

Figure 22.38 This intra-ampullary papillary tubular neoplasm is located entirely within the ampullary channel. (Courtesy of Dr. George F. Gray Jr.)

rejection of the pancreatic allograft.[486] *Multiple myeloma* and both B- and T-cell leukemias rarely involve the pancreas as well and may also mimic pancreatitis or other neoplasms.[487–489] Pancreatic *Castleman's disease* and *Rosai–Dorfman disease* have also been rarely reported.[490,491]

Mesenchymal and Other Primary Tumors

Benign mesenchymal tumors of the pancreas, all extremely rare, include *lymphangioma* (not to be confused with the more common microcystic cystadenoma),[492,493] *adenomatoid tumor*,[494] *schwannoma* (Fig. 22.37),[495,496] *solitary fibrous tumor* (which can behave in a malignant fashion),[497,498] and PEComas.[499–501]

Primary sarcomas of the pancreas are also rare, and most malignant tumors of sarcomatous appearance involving the pancreas are either anaplastic carcinomas or pancreatic involvement by retroperitoneal sarcomas. Primary *liposarcomas*,[502] *leiomyosarcomas*,[503] *clear cell sarcoma*,[504] *angiosarcoma*,[505] *malignant peripheral nerve sheath tumor*,[506] *follicular dendritic cell sarcomas*,[507] and *phyllodes tumor*[508] have been rarely described. There have also been descriptions of pancreatic *gastrointestinal stromal tumor* (*GIST*)[509] and *inflammatory myofibroblastic tumor*[510,511] of the pancreas.

Miscellaneous Tumors and Tumorlike Lesions

Other rare tumors and tumorlike lesions include *intrapancreatic malignant mesothelioma*[512]; *intrapancreatic accessory spleen*[513]; *lipomatous pseudohypertrophy*, which may mimic adenocarcinoma radiographically[514]; and "*solid*" or "*cellular*" *hamartoma*, an exceedingly rare tumor which is CD117 positive and may mimic a GIST.[515]

Metastatic Tumors

Most tumors metastatic to the pancreas involve the organ by direct extension, either from an adjacent viscus or peripancreatic lymph nodes. The lung, large bowel, kidney, and breast are the most common sites for the primary tumor.[516,517] Melanomas, sarcomas, and mesotheliomas can also involve the pancreas secondarily.[518] In some cases, the metastatic tumor has been seen to involve the epithelium of the pancreatic ducts and even to exhibit pagetoid features.[519]

Ampullary Region

Adenomas and Flat Dysplasia

Ampullary adenomas (adenomas of the duodenal surface of the ampulla) may occur sporadically or in the context of familial adenomatous polyposis.[520] In the past, by the time exploration was carried out, an invasive carcinoma was almost invariably present at the base. As a result, the whole lesion was regarded as malignant. With the increased use of endoscopic procedures for the early detection of these lesions, the clinicopathologic features of these lesions have become better characterized. Ampullary adenomas may be tubular or villous, and the morphologic characteristics are akin to those of colorectal adenomas.[521] Paneth cells and neuroendocrine cells are particularly common in this location.[522] The presence of invasive adenocarcinoma increases with increasing size of the adenoma.[523] Endoscopic resection has essentially replaced pancreaticoduodenectomy in the management of these lesions, and the prognosis is excellent with complete excision.[524] Flat dysplasia in this area has not been well characterized, presumably because these lesions do not cause symptoms or are overrun by associated adenocarcinoma prior to resection.[525]

Intra-ampullary Papillary–Tubular Neoplasm

Intra-ampullary papillary–tubular neoplasms (IAPNs) are, by definition, preinvasive, mass-forming neoplasms that are located almost exclusively within the ampulla; that is, more than 75% of the lesion must be within the ampullary channel (Fig. 22.38) and/or the distalmost segments of the pancreatic or common bile duct, with only minimal involvement of the duodenal mucosa or proximal pancreatic or common bile ducts.[526] Similar to IPMN and counterparts in the gallbladder, the epithelium may be of intestinal or gastric/pancreatobiliary type, and shows various degrees of papillary or tubular growth patterns. Approximately 75% are associated with an invasive component.

Ampullary Carcinoma

Ampullary carcinoma has historically been the term employed for any malignant epithelial tumor centered in the ampulla of Vater, but because of the anatomic complexity inherent in this area, it can be challenging to distinguish between adenocarcinomas of the distal common bile duct, periampullary duodenum, pancreatic head, and true ampulla. Controversy regarding terminology remains, but current

literature classifies ampullary carcinomas into four distinct groups based on anatomic location[527,528]: (1) intra-ampullary carcinomas associated with IAPNs; (2) ductal ampullary carcinomas; (3) periampullary/duodenal carcinomas; and (4) ampullary carcinoma not otherwise specified (N.O.S.). Adenocarcinomas associated with IAPN have the best prognosis. The ductal type is characterized by a constrictive, stenotic growth in the distalmost common bile duct or pancreatic duct at the ampulla, without a significant noninvasive component. These have the worst prognosis but are still less aggressive than pancreatic ductal adenocarcinomas. Periampullary/duodenal carcinomas bulge into the duodenal lumen and have only minimal intra-ampullary extent, although they typically eccentrically involve the ampullary orifice. Ampullary carcinomas N.O.S. are located at the papilla of Vater but do not have the distinguishing characteristics of the other three types. Ampullary carcinomas should be distinguished from carcinomas of pancreas, common bile duct, and duodenum with secondary involvement of the ampulla, because true ampullary carcinomas tend to have a better prognosis.[529,530] Such a distinction, however, may not be possible in advanced cases. Furthermore, underlying pancreatic head adenocarcinomas and other non-ampullary primary tumors may colonize the ampullary mucosa, leading to diagnostic confusion.

Clinically, most individuals are over the age of 60, and there is a slight male predominance.[528] Several cases have been described in patients with familial adenomatous polyposis and with neurofibromatosis type 1.[531,532]

As discussed previously, the gross appearance depends upon the subtype of ampullary carcinoma.[528] Periampullary/duodenal tumors usually bulge into the duodenal lumen, whereas those associated with IAPNs tend to fill the ampullary channel. The ductal type tumors typically have only a small lesion at the ampulla but cause a plaque-like or stenotic growth in the distal ducts. Microscopically, nearly all ampullary malignant tumors are adenocarcinomas (Fig. 22.39), often poorly differentiated, with intestinal, pancreatobiliary, or a mixed phenotype. Morphologic variations on the theme of ampullary carcinoma include examples with a prominent Paneth cell component,[522] adenosquamous carcinoma,[533] micropapillary carcinoma,[534] and cases exhibiting hepatoid differentiation.[535]

Immunohistochemically, the keratin profile tends to match the morphology, in the sense that the tumors with pancreatobiliary appearance are CK7+/CK20–, whereas those with an intestinal morphology are usually CK7–/CK20+.[536] Furthermore, the combination of MUC2 and CDX2 positivity is typical of the intestinal type tumors but not pancreatobiliary type.[537] Mutations of *TP53* have been detected in the majority of ampullary carcinomas, with a corresponding accumulation of the abnormal product as detected immunohistochemically.[538,539] *DPC4* mutations are rare in ampullary adenocarcinoma, and only a minority (30%–40%) harbor *KRAS* gene mutations.[540,541]

Ampullary carcinoma may invade the adjacent duodenal mucosa, duodenal wall, pancreas, and common bile duct by direct extension. Perineural invasion may also be present. Regional lymph node metastases are found in 35%–50% of the cases.[542,543] As noted previously, the prognosis of ampullary carcinoma is significantly better than that of pancreatic carcinoma and bile duct carcinoma, hence the importance of the distinction. The overall 5-year survival rate, which was around 25% in former series, has risen to 40%–50% or above in more recent studies.[528,529,544] As expected, this figure is even higher in the absence of lymph node metastases.[528] As in most other sites, the stage of disease is the most important prognostic indicator.[545,546] Other adverse prognostic factors include pancreatobiliary histologic subtype and tumor budding is said to be a strong negative prognostic indicator.[545,547] The treatment of choice of ampullary carcinoma remains the Whipple procedure; however, ampullectomy may be considered in patients with small, superficial carcinomas or who are poor operative risks.[548]

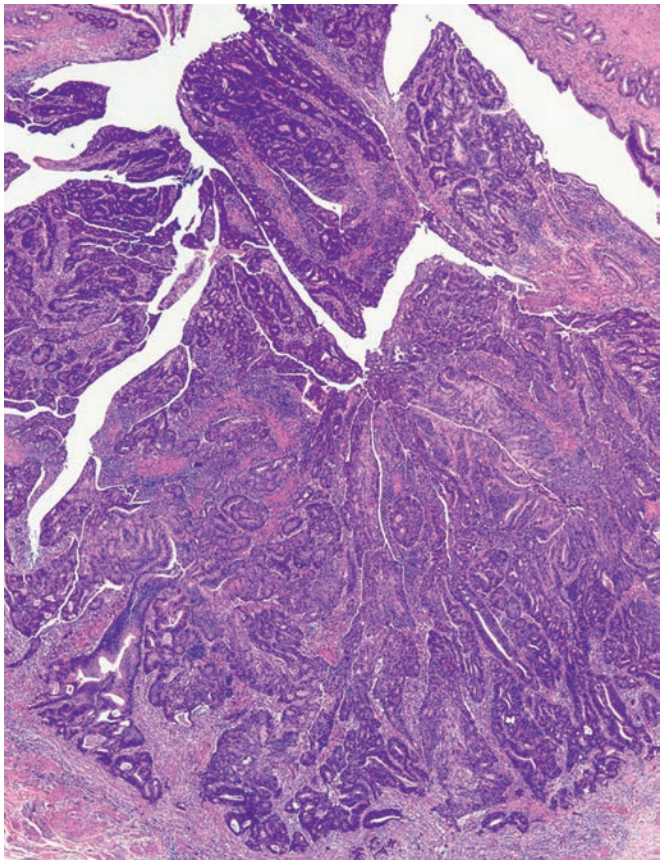

Figure 22.39 Invasive ampullary adenocarcinoma arising from an intra-ampullary papillary–tubular neoplasm of intestinal type.

Neuroendocrine Neoplasms

Well-differentiated neuroendocrine neoplasms can also occur in this location, as well as *poorly differentiated NEC*.[549–552] In contrast to their counterparts in the rest of the duodenum, ampullary carcinoid tumors are more likely to be associated with neurofibromatosis type 1.[553] Mixed adenocarcinoma/NET and mixed acinar/NECs have been rarely reported.[554–556]

Miscellaneous Tumors and Tumorlike Lesions

Other tumors and tumorlike conditions at this site include *adenomyoma*[557,558] and *adenomyomatous hyperplasia*,[559,560] the latter thought to be a sequela of chronic papillitis, and GISTs.[561] *Gangliocytic paraganglioma* is almost exclusively found in this location but will be discussed in detail in Chapter 15.[562] Primary *malignant lymphomas* have also been rarely described in this location.[563–564]

The diagnosis of *fibrosis of the papilla of Vater* is sometimes made in patients with right upper abdominal pain in whom a "pinpoint ampullary opening" is found at surgery.[557] More often than not, the microscopic sections show no significant abnormalities. In our experience, clear-cut inflammatory or fibrotic changes in the papilla of Vater have always been associated with chronic gallbladder or pancreatic disease, or previous surgical/endoscopic manipulation.[565] Of note, patients with sclerosing IgG4 disease may have involvement of the ampulla.[566]

Abstract

A renal biopsy is an important tool in the evaluation of a patient with medical kidney disease. There is extensive overlap of clinical manifestations of a variety of kidney diseases, and the pathologic examination of tissues using light microscopy, immunofluorescence microscopy, and electron microscopy enables a renal pathologist to render an accurate diagnosis. Unfortunately, the host response to a variety of injurious agents also shows significant morphologic overlap. Hence, the renal biopsy interpretation should not be performed in a clinical vacuum and the value of timely communication with the nephrologist can never be underestimated. A thorough and systematic evaluation of various compartments, that is, glomeruli, tubules, interstitium, and blood vessels, points to the primary site of injury. The glomerular diseases are traditionally classified based on the presenting clinical syndrome, laboratory investigations, and morphologic pattern. Over the last two decades, many scientific advances have helped us gain insights into the relevant pathophysiological mechanisms, and these etiologic factors are being increasingly utilized in the classification of diseases. Better understanding of specific diseases such as focal segmental glomerulosclerosis, membranous glomerulonephritis, membranoproliferative glomerulonephritis, atypical hemolytic uremic syndrome, immunoglobulin (Ig)G4-related tubulointerstitial nephritis, and autosomal dominant tubulointerstitial kidney disease can aid in identifying more specific therapeutic targets. An allograft biopsy is the gold standard for assessment of graft dysfunction and institution of appropriate therapy. In addition to rejection, infections and drug toxicities can be diagnosed on biopsy and the extent of irreversible chronic changes can be estimated. Better laboratory tools and morphologic assessment methods have helped characterize the diagnostic and prognostic features of antibody-mediated rejection.

Renal Biopsy

Renal biopsy is an important tool used in the evaluation of patients with renal disease.[1–3] Utilizing this procedure, it is possible to establish an accurate diagnosis, obtain critical information on the evolution and prognosis of the disease process, and develop a rational approach to the treatment of a renal disorder.[4–6] Even in advanced stages of kidney damage, a biopsy can provide clues regarding the possibility of recurrence of the disease following transplantation. The renal biopsy is also important in the management of the transplant recipient, representing the most accurate method for determining the presence of antibody- or T cell–mediated rejection, acute tubular injury, calcineurin inhibitor nephrotoxicity, or the development of de novo or recurrent glomerulonephritis in the allograft.

Renal disease is usually manifested by a limited number of symptoms that are commonly grouped in clinical syndromes, that is, nephrotic syndrome, persistent proteinuria, acute nephritic syndrome, persistent or recurrent hematuria, asymptomatic renal insufficiency, hypertension, rapidly progressive renal failure, acute renal failure, and chronic renal failure. Given the fact that the kidney reacts to a variety of injurious agents with a limited number of histopathologic patterns of injury, a given clinical syndrome can be associated with several histopathologic patterns, while a single histopathologic pattern may be linked to more than one syndrome. The accurate interpretation of a renal biopsy requires detailed knowledge of the structure and function of the normal kidney, as well as an understanding of the clinical, morphologic, and histopathogenic aspects of renal disease. To evaluate a kidney biopsy, the pathologist should correlate the clinical and laboratory information with light microscopic, immunofluorescence, and ultrastructural findings.

Handling of the Biopsy

Most renal biopsies are done by either the percutaneous route using a cutting needle or by direct exposure of the kidney (open biopsy, often a wedge sampling of outer cortex). Most centers use 16–18-gauge needles for adults and 18-gauge needles for children less than 8 years of age. The specimen should be divided for light microscopy, immunofluorescence, and electron microscopy. Ideally, two biopsy cores should be obtained when a needle biopsy is performed. From the first core, two or more samples measuring 0.5–1 mm in thickness are taken from each end with a fresh razor or scalpel blade and placed in a cold solution of 2% glutaraldehyde in phosphate or cacodylate buffer for electron microscopy studies while the remaining tissue is placed in saline. If the second core is adequate, samples should also be taken from each end for electron microscopy, while the remainder is snap frozen in liquid nitrogen or in isopentane cooled on dry ice for immunofluorescence. For light microscopy, the tissue that was placed in saline should be transferred to a fixative, most common being 10% buffered formalin. If only one core is obtained, material should be taken from each end for electron microscopy and the remainder divided for light microscopy and immunofluorescence. If the core is too small, the specimen should be divided for electron microscopy and immunofluorescence studies since most of the light microscopic information can be obtained from the study of semi-thin sections of the plastic-embedded tissue processed for electron microscopy. Longitudinal division of the cores should be avoided. The triaging of the biopsy sample should ideally ensure that all three portions include cortex. On gross examination of the cores under dissecting microscope or loupe (magnifying device), glomeruli in well-preserved cortex appear as pale or congested bulges; however, this may not be evident when cores with sclerotic glomeruli or fibrotic interstium are examined.

Light Microscopy

A variety of fixatives have been recommended for the light microscopic study of renal biopsies. Zenker, Helly, Bouin, and Van der Griff fixatives are sometimes used and many pathologists feel that mercuric solutions provide the best architectural and cytologic detail. However, 10% neutral formalin can also provide good morphologic detail while also preserving the sample for future immunohistochemical studies or immunofluorescence microscopy on paraffin-embedded tissues, if needed.[7,8] To evaluate for glycogen or crystals of urate, uric acid, and other water-soluble substances, tissue should be fixed in ethanol. A panel of hematoxylin and eosin (H&E), periodic acid–Schiff (PAS), methenamine silver, and trichrome stains are recommended for the routine evaluation of renal biopsies, but from the practical point of view, PAS is the most useful, is easiest to perform, and can also provide most of the information obtained from other stains. It is recommended that the biopsy core be serially sectioned (2–3 µm thick) and that three to four tissue sections be placed on each slide. At regular intervals, one slide is stained with H&E, one with PAS, one with trichrome, and another with silver stain. By following this procedure, the maximum number of glomeruli can be examined. The remaining unstained slides are saved in case special stains or immunohistochemical stains are needed.

Electron Microscopy

There is a general misconception that electron microscopy is a complex and time-consuming procedure. In fact, satisfactory processing methods have been developed that require less than 5 hours.[9] Many fixatives have been developed for this procedure, each of which has specific advantages. Some pathologists prefer a primary fixation in osmium tetroxide for the optimal demonstration of deposits and basement membrane structure, but glutaraldehyde fixation with post-osmification is more convenient and is suitable as a routine procedure. For tissue embedding, various epoxy resins with comparable characteristics are available and their selection is a matter of personal preference. Semi-thin (1 µm thick) sections obtained from the plastic-embedded tissue blocks are stained with toluidine blue or methylene blue and carefully studied as they can yield a great deal of information, especially when examined at high magnification (Fig. 23.1).[10] Thin sections from the blocks selected for ultrastructural study are double-stained with uranyl acetate and lead citrate for electron microscopic examination.

Immunofluorescence Microscopy

Direct immunofluorescence performed on frozen sections is the simpler, faster, and most satisfactory method for the routine evaluation of a renal biopsy, but indirect methods may be used for extra sensitivity or for a specific antibody. The portion of the biopsy specimen selected for immunofluorescence is oriented in standard frozen section embedding compound on a piece of cork and is snap frozen by immersion in a beaker containing either isopentane or methylbutane surrounded by liquid nitrogen or dry ice. Frozen sections of 2–4 µm thick are cut and stained with specific antibodies and examined under ultraviolet light using either transmitted or incident illumination, and the reactions are graded subjectively using a scale of 0 to 3+ (or 4+, depending on individual labs) and recorded by photography. The antibodies that are most commonly used are those against immunoglobulin (Ig)G, IgA, IgM, kappa and lambda light chains, C1q, C3, C4, and fibrinogen or fibrin. Immunostaining for a variety of other antigens can also be performed for selective diagnostic purposes. For example, C4d is very useful for the diagnosis of antibody-mediated acute allograft rejection.[11,12] IgG subclass

identification (IgG1, IgG2, IgG3, IgG4) and phospholipase A2 receptor 1 (PLA_2R) staining is helpful in the diagnosis of primary membranous nephropathy.

In those cases in which glomeruli are not present in the portion of the submitted biopsy specimen, immunofluorescence studies can be successfully performed on pronase predigested tissue sections prepared from the portion of the biopsy allocated for light microscopy.[8] It should be mentioned, however, that immunofluorescence for detecting C3 on these specimens is less sensitive when compared with that performed on frozen tissue sections. In addition, anti-glomerular basement membrane (GBM) disease cannot be diagnosed by this pronase method due to high background staining.

Immunohistochemical studies can also be performed on formalin-fixed, paraffin-embedded biopsy specimens. In addition to extensive panel needed in the evaluation of incidental solid tumors or hematolymphoid neoplasms, the commonly used immunohistochemical stains in the context of medical renal biopsies include BK (or SV40) stain in the diagnosis of BK polyomavirus nephropathy,[13,14] adenovirus stain, cytomegalovirus stain, and C4d and amyloid A stain. Epstein–Barr virus (EBV) in situ hybridization is helpful in suspected cases of post-transplant lymphoproliferative disorders.

Biopsy Interpretation

Although potentially challenging, the diagnosis of renal biopsy specimens is based on the same foundation of careful observation and clinicopathologic correlation that is used in other areas of pathology. A knowledge of normal morphology is essential for the recognition of any alteration that may occur in the various components of the kidney. Obtaining adequate clinical history is crucial to any renal biopsy interpretation. A checklist that can be used during the biopsy evaluation is provided in Table 23.1.

A renal biopsy must contain glomeruli to be considered adequate, but there is disagreement over the number of glomeruli required to make a diagnosis. The definition of adequacy largely depends on the disease under consideration. In disorders characterized by irregular or crescentic proliferation, the assessment should be based on a minimum of 10 glomeruli, whereas, in diffuse lesions (such as membranous glomerulonephritis [MGN]), the identification of specific features in a single glomerulus may be sufficient, especially if ultrastructural studies are also performed. While there is often a variation in the severity of a specific lesion among different glomeruli, even in diffuse processes, a good guideline to follow is that at least 5–10 glomeruli should be examined to properly assess the extent of the disease.

Normal Structure of the Glomerulus

Since most of the changes seen in renal biopsies occur in the glomerulus, we will briefly review the morphology of this structure. The glomerulus is a vascular structure composed of a tuft of specialized capillaries that arise from the afferent arteriole to form lobules, then rejoin the vascular pole to drain into the efferent arteriole. Normally, the lobules are poorly defined, but they are highlighted in some disease processes. Each lobule consists of a cluster of capillaries supported by the mesangium, which forms the centrolobular or axial framework of the glomerular tuft. The tuft of capillaries lies within the lumen of the expanded proximal end of the nephron, or Bowman space, which is lined on its parietal aspect by a layer of attenuated epithelial cells overlying a thick basement membrane. Together, the latter two structures make up the **Bowman capsule**, which is continuous at the vascular pole of the glomerulus with the adventitia of the afferent and efferent arterioles. At the urinary pole, the basement membrane of the Bowman capsule merges with that of the proximal tubule. Each glomerulus measures approximately 200 µm in diameter, but they are all not of the same size. Those located in the juxtamedullary area are about 20% larger than those elsewhere in the cortex. The cellularity of the glomerulus varies in different diseases, and an accurate assessment requires histologic preparations of 2–4 µm thickness. The presence of more than three cells in an individual glomerular mesangial region away from the vascular pole is considered hypercellularity.

The walls of the glomerular capillaries are clothed by a reflected layer of cells of the Bowman capsule. These highly specialized epithelial cells are known as podocytes (visceral epithelial cells) because they have numerous tiny foot processes that rest on the basement membrane that separates them from the attenuated, fenestrated endothelium of the capillaries. The **GBM** is a trilaminar structure composed of a central electron-dense zone, or lamina densa, bordered by two narrow electron-lucent layers: the lamina rara interna and the lamina rara externa. The major components of the GBM are type IV collagen, laminin, heparan sulfate proteoglycans, and entactin, but minor amounts of other proteins have also been found.[15]

The principal function of the glomerulus is filtration, and the GBM is the main component of the filtration barrier. In normal adults, the GBM measures 310–380 nm in thickness; it is somewhat thinner in children (and achieving adult thickness by 10–12 years age), and slightly thicker in males than in females.[16] The GBM does not completely surround the capillary lumen since the vessel is attached to the mesangium, which consists of mesangial cells embedded in a basement membrane–like material, the mesangial matrix (Fig. 23.2). By electron microscopy, the mesangial matrix appears more fibrillar than the GBM. It is composed of collagen types IV, V, and VI, fibronectin, laminin, entactin, and sulfated glycosaminoglycans, including heparan sulfate and chondroitin sulfate.[17] The mesangial cells have cytoplasmic processes that contain α-smooth muscle actin, α-actinin, and myosin filaments, characteristics shared by smooth muscle cells, pericytes, and myofibroblasts.[16,18,19] Mesangial cells thus possess contractile properties and are probably involved in the regulation of blood flow through the glomeruli and modulation of the filtration process.[20] They produce growth factors that allow normal cell turnover.[19] Mesangial cells may also have some phagocytic

activity and play a role in the clearance of debris, including immune deposits from the mesangium.[21] Although obvious ultrastructural differences exist between the endothelial and mesangial cells, these differences are not always evident in glomerular diseases, and the distinction between the endothelium and the mesangium is usually based on the location of these structures in the glomerulus.

The visceral epithelial cells/podocytes are involved in basement membrane synthesis and, by their unique structure, play an important role in glomerular permeability. These cells cover the GBM on its urinary side and are attached to it by cytoplasmic extensions or foot processes that, under the scanning electron microscope, appear as a complex of interdigitating structures originating from different epithelial cells (Fig. 23.3). The foot processes are approximately 25–60 nm apart, with a connecting slit-pore diaphragm 4–7 nm thick that shows similarities with tight and adherens junctions. Several molecules identified in podocyte foot processes and slit diaphragms over the last two decades contribute to the structural integrity and permselectivity of the filtration barrier.[22] Bowman capsule limits the urinary space and is lined by a layer of flattened parietal epithelial cells that express cytokeratin proteins. In contrast, the visceral epithelial cells do not immunoreact for cytokeratin but do for vimentin and desmin.[23] Recent evidence suggests that parietal epithelial stem

Classification of disease distribution when single glomeruli are considered
- Segmental: a lesion involving only a part of the glomerulus
- Global: a lesion involving the entire glomerulus

cells are critical in glomerular repair and maybe involved in the regeneration of podocytes and tubular epithelial cells.[24,25]

Classification of Glomerular Disease

Glomerulonephritis is a term denoting an inflammation of the glomerulus, while **glomerulopathy** is an all-embracing term for disorders affecting this structure. In glomerular diseases, other parts of the nephron may also be involved, but the diagnosis hinges on the identification of a derangement of the normal glomerular configuration. While the changes may be recognizable by routine light microscopy, the findings from immunofluorescence are often significant. Electron microscopy is always informative and is sometimes the only means whereby the structural changes can be detected and defined. The damage to the glomeruli may take the form of definable morphologic patterns, and subdivisions in the character or distribution of the glomerular lesions are used to classify glomerulonephritis. Although there is general agreement on the definitions applied to the distribution of glomerular lesions (Box 23.1), more specific categorizations are sometimes controversial.

In this chapter, glomerular lesions are subdivided into those associated with the nephrotic syndrome or persistent proteinuria, those seen in acute nephritis or hematuria, and lesions associated with vascular diseases, such as systemic vasculitis, hemolytic uremic syndrome (HUS), and systemic sclerosis. Separate sections, including those describing tubulointerstitial lesions, renal vascular disorders, cystic diseases, and the interpretation of biopsies of transplanted kidneys, will be presented.

Glomerular Lesions Associated With the Nephrotic Syndrome

The nephrotic syndrome is clinically characterized by the occurrence of massive proteinuria, hypoproteinemia, edema, and hyperlipidemia. Damage to the filtration barrier of the glomerulus allows proteins, particularly albumin, to be filtered into the urine. The criterion for the syndrome is the excretion of more than 3.5 g of protein in a 24-hour period. A spectrum of morphology has been correlated with the syndrome, but some glomerular lesions are not accompanied by significant inflammatory or proliferative response within the glomerulus, including primary nephrotic syndrome with minimal change disease (MCD), MGN, diabetes mellitus, amyloidosis, and various forms of congenital nephrotic syndrome. The major histologic, electron microscopic, and immunofluorescence findings in each of these conditions are summarized in Table 23.2.

Minimal Change Disease

MCD (also known as nil lesion, and minimal change nephrotic syndrome) is the most common cause of idiopathic nephrotic syndrome in children, accounting for 80%–90% of all cases of idiopathic nephrotic syndrome in childhood,[26,27] and 10%–15% of adult cases.[28,29] Most of the affected children are under the age of 6 years at initial diagnosis, the majority being 3 or 4 years old.[26,27] There appears to be a male predominance, especially in children, where the male to female ratio is 2 to 3 : 1.[30] MCD is more common among whites, Asians, and Hispanics than blacks.[31] While MCD is idiopathic in 80%–90% of children, in a minority of cases it has been associated with viral infections, recent immunizations, ingestion of heavy metals (e.g., mercury or lead), allergies to some foods, dust, bee stings, and poison ivy, and drug reactions to a variety of agents, including lithium, interferon, and pamidronate. While the exact mechanism of MCD development is unclear, the final common event likely involves podocyte injury. In adult patients, especially the elderly, MCD can manifest as a hypersensitivity reaction to the use of nonsteroidal anti-inflammatory drugs.[32] In these cases, the disease is often accompanied by renal insufficiency and the development of acute interstitial nephritis.[33] In most of these patients, cessation of the offensive medication results in resolution of the proteinuria. MCD has also been reported in association with lymphoid malignancies, usually Hodgkin lymphoma.[34] Remission of the nephrotic syndrome has been obtained in these cases with the cure of the lymphoma. Other neoplastic diseases that might cause MCD include leukemias, carcinomas, and thymomas, among others. MCD is a now well-defined renal manifestation of lupus nephritis or may be seen in recipients of hematopoietic stem cell transplantation.[35,36] De novo MCD has been reported in patients with post-transplant nephrotic syndrome.[37] None of the recipients had focal segmental glomerulosclerosis (FSGS) as a primary disease. The pathogenesis of idiopathic MCD remains unknown, but it has been suggested that a circulating factor/s produced by T lymphocytes that damage one or more elements of the glomerular permeability barrier is responsible for the proteinuria seen in this condition.[38,39] Patients with MCD do show T-cell subset abnormalities, and elevated levels of interleukin-13 (IL-13) were demonstrated during relapses.[40] IL-13 has been shown to increase the expression of CD80 in podocytes. CD80, in turn, has been identified in the urine of patients of MCD and appears to be a potential diagnostic biomarker.[41] Various injurious stimuli appear to activate the podocyte enzymatic pathways, resulting in disruption of actin cytoskeleton and slit diaphragm. In addition to structural disruption of the permeability barrier, the loss of podocyte negatively charged glycocalyx may contribute to the selective leakage of anionic plasma proteins such as albumin.

Table 23.2 Glomerular lesions associated with the nephrotic syndrome

DISEASE	LIGHT MICROSCOPY	IMMUNOFLUORESCENCE	ELECTRON MICROSCOPY
Minimal change disease	Normal; minimal or no mesangial prominence	Usually negative for Ig and C3	Extensive foot process effacement
Focal and segmental glomerulosclerosis	Focal and segmental glomerulosclerosis	Nonspecific trapping of IgM and C3 in sclerosed segments	Extensive foot process effacement
C1q nephropathy	Mesangial hypercellularity common, ± focal segmental glomerulosclerosis	C1q mesangial granular deposits	Mesangial deposits
Membranous glomerulopathy	Uniform capillary wall thickening, sometimes with spike and dome pattern	IgG and C3 granular deposits along capillary wall (IgM, IgA, C1q in membranous lupus nephritis)	Four stages of subepithelial and intramembranous deposits
Diabetic nephropathy	Nodular and diffuse mesangial sclerosis; insudative lesions	IgG linear staining along capillary walls and tubular basement membranes	Diffuse thickening of basement membranes; increased mesangial matrix
Amyloidosis	Mesangial, capillary wall, and vascular amorphous deposits; weak PAS; methenamine silver negative; Congo red positive with apple-green birefringence	Based on subtype, smudgy staining for Ig light or heavy chains, amyloid AA, or other	Fibrils 8–10 nm in diameter
Light chain deposition disease	Mesangial widening and deposition of PAS-positive material	Kappa or lambda light chain restricted; granular mesangial and linear basement membranes	Finely granular material along the basement membranes, mesangium
Heavy chain deposition disease	Mesangial widening and deposition of PAS-positive material	Isolated heavy chain–restricted (frequently γ); granular mesangial and linear basement membranes	Finely granular material along the basement membranes, mesangium
Fibrillary glomerulonephritis	Mesangial widening and occasional hypercellularity, capillary wall thickening	Variable IgG, C3, occasional IgM, IgA; frequently polytypic	Fibrils 16–20 nm in diameter
Immunotactoid glomerulopathy	Mesangial widening and occasional hypercellularity, capillary wall thickening	Variable IgG, C3, occasional IgM; frequently monotypic with light chain restriction	Fibrils 30–50 nm in diameter, often in parallel bundles
Congenital Nephrotic Syndrome			
Finnish type	Tubular ectasia, microcysts, glomerular sclerosis	Nonspecific trapping of IgM and C3	Diffuse foot process effacement
Diffuse mesangial sclerosis	Mesangial consolidation, pseudocrescents, fetal glomeruli	Negative or nonspecific trapping of IgM and C3	Diffuse foot process effacement

MCD typically presents with heavy proteinuria, often of selective type, leading to the nephrotic syndrome. Microscopic hematuria is seen in less than 15% of patients,[42] but macroscopic hematuria is rare. Blood pressure is usually normal at onset, and less than 20% of patients have hypertension.[43] Given the high probability that nephrotic syndrome in a child is due to MCD, pediatric patients are treated empirically with steroids and do not undergo a renal biopsy unless the nephrotic syndrome is steroid resistant. Complete remission is common within 8 weeks of starting corticosteroid therapy.[26,27] After withdrawal of the steroids, however, about half of the patients have intermittent relapses, a phase which may last for up to 10 years. The relapses are usually steroid responsive and the disease does not progress to chronic renal failure. Patients who achieve only partial remission with corticosteroid therapy may benefit from immunosuppressive drugs such as cyclophosphamide or cyclosporine.[29] Newer agents such as anti-CD20 and anti-CTLA-4 (cytotoxic T-lymphocyte-associated protein 4) antibodies are being tested in such patients.[44,45] The development of azotemia should suggest an incorrect diagnosis and should raise the possibility of missed FSGS. Relapse is uncommon after a disease-free interval of 2 years.

The glomeruli in MCD appear normal or show minimal abnormality by light microscopy (Fig. 23.4). The glomerular capillaries are patent, and there is no increase in the thickness of the capillary walls, but podocyte hypertrophy may be appreciated. Some cases may show minor degrees of mesangial enlargement with a minimal increase in mesangial matrix and cellularity. The convoluted tubules may present focal vacuolization due to the accumulation of large amounts of lipid and protein transport droplets. Because of these light microscopic features and the finding of lipoid particles (oval fat bodies) in the urine of these patients, Munk in 1913 proposed the term lipoid nephrosis for this condition.[46] Only after ultrastructural studies were done in such cases was it established that the glomeruli, rather than the tubules, were the primary site of pathology. It should be borne in mind that biopsies from adult or elderly patients may

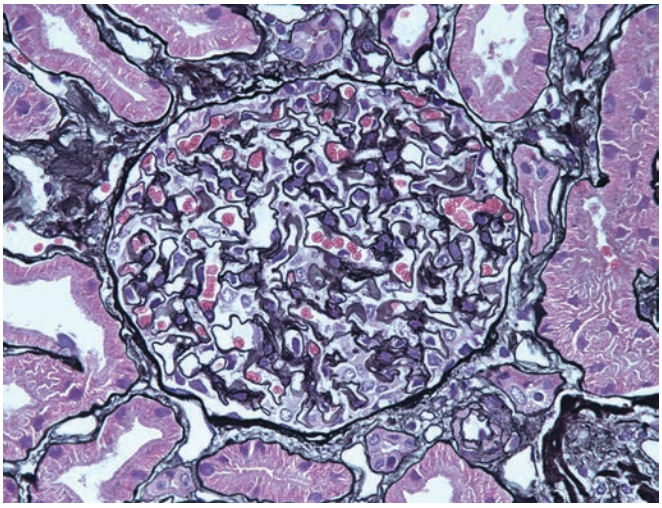

Figure 23.4 Glomerulus From a Patient With Minimal Change Disease. The glomerulus is normocellular, the capillary loops are patent, and the basement membrane is normal in thickness.

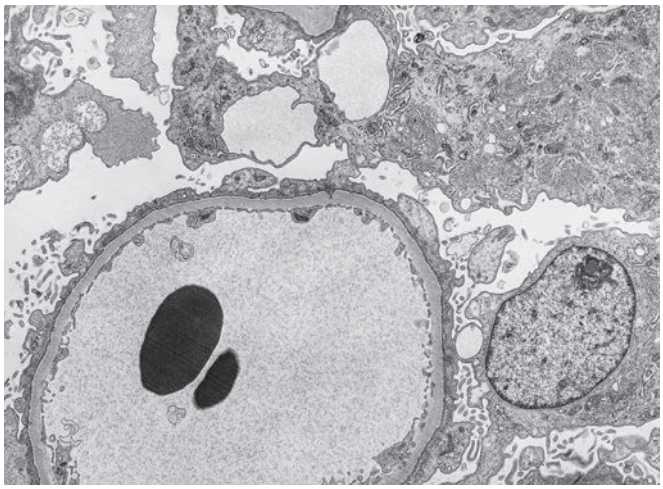

Figure 23.5 Portion of a glomerulus from a patient with minimal change disease showing obliteration of foot processes. The visceral epithelial cell cytoplasm shows microvillus and cyst formation (×8400).

not be entirely normal on light microscopy and can show a variety of preexisting pathologies such as age-related glomerulosclerosis, hypertensive arteriosclerosis, chronic tubulointerstitial damage, or mild diabetic nephropathy.

The characteristic ultrastructural appearance of the glomeruli is of total foot process effacement with the basement membrane being covered by sheets of cytoplasm. Loss of the visceral epithelial processes is accompanied by distortion of the filtration slits, with a decrease in the number of slit diaphragms.[47] Visceral epithelial cells/podocytes show prominent intracytoplasmic organelles, suggesting increased cytoplasmic activity, and frequently contain cystoplasmic cysts/vacuoles. Numerous microvilli (i.e., villous projections of podocyte cytoplasm into urinary space) are often seen in MCD (Fig. 23.5). There is a frequent increase in the density of the cytoskeleton, especially actin filaments, in the cytoplasm adjacent to the basement membrane, but no electron-dense deposits are present. Lower degrees of podocyte foot process effacement maybe observed in MCD patients with partial response to therapy.

Immunofluorescence studies are almost invariably negative for immunoglobulin and complement, but small amounts of IgM and C3 can occasionally be seen in cases with mesangial prominence. Albumin can be demonstrated as fine droplets in the cytoplasm of the proximal tubule cells when the tissue is stained for this protein (Fig. 23.6).

Because a biopsy is susceptible to sampling error, it should be kept in mind that lesions that affect only some glomeruli, such as FSGS, can lead to a misdiagnosis of MCD. Conversely, since tubular atrophy (TA) and interstitial scarring are not features of MCD, a diagnosis of FSGS should be considered if these findings are seen on a biopsy, especially in a child. It has been recently proposed that reduced expression of dystroglycan and CD44 observed in MCD can help differentiate it from FSGS, but further confirmation is needed.[48,49]

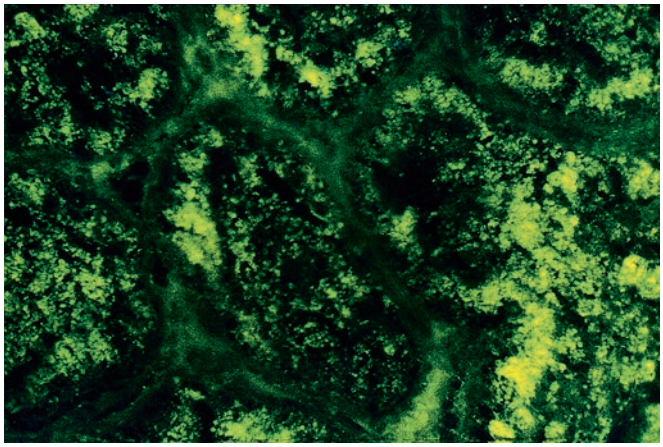

Figure 23.6 Immunofluorescence preparation demonstrating numerous albumin-positive resorption droplets in the proximal tubular epithelial cells.

Focal Segmental Glomerulosclerosis

FSGS, as a disease entity, is a clinicopathologic syndrome characterized by proteinuria, commonly in the nephrotic range, a high incidence of progressive renal failure, and focal and segmental sclerotic glomerular lesions. The segmental sclerosis results from an increase in mesangial matrix, causing obliteration of the glomerular capillaries. Five histologic subtypes have been described, including collapsing variant, "tip" lesion, cellular variant, perihilar lesion, and FSGS-NOS (not otherwise specified) variant.[50,51] This histologic classification is hierarchical and is referred to as "Columbia classification of FSGS." The presence of even a single collapsing lesion qualifies for a diagnosis of collapsing variant of FSGS. In the absence of a collapsing FSGS lesion, a "tip lesion," if present, trumps other variants. The next lesion in the hierarchy is cellular FSGS, followed by perihilar and NOS variants. Although the FSGS lesion identified in the biopsy may change over time in an individual patient, these morphologic variants do have clinical relevance.[52–54] The patients with collapsing FSGS have poor outcomes while patients with a "tip" variant respond well to immunosuppressive therapy, akin to MCD. Perihilar variants often point to a structural adaptive response to renal parenchymal loss or glomerular hyperfiltration due to a variety of other etiologies; the renal presentation is usually subnephrotic proteinuria rather than a full nephrotic syndrome as would be more common with collapsing and tip variants.

From an etiologic standpoint, FSGS may be primary or secondary to various forms of injuries or pathogenic mechanisms. The morphologic variants of FSGS are not helpful in distinguishing primary

from secondary FSGS and a biopsy diagnosis of FSGS should prompt an evaluation of etiology. The pathogenesis of primary FSGS is unknown, but it appears to be the result of circulating "permeability" factor(s), possibly a lymphokine or a cytokine, which leads to epithelial cell injury resulting in segmental scar and ultimately glomerular obsolescence.[55] The potential circulating permeability factors include cardiotrophin-like cytokine 1 and urokinase plasminogen activator receptor, but they have not been shown to be entirely sensitive or specific.[52,56]

FSGS can be secondary to a variety of conditions including drugs, viral infections, healed glomerulonephritis, and structural adaptive responses. In addition, genetic associations with either autosomal dominant or recessive mode of inheritances are being increasingly recognized as a cause of FSGS.[52,57,58] Mutations have been detected in several podocyte genes encoding proteins in the slit diaphragm, cytoskeleton, mitochondria, transcription, and DNA repair. Several patients with FSGS who would have been previously categorized as a "idiopathic" FSGS might in fact have a genetic form of FSGS.[52,59] Even in cases without a single gene mutation, there appears to be a familial susceptibility to developing FSGS. Recent studies have established a strong association between apolipoprotein L1 *(APOL1)* gene and FSGS in blacks.[60,61] The risk alleles G1 and G2 are more commonly seen in blacks and are also linked to higher rates of progressive kidney disease. The *APOL1* gene product is expressed in podocytes and platelets and although the exact mechanism of kidney disease causation is unknown, the risk alleles appear to confer an evolutionary protection against *Trypanosoma brucei* infections.[60]

The glomerular lesion of secondary FSGS can be histologically identical to that seen in primary FSGS and can occur in a variety of clinical settings with a clinical presentation indistinguishable from that of primary FSGS. Since the pathogenetic mechanisms involved in these disorders and their treatment differs significantly from that of primary FSGS, it is of paramount importance that they be excluded before a diagnosis of primary FSGS is made.[62–64] In Box 23.2 are listed the conditions most commonly associated with FSGS which should be excluded before making the diagnosis of primary FSGS.

Primary FSGS is responsible for approximately 10%–15% of the cases of nephrotic syndrome in children and 20%–30% in adults. It constitutes the predominant cause of idiopathic nephrotic syndrome in adult patients, especially in blacks.[65] Nephrotic range proteinuria is common and the clinical manifestation can be an abrupt onset of nephrotic syndrome or insidious onset of subnephrotic proteinuria. Examination of the urinary sediment will often lead to the detection of microscopic hematuria. Forty to 60% of patients have been shown to develop end-stage renal disease (ESRD) within 10–20 years,[66,67] and recurrence following transplantation has been reported in 30%–40% of patients, often within weeks, leading to graft loss.[68–72] The response to steroid therapy is limited, often prompting a second line of aggressive immunosuppressive therapy and plasmapheresis that aids the removal of the circulating permeability factor.

Pathologically, in primary or secondary FSGS, the segmental sclerosis, collapse, or obliteration of capillary lumen (i.e., depending on the morphologic variants) usually affects one or more lobules of the glomerular tuft. Early lesions may show an increased mesangial matrix and mild mesangial hypercellularity; only when the sclerosis is advanced do these areas become hypocellular, often with adhesions to the Bowman capsule (Fig. 23.7). The visceral epithelial cells can line the sclerotic segments and these adhesions, and hence the term "podocyte capping." The loops in the sclerosed areas are distorted, and they may contain hyaline material (hyalinosis), which is thought to represent plasmatic insudation, and lipid-laden "foam" cells.[73] These findings in the absence of collapsing, cellular and tip variant features (described later) and present in a nonperihilar distribution define a FSGS-NOS subtype.[50,58]

Modified from D'Agati VD, Kaskel FJ, Falk RJ. Focal segmental glomerulosclerosis. *N Engl J Med*. 2011;365(25):2398–2411.

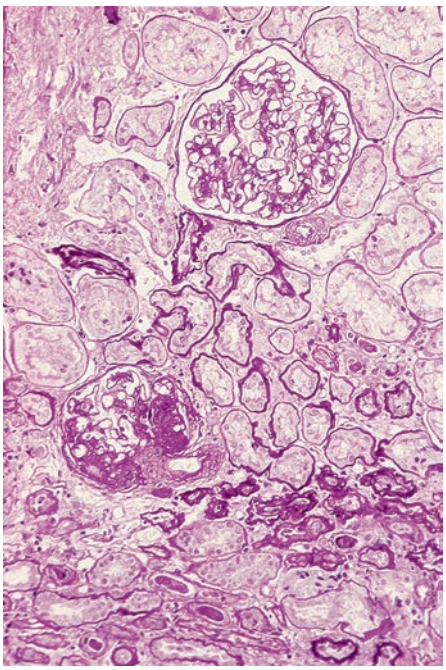

Figure 23.7 Biopsy From a Patient With Focal and Segmental Glomerulosclerosis. One of the glomeruli shows segmental sclerosis, while the other appears unremarkable. Tubular atrophy is also seen (periodic acid–Schiff stain; PAS).

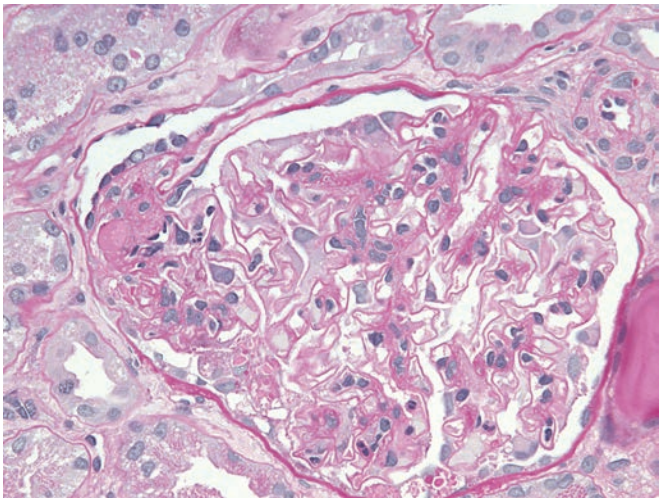

Figure 23.8 Tip variant of focal segmental glomerulosclerosis shows Bowman capsular adhesion and hyaline insudation at the tubular pole. The adjacent podocytes also show hypertrophy with cytoplasmic protein droplets (PAS).

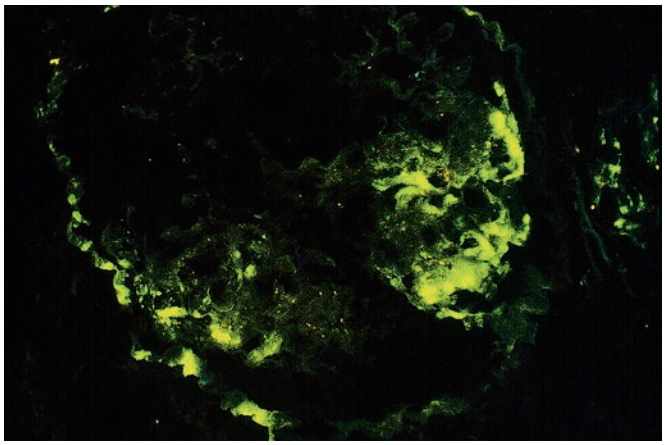

Figure 23.9 Immunofluorescence microscopy demonstrating segmental deposition of IgM in a biopsy from a patient with focal and segmental glomerulosclerosis (anti-IgM).

On occasion, sclerosis or consolidation is seen in the portion of the glomerulus opposite the hilus forming an adhesion in the vicinity of the opening of the Bowman space into the proximal tubule (glomerular tip lesion).[74] The consolidated portion of the capillary tuft in "tip" lesion may display endothelial swelling and entrapped foam cells (Fig. 23.8). The visceral epithelial cells overlying the involved segment are enlarged and vacuolated and often contain intracytoplasmic hyaline droplets. Some lesions are less cellular with an increase in mesangial matrix. The sclerotic segments in "perihilar" variant are localized next to the vascular pole, and it is a typical finding in secondary forms of FSGS attributable to adaptive functional response. The most controversial and least common subtype is the "cellular" variant in which the segmental lesion demonstrates intracapillary hypercellularity, and sometimes foam cells and karyorrhexis; hyperplasia of overlying podocytes is quite common. The collapsing FSGS lesion is described in detail in the subsequent section.

The extent of capillary tuft affected by sclerosis increases with eventual global sclerosis as the disease progresses. Areas of TA are common, and while this finding is not by itself diagnostic of FSGS, it should raise the possibility in biopsies which otherwise show MCD.[75] Interstitial fibrosis (IF) accompanies tubular loss and atrophy, and the extent of the tubulointerstitial damage is a prognostic indicator of the disease.[64,76,77] Since the glomerular injury in FSGS typically begins in the corticomedullary region, the lesion can be missed if this population of glomeruli is not included in the biopsy.

As FSGS represents podocyte injury, the most significant ultrastructural feature to be evaluated is podocyte foot process effacement, especially in capillary loops (and glomeruli) unaffected by sclerosis. Extensive podocyte foot process effacement is a feature of primary FSGS and is often seen in collapsing, tip, and cellular FSGS subtypes. Some secondary forms of FSGS and perihilar morphologic variants typically have less degree of foot process effacement.[53,78,79] A variable increase in mesangial matrix is customary in all glomeruli, and some degree of mesangial hypercellularity is not uncommon. In sclerosed segments, the GBMs are often folded and focally thickened; on occasion, foci of podocyte cell membrane detachment from GBM are seen and intervening space can accumulate multilayered basement membrane–like material and cellular debris. The hyaline deposits are composed of finely granular material that has a similar appearance and electron density to that of the insudative material seen in diabetic nephropathy. These insudations are predominantly subendothelial and located in the areas of segmental sclerosis; immunofluorescence studies show that they contain IgM and C3 (Fig. 23.9), but no immunoglobulin or complement deposition is seen in unaffected glomeruli.

Collapsing Glomerulopathy

Collapsing glomerulopathy is a clinically and pathologically distinct variant of FSGS that is characterized by the widespread collapse of glomerular capillary loops, and predominance in blacks attributable to the *APOL1* risk alleles.[50,60,80] Patients usually present with abrupt onset of nephrotic syndrome or nephrotic range proteinuria and renal impairment. An idiopathic form of collapsing FSGS[81,82] has poor prognosis with rapid loss of renal function and virtually no response to immunosuppressive therapy.[83] A circulating permeability factor might be responsible as evidenced by a rapid recurrence in an allograft.[84] Collapsing FSGS can be a secondary process associated with intravenous (IV) drug abuse and/or human immunodeficiency virus (HIV) infection.[85–87] This variant of FSGS constitutes about 80%–85% of the glomerular changes reported in HIV-infected patients.[88] Collapsing glomerulopathy has also been reported in association with some autoimmune diseases, lymphoproliferative disorders, drugs such as bisphosphonates and interferons, severe allograft ischemia, and non-HIV viral infections, such as hepatitis C, cytomegalovirus, and parvovirus B19.[52,85,89,90] Treatment of the underlying cause is helpful in inducing remission in these secondary forms.

The characteristic histologic feature is a predominantly collapsing type of focal glomerulosclerosis that is segmental and often global. The segmental sclerosis is characterized by localized hypertrophy and hyperplasia of the epithelial cells overlying the collapsed segment (Fig. 23.10).[91] These cells are often swollen and vacuolated and may contain abundant resorption droplets. The presence of even a single glomerulus with collapsing FSGS lesion is adequate for this diagnosis. The hyperplastic epithelial cells in this lesion represent either a proliferation of dysregulated podocytes or migrated parietal epithelial cell in response to injury.[92–94] Relative to the extent of glomerular sclerosis, tubulointerstitial injury is more severe in collapsing glomerulopathy than in typical FSGS. The tubular epithelial cells may present degenerative changes and the tubular lumens are often markedly dilated and show extensive proteinaceous cast formation.

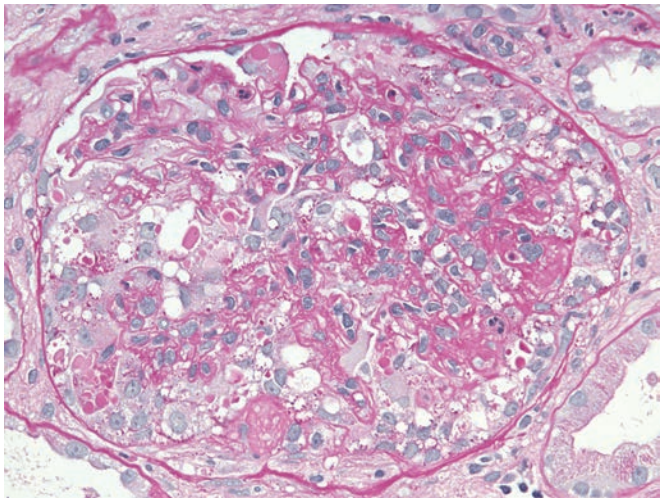

Figure 23.10 Collapsing variant of focal segmental glomerulosclerosis lesion is characterized by the retracted glomerular basement membrane and hyperplastic overlying podocytes obliterating the Bowman space. The podocytes have prominent cytoplasm protein droplets (PAS).

The interstitium often exhibits a prominent inflammatory infiltrate mainly composed of lymphocytes.

The most common immunofluorescence finding in the glomeruli in patients with collapsing glomerulopathy is IgM and C3 in a segmental distribution in the lesional glomerulus. Less commonly, C1q may also be localized. The podocyte protein resorption droplets are highlighted by IgG, IgA, and albumin. The changes seen by electron microscopy are generally those of typical FSGS, and the podocyte foot processes are extensively effaced. The GBM is diffusely wrinkled in areas of collapse. A distinctive but nonspecific feature is the finding of endothelial tubuloreticular inclusions in over 90% of patients with HIV-associated collapsing glomerulopathy.[95,96] These structures are rarely seen in idiopathic collapsing glomerulopathy or in collapsing glomerulopathy associated with other causes. Numerous endothelial tubuloreticular inclusions are also seen in patients with systemic lupus erythematosus (SLE) or in patients treated with interferon alpha.

C1q Nephropathy

C1q nephropathy is a relatively uncommon and controversial immune complex–mediated glomerulopathy that is characterized by the presence of dominant or codominant C1q deposition in the mesangium. Patients may present with nephrotic syndrome or mild proteinuria with or without hematuria.[97–100] The condition typically affects adolescents and young adults and appears to be more common in blacks than in whites.[99,101,102] C1q nephropathy with normal histology or mesangial proliferation responds to corticosteroids, but FSGS histology is associated with poorer outcome.[103] Progression to renal failure is slow, and it has been estimated that the 5-year renal survival rate is about 78%.[101] It is not entirely clear as to whether C1q nephropathy is a specific clinical entity or is part of the clinicopathologic spectrum of MCD and FSGS.[102,104]

Light microscopic findings vary from slight to marked mesangial hypercellularity with an increase in mesangial matrix, with or without segmental glomerulosclerosis. Electron microscopy studies invariably demonstrate mesangial immune complex deposits. Subendothelial or subepithelial deposits are uncommon. On immunofluorescence, C1q is often accompanied by IgG, IgM, and C3; IgA has been reported in about 60% of the cases.[100] The main differential diagnosis of C1q nephropathy is lupus nephritis which can also have prominent C1q deposition in the mesangium together with immunoglobulins and C3. Clinical presentation, serologic evidence, extraglomerular deposits, and presence of tubuloreticular inclusions help differentiate between class II lupus nephritis and C1q nephropathy.

Box 23.3 Entities associated with membranous glomerulopathy

Autoimmune disease

Autoantibodies to phospholipase A2 receptor (~80% of "primary" MGN)

Autoantibodies to THSD7A (~10% of "primary" MGN)

Systemic lupus erythematosus, mixed connective tissue diseases, Sjögren syndrome, rheumatoid arthritis, IgG4-related systemic disease, sarcoidosis, Hashimoto thyroiditis, Graves disease, Weber–Christian panniculitis, myasthenia gravis, bullous pemphigoid, autoimmune enteropathy, primary biliary cholangitis

Infections

Hepatitis B, hepatitis C, syphilis, Epstein–Barr virus, malaria, leprosy, tuberculosis, schistosomiasis, filariasis, hydatid disease, enterococcal endocarditis, brucellosis, staphylococcal infection

Neoplastic diseases

Carcinoma (lung, gastrointestinal tract, breast, prostate, kidney), seminoma, lymphoma (especially non-Hodgkin), leukemia, melanoma

Drugs and toxic agents

Nonsteroidal anti-inflammatory drugs, D-penicillamine, bucillamine, anti-tumor necrosis factor agents, organic gold, probenecid, captopril, trimethadione, lithium, clomethiazole, diclofenac, hydrocarbons, formaldehyde, solvents, mercury

Alloimmune etiology

De novo MGN due to chronic antibody-mediated rejection, graft versus host disease in hematopoietic stem cell transplantation, neutral endopeptidase directed response in neonatal MGN, replacement therapy with recombinant aryl sulfatase and α-glucosidase

Miscellaneous associations

Sickle cell disease, diabetes mellitus, Kimura disease, sclerosing cholangitis, antiglomerular basement membrane disease, cryoglobulinemia, Guillain–Barré syndrome

MGN, Membranous glomerulonephritis; *THSD7A*, thrombospondin type-1 domain–containing 7A.

Membranous Glomerulonephritis

MGN (a.k.a. membranous nephropathy) is a glomerular disease of diverse etiology characterized by subepithelial immune complex deposits and variable basement membrane thickening, without infiltration by inflammatory cells. MGN accounts for 20%–30% of all cases of idiopathic nephrotic syndrome in adults[105] and 1%–9% in children.[106] In large majority of cases, this condition occurs in a primary ("idiopathic") form, but the disease has been related to a wide variety of conditions (secondary) in approximately 20%–25% of adults and 80% of children with MGN (Box 23.3).[107] Over 85% of cases of secondary MGN are caused by infection, neoplasia, or SLE. The most common causes worldwide are malaria and schistosomiasis, while SLE, neoplasia, hepatitis B infection, and drugs are the most frequent in the United States.[107] Rare familial cases of MGN, probably related to a genetically transmitted mechanism, have been reported.[108]

The pathogenetic mechanism that leads to the immune complex localization in the subepithelial aspect of the GBM, especially in primary forms, is being increasingly understood. Two mechanisms presumed responsible for the development and localization of the deposits along the GBM are that of *in situ* immune complex formation in the subepithelial capillary wall or that of circulating immune complexes being deposited in that location. Experimental studies suggest that in most cases, the immune complexes are formed *in situ* by the binding of circulating antibodies with antigens that are normally present in the glomerulus or with extrinsic antigens that have previously been planted as free antigens in the subepithelial area.[109]

Primary human MGN appears to be largely an autoimmune disease with *in situ* glomerular immune complex formation. Over 70%–80% of primary MGN patients have autoantibodies directed against PLA_2R expressed in podocytes and proximal tubules.[110,111] These circulating PLA2R autoantibodies are IgG4 subtype and the plasma levels correlate with disease activity and therapeutic response,[112] and may predict the risk of post-transplantation recurrence.[113] Genome-wide association studies have strongly linked the disease to specific HLA-DQA1 and PLA2R alleles. Individuals with at risk polymorphisms may have increased propensity to present the autoantigen, precipitating MGN.[114] Approximately 5%–10% of patients with primary MGN have autoantibodies (IgG4 subtype) to a recently described second podocyte antigen, thrombospondin type-1 domain–containing 7A (THSD7A), further expanding the role of autoimmunity in these patients.[115,116]

In a subset of patients with MGN, alloimmune response appears to play a role in developing MGN. Neutral endopeptidase (NEP), expressed in podocytes and proximal tubular brush border, has been identified as the target antigen of antibodies deposited in the subepithelial space in patients with antenatal MGN.[117] In these cases, it is likely that the anti-NEP antibodies produced by the mother are transplacentally transferred to her child with genetic deficiency of NEP.[118] Some patients with Pompe disease and mucopolysaccharidosis IV receiving recombinant α glucosidase and aryl sulfatase B, respectively, also develop alloimmune responses resulting in MGN.[114] Lastly, *de novo* MGN in allografts also appears to be an alloimmune response.

Conditions associated with secondary MGN include chronic infections, neoplasms, autoimmune diseases (SLE, rheumatoid arthritis, IgG4-related systemic disease), drugs, and sarcoidosis. Drugs commonly associated with MGN include nonsteroidal anti-inflammatory drugs, penicillamine, gold, lithium, mercury, captopril, and anti-tumor necrosis factor agents. In some instances of secondary MGN, hepatitis B antigens (HBsAg, HBcAg, and HBeAg), virus-like particles (hepatitis C), tumor antigens, thyroglobulin, and DNA-containing material have been identified in the immune complexes, but it is unclear if these antigens are indeed pathogenic.[119] Exogenous antigen such as cationic bovine serum albumin (BSA) derived from milk has been identified within subepithelial deposits in young children with MGN.[120] These children have no other evidence of milk allergy but have anti-BSA antibodies in circulation. Secondary forms of MGN typically lack circulating PLA2R, but a small subset of patients with hepatitis B, hepatitis C, malignant neoplasm, and sarcoidosis have circulating serum PLA2R. While this may be coincidental, it also raises the possibility that "primary" MGN is triggered by an underlying disease. In both primary and secondary forms, complement is activated at the capillary wall site and appears to have a role in the development of the proteinuria.

The incidence of MGN in different populations varies; there is a particularly high frequency in Japanese children[121] and in certain African populations,[122,123] probably related to a high incidence of hepatitis B infection and parasitic infestations. Although MGN may occur at any age, it is rare in children and adolescents. Eighty to 90% of the patients are over the age of 30 at the time of diagnosis, with a peak incidence in the fourth and fifth decades.[124] The disease is twice as common in males. Sixty to 80% of patients have the nephrotic syndrome at onset, and others are usually referred for investigation of asymptomatic proteinuria or an abnormal urinalysis.[125] The proteinuria is usually nonselective, but a highly selective proteinuria is seen in about 20% of cases.[124] Macroscopic hematuria is rare, but as many as 90% of patients have microscopic hematuria at some time during the course of the disease.[124,126] Hypertension is usually found after renal insufficiency has developed, but it can be seen in 30% of the patients at presentation.[107] Rare cases with circulating anti-GBM antibody and/or antineutrophil cytoplasmic antibody (ANCA) have also been reported.[125] Serum levels of C3, as well as other components of complement, are normal; however, if reduced, this suggests a secondary form of the disease.

The natural history and overall prognosis of MGN can be significantly affected by the underlying disease and the way it is treated. When MGN is secondary to drugs, toxic substances, or infections, removal of the etiologic agent will often result in the disappearance of the clinical symptoms and resolution of the renal lesion. The nephrotic syndrome may abate and the glomerular changes regress after resection and treatment of a malignant tumor. In patients with membranous lupus nephritis, the course is indolent, whereas those who develop a superimposed anti-GBM antibody disease undergo a rapid progression to renal failure. Most patients with primary MGN present with chronic proteinuria and have recurrent episodes of nephrotic syndrome persisting over many years. Only 20%–25% of these patients progress to renal failure terminating in ESRD.[127] Partial or complete spontaneous remission has been reported in 20%–65% of cases.[127,128] The likelihood of spontaneous remission is greatly increased in children[106] and in patients who presented with proteinuria without the nephrotic syndrome and in whom the biopsy demonstrated a stage I glomerular lesion.[129] Recurrence or *de novo* development of MGN after renal transplantation can occur. The recurrence rates have ranged from 10% to 30% in different series, while the *de novo* rate is more common, accounting for about twice as many cases of MGN in transplant recipients.[130]

The structural features of the glomerular capillary wall have been used to define four histopathologic stages of the disease.[131] In **stage I**, the glomeruli appear normal by light microscopy, and there are no significant changes in the thickness of the basement membrane. At this early stage, an incorrect diagnosis of MCD is possible if the biopsy is only studied by light microscopy. With the electron microscope, these cases show sparse immune complex deposits between the epithelial cell cytoplasm and the lamina densa of the basement membrane, but the latter appears homogeneous and uniform in thickness. The deposits can be irregular, dome shaped, or appear as small humps with a well-defined line between the lamina densa and the epithelial cell. Foot processes over the deposits are obliterated, but they often appear normal elsewhere (Fig. 23.11).

In **stage II**, the capillary walls are thickened and many subepithelial deposits are present, separated by extensions of basement membrane (Fig. 23.12A). The deposits do not stain with silver impregnation techniques, but the extensions of basement membrane do, thus creating the impression that the capillary loop is covered by spikes (see Fig. 23.12B). These spikes have been shown to be composed of type IV collagen and noncollagenous extracellular matrix components, including laminin, heparan sulfate, proteoglycans, and vitronectin. The epithelial foot process effacement is extensive throughout the loops.

When the disease is more advanced (**stage III**), the deposits are encircled by a newly formed basement membrane (Fig. 23.13). The capillary walls are markedly thickened and the capillary lumina

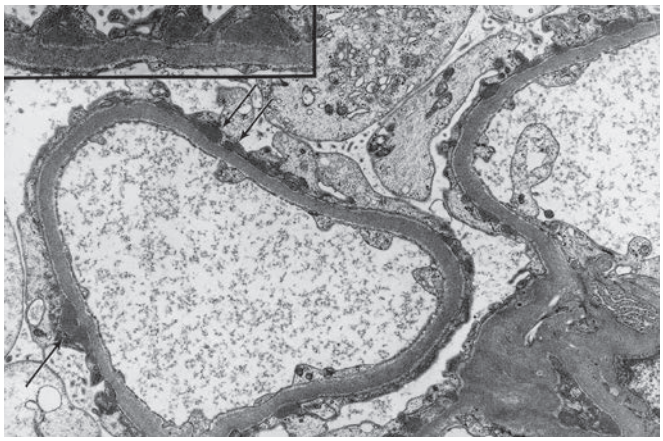

Figure 23.11 Membranous Glomerulonephritis, Stage I. Basement membrane is normal thickness. Small subepithelial deposits *(arrows)* are separated from the basement membrane by a thin clear zone *(inset)*. The epithelial foot processes are obliterated (×6000; inset ×9100).

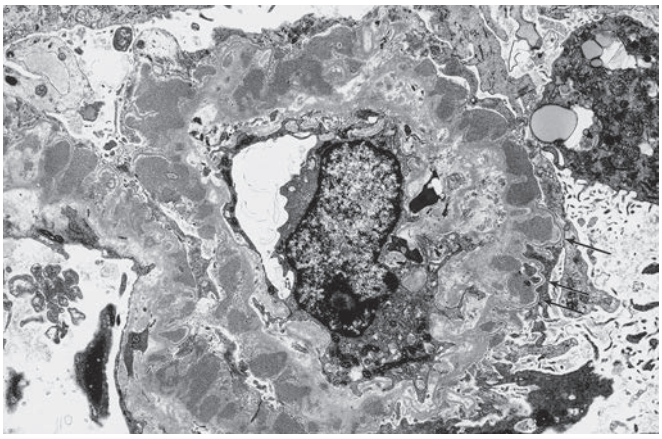

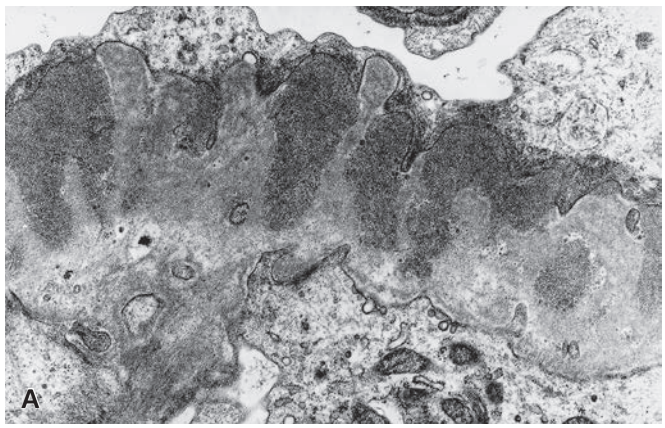

Figure 23.13 Membranous Glomerulonephritis, Stage III. The basement membrane is markedly thickened and the deposits appear surrounded by a newly formed basement membrane *(arrows)* (×6900).

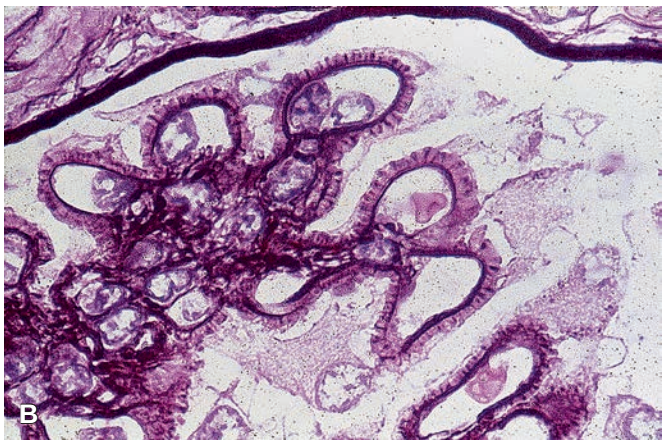

Figure 23.12 A, Membranous glomerulonephritis, stage II. Subepithelial deposits are separated by projections of the basement membrane (×18,000). **B,** Silver preparation showing spike formation along the thickened basement membrane (methenamine silver).

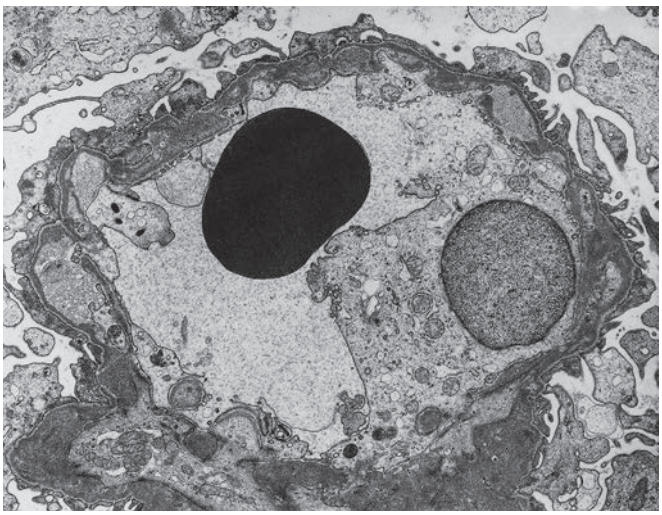

Figure 23.14 Membranous Glomerulonephritis, Stage IV. The basement membrane is markedly irregular and most of the deposits have been reabsorbed, leaving large electron-lucent areas (×9360).

narrowed. The basement membrane shows a reduplicated or moth-eaten appearance with PAS and silver stains. By electron microscopy, many of the deposits in stage III disease have a rarefied appearance that indicates resolution, and small spherical structures, which have been confused with virus particles, may be present during dissolution of the deposits. Individual deposits may also contain striated membranous bodies that are probably formed by degeneration of entrapped cellular components.

During the late stage of the disease (**stage IV**), deposits gradually lose their electron density and the basement membrane becomes vacuolated, folded, and thickened. Deposits may no longer be evident (Fig. 23.14). Capillary lumina become obliterated, and the glomerular tufts show segmental or global sclerosis. TA and vascular sclerosis can be prominent, making the diagnosis difficult. In the end-stage of the disease, the differential diagnosis includes various types of chronic glomerulonephritis. Although the degree of proteinuria does not parallel the stages of the renal lesion, stage I carries a better prognosis than more advanced disease and spontaneous remission is more likely. However, there seems to be no difference in prognosis between stages II, III, and IV. Histologic progression can occur without clinical progression, and clinical remission can occur in the absence of histologic regression.[107]

Immunofluorescence microscopy in all stages of MGN reveals a generalized, peripheral granular pattern of IgG, C3, kappa and lambda, sometimes with IgM (Fig. 23.15). The reaction for IgA is usually absent, and if it is strong and associated with the early components

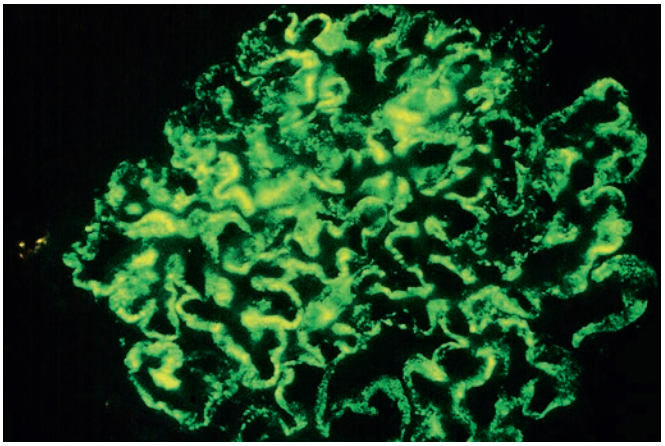

Figure 23.15 Immunofluorescence preparation of membranous glomerulonephritis showing peripheral granular deposits of IgG (anti-IgG).

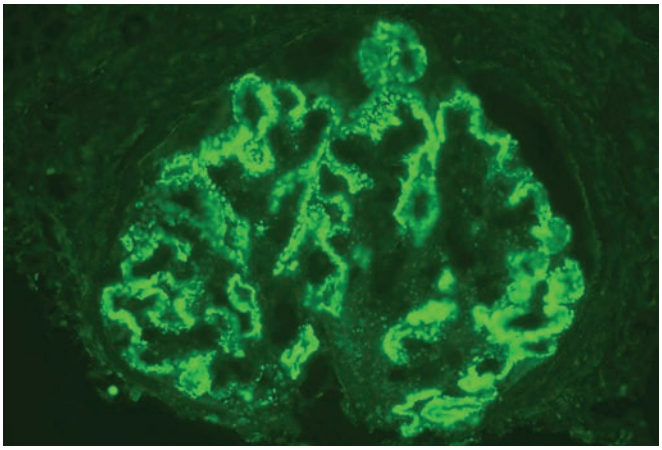

Figure 23.16 Diffuse granular capillary wall staining with antibody to PLA2R supports a diagnosis of primary membranous nephropathy (anti-PLA2R).

of complement (C1q and C4), the possibility of lupus MGN must be considered. Although not evaluated on routine diagnostic studies, there is strong reactivity for terminal complement components (i.e., C5b–C9 membrane attack complex). Extraglomerular deposits have only rarely been reported in primary MGN.[126] The finding of granular deposits along the tubular basement membrane (TBM) should always raise the possibility of membranous lupus nephritis.[132] MGN with anti-TBM antibodies typically have linear TBM staining for IgG and sometimes with C3. Although not entirely sensitive or specific, with regards to IgG subclass staining, primary MGN deposits are mainly IgG4+, while membranous lupus nephritis deposits are positive for IgG1–IgG4 with IgG3 dominance. Primary MGN deposits stain for PLA2R by immunofluorescence microscopy and can be positive despite the lack of circulating antibodies as in early remission stage (Fig. 23.16).[133,134] Hence, renal biopsy is considered a sensitive tool for diagnosing primary MGN. Recurrent MGN in post-transplantation biopsies is also characterized by deposits that are IgG4 dominant and PLA2R positive. In contrast, *de novo* MGN deposits are IgG1 dominant and PLA2R negative.[135,136] *De novo* MGN is often associated with chronic antibody-mediated rejection (AMR) and hence is considered an alloimmune phenomenon.

Notable morphologic characteristics of MGN throughout its evolution are the absence of mesangial hypercellularity and a lack of inflammatory cells within the glomeruli. On occasion, however, mesangial hypercellularity can occur, especially in patients with secondary forms of MGN, such as SLE, hepatitis B, or gold- or penicillamine-associated disease. In addition to epimembranous and intramembranous deposits, small amounts of immune complex deposition may be seen in the mesangial and/or subendothelial areas.[137] Margination of leukocytes in the glomerular capillaries may be an indication of renal vein thrombosis.[138] Crescent formation is uncommon and if focal, should suggest secondary MGN (e.g., due to SLE) or a superimposed disease. Diffuse fulminant crescentic disease is a rare and late consequence of the superimposition of anti-GBM or ANCA disease.[125] Rarely, patients with MGN have tubulointerstitial nephritis (TIN) because of antitubular basement membrane antibodies. These patients are almost invariably children, present with nephrotic syndrome and Fanconi syndrome and progress to ESRD.[139]

Diabetic Nephropathy

Diabetic nephropathy is a clinical syndrome characterized by persistent proteinuria, hypertension, and progressive decline in renal function. It is considered to be the leading cause of ESRD, accounting for approximately 40% of the new cases in the United States undergoing long-term dialysis.[140] It is estimated that 20%–40% of all diabetic patients will develop diabetic nephropathy.[141] In type 1 diabetes, the cumulative incidence of diabetic nephropathy is about 25% after 25–40 years of disease.[142] Evidence suggests that the risk of overt nephropathy and progression to ESRD is similar in type 2 diabetes.[143] Microalbuminuria is the earliest manifestation of diabetic nephropathy but cannot be detected by standard urine dipstick method. Proteinuria, usually of nonselective type, is the most consistent overt manifestation of diabetic nephropathy. The nephrotic syndrome has been reported in 6%–40% of the cases and constitutes a sign of poor prognosis. About 28%–48% of patients may present with moderate microscopic hematuria. Hypertension is a late complication seen with advanced renal failure. The rate of progression to end-stage kidney disease is dependent on a variety of factors including genetics, environmental factors, therapeutic interventions, and comorbidities. Blacks and Native Americans with type II diabetes mellitus are at greater risk of developing diabetic nephropathy.

The development of diabetic nephropathy is related to multiple factors, and inadequate glycemic control is one of the most important. Persistent hyperglycemia causes accumulation of advanced glycosylated end products in various organs including kidney with resultant injury, tissue remodeling, and extracellular matrix deposition. It also causes defects in mitochondrial electron transport, increased production of reactive oxygen species, and increased oxidative stress. Many cellular proteins, including GBM collagen and matrix proteins, are affected. Inherited risk factors such as certain polymorphisms in genes involved in the renin angiotensin system and insulin resistance appear to play a role.[144]

Diabetic microangiopathy occurring throughout the body is the most characteristic morphologic change in the diabetic, and its hallmark is an increase in the amount of vascular basement membrane material. There are no significant morphologic differences in the renal lesions caused by type 1 and type 2 diabetes.[145] All areas of the kidney may be affected by diabetes, but the most striking lesions are found in the glomeruli and blood vessels, including diffuse glomerulosclerosis, nodular glomerulosclerosis, and the so-called insudative lesions (fibrin caps, capsular drops, and arteriolar hyalinosis).[146] Diabetic glomerulosclerosis is the general term for all of these lesions, and they are considered to be an expression of the microangiopathy.

Diffuse glomerulosclerosis, the most common lesion in diabetic nephropathy, is characterized by a diffuse increase in the mesangial

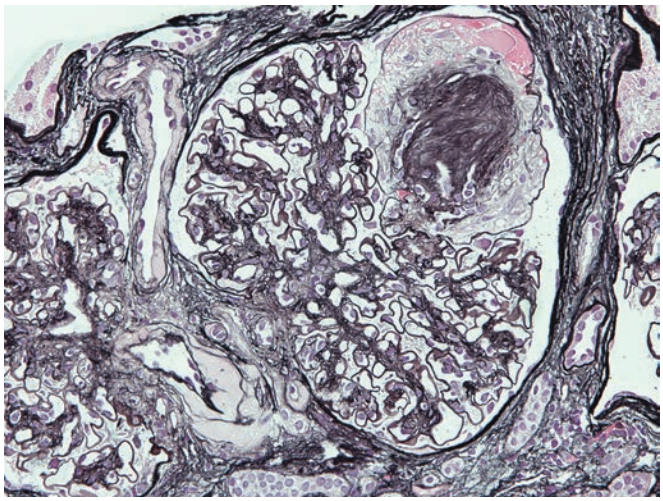

Figure 23.17 Diabetic glomerulosclerosis with segmental mesangial Kimmelstiel–Wilson nodule and adjacent microaneurysm. Other mesangial areas have mild diffuse mesangial sclerosis. Arteriolar hyaline insudation is seen near the vascular pole (methenamine silver stain).

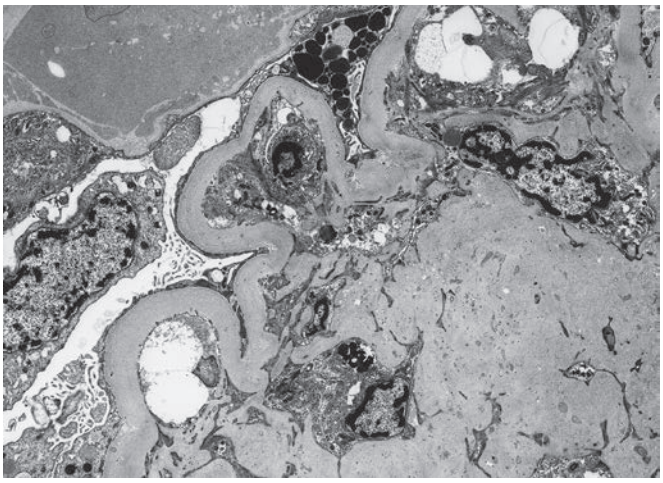

Figure 23.18 Nodular Diabetic Glomerulosclerosis. The massive enlargement of the mesangium is due to an increase in mesangial matrix. The basement membrane is markedly thickened and a capsular drop is present at the left upper corner of the figure (×4400).

matrix and thickening of the capillary walls (Fig. 23.17). Thickening of the GBM is the most consistent finding in diabetic nephropathy and is often seen in both diffuse and nodular glomerulosclerosis. Although minor degrees of basement membrane thickening are not specific for diabetes, measurement of the basement membrane width is the most effective way to quantitate early diabetic glomerular lesions. In advanced stages, the GBM may be many times its normal thickness, often with accentuation of the normal fibrillar structure. The GBM thickening and mesangial changes can be seen by electron microscopy before the damage is visible by light microscopy. The earliest structural alteration in diabetic glomerulopathy that can be quantified is increased thickness of the GBM, which can be documented as early as 1.5–2.5 years after the onset of type I diabetes mellitus. A clear increase in the mesangial matrix and cellularity can be detected on light microscopy as early as 5–7 years after the onset of diabetes mellitus[147] or within 2–5 years following renal transplantation.[148] Recently, a histologic classification of diabetic nephropathy has been proposed, but its clinical utility has not yet been validated.[149]

Nodular glomerulosclerosis (Kimmelstiel–Wilson lesion) is the characteristic histopathologic lesion in diabetic glomerulosclerosis. It consists of large acellular nodules located in the intercapillary regions (see Fig. 23.17). These nodules vary in size and often have a laminated appearance. They are eosinophilic, argyrophilic, and PAS positive and blue with trichrome stain. Ultrastructurally, the nodules are composed of masses of extracellular mesangial matrix (Fig. 23.18). Both the mesangial widening and the nodules are the result of an increase in the synthesis and/or decrease in the degradation of the mesangial matrix.[146] The capillary loops that surround the nodules may have narrow lumens because of the expansion of the mesangium, but they can also be aneurysmally dilated and some have peripheral mesangial extensions. Focal areas of mesangiolysis may also be present. Diffuse and nodular diabetic glomerulosclerosis can be found together, not only in the same patient, but also in the same glomerulus. Although nodular glomerulosclerosis is virtually pathognomonic of diabetic nephropathy, identical light microscopic lesions can be found in cases of light chain deposition disease (LCDD). In the latter condition, however, the nodules are composed of granular electron-dense material that shows light chain restriction with antibodies to kappa and lambda light chains. Nodular glomerulosclerosis mimicking diabetic nephropathy has rarely been reported in patients without manifested diabetes, but with longstanding hypertension and/or smoking history, and is referred to as "idiopathic" nodular glomerulosclerosis.[150] Diffuse nodular deposits of amyloid can sometimes be confused with diabetic glomerulosclerosis by light microscopy, but the ultrastructural identification of amyloid fibrils will establish the diagnosis.

Insudative lesions are the least specific of the glomerular changes in diabetes. Ultrastructurally, they are seen to be masses of electron-dense material, often containing lipid droplets. Common locations of these lesions are the periphery of the loop in a subendothelial location (fibrin caps), within the basement membrane of the Bowman capsule (capsular drops), or in the mesangium or GBM. In blood vessels, they are more extensive in the subintima and media but can also involve the adventitia. This insudative lesion, known as hyalinosis, can affect the afferent and efferent arterioles and may ultimately replace the smooth muscle cells. The severity of the arteriolar hyalinosis correlates significantly with the percentage of sclerosed glomeruli, suggesting that the vascular lesion contributes to the ischemic global glomerulosclerosis. Histochemical and immunofluorescence studies indicate that the insudative material represents infiltration by constituents of the plasma, including proteins, lipids, and mucopolysaccharides.

Atubular glomeruli can also be found in diabetic glomerulosclerosis as a late manifestation of the disease, predominantly in patients with proteinuria.[151] Atubular glomeruli are defined as those glomeruli that have open glomerular capillaries but have lost their connection with the proximal tubule and are presumably nonfunctioning. Although accurate identification of these glomeruli requires serial sections, small glomeruli surrounded by tissue with marked tubular loss are most probably atubular.

The most characteristic tubular change is diffuse thickening of the tubular basement membrane. When the disease is advanced, there is also TA and interstitial scarring that may be accompanied by chronic inflammatory infiltrate. The presence of interstitial neutrophils or tubular neutrophil casts should raise concern for superimposed acute pyelonephritis. Glycogen vacuolization of the renal proximal tubular epithelial cells (Armanni–Ebstein lesion), associated with uncontrolled hyperglycemia, was common in the past, but is rarely seen today. Approximately a third of renal biopsies

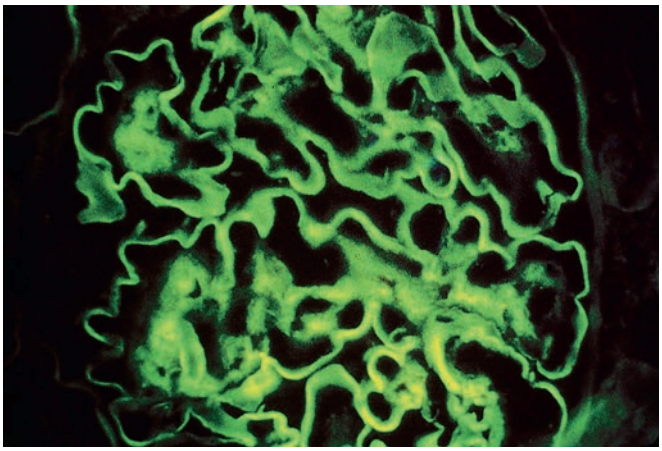

Figure 23.19 Diabetic glomerulosclerosis with linear staining for IgG along the glomerular basement membrane (anti-IgG).

with diabetic nephropathy have superimposed glomerular disease,[152] and this list includes membranous nephropathy, IgA nephropathy (IgAN), postinfectious glomerulonephritis (especially IgA-dominant variant described later), and others. Cellular crescents are rare in diabetic glomerulosclerosis, but foci of organizing fibroepithelial crescents occur with superimposed ANCA-mediated glomerulonephritis,[153] and their presence is associated with aggressive clinical course.[154]

Diffuse linear reaction for IgG along the glomerular capillary, tubular, and Bowman capsular basement membranes is the most characteristic immunofluorescence finding in diabetic nephropathy (Fig. 23.19). Less intense reaction in a similar distribution may also be seen for IgM, fibrin, and albumin, but staining for C3, if present, is often granular. These linear reactions are unrelated to either the duration or the severity of the glomerular lesions and evaluation studies do not show specific antibody activity to basement membrane antigens. Insudative lesions may react with a variety of reagents but most frequently contain IgM and C3.

Amyloidosis

The term amyloidosis designates a heterogeneous group of disorders characterized by the extracellular deposition of nonbranching linear fibrils with a mean diameter of 10 nm and a β-pleated sheet configuration on x-ray diffraction analysis. It is this configuration that is responsible for the tinctorial and optical characteristics seen on Congo red staining, which produces the typical apple-green birefringence seen on tissue sections when they are examined under polarized light. Amyloid itself does not have a consistent chemical composition but is instead a group of proteins that share common physical characteristics. At present, more than 30 structurally unrelated proteins have been identified as amyloid precursors associated with human disease, but most forms are localized with rare or no involvement of kidney (Table 23.3).[155–157] In addition to the fibrillary protein, amyloid deposits contain nonfibrillary proteins, including glycosaminoglycans, apolipoprotein E (Apo E), and amyloid P component. The amyloid P component (also known as serum amyloid P or SAP) is a 25-kDa glycoprotein member of the pentraxin family that includes C-reactive protein. Amyloid P component is present in all types of amyloid, accounting for about 15% of their mass. It is believed that amyloid P component may prevent degradation of the amyloid fibrils once they are formed.[158] Better understanding of the amyloid fibril composition, formation, and stabilization has helped the emerging field of targeted therapies in amyloidosis.[159]

The classification of amyloidosis is based on the type of precursor protein that forms the amyloid fibrils and the distribution of the amyloid deposits as to whether it is systemic or localized (see Table 23.3). By convention, the amyloid fibril type is designated A for amyloid, followed by an abbreviated form of the name of the fibril protein. **Amyloid light-chain (AL) amyloidosis** (formerly known as "primary" or "associated with multiple myeloma") is the most common form of systemic amyloidosis in the Western world.[157] In this type of amyloidosis, the amyloid fibrils are composed of the N-terminal residues of the variable region of an immunoglobulin light chain. The specific amino acid sequences and post-translational modifications of light chains confer the amyloidogenicity. A minority have overt multiple myeloma, while others have monoclonal spike in the serum and/or urine. The amyloidogenic light chains are more frequently lambda than kappa type, in contrast to normal or cast nephropathy light chains.[160] Rarely, the amyloid deposits are derived from monoclonal immunoglobulin light and heavy chains or just heavy chains, and the disease is referred to as AHL amyloidosis or AH amyloidosis, respectively.

Amyoid A (AA) amyloidosis (formerly known as secondary amyloidosis) is a rare complication of persistent inflammation that may develop in patients affected by chronic rheumatic diseases, long-lasting infections, inflammatory bowel disease, periodic fever syndromes, familial Mediterranean fever, and malignancies.[161–163] It is the most common type of amyloidosis in the parts of developing world with endemic tuberculosis and leprosy. In this type of amyloidosis, the AA amyloid deposits are formed by the N-terminal proteolytic fragments of the acute-phase reactant serum amyloid A (SAA), a polymorphic apolipoprotein of high density that, upon chronic inflammatory stimuli, may reach persistently high plasma concentrations.[164,165] Certain polymorphisms in *SAA* gene appear to confer increased risk of developing AA amyloidosis in patients.[163]

Hereditary systemic amyloidosis is a diverse group of autosomal dominant, late-onset (sometimes sixth or seventh decade of life) disorders that occurs much less frequently than AL or AA amyloidosis. These amyloidoses are caused by mutations in the genes coding for some plasma proteins, including transthyretin, apolipoprotein A-I, apolipoprotein A-II, apolipoprotein A-IV, fibrinogen A α-chain, gelsolin, cystatin C, and lysozyme.[166] Specific amino acid substitutions allow each of these soluble circulating proteins to be prone to aggregate and form amyloid fibrils in organs and tissues. The natural history of these conditions varies by the protein, as well as the tissue distribution. For example, transthyretin amyloidosis, which is the most common form of hereditary systemic amyloidosis, typically affects the peripheral and autonomic nervous systems, manifesting as progressive sensory–motor neuropathy, gastrointestinal and bladder dysfunction, impotence, and orthostatic hypotension, whereas apolipoprotein A-I, apolipoprotein A-II, apolipoprotein A-IV, fibrinogen α-chain, and lysozyme amyloidosis are more often associated with a marked visceral burden of amyloid that clinically results in progressive kidney and liver disease.[162]

Familial Mediterranean fever is a common form of the nephropathic familial amyloidoses. The deposits of amyloid in this condition consist of amyloid AA, and, in contrast to other forms of familial amyloidosis which are autosomal dominant, familial Mediterranean fever is associated with autosomal recessive inheritance.[167] Mutations in *MEFV* gene encoding pyrin/marenostrin result in activation of IL-1β pathway with subsequent elevations of SAA levels, especially during febrile episodes. Other related periodic fever syndromes due to mutations in genes encoding cryopyrin, and tumor necrosis factor also cause autoinflammation with eventual precipitation of AA amyloid.[163]

A subtype of amyloidosis of ill-defined etiology is ALECT2, characterized by accumulation of leukocyte chemotactic factor 2.[168,169] No mutation in *LECT2* gene has been identified, but all sequenced

Table 23.3 Amyloid fibril proteins and their precursors in humans

AMYLOID PROTEIN	PRECURSOR PROTEIN	DISTRIBUTION	RENAL BIOPSY FEATURES OR ASSOCIATED CONDITION
Neoplasm-Associated (AL) Amyloidosis			
AL	Immunoglobulin light chain	Systemic or localized	Glomerular, interstitial, and vascular deposits; multiple myeloma, B-cell lymphoma
AH	Immunoglobulin heavy chain	Systemic or localized	Glomerular, interstitial, and vascular deposits; multiple myeloma, B-cell lymphoma
Chronic Inflammation-Associated Amyloidosis			
AA	(Apo) serum AA	Systemic	Chronic infections or inflammation. Seen in hereditary inflammatory syndromes (Familial Mediterranean fever, hyper-IgD syndrome, familial cold urticarial, Muckle-Wells syndrome)
Hereditary (or Mutation Associated) Amyloidosis			
ATTR	Transthyretin	Systemic	Predominantly glomerular deposits or limited to medullary interstitium
AApoAI	Apolipoprotein AI	Systemic	Arterial and medullary interstitial deposits in kidney; localized deposits in aorta, meniscus
AApoAII	Apolipoprotein AII	Systemic	Medullary interstitial and vascular deposits
AGel	Gelsolin	Systemic	Glomerular deposits
ALys	Lysozyme	Systemic	Glomerular and vascular deposits
AFib	Fibrinogen alpha-chain	Systemic	Only glomerular deposits that stain for fibrinogen
ACys	Cystatin C	Systemic	Cerebral vessels (no renal involvement)
ALECT2	Leukocyte chemotactic factor 2	Localized	Glomerular, cortical interstitial and vascular deposits. No mutation, only a common polymorphism in *LECT2* gene identified
ABri	ABriPP	Systemic	Familial dementia
Other Types of Amyloid Deposition			
AApoAIV	Apolipoprotein AIV	Systemic	Sporadic, associated with aging
ATTR	Transthyretin	Systemic	Nonfamilial senile form
$A\beta_2M$	β_2-Microglobulin	Systemic or localized	Hemodialysis associated; localized form in joints
ADan	ADanPP	Localized	Familial dementia (Danish type)
Aβ	Aβ protein precursor (AβPP)	Localized	Alzheimer disease, associated with aging

Table 23.3 Amyloid fibril proteins and their precursors in humans—cont'd

AMYLOID PROTEIN	PRECURSOR PROTEIN	DISTRIBUTION	RENAL BIOPSY FEATURES OR ASSOCIATED CONDITION
APrP	Prion protein	Localized	Spongiform encephalopathies
ACal	(Pro) calcitonin	Localized	Medullary thyroid carcinoma
AIAPP	Islet amyloid polypeptide	Localized	Islet of Langerhans; Insulinomas
AANF	Atrial natriuretic factor	Localized	Cardiac atria
APro	Prolactin	Localized	Aging pituitary, Prolactinomas
AIns	Insulin	Localized	Iatrogenic
AMed	Lactadherin	Localized	Senile aortic, arterial media
AKer	Kerato-epithelin	Localized	Cornea, familial
ALac	Lactoferrin	Localized	Cornea (trichiasis)
AOaap	Odontogenic ameloblast-associated protein	Localized	Odontogenic tumors
ASemi	Semenogelin I	Localized	Seminal vesicle
ATau	Tau	Localized	Alzheimer disease, frontotemporal dementia, aging, other cerebral conditions

Modified from Westermark P, Benson MD, Buxbaum JN, et al. A primer of amyloid nomenclature. *Amyloid*. 2007;14:179–183.

cases show a specific polymorphism. Produced in the liver, LECT2 is a plasma cytokine that increases the phagocytic and bacteriocidal activity of macrophages. ALECT2 is typically seen in elderly individuals of Mexican ancestry, although other ethnic populations can be affected. These patients often have comorbidities such as diabetes mellitus and hypertension.

Another form of amyloidosis is **dialysis-related amyloidosis**, a serious complication in patients undergoing long-term dialysis that is caused by the deposition of fibrillar β_2-microglobulin (amyloid β_2M).[170] This type of amyloid has a predilection for musculoskeletal deposition. β_2-Amyloid can cause carpal tunnel syndrome and a destructive arthropathy of medium-sized and large joints, especially of the shoulders and knees. Visceral amyloid deposition occurs late, usually after 15 years of hemodialysis, and may involve the heart, liver, lungs, and gastrointestinal system.[162] End-stage kidneys may also be involved by β_2-microglobulin amyloidosis, but this has no clinical significance.

Nonselective proteinuria, with or without the nephrotic syndrome, is the most common manifestation of renal involvement by amyloidosis. Approximately 25% of the patients with AL amyloidosis have the nephrotic syndrome at diagnosis, and a total of about 40% will develop the syndrome during the course of the disease.[171] Over 90% of patients with AA amyloidosis have renal insufficiency or nephrotic syndrome at diagnosis; however, the degree of proteinuria does not correlate with the extent of the amyloid deposition in the kidney. The prognosis for a patient with renal amyloidosis is poor, especially in those with AL amyloidosis.[171,172]

Because the kidney is frequently affected in AL, AA, and several familial amyloidoses, a kidney biopsy is often a method by which the disease is identified.[173,174] Amyloid can be found anywhere in the kidney but especially accumulates in glomeruli. Deposition is initially mesangial, producing diffuse widening of axial areas but progressively involves the capillary walls (Fig. 23.20A and B). Substantial mesangial deposition can produce nodules that may resemble those of diabetic glomerulosclerosis or LCDD. However, in amyloidosis, because the nodules are composed of amyloid protein rather than mesangial matrix, PAS staining is weak and trichrome stain is grayish blue in mesangium. Diffuse spread throughout the glomerulus can produce a picture reminiscent of membranous nephropathy, especially with the formation of basement membrane spicules. Amyloid deposition in the tubulointerstitium produces TA and IF, and in a small percentage of patients (~10%), the glomerular deposits are absent and amyloid is restricted to the tubulointerstitium or blood vessels. Several differences have been described in the distribution of amyloid deposits in various subtypes. For example, ALECT2 primarily affects cortical interstitium along with glomeruli and blood vessels, but the medulla is spared; AFib-α exclusively involves glomeruli and AApoAI/AII/AIV affects medullary interstitium with relative glomerular sparing.[157] Histochemical techniques used for the diagnosis of amyloid include Congo red and thioflavin T stains (Fig. 23.21A and B). Thioflavin T is extremely sensitive but not entirely specific, whereas the production of an apple-green color by polarized light in Congo red–stained sections is accepted as the most reliable light microscopic method for diagnosis. Each technique requires a critical amount of amyloid before a positive reaction can be elicited. Because of this, small amounts of amyloid may be missed and, even more important, neither technique is effective with very thin sections. The staining should be performed on sections cut at least 8 µm thick and always with appropriate controls. The fibrils of AL and AA amyloidosis can be distinguished by pretreating tissue sections with potassium permanganate before the Congo red staining. Under these conditions, AA amyloid fibrils lose their affinity for the Congo red stain, and the birefringence is lost, whereas AL amyloid is not affected. This technique, however, is not as reliable as immunostaining with currently available AA antibodies.

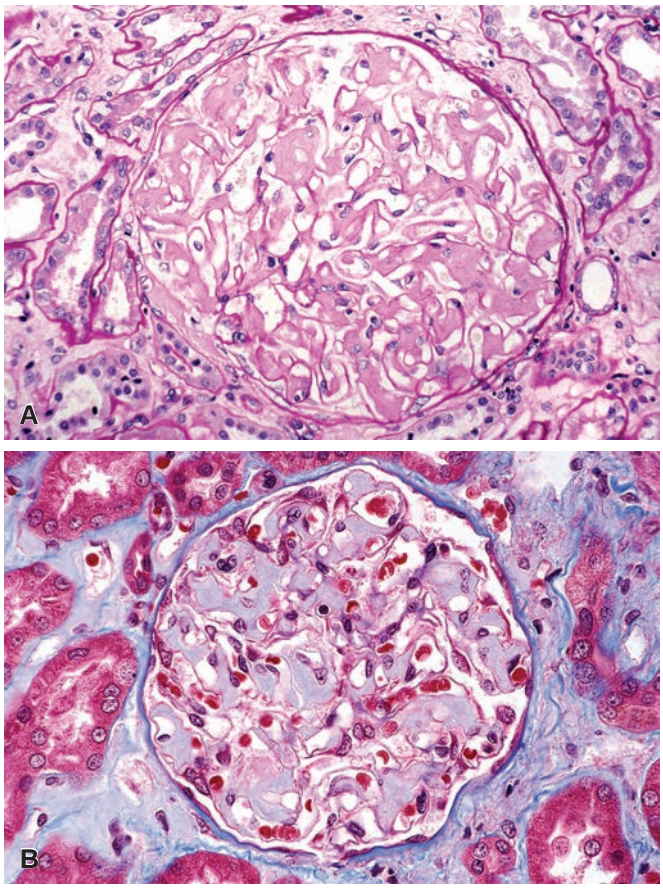

Figure 23.20 Acellular Amorphous Deposits of Amyloid in the Mesangium With Patchy Glomerular Capillary Wall Extension. A, These deposits are weakly PAS positive in comparison to the Bowman capsule. **B,** Amyloid deposits have a grayish blue appearance on trichrome stain.

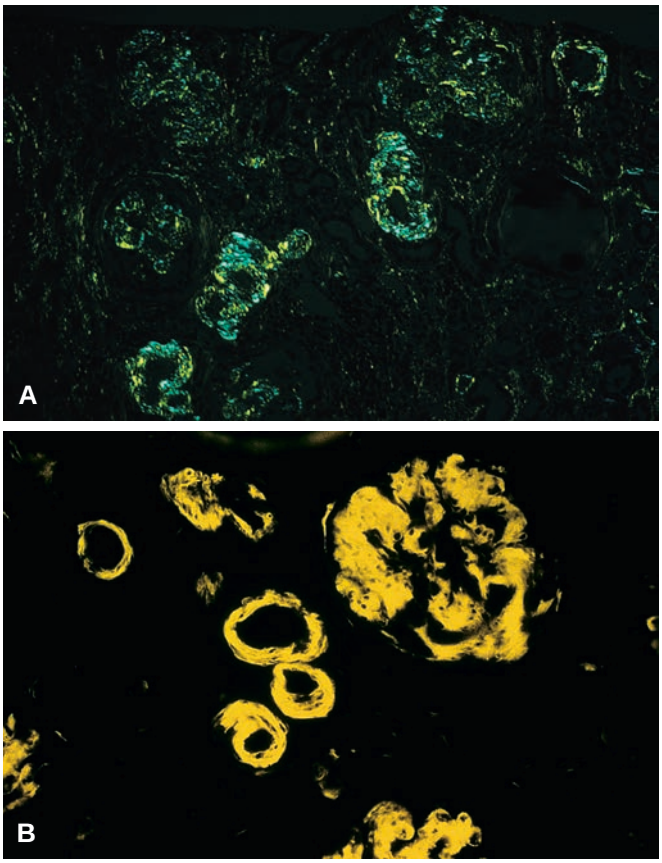

Figure 23.21 A, Deposits of amyloid exhibiting birefringence under polarized light (Congo red stain). **B,** Fluorescence of amyloid under ultraviolet light (thioflavin T stain).

In the early stages of renal involvement when histochemical preparations fail to detect the deposits of amyloid, electron microscopy is the only method available to establish the diagnosis. Ultrastructurally, the amyloid fibrils in tissue sections form random aggregates of rigid, nonbranching fibrils measuring 8–10 nm in diameter (Fig. 23.22). Initially, the amyloid is seen in mesangium and the deposition subsequently extends into the subendothelial zone and through the basement membrane. When amyloid penetrates the basement membrane, epithelial foot processes are effaced and are often separated from the membrane.

Because the amyloidogenic light chain in AL amyloidosis is produced by clonal plasma cells, immunofluorescence or immunoperoxidase studies will show restrictive immunoreactivity for either kappa or, more frequently, lambda light chain. It should be emphasized, however, that a negative reaction for both light chains does not exclude the diagnosis of AL amyloidosis. This is because the main constituent of amyloid deposits in some cases of AL amyloidosis is the light chain variable region alone and the commercially available antibodies are typically raised against the light chain constant region.[175] Monoclonal heavy chain staining (IgG, IgA, or IgM) may instead be seen in AH amyloidosis or may be present in addition to light chain restriction, as in AHL amyloidosis. Sometimes the "stickiness" of amyloid causes nonspecific immunoglobulin staining and an erroneous subtyping of amyloid deposits.[175] Amyloid A usually can be demonstrated by the currently available anti-AA protein

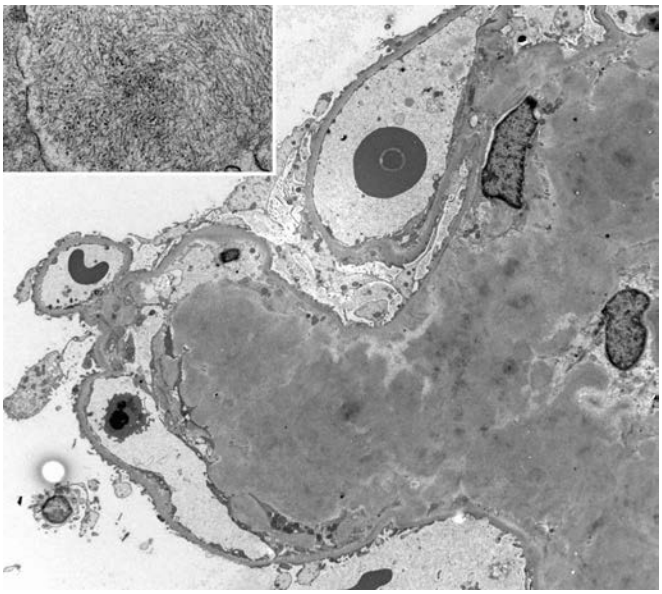

Figure 23.22 Portion of a glomerulus with large amounts of mesangial deposits of amyloid. The typical fibrillary ultrastructural appearance of the amyloid fibrils is shown at high magnification (×5000; inset ×54,000).

antibodies. Since amyloid P component is present in all types of amyloid, it can be used as a pan-amyloid marker to highlight the extent of amyloid deposition. It is important to keep in mind, however, that amyloid P component is not specific for amyloid and is present in the organized deposits of immunotactoid glomerulopathy[176] and in normal GBM and blood vessels[177]; therefore, a positive stain does not denote the presence of true amyloid deposition, and it is necessary to establish the presence of amyloid by a positive Congo red stain.

Other less common amyloid subtypes such as LECT2, ApoAI, ApoAII, and transthyretin can be characterized by performing immunohistochemical stains. However, the list of amyloid subtypes is quite extensive, and given the limited renal biopsy material, it is now standard of care to perform mass spectrometry on laser microdissected amyloid deposits on paraffin sections. Approximately 90% of renal amyloidosis cases belong to either AL or AA type. An initial panel of immunofluorescence and/or immunohistochemistry can be performed to evaluate for AL and AA amyloidosis and failure to subtype the amyloid with this initial testing should prompt mass spectrometry analysis.[175]

Fibrillary Glomerulonephritis

Fibrillary glomerulonephritis is characterized by extracellular deposition of nonbranching, randomly arrayed fibrils approximately 10–30 nm in diameter.[178–180] Reported in just 0.5%–1.0% of the cases in three large series of native kidney biopsies,[180–182] it most commonly affects middle-aged adults but can also occur in older individuals and children as young as 10 years of age.[181,183] It is more common in whites than in blacks (ratio 8.3 : 1) and affects females more often than males (1.8 : 1).[181,184] Patients typically present with heavy proteinuria, often in the nephrotic range.[181] Microscopic hematuria is common, but on occasion gross hematuria may occur. About 75% of patients develop hypertension, sometimes severe.[182,184] Low serum complements are only rarely encountered in fibrillary glomerulonephritis. No specific serum or urine protein abnormalities have been recorded, and the patients have a low incidence of associated lymphoproliferative malignancy. The prognosis for patients with fibrillary glomerulonephritis is poor. Roughly half of these patients progress to ESRD within 2 years of the initial diagnosis.[181,182] Fibrillary glomerulonephritis has been reported to recur in almost a third of the patients who undergo renal transplantation.[184–186]

The light microscopic findings of fibrillary glomerulonephritis can be variable. Common features include mesangial hypercellularity, mesangial expansion with amorphous PAS-positive material, and thickening of the glomerular capillary walls (Fig. 23.23A). The overall appearance of the lesions can resemble mesangial proliferative, membranoproliferative, focal and diffuse proliferative, and MGN. Crescents are not uncommon and can occur in about one-fourth to one-third of cases. An important characteristic of these amorphous deposits is that they do not stain with Congo red or thioflavin T stains (thus differentiating them from amyloid fibrils) and they are observed in the absence of circulating cryoglobulins.

Ultrastructurally, the deposits can be found in all glomerular compartments, including the mesangium, GBM, and subendothelial and subepithelial areas. The fibrillary deposits in fibrillary glomerulonephritis are randomly oriented and measure 10–30 nm in diameter (see Fig. 23.23B). In rare cases of fibrillary glomerulonephritis, fibrils have been reported in the peritubular capillary walls and in the tubular basement membrane.[187,188] Patients usually exhibit extensive effacement of the podocyte foot processes, a finding that correlates with severe proteinuria observed in these patients. Immunofluorescence microscopy most often reveals IgG and C3 in a distribution that corresponds to the fibrillary deposits (see Fig. 23.23C). On occasion, small amounts of IgM and IgA can also be seen.[181] With regards to IgG subclasses deposited, IgG4 is the dominant one, often in combination with IgG1.[181] Both kappa and lambda light chains are detected in most cases of fibrillary glomerulonephritis. Light chain restriction is seen in approximately 15% of patients with fibrillary glomerulonephritis.

Immunotactoid Glomerulopathy

Although initially described together with fibrillary glomerulonephritis, immunotactoid glomerulopathy is recognized as a distinct entity. When strict diagnostic criteria are used, immunotactoid glomerulopathy is exceedingly rare, occurring with only one-tenth the frequency of fibrillary glomerulonephritis.[181] Although the clinical presentation of immunotactoid glomerulopathy is quite similar to that of fibrillary glomerulonephritis, these conditions differ in that immunotactoid glomerulopathy tends to occur in older individuals and is more likely to have an associated monoclonal gammopathy or lymphoproliferative malignancy, serum M-spike, and a worse long-term survival.[180]Approximately 40% of immunotactoid glomerulopathy patients have associated hypocomplementemia suggestive of complement activation by pathogenic immunoglobulins. The light microscopy findings are variable and amorphous Congo red negative deposits are often seen in the mesangium and capillary walls. The immunotactoid deposits consist of microtubular structures with a hollow core ranging from 30 to 50 nm in width and arranged in parallel or stacked arrays.[178–180] Vast majority of immunotactoid deposits (in 70%–90% of patients) are composed of monoclonal light chains, most often kappa type. When such monotypic deposits are seen in immunotactoid glomerulopathy, the IgG deposits often belong to IgG1 subclass.

Light Chain Deposition Disease

LCDD is a rare systemic disorder caused by the overproduction and extracellular deposition of monoclonal immunoglobulin light chain.[189,190] A minority of cases may also have heavy chain determinants, and these cases are regarded as having light and heavy chain deposition disease (LHCDD).[189] On rare occasion, isolated heavy chain is deposited (HCDD, discussed later), and all these disorders with similar pathology constitute monoclonal immunoglobulin deposition disease (MIDD).[191] Although the principal clinical manifestations are dominated by renal disease, patients may present secondary symptoms produced by cardiac, hepatic, or neural damage.[192] In addition, abnormal light chains can be deposited in many other organs, including the skin, spleen, thyroid gland, adrenal glands, gastrointestinal tract, and lungs.[192]

LCDD has many histologic features in common with AL amyloidosis; however, in contrast to amyloidosis where the deposits are fibrillar, LCDD deposits are granular, do not stain with Congo red or thioflavin T, and do not contain amyloid P protein.[193,194] Also, while the deposits in amyloidosis consist mainly of lambda light chains, 80% of LCDD cases are composed of kappa light chains. The pathogenic light chains in LCDD have unique alterations in the complementarity-determining and framework portions of the variable region.[189,195] Males are more frequently affected, with a ratio of approximately 2 : 1.[191] About 60%–70% of the reported patients with LCDD have had well-documented multiple myeloma or another lymphoplasmacytic disorder at the time of, or subsequent to, the diagnosis of the nephropathy.[191,196] Although 15%–20% of patients lack monoclonal light chains in serum or urine by immunofixation method, abnormal serum free light chain ratio is detectable in all patients with LCDD and LHCDD.[191] Serum complement levels are typically normal unless associated with monoclonal heavy chains (as in LHCDD). LCDD occurs more frequently in middle aged to

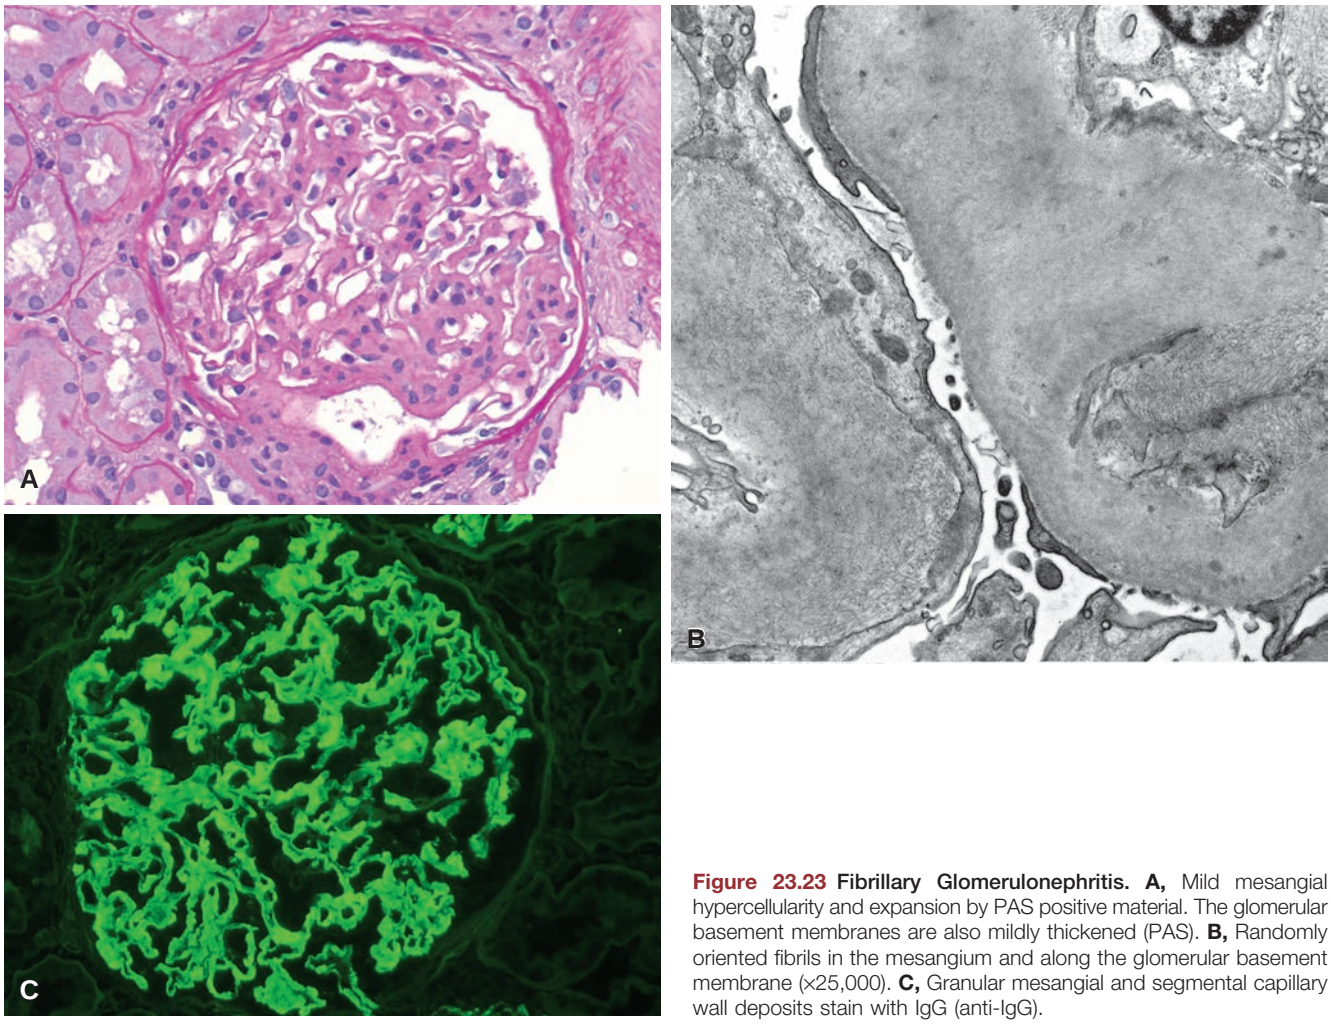

Figure 23.23 Fibrillary Glomerulonephritis. A, Mild mesangial hypercellularity and expansion by PAS positive material. The glomerular basement membranes are also mildly thickened (PAS). **B,** Randomly oriented fibrils in the mesangium and along the glomerular basement membrane (×25,000). **C,** Granular mesangial and segmental capillary wall deposits stain with IgG (anti-IgG).

older individuals, but it has been reported in older children.[197] Most patients present with renal failure associated with heavy and nonselective proteinuria, reaching nephrotic range in over a third.[191] Concurrent cast nephropathy has been diagnosed in a third of patients with LCDD and the presenting feature is typically acute renal failure.[189] Microscopic hematuria is common. Renal insufficiency can progress to an end-stage kidney disease, at which time the patient will require dialysis or renal transplant. Without effective treatment to reduce light chain production, LCDD almost invariably recurs after renal transplantation, and the recurrence may occur within weeks to years after transplantation.[198] The prognosis for patients with LCDD is generally poor, and death is often attributed to cardiac disease or complications of infection.[199] The 5-year survival is approximately 70% but is less if there is coexisting multiple myeloma or light chain cast nephropathy.

Affected glomeruli are enlarged, and the deposition of the markedly PAS-positive material produces capillary wall thickening and nodular expansion of the mesangium. The extent of glomerular involvement can vary in a biopsy from minimal mesangial expansion to a fully developed nodular glomerulosclerosis that resembles diabetic glomerulosclerosis,[193] but other morphologic features characteristic of diabetes, such as severe arteriolar hyalinosis, fibrin caps, and capsular drops are absent (Fig. 23.24). Although the pathogenesis of the glomerulosclerosis in LCDD is not entirely clear, experimental studies have shown that mesangial cells exposed to light chains obtained from a patient with LCDD produce transforming growth factor β (TGF-β), which triggers the production of matrix proteins, such as type IV collagen, laminin, and fibronectin.[174,200,201] The tubular basement membranes are thickened and present a homogeneous glassy appearance. Light chain–restricted casts are found in rare cases with concurrent cast nephropathy, and a minority of patients have concurrent AL amyloidosis.[189]

Immunofluorescence microscopy demonstrates linear staining of the monoclonal light chain along the glomerular and tubular basement membranes, as well as the vessel wall; mesangial deposits are also highlighted by the monoclonal light chain (Fig. 23.25). Electron microscopy studies reveal a continuous deposition of a powdery electron-dense material in the GBM, the mesangium, and along the tubular and vascular basement membranes (Fig. 23.26A).[190] Ultrastructurally, the material differs from dense deposit disease (DDD) in that it is finely granular, relatively homogeneous in thickness, and distributed along the inner aspect of the GBM and in the outer aspect of the tubular basement membrane (see Fig. 23.26B).

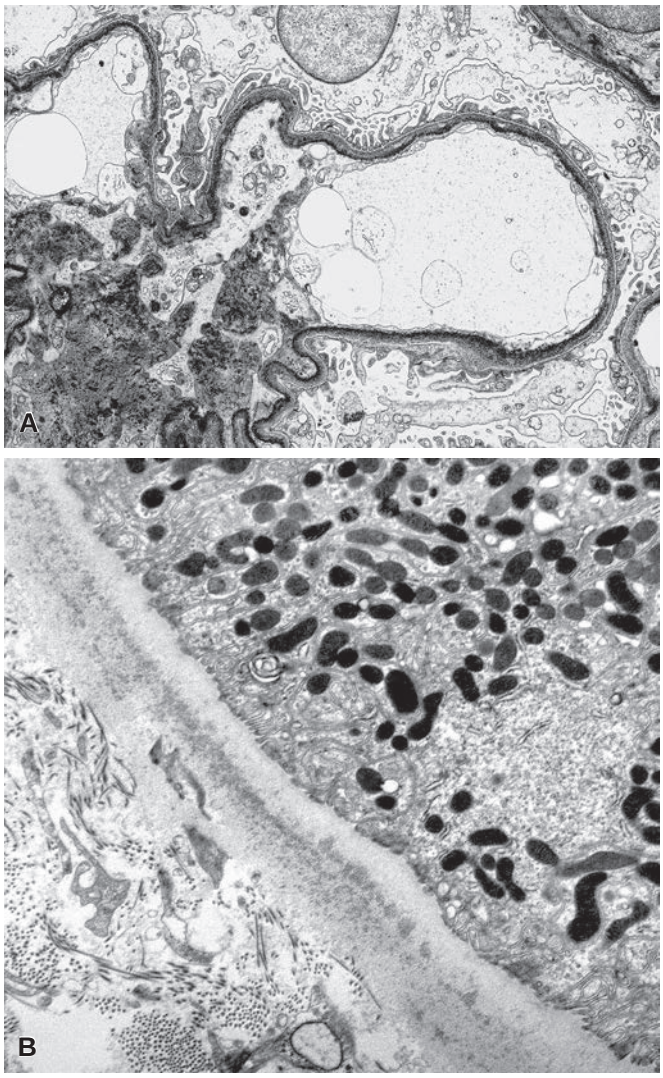

Figure 23.26 Light Chain Deposition Disease. A, Subendothelial and mesangial deposition of granular electron dense material (×7000). **B,** Similar granular electron-dense deposits are seen along the outer aspect of tubular basement membrane (×8000).

Heavy Chain Deposition Disease

Heavy chain deposition disease (HCDD) is much less common than LCDD.[191,195] It is characterized by systemic deposition of a monoclonal immunoglobulin heavy chain. The deposited heavy chain is gamma in most cases, and all subclasses of gamma heavy chain have been reported to participate in the disease. A deletion of the first constant domain (CH1) of the heavy chain has been reported in all documented cases and is likely necessary for the secretion of a free heavy chain by a plasma cell clone of HCDD.[189] The clinical manifestations and histologic features of HCDD are quite similar to those of LCDD.[189,191,202] In contrast to amyloidosis and LCDD, patients with HCDD often manifest hypocomplementemia, possibly due to the complement-fixing properties of IgG subclass deposited.[203] The diagnosis of HCDD can be done by the immunofluorescent demonstration of positivity for heavy chains (usually gamma, IgG) and negativity for both kappa and lambda light chains. The reactivity for the heavy chain occurs along the glomerular, tubular, and vascular basement membranes and in the mesangium.[202]

Proliferative Glomerulonephritis With Monoclonal Immunoglobulin G Deposits

Proliferative glomerulonephritis with monoclonal immunoglobulin G deposits (PGNMIGD) is a recently described, rare proliferative glomerular disease with monoclonal immunoglobulin G deposits.[204] It is often seen in middle aged or older individuals, with a female predominance. Over two-thirds of these patients present with nephrotic syndrome and renal impairment, while others have less degrees of proteinuria and hematuria. Despite having monoclonal IgG deposits on kidney biopsy, monoclonal gammopathy is seen in less than 30% of patients and underlying multiple myeloma is rare. A minority of patients (~25%) have reduced serum complement levels, but there is no clinical or serologic evidence of connective tissue disorder or cryoglobulinemia. While some patients may respond to steroids or other immunosuppressive therapy such as rituximab,

PGNMIGN is typically a slowly progressive kidney disease that recurs in allografts.[205] The light microscopic findings are quite variable with membranoproliferative pattern being the most common; endocapillary proliferation, crescents, membranous, mesangioproliferative, and segmental sclerosis patterns have also been described.[204,206] Immunofluorescence microscopy reveals granular mesangial and capillary wall deposits composed of IgG and C3 with associated light chain restriction (IgG3κ most common); IgM and C1q may sometimes be seen. PGNMIGD is defined by IgG subclass restriction and cannot be rendered without immunofluorescence microscopy analysis of IgG subclasses (IgG1–4). IgG3 deposition is most common (followed by IgG1) in PGNMIGD, and its frequent association with hypocomplementemia is possibly related to its complement-fixing abilities and nephritogenicity. Ultrastructural examination localizes the deposits to mesangium and subendothelium with occasional subepithelial deposits identified. Extraglomerular deposits and organized substructure are not typical features of this entity.

Congenital Nephrotic Syndrome

The nephrotic syndrome is uncommon in the first year of life[207] but is being increasingly recognized that in majority of cases, it is caused by mutations in just one of four genes.[208] The term congenital nephrotic syndrome encompasses a heterogeneous group of conditions but is reserved for patients who present clinical symptoms of nephrotic syndrome at birth or within the first 3 months of life. Two distinct inherited types have been recognized: congenital nephrotic syndrome of the Finnish type and diffuse mesangial sclerosis (DMS). Neither form responds to steroids or immunosuppressive therapy, and renal transplantation is the only way to prolong and improve the quality of life. A renal biopsy is essential to differentiate these two types of congenital nephrotic syndrome from other renal disorders of the neonatal period, including MGN (associated with congenital syphilis or mercury intoxication), congenital toxoplasmosis, HIV (especially in the offspring of narcotic addicts), malaria, cytomegalovirus infection, and MCD.[209–211] In the absence of infections, routine molecular testing of steroid-resistant congenital and infantile nephrotic syndrome is now standard clinical practice.[212]

Congenital Nephrotic Syndrome of the Finnish Type

Congenital nephrotic syndrome of the Finnish type is a rare autosomal recessive disease caused by mutations of the *NPHS1* gene located on chromosome 19q13.1.[213,214] This gene encodes nephrin protein that is an integral component of the podocyte slit membrane and plays a crucial role in normal glomerular filtration.[215,216] The estimated incidence of the disease in the genetically isolated population of Finland is approximately 1 : 10,000 newborns,[217] but it has been reported, though with much less frequency, throughout the world in families with no known Finnish ancestry.[43] More than 70 mutations in *NPHS1* gene have been identified worldwide, and majority are frameshift mutations (Fin-major) leading to complete absence of nephrin expression and an early onset severe nephrotic syndrome with rapid progression to end-stage kidney disease. The Fin-minor nonsense mutations result in truncated or nonfunctioning nephrin protein with less severe disease.

The diagnosis may be suspected in utero from the characteristic family history and the finding of elevated alpha-fetoprotein levels in the amniotic fluid and maternal serum, but this is neither highly specific nor sensitive. More recently, *NPHS1* gene sequencing for known and novel mutations is being performed for the prenatal diagnosis of the disease. The disease manifests in the fetal stage with heavy proteinuria in utero. At birth, the patients have large placentas, proteinuria, edema, and a high susceptibility to infections.[43]

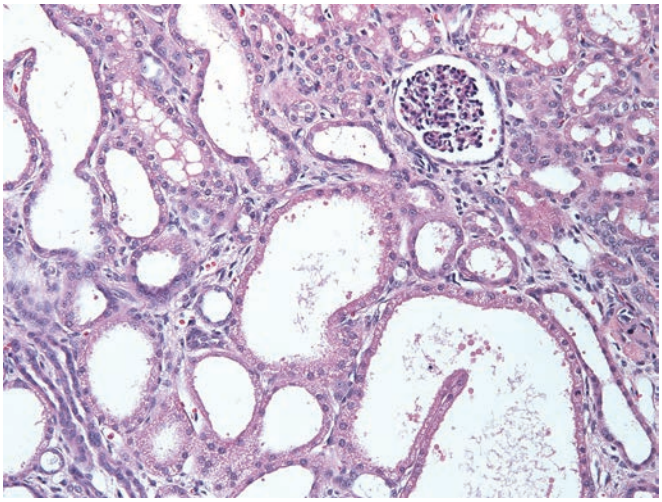

Figure 23.27 Microcystic dilation of proximal tubules and interstitial scarring in a 1-year-old child with congenital nephrotic syndrome, Finnish type.

Premature birth, mild abnormalities in face and limbs, and poor somatic development are common findings. The nephrotic syndrome often makes its appearance during the first days of life and does not respond to steroid therapy. The disease is progressive during the first 2 years of life, and kidney transplantation is the only successful life-saving treatment. The nephrotic syndrome recurs post transplantation in 20%–30% of cases and is attributed to circulating antinephrin antibodies, detected especially in patients with Fin-major mutations.[218,219]

The most striking histologic feature is ectasia of the proximal and distal tubules with flattening of the tubular epithelium (Fig. 23.27). The glomeruli show minimal changes early on but subsequently develop varying degrees of mesangial proliferation, sclerosis, and dilation of the Bowman space. There may also be an increased number of immature glomeruli. Progressive renal disease is associated with increased TA and IF. Obliteration of epithelial foot processes and other podocyte changes seen in MCD are observed by electron microscopy. Immunofluorescence is usually negative for immunoglobulins and complement components, but mesangial and capillary staining for IgM and C3 have been reported in partially sclerosed glomeruli.

Diffuse Mesangial Sclerosis

DMS is a rare condition characterized by the early onset of severe proteinuria, characteristic glomerular morphology, and rapid progression to end-stage renal failure before the age of 3 years.[220] DMS can occur in an isolated form or associated with some well-characterized syndromes. Denys–Drash syndrome (DDS), a rare autosomal dominant disorder, is characterized by early onset nephrotic syndrome, male pseudohermaphroditism, and Wilms tumor. Incomplete forms of the syndrome, consisting of glomerulopathy associated with either genital abnormality or Wilms tumor, have also been described. Mutations of the *WT1* suppressor gene located on chromosome 11p13 have been demonstrated in nearly all patients with the complete or incomplete forms of the syndrome.[221,222] Other syndromes described with glomerular pathology of DMS include Galloway–Mowat syndrome (*WDR73* gene mutation), Pierson syndrome (*LAMB2* gene mutation), and a familial steroid resistant nephrotic syndrome (with mutations in *PLCE1* gene), all with autosomal recessive modes of inheritance.[208,223] Young children with Galloway–Mowat syndrome

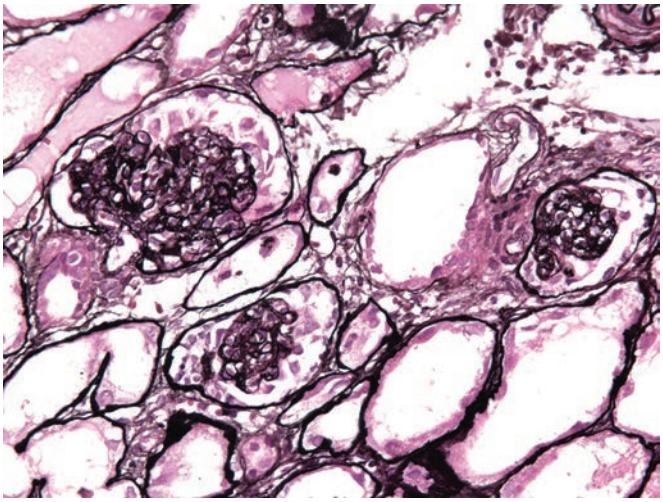

Figure 23.28 Mesangial sclerosis and consolidation with prominent overlying podocytes are typical for diffuse mesangial sclerosis (methenamine silver).

have microcephaly and seizures in addition to steroid-resistant nephrotic syndrome. Ocular abnormalities such as microcoria, neurologic deficits, and congenital nephrotic syndrome characterize Pierson syndrome. The proteins encoded by all these candidate genes have a role in either podocyte differentiation or function of glomerular filtration barrier. A genetic basis for the sporadic cases of DMS is very much plausible but is unclear in most instances. On rare occasions, cytomegalovirus inclusions were identified in newborns with congenital nephrotic syndrome and glomerular changes of DMS.[209]

In patients with DMS, the nephrotic syndrome can develop as early as first week of life, but it is more likely to appear after the third month. In contrast to the Finnish type, the nephrotic syndrome in DMS is not associated with a large placenta, premature birth, or low birth weight. DMS does not recur after transplantation.[220]

By light microscopy, the glomeruli in early DMS show prominent crowded podocytes reminiscent of fetal appearance. Pseudocrescents with proliferating visceral and parietal epithelial cells have been observed.[43] Subsequently, the glomeruli display increased mesangial sclerosis and consolidation (Fig. 23.28). In advanced stages, there is marked TA with IF. The findings by electron microscopy are extensive obliteration of the epithelial foot processes, basement membrane thickening and lamellation, and an increase in the mesangial matrix. By immunofluorescence, deposition of IgM, C3, and C1q is demonstrable in the sclerotic mesangial areas.

Glomerular Lesions Associated With the Syndrome of Acute Nephritis

Another major clinical presentation of patients with glomerular lesions is the acute nephritis syndrome. Patients with this syndrome present with hematuria, azotemia, oliguria, and mild to moderate hypertension. Urinalysis reveals an "active" sediment, which consists of the presence of red blood cells, leukocytes, and red blood cell casts. Proteinuria is common but is rarely in the nephrotic range. Edema, when present, is usually mild and is frequently manifested by facial puffiness. Variants of the clinical syndrome include milder forms with microscopic hematuria and non-nephrotic proteinuria, on occasion associated with mild hypertension, and a fulminant form known as rapidly progressive glomerulonephritis. As with the nephrotic syndrome, the histopathologic lesions that can give rise to this clinical presentation are varied.

Diffuse Endocapillary Proliferative Glomerulonephritis

Diffuse endocapillary (or intracapillary) proliferative glomerulonephritis is a term used to describe lesions characterized by both mesangial and endothelial proliferation. Although this category has become virtually synonymous with acute poststreptococcal glomerulonephritis, it may occur after infections caused by other bacteria including staphylococci, meningococci, pneumococci, *Klebsiella*, *Salmonella*, enterococci, *Brucella*, *Leptospira*, and mycobacteria.[224,225] It can also arise as a complication of rickettsial infections; viral diseases including hepatitis B, varicella, mumps, measles, cytomegalic virus, and infectious mononucleosis; and parasitic conditions such as malaria, trichinosis, and toxoplasmosis.[226]

Acute Poststreptococcal Glomerulonephritis

Poststreptococcal glomerulonephritis is primarily a disease of childhood, usually occurring between the ages of 5 and 15 years, but it can affect individuals of any age.[227] Approximately 5% of the patients are younger than 2 years of age.[225] Males are affected more commonly than females, with a ratio of 2 : 1.[226,227] Significantly higher incidence of poststreptococcal glomerulonephritis is seen in less developed countries when compared to the Western world and may even be underestimated due to subclinical cases.[228] The disease profile in developed countries is often different, more frequently affecting elderly individuals with comorbidities.[227]

In the classic form, the disease occurs within 1–4 weeks after infection with a nephritogenic strain of group A β-hemolytic streptococci. The rheumatogenic strains of group A β-hemolytic streptococci (causing rheumatic fever) differ from the nephrotogenic strains by the surface M proteins. Primary infections may be either pharyngeal or, less commonly, cutaneous. The principal serotypes implicated in glomerulonephritis are streptococci of group M types 12, 4, 1, and 49.[226] The risk for developing glomerulonephritis after infection with a nephritogenic streptococcus is variable, depending on a variety of host and virulence factors, but the overall risk is estimated to be about 15%.[229] The clinical, morphologic, and serologic findings indicate that poststreptococcal glomerulonephritis is an immune complex disease, and the main target antigens implicated thus far include "streptococcal pyrogenic exotoxin B" (SPEB) and "nephritis-associated plasmin receptor."[230] SPEB is a cationic protein that colocalizes in the subepithelial deposits and both antigens promote plasmin activity, contributing to glomerular tissue injury. In addition, the circulating antigen-antibody complexes deposit in subendothelium, activate the alternative and possibly lectin complement pathway, and trigger an inflammatory response.[228]

Clinically, this disease is manifested by a rather abrupt onset of gross hematuria, edema, proteinuria, hypertension, and impaired renal function.[228,231] Antibodies to certain streptococcal antigens, such as antistreptolysin O (ASO), are elevated, but this finding may not be helpful in diagnosis due to the ubiquitous nature of streptococcal infections. The serum levels of hemolytic complement activity and C3 protein are abnormally reduced early in course of the disease, but the values return to normal in less than 8 weeks. During the acute episode of poststreptococcal glomerulonephritis, 2%–5% of the patients die as a result of complications such as pulmonary edema, hypertensive encephalopathy, or rapidly progressive renal failure due to crescentic glomerulonephritis; and these figures are much higher in elderly patients.[228,232] The long-term prognosis of patients with acute poststreptococcal glomerulonephritis is good, especially in children, with only a small number of patients progressing to chronic renal failure many years after the acute episode.[225,233] Recovery in adults is less predictable than in children, especially

with persistent proteinuria or when the initial episode is associated with severe renal impairment and nephrotic syndrome.[226,227,230] Progression of renal disease is more common in patients who develop crescentic glomerulonephritis. Since the clinical syndrome of acute poststreptococcal glomerulonephritis may be quite distinctive and the overall prognosis is excellent, biopsies are not commonly performed unless atypical features complicate the presentation, such as nephrotic syndrome, anuria, acute renal failure, persistent or severe hypertension, or lack of recovery after 6 weeks. On long-term follow-up, approximately 17% of the patients have persistent mild proteinuria, microhematuria, or hypertension.[230] Recent studies have indicated an overlap between atypical postinfectious glomerulonephritis and C3 glomerulonephritis (C3GN), as several of these patients with persistent late symptoms have alternative complement pathway abnormalities.[234] In addition, it appears that streptococcal infections may act as a trigger for precipitating C3 glomerulopathy in a genetically predisposed individual.[235,236]

Light microscopic examination of biopsies taken within a few weeks of onset of disease shows diffuse enlargement of the glomerular tufts that tend to narrow the Bowman space. Glomerular intracapillary cellularity is increased due to mesangial proliferation and, to a lesser extent, proliferating and swollen endothelial cells. This results in narrowing of the capillary lumina and accentuation of the lobular glomerular pattern. Infiltration by leukocytes can contribute to the capillary obstruction as well, and, when prominent, the term *exudative* glomerulonephritis has been used (Fig. 23.29). Accompanying the polymorphonuclear leukocytes are mononuclear cells and, on occasion, eosinophils. Segmental necrosis and thrombosis with crescent formation are uncommon findings but indicate poor prognosis.

The most characteristic ultrastructural feature in the early stages of the disease is the presence of subepithelial, dome-shaped, electron-dense deposits called humps (Fig. 23.30). The deposits are separated from the lamina densa by a recognizable lamina rara externa, and the foot processes of the podocytes overlying the humps are usually obliterated. In general, there is a correlation between the number of humps and the degree of polymorphonuclear cell infiltration, but the humps may occur in loops devoid of leukocytes. Intramembranous deposits, some of them in continuity with the humps, and small subendothelial and mesangial deposits are not uncommon.

Immunofluorescence studies during the acute phase of the disease typically reveal granular staining for IgG and C3 along the capillary loops where the humps are located (Fig. 23.31). Small amounts of IgM and IgA may be found. Properdin is frequently present and this, coupled with the strong reactivity for C3 and the absence of C1q and C4 in the deposits, suggests involvement of the alternative complement pathway.

Serial biopsies show a gradual resolution of the glomerular changes. Cellularity decreases and the humps generally disappear in 6–8 weeks, though they can be identified up to 6 months after the onset of the disease. During the resolving phase, the basement membrane may show focal irregularities with decreased electron density, the capillary lumina become patent, and the endothelial swelling and polymorphonuclear leukocytic infiltration disappear. Electron-dense deposits either are no longer visible or are confined to the mesangium.[228] IgG may not be demonstrable, and C3 staining gradually disappears from the periphery and becomes restricted to the mesangial areas. Complete restoration to normal histology occurs as early as 6 months and certainly within 2–3 years. In a small

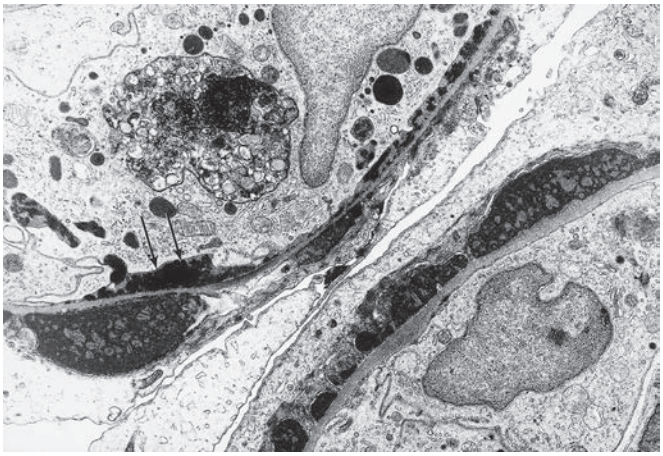

Figure 23.30 Biopsy From a Patient With Acute Poststreptococcal Glomerulonephritis. There are numerous humps along the basement membrane. The capillary loops are obliterated by cell proliferation and inflammatory cells. Small amounts of fibrin are present in the subendothelial areas *(arrows)* (×9800).

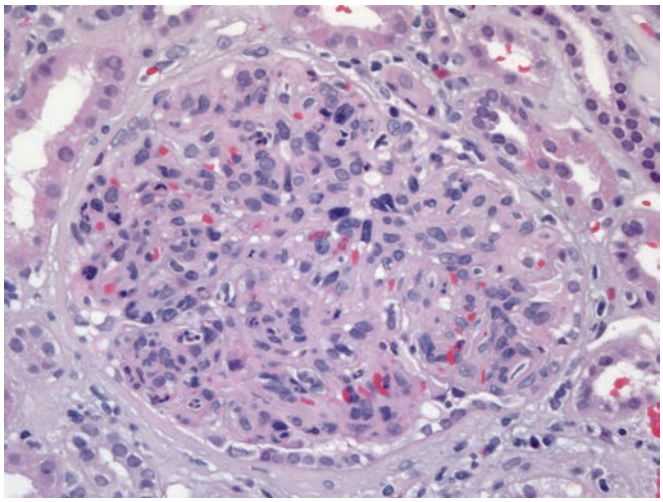

Figure 23.29 Diffuse Proliferative Glomerulonephritis. There is marked hypercellularity due to an increase in mesangial and endothelial cells and infiltration by inflammatory cells.

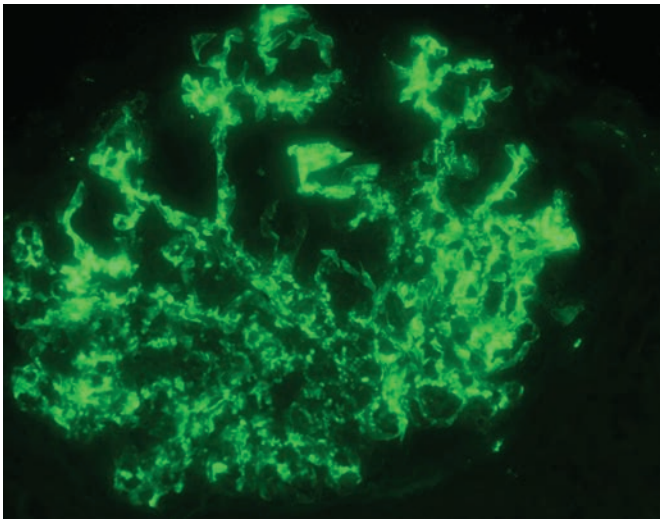

Figure 23.31 Poststreptococcal Glomerulonephritis. The coarse granular immunostaining for C3 along the capillary loops corresponds to the humps seen by electron microscopy (anti-C3).

percentage of cases, mesangial hypercellularity, mesangial deposits, and increased mesangial matrix may persist for years after the acute episode, and the mesangial prominence tends to be focal and segmental.

IgA-Dominant Staphylococcal Infection-Associated Glomerulonephritis

Infection-associated glomerulonephritis in the developed countries is being increasingly caused by *Staphylococcus aureus,* especially the drug-resistant strains.[237,238] Unlike poststreptococcal glomerulonephritis, staphylococcal infection-associated glomerulonephritides are more common in the elderly population (over 60 years of age) with comorbidities such as diabetes mellitus, drug abuse, alcoholism, and malignancy.[228,238] The underlying infection is typically ongoing (rather than "post-infection") and is often brought to attention by the kidney disease. The characteristic feature of this entity is IgA-dominant or co-dominant immune deposits that are seen in addition to C3.[227,239,240] The IgA-dominant host immune responses appear to play a role in this morphologic variant of infection-associated glomerulonephritis. It has been postulated that the *S. aureus* enterotoxins and possibly other antigens function as "superantigens," capable of binding directly to the major histocompatibility complex (MHC) class II molecules on antigen presenting cells without the required intracellular antigen processing to form receptor-fitting peptides.[241,242] In addition, these superantigens bind to T-cell receptors, causing massive T-cell activation, proliferation, and cytokine release. These events in turn trigger polyclonal B-cell activation, and patients with *S. aureus* infections were shown to have polyclonal elevation of serum IgA and IgG. The most common presentation is acute renal injury, proteinuria often in the nephrotic range, and hematuria.[239,243] There appears to be a male predominance, and two-thirds of the patients have mild hypocomplementemia. A small percentage of patients may present with lower extremity rash, reminiscent of Henoch–Schönlein purpura (HSP).[226,244] Reported underlying infections have included osteomyelitis, pneumonia, septic arthritis, empyema, sinusitis, and endocarditis, among others. The latent period between the onset of infection and renal manifestations appears to be 4–5 weeks, but in most cases the infection is not recognized until the time of the kidney biopsy. Treatment of underling infection is the main form of therapy and overall, the prognosis is inferior to poststreptococcal glomerulonephritis, possibly related to the patient's age and associated comorbidities.

The glomerular changes on biopsy can be variable,[226] ranging from mild mesangial hypercellularity to diffuse endocapillary proliferation and on occasion, crescents; exudative features are not uncommon, although seen less frequently than in poststreptococcal glomerulonephritis. There is usually accompanying acute tubular injury and interstitial inflammation, but vasculitis is not a feature observed on kidney biopsy. In patients with diabetes mellitus, subtle changes of glomerular endocapillary proliferation may be masked by prominent Kimmelstiel–Wilson nodules.[245] The electron-dense deposits are primarily in the mesangium and paramesangium, but occasional subendothelial deposits are not uncommon. The subepithelial "humps," the hallmark of infection-related glomerulonephritis, are seen in less than 50% of patients. When present, these subepithelial deposits are often smaller and less "hump"-like. The glomerular immune deposits are composed predominantly of IgA and C3 with less intense or absent IgG. Light chain κ and λ staining is usually seen, and λ can be more intense than κ. These immunofluorescence findings can lead to a misdiagnosis of IgAN, especially in the absence of obvious infection or if the skin rash is reminiscent of HSP. Distinguishing between these two entities is extremely important as immunosuppression for a presumed IgAN will exacerbate an unrecognized infection. Low serum complement levels and subepithelial humps, if present, indicate infection-associated glomerulonephritis rather than IgAN.[226,246]

C3-Related Glomerular Diseases and Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN; also known as *mesangiocapillary glomerulonephritis*) is a term used to designate a distinctive histopathologic pattern of glomerular injury characterized by a combination of mesangial cell proliferation with lobular accentuation (Fig. 23.32) and capillary wall thickening with double contours and extension of the mesangial cell cytoplasm into the periphery of the loop (Fig. 23.33). Based on the ultrastructural morphology and distribution of the deposits, MPGN was traditionally subdivided into two major types: in the first (type I), the deposits are primarily subendothelial (Fig. 23.34); in the second (type II), the deposits are extremely dense and lie within the basement membrane. However, only a minority of later group (about 25%) exhibit the membranoproliferative pattern, and hence the preferred

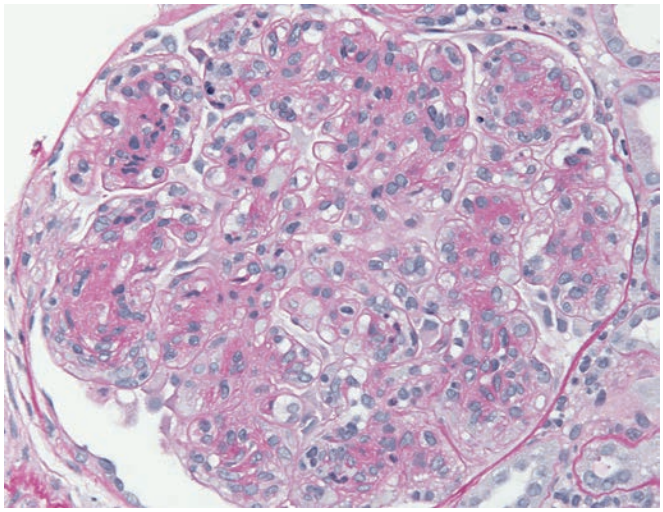

Figure 23.32 Membranoproliferative Pattern Glomerulonephritis. There is an increase in lobulation, diffuse mesangial hypercellularity, and thickening of the capillary walls.

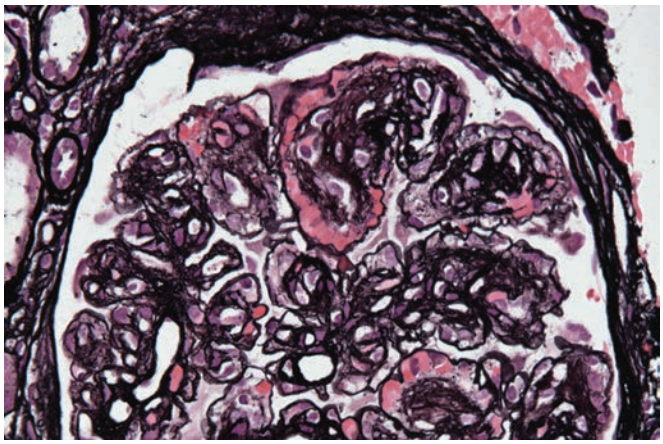

Figure 23.33 Silver preparation showing marked increase in mesangial matrix in the centrolobular areas with peripheral extension of the mesangium producing a double contour (membranoproliferative) pattern in the loops (methenamine silver).

and currently used term DDD instead of MPGN type II.[247] In addition, other variants referred to as type III, which show either extensive disruptions of the lamina densa or frequent subepithelial deposits, have been described.[248–250]

Although the traditional subdivision of MPGN implied various morphologic patterns of a single clinicopathologic entity, the conditions do not share a common pathogenesis and they are linked only by the morphologic similarities on routine light microscopy. Recent studies have helped gain insight into the pathophysiological mechanisms of "MPGN" and related entity of C3GN.[251–253] Although the classification scheme is evolving, these disorders fall broadly into two categories (Box 23.4).[254,255] The first, *C3 glomerulopathy*, consists of glomerular diseases with prominent C3 deposition with little or no immunoglobulin deposition. It encompasses DDD, C3GN, and familial forms of MPGN and is associated with dysregulation of alternative complement pathway. A subset of previously designated MPGN type I and type III belongs to C3 glomerulopathy category under this new classification. The second group, *idiopathic MPGN with prominent immune complex deposition* (in addition to C3), includes approximately 70% of type I and 60% type III MPGN, as defined by the traditional classification.[256] Several patients in the second group also appear to have alternative complement pathway abnormalities, posing a challenge for an immunofluorescence-based classification system.[254]

Box 23.4 C3-related glomerular diseases and membranoproliferative glomerulonephritis (MPGN)

C3 glomerulopathy (isolated/predominant C3 deposits)
- Dense deposit disease (previous term type II MPGN)
- C3 glomerulonephritis
- Familial C3 glomerulopathy (abnormal CFHR3-1 protein, type III MPGN features)
- CFHR5 nephropathy (mutations in *CFHR5* gene)

Idiopathic MPGN (immune complex deposition; C3 and immunoglobulin deposition)
- MPGN type I morphology
- MPGN type III morphology

Secondary causes of MPGN morphology

Infections
Hepatitis B and C, endocarditis, visceral abscesses, shunt nephritis, malaria, schistosomiasis, mycoplasma, HIV, and Epstein–Barr virus infections

Immunologic and systemic disorders
Systemic lupus erythematosus, scleroderma, Sjögren syndrome, rheumatoid arthritis, sarcoidosis, mixed essential cryoglobulinemia with or without hepatitis C infection, ulcerative colitis, sickle cell disease

Dysproteinemia
MGUS, type I cryoglobulinemia, Waldenström macroglobulinemia, fibrillary glomerulonephritis, immunotactoid glomerulopathy

Neoplastic diseases
Carcinoma, chronic lymphocytic leukemia, non-Hodgkin lymphoma, melanoma

Hereditary diseases
α1-Antitrypsin deficiency, complement deficiency, hereditary angioedema, Wiskott–Aldrich syndrome, Sherwood–Proesmans syndrome, autosomal recessive MPGN type I

Miscellaneous
Drug abuse (heroin, pentazocine), Kartagener syndrome, Turner syndrome, Down syndrome, transplant glomerulopathy, chronic thrombotic microangiopathy

CFHR, Complement factor H-related protein or gene; *MGUS*, monoclonal gammopathy of undetermined significance; *MPGN*, membranoproliferative glomerulonephritis.

C3 Glomerulopathy

C3 glomerulopathy is characterized by abnormal persistent activation of alternative complement pathway and predominant glomerular deposition of C3, with a proposed definition of C3 immunofluorescence intensity ≥2 levels (scale 0–3+) above immunoglobulins or C1q.[254] These patients often have genetic abnormalities of, or circulating autoantibodies directed against, complement components.[251,257,258] Serum C3 levels are often reduced, and histology is variable, including some with membranoproliferative features. The main entities in this category are DDD and C3GN. Others include familial forms with type III MPGN features caused by an abnormal complement factor H-related protein (CFHR3-1), and an autosomal dominant form with mutations in *CFHR5* (see Box 23.4).[253,259] It is interesting that some patients with "atypical" postinfectious glomerulonephritis (with or without documented infection) also have mutations in complement genes or have related autoantibodies.[234] It has been suggested that an infection or other triggers unmask a C3GN in a predisposed individual.[235,236] Novel treatment approaches are being developed to treat C3 glomerulopathy, hence the importance of accurate diagnosis.[260,261] Plasma infusions and plasmapheresis aim to correct complement deficiencies or remove circulating autoantibodies. Inhibition of alternative complement pathway (C5 inhibition) and restoration of normal functional state may also be effective in these patients.

Dense Deposit Disease

DDD, previously termed as type II MPGN, is a C3 glomerulopathy characterized by a unique broad, linear intramembranous electron-dense deposits. DDD is rare and has been estimated to affect two to three people per one million population.[261,262] Both sexes are equally affected, with the diagnosis usually made in children between the ages of 5 and 15 years.[263] Affected patients typically present with nephrotic proteinuria, hematuria, and renal insufficiency. Most patients with DDD have hypocomplementemia and continue to have low levels of complement throughout the course of the disease. C4 levels are usually normal.[264] Over 80% of patients with DDD

are positive for serum C3 nephritic factor (C3NeF), an autoantibody directed against C3bBb, a convertase of the alternative pathway of complement cascade. Because C3NeF can be found in idiopathic MPGN and C3GN (previously type I and III MPGN), a definitive diagnosis of DDD depends on the ultrastructural demonstration of dense deposits within the GBM. Other unusual aspect of DDD is its association with macular degeneration and acquired partial lipodystrophy (loss of subcutaneous fat in upper half of the body) in approximately 3%–5% of cases. Patients with these conditions were found to have hypocomplementemia and C3NeF regardless of whether or not they develop DDD.[265–269]

DDD has a poor prognosis and in about 50% of the cases, the lesion slowly progresses to an end-stage kidney within 10–15 years of diagnosis. Abrupt decline in renal function can be seen with crescentic disease. On rare occasions, there have been reports of morphologic regression.[270–272] Recurrence after renal transplantation occurs in virtually all renal allografts.[273] Chronic activation of alternative complement pathway is the culprit and is mediated in most instances by C3NeF that inhibits the activation blocker, C3 convertase. Other less common autoantibodies documented in DDD are against factor H, factor B, and C3. Genetic predisposition plays a role and mutations in *CFH* gene have been detected in 17% of patients. Certain allelic variants of *CFH*, *CFI*, *C3*, and *CFHR5* and *C3* mutations have been associated with DDD.[257,258,262] It appears that infections, chemotherapy, and other unknown factors may precipitate DDD in these predisposed patients. Interestingly, adults with DDD may have coexistent monoclonal gammopathy, and the pathogenic light (or heavy) chains interfere with the control of the alternative complement pathway.[274]

On light microscopy, the general morphologic features can be quite variable. In a study of a large series of renal biopsies, nearly half showed mild, mesangial hypercellularity, whereas only about 25% had the typical membranoproliferative pattern (see Figs. 23.32 and 23.33). Approximately 17% had a crescentic glomerulonephritis pattern (Fig. 23.35), and 12% had an acute proliferative and exudative pattern that could be easily confused with postinfectious glomerulonephritis.[247] A feature that establishes the diagnosis is an eosinophilic, refractile, and ribbon-like thickening of the basement membrane, which is most pronounced along the GBM, although it can be seen in the Bowman capsule and in the tubular basement membrane. The deposited material is strongly PAS positive, stains blue with Masson trichrome, is pale on Jones stain, and can easily be recognized by its dark color on toluidine blue–stained plastic-embedded tissue sections. Ultrastructurally, the material is extremely electron dense and lacks the prominent granularity of immune complex deposits. It is centrally positioned within the lamina densa of basement membrane but may vary in thickness or be focally discontinuous (Fig. 23.36A). Similar deposits can be found in the mesangium as homogeneous nodules or, less frequently, subepithelial humps.[275] These deposits can be seen in choroidal blood vessels and ocular Bruch membrane. The immunofluorescence pattern is typical and diagnostic. A linear or double-contoured staining for C3 along the glomerular capillary walls is associated with a bright nodular or ring-like reaction in the mesangium (see Fig. 23.36B). A focal and often discontinuous linear C3 reaction can be seen in the Bowman capsule and in some tubular basement membranes. Immunoglobulin and early components of complement are usually absent and if present, significantly less intense than C3. Using laser-capture mass spectrometry, it has been found that these deposits are composed of C3 and other late complement components, CFHP1, clusterin, vitronectin, and unsaturated lipids associated with ApoE among others.[276]

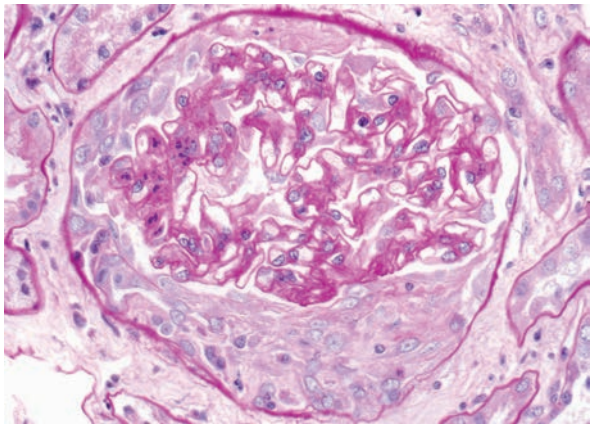

Figure 23.35 Dense deposit disease has variable histologic manifestations. Crescent formation with mild segmental mesangial expansion by inflammatory cells in a young patient (PAS).

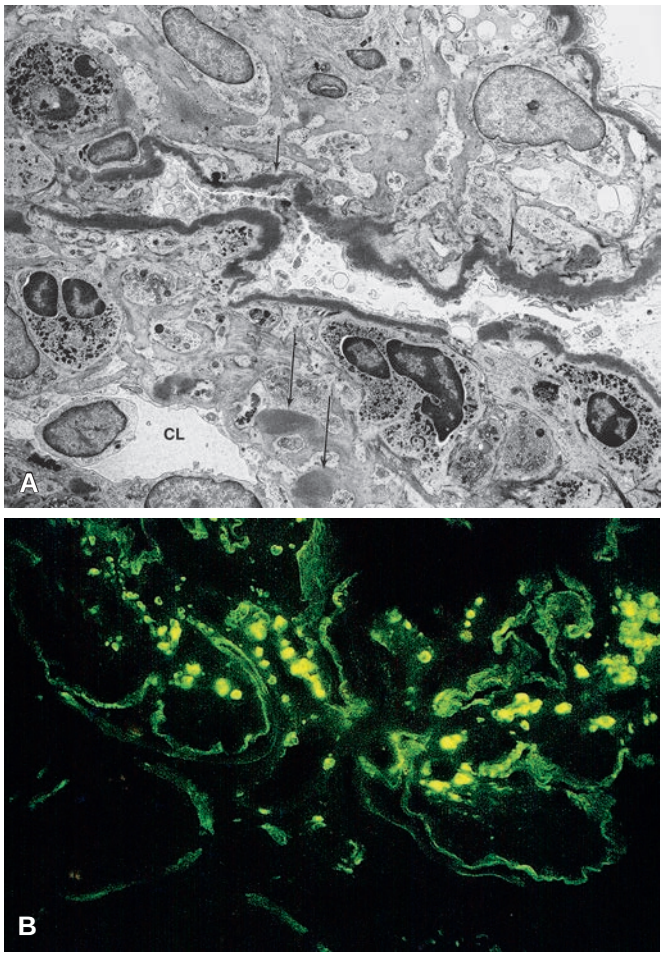

Figure 23.36 **A,** There is homogeneous, highly dense material within the lamina densa *(short arrows)* and nodular deposits *(long arrows)* of the same electron density in the mesangium. The capillary lumen (CL) in the left lower portion of the figure is narrowed due to peripheral extension of the mesangium. Numerous neutrophils are also present (×4000). **B,** Immunofluorescent staining for C3 showing weak linear staining along glomerular capillary and tubular basement membranes *(right lower corner)* and bright granular deposits in the mesangium, some of which have a ring-like pattern.

A, Segmental mesangial proliferation and glomerular basement membrane thickening (methenamine silver). **B,** Intramembranous and subepithelial electron-dense deposits with focal glomerular basement membrane duplication (×7000). **C,** Granular segmental mesangial and capillary wall deposits with C3. No immunoglobulin staining was observed by immunofluorescence (anti-C3).

C3 Glomerulonephritis

C3GN is a type of C3 glomerulopathy characterized by isolated C3 deposits, minimal or no immunoglobulin deposition, and dysregulated alternative complement pathway. However, unlike DDD, the electron-dense deposits are amorphous and not as electron dense, broad, or linear. It includes majority of cases previously designated as type I and III MPGN and other glomerulonephritides without membranoproliferative morphology.[254,256,277] Patients with C3GN are often adults, with a mean age of 30 years at presentation, but it has been reported in children as young as 7 years and elderly individuals older than 70 years. The renal manifestations are variable, ranging from mild proteinuria to nephrotic syndrome. Microscopic hematuria, hypertension, and renal insufficiency are frequently present. Serum complement C3 levels are low in approximately 40% of patients, but C4 is typically normal.[278] C3NeF is detectable in approximately 45% of patients. Older individuals with C3GN can also have circulating monoclonal immunoglobulins, although a direct pathogenic link to C3GN has not been established. The light microscopic findings of C3GN are variable, ranging from minimal changes to diffuse proliferative to membranoproliferative patterns (Fig. 23.37A).[256] Crescents are occasionally present and proliferative glomerulonephritis can also show exudative features, reminiscent of postinfectious glomerulonephritis.[234] The chronic tubulointerstitial damage typically ranges from mild to moderate depending on the chronicity of the disease. Ultrastructurally, amorphous deposits are predominantly in the mesangium and the capillary wall deposits can be in subendothelial, and/or subepithelial and intramembranous (type I or III MPGN pattern described in the next section) (see Fig. 23.37B). By mass spectrometry, these deposits are composed of alternative and terminal complement pathway components, identical to DDD.[277] As mentioned earlier, the glomerular deposits stain strongly for C3 with little or no immunoglobulin (see Fig. 23.37C).[254]

A diagnosis of C3GN (and DDD) should prompt thorough investigation for complement factor levels (factor H, factor I, factor B, membrane attack complex), anti-factor H autoantibodies and alternative complement pathway functional and hemolytic assays.[254] Mutations in genes encoding complement regulatory factors (factor H, factor I, CD46, CFHR5) and certain complement factor alleles that confer higher risk of developing disease have also been

documented in C3GN. Patients can have more than one acquired or inherited abnormality related to C3GN.[277]

Membranoproliferative Glomerulonephritis With Immune Complexes

This group of diseases is characterized by mesangial hypercellularity and GBM duplication, with prominent C3 and immunoglobulin (and/or C1q) deposition, indicative of both classical and alternative complement pathway activation.[254,279] Extrapolating the historical data of type I MPGN, it likely accounts for approximately 5% of ESRD cases secondary to glomerulonephritis. Membranoproliferative pattern with immune complexes can be primary/idiopathic or more commonly, secondary to chronic infections, monoclonal gammopathy, systemic autoimmunity, and hereditary diseases (see Box 23.4). It is also believed that the majority of cases once thought to be "idiopathic" are associated with hepatitis C infection.[280] Further, recent advances in elucidating the pathogenetic mechanisms of MPGN, especially C3 glomerulopathy, has altered the prevalence of "idiopathic" MPGN. It is now a *diagnosis of exclusion*, especially in adults, and perhaps will become an increasingly uncommon diagnosis in the future.[279,281] Based on the historical data, primary/idiopathic form of the disease, affects primarily children and young adults, with 90% of patients being between 8 and 16 years of age at the time of diagnosis.[275,282] Onset before the age of 4 years is rare. Clinical presentation varies, and there does not appear to be a gender predominance. At least 50% of the patients present with nephrotic syndrome, and 25% may present with a combination of asymptomatic hematuria and asymptomatic proteinuria. Finally, up to one-third of patients may present with acute nephritic syndrome associated with abnormal urinary sediment, hypertension, and renal insufficiency.[275,282,283]

About two-thirds of the patients have hypocomplementemia with marked variation of its level over the course of the disease. The predominant complement depletion is C3, but early (i.e., C1q, C4, and C2) and terminal (C5, C6, C7, and C9) components of the classic pathway of complement activation maybe reduced as well. Components of the alternative pathway (i.e., factor B), are also frequently low,[284] and C3NeF is detected in more than half of patients with type I MPGN. Mutations in alternative complement pathway genes (*CFH* and *CFI*) have been detected in a minority of these patients (with type I pattern), blurring the line between the categories of C3 glomerulopathy and MPGN with immune complexes.[257] It has been speculated that in these cases, the underlying genetic or acquired complement dysregulation is triggered or exacerbated by the immune complex deposition[251] Historically, the clinical course of "primary/idiopathic" MPGN is usually indolent but relentless, progressing to renal failure over a period of 10 or more years.[285] The disease has been reported to recur in 30%–50% of the patients who undergo renal transplantation[273,286] and the risk of recurrence appears to be higher in patients with low serum complement levels.[287]

On light microscopy, the glomeruli appear diffusely enlarged, with thickening of the capillary walls and prominent mesangial proliferation that produces lobulation of the tuft (see Fig. 23.32). Mesangial matrix accumulates in the center of the lobules, forming nodules resembling diabetic glomerulosclerosis. In addition to the lobular pattern, exudative, crescentic, and focal segmental histologic variants have been described.[283] In sections stained with PAS or Jones methenamine silver stain, continuation of the mesangial matrix can be seen to surround capillary loops, producing a double contour or "tram-track" pattern (see Fig. 23.33). Within the double contours, hyaline material corresponding to subendothelial deposits are often prominent. The presence of hyaline thrombi within the capillary lumens should raise the possibility of cryoglobulinemia or lupus nephritis.

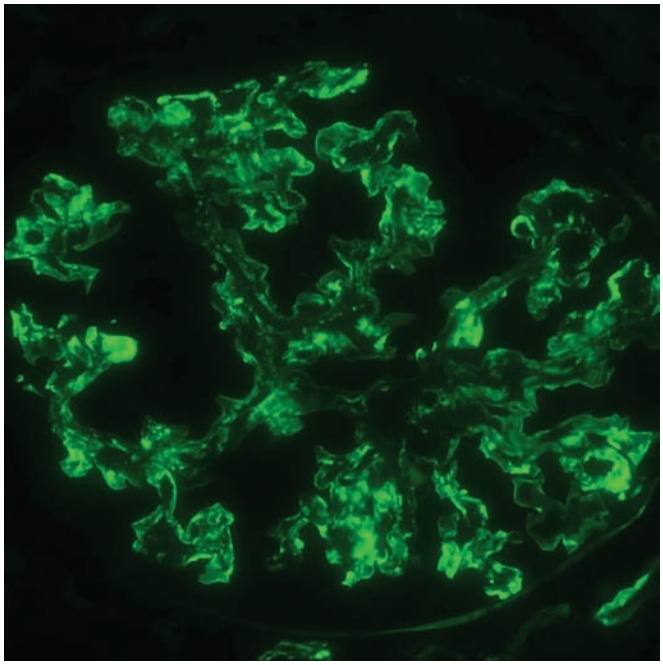

Figure 23.38 Membranoproliferative Glomerulonephritis With Immune Complexes. Immunofluorescence preparation demonstrating immunoreactivity for IgG (and C3) in the mesangium and along patchy capillary loops (anti-IgG).

Immunofluorescence usually demonstrates a granular reaction for IgG and C3 along the capillary walls and mesangium (Fig. 23.38). In addition, IgM, C1q, and C4 can be present. Electron microscopy demonstrates that the mesangial areas are enlarged by cellular proliferation and accumulated matrix, and that the capillary lumina are reduced by a combination of peripheral mesangial expansion and interposition of cells and matrix beneath the endothelium. Typically, there is a continuous layer of mesangial cytoplasm around the entire capillary with an irregular layer of new matrix underlying the intact basement membrane. Electron-dense deposits in type I MPGN pattern are typically seen in the mesangial and subendothelial regions (see Fig. 23.34). Type III pattern MPGN is a very uncommon and controversial variant of MPGN, of which two morphologic subtypes have been defined. In the first subtype, referred to as the Burkholder variant, the glomerular lesion presents combined features of MPGN type I and MGN.[249] Ultrastructural examination of the capillary walls demonstrates mesangial interposition, subendothelial deposits, and numerous subepithelial deposits associated with basement membrane spikes. In the second subtype described by Anders and associates in 1977, the glomerular lesion resembles a hybrid between type I and type II MPGN.[248,250,288] Despite the pathologic differences, both variants of type III MPGN are clinically similar and do not differ significantly from MPGN type I.

Diffuse Mesangioproliferative Glomerulonephritis

Diffuse proliferation of the mesangial cells and matrix without significant involvement of capillary walls or lumina occurs in a variety of renal diseases, including IgAN, HSP, SLE, and the resolving stage of postinfectious glomerulonephritis. The differential diagnosis of these conditions requires correlation of the light, electron, and immunofluorescent microscopic findings with the patient's clinical data. Only IgAN is discussed in this section.

IgA Nephropathy

IgAN (previously called Berger disease) is defined by the predominant deposition of IgA in the glomerular mesangium. The distribution of IgAN varies greatly among different geographic regions of the world. It is the most common primary glomerular disease diagnosed in some Asian countries, including Japan, mainland China, and Singapore, accounting for about one-third of all renal biopsy diagnoses in these regions, 20% in Europe, and 10% in the United States.[289,290] The cause of these wide differences in incidence has partially been attributed to differences in the indication for renal biopsy in Asia when compared to the United States. Familial clustering has been reported in approximately 10% of the patients.[291–293] The familial forms of IgAN follow autosomal dominant transmission with incomplete penetrance. The first-degree relatives without clinical evidence of IgAN have high levels of galactose-deficient IgA (GD-IgA). Genome-wide associated studies using single nucleotide polymorphisms have revealed several susceptibility loci, the most common being MHC locus on 6p21.[294] These studies have also highlighted the role of mucosal defense systems and alternative complement pathway in the pathogenesis of IgAN.[295]

The diagnosis of IgAN is primarily based on the demonstration of IgA deposits in the mesangium, a feature seen in association with several conditions. HSP nephritis and IgAN are two closely related conditions that form part of the syndrome.[296] Mesangial IgA deposition has also been described in association with a variety of diseases, including chronic liver disease, inflammatory bowel disease, connective tissue disorders, neoplastic diseases, and viral and bacterial infections (Box 23.5).[297] IgAN results from the deposition of circulating immune complexes in the glomerular mesangium, leading to the activation of the complement cascade via the alternative pathway. The deposited IgA in idiopathic form is predominantly aberrantly glycosylated polymeric IgA1.[298,299] The serum levels of this GD-IgA are elevated in IgAN patients and this is reportedly an independent risk factor for progression of renal disease.[300] It appears that GD-IgA serves as an autoantigen and the subsequent immune complex deposition stimulates mesangial cell proliferation.

IgAN can occur at any age, but it is more common in the second and third decades.[301] It is uncommon in children under the age of 10.[297] Males are affected two to six times more often than females. Most patients are diagnosed upon detection of microscopic hematuria during routine physical examination. About less than half the patients have a history of recurrent episodes of macroscopic hematuria, one-third of which occurred synchronously or within a few days after a respiratory or, less commonly, a gastrointestinal or urinary tract infection.[297,302] This may be related to increased host IgA response to mucosal antigens. Patients often have proteinuria, which is usually mild though it can on occasion be severe. Roughly 5%–10% develop the nephrotic syndrome. It is currently estimated that 25%–40% of the cases slowly progress to chronic renal failure over a period of 20 years.[303] About 60% of the patients who received transplants experienced recurrence of the disease in the donor kidney and a small percentage of them lose their graft to recurrent disease.[304]

It is now recognized that IgAN may display a wide variety of histologic patterns, ranging from normal or nearly normal to a diffuse crescentic glomerulonephritis.[289,290] Widening of the mesangium by increased matrix and hypercellularity is the most common microscopic finding (Fig. 23.39). The mesangial involvement is often uneven and varies among the glomeruli and glomerular lobules. Healing of the focal proliferative lesion may lead to FSGS. Glomerular scarring is associated with TA and IF. Various classification systems, such as Haas and more recently Oxford, are used to score and characterize the histologic features, and several studies have validated these systems in predicting the renal outcomes.[305–308] By electron microscopy, it is possible to demonstrate mesangial deposits in all glomeruli, indicating that the lesion is diffuse, not focal (Fig. 23.40). On occasion, small subendothelial or subepithelial deposits may also be found, especially in patients with more severe disease.

The immunofluorescence pattern parallels the distribution of the deposits seen by electron microscopy. There is strong diffuse mesangial reactivity for IgA, and it can extend into the capillary loops (Fig. 23.41). IgG is also common and may rival IgA in intensity. About one-third of the cases show weak reactivity for IgM and fibrinogen. C3 reactivity is strong, with a pattern identical to immunoglobulins, but no reactivity for either C1q or C4 is seen, indicating that the complement is activated via the alternative pathway. Deposits of IgA are not limited to the glomeruli in IgAN. They can also be demonstrated in the blood vessels of the superficial dermis of normal-appearing skin in patients with IgAN without systemic manifestations of HSP.[309,310] These findings, together with the

Box 23.5 Entities associated with secondary IgA nephropathy

Liver diseases

Alcoholic cirrhosis, viral hepatitis, toxic liver disease, cystic fibrosis

Gastrointestinal diseases

Crohn disease, ulcerative colitis, celiac disease

Infectious diseases

HIV infection, tuberculosis, brucellosis, leprosy, *Staphylococcus aureus*, *Mycoplasma pneumoniae*, *Clostridium difficile*, *Yersinia enterocolitica*

Rheumatologic diseases

Rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, Behçet disease, Reiter syndrome

Neoplastic diseases

Various carcinomas, including squamous cell carcinomas, small cell lung carcinoma, renal cell carcinoma, and a variety of adenocarcinomas, non-Hodgkin lymphoma, polycythemia vera, mycosis fungoides/Sézary syndrome

Skin diseases

Dermatitis herpetiformis, psoriasis

Miscellaneous diseases

Sarcoidosis, silicosis, bronchiolitis obliterans, uveitis with retinal vasculitis

phenotypic and pathogenetic similarities shared by these conditions, suggest that HSP may be a systemic form of primary IgAN or, conversely, that IgAN is a renal-limited form of HSP.[311,312]

Crescentic Glomerulonephritis

Crescentic glomerulonephritis is a histopathologic term used to designate a severe form of glomerulonephritis in which 50% or more of the glomeruli are involved by epithelial crescents. This type of glomerular injury is associated with a clinical syndrome known as rapidly progressive glomerulonephritis that is characterized by the rapid and progressive loss of renal function accompanied by hematuria, red cell casts in urine, variable degrees of proteinuria, and severe oliguria. Untreated, this disease can result in death within weeks. The terms crescentic glomerulonephritis and *rapidly progressive glomerulonephritis* are often used interchangeably. Like crescentic glomerulonephritis, *extracapillary proliferative glomerulonephritis* is a pathologic term for this lesion which indicates that the cell proliferation is primarily in the Bowman space. All three of the previous terms are considered proper designations for this form of glomerular injury.

Studies using cell markers showed that the crescents are composed of a mixed population of cells primarily consisting of glomerular epithelial cells and macrophages. It has been postulated that crescent formation results from disruption of the glomerular capillaries that allows leukocytes, fibrin, and other plasma proteins to escape into the Bowman space, where they induce epithelial cell proliferation and macrophage maturation that together produce cellular crescents (Fig. 23.42). This is supported by the invariable immunofluorescent finding of fibrin in active crescentic glomerulonephritis (Fig. 23.43) and the demonstration of GBM ruptures that are better visualized on silver-stained histologic preparations or by electron microscopy (Fig. 23.44). As the disease progresses, the extracapillary proliferating cells are transformed into fibroepithelial crescents which incorporate fibroblasts and collagen. Over time, the sclerosis progresses and the glomeruli become completely scarred.

Crescentic glomerulonephritis can be caused by a wide variety of diseases either restricted to the kidney or systemic. Using immunofluorescence and electron microscopy techniques, three main categories that reflect different pathogenic mechanisms have been identified: (1) anti-GBM glomerulonephritis; (2) immune complex crescentic glomerulonephritis; and (3) pauci-immune crescentic glomerulonephritis, usually associated with ANCA (Table 23.4). In each group, the disease may be associated with a known disorder or may be idiopathic.

Antiglomerular Basement Membrane Disease

This form of glomerulonephritis is characterized by the immunofluorescent demonstration of linear deposits of IgG and, in many instances, C3 along the GBM. Anti-GBM disease is a rare autoimmune disease and accounts for 15% of the cases of crescentic glomerulonephritis.[313] It can occur as a renal-limited disease or as a pulmonary renal syndrome induced by a cross reaction of the anti-GBM antibodies with pulmonary basement membranes (Goodpasture syndrome). The incidence of anti-GBM disease has two peaks with respect to patient age.[314,315] The first is in the second and third decades of life, has a male predominance, and a higher frequency of pulmonary involvement (Goodpasture syndrome). The second occurs in the sixth and seventh decades, has a female predominance, and is more often a renal-limited disease.

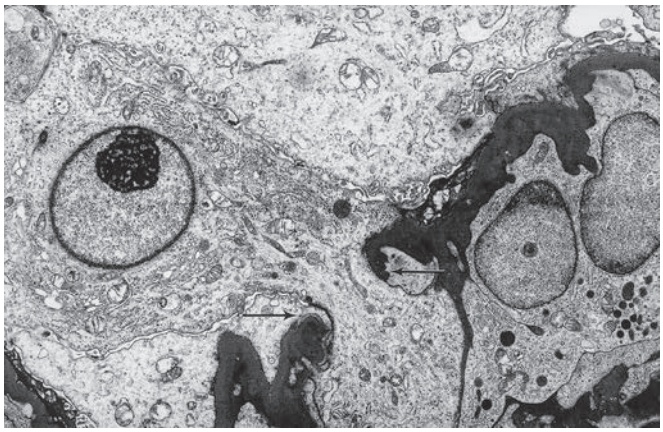

Figure 23.44 Disruption of the glomerular basement membrane *(arrows)* in a case of crescentic glomerulonephritis (×9000).

Renal anti-GBM disease is typically characterized by an abrupt onset of acute glomerulonephritis with severe oliguria or anuria.[315] On rare occasions, however, the onset is more insidious and the patient may remain essentially asymptomatic until the development of uremic symptoms. Patients with Goodpasture syndrome present with glomerulonephritis and pulmonary involvement, which is more often in the form of severe pulmonary hemorrhage. A preceding upper respiratory infection has been documented in about one-fourth of these patients. Pulmonary hemorrhage has also been observed after exposure to various inhalants, particularly hydrocarbons and there is an association with cigarette smoking. The circulating anti-GBM antibodies can be detected by enzyme immunoassay, but the titers do not correlate with disease severity. Treatment includes cytotoxic agents and plasmapheresis, but serum creatinine at presentation greater than 5 mg/dL is associated with poor prognosis.

The principal antigen to which anti-GBM antibodies react is localized to the carboxyl terminus of the NC1 domain of the α3 chain of type IV collagen (Goodpasture epitope).[316,317] It has been suggested that hydrocarbons inhibit the enzyme that catalyzes the formation of sulfilimine bonds between collagen hexamers, thus causing conformational change, neo-epitope exposure, and subsequent autoantibody formation against the Goodpasture antigen.[318,319] Genetic predisposition may play a role, and there is a strong association between certain HLA class II antigens and risk of developing anti-GBM nephritis.

Anti-GBM disease can complicate other diseases. It can arise de novo following renal transplantation in patients with Alport syndrome (AS)[320,321] and has been reported in association with membranous nephropathy preceding, concurrent with, or following this disease.[322,323] Up to one-third of the patients with anti-GBM disease have circulating ANCA, especially with specificity for myeloperoxidase (MPO).[324–326]

Table 23.4 Differential diagnosis of crescentic glomerulonephritis

CATEGORY	ANTI-GLOMERULAR BASEMENT MEMBRANE NEPHRITIS	PAUCI-IMMUNE GLOMERULONEPHRITIS	IMMUNE COMPLEX–MEDIATED GLOMERULONEPHRITIS
Light microscopy	No mesangial or endocapillary proliferation in unaffected glomeruli or tufts	No mesangial or endocapillary proliferation in unaffected glomeruli or tufts	Variable mesangial or endocapillary proliferation typically present
IF (other than fibrinogen in glomerular necrosis)	Linear lace-like staining in GBM (±TBM)	Absent (± nonspecific C3 in glomerular tuft)	Present (varies based on the disease entity)
Electron-dense deposits (on EM)	Absent	Absent	Present
Serology	Anti-GBM antibodies +	ANCA + (in 85% of patients)	ANA, ds-DNA, ASO, cryoglobulins, etc. (based on entity)
Comments	No small vessel vasculitis unless associated with ANCA	Vasculitis may be present	Vasculitis present, but less common than in pauci-immune GN
Other associations and examples	Goodpasture syndrome with pulmonary involvement	Microscopic polyangiitis, granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis	Examples include lupus nephritis, IgA nephropathy, infection-associated GN, cryoglobulinemic GN, membranoproliferative GN

ANA, Antinuclear antibodies; *ANCA*, antineutrophil cytoplasmic antibodies; ASO, antistreptolysin O; *EM*, electron microscopy; *GBM*, glomerular basement membrane; *GN*, glomerulonephritis; *IF*, immunofluorescence microscopy; *TBM*, tubular basement membrane.

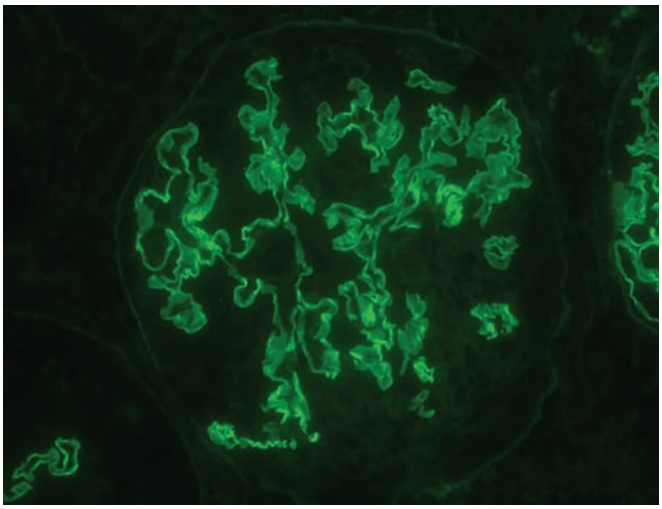

Figure 23.45 Continuous linear IgG reactivity along the capillary walls in a case of anti-GBM glomerulonephritis (anti-IgG).

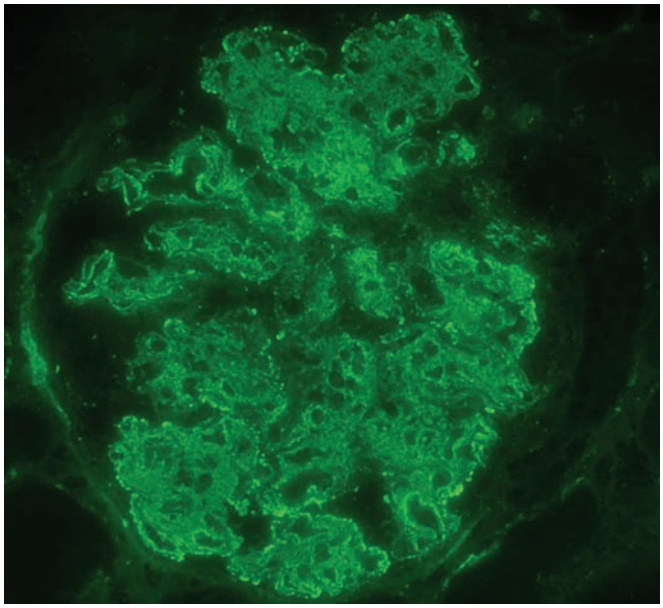

Figure 23.46 Coarse granular deposits of IgG are prominent in the mesangium and along the capillary walls in a patient with crescentic lupus nephritis (anti-IgG).

The presence of ANCA in patients with anti-GBM disease is associated with small vessel vasculitis in various organs in addition to lung and kidney.

The typical light microscopic lesion in renal anti-GBM disease is that of a necrotizing glomerulonephritis with crescent formation either in a focal or diffuse pattern. In the involved areas, the glomerular capillaries are disrupted and clusters of granulocytes are often present, but there is minimal intracapillary cell proliferation. The uninvolved segments may appear normal or slightly infiltrated by leukocytes or mononuclear inflammatory cells. The most severely involved glomeruli may exhibit extensive necrosis, disruption of the Bowman capsule, and intense periglomerular inflammation with multinucleated giant cells. Electron microscopy may demonstrate the presence of a subendothelial lucent zone near foci of necrosis, but this is not a constant or specific feature. Disruptions of the GBM and fibrin deposition can also be seen. An important negative ultrastructural finding in anti-GBM disease is the absence of electron-dense deposits.

Immunofluorescence studies demonstrate a continuous linear immunostaining of the glomerular capillaries for IgG, often accompanied by a focal linear staining for C3 and in several instances both κ and λ (Fig. 23.45). Distal tubules also express α3 chain, and hence, linear tubular basement membrane staining with IgG is not uncommon. It must be kept in mind that a similar IgG immunofluorescence pattern of GBM can be seen in other glomerular lesions, including diabetic nephropathy and HCDD, so it is necessary to confirm the diagnostic impression with the demonstration of circulating anti-GBM antibodies. It is helpful to note that diabetic nephropathy is usually associated with strong linear staining of all basement membranes with albumin in addition to IgG; HCDD has diffuse linear staining of vascular and tubular basement membranes, in addition to GBM, with IgG.

Immune Complex Crescentic Glomerulonephritis

Immune complex crescentic glomerulonephritis represents about 25% of all cases of crescentic glomerulonephritis.[313] It occurs most frequently as a complication of any of the immune complex glomerulonephritides, including postinfectious glomerulonephritis, MPGN, cryoglobulinemic glomerulonephritis, SLE, IgAN, and HSP (Fig. 23.46). In a minority of the cases of immune complex crescentic glomerulonephritis, the underlying cause cannot be determined. These patients are diagnosed as having idiopathic immune complex glomerulonephritis, and underlying infection should always be excluded in these cases. The prognosis of idiopathic immune complex crescentic glomerulonephritis, although poor, is better than that of anti-GBM disease.[313]

The light microscopic features of immune complex crescentic glomerulonephritis depend upon the underlying glomerular disease. The glomerular segments adjacent to the crescents usually present some degree of necrosis, but this is not as extensive as that seen in anti-GBM or pauci-immune glomerulonephritis. An important finding that can help distinguish immune complex crescentic glomerulonephritis from both anti-GBM and pauci-immune crescentic glomerulonephritis is the presence of various combinations of capillary wall thickening and mesangial/endocapillary cell proliferation, features that are typically absent in the latter two types of crescentic glomerulonephritis (Fig. 23.47).[313] Electron microscopy and immunofluorescence allow the confirmation of immune complex deposits, thus establishing the diagnosis of immune complex crescentic glomerulonephritis. The diagnosis of a specific category of immune complex crescentic glomerulonephritis can usually be achieved by the careful correlation of the patient's clinical and laboratory data with light, immunofluorescence, and electron microscopic findings.

Pauci-Immune Crescentic Glomerulonephritis

Pauci-immune crescentic glomerulonephritis is characterized by the absence or minimal staining for immunoglobulin by immunofluorescence. It is the most common form of crescentic glomerulonephritis diagnosed by renal biopsy (about 60% of the cases), more frequently affects elderly individuals, and is equally distributed between the genders.[313,327]

Pauci-immune crescentic glomerulonephritis can occur as a renal-limited disease or as a component of systemic necrotizing small vessel vasculitis. Constitutional symptoms include fever, arthralgias, and myalgias, and the extrarenal manifestations in systemic disease vary by the organ/s affected. Patients with pauci-immune

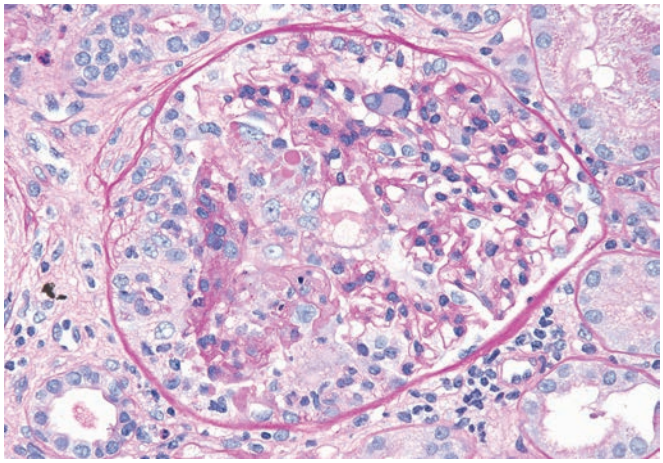

Figure 23.47 Destruction of the capillary tuft by a cellular crescent in a patient with pauci-immune glomerulonephritis. It is characterized by the absence of deposits on immunofluorescence, and note the lack of mesangial or endocapillary proliferation in preserved portions of the capillary tuft.

crescentic glomerulonephritis tend to respond better to treatment than those with anti-GBM glomerulonephritis and, therefore, have a better prognosis. Treatment options for remission induction include steroids, cyclophosphamide, and rituximab, and disease relapses are not uncommon.[328–330]

Approximately 80%–90% of pauci-immune crescentic glomerulonephritis cases occur in ANCA-positive patients.[328] ANCAs have been recognized as serologic markers for pauci-immune glomerulonephritis with or without evidence of extrarenal disease.[331,332] By indirect immunofluorescence with ethanol-fixed neutrophils as substrate, two distinct immunostaining patterns have been recognized: cytoplasmic (C-ANCA) and perinuclear (P-ANCA). Enzyme-linked immunosorbent assay (ELISA) has shown that most C-ANCA– and P-ANCA–positive sera recognize proteinase 3 (PR3), which is a serine protease of 29 kDa, and MPO, respectively. Both are localized to the azurophilic granules of the neutrophils and monocytes, are translocated to the cell surface during cell activation, and are thus able to interact directly with circulating ANCA. Subsequent activation of cell signal transduction pathways and alternative complement pathway facilitate leukocyte adhesion to endothelial cells and vessel damage. Patients with pauci-immune crescentic glomerulonephritis without evidence of extrarenal vasculitis most often have P-ANCA/MPO-ANCA, those with granulomatosis with polyangiitis (GPA) most often have C-ANCA/PR3-ANCA, while those with microscopic polyangiitis have approximately an equal incidence of P-ANCA and C-ANCA.[328] The potential triggers for ANCA production include immune dysregulation, molecular mimicry of microbial factors, and drugs such as propothiouracil, hydralazine, penicillamine, minocycline, and others. Genetic predisposition may play a role as evidenced by HLA class II associations, frequency of certain gene polymorphisms and presence of epigenetic alteration of MPO and PR3 surface expression.[333] Approximately 10%–20% of pauci-immune glomerulonephritis patients lack ANCA, and other less frequent autoantibodies may have potential pathogenic role.[334,335] These include anti-LAMP2 (lysosomal-associated membrane protein-2), anti-moesin, and anti-plasminogen antibodies. Serum complement levels are typically normal in pauci-immune glomerulonephritis, but recent studies have highlighted the role of alternative complement pathway in the pathogenesis of this disease.[336] Cell mediated immune mechanisms also seem to play a role in the development of crescentic lesions.[328]

The light microscopic appearance of pauci-immune crescentic glomerulonephritis is indistinguishable from that of anti-GBM disease (see Fig. 23.47). Immunofluorescence studies may reveal small irregular focal staining for C3. Fibrinogen is frequently found in the crescents or in the necrotic areas of the glomerular tuft. Electron microscopy often demonstrates ruptures of the GBM as well as fibrin deposition. The absence of immune complex deposits differentiates pauci-immune crescentic glomerulonephritis from immune complex crescentic glomerulonephritis.

Lupus Nephritis

SLE is a multisystem, autoimmune disease with a broad range of clinical presentation that has a high morbidity and mortality. The American Rheumatism Association has established diagnostic criteria for this condition based on clinical and serologic manifestations.[337] SLE can affect adults as well as children; two-thirds of patients present symptoms between 16 and 30 years of age. In children, SLE usually occurs in adolescence; it is uncommon before the age of 10 and very rare before the age of 5.[338,339] It is 10 times more common in females than males, with black females being affected more frequently than white. A drug-induced lupus-like disease, most commonly linked with hydralazine, procainamide, isoniazid, methyldopa, chlorpromazine, and quinidine, has also been recognized.[340,341] The renal lesions in these cases are similar to those seen in spontaneous SLE.

Serum antinuclear antibodies (ANAs) are detected in over 95% of patients and their presence is a sensitive marker of SLE, while anti-double-stranded DNA and anti-Sm antibodies are more specific markers. Other notable antibodies detected in SLE patients include antiphospholipid antibodies, ADAMTS13, and lupus anticoagulant.[342] There is a genetic predisposition for developing SLE, and recent genome-wide association studies have identified polymorphisms in several immunity-related genes that confer an increased risk.[343,344] This extensive loss of self-tolerance to a variety of intrinsic antigens in genetically susceptible individuals can be triggered by environmental factors such as ultraviolet light, estrogens, and drugs.

Immune-mediated nephritis is a common complication of SLE. The immune deposits in the kidney (and elsewhere) are derived from either circulating complexes or from an *in situ* combination of antigen and antibody.[342] Complement activation follows along with inflammatory response and organ damage. Immune-complex deposition is the most common form of glomerular injury, but immune deposits are absent in lupus-associated thrombotic microangiopathy (TMA) and podocytopathies (such as MCD) and the injury in these settings is antibody mediated. It appears that the tubulointerstitial inflammation in SLE is more T-cell mediated.

Clinical evidence of renal involvement, as determined by urinalysis, or impaired renal function is seen in approximately 40%–80% of unselected patients with SLE. It is likely, however, that clinical assessment underestimates the actual frequency since histologic evidence of renal disease may be present even when the urinalysis is essentially normal. The clinical spectrum of lupus nephritis is wide, encompassing the acute nephritic syndrome, the nephrotic syndrome, acute and chronic renal failure, and isolated abnormalities in the urinary sediment. The most constant feature found in nearly all patients with clinical lupus nephritis is proteinuria. Microscopic hematuria is almost always present, but rarely does it develop in isolation; macroscopic hematuria is rare.

A kidney biopsy is essential in the renal assessment of patients with SLE and is indicated in all patients with abnormalities of urine sediment or renal function. In patients with these abnormalities, the clinical presentation does not accurately predict the disease

Table 23.5 International Society of Nephrology/Renal Pathology Society classification of lupus nephritis

CLASS	PATHOLOGY DIAGNOSIS	DESCRIPTION
I	Minimal mesangial LN	Normal by LM, mesangial deposits by IF and EM
II	Mesangial proliferative LN	Mesangial proliferation on LM, mesangial deposits by IF and EM
III	Focal LN (<50% of glomeruli)	Active or chronic lesions by LM in <50% glomeruli, usually subendothelial (in addition to mesangial) deposits by IF and EM
III (A)	Active lesions	Active lesions include endocapillary proliferation, cellular crescents, karyorrhexis/necrosis, neutrophils, and wire loops
III (A/C)	Active and chronic lesions	
III (C)	Chronic lesions	Chronic lesions include segmental or global glomerulosclerosis attributable to LN, and fibrous crescents
IV	Diffuse LN (≥50% of glomeruli)	Active or chronic lesions by LM in >50% glomeruli, usually subendothelial (in addition to mesangial) deposits by IF and EM
IV (A)	Active lesions	Subclassification of active lesions as S (segmental) or G (global) based on extent of glomerular tuft affected
IV (A/C)	Active and chronic lesions	
IV (C)	Chronic lesions	Subclassification of chronic lesions as S (segmental) or G (global) based on extent of glomerular tuft affected
V	Membranous LN	Subepithelial deposits present by LM, IF, and EM; can co-exist with class III or IV
VI	Advanced sclerosing LN (≥90% globally sclerosed glomeruli without residual activity)	Global glomerulosclerosis attributable to LN

EM, Electron microscopy; *IF*, immunofluorescence microscopy; *LN*, lupus nephritis.

severity and the renal biopsy findings provide prognostic information and aid in the formulation of the treatment plan.

The pathologic findings of lupus nephritis are extremely diverse and may occur in all four renal compartments: glomeruli, tubules, interstitium, and blood vessels. This diversity may be the result of differences in the immune response in different patients or in the same individual over time. Standardized histologic classification of lupus nephritis developed by the International Society of Nephrology (ISN)/Renal Pathology Society (RPS)[345] provides clear definitions for diagnostic categories based on quantitative assessment of individual histologic lesions. This classification has preserved some of the basic structure of earlier WHO classifications[346–348] but has successfully eliminated some of the ambiguities that existed in the WHO classifications. The ISN/RPS classification defines six major classes (Table 23.5) and several published studies have shown a significant improvement in interobserver reproducibility and in predicting renal outcome when this classification is used.[349–352]

As per the ISN/RPS classification, class I (minimal mesangial lupus nephritis) comprises those cases in which the glomeruli appear normal by light microscopy but show immune complex deposits by immunofluorescence and/or electron microscopy. Patients with class I nephritis usually manifest mild microscopic hematuria and/or mild proteinuria, and renal function is typically normal.

Class II (mesangial proliferative lupus nephritis) is defined by any degree of mesangial hypercellularity and/or mesangial matrix expansion as seen by light microscopy, accompanied by the demonstration of mesangial immune complex deposits by immunofluorescence and electron microscopy (Fig. 23.48). The classification allows for the presence of rare minute subepithelial or subendothelial deposits identifiable only by electron microscopy or immunofluorescence, but not by light microscopy. Clinically, majority of patients have mild renal involvement as demonstrated by an inactive urine sediment. Less than 50% of the patients have mild hematuria and/or proteinuria, which usually does not exceed 1 g per 24 hours. The nephrotic syndrome is exceedingly rare, and, when present, it may be a manifestation of concomitant MCD.[353,354]

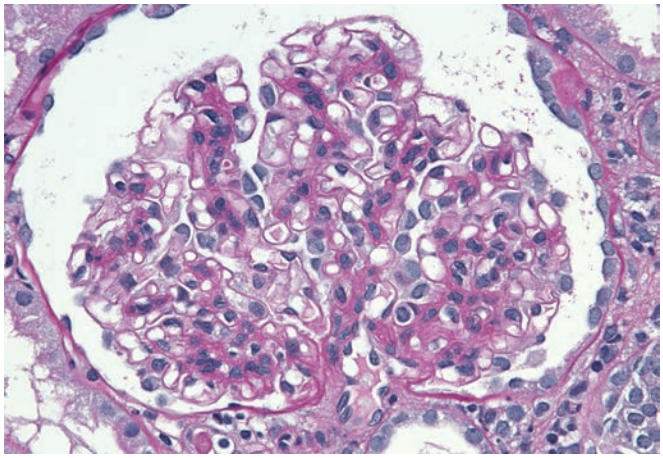

Figure 23.48 Lupus Nephritis, ISN/RPS Class II. There is mild diffuse mesangial hypercellularity and an increase in matrix. Mesangial deposits can be identified by immunofluorescence and electron microscopy.

Class III (focal lupus nephritis) is defined as focal segmental and/or global endocapillary, and/or extracapillary glomerulonephritis affecting less than 50% of the glomeruli. The biopsy may reveal a variable admixture of proliferative, necrotizing, and sclerosing lesions. The less affected glomeruli usually exhibit a diffuse mesangial prominence as seen in class II. The segmental proliferative lesions may be associated with leukocyte infiltration, fibrinoid material, and necrotic debris (Fig. 23.49A). Focal areas of necrosis containing fragmented nuclei known as hematoxylin bodies may be present (see Fig. 23.49B). These structures are considered pathognomonic

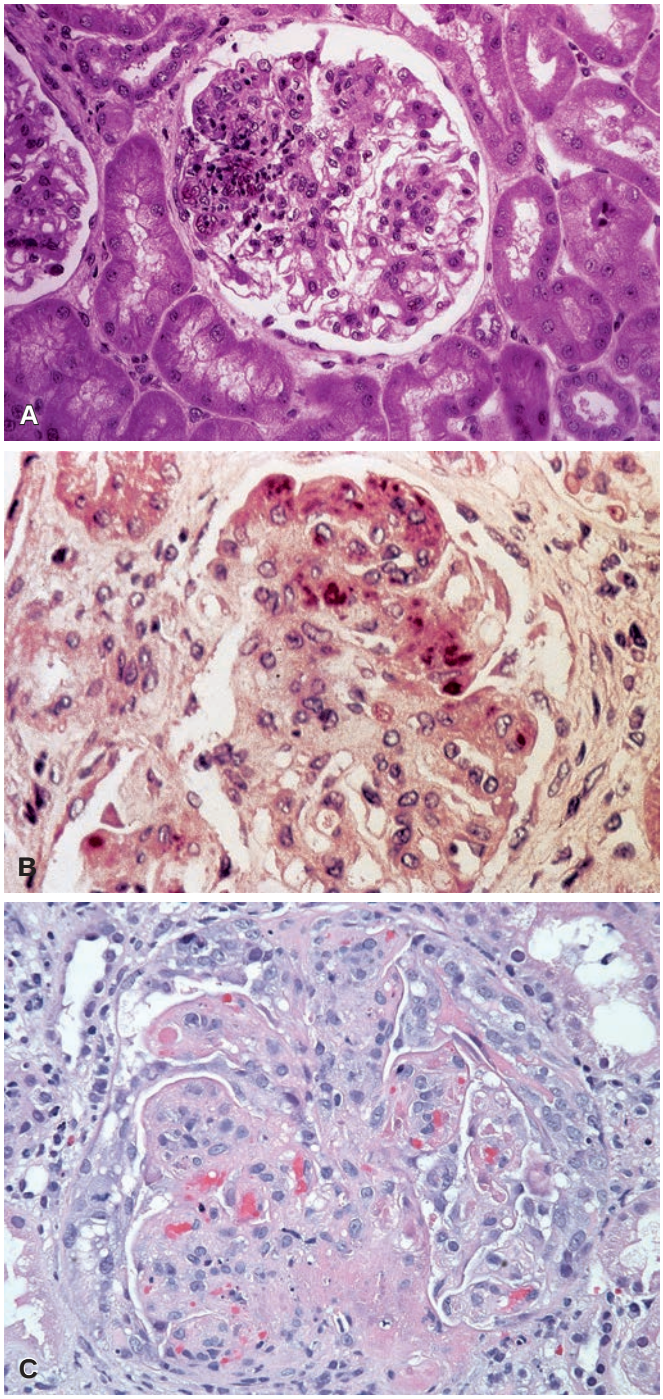

Figure 23.49 Lupus Nephritis, International Society of Nephrology/Renal Pathology Society Class III. A, There is focal and segmental glomerulonephritis characterized by segmental necrosis, adhesions to the Bowman capsule, and leukocytic infiltration. **B,** A glomerulus with a well-circumscribed area of necrosis containing numerous small hematoxylin bodies. **C,** Glomerulus with necrosis, fibrin extravasation, and a cellular crescent.

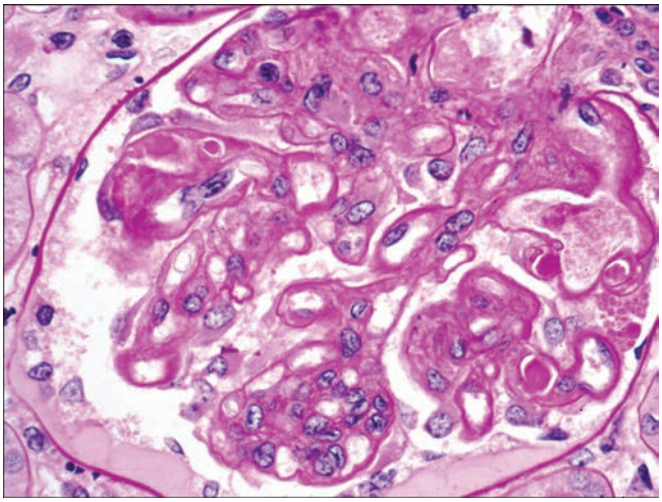

Figure 23.50 Lupus Nephritis, ISN/RPS Class IV. Glomerulus from a patient showing several wire loops (subendothelial deposits) and intraluminal hyaline thrombi (deposits) (PAS).

of lupus nephritis but are found in only 1%–2% of renal biopsies from these patients.[342] They range considerably in size from minute fragments to round masses approximately the size of the nucleus and have a characteristic lilac tinge on H&E-stained sections.[342,355] The segmental necrotic lesions may be associated with cellular crescent formation (see Fig. 23.49C) and tend to resolve by segmental sclerosis with focal capsular adhesions or the development of fibrous crescents. Despite the focal nature of the lesion by light microscopy, immunofluorescence generally reveals a more diffuse deposition of immunoglobulins and complement. Electron microscopy often demonstrates deposits in the mesangial and subendothelial regions, and, less frequently, in the subepithelial areas. In the ISN/RPS classification, III (A) refers to active lesions, III (C) refers to healed, chronic, inactive lesions, and III (A/C) indicates a combination of active and chronic lesions. The proportion of glomeruli affected by active or healed lesions should be included in the diagnostic report. The clinical picture of patients with class III lupus nephritis is quite variable. Approximately half of the patients have active urinary sediment, and about 50% have proteinuria, which may be in the nephrotic range in up to one-third of the cases. Renal insufficiency is rather uncommon and occurs in 10%–25% of the patients.

Class IV (diffuse lupus nephritis) is defined as diffuse segmental and/or global endocapillary and/or extracapillary glomerulonephritis affecting 50% or more of the glomeruli included in the biopsy. The lesions in this class are identical to class III but tend to be diffuse and more global, and the immune complexes are more abundant. It has been suggested that classes III and IV lupus nephritis are ends of a pathologic continuum since the differences between these classes are quantitative rather than qualitative. The immune deposits in the subendothelial areas may produce marked thickening of the capillary walls to form the characteristic "wire loop" lesions (Fig. 23.50). On occasion, the capillary lumina can be occluded by massive deposition of immune complexes ("hyaline thrombi"). Immunofluorescence studies often reveal more than one class of immunoglobulin in a coarse granular pattern in the mesangium and peripheral capillary walls in all glomeruli. IgG is almost invariably present, but IgM and IgA are also frequently found. Both C3 and C1q are frequently found and the staining for C1q is particularly strong. When all immunoglobulins and complement components are present, the pattern is often referred to as "full house," an immunofluorescent profile seen in all lupus classes and is considered characteristic of lupus nephritis (Fig. 23.51). Reactivity for fibrin and fibrinogen are commonly seen in crescentic and necrotizing lesions. Electron microscopy demonstrates large subendothelial electron-dense deposits usually accompanied by mesangial and sometimes subepithelial and/or intramembranous deposits (Fig. 23.52A). Subendothelial deposits are primarily found in proliferative lupus nephritis (classes III and

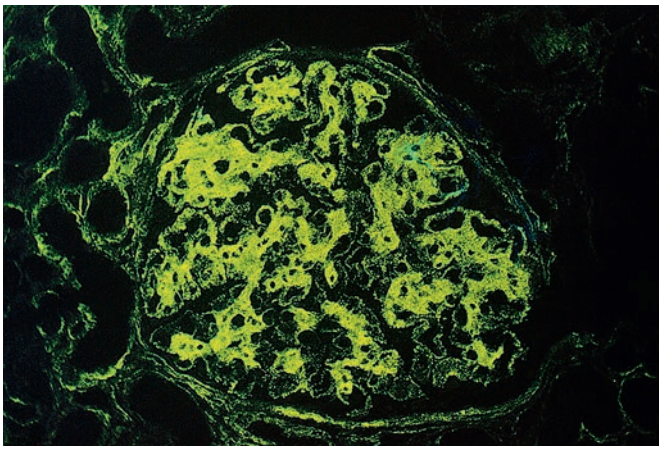

Figure 23.51 Immunofluorescence showing large amounts of granular immune complex deposits not only in the mesangium and glomerular capillary loops, but also along tubular basement membranes, interstitium, blood vessels, and Bowman capsule (anti-IgG).

IV) and are considered to be a marker of activity.[356] On occasion, electron-dense deposits may show a distinctive fingerprint-like crystalline pattern, possibly representing cryoglobulins (see Fig. 23.52B).[357] This substructure, although nonspecific for lupus nephritis, are usually associated with class IV lesion. The endothelial cells may be swollen and contain tubuloreticular inclusions (see Fig. 23.52C). Studies have demonstrated that these *myxovirus-like* structures are inducible *in vitro* in normal lymphocytes on exposure to interferon alpha, earning them the descriptive term "interferon footprints."[358] The ISN/RPS classification subdivides class IV lupus nephritis into those cases with diffuse segmental versus diffuse global proliferations. The designation IV-S is used if over 50% of the involved glomeruli exhibit segmental lesions; the designation of IV-G is used if over 50% of affected glomeruli show global lesions. This subdivision is rather arbitrary and of unclear significance but was included to further investigate possible differences in outcome and pathogenesis between these subgroups.[359] The clinical symptoms in patients with class IV lesions are quite severe and may include nephrotic range proteinuria and active urine sediment. Without therapy, these patients are considered to have the worst prognosis since a high percentage progress rapidly to renal failure.

Class V (membranous lupus nephritis) is defined by the presence of global or segmental continuous subepithelial immune complex deposits or their morphologic sequelae by light microscopy. The membranous changes may occur alone or with a background of mesangial hypercellularity and mesangial immune complex deposits. Small subendothelial deposits can be identified by immunofluorescence or electron microscopy but not by light microscopy. The peripheral glomerular capillary walls often appear diffusely thickened (Fig. 23.53) and the so-called spike and dome pattern may be demonstrated on silver methenamine stain. By electron microscopy, the GBM shows the same ultrastructural stages seen in idiopathic MGN. However, in contrast to this condition, mesangial deposits are commonly found in membranous lupus nephritis patients. Virtually all patients have proteinuria at presentation, and 60%–70% have the nephrotic syndrome. About 50% of the patients have hematuria.

Class VI (advanced sclerosing lupus nephritis) is defined by global glomerulosclerosis affecting over 90% of the glomeruli without residual activity. In less advanced lesions, mesangial and endocapillary hypercellularity may be seen and small amounts of immune complex deposits can be detected by immunofluorescence or electron

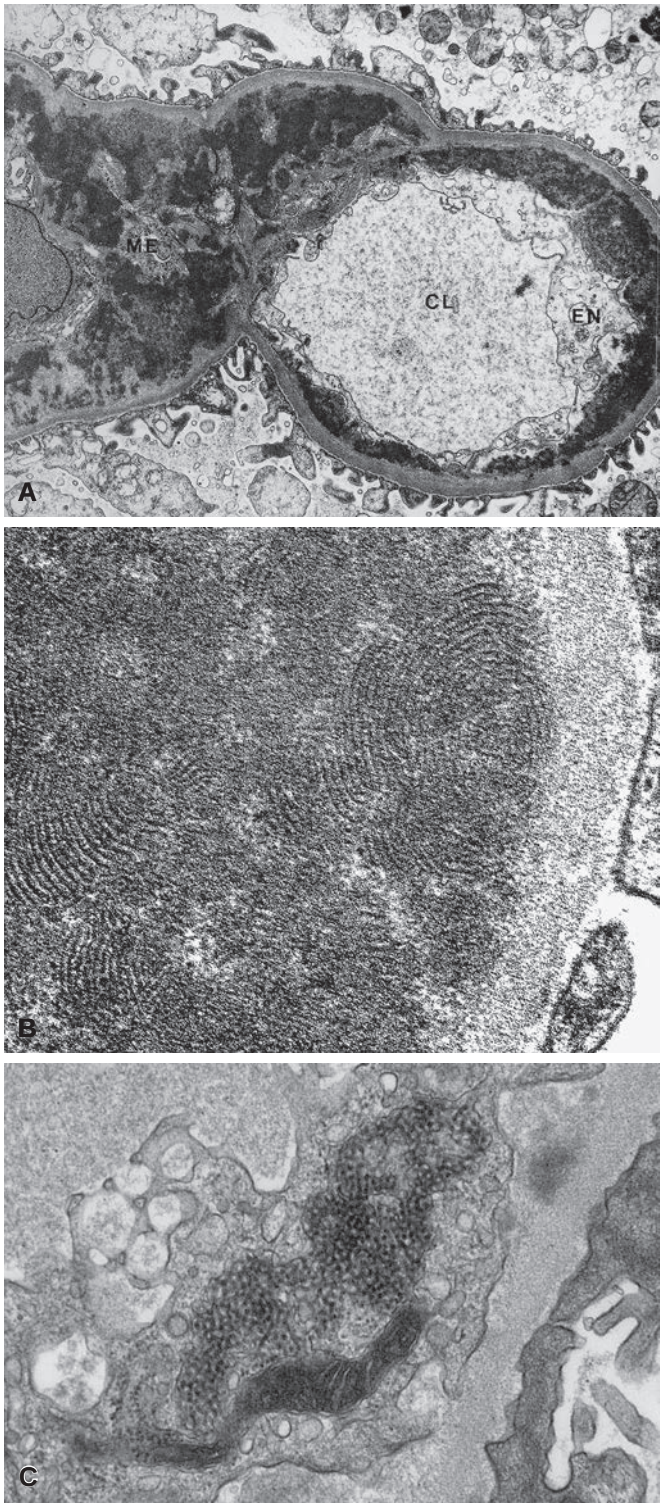

Figure 23.52 **A,** Capillary loop showing marked accumulation of deposits in the mesangium and subendothelial regions. The deposits in the latter location represent the wire loop seen by light microscopy. *CL*, Capillary lumen; *EN*, endothelial cell; *ME*, mesangium (×7000). **B,** Subendothelial deposits displaying a fingerprint-like pattern (×77,000). **C,** Tubuloreticular inclusions in an endothelial cell (×30,000).

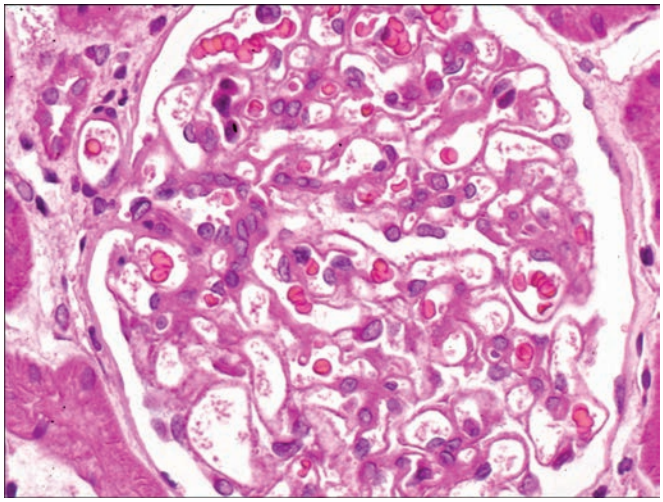

Figure 23.53 Lupus Nephritis, ISN/RPS Class V. The capillary walls are thickened and the mesangial matrix is segmentally increased.

microscopy in the mesangium and thickened capillary walls. Severe TA, IF, inflammation, and arteriosclerosis are usually present. Patients with class VI lesions often have significant proteinuria and severe renal insufficiency and are unlikely to respond to immunosuppressive therapy.

While most cases of lupus nephritis fall into the above categories, some overlap between classes exists. The most common involves classes III and V, and IV and V, and have been designated as combined classes III + V, and IV + V. The transformation of lupus nephritis lesions from one class to another is not uncommon over the course of the disease. It has been reported in 10%–50% of patients who undergo successive renal biopsies,[360,361] and it has occurred between all morphologic types: focal to diffuse,[362] focal to membranous, diffuse to membranous,[363] membranous to diffuse proliferative, and membranous to membranous with focal proliferative lesions.[361,364,365]

Tubulointerstitial inflammation can be found in all classes of lupus nephritis, even in those with minimal glomerular lesions.[360] Severe active TIN is most frequently seen in patients with classes III and IV lupus nephritis, is important in disease progression, and should be adequately assessed.[366,367] In most instances, the interstitial inflammatory infiltrate is composed of mononuclear leukocytes, including lymphocytes, monocytes, and plasma cells, although neutrophils and eosinophils can sometimes be seen. In severe cases, there is inflammatory infiltration of the tubules and the tubular epithelial cells present degenerative and regenerative changes. Tubular casts made of neutrophils, erythrocytes, and shed tubular epithelial cells may be seen in the most severe cases. In about 50% of the patients, immunofluorescence and electron microscopy can demonstrate granular immune deposits along the peritubular capillaries, basement membranes of the proximal convoluted tubules, and interstitium (see Fig. 23.51). These deposits occur more frequently in diffuse lupus nephritis than in the focal variant but may also be found in patients with membranous and mesangial proliferative forms. Lupus nephritis is one of the few renal diseases in which immune deposits can be found not only in the glomeruli but also in the extraglomerular sites. The severity of the tubulointerstitial inflammation roughly correlates with the glomerular proliferative lesions; however, a few cases of severe tubulointerstitial damage without the significant glomerular disease leading to acute renal failure have been reported.[368,369]

Renal vascular lesions are relatively common in SLE and can assume a variety of morphologic forms, including uncomplicated vascular immune deposits, noninflammatory necrotizing vasculopathy, true vasculitis with leukocyte infiltration and necrosis of the vessels walls, and TMA. All these vascular changes are signs of poor prognosis and, thus, should be recognized but are not currently included in histologic classification or activity and chronicity indices.[370]

Some authors have proposed that histologic indices derived from the semiquantitative analysis of activity and chronicity in renal biopsies of patients with SLE have a prognostic value and can serve as a therapy guide.[371] The activity index is calculated by the assessment of the following six histologic parameters: glomerular endocapillary proliferation, glomerular leukocyte infiltration, wire loop deposits and hyaline thrombi, glomerular fibrinoid necrosis and karyorrhexis, cellular crescents, and interstitial inflammation. The severity of each of these features is scored on a scale of 0 to 3+, and the fibrinoid necrosis/karyorrhexis and cellular crescents scores are doubled. Thus, the maximum activity score is 24. The chronicity index is computed by the sum of individual scores (0–3+) of the following four parameters: global glomerulosclerosis, fibrous crescents, TA, and IF. Thus, the maximum chronicity score is 12. Although the validity and the reproducibility of activity and chronicity indices have been questioned,[372] these indices help guide the management of individual cases as they provide useful information about the efficacy of therapy and the potential reversibility of the renal lesions.

Although in the past the recurrence of lupus nephritis after renal transplantation was reported to be rare, affecting only 1%–4% of the allografts, more recent studies indicate that the recurrence rate is higher (ranging from 8% to 30%) than was previously believed.[373–375]

Glomerular Lesions Associated With Vascular Diseases

Systemic Vasculitis

Vasculitis may occur in a variety of conditions, particularly in connective tissue diseases such as SLE and rheumatoid arthritis, and in hypersensitivity reactions caused by infections and drug reactions. Vasculitis may also occur as the primary manifestation of a variety of clinical conditions known as idiopathic systemic vasculitides. Clinical symptoms depend on the organ distribution, the size of the affected vessels, and the severity of the inflammation. The kidneys can be affected in different ways in systemic vasculitis. Large vessel vasculitides, such as giant cell (temporal) arteritis and Takayasu disease, can produce narrowing of the renal arteries, resulting in renal ischemia and hypertension. Medium-sized vessel vasculitides, such as polyarteritis nodosa (PAN) and Kawasaki disease, can affect intrarenal arteries and cause infarction and hemorrhage, whereas in small vessel vasculitides, such as microscopic polyangiitis (previously microscopic polyarteritis), GPA (previously Wegener granulomatosis), eosinophilic GPA (previously Churg–Strauss syndrome), HSP, and cryoglobulinemic vasculitis, the renal involvement is often manifested by glomerulonephritis.[376]

The vasculitides differ not only in their clinical and pathologic characteristics but also in their presumed pathogenesis. The large vessel vasculitides are supposedly caused by cell-mediated immune reactions to poorly defined (auto) antigens.[377] Immune complexes are involved in the pathogenesis of some small vessel vasculitides, such as HSP and cryoglobulinemia, whereas vasculitic lesions associated with microscopic polyangiitis, GPA, and eosinophilic GPA lack immune complexes and because of this, are collectively designated pauci-immune necrotizing vasculitides. Pauci-immune vasculitides are characterized by the presence of ANCA, which are valuable serologic markers for the diagnosis and monitoring of this group of vasculitides.[378,379] There is also evidence that ANCA are directly involved in the pathogenesis of these conditions.[380,381] Some of the

diseases in which vasculitis appears to be the primary histopathologic lesion will be discussed in this section.

Polyarteritis Nodosa

PAN is a primary vasculitis of largely unknown etiology that affects muscular medium-sized arteries and produces lesions of varying stages (acute and healed) with aneurysm formation. The kidneys and gastrointestinal tract are among the organs most commonly affected, while the lungs are usually spared. The clinical manifestations are related to ischemia and disease severity of the involved organ.[382] Peripheral neuropathy has been reported in approximately 75% of the cases.[383] The estimated incidence is two to three cases per million.[384] Males are affected twice as often as females, and the peak incidence is in the sixth decade of life. There is no serum marker for PAN and, by disease definition, there should be no glomerular or other capillary involvement in classic PAN.[376] ANCA serology is typically negative unless there is a rare clinical overlap with microscopic polyangiitis.[385] About one-third of the patients may be carriers of the hepatitis B virus.[386,387] It has also been reported in hepatitis C and HIV-infected patients.[388] Recently mutations in *CECR1*, a gene encoding adenosine deaminase 2, an adenosine inactivating extracellular enzyme, have been detected in familial form of PAN with autosomal recessive inheritance.[389]

The kidneys are involved in 80%–90% of the cases.[382] Renal infarctions occur frequently and may be manifested by loin pain and hematuria. Hypertension is common and may be severe or malignant.[390] The renal lesion in PAN is a necrotizing vasculitis that involves medium-sized muscular arteries, such as the renal, interlobar, and arcuate arteries (Fig. 23.54). The lesions are quite focal and tend to localize to the bifurcations, and weakening of the vessel wall leads to the formation of aneurysmal dilations, detectable on Doppler ultrasonography or CT angiography. The inflammatory process may involve part of or the entire vessel wall and is characterized by fibrinoid necrosis and leukocytic infiltration, sometimes associated with intraluminal thrombosis. The acute phase evolves into a healing phase in which the necrosis subsides and the leukocytic inflammation is replaced by mononuclear infiltrate. In the healed stage, there is fibrosis of the media and perivascular tissue, disruption of elastic lamina, and recanalization of the thrombosed vessels.[391,392]

Because of the focal nature of the vessel lesion and involvement of medium-sized vessels, evidence of vasculitis may not be seen on a needle biopsy. The glomeruli show changes associated with ischemia consisting of variable degrees of collapse and sclerosis of the tufts; glomerular necrosis or crescents are not a feature of typical PAN. Immunofluorescence and electron microscopy typically do not reveal evidence of immune complex deposits.[391]

Microscopic Polyangiitis

Microscopic polyangiitis, formerly known as microscopic polyarteritis, is a necrotizing systemic vasculitis with few or no immune complexes (pauci-immune) that affects small vessels (capillaries, venules, and arterioles) (Fig. 23.55). Involvement of small and rarely medium-sized arteries can also occur, but this is not a constant feature.[393] Because of the absence of arterial involvement in many cases, and the frequent involvement of venules, arterioles, and capillaries (including glomeruli), the term microscopic polyangiitis is now considered more appropriate for this form of vasculitis than the designation of microscopic polyarteritis.[394] Microscopic polyangiitis is distinct from PAN, is mediated by ANCA, and falls under the category of pauci-immune glomerulonephritis/vasculitis.[376] The incidence of microscopic polyangiitis is approximately 1 per 100,000.[395] Males are affected slightly more than females, and although it can occur at any age, it is more frequent during the sixth decade of life. Clinical manifestations are quite varied and nonspecific. Depending upon the organ(s) affected, the most common clinical features are hematuria and proteinuria, hemoptysis, palpable purpura, abdominal pain, myalgias, and arthralgias. Hypertension may occur, but it is usually mild. About 80%–90% of the patients have renal involvement.[396] In contrast to PAN, however, the lungs are commonly affected in microscopic polyangiitis.[397] A frequent clinical presentation of microscopic polyangiitis is as pulmonary–renal syndrome. This syndrome raises the possibility of anti-GBM disease (Goodpasture syndrome); however, the demonstration of ANCA in microscopic polyangiitis or anti-GBM antibodies in anti-GBM disease will establish the correct diagnosis. Over 80% of patients have detectable ANCA, most often P-ANCA (and anti-MPO). In addition to ANCAs, a recent study suggested a pathogenic role for anti-moesin antibodies in MPO-ANCA-associated vasculitis.[335] In the kidney, the most frequent lesion is glomerulonephritis, and the glomerular involvement ranges from a focal and

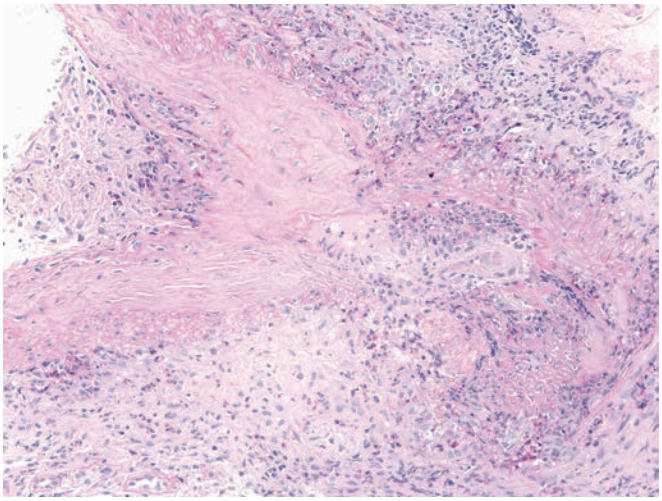

Figure 23.54 Transmural vasculitis and fibrinoid necrosis involving a medium-sized artery, likely an interlobar artery, in polyarteritis nodosa. The glomeruli sampled in the kidney biopsy lacked crescents.

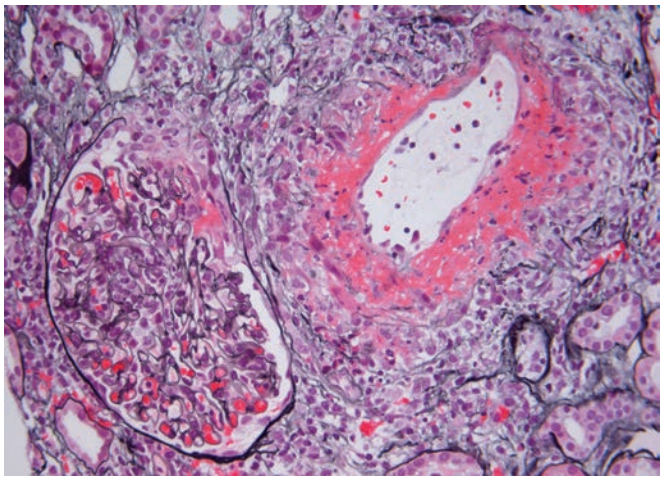

Figure 23.55 Renal biopsy from a patient with microscopic polyangiitis showing a small vessel with necrosis and inflammatory infiltrate. The glomerulus has a segmental area of necrosis, and an early crescent (methenamine silver). (Image courtesy Megan Troxell, MD, PhD.)

segmental necrosis to a severe diffuse crescentic glomerulonephritis (see Fig. 23.55).[395,396] When present, necrotizing arteritis most often affects the interlobular arteries and rarely arcuate arteries.[397] Histologically, vasculitis in microscopic polyangiitis may be indistinguishable from that seen in PAN. However, in contrast to the lesions seen in PAN, which are usually in varying stages of evolution, those in microscopic polyangiitis almost invariably appear to be temporally uniform; glomerular involvement indicates a diagnosis of microscopic polyangiitis.[398] A tubulointerstitial infiltrate including eosinophils is frequently present. Immune complex deposits are not usually seen in the glomeruli, though there have been reports of sparse deposits containing IgG or IgM with C3 in various intraglomerular locations.[398]

Granulomatosis With Polyangiitis

GPA (previously known as Wegener granulomatosis) is a multisystem disease of unknown etiology characterized by the triad of: (1) necrotizing granulomatous inflammation involving the upper respiratory tract (ear, nose, throat, and sinuses) and/or lungs; (2) necrotizing vasculitis affecting small- to medium-sized vessels (capillaries, venules, arterioles, and arteries) most prominently in the lungs and upper airways but also involving other sites as well; and (3) renal disease, most often manifested in the form of focal necrotizing glomerulonephritis.[399] Those patients who do not manifest the full triad are considered to have limited GPA. In these cases, involvement is limited to the respiratory tract and the kidneys are unaffected. The prevalence of GPA in the United States has been estimated to be 3 per 100,000,[400] with slight male predominance. It may occur at any age, but it is more common in the fourth and fifth decades.[401] The first clinical indication is usually upper respiratory symptoms which are followed by systemic phenomena related to the vasculitis.[402] About 80%–85% of patients present some signs of renal involvement, usually simultaneously with other clinical features,[403] but fewer than 20% actually present with renal functional impairment. Patients with renal involvement, if untreated, usually have a rapidly progressive and fatal disease. Therapy with cyclophosphamide, rituximab, and corticosteroids produces remission in most patients, but up to 50% of the patients may relapse.[329,403]

The differentiation of GPA from other types of vasculitis can be difficult clinically and morphologically. A positive ANCA test, especially C-ANCA (and/or PR3), can be extremely helpful in establishing or supporting the diagnosis of GPA. The specificity of C-ANCA in biopsy-proven GPA has been shown to be about 90%. The sensitivity depends upon the extent and activity of the disease. Although it has been shown that serum levels parallel the clinical activity of the disease[404] and that rising levels may be used as a predictor of relapse, there are some patients in whom C-ANCA titers do not follow disease activity.[401,403] The pathogenic role of ANCA with specificity to PR3 has been previously well established,[399] but recent studies have pointed to several pathways involving cell-mediated processes, neutrophil traps, and inflammatory mediators mediating tissue injury in GPA.[405]

The most common renal lesion is focal necrotizing glomerulonephritis, often with crescents.[406] Granulomatous glomerulonephritis occurs but it is uncommon, even in autopsy series, and is usually accompanied by necrosis of the hilar arterioles.[407] Necrotizing vasculitis involving the arterioles and small arteries occurs, but it is not a common finding in kidney biopsies. Interstitial inflammatory infiltrates are common, but necrotizing granulomata are rarely seen in renal biopsy specimens.[403]

As a rule, immune complex deposits are absent in GPA by electron microscopy, though there have been reports of the occurrence of sparse electron-dense deposits at different sites in the glomerulus.[406,408] Immunofluorescence shows fibrinogen in glomeruli and the walls of involved vessels, and small amounts of IgM and/or IgG and C3 have been reported in glomeruli and vessels.

Eosinophilic Granulomatosis With Polyangiitis

Eosinophilic granulomatosis with polyangiitis (EGPA), also known as Churg–Strauss syndrome or allergic granulomatosis, is a rare disorder characterized by asthma, eosinophilia, and systemic vasculitis affecting small- to medium-sized vessels.[409,410] The syndrome has no gender predilection, and while it has been reported in all ages, the mean age at diagnosis is approximately 50 years.[411–414] Renal involvement can be seen in 50% or more of these patients.[411–413] Patients with EGPA often have elevated IgE levels in their serum, and ANCA positivity (P-ANCA and anti-MPO) has been reported in 40%–80% of the cases.[414–416] In contrast to other vasculitides, renal involvement in EGPA rarely predominates. It is manifested by microscopic hematuria and mild proteinuria and, less frequently, by the nephrotic syndrome or rapidly progressive renal failure.[411–414,417] The renal prognosis in EGPA is generally better than that of other pauci-immune vasculitides, such as GPA or microscopic polyangiitis.[417] Patients usually respond to high dose steroids, but cyclophosphamide and rituximab are effective in refractory cases.[418]

The most common light microscopic abnormality on renal biopsy is that of a focal and segmental necrotizing glomerulonephritis with crescent formation similar to that found in other ANCA-associated vasculitides, with eosinophil-rich arteritis (a distinctive feature) in a minority of cases.[419,420] The interstitium may be affected by inflammatory cells, including eosinophils, lymphocytes, and plasma cells. Interstitial granulomas can also occur but are uncommon. Immunofluorescence studies may show positivity for IgM, C3, and fibrinogen in glomeruli in the segmental areas of necrosis. No immune complex deposits are found by electron microscopy.

Henoch–Schönlein Purpura

HSP is a distinct systemic vasculitic syndrome that is characterized by palpable purpura (most often symmetrically distributed over the extensor-dependent surfaces of the lower extremities and buttocks), migratory arthralgias, abdominal manifestations (including pain, vomiting, and intestinal bleeding), and renal disease.[421,422] The clinical manifestations of the syndrome are caused by a systemic small vessel vasculitis of the leukocytoclastic type. The inflammatory reaction seen in the skin, kidney, and other organs is caused by deposition of IgA-containing immune complexes. HSP can occur at any age but is more common in young children, with over 50% of the cases under 5 years and over 75% under 10 years.[423,424] A male predominance has been reported in both children and adults, with a ratio of up to 2 : 1.[422,423] HSP is uncommon in blacks, and familial cases have rarely been reported.[425] About one-fourth of the patients have a history of allergies. Renal involvement has been reported to occur in approximately 20%–55% of children[426,427] and 50%–85% of adults[423,428] and ranges from mild hematuria and proteinuria with no reduction in renal function to the nephrotic syndrome and severe renal insufficiency. Upper respiratory tract infections often precede the onset of HSP. The disease undergoes complete, spontaneous remission in half of the patients, usually within a year of onset, but in many others, it progresses to ESRD over a period of 5–10 years. The prognosis in children is excellent with ESRD reportedly occurring in only 2% of patients. In general, there is good correlation between the severity of the lesion and the clinical manifestations, and patients with the nephrotic syndrome usually progress to renal failure.[428] Recurrence can occur in allografts, but it is rarely responsible for graft failure.

By light microscopy, the most characteristic feature is a mesangial proliferative glomerulonephritis with a variable degree of crescent formation. The mesangial changes, which may be focal or diffuse, include both mesangial hypercellularity and an increase in mesangial matrix. Occasional cases may show a membranoproliferative pattern. In the most severe cases, the glomerular tufts may be infiltrated by polymorphonuclear leukocytes and mononuclear cells and may exhibit areas of necrosis. Vasculitis involving glomerular arterioles and interlobular arteries can also occur, but this is rare finding on renal biopsies. Tubulointerstitial changes of atrophy and IF correlate with the degree of glomerular damage. Electron microscopy shows mesangial deposits that may extend into the subendothelial areas. Subepithelial deposits similar to those in membranous nephropathy or resembling the humps of postinfectious glomerulonephritis have been reported.[429] But in such instances, a recently characterized entity, IgA-dominant postinfectious glomerulonephritis, associated with co-dominant C3 staining and frequent hypocomplementemia, should be considered.[239] The most distinctive feature of HSP is the demonstration of dominant or co-dominant IgA by immunofluorescence. As in IgAN, the deposits may also contain IgG, IgM, C3, and properdin but not C1q or C4. The fact that the deposits consist mainly of aberrantly glycosylated polymeric IgA1 supports the notion that IgAN and HSP are spectra of the same disease.[311,430]

Cryoglobulinemic Vasculitis

Cryoglobulins are immunoglobulins or complexes of immunoglobulins that precipitate at low temperatures (4°C) and redissolve when the serum is heated to 37°C. Three types of cryoglobulinemia are recognized: type I, in which the cryoglobulins are composed exclusively of a single monoclonal immunoglobulin of either IgG or IgM class, usually generated by a lymphoplasmacytic disorder, and types II and III, which are composed of "mixed" cryoglobulins, a designation based on their composition as complexes of immunoglobulins. Type II cryoglobulins consist of a complex of monoclonal immunoglobulins (typically IgM) with rheumatoid factor activity, causing it to bind to polyclonal IgG, whereas type III cryoglobulins are a mixture of polyclonal IgM and IgG. Mixed cryoglobulins (types II and III) can be found in the serum of patients with a variety of clinical conditions, including lymphoproliferative disorders, chronic infections, chronic liver disease, and autoimmune diseases, particularly SLE.[431] In the past, no clear cause could be found in about 30% of all mixed cryoglobulinemias (and so referred to as "essential" cryoglobulinemia), but it now clear that majority are associated with hepatitis C virus infection.[432] Approximately 10%–15% of all cases of cryoglobulinemia involve type I cryoglobulins, 50%–60% type II, and 25%–40% type III.[178,432] Any of the three types of cryoglobulin can precipitate in the vasculature, forming thrombi in virtually any organ of the body, and may elicit an inflammatory reaction (vasculitis) in the vessel wall.[433,434]

A distinctive clinical syndrome characterized by a variable combination of fatigue, purpura, arthralgias, hepatosplenomegaly, lymphadenopathy, Raynaud phenomenon, and glomerulonephritis has been observed in patients with mixed cryoglobulinemia. Both sexes are affected, though it is most common in women in the fourth and fifth decades.[435] Purpura is almost always present and is usually distributed over the lower extremities. Renal disease occurs in about 50% of the patients and becomes apparent 1–3 years after the purpura, but it can be a presenting symptom.[436] Typical clinical manifestations are nephrotic-range proteinuria, microscopic hematuria, and hypertension. Acute nephritic syndrome occurs in 20%–30% of the cases, and oliguric acute renal failure in about 5% of patients with renal disease. Although rare, renal involvement can occur in type I cryoglobulinemia. In the few reported cases, the clinical manifestations and pathologic features of type I cryoglobulinemia are identical to those of mixed cryoglobulinemia.[433] Hypocomplementemia is common, especially low C4, but several cases have reduced levels of C3 as well. False negative result for serum cryoglobulins is real concern, and appropriate sample collection and transportation to maintain the serum temperature at 37°C is extremely important. Some cryoglobulins, especially type III, can take up to 7 days or more to precipitate.[437]

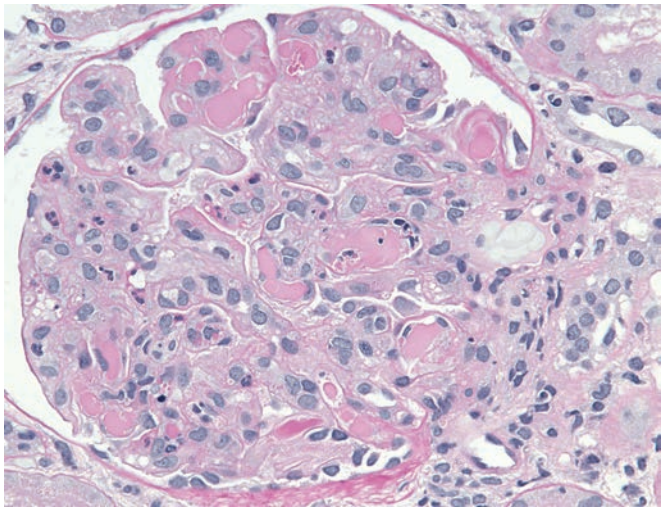

Figure 23.56 Cryoglobulinemic glomerulonephritis with diffuse proliferation, lobular accentuation and intraluminal hyaline thrombi (deposits) (PAS).

The most common renal biopsy finding in patients with all types of cryoglobulinemia is a diffuse proliferative glomerulonephritis (often with a membranoproliferative pattern). Focal and segmental glomerulonephritis and, less frequently, membranous or crescentic glomerulonephritis can also occur. Abundant glomerular intracapillary macrophages are a frequent feature. In more acute cases, the bulky deposits produce the appearance of thrombi or wire loops as can be seen in lupus nephritis (Fig. 23.56). Vasculitis is the basic pathologic lesion in every affected tissue including the kidney, where it tends to involve the interlobular arteries and afferent arterioles. Electron microscopy often demonstrates abundant subendothelial deposits and, less frequently, mesangial, intramembranous, or subepithelial deposits. In approximately half of the cases, the glomerular deposits appear as fibrillar, tubular, or annular structures or may exhibit a fingerprint-like pattern (Fig. 23.57).[438] In some cases, especially those associated with plasma cell dyscrasias, it is possible to find rhomboid- or needle-shaped crystals in the cytoplasm of glomerular epithelial and mesangial cells.[439] Immunofluorescence usually demonstrates positivity for the immunoglobulins present in the cryoglobulins in the glomeruli and vessels. C3 deposition is often found in these locations, whereas C1q and C4 occur in only about one-third of the cases. Heavy and/or light chain restriction can be observed in type I cryoglobulinemia.

Hemolytic Uremic Syndrome and Thrombotic Thrombocytopenic Purpura

TMAs constitute a group of microvascular occlusive disorders characterized by hemolytic anemia that is caused by fragmentation of erythrocytes, thrombocytopenia due to increased platelet aggregation, and thrombus formation that produces variable signs and symptoms of organ ischemia.[440] In addition to schistocytes on peripheral smear, patients with TMA have elevated serum lactate dehydrogenase, low

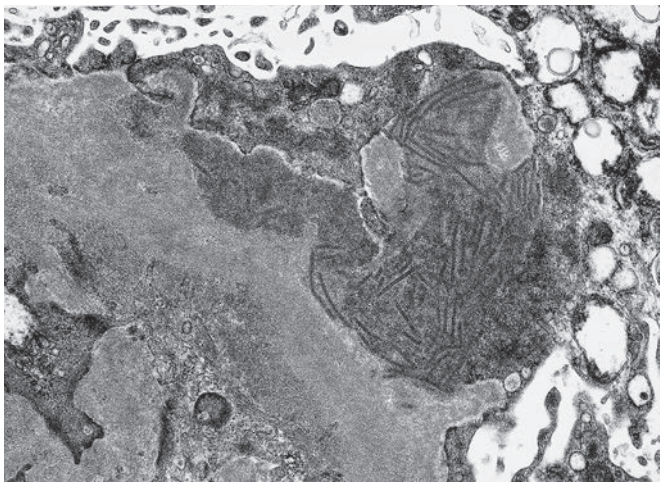

Figure 23.57 Subepithelial deposits demonstrating fibrillary configuration in a case of cryoglobulinemic glomerulonephritis (×21,500).

haptoglobin levels, and negative Coombs test. Although TMA may be a manifestation of various disease states,[441] the two most prominent conditions are thrombotic thrombocytopenic purpura (TTP) and HUS. Traditionally, the diagnosis of HUS was made when renal failure was the predominant feature and children were the ones primarily affected, whereas the term TTP was used for adult patients having predominantly central nervous system impairment. Because of the overlap of clinical manifestations, these two syndromes were previously considered to be a continuum of a single disease entity. However, newly identified pathophysiologic mechanisms have allowed these syndromes to be distinguished from each other on a molecular basis.[442] Studies have shown that patients with TTP are severely deficient in a plasma protein ADAMS13, while those with HUS have either normal or only moderately reduced levels.[443,444] ADAMS13 is a metalloprotease that cleaves the large von Willebrand factor (vWF) multimers produced by the endothelial cells. When ADAMS13 activity is deficient, the resulting abnormally large vWF multimers in the plasma have a greater ability to react with platelets and cause the disseminated platelet microthrombi characteristic of TTP. These microthrombi can be found in arterioles and capillaries in a variety of organs, including the brain, gastrointestinal tract, pancreas, skin, heart, adrenal glands, and kidneys.[445,446] The deficiency of ADAMS13 activity can be inherited, but it is more commonly caused by an acquired autoantibody (as triggered by drugs such as ticlopidine and clopidogrel) that binds and inhibits the metalloprotease.[447]

HUS is defined by the triad of thrombocytopenia, microangiopathic hemolysis, and acute renal failure. The underlying causes of HUS have been broadly divided into diarrhea-associated (D+ HUS), also known as classic HUS, and nondiarrheal forms (D– HUS), also known as atypical HUS.[448,449] The classic form occurs primarily in infants and young children, but it may appear at any age, and both sexes are equally affected. It accounts for most of the cases of HUS in North America and is characterized by sometimes occurring in small epidemics after exposure to contaminated foods, such as undercooked ground beef, unpasteurized apple juice, and dairy products, with verotoxin-producing *Escherichia coli* O157:H7 and, less commonly, with *Shigella dysenteriae* type I.[450,451] The verotoxin/Shiga-like toxin binds to globotriaosylceramide (Gb3) receptors that are expressed in highest concentration in microvascular endothelial cells in kidney, gut, pancreas, and brain and mediate endothelial damage. Patients usually present with prodromal diarrhea (often bloody) followed by acute renal failure. About one-third of the patients may present symptoms of neurologic involvement, commonly manifested by seizures, altered consciousness, and focal neurologic signs. Because thrombotic changes are most often confined to the glomeruli, patients with classic HUS usually have a good prognosis and recovery occurs in about 80%–90% of the cases. About 5% of the patients, however, die of disease, usually of cerebral causes.

D– HUS is much less common than the classic type and accounts for only 5%–10% of all cases of the disease.[449] It may occur at any age but is more frequent in adults. The etiology of D– HUS is heterogeneous.[452,453] It can be associated with nonenteric infections caused by bacteria, such as *Streptococcus pneumoniae*, *Mycoplasma pneumonia, and Legionella* or viruses, such as influenza A virus and HIV. Infection caused by *Streptococcus pneumoniae* accounts for 40% of D– HUS and 4.7% of all cases of HUS in children in the United States.[454] D– HUS can also occur in association with disorders such as SLE, systemic sclerosis, antiphospholipid antibody syndrome, malignant hypertension, or various forms of cancer, especially prostatic, gastric, breast, and pancreatic carcinomas.[440,452,453] This form of HUS can be induced by total body irradiation, antineoplastic agents (mitomycin, cisplatin, bleomycin, and gemcitabine, anti-vascular endothelial growth factor [VEGF]) or immunosuppressive drugs (cyclosporine, tacrolimus, OKT3, sirolimus, and interferon), quinine, and oral contraceptives. A severe form occurs in association with pregnancy, especially in the postpartum period.[455] The overall prognosis of these patients is poor, with a high mortality rate from central nervous system disease or uncontrollable bleeding, and, if they survive, usually develop chronic renal failure.

Several forms of D– HUS are hereditary, involving complement regulatory proteins, factor H, factor B, C3, membrane cofactor protein (MCP or CD46), or factor I.[453,456] Defects in these proteins as a result of mutations of the corresponding genes cause excessive alternative complement pathway activation that damages endothelial cells, leading to a prothrombotic stage and local accumulation of platelet–fibrin thrombi. Certain high-risk haplotypes have also been identified and might account for variability in penetrance among family members. It has also been proposed that environmental triggers such as infection, pregnancy, transplantation, oral contraceptive pills, and drugs act as a second hit, overwhelm the delicate complement "balance" in these patients, and precipitate atypical HUS in adult life. Low serum C3 levels in HUS may indicate a genetic component.[457] Other genetic disorders affecting cobalamin metabolism and coagulation pathway also cause clinical features and histologic changes of TMA.[441]

A biopsy taken early in the disease course shows fibrinoid necrosis, intimal and subintimal fibrin deposits with entrapped fragmented red cells, thrombosis, and endothelial cell proliferation in small arteries and arterioles. The glomeruli may be affected similarly (Fig. 23.58), exhibit acute ischemic changes, or be infarcted. There is endothelial swelling with narrowing of the capillary lumina. The mesangium is expanded, and, in severe cases, mesangiolysis may occur. As the lesion progresses, there is an intense basophilic intimal thickening in the small arteries and arterioles which greatly restricts the vascular lumina. These mucoid intimal changes usually develop over several weeks, although they may be seen in very early phase of the disease. Aneurysmal dilation, accompanied by proliferation of some arterioles, particularly at the hilus of the glomerulus is a typical finding. Insidious presentation and chronic glomerular TMA lesions are characterized mainly by mesangiolysis and basement membrane irregularities and double contours (Fig. 23.59).

Electron microscopy reveals the most characteristic feature of HUS: narrowing of the capillary lumen due to marked widening of the subendothelial space that is filled with a pale, finely particulated

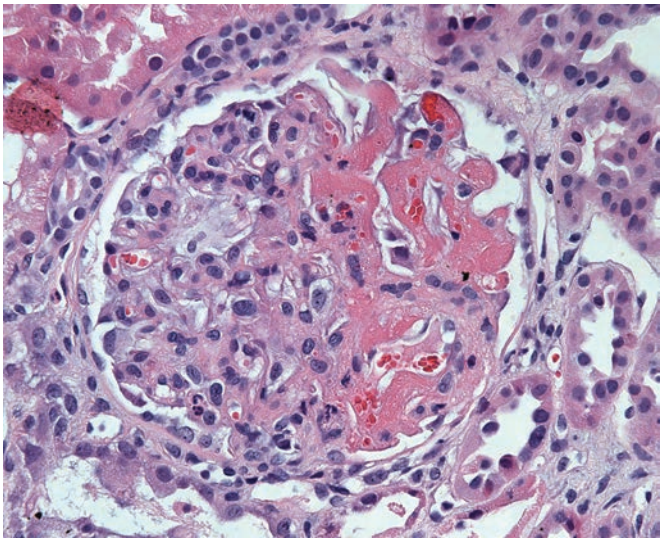

Figure 23.58 Glomerulus with capillary fibrin thrombi, karyorrhexis and entrapped fragmented red blood cells in acute thrombotic microangiopathy.

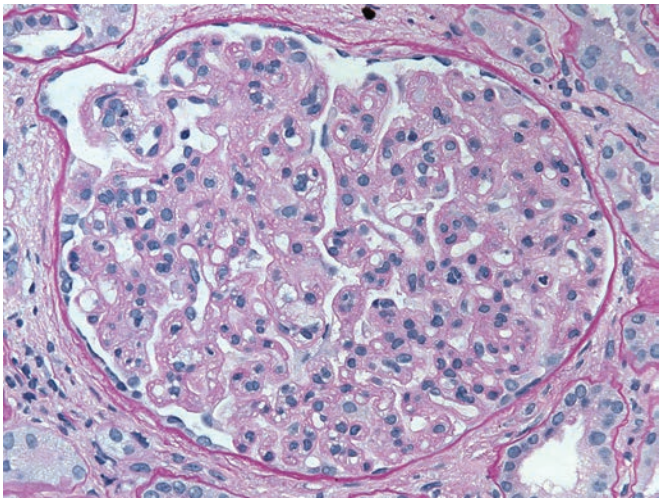

Figure 23.59 Glomerulus From a Patient With Antiphospholipid Antibody Syndrome. Diffuse glomerular basement membrane multilayering is seen along with mesangiolysis and endothelial swelling (PAS).

or fibrillar material that stains positively for fibrinogen by immunohistochemical methods (Fig. 23.60). In the chronic phase, an irregular, thin layer of basement membrane–like substance is present between the endothelial cell cytoplasm and the electron-lucent area. Because of its argyrophilic characteristics, this material can produce a double contour on light microscopy, thus simulating a membranoproliferative pattern (see Fig. 23.59). Fibrin and platelet aggregates may occlude the capillary lumina, and the endothelium is often disrupted in these thrombosed areas. The mesangial cells are swollen and hypertrophic and contain many phagolysosomes. Extensive foot process effacement is seen in the areas of capillary wall collapse. In the later stages, interlobular arteries and arterioles are affected by a mucinous, onion-skin–like obliterating vasculopathy devoid of inflammation. The vascular lesions are identical to those seen in systemic sclerosis and malignant hypertension, so careful analysis of the clinical data is required for accurate diagnosis.

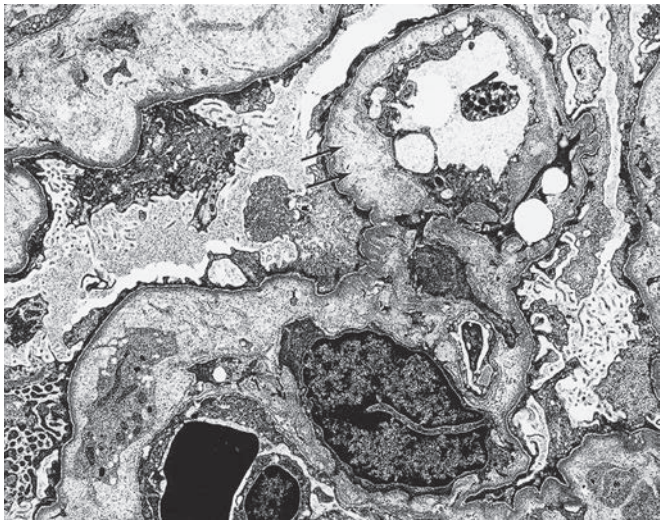

Figure 23.60 Portion of a glomerulus showing a prominent subendothelial electron-lucent zone *(arrows)* and mesangiolysis in a case of acute thrombotic microangiopathy (×9000).

Systemic Sclerosis

Systemic sclerosis, progressive systemic sclerosis, or systemic scleroderma are terms used to designate a connective tissue disorder of unknown etiology characterized by multiple organ system involvement. Although a rare disease, with a reported prevalence ranging from 3.1 to 20.8 per 100,000,[458] systemic sclerosis is associated with significant morbidity and mortality. Women are more commonly affected than men, with a ratio of approximately 3 : 1.[459] It may occur at any age but is more common between the fourth and sixth decades of life. The pathogenesis of systemic sclerosis is not fully understood but most likely involves a complex interplay of excessive fibrosis, vascular abnormalities, and abnormalities in the immune system.[460,461] Most patients are ANA positive, which is a rather nonspecific feature. Several other autoantibodies such as RNA polymerase III, antitopoisomerase-1, and anticentromere antibodies are specific markers of systemic sclerosis but are not clearly linked to the pathogenesis of systemic sclerosis.[462] The autoimmune mechanisms in these patients potentially target endothelial cells and fibroblasts. The downstream effects of this targeted injury include increased vascular permeability, endothelial apoptosis, and platelet aggregation, and increased matrix production mediated by fibroblast-derived TGF-β and reduced matrix degradation.

The clinical features of the disease are produced by differing combinations of excessive collagen deposition and vascular disease, the former causing deformation and morbidity, and the latter being the mechanism of most systemic complications. Diffuse form of the disease with widespread cutaneous fibrosis is frequently associated with severe organ involvement while a disease limited to the distal extremities has milder organ involvement. Raynaud syndrome, skin thickening, digital pulp atrophy (sclerodactyly), and telangiectasia are the primary clinical manifestations of systemic sclerosis. Musculoskeletal involvement includes periarticular, tendon, and nerve entrapment, flexion contractures, acral osteolysis, and myopathy. In the gastrointestinal tract, the disease can cause esophageal dysmotility and malabsorption. Pulmonary hypertension and IF, cardiomyopathy, and scleroderma renal crisis are the major causes of mortality. Renal involvement occurs in 60%–70% of the patients.[463,464] Two clinical forms of renal involvement have been recognized: an acute and rapidly progressive form of renal failure often associated with malignant hypertension, systemic vasoconstriction,

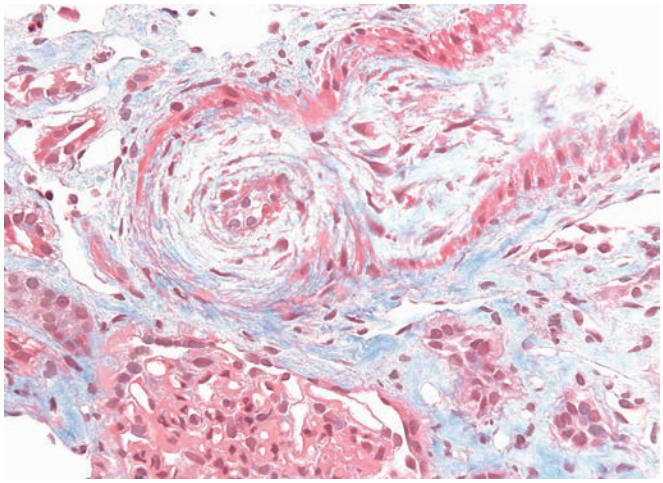

Figure 23.61 Interlobular artery showing stenosing intimal mucoid edema in a patient with systemic sclerosis and acute renal failure (trichrome).

and microangiopathic hemolytic anemia (referred to as scleroderma renal crisis); and a more common, slowly progressive chronic form that is manifested by varying combinations of proteinuria, hypertension, and azotemia.[464–466] Scleroderma renal crisis in most cases can be successfully treated with angiotensin-converting enzyme (ACE) inhibitors and effective blood pressure control, but some patients do progress to end-stage kidney.[465]

The main morphologic changes in scleroderma renal crisis are in the interlobular arteries that show intimal thickening by loose, myxoid fibrous tissue (Fig. 23.61).[440] Subendothelial fibrin deposition and intimal hemorrhage may also be seen. The muscular wall of the artery is usually attenuated and stretched around the excessive intima, and periarterial fibrosis may be prominent. Arterioles frequently exhibit fibrinoid necrosis and thrombosis, which may continue uninterrupted into the glomeruli. The arcuate and interlobar arteries are minimally involved in acute systemic sclerosis renal damage, but in chronic disease, they may show nonspecific, sclerotic intimal thickening that can be difficult to distinguish from normal age-related changes. The glomeruli are typically small and show varying degrees of acute ischemic changes and, on occasion, intracapillary fibrin thrombi. Juxtaglomerular hyperplasia may be prominent, especially in patients with malignant hypertension and hyperreninemia. In the chronic form, varying degrees of glomerulosclerosis, TA, and interstitial scarring are observed.[467]

By electron microscopy, affected blood vessels show intimal widening by amorphous electron-lucent material corresponding to the myxoid ground substance seen by light microscopy. The glomeruli present basement membrane wrinkling with focal widening of the subendothelial area, which may contain fibrin strands. In the chronic form, the vascular lumina of the arteries are narrowed by dense concentric intimal fibroelastosis. Immunofluorescence studies often demonstrate reactivity for fibrinogen, with or without IgM and C3, in the intima of blood vessels and along the glomerular capillaries. Since the renal lesions in systemic sclerosis, HUS, and malignant hypertension can be identical, careful evaluation of the patient's clinical history and laboratory data is essential in establishing the diagnosis.

Renal Diseases of Pregnancy

Renal disease may be initiated or exacerbated during pregnancy. Because of the extent and complexity of the topic and space limitations, only preeclampsia will be discussed here.

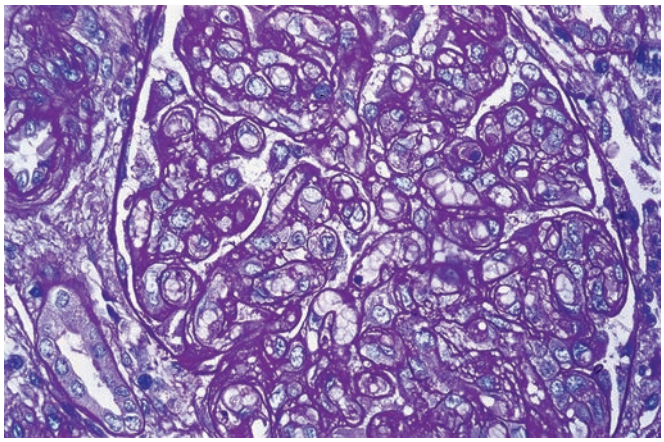

Figure 23.62 Preeclamptic Renal Disease. The glomerular capillary lumina are obliterated by swollen endothelial cells.

Preeclampsia

Preeclampsia is a pregnancy-induced systemic syndrome characterized by new-onset hypertension, proteinuria, and edema that usually occurs after the 20th week of gestation. When the syndrome progresses to a convulsive stage, it is termed eclampsia, and HELLP syndrome refers to a subset of preeclampsia patients with hemolysis, elevated liver enzymes, and low platelets. Preeclampsia affects approximately 3%–5% of pregnancies worldwide. Most cases occur in primigravidas, with an incidence as high as 7.5%.[468,469] Although the etiology of the syndrome remains unknown, recent studies have shown that a reduction of VEGF—caused by an excess circulating antiangiogenic factors, most notably soluble FMS-like tyrosinase kinase (sFlt1) and soluble endoglin, which are highly elevated during preeclampsia—plays an important role in the pathogenesis of the syndrome.[468–470] Derived from placenta, sFlt1 serves as a receptor for VEGF. VEGF is important not only in angiogenesis but is also a critical factor for the maintenance and health of the fenestrated and sinusoidal endothelium found in the renal glomerulus, brain, and liver.[471]

The changes in preeclampsia occur primarily in the glomeruli, which appear characteristically enlarged, swollen, and bloodless, with thickened capillary walls (Fig. 23.62). The bloodless pattern is produced by an intense swelling and hypertrophy of the endothelial and, to a lesser extent, the mesangial cells (endotheliosis).[470] Glomerular cellularity is usually normal or mildly increased. By electron microscopy, the capillary lumens appear narrow or obliterated by swollen endothelium, which often exhibits a loss of its normal fenestration. When mesangial cell hypertrophy is severe, the mesangium may become interposed between the endothelium and the basement membrane. Distinct strands of fibrin are present in translucent subendothelial zones containing loose fibrillar material.[472] Immunofluorescence studies have shown that the deposits in the glomeruli consist mainly of fibrinogen. Immunoglobulins, especially IgM, may on occasion be present due to nonspecific trapping in injured glomeruli. The afferent arterioles and their endothelial cells retain a normal appearance, which is striking in contrast to the swollen, vacuolated glomerular endothelial cells. Patients in whom preeclampsia nephropathy is superimposed on essential hypertension have hypertensive arterial and arteriolar changes in addition to the glomerular lesion.

Preeclampsia usually carries a good prognosis, and the changes in the glomerular capillaries disappear in a few weeks following delivery. Blood pressure falls to normal levels within a month. However, preeclampsia recurs in approximately 20% of subsequent pregnancies.

The clinical presentation of HELLP syndrome in a pregnant woman might indicate an underlying atypical HUS due to mutations in genes encoding alternative complement pathway components or circulating autoantibodies to complement factors.[473] It is being recognized that pregnancy-related stress may serve as a trigger for precipitating atypical HUS in a genetically predisposed individual.

Hereditary Glomerular Diseases

Alport Syndrome

AS (also known as hereditary nephritis) is an inherited type IV collagen disorder of the basement membranes manifested by progressive nephritis associated with deafness and ocular abnormalities.[474–476] In the United States, it accounts for 2.5% of children and 0.3% of adults with ESRD.[140] Males are more commonly affected than females. AS is a genetically heterogeneous disorder. Approximately 85% of the patients have the X-linked dominant form of the syndrome resulting from mutations in the *COL4A5* gene located at Xq22, which encodes the α5 chain of type IV collagen. Most of the remaining patients have autosomal recessive AS due to mutations in either the *COL4A3* or *COL4A4* genes, while only a minority of families exhibit the autosomal dominant disease that also arises from mutations in these genes.[477–481] To date, over 800 different mutations have been identified in X-linked dominant AS by different groups of investigators in various parts of the world.[475,480]

The disorder is usually manifested in children and young adults by recurrent microscopic or gross hematuria. Although proteinuria is usually mild, in advanced stages of the disease it can be in the nephrotic range. In males, the disease is usually progressive. In X-linked disease, the risk for males progressing to ESRD before the age of 40 is 90% compared with only 12% in females,[475,482] and the location of the mutation appears to determine the age of onset of ESRD.[483] In autosomal recessive AS, females are affected as severely and as early as males with X-linked disease. While patients with autosomal dominant disease show a great variability in their clinical course, this is generally milder than in males with X-linked AS. Bilateral high-frequency sensorineural hearing loss is the most common extrarenal manifestation of AS, often occurring in childhood in males, with females being affected later in life. Hearing impairment is always accompanied by renal involvement, but there is no relationship between the severity of the hearing loss and renal disease. Ocular abnormalities occur in 15%–30% of patients and appear to be confined to juvenile kindreds.[483,484]

Other uncommon variant of AS includes its association with diffuse leiomyomatosis (esophagus, tracheobronchial tree, and urogenital tract), which has been reported in 2%–3% of families with the juvenile form of the disease.[474,485] After transplantation, 3%–5% of males with AS develop anti-GBM nephritis, presumably because tolerance for the normal GBM antigen has not been acquired at birth.[475,486] Most patients with X-linked AS and anti-GBM nephritis in the allograft have antibodies to the NC1 domain of the α5 chain of collagen IV, but antibodies against the NC1 domain of the α3 chain have also been reported.[487]

The light microscopic features in the kidney are nonspecific, and the diagnosis depends on the electron microscopic and immunofluorescence findings. In biopsies taken in the early stage of the disease, the glomeruli appear normal or may show mild mesangial hypercellularity with minor thickening of the capillary walls. As the disease progresses, however, the glomeruli undergo segmental and global sclerosis. Tubulointerstitial changes appear relatively early, and consist of irregular areas of nonspecific sclerosis. The presence of interstitial foam cells in the absence of nephrotic-range proteinuria is a characteristic but nonspecific feature of AS (Fig. 23.63).

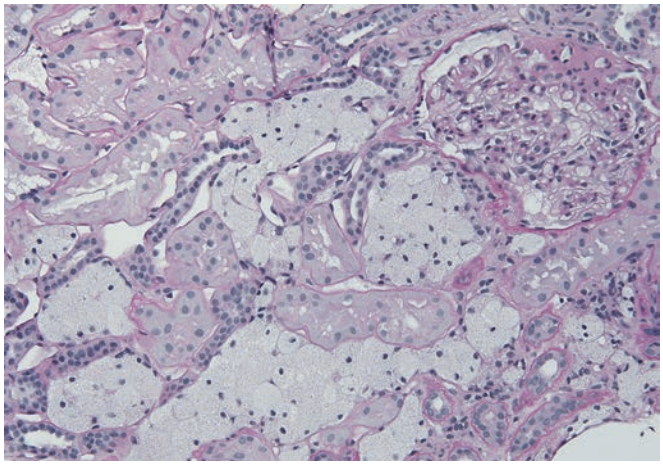

Figure 23.63 Interstitial foam cells and focal segmental glomerulosclerosis in a patient with microscopic hematuria and ultrastructural features of Alport syndrome (PAS).

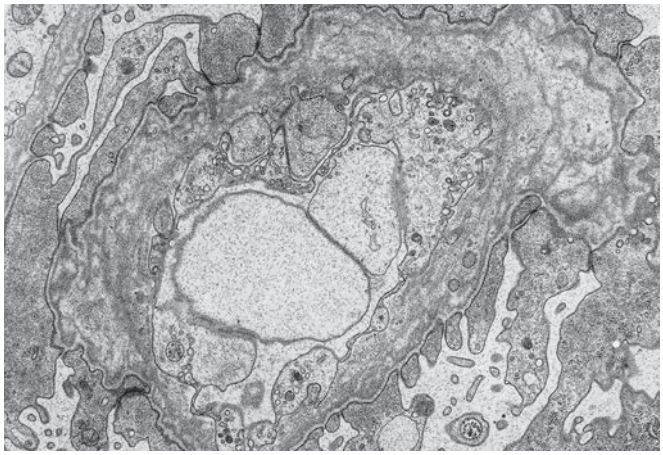

Figure 23.64 Glomerular capillary loop showing diffuse, irregular, thickening of the glomerular basement membrane. The lamina densa is split into multiple interwoven lamellae (×11,400).

The most specific finding of AS can only be seen by electron microscopic examination of the glomeruli. The typical lesion is thickening of the GBM with transformation of the lamina densa into multiple interwoven lamellae (Fig. 23.64). The epithelial aspect of the basement membrane often has a scalloped appearance, whereas the endothelial surface is usually smooth. The typical lesion of the GBM occurs in most but not all patients with AS. Affected young males and heterozygous females of any age may only have attenuated GBM measuring as little as 100 nm or even less,[488] representing the earliest manifestation of disease; the extent and severity of the multilamellation increases with age. Some authors have found a correlation between the percentage of the GBM having a splitting of the lamina densa and the degree of proteinuria in patients with AS, which suggests that the increased permeability of the GBM to protein is the functional consequence of the GBM alteration.[489] Although multilamellation of the GBM suggests hereditary nephritis, it can also be seen in other conditions, such as in the resolving stages of MGN and in IgAN-associated GBM repair.[490]

The panel of antibodies used in routine immunofluorescence studies usually fails to show any reactivity, although small and

[a]Approximately 10% of males with X-linked AS (attributable to missense and intron mutations) exhibit positive immunostaining of the renal basement membranes for the α3, α4, and α5 chains, and the epidermal basement membranes for the α5 chain.
[b]Approximately 30% of females with X-linked AS exhibit positive uninterrupted immunostaining (with reduced intensity in some) of the renal basement membranes for the α3, α4, and α5 chains, and the epidermal basement membranes for the α5 chain.
[c]Some patients with autosomal recessive AS exhibit positive immunostaining (but reduced intensity) of the renal basement membranes for the α3, α4, and α5 chains.
[d]Some patients with thin basement membrane disease exhibit reduced intensity staining of the glomerular basement membranes for the α3, α4, and α5 chains.
Modified from Kashtan CE. The nongenetic diagnosis of thin basement membrane nephropathy. *Semin Nephrol*. 2005;25:159–162.

scattered deposits of IgM and C3 can sometimes be seen in partially sclerosed glomeruli. Staining for specific monoclonal antibodies directed against different subunits of type IV collagen has greatly facilitated the diagnosis of AS.[491,492] Kidneys from individuals who are not affected by AS show strong continuous immunostaining with antibodies to the α3, α4, and α5 chains along the GBM, and the basement membrane of the Bowman capsule and the distal convoluted tubules. This reactivity is absent in male patients with X-linked AS. Skin biopsies examined by immunofluorescence can also be an important diagnostic tool since the α5 chain is expressed in the normal epidermal basement membrane but not in X-linked AS patients. Therefore, in male patients with a clinical and familial history suggestive of X-linked AS, skin examination for the α5 chain may obviate the necessity for a kidney biopsy. It should be borne in mind, however, that some affected males do retain the expression of the α5 chain in their basement membranes.[493] A mosaic staining pattern (interrupted or segmentally weaker staining) for the α5 chain is frequently seen in the epidermal and renal basement membranes of heterozygous females with X-linked AS, reflective of random inactivation of X chromosome in females. While this finding is diagnostic of the carrier state, a normal result does not exclude heterozygosity. The immunofluorescence/immunohistology findings in the basement membranes of patients with AS are summarized in Table 23.6.

When the diagnosis of AS cannot be unequivocally excluded on a kidney biopsy or if a female relative of a patient with X-linked AS is suspected to be the carrier of the disease, genetic testing should be performed. The sensitivity of the linkage analysis is only 60%, but the next-generation sequencing has proven to be vastly more sensitive (90%) in detecting the mutations in AS, especially in patients with autosomal dominant AS.[480] Genetic testing is increasingly considered standard of care in all patients suspected of AS and thin basement membrane nephropathy (TBMN).[494]

Thin Basement Membrane Nephropathy

The descriptive term TBMN is used to designate a hereditary renal disease that is characterized by the uniform thinning of the GBM and normal patient survival without deterioration of renal function. Benign familial hematuria is another designation that has also been

used for this condition; however, it is now considered inappropriate since it could embrace other pathologic entities, such as familial cases of IgAN, in which the prognosis is not always benign. Although TBMN has generally been considered an autosomal dominant hereditary condition, recent genetic studies indicate that it is a heterogeneous disease with some being related to mutations in the *COL4A3* and *COL4A4* genes with autosomal recessive inheritance.[495,496] It has been shown that patients with TBMN exhibiting these *COL4A3 and COL4A4* mutations are in fact carriers of autosomal recessive AS, and thus TBMN falls within the spectrum of type IV collagen diseases.[497,498] These findings further emphasize the importance of genetic testing in TBMN.[494]

TBMN is the most common cause of persistent hematuria in children and adults, and although its true incidence is unknown, it has been estimated that it affects at least 1% of the population.[499,500] Both sexes are equally affected, and even though it can manifest at any age, it is seldom reported after the age of 50 years. The onset of the hematuria is usually in childhood, and it is typically microscopic and persistent; however, on occasion, it may be macroscopic and recurrent.[499] Mild proteinuria is not uncommon, but heavy proteinuria in the nephrotic range is rare. Severe proteinuria likely represents a manifestation of a coexistent glomerular lesion, such as MCD, IgAN, focal glomerulosclerosis, or MGN.[501] In contrast to patients with AS, those with TBMN have only rarely been reported to exhibit extrarenal manifestations of AS.[499]

Aside from finding erythrocytes in the Bowman space and renal tubules, renal biopsies appear normal by light microscopy.[492,502] The diagnosis is made by the ultrastructural demonstration of a uniform thinning of the lamina densa of the GBM (Fig. 23.65). The overall width of the GBM is reduced to one-third or is ≤200 nm.[492,498,502] Immunofluorescence studies are usually negative for immunoglobulins and complement components, but deposits of IgM and IgG, with and without C3, have occasionally been reported.[502] Immunohistochemical evaluation for type IV collagen may assist in distinguishing TBMN from AS. A normal distribution of type IV collagen α chains is supportive of the diagnosis of TBMN.[492]

Fabry Disease

Fabry disease, also known as Anderson–Fabry disease and angiokeratoma corporis diffusum universalis, is an uncommon inherited X-linked disorder caused by a deficiency of the enzyme α-galactosidase A found in lysosomes. This results in the accumulation of the neutral glycosphingolipid Gb3 in the lysosomes of many tissues, including the kidneys, heart, neurons of the dorsal root of ganglia, and blood vessels in affected males and, to less extent, in female carriers. The incidence of the disease has been estimated to range from 1 in 40,000 to 1 in 117,000 live male births. About 5% of the cases are sporadic. More than 500 mutations of the α-galactosidase gene located on chromosome Xq22.1 have been described and most are family specific.[503] The most common presenting symptoms of the disease in children or adolescents are painful paresthesias in the lower extremities, hypohidrosis or anhidrosis, corneal opacities, and skin lesions that consist of small angiokeratomas scattered throughout the body, especially the abdomen, buttocks, lips, genitalia, and upper thighs. These patients have little or no α-galactosidase A enzyme activity. In contrast, males with residual α-galactosidase A enzyme present with renal failure and cardiac disease in the fourth decade of life. Female carriers, being heterozygous for the genetic abnormality, are usually only mildly affected, with rare occurrence of end-stage kidney disease.

Renal involvement is often manifested by hematuria and proteinuria in the second decade of life, followed by gradual deterioration of renal function in the third and fourth decades. Death occurs around the fifth decade from renal, cardiac, or cerebrovascular involvement. Recurrence in the transplanted kidney has been reported, but there is no indication that this event has a significant impact on long-term allograft survival in most patients.[504] Treatment of extrarenal disease includes enzyme replacement therapy with recombinant α-galactosidase.[505,506]

On light microscopy, the visceral epithelial cells are enlarged and vacuolated, giving a honeycomb appearance to the glomeruli. Similar changes are seen in the parietal epithelium, and in endothelial and mesangial cells (Fig. 23.66). There is also prominent vacuolization in the distal convoluted tubules and loops of Henle, as well as in the arteries. The vacuoles in each of these locations are PAS negative. With increasing age, there is segmental and global glomerulosclerosis with interstitial scarring and nodular arteriolar hyalinosis. Electron microscopy demonstrates a massive accumulation of laminated

inclusion bodies in the cytoplasm of the affected cells. Each is surrounded by a single unit membrane and measures up to 5 μm in diameter. They are either round with a concentric myelin-like structure, or ovoid with parallel layers ("zebra" bodies) (Fig. 23.67). Similar inclusions are present outside of the glomeruli in the endothelial and smooth muscle cells of blood vessels, and in the tubular epithelium, especially those of the convoluted tubule and the loops of Henle. Although the ultrastructural pattern is almost diagnostic of the disease, similar inclusions are seen in other conditions such as chloroquine toxicity and I-cell disease[507,508] and, hence the importance of clinical and biochemical correlation.

Nail–Patella Syndrome

Nail–patella syndrome (NPS; also known as hereditary onycho-osteodysplasia) is an uncommon autosomal dominant disorder defined by the association of nail dysplasia, absent or hypoplastic patella, elbow dysplasia, iliac horns, open angle glaucoma, and nephropathy.[509] It is caused by mutations of the *LMX1B* gene located on chromosome 9q34.1. T[510] The *LMX1B* gene encodes LIM homeodomain transcription factor expressed in podocytes and is crucial in limb development. The incidence of the syndrome has been estimated to be 1 per 50,000 live births. Nail dysplasia is the most constant feature of the syndrome and can be observed at birth, but nephropathy and glaucoma are the most relevant clinical manifestations. Renal involvement occurs in about 30%–50% of patients.[511,512] Asymptomatic proteinuria is the most common event, but the nephrotic syndrome can occur and some patients progress to renal failure.[512]

Light microscopy of the kidney shows nonspecific changes such as focal thickening of the glomerular capillary walls and FSGS. By electron microscopy, the GBM appears irregularly thickened and often exhibits electron-lucent areas, giving it the so-called moth-eaten appearance. Collagen-like fibers are seen in the electron-lucent areas and in the mesangium, further enhanced by phosphotungstic acid stain (Fig. 23.68). The LIM homeodomain transcription factor regulates the transcription of type IV collagen and podocyte proteins, thus contributing to these ultrastructural changes. No recurrences of the renal changes have been reported after transplantation.[513]

Collagen Type III Glomerulopathy

Collagen type III glomerulopathy (also known as collagenofibrotic glomerulopathy)[514] is an idiopathic glomerular disease that is characterized by the massive accumulation of atypical type III collagen fibrils within the mesangial matrix and subendothelial space and an increase in serum type III procollagen peptide levels. This type of collagen is absent in normal human kidneys. Although initially thought to be a clinical variant of NPS, it is now considered to be a separate clinicopathologic entity.[515] Collagen type III glomerulopathy occurs in both familial and sporadic forms, and the familial cases show an autosomal recessive pattern of inheritance.[516–518] The disease affects both sexes equally and manifests during childhood. Children often present with increasing proteinuria leading to the nephrotic syndrome, hypertension, and progressive renal failure.[514,517] An important feature in these patients is that they may develop HUS,[517] and associated inherited factor H deficiency has been documented in the literature.[519] In adults, the disease is often sporadic and has a more indolent course.

Light microscopy shows a diffuse increase in the mesangial matrix and generalized widening of the glomerular capillary walls, sometimes associated with mesangial cell interposition. By electron microscopy, there is a large accumulation of fibrils in the subendothelial aspect of the GBM and in the mesangial matrix. These curvilinear fibrils have a distinctive transverse band periodicity of approximately 60 nm, characteristic of type III collagen. Conventional immunofluorescence studies are either negative or show nonspecific deposits of immunoglobulins, especially IgM and complement components. The most important diagnostic feature is the presence of strong mesangial and capillary loop reactivity with anticollagen type III antibodies. Type III collagen deposition can also be seen in other organs, including the liver, spleen, myocardium, and thyroid gland.[520,521]

Fibronectin Glomerulopathy

Fibronectin glomerulopathy is an autosomal dominant disease with age-related penetrance, characterized by massive fibronectin deposition in the glomeruli.[522–524] Both sexes are equally affected, and in approximately 40% of the patients, it is caused by mutations of the *FN1* gene located on chromosome 2q34.[525] Clinically, the disease

usually manifests as proteinuria (often within the nephrotic range), microscopic hematuria, and the slow deterioration of renal function that occurs over a period of several years.

By light microscopy, the glomeruli appear enlarged and lobulated, with a minimal degree of hypercellularity. The most characteristic feature is a marked enlargement of the mesangium and subendothelial space, resulting from the deposition of a homogeneous PAS-positive, Congo red–negative material that, by electron microscopy, has a dense granular appearance. Intermixed within the deposits are focal filamentous structures measuring 12–16 nm in diameter. Immunohistochemical or immunofluorescence studies demonstrate strong positivity for fibronectin in the areas corresponding to the deposits, but immunoglobulins and complement deposition are absent or scant at best. The disease has been reported to recur after renal transplantation, and an underlying abnormality in the metabolism of circulating fibronectin is involved in the pathogenesis of this condition.[526] The *FN1* mutations detected thus far affect the heparin-binding domains of the fibronectin, causing conformational changes to the protein. It has been suggested that the mutant fibronectin deposited in the glomerulus results in defective endothelial spreading and podocyte cytoskeletal organization, contributing to the proteinuria.[525,527]

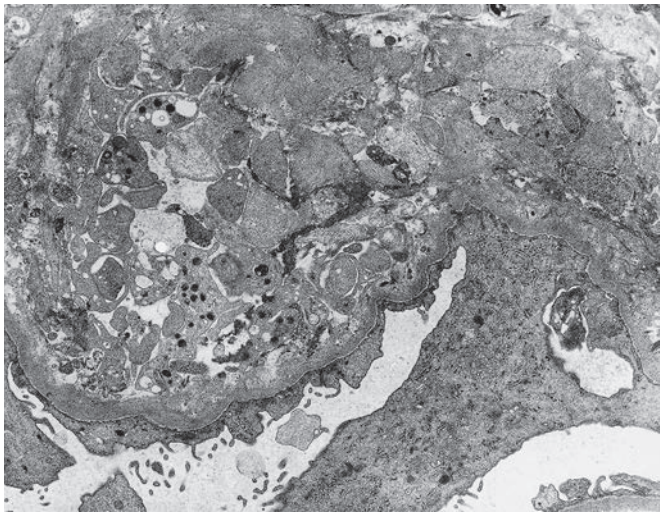

Figure 23.69 Hyperacute Rejection. There is endothelial denudation of the glomerular basement membrane and capillary occlusion by degranulated platelets (×7980).

Renal Transplant Pathology

Renal biopsies on transplanted kidneys are performed to determine: (1) whether the failure of the graft is due to rejection, nephrotoxicity caused by immunosuppressive drugs (i.e., cyclosporine A [CsA], tacrolimus), or other causes, such as acute tubular necrosis (ATN), acute infectious pyelonephritis, obstruction of the vasculature or urinary outflow tract, or recurrent or de novo glomerular disease; or (2) if rejection is present, to evaluate the intensity and nature of the rejection and to predict the potential reversibility of the lesions with therapy.

Allograft Rejection

Traditionally, rejection has been classified as hyperacute, acute, and chronic. Hyperacute rejection is antibody-mediated, while acute and chronic rejections can be either T-cell mediated (cellular rejection) or antibody mediated (humoral).

Hyperacute Rejection

Hyperacute rejection may occur within minutes or hours after revascularization, the immediate result being the abrupt cessation of urine flow. The diagnosis may be obvious to the surgeon with mottling cyanosis and diminished turgor in the graft. The reaction is produced by the interaction of preformed circulating antibodies in the recipient with antigens on donor endothelial cells such as HLA, ABO, and other less characterized endothelial antigens.[528,529] These preformed antibodies are often related to previous pregnancies, blood transfusions, or previous kidney transplant.[530] The introduction of routine transplant screening and cross-matching techniques has made this a rare complication, with an estimated incidence of less than 0.5% of transplants.[530,531]

In hyperacute rejection, fibrin thrombi are present in all the renal vessels, including the glomerular and peritubular capillaries. Early features (1–12 hours after implantation) may be limited to platelet and neutrophil margination in these vascular spaces. The thrombosis is associated with infarction and cortical and medullary tubular necrosis. These histologic features resemble those of severe acute AMR. Immunofluorescence may show linear staining for IgM or IgG and C3 along the glomerular and peritubular capillaries. Positive staining for C4d in peritubular capillaries supports the diagnosis, but poor perfusion and tissue necrosis often precludes demonstration of C4d deposition. Electron microscopy shows platelets, fibrin, sludged red blood cells, and evidence of necrosis of the endothelial cells of glomerular capillaries and other vessels (Fig. 23.69).[530]

Acute Rejection

Acute rejection, despite its name, can occur at any time during the post-transplantation period. It is most often seen in the months following implantation and becomes less common after the first year. Two types of acute allograft rejection are recognized: antibody mediated and T-cell mediated.

AMR is caused by anti-donor-specific antibodies (DSAs) directed against graft endothelium in glomeruli and peritubular capillaries. The target antigens are HLA class I and II molecules and in ABO-incompatible grafts, ABO antigens.[530] Less common endothelial cell–specific antigens, angiotensin II type I receptor, and other non-MHC antigens have also been implicated. Early on, these pathogenic DSAs are preformed in recipient circulation (resulting in positive cross match) but late post-transplant acute AMR is caused by *de novo* DSA.[532] The histologic features of acute AMR are mainly in glomeruli, peritubular capillaries, and arteries. The glomeruli show endothelial cell swelling, an increase in cellularity, and occasional fibrin thrombi.[533] The peritubular capillaries are dilated with intraluminal cells, referred to as "peritubular capillaritis" (Fig. 23.70). Neutrophils and monocytes predominate the glomerular and peritubular capillary infiltrate.[534] The arteries (and arterioles) may show endothelialitis or fibrinoid necrosis.[530] Interstitial hemorrhage, tubular necrosis, and infarction are also seen, but interstitial inflammation and tubulitis are not predominant features unless combined with T cell–mediated rejection. On occasion, the histology of acute AMR is limited to acute tubular injury alone. Electron microscopy demonstrates endothelial cell swelling associated with separation of the endothelium from the basement membrane by fluffy fibrillar material, which occasionally contains fibrin strands and platelet fragments (Fig. 23.71). The immunofluorescence or immunohistochemical demonstration of C4d deposition in graft peritubular capillaries is a durable and reliable marker of AMR, circulating anti-donor antibodies, and poor graft survival (Fig. 23.72).[11,534,535] C4d is a 44.5-kDa

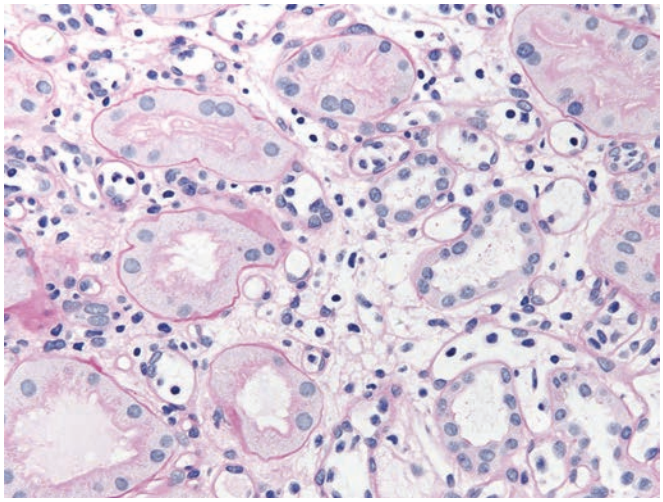

Figure 23.70 Peritubular Capillaritis With Dilated Capillaries and Intraluminal Mononuclear Cells. Prominent interstitial edema is also seen (PAS).

stable inactive degradation product of the complement factor C4 that is formed when the classic complement cascade is activated by binding of DSA to the endothelium of the graft.[536] Overall, immunofluorescence method is more sensitive than the immunohistochemical method, and it is taken into account in the scoring of positive C4d staining in peritubular capillaries.[537] Interestingly, diffuse peritubular capillary C4d is a constant feature in ABO-incompatible grafts, even in the absence of other histologic features of AMR, likely representing an accommodation reaction.[538] It is increasingly being recognized that AMR can occur in the absence of C4d deposition, prompting further study of C4d-negative AMR.[539,540] AMR is not steroid responsive, and treatment modalities have included plasmapheresis, IV immunoglobulin, rituximab, and more recently, complement inhibition.

In the early stages of **acute T cell–mediated rejection**, light microscopy reveals edema and focal infiltration of the interstitium by lymphocytes (Fig. 23.73). As the rejection progresses, the inflammatory infiltrate becomes more diffuse and the lymphocytes, many of them immunoblasts, are accompanied by plasma cells, monocytes, and macrophages. Granulocytes may be present, but they are not numerous. When they are abundant, the possibility of AMR or pyelonephritis should be considered.[541] Eosinophils can also be present but rarely in large numbers. A characteristic finding in acute T cell–mediated rejection is invasion of the tubular epithelial cells by lymphocytes, a feature referred to as tubulitis. Tubulitis has been regarded as a reliable marker for acute rejection even though it can be seen in other forms of interstitial nephritis.[541,542] The intensity of the infiltrate and tubular injury are features often used to grade the rejection. The infiltrate is more concentrated in the cortex than in the renal medulla. Immunophenotyping shows that most of the

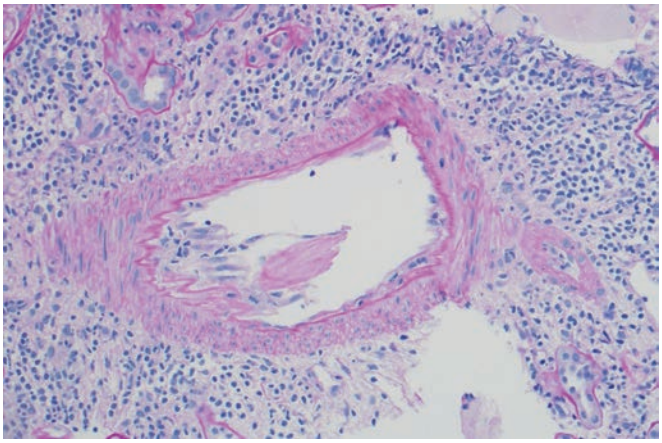

Figure 23.74 Acute Vascular Rejection (Banff IIA). An interlobular artery with intimal arteritis (PAS).

lymphoid cells are T lymphocytes, and as many as 60%–80% are CD8-positive cells, the remainder being CD4-positive T lymphocytes, plasma cells, and monocytes/macrophages. This immunologic tissue injury mediated by T cells is directed against MHC and non-MHC donor antigens. Immunofluorescence is generally negative, except for focal fibrin in affected vessels in a few cases and immunoglobulins in inflammatory cells. C4d stain is negative in a pure T cell–mediated rejection. Electron microscopy shows tubular damage and regeneration, and many inflammatory cells in the interstitium. Glomeruli are usually spared, but mononuclear cells in glomeruli (i.e., glomerulitis) can on occasion be a feature of T cell–mediated rejection and is unclear if it represents a component of AMR. Tubulointerstitial rejection that is predominantly T-cell mediated is considered readily reversible with pulse steroid therapy.

Mononuclear cells may infiltrate beneath the endothelium of arteries or arterioles, and it signifies early vascular rejection (Fig. 23.74). The cells are typically CD3+ T cells or CD68+ monocytes/macrophages. Associated swelling and vacuolization of vascular endothelial cells are often present, and the adjacent smooth muscle cells may show vacuolization caused by dilation of the endoplasmic reticulum. The intimal changes can be accompanied by either thrombosis or intimal proliferation. Thromboses are often small and nonocclusive, but in those cases progressing to irreversible rejection, they become obliterative and widespread with transmural necrosis of the vessel walls. Milder forms of intimal arteritis are often considered T-cell mediated, while AMR likely mediates most cases of transmural arteritis. Endarteritis is usually present in the background of severe tubulointerstitial inflammation. On occasion, it is observed with little or no interstitial inflammation (isolated endarteritis), and recent data suggest these cases mimic the behavior and survival of T cell–mediated tubulointerstitial and vascular rejection.[543] The diagnostic criteria and scoring of cellular rejection and AMR are delineated in Box 23.6.

Although it is convenient for descriptive purposes to consider the two types of allograft rejection reactions separately, many cases are a combination of antibody- and T cell–mediated changes. Since the T cell–mediated component of allograft rejection is more responsive to some forms of therapy than the antibody-mediated form, it is important to identify and, as far as possible, quantitate the relative contribution of the two components. This is essential in assisting the clinician in determining the appropriate form of treatment. It is also of importance in studying follow-up biopsies after therapy, particularly when the therapeutic response has not been favorable.

Chronic Rejection

Chronic rejection occurs anywhere from several months to several years after transplantation and, once initiated, can be progressive and irreversible. It constitutes the most common cause of graft failure after the initial 6–12 months post transplantation. Chronic rejection is not a distinct entity but rather the end stage of repeated episodes of acute antibody- and/or T cell–mediated rejection.[544] In addition, long-term administration of CsA or tacrolimus probably contributes to the development of some of the changes seen in chronic rejection.

Clinically, there is a gradual decrease in renal function. The deterioration may be preceded by proteinuria, sometimes nephrotic range,[545] and is commonly associated with hypertension. Microscopically, the changes can be seen in glomeruli, arteries, and tubulointerstitium. Nonspecific features of TA and IF may be accompanied by features of underlying T cell–mediated rejection such as interstitial inflammation and tubulitis in nonatrophic cortex. The blood vessels, especially the interlobular and arcuate arteries, show severe obliterative fibrointimal proliferation or mucoid widening of the intima, referred to as chronic transplant arteriopathy.[541] Fibrosis of the media and intimal foam cells may be seen, but reduplication of the elastic lamina is typically a feature of hypertensive arteriosclerosis. The distribution of the vascular lesions is irregular and some blood vessels appear normal while others present lesions of variable degrees of severity. The glomerular lesions consist of ischemic glomerular capillary collapse, and segmental and global sclerosis.[546] While these changes described may be present in T cell– or antibody-mediated alloimmune injury, the hallmarks of chronic AMR are transplant glomerulopathy and peritubular capillaropathy.[541] Reflective of repeated insults to the glomerular and peritubular capillary endothelium, this histologic evidence of chronic AMR is often accompanied by positive C4d stain in peritubular capillaries and circulating DSA.[539] Transplant glomerulopathy is characterized by duplication of GBMs, often accompanied by mononuclear glomerulitis and peritubular capillaritis (Fig. 23.75). The capillary walls are thickened due to marked widening of the subendothelial space or mesangial interposition, better demonstrated by silver staining or electron microscopy. Similar multilamination of peritubular capillary basement membranes is evident on electron microscopy.[547] No immune complexes are seen, although immunofluorescent studies occasionally show linear or granular deposition of IgM, IgG, and complement components. Peritubular capillary C4d deposition in chronic AMR may be patchy and focal, perhaps in part due to loss of peritubular capillaries with repeated endothelial insults. Of note, immunohistochemical staining of glomerular endothelium with C4d suggests chronic AMR, especially if immune complex glomerulonephritis is excluded.

The Banff Classification

To help establish uniform therapeutic guidelines for clinical management and to provide an objective evaluation of clinical trials of new antirejection agents, several classification systems for the evaluation of the histologic appearance of renal allograft biopsies have been developed over the past several decades. The best known of these is the Banff Working Classification of Renal Allograft Pathology, which was formulated by an international group of renal pathologists, nephrologists, and transplant surgeons who met in Banff, Canada, in August, 1991, and which was first published in 1993.[548] Since its introduction, this classification has undergone several revisions, the latest of which was published in 2014.[540]

Per Banff classification, there are six diagnostic categories: normal, AMR, borderline changes, T cell–mediated rejection, IF and TA without evidence of any specific etiology, and other changes not considered

Box 23.6 Banff diagnostic categories for renal allograft biopsies

1. Normal
2. ABMR
   Hyperacute rejection
   Acute/active ABMR; all three features must be present for diagnosis
   a. Histologic evidence of acute tissue injury, including one or more of the following:
      Microvascular inflammation ($g > 0$ and/or ptc > 0), intimal or transmural arteritis ($v > 0$), acute thrombotic microangiopathy, in the absence of any other cause, acute tubular injury, in the absence of any other apparent cause
   b. Evidence of current/recent antibody interaction with vascular endothelium, including at least one of the following:
      Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections[a]), at least moderate microvascular inflammation ([g + ptc] ≥ 2), increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated
   c. Serologic evidence of DSAs (HLA or other antigens)
   Chronic, active ABMR; all three features must be present for diagnosis
   a. Morphologic evidence of chronic tissue injury, including one or more of the following:
      TG (cg > 0), if no evidence of chronic thrombotic microangiopathy due to other causes, severe peritubular capillary basement membrane multilayering (requires EM), arterial intimal fibrosis of new onset, excluding other causes
   b. Evidence of current/recent antibody interaction with vascular endothelium, including at least one of the following:
      Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections), at least moderate microvascular inflammation ([g + ptc] ≥ 2), increased expression of gene transcripts in the biopsy tissue indicative of endothelial injury, if thoroughly validated
   c. Serologic evidence of DSAs (HLA or other antigens)
   C4d staining without evidence of rejection; all three features must be present for diagnosis
      Linear C4d staining in peritubular capillaries (C4d2 or C4d3 by IF on frozen sections, or C4d > 0 by IHC on paraffin sections[a]), g = 0, ptc = 0, cg = 0 (by light microscopy and by EM if available), v = 0; no thrombotic microangiopathy, no peritubular capillary basement membrane multilayering, no acute tubular injury (in the absence of another apparent cause for this), no acute T cell–mediated rejection (Banff 97 type 1A or greater) or borderline changes
3. Borderline changes: "Suspicious" for acute T cell–mediated rejection
   Focal moderate tubulitis with mild interstitial inflammation or interstitial inflammation with focal mild tubulitis (not meeting criteria for type IA); no intimal arteritis
4. T cell–mediated rejection
   Acute T cell–mediated rejection
      Type IA: Significant interstitial infiltration (>25% of parenchyma affected) and foci of moderate tubulitis (5–10 mononuclear cells/tubular cross section)
      Type IB: Significant interstitial infiltration (>25% of parenchyma affected) and foci of severe tubulitis (>10 mononuclear cells/tubular cross section)
      Type IIA: Mild to moderate intimal arteritis comprising <25% of the luminal area (v1)
      Type IIB: Severe intimal arteritis comprising >25% of the luminal area (v2)
      Type III: "Transmural" arteritis and/or arterial fibrinoid change and necrosis of medial smooth muscle cells with accompanying lymphocytic inflammation (v3)
   Chronic active T cell–mediated rejection
      "Chronic allograft arteriopathy" (arterial intimal fibrosis with mononuclear cell infiltration in fibrosis, formation of neo-intima)
5. Interstitial fibrosis and tubular atrophy, no evidence of any specific etiology
   I. Mild interstitial fibrosis and tubular atrophy (<25% of cortical area)
   II. Moderate interstitial fibrosis and tubular atrophy (26%–50% of cortical area)
   III. Severe interstitial fibrosis and tubular atrophy/loss (>50% of cortical area)
6. Other
   Changes not considered to be due to rejection—acute and/or chronic
   Calcineurin inhibitor toxicity, polyomavirus infection and others

[a]C4d scoring in peritubular capillaries: C4d0: 0%; C4d1: 1%–9%; C4d2: 10%–50%; C4d3: >50%.

to be due to rejection. The details of the current Banff classification are shown in Box 23.6. In this classification, an adequate core biopsy must contain a minimum of 10 glomeruli and at least two arteries; a marginal sample is that with 7–10 glomeruli and one artery; and an unsatisfactory biopsy is a core with fewer than 7 glomeruli or no arteries.

Cyclosporine A (Cyclosporin) Toxicity

CsA is an immunosuppressant drug that belongs to the calcineurin inhibitors group which selectively targets IL-2–dependent T-cell proliferation.[549] It is extremely effective in controlling transplant rejection; unfortunately, however, it is nephrotoxic. Other CsA-related toxicities include hepatotoxicity, neurotoxicity, gingival hyperplasia, hypertrichosis, and malignancies, particularly lymphomas.[550,551] Nephrotoxicity can occur not only in patients receiving renal transplants but also in those receiving the drug for any other reason. CsA nephrotoxicity is dose related and has been classified into functional toxicity in which there are no structural changes and morphologic forms in which the toxicity is manifested by a variety of lesions affecting tubules, vessels, and renal interstitium. Three major morphologic forms are recognized: acute nephrotoxicity, chronic nephrotoxicity, and TMA.[541]

Functional Toxicity

Functional CsA toxicity probably affects every patient who receives this medication. A mild decrease in renal function and a mild elevation of serum creatinine levels are seen soon after therapy starts, but both are reversible if the dosage is reduced. Hypertension is seen in up to 50% of the patients.[552] Renal biopsies in these patients appear normal or at most show some dilation and congestion of

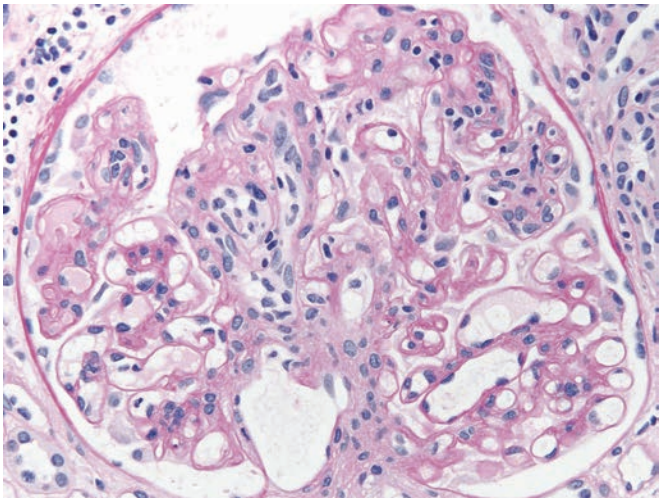

Figure 23.75 Transplant Glomerulitis and Glomerulopathy. The glomerulus shows increased intraluminal mononuclear inflammatory cells, consistent with transplant glomerulitis. The glomerular basement membrane double contours are a feature of chronic rejection (PAS).

peritubular capillaries. The pathogenesis is an alteration of intrarenal hemodynamics that results from the ability of CsA to induce intense renal vasoconstriction.

Acute Toxicity

The clinical manifestations of acute CsA toxicity are similar to that seen in functional toxicity, but tend to be more severe. Genetic factors seem to account for dose-independent susceptibility to acute toxicity in an individual.[553] Histologically, the lesion is characterized by vacuolization of the proximal tubules, often in an isometric pattern, with giant mitochondria, large lysosomes, and microcalcifications.[552] Electron microscopic studies have demonstrated that the vacuolization is the result of dilation of the endoplasmic reticulum. In addition, the arterioles may show individual medial smooth-muscle cell degeneration, necrosis/apoptosis and myocyte drop-out, endothelial cell swelling, intimal thickening, and mucoid medial edema, which together may result in significant narrowing of the vascular lumina. Acute nephrotoxicity is usually dose dependent and reversible.

Thrombotic Microangiopathy

Patients with CsA toxicity can develop symptoms of HUS a few days or weeks after transplantation. The histologic findings are those of TMA with platelet and fibrin thrombi in the glomeruli and vessels, and minimal inflammatory infiltrate.[541] The prognosis of these patients is generally poor, but in some instances the lesions have resolved after the drug has been withdrawn.

Chronic Toxicity

Chronic CsA toxicity is clinically manifested by slow progression into renal failure and hypertension. Biopsies show arteriolopathy and IF with TA, features that are not entirely specific.[554,555] The arteriolopathy consists of nodular or diffuse hyalinosis of the vessel walls, or mucoid thickening of the intima, resulting in the narrowing or complete occlusion of the vascular lumina.[541] The nodular hyalinosis replaces the necrotic myocytes and typically affects the outer media with eventual circumferential involvement. The changes are usually accompanied by patchy IF and TA (striped fibrosis), best seen in the cortex. The glomeruli are usually spared in the early stages, but subsequent segmental and global glomerulosclerosis ensues.[554] In contrast to acute nephrotoxicity, the changes in chronic nephrotoxicity are irreversible.

Tacrolimus (FK506) Toxicity

Tacrolimus is an immunosuppressant drug that is also used in the control of transplant rejection. The morphologic changes associated with tacrolimus toxicity are identical to those of CsA toxicity.[556] These changes include vacuolization of the straight and convoluted portion of the proximal tubules, myocyte vacuolization, peritubular calcifications, TMA, arteriolar hyalinosis, and IF.

Polyomavirus Nephropathy

The human polyoma virus type I has surfaced as a significant pathogen in kidney transplant recipients, causing polyomavirus nephropathy. Approximately 85% of polyomavirus nephropathy is attributed to BK virus, with the remainder caused by JC virus.[557] BK virus reactivation occurs in 10%–60% of renal transplants and 1%–5% of renal allografts develop BK nephropathy.[558] High-risk patients are monitored by serial measurements of urine and plasma polyoma viral loads. A plasma level of 10^4 virions/mL is considered highly specific (but significantly less sensitive) for polyomavirus nephropathy. The typical presentation is impaired renal function that is resistant to immunosuppressive therapy. The definite diagnosis of polyomavirus nephropathy requires the histologic demonstration of polyomavirus. The interstitium usually is infiltrated by mononuclear inflammatory cells, mimicking the changes seen in acute rejection.[559] Renal tubular epithelial cells typically show enlarged nuclei with amorphous basophilic viral inclusions.[560] Immunohistochemical stains can be helpful in assisting in the demonstration of the infected cells (Fig. 23.76). The immunostains can either be directed specifically to BK and JC virus or can be for SV40, another polyomavirus that has a shared large T antigen. Treatment of polyomavirus nephropathy primarily includes reduced immunosuppression. A coexistent acute rejection poses a diagnostic challenge, and the presence of endarteritis confirms the presence of acute rejection.

Tubulointerstitial Diseases

Tubulointerstitial disease is a generic term used to designate a heterogeneous group of disorders that primarily affect the renal interstitium and tubules and only secondarily involves the other structures of the kidney. The frequency with which tubulointerstitial diseases affect the kidney is difficult to determine; however, it is believed that primary tubulointerstitial disease is the cause of renal failure in an estimated 20%–40% of all patients undergoing treatment for ESRD. The clinical presentations are usually very similar, but the etiologies are quite different and include infection, obstruction, and immune-mediated and toxic-tubulointerstitial diseases (Box 23.7). The functional manifestations include impaired concentrating ability, impaired ability to secrete acid, diminished reabsorption of sodium, hyperkalemia, and azotemia. Symptoms may be acute or chronic with corresponding morphologic changes.

Box 23.7 Classification of tubulointerstitial diseases

Genetic
- Ciliopathies
- Nephronophthisis
- ADTKD
  - Mutations in UMOD, MUC1, HNF1β
- Mitochondrionopathies
- Crystal deposition and transport diseases

Infections
- Acute pyelonephritis
- Ascending infection
- Hematogenous spread
- Bacterial, fungal, viral, other
- Chronic pyelonephritis
- Nonobstructive (reflux associated)
- Obstructive
- Xanthogranulomatous
- Malakoplakia

Obstructive uropathy
- Hydronephrosis without infection
- Reflux-associated nephropathy

Metabolic
- Nephrocalcinosis
- Acute phosphate nephropathy
- Urate nephropathy
- Secondary oxalosis

Immunologic tubulointerstitial nephritis
- Drug induced (antibiotics, diuretics, nonsteroidals)
- Associated with systemic vasculitis
- Lupus associated, Sjögren syndrome-associated
- Antitubular basement membrane disease
- IgG4-related tubulointerstitial nephritis
- Tubulointerstitial nephritis with uveitis

Toxic tubulointerstitial nephritis
- Drug induced
  - Aminoglycosides
  - Cyclosporine
  - Lithium
  - Analgesics
  - Cisplatin
- Heavy metals toxicity
  - Lead, mercury, and others
- Other
  - Radiation
  - Sarcoid
  - Idiopathic

ADTKD, Autosomal dominant tubulointerstitial kidney disease; *HNF1β*, HNF1β mutation; *MUC-1*, mucin-1 related kidney disease; *UMOD*, uromodulin-related kidney disease.

Acute Tubular Necrosis

ATN is a clinicopathologic syndrome that is characterized by the acute suppression of renal function accompanied by morphologic evidence of tubular epithelial cell injury. Two subtypes of ATN have been recognized: ischemic and toxic.

The ischemic form of ATN is the most common and results from hypoperfusion of the kidney. It is usually associated with hypotension that occurs in a wide variety of conditions such as severe traumatic lesions and burns, shock after a surgical operation, septic shock, pancreatitis, and dehydration after diarrhea, vomiting, or extensive sweating.

The less common nephrotoxic form is a chemically induced injury of the tubular epithelial cells that can be caused by a wide variety of substances, including organic solvents (e.g., carbon tetrachloride, ethylene glycol), heavy metals (e.g., mercury, lead), drugs such as antibiotics (e.g., amphotericin B, gentamicin), antivirals (tenofovir, acyclovir, indinavir), chemotherapeutic agents (e.g., methotrexate, cisplatin), nonsteroidal anti-inflammatory agents, calcineurin inhibitors, and radiographic contrast agents. Hemoglobin and myoglobin are considered endogenous toxins capable of causing ATN when present in urine in high concentrations. Hemoglobinuria can be due to incompatible blood transfusion, malaria, and paroxysmal hemoglobinuria. Myoglobinuric acute renal failure can be caused by the liberation of myoglobin from muscles caused by trauma (crush injury), myositis, ischemia, excessive exertion, or exposure to toxins (snake venom, alcohol, cocaine). It is believed that, while the toxicity of the hemoglobin and myoglobin may contribute to the pathogenesis of ATN, ischemia and microcirculatory disturbances probably play a greater role in its development.[561]

Clinically, ATN is manifested by rapidly increasing serum creatinine levels associated with oliguria or anuria. Less frequently, ATN induces nonoliguric renal failure. Urinalysis typically demonstrates sloughed degenerated epithelial cells and granular casts. The clinical course of ATN is highly variable, and the prognosis largely depends on the clinical setting in which it occurs.

The morphologic changes in ischemic ATN depend on the severity of the renal failure and the evolution of the lesion.[561,562] In early stages, the cellular changes can range from minimal cell swelling to individual cell necrosis accompanied by focal denudation of the basement membrane and desquamation of the necrotic cells into the tubular lumen (Fig. 23.77A). The proximal tubules may appear dilated and their PAS-positive brush border thinned or absent. Hyaline, granular, and pigmented casts are common, especially in the distal and collecting ducts. These casts consist mainly of Tamm–Horsfall protein mixed with cellular necrotic debris. Other findings in ischemic ATN are interstitial edema and the accumulation of mononuclear leukocytes within the vasa recta of the outer medulla. As the disease progresses after the initial injury, evidence of tubular regeneration can be seen. Changes that are believed to represent regeneration include flattened epithelium with dilation of the tubular lumen, the presence of large nuclei with prominent nucleoli, and mitotic activity (see Fig. 23.77B).

Toxic ATN is characterized by extensive necrosis of the tubular cells along segments of the proximal tubule. Depending on the type of poisoning, several patterns of injury have been recognized.[561,563] For example, ethylene glycol produces marked ballooning and

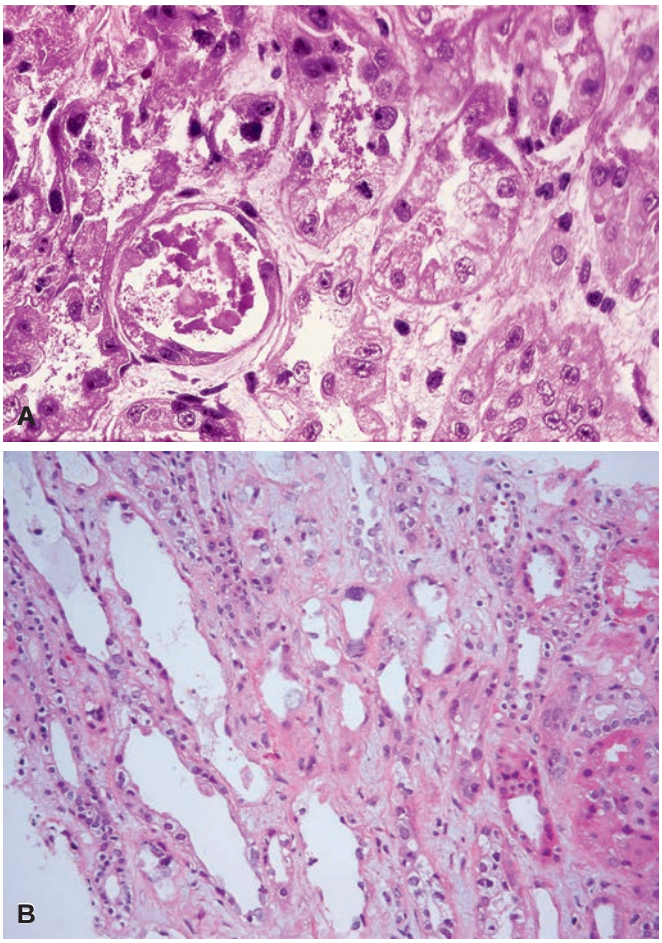

Figure 23.77 Acute Tubular Necrosis. A, There is focal necrosis and desquamation of the cells into the tubular lumen. **B,** The tubules are dilated and lined by flattened epithelium.

hydropic or vacuolar degeneration of the proximal convoluted tubules, and extensive deposition of oxalate crystals in the tubular lumina, whereas carbon tetrachloride poisoning is characterized by the accumulation of neutral lipids in the injured cells followed by necrosis.[563] In acute lead nephropathy, dark intranuclear eosinophilic inclusions are seen in addition to the cellular necrosis. Hemoglobinuric and myoglobinuric ATN following hemolysis or severe muscle damage shows histologic features of ischemic ATN, with numerous deeply pigmented, red–brown casts in the distal and collecting ducts. These casts stain positively with hemoglobin A and myoglobin immunohistochemical stains, respectively. Tenofovir and related antiviral drugs cause tubular nucleomegaly and pleomorphism, and sometimes megamitochondria can be visualized.

Recent studies have suggested that kidney injury molecule-1 (KIM-1) can be a useful immunohistochemical marker that can assist in the histopathologic diagnosis of tubular injury. KIM-1 is an immunoglobulin superfamily cell-surface protein that is undetectable in normal kidney but is highly overexpressed in proximal tubule cells after ischemic or nephrotoxic acute renal injury.[564,565] KIM-1 is a sensitive and specific early indicator of proximal tubular injury and can be detected in the urine and blood of individuals with acute renal injury.[566–568] Acute kidney injury can lead to chronic kidney disease and a progression to end-stage kidney disease especially in the presence of other predisposing factors or preexisting chronic kidney disease.[569]

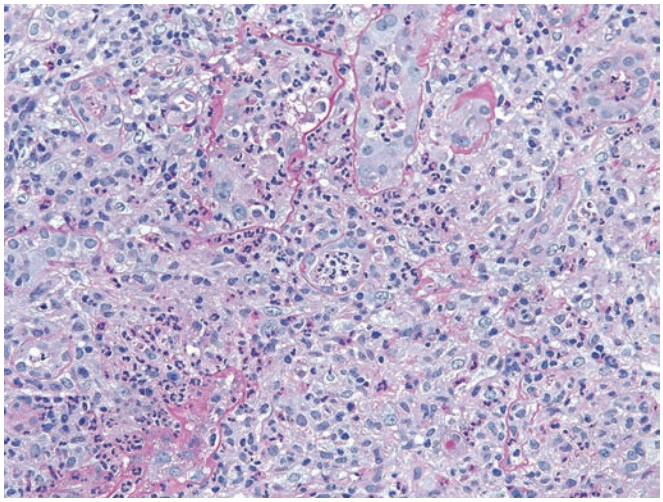

Figure 23.78 Acute Pyelonephritis in a Patient Presenting With Fever and Elevated Serum Creatinine. There is acute inflammatory infiltrate in the interstitium and tubular lumina.

Acute and Chronic Pyelonephritis

Infectious TIN is generally designated as pyelonephritis, implying that the inflammatory process involves the collecting system, as well as the renal parenchyma.[570] There are three peaks of incidence: infancy and early childhood, women of childbearing age, and both men and women older than 60 years of age. Both acute and chronic pyelonephritis are frequently associated with congenital or acquired obstructive lesions of the lower urinary tract or are associated with conditions resulting in residual retention of urine in the bladder. Congenital lesions are often the cause of pyelonephritis in infancy and early childhood. In older adults, obstruction by nodular hyperplasia of the prostate gland in men and the development of cystoceles in women are important etiologic factors. In addition, conditions such as cancer of the cervix and nephrolithiasis are also commonly associated with renal infection.

Acute pyelonephritis is most often associated with an ascending infection and the acute inflammatory infiltrate involves the renal medulla and cortex (Fig. 23.78). The inflammatory cells are mostly polymorphonuclear leukocytes, and they are present in the interstitium and within the tubular lumina. Foci of necrosis and abscess formation can also be present in the cortex. The kidney can occasionally be infected by organisms arriving via the hematogenous route, resulting in the formation of many small cortical abscesses with little involvement of the medulla. Special stains may reveal the responsible pathogens. The ascending infections are caused by the normal gram-negative flora of the intestinal tract. By far the most common is *Escherichia coli*, followed by *Klebsiella* and *Enterobacter*. *S. aureus* or fungal organisms, including *Candida* and *Aspergillus*, may be the cause of hematogenous infections, and they are seen more often in immunosuppressed individuals.

Chronic pyelonephritis produces a coarse fibrosis of the kidney parenchyma that is distinctly focal in its distribution. Cortical and papillary scars overlie dilated, blunted, deformed calyces. The architecture of the medulla is distorted, and papillae may be flattened. Light microscopy shows tubular damage, interstitial inflammation, and fibrosis (Fig. 23.79). The tubules are atrophic or dilated and are lined by flattened epithelium and filled with hyaline casts, a pattern that has been called thyroidization. Lymphocytes, histiocytes, and plasma cells form the bulk of the inflammatory infiltrate. In chronic pyelonephritis associated with reflux or obstruction,

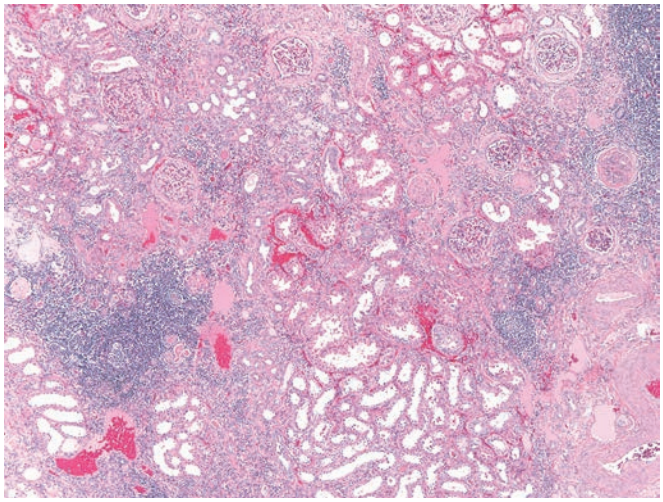

Figure 23.79 Nephrectomy Specimen From a Patient With Obstructive Hydronephrosis. There is interstitial scarring with intense mononuclear inflammatory cell infiltration. The tubules are atrophic, and the glomeruli are relatively spared with periglomerular fibrosis.

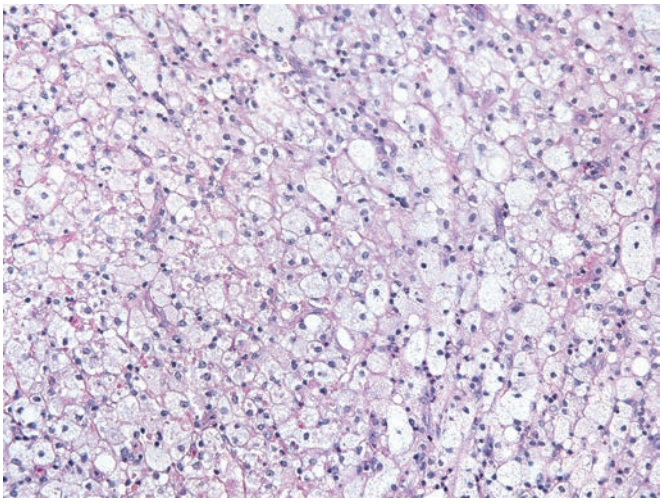

Figure 23.80 Foamy Histiocytes in Xanthogranulomatous Pyelonephritis. Lymphocytes and plasma cells were also present at the edges of this mass-like lesion.

Tamm–Horsfall protein can be identified in the interstitium as small bodies of amorphous fibrillary material that are strongly PAS positive and surrounded by inflammatory cells. The glomeruli are not primarily involved, but they can be initially affected by periglomerular fibrosis (see Fig. 23.79). Ischemic changes consisting of focal and segmental sclerosis and hyalinosis may also occur.

The histopathologic changes associated with chronic pyelonephritis have also been described in vesicoureteral reflux and chronic urinary obstruction.[571] An extreme form of localized scarring is seen in the so-called Ask–Upmark kidney, where total fibrosis of a lobule produces an appearance of segmental hypoplasia.

Xanthogranulomatous pyelonephritis is an uncommon and distinct type of chronic infectious pyelonephritis in which yellow, lobulated masses diffusely replace the renal architecture.[572] There are cases in which only a portion of the kidney, such as one pole, is involved. The condition is usually unilateral, although rare bilateral cases have been reported. This disease can occur at any age: it has been reported in patients as young as 11 months to as old as 89 years but is more common in adults in the fifth through the seventh decades.[570,573] It is twice as common in women as in men.[570,574] Urinary obstruction is almost invariably present and is most often caused by stones. Other causes of obstruction include postradiation strictures, congenital pelviureteric stenosis, and tumors.[575] The mass-occupying nature of this lesion frequently mimics that of a renal cell carcinoma and can result in unnecessary nephrectomies. A correct preoperative diagnosis is rarely made. Microscopically, there is a diffuse granulomatous inflammatory infiltrate that includes large numbers of foamy histiocytes and some multinucleated giant cells, as well as lymphocytes, plasma cells, and neutrophils (Fig. 23.80).[576] If renal cell carcinoma is suspected, the presence of histiocytes in xanthogranulomatous pyelonephritis can be confirmed on CD163 immunostain and the lack of infiltrating carcinoma can be demonstrated by the absence of cytokeratin expression. Electron microscopy shows that the foamy macrophages initially contain bacteria and subsequently contain numerous phagolysosomes with a myeloid configuration and amorphous material.[577] The lesion is destructive, tending to obliterate renal parenchyma within the affected areas. *E. coli* is the usual etiologic agent, but *Proteus mirabilis* and *S. aureus* have also been found to be responsible.[570]

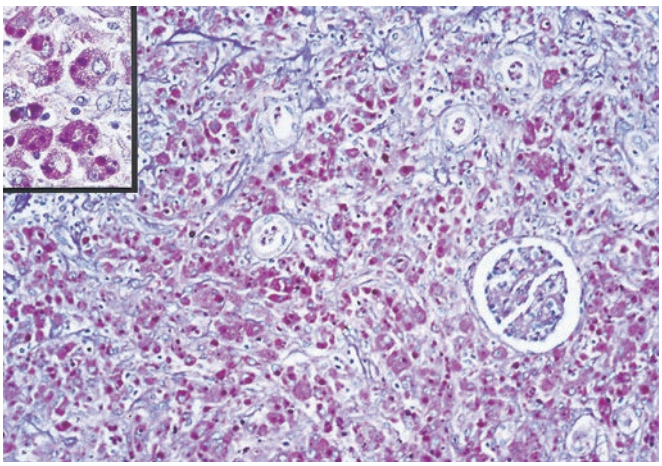

Figure 23.81 Nephrectomy Specimen From a Patient With Malakoplakia. The interstitium is infiltrated by numerous macrophages with granular cytoplasm. *Inset:* Several Michaelis–Gutmann bodies are seen in the cytoplasm.

Malakoplakia is a rare, histologically distinct, inflammatory reaction usually caused by enteric bacteria that can involve many organs but most frequently affects the urinary system.[578] In the kidney, the gross and microscopic appearances of this condition resemble those of xanthogranulomatous pyelonephritis. Confluent nodules of homogeneous yellow–tan tissue replace large areas of renal parenchyma. Fibrosis is also prominent. The inflammatory infiltrate consists largely of histiocytes with relatively few lymphocytes and plasma cells. The distinctive Michaelis–Gutmann bodies, composed of iron and calcium, are found both within the histiocytes and extracellularly in the stroma (Fig. 23.81). Ultrastructurally, these bodies are round with a core of concentric membranes, amorphous material or foci of calcification, and are highlighted on PAS stain (see Figs. 23.81 inset, and 23.82).[579] The pathogenesis of this cellular accumulation is unknown, but there is evidence that the lesions result from a defective macrophage function that compromises the lysosomal degradation of engulfed bacteria and overloads the cytoplasm with undigested cellular debris.[580]

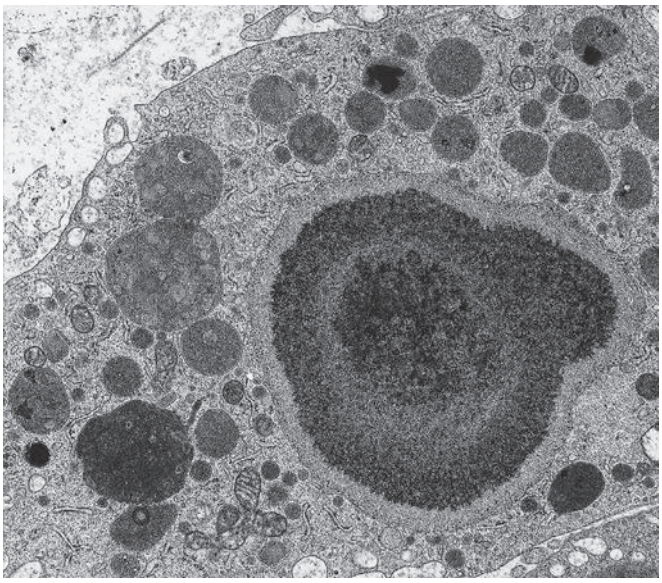

Figure 23.82 Electron micrograph of a histiocyte showing numerous phagolysosomes and a Michaelis–Gutmann body with calcified central core (×11,400).

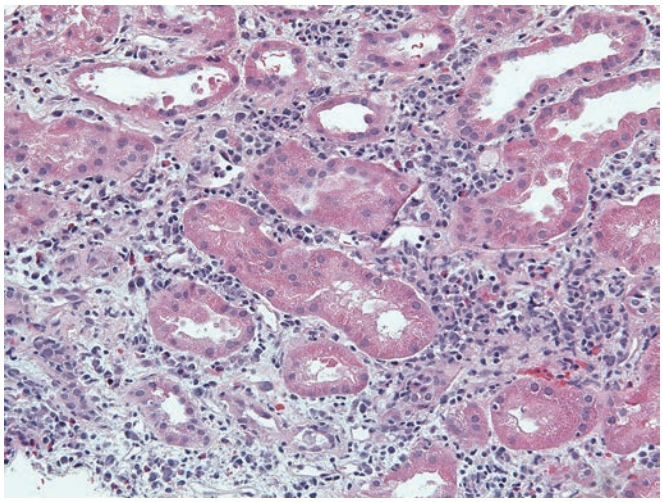

Figure 23.83 Antibiotic therapy–related acute allergic tubulointerstitial nephritis with interstitial edema and inflammation composed of lymphocytes, monocytes, plasma cells, and eosinophils.

Acute Allergic Tubulointerstitial Nephritis

Many drugs, including β-lactam antibiotics, proton pump inhibitors, nonsteroidal anti-inflammatory drugs, diuretics, and diverse other substances, can be responsible for acute TIN.[581–583] According to a series, omeprazole, amoxicillin, and ciprofloxacin are the most common offenders.[584] The clinical presentation is quite variable, but fevers and azotemia are common, and eosinophilia occurs in a majority of cases. Microscopic hematuria is not uncommon. A skin rash, usually described as maculopapular, is sometimes seen. Urinalysis reveals hematuria, sterile pyuria, and moderate proteinuria, and eosinophils may be detected in the sediment.[585] Acute interstitial nephritis combined with MCD producing nephrotic-range proteinuria has been described with nonsteroidal anti-inflammatory drugs.[586]

Light microscopy reveals generalized interstitial edema and infiltration of the interstitium by lymphocytes, macrophages, plasma cells, and eosinophils (Fig. 23.83).[587] Damage to tubular epithelial cells with evidence of regeneration is always found, and lymphocytes maybe seen infiltrating the epithelium. The glomeruli and vessels are not usually involved. Occasionally, ill-formed granulomas with giant cells can be seen with some drugs and in that setting, the differential diagnosis includes sarcoidosis, infections, and GPA.[588]

Although bacterial infection and drugs are the most common causes of acute interstitial nephritis, a similar picture can be found in patients with autoimmune or immunologic disease such as SLE, Sjögren syndrome, IgG4-related TIN, TIN with uveitis, or, rarely, in association with antitubular basement membrane antibodies.[589] The clinical and pathologic findings are parallel to those seen in allergic TIN. Although the renal disease in SLE predominantly affects glomeruli, coexistent interstitial inflammation is common and, on rare occasion, TIN exists in isolation. Sjögren's syndrome-related TIN is characterized by lymphoplasmacytic infiltrate and associated glomerular disease is uncommon. The clinical presentation, extrarenal manifestations, and serologic studies are helpful in the diagnosis of SLE and Sjögren's syndrome. In both diseases, the tubular basement membrane and interstitial deposits, when present, stain for IgG and C3 and, in the case of SLE, can show a full-house pattern. A syndrome of acute TIN with anterior uveitis and constitutional symptoms such as fever, weight loss, and anorexia can occur, usually in adolescent and young adult women.[590] Renal presentation of mild proteinuria and Fanconi syndrome is typical and the etiology is unclear. Interstitial granulomas can be present in a minority of these cases and potential etiologic factors include autoimmune, genetic, and infections such as *Mycoplasma*, *Klebsiella*, *Toxoplasma*, EBV, and herpes zoster.

Immunoglobulin G4–Related Tubulointerstitial Nephritis

IgG4-related related disease is a systemic fibroinflammatory disease, and the kidney involvement is characterized by polyclonal plasma cell–rich interstitial inflammation.[591] The frequent clinical presentation of IgG4-related TIN is chronic renal insufficiency and proteinuria that is typically mild unless the patient has glomerular involvement resulting in nephrotic syndrome. The presence of hypergammaglobulinemia and elevated serum IgG and IgG4 levels supports the diagnosis and approximately 50% of the patients have hypocomplementemia. Serum ANA is occasionally positive, and peripheral eosinophilia may be present. Imaging studies can reveal low attenuation cortical mass–like lesions, corresponding to patchy fibroinflammatory process. The plasma cell–rich interstitial infiltrate frequently alternates with paucicellular fibrotic areas, especially with increasing chronicity. The dense IF has a characteristic storiform pattern. The presence of greater than 10 IgG4+ cells/40× field, although not entirely specific, meets the criteria for renal IgG4-related TIN (Fig. 23.84).[592] Immunofluorescence and electron microscopy reveal tubular basement membrane deposits in greater than 80% of cases and these are IgG, C3, κ and λ positive. It should be noted that plasma cell–rich and IgG4 cell–rich infiltrate can be observed in a variety of lesions such as chronic pyelonephritis and vasculitis-associated tubulointerstitial inflammation. The accurate diagnosis of IgG4-related TIN rests on evidence of systemic disease either in the form of elevated IgG4 levels or extrarenal disease.[592] Glomerular involvement is seen in less than 10% of IgG4-related TIN, often represented by a secondary membranous nephropathy with the deposits being PLA2R negative.[593]

Analgesic Abuse Nephropathy

Analgesic abuse nephropathy is a bilateral renal disease characterized by papillary necrosis and chronic TIN that results from the

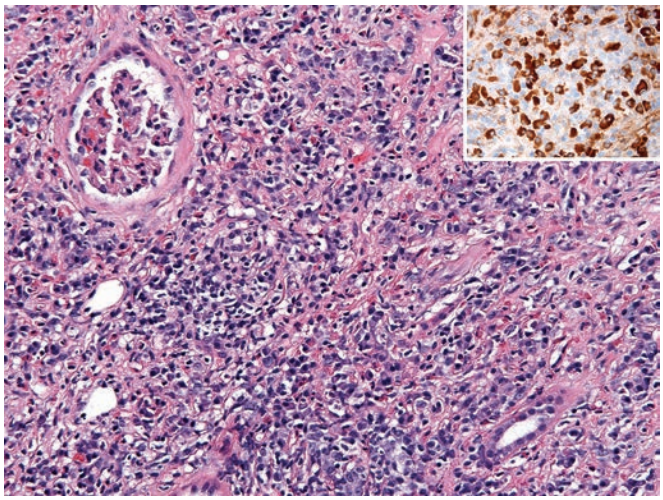

Figure 23.84 IgG4-related tubulointerstitial nephritis with dense storiform fibrosis, tubular destruction, and intense lymphoplasmacytic infiltrate. In the appropriate clinical setting, the presence of greater than 10 IgG4+ cells/HPF supports the diagnosis.

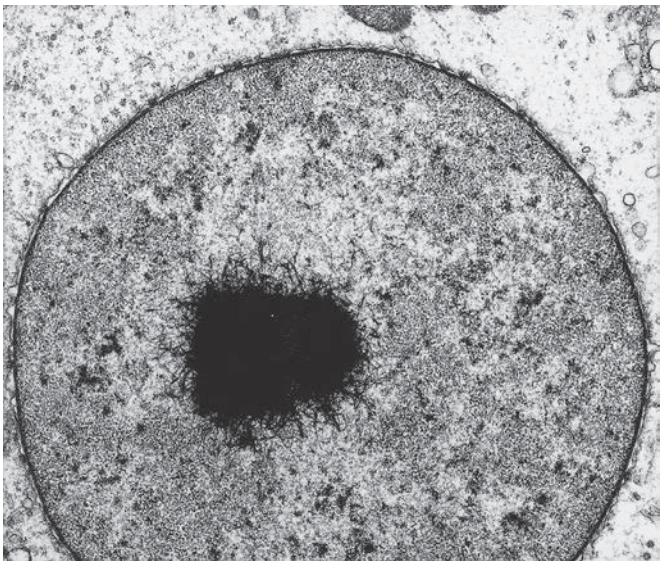

Figure 23.85 Intranuclear lead inclusions showing dense central cores surrounded by fibrillar material (×15,600).

excessive intake of analgesic mixtures containing aspirin or antipyrine, combined with phenacetin, acetaminophen (paracetamol), or salicylamide, and caffeine or codeine.[594] The incidence of analgesic nephropathy varies in different countries. In the early 1990s, the reported incidence of analgesic nephropathy among patients receiving dialysis was estimated to be 0.8% in the United States, 3% in Europe, and 9% in Australia.[595,596] The condition is more common in women than in men. Phenacetin has been removed from the United States market more than 20 years ago and since then, the incidence of analgesic nephropathy, although not eliminated, has reduced dramatically.[597,598]

The most important diagnostic feature is a history of chronic pain syndromes and analgesic abuse over several years or decades. Renal function abnormalities include impaired urine concentration defects and impaired sodium conservation. Urinary infection is a complication in about 50% of the cases. On occasion, fragments of necrotic papillae are excreted. This may cause gross hematuria or renal colic due to obstruction of the ureter by the necrotic tissue. Renal imaging studies are helpful in detecting papillary necrosis and calcification. Progressive impairment of renal function may lead to chronic renal failure. An important association in analgesic nephropathy is the increased risk for developing transitional cell carcinoma.[599]

In the early stages of analgesic nephropathy, the cortex is normal, but the papillae are firmer and show gray streaks. Microscopically, there is interstitial homogenization, and thickening of the basement membranes of the loops of Henle and peritubular capillaries. Foci of necrotic epithelial, endothelial, and interstitial cells are associated with fine calcification. As the disease progresses, the papillae are shrunken and they have a brown coloration. Microscopically, confluent zones of necrosis within the inner medulla involve the loops of Henle, peritubular capillaries, and vasa recta, and the cortex may contain foci of TA, IF, and patches of chronic inflammation. In advanced disease, the kidneys are shrunken and the gross and microscopic changes mimic chronic pyelonephritis. Total papillary necrosis occurs and extensive calcification is usually present. Papillary necrosis is not specific for analgesic nephropathy. It can also occur in a variety of other conditions including diabetes mellitus, urinary tract obstruction, and sickle cell disease.[600]

Heavy Metals Nephrotoxicity

Renal damage can result from environmental or occupational exposure to heavy metals, such as lead, cadmium, mercury, uranium, chromium, copper, and arsenic,[601–604] or the administration of therapeutic forms of platinum,[605] gold,[606] and bismuth.[607,608] Due to its rather characteristic morphologic features and clinical importance, only the changes in the kidney produced by lead exposure will be discussed.

Lead Nephropathy

Lead poisoning may be the result of occupational or environmental exposure.[609,610] Workers at risk include electric storage battery makers, painters, welders, foundrymen, and jewelers. Children may be exposed by eating flaking lead paint. Inadvertent ingestion of lead can occur from drinking water contaminated by lead pipes, earthenware, or from adulterated wine or moonshine liquor. Lead is also present as an atmospheric contaminant resulting from the use of lead-containing gasoline and various industrial processes. Associated with chronic kidney disease, it can often go unrecognized in the modern era.[611]

The organs most commonly affected by lead exposure are the central and peripheral nervous systems, gastrointestinal tract, and kidney. The most striking morphologic changes in lead exposure occur in the tubules and consist of eosinophilic intranuclear or cytoplasmic acid-fast inclusions that stain red with Giemsa stain. These inclusions consist of a lead–protein complex that by electron microscopy appear as compact cores surrounded by a loose meshwork of fibrils (Fig. 23.85). They may be seen in tubular epithelial cells in urinary sediment during acute poisoning.[612] Lead-containing inclusions have also been found in the liver and neural tissue.

Renal biopsies in chronic lead nephropathy often show TA and IF with minimal inflammatory reaction. Arteriolar changes reminiscent of hypertensive nephrosclerosis may be present even in the absence of hypertension. The inclusions are often absent when the disease is longstanding or after the administration of chelating agents.

Nephrolithiasis and Nephrocalcinosis

Nephrolithiasis is a common disorder defined as the development and accumulation of stones within the collecting system of the kidney.

The estimated incidence in the United States ranges from 7 to 21 cases per 10,000 population.[613] Men are affected approximately four times more frequently than women, and the predominant age at onset is in the third to fifth decades. The most characteristic symptoms of nephrolithiasis are pain and hematuria. The classic pain is that of severe, abrupt, flank pain (renal colic) that only resolves after the passage or removal of the stone. The hematuria can be gross or microscopic and most commonly occurs with large calculi during infection or colic. About 75% of the stones are composed of a combination of calcium oxalate or calcium oxalate mixed with calcium phosphate; 15% are the so-called struvite stones that are composed of magnesium ammonium phosphate and are often associated with urea-splitting bacterial infections; 6%–10% consist of uric acid; and 1%–2% of cystine. Renal stones within the pelvic calyceal system can cause gross and microscopic changes in the renal parenchyma that are identical to those seen in pyelonephritis and hydronephrosis.

The presence of calcium within the renal parenchyma is known as nephrocalcinosis.[614] Calcium deposition occurs on tubular basement membranes and in the interstitium. TA, IF, and periglomerular fibrosis are also present. Some of the glomeruli may be sclerosed. Several systemic disorders are associated with nephrocalcinosis and the formation of stones. Calcium phosphate and oxalate stones occur in hyperparathyroidism, sarcoidosis, milk–alkali syndrome, excessive dietary intake of vitamin D, multiple myeloma, and renal tubular acidosis. Abundant intratubular calcium phosphate deposition can occur in patients who receive oral sodium phosphate bowel purgative prior to colonoscopy. Referred to as acute phosphate nephropathy, it is often associated with inadequate hydration and concomitant use of diuretics, ACE inhibitors, or angiotensin receptor blockers. Renal insufficiency occurs weeks or months after the colonoscopy was performed.[615]

Uric acid stone formation takes place in an acid urine in the presence of hyperuricosuria, which may result from an inborn error of metabolism such as gout or the Lesch–Nyhan syndrome, glycogen storage disease following treatment of hematopoietic malignancies, overindulgence in dietary proteins, or the use of uricosuric drugs.[616] Uric acid stones are usually radiolucent, and because they are often small they may be passed, but larger ones in the renal pelvis can grow and become staghorn calculi. Uric acid crystals are also deposited within the renal parenchyma, and they can be seen within the collecting tubules as elongated or rectangular crystals or as doubly refractile crystals in the interstitium surrounded by a giant cell reaction.[617,618]

A clinical sign of cystinuria is calculi in the urinary tract. The stones are formed in acid urine. They are typically yellow–brown and radiopaque. Cystine crystals appear as microscopic, flat hexagons in the urine, and this feature constitutes the clue for the diagnosis. The disorder is characterized by the defective transport of cystine, lysine, arginine, and ornithine by epithelial cells of the renal tubules and the gastrointestinal tract; it is transmitted as an autosomal recessive trait with an incidence of 1 in 20,000.[619,620] Complications of calculi formation include urinary tract obstruction and infection, which may result in renal failure. This entity is distinct from cystinosis, a lysosomal storage disorder that presents as a severe nephropathic form in infants.[621]

Hyperoxaluria is characterized by recurring calcium oxalate nephrolithiasis and/or nephrocalcinosis, often terminating in chronic renal failure (Fig. 23.86). Primary hyperoxaluria is a rare autosomal recessive disorder of glyoxylate metabolism resulting in hyperoxaluria in children.[622] Approximately 80% of mutations detected in these patients affect gene encoding alanine glyoxylate aminotransferase.[623] Ethylene glycol poisoning, methoxyflurane anesthesia, pyridoxine deficiency, excess ascorbic acid ingestion, pyridoxine (vitamin B6) deficiency, and various chronic gastrointestinal disorders (including Crohn disease, chronic pancreatitis, celiac sprue, and status post-jejunoileal bypass procedure) have been associated with oxalosis.[624,625] In the kidney, oxalate crystals are deposited in the interstitium, tubules, and, rarely, the glomeruli. They have radial striations that show up particularly well with polarized light (Fig. 23.87). TA, IF and inflammation, and glomerulosclerosis are the end results.

Xanthinuria is a rare hereditary condition transmitted as an autosomal recessive trait. The enzyme xanthine oxidase, which is responsible for the conversion of xanthine and hypoxanthine to uric acid, is deficient. Xanthine stone formation occurs in one-third of patients with this disorder. Similar stones are seen as a complication of allopurinol therapy since this drug blocks xanthine oxidase activity.[626]

Light Chain Cast Nephropathy

Light chain cast nephropathy, also known as Bence Jones cast nephropathy, myeloma cast nephropathy, or myeloma kidney, is the most common form of renal disease associated with multiple myeloma.[627] Clinically, it may present as progressive renal insufficiency or acute renal failure, often precipitated by dehydration, hypercalcemia, IV infusion of contrast media, nonsteroidal anti-inflammatory drugs, hyperuricemia, nephrotoxic infections, or loop diuretics, such

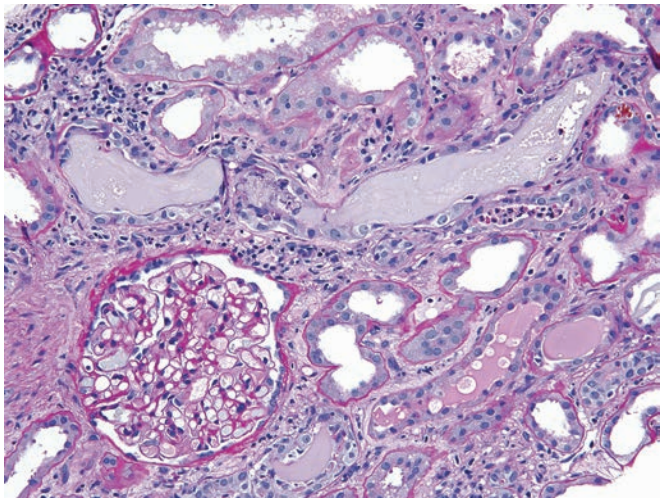

Figure 23.88 Light Chain Cast Nephropathy. Large, dense PAS-negative tubular casts associated with tubular injury and intratubular neutrophils (PAS).

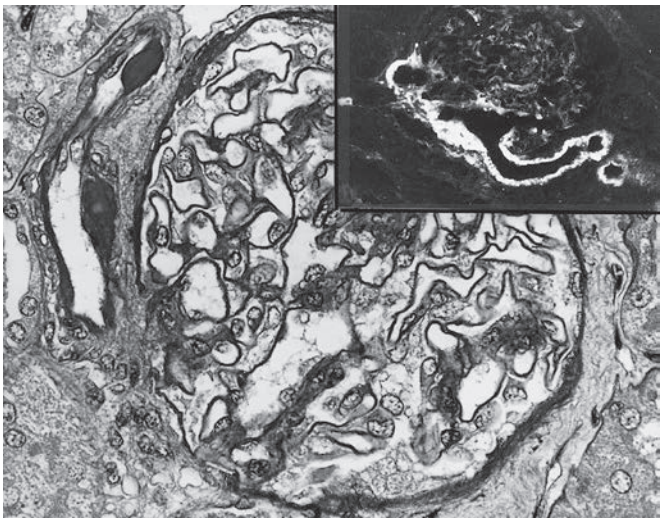

Figure 23.89 Afferent Arteriole With Subintimal Homogeneous Hyaline Material. *Inset:* Immunofluorescence preparation showing reaction for C3. as furosemide. Proteinuria is found, although not usually in the nephrotic range, and it most often consists predominantly of immunoglobulin light chains (Bence Jones protein). Circulating monoclonal light chains can be confirmed by serum protein electrophoresis or free light chain assay. The light chains are normally filtered by the glomeruli and reabsorbed and metabolized by proximal tubular cells. In patients with multiple myeloma, the excess monoclonal light chains overwhelm the catabolic capacity of the proximal tubules, thus allowing them to reach the distal nephron where the presence of Tamm–Horsfall protein may facilitate their precipitation in the form of voluminous casts. These monoclonal free light chains can also cause proximal tubular cell cytotoxicity, TIN, and ultimately damage the entire nephron, resulting in renal failure.[628]

By light microscopy, the distal and collecting tubules appear occluded by numerous dense, markedly eosinophilic, lamellated and fractured casts, sometimes surrounded by multinucleated giant cells derived from interstitial macrophages that invade the tubules through breaks in the basement membrane (Fig. 23.88).[629,630] Some casts may exhibit Congo red and thioflavin T positivity, but this alone is not indicative of amyloidosis. The tubular cells may appear flattened or can show varying degrees of degeneration with necrosis and denudation of the tubular basement membranes. Depending on the stage of the disease, there is a variable degree of IF usually associated with acute and/or chronic inflammatory cell infiltrates. Prominent intratubular collections of neutrophils may be seen, mimicking acute pyelonephritis. Sometimes the casts may contain rhomboid or needle-shaped crystalline structures that may also be found in the tubular epithelium and, on rare occasions, in the glomeruli.[631] Immunofluorescence studies demonstrate that the casts are largely made of the pathogenic light chain, either kappa or lambda (although kappa tends to be more frequent).

Renal Vascular Disease

Renal Arteriolar Disease

The kidney plays an essential role in hypertension, and the vessels of the kidney are susceptible to a variety of pathologic changes directly related to increased pressure.[632] The vessels most susceptible are small arteries and arterioles, with preglomerular vessels being more prominently affected. Vascular narrowing of these intrarenal vessels eventually leads to glomerular sclerosis, TA, and IF (nephrosclerosis). The hypertensive vascular changes of the small vessels of the kidney fall into three general categories: hyaline arteriolosclerosis, myointimal hypertrophy and hyperplasia, and fibrinoid necrosis.[633]

In **hyaline arteriolosclerosis**, the outer part of the wall of affected vessels is thickened by deposition of a homogeneous, eosinophilic, PAS-positive material (Fig. 23.89). Associated changes are atrophy of the smooth muscle cells in the vessel walls and a uniform thickening of the basement membrane. Hyaline arteriolosclerosis is most marked in the afferent arteriole and in smaller vessels lacking an internal elastic lamina. Mild hyaline arteriolosclerosis is often seen with increasing age, but it is more prominent in patients with hypertension or diabetes. The effects are more marked in hypertension where the arteriolar lumens become severely narrowed, causing diffuse renal ischemia and symmetric shrinking of the kidneys. It is believed that the hyaline deposition results from leakage of plasma components across the vascular endothelium, triggering extracellular matrix production by smooth muscle cells. The hyalinized arterioles usually immunoreact for IgM and complement components, especially C3 (see Fig. 23.89 inset). Hyaline arteriolosclerosis is a major morphologic feature in benign nephrosclerosis, in which the interlobular and arcuate arteries may also exhibit medial hypertrophy and reduplication of the elastic lamina.

The second type of vascular abnormality seen in hypertension is that hyperplasia involving the smooth muscle and intima of small arteries and arterioles **(myointimal hypertrophy and hyperplasia)**. Hyperplastic arteriolosclerosis is generally associated with acute or persistent severe high blood pressure and, therefore, is seen more often in accelerated/malignant than benign hypertension. In the early stages, the lesions are characterized by profuse intimal thickening by myxoid and sparse cellular connective tissue that drastically reduces the vascular lumen. Over time, this acute change shows progressive intimal scarring and uniform concentric thickening of the vessel wall by a proliferation of myointimal cells, and deposition of basement membrane–like material. The microscopic appearance of this lesion has led to the descriptive term of "onion skinning" (Fig. 23.90). These changes are more pronounced in arcuate and

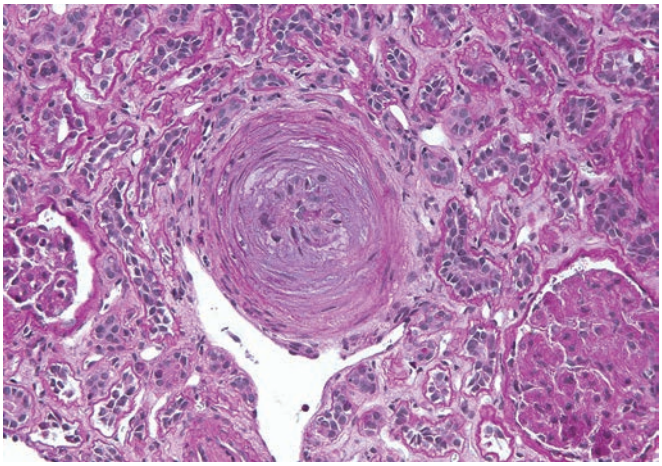

Figure 23.90 Malignant Hypertension. Interlobular artery with thinning of the media and marked intimal edema and early fibrosis. The cortex shows glomerular ischemic changes and extensive tubular atrophy (PAS).

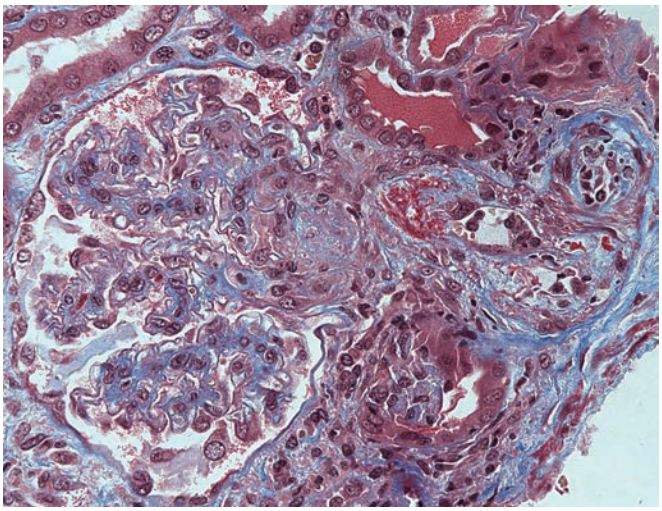

Figure 23.91 Malignant Hypertension. Fibrinoid necrosis and intimal edema of the afferent arteriole with ischemic shrinkage of the glomerular capillary tuft (trichrome).

interlobular arteries but extend into the arterioles where they may coexist with hyalinosis from longstanding hypertension.

Fibrinoid necrosis of the afferent arteriole has been regarded as the hallmark of accelerated (malignant) hypertension. The necrosis is usually superimposed on a preexisting hyperplastic or hyaline lesion, but it can be the initial event in young patients with severe acute malignant hypertension. The architecture of the media of affected vessels is obliterated by the necrotizing process and further obscured by deposition of deeply eosinophilic, fibrillar material which, by histochemical and immunofluorescent techniques, has been demonstrated to be fibrin and fibrinogen.[634] The arteriolar lumen may be reduced in size as a result of wall thickening, extravasation of red blood cells, and intraluminal thrombosis.

In malignant hypertension, the glomeruli often show variable degrees of ischemic change, characterized by wrinkling and collapse of the capillary walls (Fig. 23.91). In addition to this diffuse pattern of ischemic damage, segmental lesions such as apparent necrosis in direct continuity with arteriolar lesions may be seen. By electron microscopy, the endothelium often appears swollen and sometimes

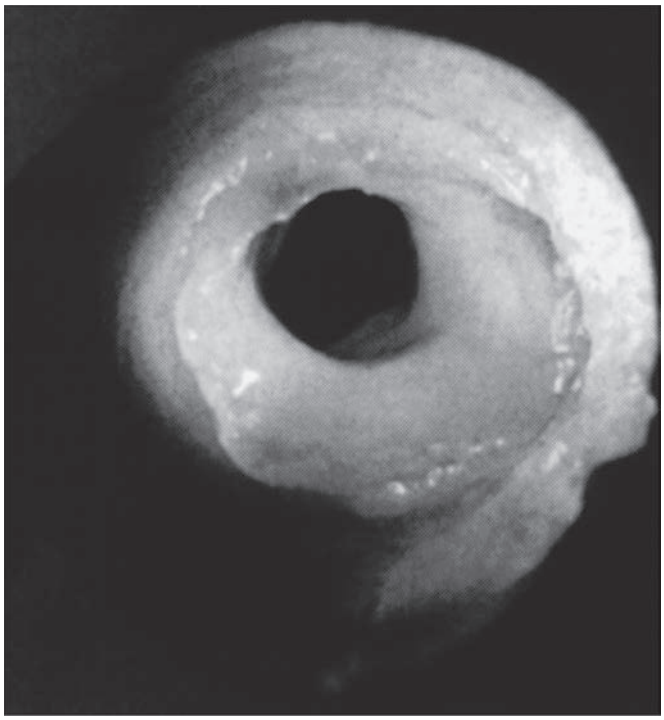

Figure 23.92 Eccentric arteriosclerotic plaque in renal artery causing almost complete obstruction and hypertension. This was resected and arterial continuity reestablished.

focally disrupted or separated from the GBM by the accumulation of electron-lucent material. On occasion, subendothelial or intracapillary strands of fibrin may be seen. Immunofluorescence microscopy may reveal fibrin, fibrinogen, IgM, and complement components in a segmental distribution.

Renal Arterial Disease

The larger arteries in the kidney can also be the site of renal vascular disease. Atheromatous involvement is accelerated in patients with hypertension and may be a source of atheromatous emboli and give rise to renal parenchymal infarcts. Arteries down to the arcuate size can show arteriosclerotic changes, but smaller vessels are more commonly involved by intimal thickening of the hyperplastic type, similar to that seen in the small arteries. Disease of the major arteries becomes particularly important when it involves a main renal artery and causes significant stenosis, resulting in secondary hypertension (Fig. 23.92).[635] The lesions involving the main renal artery can be broken down into three categories: atherosclerosis, dysplastic diseases of the fibromuscular vessels, and a miscellaneous group that includes congenital anomalies, Takayasu aortitis, and radiation injury.

The most common cause of renal artery stenosis is obstruction of the lumen by an **atheromatous plaque** at the orifice of the main renal artery.[635] It is usually associated with severe atheromatous disease of the aorta and is seen more often in males and in patients with diabetes mellitus. Major complications of the lesions include saccular or dissecting aneurysm formation and the occurrence of cholesterol emboli. Microscopically, these emboli appear as needle-like spaces representing cholesterol crystals embedded in amorphous debris frequently surrounded by multinucleated giant cells. Although symptomatic presentation is rare, cholesterol emboli occur immediately after or with a few months of angiographic or surgical procedures involving vessels.

Table 23.7 Dysplastic lesions of the renal artery

DIAGNOSIS	AGE INCIDENCE	SEX INCIDENCE	RELATIVE FREQUENCY (%)	LESION
Intimal fibroplasia	1–50	M = F	1–2	Narrowing by intimal proliferation without lipid
Medial fibroplasia with aneurysms	30–60	F > M	60–70	"String of beads," alternating stenosis and mural thinning
Medial hyperplasia	30–60	F > M	5–15	Smooth muscle hyperplasia and thickening
Perimedial fibroplasia	30–60	F > M	15–24	Fibrosis of outer media, occasionally aneurysms
Medial dissection	30–60	F > M	5–15	Fibrosis of media with dissecting aneurysms
Periarterial fibroplasia	15–50	F > M	1	Perivascular fibrosis and inflammation

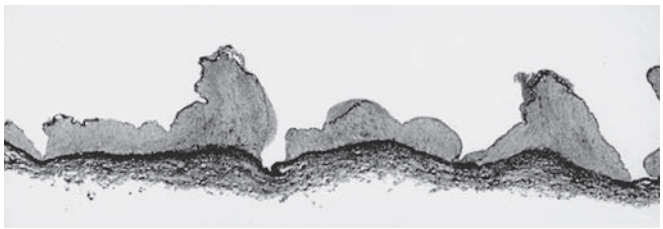

Figure 23.93 Fibromuscular Dysplasia in a Young Woman With Hypertension. Note aneurysmal formations in this longitudinally sectioned artery demonstrating medial fibrodysplasia with mural aneurysms.

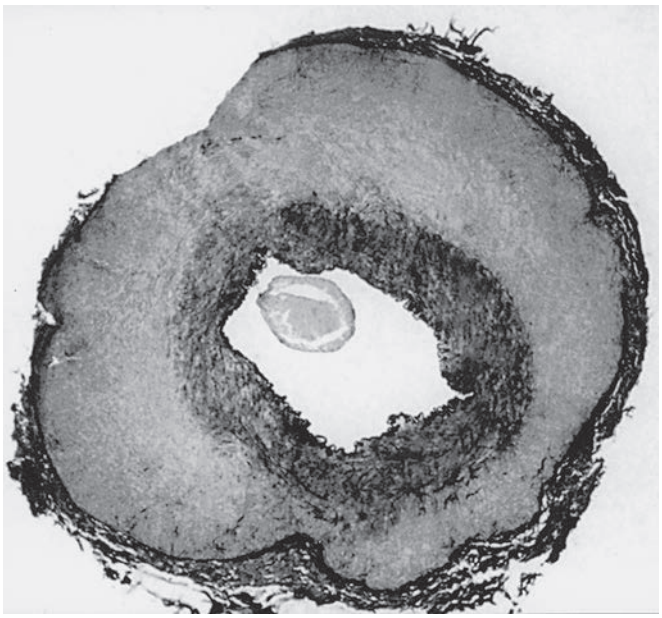

Figure 23.94 Fibromuscular Dysplasia in a 23-Year-Old Woman With Hypertension. Segmental resection revealed an artery with the perimedial variety of fibrodysplasia.

The second group of conditions that leads to stenosis are **dysplastic lesions of the renal artery,** currently termed **fibromuscular dysplasia**, which account for less than 10% of the cases of renal artery stenosis.[636–638] These lesions can involve other systemic vessels, suggesting that there may be an underlying defect in vessel structure, and can become clinically important when they cause obstruction of a major renal artery, thereby leading to severe hypertension unresponsive to antihypertensive drugs. Typically, these lesions occur in the distal two-thirds of the artery and are bilateral in 50% of the cases. Fibromuscular dysplasia can be divided into three types: intimal, medial, and periarterial/adventitial. The medial category in turn consists of three subtypes: medial fibroplasia, medial hyperplasia, and perimedial fibroplasia. As the terms indicate, differences are somewhat subtle, but given that different patient populations may be affected in each subgroup, this categorization is clinically useful (Table 23.7).

The lesion in *intimal fibromuscular dysplasia* is hyperplasia of the intima, and microscopically it is virtually indistinguishable from the proliferative stage of atherosclerosis, although it is not associated with an increased deposition of lipids. The architecture of the elastica and media are preserved so the only abnormality in the vessel wall is the intimal hyperplasia. Individuals as young as 1 year of age have been affected, but it is seen more often in the third and fourth decades. The most common of the dysplastic lesions is *medial fibroplasia*. In this condition, multiple foci of stenosis alternating with microaneurysms produce a "string of beads" appearance (Fig. 23.93).[637] Microscopically, atrophy of the muscle coat and fibrosis of the media near small aneurysms alternate with foci of muscular hypertrophy and fibrosis in the stenotic areas. Second in frequency is *perimedial fibroplasia* (Fig. 23.94). In this variant, segmental aneurysmal dilation does not occur, and the outer half of the media, elastica, and intima maintain their normal architecture. *Medial hyperplasia* is seen less frequently. Hyperplasia of the muscle produces a uniform circumferential thickening of the vessel wall with narrowing of the lumen. *Periarterial fibromuscular dysplasia* is a rare lesion in which fibrosis of the adventitia extends into the surrounding adipose and connective tissue, causing extrinsic constriction of the vessel (rather than thickening from within the wall).

Among the **miscellaneous causes** of renal artery stenosis, *radiation injury* is of particular interest.[639] The lesion is characterized by a loss of muscle and an intense fibrosis in all layers of the vessel wall. It is usually a distant event that follows radiation therapy for a malignant tumor where the renal artery was included in the irradiated area. *Takayasu aortitis* or pulseless disease is a chronic sclerosing aortitis of unknown etiology that can cause renal artery stenosis from narrowing of the ostium.[640] An inflammatory infiltrate with giant cells is frequently present, suggesting an immunologic mechanism.

An ischemic kidney is smaller than the contralateral kidney, irrespective of the etiology. Glomeruli are small with ischemic wrinkling of the basement membranes, and the tubules are atrophic. The atrophic tubules have simplified epithelium with inconspicuous lumina mimicking parathyroid, often referred to as "endocrine

change." IF is present, and the hyperplastic juxtaglomerular apparatus shows increased granularity with special stains. The small vessels are protected from the hypertension, in contrast to the contralateral kidney, where biopsy may show hypertensive microvascular disease.

Radiation Nephropathy

Radiation nephropathy is the term used to designate the renal disease that occurs with irradiation of the abdomen (or total body) during the treatment of malignant tumors. More recently, this has also been noted in association with use of radiolabeled substances such as monoclonal antibodies, antibody fragments, and low-molecular-weight oncophilic peptides.[440] Although the term acute radiation nephritis has also been used for this disease, since no inflammation occurs immediately after kidney irradiation and histologic examination of the radiation-damaged kidneys usually reveals only minimal proliferation and inflammatory changes, the terms acute and chronic radiation nephropathy, rather than nephritis, are preferred.[440,641] The severity of the pathologic changes in the damaged kidney depends upon multiple factors, including radiation dosage, method of irradiation, age of the patient, amount of perirenal fat, preexistence of renal disease, and the concomitant use of chemotherapeutic agents, as well as individual susceptibility. In general, a radiation dose of 9.8 Gy in the absence of exposure to nephrotoxic drugs and other predisposing factors is associated with 5% incidence of kidney toxicity.[642]

Acute radiation nephropathy usually occurs 6–12 months after radiation exposure.[440] However, the period of latency can be shorter, especially in children. Clinically, the disease is manifested by the gradual onset of edema, hypertension, dyspnea on exercise, pleural and peritoneal serous effusions, anemia, headaches, and urinary changes, which include proteinuria and the presence of casts. Rare cases of radiation nephropathy causing nephrotic syndrome have been reported.[643] The glomerular filtration rate decreases and over half of the patients progress to renal failure. Those who recover from the acute episode usually have persistent proteinuria and renal impairment. On occasion, malignant hypertension may develop during the acute radiation syndrome. The mortality of patients with this complication is high.

Chronic radiation nephropathy either follows the acute phase or develops insidiously over a period of years. Although no specific threshold has been established for total cumulative radiation exposure that leads to this form of injury, it appears that relatively small doses of radiation (500–1000 rad) may, in susceptible individuals, cause renal damage. In most patients, the findings of mild proteinuria and moderate hypertension are not detected until many years after radiation exposure.

Depending on the severity and the stage of the disease, kidney biopsies from patients with radiation nephropathy will show a wide range of glomerular changes.[440] Some glomeruli may appear segmentally or completely scarred, while others may show no significant changes. Segmental areas of fibrinoid necrosis of the tuft in continuity with similar changes in the arterioles may be seen. The glomerular capillary walls may be thickened, and a double contour may be demonstrated by silver impregnation techniques.[644] The mesangium may be prominent as a result of an increase in mesangial matrix. Mesangiolysis and adhesions to the Bowman capsule may be seen. Vascular injury is manifested by fibrinoid necrosis of the arterioles and small arteries, sometimes accompanied by thrombosis. A loose myxoid intimal thickening involving arterioles and interlobular arteries is a frequent feature. The glomerular and vascular changes are within the spectrum of pathology seen in TMA. Swelling of the tubular epithelium with desquamation of the cells, and basement membrane thickening and splitting followed by tubular loss and atrophy are common findings and may be severe. Regeneration is often abnormal so that the cells may have poorly formed cytoplasm and abnormal nuclei. The interstitium is focally scarred and has no significant inflammation.

Electron microscopic examination of the glomeruli shows a widening of the subendothelial zone that may contain flocculent material or strands of fibrin. Focal extension of the mesangium into the subendothelial space may also be seen, sometimes associated with GBM duplication. The endothelial cells may appear swollen or focally detached from the endothelial aspect of the GBM. Immunofluorescence may show focal deposition of IgM and fibrinogen in glomeruli and blood vessels.

Hematopoietic Stem Cell Transplantation–Associated Thrombotic Microangiopathy

Hematopoietic stem cell transplantation (HSCT)-associated TMA is the term used to designate a syndrome of late-onset renal insufficiency that has been reported to occur in up to 20% of patients who have received a bone marrow transplant and was previously referred to as bone marrow transplant nephropathy.[440,645] Although hematopoietic stem cells can be derived from bone marrow, peripheral blood is the most common source now.[36] Total body irradiation is an important component of the treatment in these patients and appears to be the main factor in the development of HSCT-associated TMA. However, other factors, such as drug therapy and infections also contribute to this syndrome.[440,645] It is also known that HSCT-associated TMA can occur in autologous or allogeneic HSCT, in the absence of graft versus host disease, total body irradiation, cyclosporine use, or infections. Individual susceptibility may also be an important factor, as a few pediatric patients with HSCT-associated TMA were found to have mutations in complement genes or develop autoantibodies against complement factors posttransplantation.[646]

The renal insufficiency usually manifests 9–12 months after the transplant but can be variable given the wide variety of treatment protocols and associated comorbidities.[36] In some patients, the clinical picture can be similar to that of HUS with a rapid decline of renal function, while in others there may be a slow decline in renal function without apparent ongoing hemolysis.[647–649] The renal lesions, regardless of whether or not the patient has clinical evidence of systemic HUS, typically affect the glomeruli, small arteries, and arterioles and are histologically similar to those reported in radiation nephropathy and HUS.[440]

Cystic Diseases of the Kidney

Renal cystic diseases are a large family of hereditary, sporadic, developmental, and acquired disorders characterized by the presence of cysts in one or both kidneys.[650–653] Only the most common cystic renal diseases will be discussed in this section. A subset of hereditary cystic diseases with gene mutations involving primary (nonmotile) cilia is now being reclassified as "ciliopathies." This category of disease includes autosomal dominant polycystic kidney disease (ADPKD), autosomal recessive polycystic kidney disease (ARPKD), and nephronophthisis (NPHP), and other related ciliopathies. Primary cilia are antenna-like projections on the apical surfaces of almost all cells and consist of a basal body and an axoneme with nine peripheral doublets. Primary cilia detect flow as well as a variety of stimuli and participate in transmembrane transport of proteins.

Multicystic Renal Dysplasia

In this disorder, the development of the kidney is disorganized because of anomalous differentiation of the metanephros (Fig. 23.95).

Figure 23.95 Dysplastic Kidney of an Infant. Opposite kidney appeared normal by pyelogram.

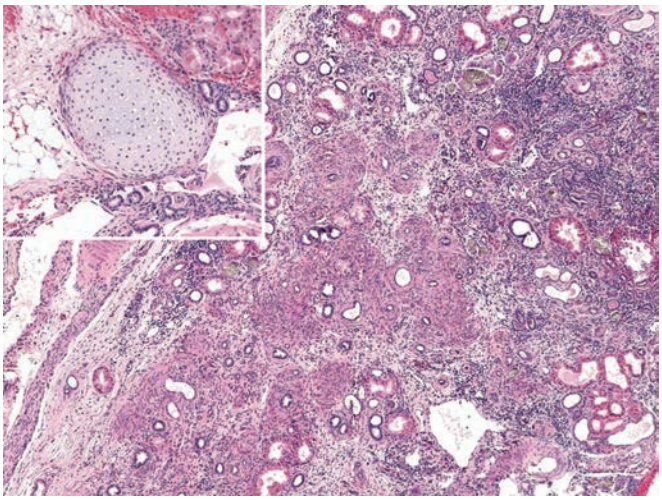

Figure 23.96 Dysplastic kidney showing embryonic-like connective tissue and primitive tubules. Immature cartilage is also seen focally *(inset)*.

Multicystic renal dysplasia is the most common form of cystic renal disease in children and the most common cause of abdominal masses in newborns. The dysplasia is usually unilateral but can be bilateral, segmental, or focal. Abnormalities of the collecting system are common and include obstruction of the uretero-pelvic junction, ureteral atresia, and urethral obstruction. Malformations of other organs, especially of the heart, can occur in conjunction with renal dysplasia. The clinical presentation largely depends on the extent of the dysplastic involvement and the degree of associated urinary obstruction. Most dysplastic kidneys arise sporadically but a few are familial or occur in syndromes of multiple malformations.[654,655] A large reniform mass of cysts of various sizes obscures any renal parenchyma that may be present. In focal and segmental dysplasia, only part of the kidney is involved by the dysplasia and cyst formation. Microscopically, the findings are quite characteristic.[656,657] The cysts are lined by cuboidal epithelial cells and surrounded by immature stromal elements. Primitive tubules and glomerular structures may be present, as may islands of dysplastic mesenchyme including cartilage and fibromuscular tissue (Fig. 23.96).

Autosomal Dominant Polycystic Kidney Disease

ADPKD is a hereditary condition characterized by expanding cysts that progressively destroy the renal parenchyma of both kidneys, ultimately causing renal failure. It is one of the most common hereditary human disorders, occurring in about 1 or 2 per 1000 live births and accounting for approximately 10% of cases requiring dialysis or renal transplantation.[658] The pattern of inheritance is autosomal dominant with complete penetrance, and each offspring of an affected individual has a 50% chance of inheriting the disease. The disease is genetically heterogeneous and is caused by a mutation in two genes, *PKD1* and *PKD2*, that are located on chromosomes 16p13.3 and 4q13–23, respectively.[659,660] The protein products of the PKD genes, polycystin-1 and polycystin-2, have similar cellular distribution resulting in phenotypic similarities between *PKD1*- and *PKD2*-mutated ADPKD.[661,662] Polycystin-1 is an epithelial cell membrane receptor involved in signaling of renal tubular epithelial cell proliferation and differentiation. Polycystin-2 has similarities to a sodium/calcium channel and likely modulates intracellular calcium levels; this ion channel function is enabled by heterodimerization of polycystin 1 and 2. The polycystin complex is implicated in the regulation of the cell cycle via multiple transduction pathways, as well as in the mechanosensory function of the renal primary cilium.[663] Abnormalities in tubular cell proliferation, apoptosis, cell polarity, and secretions have been detected within the cysts. Mutations in the *PKD1* gene are responsible for about 85%–90% of all cases of ADPKD, while mutations in *PKD2* cause the disease in majority of the remaining patients. A small number of families with ADPKD do not demonstrate linkage to either *PKD1* or *PKD2*, which suggests the potential presence of an as yet unidentified *PKD3* gene.[664] Males and females are affected equally, and there is no racial predilection. Although it can present at any time during life, it most frequently becomes symptomatic during the fourth and fifth decades with a gradual onset of renal failure. Early-onset ADPKD can occur rarely in children, causing a diagnostic challenge, and the presence of glomerular cysts should favor ADPKD.[665]

Clinical manifestations of ADPKD include flank pain, flank masses, hematuria, hypertension, and renal failure. Approximately 20% of patients with ADPKD develop nephrolithiasis, and uric acid stones are more common than calcium oxalate stones.[666] Although individuals with *PKD1* are clinically indistinguishable from those with *PKD2*, the latter patients have a less severe disease course with a later mean age at diagnosis, onset of hypertension, and ESRD.[667] Radiographic findings are usually diagnostic, and sonography and computed tomography are reliable procedures for the demonstration of early involvement. Gene linkage analysis allows prenatal diagnosis but requires at least four affected family members.[658] Although direct sequencing is more sensitive, even by this method, only 70% of ADPKD mutations are detected.

ADPKD is bilateral, but significant asynchrony of involvement of the kidneys may be noted on occasion. The kidneys are markedly enlarged and have a bosselated outer cortical surface produced by multiple cysts of varying sizes (Fig. 23.97). When the disease is severe, normal renal parenchyma is apparent only microscopically. The cysts develop in all segments of the renal tubule and glomerular capsule as saccular expansions or diverticula. In the early stages, the fluid of the cysts is derived from glomerular filtrate. As the cysts enlarge, however, they commonly become disconnected from the tubule of origin, thereafter filling with fluid exclusively by transepithelial secretion.[668] On light microscopy, the cysts are lined by cuboidal, flattened epithelium, and hyperplastic polypoid foci are often found. Intervening renal parenchyma appears relatively normal, although foci of interstitial scarring, TA, and IF are common. The development of renal adenomas has been reported to occur in about 20% of patients with ADPKD.[669] ADPKD is considered

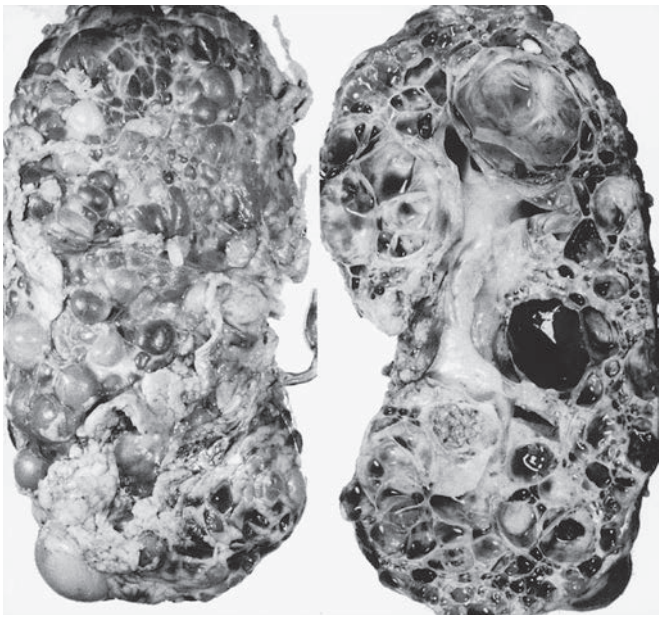

Figure 23.97 External and cut surface of a nephrectomy specimen from a patient with autosomal dominant polycystic kidney disease.

a systemic condition since over half of the patients develop cysts in other organs including the liver, pancreas, spleen, pineal gland, seminal vesicles, and lungs.[670] Other abnormalities include the presence of cerebral and coronary artery aneurysms, mitral valve prolapse, abnormal aortic valves, colonic diverticula, and skeletal malformations,[658,671,672]

Autosomal Recessive Polycystic Kidney Disease

ARPKD is a rare hereditary disorder with an estimated incidence of 1 per 20,000 live births.[673] ARPKD is caused by mutations of a gene located on chromosome 6p21.1–p12 named polycystic kidney hepatic disease gene *(PKHD1)*[674,675] whose related protein polyductin,[676] also known as fibrocystin,[677] is highly expressed in the epithelial cells of the collecting ducts and thick ascending loops of Henle and, to a lesser extent, in the biliary and pancreatic duct epithelia.[678] Of date, more than 300 *PKHD1* mutations have been identified and the majority of patients are compound heterozygotes.[679] As in other polycystic kidney diseases, polyductin localizes to the primary cilia of the renal epithelial cells.[678] Although the liver and both kidneys are invariably affected, the severity of involvement varies, thus creating a spectrum of clinical presentation.[680] In the neonatal period, the renal symptoms usually predominate.[681] Truncating *PKHD1* mutations are associated with severe neonatal disease.[682] Later in life, patients seek medical attention because of hepatic disease, which consists of congenital hepatic fibrosis with a variable degree of biliary dysgenesis and bile duct ectasia. These patients may also develop portal hypertension with hepatosplenomegaly and esophageal varices. Occasional patients may present with liver cysts, but cysts in other viscera aside from the kidneys and liver are rare and their presence should suggest an alternate diagnosis.

Majority of patients with ARPKD present with large abdominal masses at birth. They may also have the "Potter" phenotype with its characteristic facies secondary to oligohydramnios, joint deformities, and pulmonary hypoplasia. Newborns that have the severe form of the disease die shortly after birth, usually due to respiratory failure. Patients who survive the perinatal period develop renal failure, hypertension, and portal hypertension. The estimated perinatal mortality is 30%–50%; for those who survive the first month of life, the reported mean 5-year survival rate is 80%–95%.[676,683]

The kidneys are markedly enlarged bilaterally but retain their reniform configuration. The cysts tend to be linear and radiate from the medulla to the outer cortex. They develop in the collecting ducts, which expand to a large size due to fluid accumulation within the cyst cavity. Microscopically, the cysts appear as dilated tubular structures lined by cuboidal or flattened epithelium. The intervening tissue may contain uninvolved nephrons, but this depends on the severity of the disorder.

Nephronophthisis

Although NPHP has traditionally been grouped with medullary cystic kidney disease based on similarities in their clinical and pathologic features, these conditions are now regarded as two distinct entities.[684] NPHP is an autosomal *recessive* cystic disease characterized by tubular basement membrane disruption, IF, and cyst formation. It is the most frequent genetic cause of ESRD in children and adolescents, accounting for 10%–20% of cases of renal failure in this age group.[685] Three clinical forms, referred to as juvenile,[686] infantile,[687] and adolescent,[688] with a median age at onset of ESRD of 13 years, 1–3 years, and 19 years, respectively, have been recognized. NPHP is genetically heterogeneous, and mutations have been detected in increasing number of genes.[689] The mutations are in genes encoding primary cilia proteins *(NPHP1-NPHP18, NPHPL1, NPHP2L, AHI1, CC2D2A, MSK1, ATXN10, B9D2)*, and patients often have associated renal disease of NPHP, which is now considered a form of "ciliopathy."[690,691] Majority of proteins encoded by the NPHP genes are known as nephrocystins, and it has been proposed that mutated proteins alter the function of primary cilia, causing renal cystic disease and, in some, extrarenal manifestations.[684,691]

Typical signs and symptoms of NPHP include the inability to concentrate urine, polydipsia, anuresis, severe anemia, and growth retardation. The disease occurs in a pure renal from in approximately 85% of the patients. About 12% of the cases are associated with retinitis pigmentosa (Senior–Løken syndrome).[692–694] Other less common associations that have been described include hepatic fibrosis, skeletal malformations, and various defects in the central nervous system. Clinical syndromes described with NPHP and extrarenal manifestations include Bardet–Biedl syndrome, Joubert syndrome, and Meckel–Gruber syndrome.[690,691]

All types of NPHP have similar macroscopic and histopathologic features. Renal involvement is always bilateral. Both kidneys are moderately reduced in size and exhibit a granular surface. On cut sections, the cortex and medulla are both thinned. The corticomedullary junction is indistinct and typically the site of a variable number of thin-walled, fluid-filled cysts, ranging in size from barely visible up to 2.0 cm in diameter. The cysts may also occur deeper in the renal medulla and occasionally in the papillae. Microdissection studies have shown that the cysts arise from the loop of Henle, distal convoluted tubules, and collecting ducts. Histologic findings are nonspecific and depend on the severity of the disease. Tubulointerstitial fibrosis with lymphocytic inflammatory infiltrate, TA, and cyst formation is seen. The TA is often accompanied by a marked thickening of the tubular basement membrane and is better seen in PAS-stained sections. Pools of Tamm–Horsfall protein without clinical evidence of obstructive or reflux nephropathy in a young patient should prompt genetic evaluation for NPHP. By electron microscopy, these basement membranes can appear homogeneously thickened, split into thin lamellae, reticulated, or completely disintegrated.[695]

Autosomal Dominant Tubulointerstitial Kidney Disease

Autosomal *dominant* tubulointerstitial kidney disease (ADTKD) represents a new terminology for a group of disorders that are characterized by TA, IF, thickening and lamellation of tubular basement membranes, and in some cases, tubular microcysts. This entity encompasses mucin-1–related kidney disease (MUC-1), uromodulin-related kidney disease (UMOD), renin mutation with tubulointerstitial nephritis *(REN)*, and kidney disease due to *HNF1β* mutation (HNF1B), with two former diseases being most frequently encountered.[696,697] ADTKD-MUC1 was previously referred to as medullary cystic kidney disease type I (MCKD1), and the previous terminology for ADTKD-UMOD was medullary cystic kidney disease type 2 (MCKD2). These disorders share clinical and morphologic similarities with NPHP, but cysts are not uniformly observed.[650,696]

Patients with ADTKD-MUC1 develop progressive renal failure in adulthood. The median age at end-stage kidney disease is 62 years, although it varies within families.[698] The disease is caused by mutations in *MUC1* gene that maps to chromosome 1q21.[696,699] The protein, mucin-1, is expressed in distal tubules and collecting ducts and presumably protects the epithelial surfaces from bacteria. ADTKD-UMOD is caused by mutations in *UMOD* gene located on chromosome 16p12.[700,701] The mutant uromodulin (Tamm–Horsfall protein) is misfolded, leading to accumulation within the endoplasmic reticulum of the thick ascending loop of Henle and distal tubules. The end-stage renal failure occurs from 20–70 years, with a median age being 54 years.[700,701]

Both MUC-1 and UMOD-associated ADTKD patients have minimal proteinuria accompanying chronic renal failure and usually lack extrarenal disease.[696,697] There is an association with hyperuricemia and gout, especially in ADTKD-UMOD patients.[700,701] The kidneys are normal or moderately reduced in size. Small corticomedullary cysts maybe seen in both diseases and in ADTKD-UMOD, cysts can also be detected in cortex and medulla. Microscopically, there is diffuse interstitial inflammation with fibrosis and TA interspersed with hypertrophied and dilated tubules. Ultrastructural similarities with NPHP include tubular basement membrane lamellation. Patients with UMOD mutations have characteristic intracytoplasmic fibrillar inclusions composed of uromodulin in the thick ascending loops of Henle and on rare occasion, glomerular cysts.[702]

Interstitial nephritis attributable to mutated *REN*, a gene encoding renin, is rare, and renal cysts are not a typical feature in these patients. Anemia and hyperuricemia are common presenting features along with chronic renal failure.[696] Heterozygous mutations in *REN* result in reduced production of renin in juxtaglomerular cells and intracellular accumulation of unfolded precursor protein causes accelerated apoptosis and nephron loss.[703,704] Up to a third of patients with *HNF1β* mutations have congenital abnormalities of the kidney and urinary tract, and the age at presentation in such instances is typically in utero and in young children.[705] The renal cysts can be either widespread or limited to glomeruli and adjacent parenchyma often shows features of dysplasia. Adults with these mutations come to attention due to unexplained chronic renal failure, minimal proteinuria, and tubulointerstitial disease.[706] The transcription factor HNF1β is also expressed in pancreas and hence the association with maturity onset diabetes mellitus.

Medullary Sponge Kidney

Medullary sponge kidney (MSK) is a renal cystic disorder characterized by tubular ectasia of the collecting ducts and cyst formation confined to the medullary pyramids.[707] It typically affects both kidneys and represents developmental malformation of the collecting system. The true incidence of MSK is unknown, although it has been estimated at 1 per 5000 population.[708] The disease is asymptomatic unless complicated by nephrolithiasis, hematuria, or infections. In these instances, the diagnosis is established when the patient undergoes radiographic examination.[709] Typically, symptoms start in adulthood, but presentation in adolescence and childhood has been reported.[710] In patients with recurrent nephrolithiasis, the stones are composed of calcium oxalate and/or calcium phosphate and a third of the patients have distal renal tubular acidosis. Both sexes are equally affected. Most cases appear sporadically, but a few familial clusters have been documented.[710] MSK has been reported in association with various conditions such as hemihypertrophy, Wilms tumor, congenital hepatic fibrosis, multiple endocrine neoplasia type 2 (MEN2), Marfan syndrome, and Ehlers–Danlos syndrome. Mutations or polymorphisms of glial cell line–derived neurotrophic factor (GDNF) and receptor tyrosine kinase (RET) genes (previously known to be involved in genitourinary development) have been recently reported in MSK, confirming a genetic component in a minority of patients.[711]

The involved kidneys are usually normal in size, but they can be slightly enlarged in those cases with pronounced sponge-like changes. The cysts are multiple, small, and limited to the medullary pyramids and papillae. They usually affect all pyramids in both kidneys; however, on occasion, only one or two pyramids or only one kidney may be affected. The cysts are lined by collecting duct epithelium and usually communicate with collecting tubules. Concretions adherent to the walls of the cysts and the dilated collecting ducts may be seen. The interstitium often shows severe inflammation and scaring, frequently accompanied by TA, especially near the papillary tips. In instances where there is nephrolithiasis and pyelonephritis, the cortex may show significant cortical scarring.

Acquired Renal Cystic Disease

Although acquired renal cystic disease (ARCD) was initially reported in patients undergoing long-term dialysis, similar changes can also occur in uremic nondialyzed patients.[712] ARCD has been reported to occur in 7%–22% of patients with renal failure who are not on dialysis, 40% of patients who have been on dialysis for 3 years, and 80%–90% of patients who have been on dialysis for 10 years or more.[713] The etiology of ARCD has not yet been well established, and it has been suggested that the cysts found in this condition result from obstruction of the renal tubules by local fibrosis, oxalate deposition, or epithelial hyperplasia. The cysts often regress after transplantation. Men are more affected than women. In most cases, the disease is asymptomatic, but sometimes the cysts bleed, rupture, or become infected, causing fever, hematuria, and flank pain. The most serious complication, however, is the development of renal carcinomas in the walls of the cysts. It has been estimated that renal cell carcinoma is found 50 times more frequently in dialysis patients with ARCD than in the general population.

The cysts in ARCD are usually bilateral and occur in both the renal cortex and medulla.[714] Their number can vary from a few subcapsular cysts to diffuse involvement of almost the entire renal parenchyma. A diagnosis of ARCD requires five or more cysts are found on imaging studies and absence of known cystic renal disease as the cause of renal failure. The cysts are filled with straw-colored or hemorrhagic fluid and often contain calcium oxalate crystals. Most cysts are less than 0.5 cm, but they can measure up to 2–3 cm in diameter. Microscopically, cysts are lined by flattened epithelium or by hyperplastic cuboidal or columnar cells with prominent eosinophilic cytoplasm, sometimes forming papillary projections. Renal neoplasms arising in this setting are fully discussed in Chapter 24.[715]

Simple Cysts

Simple cysts are the most common cystic abnormality encountered in the kidneys.[716] They are found in about 5%–12% of the general population undergoing abdominal ultrasound examination for various reasons.[717,718] Their occurrence increases with age, with an incidence of less than 0.1% in children and up to 20% in individuals over 50 years of age.[713] They are usually asymptomatic and are often detected at autopsy or as an incidental finding in the radiologic evaluation for other diseases. On occasion, however, when complicated by hemorrhage or infection, they can cause pain. Simple cysts can be solitary or multiple and bilateral. They occur more commonly in the renal cortex, and although their etiology has not been well established, it is believed that they originate from diverticula of cortical tubules.[719] Most are under 5 cm in diameter, but larger cysts have been documented.[718] Usually unilocular, on occasion they can be bilocular or multilocular. The cysts are normally translucent, filled with clear serous fluid, and lined by a single layer of cuboidal or flattened epithelium. Cases complicated by hemorrhage or infection can have thick capsular walls with hemosiderin-laden macrophages and atrophic lining epithelium.

Pediatric Tumors and Tumorlike Conditions

Nephroblastic Tumors

Wilms Tumor (Nephroblastoma)

General Features

Wilms tumor is also known as nephroblastoma (currently the preferred term).[1,2] It constitutes the prototypical example of a neoplastic process that faithfully recapitulates embryogenesis at the morphologic and molecular levels.[3-5] It is seen primarily in infants, 50% of the cases occurring before the age of 3 years and 90% before the age of 6 years.[6-8] However, Wilms tumor is only exceptionally seen as a congenital neoplasm, a point of great importance in the differential diagnosis with mesoblastic nephroma.[9] There are also well-documented cases of Wilms tumors in adolescents[10] and adults, but this may represent a somewhat different disease with distinct genetic features and significantly worse clinical outcomes.[11-15] There is no appreciable sex predilection. The risk in Caucasians is lower than in Asians, but higher than in patients of African descent.

The classic location for Wilms tumor is the kidney. Both kidneys are equally affected, the incidence of synchronous or metachronous bilateral involvement being 5%–10%.[16,17] Cases with the typical morphologic features of Wilms tumor have rarely been recorded in extrarenal sites, including retroperitoneum, sacrococcygeal region, testis, uterus (sometimes presenting as a cervical polyp), inguinal canal, and mediastinum.[18-24] Some of them have arisen within a teratoma, and even those in which this feature was not evident have been viewed by some authors as teratomas with a predominant or exclusive nephroblastic component.

Wilms tumor has been reported in monozygous twins and other familial settings.[7] Conditions associated with the highest risk of Wilms tumor are Wilms–aniridia genital anomaly–retardation (WAGR) syndrome, omphalocele–macroglossia (Beckwith–Wiedemann syndrome), hemihypertrophy, Denys–Drash syndrome, and familial nephroblastoma.[25-28] Other conditions associated with Wilms tumor are renal and genital malformations, cutaneous nevi and angiomas, trisomy 18, Klippel–Trénaunay syndrome, neurofibromatosis, Bloom syndrome, Frasier syndrome, Simpson-Golabi-Behmel syndrome, Perlman syndrome, and cerebral gigantism (Sotos syndrome).[28-32] The incidence of congenital abnormalities of the urogenital tract is particularly high for Wilms tumors occurring during the first

Abstract

This chapter covers the entire spectrum of neoplasms and non-neoplastic tumoral lesions that may involve the kidney. Pediatric tumors are detailed and include Wilms tumor (nephroblastoma), clear cell sarcoma of kidney, congenital mesoblastic nephroma, rhabdoid tumor, and cystic nephroma. The metanephric family of tumors is also addressed. An update on specific subtypes of renal cell carcinoma is provided, based on the 2016 WHO classification, and newer emerging entities are also covered. Other less common intrarenal neoplasms are also highlighted. Finally, lesions of the upper urinary tract (i.e. renal pelvis and ureter) are discussed.

Keywords

Wilms tumor
clear cell sarcoma of kidney
renal rhabdoid tumor
congenital mesoblastic nephroma
metanephric adenoma
renal cell carcinoma
oncocytoma
papillary adenoma
angiomyolipoma
urothelial carcinoma
ureter
renal pelvis

year of life and/or involving both kidneys. Wilms tumor has also been encountered in association with other malignancies, such as osteosarcoma, botryoid variant of embryonal rhabdomyosarcoma, retinoblastoma, hepatocellular carcinoma, and neuroblastoma.[33-36]

Clinical Features

The classic clinical presentation of Wilms tumor is in the form of an abdominal mass felt by the mother when handling the child. Hematuria and pain are rare. Hypertension, present in a minority of the cases, has been shown to be caused by renin secretion by the tumor.[37] Proteinuria may be the result of tumor-associated glomerular disease in the non-neoplastic kidney.[38] Sometimes the first symptoms are related to traumatic rupture. Cases have been reported presenting as sudden death resulting from tumor embolism.[39]

Imaging studies show a solid intrarenal mass that often displaces and distorts the collecting system. Foci of calcification may be identified.[40]

Morphologic Features

Grossly, most Wilms tumors are solitary, well circumscribed, rounded, and of soft consistency. Their size is extremely variable, and their median weight is 550 g. The cut section is predominantly solid and pale gray or tan and often exhibits areas of cystic change, necrosis, and hemorrhage (Fig. 24.1). A lobular pattern resulting from fibrous septation is common. Multicentric tumor foci are found in 7% of the cases.

Microscopically, three major components are identified: undifferentiated blastema, mesenchymal (stromal) tissue, and epithelial tissue.[41-43] Most Wilms tumors show a representation of all three components, but the proportions vary widely from case to case and sometimes from region to region in the same tumor. Some tumors are biphasic, and still others are monophasic (monomorphous). The *blastomatous* areas are extremely cellular and composed of small round-to-oval primitive cells; the cytoplasm is usually very scant, but sometimes is more abundant and exhibits an oncocytoid appearance. Adjacent nuclei commonly appear to overlap. The pattern of growth may be diffuse, nodular, cordlike (serpentine), or basaloid (with peripheral palisading). Particularly on biopsy, Wilms tumors in which the blastomatous component predominates can be confused with any of the small round cell tumors (including neuroblastoma), rhabdoid tumor, or clear cell sarcoma of kidney. The *mesenchymal* elements usually have spindle cells with fibroblastic or smooth muscle features, but may also exhibit differentiation toward various heterologous cell types, particularly skeletal muscle.[44]

The *epithelial* component is characterized by the formation of embryonic tubular (and sometimes glomerular) structures that closely recapitulate the appearance of normal developing metanephric tubules (and glomeruli) at the light microscopic, ultrastructural, and lectin histochemistry levels (Fig. 24.2).[45-48] The differentiation can be so pronounced that tumor analogues of nearly all segments of the normal nephron can be formed.[49] These tubular structures can be small and round, thus simulating the rosettes of neuroblastoma. Features favoring tubules over rosettes are presence of a lumen, single cell layer, distinct basal lamina, and surrounding fibromyxoid stroma.[41] The differential diagnosis of predominantly epithelial Wilms tumors also includes cystic nephroma, renal cell carcinoma (RCC), and metanephric adenoma.[41,50] Exceptionally, marked hydropic changes are seen in the tubular epithelial component.[51] Heterologous epithelium may include ciliated, mucinous, squamous, or transitional epithelium (Fig. 24.3).[41,52]

In the type known as *papillonodular*, grossly evident projections are seen extending from the septa into the cyst lumina, resulting in a fibroadenoma-like appearance on low-power microscopic examination.[53,54]

Other heterologous tissues described in Wilms tumor are endocrine cells of various types[52]; renin-producing cells[55]; neuroepithelium, neuroblasts, and mature ganglion cells[56,57]; neuroglia[58]; adipose tissue; and cartilage, bone, and hematopoietic cells.[41] Sometimes the variety of tissues present is such that the distinction between Wilms tumor and teratoma becomes blurred[41]; the term *teratoid Wilms tumor* has been used to describe these cases.[59,60]

The distinct cystic partially differentiated Wilms tumor is discussed separately later.

Anaplastic features may be present focally or extensively in Wilms tumors (approximately 5%–8% of cases); they are discussed fully in the section on prognosis.

Immunohistochemical Features

The immunohistochemical profile of the various components of Wilms tumor mirrors that of their counterparts in the developing kidney.[61-63]

The epithelial elements react for keratin and epithelial membrane antigen (EMA)[61,64]; the mesenchymal elements show a reactivity pattern consonant with their morphologic appearance (such as

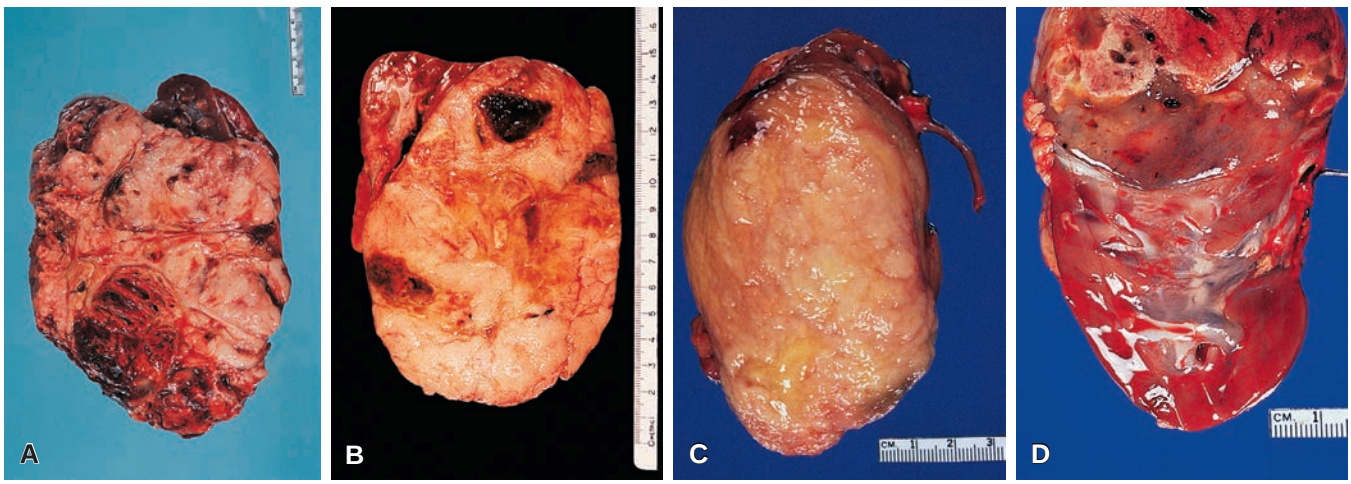

Figure 24.1 Various Gross Appearances of Wilms Tumor. A and **B,** Variegated appearance. **C,** More homogeneous and nodular. **D,** Extensive areas of infarct-like necrosis.

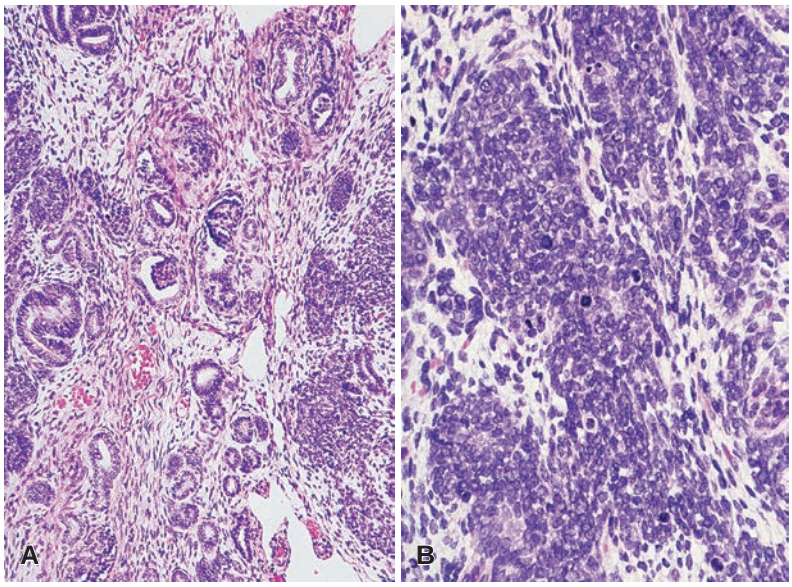

Figure 24.2 Microscopic Appearance of Wilms Tumor. A, Low-power microscopic view showing a combination of blastema, stroma, epithelial tubular formations, and immature glomeruli. **B,** High-power view showing blastema, stroma, and immature tubular formations.

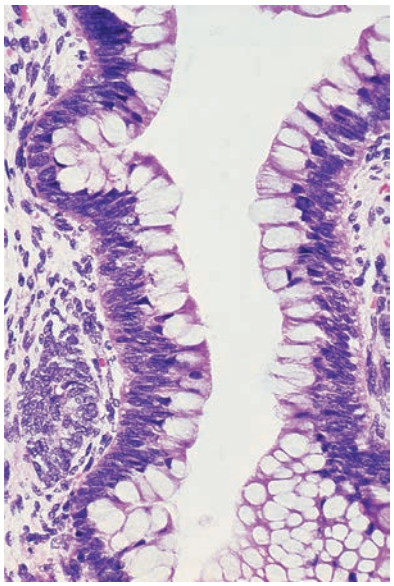

Figure 24.3 Mucinous epithelium in Wilms tumor.

positivity for myogenin and desmin in the rhabdomyomatous foci)[65]; and the neural elements—when present—exhibit reactivity for neuron-specific enolase, glial fibrillary acidic protein, and S-100 protein.[64] Additional immunoreactivities of Wilms tumor include nuclear WT1 (80%, typically in epithelial and blastemal components), nuclear PAX8, CD56 (96%), and (unexpectedly) TTF-1; the latter, which is found in 17% of cases, represents a potential source of misdiagnosis.[66,67]

Molecular Genetic Features

The genetic loci predisposing to Wilms tumor are *WT1* and *WT2*. The former is located in 11p13 and encodes a zinc finger transcription factor that is expressed in the early development of the urogenital system, with its germline point mutation and deletion being the underlying genetic alteration in Denys–Drash syndrome and WAGR syndrome, respectively.[68-70] *WT2* is located in 11p15.5, which contains the gene for insulin growth factor II, and is implicated in tumors associated with Beckwith–Wiedemann syndrome.[71-74] Alterations of these genes may also be identified in sporadic tumors. A relationship has been shown between the level of expression of these genes and the microscopic features of the tumor.[68,75-79]

Inactivation of the *WTX* gene located on the X chromosome is found in 6%–30% of cases of sporadic Wilms tumor.[79,80] This results from somatic deletion or, less commonly, inactivating mutation of the gene on the single X chromosome in tumors of males or the active X chromosome in tumors of females.[81-83] The pathogenetic role of *WTX* alteration in Wilms tumor is not fully elucidated, but downregulation of WTX leads to increased signaling in the Wnt pathway.[83]

Activating mutation of the β-catenin gene *CTNNB1* is found in 14%–20% of Wilms tumors, resulting in disturbance of the Wnt signaling pathway. It may be found in tumors with *WT1* mutation, but not with *WT1* wild-type.[84-86]

Abnormalities in other chromosomes—1, 7q, 8, 12, and 16—have also been encountered.[14,87,88] These genetic changes are identical in the various histologic components of the tumor, and 1p and 16q loss of heterozygosity (LOH) are discussed further under prognosis.[89] Mutations of *TP53* and/or overexpression of the protein are found in only 5% of the cases of Wilms tumor. They are largely restricted to the anaplastic foci and carry an unfavorable prognostic connotation.[90,91] Similarly, MYCN amplification is seen in rare cases with aggressive behavior, most commonly with diffuse anaplasia. More recently, mutations in the SIX/2 pathway and the DROSHA/DGCR8 miRNA microprocessor complex have been described in high-risk blastemal Wilms tumors.[92]

Spread and Metastases

In advanced cases, local spread occurs in the perirenal soft tissues. From here, the tumor may directly involve the adrenal glands, bowel, liver, vertebrae, and paraspinal region; the latter may result in spinal cord compression.[93] Invasion of the renal vein is common, but extension into the renal pelvis or ureter is a rare and late event.

Table 24.1 Staging of nephroblastoma, rhabdoid tumor of the kidney, clear cell sarcoma of the kidney (Children's Oncology Group)

STAGE	DESCRIPTION
Stage I	Completely resected tumor limited to the kidney. No intraoperative rupture or biopsy of the tumor prior to removal. No involvement of the vessels of the renal sinus. No evidence of tumor beyond the margins of resection. Regional lymph nodes confirmed negative microscopically.
Stage II	Completely resected tumor with no evidence of tumor at or beyond margins of resection. Tumor extends beyond the kidney as evidenced by regional extension of the tumor (through renal capsule, extensive invasion of the soft tissue of the renal sinus) or tumor in blood vessels within the nephrectomy specimen, but outside renal parenchyma. This includes blood vessels of the renal sinus.
Stage III	Residual tumor present after surgery, confined to abdomen. This includes the following: • Lymph nodes within the abdomen/pelvis are involved by tumor. • Tumor has penetrated through the peritoneal surface. • Tumor implants are on the peritoneal surface. • Gross or microscopic tumor remains postoperatively (positive surgical margins on microscopic exam). • Involvement of vital structures precludes complete resection. • Tumor spillage before or during surgery. • Tumor is treated with preoperative chemotherapy (with or without any prior biopsy, including fine-needle aspiration). • Tumor is removed in more than one piece (e.g. tumor is found in tissues separate from nephrectomy specimen, such as separately excised adrenal, or separately removed thrombus from renal vein). • Extension of primary tumor into thoracic vena cava and/or heart.
Stage IV	Hematogenous metastases or lymph node metastases outside the abdominopelvic region
Stage V	Bilateral renal involvement present at diagnosis. Each kidney should be substaged separately by above criteria.

Metastases in regional lymph nodes are found in 15% of the cases. The most common sites of distant metastases are lungs, liver, and peritoneum.[94] The presence of lung metastases in a child with a retroperitoneal neoplasm strongly favors a diagnosis of Wilms tumor over that of neuroblastoma. Conversely, the presence of bone metastases suggests a diagnosis other than Wilms tumor, since they occur in only 1% of the cases.

Therapy

The therapy for Wilms tumor has been relatively standardized and is based largely on protocols from either the International Society of Paediatric Oncology (SIOP) or the Children's Oncology Group (COG).[2,95-98] The specifics of these protocols are being continuously updated.[99] The main differences between the two approaches are based on the use of presurgical therapy. The SIOP typically espouses preoperative chemotherapy followed by surgical resection. In this model, some regions require biopsies to confirm diagnosis prior to chemotherapy, while others do not. Further therapy is based on the initial response as measured by a post-therapy classification.[100] Advocates of the SIOP approach cite fewer intraoperative tumor ruptures (due to therapy-related tumor shrinkage) and less upstaging. The COG typically advocates for initial surgical resection with subsequent therapy determined by tumor histology and stage. Its advocates cite prognostic stratification that allows for more tailored therapy. Despite these differences, the clinical outcomes for both the SIOP and COG approaches are very similar.[99,101]

Prognosis

The overall cure rate for unilateral Wilms tumor is 80%–90%.[102] A small percentage of long-term survivors of Wilms tumor develop a second malignant neoplasm, either because of a genetic predisposition to neoplasia or secondary to therapy.[103]

The prognostic connotations of various clinical and morphologic parameters are as follows:

1. *Age*. Patients under 2 years of age have significantly fewer metastases and a better 5-year survival rate than those over 2 years.[104,105]
2. *Stage*. Clinicopathologic staging of Wilms tumor is the most important prognostic determinant, based on either the SIOP or the COG systems (Table 24.1). Capsular invasion, rupture at surgery, extrarenal vein invasion, tumor implants, lymph node metastases, distant metastases, and bilaterality are the main criteria used.[106] Unfortunately, staging of Wilms tumor by the pathologist is fraught with pitfalls. The tumor "capsule" (or pseudocapsule) can be confused with the renal capsule; the renal sinus and surgical margins may be difficult to evaluate; and the renal vein may retract considerably, giving a false impression—when invaded—that tumor is present at the margin. It is important for sections to be taken from the renal sinus, the junction between tumor and normal kidney, the tumor capsule, and the uninvolved renal parenchyma. In a study of stage I cases, the following four features were found to be associated with increased rate of relapse: presence of an inflammatory pseudocapsule, invasion of the renal sinus, extensive infiltration of the renal capsule, and tumor infiltration of intrarenal vessels.[107]
3. *Size*. Tumor mass, as measured by the weight of the excised specimen, is an important determinant of outcome, especially in stage I tumors.[108]
4. *Anaplasia*. For a case of Wilms tumor to be placed into the anaplastic category, it should meet the following three criteria: (1) marked enlargement of nuclei within the blastemal, epithelial, or stromal cell lines (excepting skeletal muscle cells) to at least three times the diameter of adjacent nuclei of the same cell type; (2) obvious hyperchromasia of the enlarged nuclei; and (3) multipolar mitotic figures (Fig. 24.4).[109]

   Anaplasia thus defined is present in about 4% of the cases, the incidence being higher in patients of African descent and in older patients.[110] It is very uncommon in tumors from patients under 2 years of age; this is probably the reason for the better prognosis exhibited by this age group. Sometimes it is found in the metastases and not in the primary tumor.

   Currently, *focal* anaplasia applies only to cases in which the previously defined changes are restricted *to one or a few discrete*

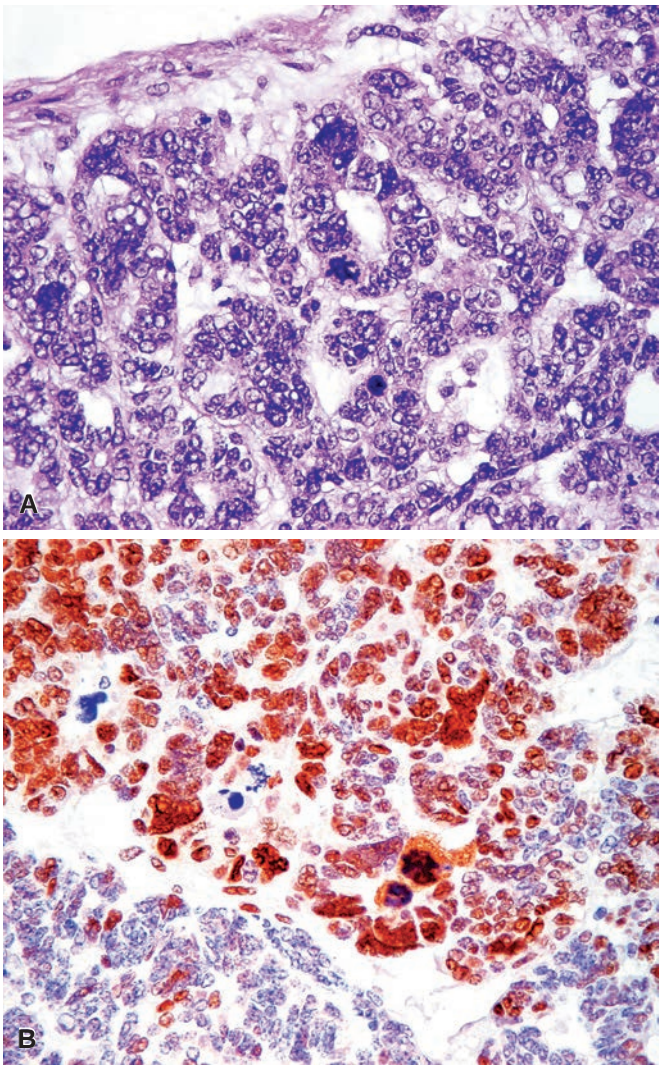

Figure 24.4 Anaplastic ("Unfavorable Histology") Wilms Tumor. **A,** Marked pleomorphism with giant hyperchromatic nuclei and atypical mitoses. **B,** Strong nuclear immunoreactivity for p53.

loci within the primary tumor, with no anaplasia or marked nuclear atypia elsewhere.[111] Specifically, focal anaplasia cannot be present in tumor infiltrating outside the kidney (e.g. renal sinus) or in intravascular tumor. Thorough tumor sampling (one section for each centimeter of tumor diameter) and careful mapping of where sections were taken is obviously needed to evaluate this feature properly.[112] Cases with localized anaplasia in which the background tumor shows a degree of "marked" atypia (i.e. bordering on anaplasia, but falling short of the minimal threshold, typically due to nuclear pleomorphism without other features) have been referred to as showing "nuclear unrest" and are classified as diffuse anaplasia. Wilms tumors with anaplasia are referred to as having "unfavorable histology" in the sense of exhibiting a lesser response to chemotherapy. This predictive connotation is greater when the anaplasia is diffuse rather than focal, and since anaplasia predicts response to therapy, its significance in stage I tumors is debated.[113]

5. *Extensive tubular differentiation*. This is said to be a good prognostic sign. According to some authors, this is also true for cases with extensive glomerular differentiation.[114-116] This finding does not currently direct initial therapy.
6. *Skeletal muscle differentiation*. This feature does not seem to have a significant effect on prognosis, except when present in massive amounts. In the latter instance it is said to be associated with a better prognosis.[116-118] This finding does not currently direct initial therapy.
7. *Post-chemotherapy morphology*. The SIOP classification is based largely on response to chemotherapy with three simple categories: completely necrotic (low risk), blastemal predominant (high risk), and "others" (intermediate risk).[100] The incidence of anaplasia does not seem to be affected by this treatment modality (i.e. there is no evidence that therapy induces cytologic changes mimicking anaplasia).[119]
8. *TP53 mutation*. Mutations of the *TP53* gene, evaluated indirectly through the immunohistochemical detection of P53 protein overexpression, correlate with the presence of anaplasia at the histologic level and therefore with an unfavorable outcome.[120,121]
9. LOH at 1p and 16q. Some studies have suggested that LOH at 1p and 16 q is an adverse prognostic factor in favorable histology Wilms tumors.[122-125] Future COG and/or SIOP trials will likely attempt to further validate this finding.

Many of these prognostic parameters are used in the revised SIOP working classification for nephroblastoma (Table 24.2).

Cystic Partially Differentiated Wilms Tumor (Nephroblastoma)

Cystic partially differentiated Wilms tumor typically occurs in very young children, most less than 24 months old.[126] By definition, this tumor should have an exclusively cystic gross appearance with thin septa and no solid nodules. It is typically large (mean of 10 cm), but well circumscribed. Histologically, the thin septa contain an admixture of different tissues, including fibrous tissue, skeletal muscle, fat, cartilage, blastema, and nephroblastomatous epithelium. Cysts may show papillary infolding, but no microscopic nodular masses should protrude from the cyst wall, as their presence suggests a cystic Wilms tumor. Hemorrhage, necrosis, and calcification are not features of cystic partially differentiated Wilms tumor. Surgical resection is typically curative and adjuvant therapy is not recommended for this clinically benign neoplasm. The main differential diagnosis is pediatric cystic nephroma, which (by definition) does not contain nephroblastomatous elements.

Nephroblastomatosis and Nephrogenic Rests

Nephroblastomatosis and *nephrogenic rests* are defined as persistent foci of embryonal cells (after 36 weeks gestation), but they are discussed here because of their frequent confusion and histogenetic relationship with Wilms tumor.[2,127-129] Nephrogenic rests are seen in up to 40% of patients with Wilms tumor and approximately 1% of neonates.[127] The term nephroblastomatosis refers to diffuse or multifocal nephrogenic rests. In its most florid form, the process is often associated with a variety of congenital anomalies and with hypertension.[130]

Nephrogenic rests have been divided into *perilobar* and *intralobar* forms (Fig. 24.5). The former, which is more common, is located peripherally, has sharply demarcated margins, is composed predominantly of blastema and tubules with scanty (or sclerotic) stroma, and is often multifocal. The intralobar form is randomly distributed in the cortex and medulla and has irregular margins. It shows a predominance of stroma over blastema and tubules and is usually solitary.[131-133] Further methods of nephrogenic rest subclassification have also been proposed.[132]

Nephroblastomatosis can be diagnosed by computed tomography (CT) scan, magnetic resonance imaging (MRI), or ultrasound.[134] Grossly, the most exuberant examples of this disease can be

Table 24.2 Staging of pediatric renal tumors (International Society of Paediatric Oncology) (post-chemotherapy)

Stage I	Viable tumor limited to the kidney, or surrounded by an intact fibrous pseudocapsule and completely resected. No renal sinus invasion of soft tissue or vessels. Necrotic tumor or chemotherapy induced changes may be present in renal sinus or soft tissue outside of kidney without upstaging, as long as these changes do not extend to resection margins. Prior percutaneous core needle (Tru-cut) biopsy or fine-needle aspiration does not upstage the tumor. Tumor may infiltrate adrenal gland if adrenal capsule is intact. Tumor may be adherent to liver capsule but may not infiltrate liver parenchyma.
Stage II	Completely resected viable tumor extends beyond kidney or penetrates through the renal capsule or fibrous tumor pseudocapsule into perirenal fat. Tumor may infiltrate the renal sinus and/or invade blood vessels, but resection margins are clear. Tumor may infiltrate adjacent organs or vena cava, if completely resected with clear margins.
Stage III	Incomplete excision. Gross residual tumor remains in the patient, or tumor extends to resection margins on microscopic exam, including necrotic tumor or chemotherapy induced changes at resection margin. • Tumor in any abdominal lymph node, including necrotic tumor or tumor with chemotherapy effect. • Tumor rupture before or during resection surgery • Tumor penetrates peritoneal surface. • Tumor thrombi present at resection margins of vessels or ureter, transected or removed piecemeal. • Wedge biopsy of the tumor prior to preoperative chemotherapy or surgery.
Stage IV	Hematogenous metastases or spread of tumor beyond the abdomen and pelvis.
Stage V	Bilateral renal tumors. Each side should be substaged by above criteria.

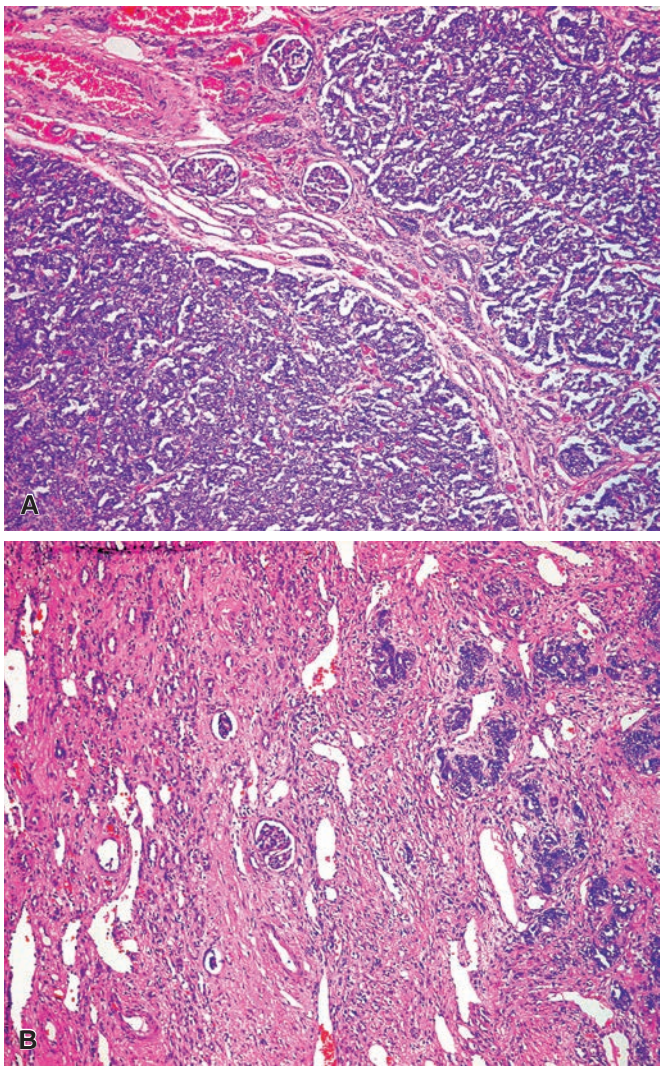

Figure 24.5 Nephrogenic rests. Perilobar **(A)** and intralobar **(B)** types.

distinguished from Wilms tumor because of the diffuse or multifocal nature of the process and the involvement of the entire subcapsular region. Microscopically, the mass is typically unencapsulated and composed of tightly packed nephrogenic epithelial cells that have a primitive but not anaplastic appearance. Stromal tissue is scanty; cartilage, striated cells, and primitive mesenchyme are absent. However, hyperplastic rests may have some foci that are cytologically indistinguishable from Wilms tumor, but have the distribution of a rest and no capsule. Other histologic mimics of nephrogenic rests include dysplastic medullary ray nodules (most commonly in Beckwith–Wiedemann syndrome) and embryonal hyperplasia (often in multicystic dysplasia and end-stage kidneys).[135,136]

In cases associated with Wilms tumor, they have been found to share similar mutations.[137] Perilobar rests often have 11p15 alterations and are commonly associated with hemihypertrophy and/or Beckwith–Wiedemann syndrome, while intralobar rests commonly have *WT1* mutations and may be associated with Denys–Drash syndrome.[138] CTNNB1 mutations are seen in intralobar rests, even in the absence of *WT1* mutation.[139]

A conservative therapeutic approach is indicated in cases of nephrogenic rests and nephroblastomatosis[140]; however, nephrogenic rests in patients less than 1 year of age (particularly if perilobar) and especially diffuse hyperplastic nephroblastomatosis are associated with the highest risk of contralateral Wilms tumor.[141]

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma represents the most common renal tumor of newborns and is usually discovered before 6 months of age.[142] Extraordinary examples in adults have been reported, but the diagnosis is rare after 2 years of age and should be carefully scrutinized outside that setting.[143,144] Grossly, the tumor is solid, yellow-gray to tan, with a whorled configuration reminiscent of uterine leiomyoma (Fig. 24.6). Most are centered near the hilus of the kidney. The tumor often appears well circumscribed, but it may infiltrate the renal parenchyma and even the perirenal fat microscopically. Areas of hemorrhage and necrosis are usually absent. A cystic variant of this tumor has been described.[145,146]

Microscopically, two distinct patterns are seen. "Classic" congenital mesoblastic nephroma resembles "infantile fibromatosis" of the renal sinus with long sweeping and intersecting fascicles composed

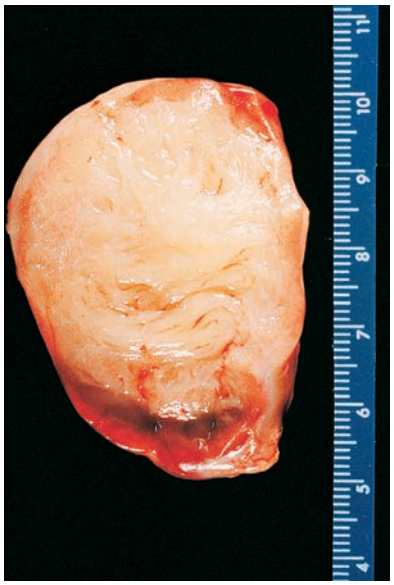

Figure 24.6 Congenital Mesoblastic Nephroma. Gross appearance of the well-circumscribed character of this tumor and its white fibrous cut surface are well illustrated.

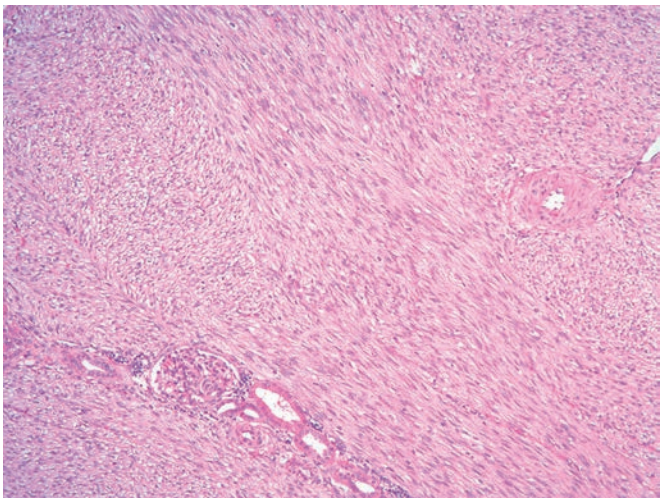

Figure 24.7 Congenital Mesoblastic Nephroma, Classic Type. Microscopic appearance showing a monotonous proliferation of spindle cells with bland nuclei, resembling fibromatosis.

of cytologically bland, elongated spindle cells (Fig. 24.7).[147] There is typically fine intracellular collagen imparting a light eosinophilic appearance. Tubules and glomeruli (sometimes exhibiting hyperplastic or metaplastic changes) may be entrapped by the spindle tumor cells. Small islands of hyaline cartilage and foci of extramedullary hematopoiesis may be present. There is no capsule separating the tumor from the uninvolved renal parenchyma.

Cellular congenital mesoblastic nephroma is comprised of more densely cellular plump spindle cells with larger nuclei, resembling infantile fibrosarcoma (Fig. 24.8).[148,149] They are mitotically active, have a tendency to infiltrate the renal pelvis or perirenal tissue, and may contain areas of hemorrhage and necrosis.[150] When classic and cellular patterns coexist, the tumors are designated as mixed.

Immunohistochemically, the neoplastic cells often show expression of smooth muscle actin, while desmin staining is rare. CD34 is typically negative.

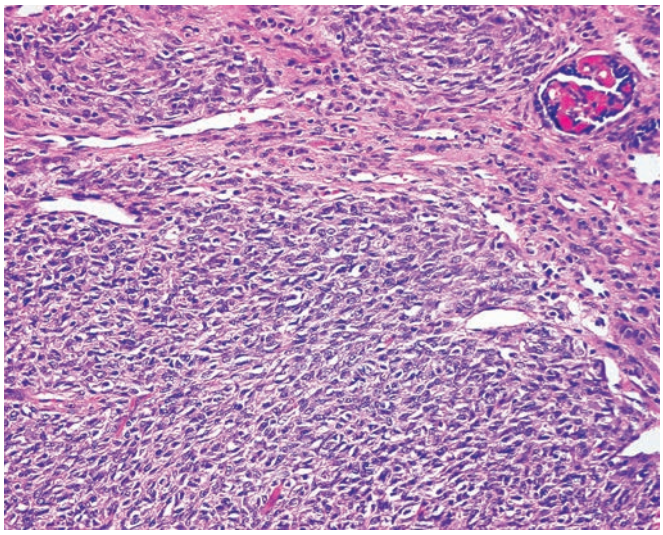

Figure 24.8 Congenital Mesoblastic Nephroma, Cellular Type, Accompanied by Mitotic Activity. An entrapped glomerulus is present in a corner. Some of these tumors behave in an aggressive fashion.

Congenital mesoblastic nephromas lack the abnormalities in chromosome 11 that characterize Wilms tumor and are associated instead with polysomies for chromosomes 8, 11, 17, and 20.[151-153] Cellular congenital mesoblastic nephroma contains the t(12;15)(p13;q25) translocation, which results in the *ETV6–NTRK3* gene fusion, the latter being detectable in paraffin-embedded material.[154] This gene fusion is not found in classic mesoblastic nephroma.[154,155] It appears that the occurrence of gene fusion antedates acquisition of chromosomal polysomies.[152] The sharing of the same genetic abnormality between cellular congenital mesoblastic nephroma and infantile fibrosarcoma supports the notion that these two tumors represent a single neoplastic entity.[152] Most mixed congenital mesoblastic nephromas lack the ETV6 fusion.[156]

The large majority of congenital mesoblastic nephromas are cured following nephrectomy.[157] Therefore, radiation therapy or chemotherapy is not indicated. In up to 7% of the cases, recurrence with local invasion of retroperitoneum will occur and may prove fatal.[148,158] Cases associated with distant metastases to lung and brain have rarely been reported[159,160]; most of these aggressive tumors have had atypical morphologic features.[148,161] Beckwith and Weeks[162] have pointed out that in all but one of the recurrent congenital mesoblastic nephromas the patients were over 3 months of age at the time of the original nephrectomy; they believe that age at diagnosis and adequacy of excision may be more important prognostic factors than the morphologic features of the tumor. In a recent series, stage III cellular congenital mesoblastic nephromas in patients aged 3 months or older were particularly prone to develop local recurrences.[163]

Clear Cell Sarcoma

Clear cell sarcoma, formerly known as bone-metastasizing renal tumor and not to be confused with clear cell sarcoma of soft tissue, is a distinctive renal malignancy.[142,164-166] It comprises approximately 4% of childhood renal tumors; its incidence peaks during the second year of life. Isolated cases have been described in adults[167,168] and in association with familial colonic polyposis.[169] Grossly, the tumor tends to be large, sharply outlined, and centered in the medullary or mid region of the kidney. They have a homogeneous cut surface of light brown-to-gray color and myxoid appearance

Figure 24.9 Gross Appearance of Clear Cell Sarcoma of Kidney. The tumor is well circumscribed and whitish, and it bulges on the cut surface.

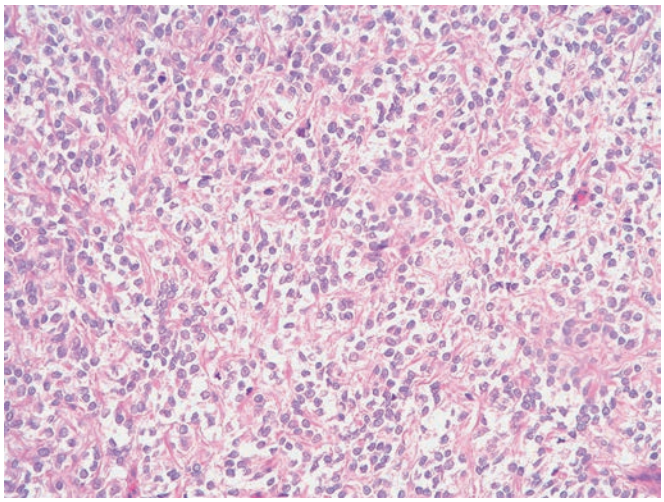

Figure 24.10 Clear cell sarcoma of kidney, prototypical appearance.

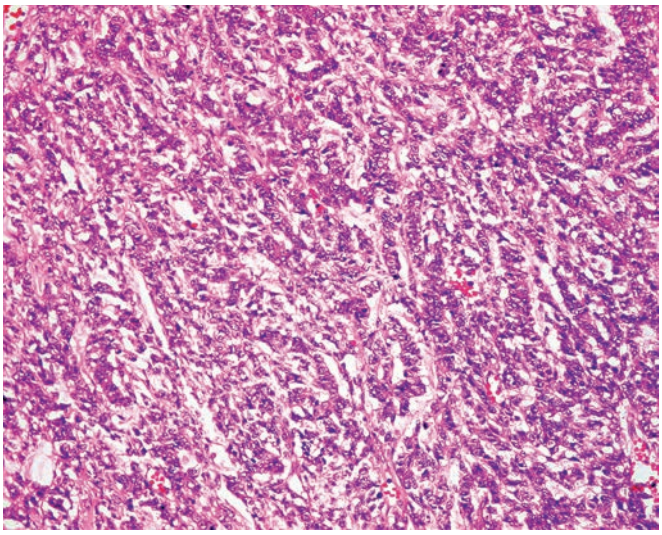
(Fig. 24.9). The consistency is usually hard, and cystic formations are common.

Microscopically, the most common pattern is that of a diffuse growth of relatively small cells with round normochromatic nuclei, inconspicuous nucleoli, light-staining (sometimes vacuolated) cytoplasm, and indistinct cell margins (Fig. 24.10); however, the morphology is very heterogeneous. Despite the tumor name, clear cytoplasm is a prominent feature in only 20% of the cases. Nuclear grooves are common, and mitoses are infrequent. The fibrovascular stroma may result in arrangements of the tumor cells in nests, palisades, cords, or trabeculae (Fig. 24.11). The latter should not be confused with the tubules or the serpentine arrangement of Wilms tumor. Myxoid changes, fibrosis, and hyalinization may be present, the appearance of the hyalinized tissue sometimes simulating osteoid (Fig. 24.12). Cysts may result from dilation of entrapped tubules or from stromal degeneration. It has been remarked that the distinctive alveolar and arborizing vascular stroma is a more reliable diagnostic



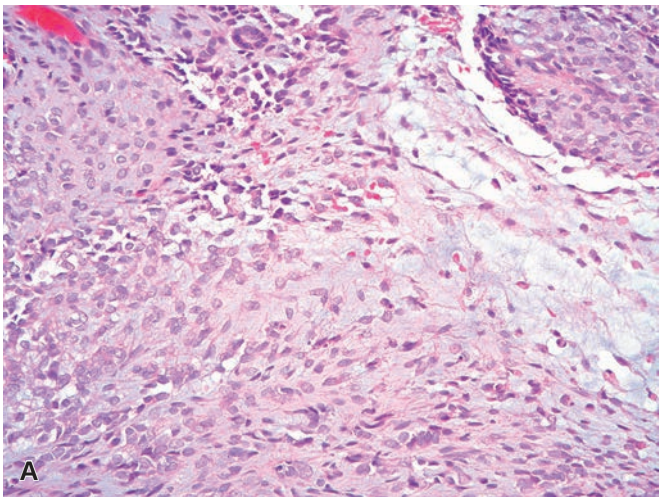


Figure 24.11 Clear cell sarcoma of kidney, trabecular pattern of growth.

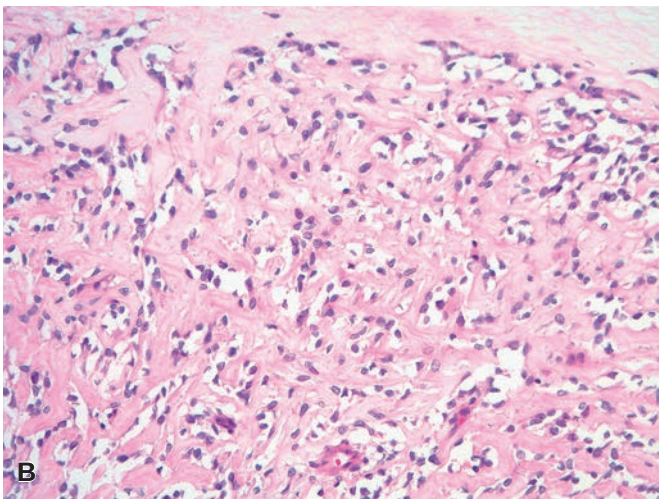

Figure 24.12 Clear Cell Sarcoma of Kidney. A, Myxoid pattern. **B,** Sclerotic pattern.

feature than the clear cells or the sclerosis.[170] As many as nine histologic patterns of this tumor have been described, that is, classic, myxoid, sclerosing, cellular, epithelioid, palisading, spindle, storiform, and anaplastic.[171]

Clear cell sarcoma of kidney has recently been shown to harbor two main, and mutually exclusive, genetic events: somatic internal tandem duplication within the *BCOR* gene sequence (approximately 85%) and YWHAE-NUTM2 fusion (approximately 10%).[172-175] A small subset of cases harbor neither event.[172] These genetic features, as well as typical patient age and histology, are shared by a subset of extrarenal undifferentiated round cell sarcomas of infancy,[176] suggesting a close relationship that was first noted histologically and ultrastructurally in 1991.[177] Immunohistochemistry has historically not been helpful in confirming the diagnosis of clear cell sarcoma of kidney, but they are usually PAX8 negative.[67] A new commercially available BCOR antibody has high sensitivity and specificity for clear cell sarcoma of kidney (and the other tumors harboring these same genetic events).[178] One caveat is that a rare subset of synovial sarcomas may show BCOR overexpression.[179]

Untreated clear cell sarcoma is a very malignant tumor, with a high tendency for relapse and a propensity for skeletal metastases, particularly skull.[166] In this regard, it should be noted that skeletal metastases are extraordinarily rare in conventional Wilms tumors. Metastases of clear cell sarcoma also occur to regional lymph nodes, brain, lung, and liver. In contrast to Wilms tumor, these metastases tend to develop after long intervals following the removal of the primary tumor (5 years or more).

The overall survival rate in a series of 351 cases entered in a National Wilms Tumor Study (NWTS) trial was 69%. Multivariate analysis showed that treatment with doxorubicin, stage, age at diagnosis, and tumor necrosis were independent prognostic factors. Of note, stage I patients had a 98% survival rate.[171]

Rhabdoid Tumor

Rhabdoid tumor of kidney is a distinct aggressive malignancy that is part of a larger family of SMACRB1-associated neoplasms.[142,180] Most cases occur in young infants, the median age at diagnosis being 18 months; 80% occur before 2 years of age.[181] Some of the cases have resulted in hypercalcemia.[182,183]

Grossly, rhabdoid tumor is solid, soft, and relatively well circumscribed. Microscopically, it is a monomorphic neoplasm that always involves the medullary region and has a generally diffuse but sometimes alveolar or trabecular pattern of growth. The tumor cells are medium sized and generally round or oval with vesicular nuclei and prominent nucleoli and indistinct cell borders (Fig. 24.13). However, they can also be spindled, prompting the possibility of confusion with mesoblastic nephroma or clear cell sarcoma. The most characteristic feature is the presence of a large cytoplasmic eosinophilic hyaline globule that displaces the nucleus laterally to result in a plasmacytoid or rhabdomyosarcomatous appearance (Fig. 24.14). Ultrastructurally, this globule is made up of a tangle of intermediate filaments.[184] Immunohistochemically, there is strong reactivity for vimentin and usually also for keratin, but generally not muscle (i.e. myogenin) or neural markers. It should be remarked that focal rhabdoid features resulting from accumulation of cytoplasmic filaments can be seen in many other renal tumors, including Wilms tumor, mesoblastic nephroma, and RCC.[185] Loss of immunohistochemical expression of SMARCB1 (INI1/hSNF5/BAF47) is a feature of great help in the differential diagnosis with other pediatric small cell tumors.[186,187] This results from biallelic alteration (deletion or mutation) of the *hSNF5/INI1* locus at chromosome 22q11.2.[188] Rare tumors retain SMARCB1 expression due to an alternative mutation in SMARCA4/BRG1. In about 15% of the cases, renal rhabdoid tumor is associated with primary atypical teratoid/rhabdoid tumors in the posterior fossa, and those patients typically harbor germline mutations in SMARCB1.

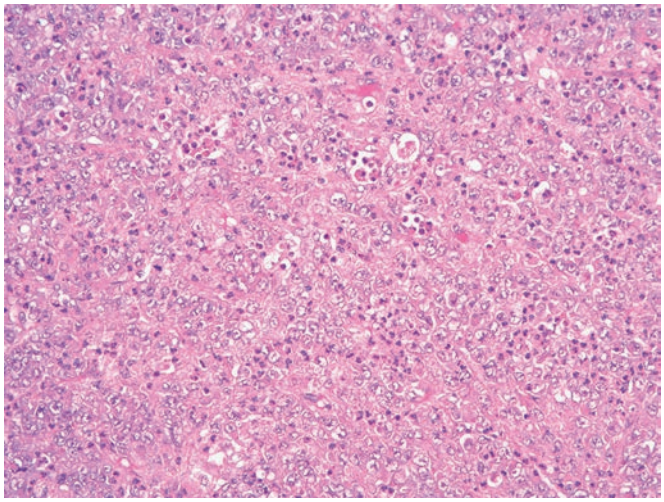

Figure 24.13 Rhabdoid Tumor of Kidney. Syncytial sheets of highly atypical cells, often with admixed inflammation.

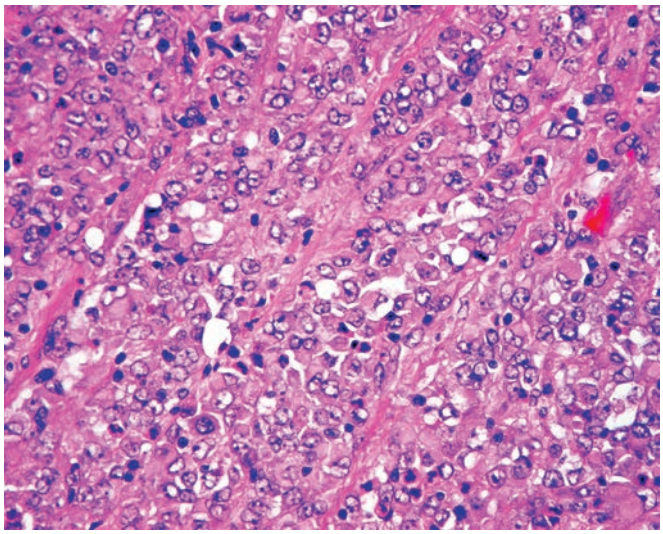

Figure 24.14 Rhabdoid Tumor of Kidney. The nuclear grade is high. An eosinophilic amorphous ("hyaline") material fills the scanty cytoplasm and pushes the nucleus aside.

The behavior is extremely aggressive, even when occurring in young infants. The death rate is over 75%. High tumor stage and male sex are unfavorable prognostic signs.[185]

Tumors morphologically, immunophenotypically, and genetically indistinguishable from rhabdoid tumor of kidney have been reported in many other anatomic sites.[189-191]

Rhabdoid tumor of infantile kidney should not be equated to RCC with rhabdoid features (see later). Medullary carcinoma of the kidney may have significant histologic overlap with rhabdoid tumor, including loss of SMARCB1/INI-1 nuclear expression; however, patients with medullary carcinoma present at an older age and often have sickle cell trait. Many reported examples of rhabdoid tumor in patients over 5 years of age likely represent renal medullary carcinoma.[181]

Figure 24.15 Gross appearance of pediatric cystic nephroma involving most of the kidney.

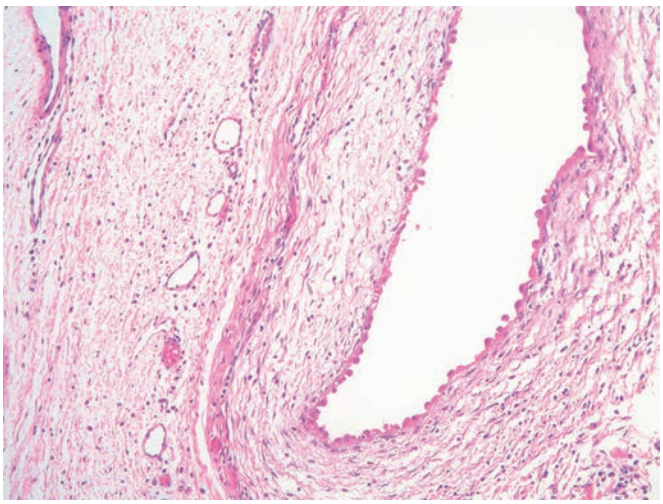

Figure 24.17 Pediatric Cystic Nephroma. The epithelial lining of the cyst has a hobnail quality and the stroma is loose and hypocellular.

Pediatric-Type Cystic Nephroma and DICER1 Renal Sarcoma

Pediatric cystic nephroma (multilocular cystic nephroma, multilocular cyst) is an uncommon but distinctive lesion that arises in early infancy.[192] While this diagnostic term has previously been applied to tumors in all age groups, the World Health Organization (WHO) recommends that the term be restricted to infants, given that those tumors are genetically distinct and may be associated with a tumor predisposition syndrome (i.e. germline mutation in DICER1).[193-195] Clinical manifestations result from the presence of a mass or, not uncommonly, from ureteral obstruction by one of the daughter locules.

Grossly, the lesion is usually solitary, unilateral, and sharply delineated from the uninvolved renal parenchyma.[196] The usual size range is between 5 and 15 cm, and the outer surface is coarsely nodular. The cut surface shows a multilocular appearance, the individual cysts measuring from 1 mm to 3 cm or more (Fig. 24.15). The wall of these cysts is thin and sometimes translucent and lacks papillary projections. The fluid within the cavity is usually serous. The cysts do not communicate with each other or with the pelvis. The remaining renal parenchyma is normal. Extension of the lesion beyond the renal capsule may occur.

Microscopically, there are cysts of varying caliber separated by a spindled stroma (Fig. 24.16). The cysts are lined by epithelium that ranges in height from columnar to extremely flat, resembling endothelium and simulating the appearance of lymphangioma. A "hobnail" pattern is common (Fig. 24.17). The stroma between the cysts usually has a fibroblastic, nondescript nature (sometimes immunoreactive for hormone receptors), with variable stromal condensation adjacent to the cyst lining (Fig. 24.18).[197] Small well-differentiated tubules may be seen, but the presence of nephroblastomatous elements would preclude the diagnosis of cystic nephroma. As noted, many pediatric cystic nephromas have underlying *DICER1* mutations,[192] explaining their reported association with pleuropulmonary blastoma.

Rarely, intrarenal spindle cell sarcomas are identified in pediatric patients and have been described under various names, including embryonal sarcoma and anaplastic sarcoma.[198-200] The location may be parenchymal or pelvicalyceal. Microscopically, the common denominator is a spindle cell component containing (either in a diffuse fashion or as multiple foci) varying levels of pleomorphism with some examples showing bizarre pleomorphic cells and atypical mitotic figures. Chondromatous and osteoid foci are sometimes present. Immunohistochemically, a haphazard pattern of reactivity is recorded; however, keratin stains are negative. An associated cystic component, sometimes with features of cystic nephroma, has been described.[201] The behavior has been very aggressive.[198] The overall appearance of this tumor resembles pleuropulmonary blastoma of childhood, of which it may represent the renal counterpart. Recent studies have supported this histologic impression, showing frequent *DICER1* mutations and proposing a genetic pathogenesis of cystic nephroma and *DICER1*-renal sarcoma that parallels type 1 to type II/III malignant progression in pleuropulmonary blastoma.[202]

Intrarenal Neuroblastoma

Neuroblastoma can invade the kidney secondarily from the adrenal or other retroperitoneal site, or it may initially present as a primary intrarenal tumor, and should be classified as outlined in the chapter

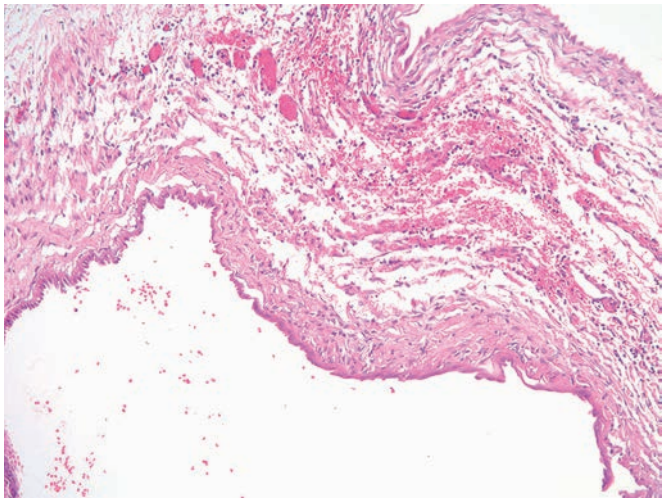

Figure 24.18 Pediatric Cystic Nephroma. The stroma shows subtle cellularity adjacent to the epithelium, which is more atrophic.

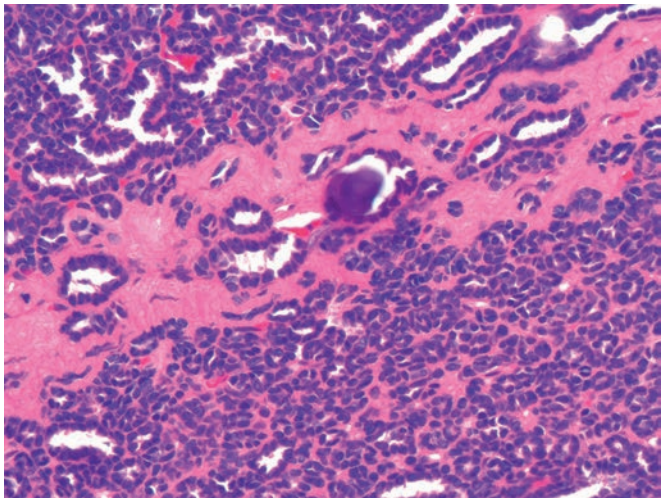

Figure 24.20 Metanephric Adenoma. The lesion is extremely cellular with a small tubular pattern.

Figure 24.19 Gross appearance of Ewing sarcoma, primary in the kidney.

on adrenal pathology.[203] When intrarenal, a misdiagnosis of Wilms tumor is likely. This issue is further complicated by the fact that the embryonal tubules of Wilms tumor can simulate rosettes and that true neuroblastic elements can occur in Wilms tumor. Immunohistochemical and molecular genetic evaluation are of help in this differential diagnosis.[41,204]

Intrarenal Ewing Sarcoma

Ewing sarcoma can also occur as a primary renal mass.[205,206] Its morphologic, immunohistochemical, and molecular genetic features are analogous to those at other sites. Most patients are young adults, and the clinical course is very aggressive.[207] Many of the cases are centered in the medullary/pelvic region (Fig. 24.19). The main differential diagnosis is with blastema-predominant Wilms tumor, from which it is distinguished by its positivity for CD99 and its (usual) negativity for WT1.[205] Ideally, the diagnosis should be confirmed by the demonstration by cytogenetics, fluorescence in situ hybridization (FISH), or reverse transcriptase-polymerase chain reaction (RT-PCR) of the t(11;22) translocation involving *EWSR1*.[208,209]

The initial analysis of 146 cases of primary malignant "neuroepithelial" tumors of the kidney from the NWTS Pathology Center files[210] and a subsequent review of additional cases[205] led the authors to the frustrating conclusion that these represent a diverse group of high-grade tumors which are not always easy to place in a specific category, even after their evaluation with immunohistochemical and molecular genetic tools. We would recommend keeping the diagnosis of Ewing sarcoma pure by requiring molecular confirmation. In our opinion, unusual tumors that do not fit into the Ewing sarcoma family, and for which other specific diagnostic categories are excluded (e.g. Wilms tumor), are best reported descriptively under terms such as "malignant neoplasm with neuroectodermal (or neuroepithelial) differentiation."

Rarely, other undifferentiated round cell sarcomas have been reported in the kidney, such as those associated with CIC-DUX4 fusion.[211,212]

Intrarenal Synovial Sarcoma

Synovial sarcoma, which is histologically and genetically identical to its soft tissue counterpart, may rarely occur in the kidney.[213,214] It is important to note that there are variable reports of PAX-8 expression in synovial sarcoma, some reporting reactivity in the spindle cells and some in glands (which may simply represent entrapped renal tubules).[67,215,216]

Metanephric Tumors

Metanephric adenoma tends to occur in young or middle-aged female patients. While more common in adults, metanephric adenoma is described here to include the related forms with a stromal component, which are more common in children. Grossly, they are solid and tan to gray in color. Microscopically, they are mostly composed of tightly packed small back-to-back tubules with minute lumina accompanied by very scanty stroma (Figs. 24.20 and 24.21).[217-219] More elongated branching tubules and areas with papillary architecture are not uncommon. The neoplastic cells are small and basophilic with almost no cytoplasm; nuclear features are bland. The overall appearance is very reminiscent of developing metanephric tubular epithelium.[220] Psammoma bodies are very common and

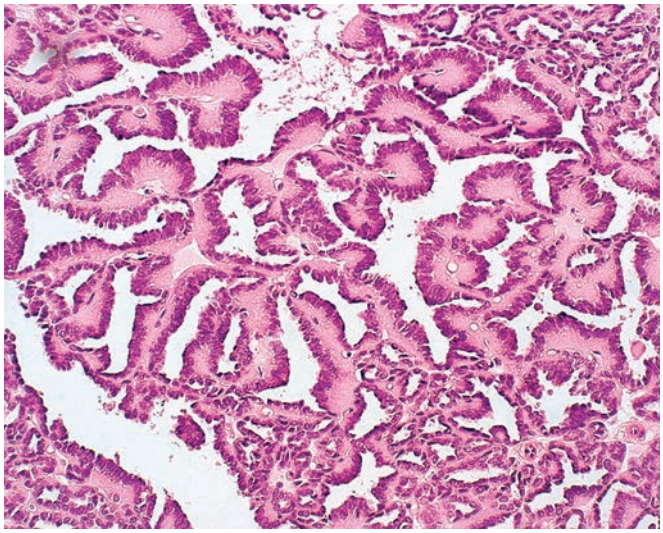

Figure 24.21 Papillary pattern of growth of metanephric adenoma.

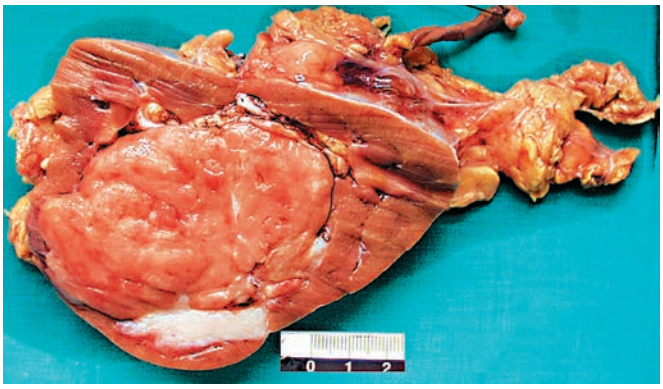

Figure 24.22 Gross Appearance of Metanephric Adenofibroma. The tumor is solid and vaguely nodular.

may be numerous. Secondary changes such as hemorrhage or cyst formation are common. Some of these features are also apparent on cytologic examination.[221]

Immunophenotypically, metanephric adenomas express both nuclear PAX8 and WT1, and cytoplasmic CD57 staining is common.[222] CK7 is negative or only focally positive. Genetically, approximately 90% have BRAF V600E mutations,[223] and BRAF immunohistochemistry (diffuse cytoplasmic staining) may serve as a surrogate marker.[224,225] The genetic features indicative of Wilms tumor and papillary RCC are absent.

The behavior of metanephric adenoma is benign.

Metanephric stromal tumor is a recently described pediatric renal neoplasm, occurring primarily in early childhood. It typically presents grossly as a fibrous lesion centered in the renal medulla that contains smooth-walled cysts. Microscopically, the neoplastic cells are spindle shaped, but admixed epithelioid features occur. The tumor entraps native renal tubules and blood vessels with onion-skin cuffing and myxoid change around each of the structures. Juxtaglomerular cell hyperplasia may also be seen within entrapped glomeruli (which may be associated with hypertension). There may be heterologous differentiation in the form of glia or cartilage and various types of associated vascular alterations (i.e. angiodysplasia). Immunohistochemically, most cases are reactive for CD34. Surgical excision is curative.[226]

Metanephric adenofibroma is a biphasic tumor in which an epithelial component similar to that of metanephric adenoma is intimately admixed with a bland spindle cell stroma similar to that of metanephric stromal tumor (Fig. 24.22).[227,228] Ages range from 1 to 36 years, but the mean is 7 years. The spindle cell component commonly expresses CD34 and entraps normal renal structures. The epithelial component has similar morphology and immunophenotype to metanephric adenoma. In some reported cases, part of the epithelial component was indistinguishable from that of Wilms tumor and in others it closely resembled papillary RCC.[227] The behavior of typical metanephric adenofibroma is benign.

Renal Cell Carcinoma

While **MiT family translocation RCCs** represent the most common RCC subtype in children, they are fully described in the adult renal neoplasia section since they are more commonly seen in that setting (due to much higher incidence of RCC in adults). Most other subtypes of renal cell carcinoma have also been reported in children and young adults.

Other Pediatric Tumor Types

Isolated examples of pediatric neoplasms not clearly belonging to any of the previous categories have been described. They include *ossifying renal tumor of infancy* (presenting as a calcified mass in the renal pelvis and composed of spindle cells in a partially calcified osteoid matrix),[229] *intrarenal teratoma* (to be distinguished from teratoid Wilms tumor),[230] intrarenal pure *yolk sac tumor*,[231] and desmoplastic small round cell tumor.[232-234]

Adult Tumors and Tumorlike Conditions

Renal Cell Carcinoma

General Features

RCC is generally a tumor of adults (average age at diagnosis: 55–60 years).[235] Many of the RCCs occurring in children have an appearance and behavior equivalent to those developing in adults,[236-239] but a high percentage belong to the MiT family translocation types.[240,241] The male to female ratio of adult RCC is about 2:1, and the incidence of bilaterality is 1%. Cigarette smoking and high blood pressure are said to increase the risk for development of the disease.[242] The list of diseases, hereditary and non-hereditary, that are associated with increased risk of RCC (including disease specific subtypes) continues to expand.[243]

Conditions that may be complicated by RCC are the following:

1. *von Hippel–Lindau (VHL) disease*. RCC occurs in 50% or more of individuals with this autosomal dominant syndrome, which is also characterized by the presence of CNS (usually cerebellar) and retinal hemangioblastomas; cysts of kidney, liver, and pancreas; clear cell tumors in a variety of sites (including inner ear and paratestis); and pheochromocytomas.[244,245] RCCs (of the clear cell subtype) in these patients tend to be multiple and associated with cysts, some of which show atypical changes in the lining epithelium.[246-248] The cysts, atypical cysts, and renal tumors of these patients have a similar immunohistochemical profile.[249] The VHL disease gene, called *VHL*, has been identified at chromosome 3p25.5. This tumor-suppressor gene is mutated in the germline of affected individuals, and in VHL-associated RCCs it is associated with a subsequent deletion of *VHL* in the wild-type allele. The marked degree of vascularization that often accompanies RCC (and other VHL-defective tumors, such as

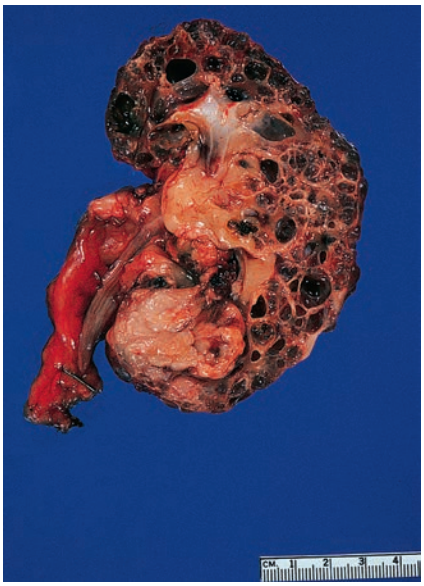

Figure 24.23 Renal Cell Carcinoma Developing in the Adult Form of Polycystic Kidney Disease. The tumor was multicentric.

cerebellar hemangioblastoma) is probably explained by the tumor's overproduction of hypoxia-inducible factor and its targets, such as vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), transforming growth factor alpha (TGF-α), and erythropoietin.[250] Microscopically, a small subset of clear cell RCCs associated with VHL disease have some features reminiscent of clear cell–papillary RCC.[251] Additionally, the background kidney parenchyma may contain multiple microscopic clear cell "tumorlets."

2. *Acquired cystic disease of the kidney*. Approximately 30%–40% of patients on long-term dialysis develop an acquired form of polycystic renal disease,[252] and 3%–7% of these are complicated by the appearance of RCC.[253] Atypical cysts with papillary hyperplasia of the lining epithelium is a consistent feature in these cases and the likely pathogenetic basis for tumor development.[253] While any subtype may be seen in this setting, a subset has unique morphologic, immunohistochemical, and molecular genetic features described later (see section "Acquired Cystic Kidney Disease Associated Renal Cell Carcinoma").[254]
3. *Adult form of polycystic kidney disease* (Fig. 24.23). As with the preceding entity, the carcinoma in these cases is accompanied and probably preceded by atypical cysts that begin as foci of papillary epithelial hyperplasia.[255] The tumors are frequently multifocal/bilateral and often have papillary or clear cell morphology.[256]
4. *Birt-Hogg-Dubé syndrome (germline folliculin mutation)* is characterized by a constellation of findings that include skin adnexal tumors (fibrofolliculoma), basilar pulmonary cysts with frequent spontaneous pneumothorax, and renal neoplasia.[257] The renal tumors are often oncocytic and include oncocytoma, chromophobe RCC, and hybrid oncocytic tumors.[258] The hybrid tumors may have a unique appearance with a so-called checkerboard pattern characterized by alternating eosinophilic and clear cells; however, unlike chromophobe RCC, the nuclei are small and almost pyknotic while the cytoplasm is somewhat vacuolated. The background kidney parenchyma may also show renal oncocytosis.[259]
5. *Hereditary leiomyomatosis and RCC syndrome (germline fumarate hydratase mutation)* is autosomal dominant and characterized by the presence of cutaneous and uterine leiomyomas and RCCs. These renal tumors are now regarded as a specific subtype of RCC (i.e. HLRCC associated [or fumarate hydratase deficient] RCC).[260,261]
6. *Hereditary paraganglioma syndrome (germline succinate dehydrogenase mutation)*. Patients are predisposed to paragangliomas, renal neoplasms, pituitary adenomas, and a unique type of gastrointestinal stromal tumor (GIST). Recent studies have shown that the renal tumors represent a distinct subtype, described later as "SDH-deficient RCC."[262-264]
7. *Tuberous sclerosis*. Although the classic renal tumor associated with this neurocutaneous syndrome is angiomyolipoma (AML), RCCs may be encountered, sometimes seen in intimate connection with the former.[265,266] While cases of oncocytoma have been described in this setting, the main RCC subtypes seem identical to sporadic tumors classified as "eosinophilic solid and cystic (ESC)," "RCC with angioleiomyomatous stroma," and a heterogeneous spectrum of oncocytic tumors resembling either chromophobe RCC or hybrid oncocytic tumors (further described under individual RCC subtypes later).[265-267]
8. *Neuroblastoma*. Several cases of RCC developing in children previously treated for neuroblastoma have been reported; however, this seems to be a heterogeneous group of tumors that include post-therapy–related MiT family translocation carcinomas, sporadic type RCCs, and a unique renal neoplasm with "oncocytoid" features that, in our opinion, shares some features with the recently described "ESC" RCC.[268,269]
9. *PTEN Hamartoma Tumor Syndrome (germline PTEN mutation)* is the molecular diagnostic term used for the disorders that include Cowden syndrome, Bannayan-Riley-Ruvalcaba syndrome, and a spectrum of other clinical presentations. This syndrome is rarely associated with RCCs with a papillary, clear cell, or chromophobe morphology.[270,271]
10. *Hereditary papillary RCC syndrome* is associated with a germline mutation in the *MET* gene. It predisposes to type 1 papillary RCCs, which may number in the hundreds.
11. *Hemoglobinopathy* (most commonly sickle cell trait) is associated with two types of RCC that occur a young age, renal medullary carcinoma and the extremely rare *VCL-ALK* fusion associated renal neoplasm.
12. Other rare syndromes with an increased risk of renal neoplasia are described, such as BAP1 tumor predisposition syndrome and MiTF-associated cancer syndrome.

Clinical Features

RCC usually presents with hematuria (59%), flank pain (41%), or as an abdominal mass (45%). However, the combination of these three features, classically regarded as the diagnostic triad of RCC, occurs in only 9% of the patients.[272] Other manifestations are weight loss (28%), anemia (21%), fever (7%), and symptoms caused by a metastatic deposit (10%). Rare systemic/paraneoplastic manifestations include leukemoid reaction, systemic amyloidosis, polyneuromyopathy, gastrointestinal disturbances, hepatosplenomegaly, hypercalcemia, polycythemia, and hepatic dysfunction.[273-282]

In general, the investigation of a suspected renal mass begins with CT scan or MRI.[283] With the increasing use of these modalities, the number of incidentally detected RCCs has increased substantially.[284,285] In expert hands, core needle biopsy has been shown to provide adequate diagnostic material in about 80% of the cases.[286] Many centers proceed directly to partial nephrectomy without biopsy in surgical candidates; however, as active surveillance of renal mass lesions and local ablation techniques gain acceptance, biopsy rates will likely increase.[287]

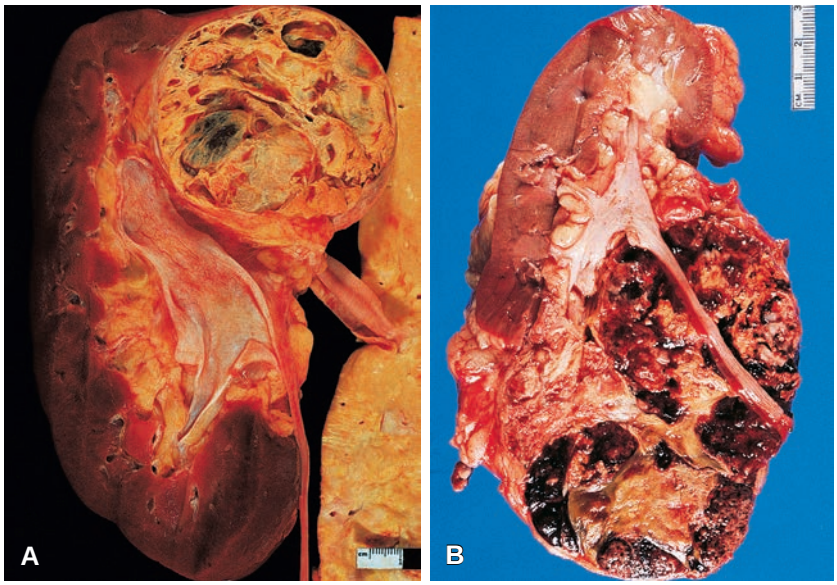

Figure 24.24 Gross Appearances of Renal Cell Carcinoma. Both tumors are relatively well circumscribed and variegated, with a combination of cystic, solid, and hemorrhagic areas. The tumor shown in **A** has a bright yellow color, whereas that portrayed in **B** has extensive areas of hemorrhage.

Subtypes of Renal Cell Carcinoma

Subtyping of RCC has become increasingly complicated since the modern classification was proposed in 1997.[288,289] Diagnosing specific subtypes is important because each has distinct underlying molecular correlates, unique immunophenotypes, varying biologic potential for aggressive behavior, emerging therapeutic implications, and in some cases important predisposition information for family members.[290,291] Therefore, each of the specific RCC subtypes is discussed separately to include histology, immunohistochemistry, and any known genetic features.

Clear Cell Renal Cell Carcinoma

Clear cell RCC is the most common type of RCC, accounting for 65%–70% of all renal cancers. Grossly, most clear cell RCCs are well delineated and centered on the cortex (Fig. 24.24). On occasion, only a small portion is connected with the cortex, the bulk of the tumor appearing as an extrarenal mass. Extension to the renal pelvis occurs only late in the course of the disease. In approximately 5% of the cases, multiple tumor nodules are seen scattered throughout the organ, but in some cases this may represent retrograde venous extension from the dominant tumor.[292,293]

In a typical case of clear cell RCC, the cut surface shows a solid, golden-yellow tumor, sharply separated from the surrounding tissues by a fibrous pseudocapsule. The common occurrences of hemorrhage, necrosis, calcification, and cystic change result in the variegated appearance that is so characteristic of this neoplasm (Fig. 24.25). On occasion, the cystic degeneration is so advanced that a mural nodule remains as the only evidence of the real nature of the lesion. Sometimes even this disappears, and the diagnosis is made only on microscopic examination.[294]

Microscopically, the tumor cells of clear cell RCC are relatively large, the appearance of the cytoplasm ranging from optically clear to deeply granular, with many transitional forms (Fig. 24.26).[295-298] The clear cell appearance of the tumor cells results from the accumulation of glycogen (because of abnormalities of carbohydrate metabolism)[299] and lipids. The nuclei are generally centrally located; their size, chromatin pattern, and nucleolar appearance vary notably from case to case, this constituting the main basis for microscopic grading (Table 24.3). In the usual case, the pattern of growth is predominantly solid, with formation of alveolar and acinar patterns of tumor cells separated by a stroma that is characteristically endowed with a prominent network of small, thin-walled blood vessels. This vascular pattern is an important diagnostic criterion, especially for cases with granular eosinophilic cytoplasm. Other patterns include tubular formation, microscopic and/or macroscopic cysts, associated intraluminal erythrocytes, and regression. Rarely, pseudopapillary architecture may be present. Tumors with extensive regression show large areas of edematous or collagenized stroma that contain a well-formed arborizing vasculature; in difficult cases, low-molecular-weight cytokeratin or EMA immunostains can highlight the subtle population of residual neoplastic cells that mimic histiocytes. Multiple sections usually show diverse patterns within

Figure 24.25 Renal cell carcinoma with multilocular gross appearance.

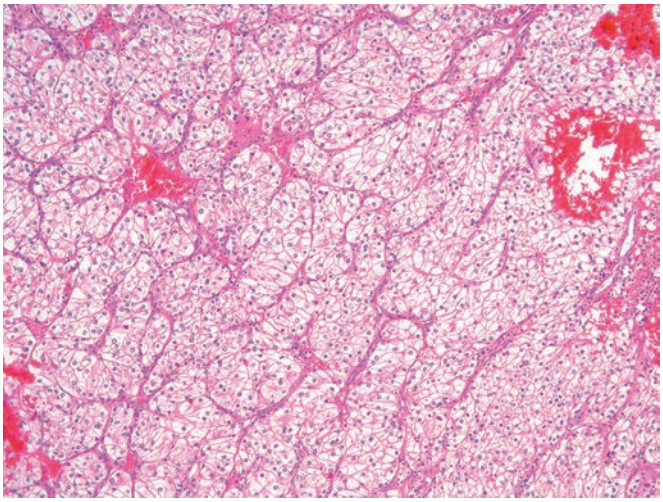

Figure 24.26 Renal cell carcinoma, clear cell type.

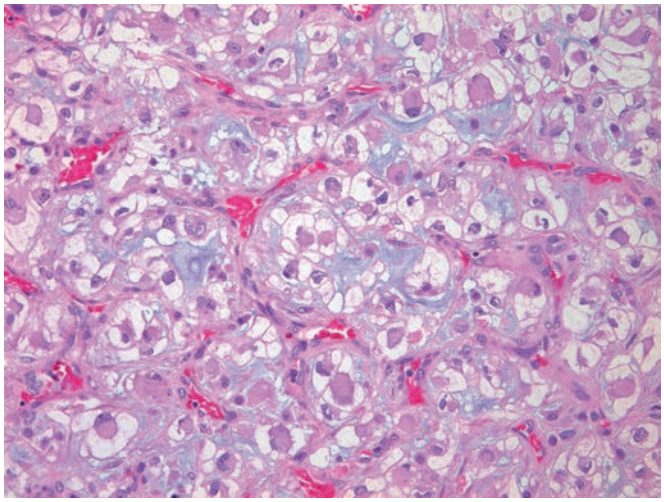

Figure 24.27 Renal cell carcinoma, clear cell type, with rhabdoid differentiation.

Table 24.3 World Health Organization/International Society of Urological Pathology Grading System for clear cell renal cell carcinoma and papillary renal cell carcinoma

GRADE	CRITERIA
1	Nucleoli are absent or inconspicuous and basophilic at ×400 magnification
2	Nucleoli are conspicuous and eosinophilic at ×400 magnification and visible but not prominent at ×100 magnification
3	Nucleoli are conspicuous and eosinophilic at ×100 magnification
4	Extreme nuclear pleomorphism and/or rhabdoid differentiation and or sarcomatoid differentiation

the same tumor. High-grade progression may lead to sarcomatoid and/or rhabdoid histologic patterns. Rhabdoid differentiation is characterized by abundant homogeneous eosinophilic cytoplasm and an eccentric nucleus; the background architecture may retain a nested pattern with associated blood vessels (Fig. 24.27) or undifferentiated sheet-like growth. The stroma of RCC is nondescript and, in general, not desmoplastic as typical of collecting duct carcinoma or urothelial carcinoma. A lymphocytic infiltrate of variable degree is often present.

Immunohistochemically, clear cell RCC shows reactivity for epithelial markers such as keratin and EMA. Coexpression of keratins and vimentin is the rule, a feature not present in normal tubular cells.[300,301] Other antigens detected in the cells of clear cell RCC are CD10,[302] carbonic anhydrase IX,[303,304] RCC marker, PAX-2[305] and PAX-8. With current antibodies, PAX-8 has higher sensitivity. Cytokeratin 7 expression, which may be used in the differential diagnosis of other renal neoplasms with clear cytoplasm, is typically rare in clear cell RCC and limited to a focal or patchy pattern of reactivity. It should be recognized that any epithelial cyst lining in the kidney may stain strongly for cytokeratin 7.

From the standpoint of differential diagnosis, the choice of the markers to use depends on the specific situation at hand (i.e. whether one is trying to decide to which subtype a given RCC belongs [to be discussed later] or whether a given clear cell carcinoma in an extrarenal site represents a metastasis of a RCC or not).[306] In regard to the latter, the most useful *positive* markers are the coexpression of keratin and PAX-8. It is, however, the *negative* markers that are of greatest use depending on the circumstance, to wit: (1) in the differential diagnosis with adrenal cortical carcinoma, the fact that clear cell RCC is negative for inhibin, MelanA, and SF-1[307,308]; (2) in the differential diagnosis with clear cell carcinoma of the ovary, the fact that clear cell RCC is usually negative for keratin 34βE12 and CK7[309-311]; (3) in the differential diagnosis with clear cell carcinoma of the thyroid, the fact that RCC is negative for thyroglobulin and TTF-1; (4) in the differential diagnosis with mesothelioma the fact that RCC is negative for calretinin, mesothelin, and CK 5/6,[312] and so forth.[313-317] While we generally find PAX-8 to be the most useful renal epithelial marker based on sensitivity and specificity, the number of tumors that may express PAX-8 must be carefully considered.[318] In addition, one must be aware of the possibility of cross-reactivity with other PAX epitopes when using a polyclonal antibody (e.g. cross-reactivity with PAX5 in B-cell lymphoma).

The notable feature of the genetic aspects of RCC is that there is a very close relationship with the various morphologic subtypes,[319,320] which can be investigated by conventional cytogenetics, PCR, FISH, microsatellite analysis, single nucleotide polymorphism (SNP) microarray, or sequencing techniques.[321-324] A distinctive abnormality found in most cases of clear cell RCC is alteration of the *VHL* tumor suppressor, either by a terminal deletion of the short arm of chromosome 3, beginning at 3p13,[325-334] silencing through promoter methylation, and somatic mutation. Since this abnormality does not characterize other types of RCC, its detection could be utilized to aid in differential diagnosis; however, this is rarely done in routine practice due to the different possible modes of *VHL* alteration. While the *VHL* gene on 3p25–26 is typically implicated (with inactivation of both copies), other tumor suppressor genes on 3p may also play a role, such as *KD-M6A*, *KMM5C*, *SETD2*, and *PBRM1*.[325,328,330,332,333,335-338] Mutations in *BAP1* have been associated with high-grade tumors and poor outcome. The molecular changes have shed light on the pathogenesis of some clinical and morphologic features of clear cell RCC, as well as provided the basis for the design of various targeted therapies. The VHL gene product is required for degradation of HIF-1α (hypoxia inducible factor α). With loss of VHL protein in clear cell RCC, HIF-1α accumulates, resulting in activation of a variety of

hypoxia-inducible genes and hence increased production of their products. These include VEGF, platelet-derived growth factor-B (PDGF-B), TGF-α, GLUT-1, metalloproteinases, and erythropoietin.[322,339,340] Furthermore, the AKT-mTOR pathway can also affect HIF-1α, since mTOR normally promotes translation of HIF-1α.[339] Targeted therapy may therefore utilize tyrosine kinase inhibitors for VEGF receptor and PDGF receptor (such as sunitinib and sorafenib), inhibitors for mTOR (such as temsirolimus), and/or antibodies targeting VEGF (bevacizumab).[322,339]

Clear cell RCC has a high rate of metastatic disease, sometimes years after initial diagnosis. Prognostic factors are discussed later in a separate section.

Papillary Renal Cell Carcinoma

Papillary RCC is the second most common subtype with series typically reporting that it accounts for 15% to 18% of all RCCs. Classification within this category continues to rapidly evolve. It has been proposed that papillary RCC can be further subdivided into two types: *type 1*, in which the papillae are lined by a single layer of cells with scanty pale cytoplasm; and *type 2*, in which the papillae are lined by a pseudostratified epithelium composed of cells with abundant eosinophilic cytoplasm, typically of higher nuclear grade.[341,342] Molecular studies have confirmed the type II category to be a very heterogeneous group of tumors, and one could argue that these should not be combined with type 1 in the classification scheme.[343]

Type 1 papillary RCC represents the prototypical papillary RCC. They are more likely than clear cell RCC to be localized to the kidney, but also more likely to be multicentric or bilateral.[344-346] Grossly, the tumors are often encapsulated and the cut surface has a tan-brown appearance; the intracystic papillary growth may mimic extensive necrosis. Microscopically, a thick fibrous capsule is typical, and the individual neoplastic cells line the inner layer of the capsule. Complex papillary formations fill the intracystic space (Fig. 24.28A), often accompanied by prominent stromal infiltration by neutrophils or foamy macrophages.[347,348] The neoplastic cells lining the papillae consist of a single layer of low cuboidal epithelium, often with little cytoplasm (see Fig. 24.28B). Psammoma bodies may be numerous and the nuclear grade is variable.[349,350] Other, histologic patterns of type 1 papillary RCC include solid growth, in which papillae are collapsed together (Fig. 24.29), and the "biphasic squamoid alveolar" pattern (Fig. 24.30). Papillary RCCs may undergo intratumoral hemorrhage and necrosis; intracytoplasmic hemosiderin deposition and cytoplasmic clearing are not uncommon in such foci. In fact, type 1 papillary RCC may undergo near complete infarction leaving only a thick fibrous capsule filled with necrosis and cholesterol granulomas. Numerous sections of the capsule will often reveal foci of residual viable tumor.

Immunohistochemically (and in contrast with clear cell RCC) there is strong expression of keratin 7 and AMACR in type 1 tumors.[351] According to this classification scheme, it is the type 1 tumors that have the underlying chromosome 7, 17, and Y abnormalities.[352-354] In contrast to clear cell RCC, there is no loss of 3p. Type 1 papillary RCC has a better prognosis than clear cell RCC.[344,355] In rare instances, type I papillary RCC is hereditary, associated with germline mutations of the *c-MET* oncogene, often presenting with hundreds of small tumors.[356]

Type 2 papillary RCC represents a heterogeneous collection of high-grade RCCs with papillary architecture (Fig. 24.31). Recent molecular studies have shown that MiT family translocation RCCs and RCCs associated with hereditary leiomyomatosis are frequently misclassified as "type 2" papillary RCC. Of the remaining type 2 tumors, different genetic subgroups include sporadic fumarate

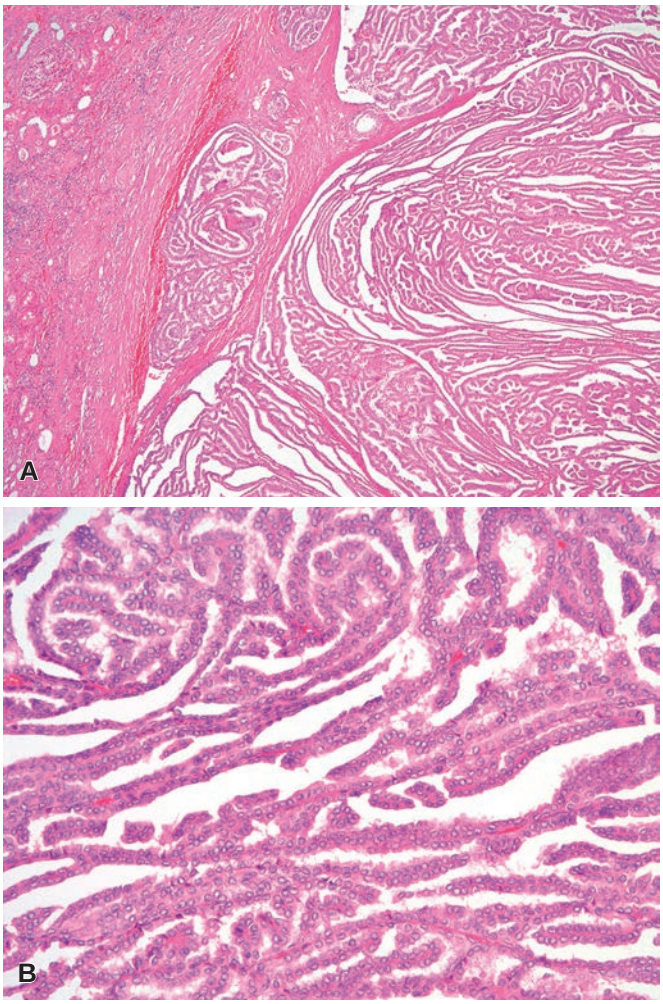

Figure 24.28 Renal Cell Carcinoma, Papillary Type 1. A, Typical thick fibrous capsule with papillary tumor filling a cystic space. **B,** Single cuboidal layer of cytologically bland cells.

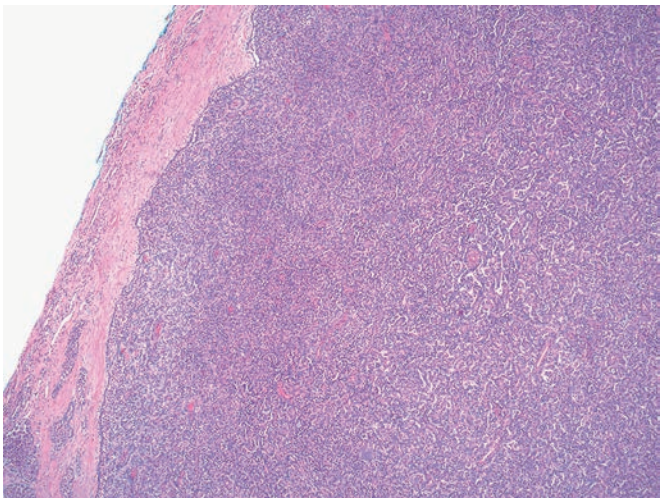

Figure 24.29 Renal cell carcinoma, papillary type 1, with solid growth.

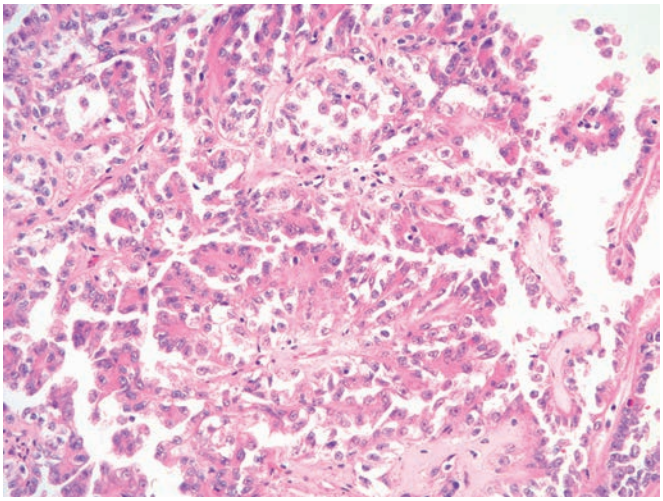

Figure 24.31 Renal cell carcinoma, papillary type 2.

hydratase mutation (i.e. not associated with hereditary leiomyomatosis), *CDKN2A* silencing mutation, *SETD2* mutation, *NF2* mutation (Hippo pathway tumor suppresser), and *NRF2-ARE*.[343] It is provocative that a subset of the studied carcinomas share alterations in the Hippo pathway with the "mucinous, tubular, and spindle cell carcinoma" of the kidney (which has known histologic and immunophenotypic overlap with papillary RCC), suggesting a close relationship in that subgroup. It is likely that the type 2 category will undergo changes as distinct molecular, and possibly morphologic, subtypes emerge.

Some papillary RCCs have mixed histologic features that are difficult to classify as either type 1 or type 2, but genetic and clinical outcome studies suggest a closer relationship to type 1 papillary RCC in many of these tumors[357,358]; grading and staging should be emphasized in such cases.

Another morphologic subset of cases is "oncocytic papillary carcinoma." These are not fully characterized, but often have a single layer of lower-grade round nuclei, and some show elevation of the nuclei off the basement membrane (i.e. reverse polarity).[359-361]

It should also be realized that papillary RCC (like all other types) can undergo anaplastic or sarcomatoid changes, but rhabdoid differentiation is uncommon.[362-364]

Figure 24.32 Multilocular cystic renal neoplasm of low malignant potential.

Multilocular Cystic Renal Neoplasm of Low Malignant Potential

These are rare macrocystic renal tumors, representing less than 1% of renal neoplasms, that are composed of thin septa without any macroscopic tumor nodules or expansile growth. Microscopically, the cysts are lined by a layer of clear epithelial cells, but the key diagnostic feature is the presence of small clusters of clear neoplastic cells in the thin walls of the septa (Fig. 24.32).[365] The presence of any solid nodules of tumor cells would warrant a diagnosis of clear cell RCC. Genetically, these tumors have 3p alterations similar to clear cell RCC, so they may simply represent an early phase of clear cell. When solid foci of tumor regression are present, the tumors are probably best diagnosed as clear cell RCC.[366] If diagnosed using strict histologic criteria with very close gross correlation, multilocular cystic renal neoplasm of low malignant potential follows a benign clinical course.[365] It is likely that staging has little prognostic value in these tumors.[367] The main differential diagnostic considerations are clear cell RCC, clear cell–papillary RCC, benign renal cortical cysts, and cystic nephroma (mixed epithelial and stromal tumor [MEST]).

Chromophobe Renal Cell Carcinoma

Chromophobe RCC comprises about 5% of all cases of RCC. It is grossly well circumscribed, solitary, with a homogeneous gray to brown cut surface, typically devoid of hemorrhage or necrosis (Fig. 24.33).[368] Microscopically, there is a characteristic broad "alveolar" arrangement of the tumor at low power, but some cases have smaller nests. There are two main histologies: classic (or "plant-cell") type and eosinophilic variant. In the classic type, the neoplastic cells have sharply defined borders and abundant cytoplasm with very prominent cell membranes (Fig. 24.34).[369] The cytoplasm has a pale, acidophilic quality, and there is often a vague clear perinuclear region.[370] The eosinophilic variant has more pronounced perinuclear clearing, but less prominent cell membranes (Fig. 24.35). Some cases have mixed features. Calcification is present in nearly half of the cases. The nuclear features, which are critical to diagnosis, are characterized by irregular nuclear membranes, hyperchromasia, and frequent binucleation. In our opinion, these specific nuclear features are both necessary and sufficient for classification as chromophobe RCC. Rare cases are associated with multicystic, microcystic, and adenomatous patterns of growth or neuroendocrine-like features (Fig. 24.36).[371-373] The characteristic cytoplasmic and nuclear features of

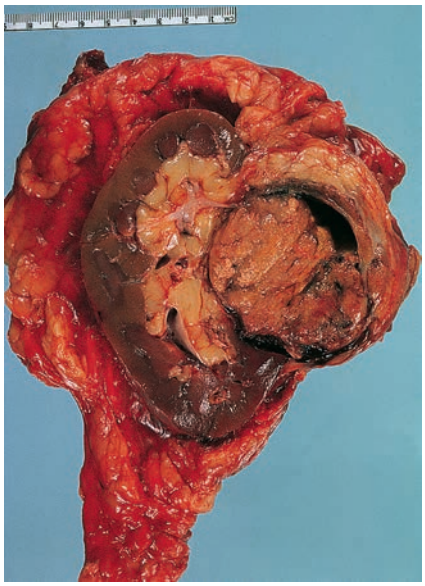

Figure 24.33 Gross Appearance of Renal Chromophobe Cell Carcinoma. The tumor is well circumscribed and has a light brown color.

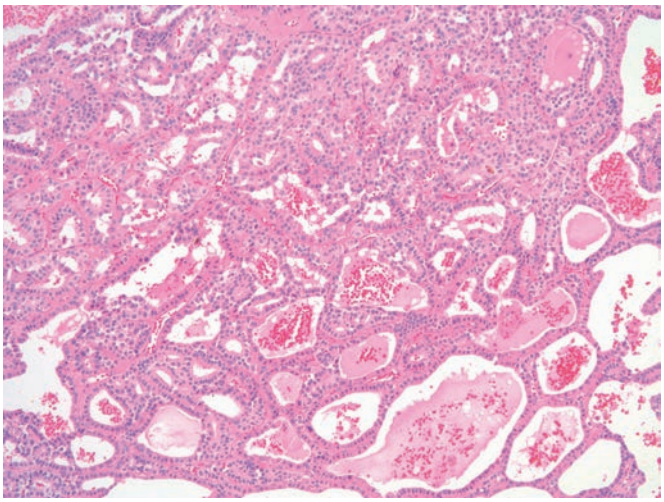

Figure 24.36 Chromophobe renal cell carcinoma, microcystic pattern.

the tumor can be recognized in fine-needle aspiration specimens and biopsies.[374,375]

This cytoplasmic appearance is due to the presence of numerous cytoplasmic microvesicles that are well appreciated by electron microscopy, but this is no longer employed for routine diagnosis.[376] These microvesicles stain for Hale colloidal iron; however, the stain is technically difficult to perform and we do not require its use.[368,377-379] The number of publications promoting the use of adjunctive immunohistochemistry in the distinction between chromophobe RCC and oncocytoma is overwhelming, to say the least. In our experience, the immunophenotype of cases with prototypical histologic features of chromophobe RCC can be much more heterogenous than would be suggested by the literature. Therefore, we rely almost exclusively on H&E morphology for this distinction (see section on renal oncocytoma for full discussion on the handling of "difficult to classify" cases). Based on a recent publication, even expert pathologists' use of immunohistochemistry and special stains in this setting varies quite dramatically.[380] With that caveat, chromophobe RCC is reported to commonly express EMA, CD117, keratin 7, CD9, CD82,[381] paxillin, parvalbumin,[382] claudin-7 and -8,[383,384] Ep-Cam (an epithelial adhesion molecule),[385] and E-cadherin, but not N-cadherin or vimentin.[386-389] A high percentage of chromophobe RCCs have been found to be immunoreactive for CD10 at least focally.[390] It should also be highlighted that, in contrast to most RCC subtypes, at least 20% of chromophobe RCCs are negative for PAX-8.[391,392]

Frequent loss of chromosomes 1, 2, 6, 10, 13, 17, and 21 has been found by comparative genomic hybridization[393] and microsatellite markers.[394,395] Other reported losses include chromosomes 3, 5, 8, 9, 11, 18, and Y. While the important work reported by The Cancer Genome Atlas (TCGA) revealed fascinating insights into the biology of chromophobe RCC, the molecular events were very heterogeneous, and a practical diagnostic marker was not identified.[396]

Chromophobe RCC can undergo sarcomatoid transformation; as a matter of fact, it may have a greater tendency to this event than many other types.[395,397] As a whole, the prognosis of chromophobe RCC is much more favorable than that of clear cell RCC, but distant metastases can develop (particularly liver), especially when the tumors are high stage at presentation.[398,399] The current consensus is that grade does not provide additional prognostic information for

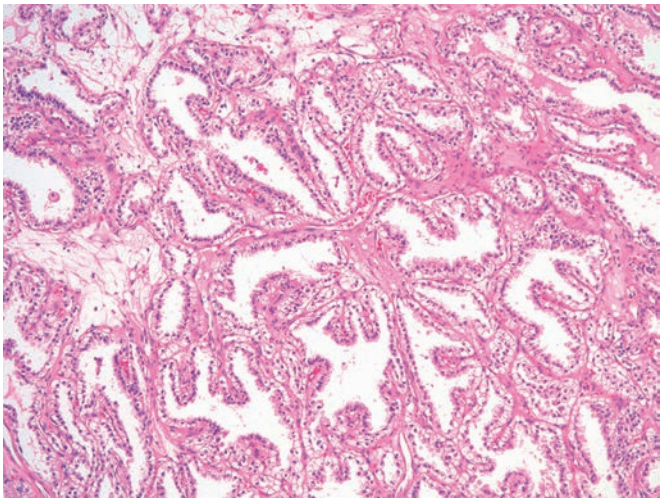

Figure 24.37 Clear cell–papillary renal cell carcinoma with predominant papillary architecture. The linear nuclear alignment and sub-nuclear cytoplasm are also evident.

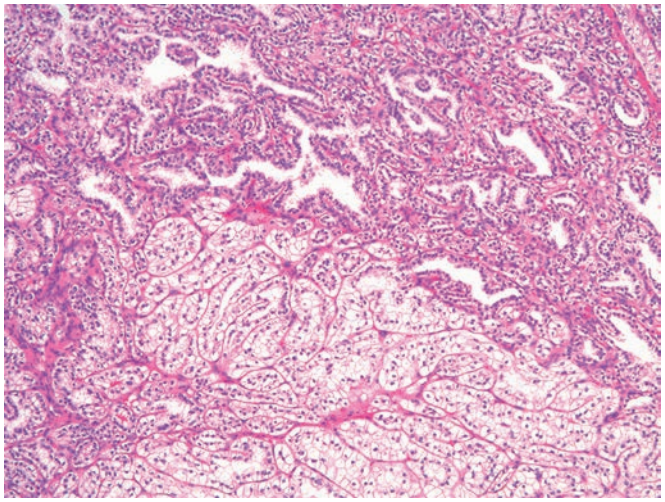

Figure 24.38 Clear cell–papillary renal cell carcinoma with mixed branching tubules and more solid clear cell pattern.

chromophobe RCC[400]; however, if sarcomatoid transformation has developed, the prognosis becomes very poor.

Clear Cell–Papillary Renal Cell Carcinoma

Clear cell–papillary RCC was first described by Tickoo et al. within a series of RCCs arising in end-stage kidney disease, but it is now recognized as more common in a sporadic setting.[401-403] In fact, two large studies have similarly shown that it represents the fourth most common RCC after clear cell, papillary, and chromophobe.[404,405] Grossly, clear cell–papillary RCC is circumscribed and often encapsulated. It may be solid, but is often cystic. Microscopically, cystic areas are lined by a single low cuboidal layer of clear cells with areas of papillary tufts lined by similar cells. More solid areas have an admixture of architectural patterns, including tubular, acinar, and nested. The clear cells are cytologically low grade (International Society of Urological Pathology [ISUP] nuclear grade 1–2), and there is frequently reverse polarity with subnuclear clearing and a linear arrangement of the nuclei (Fig. 24.37). The tubular pattern almost always shows branching. Solid and nested areas may have significant overlap with clear cell carcinoma, but the absence of the dense fibrovascular septa, the linear nuclear arrangement, and the presence of other architectural patterns aid in diagnosis as clear cell–papillary RCC (Fig. 24.38). Tumor cell necrosis and invasion of renal sinus vessels should be absent.

The capsule of the tumor may show smooth muscle metaplasia, but this should not change the classification as clear cell–papillary RCC if other features are typical. Such tumors were originally described as part of the spectrum of "renal angiomyoadenomatous tumor,"[402,406] but clear cell–papillary RCC is now considered distinct from "RCC with (angio)leiomyomatous stroma."

Immunophenotypically, these tumors show strong and diffuse immunoreactivity for cytokeratin 7. CD10 and racemase are typically negative, while CA-IX ("cup-like" pattern), PAX-8, and high-molecular-weight keratin are often positive. Nuclear GATA-3 expression has been recently reported.[407,408] When immunohistochemistry is needed, cytokeratin 7 often provides sufficient support to exclude clear cell subtype (which is negative or shows only focal staining); in fact, the absence of cytokeratin 7 staining should prompt careful reconsideration of a clear cell–papillary diagnosis. Cytokeratin 7 stains should be evaluated in solid foci because cyst-lining epithelial cells of many tumor types show strong immunoreactivity. Genetically, there is no specific finding in clear cell–papillary RCC, but they do not have the changes characteristic of either clear cell RCC or papillary RCC.[409-411]

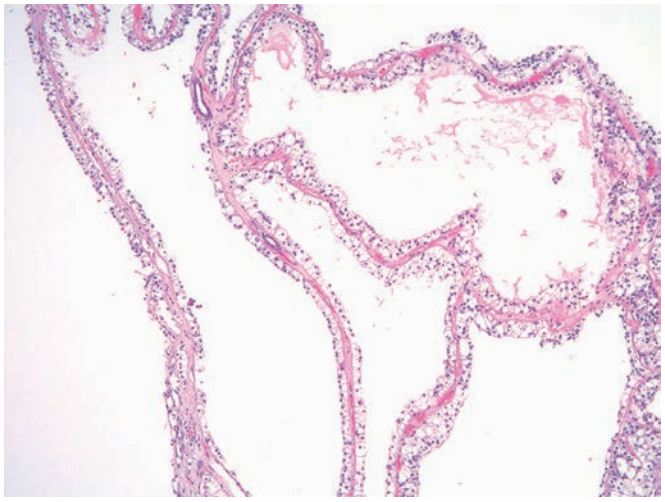

Figure 24.39 MiT Family Translocation Renal Cell Carcinoma. Rare cases may mimic clear cell–papillary or multilocular cystic renal neoplasm.

When diagnosed by strict criteria, no recurrence or metastasis has been reported in clear cell–papillary RCC[402,412,413]; therefore, the differential diagnostic distinction from clear cell RCC and a subset of MiT family translocation RCC is critical. Other less critical distinctions, such as multilocular cystic renal neoplasm of low malignant potential and atypical renal cysts, may be difficult and somewhat subjective.[414,415] In our experience, papillary RCC rarely enters into consideration. It is important to note that some low-grade clear cell RCCs have foci reminiscent of clear-cell papillary RCC, often due to linear alignment of nuclei. Studies have shown that tumors with such mixed features have genetic features and a clinical outcome supporting clear cell subtype.[416,417] Rare subsets of MiT family translocation carcinomas (specifically fusion types SFPQ-TFE3 and NONO-TFE3) may also mimic clear cell–papillary RCC (or possibly multilocular cystic renal neoplasm) based on suprabasal nuclear palisading and subnuclear vacuoles (Fig. 24.39).[418,419] In our practice, we would generally regard the presence of intracystic

papillary excrescences as favoring clear cell–papillary RCC over multilocular cystic renal neoplasm of low malignant potential. The distinction of an atypical renal cyst (with focal papillary excrescences lined by clear cells) from a macrocystic clear cell–papillary may be very subjective.[414] In the presence of papillary tufts within multiple cystic locules of the same lesion, we would favor clear cell–papillary RCC.

Finally, some patients with VHL disease have tumors with morphologic features similar to clear cell–papillary RCC; these are controversial, but in our opinion they are best interpreted as clear cell RCC, given their association with 3p abnormality.[251]

MiT Family Translocation Renal Cell Carcinomas

An exciting new chapter of renal tumor pathology opened with the discovery that some tumors are associated with nonrandom chromosomal alterations involving members of the microphthalmia transcription factor subfamily.[420-422] The better studied of these are those involving region Xp11.2, resulting in fusion of the *TFE3* gene.[423] Most of the initial cases were reported in young people; while they represent approximately 40% of pediatric RCCs, they can also develop in adults.[424,425] Microscopically, the overall features are typically those of an RCC but are very heterogeneous. Papillary structures may be prominent, and the tumor cells can be either clear or have a markedly granular eosinophilic cytoplasm; however, some cases are more solid and clear cell predominant, closely mimicking clear cell RCC (Fig. 24.40). Admixed psammoma bodies may be abundant. There are numerous fusion partners reported, some correlations having been found between the type of gene fusion and the tumor morphology.[419] Aberrant increased nuclear immunoreactivity for *TFE3* is consistently detected in these cases, but many labs find the antibody technically challenging to use and prefer FISH testing (as do we).[426] These tumors usually express PAX2 and PAX8, but do not usually express MiTF.[427] One specific fusion (RBM10-TFE3) may be difficult to detect by FISH due to cryptic inversion.[428,429]

Another, even less common translocation-associated RCC involves t(6;11), the resulting fusion affecting the *TFEB* gene at 6p21.[430] Microscopically, these tumors show nested and acinar-like areas of cells with clear or granular acidophilic cytoplasm with round nuclei. Some cases show a biphasic pattern with a population of smaller cells surrounding eosinophilic basement membrane–like material (Fig. 24.41). They may be difficult to morphologically distinguish from Xp11.2-related tumors, and they may express HMB45 or Melan-A. It is clear that the subject is rapidly evolving and that additional variations, both at the morphologic and the molecular genetic level, are being described.[431] Case in point, aggressive RCCs with TFEB amplification are recently described.[432-434]

Rare hybrid melanotic tumors showing mixed features of MiT family translocation carcinoma and AML are also described. [435]

Collecting Duct Carcinoma

Collecting duct carcinoma constitutes less than 1% of all RCCs under current criteria. These tumors are centered in the medulla, have destructive infiltrative growth often with surrounding desmoplastic reaction, and are almost always high stage at diagnosis.[436-438] Common histologic patterns include tubulopapillary, solid sheets, nests, cords, cribriform, and infiltrating glands or elongated tubules (Fig. 24.42).[438] Sarcomatoid differentiation may also be present. Atypical changes in the adjacent ducts (i.e. dysplasia) may be seen, but distinction from reactive tubular changes is often subjective.

Genetic profile information is limited for collecting duct carcinoma because of its rarity and the evolving diagnostic criteria that now further restricts its diagnosis.[439,440] Likewise, immunophenotypic data

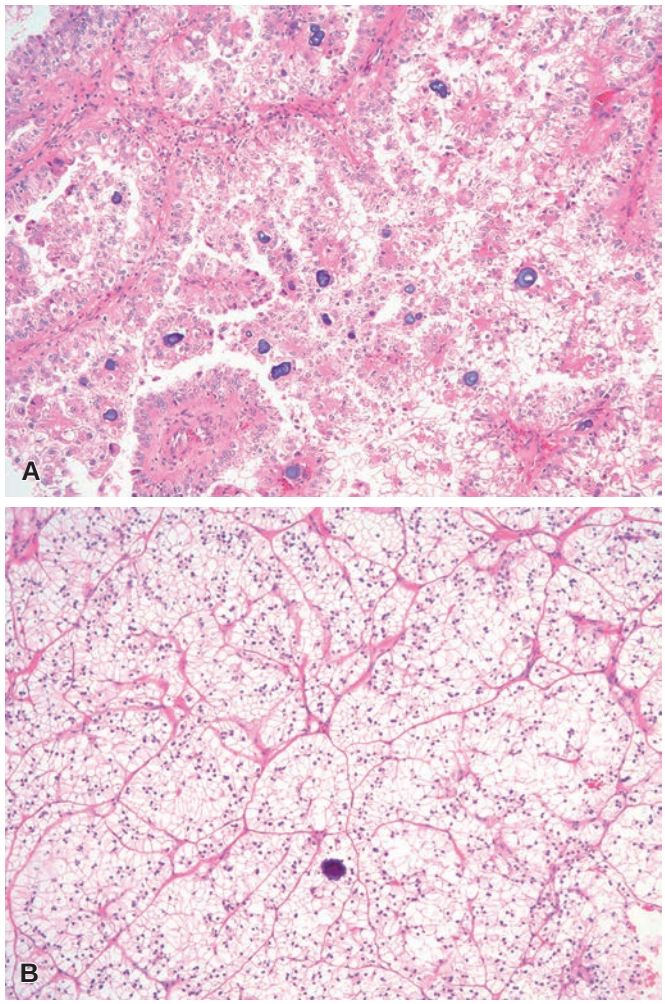

Figure 24.40 MiT Family Translocation Renal Cell Carcinoma, TFE3 Type, With Psammoma Bodies. A, Papillary pattern. **B,** Nested pattern mimicking clear cell RCC.

have historically varied, likely due to inclusion of a broad spectrum of tumors in the past.

The behavior of collecting duct carcinoma is generally very aggressive, many of the patients having distant metastases at the time of presentation.[441,442] Most importantly, collecting duct carcinoma should be a diagnosis of exclusion. Urothelial carcinoma (with or without glandular differentiation), metastatic carcinoma from a distant site, renal medullary carcinoma, and RCC with fumarate hydratase mutation should be carefully considered because each is more common. Additional sections from the collecting system may be most helpful in distinction from urothelial carcinoma, but immunohistochemistry may be needed if no definitive urothelial precursor lesion is identified. We would generally require at least a PAX8-positive/p63-negative phenotype for this diagnosis. Unfortunately, at least 25% of upper tract urothelial carcinoma express PAX8, so even immunohistochemical distinction may be difficult in some cases. Nuclear SMARCB1 should be retained, which is a distinguishing feature from medullary carcinoma.[443-445] Fumarate hydratase (FH) loss by immunohistochemistry and/or genetic counseling/testing may be needed to exclude fumarate hydratase–deficient RCC (hereditary leiomyomatosis and RCC syndrome).[446]

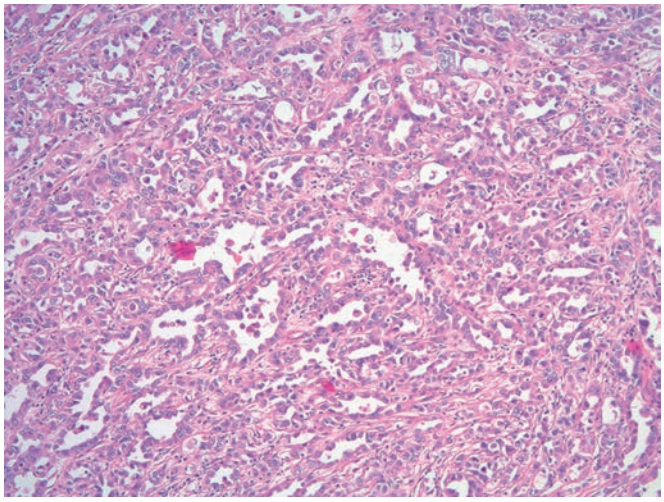

Figure 24.44 Fumarate hydratase–deficient renal cell carcinoma with infiltrating glandular pattern.

Fumarate Hydratase–Deficient Renal Cell Carcinoma (Hereditary Leiomyomatosis and Renal Cell Carcinoma–Associated Renal Cell Carcinoma)

These aggressive RCCs are associated with mutations in *FH* (the gene encoding fumarate hydratase), most of which are germline and associated with hereditary leiomyomatosis and RCC syndrome.[261,446,447] Many of these patients have cutaneous leiomyomas, and women may have a personal or family history of early hysterectomy for uterine leiomyomas. The renal tumors have significant morphologic overlap with collecting duct carcinoma and type II papillary RCC; however, it is no longer appropriate to diagnose or refer to these tumors as the latter. Unlike other hereditary renal neoplasia syndromes, patients may present with only a single unilateral mass due to low penetrance. Macroscopically, tumors are very heterogeneous with variable cystic and solid appearance; in some cases background renal cortical cysts can be seen. Microscopically, the classic pattern is papillary with abundant eosinophilic cytoplasm and large nucleoli with surrounding peri-nucleolar halos (Fig. 24.43).[261] Other patterns include tubular, tubulocytsic, solid, and cribriform, with admixtures being common (Fig. 24.44).[261,446,448] The characteristic peri-nucleolar clearing may be present only focally. Many tumors previously regarded as "de-differentiated tubulocystic carcinoma" represent FH-deficient RCC (Fig. 24.45).[449] Finally, rare cases, especially in younger patients, may not have fully developed features and can overlap with lower-grade oncocytic tumors (Fig. 24.46).[450] Immunohistochemistry can play an important role in this diagnosis, as tumors typically lose cytoplasmic expression for FH (but not in all cases). Overexpression of modified cysteine (S-(2-succino)cysteine) may also be helpful, but the antibody is not currently available from a commercial source.[446] A recent study from the TCGA reported that a subset of tumors with papillary morphology have somatic mutations in FH, suggesting a sporadic counterpart.[451] FH-deficient RCC often presents at high stage with distant metastases, and aggressive behavior may be seen even with small tumors.

Renal Medullary Carcinoma

Medullary carcinoma is a rare malignant renal neoplasm occurring most commonly in young patients of African descent (typically 20–30 years of age) with sickle cell trait, but it is rarely seen with other hemoglobinopathies.[452,453] It is centered in the medulla, and is microscopically heterogeneous with mixed morphologic patterns

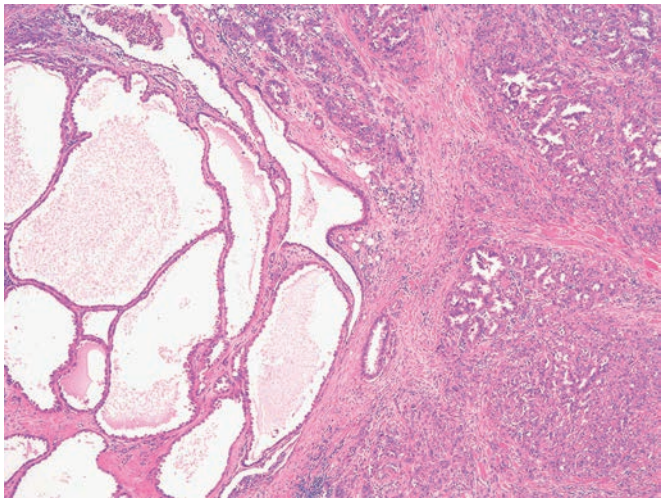

Figure 24.45 Fumarate hydratase–deficient renal cell carcinoma with mixed tubulocystic and solid pattern.

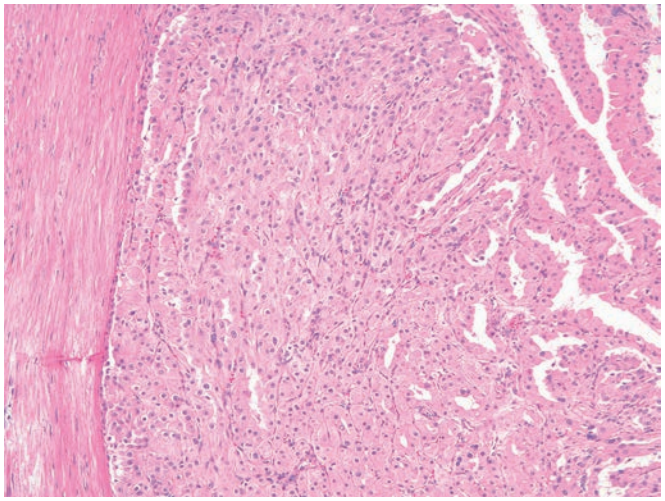

Figure 24.46 Fumarate hydratase–deficient renal cell carcinoma with deceptive "low-grade" appearance.

that include reticular (reminiscent of yolk sac tumor), rhabdoid, cribriform, tubulopapillary, and poorly differentiated solid areas, often in a background of desmoplastic stroma admixed with neutrophils and usually marginated by lymphocytes (Fig. 24.47).[454,455] Associated myxoid stroma is also common. Immunohistochemically, demonstration of nuclear SMARCB1 (INI-1) loss has become required for diagnosis.[456] Patchy nuclear expression of OCT3/4 is also characteristic. Metastases are usually present at the time of the diagnosis, and a rapidly fatal course is typical.[457,458]

A separate but seemingly very rare renal neoplasm with a *VCL-ALK* fusion has recently been described in children with sickle cell trait. This *VCL-ALK* fusion–associated RCC is distinct from renal medullary carcinoma with a unique spindled to polygonal eosinophilic cell population containing conspicuous intracytoplasmic vacuoles. Unlike renal medullary carcinoma, these have followed an indolent clinical course.[459-461]

Tubulocystic Carcinoma

Tubulocystic carcinoma is a rare subtype of RCC with unique pathologic features that constitutes less than 1% of renal neoplasms. Grossly, its appearance has been described as spongy and "bubble wrap."[462] Microscopically, there are variably sized cystically dilated tubules lined by a single layer of eosinophilic epithelium with a cuboidal, flat, or hobnail appearance (Fig. 24.48).[462,463] The nuclei are often enlarged with prominent nucleoli. The individual cysts are separated by a scant fibrous stroma. The prognosis tends to be favorable.[462] While a subset of cases with high-grade areas showing solid or destructive growth are described under the term "dedifferentiated tubulocystic carcinoma," many of these represent fumarate hydratase–deficient RCC.[449,464,465] While there has been suggestion of a genetic relationship to papillary RCC, this remains controversial and no distinct genetic signature has been reported for tubulocystic carcinoma.[466,467]

Mucinous Tubular and Spindle Cell Carcinoma

Mucinous tubular and spindle cell carcinoma (MTSCC) is a unique type of low-grade RCC. Microscopically, the tumor is composed of an admixture of spindle cells and elongated tubules lined by bland cuboidal cells with variable amounts of myxoid/mucinous stroma (Fig. 24.49).[468-470] Cases containing scanty mucin ("mucin-poor") can be easily misdiagnosed, the presence of a spindle cell component being an important clue for their correct identification.[471] Focal neuroendocrine features have been occasionally found.[472] The immunohistochemical profile of MTSCC is similar to that of papillary

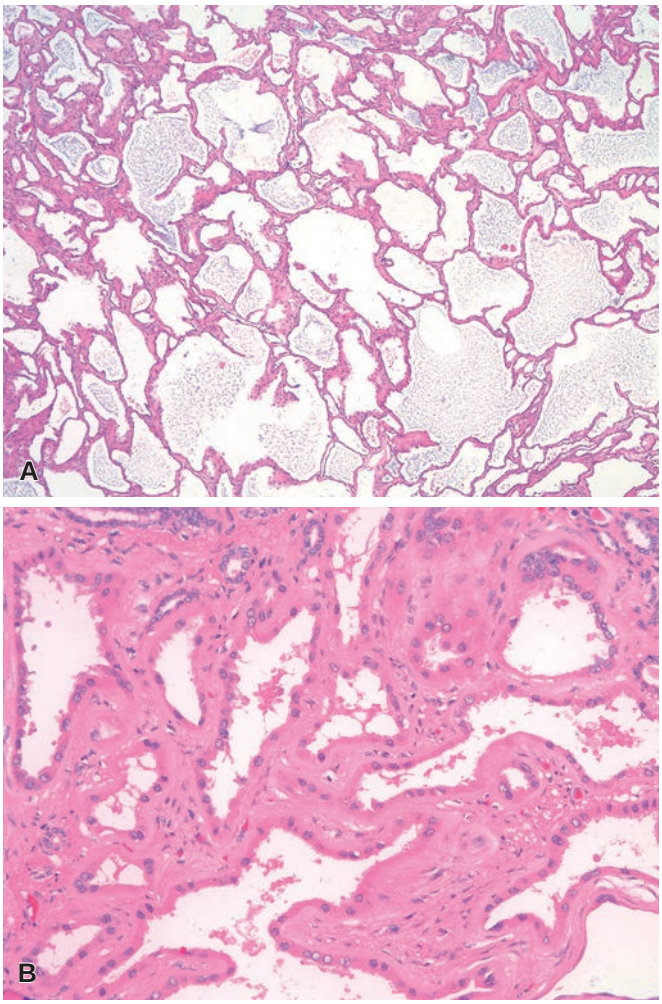

Figure 24.48 Tubulocystic Carcinoma. A, Prototypical low-power architecture. **B,** Lining cells are eosinophilic and atypical.

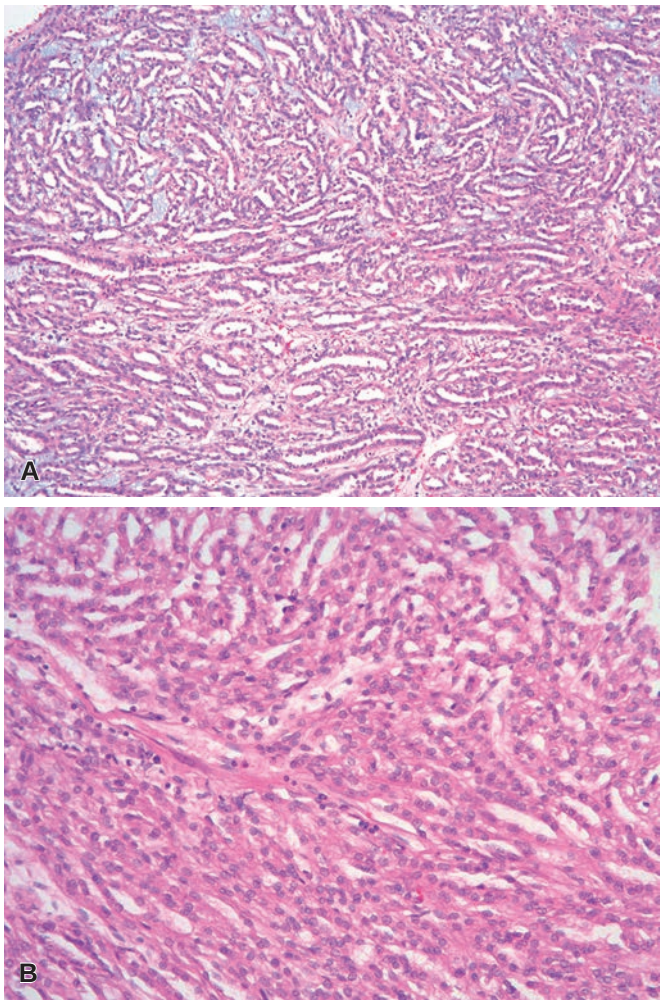

Figure 24.49 Mucinous, Tubular, and Spindle Cell Carcinoma. A, Classic tubular architecture with interspersed mucin. **B,** Spindled morphology with bland cytologic features.

RCC,[473] but their cytogenetic profile is different.[474] Whether MTSCC is a variant of papillary RCC or a distinct tumor subtype has been debated; however, the recent finding of recurring alterations in the Hippo pathway in MTSCC provides strong evidence for the latter.[475-477] The prognosis is generally favorable, unless the tumor is accompanied by a high grade sarcomatoid component, an exceedingly rare event.[478]

Acquired Cystic Kidney Disease–Associated Renal Cell Carcinoma

This neoplasm is seen only in patients with acquired cystic kidney disease related to dialysis. Patients with acquired cystic kidney disease are at a high risk for developing RCC of any subtype.[253,401,479] The diagnosis of "acquired cystic kidney disease–associated RCC" should be reserved for cases with unique and specific histologic features.[401,480,481] The tumors often have macrocystic growth, but solid and papillary architecture is also frequent. The cytoplasm of the neoplastic cells is typically eosinophilic, and prominent nucleoli are common. Two characteristic features include intratumoral oxalate crystals and a unique sieve-like architecture characterized by inter- and intracellular "lumina" separated by very thin strands of cytoplasm (Fig. 24.50). The background kidney, in addition to acquired cystic disease, may contain cysts with atypical papillary proliferations. Immunophenotypically, these RCCs are often negative (or only focally positive) for cytokeratin 7, but they often express AMACR. While

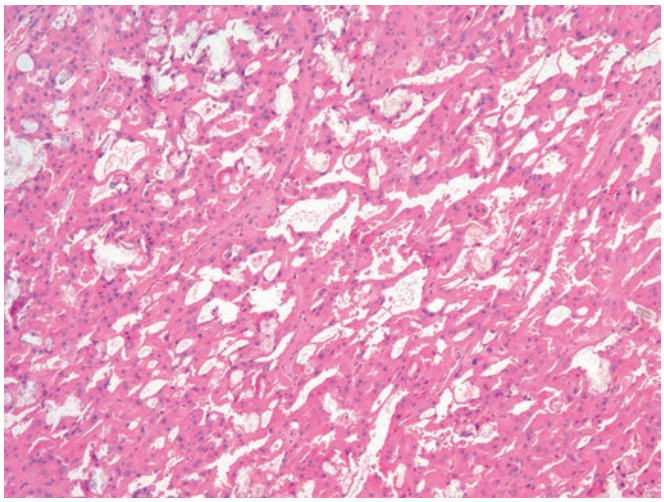

Figure 24.50 Acquired cystic kidney disease–associated renal cell carcinoma.

studies have shown no 3p loss and no chromosome 7 or 17 trisomies, a specific genetic signature has not been identified. Acquired cystic kidney disease–associated RCC generally presents at low stage (possibly due to radiographic surveillance for known cystic disease) and follows an indolent clinical course. However, rare cases may have sarcomatoid or rhabdoid differentiation and are associated with an aggressive behavior.[482]

Succinate Dehydrogenase–Deficient Renal Cell Carcinoma

This recently described subtype of RCC has distinct morphologic features, but is defined by loss of cytoplasmic SDHB expression by immunohistochemistry.[262-264] It is almost always associated with germline mutations in an *SDH* gene (most commonly *SDHB*) and occurs in a younger age range (mean, 38 years). Because of the syndromic association, patients may have a history of paraganglioma, SDH-deficient GIST, or pituitary adenoma. Grossly, the tumors are well circumscribed with tan-brown or red color; cystic areas may be seen. Morphologically, the neoplastic cells of SDH-deficient RCC have eosinophilic cytoplasm and are arranged in solid, nested, or tubular architecture, and cystic areas are common. The individual cells are monomorphic with round, cytologically bland nuclei. The most helpful diagnostic feature is the presence of an intracytoplasmic vacuole or inclusion that contains eosinophilic material, the consistency of which varies from pale and wispy to densely eosinophilic (Fig. 24.51). The tumor has a rounded, well-delineated border but commonly entraps normal renal tubules. While these typical morphologic patterns are most common, rare tumors show high-grade transformation in which the inclusions are focal and more difficult to appreciate. These cases show more cytologic atypia, denser cytoplasm, and increased mitotic activity and may invade the renal sinus (Fig. 24.52). Frank sarcomatoid change is also reported. Immunophenotypically, reactivity for CD117 and cytokeratin 7 is very rare, but PAX8 and kidney-specific cadherin are consistently positive. By definition, SDHB immunostains show loss of cytoplasmic reactivity in the neoplastic cells, while internal intratumoral blood vessels or entrapped renal tubules are positive (Fig. 24.53). SDH-deficient RCCs with typical morphologic features most commonly follow an indolent course, but metastases may occur many years after initial diagnosis (~11% of patients). Cases with high-grade transformation have an aggressive clinical course.

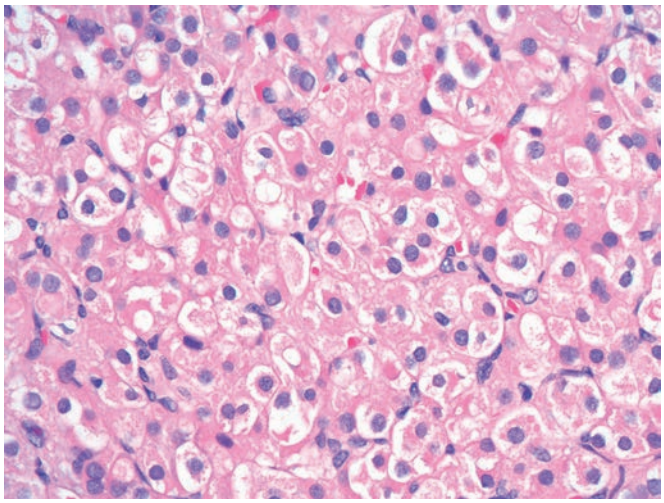

Figure 24.51 SDH-deficient renal cell carcinoma.

Eosinophilic Solid and Cystic Renal Cell Carcinoma

ESC RCC is an emerging subtype of renal neoplasia that was formally described in a series of tuberous sclerosis–associated RCCs[265]; however, it is now recognized to occur more frequently in a sporadic setting.[483,484] The sporadic tumors appear to occur exclusively in women with a wide age range. Grossly, these tumors are often tan with mixed solid and macrocytic appearance (Fig. 24.54). Histologically, the neoplastic cells are characterized by abundant eosinophilic cytoplasm, prominent granular cytoplasmic stippling (said to resemble leishmaniasis), and large round to oval nuclei with prominent nucleoli (Fig. 24.55). In cystic areas, thin septa are lined by these large eosinophilic cells, often with a hobnail arrangement. Immunohistochemically, the cells most commonly have an unusual CK20-positive/CK7-negative phenotype. Common molecular karyotype alterations, distinct from other subtypes of RCC, are described.[483,484]

While these tumors seem to have a more indolent behavior than their nuclear grade would predict, we have seen one metastasis to a regional lymph node and are aware of one liver metastasis (personal communication, Dr. Peter Argani, Johns Hopkins University). As

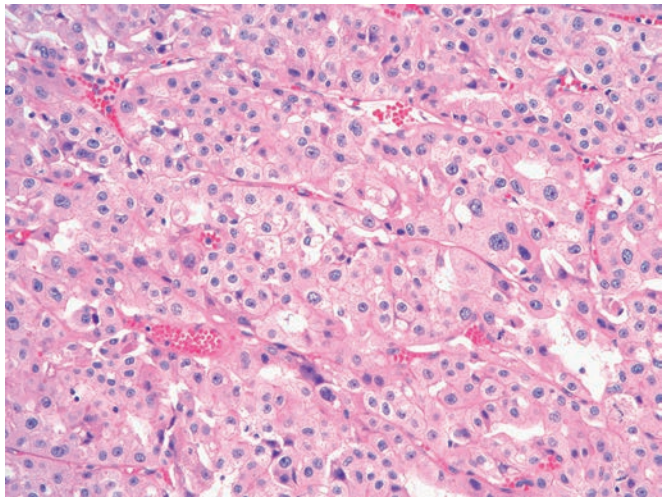

Figure 24.52 SDH-deficient renal cell carcinoma with nuclear pleomorphism and mitotic activity, clinically malignant.

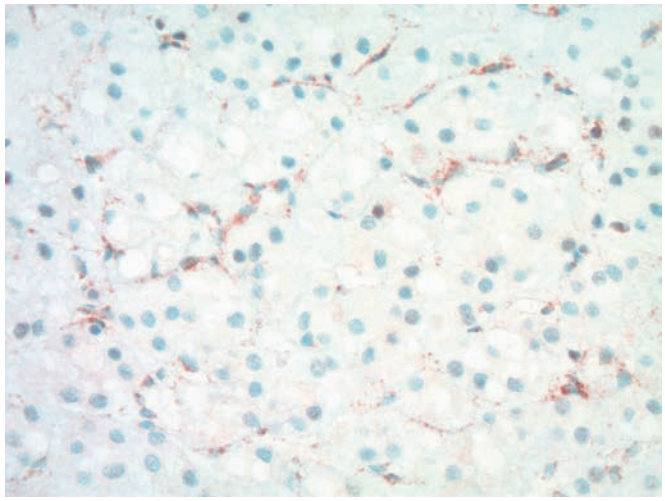

Figure 24.53 SDH-Deficient Renal Cell Carcinoma (SDHB Immunostain). Cytoplasmic loss in neoplastic cells, but retained in endothelial cells.

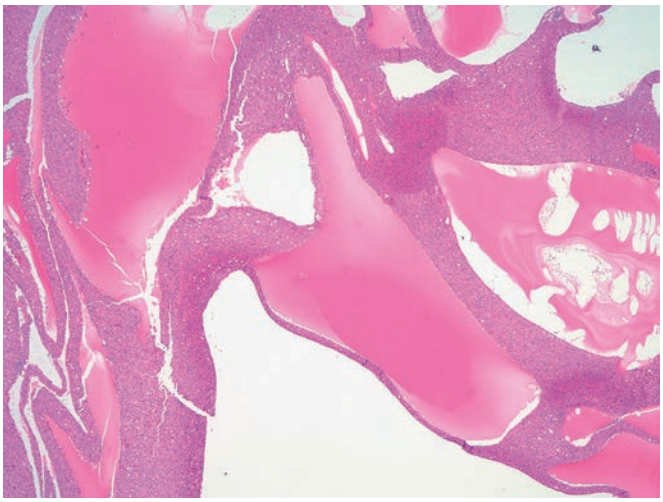

Figure 24.54 Eosinophilic, solid, and cystic (ESC) renal cell carcinoma, low-power magnification.

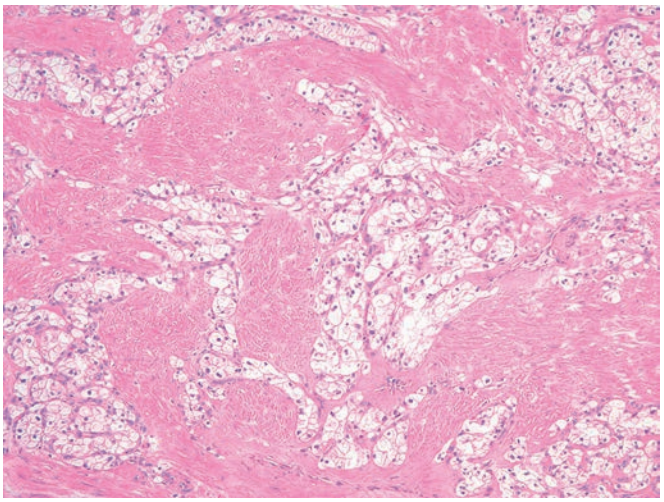

Figure 24.56 Renal cell carcinoma with (angio)leiomyomatous stroma.

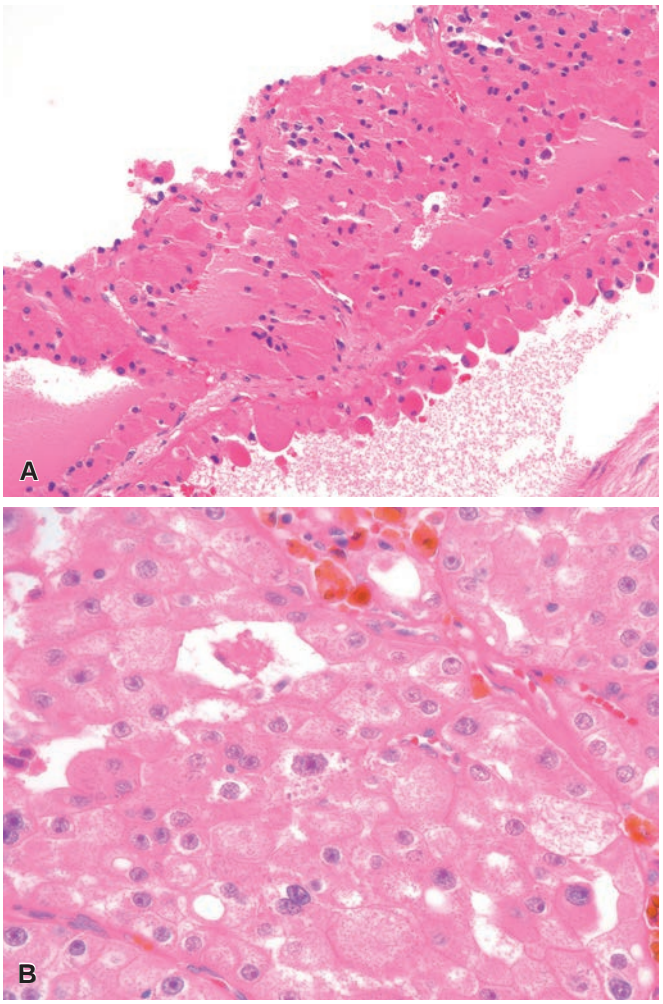

Figure 24.55 Eosinophilic, Solid, and Cystic (ESC) Renal Cell Carcinoma. A, Eosinophilic cells lining septa have a hobnail appearance. **B,** Nuclei are large with variable nucleoli and coarse cytoplasmic stippling.

discussed previously, it is our observation that "oncocytoid RCC following neuroblastoma" (when MiT family translocation carcinomas are excluded) seems to have many similarities with ESC RCC.[268,269]

Renal Cell Carcinoma, Unclassified

Some RCCs do not precisely fit one of the well-described subtypes and are designated "RCC, unclassified type."[485] Most of these tumors are large, high grade, and high stage; however, a rare subset of low grade RCCs do not fit a distinct subtype and might be considered "unclassified." In such cases, it is important to comment on the low grade nature of the tumor, since most urologists equate "unclassified RCC" with very high risk disease. Immunohistochemistry with PAX8 may be useful to confirm renal epithelial origin, but urothelial markers (p63 and high-molecular-weight keratin) are also helpful since up to 25% of upper tract urothelial carcinoma express PAX8, sometimes diffusely. Recent studies suggest distinct molecular subtypes can be identified.[486]

Other Types

Rare low-grade RCCs made up of well-differentiated, branching tubular glands lined by clear cells with abundant cytoplasm and surrounded and closely intermingled with abundant smooth muscle bundles have been described under various names (Fig. 24.56).[487-493] When clear cell–papillary RCCs are carefully separated from this group, it is thought that this represents a distinct set of clear cell–like renal neoplasms with a more indolent clinical course, currently listed as a WHO provisional entity under the name "RCC with (angio) leiomyomatous stroma." Unlike clear cell RCC, these tumors have strong and diffuse reactivity for CK7. Recent sequencing studies identified a subset with mutation in the *TCEB1* gene, but not all cases have this alteration.[492] Importantly, they do not show 3p abnormalities.[337] Interestingly, a subset of RCCs in patients with tuberous sclerosis have an identical morphology; therefore, we recommend a careful evaluation of the background kidney for AML tumorlets.[496] Based on the limited data available, these tumors seem to have an indolent clinical course (with no reported metastases) when carefully separated from clear cell RCC.

Other peculiar forms of RCC have been recently described, including a type closely simulating the appearance of a thyroid follicular carcinoma.[494-496] Additionally, renal neoplasms with ALK translocations are reported (separate from the *VCL-ALK* fusion tumors), but classification of these tumors is still evolving.

Spread and Metastases

Because of the importance of subtype, most general RCC data are heavily driven by the most common subtype, clear cell RCC. Approximately one-third of RCCs are found to invade perinephric fat and/or regional lymph nodes at the time of operation.[272] Invasion of the main renal vein used to be a common finding, but now it is seen less frequently, likely due to earlier imaging detection. From the renal vein, the tumor may extend into the inferior vena cava and occasionally even into the right atrium. RCC, like Wilms tumor, can invade the *renal sinus* (the adipose tissue compartment located within the confines of the kidney and containing numerous veins and lymphatics), a fact which is likely to increase the risk for metastatic spread.[497] As a matter of fact, it has been claimed that the renal sinus is the *principal* pathway of invasion of RCC and the explanation for the rare cases of tumor-related death in patients with small tumors.[498,499] Therefore, very careful gross examination and sampling of the renal sinus are critical.

Satellite tumors, which may represent intrarenal tumor spread or independent primaries (see earlier), are seen in approximately 6% of the cases.[292]

Approximately one-third of patients with RCC already have distant metastases at the time they seek medical attention.[500] The most common sites of distant metastases are the lung and skeleton. The bones most often involved are the pelvis and femur, but there is also a predilection for the sternum, scapula, and small bones of the hands and feet.[501,502] Metastases can also develop in the adrenal gland, liver, skin, soft tissue, central nervous system, ovary, and almost any other site.[503] RCC is actually notorious (together with malignant melanoma and choriocarcinoma) for metastasizing to the most unusual places, such as the nasal cavity, oral cavity, larynx, parotid, thyroid, heart, bladder, testis, prostate, and pituitary gland.[504-511] These metastases are often solitary, at least at the clinical level.[512] Even at autopsy, 8% of the patients have metastatic involvement of only one or two organs.[513] Because of this and the fact that the primary tumor is often clinically silent, these metastases tend to be confused with primary tumors of the organs in which they lodge. That can be the case when RCC metastasizes to the ovary,[514] and even more so when it metastasizes to the *contralateral* adrenal gland.[515,516] In these instances, detection of EMA, keratin, and PAX-8 positivity favors a diagnosis of RCC.[517] An additional source of misinterpretation stems from the fact that sometimes these metastases develop years or decades after the removal of the primary tumor.[518,519] Several cases have been documented in which these metastases have undergone spontaneous regression.[520,521]

Metastases are extremely rare in tumors that measure 3 cm or less, but they can certainly occur, indicating that the once-popular practice of separating RCC from adenoma on the basis of size alone is unreliable.[522]

Therapy

The primary treatment of RCC is surgical excision. While transabdominal or thoracoabdominal radical nephrectomy with removal of the entire kidney, surrounding fat, Gerota fascia, and adrenal gland has historically been preferred, a laparoscopic approach with only a segmental resection of the kidney is now more common and yields long-term results comparable to those of open surgery.[523-527] No consistent benefits have yet been demonstrated for administration of adjunctive radiation therapy or chemotherapy; neoadjuvant therapy is sometimes utilized in select cases in an attempt to reduce tumor size prior to surgery.[528]

RCCs that are bilateral, that develop in the setting of VHL disease, or that occur in a solitary kidney are treated with partial nephrectomy, if technically feasible.[529-533] Some authors have proposed this approach for small RCCs in general.[287,534,535]

Various immune-based therapeutic approaches (such as interleukin-2 and α-interferon) are currently being tried in metastatic RCC; these have met with erratic if occasionally impressive results.[536-538] In recent years, targeted therapy using various agents such as sunitinib (multitargeted receptor tyrosine kinase inhibitor), bevacizumab (antibody-blocking VEGF A), temsirolimus (mTOR inhibitor), and everolimus (mTOR inhibitor) has yielded promising responses for metastatic RCC.[539] Targeted therapies that might selectively treat specific subtypes of RCC are the source of many ongoing studies.

Prognosis

The overall 5-year survival rate for RCC is approximately 70%. The prognosis is related to several clinicopathologic parameters.

1. *RCC subtype*. The prognostic significance associated with the various microscopic variants of RCC is discussed in connection with those variants.[540]
2. *Staging*. In patients who do not have distant metastases at diagnosis, stage on the basis of surgical findings is one of the strongest prognostic factors. The AJCC 8th edition bases staging on tumor size and spread beyond the kidney.[541] Based on numerous studies by Bonsib, it is clear that the main route of RCC extension outside of the kidney parenchyma involves the blood vessels of the renal sinus.[498,542,543] While renal vein involvement is typically easy to recognize grossly, very careful gross inspection of the tumor/stromal interface where tumor abuts fat is critical (Fig. 24.57).[544] Any separate tumor nodule present in the sinus fat is almost certainly pT3 disease based on involvement of renal sinus blood vessels. A bulging interface at the renal sinus should be carefully sampled to determine if the tumor is microscopically entering a blood vessel. Destructive invasion of adipocytes is actually rare and likely represents late invasion through the wall of a blood vessel. Direct contiguous invasion of the adrenal gland (pT4) should be distinguished from a separate adrenal nodule (pM1). The prognosis seems to be particularly poor in cases with invasion of the adrenal gland.[545]
3. *Distant metastases*. The presence of distant metastasis at the time of operation is, not surprisingly, the single most important unfavorable prognostic parameter.[546]
4. *Tumor size*. Size of the primary tumor relates to prognosis for the very small (<4 cm) and the very large (>10 cm) tumors but not for those between these extremes, which represent the large majority.[547-549] For such tumors (4–10 cm), size seems to be a

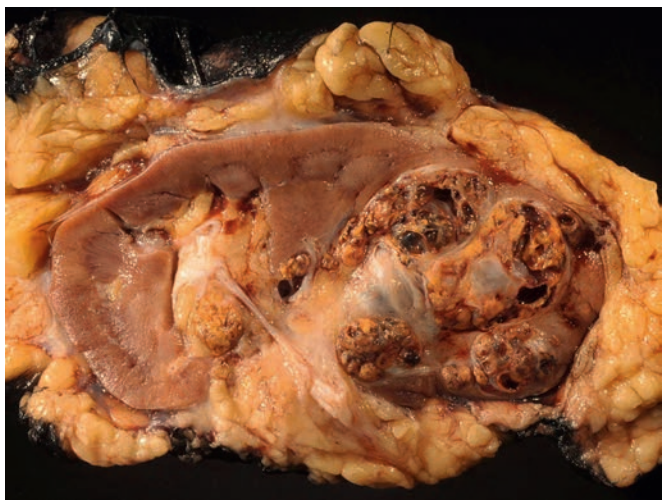

Figure 24.57 Clear cell renal cell carcinoma with definitive macroscopic invasion of renal sinus (pT3).

continuous and therefore relative variable.[550] Out of necessity, an arbitrary size cutoff is needed, and this cutoff has been established to be 7 cm between T1 and T2 tumors in the 2016 TNM staging system; however, it has been suggested that different size cutoffs might be more predictive of the survival of stage I patients after radical nephrectomy.[551,552] As Bonsib has emphasized, increasing tumor size correlates very highly with invasion of the renal sinus, such that it is difficult to identify a pT2 clear cell RCC after very careful gross evaluation.[543]

5. *Renal vein invasion*. Gross invasion of the renal vein has been regarded as a poor prognostic sign and therefore constitutes a criterion for surgical staging.[541,549] Microscopic lymphovascular invasion has also been found to be an important predictor of relapse, but this has been variably defined.[553-555]
6. *Microscopic grade*. Nuclear grade of the tumor as determined in microscopic sections is an important predictor of survival in clear cell carcinoma (but not in chromophobe cell carcinoma, and possibly some rare variants as noted earlier).[400,556-559] It is strongly correlated with surgical staging, but it also maintains statistical validity independently from it.[547,560] Grading is performed using the WHO/ISUP grading system, which has proven utility in clear cell and papillary RCC (see Table 24.3).[559,561,562] Rhabdoid and sarcomatoid differentiation have now been incorporated into the grading system and are regarded as grade 4. Some have advocated for the use of nuclear morphometry to further refine the criteria for nuclear grading, but this is not standard practice.[563-565]
7. *Necrosis*. Coagulative tumor necrosis has been shown to be a strong predictor of outcome, and there has been a proposal to integrate necrosis into the grading system.[566-568]

Adenomas

Renal papillary adenomas, defined as minute cortical foci of tubular or (more commonly) papillary epithelium, are present in approximately 20% or more of adult kidneys; most of them measure 1–3 mm in diameter and by the latest WHO definition are less than 1.5 cm, lack a tumor capsule, and are no more than nucleolar grade 2.[569-572] The cytoplasm of the proliferating cells is typically acidophilic rather than clear and not particularly abundant.[573] Psammoma bodies may be present. Papillary adenomas are particularly common and numerous in end-stage kidneys in patients on long-term dialysis *(renal adenomatosis)*.[574,575] Since these adenomas share the same cytogenetic findings as type 1 papillary RCC, they likely represent early forms of the disease without metastatic potential. In contrast, other subtypes of renal neoplasia are no longer divided into adenomas and carcinomas based on size, such that small clear cell RCCs are still diagnosed as carcinoma.

Oncocytoma, "Difficult to Classify" Oncocytic Tumors, and Oncocytosis

The diagnosis of renal oncocytoma represents one of the more problematic and controversial topics in renal neoplasia classification today.[380] Renal oncocytomas reportedly make up 5%–9% of all primary nonurothelial epithelial renal neoplasms; however, this number depends largely on the diagnostic criteria employed.[576] Our diagnostic approach is to identify three histologic groups of low-risk oncocytic tumors: classic prototypical oncocytoma, classic prototypical chromophobe RCC, and oncocytic tumors that are "difficult to classify." This section describes classic oncocytoma, followed by comments on handling problematic cases. Grossly, renal oncocytoma is typically solid and mahogany brown, often has a central stellate scar, and can reach large sizes (Fig. 24.58).[577] They can be multicentric and bilateral.[578] Invasion of the perirenal tissues or renal vein may

Figure 24.58 Gross Appearance of Oncocytoma of Kidney. The tumor is characteristically well circumscribed, mahogany brown, and has a central fibrous scar.

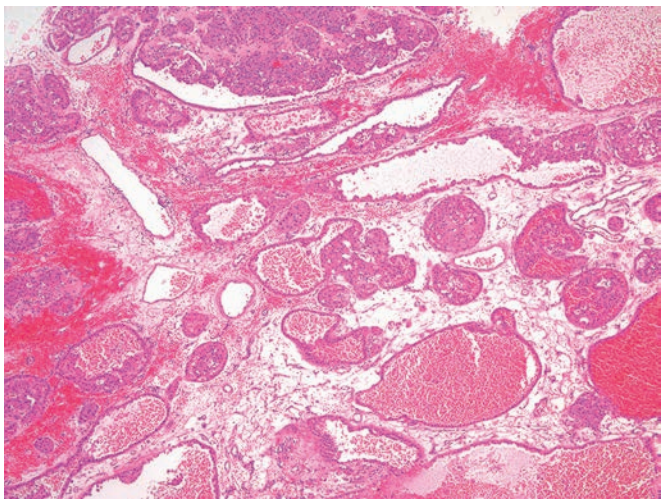

Figure 24.59 Typical nesting and cystic pattern of renal oncocytoma.

be encountered.[576,579-582] Some of these gross features (particularly the central scar) have been used to distinguish oncocytomas from RCC on CT scan, but the level of accuracy is poor.[583] Microscopically, oncocytomas are composed entirely of cells with abundant acidophilic granular cytoplasm, growing in a nesting ("alveolar") or tubular fashion (Fig. 24.59). In some foci, nests and tubules often "float" in an edematous stroma. The nuclei of oncocytoma cells are usually small, round, and regular (Fig. 24.60).[584] Pockets of "degenerative type" nuclear atypia can occur, and some scattered binucleate cells may be present..[585,586] Psammoma bodies can be present, most of them in an intraluminal location. A variant of oncocytoma has been described composed of small cells (i.e. "oncoblasts"), which can easily be misinterpreted.[587,588] Renal tumors with oncocytic cytoplasm and a predominant papillary pattern should probably be placed with the papillary RCCs.[589] Immunohistochemically, the tumor cells express pancytokeratin, low-molecular-weight keratins, CD117, S-100A1 protein,[590] and E-cadherin, but show only focal or no

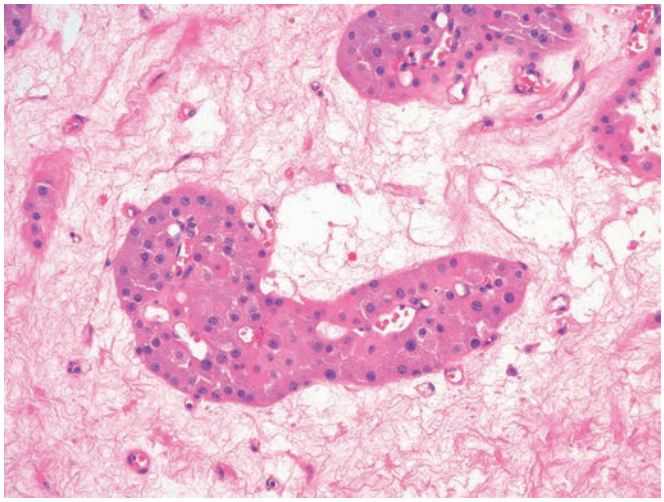

Figure 24.60 Renal Oncocytoma. Nuclei are round and monomorphic.

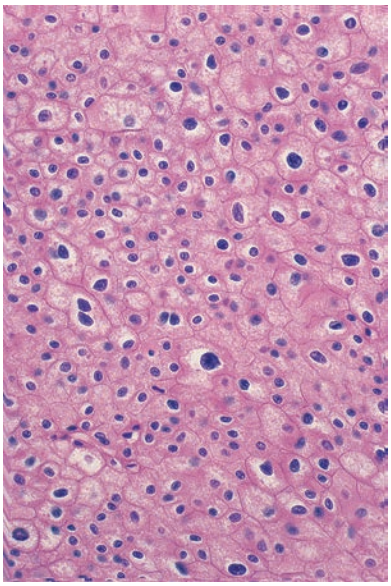

Figure 24.61 Perinuclear halos, binucleation, and "koilocytotic atypia" are features of a prototypical chromophobe renal cell carcinoma.

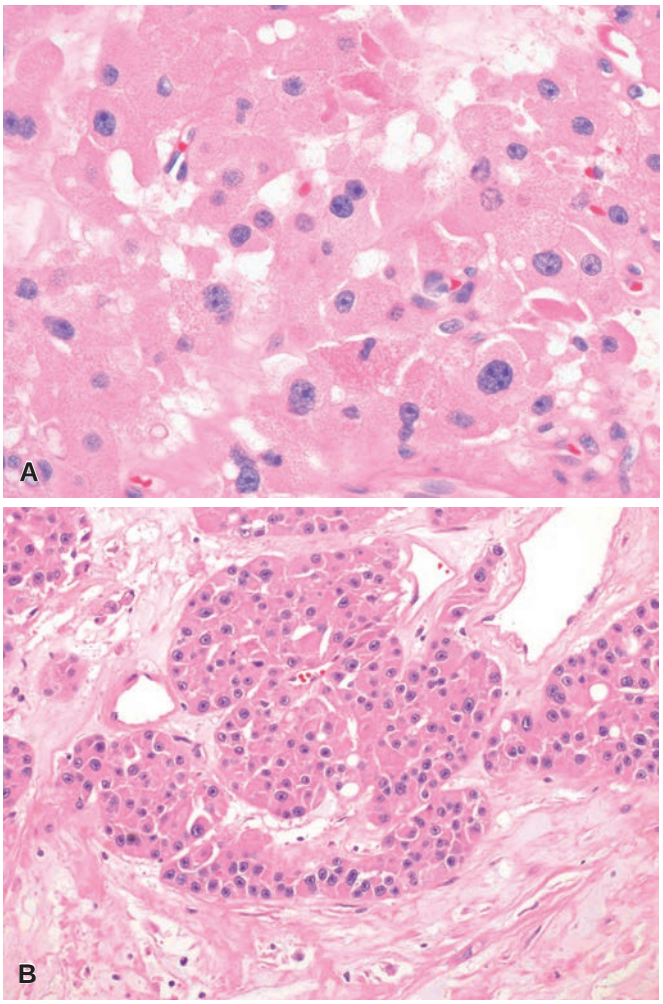

Figure 24.62 Oncocytic Renal Neoplasms With Features Not Prototypical for Either Oncocytoma or Chromophobe. A, This tumor has more variability in nuclear size with multiple nucleoli, but nuclei remain relatively round with no perinuclear clearing. **B,** This case has very prominent and consistent macronucleoli. Other foci showed solid growth. Such tumors have significant variability in diagnosis, even among experts.

reactivity for vimentin.[591-593] Cytokeratin 7 is usually negative or only positive in scattered cells; however, entrapped tumor nests within the central scar (often associated with cytoplasmic clearing) have stronger expression of cytokeratin 7.[594] Hale colloidal iron is typically negative.[379] Ultrastructurally, packing of the cytoplasm by mitochondria is the most striking feature.[595-598] Cytogenetically, oncocytomas lack the 3p abnormalities of clear cell RCC and display different chromosomal alterations, particularly loss of chromosome 1, rearrangements of 11q13, and deletion of chromosome 14.[599,600]

If strict morphologic criteria are employed, the overwhelming majority of oncocytomas will be cured by excision regardless of size[582,584,601-605] and/or the presence of atypical microscopic features such as vascular invasion or perirenal fat infiltration.[606,607] Only exceptional cases of well-documented renal oncocytomas have been reported to metastasize.[576,608]

The main differential diagnosis of renal oncocytoma is with the eosinophilic variant of chromophobe RCC, succinate dehydrogenase–deficient RCC, and less commonly epithelioid AML. The cells of chromophobe RCC have wrinkled, raisin-like hyperchromatic nuclei, whereas those of oncocytoma tend to be perfectly round. As stated before, the presence of well-developed perinuclear halos and/or irregular nuclear membranes with frequent binucleation are sufficient for classification as chromophobe RCC (Fig. 24.61).[427]

Some cases are more difficult to classify, and expert consultants often differ in their methods and terminology used to diagnose such cases. There are several approaches: (1) divide all cases into either chromophobe or oncocytoma by morphology, (2) classify difficult cases as chromophobe or oncocytoma using adjunctive immunostains/special stains, or (3) keep strict diagnostic criteria for the diagnosis of chromophobe RCC and oncocytoma by using a separate diagnostic term for "gray zone" cases. Until this diagnostic problem is better addressed by studies, we prefer the latter and have adopted what we find to be a practical diagnostic approach. Most of these "gray zone" cases maintain round nuclear contours without perinuclear clearing (i.e. not classic chromophobe) but have greater variability in nuclear size, greater degree of irregular nuclear chromatin, and variable macronucleoli (Fig. 24.62). To our knowledge, no adjunctive test (whether immunostain, histochemical stain, or cytogenetic test)

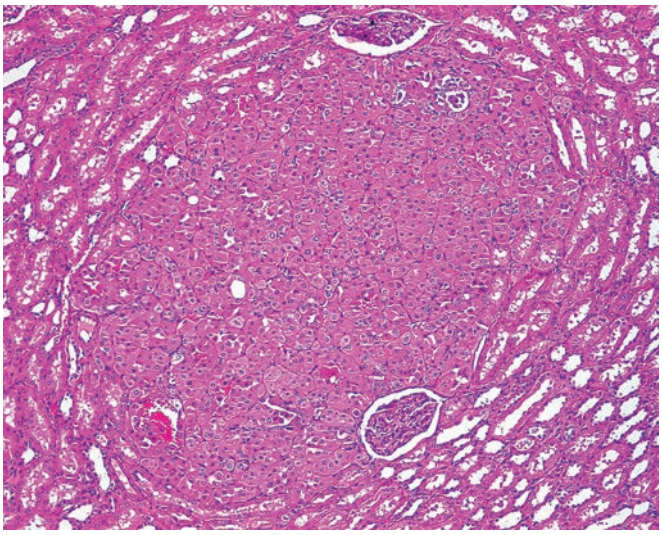

Figure 24.63 So-called renal oncocytosis. Many similar nodules were scattered throughout the kidney.

has been shown to predict behavior in such tumors. This approach avoids arbitrarily dividing some cases into either a benign or malignant category. Therefore, we prefer to simply utilize the diagnostic term "oncocytic renal neoplasm of low malignant potential," but other similar terms have been applied. While we have seen extremely rare liver metastases in such cases (far less than 1% based on several hundred cases), it is our anecdotal experience that the vast majority behave in a benign fashion.

As alluded to in the section on unclassified RCC, rare low grade RCCs may have significant overlap with this oncocytic spectrum of neoplasia. We generally reserve the rare diagnosis of "RCC, low-grade oncocytic type" for cases with sheet-like growth and obvious mitotic activity, but without nuclear features of chromophobe RCC.

Oncocytosis is the term proposed for a condition characterized by the presence of innumerable oncocytic nodules in one or both kidneys, usually associated with the presence of a dominant nodule (Fig. 24.63). The disease can affect adults and children, and many cases are likely related to Birt-Hogg-Dubé syndrome.[609] Microscopically, the oncocytic tubules intermingle with the normal parenchyma and may be associated with diffuse oncocytic change in the renal tubules and oncocytic cortical cysts.[259] The larger oncocytic nodules/tumors show morphologic features reminiscent of both oncocytoma and chromophobe RCC, but often show immunohistochemical and cytogenetic profiles distinct from them.[610]

Neuroendocrine Tumors

Small cell neuroendocrine carcinomas of the kidney (or other high-grade neuroendocrine carcinomas) with features similar to those of the lung have been described.[611-613] They show evidence of neuroendocrine differentiation ultrastructurally and immunohistochemically.[611,614,615] These should be distinguished from urothelial carcinoma of the renal pelvis with neuroendocrine differentiation.[616-618] The behavior of the few reported cases has been very aggressive.

Carcinoid tumor (well-differentiated neuroendocrine neoplasm), which should be sharply segregated from small cell carcinoma, has been reported in a pure form[619-621] and as a component of cystic teratoma.[622-624] Microscopically, the tumor cells are well differentiated at the morphologic, immunohistochemical, and ultrastructural levels.[625-627] The pattern of growth is often trabecular (and therefore similar to that seen in rectal carcinoid and in the carcinoid component of strumal carcinoid of the ovary), but a wide range of appearances has been documented, including nesting (insular) and glandular.[625,628] The cytoplasm of the tumor cells may have an oncocytic quality.[629] Stage at presentation is the most important factor in determining outcome.[627,630] It is important for a metastasis from another anatomic site (e.g. gastrointestinal tract) to be excluded clinically.

Paraganglioma may also rarely involve the kidney.[631]

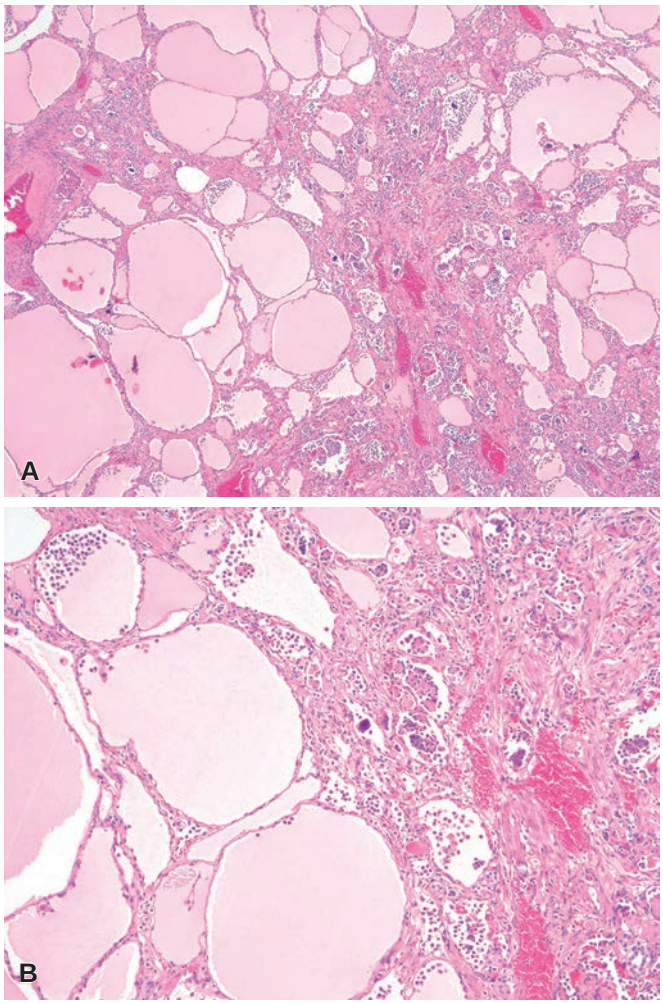

Figure 24.64 "Atrophic Kidney-Like Tumor." A, Cystically dilated follicles of various sizes are typical, with admixed smaller tubules. **B,** Follicles are lined by a flattened epithelium, and psammoma bodies and amorphous calcifications are present.

Other Epithelial Tumors

We have seen several examples of "atrophic kidney-like tumor," which was described by Hes et al. in 2014 as a "distinctive renal neoplasm simulating atrophic kidneys with 2 types of microcalcifications."[632] These are characterized by a circumscribed and encapsulated collection of cystically dilated "follicles" filled with eosinophilic secretions and admixed with smaller renal tubular-like structures (Fig. 24.64). The follicles are lined by an atrophic lining epithelium, and the lumina may contain "sloughed" cells. Variable loose to collagenized stroma is present, and psammoma bodies or more amorphous calcifications are numerous. Some similar tumoral masses have been reported as "thyroid-like follicular RCC," which we believe is a different lesion. These "atrophic kidney-like tumors" have all

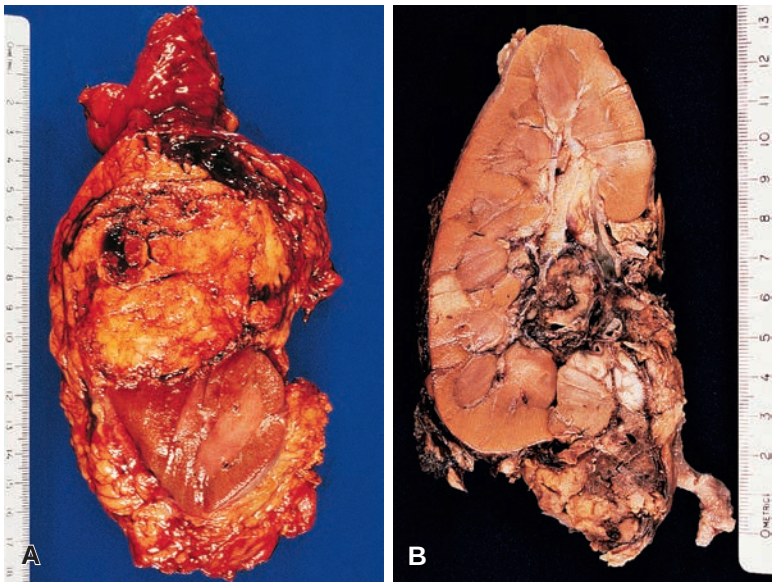

Figure 24.65 **A** and **B,** Gross appearances of angiomyolipoma of kidney. Both tumors are variegated, with a predominance of yellow areas, admixed with hemorrhagic foci.

occurred in young patients (typically 20–40 years of age but also in young children) and have followed a benign clinical course. Their exact nature is still debated.

Very unusual and as yet not fully characterized morphologic types of renal epithelial neoplasms include *myoepithelioma and myoepithelial carcinoma*[633,634]; *spiradenocylindroma* (a sweat gland tumorlike renal neoplasm developing in the wall of a renal cyst and having a somatic mutation in the *CYLD1* gene)[635]; and *papillary tumor of the renal medulla* (a type of carcinoma that is different morphologically and cytogenetically from the usual papillary RCC and from collecting duct carcinoma).[636]

Angiomyolipoma

AML has undergone a remarkable transformation, from a rare and rather pedestrian tumor type restricted to the kidney to a biologically fascinating and morphologically heterogeneous entity that can occur in a wide variety of extrarenal sites, including liver, pelvic region, retroperitoneum (unconnected to the kidney), uterus, somatic soft tissues, large bowel, nasal cavity, and bone.[637-641] This family of phenotypically similar tumors is now collectively known as PEComa, which include lymphangiomyoma(tosis) of lung and lymph nodes and so-called clear cell tumor ("sugar tumor") of lung.[642-647] This section will focus specifically on primary renal AML.

Most patients are adults. The tumor may be found incidentally or result in retroperitoneal hemorrhage, which can be massive and even fatal.[648] Approximately one-third of the patients with renal AML suffer from tuberous sclerosis, the incidence being higher if the tumors are multiple or bilateral. It has been estimated that approximately 80% of the patients with the complete or severe form of tuberous sclerosis have renal AMLs,[649] and it has been shown that patients with the closely related genetic disease known as *TSC2/PKD1 contiguous gene syndrome* also have an increased incidence of renal AML.[650]

In some cases, the appearance of AML on ultrasonography and CT scan is highly characteristic,[651] and the diagnosis can be confirmed by fine-needle aspiration or needle biopsy, supplemented by immunocytochemistry as needed.[652,653]

The gross appearance of the tumor depends on the relative amounts of the various components and may closely simulate RCC because of the admixture of yellow areas (lipid rich) and hemorrhagic areas (vessels) (Fig. 24.65). Capsular invasion is present in one-fourth of the cases, and there can be extension into the perirenal soft tissues. In its conventional form, AML is composed of an intimate admixture of blood vessels and tumor cells; the neoplastic cells are heterogenous, having either an eosinophilic spindle cell appearance imparting "myoid" features or intracytoplasmic lipid closely mimicking adipocytes (Fig. 24.66).[654,655] Less commonly, epithelioid cells are the predominant cell type. The associated tortuous thick-walled blood vessels lacking elastic tissue lamina often have bundles of tumor cells that seem to emanate from the vessel walls, a very helpful diagnostic feature (Fig. 24.67). Some epithelioid AMLs may have marked cytologic atypia that closely mimics a poorly differentiated RCC (Fig. 24.68). Multicentric microscopic foci are common and suggest tuberous sclerosis; exceptionally, they may be seen involving the glomeruli.[656] In some cases, the AML proliferation is accompanied by cysts lined by cuboidal to hobnail cells resting on a cellular spindle cell stroma with a cambium layer-like appearance. This

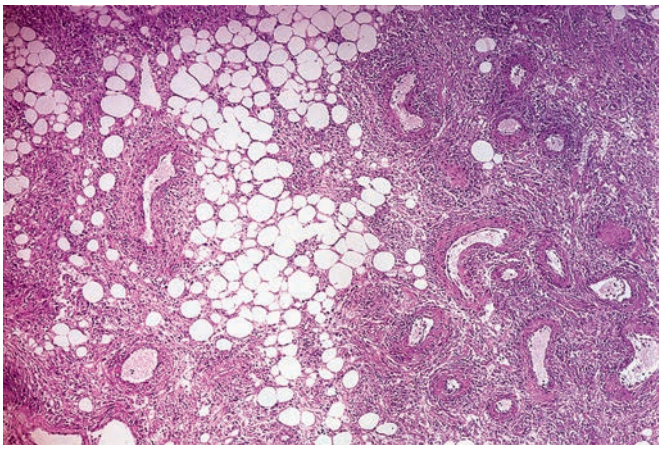

Figure 24.66 **Typical Renal Angiomyolipoma.** The tumor is composed of lipid-rich and myoid-like cells with admixed blood vessels.

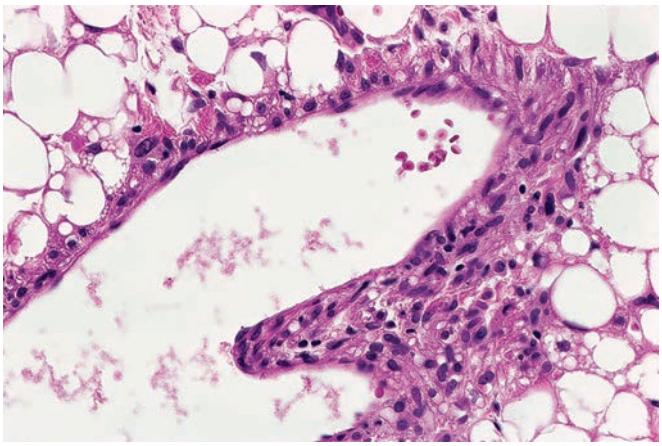

Figure 24.67 Intimate relationship of the eosinophilic neoplastic cells of angiomyolipoma with a large vessel. This is an important diagnostic clue.

peculiar cystic variant of AML (AMLEC) is also characterized by the frequent expression of hormone receptors.[657,658]

Immunohistochemically, AMLs (and all PEComas) are notable because, in addition to the expected smooth muscle markers (such as actin), they regularly express melanocytic markers such as HMB-45, Mart-1/Melan-A, microphthalmia transcription factor, and tyrosinase; however, expression of melanocytic markers may be quite focal.[659-666] Cathepsin-K is strongly and diffusely expressed in AML, and (in the kidney) we find it more useful than other melanocytic markers; however, it is also commonly expressed in MiT family translocation RCC.[667-669] To our knowledge, nuclear PAX8 expression has not been reported in AML; therefore, it has utility in the distinction from RCC. At the ultrastructural level, this immunohistochemical profile is associated with the presence of unique cytoplasmic crystalloids[642] and of organelles consistent with premelanosomes.[670-672] Unfortunately, the renal AMLs of tuberous sclerosis patients with mutation of the *TSC1* and *TSC2* genes have been found to show inconsistent hamartin and tuberin expression.[673-675]

Recently, our concepts on the nature of PEComas have become ever murkier by the demonstration that a subset of these tumors harbors *TFE3* gene fusions and exhibits aberrant immunoreactivity for TFE3 protein (like translocation-associated RCCs and alveolar soft part sarcoma).[676] Apparently, these tumors differ in several respects from the "conventional" PEComas lacking these molecular features.[677]

AMLs in which spindle cells with a smooth muscle appearance predominate may mimic leiomyomas, leiomyosarcomas, or GISTs (Fig. 24.69).[666,678] Lipid-rich AMLs, in which the adipose tissue is predominant, can be easily confused with an atypical lipomatous tumor (well-differentiated liposarcoma). It should be highlighted that AMLs may express MDM-2 by immunohistochemistry (an adjunctive test for atypical lipomatous tumor/well-differentiated liposarcoma); therefore, FISH evaluation for MDM-2 amplification is more useful in this specific context[679] Highly pleomorphic AMLs rich in epithelioid cells closely resemble RCC.[680-682] AMLs composed of monomorphic epithelioid cells with homogeneous acidophilic cytoplasm may be mistaken for oncocytomas.[683-685]

The treatment of renal AML is surgical, and excision is usually curative.[686] However, cases resulting in death from massive local recurrence are on record.[687] It is also now abundantly clear that AML is capable of distant metastases; however, the regional lymph node involvement that sometimes accompanies renal AML is an expression of multicentricity rather than true embolic metastases.[688-690] Cases with indisputable metastatic spread in the form of huge retroperitoneal deposits or nodules in the lung and other organs have been documented.[691-694] Practically all of these biologically malignant cases had highly atypical epithelioid features morphologically, which leads to the question as to whether it is possible to make a diagnosis of malignant AML on morphologic grounds.[695,696] It is obvious that a potential for malignant behavior cannot be excluded for AMLs with "aggressive" morphologic features.[682,697] According to a recent study, presence of three or more of the following features is predictive of malignant behavior: (1) ≥70% atypical epithelioid cells (polygonal cells with prominent nucleoli and nuclear size exceeding twice the size of adjacent nuclei); (2) ≥2 mitotic figures per 10 high-power fields; (3) atypical mitotic figures; and (4) necrosis.[696]

Juxtaglomerular Cell Tumor

Patients with juxtaglomerular cell tumor usually present clinically with hypertension because of excessive renin production,[698] but some cases are nonfunctioning.[699] Most patients are adult, but cases have also been reported in children.[700] Grossly, all reported cases have been unilateral and solitary. Most have been less than 3 cm in diameter and located in the cortex, but occasional examples have reached 8 cm.[701] They are solid and well circumscribed, with a gray-white to light yellow cut surface.

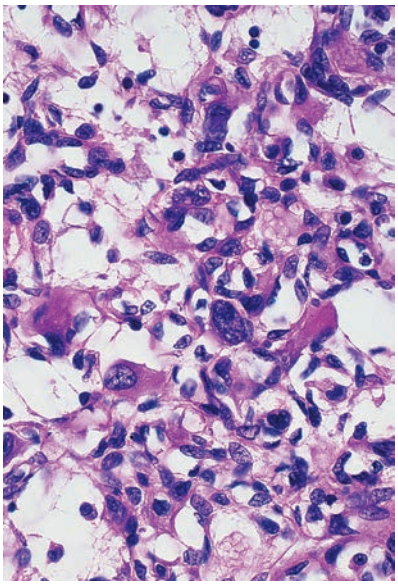

Figure 24.70 Microscopic Appearance of Juxtaglomerular Cell Tumor. The lesion has a distinct vascular background.

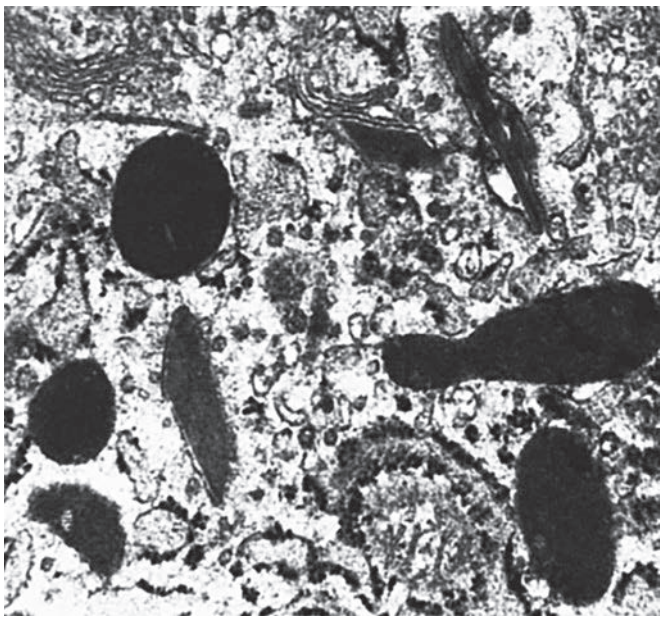

Figure 24.71 Secretory Granules of Juxtaglomerular Cell Tumor as Seen Ultrastructurally. Some of them are diamond shaped, identical to those seen in normal juxtaglomerular cells. This case has been reported by Conn et al.[848] (Courtesy of Dr. M.R. Abell, Ann Arbor, MI.)

The light microscopic appearance is reminiscent of hemangiopericytoma and glomus tumor, not surprisingly considering the fact that juxtaglomerular cells are specialized vessel-related epithelioid smooth muscle cells.[701,702] The tumor cells are uniform and round to polyhedral and have a granular acidophilic cytoplasm (Fig. 24.70). Mast cells are numerous. In some cases the tumor cells are spindled, and the pattern of growth may be papillary.[703] The intracytoplasmic renin granules may be demonstrated with PAS and Bowie stains, and their nature may be confirmed with immunohistochemical techniques.[698,702,704] In contrast to conventional or epithelioid AML, juxtaglomerular cell tumor is negative for HMB-45.[705] They are consistently positive for

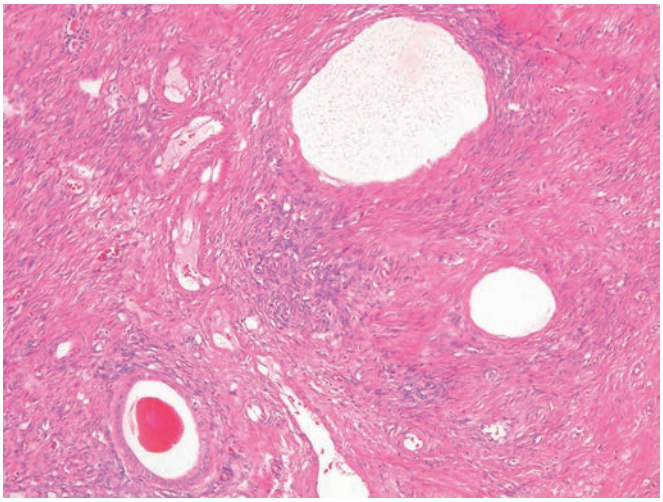

Figure 24.72 Mixed epithelial and stromal tumor with classic ovarian-like stroma.

CD34 and CD117 and show focal staining for smooth muscle actin.[706] Ultrastructurally, adrenergic nerve terminals are seen in contact with the tumor cells, which have various types of secretory granules, some of them containing a typical rhomboid crystalline material thought to be renin protogranules (Fig. 24.71).[704,707-709] Cytogenetically, some recurrent chromosome imbalances have been reported.[710,711] All but one of the reported cases have behaved in a benign fashion,[699] but some patients have remained hypertensive following nephrectomy.[701,712]

It should be noted that renin secretion can be associated with other renal and extrarenal neoplasms, such as RCC, Wilms tumor, and pancreatic adenocarcinoma.[713-715]

MEST is the preferred diagnostic term applied to biphasic tumors, generally occurring in middle-aged and older women, that have been called cystic nephroma, MEST, or REST in adults.[716,717] Several recent studies have shown that the similarities, overlaps, and hybrid forms at the clinical, morphologic, phenotypic, and molecular levels are such as to suggest that cystic nephroma and MEST are two different manifestations of the same basic process.[717-720] As discussed in the section on pediatric renal neoplasia, the name cystic nephroma is now preferred for the pediatric cases that often have *DICER1* mutations and frequent syndromic association. MEST may be solid and cystic and may bulge into the renal pelvis. Microscopically, the spindle cell proliferation in between the individual cysts resembles ovarian stroma (Fig. 24.72), including the expression of hormone receptors. The epithelial component is, for the most part, is similar to cystic nephroma (and therefore consistent with renal ductal epithelium, also at the immunohistochemical and ultrastructural level[721]), but is more heterogeneous and may exhibit features suggestive of müllerian-type differentiation, including epithelium of endometrioid, tubal, clear cell, and squamous cell type. In addition, the epithelial component may be more predominant than typically seen in pediatric cases (Fig. 24.73). Cases with great predominance of the stromal or adipose component can be confused with leiomyomas or AMLs.[722] The behavior is generally benign, although a few histologically malignant examples have been reported.[723,724]

Other Benign Tumors and Tumorlike Conditions

Medullary fibroma is also referred to as *renomedullary interstitial cell tumor*, under the assumption that it arises from the medullary interstitial cell.[725] The latter is a specialized stromal element that

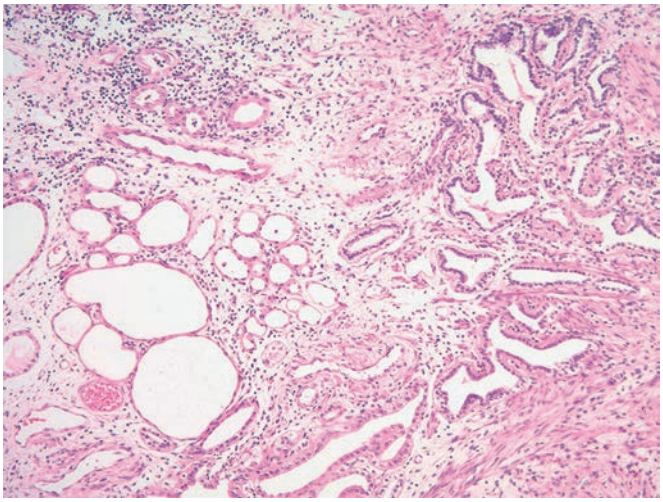

Figure 24.73 Mixed epithelial and stromal tumor with crowded and various shaped glands.

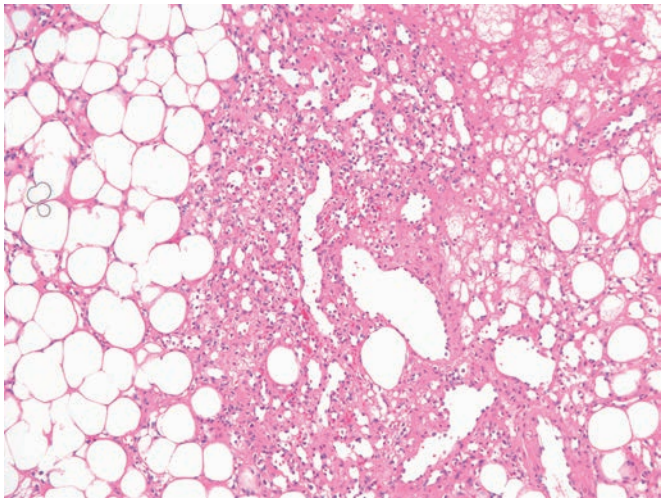

Figure 24.74 Anastomosing hemangioma in the renal hilum.

produces prostaglandins and is believed to be involved in the regulation of intrarenal blood pressure.[726] The tumors are asymptomatic and invariably found incidentally as minute (usually 3 mm or less) white nodules in the midportion of the medullary pyramids.[727] Microscopically, they are composed of small, stellate, or polygonal cells in a loose stromal background, with entrapped tubules at the periphery.

The rare renal **leiomyoma** is usually located in the cortex or capsule but may also arise in association with hilar blood vessels.[668,728] True leiomyomas occur almost exclusively in women. They may represent an incidental histologic finding at surgery or, as with many tumors, an incidental radiographic finding.[729] In our opinion, many "leiomyomas" reported in the literature represent "lipid-poor" AMLs that closely resemble smooth muscle.[668,730] Immunophenotypically, strong and diffuse desmin expression and absence of cathepsin-K is most helpful since most AMLs show the opposite pattern.[668]

Although reported in the literature, the diagnosis of a renal **lipoma** should be met with great suspicion.[731,732] Before the diagnosis is made, alternative (and more likely) possibilities should be considered: lipid-rich AML or atypical lipomatous tumor of the retroperitoneum (some of which are centered in the perirenal region and which can look very "lipoma-like"). Pelvic/parapelvic lipomatosis could also be considered.

Primary **hemangioblastomas** have been reported in the kidney. These may be difficult to distinguish from clear cell RCC, given the significant overlap in immunophenotype.[733,734]

Myxoma presents as a gelatinous intraparenchymal tumor; its appearance is identical to that of myxoma of soft tissue.[735]

Benign peripheral nerve tumors of both *schwannoma*[736-738] and *perineurioma* type[739] have been described.

Vascular tumors and tumorlike conditions of various types rarely arise in the kidney.[740] *Arteriovenous malformations* are identical to their soft tissue counterparts.[740] *Hemangioma* is frequently located in the medullary portion, where it can give rise to copious hematuria.[727] Microscopically, most are of the capillary type, with a sieve-like pattern reminiscent of splenic pulp.[740] Many exhibit an anastomosing pattern mimicking angiosarcoma (Fig. 24.74).[741] They should be distinguished from RCCs with a prominent angiomatoid component. *Lymphangioma* can also involve the kidney,[742,743] but before this diagnosis is made, the more likely possibility of cystic nephroma/MEST should be considered and ruled out. The myopericytoma family of tumors, predominantly *glomus tumor* (some of them with atypical features)[744] and the closely related *glomangiomyoma*, can present as intrarenal masses, raising the differential diagnosis with juxtaglomerular cell tumor.[745-747]

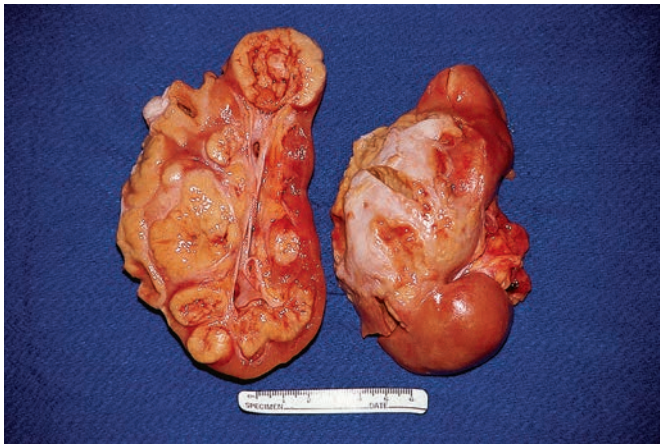

Figure 24.75 Massive renal involvement by malakoplakia.

Solitary fibrous tumor (SFT) has been seen involving the renal parenchyma or the renal capsule, sometimes in association with hypoglycemia.[748-750] Many of the cases historically reported as renal hemangiopericytoma are now considered SFT.[751] As in other sites, most SFTs are benign, with occasional examples behaving aggressively.[752]

Inflammatory myofibroblastic tumor may affect primarily the kidney; the behavior is generally indolent.[753]

Hydatid cyst can present as an intrarenal mass in countries where this parasitosis is endemic.

Hematomas can develop in the kidney or perirenal tissues as a result of trauma, from rupture of hemangiomas, and sometimes for no apparent cause. Some perirenal hematomas may contain peculiar periodic formations ("Liesegang structures") with radial striations that can simulate the appearance of parasites and that have been confused with such.[754]

Rosai–Dorfman disease (sinus histiocytosis with massive lymphadenopathy) and **malakoplakia** can result in renal masses (Fig. 24.75).[755-759]

Sarcomas

Sarcomas of various types can arise in the adult kidney, including the renal capsule.[760-762] These include *leiomyosarcoma* (classic or myxoid),[763-765] *synovial sarcoma* (increasingly recognized at this site),[766-769] *fibrosarcoma* (exceptional), *pleomorphic rhabdomyosarcoma* (just as rare),[770] so-called *malignant fibrous histiocytoma (pleomorphic undifferentiated sarcoma, NOS)*,[771] *liposarcoma* (but need to rule out renal extension of a retroperitoneal tumor),[772] *angiosarcoma*,[740,773,774] *osteosarcoma*,[775-777] *chondrosarcoma*,[778] *malignant mesenchymoma*,[779,780] and *clear cell sarcoma* (malignant melanoma of soft parts, not to be confused with the pediatric-type renal clear cell sarcoma).[781] Some of the chondrosarcomas have been of the mesenchymal variety.[782] Some of the smooth muscle tumors have occurred in immunosuppressed patients in association with Epstein–Barr virus infection.[783] The synovial sarcomas, before the possibility of their intrarenal occurrence was realized and documented by molecular studies, were probably included in the heterogeneous group of embryonal sarcomas of the kidney.[766] The reported cases have been of the monophasic type and some had rhabdoid features.[784] It is well to remember that the entrapment of cystically dilated tubules lined by hobnail epithelium can simulate a biphasic appearance (just as the entrapment of bronchoalveolar epithelium can result in a similar appearance in primary or metastatic monophasic synovial sarcoma in the lung).

An important warning is appropriate at this point: Before a diagnosis of primary sarcoma of the kidney of any type is made, the more common possibilities of sarcomatoid RCC (or urothelial carcinoma) and primary retroperitoneal soft tissue sarcoma (particularly de-differentiated liposarcoma) with secondary renal invasion should be considered.

Malignant Lymphoma and Related Lymphoid Lesions

Malignant lymphoma of the kidney is usually the expression of generalized disease,[785] but sometimes the kidney is the only site of tumor.[786-788] Bilaterality is common in either situation. Renal failure may result from diffuse involvement of the organ.[789,790] The majority of the cases are of large B-cell type.[791] Other types have been described, including low-grade B-cell lymphoma of so-called MALT type (containing lymphoepithelial lesions within renal tubules).[792,793] Some such cases have been reported in the setting of AIDS[794] and others in organ transplant recipients,[795] sometimes with involvement of the renal allograft.[796]

Two varieties of lymphoma with a predilection for secondary renal involvement are thymic large B-cell lymphoma with sclerosis and lymphomatoid granulomatosis/angiotrophic large cell lymphoma.[797]

Plasmacytomas may be found within the kidney, usually as a result of dissemination in multiple myeloma but sometimes as an expression of extramedullary tumor.[798]

Metastatic Tumors

Metastatic carcinoma can affect the kidney as a part of a disseminated process, but the renal involvement is only rarely of clinical significance.[799,800] The metastasis may appear years or decades after the removal of the primary tumor.[801] On CT scan, renal metastases tend to be small, multiple, bilateral, wedge shaped, intracortical, and less exophytic than primary RCC.[802] In contrast to the latter, metastatic tumors are bilateral in a high proportion (over 50%) of cases.[803] About one-third of the patients have microscopic hematuria.[803] Sometimes the metastases are exclusively limited to the renal glomeruli, in an intracapillary or extracapillary fashion, and may be diagnosed by needle biopsy.[804,805] The most common primary sites are the lung, skin (malignant melanoma), breast, gastrointestinal tract, pancreas, ovary, and testis (nonseminomatous germ cell tumors, particularly choriocarcinoma).[806] Examples of odd types of metastatic tumors to the kidney simulating primary renal tumors include SETTLE, adenoid cystic carcinoma of breast,[807] and the follicular variant of papillary thyroid carcinoma.[808]

Tumors of Renal Pelvis and Ureter

Urothelial Carcinoma

Most urothelial carcinomas of the renal pelvis occur in adults (in whom they constitute about 7% of all primary renal carcinomas).[809,810] While a history of analgesic abuse and/or coexistence of renal papillary necrosis,[811,812] Thorotrast exposure for radiographic purposes,[813] or cyclophosphamide therapy[814] may be predisposing factors in a small subset of cases, smoking is likely the greatest risk factor.′ These tumors have also been reported in horseshoe kidneys; their incidence may actually be increased in this congenital abnormality.[815] Some cases have developed as a manifestation of the hereditary nonpolyposis colorectal cancer syndrome, and these rare cases may show abnormal expression of mismatch repair proteins by immunohistochemistry.[816,817] Hematuria is the most common clinical presentation.[818,819] Synchronous or metachronous tumors elsewhere in the urinary tract (most of them in the bladder) are found in over half of the patients[811,820]; exceptionally, an independent RCC may be found in the same kidney.[821-823] Intravenous and retrograde pyelography provides the most accurate means of diagnosis.[818] The sensitivity and accuracy of cytologic examination are higher than for RCC, particularly for the high-grade tumors.[824]

Grossly, these tumors form soft, gray-to-red masses with smooth, glistening surfaces that resemble the urothelial tumors of the bladder (Fig. 24.76).[812] They often diffusely involve the entire renal pelvis and form arborescent masses that may extend down the ureter. Occasionally, they are circumscribed to a calyx or even to the inside of a calyceal cyst.[825] High-grade lesions can spread massively into the renal parenchyma and even reach the renal capsule. They can be distinguished grossly from RCC because of their granular appearance and extensive pelvic involvement.

Urothelial carcinomas of the ureter may be located anywhere along the length of the organ and usually result in dilation of the proximal portion due to lumen obstruction by the tumor.[826,827]

The microscopic appearance of these urothelial carcinomas, whether located in the renal pelvis or ureter, is identical to that of their more common homologues in the bladder. The majority are high-grade neoplasms, the percentage (about 70%) being much higher than for the same tumor type in the bladder.[828] The pelvic neoplasms sometimes extend proximally along the collecting tubules, a pattern that should not be confused with adenocarcinoma.[829] The adjacent urothelium may show urothelial carcinoma in situ.[830] It should be pointed out that upper tract biopsies are fraught with artifacts that can mimic urothelial neoplasia.[831,832] The similarities with urothelial carcinomas of the bladder also apply to the occurrence of variants such as the *micropapillary type*[833,834] and others,[835] as well as their immunohistochemical profile, including coexpression of keratins 7 and 20[836] and overexpression of p53 protein (particularly in the high-grade tumors).[837] In our experience, up to 25% of upper tract urothelial carcinomas may express nuclear PAX-8.[838,839]

The standard treatment of pyeloureteral urothelial carcinoma is nephroureterectomy. Segmental resection has sometimes been employed for midureteral lesions,[825] and endoscopic removal has been done for low-grade noninvasive lesions, but the high incidence of multicentricity and coexistent carcinoma in situ (particularly with

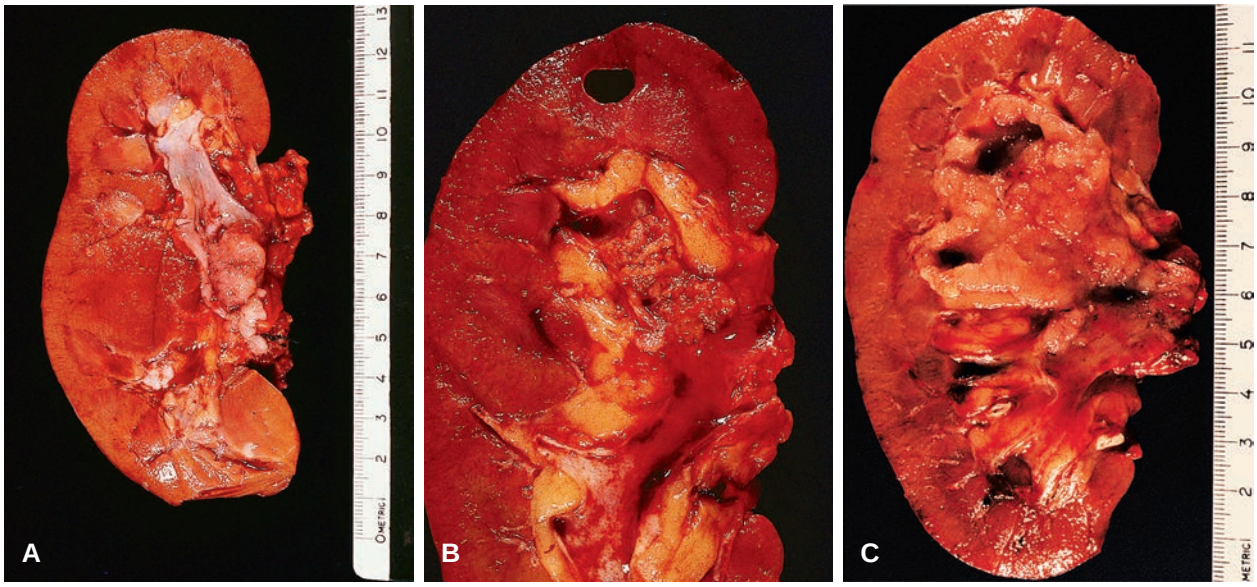

Figure 24.76 Gross Appearances of Urothelial Carcinoma of Renal Pelvis. A and **B,** The tumor protrudes into the pelvic cavity and has a granular surface. **C,** The tumor coats the pelvis and calyces.

the high-grade tumors) indicates that radical surgery is the treatment of choice for the large majority of cases.[840,841] Furthermore, these tumors have a tendency to implant along the ureter, especially in its terminal (intramural) portion. Therefore a resection of the bladder cuff may be performed to avoid tumor recurrence.[842,843] The overall 5-year survival rate in the surgically resected cases is about 50%.[809,811] The prognosis is largely determined by the stage of the lesion for both the pelvic and ureteral lesions.[844-848] Unfortunately, most of the patients present with locally advanced (pT2 or more) disease at the time of surgery.[828,835]

Other Carcinoma Types

Primary squamous cell carcinoma[813,819,849,850] and *primary adenocarcinoma*[851-854] rarely occur in the upper urinary tract. Essentially all rare subtypes and urothelial carcinoma variants described in the urinary bladder may also be identified in the pelvicalyceal and ureteral system, including hepatoid carcinoma,[855] *lymphoepithelioma-like carcinoma,*[856] sarcomatoid urothelial carcinoma,[835,857-859] giant cell carcinoma,[860-862] small cell neuroendocrine carcinoma,[618,863] carcinoma with trophoblastic features,[864-867] and carcinoma with rhabdoid features.[868] **Verrucous carcinoma** has been reported in the pelvis of a horseshoe kidney associated with staghorn calculi.[869] Clinicopathologic features are identical to those described in the urinary bladder.

Other Tumors and Tumorlike Conditions

Fibroepithelial polyp[870,871] (Fig. 24.77) and **hypertrophic infundibular stenosis of the calyces**[872] are two rare tumorlike masses of the pelvic region.

Pelvic lipomatosis and **fibrolipomatosis** result from excessive proliferation of peripelvic fat with or without accompanying fibrous tissue and may simulate a neoplasm radiographically.[873]

Amyloidosis can present as a localized nodule in the wall of one or both ureters (so-called amyloid tumor).[874]

Myelolipoma morphologically similar to its more common adrenal counterpart can present as a mass in the renal sinus.[875]

Malakoplakia of the pelvis or ureter may result in obstruction and hydronephrosis.[876,877]

Figure 24.77 Benign fibroepithelial polyp emerging from lower calyx of the left kidney in a 61-year-old woman. The tumor caused hematuria, and total nephrectomy was performed.

Stone granuloma is a complication of ureteroscopy and ureteral stone fragmentation; it is characterized by the presence of embedded particles of calcium oxalate associated with macrophages and foreign body giant cells, with surrounding fibrosis and dilation of the proximal ureter.[878]

Endometriosis of the ureter presents with hydroureter, often accompanied by hydronephrosis. The disease may be extrinsic to the ureter or present within its wall. As in other sites, endometriosis may rarely be associated with secondary Müllerian neoplasms.

Most patients have a past history of hysterectomy with salpingo-oophorectomy.[879]

Subepithelial hematoma of the renal pelvis (Antopol–Goldman lesion) can present with gross hematuria and radiographically simulate a malignant tumor. The etiology is unknown.[880,881]

"**Urinoma**" results from the extravasation of urine into the renal perihilar and peripelvic fat; in the early stages there is lipolysis with foamy macrophages and multinucleated giant cells, followed by fibrosis and deposition of "urinary precipitates." Demonstration of Tamm–Horsfall protein by immunostaining confirms the fact that the amorphous extracellular precipitates are derived from uroprotein.[882]

Benign pyeloureteral tumors include *inverted papilloma* (sometimes multiple),[883,884] *nephrogenic adenoma*,[885-888] *villous adenoma*,[889] *hemangioma*,[890] *leiomyoma*,[891] *SFT*,[892] *neurofibroma*, *granular cell tumor*,[893] and *glomus tumor*.[894] The hemangiomas are often located at the tips of the papillae, are multiple in about 10% of the cases, and may result in recurrent episodes of hemorrhage.[895,896] Owing to their small size, extensive sectioning may be needed to find the lesion. The nephrogenic adenoma may show gastric metaplasia.[897]

Malignant tumors of nonepithelial type are exceptional. A few cases of *leiomyosarcoma* have been reported.[898] Non-Hodgkin *malignant lymphoma* of the retroperitoneum can involve the ureter secondarily.[899] A case of primary malignant lymphoma has been reported in the pelvis of a transplanted kidney.[900] A few cases of benign and malignant tumors have been reported in ureteroileal conduits.[901,902]

Metastatic carcinomas to the retroperitoneum can invade the ureteral wall and result in obstruction; the breast and lung are the most common sites for the primary tumors.[903,904]
